Preface

The International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research papers in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues. The first MFCS conference was organized in 1972 in Jabłonna (near Warsaw, Poland). Since then, the conference traditionally moved between the Czech Republic, Slovakia, and Poland. A few years ago, the conference started traveling around Europe: in 2018 it was held in Liverpool, United Kingdom. MFCS 2019, the 44th edition of MFCS, is the first MFCS being held in Germany.

Out of 198 submitted papers, 78 have been finally accepted. The authors of the submitted papers represent nearly 40 countries. Each paper was assigned to three PC members, who reviewed and discussed them thoroughly over a period of nearly seven weeks. As the co-chairs of the program committee, we would like to express our deep gratitude to all the committee members for their hard, dedicated work. The quality of the submitted papers was very high and many good papers had to be rejected.

MFCS 2019 features five invited talks, by Kurt Mehlhorn (Max-Plack Institute Saarbrücken, Germany), Alexandra Silva (University College London, UK), Daniel Lokshtanov (University of California at Santa Barbara, USA), Kavitha Telikepalli (Tata Institute of Fundamental Research, India) and Jérôme Leroux (LaBRI, France). We are looking forward to their excellent talks.

Since 2016, the MFCS 2019 proceedings are published in the Dagstuhl/LIPIcs series. We would like to thank Michael Wagner and the LIPIcs team for all their kind help and support. We also like to thank Birgit Willms for her dedicated support in the local organization of MFCS 2019 in Aachen.

Abstract

The goal of the LEDA project was to build an easy-to-use and extendable library of correct and efficient data structures, graph algorithms and geometric algorithms. We report on the use of formal program verification to achieve an even higher level of trustworthiness. Specifically, we report on an ongoing and largely finished verification of the blossom-shrinking algorithm for maximum cardinality matching.

2012 ACM Subject Classification Theory of computation → Design and analysis of algorithms; Software and its engineering → Formal software verification; Software and its engineering → Software libraries and repositories

Keywords and phrases graph algorithms, formal correct proofs, Isabelle, LEDA, certifying algorithms

Digital Object Identifier 10.4230/LIPIcs.MFCS.2019.1

Category Invited Talk

1 Introduction

This talk is a follow-up on two previous invited MFCS-talks given by the second author:

- *LEDA: A Library of Efficient Data Types and Algorithms* in MFCS 1989 [31], and
- *From Algorithms to Working Programs: On the Use of Program Checking in LEDA* in MFCS 1998 [33].

After a review of these papers, we discuss the further steps taken to reach even higher trustworthiness of our implementations.

- Formal correctness proofs of checker programs [5, 39], and
- Formal verification of complex graph algorithms [1].

The second item is the technical core of the paper: it reports on the ongoing and largely finished verification of the blossom-shrinking algorithm for maximum cardinality matching in Isabelle/HOL by the first author.

Personal Note by the Second Author. As this paper spans 30 years of work, the reader might get the impression that I followed a plan. This is not the case. As a science, in this case computer science, progresses, there are logical next steps. I took these steps. I did not know 30 years ago, where the journey would lead me.

2 Level One of Trustworthiness: The LEDA Library of Efficient Data Types and Algorithms

In 1989, Stefan Näher and the second author set out to build an easy-to-use and extendable library of correct and efficient data structures, graph algorithms and geometric algorithms. The project was announced in an invited talk at MFCS 1989 [31] and the library is available from Algorithmic Solutions GmbH [27]. LEDA, the library of efficient data types and

template <class NT>
void DIJKSTRA_T(const graph& G, node s, const edge_array<NT>& cost,
                   node_array<NT>& dist, node_array<edge>& pred)
{
  node_pq<NT>  PQ(G);   // a priority queue for the nodes of G
  node v; edge e;
  dist[s] = 0;          // distance from s to s is zero
  PQ.insert(s,0);       // insert s with value 0 into PQ
  forall_nodes(v,G) pred[v] = nil; // no incoming tree edge yet
  while (!PQ.empty())   // as long as PQ is non-empty
  { node u = PQ.del_min();   // let u be the node with minimum dist in PQ
    NT du = dist[u];         // and du its distance
    forall_adj_edges(e,u)    // iterate over all edges e out of u
    { v = G.opposite(u,e);   // makes it work for ugraphs
      NT c = du + cost[e];   // distance to v via u
      if (pred[v] == nil && v != s )            // v already reached?
        PQ.insert(v,c);                         // first path to v
      else if (c < dist[v]) PQ.decrease_p(v,c); // better path
           else continue;
      dist[v] = c;           // store distance value
      pred[v] = e;           // and incoming tree edge
    }
   }
  }
```

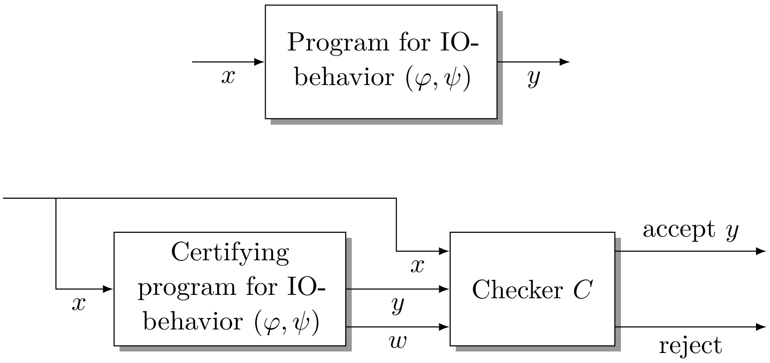
Figure 1 The LEDA implementation of Dijkstra's algorithm: Note that the executable code above is similar to a typical pseudo-code presentation of the algorithm.

algorithms, offers a flexible data type graph with loops for iterating over edges and nodes and arrays indexed by nodes and edges. It also offers the data types required for graph algorithms such as queues, stacks, and priority queues. It thus created a framework in which graph algorithms can be formulated easily and naturally, see Figure 1 for an example. The design goal was to create a system in which the difference between the pseudo-code used to explain an algorithm and what constitutes an executable program is as small as possible. The expectation was that this would ease the burden of the implementer and make it easier to get implementations correct.

3 Level Two of Trustworthiness: Certifying Algorithms

Nevertheless, some implementations in the initial releases were incorrect, in particular, the planarity test[1]; it declared some planar graphs non-planar. At around 1995, we adopted the concept of certifying algorithms [33, 30] for the library and reimplemented all algorithms [34]. A certifying algorithm computes for each input a easy-to-check certificate (witness) that demonstrates to the user that the output of the program for this particular input is correct; see Figure 2. For example, the certifying planarity test returns a Kuratowski subgraph if it

[1] Most of the implementations of the geometric algorithms were also incorrect in their first release as we had naïvely used floating point arithmetic to implement real arithmetic and the rounding errors invalidated the implementations of the geometric primitives. This lead to the development of the exact computation paradigm for geometric computing by us and others [20, 45, 14, 44, 32]. In this paper, we restrict to graph algorithms.



x
Program for IO-behavior (φ, ψ)
y
x
Certifying program for IO-behavior (φ, ψ)
x
y
w
Checker C
accept y
reject

Figure 2 The top figure shows the I/O behavior of a conventional program for IO-behavior (φ, ψ); here φ is the precondition and ψ is the postcondition. The user feeds an input x satisfying $\varphi(x)$ to the program and the program returns an output y satisfying $\psi(x, y)$. A certifying algorithm for IO-behavior (φ, ψ) computes y and a witness w. The checker C accepts the triple (x, y, w) if and only if w is a valid witness for the postcondition $\psi(x, y)$, i.e., it proves $\psi(x, y)$. (reprinted from [5])

declares the input graph non-planar and a (combinatorial) planar embedding if it declares the input graph planar, and the maximum cardinality matching algorithm computes a matching and an odd-set-cover that proves its optimality; see Figures 3 and 4. The state of the art of certifying algorithms is described in [30]. We also implemented checker programs that check the witness for correctness and argued that the checker programs are so simple that their correctness is evident. From a pragmatic point of view, the goals of the project were reached by 2010. The library was easy-to-use and extendable, the implementations were efficient, and no error was discovered in any of the graph algorithms for several years despite intensive use by a commercial and academic user community.

Note that, most likely, errors would not have gone undiscovered because of the use of certifying algorithms and checker programs. Only if a module produced an incorrect output and hence an invalid certificate and the checker program missed to uncover the invalidity of the certificate would an error go unnoticed. Of course, the possibility is there and the phrase “most likely” in the preceding sentence has no mathematical meaning.

Alternative libraries such as Boost and LEMON [43, 28] are available now and some of their implementations are slightly more efficient than ours. However, none of the new libraries pays the same attention to correctness. For example, all libraries allow floating point numbers as weights and capacities in network algorithms, but only LEDA ensures that the intricacies of floating point arithmetic do not invalidate the implementations; see [6] and [34, Section 7.2].

4 Level Three of Trustworthiness: Formal Verification of Checkers

We stated above that the checker programs are so simple that their correctness is evident. Shouldn’t they then be amenable to formal verification? Harald Ganzinger and the second author attempted to do so at around 2000 and failed. About 10 years later (2011 – 2014) Eyad Alkassar from the Verisoft Project [42], Sascha Böhme and Lars Noschinski from Tobias Nipkow’s group at TU München, and Christine Rizkallah and the second author succeeded in formally verifying some of the checker programs [5, 39]. In order to be able to talk about formal verification of checker programs, we need to take a more formal look at certifying algorithms.

A *matching* in a graph G is a subset M of the edges of G such that no two share an endpoint.

An odd-set cover OSC of G is a labeling of the nodes of G with non-negative integers such that every edge of G (which is not a self-loop) is either incident to a node labeled 1 or connects two nodes labeled with the same i, $i \geq 2$.

Let n_i be the number of nodes labeled i and consider any matching N. For i, $i \geq 2$, let N_i be the edges in N that connect two nodes labeled i. Let N_1 be the remaining edges in N. Then $|N_i| \leq \lfloor n_i/2 \rfloor$ and $|N_1| \leq n_1$ and hence

$$|N| \leq n_1 + \sum_{i \geq 2} \lfloor n_i/2 \rfloor$$

for any matching N and any odd-set cover OSC. It can be shown that for a maximum cardinality matching M there is always an odd-set cover OSC with

$$|M| = n_1 + \sum_{i \geq 2} \lfloor n_i/2 \rfloor,$$

thus proving the optimality of M. In such a cover all n_i with $i \geq 2$ are odd, hence the name.

list<edge> MAX_CARD_MATCHING(*graph G*, *node_array<int>& OSC*)

computes a maximum cardinality matching M in G and returns it as a list of edges.
The algorithm ([12], [15]) has running time $O(nm \cdot \alpha(n,m))$.
An odd-set cover that proves the maximality of M is returned in OSC.

bool CHECK_MAX_CARD_MATCHING(*graph G*, *list<edge> M*, *node_array<int> OSC*)

checks whether M is a maximum cardinality matching in G and OSC is a proof of optimality. Aborts if this is not the case.

Figure 3 The LEDA manual page for maximum cardinality matchings (reprinted from [33]).

We consider algorithms which take an input from a set X and produce an output in a set Y and a witness in a set W. The input $x \in X$ is supposed to satisfy a precondition $\varphi(x)$, and the input together with the output $y \in Y$ is supposed to satisfy a postcondition $\psi(x,y)$. A *witness predicate* for a specification with precondition φ and postcondition ψ is a predicate $\mathcal{W} \subseteq X \times Y \times W$, where W is a set of witnesses with the following *witness property*:

$$\varphi(x) \wedge \mathcal{W}(x,y,w) \longrightarrow \psi(x,y). \tag{1}$$

The checker program C receives a triple[2] (x,y,w) and is supposed to check whether it fulfills the witness property. If $\neg\varphi(x)$, C may do anything (run forever or halt with an arbitrary output). If $\varphi(x)$, C must halt and either accept or reject. It is required to accept if $\mathcal{W}(x,y,w)$ holds and is required to reject otherwise. This results in the following proof obligations.

Checker Correctness: We need to prove that C checks the witness predicate assuming that the precondition holds, i.e., on input (x,y,w):

(i) If $\varphi(x)$, C halts.

(ii) If $\varphi(x)$ and $\mathcal{W}(x,y,w)$, C accepts (x,y,w), and if $\varphi(x)$ and $\neg\mathcal{W}(x,y,w)$, C rejects the triple.

Witness Property: We need to prove implication (1).

[2] We ignore the minor complication that X, Y, and W are abstract sets and programs handle concrete representations.

```
static bool return_false(string s)
{ cerr << "CHECK_MAX_CARD_MATCHING: " << s << "\n"; return false; }

bool CHECK_MAX_CARD_MATCHING(const graph& G, const list<edge>& M,
                                    const node_array<int>& OSC)
{ int n = Max(2,G.number_of_nodes());
  int K = 1;
  array<int> count(n);
  for (int i = 0; i < n; i++) count[i] = 0;
  node v; edge e;

  forall_nodes(v,G)
  { if ( OSC[v] < 0 || OSC[v] >= n )
     return_false("negative label or label larger than n - 1");
    count[OSC[v]]++;
    if (OSC[v] > K) K = OSC[v];
  }

  int S = count[1];
  for (int i = 2; i <= K; i++) S += count[i]/2;
  if ( S != M.length() )
    return_false("OSC does not prove optimality");

  forall_edges(e,G)
  { node v = G.source(e); node w = G.target(e);
    if ( v == w || OSC[v] == 1 || OSC[w] == 1 ||
            ( OSC[v] == OSC[w] && OSC[v] >= 2) ) continue;
    return_false("OSC is not a cover");
  }
  return true;
}
```

Figure 4 The checker for maximum cardinality matchings (reprinted from [33]).

In case of the maximum cardinality matching problem, the witness property states that an odd-set cover OSC as defined in Figure 3 with $|M| = n_1 + \sum_{i\geq 2}\lfloor n_i/2 \rfloor$ proves that the matching M has maximum cardinality. Checker correctness amounts to the statement that the program shown in Figure 4 is correct.

We proved the witness property using Isabelle/HOL [37]; see Section 5.1 for more information on Isabelle/HOL. For the checker correctness, we used VCC [9] and later Simpl [41] and AutoCorres [16]. The latter approach has the advantage that the entire verification can be performed within Isabelle. Simpl is a generic imperative programming language embedded into Isabelle/HOL, which was designed as an intermediate language for program verification. We implemented checkers both in Simpl and C. Checkers written in Simpl were verified directly within Isabelle. For the checkers written in C, we first translated from C to Isabelle using the C-to-Isabelle parser that was developed as part of the seL4 project [21], and then used the AutoCorres tool developed at NICTA that simplifies reasoning about C in Isabelle/HOL. Christine spent several months at NICTA to learn how to use the tool. We verified the checkers for connectivity, maximum cardinality matching, and non-planarity. In particular, for the non-planarity checker it was essential that Lars Noschinski in parallel formalized basic graph theory in Isabelle [38].

A disclaimer is in order here. We did not verify the C++ program shown in Figure 4. Rather we verified a manual translation of this program into Simple or C, respectively. For this translation, we assumed a very basic representation of graphs. The nodes are numbered from 0 to $n-1$, the edges are numbered from 0 to $m-1$ with the edges incident to any vertex numbered consecutively and arrays of the appropriate dimension are used for cross-referencing and for encoding adjacency lists.

The verification attempt for the maximum cardinality checker shown in Figure 4 discovered a flaw. Note that the program does not check whether the edges in M actually belong to G. When we wrote the checker, we apparently took this for granted. The verification attempt revealed the flaw.

We also considered going further and briefly tried to verify the LEDA maximum cardinality matching algorithm [34, Section 7.7]. The program has 330 lines of code and the description of the algorithm, its implementation and its correctness proof spans over 20 pages. We found the task too daunting and, extrapolating from the effort required for the verification of the checkers, estimated the effort as several man-years.

5 Level Four of Trustworthiness: Formal Verification of Complex Algorithms

A decade later, we perform the formal verification of the blossom-shrinking algorithm for maximum cardinality. We give a short account of the verification which will be described in detail in our forthcoming publication [1]. On a high-level Edmond's blossom-shrinking algorithm [12] works as follows. The algorithm repeatedly searches for an augmenting path with respect to the current matching. Initially, the current matching is empty. Whenever an augmenting path is found, augmentation of the path increases the size of the matching by one. If no augmenting path exists with respect to the current matching, the current matching has maximum cardinality.

The search for an augmenting path is via growing alternating trees rooted at free vertices, i.e. vertices not incident to an edge of the matching. The search is initialised by making each free vertex a root of an alternating tree; the matched nodes are in no tree initially. In an alternating tree, vertices at even depth are entered by a matching edge, vertices at odd depth are entered by a non-matching edge, and all leaves have even depth. In each step of the growth process, one considers a vertex, say u_1, of even depth that is incident to an edge $\{u_1, u_2\}$ not considered before. If u_2 is not in a tree yet, then one adds u_2 (at odd level) and its mate (at even level) under the current matching to the tree. If u_2 is already in a tree and has odd level then one does nothing as one simply has discovered another odd length path to u_2. If u_2 is already in a tree and has even level then one has either discovered an augmenting path (if u_2 is in a different tree than u_1) or a blossom (if u_2 and u_1 are in the same tree). In the latter case, consider the tree paths from u_2 and u_1 back to their common root and let u_3 be the lowest common ancestor of u_2 and u_1. The edge $\{u_1, u_2\}$ plus the tree paths from u_1 and u_2 to u_3 form an odd length cycle. One collapses all nodes on the cycle into a single node and repeats the search for an augmenting path in the quotient (= shrunken) graph. If an augmenting path is found in the quotient graph, it is lifted (refined) to an augmenting path in the original graph. If no augmenting path exists in the quotient graph, no augmenting path exists in the original graph. In this section, we describe in detail the algorithm outlined above, and the process of formalising and verifying it in Isabelle/HOL.

5.1 Isabelle/HOL

Isabelle/HOL [40] is a theorem prover for classical Higher-Order Logic. Roughly speaking, Higher-Order Logic can be seen as a combination of functional programming with logic. Isabelle's syntax is a variation of Standard ML combined with (almost) standard mathematical notation. Application of function f to arguments $x_1 \ \dots \ x_n$ is written as $f \ x_1 \ \dots \ x_n$ instead of the standard notation $f(x_1, \ \dots \ , x_n)$. We explain non-standard syntax in the paper where it occurs.

Isabelle is designed for trustworthiness: following the LCF approach [35], a small kernel implements the inference rules of the logic, and, using encapsulation features of ML, it guarantees that all theorems are actually proved by this small kernel. Around the kernel, there is a large set of tools that implement proof tactics and high-level concepts like algebraic data types and recursive functions. Bugs in these tools cannot lead to inconsistent theorems being proved since they all rely on the kernel only, but only to error messages when the kernel refuses a proof. Isabelle/HOL comes with a rich set of already formalized theories, among which are natural numbers and integers as well as sets and finite sets.

5.2 Preliminaries

An edge is a set of vertices with size 2. A graph $\mathcal{G}$ is a set of edges. A set of edges $\mathcal{M}$ is a matching iff $\forall e, e' \in \mathcal{M}.\ e \cap e' = \emptyset$. In Isabelle/HOL that is represented as follows:

```
matching M ⟷ (∀e1 ∈ M. ∀e2 ∈ M. e1 ≠ e2 ⟶ e1 ∩ e2 = {})
```

In may cases, a matching is a subset of a graph, in which case we call it a matching w.r.t. the graph. For a graph $\mathcal{G}$, $\mathcal{M}$ is a maximum matching w.r.t. $\mathcal{G}$ iff for any matching $\mathcal{M}'$ w.r.t. $\mathcal{G}$, we have that $|\mathcal{M}'| \leq |\mathcal{M}|$.

5.3 Formalising Berge's Lemma

A list of vertices $u_1 u_2 \dots u_n$ is a path w.r.t. a graph $\mathcal{G}$ iff every $\{u_i, u_{i+1}\} \in \mathcal{G}$. A path $u_1 u_2 \dots u_n$ is a simple path iff for every $1 \leq i \neq j \leq n$, $u_i \neq u_j$. A list of vertices $u_1 u_2 \dots u_n$ is an alternating path w.r.t. a set of edges E iff for some E' (i) $E' = E$ or $E' = \{e \mid e \notin E\}$, (ii) $\{u_i, u_{i+1}\} \in E'$ holds for all even numbers i, where $1 \leq i < n$, and (iii) $\{u_i, u_{i+1}\} \notin E'$ holds for all odd numbers i, where $1 \leq i \leq n$. We call a list of vertices $u_1 u_2 \dots u_n$ an augmenting path w.r.t. a matching $\mathcal{M}$ iff $u_1 u_2 \dots u_n$ is an alternating path w.r.t. $\mathcal{M}$ and $u_1, u_n \notin \bigcup \mathcal{M}$. It is often the case that an augmenting path γ w.r.t. to a matching $\mathcal{M}$ is also a simple path w.r.t. a graph $\mathcal{G}$, in which case we call the path an augmenting path w.r.t. to the pair $\langle \mathcal{G}, \mathcal{M} \rangle$. Also, for two sets s and t, $s \oplus t$ denotes the symmetric difference of the two sets. We overload $\oplus$ to arguments which are lists in the obvious fashion.

▶ **Theorem 1** (Berge's Lemma). *For a graph $\mathcal{G}$, a matching $\mathcal{M}$ is maximum w.r.t. $\mathcal{G}$ iff there is not an augmenting path γ w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$.*

Our proof of Berge's lemma is shorter than the standard proof. The standard proof consists of three steps. First, for any two matchings $\mathcal{M}$ and $\mathcal{M}'$, every connected component of the graph $\mathcal{M} \oplus \mathcal{M}'$ is either (i) a singleton vertex, (ii) a path, or (iii) a cycle. Second, for a set of edges $C \subseteq \mathcal{M} \oplus \mathcal{M}'$ s.t. $|C \cap \mathcal{M}| < |C \cap \mathcal{M}'|$, the edges from C form a path. Third, such a set C of edges exists, if $|\mathcal{M}| < |\mathcal{M}'|$. We observe that it is easier to directly show that such a C exists and that all its edges can be arranged in a path, without having to prove the first step about all connected components. We found this different proof during the process of formalising the theorem, and finding this shorter proof was primarily motivated by making the formalisation shorter and more feasible. The discovery of simpler proofs or more general theorem statements is one potential positive outcome of verifying algorithms, and mathematics in general, in interactive theorem provers [3, 2, 10].

Algorithm 1 FIND_MAX_MATCHING($\mathcal{G}, \mathcal{M}$).

```
$\gamma :=$ AUG_PATH_SEARCH($\mathcal{G}, \mathcal{M}$)
if $\gamma$ is some augmenting path
  return FIND_MAX_MATCHING($\mathcal{G}, \mathcal{M} \oplus \gamma$)
else
  return $\mathcal{M}$
```

Now consider Algorithm 1. Berge's lemma implies the validity of that algorithm as a method to compute maximum matchings in graphs. The validity of Algorithm 1 is stated in the following corollary.

▶ **Corollary 1.** *Assume that* AUG_PATH_SEARCH($\mathcal{G}, \mathcal{M}$) *is an augmenting path w.r.t.* $\langle \mathcal{G}, \mathcal{M} \rangle$*, for any graph* $\mathcal{G}$ *and matching* $\mathcal{M}$*, iff* $\mathcal{G}$ *has an augmenting path w.r.t.* $\langle \mathcal{G}, \mathcal{M} \rangle$*. Then, for any graph* $\mathcal{G}$*,* FIND_MAX_MATCHING($\mathcal{G}, \emptyset$) *is a maximum matching w.r.t.* $\mathcal{G}$*.*

As shown in Corollary 1, Algorithm 1 depends on the function AUG_PATH_SEARCH which is a sound and a complete procedure to compute augmenting paths in graphs.

In Isabelle/HOL, the first step is to formalise the path concepts from above. Paths and alternating paths are defined recursively in a straightforward fashion. An augmenting path is defined as follows:

```
augmenting_path M p ≡ (length p ≥ 2) ∧ alt_path M p
                       ∧ hd p ∉ Vs M ∧ last p ∉ Vs M
```

The formalised statement of Berge's lemma is as follows:

```
theorem Berge:
  assumes
    finite M and matching M and M ⊆ E
    and
    (∀e∈E. ∃u v. e = {u,v} ∧ u ≠ v) and finite (Vs E)
  shows (∃p. augmenting_path M p ∧ path E p ∧ distinct p) ⟷
          (∃M' ⊆ E. matching M' ∧ card M < card M')
```

Note that in the formalisation when the paths need to be simple, such as in Berge's lemma above, we have the additional assumption that all vertices are pairwise distinct, denoted by the Isabelle/HOL predicate *distinct*. Just to clarify Isabelle's syntax: the lemma above has two sets of assumptions, one on the matching and the other on the graph. The matching has to be a finite set, which is a matching w.r.t. the given graph. The graph has to have edges which only have two vertices, and its set of vertices has to be finite.

In Isabelle/HOL Algorithm 1 is formalised within the following *locale*.

```
locale find_max_match =
  fixes aug_path_search::'a set set ⇒ 'a set set ⇒ ('a list) option and
    E
  assumes
    aug_path_search_complete:
    matching M ∧ M ⊆ E ∧ finite M ∧
      (∃p. path E p ∧ distinct p ∧ augmenting_path M p)
```

```
         ⟹ (∃p. aug_path_search E M = Some p)
    and
    aug_path_search_sound:
    matching M ∧ M ⊆ E ∧ finite M ∧ aug_path_search E M = Some p ⟹
             path E p ∧ distinct p ∧ augmenting_path M p
    and
    graph: ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v finite (Vs E)
```

A locale is a named context: definitions and theorems proved within locale `find_max_match` can refer to the parameters and assumptions declared there. In this case, we need the locale to identify the parameter `aug_path_search` of the locale, corresponding to the function Aug_Path_Search, which is used in Algorithm 1. The function `aug_path_search` should take as input a graph and a matching. It should return an `('a list) option` typed value. Generally speaking, the value of an `'a option` valued term could be in one of two forms: either `Some x`, or `None`, where `x` is of type `'a`. In the case of `aug_path_search`, it should return either `Some p`, where `p` is a path in case an augmenting path is found, or `None`, otherwise. There is also the function `the`, which given a term of type `'a option`, returns `x`, if the given term is `Some x`, and which is undefined otherwise. Within that locale, the definition of Algorithm 1 and its verification theorem are as follows. Note that the verification theorem has four conclusions: the algorithm returns a subset of the graph, that subset is a matching, that matching is finite and the cardinality of any other matching is bounded by the size of the returned matching.

```
  find_max_matching M =
     (if (∃p. aug_path_search E M = Some p) then
        (find_max_matching (M ⊕ (set (edges_of_path (the (aug_path_search E M))))))
      else M)

lemma find_max_matching_works:
  shows (find_max_matching {}) ⊆ E
    matching (find_max_matching {})
    finite (find_max_matching {})
    ∀M. matching M ∧ M ⊆ E ∧ finite M ⟶ card M ≤ card (find_max_matching {})
```

Functions defined within a locale are parameterised on the constants which are declared in the locale's definition. When a function is used outside a locale, these parameters must be specified. So, if `find_max_matching` is used outside the locale above, it should take a function which computes augmenting paths as a parameter. Similarly, theorems proven within a locale implicitly have the assumptions of the locale. So if we use the lemma `find_max_matching_works`, we would have to prove that the functional argument to `find_max_matching` satisfies the assumptions of the locale, i.e. that argument is a sound and complete procedure for computing augmenting paths. The way theorems from locales are used will be clearer in the next section when we refer to the function `find_max_matching` and use the lemma `find_max_matching_works` outside of the locale `find_max_match`. The use of locales for performing gradual refinement of algorithms allows to focus on the specific aspects of the algorithm relevant to a refinement stage, with the rest of the algorithm abstracted away.

5.4 Verifying that Blossom Contraction Works

In Corollary 1, which specifies the soundness of Find_Max_Matching, we have not explicitly specified the function Aug_Path_Search. Indeed, we have only specified what its output has to conform to. We now refine that specification and describe Aug_Path_Search algorithmically.

Firstly, for a function f and a set s, let $f(\!|s|\!)$ denote the image of f on s. Also, for a set of edges E, and a function f, the quotient E/f is the set $\{f(\!|e|\!) \mid e \in E\}$. We now introduce the concepts of a *blossom*. A list of vertices $u_1 u_2 \dots u_n$ is called a cycle if $3 < n$ and $u_n = u_1$, and we call it an odd cycle if n is even. A pair $\langle u_1 u_2 \dots u_{i-1}, u_i u_{i+1} \dots u_n \rangle$ is a blossom w.r.t. a matching $\mathcal{M}$ iff (i) $u_i u_{i+1} \dots u_n$ is an odd cycle, (ii) $u_1 u_2 \dots u_n$ is an alternating path w.r.t. $\mathcal{M}$, and (iii) $u_1 \notin \bigcup \mathcal{M}$. We also refer to $u_1 u_2 \dots u_i$ as the stem of the blossom. In many situations we have a pair $\langle u_1 u_2 \dots u_{i-1}, u_i u_{i+1} \dots u_n \rangle$ which is a blossom w.r.t. a matching $\mathcal{M}$ where $u_1 u_2 \dots u_{i-1} u_i u_{i+1} \dots u_{n-1}$ is also a simple path w.r.t. a graph $\mathcal{G}$ and $\{u_{n-1}, u_n\} \in \mathcal{G}$. In this case we call it a blossom w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$.

Based on the above definitions, we prove that contracting (i.e. shrinking) the odd cycle of a blossom preserves the existence of an augmenting path, which is the second main result needed to prove the validity of the blossom-shrinking algorithm, after Berge's lemma.

▶ **Theorem 2.** *Consider a graph $\mathcal{G}$ and a vertex $u \notin \bigcup \mathcal{G}$. Let for a set s, the function P_s be defined as $P_s(x) = \mathsf{if}\ x \in s\ \mathsf{then}\ u\ \mathsf{else}\ x$. Then, for a blossom $\langle \gamma, C \rangle$ w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$, if s is the set of vertices in C, then we have an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$ iff there is an augmenting path w.r.t. $\langle \mathcal{G}/P_s, \mathcal{M}/P_s \rangle$.*

Theorem 2 is used in most expositions of the blossom-shrinking algorithm. In our proof for the forward direction (if an augmenting path exists w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$, then there is an augmenting path w.r.t. $\langle \mathcal{G}/P_s, \mathcal{M}/P_s \rangle$, i.e. w.r.t. the quotients), we follow a standard textbook approach [22]. In our proof for the backward direction (an augmenting path w.r.t. the quotients can be lifted to an augmenting path w.r.t. the original graph) we define an (almost) executable function refine that does the lifting.[3] We took the choice of explicitly defining that function with using it in the final algorithm in mind. This is similar to the approach used in the informal proof of soundness of the variant of the blossom-shrinking algorithm used in LEDA [34].

Now, using Theorem 2, one can show that Algorithm 2 is a sound and complete procedure for computing augmenting paths.

Algorithm 2 AUG_PATH_SEARCH($\mathcal{G}, \mathcal{M}$).

```
if COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$) is a blossom $\langle \gamma, C \rangle$ w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$
  return refine(AUG_PATH_SEARCH($\mathcal{G}/P_C, \mathcal{M}/P_C$))
else if COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$) is an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$
  return COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$)
else
  return no augmenting path found
```

The soundness and completeness of this algorithm assumes that COMPUTE_BLOSSOM can successfully compute a blossom or an augmenting path in a graph iff either one exists. This is formally stated as follows.

▶ **Corollary 2.** *Assume that, for a graph $\mathcal{G}$ and a matching $\mathcal{M}$ w.r.t. $\mathcal{G}$, there is a blossom or an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$ iff* COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$) *is a blossom or an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$. Then for any graph $\mathcal{G}$ and matching $\mathcal{M}$,* AUG_PATH_SEARCH($\mathcal{G}, \mathcal{M}$) *is an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$ iff there is an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M} \rangle$.*

[3] The function refine, as defined later, is executable except for a choice operation.

To formalise that in Isabelle/HOL, an odd cycle and a blossom are defined as follows:

```
odd_cycle p ≡ (length p ≥ 3) ∧ odd (length (edges_of_path p)) ∧ hd p = last p

blossom M stem C ≡ alt_path M (stem @ C) ∧
  distinct (stem @ (butlast C)) ∧ odd_cycle C ∧ hd (stem @ C) ∉ Vs M ∧
  even (length (edges_of_path (stem @ [hd C])))
```

In the above definition `@` stands for list concatenation and `edges_of_path` is a function which, given a path, returns the list of edges constituting the path.

To define the function refine that refines a quotient augmenting path to a concrete one or to formalise the theorems showing that contracting blossoms preserves augmenting paths we first declare the following locale:

```
locale quot =
  fixes P s u
  assumes ∀v∈s. P v = v and u∉s and (∀v. v∉s ⟶ P v = u)
```

That locale fixes a function `P`, a set of vertices `s` and a vertex `u`. The function `P` maps all vertices from `s` to the given vertex `u`.

Now, we formalise the function refine which lifts an augmenting path in a quotient graph to an augmenting path in the concrete graph. The function refine takes an augmenting path p in the quotient graph and returns it unchanged if it does not contain the vertex u and deletes u and splits p into two paths p_1 and p_2 otherwise. In the latter case, p_1 and p_2 are passed to `replace_cycle`. This function first defines two auxiliary paths `stem2p2` and `p12stem` using the function `stem2vert_path`. Let us have a closer look at the path `stem2p2`. `stem2vert_path` with last argument `hd p2` uses `choose_con_vert` to find a neighbor of `hd p2` on the cycle C. It splits the cycle at this neighbor and then returns the path leading to the base of the blossom starting with a matching edge. Finally, `replace_cycle` glues together p_1, p_2 and either `stem2p2` and `p12stem` to obtain an augmenting path in the concrete graph.

```
choose_con_vert vs E v ≡ (SOME v'. v' ∈ vs ∧ {v, v'} ∈ E)

stem2vert_path C E M v ≡
let find_pfx' = (λC. find_pfx ((=) (choose_con_vert (set C) E v)) C) in
  if (last (edges_of_path (find_pfx' C)) ∈ M) then
    (find_pfx' C)
  else
    (find_pfx' (rev C))

replace_cycle C E M p1 p2 ≡
 let stem2p2 = stem2vert_path C E M (hd p2);
     p12stem = stem2vert_path C E M (last p1) in
 if p1 = [] then
   stem2p2 @ p2
 else
   (if p2 = [] then
      p12stem @ (rev p1)
    else
     (if {u, hd p2} ∉ quotG M then
        p1 @ stem2p2 @ p2
      else
        (rev p2) @ p12stem @ (rev p1)))
```

```
refine C E M p ≡
 if (u ∈ set p) then
   (replace_cycle C E M (fst (pref_suf [] u p)) (snd (pref_suf [] u p)))
 else p
```

In Isabelle/HOL the two directions of the equivalence in Theorem 2 are formalised as follows:

```
theorem quot_apath_to_apath:
  assumes
    odd_cycle C and alt_path M C and distinct (tl C) and path E C
    and
    augmenting_path (quotG M) p' and distinct p' and path (quotG E) p'
    and
    matching M and M ⊆ E
    and
    s = (Vs E) - set C
    and
    ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v
  shows augmenting_path M (refine C E M p') ∧ path E (refine C E M p') ∧
          distinct (refine C E M p')

theorem aug_path_works_in_contraction:
  assumes
    path E (stem @ C) and blossom M stem C
    and
    augmenting_path M p and path E p and distinct p
    and
    matching M and M ⊆ E and finite M
    and
    s = (Vs E) - set C and u ∉  Vs E
    and
    ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v and finite (Vs E)
  shows ∃p'. augmenting_path (quotG M) p' ∧ path (quotG E) p' ∧ distinct p'
```

A main challenge with formalising Theorem 2 in Isabelle/HOL is the lack of automation for handling symmetries in its proof.

To formalise Algorithm 2 we use a locale to assume the existence of the function which computes augmenting paths or blossoms, iff either one exist. That function is called `blos_search` in the locale declaration. Its return type and the assumptions on it are as follows:

```
datatype 'a blossom_res =
    Path (aug_path: "'a list") | Blossom (stem_vs: "'a list") (cycle_vs: "'a list")

bloss_algo_complete:
  (((∃p. path E p ∧ distinct p ∧ augmenting_path M p)
        ∨ (matching M ∧ (∃stem C. path E (stem @ C) ∧ blossom M stem C))))
     ⟹ (∃blos_comp. blos_search E M = Some blos_comp)

bloss_algo_sound:
  (∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v) ∧ blos_search E M = Some (Path p)
      ⟹ (path E p ∧ distinct p ∧ augmenting_path M p)
  blos_search E M = Some (Blossom stem C)
      ⟹ (path E (stem @ C) ∧ (matching M ⟶ blossom M stem C))
```

The locale also fixes a function *create_vert* which creates new vertex names to which vertices from the odd cycle are mapped during contraction. Within that locale, we define Algorithm 2 and prove its soundness and completeness theorems, which are as follows:

```
quotG E ≡ (quot_graph P E) - {{u}}

find_aug_path E M =
   (case blos_search E M of Some blossom_res ⇒
      case blossom_res of Path p ⇒ Some p
      | Blossom stem cyc ⇒
          let u = create_vert (Vs E);
              s = Vs E - (set cyc);
              quotG = quot.quotG (quot_fun s u) u;
              refine = quot.refine (quot_fun s u) u cyc E M
          in (case find_aug_path (quotG E) (quotG M) of Some p' ⇒ Some (refine p')
              | _ ⇒ None)
     | _ ⇒ None)
```

```
lemma find_aug_path_sound:
  assumes
    matching M and M ⊆ E and finite M
    and
    ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v and finite (Vs E)
    and
    find_aug_path E M = Some p
  shows augmenting_path M p ∧ path E p ∧ distinct p
```

```
lemma find_aug_path_complete:
  assumes
    augmenting_path M p and path E p and distinct p
    and
    matching M and M ⊆ E and finite M
    and
    ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v and finite (Vs E)"
  shows ∃p'. find_aug_path E M = Some p'
```

Note that in *find_aug_path*, we instantiate both arguments *P* an *s* of the locale *quot* to obtain the quotienting function *quotG* and the function for refining augmenting path *refine*.

Lastly, what follows shows the validity of instantiating the functional argument of *find_max_matching* with *find_aug_path*, which gives us the following soundness theorem of the resulting algorithm.

```
lemma find_max_matching_works:
  assumes
    finite (Vs E) and ∀e∈E. ∃u v. e = {u, v} ∧ u ≠ v
  shows
    find_max_match.find_max_matching find_aug_path E {} ⊆ E
    matching (find_max_match.find_max_matching find_aug_path E {})
    finite (find_max_match.find_max_matching find_aug_path E {})
    ∀M. matching M ∧ M ⊆ E ∧ finite M
        ⟶ card M ≤ card (find_max_match.find_max_matching find_aug_path E {})
```

5.5 Computing Blossoms and Augmenting Paths

Until now, we have only assumed the existence of the function COMPUTE_BLOSSOM, which can compute augmenting paths or blossoms, if any exist in the graph. We now refine that to an algorithm which, given two alternating paths resulting from the ascent of alternating trees, returns either an augmenting path or a blossom.

We first introduce some notions and notation. For a list l, let $|l|$ be the length of l. For a list l and a natural number n, let $\mathsf{drop}\ n\ l$ denote the list l, but with the first n elements dropped. For a list l, let $h :: l$ denote adding an element h to the front of a list l. For a non-empty list l, let $\mathsf{first}\ l$ and $\mathsf{last}\ l$ denote the first and last elements of l, respectively. Also, for a list l, let $\mathsf{rev}\ l$ denote its reverse. For two lists l_1 and l_2, let $l_1 \frown l_2$ denote their concatenation. Also, let $\mathsf{longest\_disj\_pref}\ l_1\ l_2$ denote the pair of lists $\langle l'_1, l'_2\rangle$, where l'_1 and l'_2 are the longest disjoint prefixes of $l1$ and l_2, respectively, s.t. $\mathsf{last}\ l'_1 = \mathsf{last}\ l'_2$. Note: $\mathsf{longest\_disj\_pref}\ l_1\ l_2$ is only well-defined if there is are l'_1, l'_2, and l s.t. $l_1 = l'_1 \frown l$ and $l_2 = l'_2 \frown l$, and if both l'_1 and l'_2 are disjoint except at their endpoints.

We now are able to state the following two lemmas concerning the construction of a blossom or an augmenting path given paths resulting from alternating trees search.

▶ **Lemma 1.** *If γ_1 and γ_2 are both (i) simple paths w.r.t. $\mathcal{G}$, (ii) alternating paths w.r.t. $\mathcal{M}$, and (iii) of odd length, and if we have that (iv)* $\mathsf{last}\ \gamma_1 = \mathsf{last}\ \gamma_2$*, (v)* $\mathsf{last}\ \gamma_1 \notin \bigcup \mathcal{M}$*, (vi)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \in \mathcal{G}$*, (vii)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \notin \mathcal{M}$*, and (viii)* $\mathsf{longest\_disj\_pref}\ \gamma_1\ \gamma_2$ *is well-defined and* $\langle \gamma'_1, \gamma'_2\rangle = \mathsf{longest\_disj\_pref}\ \gamma_1\ \gamma_2$*, then* $\langle \mathsf{rev}(\mathsf{drop}\ (|\gamma'_1| - 1)\ \gamma_1), (\mathsf{rev}\ \gamma'_1) \frown \gamma'_2\rangle$ *is a blossom w.r.t. $\langle \mathcal{G}, \mathcal{M}\rangle$.*

▶ **Lemma 2.** *If γ_1 and γ_2 are both (i) simple paths w.r.t. $\mathcal{G}$, (ii) alternating paths w.r.t. $\mathcal{M}$, (iii) of odd length, and (iv) disjoint, and if we have that (v)* $\mathsf{last}\ \gamma_1 \notin \bigcup \mathcal{M}$*, (vi)* $\mathsf{last}\ \gamma_2 \notin \bigcup \mathcal{M}$*, (vii)* $\mathsf{last}\ \gamma_1 \neq \mathsf{last}\ \gamma_2$*, (viii)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \in \mathcal{G}$*, and (ix)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \notin \mathcal{M}$*, then* $(\mathsf{rev}\ \gamma_1) \frown \gamma_2$ *is an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M}\rangle$.*

Based on the above lemmas we refine the algorithm COMPUTE_BLOSSOM as shown in Algorithm 3.

Algorithm 3 COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$).

```
if $\exists e \in \mathcal{G}. e \cap \bigcup \mathcal{M} = \emptyset$
  return Augmenting path choose $\{e \mid e \in \mathcal{G} \wedge e \cap \bigcup \mathcal{M} = \emptyset\}$
else if compute_alt_path$(\mathcal{G}, \mathcal{M}) = \langle \gamma_1, \gamma_2\rangle$
  if last $\gamma_1 \neq$ last $\gamma_2$
    return Augmenting path (rev $\gamma_1) \frown \gamma_2$
  else
    $\langle \gamma'_1, \gamma'_2\rangle =$ longest_disj_pref $\gamma_1\ \gamma_2$
    return Blossom $\langle$rev(drop $(|\gamma'_1| - 1)\ \gamma_1)$, (rev $\gamma'_1) \frown \gamma'_2\rangle$
else
  return No blossom or augmenting path found
```

The following corollary shows the conditions under which COMPUTE_BLOSSOM works.

▶ **Corollary 3.** *Assume the function* $\mathsf{compute\_alt\_path}(\mathcal{G}, \mathcal{M})$ *returns two lists of vertices $\langle \gamma_1, \gamma_2\rangle$ s.t. both lists are (i) simple paths w.r.t. $\mathcal{G}$, (ii) alternating paths w.r.t. $\mathcal{M}$, and (iii) of odd length, and also (iv)* $\mathsf{last}\ \gamma_1 \notin \bigcup \mathcal{M}$*, (v)* $\mathsf{last}\ \gamma_2 \notin \bigcup \mathcal{M}$*, (vi)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \in \mathcal{G}$*, and (vii)* $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \notin \mathcal{M}$*, iff two lists of vertices with those properties exist. Then there is a blossom or an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M}\rangle$ iff* COMPUTE_BLOSSOM($\mathcal{G}, \mathcal{M}$) *is a blossom or an augmenting path w.r.t. $\langle \mathcal{G}, \mathcal{M}\rangle$.*

In Isabelle/HOL, to formalise the function COMPUTE_BLOSSOM, we firstly defined a function, *longest_disj_pfx*, which finds the longest common prefix in a straightforward fashion with a quadratic wort-case runtime. The formalised versions of Lemma 1 and 2, which show that the output of *longest_disj_pfx* can be used to construct a blossom or an augmenting path are as follows:

```
lemma common_pfxs_form_blossom:
  assumes
    (Some pfx1, Some pfx2) = longest_disj_pfx p1 p2"
    and
    p1 = pfx1 @ p and p2 = pfx2 @ p"
    and
    alt_path M p1 and alt_path M p2 and last p1 ∉ Vs M and {hd p1, hd p2} ∈ M"
    and
    hd p1 ≠ hd p2"
    and
    even (length p1) and even (length p2)
    and
    distinct p1 and distinct p2
    and
    matching M
  shows blossom M (rev (drop (length pfx1) p1)) (rev pfx1 @ pfx2)
```

```
lemma construct_aug_path:
  assumes
    set p1 ∩ set p2 = {}
    and
    p1 ≠ [] and p2 ≠ []
    and
    alt_path M p1 and alt_path M p2 and last p1 ∉ Vs M and last p2 ∉ Vs M
    and
    {hd p1, hd p2} ∈ M and
    and
    even (length p1) and even (length p2)
  shows augmenting_path M ((rev p1) @ p2)
```

The function COMPUTE_BLOSSOM is formalised as follows:

```
"compute_blossom G M ≡
 (if (∃e. e ∈ unmatched_edges G M) then
       let
         singleton_path =
            (SOME p. ∃v1 v2. p = [v1 ,v2] ∧ {v1, v2} ∈ unmatched_edges G M)
       in
         Some (Path singleton_path)
   else
    case compute_alt_path G M
      of Some (p1,p2) ⇒
        (if (set p1 ∩ set p2 = {}) then
           Some (Path ((rev p1) @ p2))
         else
           (let
              (pfx1, pfx2) = longest_disj_pfx p1 p2;
              stem = (rev (drop (length (the pfx1)) p1));
              cycle = (rev (the pfx1) @ (the pfx2))
```

```
          in
           (Some (Blossom stem cycle))))
    | _ ⇒ None)"
```

We use a locale again to formalise that function. That locale parameterises it on a function that searches for alternating paths and poses the soundness and completeness assumptions for that alternating path search function. This function is equivalent to the unspecified function compute_alt_path in Corollary 3 and locale's assumptions on it are formalised statements of the seven assumptions on compute_alt_path in Corollary 3.

5.6 Computing Alternating Paths

Lastly, we refine the function compute_alt_path to an algorithmic specification. The algorithmic specification of that function performs the alternating tree search, see Algorithm 4. If the function positively terminates, i.e. finding two vertices with even labels, returns two alternating paths by ascending the two alternating trees to which the two vertices belong. This tree ascent is performed by the function follow . That function takes a functional argument f and a vertex, and returns the singleton list $[u]$ if $f(u) = \text{None}$, and $u :: (\text{follow } f\ (f(u)))$ otherwise.

Algorithm 4 compute_alt_path($\mathcal{G}, \mathcal{M}$).

```
ex = $\emptyset$ // Set of examined edges
foreach $u \in \bigcup \mathcal{G}$
    label $u$ = None
    parent $u$ = None
$U = \bigcup \mathcal{G} \setminus \bigcup \mathcal{M}$ // Set of unmatched vertices
foreach $u \in U$
    label $u = \langle u, \text{even} \rangle$
while $(\mathcal{G} \setminus \text{ex}) \cap \{e \mid \exists u \in e, r \in \bigcup \mathcal{G}.\text{label } u = \langle r, \text{even} \rangle\} \neq \emptyset$
    // Choose a new edge and labelled it examined
    $\{u_1, u_2\} = \text{choose } (\mathcal{G} \setminus \text{ex}) \cap \{\{u_1, u_2\} \mid \exists r.\text{label } u_1 = \langle r, \text{even} \rangle\}$
    $\text{ex} = \text{ex} \cup \{\{u_1, u_2\}\}$
    if label $u_2$ = None
        // Grow the discovered set of edges from $r$ by two
        $u_3 = \text{choose } \{u_3 \mid \{u_2, u_3\} \in \mathcal{M}\}$
        $\text{ex} = \text{ex} \cup \{\{u_2, u_3\}\}$
        label $u_2 = \langle r, \text{odd} \rangle$; label $u_3 = \langle r, \text{even} \rangle$; parent $u_2 = u_1$; parent $u_3 = u_2$
    else if $\exists s \in \bigcup \mathcal{G}.\text{label } u_2 = \langle s, \text{even} \rangle$
        // Return two paths from current edge's tips to unmatched vertex(es)
        return $\langle \text{follow parent } u_1, \text{follow parent } u_2 \rangle$
return No paths found
```

The soundness and completeness of Algorithm 4 is stated as follows.

▶ **Theorem 3.** *The function* compute_alt_path($\mathcal{G}, \mathcal{M}$) *returns two lists of vertices* $\langle \gamma_1, \gamma_2 \rangle$ *s.t. both lists are (i) simple paths w.r.t.* $\mathcal{G}$*, (ii) alternating paths w.r.t.* $\mathcal{M}$*, and (iii) of odd length, and also (iv)* last $\gamma_1 \notin \bigcup \mathcal{M}$*, (v)* last $\gamma_2 \notin \bigcup \mathcal{M}$*, (vi)* $\{\text{first } \gamma_1, \text{first } \gamma_2\} \in \mathcal{G}$*, and (vii)* $\{\text{first } \gamma_1, \text{first } \gamma_2\} \notin \mathcal{M}$*, iff two lists of vertices with those properties exist.*

The primary difficulty with proving this theorem is identifying the loop invariants, which are as follows:

(i) For any vertex u, if for some r, label $u = \langle r, \mathsf{even}\rangle$, then the vertices in the list follow parent u have labels that alternate between $\langle r, \mathsf{even}\rangle$ and $\langle r, \mathsf{odd}\rangle$.

(ii) For any vertex u_1, if for some r and some l, we have label $u_1 = \langle r, l\rangle$, then the vertex list $u_1 u_2 \ldots u_n$ returned by follow parent u_1 has the following property: if label $u_i = \langle r, \mathsf{even}\rangle$ and label $u_{i+1} = \langle r, \mathsf{odd}\rangle$, for some r, then $\{u_i, u_{i+1}\} \in \mathcal{M}$, otherwise, $\{u_i, u_{i+1}\} \notin \mathcal{M}$.

(iii) The relation induced by the function parent is well-founded.

(iv) For any $\{u_1, u_2\} \in \mathcal{M}$, label $u_1 = \text{None}$ iff label $u_2 = \text{None}$.

(v) For any u_1, if label $u_1 = \text{None}$ then parent $u_2 \neq u_1$, for all u_2.

(vi) For any u, if label $u \neq \text{None}$, then last (follow parent u) $\notin \bigcup \mathcal{M}$.

(vii) For any u, if label $u \neq \text{None}$, then label (last (follow parent u)) $= \langle r, \mathsf{even}\rangle$, for some r.

(viii) For any $\{u_1, u_2\} \in \mathcal{M}$, if label $u_1 \neq \text{None}$, then $\{u_1, u_2\} \in \mathsf{ex}$.

(ix) For any u, follow parent u is a simple path w.r.t. $\mathcal{G}$.

(x) Suppose we have two vertex lists γ_1 and γ_2, s.t. both lists are (i) simple paths w.r.t. $\mathcal{G}$, (ii) alternating paths w.r.t. $\mathcal{M}$, and (iii) of odd length, and also (iv) last $\gamma_1 \notin \bigcup \mathcal{M}$, (v) last $\gamma_2 \notin \bigcup \mathcal{M}$, (vi) $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \in \mathcal{G}$, and (vii) $\{\mathsf{first}\ \gamma_1, \mathsf{first}\ \gamma_2\} \notin \mathcal{M}$. Then there is at least an edge from the path rev $\gamma_1 \frown \gamma_2$ which is a member of neither $\mathcal{M}$ nor ex.[4]

To formalise Algorithm 4 in Isabelle/HOL, we first define the function which follows a vertex's parent as follows:

```
follow v = (case (parent v) of Some v' ⇒ v # (follow v') | _  ⇒ [v])
```

Again, we use a locale to formalise that function, and that locale fixes the function *parent*. Note that the above function is not well-defined for all possible arguments. In particular, it is only well-defined if the relation between pairs of vertices induced by the function *parent* is a well-founded relation. This assumption on *parent* is a part of the locale's definition.

Then, we then formalise compute_alt_path as follows:

```
compute_alt_path ex par flabel =
   (if (∃v1 v2. {v1, v2} ∈ G - ex ∧ (∃r. flabel v1 = Some (r, Even))) then
      let
        (v1,v2) = (SOME (v1,v2). {v1, v2} ∈ G - ex ∧
                                 (∃r. flabel v1 = Some (r, Even)));
        ex' = insert {v1, v2} ex;
        r = (SOME r. flabel v1 = Some (r, Even))
      in
        (if flabel v2 = None ∧ (∃v3. {v2, v3} ∈ M) then
          let
            v3 = (SOME v3. {v2, v3} ∈ M);
            par' = par(v2 := Some v1, v3 := Some v2);
            flabel' = flabel(v2 := Some (r, Odd), v3 := Some (r, Even));
            ex'' = insert {v2, v3} ex';
            return = compute_alt_path ex'' par' flabel'
          in
            return
        else if ∃r. flabel v2 = Some (r, Even) then
           let
             r' = (SOME r'. flabel v2 = Some (r', Even));
             return = Some (parent.follow par v1, parent.follow par v2)
```

[4] The hypothesis of this invariant is equivalent to the existence of an augmenting path or a blossom w.r.t. $\langle \mathcal{G}, \mathcal{M}\rangle$.

```
            in
              return
         else
           let
              return = None
           in
             return)
     else
       let
         return = None
       in
         return)
```

Note that we do not use a while combinator to represent the while loop: instead we formalise it recursively, passing the context along recursive calls. In particular, we define it as a recursive function which takes as arguments the variables representing the state of the while loop, namely, the set of examined edges `ex`, the parent function `par`, and the labelling function `flabel`.

5.7 Discussion

The algorithm in LEDA differs from the description above in one aspect. If no augmenting path is found, an odd-set cover is constructed proving optimality. Also the correctness proof uses the odd-set cover instead of the fact that an augmenting path exists in the original graph if and only if one exists in the quotient graph.

For an efficient implementation, the shrinking process and the lifting of augmenting paths are essential. The shrinking process is implemented using a union-find data structure and the lifting is supported by having each node in a contracted cycle point to the edge that closes the cycle in a blossom [34].

6 Level Five of Trustworthiness: Extraction of Efficient Executable Code

In this section we examine the process of obtaining trustworthy executable and efficient code from algorithms verified in theorem provers. First we discuss the problem in general and then we examine our formalization of the blossom-shrinking algorithm.

Most theorem provers are connected to a programming language of some sort. Frequently, as in the case of Isabelle/HOL, that programming language is a subset of the logic and close to a functional programming language. The theorem prover will usually support the extraction of actual code in some programming language. Isabelle/HOL supports Standard ML, Haskell, OCaml and Scala.

To show that code extraction "works", here are some random non-trivial examples of verifications that have resulted in reasonably efficient code: Compilers for C [29] and for ML [23], a SPIN-like model checker [13], network flow algorithms [26] and the Berlekamp-Zassenhaus factorization algorithm [11].

We will now discuss some approaches to obtaining code from function definitions in a theorem prover. In the ACL2 theorem prover all functions are defined in a purely functional subset of Lisp and are thus directly executable. In other systems, code generation involves an explicit translation step. The trustworthiness of this step varies. Probably the most trustworthy code generator is that of HOL4, because its backend is a verified compiler for

CakeML [23], a dialect of ML. The step from HOL to CakeML is not verified once and for all, but every time it is run it produces a theorem that can be examined and that states the correctness of this run [36]. The standard code generator in Isabelle/HOL is unverified (although its underlying theory has been proved correct on paper [18]). There is ongoing work to replace it with a verified code generator that produces CakeML [19].

So far we have only considered purely functional code but efficient algorithms often make use of imperative features. Some theorem provers support imperative languages directly, e.g. Java [4]. We will now discuss how to generate imperative code from purely functional one. Clearly the code generator must turn the purely functional definitions into more imperative ones. The standard approach [7, 36] is to let the code generator recognize monadic definitions (a purely functional way to express imperative computations) and implement those imperatively. This is possible because many functional programming languages do in fact offer imperative features as well.

Just as important as the support for code extraction is the support for verified stepwise refinement of data types and algorithms by the user. Data refinement means the replacement of abstract data types by concrete efficient ones, e.g. sets by search trees. Algorithm refinement means the stepwise replacement of abstract high-level definitions that may not even be executable by efficient implementations. Both forms of refinement are supported well in Isabelle/HOL [17, 24, 25].

We conclude this section with a look at code generation from our formalization of the blossom-shrinking algorithm. It turns out that our formalization is almost executable as is. The only non-executable construct we used is *SOME* `x. P` that denotes some arbitrary `x` that satisfies the predicate `P`. Of course one can hide arbitrarily complicated computations in such a contruct but we have used it only for simple nondeterministic choices and it will be easy to replace. For example, one can obtain an executable version of function `choose_con_vert` (see Section 5.4) by defining a function that searches the vertex list `vs` for the first `v'` such that `{v, v'}` $\in$ `E`. This is an example of algorithm refinement. To arrive at efficient code for the blossom-shrinking algorithm as a whole we will need to apply both data and algorithm refinement down to the imperative level. At least the efficient implementations referred to above, just before Section 5.1, are intrinsically imperative.

Finally let us note that instead of code generation it is also possible to verify existing code in a theorem prover. This was briefly mentioned in Section 4 and Charguéraud [8] has followed this approach quite successfully.

7 The Future

The state of the art in the verification of complex algorithms has improved enormously over the last decade. Yet there is still a lot to do on the path to a verified library such as LEDA. Apart from the shere amount of material that would have to be verified there is the challenge of obtaining trustworthy code that is of comparable efficiency. This requires trustworthy code generation for a language such C or C++, including the memory management. This is a non-trivial task, but some of the pieces of the puzzle, like a verified compiler, are in place already.

Guarded Kleene Algebra with Tests: Verification of Uninterpreted Programs in Nearly Linear Time

Alexandra Silva
University College London, UK
alexandra.silva@ucl.ac.uk

Abstract

Guarded Kleene Algebra with Tests (GKAT) is a variation on Kleene Algebra with Tests (KAT) that arises by restricting the union (+) and iteration (*) operations from KAT to predicate-guarded versions. We develop the (co)algebraic theory of GKAT and show how it can be efficiently used to reason about imperative programs. In contrast to KAT, whose equational theory is PSPACE-complete, we show that the equational theory of GKAT is (almost) linear time. We also provide a full Kleene theorem and prove completeness for an analogue of Salomaa's axiomatization of Kleene Algebra. We will also discuss how this result has practical implications in the verification of programs, with examples from network and probabilistic programming. This is joint work with Nate Foster, Justin Hsu, Tobias Kappe, Dexter Kozen, and Steffen Smolka.

Picking Random Vertices

Daniel Lokshtanov
University of California, San Diego, USA
daniello@ii.uib.no

Abstract

We survey some recent graph algorithms that are based on picking a vertex at random and declaring it to be a part of the solution. This simple idea has been deployed to obtain state-of-the-art parameterized, exact exponential time, and approximation algorithms for a number of problems, such as Feedback Vertex Set and 3-Hitting Set. We will also discuss a recent 2-approximation algorithm for Feedback Vertex Set in Tournaments that is based on picking a vertex at random and declaring it to *not* be part of the solution.

Popular Matchings: Good, Bad, and Mixed

Telikepalli Kavitha
Tata Institute of Fundamental Research, Mumbai, India
kavitha@tifr.res.in

Abstract

We consider the landscape of popular matchings in a bipartite graph G where every vertex has strict preferences over its neighbors. This is a very well-studied model in two-sided matching markets. A matching M is *popular* if it does not lose a head-to-head election against any matching, where each vertex casts a vote for the matching where it gets a better assignment. Roughly speaking, a popular matching is one such that there is no matching where more vertices are happier. The notion of popularity is more relaxed than *stability*: a classical notion studied for the last several decades. Popular matchings always exist in G since stable matchings always exist in a bipartite graph and every stable matching is popular.

Algorithmically speaking, the landscape of popular matching seems to have only a few bright spots. Every stable matching is a *min-size* popular matching and there are also simple linear time algorithms for computing a *max-size* popular matching and for the *popular edge* problem. All these algorithms reduce the popular matching problem to an appropriate question in stable matchings and solve the corresponding stable matching problem.

We now know NP-hardness results for many popular matching problems. These include the min-cost/max-weight popular matching problem and the problem of deciding if G admits a popular matching that is neither a min-size nor a max-size popular matching. For non-bipartite graphs, it is NP-hard to even decide if a popular matching exists or not.

A *mixed* matching is a probability distribution or a lottery over matchings. A popular mixed matching is one that never loses a head-to-head election against any mixed matching. As an allocation mechanism, a popular mixed matching has several nice properties. Moreover, finding a max-weight or min-cost popular mixed matching in G is easy (by solving a linear program). Interestingly, there is always an optimal popular mixed matching Π with a simple structure: $\Pi = \{(M_0, \frac{1}{2}), (M_1, \frac{1}{2})\}$ where M_0 and M_1 are matchings in G. Popular mixed matchings always exist in non-bipartite graphs as well and can be computed in polynomial time.

Petri Net Reachability Problem

Jérôme Leroux
Univ.Bordeaux, CNRS, Bordeaux-INP, France
leroux@labri.fr

Abstract

Petri nets, also known as vector addition systems, are a long established model of concurrency with extensive applications in modelling and analysis of hardware, software and database systems, as well as chemical, biological and business processes. The central algorithmic problem for Petri nets is reachability: whether from the given initial configuration there exists a sequence of valid execution steps that reaches the given final configuration. The complexity of the problem has remained unsettled since the 1960s, and it is one of the most prominent open questions in the theory of verification. In this presentation, we overview decidability and complexity results over the last fifty years about the Petri net reachability problem.

1 Outline

The presentation focuses on the reachability problem for vector addition systems with states given as multi-dimensional weighted automata. Main results about 1) reachability in small dimensions, 2) boundedness problems, and 3) decidability and complexity results for the reachability problem in any dimension will be overviewed.

- For small dimensions, the complexity of the reachability problem depends on the dimension and on the way weights are encoded (in unary or in binary). In dimension one, the reachability problem can be easily shown to be NL-complete when weights are written in unary thanks to a hill-cutting argument (the same argument that applies on pushdown automata). When updates are given in binary, this argument can only provide a complexity in between NP and PSPACE. Nevertheless, by using some additional arguments, the problem was proved to be NP-complete in [5]. The complexity of the reachability problem is also known in dimension two. Thanks to a precise analysis of the algorithm introduced in [12], the problem was proved to be PSPACE-complete in [1] for binary updates. This last result was extended later in [4] to show that the problem is NL-complete for unary updates. In dimension three the complexity of the reachability problem is nowadays open whatever the encoding of the weights.
- The Karp and Miller algorithm introduced in [6] is central for deciding the reachability problem in general dimension. It provides a way for computing the maximal value of a bounded counter. Notice that even if this value can be Ackermannian [16], deciding the boundedness of a counter is known to be EXPSPACE-complete [3] by extending the Rackoff's proof [17].

- The reachability problem was first proved to be decidable by Mayr [14, 15] in 1981. This proof was improved later by Kosaraju [7] and Lambert [8] by introducing an algorithm that decompose the set of executions. We call this decomposition the KLM decomposition (following the initials of the contributed authors). In [10] we proved that the KLM decomposition can be interpreted as ideal decompositions for a natural well-quasi order on the set of executions. In that paper we also provided a cubic-Ackermaninan complexity upper-bound of the reachability problem; the very first complexity upper-bound for the reachability problem. This bound was recently improved in [11], by proving that there exists a KLM decomposition algorithm that works in time primitive recursive in fixed dimension, and at most Ackermannian in general. Concerning lower-bounds, recently in [2], the complexity of the problem was shown to be TOWER-hard, improving the best-known EXPSPACE complexity lower-bound given by Lipton [13] in 1976. Nowadays, the exact complexity of the reachability problem is still open between TOWER and ACKERMANN. In order to close that problem, either we need to improve the recent TOWER lower bound, or we need to design an algorithm improving the ACKERMANN upper bound. The very simple algorithm introduced in [9], based on Presburger inductive invariant seems to be a good candidate for that late direction.

An Improved Online Algorithm for the Traveling Repairperson Problem on a Line

Marcin Bienkowski
Institute of Computer Science, University of Wrocław, Poland
marcin.bienkowski@cs.uni.wroc.pl

Hsiang-Hsuan Liu
Institute of Computer Science, University of Wrocław, Poland
alison.hhliu@cs.uni.wroc.pl

Abstract

In the online variant of the traveling repairperson problem (TRP), requests arrive in time at points of a metric space $\mathcal{X}$ and must be eventually visited by a server. The server starts at a designated point of $\mathcal{X}$ and travels at most at unit speed. Each request has a given weight and once the server visits its position, the request is considered serviced; we call such time *completion time* of the request. The goal is to minimize the weighted sum of completion times of all requests.

In this paper, we give a 5.429-competitive deterministic algorithm for line metrics improving over 5.829-competitive solution by Krumke et al. (TCS 2003). Our result is obtained by modifying the schedule by serving requests that are close to the origin first. To compute the competitive ratio of our approach, we use a charging scheme, and later evaluate its properties using a factor-revealing linear program which upper-bounds the competitive ratio.

1 Introduction

The traveling repairperson problem (TRP) is a variant of the traveling salesperson problem (TSP), where the goal is to minimize the *total latency* instead of a more standard objective of minimizing the total length of a route. In the TRP, there are m requested points of a given metric space $\mathcal{X}$ and they must be eventually visited by a server. Request r_j is a triple (p_j, a_j, w_j), where $p_j \in \mathcal{X}$ denotes request position, $a_j \geq 0$ its release time and w_j its weight.

The server starts at a designated point of $\mathcal{X}$ called *origin* and travels at most at unit speed. That is, for any two times $t < t'$ the distance between positions of the server at times t and t' is at most $t' - t$. Each request r_j must be eventually serviced by moving the server to point p_j. The request cannot be serviced before its release time a_j; we call the time when it is eventually serviced its *completion time* and we denote it C_j. The goal is to find a route for the server (a *schedule*) that minimizes the cost, defined as the weighted sum of completion times, i.e., $\sum_{j=1}^{m} w_j \cdot C_j$.

The TRP has a natural online variant. There, an online algorithm ALG, at time t, knows only requests that arrived before or at time t. The number of requests m is also not known by an algorithm a priori. In the online setting, the goal is to minimize the competitive ratio [11], defined as the maximum over all inputs of the ALG-to-OPT cost ratio, where OPT denotes the optimal offline algorithm.

1.1 Previous work

The online variant has been first investigated by Feuerstein and Stougie [13]. They considered the case where $\mathcal{X}$ is a real line and, adapting an algorithm for the so-called cow-path problem [7], presented a 9-competitive solution. They also gave a lower bound (that holds also already for a line) of $1+\sqrt{2}$. The result has been subsequently improved by Krumke et al. [18], who gave a deterministic algorithm Interval attaining competitive ratio of $(1+\sqrt{2})^2 < 5.829$ and a randomized 3.874-competitive solution. Their algorithm works for an arbitrary metric space.

A natural extension to the TRP is a so-called *dial-a-ride problem*, where each request is an object with a source and a destination and the goal is to transport the object [9, 13, 18]. There, the server may have a fixed capacity allowing it to store at most k objects, or this capacity may be infinite. The 5.829-competitive deterministic algorithm by Krumke et al. [18] extends also to this variant and no better algorithms are known even for specific metric spaces.

Some papers considered an extension of the TRP to $k \geq 1$ servers. Bonifaci and Stougie showed how to adapt the algorithm Interval by Krumke et al. [18] to this setting without an increase of the competitive ratio [10]. However, the best known lower bound for multiple servers is 2 (i.e., smaller than the lower bound for the one-server case) [10]. Furthermore, for the particular case of line metrics, the ratio converges to 1 with growing k, and is between $1 + 1/(2k-1)$ [14] and $1 + O((\log k)/k)$ [10].

Another strand of papers considered different objectives, such as minimizing the total makespan [3, 4, 5, 6, 8, 9] or maximum flow time [16, 17, 19], with a special focus on line metrics. Finally, the offline variant (also known as *minimum latency problem*) has been extensively studied both from the computational hardness and approximation algorithms perspectives, see, e.g., [1, 2, 12, 15, 20, 21].

1.2 Our contribution

In this paper, we focus on the TRP on line metrics and give a 5.429-competitive algorithm Reroute. This improves the long standing record of 5.829 achieved by the algorithm Interval by Krumke et al. [18].

Similarly to the algorithm Interval, Reroute partitions an input into phases of geometrically increasing lengths, and in each phase greedily tries to service the set of pending requests of maximum weight. However, our algorithm Reroute tries to modify the route, so to ensure that (i) either it services requests only in the initial part of the phase, (ii) or in the later part of the phase, it services only requests that are far away from the origin. As such requests cannot be serviced early by any algorithm (also by Opt), this allows us to charge the cost of Reroute against the cost of Opt in a more efficient way.

For the analysis, we construct a charging scheme that maps the total weight serviced by Reroute in particular time intervals to the total weight serviced in appropriate intervals by Opt. This yields a set of linear inequalities that need to hold for any input instance. On this basis, we create a maximization LP (linear program), whose objective value is an upper bound on the competitive ratio. Finally, to bound the value of such factor-revealing LP, we explicitly construct a solution to its dual.

2 Algorithms Interval and ReturnFirst

As our algorithm is built on the phase-based approach of the algorithm Interval proposed by Krumke et al. [18], we start with a description of the latter.

Let $f = \min_j \{\max\{p_j, a_j\}\}$ be the earliest time at which Opt may service a request. (Note that an online algorithm can learn f before or at time f.) Without loss of generality, we may assume that there are no requests that arrive at time 0 at the origin, and hence $f > 0$.

We partition time into phases. Phase 0 starts at time 0 and ends at time f. Phase $i \geq 1$ starts at time $f \cdot \alpha^{i-1}$ and ends at time $f \cdot \alpha^i$, where $\alpha = 1 + \sqrt{2}$. At the beginning of any phase $i \geq 1$, Interval computes and executes a schedule that

- starts at the final server position from the last phase;
- stops at distance at most $f \cdot \alpha^{i-1}$ from the origin;
- has length at most $f \cdot (\alpha^i - \alpha^{i-1})$;
- among schedules satisfying the previous three conditions maximizes the total weight of serviced requests (which are pending when the phase starts).

To simplify the notation, in the rest of the paper, we assume that $f = 1$.[1] We start with a slight modification of the algorithm Interval, called ReturnFirst (RetF). At the beginning of any phase $i \geq 1$, RetF computes and executes a schedule that

- starts at the final server position from the last phase;
- in the first part of the schedule (called *return part*), the server returns to the origin;
- the second part of the schedule (called *serving part*) starts at the origin, is of length at most α^{i-1}, and among such schedules maximizes the total weight of serviced requests (which are pending when the phase starts).

▶ **Observation 1.** *At the beginning of each phase $i \geq 1$, RetF has its server at a distance at most α^{i-2} from the origin. Furthermore, the total length of both parts of the schedule is at most the phase length.*

Proof. The first property is clearly satisfied at the beginning of phase 1, which is started with the server at the the origin. In the subsequent phases, this property follows inductively: as in phase $i - 1$ the serving part of the schedule starts at the origin and has length at most α^{i-2}, at be beginning of phase i the server distance to the origin is at most α^{i-2}.

The second property follows as the total length of the planned schedule in phase i is at most $\alpha^{i-2} + \alpha^{i-1} = \alpha^i - \alpha^{i-1}$, which is the length of the phase. Note that this property holds as long as $\alpha \geq 1 + \sqrt{2}$. ◀

While RetF may produce schedules that are worse than those of Interval, using similar arguments to those of [18], one can show that RetF is α^2-competitive. In particular, the following bound holds both for Interval and RetF; we present its proof for completeness.

In our arguments, we use Alg_i and Opt_i to denote the total weight of requests serviced by an online algorithm and Opt, respectively, in a phase i. Observe that for RetF and Interval, $\text{Alg}_0 = 0$.

▶ **Lemma 2** ([18]). *Let L be the index of the last phase in which Opt services any request. Then, RetF services all requests within the first $L + 1$ phases, and for any phase $j \in \{1, \ldots, L+1\}$, it holds that $\sum_{i=j}^{L+1} \text{Alg}_i \leq \sum_{i=j-1}^{L} \text{Opt}_i$.*

[1] All terms occurring in the proof, both related to distances and to time, have a multiplicative factor f, which cancels out when the competitive ratio is computed.

Proof. Consider the schedule S_k of $\textsc{Opt}$ in phases $0, 1, \ldots, k$, where $k \in \{0, \ldots, L\}$. Schedule S_k starts at the origin, its length is equal to α^k and the total weight serviced by S_k is $w(S_k) = \sum_{i=0}^{k-1} \textsc{Opt}_i$. In phase $k+1$, when $\textsc{RetF}$ chooses the route for the serving part, S_k is among feasible options. If $\textsc{RetF}$ chose such route, then each request serviced by schedule S_k in $\textsc{Opt}$'s solution is serviced by $\textsc{RetF}$ (in phase $k+1$ or already in earlier phases). Thus, the total weight serviced by $\textsc{RetF}$ in phases $1, \ldots, k+1$ would be at least $w(S_k)$. As $\textsc{RetF}$ chooses the schedule for the serving part which is at least as good as S_k, it holds that

$$\textstyle\sum_{i=1}^{k+1} \textsc{Alg}_i \geq w(S_k) = \sum_{i=0}^{k} \textsc{Opt}_i \,. \tag{1}$$

If we set $k = L$, then the above inequality implies that $\textsc{RetF}$ services all requests already in the first $L+1$ phases, i.e.,

$$\textstyle\sum_{i=1}^{L+1} \textsc{Alg}_i = \sum_{i=0}^{L} \textsc{Opt}_i \,. \tag{2}$$

The lemma for $j = 1$ follows by (2), and the lemma for $j \geq 2$ follows by subtracting (1) from (2) and setting $k = j - 2$. ◀

3 Modifying the schedule

We now take a closer look at the structure of schedules produced by $\textsc{RetF}$ in particular phases. We show that the schedule produced in a given phase can be modified, so that it services the same set of requests as $\textsc{RetF}$, but either it ends substantially earlier than the phase end or from some time it services only far requests.

▶ **Lemma 3.** *Fix any $c \in [0, 1]$ and let $\ell = \alpha^{i-1} + c \cdot \alpha^{i-2}$. Fix a schedule S for phase i produced by the algorithm $\textsc{RetF}$. On the basis of S and c, it is possible to construct schedule $\tilde{S}$ that services the same set of requests as S and*

- *Either the length of $\tilde{S}$ is at most ℓ,*
- *or after executing the prefix of $\tilde{S}$ of length ℓ, the server distance from the origin is at least $(1/3) \cdot (\alpha - 1 + 5c) \cdot \alpha^{i-2}$, and afterwards the server travels away from the origin (with unit speed).*

Proof. In the following proof, server positions are real numbers, with zero denoting the origin. Let p denote the server position at the beginning of phase i. Note that we may assume that $p \geq 0$ without loss of generality. As in the proof of Observation 1, it can be inductively shown that in the produced schedule $\tilde{S}$, the server ends phase $i-1$ at most at distance α^{i-2} from the origin. Thus, $p \leq \alpha^{i-2}$.

Let $[b, u]$ be the interval containing all points visited by the serving part of S. As this part starts at zero, $b \leq 0 \leq u$. Let $x \in \{b, u\}$ be the interval endpoint closer to the origin and y be the further one (with ties broken arbitrarily). Observe that the shortest possible schedule that starts at zero and services all requests from interval $[b, u]$ has length $2 \cdot |x| + |y|$. As the serving part of S services this interval and its length is at most α^{i-1}, it holds that

$$2 \cdot |x| + |y| \leq \alpha^{i-1} \text{ and thus } |x| \leq \alpha^{i-1}/3 \,. \tag{3}$$

We use (3) extensively in our bounds below.

We define two possible schedules S_{xy} and S_{yx} for phase i; we show that at least one of them satisfies the requirements of the lemma.

- S_{xy} starts at p, goes to x (possibly going through zero if p and x are on the opposite sides of the origin), and then proceeds through 0 to y. Its length is $|p - x| + |x| + |y|$.

- S_{yx} starts at p, goes to y (possibly going through zero if p and y are on the opposite sides of the origin), and then proceeds through 0 to x. Its length is $|p-y|+|y|+|x|$.

We consider four cases depending on values of x, y, p and c. Note that all these values are known by RetF at the beginning of phase i.

Case 1. If $x<0$ and $p+3\cdot|x| \geq (\alpha-c)\cdot\alpha^{i-2}$, we set $\tilde{S}=S_{yx}$.
We show that the length of $\tilde{S}$ is at most ℓ. As $x<0$, it holds that $y\geq 0$. If $y\leq p$, the length of $\tilde{S}$ is $(p-y)+y+|x| = p+|x| \leq \alpha^{i-2}+\alpha^{i-1}/3 < \alpha^{i-1} \leq \ell$. Otherwise $y>p$, and then the length of $\tilde{S}$ is

$$\begin{aligned}(y-p)+y+|x| &= 2\cdot y - p + |x| \leq 2\cdot(\alpha^{i-1}-2\cdot|x|) - p + |x| \\ &= 2\cdot\alpha^{i-1} - (p+3\cdot|x|) \leq 2\cdot\alpha^{i-1} - (\alpha-c)\cdot\alpha^{i-2} = \ell\,.\end{aligned}$$

Case 2. If $x<0$ and $p+3\cdot|x| < (\alpha-c)\cdot\alpha^{i-2}$, we set $\tilde{S}=S_{xy}$.
If the length of $\tilde{S}$ is at most ℓ, then the lemma follows. Otherwise, we analyze the prefix of $\tilde{S}$ of length ℓ. It contains the server movement from p to x and then to 0: this holds because the total length of this movement is $p+2\cdot|x| < (\alpha-c)\cdot\alpha^{i-2} \leq \alpha^{i-1} \leq \ell$. Thus, after having executed the prefix of $\tilde{S}$ of length ℓ, the server is traveling away from the origin towards y and its position is equal to

$$\begin{aligned}\ell-(p+2\cdot|x|) &= \alpha^{i-1}+c\cdot\alpha^{i-2}-(2/3)\cdot(p+3\cdot|x|)-p/3 \\ &> \alpha^{i-1}+c\cdot\alpha^{i-2}-(2/3)\cdot(\alpha-c)\cdot\alpha^{i-2}-\alpha^{i-2}/3 \\ &= (1/3)\cdot(\alpha-1+5c)\cdot\alpha^{i-2}\,.\end{aligned}$$

Case 3. If $x\geq p\geq 0$, we set $\tilde{S}=S_{xy}$.
The length of $\tilde{S}$ is then $(x-p)+x+|y| = 2\cdot x+|y|-p \leq \alpha^{i-1}-p \leq \ell$.

Case 4. If $p>x\geq 0$, we set $\tilde{S}=S_{xy}$.
The reasoning here is similar to the one from Case 2. If the length of $\tilde{S}$ is at most ℓ, then the lemma follows. Otherwise, we analyze the prefix of $\tilde{S}$ of length ℓ. It contains the server movement from p to 0 through x: this holds because the length of this movement is equal to $p\leq\alpha^{i-2}<\ell$. Thus, after having executed the prefix of $\tilde{S}$ of length ℓ, the server is traveling away from the origin towards y and its distance from the origin is equal to

$$\ell-p \geq \alpha^{i-1}+c\cdot\alpha^{i-2}-\alpha^{i-2} = (\alpha+c-1)\cdot\alpha^{i-2} > (1/3)\cdot(\alpha-1+5c)\cdot\alpha^{i-2}\,.$$

The last inequality follows as $\alpha > 1+c$. ◀

4 Algorithm Reroute

Our algorithm Reroute(β) is parameterized with a constant $\beta\in[2/\alpha,1]$ and follows the phase framework of RetF. At the beginning of any phase $j\geq 1$, Reroute(β) computes the schedule S in the same way RetF would do, modifies it according to Lemma 3 using $c=\beta\cdot\alpha^2-2\cdot\alpha\in[0,1]$ obtaining schedule $\tilde{S}$, and then executes $\tilde{S}$ within phase j.

For any real $\xi\geq[\beta,1]$, we define

$$\tau_\beta(\xi) = \frac{5\cdot\beta\cdot\alpha^2-9\alpha-1}{3\alpha} + (\xi-\beta)\cdot\alpha\,. \tag{4}$$

The following lemma shows that requests that are serviced late by Reroute(β) in a given phase are far away from the origin, and hence cannot be serviced too early by Opt.

▶ **Lemma 4.** *Fix $\beta \in [2/\alpha, 1]$. For any phase i and any value $\xi \geq \beta$, in time interval $(\xi \cdot \alpha^i, \alpha^i]$, $\textsc{Reroute}(\beta)$ services only requests whose distance to the origin is at least $\tau_\beta(\xi) \cdot \alpha^{i-1}$.*

Proof. By the definition of $\textsc{Reroute}(\beta)$, its schedule $\tilde{S}$ for phase i is constructed as described in Lemma 3 with $c = \beta \cdot \alpha^2 - 2\alpha \in [0, 1]$. Let $\ell = \alpha^{i-1} + c \cdot \alpha^{i-2} = \beta \cdot \alpha^i - \alpha^{i-1}$. Recall that phase i starts at time α^{i-1}. By Lemma 3, two cases are possible.

- If the length of $\tilde{S}$ is at most ℓ, then the execution of $\tilde{S}$ ends at or before time $\alpha^{i-1}+\ell = \beta\cdot\alpha^i$. Then, the lemma follows trivially as $\textsc{Reroute}(\beta)$ does not service anything in the remaining part of phase i, i.e., in the time interval $(\beta \cdot \alpha^i, \alpha^i]$.
- Otherwise, the length of $\tilde{S}$ is larger than ℓ. Then, at time $\alpha^{i-1} + \ell = \beta \cdot \alpha^i$, the server still executes $\tilde{S}$, is at distance at least $(1/3) \cdot (\alpha - 1 + 5c) \cdot \alpha^{i-2}$ from the origin and it travels away from the origin with unit speed. Within time interval $[\beta \cdot \alpha^i, \xi \cdot \alpha^i]$, the server either finishes executing $\tilde{S}$ or it increases its distance to the origin by $\xi \cdot \alpha^i - \beta \cdot \alpha^i$. In the former case, the lemma follows trivially, and in the latter case, the server distance to the origin at time $\xi \cdot \alpha^i$ is at least

$$\begin{aligned}\frac{\alpha - 1 + 5c}{3} \cdot \alpha^{i-2} + (\xi - \beta) \cdot \alpha^i &= \frac{5 \cdot \beta \cdot \alpha^2 - 9\alpha - 1}{3} \cdot \alpha^{i-2} + (\xi - \beta) \cdot \alpha^i \\ &= \tau_\beta(\xi) \cdot \alpha^{i-1} .\end{aligned}$$

  From time $\xi \cdot \alpha^i$, the server continues to travel away from the origin, and thus the lemma follows. ◀

4.1 Relating Reroute to Opt

We analyze the performance of algorithm $\textsc{Reroute}(\beta)$ for a fixed parameter β, such that $2/\alpha \leq \beta \leq 1$. Moreover, we choose β, so that $\tau_\beta(\beta) \geq 1/\alpha$. In our analysis we use a parameter ξ, such that $\beta \leq \xi \leq 1$ and $\tau_\beta(\beta) \leq \tau_\beta(\xi) \leq 1$. Concrete values of β and ξ will be fixed later.

Let L be the index of the last phase in which $\textsc{Opt}$ services a request. On the basis of β and ξ, we partition both $\textsc{Alg}_i$ (the total weight of requests serviced in phase $i \in \{1, \dots, L+1\}$ by $\textsc{Reroute}$) and $\textsc{Opt}_i$ (the total weight of requests serviced in phase $i \in \{0, \dots, L\}$ by $\textsc{Opt}$) into three parts:

- A_i^a: the weight serviced by $\textsc{Reroute}(\beta)$ in time interval $(\alpha^{i-1}, \beta \cdot \alpha^i]$,
- A_i^b: the weight serviced by $\textsc{Reroute}(\beta)$ in time interval $(\beta \cdot \alpha^i, \xi \cdot \alpha^i]$,
- A_i^c: the weight serviced by $\textsc{Reroute}(\beta)$ in time interval $(\xi \cdot \alpha^i, \alpha^i]$,
- O_i^a: the weight serviced by $\textsc{Opt}$ in time interval $[\alpha^{i-1}, \tau_\beta(\beta) \cdot \alpha^i)$,
- O_i^b: the weight serviced by $\textsc{Opt}$ in time interval $[\tau_\beta(\beta) \cdot \alpha^i, \tau_\beta(\xi) \cdot \alpha^i)$,
- O_i^c: the weight serviced by $\textsc{Opt}$ in time interval $[\tau_\beta(\xi) \cdot \alpha^i, \alpha^i)$.

Note that the validity of this partitioning requires that $1/\alpha \leq \beta \leq \xi \leq 1$ and $1/\alpha \leq \tau_\beta(\beta) \leq \tau_\beta(\xi) \leq 1$. We slightly modify the definition of A_0^a and O_L^c to include also the initial and final time points, i.e., to be the weight serviced by $\textsc{Reroute}(\beta)$ in $[\alpha^0, \beta \cdot \alpha^1]$ and the weight serviced by $\textsc{Opt}$ in $[\tau_\beta(\xi) \cdot \alpha^L, \alpha^L]$, respectively. Clearly, $\textsc{Alg}_i = \mathrm{A}_i^a + \mathrm{A}_i^b + \mathrm{A}_i^c$ and $\textsc{Opt}_i = \mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c$.

As $\textsc{Reroute}$ services the same set of requests as $\textsc{RetF}$, the guarantee of Lemma 2 applies to the schedule produced by $\textsc{Reroute}(\beta)$ as well. In particular, $\textsc{Reroute}(\beta)$ finishes servicing all requests till the end of phase $L + 1$ (it does not service anything in phase 0) and for any phase $j \in \{1, \dots, L + 1\}$, it holds that

$$\sum_{i=j}^{L+1} \left(\mathrm{A}_i^a + \mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \sum_{i=j-1}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) . \tag{5}$$

Fix any phase $j \in \{1, \ldots, L+1\}$ and consider all requests contributing to the sum $\sum_{i=j}^{L+1}(\mathrm{A}_i^b + \mathrm{A}_i^c)$. By Lemma 4, each such request has to be serviced by Opt at time $\tau_\beta(\beta) \cdot \alpha^{j-1}$ or later (because its distance to the origin is at least $\tau_\beta(\beta) \cdot \alpha^{j-1}$). Thus,

$$\sum_{i=j}^{L+1} \left(\mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \mathrm{O}_{j-1}^b + \mathrm{O}_{j-1}^c + \sum_{i=j}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) . \tag{6}$$

Similarly, consider all requests contributing to the sum $\mathrm{A}_j^c + \sum_{i=j+1}^{L+1}(\mathrm{A}_i^b + \mathrm{A}_i^c)$. Again, by Lemma 4, each such request has to be serviced by Opt at time $\tau_\beta(\xi) \cdot \alpha^{j-1}$ or later (because its distance to the origin is at least $\tau_\beta(\xi) \cdot \alpha^{j-1}$). Hence,

$$\mathrm{A}_j^c + \sum_{i=j+1}^{L+1} \left(\mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \mathrm{O}_{j-1}^c + \sum_{i=j}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) . \tag{7}$$

Finally, observe that the total cost of Reroute(β) can be upper-bounded by $\sum_{i=1}^{L+1}(\beta \cdot \alpha^i \cdot \mathrm{A}_i^a + \xi \cdot \alpha^i \cdot \mathrm{A}_i^b + \alpha^i \cdot \mathrm{A}_i^c)$ and the cost of Opt can be lower-bounded by $\sum_{i=0}^{L}(\alpha^{i-1} \cdot \mathrm{O}_i^a + \tau_\beta(\beta) \cdot \alpha^i \cdot \mathrm{O}_i^b + \tau_\beta(\xi) \cdot \alpha^i \cdot \mathrm{O}_i^c)$.

4.2 Factor-revealing LP

Let us now consider what happens when an adversary constructs an instance $\mathcal{I}$ for the algorithm Reroute. When Opt is run on $\mathcal{I}$, this defines L as the index of the last phase when Opt services a request and this also defines non-negative values of variables $\mathrm{O}_i^a, \mathrm{O}_i^b, \mathrm{O}_i^c$ for $i \in \{0, \ldots, L\}$. When Reroute(β) is run on $\mathcal{I}$, this defines non-negative values of variables $\mathrm{A}_i^a, \mathrm{A}_i^b, \mathrm{A}_i^c$ for $i \in \{1, \ldots, L+1\}$. As shown above, these variables satisfy inequalities (5), (6) and (7). Moreover, the goal of the adversary is to maximize the ratio between the cost of Reroute(β) and the cost of Opt.

This maximization problem may become only easier for the adversary if instead of creating an actual input sequence, the adversary simply chooses L and the non-negative values of variables $\mathrm{A}_i^a, \mathrm{A}_i^b, \mathrm{A}_i^c$, $\mathrm{O}_i^a, \mathrm{O}_i^b, \mathrm{O}_i^c$ for $i \in \{0, \ldots, L\}$, satisfying inequalities (5), (6) and (7), so to maximize the objective value of Reroute-to-Opt cost ratio.

The values of all variables can be multiplied by a fixed value without changing the objective value. Thus, instead of maximizing the cost ratio, the adversary may maximize total cost of Reroute(β) with an additional constraint ensuring that the total cost of Opt is at most 1.

This leads to the following factor-revealing linear program $\mathcal{P}(L, \beta, \xi)$, whose optimal value $P^*(L, \beta, \xi)$ is an upper bound on the competitive ratio of Reroute(β) for a given L. This relation holds for any choice of parameter $\xi \in [\beta, 1]$. The goal of $\mathcal{P}(L, \beta, \xi)$ is to maximize

$$\sum_{i=1}^{L+1} \left(\beta \cdot \alpha^i \cdot \mathrm{A}_i^a + \xi \cdot \alpha^i \cdot \mathrm{A}_i^b + \alpha^i \cdot \mathrm{A}_i^c\right)$$

subject to the following constraints

$$\sum_{i=j}^{L+1} \left(\mathrm{A}_i^a + \mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \sum_{i=j-1}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) \qquad \text{for all } j \in \{1,\dots,L+1\}$$

$$\sum_{i=j}^{L+1} \left(\mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \mathrm{O}_{j-1}^b + \mathrm{O}_{j-1}^c + \sum_{i=j}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) \qquad \text{for all } j \in \{1,\dots,L+1\}$$

$$\mathrm{A}_j^c + \sum_{i=j+1}^{L+1} \left(\mathrm{A}_i^b + \mathrm{A}_i^c\right) \leq \mathrm{O}_{j-1}^c + \sum_{i=j}^{L} \left(\mathrm{O}_i^a + \mathrm{O}_i^b + \mathrm{O}_i^c\right) \qquad \text{for all } j \in \{1,\dots,L+1\}$$

$$\sum_{i=0}^{L} \left(\alpha^{i-1} \cdot \mathrm{O}_i^a + \tau_\beta(\beta) \cdot \alpha^i \cdot \mathrm{O}_i^b + \tau_\beta(\xi) \cdot \alpha^i \cdot \mathrm{O}_i^c\right) \leq 1$$

and non-negativity of the variables. Note that the left hand side of the last inequality is a lower bound on the cost of Opt

It remains to upper-bound the value of $P^*(L, \beta, \xi)$. Such upper bound is given by the value of any feasible solution to the dual program $\mathcal{D}(L, \beta, \xi)$. The goal of $\mathcal{D}(L, \beta, \xi)$ is to minimize $\mathcal{R}$ subject to the following constraints

$$\sum_{i=1}^{j} q_i^a \geq \beta \cdot \alpha^j \qquad \text{for all } j \in \{1,\dots,L+1\} \tag{8}$$

$$\sum_{i=1}^{j-1} \left(q_i^a + q_i^b + q_i^c\right) + q_j^a + q_j^b \geq \xi \cdot \alpha^j \qquad \text{for all } j \in \{1,\dots,L+1\} \tag{9}$$

$$\sum_{i=1}^{j} \left(q_i^a + q_i^b + q_i^c\right) \geq \alpha^j \qquad \text{for all } j \in \{1,\dots,L+1\} \tag{10}$$

$$\alpha^{j-1} \cdot \mathcal{R} \geq \sum_{i=1}^{j} \left(q_i^a + q_i^b + q_i^c\right) + q_{j+1}^a \qquad \text{for all } j \in \{0,\dots,L\} \tag{11}$$

$$\tau_\beta(\beta) \cdot \alpha^j \cdot \mathcal{R} \geq \sum_{i=1}^{j} \left(q_i^a + q_i^b + q_i^c\right) + q_{j+1}^a + q_{j+1}^b \qquad \text{for all } j \in \{0,\dots,L\} \tag{12}$$

$$\tau_\beta(\xi) \cdot \alpha^j \cdot \mathcal{R} \geq \sum_{i=1}^{j+1} \left(q_i^a + q_i^b + q_i^c\right) \qquad \text{for all } j \in \{0,\dots,L\} \tag{13}$$

and non-negativity of the variables. Note that sets of inequalities (8), (9), (10), (11), (12) and (13) correspond to sets of variables A_i^a, A_i^b, A_i^c, O_i^a, O_i^b and O_i^c, respectively, in the primal program $\mathcal{P}(L, \beta, \xi)$.

▶ **Lemma 5.** *There exist values β and ξ, such that for any L, there exists a feasible solution to $\mathcal{D}(L, \beta, \xi)$ whose value is at most $2\sqrt{2} + 13/5 < 5.429$.*

Proof. We choose

$$\beta = (9\alpha + 4)/(5\alpha^2) = (3 + \sqrt{2})/5 \approx 0.883 \text{ and}$$
$$\xi = \beta + (1 - \beta)/\alpha = (4\sqrt{2} - 1)/5 \approx 0.931\,.$$

For these values of β and ξ, it holds that

$$\tau_\beta(\beta) = 1/\alpha = \sqrt{2} - 1 \approx 0.414 \text{ and}$$
$$\tau_\beta(\xi) = \tau_\beta(\beta) + (\xi - \beta) \cdot \alpha = 1/\alpha + (2 - \sqrt{2})/5 = (5 + \sqrt{2})/(5 + 5\sqrt{2}) \approx 0.531\,.$$

We set the dual variables as follows:

$$\begin{aligned}
&q_1^a = \beta \cdot \alpha\,, && \\
&q_1^b = (\xi - \beta) \cdot \alpha\,, && \\
&q_1^c = (1 - \xi) \cdot \alpha\,, && \\
&q_j^a = \beta \cdot (\alpha - 1) \cdot \alpha^{j-1} && \text{for } j \in \{2, \dots, L+1\}\,, \\
&q_j^b = 0 && \text{for } j \in \{2, \dots, L+1\}\,, \\
&q_j^c = (1 - \beta) \cdot (\alpha - 1) \cdot \alpha^{j-1} && \text{for } j \in \{2, \dots, L+1\}\,.
\end{aligned}$$

Our choice of β, ξ and dual variables satisfy (8), (9) and (10) conditions of $\mathcal{D}(L, \beta, \xi)$ with equality. Actually, (8), (10) and (9) for $j = 1$ hold with equality for any choice of β and ξ. For $j \in \{2, \dots, L+1\}$, the left hand side of (9) is equal to $\alpha^{j-1} + \beta \cdot (\alpha - 1) \cdot \alpha^{j-1} = (\beta \cdot \alpha + 1 - \beta) \cdot \alpha^{j-1}$, and the right hand side is equal to $\xi \cdot \alpha^j$; these values coincide for $\xi = \beta + (1 - \beta)/\alpha$.

Given the fixed values of the dual variables, we choose $\mathcal{R}$ as the minimum value satisfying inequalities (11), (12) and (13). Substituting the chosen values of the dual variables in these inequalities and using $\tau_\beta(\beta) = 1/\alpha$, yields

$$\begin{aligned}
&\mathcal{R} \geq (\beta \cdot \alpha)/\alpha^{-1} = \beta \cdot \alpha^2 && \text{by (11) for } j = 0\,, \\
&\mathcal{R} \geq (\alpha^j + \beta \cdot (\alpha - 1) \cdot \alpha^j)/\alpha^{j-1} = \beta \cdot \alpha^2 + \alpha - \beta \cdot \alpha && \text{by (11) for } j \geq 1\,, \\
&\mathcal{R} \geq (\beta \cdot \alpha + (\xi - \beta) \cdot \alpha)/\tau_\beta(\beta) = \xi \cdot \alpha^2 && \text{by (12) for } j = 0\,, \\
&\mathcal{R} \geq (1 + \beta \cdot (\alpha - 1)) \cdot \alpha^j/(\tau_\beta(\beta) \cdot \alpha^j) = \beta \cdot \alpha^2 + \alpha - \beta \cdot \alpha && \text{by (12) for } j \geq 1\,, \\
&\mathcal{R} \geq \alpha^{j+1}/(\tau_\beta(\xi) \cdot \alpha^j) = \alpha/\tau_\beta(\xi) && \text{by (13) for } j \geq 0\,.
\end{aligned}$$

Thus, using $\beta \leq \xi$ and $\xi = \beta + (1 - \beta)/\alpha$, we obtain

$$\begin{aligned}
\mathcal{R} &= \max\left\{\beta \cdot \alpha^2,\ \beta \cdot \alpha^2 + \alpha - \beta \cdot \alpha,\ \xi \cdot \alpha^2,\ \frac{\alpha}{\tau_\beta(\xi)}\right\} \\
&= \max\left\{\xi \cdot \alpha^2,\ \frac{\alpha}{\tau_\beta(\xi)}\right\} \\
&= \max\left\{2\sqrt{2} + 13/5,\ (15 + 10\sqrt{2})/(5 + \sqrt{2})\right\} \\
&= 2\sqrt{2} + 13/5 < 5.429\,,
\end{aligned}$$

which concludes the proof. ◀

▶ **Theorem 6.** *For $\beta = (3 + \sqrt{2})/5 \approx 0.883$, the competitive ratio of* Reroute(β) *for the traveling repairperson problem is at most $2\sqrt{2} + 13/5 < 5.429$.*

Proof. Fix any input sequence $\mathcal{I}$, run Opt on $\mathcal{I}$, and partition its execution into phases. Let L be the index of the last phase in which Opt services a request.

Let $\xi = \beta + (1 - \beta)/\alpha$. As discussed above, the competitive ratio of Reroute(β) is upper-bounded by the optimal value $P^*(L, \beta, \xi)$ of the maximization program $\mathcal{P}(L, \beta, \xi)$. By weak duality, the feasible solution to the dual minimization program $\mathcal{D}(L, \beta, \xi)$ of value $2\sqrt{2} + 13/5$ proposed in Lemma 5 is an upper bound on the optimal primal solution $P^*(L, \beta, \xi)$. Hence, $2\sqrt{2} + 13/5$ is an upper bound on the competitive ratio of Reroute(β). ◀

5 Final remarks

Our computer-based experiments show that further partitioning of phases into more than three intervals does not lead to an improvement of the competitive ratio.

Furthermore, it is possible to show that our solution to the dual program is asymptotically best possible and the ratio cannot be improved by simply choosing better parameters β and ξ. That is, with growing L, the optimal value of the dual $\mathcal{D}(L, \beta, \xi)$ converges to the value $2\sqrt{2} + 13/5$ given by Lemma 5, as demonstrated in the lemma below.

▶ **Lemma 7.** *Fix any L. For any values of β and ξ, satisfying $1/\alpha \le \beta \le \xi \le 1$ and $1/\alpha \le \tau_\beta(\beta) \le \tau_\beta(\xi) \le 1$, the value of any feasible solution to the dual program $\mathcal{D}(L, \beta, \xi)$ is at least $(2\sqrt{2} + 13/5)/(1 + \alpha^{-L})$.*

Proof. Fix any $j \in \{1, \dots, L\}$. By combining requirement (11) with (10), we obtain

$$\begin{aligned}(\mathcal{R} - \alpha) \cdot \alpha^{j-1} &= \mathcal{R} \cdot \alpha^{j-1} - \alpha^j \\ &\ge \sum_{i=1}^{j} \left(q_i^a + q_i^b + q_i^c\right) + q_{j+1}^a - \sum_{i=1}^{j} \left(q_i^a + q_i^b + q_i^c\right) \\ &= q_{j+1}^a \,.\end{aligned}$$

Summing this relation over all $j \in \{1, \dots, L\}$ and using (8) yields

$$(\mathcal{R} - \alpha) \cdot \frac{\alpha^L - 1}{\alpha - 1} \ge \sum_{j=1}^{L} q_{j+1}^a = -q_1^a + \sum_{j=1}^{L+1} q_j^a \ge \beta \cdot \alpha^{L+1} - q_1^a \,.$$

Now we observe that (11) for $j = 1$ implies $q_1^a \le \mathcal{R}/\alpha < \mathcal{R}/(\alpha - 1)$. By substituting this in the inequality above and multiplying both sides by $\alpha - 1$, we get

$$(\mathcal{R} - \alpha) \cdot (\alpha^L - 1) \ge \beta \cdot (\alpha - 1) \cdot \alpha^{L+1} - \mathcal{R} \,.$$

Finally, we divide both sides by α^L, obtaining

$$\mathcal{R} - \alpha \ge (\mathcal{R} - \alpha) \cdot (\alpha^L - 1)/\alpha^L \ge \beta \cdot (\alpha - 1) \cdot \alpha - \mathcal{R}/\alpha^L \,,$$

and therefore,

$$\mathcal{R} \cdot (1 + \alpha^{-L}) \ge \beta \cdot \alpha^2 + \alpha - \beta \cdot \alpha \,.$$

As in our construction we require $\tau_\beta(\beta) \ge 1/\alpha$, it holds that $\beta \ge (9\alpha + 4)/(5\alpha^2) = (3 + \sqrt{2})/5$. Combining this bound with the value of $\alpha = 1 + \sqrt{2}$ yields

$$\mathcal{R} \ge (\beta \cdot \alpha^2 + \alpha - \beta \cdot \alpha)/(1 + \alpha^{-L}) \ge (2\sqrt{2} + 13/5)/(1 + \alpha^{-L}) \,.$$ ◀

Abstract

We study the problem of sorting under incomplete information, when queries are used to resolve uncertainties. Each of n data items has an unknown value, which is known to lie in a given interval. We can pay a query cost to learn the actual value, and we may allow an error threshold in the sorting. The goal is to find a nearly-sorted permutation by performing a minimum-cost set of queries.

We show that an offline optimum query set can be found in polynomial time, and that both oblivious and adaptive problems have simple query-competitive algorithms. The query-competitiveness for the oblivious problem is n for uniform query costs, and unbounded for arbitrary costs; for the adaptive problem, the ratio is 2.

We then present a unified adaptive strategy for uniform query costs that yields: (i) a 3/2-query-competitive randomized algorithm; (ii) a 5/3-query-competitive deterministic algorithm if the dependency graph has no 2-components after some preprocessing, which has query-competitive ratio $3/2 + \mathrm{O}(1/k)$ if the components obtained have size at least k; (iii) an exact algorithm if the intervals constitute a laminar family. The first two results have matching lower bounds, and we have a lower bound of 7/5 for large components.

We also show that the advice complexity of the adaptive problem is $\lfloor n/2 \rfloor$ if no error threshold is allowed, and $\lceil n/3 \cdot \lg 3 \rceil$ for the general case.

1 Introduction

Sorting is one of the most fundamental problems in computer science and an essential part of any system dealing with large amounts of data. High-performance algorithms such as QuickSort [19] have been known for decades, but the demand for fast sorting of huge amounts of data is such that improvements in sorting algorithms are still an active area of research; see, e.g., [26].

In a distributed application with dynamic data, it may not be feasible to maintain a precise copy of the information in each replica. In particular, to access a local cached information may be much cheaper, even though not as precise, than to query a master database or to run a distributed consensus algorithm. One approach is to maintain in the replicas, for each data item, an interval that bounds the actual value. These intervals can be updated much faster than to guarantee a strict consistency of the data. When higher

[1] Corresponding author.

precision is required, the system can query the master database for a more fine-grained interval or for the actual data value. Therefore a trade-off between data precision and system performance can be established. The TRAPP system, proposed by Olston and Widom [24], relies on this concept.

This idea has led to theoretical investigation on **uncertainty problems with queries** [7, 11, 12, 13, 14, 17, 22]. Such problems also appear in optimization scenarios in which an extra effort can be incurred in order to obtain more precise values of the input data, such as by investing in market research, which is expensive so its cost should be minimized. These works build upon more established frameworks of optimization with uncertainty, such as online [5], robust [3] and stochastic [4] optimization. In particular, the analysis of algorithms in terms of competitiveness against an adversary is inherited from the online optimization literature.

In this paper, we investigate the problem of sorting data items whose actual values are unknown, but for which we are given intervals on which the actual values lie. We can **query** an interval and then learn the actual value of the corresponding data item, but this incurs some cost. The goal, then, is to sort the items by performing a set of queries of minimum cost. Furthermore, the precision in the sorting may be relaxed, so that inversions may occur if the actual values are not too far apart.

We distinguish between two types of algorithms for uncertainty problems with queries. An **adaptive** algorithm may decide which queries to perform based on results from previous queries. An **oblivious** algorithm, however, must choose the whole set of queries to perform in advance; i.e., it must choose a set of queries that certainly allow the problem to be solved without any knowledge of the actual values. In this paper, both algorithms are compared with an offline optimum query set, i.e., a minimum-cost set of queries that proves the obtained solution to be correct.[2] An algorithm (either adaptive or oblivious) is **α-query-competitive** if it performs a total query cost of at most α times the cost of an offline optimum query set.

Another related problem is that of finding an **optimum query set**. Here we are given the actual data values, and want to identify a minimum-cost set of queries that would be sufficient to prove that the solution is correct. Solving this problem is useful, for example, to perform experimental evaluation of online algorithms, since we are actually finding the offline optimum solution for the uncertainty problem. This is also called the **verification version** of the corresponding uncertainty problem with queries [8, 11].

We are also interested in the **advice complexity** of the problems we study. In this setting, an online algorithm has access to an oracle that can give helpful information when making decisions. The advice complexity is the number of bits of advice that are sufficient and necessary for an online algorithm to solve the problem exactly. This is a research topic that has gained substantial attention; see [6] for a survey.

Our contribution. We begin by showing how to compute an optimum query set in polynomial time, and that both oblivious and adaptive problems have simple algorithms with matching deterministic lower bounds. The query-competitive ratio of the oblivious problem is n if we have uniform query costs, and unbounded for arbitrary costs; for the adaptive problem, the query-competitive ratio is 2. The optimal oblivious algorithm is trivial; for the

[2] This nomenclature differs to that used by Feder et al. [14]. They call an adaptive algorithm an **online** algorithm, and an oblivious algorithm an **offline** algorithm. We disagree with this nomenclature, since both types of algorithms are online in the standard sense of not knowing the data. Also, they compare an oblivious algorithm to an optimal oblivious strategy, and not to an offline optimum query set.

adaptive case, we have a simpler algorithm for uniform query costs, and a more sophisticated one for arbitrary query costs. If query costs are uniform and the error threshold is zero, then the simpler algorithm can be implemented as an oracle for any comparison-based sorting algorithm, preserving time complexity and stability.

Those results are rather simple and it seems like the query-competitiveness of the problem is settled. However, we present a unified adaptive strategy that attains different improvements for uniform query costs. First, we obtain a 3/2-query-competitive algorithm by using randomization. Second, if the error threshold is zero, and after some preprocessing the dependency graph has no 2-components, the strategy yields a deterministic 5/3-query-competitive algorithm; if the obtained graph has components of size at least k, then the same algorithm has query-competitive ratio $3/2 + \mathrm{O}(1/k)$. The first two results have a matching lower bound, and for large components we have a lower bound of 7/5. The problem can also be solved exactly if the intervals constitute a laminar family.

Finally, we show that the advice complexity for adaptive algorithms is exactly $\lfloor n/2 \rfloor$ bits if there is no error threshold, and exactly $\lceil n/3 \cdot \lg 3 \rceil$ bits for the general case.

Related work. The first work to investigate the minimum number of queries to solve a problem is by Kahan [20], who showed optimal oblivious strategies to find the minimum, maximum and median of n values in uncertainty intervals.

Olston and Widom [24] proposed the TRAPP system, a distributed database based on uncertainty intervals. The authors: (1) gave an optimal oblivious strategy for finding the minimum (and equivalently, the maximum) of a sequence of values within an error bound; (2) showed that it is NP-hard to find an optimum oblivious query set to compute the sum of a sequence of values within an error bound, with a reduction from the knapsack problem. The paper also discusses strategies for counting and finding the average of a sequence of values. Khanna and Tan [21] generalized these results for arbitrary query costs and different levels of precision.

Feder et al. [14] considered the uncertainty version of the problem of finding the k-th largest value on a sequence (i.e., the generalized median problem). The authors presented optimal oblivious and adaptive strategies for the problem, both running in polynomial time. Both strategies are optimal, and the ratio between the oblivious and the adaptive strategy (also called the **price of obliviousness**) is $\frac{2k-1}{k} < 2$ for uniform query costs, and k for arbitrary query costs.[3]

Bruce et al. [7] studied geometric problems where the points are given in uncertainty areas. The authors gave 3-query-competitive algorithms for finding the maximal points and the convex hull in a two-dimensional space. They also proposed the concept of **witness sets**, which has been used subsequently in various works on uncertainty problems with queries. Charalambous and Hoffman [8] showed that it is NP-hard to find an optimum query set for the maximal points problem.

Feder et al. [13] studied the uncertainty variant of the shortest path problem. They showed that to solve optimally the oblivious version of the problem is neither NP nor co-NP, unless NP = co-NP. Their paper also discusses the complexity of the problem for various particular cases.

Erlebach et al. [12] proved that the minimum spanning tree problem with uncertainty admits an adaptive 2-query-competitive algorithm, which is the best possible for a deterministic algorithm. Erlebach, Hoffmann and Kammer [11] studied a generalization called the

[3] The works cited up to this point do not evaluate the algorithms using the competitiveness framework.

cheapest set problem, for which there is an adaptive algorithm with at most $d \cdot \mathrm{opt} + d$ queries, where d is the maximum cardinality of a set. They also generalized the result in the previous work to obtain an adaptive 2-query-competitive algorithm for the problem of finding a minimum-weight base on a matroid.

Gupta, Sabharwal and Sen [18] studied various of the previous problems in the setting where a query may return a refined interval, instead of the exact value of the data item.

Megow, Meißner and Skutella [22] improved the result for the minimum spanning tree problem with a randomized adaptive algorithm, obtaining query-competitive ratio 1.7. (The problem has lower bound 1.5 for randomized algorithms.) They also considered non-uniform query costs and proved that their results can be extended to find a minimum-weight base on a matroid. Furthermore, they showed that an optimum query set and the actual value of the minimum spanning tree can be computed in polynomial time. Some experimental evaluation of those algorithms were presented in [15].

Ryzhov and Powell [25] investigated how to solve a linear program while minimizing the query cost when the coefficients of the objective function are uncertain. They presented a policy which is asymptotically optimal. Yamaguchi and Maehara [28] studied the variant with packing constraints and coefficients following a probability distribution, and showed how to apply this to stochastic problems such as matching, matroid and stable set problems.

Note that all the work cited so far deals with problems whose classical (offline) versions can be solved in polynomial time. Uncertainty versions with queries have been proposed for the knapsack problem [17] and the scheduling problem [2, 9]. Since those problems are NP-hard, we might include the query cost into the solution cost and look for a competitive algorithm if we are looking for a polynomial-time algorithm. Another option is to limit the maximum number of queries performed, and then to try to optimize the solution cost.

For a survey on the topic, see [10]. Other references for related problems are also cited in [11].

Another sorting problem with uncertainty was studied by Ajtain et al. [1]. In that problem, the values to be sorted are unknown, but their relative order can be tested by a comparison procedure. However, comparing values that are too close returns imprecise answers, so in principle we should compare all $\binom{n}{2}$ pairs to obtain a sorting with some error guarantee. The authors show how to solve the problem using only $\mathrm{O}(n^{3/2})$ comparisons.

Organization of the paper. In Section 2, we present the sorting problem with uncertainty and some basic facts, and in Section 3 we give algorithms to find an offline optimum query set and for the oblivious setting. We treat deterministic adaptive algorithms in Section 4. In Section 5, we show how to improve the adaptive result for uniform query costs by using a randomized algorithm, or by assuming some structure in the dependency graph. We investigate the advice complexity for adaptive algorithms in Section 6, and finally, in Section 7, we discuss possible future research directions.

2 Sorting with Uncertainty

In the sorting problem with uncertainty, there are n numbers $v_1, \ldots, v_n \in \mathbb{R}$ whose exact value is unknown. We are given n uncertainty intervals $I_1, \ldots, I_n$ with $v_i \in I_i = [\ell_i, r_i]$, a cost $w_i \in \mathbb{R}_+$ for querying interval I_i, and an error threshold $\delta \geq 0$. After querying I_i, we obtain the exact value of v_i; we can also say that we replace I_i with interval $I'_i = [v_i, v_i]$. The goal is to obtain a permutation $\pi : [n] \to [n]$ such that $v_i \leq v_j + \delta$ if $\pi(i) < \pi(j)$ by performing a minimum-cost set of queries.

We begin by defining the following dependency relation between intervals, which is essential to solve the problem.

▶ **Definition 2.1.** *Two intervals I_i and I_j such that $r_i - \ell_j > \delta$ and $r_j - \ell_i > \delta$ are* ***dependent****. Two intervals that are not dependent are* ***independent****.*

▶ **Lemma 2.2.** *The relative order between two intervals can be decided without querying either of them if and only if they are independent.*

Proof. Let I_i and I_j be such that $r_i - \ell_j \leq \delta$. Since $v_i \leq r_i$ and $v_j \geq \ell_j$, we have that $v_i \leq v_j + \delta$ and we can set $\pi(i) < \pi(j)$ without querying both I_i and I_j.

Conversely, let I_j and I_j be two dependent intervals. We cannot set $\pi(i) < \pi(j)$, because it may be the case that $v_i = r_i$ and $v_j = \ell_j$, thus $r_i - \ell_j > \delta$ implies that $v_i > v_j + \delta$. By a symmetric argument, we cannot set $\pi(j) < \pi(i)$, so we cannot decide the relative order between the intervals. ◀

The graphs defined by this dependency relation are exactly the **co-threshold tolerance** (co-TT) graphs [23]. $G = (V, E)$ is a **threshold tolerance** graph if there are functions $w : V \to \mathbb{R}$ and $t : V \to \mathbb{R}$ such that $uv \in E$ if and only if $w(u) + w(v) \geq \min(t(u), t(v))$. A co-TT graph is the complement of any threshold tolerance graph, or equivalently, $G = (V, E)$ is a co-TT graph if and only if there are functions $a : V \to \mathbb{R}$ and $b : V \to \mathbb{R}$ such that $uv \in E$ if and only if $a(u) < b(v)$ and $a(v) < b(u)$ [23]. The proof of Theorem 2.3 is omitted.

▶ **Theorem 2.3.** *The graphs defined by the dependency relation in Definition 2.1 are exactly the co-TT graphs.*

The following result will be useful.

▶ **Lemma 2.4** ([23]). *Every co-TT graph is chordal.*

When $\delta > 0$, it is useful to distinguish intervals of width smaller than δ, which we call **trivial** intervals. It is easy to check that two trivial intervals cannot be dependent, so when a trivial and a non-trivial interval are dependent, it is enough to query the non-trivial interval in order to decide their relative order. This does not mean, however, that trivial intervals should never be queried, and in particular adaptive algorithms may decide to do that.

It is also clear that the dependency graph is an interval graph when $\delta = 0$. This is also true when $\delta > 0$ and there are no trivial intervals, in which case we can simply replace each interval $I_i = [\ell_i, r_i]$ with $I_i^{(\delta)} = [\ell_i^{(\delta)}, r_i^{(\delta)}] := [\ell_i + \delta/2, r_i - \delta/2] \neq \emptyset$, and it is easy to check that I_i and I_j are dependent with error threshold δ if and only if $I_i^{(\delta)}$ and $I_j^{(\delta)}$ are dependent with error threshold 0. Note however that we cannot use this reduction to solve the sorting problem, since the precise values could fall outside of the given interval.

3 Warm-Up: Offline and Oblivious Algorithms

The first result we present concerns finding the optimum query set for a given set of intervals, assuming we know the actual values in each interval. I.e., given the intervals $I_1, \ldots, I_n$ and the actual values $v_1, \ldots, v_n$, find a minimum-cost set Q of intervals to query, such that Q is sufficient to prove an ordering for $I_1, \ldots, I_n$ without the knowledge of $v_1, \ldots, v_n$. Solving this problem is useful, for example, to perform experimental evaluation of algorithms, since we are actually finding the offline optimum solution for the online (either oblivious or adaptive) problem. The ideas we present here will also be useful when solving the online problem.

We show that the problem can be solved optimally in polynomial time. The key observations behind the algorithm are the following. In order to simplify notation, we write $I_i \supset I_j$ for intervals I_i and I_j if $\ell_i < \ell_j$ and $r_j < r_i$.

▶ **Proposition 3.1.** *Let I_i and I_j be intervals with actual values v_i and v_j. If $I_j \supset [v_i - \delta, v_i + \delta]$, then I_j is queried by every optimum solution.*

Proof. Even if we have queried I_i, we have to query I_j because we may have $v_j \in [\ell_j, v_i - \delta)$ or $v_j \in (v_i + \delta, r_j]$. ◀

▶ **Proposition 3.2.** *Let I_i and I_j be two dependent intervals, v_i the actual value in I_i and v_j the actual value in I_j. If $I_i \not\supset [v_j - \delta, v_j + \delta]$ and $I_j \not\supset [v_i - \delta, v_i + \delta]$, then it is enough to query either I_i or I_j to decide their relative order.*

Proof. If we query I_i, then $v_i \notin [\ell_j + \delta, r_j - \delta]$, so we can pick a reasonable order between I_i and I_j. The argument is symmetrical if we query I_j. ◀

The algorithm begins with a query set Q containing all intervals that satisfy the condition in Proposition 3.1. Due to Proposition 3.2, it is enough to complement Q with a minimum-cost vertex cover in the dependency graph defined by the remaining intervals, which can be found in polynomial time for chordal graphs [16].

▶ **Theorem 3.3.** *The problem of finding an optimum query set for the sorting problem with uncertainty can be solved optimally in polynomial time.*

Now we consider oblivious algorithms. In this case, all non-trivial intervals with some dependence must be queried, and clearly this is the best possible strategy. In the following theorem, we show that this implies a tight bound of n on the query-competitive ratio for the case with uniform costs, and that in the general case the query-competitive ratio is unbounded.

▶ **Theorem 3.4.** *If query costs are uniform, any oblivious algorithm for sorting with uncertainty has query-competitive ratio exactly n. For arbitrary costs, the query-competitive ratio is unbounded.*

Proof. For the upper bound with uniform costs, a naïve algorithm that queries all intervals and then sorts the numbers suffices.

For both lower bounds, we have $n - 1$ independent intervals with length greater than 2δ, plus an interval I_n which contains all the other ones. Both an algorithm and the optimum solution must query I_n in order to decide where v_n fits in the order. If the algorithm does not query some I_i with $i < n$, then the adversary can set $v_n \in (\ell_i + \delta, r_i - \delta) \neq \emptyset$ and the algorithm cannot decide the order. Thus, without the knowledge of v_n, the algorithm must query all I_i with $i < n$. However, it may be the case that $v_n \notin I_i$ for all $i < n$, and querying I_n suffices to decide the order. This gives a lower bound of n on the query-competitive ratio for uniform query costs. For the general case, w_n can be arbitrarily small and the query-competitive ratio is unbounded. ◀

4 Deterministic Adaptive Algorithms

Now let us consider deterministic adaptive algorithms. We begin with a lower bound.

▶ **Lemma 4.1.** *Any deterministic adaptive algorithm for the sorting problem with uncertainty has query-competitive ratio at least 2, even if query costs are uniform and the dependency graph has large components.*

Proof. Consider intervals I_1 and I_2 with uniform query cost, $\ell_1 < \ell_2 < r_1 < r_2$ and $r_1 - \ell_2 > 2\delta$. If the algorithm queries I_1, then the adversary chooses $v_1 \in (\ell_2 + \delta, r_1 - \delta)$. The algorithm must also query I_2 to decide the order, but then the adversary can choose $v_2 \in [r_1 - \delta, r_2]$ and one query would be sufficient. The argument is symmetrical if the algorithm queries I_2 first, with $v_2 \in (\ell_2 + \delta, r_1 - \delta)$ and $v_1 \in [\ell_1, \ell_2 + \delta]$. To obtain a large component, make several independent copies of this structure and connected them by a large interval containing all the others. ◀

First we give a simple deterministic 2-query-competitive adaptive algorithm for the case with uniform query costs. It is inspired by the algorithm of Erlebach et al. [12] for the minimum spanning tree problem with uncertainty, and it relies on the following concepts, which were introduced in [7]. Let $\mathcal{I} = \{I_1, \dots, I_n\}$ be a set of intervals for the sorting problem with uncertainty. We say that a set $W \subseteq \mathcal{I}$ of intervals is a **witness set** if at least one of the intervals in W must be queried to decide the order of $\mathcal{I}$, even if all intervals except those in W are queried. Due to Lemma 2.2, any pair of dependent intervals constitute a witness set. A set of intervals $\mathcal{I}' = \{I'_1, \dots, I'_n\}$ is a **refinement** of $\mathcal{I}$ if $\mathcal{I}'$ is obtained from $\mathcal{I}$ by performing a sequence of queries. Proposition 4.2 follows simply from $\mathcal{I}'$ having more information than $\mathcal{I}$.

▶ **Proposition 4.2.** *Let $\mathcal{I}'$ be a refinement of $\mathcal{I}$. If some set of intervals $W \subseteq \mathcal{I}' \cap \mathcal{I}$ is a witness set for $\mathcal{I}'$, then it is a witness set for $\mathcal{I}$.*

The algorithm, then, consists in the following. While there is some pair of dependent intervals, we query all intervals in this pair that have not been queried yet. When an interval I_i is queried, it is replaced by $[v_i, v_i]$. (Note that, even after querying I_i, it may still be dependent to a non-trivial interval.) Finally, intervals are sorted by breaking ties arbitrarily.[4]

For a better understanding of the algorithm, consider the examples in Figure 1, assuming $\delta = 0$. In Figure 1a, the optimum solution must query I_1 and I_3, since $v_1 \in I_3$ and $v_3 \in I_1$, and this is enough because I_2 will be independent after querying I_1. If the algorithm first queries I_1 and I_2, it must also query I_3. In Figure 1b it is enough to query I_1, but the algorithm will query a dependent pair, say, I_1 and I_2. Either way, the algorithm does not spend more than twice the optimum number of queries.

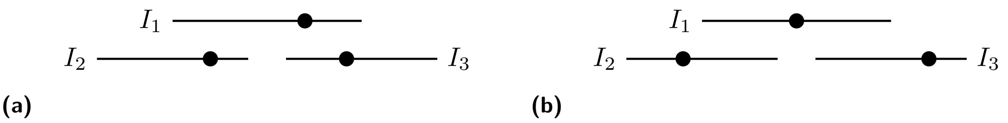

Figure 1 Example instances of the problem.

▶ **Theorem 4.3.** *The simple adaptive algorithm for sorting with uncertainty is 2-query-competitive for uniform query costs.*

Proof. Note that the optimum solution must query at least one interval in each witness set. For every pair $\{I_i, I_j\}$ of dependent intervals selected by the algorithm, we have that:

[4] If $\delta = 0$, then the algorithm can be implemented with stable sorting and in $O(n \lg n)$ time by running a standard stable sorting algorithm (e.g., MergeSort) and querying two intervals when MergeSort needs to know the relative order between them. It does not work, however, if $\delta > 0$, since the relation $v_i \le v_j + \delta$ is not transitive.

(1) if both I_i and I_j have not been queried yet, the algorithm queries the witness set $\{I_i, I_j\}$; (2) if I_i has already been queried then, by Proposition 3.1, $\{I_j\}$ is a witness set, which is queried by the algorithm. We can conclude that the algorithm only queries disjoint witness sets of size at most 2, and thus it queries at most twice the minimum number of intervals. ◀

For arbitrary query costs, the problem also admits a 2-query-competitive deterministic adaptive algorithm, although not as simple. The algorithm first queries a minimum-cost vertex cover S_1 on the dependency graph. Then, it queries all non-trivial intervals that are still dependent after querying S_1, which we denote by the set S_2.

▶ **Theorem 4.4.** *The adaptive algorithm for sorting with uncertainty with arbitrary query costs is 2-query-competitive.*

Proof. Let Q be an optimum query set. The set of intervals not contained in Q must be independent. By the duality between independent sets and vertex covers, Q must be a vertex cover. Thus $w(S_1) \leq w(Q)$, since S_1 has minimum cost. Furthermore, note that every interval in S_2 is a singleton witness set, since S_2 is a set of independent intervals. Thus $w(S_2) \leq w(Q)$ as well, and $w(S_1 \cup S_2) \leq 2 \cdot w(Q)$. ◀

5 Improved Adaptive Algorithms for Uniform Query Costs

We now explore refined analysis of query-competitive sorting. We present a unified strategy that yields different improvements to Theorem 4.3, depending on what assumptions we make.

The core observation is that the bad 2-interval instance in the proof of Lemma 4.1 is the only structure that prevents an algorithm from performing better than twice the optimum. The first strategy that comes to mind, then, is to use randomization: a simple randomized strategy attains query-competitive factor 3/2 on the instance of Lemma 4.1. Before extending the algorithm to arbitrary instances, we give a lower bound for any randomized algorithm.

▶ **Lemma 5.1.** *Any randomized adaptive algorithm has query-competitive ratio at least* 3/2 *against an adversary that is oblivious to the randomized tosses, even for uniform query costs.*

Proof. Use the same bad instance as Lemma 4.1, set probability 1/2 for each of the two possible inputs and apply Yao's minimax principle. ◀

The algorithm is based on the following property of the dependency graph, whose proof we omit.

▶ **Lemma 5.2.** *If I_x is an interval with minimum r_x, then the vertex x is simplicial, i.e., its neighborhood is a clique.*

The algorithm begins by querying intervals that are singleton witness sets according to a generalization of the condition in Proposition 3.1. Then, if a component of the remaining dependency graph is an edge, the randomized strategy is applied. Else, the algorithm considers a non-queried vertex x with minimum r_x, a neighbor y of x with minimum r_y, and another neighbor z of x (or of y if y is the only neighbor of x) with minimum r_z. The algorithm first queries I_y. If x and y are still adjacent, or if x and z are adjacent, then we query both I_x and I_z. We repeat this strategy until the dependency graph has no edges.

A pseudocode is presented in Algorithm 1; we parameterize the probability p in the randomized strategy since the algorithm will be reused afterwards. We also maintain a set $\mathcal{V}$ of the values resulting of queried intervals.

Algorithm 1 Improved adaptive algorithm for the sorting problem with queries.

```
   Input: $(I_1, \dots, I_n, p)$
1  $\mathcal{V} \leftarrow \emptyset$;
2  while there are $i, j$ with $I_i \supset [\ell_j - \delta, r_j + \delta]$ or $I_i \supset [v_j - \delta, v_j + \delta]$ with $v_j \in \mathcal{V}$ do
3      query $I_i$, add $v_i$ to $\mathcal{V}$;
4  while there is some dependency do
5      if some component is an edge $ij$ then
6          pick $i$ with probability $p$ (and $j$ with probability $1 - p$); assume $i$ is picked;
7          query $I_i$, add $v_i$ to $\mathcal{V}$;
8          if $I_j \supset [v_i - \delta, v_i + \delta]$ then
9              query $I_j$, add $v_j$ to $\mathcal{V}$;
10     else
11         let $I_x$ non-queried with $\min r_x$, and $y$ be a neighbor of $x$ with $\min r_y$;
12         let $z$ be another neighbor of $x$ (or of $y$ if $x$ is a leaf), with $\min r_z$;
13         query $I_y$, add $v_y$ to $\mathcal{V}$;
14         if $I_x \supset [v_y - \delta, v_y + \delta]$ or $I_x, I_z$ are dependent then
15             query $I_x$, add $v_x$ to $\mathcal{V}$;
16             query $I_z$, add $v_z$ to $\mathcal{V}$;
17     while there is $I_i \supset [v_j - \delta, v_j + \delta]$ for some $v_j \in \mathcal{V}$ do
18         query $I_i$, add $v_i$ to $\mathcal{V}$;
```

▶ **Theorem 5.3.** *Algorithm 1 has expected query-competitive ratio $3/2$ if $p = 1/2$.*

Proof. We form a partition $V_1, \dots, V_m$ of the set of input intervals with the following property. Let $a(V_i)$ be the number of intervals in V_i that are queried by the algorithm, and let $q(V_i) := |Q \cap V_i|$, where Q is an optimum query set. We show that $\mathbb{E}[a(V_i)/q(V_i)] \leq 3/2$ for every i, from which the theorem follows.

If the algorithm queries an interval I_i in Line 3 or Line 18, then $\{I_i\}$ is the next set in the partition. Due to Proposition 3.1, it is a singleton witness set, so $a(\{I_i\})/q(\{I_i\}) = 1$.

If the algorithm runs Lines 6–9 for edge ij, then $W = \{I_i, I_j\}$ is the next set in the partition. We consider the following cases.

1. If $I_i \supset [v_j - \delta, v_j + \delta]$ and $I_j \supset [v_i - \delta, v_i + \delta]$, then $q(W) = 2$ and $a(W) = 2$.
2. Otherwise, $q(W) \geq 1$ because this is a witness pair.
   a. If $I_i \supset [v_j - \delta, v_j + \delta]$ but $I_j \not\supset [v_i - \delta, v_i + \delta]$, then with probability $1/2$ the algorithm queries I_i and this is enough, and with probability $1/2$ it queries both, so $\mathbb{E}[a(W)] = 3/2$; the same holds for the symmetrical case.
   b. If $I_i \not\supset [v_j - \delta, v_j + \delta]$ and $I_j \not\supset [v_i - \delta, v_i + \delta]$, then Line 9 is not executed and $a(W) = 1$.

If the algorithm runs Lines 11–16 for x, y and z, then we have two cases.

1. If x and z are not neighbors, and x and y are not neighbors after Line 13, then $W = \{I_x, I_y\}$ is the next set in the partition. Since it is a witness set, $q(W) \geq 1$. But the algorithm will not query I_x because y is the only neighbor of x, so $a(W) = 1$.
2. Otherwise, $W = \{I_x, I_y, I_z\}$ is the next set in the partition. We have two subcases.
   a. If x and z are neighbors, then xyz is a clique by Lemma 5.2. So $q(W) \geq 2$, since otherwise a pair is unsolved.
   b. Otherwise, $I_x \supset [v_y - \delta, v_y + \delta]$ and $\{I_x\}$ is a singleton witness set. Since x and z are not neighbors, then y and z are neighbors and, by Lemma 2.2, $\{I_y, I_z\}$ is a witness set.

   Either way, $q(W) \geq 2$ and $a(W) = 3$.

We conclude that the expected query-competitive ratio is $3/2$. ◀

Our second strategy to obtain an improvement on Theorem 4.3 is, instead of using randomization, to assume that the graph does not have 2-components, i.e., components consisting of a single edge. This is not enough, however, since in Lemma 4.1 we have shown that we can have a large component. So our hypothesis is that $\delta = 0$ and, after executing the loop of Lines 2–3, the remaining dependency graph, which becomes a proper interval graph, has no 2-components. (Note that Theorem 5.3 is still true if we remove Lines 2–3 of the algorithm.) Let us prove a lower bound for this case.

▶ **Lemma 5.4.** *Any deterministic adaptive algorithm has query-competitive ratio at least* $5/3$*, even if* $\delta = 0$ *and the dependency graph is a proper interval graph with no* 2*-components.*

Proof. Consider five proper intervals I_a, I_b, I_c, I_d, I_e with $\ell_a < \ell_b < \ell_c < \ell_d < \ell_e$. The dependencies are defined by two triangles, abc and cde.

If the algorithm first queries I_c, then we set $v_c \in I_c \setminus (I_a \cup I_b \cup I_d \cup I_e)$, and we can make ab and de behave as the bad instance of Lemma 4.1.

If the algorithm first queries I_a, then we set $v_a \in I_b \cap I_c$, so the algorithm will be forced to query I_b and I_c, and we set $v_b, v_c \in (I_b \cup I_c) \setminus (I_a \cup I_d \cup I_e)$, so the optimum can avoid I_a. Then we can make de behave as the bad instance of Lemma 4.1. The argument is symmetric if the algorithm first queries I_e.

If the algorithm first queries I_b, then we set $v_b \in I_a \cap I_c$, so the algorithm will be forced to query I_a and I_c, and we set $v_a, v_c \in (I_a \cup I_c) \setminus (I_b \cup I_d \cup I_e)$, so the optimum can avoid I_b. Then we can make de behave as the bad instance of Lemma 4.1. The argument is symmetric if the algorithm first queries I_d. ◀

▶ **Theorem 5.5.** *Algorithm 1 (with* $p = 0$ *or* 1*) is* $5/3$*-query-competitive if* $\delta = 0$ *and the dependency graph has no* 2*-components after finishing the loop of Lines 2–3.*

Proof. The analysis is similar to that of Theorem 5.3. We will give a partition $V_1, \ldots, V_m$ of the set of intervals with the following property. Let $a(V_i)$ be the number of intervals in V_i that are queried by the algorithm, and let $q(V_i) := |Q \cap V_i|$, where Q is an optimum query set. We will have that $a(V_i)/q(V_i) \leq 5/3$ for every i, and then the theorem follows. The analysis for the cases of Lines 3, 11–16 and 18 are identical.

If the algorithm runs Lines 6–9 for edge ij, then let C be the component containing ij in the dependency graph after finishing the loop of Lines 2–3. We claim that i and j are the only vertices of C queried in Lines 6–9: Lines 11–16 force that intervals are queried from left to right; thus, since the dependency graph at this point is a proper interval graph, if an interval i' is queried in Line 18, then after that no interval j' with $r_{j'} < r_{i'}$ will have some dependency. Pick an arbitrary set W' of the partition consisting of vertices of C. We merge $\{I_i, I_j\}$ and W' into a single set W of the partition, and from the previous cases we have that $a(W)/q(W) \leq 5/3$. ◀

This proof indicates that the analysis can be improved if we require the graph to have *large* components after finishing the loop of Lines 2–3.

▶ **Theorem 5.6.** *Algorithm 1 (with* $p = 0$ *or* 1*) has query-competitive factor* $3/2 + \mathrm{O}(1/k)$ *if* $\delta = 0$ *and each component of the dependency graph has size at least* k *after finishing the loop of Lines 2–3.*

Proof. We only have to reconsider the case of Lines 6–9 in the proof of Theorem 5.5. If the algorithm runs Lines 6–9 for edge ij, then let C be the component containing ij in the dependency graph after finishing the loop of Lines 2–3. We merge $\{I_i, I_j\}$ and all partition sets containing vertices of C into a single set W of the partition. Since i and j are the only vertices of C queried in Lines 6–9 and C has size at least k, from the other cases we have that $a(W)/q(W) \leq 3/2 + \mathrm{O}(1/k)$. ◀

The analysis is tight since we can have a chain of k triangles plus 1 edge, such that we can force the algorithm to query all intervals, while the optimum can avoid one interval in each triangle and one interval in the extra edge. For large components, we still have a lower bound of $7/5$ for any deterministic algorithm.

▶ **Lemma 5.7.** *Any deterministic adaptive algorithm has query-competitive ratio at least* $7/5$*, even if* $\delta = 0$ *and the dependency graph is a proper interval graph with large components.*

Proof. (Lemma 5.7.) Consider the graph of Figure 2, which has $7k + 2$ vertices. For $i = 0, \ldots, k-1$, vertices $7i + 3, \ldots, 7i + 7$ consist in a copy of the instance of Lemma 5.4. For $i = 0, \ldots, k$, vertices $x_i = 7i + 1$ and $y_i = 7i + 2$ are dependent, x_i is dependent to $7(i-1) + 7$ if $i > 0$, and y_i is dependent to $7i + 3$ if $i < k$. We set $v_{x_i}, v_{y_i} \in I_{x_i} \cap I_{y_i}$, so both the algorithm and the optimum must query I_{x_i} and I_{y_i}, but querying them gives us no information about the remaining vertices. From Lemma 5.4, we can force any deterministic algorithm to query all vertices in the graph, while the optimum solution can query only 3 vertices of $7i + 3, \ldots, 7i + 7$. ◀

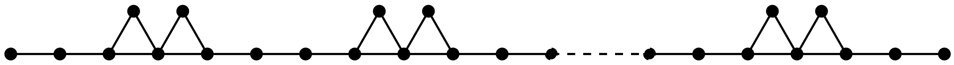

Figure 2 Instance which attains the lower bound for proper interval graphs with large components.

It remains an open question to close the gap between the lower bound of $7/5$ and the upper bound of $3/2 + \mathrm{O}(1/k)$. Finally, we note that the problem can be solved exactly for laminar families of intervals, since all queries will happen at Line 3 of the algorithm.

▶ **Theorem 5.8.** *Algorithm 1 obtains an optimum solution if* $\delta = 0$ *and the intervals constitute a laminar family.*

6 Advice Complexity for Adaptive Algorithms

In this section we investigate the advice complexity of solving the adaptive version of the problem. We assume arbitrary query costs, and for consistency that the oracle answers questions regarding a fixed optimum solution for the given instance.

First, we deal with the case when $\delta = 0$. Let n be the number of given intervals. We claim that $\lfloor n/2 \rfloor$ bits of advice are sufficient to solve the problem exactly, and that there are instances for which $\lfloor n/2 \rfloor$ bits are necessary.

▶ **Lemma 6.1.** *The advice complexity of the adaptive sorting problem with uncertainty is at least* $\lfloor n/2 \rfloor$*, where* n *is the number of intervals, even if* $\delta = 0$*.*

Proof. Assume n even and consider $n/2$ independent copies of the bad instance of Lemma 4.1. At least 1 bit of advice is necessary to decide the relative order between each pair. ◀

For an adaptive algorithm with a matching upper bound, we note that, if $\delta = 0$, then any triangle ijk contains a vertex j such that $I_j \subseteq I_i \cup I_k$ (just take i with minimum ℓ_i and k with maximum r_k). Thus, we can ask the oracle whether the optimum solution queries I_j; if not, then we must query all neighbors of j; otherwise, we query I_j, and since $I_j \subseteq I_i \cup I_k$, we will know at least one of I_i and I_k that also must be queried. If the dependency graph contains no triangles, then it is a forest, because any cycle in a chordal graph must contain a triangle. Therefore, we can pick a leaf i and ask the oracle whether the optimum solution queries its neighbor j; if not, then we query all neighbors of j; otherwise, we query I_j and we will know if I_i must or not be queried. Since we decide at least two intervals with one bit of advice, then $\lfloor n/2 \rfloor$ bits are sufficient. We present a pseudocode in Algorithm 2.

Algorithm 2 An adaptive algorithm that finds an optimum solution with $\lfloor n/2 \rfloor$ bits of advice when $\delta = 0$.

```
Input: $(I_1, \ldots, I_n)$
$\mathcal{V} \leftarrow \emptyset$;
while there is some dependency do
    if there is a triangle $K$ then
        let $i \in K$ with minimum $\ell_i$, $k \in K$ with maximum $r_k$, and $j \in K \setminus \{i, k\}$;
    else let $i$ be a leaf, and $j$ be the neighbor of $i$ ;
    ask the oracle whether the optimum solution queries $j$;
    if yes then query $I_j$, add $v_j$ to $\mathcal{V}$;
    else foreach neighbor $z$ of $j$ do
        query $I_z$, add $v_z$ to $\mathcal{V}$;
    while there is $I_i \supset [v_j - \delta, v_j + \delta]$ for some $v_j \in \mathcal{V}$ do
        query $I_i$, add $v_i$ to $\mathcal{V}$;
```

▶ **Theorem 6.2.** *The advice complexity of the adaptive sorting problem with uncertainty is $\lfloor n/2 \rfloor$ when $\delta = 0$, where n is the number of intervals.*

Now we consider the case when $\delta > 0$. Here, we can improve the lower bound to $\lceil n/3 \cdot \lg 3 \rceil$ and still have an algorithm with matching upper bound. Both are based on the fact that to encode k distinct values amortized $\lg k$ bits are sufficient and necessary [27].

▶ **Lemma 6.3.** *The advice complexity of the adaptive sorting problem with uncertainty is at least $\lceil n/3 \cdot \lg 3 \rceil$, where n is the number of intervals.*

Proof. Assume n multiple of 3 and consider $n/3$ independent triangles; it suffices to bound the number of bits of advice necessary to solve each triangle. Suppose by contradiction that there is an algorithm that solves any triangle with one bit of advice, and consider the following instances $\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3$. In each $\mathcal{I}_i$, the k-th triangle has intervals I_1, I_2, I_3 such that $\ell_1 < \ell_2 < \ell_3 - \delta$, $r_1 + \delta < r_2 < r_3$, $\ell_2 \leq \ell_1 + \delta$, $r_2 \geq r_3 - \delta$ and $r_1 - \ell_3 > 2\delta$. We have $v_j = r_j$ for all j in $\mathcal{I}_1$; in $\mathcal{I}_2$, $v_1 = \ell_1$, $v_2 \in (\ell_3 + \delta, r_1 - \delta)$, $v_3 = r_3$; and $v_j = \ell_j$ for all j in $\mathcal{I}_3$. The only optimum solution for $\mathcal{I}_1, \mathcal{I}_2, \mathcal{I}_3$ is not to query I_1, I_2, I_3, respectively. (See Figure 3.)

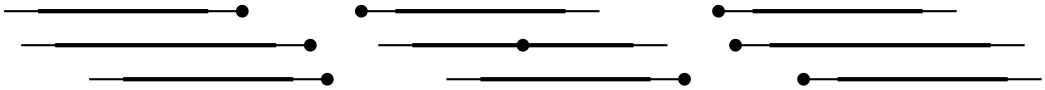

Figure 3 Instances for the lower bound on advice complexity when $\delta > 0$.

By the pigeonhole principle, the algorithm must have the same advice for at least two of those inputs. So, it suffices to prove that any deterministic algorithm fails in one instance of any subset with at least two of those instances. Since the intervals are structurally identical, any algorithm for a triangle performs no better than an algorithm in the following form, for fixed $x, y \in \{1, 2, 3\}$, $x \neq y$: query I_x, and if no helpful information is given, query I_y. The instances are constructed in such a way that, for instance $\mathcal{I}_i$, the algorithm does not get any helpful information by querying I_x with $i \neq x$, so it fails on instances $\mathcal{I}_x$ and $\mathcal{I}_y$. Since one bit is not sufficient, at least three different values must be encoded in the advice for each triangle, so $\lceil n/3 \cdot \lg 3 \rceil$ bits are necessary for the whole instance. ◀

The algorithm that attains the upper bound relies on Lemma 5.2. It considers the clique K consisting of vertex x with minimum r_x and its neighborhood. Then it asks the oracle for the index of a vertex y in K that is not queried in the optimum solution or, if there is no such vertex in K, then the oracle must return $y = x$. Either way, the algorithm queries all intervals in $K \setminus \{y\}$, and if $y = x$ then the algorithm will know if y must also be queried after querying everyone else. So it uses $\lg |K|$ bits of advice to decide at least $|K|$ intervals, and the bound follows since $\lg k/k$ has its maximum at $k = 3$ when k is integer. A pseudocode is presented in Algorithm 3.

Algorithm 3 An adaptive algorithm that finds an optimum solution with $\lceil n/3 \cdot \lg 3 \rceil$ bits of advice.

```
Input: $(I_1, \ldots, I_n)$
$\mathcal{V} \leftarrow \emptyset$;
while there is some dependency do
    let $x$ with minimum $r_x$, and $K$ be the clique consisting of $x$ and its neighborhood;
    ask the oracle for a vertex $y \in K$ not queried in the optimum solution, or $y = x$ if
      there is no such vertex;
    foreach $z \in K \setminus \{y\}$ do
        query $I_z$, add $v_z$ to $\mathcal{V}$;
    while there is $I_i \supset [v_j - \delta, v_j + \delta]$ for some $v_j \in \mathcal{V}$ do
        query $I_i$, add $v_i$ to $\mathcal{V}$;
```

▶ **Theorem 6.4.** *The advice complexity of the adaptive sorting problem with uncertainty is* $\lceil n/3 \cdot \lg 3 \rceil$*, where n is the number of intervals.*

7 Future Work Directions

One interesting question is how the sorting problem can take advantage of queries with different levels of precision, as in [21]. A variety of other classical optimization problems could also be studied in similar uncertainty variants with queries.

Abstract

We study online competitive algorithms for the *line chasing problem* in Euclidean spaces $\mathbb{R}^d$, where the input consists of an initial point P_0 and a sequence of lines $X_1, X_2, ..., X_m$, revealed one at a time. At each step t, when the line X_t is revealed, the algorithm must determine a point $P_t \in X_t$. An online algorithm is called c-competitive if for any input sequence the path $P_0, P_1, ..., P_m$ it computes has length at most c times the optimum path. The line chasing problem is a variant of a more general convex body chasing problem, where the sets X_t are arbitrary convex sets.

To date, the best competitive ratio for the line chasing problem was 28.1, even in the plane. We improve this bound by providing a simple 3-competitive algorithm for any dimension d. We complement this bound by a matching lower bound for algorithms that are memoryless in the sense of our algorithm, and a lower bound of 1.5358 for arbitrary algorithms. The latter bound also improves upon the previous lower bound of $\sqrt{2} \approx 1.412$ for convex body chasing in 2 dimensions.

1 Introduction

Convex body chasing is a fundamental problem in online computation. It asks for an incrementally-computed path that traverses a given sequence of convex sets provided one at a time in an online fashion and is as short as possible. Formally, the input consists of an initial point $P_0 \in \mathbb{R}^d$ and a sequence $X_1, X_2, ..., X_m \subseteq \mathbb{R}^d$ of convex sets. The objective is to find a path $\mathbf{P} = (P_0, P_1, ..., P_m)$ with $P_t \in X_t$ for each $t = 1, 2, ..., m$ and minimum total length $\ell(\mathbf{P}) = \sum_{t=1}^{m} \ell_{P_{t-1}P_t}$. (Throughout the paper, by $\ell(P, Q)$ or ℓ_{PQ} we denote the Euclidean distance between points P and Q in $\mathbb{R}^d$.) This path $\mathbf{P}$ must be computed *online*, in the following sense: the sets X_t are revealed over time, one per time step. At step t, when set X_t is revealed, we need to immediately and irrevocably identify its visit point $P_t \in X_t$. Thus the choice of P_t does not depend on the future sets $X_{t+1}, ..., X_m$.

As can be easily seen, in this online scenario computing an optimal solution is not possible, and thus all we can hope for is to find a path whose length only approximates the optimum value. A widely accepted measure for the quality of this approximation is the competitive ratio. For a constant $c \geq 1$, we will say that an online algorithm $\mathcal{A}$ is *c-competitive* if it computes a path whose length is at most c times the optimum solution (computed offline). This constant c is called the *competitive ratio* of $\mathcal{A}$. Our objective is then to design an online algorithm whose competitive ratio is as close to 1 as possible.

The convex body chasing problem was originally introduced in 1993 by Friedman and Linial [11], who gave a constant-competitive algorithm for chasing convex bodies in $\mathbb{R}^2$ (the plane) and conjectured that it is possible to achieve constant competitiveness in any d-dimensional space $\mathbb{R}^d$. As shown in [11], this constant would have to depend on d; in fact it needs to be at least $\sqrt{d}$.

The Friedman-Linial conjecture has remained open for over two decades. In the last several years this topic has experienced a sudden increase in research activity, partly motivated by connections to machine learning (see [3, 7]), resulting in rapid progress. In 2016, Antoniadis *et al.* [1] gave a $2^{O(d)}$-competitive algorithm for chasing affine spaces of any dimension. In 2018, Bansal *et al.* [3] gave an algorithm with competitive ratio $2^{O(d \log d)}$ for nested families of convex sets, where the input set sequence satisfies $X_1 \supseteq X_2 \supseteq ... \supseteq X_m$. Soon later their bound was improved to $O(d \log d)$ by Argue *et al.* [2], and then to $O(\sqrt{d \log d})$ by Bubeck *et al.* [6]. Finally, Bubeck *et al.* [7] just recently announced a proof of the Friedman-Linial conjecture, providing an algorithm with competitive ratio $2^{O(d)}$ for arbitrary convex sets.

One other natural variant of convex body chasing that also attracted attention in the literature is *line chasing*, where all sets X_t are lines. Friedman and Linial [11] gave an online algorithm for line chasing in $\mathbb{R}^2$ with ratio 28.53. Their algorithm was simplified by Antoniadis *et al.* [1], who also slightly improved the ratio, to 28.1. Earlier, in 2014, Sitters [16] showed that a generalized work function algorithm has constant competitive ratio for line chasing, but he did not determine the value of the constant.

1.1 Our results

We study the line chasing problem discussed above. We give a 3-competitive algorithm for line chasing in $\mathbb{R}^d$, for any dimension $d \geq 2$, significantly improving the competitive ratios from [11, 1, 16]. Our algorithm is very simple and essentially memoryless, as it only needs to keep track of the last line in the request sequence. We start by providing the algorithm for line chasing in the plane, in Section 2, and later in Section 3 we extend it to an arbitrary dimension. In Section 4, we provide a matching lower bound of 3 for algorithms that are memoryless in the sense stated above and oblivious with respect to rotation, translation and uniform scaling of the metric space. We also provide a lower bound for arbitrary algorithms (see Section 5), showing that no online algorithm can achieve competitive ratio better than 1.5358. This improves the lower bound of $\sqrt{2} \approx 1.412$ for line chasing established in [11], which was previously also the best known lower bound for the more general problem of convex body chasing in the plane.

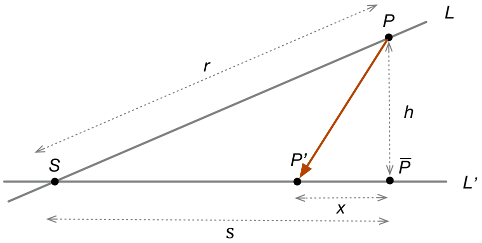

Figure 1 Algorithm Drift moves from P to P'.

1.2 Other related work

Set chasing problems are also known as *Metrical Service Systems* (see below) and belong to a very general class of problems for online optimization and competitive analysis called *Metrical Task Systems (MTS)* [5]. An instance of MTS specifies a metric space M, an initial point $P_0 \in M$, and a sequence of non-negative functions $\tau_1, \tau_2, ..., \tau_m$ over M called *tasks*. These tasks arrive online, one at a time. At each step t, the algorithm needs to choose a point $P_t \in M$ where it moves to "process" the current task τ_t. The goal is to minimize the total cost defined by $\sum_{t=1}^{m}(\mu(P_{t-1}, P_t) + \tau_t(P_t))$, where $\mu()$ is the metric in M. Thus in MTS, in addition to movement cost, at each step we also pay the cost of "processing" τ_t. For any metric space M with n points, if we allow arbitrary non-negative task functions then a competitive ratio of $2n - 1$ can be achieved and is optimal. This general bound is not particularly useful, because in many online optimization problems that can be modeled as an MTS, the metric space M has additional structure and only tasks of some special form are allowed, which makes it possible to design online algorithms with constant competitive ratios, independent of the size of M.

An MTS where $M = \mathbb{R}^d$ and all functions τ_t are convex is referred to as *convex function chasing*, and was studied in [1, 4, 13]. For the special case of convex functions on the real line, a 2-competitive algorithm was given in [4].

An MTS where each task function τ_t takes value 0 on a subset $X_t \subseteq M$ and ∞ elsewhere is called a *Metrical Service System (MSS)* [9]. In other words, in an MSS, in each step t the algorithm needs to move to a point in X_t. To achieve a competitive ratio independent of the size of M, it is generally required to restrict the sets X_t to be in some subset $\mathcal{X} \subsetneq \mathcal{P}(M)$. For instance, finite competitive ratios can be achieved when $\mathcal{X}$ is the set of sets of size at most k [10, 8, 15]. If $M = \mathbb{R}^d$ and $\mathcal{X}$ is the set of convex subsets, this is precisely the convex body chasing problem, and if $\mathcal{X}$ is the set of lines, it is the line chasing problem. One variant of MSS that has been particularly well studied is the famous *k-server problem* (see, for example, [14, 12]), in which one needs to schedule movement of k servers in response to requests arriving online in a metric space, where each request must be covered by one server. (In the MSS representation of the k-server problem, each set X_t consists of all k-tuples of points that include the request point at step t.)

2 A 3-Competitive Algorithm in the Plane

In this section, we present our online algorithm for line chasing in $\mathbb{R}^2$ with competitive ratio 3. The intuition is this: suppose that the last requested line is L and that the algorithm moved to point $P \in L$. Let L' be the new request line, S the intersection point of L and L', and $r = \ell_{SP}$. A naïve greedy algorithm would move to the point $\bar{P}$ on L' nearest to P (see

Figure 1) at cost $h = \ell_{P\bar{P}}$. If h is small, then $r - \ell_{S\bar{P}} = o(h)$, that is the distance between the greedy algorithm's point and S decreases only by a negligible amount. But the adversary can move to S, paying cost r, and then alternate requests on L and L'. On this sequence the overall cost of this algorithm would be $\omega(r)$, so it would not be constant-competitive. This example shows that if the angle between L and L' is small then the drift distance towards S needs to be roughly proportional to h. Our algorithm is designed so that this distance is roughly $h/\sqrt{2}$ if h is small (with the coefficient chosen to optimize the competitive ratio), and that it becomes 0 when L' is perpendicular to L.

Algorithm 1 Algorithm Drift.

Suppose that the last request is line L and that the algorithm is on point $P \in L$. Let the new request be L' and for any point $X \in L$, let $\bar{X}$ be the orthogonal projection of X onto L'. If L' does not intersect L, move to $P' = \bar{P}$. Otherwise, let $S = L \cap L'$ be the intersection point of L and L'. Let also $r = \ell_{SP}$, $h = \ell_{P\bar{P}}$, and $s = \ell_{S\bar{P}}$ (see Figure 1). Move to point $P' \in L'$ such that $\ell_{SP'} = s - x$, where $x = \frac{1}{\sqrt{2}}(h + s - r)$.

▶ **Theorem 1.** *Algorithm* Drift *is* 3*-competitive for the line chasing problem in* $\mathbb{R}^2$.

Proof. We establish an upper bound on the competitive ratio via amortized analysis, based on a potential function. The (always non-negative) value of this potential function, $\Phi(P, A)$, depends on locations $P, A \in L$ of the algorithm's and the adversary's point on the current line L. If L' is the new request line, and $P', A' \in L'$ are the new locations of the algorithm's and adversary's points, we want this function to satisfy

$$\ell_{PP'} + \Phi(P', A') - \Phi(P, A) \;\leq\; 3\,\ell_{AA'}. \tag{1}$$

Since initially the potential is 0 and is always non-negative, adding inequality (1) for all moves will establish 3-competitiveness of Algorithm Drift.

The potential function we use in our proof is $\Phi(P, A) = \sqrt{3}\,\ell_{AP}$. Substituting this formula, inequality (1) reduces to

$$\ell_{PP'} + \sqrt{3}\,(\,\ell_{A'P'} - \ell_{AP}\,) \;\leq\; 3\,\ell_{AA'}. \tag{2}$$

It thus remains to prove inequality (2). Let $g = \ell_{A\bar{A}}$, $z = \ell_{A'\bar{A}}$, and $v = \ell_{\bar{A}\bar{P}}$.

We first discuss the trivial case of non-intersecting L and L'. Keeping with the general notation, here we have $x = 0$ and thus $\ell_{PP'} = h$. Moreover, $g = \ell_{A\bar{A}} = h$ as well. For fixed z, we have $\ell_{AA'} = \sqrt{h^2 + z^2}$, i.e., the right hand side of (2) is fixed, whereas the left hand side is maximized if A' is on the other side of $\bar{A}$ than $\bar{P}$. The left hand side is thus at most

$$h + \sqrt{3}\,z \leq \sqrt{2}\,\sqrt{h^2 + 3z^2} \;\leq\; \sqrt{2}\,\sqrt{3\,(h^2 + z^2)} = \sqrt{6}\,\ell_{AA'} < 3\,\ell_{AA'},$$

where the first inequality follows from the power mean inequality (for powers 1 and 2), proving this easy case.

The situation when L' and L do intersect is illustrated in Figure 2. (The figure shows only the case when $\bar{A}$ is between S and P'.) Orient L' from left to right (with $\bar{P}$ being to the right of S), as shown in this figure. We want to express the distances in the above inequality in terms of s, h, v, and z (keeping in mind that x and r are functions of h and s):

$$\begin{aligned} \ell_{PP'} &= \sqrt{x^2 + h^2} \\ \ell_{AP} &= vr/s \;=\; (v\sqrt{s^2 + h^2})/s \\ \ell_{AA'} &= \sqrt{z^2 + g^2} \end{aligned}$$

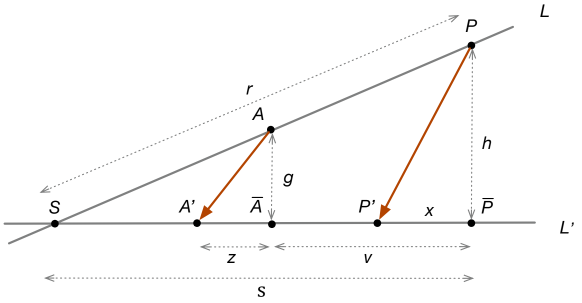

Figure 2 Notation for the analysis of Algorithm DRIFT.

The values of g and $\ell_{A'P'}$ depend on some cases, that we consider below.

Case 1. $\bar{A}$ is between S and P', as in Figure 2. Then $g = h(s-v)/s$. Our goal is first to find A' for which the bound in (2) is tightest. For a given z, among the two locations of A' at distance z from $\bar{A}$, the one on the left gives a larger value of the left-hand side of (2), while the right-hand side is the same for both. Thus we can assume that A' is to the left of $\bar{A}$, so $\ell_{A'P'} = z + v - x$. Then we can rewrite (2) as follows:

$$\tfrac{1}{\sqrt{3}}\,\ell_{PP'} - \ell_{AP} + v - x \;\le \sqrt{3}\,\sqrt{z^2+g^2} - z \tag{3}$$

By elementary calculus, the right-hand side is minimized for $z = \frac{1}{\sqrt{2}}\,g$, so we can assume that z has this value. Then inequality (3) reduces to

$$\tfrac{1}{\sqrt{3}}\,\ell_{PP'} - \ell_{AP} + v - x \;\le \sqrt{2}\,g. \tag{4}$$

After substituting $g = h(s-v)/s$ and $\ell_{AP} = vr/s$, inequality (4) reduces further to

$$s\,(\tfrac{1}{\sqrt{3}}\,\ell_{PP'} - x - \sqrt{2}h) \;\le v\,(r - s - \sqrt{2}\,h). \tag{5}$$

The expression in the parenthesis on the right-hand side of (5) is non-positive by triangle inequality, so the right-hand side is minimized when v is maximized, that is $v = s$, and then it reduces to

$$x^2 + h^2 \;\le 3(r - s + x)^2. \tag{6}$$

Recall that $x = \frac{1}{\sqrt{2}}(h + s - r)$. Since $r - h \le s \le r$, we have

$$\begin{aligned} x^2 + h^2 \;&=\; \tfrac{1}{2}(h+s-r)^2 + h^2 \\ &\le\; \tfrac{1}{2}h^2 + h^2 \\ &=\; \tfrac{3}{2}h^2 \;\le\; \tfrac{3}{2}[\,h + (\sqrt{2}-1)(r-s)\,]^2 \;=\; 3(r-s+x)^2, \end{aligned}$$

proving (6).

Case 2. $\bar{A}$ is before S. In this case we have $g = h(v-s)/s$. Just as in Case 1, we can assume that A' is to the left of $\bar{A}$, so that $\ell_{A'P'} = z + v - x$, and (2) reduces to

$$\tfrac{1}{\sqrt{3}}\,\ell_{PP'} - \ell_{AP} + v - x \;\le \sqrt{2}\,g. \tag{7}$$

After substituting $g = h(v-s)/s$ and $\ell_{AP} = vr/s$, inequality (4) reduces further to

$$s\,(\tfrac{1}{\sqrt{3}}\,\ell_{PP'} - x + \sqrt{2}h) \;\le v\,(r - s + \sqrt{2}\,h). \tag{8}$$

The expression in the parenthesis on the right-hand side of (8) is non-negative, so the right-hand side is minimized when $v = s$ (because in this case $v \geq s$), so (8) reduces to the same inequality (6) as in Case 1, completing the argument for Case 2.

Case 3. $\bar{A}$ is after $\bar{P}$. In this case we have $g = h(v+s)/s$. Symmetrically to Case 1, we can now assume that A' is to the right of $\bar{A}$, so that $\ell_{A'P'} = z + v + x$, and that $z = \frac{1}{\sqrt{2}}\, g$. Then, analogously to (4), we can rewrite (2) as follows:

$$\tfrac{1}{\sqrt{3}}\, \ell_{PP'} - \ell_{AP} + v + x \ \leq \sqrt{2}\, g \tag{9}$$

After substituting $g = h(v+s)/s$ and $\ell_{AP} = vr/s$, inequality (9) reduces further to

$$s\,(\tfrac{1}{\sqrt{3}}\, \ell_{PP'} + x - \sqrt{2}h) \ \leq v\,(r - s + \sqrt{2}\, h). \tag{10}$$

The expression in the parenthesis on the right-hand side of (10) is non-negative, so the right-hand side is minimized when $v = 0$, and then it reduces to

$$x^2 + h^2 \ \leq 3(\sqrt{2}h - x)^2. \tag{11}$$

To prove this, we proceed similarly as in Case 1:

$$x^2 + h^2 \ \leq \ \tfrac{3}{2}h^2 \ \leq \ \tfrac{3}{2}(h + r - s)^2 \ = \ 3(\sqrt{2}h - x)^2,$$

proving (11).

Case 4. $\bar{A}$ is between P' and $\bar{P}$. Then $g = h(s-v)/s$ (as in Case 1). Similar to Case 3, we can assume that A' is to the right of $\bar{A}$, so that now $\ell_{A'P'} = z - v + x$, and that $z = \frac{1}{\sqrt{2}}\, g$. Then, analogously to (4), we can rewrite (2) for this case as follows:

$$\tfrac{1}{\sqrt{3}}\, \ell_{PP'} - \ell_{AP} - v + x \ \leq \sqrt{2}\, g \tag{12}$$

After substituting $g = h(s-v)/s$ and $\ell_{AP} = vr/s$, inequality (12) reduces further to

$$s\,(\tfrac{1}{\sqrt{3}}\, \ell_{PP'} + x - \sqrt{2}h) \ \leq v\,(r + s - \sqrt{2}\, h). \tag{13}$$

We now have two sub-cases. If the expression in the parenthesis on the right-hand side of (13) is non-negative then the right-hand side is minimized when $v = 0$, so inequality (13) reduces to inequality (11) from Case 3. If this expression is negative (that is when $r + s < \sqrt{2}h$), then it is sufficient to prove (13) with v on the right-hand side replaced by s (because $v \leq s$). This reduces it to $\frac{1}{\sqrt{3}}\, \ell_{PP'} + x \leq r + s$. This last inequality follows from $\ell_{PP'} \leq r$ and $x \leq s$. ◀

3 An Algorithm for Arbitrary Dimension

In this section, we show how to extend Algorithm Drift to Euclidean spaces $\mathbb{R}^d$ for arbitrary dimension $d \geq 2$. This extension, that we call ExtDrift, is quite simple, and consists of projecting the whole space onto an appropriately chosen plane that contains the new request line. While such approach was suggested already by Friedman and Linial [11], their choice of plane may lose a constant factor in the competitive ratio. We project onto a different plane, which allows ExtDrift to also be 3-competitive.

Let P be the current ExtDrift position and L' the new request line. If $P \in L'$, ExtDrift makes no move. Otherwise, let U be the uniquely determined plane which contains both L' and P. ExtDrift makes the move prescribed by Drift in the plane U for P, L' and the projection of L onto U.

▶ **Theorem 2.** *Algorithm* ExtDrift *is 3-competitive for the line chasing problem in $\mathbb{R}^d$, for arbitrary dimension $d \geq 2$.*

Proof. We prove that (1) holds in arbitrary dimension. If $P \in L'$ then L and L' are co-planar, so the analysis from the previous section works directly.

So assume that $P \notin L'$. We first allow the adversary to perform a free move from its current position A to point $\ddot{A}$ defined as the orthogonal projection of A onto U, and then we analyze the move within U (that is, in a two-dimensional setting), as if the adversary started from point $\ddot{A}$.

We note that $\ell_{\ddot{A}X} \leq \ell_{AX}$ for any point $X \in U$, as $(\ell_{AX})^2 = (\ell_{\ddot{A}X})^2 + (\ell_{A\ddot{A}})^2$ by definition of $\ddot{A}$. It follows that:

- In the free adversary move from A to $\ddot{A}$ the potential function decreases (by taking $X = P$ in the above inequality) and both costs are 0. Further, in the move within U, with the adversary starting from $\ddot{A}$, Algorithm ExtDrift makes the same move as Drift, which implies that (1) is satisfied. Thus the complete move (combining the free adversary move and the move inside U) satisfies inequality (1) as well.
- The free move is only beneficial for the adversary: taking $X = A'$ shows that the cost of moving to A' from $\ddot{A}$ is no more costly for the adversary than moving to A' from A. ◀

4 Lower Bound for Memoryless Algorithms

We show that our algorithm achieves the optimal competitive ratio among a certain class of "memoryless" algorithms. For a metric space M, let $\mathcal{X} \subseteq \mathcal{P}(M)$ be the set of possible requests (i.e., lines in our case). In general, we can view an algorithm as a function $\mathcal{A}\colon M \times \mathcal{X}^* \to \mathcal{X}$ with $\mathcal{A}(P_0) = P_0$ and $\mathcal{A}(P_0, X_1, \ldots, X_t) \in X_t$ for each initial point $P_0 \in M$ and requests $X_1, \ldots, X_t \in \mathcal{X}$. We call an algorithm *memoryless* if $\mathcal{A}(P_0, X_1, \ldots, X_t)$ is a function of only the last position $\mathcal{A}(P_0, X_1, \ldots, X_{t-1})$, the last request X_{t-1} and the new request X_t.

However, memorylessness alone would not impose any limit on the power of line-chasing algorithms: By perturbing its positions very slightly, an algorithm could always encode the entire history in low significant bits of its current position. To get a meaningful notion of memorylessness, we therefore require an additional property, namely that the algorithm is oblivious with respect to rotation, translation or scaling of the metric space. More precisely, a *direct similarity* of $\mathbb{R}^d$ is a bijection $f\colon \mathbb{R}^d \to \mathbb{R}^d$ that is a composition of rotation, translation and scaling by some factor $r_f > 0$. In particular, for any $P, Q \in \mathbb{R}^d$, we have $\ell(f(P), f(Q)) = r_f \ell(P, Q)$. We call an algorithm $\mathcal{A}$ *rts-oblivious* if $\mathcal{A}(f(P_0), f(X_1), \ldots, f(X_t)) = f(\mathcal{A}(P_0, X_1, \ldots, X_t))$ for any $P_0 \in M$, $X_i \in \mathcal{X}$ and any direct similarity f. In general (when algorithms are allowed to use memory) there is no reason to behave differently when the input is transformed by such f, since it is just a renaming of points and scaling of distances by a uniform constant. For completeness, we provide a proof of this intuition via the following proposition:

▶ **Proposition 3.** *If there is a c-competitive algorithm for line-chasing, then there is a c-competitive rts-oblivious algorithm.*

Proof. For an initial position P_0 and request sequence $X_1, \ldots, X_t$, we assume without loss of generality that $P_0 \notin X_1$. For any such P_0 and X_1, there exists a unique direct similarity $g = g_{P_0 X_1}$ such that $g(P_0) = (0, 1)$ and $g(X_1) = \mathbb{R} \times \{0\}$. Given a c-competitive algorithm $\mathcal{A}$, we claim that the algorithm $\tilde{\mathcal{A}}$ given by

$$\tilde{\mathcal{A}}(P_0, X_1, \ldots, X_t) = g^{-1}(\mathcal{A}(g(P_0), g(X_1), \ldots, g(X_t)))$$

is rts-oblivious and c-competitive.

To see that $\tilde{\mathcal{A}}$ is rts-oblivious, consider an arbitrary direct similarity f. Notice that $g_{f(P_0)f(X_1)} = g \circ f^{-1}$. Thus,

$$\begin{aligned}\tilde{\mathcal{A}}(f(P_0), f(X_1), \dots, f(X_t)) &= (f \circ g^{-1})(\mathcal{A}(g(P_0), g(X_1), \dots, g(X_t))) \\ &= f(\tilde{\mathcal{A}}(P_0, X_1, \dots, X_t)),\end{aligned}$$

as required. To see that $\tilde{\mathcal{A}}$ is c-competitive, consider an initial position P_0 and request sequence $X_1, \dots, X_m$ along with an adversary's solution $A_0 = P_0, A_1 \in X_1, \dots, A_m \in X_m$. The cost of $\tilde{\mathcal{A}}$ can be bounded via

$$\begin{aligned}&\sum_{t=1}^{m} \ell(\tilde{\mathcal{A}}(P_0, X_1, \dots, X_{t-1}), \tilde{\mathcal{A}}(P_0, X_1, \dots, X_t)) \\ &\quad = \frac{1}{r_g} \sum_{t=1}^{m} \ell(\mathcal{A}(g(P_0), g(X_1), \dots, g(X_{t-1})), \mathcal{A}(g(P_0), g(X_1), \dots, g(X_t))) \\ &\quad \le \frac{c}{r_g} \sum_{t=1}^{m} \ell(g(A_{t-1}), g(A_t)) \\ &\quad = c \sum_{t=1}^{m} \ell(A_{t-1}, A_t),\end{aligned}$$

where the inequality uses that $\mathcal{A}$ is c-competitive against the solution $g(A_0), \dots, g(A_m)$ for the transformed input $g(P_0), g(X_1), \dots, g(X_m)$. ◀

Intuitively, an rts-oblivious algorithm does not know the absolute coordinates of its positions and requests, but only relative to each other and up to scaling. If it is memoryless, in the plane this boils down to only knowing the angle between the new and the old request line. We show now that our algorithms Drift and ExtDrift achieve the optimal competitive ratio among rts-oblivious memoryless algorithms.

▶ **Theorem 4.** *Any rts-oblivious memoryless algorithm for line-chasing has competitive ratio at least* 3.

Proof. We will construct an initial point P_0 and lines $L_0, \dots, L_m$ in $\mathbb{R}^2$ with the property that $P_0 \in L_0$ and L_t can be obtained by rotating L_{t-1} around some point $S_t \in L_{t-1}$ in clockwise direction by less than 90 degrees.

Let $P_0, \dots, P_m$ be the sequence of points visited by a given algorithm. We use notation similar to that in Figure 1: Write $\bar{P}_{t-1}$ for the orthogonal projection of P_{t-1} onto L_t and let $h_t = \ell(P_{t-1}, \bar{P}_{t-1})$ and $s_t = \ell(\bar{P}_{t-1}, S_t)$. The movement from P_{t-1} to P_t can always be viewed as first moving to $\bar{P}_{t-1}$ and then moving some distance $x_t \in \mathbb{R}$ in the direction towards intersection S_t, for a total cost $\sqrt{h_t^2 + x_t^2}$. Here, $x_t < 0$ would constitute movement away from S_t and $x_t > s_t$ would constitute movement beyond S_t.

Observe that for rts-oblivious memoryless algorithms, $\frac{x_t}{h_t}$ is a function of only $\frac{h_t}{s_t}$, i.e. $\beta(\frac{h_t}{s_t}) = \frac{x_t}{h_t}$ for some function $\beta\colon (0, \infty) \to \mathbb{R}$. Any rts-oblivious memoryless algorithm for line-chasing in the plane is uniquely determined by its associated function β as well as similar functions for the cases of counter-clockwise rotations of at most 90 degrees and parallel lines.[1] Let $\beta(0) := \limsup_{a \to 0} \beta(a) \in \mathbb{R} \cup \{-\infty, \infty\}$. Let us first show that algorithms with $\beta(0) = \infty$ or $\beta(0) \le 0$ have unbounded competitive ratio.

[1] If we require algorithms to be oblivious also with respect to reflection (which would still satisfy Proposition 3), they would be uniquely determined by β alone. Drift is the algorithm corresponding to $\beta(a) = \frac{a+1-\sqrt{a^2+1}}{\sqrt{2}a}$.

If $\beta(0) = \infty$, we choose $P_0 = (1, h)$, $L_0 = \{(x, y) \colon y = hx\}$, $L_1 = \mathbb{R} \times \{0\}$ for some small $h > 0$. The algorithm's cost is $h\sqrt{1 + \beta(h)^2}$, whereas the optimal cost is h. Choosing h arbitrarily small shows that the competitive ratio is unbounded.

If $\beta(0) \le 0$, fix some $\epsilon \in (0, \frac{1}{2}]$ and choose $a \in (0, \epsilon]$ with $\beta(a) \le \epsilon$. Let $P_0 = (1, 0)$, $L_0 = \mathbb{R} \times \{0\}$ and define L_t as the clockwise rotation of L_{t-1} around the origin $O := (0, 0)$ by angle $\arctan(a)$. Thus, we have $\frac{h_t}{s_t} = a$ for each t. Notice that $s_t\sqrt{1 + a^2} = \ell(O, P_{t-1}) = s_{t-1}(1 - a\beta(a))$, and therefore

$$\frac{s_t}{s_{t-1}} = \frac{1 - a\beta(a)}{\sqrt{1 + a^2}} \ge 1 - \frac{a^2 + a\beta(a)}{1 + a^2} \ge 1 - 2\epsilon a,$$

where the first inequality uses $\sqrt{1 + a^2} \le 1 + a^2$ and the second inequality uses $0 < a \le \epsilon$ and $\beta(a) \le \epsilon$. Hence,

$$s_t \ge (1 - 2\epsilon a)^{t-1}$$

Since $\ell(P_{t-1}, P_t) \ge h_t = as_t$, the total cost of the algorithm is

$$\sum_{t=1}^{m} \ell(P_{t-1}, P_t) \ge a \sum_{t=0}^{m-1} (1 - 2\epsilon a)^t \xrightarrow{m \to \infty} \frac{1}{2\epsilon}.$$

Meanwhile, an optimal algorithm pays total cost 1 by moving to O immediately. Letting $\epsilon \to 0$, we find again that the competitive ratio is unbounded.

It remains to consider the case $0 < \beta(0) < \infty$. Then we can choose arbitrarily small $a > 0$ such that $0 < a\beta(a) < 1$. We choose the initial point $P_0 = (\frac{1}{a}, 1)$, and the request sequence starts with $L_0 = \{(x, y) \colon y = ax\}$ and $L_1 = \mathbb{R} \times \{0\}$. For $t \ge 2$, we define L_t as the clockwise rotation of L_{t-1} around $S_t = S_2 = \left(\frac{1}{a} - \beta(a) + \sqrt{1 + a^2}\left(\beta(a) + \frac{1}{2\beta(a)}\right), 0\right)$ by angle $\arctan(a)$. The idea is that in response to L_1, the algorithm drifts to the left (towards intersection $S_1 = (0, 0)$), but the subsequent requests are such that it would have been cheaper to drift to the right (away from S_1) instead.

We have $s_1 = \frac{1}{a}$ and $s_2 = \frac{\ell(P_1, S_2)}{\sqrt{1+a^2}} = \beta(a) + \frac{1}{2\beta(a)}$. For $t \ge 3$, similarly to the previous case we get

$$\frac{s_t}{s_{t-1}} \ge 1 - \frac{a^2 + a\beta(a)}{1 + a^2} \ge 1 - a^2 - a\beta(a)$$

and therefore

$$s_t \ge \left(\beta(a) + \frac{1}{2\beta(a)}\right)\left(1 - a^2 - a\beta(a)\right)^{t-2} \qquad \text{if } t \ge 2.$$

As $m \to \infty$, the cost of the algorithm is

$$\begin{aligned}\sum_{t=1}^{\infty} \ell(P_{t-1}, P_t) &= \sum_{t=1}^{\infty} h_t\sqrt{1 + \beta(a)^2} = \sqrt{1 + \beta(a)^2}a \sum_{t=1}^{\infty} s_t \\ &\ge \sqrt{1 + \beta(a)^2}\left(1 + \left(\beta(a) + \frac{1}{2\beta(a)}\right)\frac{1}{a + \beta(a)}\right) \\ &\xrightarrow{a \to 0} \sqrt{1 + \beta(0)^2}\left(2 + \frac{1}{2\beta(0)^2}\right),\end{aligned}$$

where the limit $a \to 0$ is taken along a sequence where $\beta(a) \to \beta(0)$. In contrast, an offline algorithm can move immediately from P_0 to S_2, paying cost $\sqrt{1 + \frac{1}{4\beta(0)^2}}$ as $a \to 0$ and

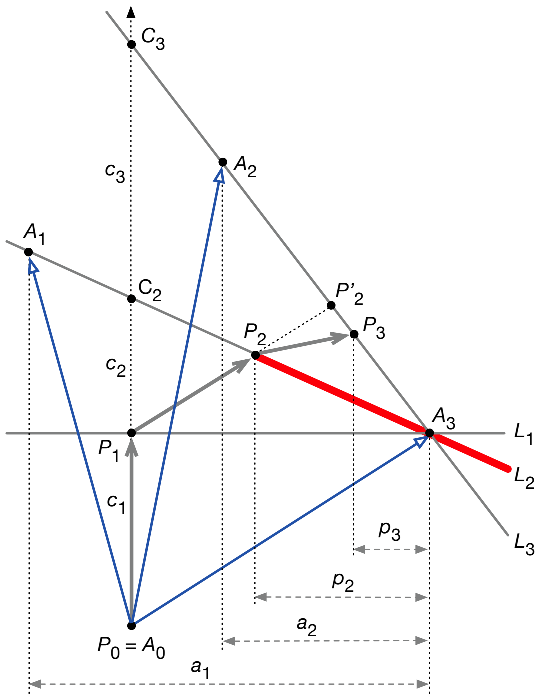

Figure 3 Visual description of our lower bound for arbitrary algorithms. Lines L_1, L_2 and L_3 are presented to an online algorithm. Blue arrows describe possible movements of Opt, while gray thick arrows describe a path of an algorithm that minimizes the competitive ratio for this adversarial construction. Red thick half-line denotes the forbidden region.

$\beta(a) \to \beta(0)$. By dividing, we see that the competitive ratio is at least

$$\sqrt{(1+\beta(0)^2)\left(4+\frac{1}{\beta(0)^2}\right)} = \sqrt{4\beta(0)^2 + \frac{1}{\beta(0)^2} + 5},$$

which is minimized for $\beta(0) = \frac{1}{\sqrt{2}}$, taking value 3. ◀

5 Lower Bound for Arbitrary Algorithms

Finally, in this section, we show how to improve an existing lower bound of $\sqrt{2} \approx 1.41$ for arbitrary algorithms to 1.5358. Our bound holds even in two dimensions, and improves also the lower bound for the more general convex body chasing in two dimensions.

▶ **Theorem 5.** *The competitive ratio of any deterministic online algorithm $\mathcal{A}$ for the line chasing problem is at least* 1.5358*.*

Proof. We describe our adversarial strategy below. On the created input, we will compare the cost of $\mathcal{A}$ to the cost of an offline optimum Opt. We assume that both $\mathcal{A}$ and Opt start at origin point $P_0 = A_0 = (0, 0)$.

Our construction is parameterized with real positive numbers $c_1 = 0.5535$, $c_2 = 0.4965$, $c_3 = 0.8743$, $a_1 = 1.3012$, $a_2 = 0.6663$, $p_2 = 0.5612$, and $p_3 = 0.1696$.

We fix points $P_1 = (0, c_1)$, $C_2 = (0, c_1 + c_2)$, $C_3 = (0, c_1 + c_2 + c_3)$ and $A_3 = (1, c_1)$, see Figure 3 for illustration. For succinctness, we use notation $\triangle(x, y) = \sqrt{x^2 + y^2}$.

Initial part: Line L_1

The first request line is the line P_1A_3, denoted L_1. Without loss of generality, we can assume that $\mathcal{A}$ moves to point P_1. This is because the adversary can either play the strategy described below or its mirror image (flipped against the line P_0P_1), so any deviation from P_1, either to the left or right, can only increase the cost of $\mathcal{A}$.

From now on, for any point Q we denote its projection on line L_1 by Q^x.

Middle part: Line L_2

Next, the adversary issues the request line C_2A_3, denoted L_2. Let $P_2 \in L_2$ and $A_1 \in L_2$ be the points to the left of A_3, such that $\ell_{P_2^x A_3} = p_2$ and $\ell_{A_1^x A_3} = a_1$.

Let $\bar{P}_2$ be the point on L_2 chosen by $\mathcal{A}$. If $\bar{P}_2$ lies to the right of point P_2, then the adversary forces $\mathcal{A}$ to move to A_1 (by giving sufficiently many different lines that go through A_1 at different angles). Opt may then serve the whole sequence by going from A_0 to A_1 at cost

$$\ell_{A_0A_1} = \triangle(c_1 + c_2 \cdot a_1,\, a_1 - 1) \leq 1.23679$$

while the cost of $\mathcal{A}$ is then at least

$$\begin{aligned}\ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{P_2A_1} &= \ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{A_3A_1} - \ell_{A_3P_2} \\ &= c_1 + \triangle(1 - p_2,\, c_2 \cdot p_2) + \triangle(a_1,\, c_2 \cdot a_1) - \triangle(p_2,\, c_2 \cdot p_2) \\ &\geq 1.89948\end{aligned}$$

Hence, the competitive ratio in this case is at least 1.5358.

We call the half-line of L_2 to the right of point P_2 *forbidden region*. From now on, we assume that the point chosen by $\mathcal{A}$ in L_2 does not lie in this region.

Final part: Line L_3

Finally, the adversary issues the request line C_3A_3, denoted L_3. Let P_2' be the intersection of line P_1P_2 with line L_3. Next, let A_2 and P_3 be the points on the line L_3 to the left of A_3, such that $\ell_{A_2^x A_3} = a_2$ and $\ell_{P_3^x A_3} = p_3$. Note that P_3 belongs to the interval $P_2'A_3$.

Let $\bar{P}_3$ be the point on L_3 chosen by $\mathcal{A}$. We consider two cases.

Case 1. $\bar{P}_3$ lies at point P_3 or to its left. In this case, the adversary forces $\mathcal{A}$ to move to A_3. Opt may serve the whole sequence by going from A_0 to A_3 paying

$$\ell_{A_0A_3} = \triangle(1,\, c_1) \leq 1.142963.$$

We may now argue that the cost of $\mathcal{A}$ is minimized if $\bar{P}_3$ is equal to P_3: If $\bar{P}_3$ is to the left of point P_2', then the cost of $\mathcal{A}$ is at least $\ell_{P_0P_1} + \ell_{P_1\bar{P}_3} + \ell_{\bar{P}_3A_3}$. Both the second and the third summand decrease when we move $\bar{P}_3$ towards P_2'. Hence, now we may assume that $\bar{P}_3$ belongs to the interval $P_2'P_3$. As the path of $\mathcal{A}$ must avoid forbidden region, its cost is at least $\ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{P_2\bar{P}_3} + \ell_{\bar{P}_3A_3}$. The sum of the last two summands decreases when we move $\bar{P}_3$ towards P_3. Therefore, we obtain that the cost of $\mathcal{A}$ is at least

$$\begin{aligned}&\ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{P_2P_3} + \ell_{P_3A_3} \\ &\quad = c_1 + \triangle(1 - p_2,\, c_2 \cdot p_2) + \triangle((c_2 + c_3) \cdot p_3 - c_2 \cdot p_2,\, p_2 - p_3) \\ &\qquad + \triangle(p_3,\, (c_2 + c_3) \cdot p_3) \geq 1.75537.\end{aligned}$$

Thus, in this case the competitive ratio is at least 1.5358.

Case 2. If $\bar{P}_3$ lies to the right of point P_3, then the adversary forces $\mathcal{A}$ to move to A_2. Opt may serve the whole sequence by going from A_0 to A_2 at cost

$$\ell_{A_0A_2} = \triangle(c_1 + (c_2 + c_3) \cdot a_2,\, 1 - a_2) \le 1.50435.$$

To go from P_1 to $\bar{P}_3$ and avoid the forbidden region, $\mathcal{A}$ has to pay at least $\ell_{P_1P_2} + \ell_{P_2\bar{P}_3}$. Therefore, its cost is at least

$$\begin{aligned}\ell_{P_0P_1} &+ \ell_{P_1P_2} + \ell_{P_2\bar{P}_3} + \ell_{\bar{P}_3A_2}\\ &\ge \ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{P_2P_3} + \ell_{P_3A_2}\\ &\ge \ell_{P_0P_1} + \ell_{P_1P_2} + \ell_{P_2P_3} + \ell_{A_2A_3} - \ell_{P_3A_3}\\ &= c_1 + \triangle(1 - p_2,\, c_2 \cdot p_2) + \triangle((c_2 + c_3) \cdot p_3 - c_2 \cdot p_2,\, p_2 - p_3)\\ &\qquad + \triangle(a_2,\, (c_2 + c_3) \cdot a_2) - \triangle(p_3,\, (c_2 + c_3) \cdot p_3) \ge 2.31039.\end{aligned}$$

Thus, in this case the ratio is also at least 1.5358. ◀

6 Final Comments

Establishing the optimal competitive ratio for line chasing with memory remains an open problem. We believe that with memory, a competitive ratio better than 3 is achievable.

The intuition is that in the first move, if L and P are the initial line and position and L' is the new request line, then the algorithm should move to the nearest point $\bar{P}$ on L'. More generally, if the requests on L and L' alternate (and their angle is small), the algorithm should initially drift slowly towards $S = L \cap L'$ and only gradually accelerate as it becomes more credible that the adversary is located at S. To gauge this credibility for general request sequences, an algorithm might store the current work function at each step.

It appears also that our lower bound of 1.5358 can be improved by introducing additional steps, although this gives only very small improvements and leads to a very involved analysis. It is possible that an approach fundamentally different from ours may give a better bound with simpler analysis.

Abstract

We study pure Nash equilibria in infinite-duration games on graphs, with partial visibility of actions but communication (based on a graph) among the players. We show that a simple communication mechanism consisting in reporting the deviator when seeing it and propagating this information is sufficient for characterizing Nash equilibria. We propose an epistemic game construction, which conveniently records important information about the knowledge of the players. With this abstraction, we are able to characterize Nash equilibria which follow the simple communication pattern via winning strategies. We finally discuss the size of the construction, which would allow efficient algorithmic solutions to compute Nash equilibria in the original game.

1 Introduction

Multiplayer concurrent games over graphs allow to model rich interactions between players. Those games are played as follows. In a state, each player chooses privately and independently an action, defining globally a move (one action per player); the next state of the game is then defined as the successor (on the graph) of the current state using that move; players continue playing from that new state, and form a(n infinite) play. Each player then gets a reward given by a payoff function (one function per player). In particular, objectives of the players may not be contradictory: those games are non-zero-sum games, contrary to two-player games used for controllers or reactive synthesis [15, 12].

Using solution concepts borrowed from game theory, one can describe interactions among the players, and in particular rational behaviours of selfish players. One of the most basic and classically studied solution concepts is that of Nash equilibria [13]. A Nash equilibrium is a strategy profile where no player can improve her payoff by unilaterally changing her strategy. The outcome of a Nash equilibrium can therefore be seen as a rational behaviour of the system. While very much studied by game theorists, e.g. over (repeated) matrix games, such a concept (and variants thereof) has been only rather recently studied over infinite-duration games on graphs. Probably the first works in that direction are [9, 8, 16, 17]. Several series of works have followed. To roughly give an idea of the existing results, pure Nash equilibria always exist in turn-based games for ω-regular objectives [19] but not in concurrent games, even with simple objectives; they can nevertheless be computed [19, 4, 7, 3] for large classes

of objectives. The problem becomes harder with mixed (that is, stochastic) Nash equilibria, for which we often cannot decide the existence [18, 5].

Computing Nash equilibria requires to (i) find a good behaviour of the system; (ii) detect deviations from that behaviour, and identify deviating players; (iii) punish them. This simple characterization of Nash equilibria is made explicit in [10]. Variants of Nash equilibria require slightly different ingredients, but they are mostly of a similar vein.

Many of those results are proven using the construction of a two-player game, in which winning strategies correspond (in some precise sense) to Nash equilibria in the original game. This two-player game basically records the knowledge of the various players about everything which can be uncertain: (a) the possible deviators in [4], and (b) the possible states the game can be in [3]. Extensions of this construction can be used for other solution concepts like robust equilibria [7] or rational synthesis [11].

In this work, we consider infinite-duration games on graphs, in which the game arena is perfectly known by all the players, but players have only a partial information on the actions played by the other players. The partial-information setting of this work is inspired by [14]: it considers repeated games played on matrices, where players only see actions of their neighbours. Neighbours are specified by a communication graph. To ensure a correct detection of deviators, the solution is to propagate the identity of the deviator along the communication graph. A fingerprint (finite sequence of actions) of every player is agreed at the beginning, and the propagation can be made properly if and only if the communication graph is 2-connected, ensuring large sets of Nash equilibria (formalized as a folk theorem). Fingerprints are not adapted to the setting of graphs, since they may delay the time at which a player will learn the identity of the deviator, which may be prohibitive if a bad component of a graph is then reached.

We therefore propose to add real communication among players. Similarly to [14], a player can communicate only with her neighbours (also specified by a communication graph), but can send arbitrary messages (modelled as arbitrary words over alphabet $\{0, 1\}$). We assume that visited states are known by the players, hence only the deviator (if any) may be unknown to the players. In this setting, we show the following results:

- We show that a very simple epidemic-like communication mechanism is sufficient for defining Nash equilibria. It consists in (a) reporting the deviator (for the neighbours of the deviator) as soon as it is detected, and (b) propagating this information (for the other players).
- We build an epistemic game, which tracks those strategy profiles which follow the above simple communication pattern. This is a two-player turn-based game, in which `Eve` (the first player) suggest moves, and `Adam` (the second player) complies (to generate the main outcome), or not (to mimic single-player deviations). The correctness of the construction is formulated as follows: there is a Nash equilibrium in the original game of payoff p if and only if there is a strategy for `Eve` in the epistemic game which is winning for p.
- We analyze the complexity of this construction.

Note that we do not assume connectedness of the communication graph, hence the particular case of a graph with no edges allows to recover the setting of [4] while a complete graph allows to recover the settings of [19, 7].

In Section 2, we define our model and give an example to illustrate the role of the communication graph. In Section 3, we prove the simple communication pattern. In Section 4, we construct the epistemic game and discuss its correctness. In Section 5, we discuss complexity issues. All proofs are available in the technical report [6].

2 Definitions

We use the standard notations $\mathbb{R}$ (resp. $\mathbb{Q}$, $\mathbb{N}$) for the set of real (resp. rational, natural) numbers. If S is a subset of $\mathbb{R}$, we write $\overline{S}$ for $S \cup \{-\infty, +\infty\}$.

Let S be a finite set and $R \subseteq S$. If m is an S-vector over some set Σ, we write $m(R)$ (resp. $m(-R)$) for the vector composed of the R-components of m (resp. all but the R-components). We also use abusively the notations $m(i)$ (resp. $m(-i)$) when i is a single element of S, and may sometimes even use m_i if this is clear in the context. Also, if $s \in S$ and $a \in \Sigma$, then $m[s/a]$ is the vector where the value $m(s)$ is replaced by a.

If S is a finite set, we write S^* (resp. S^+, S^ω) for the set of words (resp. non-empty word, infinite words) defined on alphabet S.

2.1 Concurrent games and communication graphs

We use the model of concurrent multi-player games [4], based on the two-player model of [1].

▶ **Definition 1.** *A* concurrent multiplayer game *is a tuple* $\mathcal{G} = \langle V, v_{\mathsf{init}}, \mathsf{Act}, \mathcal{P}, \Sigma, \mathsf{Allow}, \mathsf{Tab}, (\mathsf{payoff}_a)_{a\in\mathcal{P}}\rangle$*, where* V *is a finite set of vertices,* $v_{\mathsf{init}} \in V$ *is the initial vertex,* Act *is a finite set of actions,* $\mathcal{P}$ *is a finite set of players,* Σ *is a finite alphabet,* $\mathsf{Allow}\colon V \times \mathcal{P} \to 2^{\mathsf{Act}} \setminus \{\emptyset\}$ *is a mapping indicating the actions available to a given player in a given vertex,*[1] $\mathsf{Tab}\colon V \times \mathsf{Act}^{\mathcal{P}} \to V$ *associates, with a given vertex and a given action tuple the target vertex, for every* $a \in \mathcal{P}$*,* $\mathsf{payoff}_a\colon V^\omega \to \mathbb{D}$ *is a payoff function with values in a domain* $\mathbb{D} \subseteq \overline{\mathbb{R}}$.

An element of $\mathsf{Act}^{\mathcal{P}}$ is called a *move*. Standardly (see [1] for two-player games and [4] for the multiplayer extension), concurrent games are played as follows: from a given vertex v, each player selects independently an action (allowed by Allow), which altogether form a move m; then, the game proceeds to the next vertex, given by $\mathsf{Tab}(v, m)$; the game continues from that new vertex.

Our setting will refine this model, in that at each round, each player will also broadcast a message, which will be received by some of the players. The players that can receive a message will be specified using a communication graph that we will introduce later. The role of the messages will remain unclear until we commit to the definition of a strategy.

Formally, a *full history* h in $\mathcal{G}$ is a finite sequence

$$v_0 \cdot (m_0, \mathsf{mes}_0) \cdot v_1 \cdot (m_1, \mathsf{mes}_1) \cdot v_2 \dots (m_{s-1}, \mathsf{mes}_{s-1}) \cdot v_s \in V \cdot \Big(\big(\mathsf{Act}^{\mathcal{P}} \times (\{0,1\}^*)^{\mathcal{P}}\big) \cdot V\Big)^*$$

such that for every $0 \le r < s$, for every $a \in \mathcal{P}$, $m_r(a) \in \mathsf{Allow}(v_r, a)$, and $v_{r+1} = \mathsf{Tab}(v_r, m_r)$. For every $0 \le r < s$, for every $a \in \mathcal{P}$, the set $\mathsf{mes}_r(a)$ is the message appended to action $m_r(a)$ at step $r+1$, which will be broadcast to some other players. For readability we will also write h as

$$v_0 \xrightarrow{m_0, \mathsf{mes}_0} v_1 \xrightarrow{m_1, \mathsf{mes}_1} v_2 \dots \xrightarrow{m_{s-1}, \mathsf{mes}_{s-1}} v_s$$

We write $\mathit{vertices}(h) = v_0 \cdot v_1 \cdots v_s$, and $\mathit{last}(h)$ for the last vertex of h (that is, v_s). If $r \le s$, we also write $h_{\ge r}$ (resp. $h_{\le r}$) for the suffix $v_r \cdot (m_r, \mathsf{mes}_r) \cdot v_{r+1} \cdot (m_{r+1}, \mathsf{mes}_{r+1}) \dots (m_{s-1}, \mathsf{mes}_{s-1}) \cdot v_s$ (resp. prefix $v_0 \cdot (m_0, \mathsf{mes}_0) \cdot v_1 \cdot (m_1, \mathsf{mes}_1) \dots (m_{r-1}, \mathsf{mes}_{r-1}) \cdot v_r$). We write $\mathsf{Hist}_{\mathcal{G}}(v_0)$ (or simply $\mathsf{Hist}(v_0)$ if $\mathcal{G}$ is clear in the context) for the set of full histories in $\mathcal{G}$ that start at v_0. If $h \in \mathsf{Hist}(v_0)$ and $h' \in \mathsf{Hist}(\mathit{last}(h))$, then we write $h \cdot h'$ for the obvious concatenation of histories (it then belongs to $\mathsf{Hist}(v_0)$).

[1] This condition ensures that the game is non-blocking.

We add a *communication (directed) graph* $G = (\mathcal{P}, E)$ to the context. The set of vertices of G is the set of players, and edges define a neighbourhood relation. An edge $(a,b) \in E$ (with $a \neq b$) means that player b can see which actions are played by player a together with the messages broadcast by player a. Later we write $a \mathrel{-\!\!\triangleright} b$ whenever $(a,b) \in E$ or $a = b$, and $\mathbb{n}(b) = \{a \in \mathcal{P} \mid a \mathrel{-\!\!\triangleright} b\}$ for the so-called *neighbourhood* of b (that is, the set of players about which player b has information). If $a, b \in \mathcal{P}$, we write $\mathsf{dist}_G(a,b)$ for the distance in G from a to b ($+\infty$ if there is no path from a to b).

Let $a \in \mathcal{P}$ be a player. The projection of h for a is denoted $\pi_a(h)$ and is defined by

$$v_0 \cdot (m_0(\mathbb{n}(a)), \mathsf{mes}_0(\mathbb{n}(a))) \cdot v_1 \cdot (m_1(\mathbb{n}(a)), \mathsf{mes}_1(\mathbb{n}(a))) \cdot v_2 \dots$$
$$\dots (m_{s-1}(\mathbb{n}(a)), \mathsf{mes}_{s-1}(\mathbb{n}(a))) \cdot v_s \in V \cdot \Big(\Big(\mathsf{Act}^{\mathbb{n}(a)} \times (\{0,1\}^*)^{\mathbb{n}(a)}\Big) \cdot V\Big)^*$$

This will be the information available to player a. In particular, messages broadcast by the players are part of this information. Note that we assume perfect recall, that is, while playing, player a will remember all her past knowledge, that is, all of $\pi_a(h)$ if h has been played so far. We define the *undistinguishability relation* $\sim_a$ as the equivalence relation over full histories induced by π_a: for two histories h and h', $h \sim_a h'$ iff $\pi_a(h) = \pi_a(h')$. While playing, if $h \sim_a h'$, a will not be able to know whether h or h' has been played. We write $\mathsf{Hist}_{\mathcal{G},a}(v_0)$ for the set of histories for player a (also called a-histories) from v_0.

We extend all the above notions to infinite sequences in a straightforward way and to the notion of *full play*. We write $\mathsf{Plays}_{\mathcal{G}}(v_0)$ (or simply $\mathsf{Plays}(v_0)$ if $\mathcal{G}$ is clear in the context) for the set of full plays in $\mathcal{G}$ that start at v_0.

A *strategy* for a player $a \in \mathcal{P}$ from vertex v_0 is a mapping $\sigma_a \colon \mathsf{Hist}_{\mathcal{G}}(v_0) \to \mathsf{Act} \times \{0,1\}^*$ such that for every history $h \in \mathsf{Hist}_{\mathcal{G}}(v_0)$, $\sigma_a(h)[1] \in \mathsf{Allow}(\mathit{last}(h), a)$, where the notation $\sigma_a(h)[1]$ denotes the first component of the pair $\sigma(h)$. The value $\sigma_a(h)[1]$ represents the action that player a will do after h, while $\sigma_a(h)[2]$ is the message that she will append to her action and broadcast to all players b such that $a \mathrel{-\!\!\triangleright} b$. The strategy σ_a is said *G-compatible* if furthermore, for all histories $h, h' \in \mathsf{Hist}(v_0)$, $h \sim_a h'$ implies $\sigma_a(h) = \sigma_a(h')$. In that case, σ_a can equivalently be seen as a mapping $\mathsf{Hist}_{\mathcal{G},a}(v_0) \to \mathsf{Act} \times \{0,1\}^*$. An *outcome* of σ_a is a(n infinite) play $\rho = v_0 \cdot (m_0, \mathsf{mes}_0) \cdot v_1 \cdot (m_1, \mathsf{mes}_1) \dots$ such that for every $r \geq 0$, $\sigma_a(\rho_{\leq r}) = (m_r(a), \mathsf{mes}_r(a))$. We write $\mathsf{out}(\sigma_a, v_0)$ for the set of outcomes of σ_a from v_0.

A *strategy profile* is a tuple $\sigma_{\mathcal{P}} = (\sigma_a)_{a \in \mathcal{P}}$, where, for every player $a \in \mathcal{P}$, σ_a is a strategy for player a. The strategy profile is said *G-compatible* whenever each σ_a is G-compatible. We write $\mathsf{out}(\sigma_{\mathcal{P}}, v_0)$ for the unique full play from v_0, which is an outcome of all strategies part of $\sigma_{\mathcal{P}}$.

When $\sigma_{\mathcal{P}}$ is a strategy profile and σ'_d a player-d G-compatible strategy, we write $\sigma_{\mathcal{P}}[d/\sigma'_d]$ for the profile where player d plays according to σ'_d, and each other player a ($\neq d$) plays according to σ_a. The strategy σ'_d is a *deviation* of player d, or a *d-deviation* w.r.t. $\sigma_{\mathcal{P}}$. Such a d-deviation is said *profitable* w.r.t. $\sigma_{\mathcal{P}}$ whenever $\mathsf{payoff}_d\Big(\mathit{vertices}(\mathsf{out}(\sigma_{\mathcal{P}}, v_0))\Big) < \mathsf{payoff}_d\Big(\mathit{vertices}(\mathsf{out}(\sigma_{\mathcal{P}}[d/\sigma'_d], v_0))\Big)$.

▶ **Definition 2.** *A* Nash equilibrium *from v_0 is a G-compatible strategy profile $\sigma_{\mathcal{P}}$ such that for every $d \in \mathcal{P}$, there is no profitable d-deviation w.r.t. $\sigma_{\mathcal{P}}$.*

In this definition, deviation σ'_d needs not really to be G-compatible, since the only meaningful part of σ'_d is along $\mathsf{out}(\sigma[d/\sigma'_d], v_0)$, where there are no $\sim_d$-equivalent histories: any deviation can be made G-compatible without affecting the profitability of the resulting outcome.

Figure 1 A five-player game (left) and three communication graphs (right); self-loops $a \mathrel{-\!\triangleright} a$ omitted from the picture. The action alphabet is $\{\alpha, \beta\}$. The transition function is represented as arrows from one vertex to another labeled with the action profile(s) allowing to go from the origin vertex to the destination one. We write action profiles with length-5 words. Convention: no label means complementary labels (e.g. one goes from v_0 to v_0' using any action profile that is not in $\alpha^5 + (\alpha\beta + \beta\beta + \beta\alpha)\mathsf{Act}^3 + \alpha^2(\beta\alpha^2 + \alpha\beta\alpha + \alpha^2\beta)$).

▶ Remark 3. Before pursuing our study, let us make clear what information players have: a player knows the full arena of the game and the whole communication graph; when playing the game, a player sees the states which are visited, and see actions of and messages from her neighbours (in the communication graph). When playing the profile of a Nash equilibrium, all players know all strategies, hence a player knows precisely what is expected to be the main outcome; in particular, when the play leaves the main outcome, each player knows that a deviation has occurred, even though she didn't see the deviator or received any message. Note that deviations which do not leave the main outcome may occur; in this case, only the neighbours of the deviator will know that such a deviation occurred; we will see that it is useless to take care of such deviations.

2.2 An example

We consider the five-player game described in Figure 1 in which we denote the players $\mathscr{P} = \{0, 1, 2, 3, 4\}$. The action alphabet is $\mathsf{Act} = \{\alpha, \beta\}$, and the initial vertex is assumed to be v_0. We suppose the payoff function vector is defined as (to be read as the list of payoffs of the players):

$$\mathsf{payoff}(\rho) = \begin{cases} (0,0,1,1,1) & \text{if } \rho \text{ visits } v_1 \text{ infinitely often} \\ (0,0,2,2,2) & \text{if } \rho \text{ visits } v_1 \text{ finitely often and } v_1' \text{ infinitely often} \\ (0,0,0,2,2) & \text{if } \rho \text{ ends up in } v_2 \\ (0,0,2,0,2) & \text{if } \rho \text{ ends up in } v_3 \\ (0,0,2,2,0) & \text{if } \rho \text{ ends up in } v_4 \\ (0,0,3,3,3) & \text{if } \rho \text{ ends up in } v_0' \end{cases}$$

We consider a (partial) strategy profile σ whose main outcome is:

$$\rho = \big(v_0 \cdot (\alpha^5, \mathsf{mes}_\epsilon) \cdot v_1 \cdot (\alpha^5, \mathsf{mes}_\epsilon)\big)^\omega$$

where $\mathsf{mes}_\epsilon(a) = \epsilon$ for every $a \in \mathscr{P}$. Note that players 0 and 1 cannot benefit from any deviation since their payoffs is uniformly 0. Then notice that no one alone can deviate from

ρ to v'_0. Now, the three players 2, 3 and 4 can alone deviate to v'_1 and (try to) do so infinitely often. We examine those deviations. If players 0 and 1 manage to learn who is the deviator, then, together, they can punish the deviator: if they learn that player 2 (resp. 3, 4) is the deviator, then they will enforce vertex v_2 (resp. v_3, v_4). If they do not manage to learn who is the deviator, then they will not know what to do, and therefore, in any completion of the strategy profile, there will be some profitable deviation for at least one of the players (hence there will not be any Nash equilibrium whose main outcome is ρ).

We examine now the three communication graphs G_1, G_2 and G_3 depicted in Figure 1. Using communication based on graph G_1, if player 4 deviates, then player 0 will see this immediately and will be able to communicate this fact to player 1; if player 3 deviates, then player 4 will see this immediately and will be able to communicate this fact to player 0, which will transmit to player 1; if player 2 deviates, then no one will see anything, hence they will deduce the identity of the deviator in all the cases.

Using communication based on graph G_2, if either player 3 or player 4 deviates, then player 0 will see this immediately and will be able to communicate this fact to player 1 using the richness of the communication scheme (words over $\{0, 1\}$). Like before, the identity of deviator 2 will be guessed after a while.

Using communication based on graph G_3, if player 4 deviates, then player 0 will see this immediately and will be able to communicate this fact to player 1 (as before); now, no one (except players 2 and 3) will be able to learn who is deviating, if player 2 or player 3 deviates.

We can conclude that there is a Nash equilibrium with graph G_1 or G_2 whose main outcome is ρ, but not with graph G_3.

2.3 Two-player turn-based game structures

Two-player turn-based game structures are specific cases of the previous model, where at each vertex, at most one player has more than one action in her set of allowed actions. But for convenience, we will give a simplified definition, with only objects that will be useful.

A two-player turn-based game structure is a tuple $G = \langle S, S_{\texttt{Eve}}, S_{\texttt{Adam}}, s_{\mathsf{init}}, A, \mathsf{Allow}, \mathsf{Tab}\rangle$, where $S = S_{\texttt{Eve}} \sqcup S_{\texttt{Adam}}$ is a finite set of states (states in $S_{\texttt{Eve}}$ belong to player Eve whereas states in $S_{\texttt{Adam}}$ belong to player Adam), $s_{\mathsf{init}} \in S$ is the initial state, A is a finite alphabet, $\mathsf{Allow}\colon S \to 2^A \setminus \{\emptyset\}$ gives the set of available actions, and $\mathsf{Tab}\colon S \times A \to S$ is the next-state function. If $s \in S_{\texttt{Eve}}$ (resp. $S_{\texttt{Adam}}$), $\mathsf{Allow}(s)$ is the set of actions allowed to Eve (resp. Adam) in state s.

In this context, strategies will use sequences of states. That is, if a denotes Eve or Adam, an a-strategy is a partial function $\sigma_a : S^* \cdot S_a \to A$ such that for every $H \in S^* \cdot S_a$ such that $\sigma_a(H)$ is defined, $\sigma_a(H) \in \mathsf{Allow}(\mathit{last}(H))$. Note that we do not include any winning condition or payoff function in the tuple, hence the name structure.

2.4 The problems we are looking at

We are interested in the constrained existence of a Nash equilibrium. For simplicity, we define rectangular threshold constraints, but could well impose more complex constraints, like Boolean combinations of linear constraints.

▶ **Problem 1** (Constrained existence problem). *Given a concurrent game $\mathcal{G} = \langle V, v_{\mathsf{init}}, \mathcal{P}, \mathsf{Act}, \Sigma, \mathsf{Allow}, \mathsf{Tab}, (\mathsf{payoff}_a)_{a\in\mathcal{P}}\rangle$, a communication graph G for $\mathcal{P}$, a predicate P over $\mathbb{R}^{|\mathcal{P}|}$, can we decide whether there exists a Nash equilibrium $\sigma_{\mathcal{P}}$ from v_{init} such that $\mathsf{payoff}(\mathit{vertices}(\mathsf{out}(\sigma_{\mathcal{P}}, v_{\mathsf{init}}))) \in P$? If so, compute one. If the predicate P is trivial, we simply speak of the existence problem.*

The case where the communication graph has no edge was studied in depth in [4], with a generic two-player construction called the suspect construction, allowing to decide the constrained existence problem for many kinds of payoff functions. The case where the communication graph is a clique was the subject of the work [7]. The general case of a communication graph has not been investigated so far, but induces interesting developments. In the next section, we show that we can restrict the search of Nash equilibria to the search of so-called normed strategy profiles, where the communication via messages follows a very simple pattern. We also argue that deviations which do not impact the visited vertices should not be considered in the analysis. Given those reductions, we then propose the construction of a two-player game, which will track those normed profiles. This construction is inspired by the suspect-game construction of [4] and of the epistemic game of [3].

3 Reduction to profiles following a simple communication mechanism

We fix a concurrent game $\mathcal{G} = \langle V, v_{\mathsf{init}}, \mathsf{Act}, \mathscr{P}, \Sigma, \mathsf{Allow}, \mathsf{Tab}, (\mathsf{payoff}_a)_{a\in\mathscr{P}}\rangle$ and a communication graph G. We assume that $v_{\mathsf{init}} = v_0$. We will reduce the search for Nash equilibria to the search for strategy profiles with a very specific shape. In particular, we will show that the richness of the communication offered by the setting is somehow useless, and that a very simple communication pattern will be sufficient for characterizing Nash equilibria.

In the following, we write mes_ϵ for the vector assigning the empty word ϵ to every player $a \in \mathscr{P}$. Furthermore, for every $d \in \mathscr{P}$, we pick some word $\mathsf{id}_d \in \{0,1\}^+$ which are all distinct (and different from ϵ).

We first define restrictions for deviations. Let $\sigma_{\mathscr{P}}$ be a strategy profile. A player-d deviation σ'_d is said *immediately visible* whenever, writing h for the longest common prefix of $\mathsf{out}(\sigma_{\mathscr{P}}, v_0)$ and $\mathsf{out}(\sigma_{\mathscr{P}}[d/\sigma'_d], v_0)$, $\mathsf{Tab}(\mathit{last}(h), m) \neq \mathsf{Tab}(\mathit{last}(h), m')$, where $m = \sigma_{\mathscr{P}}(h)[1]$ and $m' = \big(\sigma_{\mathscr{P}}[d/\sigma'_d](h)\big)[1]$ are the next moves according to $\sigma_{\mathscr{P}}$ and $\sigma_{\mathscr{P}}[d/\sigma'_d]$. That is, at the first position where player d changes her strategy, it becomes public information that a deviation has occurred (even though some players know who deviated – all the players a with $d \rightarrowtriangle a$ – , and some other don't know). It is furthermore called *honest* whenever for every $h' \in \mathsf{out}(\sigma_{\mathscr{P}}[d/\sigma'_d], v_0)$ such that h is a (non-strict) prefix of h', $\sigma'_d(h')[2] = \mathsf{id}_d$. Somehow, player d admits she deviated, and does so immediately and forever.

The simple communication mechanism that we will design consists in reporting the deviator (role of the direct neighbours of the deviator), and propagating this information along the communication graph (for all the other players). Formally, let $\sigma_{\mathscr{P}}$ be a strategy profile, and let ρ be its main outcome. The profile $\sigma_{\mathscr{P}}$ will be said *normed* whenever the following conditions hold:

1. for every $h \in \mathsf{out}(\sigma_{\mathscr{P}}) \cup \bigcup_{d\in\mathscr{P},\ \sigma'_d} \mathsf{out}(\sigma_{\mathscr{P}}[d/\sigma'_d], v_0)$, if $\mathit{vertices}(h)$ is a prefix of $\mathit{vertices}(\rho)$, then for every $a \in \mathscr{P}$, $\sigma_a(h)[2] = \epsilon$;
2. for every $d \in \mathscr{P}$, for every d-strategy σ'_d, if $h \cdot (m, \mathsf{mes}) \cdot v \in \mathsf{out}(\sigma_{\mathscr{P}}[d/\sigma'_d], v_0)$ is the first step out of $\mathit{vertices}(\rho)$, then for every $d \rightarrowtriangle a$, $\sigma_a(h \cdot (m, \mathsf{mes}) \cdot v)[2] = \mathsf{id}_d$;
3. for every $d \in \mathscr{P}$, for every d-strategy σ'_d, if $h \cdot (m, \mathsf{mes}) \cdot v \in \mathsf{out}(\sigma_{\mathscr{P}}[d/\sigma'_d], v_0)$ has left the main outcome for more than one step, then for every $a \in \mathscr{P}$, $\sigma_a(h \cdot (m, \mathsf{mes}) \cdot v)[2] = \epsilon$ if for all $b \rightarrowtriangle a$, $\mathsf{mes}(b) = \epsilon$ and $\sigma_a(h \cdot (m, \mathsf{mes}) \cdot v)[2] = \mathsf{id}_d$ if there is $b \rightarrowtriangle a$ such that $\mathsf{mes}(b) = \mathsf{id}_d$; note that this is well defined since at most one id can be transmitted.

The first condition says that, as long as a deviation is not visible, then no message needs to be sent; the second condition says that as soon as a deviation becomes visible, then messages denouncing the deviator should be sent by "those who know", that is, the (immediate) neighbours of the deviator; the third condition says that the name (actually, the id) of the deviator should propagate according to the communication graph in an epidemic way.

Note that the profiles discussed in Section 2.2 were actually normed.

▶ **Theorem 4.** *The existence of a Nash equilibrium $\sigma_{\mathcal{P}}$ with payoff p is equivalent to the existence of a normed strategy profile $\sigma'_{\mathcal{P}}$ with payoff p, which is resistant to immediately visible and honest single-player deviations.*

The proof of this theorem, which is rather technical, can be found in [6]. We only give some intuition here. First, we explain why being resistant to immediately visible and honest deviations is enough. Notice that as long as the sequence of vertices follows the main outcome, then one can simply ignore the deviation and act only when the deviation becomes visible, in a way as if the deviator had started deviating only at this moment. This will be enough to punish the deviator. The "honest" part comes from the fact that one should simply ignore the messages sent by the deviator as it can be only in her interest to not ignore them (if it was not, then why would she send any message at all?).

Second, we show why no one should communicate as long as the sequence of vertices follows the main outcome. The reason is that if no one has deviated then any message is essentially useless, and if a deviation has happened, as explained earlier it can just be ignored as long as it has not become visible.

Finally, we demonstrate why the richness of the communication mechanism is in a way useless. Intuitively, one can understand that the only factors that should matter when playing are the sequence of the vertices that have been visited (because payoff functions only take into account the visited vertices) and the identity of the deviator. Thus the messages should only be used so that players can know of the identity of the deviator in the fastest possible way, and we show that nothing is faster than a sort of epidemic mechanism where one simply broadcasts the identity of the deviator whenever one received the information.

4 The epistemic game abstraction

We fix a concurrent game $\mathcal{G} = \langle V, v_{\mathsf{init}}, \mathsf{Act}, \mathcal{P}, \Sigma, \mathsf{Allow}, \mathsf{Tab}, (\mathsf{payoff}_a)_{a\in\mathcal{P}}\rangle$ for the rest of the section, and G be a communication graph for $\mathcal{P}$. We will implement an epistemic abstraction, which will track normed strategy profiles, and check that there is no profitable immediately visible and honest single-player deviations.

4.1 Description of the epistemic game

A *situation* is a triple (d, I, K) in $\mathcal{P} \times 2^{\mathcal{P}} \times \left(2^{\mathcal{P}}\right)^{\mathcal{P}}$, which consists of a deviator $d \in \mathcal{P}$, a list of players I having received the information that d is the deviator, and a knowledge function K that associates to every player a a list of suspects $K(a)$; in particular, it should be the case that $d \in I$ and for every $a \in I$, $K(a) = \{d\}$. We write Sit for the set of situations.

The epistemic game $\mathcal{E}^G_{\mathcal{G}}$ of $\mathcal{G}$ and G is defined as a two-player game structure $\langle S, S_{\mathtt{Eve}}, S_{\mathtt{Adam}}, s_{\mathsf{init}}, \Sigma', \mathsf{Allow}', \mathsf{Tab}'\rangle$. We describe the states and the transitions leaving those states; in particular, components Σ', Allow', Tab' of the above tuple will only be implicitely defined.

$\mathtt{Eve}$'s states $S_{\mathtt{Eve}}$ consist of elements of $V \times 2^{\mathsf{Sit}}$ such that if (v, X) is a state then for all $a \in \mathcal{P}$ the set $\{(d, I, K) \in X \mid d = a\}$ is either a singleton or empty (there is at most one situation associated with a given player a). We write $\mathsf{dev}(X)$ the set $\{d \in \mathcal{P} \mid \exists (d, I, K) \in X\}$ of agents which are a deviator in one situation of X. If $d \in \mathsf{dev}(X)$, we write (d, I^X_d, K^X_d) for the unique triple belonging to X having deviator d. Hence, $X = \{(d, I^X_d, K^X_d) \mid d \in \mathsf{dev}(X)\}$.

Intuitively, an $\texttt{Eve}$'s state (v, X) will correspond to a situation where the game has proceeded to vertex v, but, if $\mathsf{dev}(X) \neq \emptyset$, several players may have deviated. Each player $d \in \mathsf{dev}(X)$ may be responsible for the deviation; some people will have received a message denouncing d (those are in the set I_d^X), and some will deduce things from what they observe (this is given by K_d^X). Note that the (un)distinguishability relation of a player a will be deduced from X: if d deviated and $a \in I_d^X$, then a will know d deviated; if a is neither in I_d^X nor in $I_{d'}^X$, then a will not be able to know whether d or d' deviated (as we will prove later, in Lemma 5).

First let us consider the case where $X = \emptyset$, which is to be understood as the case where no deviation has arisen yet. In state $(v, \emptyset)$, $\texttt{Eve}$'s actions are moves in $\mathcal{G}$ enabled in v. When she plays move $m \in \mathsf{Act}^{\mathscr{P}}$, the game progresses to $\texttt{Adam}$'s state $((v, \emptyset), m) \in S_{\texttt{Adam}}$ where $\texttt{Adam}$'s actions are vertices $v' \in V$ such that there exists a player $d \in \mathscr{P}$ and an action $\delta \in \mathsf{Act}$ such that $\mathsf{Tab}(v, (m[d/\delta])) = v'$. When $\texttt{Adam}$ plays v', either $v' = \mathsf{Tab}(v, m)$ and the game progresses to $\texttt{Eve}$'s state $(v', \emptyset)$ or $v' \neq \mathsf{Tab}(v, m)$ and the game progresses to $\texttt{Eve}$'s state (v', X') where:

- $d \in \mathsf{dev}(X')$ if and only if there is $\delta \in \mathsf{Act}$ such that $\mathsf{Tab}(v, (m[d/\delta])) = v'$. It means that given the next state v', d is a possible deviator;
- if $d \in \mathsf{dev}(X')$, then:
  - $I_d^{X'} = \{a \in \mathscr{P} \mid d \rightarrowtriangle a\}$;
  - for every $a \in I_d^{X'}$, $K_d^{X'}(a) = \{d\}$;
  - for every $a \notin I_d^{X'}$, $K_d^{X'}(a) = \{b \in \mathscr{P} \mid \exists \beta \in \mathsf{Act} \text{ s.t. } \mathsf{Tab}(v, (m[b/\beta])) = v'\} \setminus \{b \in \mathscr{P} \mid b \rightarrowtriangle a\}$. Those are all the players that can be suspected by a, given the vertex v', and the absence of messages so far.

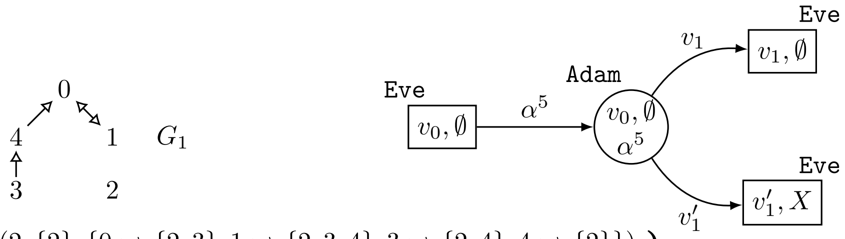
We write $X' = \mathsf{upd}((v, \emptyset), m, v')$. Note that $X' = \emptyset$ whenever (and only when) $\mathsf{Tab}(v, m) = v'$.

In a state $(v, X) \in S_{\texttt{Eve}}$ where $X \neq \emptyset$, $\texttt{Eve}$'s actions consist of functions from $\mathsf{dev}(X)$ to $\mathsf{Act}^{\mathscr{P}}$ that are compatible with players' knowledge, that is: $f : \mathsf{dev}(X) \to \mathsf{Act}^{\mathscr{P}}$ is an action enabled in (v, X) if and only if (i) for all $d \in \mathsf{dev}(X)$, for each $a \in \mathscr{P}$, $f(d)(a) \in \mathsf{Allow}(v, a)$, (ii) for all $d, d' \in \mathsf{dev}(X)$, for all $a \in \mathscr{P}$, if $a \notin I_d^X \cup I_{d'}^X$ and $K_d^X(a) = K_{d'}^X(a)$ then $f(d)(a) = f(d')(a)$;[2] that is, if a player has not received any message so far but has the same knowledge about the possible deviators in two situations, then $\texttt{Eve}$'s suggestion for that player's action must be the same in both situations. When $\texttt{Eve}$ plays action f in (v, X), the next state is $((v, X), f) \in S_{\texttt{Adam}}$, where $\texttt{Adam}$'s actions correspond to states of the game that are compatible with (v, X) and f, that is states v' such that there exists $d \in \mathsf{dev}(X)$ and $\delta \in \mathsf{Act}$ such that $\mathsf{Tab}(v, f(d)[d/\delta]) = v'$.

When $\texttt{Adam}$ chooses the action v' in $((v, X), f)$, the game progresses to $\texttt{Eve}$'s state (v', X'), where:

- $d \in \mathsf{dev}(X')$ if and only if $d \in \mathsf{dev}(X)$ and there exists $\delta \in \mathsf{Act}$ such that $\mathsf{Tab}(v, f(d)[d/\delta]) = v'$. It corresponds to a case where d was already a possible deviator and can continue deviating so that the game goes to v';
- if $d \in \mathsf{dev}(X')$, then:
  - $I_d^{X'} = I_d^X \cup \{a \in \mathscr{P} \mid \exists b \in I_d^X \text{ s.t. } b \rightarrowtriangle a\}$. New players receive a message with the deviator id;
  - for every $a \in I_d^{X'}$, $K_d^{X'}(a) = \{d\}$;

[2] Note in particular that "$K_d^X(a)$ singleton" does not imply $a \in I_d^X$, those are two distinguishable situations: the message with the identity of the deviator may not have been received in the first case, while it has been received in the second case.



$$X = \left\{ \begin{array}{l} (2, \{2\}, \{0 \mapsto \{2,3\}, 1 \mapsto \{2,3,4\}, 3 \mapsto \{2,4\}, 4 \mapsto \{2\}\}), \\ (3, \{3,4\}, \{0 \mapsto \{2,3\}, 1 \mapsto \{2,3,4\}, 2 \mapsto \{3,4\}\}), \\ (4, \{0,4\}, \{1 \mapsto \{2,3,4\}, 2 \mapsto \{3,4\}, 3 \mapsto \{2,4\}\}) \end{array} \right\}$$

Figure 2 Part of the epistemic game corresponding to the game described in Figure 1 (with graph G_1). This does not represent the whole epistemic game and a lot of actions accessible in the states we show here are not written. In situations (d, I, K) we describe K by the list of its values for players $a \notin I$, as for all a in I we have $K(a) = \{d\}$ by definition.

- for every $a \notin I_d^{X'}$, $K_d^{X'}(a) = \{b \in K_d^X(a) \mid \exists \beta \in \mathsf{Act} \text{ s.t. } \mathsf{Tab}(v, f(b)[b/\beta]) = v'\} \setminus \{c \in \mathcal{P} \mid \mathsf{dist}_G(c, a) \leq \max\{\mathsf{dist}_G(c, c') \mid c' \in I_c^X\} + 1\}$. Those are the players that could have deviated but for which player a would not have received the signal yet.

We write $X' = \mathsf{upd}((v, X), f, v')$. Note that $X' \neq \emptyset$ and that $\mathsf{dev}(X') \subseteq \mathsf{dev}(X)$.

We let $R = (v_0, X_0) \cdot ((v_0, X_0), f_0) \cdot (v_1, X_1) \ldots$ be an infinite play from $(v_0, X_0) = (v_{\mathsf{init}}, \emptyset)$. We write *visited*$(R)$ for $v_0 v_1 \cdots \in V^\omega$ the sequence of vertices visited along R. We also define $\mathsf{dev}(R) = \emptyset$ if $X_r = \emptyset$ for every r, and $\mathsf{dev}(R) = \lim_{r \to +\infty} \mathsf{dev}(X_r)$ otherwise. This is the set of possible deviators along R.

4.1.1 Winning condition of Eve

A zero-sum game will be played on the game structure $\mathcal{E}_\mathcal{G}^G$, and the winning condition of Eve will be given on the branching structure of the set of outcomes of a strategy for Eve, and not individually on each outcome, as standardly in two-player zero-sum games. We write $s_{\mathsf{init}} = (v_{\mathsf{init}}, \emptyset)$ for the initial state. Let $p = (p_a)_{a \in \mathcal{P}} \in \mathbb{R}^\mathcal{P}$, and ζ be a strategy for Eve in $\mathcal{E}_\mathcal{G}^G$; it is said winning for p from s_{init} whenever $\mathsf{payoff}(\mathit{visited}(R)) = p$, where R is the unique outcome of ζ from s_{init} where Adam complies to Eve's suggestions, and for every other outcome R' of ζ, for every $d \in \mathsf{dev}(R')$, $\mathsf{payoff}_d(\mathit{visited}(R')) \leq p_d$.

4.2 An example

In Figure 2 we present a part of the epistemic game corresponding to the game we described in Figure 1 with graph G_1. In state $(v_0, \emptyset)$, Eve can play the action profile α^5 and make the game go to $((v_0, \emptyset), \alpha^5)$ where Adam can either play $v_1 = \mathsf{Tab}(v_0, \alpha^5)$ (we say that Adam complies with Eve) or choose a different state accessible from v_0 and an action profile that consists in a single-player deviation from α, for instance $v_1' = \mathsf{Tab}(v_0, \alpha^2\beta\alpha^2) = \mathsf{Tab}(v_0, \alpha^3\beta\alpha) = \mathsf{Tab}(v_0, \alpha^4\beta)$. If Adam chooses v_1', then three players are possible deviators: 2, 3 and 4. We write X for the corresponding set of situations, and we already know that $\mathsf{dev}(X) = \{2, 3, 4\}$.

- If player 2 is the deviator, then no one (except himself) directly receives this information. Player 0 knows that player 4 did not deviate (since $4 \to 0$ in G_1), hence $K_2^X(0) = \{2, 3\}$; Player 1 has no information hence $K_2^X(1) = \{2, 3, 4\}$; Player 3 knows that he is not the deviator but cannot know more, hence $K_2^X(3) = \{2, 4\}$; Finally, player 4 can deduce many things: he knows he is not the deviator, and he saw that player 3 is not the deviator (since $3 \to 4$ in G_1), hence $K_2^X(4) = \{2\}$.

- If player 3 is the deviator, then both players 3 and 4 get the information, hence $I_3^X = \{3,4\}$. Other players can guess some things, for instance player 0 sees that player 4 cannot be the deviator, this is why $K_3^X(0) = \{2,3\}$. Etc.
- The reasoning for player 4 is similar.

In the situation we have just described, when the game will proceed to v_1', then either player 0 knows that player 4 has deviated, or he knows that player 4 didn't deviate but he suspects both 2 and 3. On the other hand, player 4 will precisely know who deviated. And player 3 knows whether he deviated or not, but if he didn't, then he cannot know whether it was player 2 or player 4 who deviated. This knowledge is stored in situation X we have described, and which is fully given in Figure 2.

Let us now illustrate how actions of Eve are defined in states with a non-empty set of situations. Assume we are in Eve's state (v_0, X), with X as previously defined. From that state, an action for Eve is a mapping $f : \{2,3,4\} \to \mathsf{Act}^{\mathcal{P}}$ such that:

$$f(2)(0) = f(3)(0) \quad f(2)(1) = f(3)(1) = f(4)(1) \quad f(3)(2) = f(4)(2) \quad f(2)(3) = f(4)(3)$$

The intuition behind these constraints is the following: Player 0 knows whether Player 4 deviated or not, but in the case she did not cannot know whether Player 2 or Player 3 deviated; Player 1 does not know who deviated, hence should play the same action in the three cases (that she cannot distinguish); Player 2 does only know whether she deviated hence in the case she did not cannot know whether Player 3 or Player 4 deviated; the case for Player 3 is similar; finally Player 4 knows for sure who deviated: she saw if Player 3 deviated and knows whether she herself deviated, thus can distinguish between the three cases.

4.3 Correctness of the epistemic game construction

When constructing the epistemic game, we mentioned that Eve's states will allow to properly define the undistinguishability relation for all the players. Towards that goal, we show by an immediate induction the following result:

▶ **Lemma 5.** *If (v, X) is an Eve's state reachable from some $(v_0, \emptyset)$ in $\mathcal{E}_{\mathcal{G}}^{G}$, then for all $d \in \mathsf{dev}(X)$:*

- *for all $a \in I_d^X$, $K_d^X(a) = \{d\}$;*
- *for all $a \notin I_d^X$, $K_d^X(a) = \mathsf{dev}(X) \setminus \{d' \in \mathsf{dev}(X) \mid a \in I_{d'}^X\}$.*

In particular, for all $d, d' \in \mathsf{dev}(X)$, for all $a \notin I_d^X \cup I_{d'}^X$, $K_d^X(a) = K_{d'}^X(a)$.

So, either a player a will have received from a neighbour the identity of the deviator, or she will not have received any deviator identity yet, and she will have a set of suspected deviators that she will not be able to distinguish.

This allows to deduce the following correspondence between $\mathcal{G}$ and $\mathcal{E}_{\mathcal{G}}^{G}$:

▶ **Proposition 6.** *There is a winning strategy for Eve in $\mathcal{E}_{\mathcal{G}}^{G}$ for payoff p if and only if there is a normed strategy profile in $\mathcal{G}$, whose main outcome has payoff p and which is resistant to single-player immediately visible and honest deviations.*

The proof of correctness of the epistemic game then goes through the following steps, which are detailed in [6]. First, given an Eve's strategy ζ, we build a function E_ζ associating with a-histories (for every $a \in \mathcal{P}$) in the original game Eve's histories in the epistemic game such that Eve plays according to ζ along E_ζ.

Then we use this function to create a strategy profile $\Omega(\zeta)$ for the original game where the action prescribed by this profile to player a after history h corresponds in some sense to

$\zeta(E_\zeta(h))(d)(a)$, where d is a suspected deviator according to player a. This works because, thanks to Lemma 5, we know that either player a knows who the deviator is, or player a has a subset of suspect deviators and Eve's suggestion for a (by construction of $\mathcal{E}^G_{\mathcal{G}}$) is the same for all those possible deviators.

Finally we prove that if ζ is a winning strategy for Eve then $\Omega(\zeta)$ is both normed and resistant to single-player immediately visible and honest deviations in $\mathcal{G}$.

To prove the converse proposition we build a function Λ associating with Eve's histories in the epistemic game families of single-player histories in the original game. We then use this correspondence to build a function Υ associating with normed strategy profiles Eve's strategies in a natural way.

Finally we prove that if σ is normed and resistant to single-player immediately visible honest deviations, then $\Upsilon(\sigma)$ is a winning strategy for Eve.

Gathering results of Theorem 4 and of this proposition, we get the following theorem:

▶ **Theorem 7.** *There is a Nash equilibrium with payoff p in $\mathcal{G}$ if and only if there is a winning strategy for* Eve *in $\mathcal{E}^G_{\mathcal{G}}$ for payoff p.*

▶ Remark 8. Note that all the results are constructive, hence if one can synthesize a winning strategy for Eve in $\mathcal{E}^G_{\mathcal{G}}$, then one can synthesize a correponding Nash equilibrium in $\mathcal{G}$.

5 Complexity analysis

We borrow all notations of previous sections. A rough analysis of the size of the epistemic game $\mathcal{E}^G_{\mathcal{G}}$ gives an exponential bound. We will give a more precise bound, pinpointing the part with an exponential blowup. We write $\mathsf{diam}(G)$ for the diameter of G, that is $\mathsf{diam}(G) = \max\{\mathsf{dist}_G(a,b) \mid \mathsf{dist}_G(a,b) < +\infty\}$.

▶ **Lemma 9.** *Assuming that* Tab *is given explicitely in $\mathcal{G}$, the number of states in the reachable part of $\mathcal{E}^G_{\mathcal{G}}$ from $s_{\mathsf{init}} = (v_{\mathsf{init}}, \emptyset)$ is bounded by*

$$|S_{\mathtt{Eve}}| \leq |V| + |V| \cdot |\mathsf{Tab}|^2 \cdot (\mathit{diam}(G) + 2) \qquad \textit{and} \qquad |S_{\mathtt{Adam}}| \leq |S_{\mathtt{Eve}}| \cdot |\mathsf{Act}|^{|\mathcal{P}|^2}$$

The number of edges is bounded by $|S_{\mathtt{Adam}}| + |S_{\mathtt{Adam}}| \cdot |S_{\mathtt{Eve}}|$.

If $|\mathcal{P}|$ is assumed to be a constant of the problem, then the size of $\mathcal{E}^G_{\mathcal{G}}$ is polynomial in the size of $\mathcal{G}$.

We will not detail algorithmics issues, but the winning condition of Eve in $\mathcal{E}^G_{\mathcal{G}}$ is very similar to the winning condition of Eve in the suspect-game construction of [4] (for Boolean or ordered objectives), or in the deviator-game construction of [7] (for mean-payoff), or in a closer context to the epistemic-game construction of [3]. Hence, when the size of the epistemic game is polynomial, rather efficient algorithms can be designed to compute Nash equilibria. For instance, in a setting where the size of $\mathcal{E}^G_{\mathcal{G}}$ is polynomial, using a bottom-up labelling algorithm similar to that of [2, Sect. 4.3], one obtains a polynomial space algorithm for deciding the (constrained) existence of a Nash equilibrium when payoffs are Boolean payoffs corresponding to parity conditions.

6 Conclusion

In this paper, we have studied multiplayer infinite-duration games over graphs, and focused on games where players can communicate with neighbours, given by a directed graph. We have shown that a very simple communication mechanism was sufficient to describe Nash equilibria.

This mechanism is sort of epidemic, in that if a player deviates, then his neighbours will see it and transmit the information to their own neighbours; the information then propagates along the communication graph. This framework encompasses two standard existing frameworks, one where the actions are invisible (represented with a graph with no edges), and one where all actions are visible (represented by the complete graph). We know from previous works that in both frameworks, one can compute Nash equilibria for many kinds of payoff functions. In this paper, we also show that we can compute Nash equilibria in this generalized framework, by providing a reduction to a two-player game, the so-called epistemic game construction. Winning condition in this two-player game is very similar to winning conditions encountered in the past, yielding algorithmic solution to the computation of Nash equilibria. We have also analyzed the size of the abstraction, which is polynomial when the number of players is considered as a constant of the problem.

The current framework assumes messages can be appended to actions by players, allowing a rich communication between players. The original framework of [14] did not allow additional messages, but did encode identities of deviators by sequences of actions. This was possible in [14] since games were repeated matrix games, but it is harder to see how we could extend this approach and how we could encode identities of players with actions, taking into account the graph structure. For instance, due to the graph, having too long identifiers might be prohibitive to transmit in a short delay the identity of the deviator. Nevertheless, that could be interesting to see if something can be done in this framework.

Parity Games: Zielonka's Algorithm in Quasi-Polynomial Time

Paweł Parys
Institute of Informatics, University of Warsaw, Poland
parys@mimuw.edu.pl

Abstract

Calude, Jain, Khoussainov, Li, and Stephan (2017) proposed a quasi-polynomial-time algorithm solving parity games. After this breakthrough result, a few other quasi-polynomial-time algorithms were introduced; none of them is easy to understand. Moreover, it turns out that in practice they operate very slowly. On the other side there is Zielonka's recursive algorithm, which is very simple, exponential in the worst case, and the fastest in practice. We combine these two approaches: we propose a small modification of Zielonka's algorithm, which ensures that the running time is at most quasi-polynomial. In effect, we obtain a simple algorithm that solves parity games in quasi-polynomial time. We also hope that our algorithm, after further optimizations, can lead to an algorithm that shares the good performance of Zielonka's algorithm on typical inputs, while reducing the worst-case complexity on difficult inputs.

1 Introduction

The fundamental role of parity games in automata theory and logic, and their applications to verification and synthesis is doubtless, hence it is pointless to elaborate on their importance. Let us only mention that the algorithmic problem of finding the winner in parity games is polynomial-time equivalent to the emptiness problem for nondeterministic automata on infinite trees with parity acceptance conditions, and to the model-checking problem for modal μ-calculus [10]. It also lies at the heart of algorithmic solutions to Church's synthesis problem [29]. The impact of parity games reaches relatively far areas of computer science, like Markov decision processes [11] and linear programming [15].

It is a long-standing open question whether parity games can be solved in polynomial time. Several results show that they belong to some classes "slightly above" polynomial time. Namely, deciding the winner of parity games was shown to be in $\mathsf{NP} \cap \mathsf{coNP}$ [10], and in $\mathsf{UP} \cap \mathsf{coUP}$ [18], while computing winning strategies is in PLS, PPAD, and even in their subclass CLS [9]. The same holds for other kinds of games: mean-payoff games [36], discounted games, and simple stochastic games [7]; parity games, however, are the easiest among them, in the sense that there are polynomial-time reductions from parity games to the other kinds of games [18, 36], but no reductions in the opposite direction are known.

Describing the algorithmic side of solving parity games, one has to start with Zielonka's algorithm [35], being an adaptation of an approach proposed by McNaughton to solve Muller

44th International Symposium on Mathematical Foundations of Computer Science (MFCS 2019).

games [28]. This algorithm consists of a single recursive procedure, being simple and very natural; one may say that it computes who wins the game "directly from the definition". Its running time is exponential in the worst case [14, 1, 16], but on many typical inputs it works much faster. For over two decades researchers were trying to cutback the complexity of solving parity games, which resulted in a series of algorithms, all of which were either exponential [5, 31, 19, 34, 30, 2], or mildly subexponential [3, 21]. The next era came unexpectedly in 2017 with a breakthrough result of Calude, Jain, Khoussainov, Li, and Stephan [6] (see also [17, 23]), who designed an algorithm working in quasi-polynomial time. This invoked a series of quasi-polynomial-time algorithms, which appeared soon after [20, 13, 24]. These algorithms are quite involved (at least compared to the simple recursive algorithm of Zielonka), and it is not so trivial to understand them.

The four quasi-polynomial-time algorithms [6, 20, 13, 24], at first glance being quite different, actually proceed along a similar line (as observed by Bojańczyk and Czerwiński [4] and Czerwiński et al. [8]). Namely, out of all the four algorithms one can extract a construction of a safety automaton (nondeterministic in the case of Lehtinen [24], and deterministic in the other algorithms), which accepts all words encoding plays that are decisively won by one of the players (more precisely: plays consistent with some positional winning strategy), and rejects all words encoding plays in which the player loses (for plays that are won by the player, but not decisively, the automaton can behave arbitrarily). This automaton does not depend at all on the game graph; it depends only on its size. Having an automaton with the above properties, it is not difficult to convert the original parity game into an equivalent safety game (by taking a "product" of the parity game and the automaton), which can be solved easily – and all the four algorithms actually proceed this way, even if it is not stated explicitly that such an automaton is constructed. As shown in Czerwiński et al. [8], all automata having the aforementioned properties have to look very similar: their states have to be leaves of some so-called universal tree; particular papers propose different constructions of these trees, and of the resulting automata (of quasi-polynomial size). Moreover, Czerwiński et al. [8] show a quasi-polynomial lower bound for the size of such an automaton.

In this paper we propose a novel quasi-polynomial-time algorithm solving parity games. It is obtained by applying a small modification to Zielonka's recursive algorithm; this modification guarantees that the worst-case running time of this algorithm, being originally exponential, becomes quasi-polynomial. The simplicity of Zielonka's algorithm remains in place; we avoid complicated considerations accompanying all the previous quasi-polynomial-time algorithms. Another point is that our algorithm exploits the structure of parity games in a rather different way from the four previous quasi-polynomial-time algorithms. Indeed, the other algorithms construct automata that are completely independent from a particular game graph given on input – they work in exactly the same way for every game graph of a considered size. The behaviour of our algorithm, in contrast, is highly driven by an analysis of the game graph given on input. In particular, although our algorithm is not faster than quasi-polynomial, it does not fit to the "separator approach" in which a quasi-polynomial lower bound of Czerwiński et al. [8] exists.

The running time of our algorithm is quasi-polynomial, and the space complexity is quadratic (more precisely, $O(n \cdot h)$, where n is the number of nodes in the game graph, and h is the maximal priority appearing there).

We remark that Lehtinen, Schewe, and Wojtczak in their recent follow up paper [25] suggested a variation of our algorithm that improves the complexity to meet the state-of-the-art complexity of broadly $2^{O((\log n)(\log h))}$, while providing polynomial bounds when the number of priorities is logarithmic.

Let us also mention the practical side of the world. It turns out that parity games are one of the areas where theory does not need to meet practice: the quasi-polynomial-time algorithms, although fastest in theory, are actually the slowest. The most exhaustive comparison of existing algorithms was performed by Tom van Dijk [32]. In his Oink tool he has implemented several algorithms, with different optimizations. Then, he has evaluated them on a benchmark of Keiren [22], containing multiple parity games obtained from model checking and equivalence checking tasks, as well as on different classes of random games. It turns out that the classic recursive algorithm of Zielonka [35] performs the best, *ex aequo* with the recent priority promotion algorithm [2]. After that, we have the strategy improvement algorithm [34, 12], being a few times slower. Far later, we have the small progress measure algorithm [19]. At the very end, with a lot of timeouts, we have the quasi-polynomial-time algorithm of Fearnley, Jain, Schewe, Stephan, and Wojtczak [13]. The other quasi-polynomial-time algorithms were not implemented due to excessive memory usage.

While developing the current algorithm, we hoped that it will share the good performance with Zielonka's algorithm, on which it is based. Unfortunately, preliminary experiments have shown that this is not necessarily the case. It turns out that

- on random games our algorithm performs similarly to the slowest algorithms implemented in Oink;
- on crafted game families that are difficult for Zielonka's algorithm, our algorithm is indeed faster from it, but not dramatically faster;
- the only think that is optimistic is that on games with a very low number of priorities our algorithm performs similarly to the fastest algorithms.

Because the empirical results of a direct implementation of the algorithm are completely unsatisfactory, we do not include a full description of our experiments. Instead, we leave an efficient implementation for a future work. Beside of the discouraging outcomes, we believe that our idea, via further optimizations, can lead to an algorithm that is both fast in practice and has a good worst-case complexity (see the concluding section for more comments).

2 Preliminaries

A parity game is played on a *game graph* between two players, called Even or Odd (shortened sometimes to E and O). A game graph consists of

- a directed graph G, where we require that every node has at least one successor, and where there are no self-loops (i.e., edges from a node to itself);
- a labeling of every node v of G by a positive natural number $\pi(v)$, called its *priority*;
- a partition of nodes of G between nodes owned by Even and nodes owned by Odd.

An infinite path in G is called a *play*, while a finite path in G is called a *partial play*. The game starts in a designated starting node. Then, the player to which the current node belongs, selects a successor of this node, and the game continues there. In effect, after a finite time a partial play is obtained, and at the end, after infinite time, this results in a play. We say that a play $v_1, v_2, \dots$ is winning for Even if $\limsup_{i\to\infty} \pi(v_i)$ is even (i.e., if the maximal priority seen infinitely often is even). Conversely, the play is winning for Odd if $\limsup_{i\to\infty} \pi(v_i)$ is odd.

A *strategy* of player $P \in \{\mathrm{Even}, \mathrm{Odd}\}$ is a function that maps every partial play that ends in a node of P to some its successor. Such a function says how P will play in every situation of the game (depending on the history of that game). When a (partial) play π follows a strategy σ in every step in which player P is deciding, we say that π *agrees* with σ.

A strategy σ is *winning* for P from a node v if every play that starts in v and agrees with σ is winning for P. While saying "player P wins from a node v" we usually mean that P has a winning strategy from v. Let $Win_P(G)$ be the set of nodes of G from which P wins; it is called the *winning region* of P. By Martin's theorem [27] we know that parity games are determined: in every game graph G, and for every node v of G either Even wins from v, or Odd wins from v. In effect, $Win_E(G)$ and $Win_O(G)$ form a partition of the node set of G.

During the analysis, we also consider games with other winning conditions. A *winning condition* is a set of plays. The winning conditions of Even and Odd considered in parity games are denoted LimsupEven and LimsupOdd, respectively. Beside of that, for every set S of nodes, let Safety(S) be the set of plays that use only nodes from S.

A *dominion* for Even is a set S of nodes such that from every $v \in S$ Even wins the game with the condition LimsupEven $\cap$ Safety(S); in other words, from every node of S he can win the parity game without leaving S. Likewise, a dominion for Odd is a set S of nodes such that from every $v \in S$ Odd wins the game with the condition LimsupOdd $\cap$ Safety(S). Notice that the whole $Win_P(G)$ is a dominion for P (where $P \in \{\text{Even}, \text{Odd}\}$). Indeed, if Even is going to win from some $v \in Win_E(G)$, the play cannot leave $Win_E(G)$ and enter a node $v' \in Win_O(G)$, as then Odd could use his winning strategy from v' and win the whole game; here we use the fact that all suffixes of a play in LimsupEven are also in LimsupEven. For $P =$ Odd the situation is symmetric.

3 Standard Zielonka's Algorithm

Before presenting our algorithm, we recall the standard Zielonka's algorithm, as a reference.

For a set of nodes N in a game graph G, and for a player $P \in \{\text{Even}, \text{Odd}\}$, we define the *attractor* of N, denoted $\textsc{Atr}_P(G, N)$, to be the set of nodes of G from which P can force to reach a node from N. In other words, $\textsc{Atr}_P(G, N)$ is the smallest set such that

- $N \subseteq \textsc{Atr}_P(G, N)$,
- if v is a node of P and some its successor is in $\textsc{Atr}_P(G, N)$, then $v \in \textsc{Atr}_P(G, N)$, and
- if v is a node of the opponent of P and all its successors are in $\textsc{Atr}_P(G, N)$, then $v \in \textsc{Atr}_P(G, N)$.

Clearly $\textsc{Atr}_P(G, N)$ can be computed in time proportional to the size of G.

Algorithm 1 Standard Zielonka's Algorithm.

```
procedure Solve_E(G, h)                          ▷ $h$ is an even upper bound for priorities in $G$
begin
    do begin
        $N_h = \{v \in \mathsf{nodes}(G) \mid \pi(v) = h\}$;      ▷ nodes with the highest priority
        $H = G \setminus \textsc{Atr}_E(G, N_h)$;               ▷ new game: reaching priority $h \to$ win
        $W_O = \textsc{Solve}_O(H, h-1)$;                  ▷ in $W_O$ we lose before reaching priority $h$
        $G = G \setminus \textsc{Atr}_O(G, W_O)$;               ▷ possibly $N_h \cap \textsc{Atr}_O(G, W_O) \neq \emptyset$
    end while $W_O \neq \emptyset$;
    return $\mathsf{nodes}(G)$;
end
```

Algorithm 1 is the standard Zielonka's algorithm. The procedure $\textsc{Solve}_E(G, h)$ returns $Win_E(G)$, the winning region of Even, if h is an even number that is greater or equal than all priorities appearing in G. A procedure $\textsc{Solve}_O(G, h)$ is also needed; it is identical to $\textsc{Solve}_E(G, h)$ except that the roles of E and O are swapped; it returns $Win_O(G)$, the

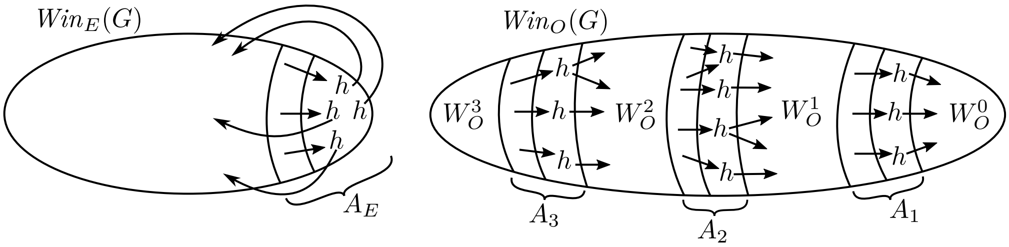

Figure 1 The structure of winning regions in a parity game.

winning region of Odd. While writing $G \setminus S$, we mean the game obtained by removing from G all nodes in S, and all edges leading to nodes in S or starting from nodes in S. We use this construct only when S is an attractor; in such a case, if all successors of a node v are removed, then v is also removed (i.e., if all successors of v belong to an attractor, then v belongs to the attractor as well). In effect $G \setminus S$ is a valid game graph (every its node has at least one successor).

We remark that the algorithm is presented in a slightly different way than usually. Namely, we use here a loop, while the usual presentation does not use a loop but rather calls recursively $\textsc{Solve}_E(G \setminus \textsc{Atr}_O(G, W_O), h)$ at the end of the procedure. This is only a superficial difference in the presentation, but is useful while modifying the algorithm in the next section.

The algorithm can be understood while looking at Figure 1. Let h be the highest priority used in G; assume that it is even. The game graph G can be divided into two parts: $Win_E(G)$ and $Win_O(G)$. In $Win_E(G)$ we can distinguish the attractor of nodes with priority h (denoted A_E). Odd either loses inside $Win_E(G) \setminus A_E$, or enters A_E, which causes that a node with priority h is seen, and then the game continues in some node of $Win_E(G)$. The winning region of Odd, $Win_O(G)$, can be divided into multiple parts. We have a part W_O^0, where Odd can win without seeing a node of priority h. Then, we have nodes of priority h from which Even is forced to enter W_O^0, and their attractor, denoted A_1. Then, we have a part W_O^1, where Odd can ensure that the play is either winning for him inside W_O^1 or enters A_1; in other words, from nodes of W_O^1 Odd can win while seeing h at most once. We also have parts W_O^i for larger i, and corresponding attractors A_i.

While running the algorithm, this partition of G is not known, and has to be discovered. To this end, the algorithm assumes first (in the game H) that all nodes of priority h are winning for Even. The first call to $\textsc{Solve}_O(H, h-1)$ returns the set W_O^0 of nodes where Odd wins without seeing a node of priority h. We then remove them from the game, together with the attractor A_1. In the next step, $\textsc{Solve}_O(H, h-1)$ returns the set W_O^1, and so on. At the end the whole $Win_O(G)$ becomes removed, and the procedure returns $Win_E(G)$.

4 Quasi-Polynomial-Time Algorithm

We now present a modification to Algorithm 1 that results in obtaining quasi-polynomial running time, in the worst case.

The modification can be understood while looking again at Figure 1. The key observation is that, while $Win_O(G)$ is of size at most n (where n is the number of nodes in G), then most of its parts W_O^i are smaller. Namely, most of them have to be of size at most $\frac{n}{2}$, and only one of them can be larger than $\frac{n}{2}$. We use this observation, and while looking for W_O^i, we search for a winning region (for a dominion) of size at most $\frac{n}{2}$. Usually this is enough;

only once it is not enough: one W_O^i can be larger than $\frac{n}{2}$ and it will not be found if we only look for a set of size at most $\frac{n}{2}$. But when the algorithm finds no set of size at most $\frac{n}{2}$, we can once search for W_O^i of an arbitrary size. After that, we know that all following sets W_O^i are again of size at most $\frac{n}{2}$. While going recursively, we notice that every W_O^i can be further subdivided in a similar way, while splitting on the priority $h-2$. If $|W_O^i| \leq \frac{n}{2}$, we again have the property that most of the parts of W_O^i are of size at most $\frac{n}{4}$, and only one of them can be larger than $\frac{n}{4}$.

To exploit this observation, in the recursive calls we pass two precision parameters, p_E and p_O (one for every of the players), saying that we search for winning sets of size at most p_E for Even, and at most p_O for Odd. The modified procedure is presented as Algorithm 2. Again, one also needs a procedure $\textsc{Solve}_O$, which is obtained from $\textsc{Solve}_E$ by literally changing every E to O and *vice versa*.

Algorithm 2 Quasi-Polynomial-Time Algorithm.

```
 1: procedure $\textsc{Solve}_E(G, h, p_E, p_O)$          ▷ $p_E, p_O$ are new "precision" parameters
 2: begin
 3:     if $G = \emptyset \lor p_E \leq 1$ then
 4:         return $\emptyset$;                        ▷ we assume that there are no self-loops in $G$
 5:     do begin
 6:         $N_h = \{v \in \mathsf{nodes}(G) \mid \pi(v) = h\}$;
 7:         $H = G \setminus \textsc{Atr}_E(G, N_h)$;
 8:         $W_O = \textsc{Solve}_O(H, h-1, \lfloor p_O/2 \rfloor, p_E)$;          ▷ precision decreased
 9:         $G = G \setminus \textsc{Atr}_O(G, W_O)$;
10:     end while $W_O \neq \emptyset$;
11:     $N_h = \{v \in \mathsf{nodes}(G) \mid \pi(v) = h\}$;
12:     $H = G \setminus \textsc{Atr}_E(G, N_h)$;
13:     $W_O = \textsc{Solve}_O(H, h-1, p_O, p_E)$;          ▷ we try once with the full precision
14:     $G = G \setminus \textsc{Atr}_O(G, W_O)$;
15:     while $W_O \neq \emptyset$ do begin
16:         $N_h = \{v \in \mathsf{nodes}(G) \mid \pi(v) = h\}$;
17:         $H = G \setminus \textsc{Atr}_E(G, N_h)$;
18:         $W_O = \textsc{Solve}_O(H, h-1, \lfloor p_O/2 \rfloor, p_E)$;          ▷ again, precision decreased
19:         $G = G \setminus \textsc{Atr}_O(G, W_O)$;
20:     end;
21:     return $\mathsf{nodes}(G)$;
22: end
```

We start the algorithm with $p_E = p_O = n$, where n is the number of nodes in G. In the procedure we have now, in a sense, three copies of the previous procedure, corresponding to three stages. In the first stage, in lines 5-10, we look for sets W_O^i of size at most $\lfloor \frac{p_O}{2} \rfloor$. If the returned set is empty, this may mean that the next W_O^i either is empty, or is of size greater than $\lfloor \frac{p_O}{2} \rfloor$. Then, in lines 11-14, we once search for a set W_O^i of size at most p_O (knowing that if it is nonempty, then its size is greater than $\lfloor \frac{p_O}{2} \rfloor$). Finally, in the loop in lines 15-20, we again look for sets W_O^i of size at most $\lfloor \frac{p_O}{2} \rfloor$ (because we have already found a set of size greater than $\lfloor \frac{p_O}{2} \rfloor$, all the remaining sets have size at most $\lfloor \frac{p_O}{2} \rfloor$).

5 Complexity Analysis

Let us analyze the complexity of our algorithm.

First, we observe that the space complexity is $O(n \cdot h)$, where n is the number of nodes, and h is the maximal priority. Indeed, the depth of the recursion is at most h, and on every step we only need to remember some sets of nodes.

We now come to the running time. As it is anyway worse than the running time of the other quasi-polynomial-time algorithms, we do not aim in proving a very tight upper bound; we only prove that the running time is quasi-polynomial.

Let $R(h,l)$ be the number of (nontrivial) executions of the $\textsc{Solve}_E$ and $\textsc{Solve}_O$ procedures performed during one call to $\textsc{Solve}_E(G,h,p_E,p_O)$ with $\lfloor \log p_E \rfloor + \lfloor \log p_O \rfloor = l$, and with G having at most n nodes (where n is fixed). We only count here nontrivial executions, that is, such that do not leave the procedure in line 4. Clearly $R(0,l) = R(h,0) = 0$. For $h,l \geq 1$ it holds that

$$R(h,l) \leq 1 + n \cdot R(h-1,l-1) + R(h-1,l)\,. \tag{1}$$

Indeed, in $\textsc{Solve}_E$ after every call to $\textsc{Solve}_O$ we remove at least one node from G, with the exception of two such calls: the last call in line 8, and the last call ever. In effect, in lines 8 and 18 we have at most n calls to $\textsc{Solve}_O$ with decreased precision (plus, potentially, the $(n+1)$-th call with empty G, which is not included in $R(h,l)$), and in line 13 we have one call to $\textsc{Solve}_O$ with full precision. Notice that $\lfloor \log p_O \rfloor$ (hence also l) decreases by 1 in the decreased-precision call.

Using Inequality (1) we now prove by induction that $R(h,l) \leq n^l \cdot \binom{h+l}{l} - 1$. For $h = 0$ and for $l = 0$ the inequality holds. For $h,l \geq 1$ we have that

$$\begin{aligned} R(h,l) &\leq 1 + n \cdot R(h-1,l-1) + R(h-1,l) \\ &\leq 1 + n \cdot \left(n^{l-1} \cdot \binom{h-1+l-1}{l-1} - 1 \right) + n^l \cdot \binom{h-1+l}{l} - 1 \\ &\leq n^l \cdot \left(\binom{h-1+l}{l-1} + \binom{h-1+l}{l} \right) - 1 \\ &= n^l \cdot \binom{h+l}{l} - 1\,. \end{aligned}$$

In effect, $R(h,l) \leq n^l \cdot (h+l)^l$. Recalling that we start with $l = 2 \cdot \lfloor \log n \rfloor$, we see that this number is quasi-polynomial in n and h. This concludes the proof, since obviously a single execution of the $\textsc{Solve}_E$ procedure (not counting the running time of recursive calls) costs polynomial time.

6 Correctness

We now justify correctness of the algorithm. This amounts to proving the following lemma.

▶ **Lemma 6.1.** *Procedure* $\textsc{Solve}_E(G,h,p_E,p_O)$ *returns a set* W_E *such that for every* $S \subseteq \mathsf{nodes}(G)$,

- *if S is a dominion for Even, and $|S| \leq p_E$, then $S \subseteq W_E$, and*
- *if S is a dominion for Odd, and $|S| \leq p_O$, then $S \cap W_E = \emptyset$.*

Notice that in G there may be nodes that do not belong to any dominion smaller than p_E or p_O; for such nodes we do not specify whether or not they are contained in W_E.

Recall that $Win_E(G)$ is a dominion for Even, and $Win_O(G)$ is a dominion for Odd. Thus, using Lemma 6.1 we can conclude that for $p_E = p_O = n$ the procedure returns $Win_E(G)$, the winning region of Even.

One may wonder why we use dominions in the statement of the lemma, instead of simply saying that if $|Win_E(G)| \leq p_E$, then $Win_E(G) \subseteq W_E$. Such a simplified statement, however, is not suitable for induction. Indeed, while switching from the game G to the game H (created in lines 7, 12, 17) the winning regions of Even may increase dramatically, because in H Odd is not allowed to visit any node with priority h. Nevertheless, the winning region of Even in G, and any dominion of Even in G, remains a dominion in H (when restricted to nodes of H).

Before proving Lemma 6.1, let us observe two facts about dominions. In their statements $P \in \{\mathrm{Even}, \mathrm{Odd}\}$ is one of the players, and $\overline{P}$ is his opponent.

▶ **Fact 6.2.** *If S is a dominion for P in a game G, and X is a set of nodes of G, then $S \setminus \mathrm{ATR}_P(G, X)$ is a dominion for P in $G \setminus \mathrm{ATR}_P(G, X)$.*

Proof. Denote $S' = S \setminus \mathrm{ATR}_P(G, X)$ and $G' = G \setminus \mathrm{ATR}_P(G, X)$. By definition, from every node $v \in S$ player P wins with the condition $\mathrm{Limsup}P \cap \mathrm{Safety}(S)$ in G, using some winning strategy. Observe that using the same strategy he wins with the condition $\mathrm{Limsup}P \cap \mathrm{Safety}(S')$ in G' (assuming that the starting node v is in S'). The strategy remains valid in G', because every node u of player P that remains in G' has the same successors in G' as in G (conversely: if some of successors of u belongs to $\mathrm{ATR}_P(G, X)$, then u also belongs to $\mathrm{ATR}_P(G, X)$). ◀

▶ **Fact 6.3.** *If S is a dominion for P in a game G, and X is a set of nodes of G such that $S \cap X = \emptyset$, then S is a dominion for P in $G \setminus \mathrm{ATR}_{\overline{P}}(G, X)$ (in particular $S \subseteq \mathsf{nodes}(G \setminus \mathrm{ATR}_{\overline{P}}(G, X))$).*

Proof. Denote $G' = G \setminus \mathrm{ATR}_{\overline{P}}(G, X)$. Suppose that there is some $v \in S \cap \mathrm{ATR}_{\overline{P}}(G, X)$. On the one hand, P can guarantee that, while starting from v, the play stays in S (by the definition of a dominion); on the other hand, $\overline{P}$ can force to reach the set X (by the definition of an attractor), which is disjoint from S. Thus such a node v could not exist, we have $S \subseteq \mathsf{nodes}(G')$.

It remains to observe that from every node $v \in S$ player P wins with the condition $\mathrm{Limsup}P \cap \mathrm{Safety}(S)$ also in the restricted game G', using the same strategy as in G. Indeed, a play in G following this strategy never leaves S, and the whole S remains unchanged in G'. ◀

We are now ready to prove Lemma 6.1.

Proof of Lemma 6.1. We prove the lemma by induction on h. Consider some execution of the procedure. By G^i, N_h^i, H^i, W_O^i we denote values of the variables G, N_h, H, W_O just after the i-th call to SOLVE_O in one of the lines 8, 13, 18; in lines 9, 14, 19 we create G^{i+1} out of G^i and W_O^i. In particular G^1 equals the original game G, and at the end we return $\mathsf{nodes}(G^{m+1})$, where m is the number of calls to SOLVE_O.

Concentrate on the first item of the lemma: fix an Even's dominion S in G (i.e., in G^1) such that $|S| \leq p_E$. Assume that $S \neq \emptyset$ (for $S = \emptyset$ there is nothing to prove). Notice first that a nonempty dominion has at least two nodes (by assumption there are no self-loops in G, hence every play has to visit at least two nodes), thus, because $S \subseteq \mathsf{nodes}(G)$ and $|S| \leq p_E$, we have that $G \neq \emptyset$ and $p_E > 1$. It means that the procedure does not return in line 4. We thus need to prove that $S \subseteq \mathsf{nodes}(G^{m+1})$.

We actually prove that S is a dominion for Even in G^i for every $i \in \{1, \dots, m+1\}$, meaning in particular that $S \subseteq \mathsf{nodes}(G^i)$. This is shown by an internal induction on i. The base case ($i = 1$) holds by assumption. For the induction step, consider some $i \in \{1, \dots, m\}$. By the induction assumption S is a dominion for Even in G^i, and we need to prove that it is a dominion for Even in G^{i+1}.

Consider $S^i = S \cap \mathsf{nodes}(H^i)$. Because $S^i = S \setminus \textsc{Atr}_E(G^i, N^i_h)$, by Fact 6.2 the set S^i is a dominion for Even in $H^i = G^i \setminus \textsc{Atr}_E(G^i, N^i_h)$, and obviously $|S^i| \leq |S| \leq p_E$. By the assumption of the external induction (which can be applied to $\textsc{Solve}_O$, by symmetry) it follows that $S^i \cap W^i_O = \emptyset$, so also $S \cap W^i_O = \emptyset$ (because W^i_O contains only nodes of G^i, while $S \setminus S^i$ contains no nodes of G^i). Thus, by Fact 6.3 the set S is a dominion for Even in $G^{i+1} = G^i \setminus \textsc{Atr}_O(G^i, W^i_O)$. This finishes the proof of the first item.

Now we prove the second item of the lemma. To this end, fix some Odd's dominion S in G such that $|S| \leq p_O$. If $p_E \leq 1$, we return $W_E = \emptyset$ (line 4), so clearly $S \cap W_E = \emptyset$. The interesting case is when $p_E \geq 2$. Denote $S^i = S \cap \mathsf{nodes}(G^i)$ for all $i \in \{1, \dots, m+1\}$; we first prove that S^i is a dominion for Odd in G^i. This is shown by induction on i. The base case of $i = 1$ holds by assumption, because $G^1 = G$ and $S^1 = S$. For the induction step, assume that S^i is a dominion for Odd in G^i, for some $i \in \{1, \dots, m\}$. By definition $G^{i+1} = G^i \setminus \textsc{Atr}_O(G^i, W^i_O)$ and $S^{i+1} = S^i \setminus \textsc{Atr}_O(G^i, W^i_O)$, so S^{i+1} is a dominion for Odd in G^{i+1} by Fact 6.2, which finishes the inductive proof.

For $i \in \{1, \dots, m\}$, let Z^i be the set of nodes (in $S^i \setminus N^i_h$) from which Odd wins with the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(S^i \setminus N^i_h)$ in G^i (that is, where Odd can win without seeing priority h – the highest even priority). Let us observe that if $S^i \neq \emptyset$ then $Z^i \neq \emptyset$ $(\clubsuit)$. Indeed, suppose to the contrary that $Z^i = \emptyset$, and consider an Odd's strategy that allows him to win with the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(S^i)$ in G^i, from some node $v_0 \in S^i$. Because $v_0 \notin Z^i$, this strategy in not winning for the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(S^i \setminus N^i_h)$, so Even, while playing against this strategy, can reach a node v_1 in N^i_h (as he cannot violate the parity condition nor leave S^i). For the same reason, because $v_1 \notin Z^i$, Even can continue and reach a node v_2 in N^i_h. Repeating this forever, Even gets priority h (which is even and is the highest priority) infinitely many times, contradicting the fact that the strategy was winning for Odd.

Observe also that from nodes of Z^i Odd can actually win with the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(Z^i)$ in G^i, using the strategy that allows him to win with the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(S^i \setminus N^i_h)$. Indeed, if a play following this strategy enters some node v, then from this node v Odd can still win with the condition $\mathsf{LimsupOdd} \cap \mathsf{Safety}(S^i \setminus N^i_h)$, which means that these nodes belongs to Z^i. It follows that Z^i is a dominion for Odd in G^i. Moreover, because $Z^i \cap N^i_h = \emptyset$, from Fact 6.3 we have that Z^i is a dominion for Odd in $H^i = G^i \setminus \textsc{Atr}_E(G^i, N^i_h)$.

Let k be the number of the call to $\textsc{Solve}_O$ that is performed in line 13 (calls number $1, \dots, k-1$ are performed in line 8, and calls number $k+1, \dots, m$ are performed in line 18). Recall that W^i_O is the set returned by a call to $\textsc{Solve}_O(H^i, h-1, p^i_O, p_E)$, where $p^k_O = p_O$, and $p^i_O = \lfloor \frac{p_O}{2} \rfloor$ if $i \neq k$. From the assumption of the external induction, if $|Z^i| \leq \lfloor \frac{p_O}{2} \rfloor$ or if $i = k$ (since $Z^i \subseteq S^i \subseteq S$ and $|S| \leq p_O$, clearly $|Z^i| \leq p_O$), we obtain that $Z^i \subseteq W^i_O$ $(\spadesuit)$.

We now prove that $|S^{k+1}| \leq \lfloor \frac{p_O}{2} \rfloor$. This clearly holds if $S^{k-1} = \emptyset$, because $S^{k+1} \subseteq S^k \subseteq S^{k-1}$. Suppose thus that $S^{k-1} \neq \emptyset$. Then $Z^{k-1} \neq \emptyset$, by $(\clubsuit)$. On the other hand, $W^{k-1}_O = \emptyset$, because we are just about to leave the loop in lines 5-10 (the k-th call to $\textsc{Solve}_O$ is in line 13). By $(\spadesuit)$, if $|Z^{k-1}| \leq \lfloor \frac{p_O}{2} \rfloor$, then $Z^{k-1} \subseteq W^{k-1}_O$, which does not hold in our case. Thus $|Z^{k-1}| > \lfloor \frac{p_O}{2} \rfloor$. Because $W^{k-1}_O = \emptyset$, we simply have $G^k = G^{k-1}$, and $S^k = S^{k-1}$, and $Z^k = Z^{k-1}$. Using $(\spadesuit)$ for $i = k$, we obtain that $Z^k \subseteq W^k_O$, and because $S^{k+1} = S^k \setminus \textsc{Atr}_O(G^k, W^k_O) \subseteq S^k \setminus W^k_O \subseteq S^k \setminus Z^k$ we obtain that $|S^{k+1}| \leq |S^k| - |Z^k| \leq p_O - (\lfloor \frac{p_O}{2} \rfloor + 1) \leq \lfloor \frac{p_O}{2} \rfloor$, as initially claimed.

If $k = m$, we have $Z^m \subseteq W_O^m$ by (♠). If $k+1 \leq m$, we have $S^m \subseteq S^{k+1}$ (our procedure only removes nodes from the game) and $Z^m \subseteq S^m$, so $|Z^m| \leq \lfloor \frac{p_O}{2} \rfloor$ by the above paragraph, and also $Z^m \subseteq W_O^m$ by (♠). Because after the m-th call to SOLVE$_O$ the procedure ends, we have $W_O^m = \emptyset$, so also $Z^m = \emptyset$, and thus $S^m = \emptyset$ by (♣). We have $S^{m+1} \subseteq S^m$, so $S^{m+1} = S \cap \mathsf{nodes}(G^{m+1}) = \emptyset$. This is exactly the conclusion of the lemma, since the set returned by the procedure is $\mathsf{nodes}(G^{m+1})$. ◀

7 Conclusions

To the list of the four existing quasi-polynomial-time algorithms solving parity games, we have added a new one. It uses a rather different approach: it analyses recursively the game graph, like Zielonka's algorithm.

Notice that the number of recursive calls in our algorithm may be smaller than in the original Zielonka's algorithm, because of the precision parameters, but it may also be larger. Indeed, while SOLVE$_E$ in the original Zielonka's algorithm stops after the first time when a recursive call returns $\emptyset$, in our algorithm the procedure stops after the second time when a recursive call returns $\emptyset$.

The algorithm, as is, turns out not to be very efficient in practice. Beside of that, we believe that it can serve as a good starting point for a more optimized algorithm. Over the years, some optimizations to Zielonka's algorithm were proposed. For example, Liu, Duan, and Tian [26] replace the loop guard $W_O = \emptyset$ by $W_O = \text{ATR}_O(G, W_O)$ (which ensures that W_O will be empty in the next iteration of the loop). Verver [33] proposes to check whether $\text{ATR}_E(G, N_h)$ contains all nodes of priority $h-1$, and if so, to extend N_h by nodes of the next highest Even priority (i.e., $h-2$). It seems that these optimizations can be applied to our algorithm as well.

A straightforward optimization is to decrease p_O and p_E to $|G|$ at the beginning of every recursive call.

Another idea is to extend the recursive procedure so that it will return also a Boolean value saying whether the returned set surely equals the whole winning region (i.e., whether the precision parameters have not restricted anything). If while making the recursive call with smaller precision (line 8) the answer is positive, but the returned set W_O is empty, we can immediately stop the procedure, without making the recursive call with the full precision (line 13).

One can also observe that the call to SOLVE$_O$ in line 13 (with the full precision) gets the same subgame H as the last call to SOLVE$_O$ in line 8 (with decreased precision). A very rough idea is to make some use of the computations performed by the decreased-precision call during the full-precision call.

We leave implementation and evaluation of the above (and potentially some other) optimizations for a future work.

Abstract

In two-player games on graphs, the players move a token through a graph to produce a finite or infinite path, which determines the qualitative winner or quantitative payoff of the game. We study *bidding games* in which the players bid for the right to move the token. Several bidding rules were studied previously. In *Richman* bidding, in each round, the players simultaneously submit bids, and the higher bidder moves the token and pays the other player. *Poorman* bidding is similar except that the winner of the bidding pays the "bank" rather than the other player. *Taxman* bidding spans the spectrum between Richman and poorman bidding. They are parameterized by a constant $\tau \in [0,1]$: portion τ of the winning bid is paid to the other player, and portion $1-\tau$ to the bank. While finite-duration (reachability) taxman games have been studied before, we present, for the first time, results on *infinite-duration* taxman games. It was previously shown that both Richman and poorman infinite-duration games with qualitative objectives reduce to reachability games, and we show a similar result here. Our most interesting results concern quantitative taxman games, namely *mean-payoff* games, where poorman and Richman bidding differ significantly. A central quantity in these games is the *ratio* between the two players' initial budgets. While in poorman mean-payoff games, the optimal payoff of a player depends on the initial ratio, in Richman bidding, the payoff depends only on the structure of the game. In both games the optimal payoffs can be found using (different) probabilistic connections with *random-turn* games in which in each turn, instead of bidding, a coin is tossed to determine which player moves. While the value with Richman bidding equals the value of a random-turn game with an un-biased coin, with poorman bidding, the bias in the coin is the initial ratio of the budgets. We give a complete classification of mean-payoff taxman games that is based on a probabilistic connection: the value of a taxman bidding game with parameter τ and initial ratio r, equals the value of a random-turn game that uses a coin with bias $F(\tau,r)=\frac{r+\tau\cdot(1-r)}{1+\tau}$. Thus, we show that Richman bidding is the exception; namely, for every $\tau<1$, the value of the game depends on the initial ratio. Our proof technique simplifies and unifies the previous proof techniques for both Richman and poorman bidding.

1 Introduction

Two-player infinite-duration games on graphs are a central class of games in formal verification [2], where they are used, for example, to solve synthesis [19], and they have deep connections to foundations of logic [21]. A graph game proceeds by placing a token on a vertex in the graph, which the players move throughout the graph to produce an infinite path ("play") π. The game is zero-sum and π determines the winner or payoff. Graph games can be classified according to the players' objectives. For example, the simplest objective is *reachability*, where Player 1 wins iff an infinite path visits a designated target vertex. Another classification of graph games is the *mode of moving* the token. The most studied mode of moving is *turn based*, where the players alternate turns in moving the token.

In *bidding games*, in each turn, an "auction" is held between the two players in order to determine which player moves the token. The bidding mode of moving was introduced in [13, 14] for reachability games, where the following bidding rules where defined. In *Richman* bidding (named after David Richman), each player has a budget, and before each turn, the players submit bids simultaneously, where a bid is legal if it does not exceed the available budget. The player who bids higher wins the bidding, pays the bid to the other player, and moves the token. A second bidding rule called *poorman* bidding in [13], is similar except that the winner of the bidding pays the "bank" rather than the other player. Thus, the bid is deducted from his budget and the money is lost. A third bidding rule on which we focus in this paper, called *taxman* in [13] spans the spectrum between poorman and Richman bidding. Taxman bidding is parameterized by $\tau \in [0, 1]$: the winner of a bidding pays portion τ of his bid to the other player and portion $1 - \tau$ to the bank. Taxman bidding with $\tau = 1$ coincides with Richman bidding and taxman bidding with $\tau = 0$ coincides with poorman bidding.

Bidding games are relevant for several communities in Computer Science. In formal methods, graph games are used to reason about systems. Poorman bidding games naturally model concurrent systems where processes pay the scheduler for moving. Block-chain technology like Etherium is an example of such a system, which is a challenging to formally verify [9, 3]. In Algorithmic Game Theory [17], auction design is a central research topic that is motivated by the abundance of auctions for online advertisements [16]. Infinite-duration bidding games can model ongoing auctions and can be used to devise bidding strategies for objectives like: "In the long run, an advertiser's ad should show at least half of the time". In Artificial Intelligence, bidding games with Richman bidding have been used to reason about combinatorial negotiations [15]. Finally, *discrete-bidding* games [11], in which the granularity of the bids is restricted by assuming that the budgets are given using coins, have been studied mostly for recreational games, like bidding chess [6].

Both Richman and poorman infinite-duration games have a surprising, elegant, though different, mathematical structure as we elaborate below. Our study of taxman bidding aims at a better understanding of this structure and at shedding light on the differences between the seemingly similar bidding rules.

A central quantity in bidding games is the *initial ratio* of the players budgets. Formally, assuming that, for $i \in \{1, 2\}$, Player i's initial budget is B_i, we say that Player 1's initial ratio is $B_1/(B_1 + B_2)$. The central question that was studied in [13] regards the existence of a necessary and sufficient initial ratio to guarantee winning the game. Formally, the *threshold ratio* in a vertex v, denoted $\texttt{Th}(v)$, is such that if Player 1's initial ratio exceeds $\texttt{Th}(v)$, he can guarantee winning the game, and if his initial ratio is less than $\texttt{Th}(v)$, Player 2 can guarantee winning the game[1]. Existence of threshold ratios in reachability games for all three bidding mechanisms was shown in [13].

Reachability Richman-bidding games have an interesting probabilistic connection [14]. To state the connection, we first need to introduce *random-turn* games. Let $p \in [0, 1]$. In a random-turn game that is parameterized by p, in each turn, rather than bidding, the player who moves is chosen by throwing a (possibly) biased coin: with probability p, Player 1 chooses how to move the token, and Player 2 chooses with probability $1 - p$. Formally, a random-turn game is a special case of a stochastic game [10]. Consider a reachability Richman-bidding game $\mathcal{G}$. We construct a "uniform" random-turn game on top of $\mathcal{G}$, denoted $\mathtt{RT}^{0.5}(\mathcal{G})$, in which we throw an unbiased coin in each turn. The objective of Player 1 remains reaching his target vertex. It is well known that each vertex in $\mathtt{RT}^{0.5}(\mathcal{G})$ has a *value*, which is, informally, the probability of reaching the target when both players play optimally, and which we denote by $val(\mathtt{RT}^{0.5}(\mathcal{G}), v)$. We are ready to state the probabilistic connection: For every vertex v in the Richman game $\mathcal{G}$, the threshold ratio in v equals $1 - val(\mathtt{RT}^{0.5}(\mathcal{G}), v)$. We note that such a connection is not known and is unlikely to exist in reachability games with neither poorman nor taxman bidding. Random-turn games have been extensively studied in their own right, mostly with unbiased coin tosses, since the seminal paper [18].

Infinite-duration bidding games have been recently studied with Richman [4] and poorman [5] bidding. For qualitative objectives, namely games in which one player wins and the other player loses, both bidding rules have similar properties. By reducing general qualitative games to reachability games, it is shown that threshold ratios exist for both types of bidding rules. We show a similar result for qualitative games with taxman bidding.

Things get interesting in *mean-payoff* games, which are quantitative games: an infinite play has a *payoff*, which is Player 1's reward and Player 2's cost (see an example of a mean-payoff game in Figure 1). We thus call the players in a mean-payoff game Max and Min, respectively. We focus on games that are played on strongly-connected graphs. With Richman bidding [4], the initial budget of the players does not matter: A mean-payoff Richman-bidding game $\mathcal{G}$ has a value $c \in \mathbb{R}$ that depends only on the structure of the game such that Min can guarantee a cost of at most c with any positive budget, and with any positive budget, Max can guarantee a payoff of at least $c - \epsilon$, for every $\epsilon > 0$. Moreover, the value c of $\mathcal{G}$ equals the value of a random-turn game $\mathtt{RT}^{0.5}(\mathcal{G})$ that is constructed on top of $\mathcal{G}$. Since $\mathcal{G}$ is a mean-payoff game, $\mathtt{RT}^{0.5}(\mathcal{G})$ is a mean-payoff stochastic game, and its value, which again, is a well-known concept, is the expected payoff when both players play optimally.

Mean-payoff poorman-bidding games have different properties. Unlike with Richman bidding, the value of the game depends on the initial ratio. That is, with a higher initial ratio, Max can guarantee a better payoff. While the probabilistic connection for mean-payoff Richman games is not entirely unexpected given the probabilistic connection for reachability Richman games, we find it surprising that mean-payoff poorman games exhibit a probabilistic connection, which is in fact richer than for Richman bidding. The connection for poorman games is the following: Suppose Max's initial ratio is $r \in [0, 1]$ in a game $\mathcal{G}$. Then, the value in $\mathcal{G}$ with respect to r is the value of the random-turn game $\mathtt{RT}^r(\mathcal{G})$ in which in each turn, we toss a biased coin that chooses Max with probability r and Min with probability $1 - r$.

[1] When the initial ratio is exactly $\mathtt{Th}(v)$, the winner depends on the mechanism with which ties are broken. Our results do not depend on a specific tie-breaking mechanism.Tie-breaking mechanisms are particularly important in discrete-bidding games [1].

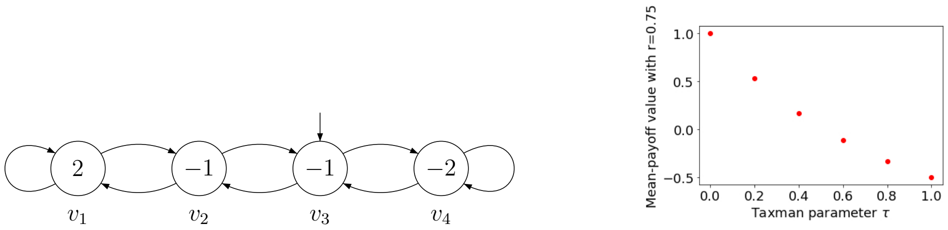

Figure 1 On the left, a mean-payoff game $\mathcal{G}$. On the right, the mean-payoff value of $\mathcal{G}$, where the initial ratio is fixed to 0.75 and the taxman parameter τ varies. The value of $\mathcal{G}$ with Richman bidding is -0.5, with poorman bidding, it is 1, and, for example, with $\tau = 0.2$, it is 0.533.

Given this difference between the two bidding rules, one may wonder how do mean-payoff taxman games behave, since these bidding rules span the spectrum between Richman and poorman bidding. Our main contribution is a complete solution to this question: we identify a probabilistic connection for a taxman game $\mathcal{G}$ that depends on the parameter τ of the bidding and the initial ratio r. That is, we show that the value of the game equals the value of the random-turn game $\mathtt{RT}^{F(\tau,r)}(\mathcal{G})$, where $F(\tau, r) = \frac{r+\tau\cdot(1-r)}{1+\tau}$. The construction gives rise to optimal strategies w.r.t. τ and the initial ratio. As a sanity check, note that for $\tau = 1$, we have $F(\tau, r) = 0.5$, which agrees with the result on Richman bidding, and for $\tau = 0$, we have $F(\tau, r) = r$, which agrees with the result on poorman bidding. In Figure 1, we depict some mean-payoff values for a fixed initial ratio and varying taxman parameter. Previous results only give the two endpoints in the plot, and the mid points in the plot are obtained using the results in this paper.

The main technical challenge is constructing an optimal strategy for Max, which, intuitively, performs a de-randomization; with a deterministic bidding strategy, Max guarantees that the ratio of the time that is spent in each vertex is the same as in a random behavior. The construction of Max strategy involves two components. First, we assign an "importance" to each vertex v, which we call *strength* and denote $\mathrm{St}(v)$. Intuitively, if $\mathrm{St}(v) > \mathrm{St}(u)$, then it is more important for Max to move in v than in u. Second, when the game reaches a vertex v, Max's bid is a careful normalization of $\mathrm{St}(v)$ so that changes in Max's ratio are matched with the accumulated weights in the game. Finding the right normalization is intricate and it consists of the main technical contribution of this paper. Previous such normalizations were constructed for Richman and poorman mean-payoff games [4, 5]. The construction for Richman bidding is much more complicated than the one we present here. The construction for poorman bidding is ad-hoc and does not generalize. Our construction for taxman bidding thus unifies these constructions and simplifies them. It uses techniques that can generalize beyond taxman bidding. Finally, we study, for the first time, complexity problems for taxman games.

Due to lack of space, some proofs appear in the full version.

2 Preliminaries

A graph game is played on a directed graph $G = \langle V, E\rangle$, where V is a finite set of vertices and $E \subseteq V \times V$ is a set of edges. The *neighbors* of a vertex $v \in V$, denoted $N(v)$, is the set of vertices $\{u \in V : \langle v, u\rangle \in E\}$. A *path* in G is a finite or infinite sequence of vertices $v_1, v_2, \ldots$ such that for every $i \geq 1$, we have $\langle v_i, v_{i+1}\rangle \in E$.

Bidding games. Each Player i has a budget $B_i \in \mathbb{R}^{\geq 0}$. In each turn a bidding determines which player moves the token. Both players simultaneously submit bids, where a bid b_i for Player i is legal if $b_i \leq B_i$. The player who bids higher wins the bidding, where we assume some mechanism to break ties, e.g., always giving Player 1 the advantage, and our results are not affected by the specific tie-breaking mechanism at use. The winner moves the token and pays his bid, where we consider three bidding mechanisms that differ in where the winning bid is paid. Suppose Player 1 wins a bidding with his bid of b.

- In **Richman** bidding, the winner pays to the loser, thus the new budgets are $B_1 - b$ and $B_2 + b$.
- In **poorman** bidding, the winner pays to the bank, thus the new budgets are $B_1 - b$ and B_2.
- In **taxman** bidding with parameter $\tau \in [0, 1]$, the winner pays portion τ to the other player and $(1 - \tau)$ to the bank, thus the new budgets are $B_1 - b$ and $B_2 + (1 - \tau) \cdot b$.

A central quantity in bidding games is the *ratio* of a player's budget from the total budget.

▶ **Definition 1** (Ratio). *Suppose the budget of Player i is B_i, for $i \in \{1, 2\}$, at some point in the game. Then, Player i's* ratio *is $B_i/(B_1 + B_2)$. The* initial ratio *refers to the ratio of the initial budgets, namely the budgets before the game begins. We restrict attention to games in which both players start with positive initial budgets, thus the initial ratio is in* $(0, 1)$.

Strategies and plays. A *strategy* is a recipe for how to play a game. It is a function that, given a finite *history* of the game, prescribes to a player which *action* to take, where we define these two notions below. For example, in turn-based games, a strategy takes as input, the sequence of vertices that were visited so far, and it outputs the next vertex to move to. In bidding games, histories and strategies are more involved as they maintain the information about the bids and winners of the bids. Formally, a history in a bidding game is $\pi = \langle v_1, b_1, i_1\rangle, \ldots, \langle v_k, b_k, i_k\rangle, v_{k+1} \in (V \times \mathbb{R} \times \{1, 2\})^* \cdot V$, where for $1 \leq j \leq k + 1$, the token is placed on vertex v_j at round j, for $1 \leq j \leq k$, the winning bid is b_j and the winner is Player i_j. Consider a finite history π. For $i \in \{1, 2\}$, let $W_i(\pi) \subseteq \{1, \ldots, k\}$ denote the indices in which Player i is the winner of the bidding in π. Let B^I_i be the initial budget of Player i. Player i's budget following π, denoted $B_i(\pi)$, depends on the bidding mechanism. For example, in Richman bidding, $B_1(\pi) = B^I_i - \sum_{j \in W_1(\pi)} b_j + \sum_{j \in W_2(\pi)} b_j$, B_2 is defined dually, and the definition is similar for taxman and poorman bidding. Given a history π that ends in v, a strategy for Player i prescribes an action $\langle b, v\rangle$, where $b \leq B_i(\pi)$ is a bid that does not exceed the available budget and v is a vertex to move to upon winning, where we require that v is a neighbor of v_{k+1}. An initial vertex, initial budgets, and two strategies for the players determine a unique infinite *play* π for the game. The vertices that π visits form an infinite path $path(\pi)$.

Objectives. An objective O is a set of infinite paths. Player 1 wins an infinite play π iff $path(\pi) \in O$. We call a strategy f *winning* for Player 1 w.r.t. an objective O if for every strategy g of Player 2 the play that f and g determine is winning for Player 1. Winning strategies for Player 2 are defined dually. We consider the following qualitative objectives:

1. In *reachability games*, Player 1 has a target vertex t and an infinite play is winning iff it visits t.

2. In *parity games*, each vertex is labeled with an index in $\{1, \ldots, d\}$. An infinite path is winning for Player 1 iff the parity of the maximal index that is visited infinitely often is odd.
3. *Mean-payoff games* are played on weighted directed graphs, with weights given by a function $w : V \to \mathbb{Q}$. Consider an infinite path $\eta = v_1, v_2, \dots \in V^\omega$. For $n \in \mathbb{N}$, the prefix of length n of η is η^n, and we define its *energy* to be $E(\eta^n) = \sum_{i=1}^{n} w(v_i)$. The *payoff* of η is $\mathtt{MP}(\eta) = \liminf_{n\to\infty} E(\eta^n)/n$. Player 1 wins η iff $\mathtt{MP}(\eta) \geq 0$.

Mean-payoff games are quantitative games. We think of the payoff as Player 1's reward and Player 2's cost, thus in mean-payoff games, we refer to Player 1 as Max and to Player 2 as Min.

Threshold ratios. The first question that arises in the context of bidding games asks what is the necessary and sufficient initial ratio to guarantee an objective.

▶ **Definition 2** (Threshold ratios). *Consider a bidding game $\mathcal{G}$, a vertex v, an initial ratio r, and an objective O for Player 1. The threshold ratio in v, denoted $\mathit{Th}(v)$, is a ratio in $[0, 1]$ such that if $r > \mathit{Th}(v)$, then Player 1 has a winning strategy that guarantees that O is satisfied, and if $r < \mathit{Th}(v)$, then Player 2 has a winning strategy that violates O.*

Random-turn games. A *stochastic game* [10] is a graph game in which the vertices are partitioned between two players and a *nature* player. As in turn-based games, whenever the game reaches a vertex that is controlled by Player i, for $i = 1, 2$, he choses how the game proceeds, and whenever the game reaches a vertex v that is controlled by nature, the next vertex is chosen according to a probability distribution that depends only on v.

Consider a bidding game $\mathcal{G}$ that is played on a graph $\langle V, E\rangle$. The *random-turn game* with ratio $r \in [0, 1]$ that is associated with $\mathcal{G}$ is a stochastic game that intuitively simulates the following process. In each turn we throw a biased coin that turns heads with probability r and tails with probability $1 - r$. If the coin turns heads, then Player 1 moves the token, and otherwise Player 2 moves the token. Formally, we define $\mathtt{RT}^r(\mathcal{G}) = \langle V_1, V_2, V_N, E, \Pr\rangle$, where each vertex in V is split into three vertices, each controlled by a different player, thus for $\alpha \in \{1, 2, N\}$, we have $V_\alpha = \{v_\alpha : v \in V\}$, nature vertices simulate the fact that Player 1 chooses the next move with probability r, thus $\Pr[v_N, v_1] = r = 1 - \Pr[v_N, v_2]$, and reaching a vertex that is controlled by one of the two players means that he chooses the next move, thus $E = \{\langle v_\alpha, u_N\rangle : \langle v, u\rangle \in E \text{ and } \alpha \in \{1, 2\}\}$. When $\mathcal{G}$ is a mean-payoff game, the vertices are weighted and we define the weights of v_1, v_2, and v_N to be equal to the weight of v.

The following definitions are standard, and we refer the reader to [20] for more details. A strategy in a stochastic game is similar to a turn-based game; namely, given the history of vertices visited so far, the strategy chooses the next vertex. Fixing two such strategies f and g for both players gives rise to a distribution $D(f, g)$ on infinite paths. Intuitively, Player 1's goal is to maximize the probability that his objective is met. An *optimal* strategy for Player 1 guarantees that the objective is met with probability at least c and, intuitively, he cannot do better, thus Player 2 has a strategy that guarantees that the objective is violated with probability at least $(1 - c)$. It is well known that optimal positional strategies exist for the objectives that we consider.

▶ **Definition 3** (Values in stochastic games). *Consider a bidding game $\mathcal{G}$, let $r \in [0, 1]$, and consider two optimal strategies f and g for the two players in $\mathit{RT}^r(\mathcal{G})$. When $\mathcal{G}$ is a qualitative game with objective O, the* value *of $\mathit{RT}^r(\mathcal{G})$, denoted $val(\mathit{RT}^r(\mathcal{G}))$, is $\Pr_{\eta\sim D(f,g)} \Pr[\eta \in O]$. When $\mathcal{G}$ is a mean-payoff game, the* mean-payoff value *of $\mathit{RT}^r(\mathcal{G})$, denoted $\mathit{MP}(\mathit{RT}^r(\mathcal{G}))$, is $\mathbb{E}_{\eta\in D(f,g)}\mathit{MP}(\eta)$.*

3 Qualitative Taxman Games

In [14, 13], reachability bidding games were studied with a slightly different definition, which we call *double-reachability*: both players have a target, where we denote by t_i the target of Player i, for $i \in \{1,2\}$, all vertices have a path to both targets, and the game ends once one of the targets is reached. They show the following results.

▶ **Theorem 4.** *[14, 13] Consider a double-reachability bidding game $\mathcal{G}$ and a vertex v. The threshold ratio exists in v with Richman, poorman, and taxman bidding. Moreover, threshold ratios have the following properties. For the target vertex t_1 of Player 1, we have $\mathit{Th}(t_1) = 0$, and for the target t_2 of Player 2, we have $\mathit{Th}(v) = 1$. Consider some other vertex v and denote $v^+, v^- \in N(v)$ the vertices with the minimal and maximal thresholds in the neighborhood of v, thus for every $u \in N(v)$, we have $\mathit{Th}(v^-) \leq \mathit{Th}(u) \leq \mathit{Th}(v^+)$.*

- *In Richman bidding, we have $\mathit{Th}(v) = \frac{1}{2}\big(\mathit{Th}(v^+) + \mathit{Th}(v^-)\big)$.*
- *In poorman bidding, we have $\mathit{Th}(v) = \mathit{Th}(v^+)/(1 + \mathit{Th}(v^+) - \mathit{Th}(v^-))$.*
- *In taxman bidding with parameter τ, we have $\mathit{Th}(v) = \big(\mathit{Th}(v^-) + \mathit{Th}(v^+) - \tau \cdot \mathit{Th}(v^-)\big)/\big(2 - \tau \cdot (1 + \mathit{Th}(v^-) - \mathit{Th}(v^+))\big)$.*

Moreover, only double-reachability Richman-bidding games exhibit the following probabilistic connection: for every vertex v, we have $\mathit{Th}(v) = 1 - val(\mathit{RT}^{0.5}(\mathcal{G}), v)$. Thus, for games played on finite graphs, the threshold ratios are all rational numbers. However, threshold ratios with poorman-bidding need not be rational in finite games.

The equivalence between double-reachability bidding games and reachability games with Richman- and poorman-bidding is shown in [4] and [5]. The following proposition is the key component in showing the equivalence as well as in the reduction from parity taxman games to reachability taxman games.

▶ **Lemma 5.** *Consider a reachability taxman game $\mathcal{G}$. Suppose that every vertex in $\mathcal{G}$ has a path to the target of Player 1. Then, for any taxman parameter, Player 1 wins from every vertex with any positive initial budget. Thus, for every vertex v, we have $\mathit{Th}(v) = 0$.*

Proof. Let $\mathcal{G} = \langle V, E, t\rangle$, where $n = |V| - 1$. Suppose the game starts from a vertex v, and let $\epsilon > 0$ be the initial budget of Player 1. Since there is a path from v to Player 1's target, there is a path of length at most n. Thus, if Player 1 wins n consecutive biddings, he wins the game. Intuitively, Player 1 carefully chooses n increasing bids such that if Player 2 wins one of these bids, Player 1's ratio increases by a constant over his initial budget. By repeatedly playing according to such a strategy, Player 1 guarantees that his ratio increases and will eventually allow him to win n biddings in a row. Formally, if $\tau = 0$, then $\mathcal{G}$ is a Richman game and the proof of the lemma can be found in [4]. Otherwise, pick a sufficiently large $r \in \mathbb{N}$ such that $\tau > \frac{2}{r-1}$ and $r \geq 3$. Fix $0 < m < \frac{\epsilon}{r^n}$. Player 1 proceeds as follows: after winning i times, for $0 \leq i$, he bids $m \cdot r^i$ and, upon winning the bidding, he moves towards t along any shortest path. Since $m + mr + \cdots + mr^{n-1} < mr^n < \epsilon$, Player 1 has sufficient budget to win n consecutive biddings. If Player 2 does not win any of the first n biddings, Player 1 wins the game. On the other hand, if Player 2 wins the k-th bidding with $1 \leq k \leq n$, we show in the full version that his ratio increases by a fixed amount $b = \frac{mr}{(1-\epsilon)(r-1)} > 0$. ◀

The following corollary shows the equivalence between reachability and double-reachability taxman games.

▶ **Corollary 6.** *Consider a reachability taxman game $\mathcal{G} = \langle V, E, t\rangle$. Let $S \subseteq V$ be the set of vertices that have no path to t. Let $T \subseteq V$ be a set of vertices such that $t \in T$ and every*

$u \in T$ has a path to t and no path to a vertex in S. Then, for every $v \in T$, we have $\mathtt{Th}(v) = 0$, for every $v \in S$, we have $\mathtt{Th}(v) = 1$. Let $\mathcal{G}'$ be a double-reachability taxman game that is obtained from $\mathcal{G}$ by merging the vertices in S and T into two targets t_1 and t_2 for Players 1 and 2, respectively. Then, for every $v \in (V \setminus (S \cup T))$, the threshold of v in $\mathcal{G}$ equals the threshold of v in $\mathcal{G}'$.

The following theorem, whose proof can be found in the full version, uses Lemma 5 to classify the bottom-strongly-connected components of a parity taxman game as those that are winning and losing for Player 1, thereby constructing a reachability taxman game.

▶ **Theorem 7.** *Parity taxman games are linearly reducible to reachability taxman games. Specifically, threshold ratios exist in parity taxman games.*

4 Mean-Payoff Taxman Games

This section consists of our main technical contribution. We start by showing a complete classification of the value in strongly-connected mean-payoff taxman games depending on the taxman parameter τ and the initial ratio. We then extend the solution to general games, where the solution to strongly-connected games constitutes the main ingredient in the solution of the general case.

4.1 Strongly-connected mean-payoff taxman games

We start by formally defining the value of a strongly-connected mean-payoff game. Lemma 5 implies that in a strongly-connected game, a player can draw the game from every vertex to any other vertex with any positive initial budget. Since mean-payoff objectives are prefix independent, it follows that the vertex from which the game starts does not matter. Indeed, if the game starts at a vertex v with Max having initial ratio $r + \epsilon$, then Max can use $\epsilon/2$ of his budget to draw the game to a vertex u and continue as if he starts the game with initial ratio $r + \epsilon/2$.

▶ **Definition 8** (Mean-payoff value). *Consider a strongly-connected mean-payoff game $\mathcal{G}$, a ratio $r \in (0,1)$, and a taxman parameter $\tau \in [0,1]$. The mean-payoff value of $\mathcal{G}$ w.r.t. r and τ, is a value $c \in \mathbb{R}$ such that for every $\epsilon > 0$*

- *if Min's initial ratio is greater than $(1 - r)$, then he has a strategy that guarantees that the payoff is at most $c + \epsilon$, and*
- *if Max's initial ratio is greater than r, then he has a strategy that guarantees that the payoff is greater than $c - \epsilon$.*

The following theorem, which we prove in the next two sections, summarizes the properties of mean-payoff taxman games.

▶ **Theorem 9.** *Consider a strongly-connected mean-payoff taxman game $\mathcal{G}$ with taxman parameter $\tau \in [0,1]$ and an initial ratio $r \in (0,1)$. The value of $\mathcal{G}$ w.r.t. τ and r equals the value of the random-turn game $\mathtt{RT}^{F(\tau,r)}(\mathcal{G})$ in which Max is chosen to move with probability $F(\tau,r)$ and Min with probability $1 - F(\tau,r)$, where $F(\tau,r) = \frac{r+\tau(1-r)}{1+\tau}$.*

We show that in order to prove Theorem 9, it suffices to prove the following intermediate lemma, whose proof can be found in the full version, and follows from the advantage of Min in the definition of payoff.

▶ **Lemma 10.** *Consider a strongly-connected mean-payoff taxman game $\mathcal{G}$, a taxman parameter τ, and an initial ratio $r \in (0,1)$ such that $\mathit{MP}(\mathit{RT}^{F(\tau,r)}) = 0$ for $F(\tau, r) = \frac{r+\tau(1-r)}{1+\tau}$. Then, for every $\epsilon > 0$ Max has a strategy that guarantees that no matter how Min plays, the payoff is greater than $-\epsilon$.*

4.2 The importance of moving

The first part of the construction of an optimal strategy for Max as in Lemma 10 is to assign, to each vertex $v \in V$, a *strength*, denoted $\mathrm{St}(v)$, where $\mathrm{St}(v) \in \mathbb{Q}_{\geq 0}$. Intuitively, if $\mathrm{St}(v) > \mathrm{St}(u)$, for $u, v \in V$, it is more important for Max to move in v than it is in u. We follow the construction in [5], which uses the concept of *potentials*, which is a well-known concept in stochastic games (see [20]) and was originally defined in the context of the strategy iteration algorithm [12]. For completeness, we present the definitions below.

Consider a strongly-connected mean-payoff game $\mathcal{G}$, and let $p \in [0,1]$. Let f and g be two optimal positional strategies in $\mathtt{RT}^p(\mathcal{G})$, for Min and Max, respectively. For a vertex $v \in V$, let $v^-, v^+ \in V$ be such that Max proceeds from v to v^+ according to g and Min proceeds from v to v^- according to f. It is not hard to see that the mean-payoff value in all vertices in $\mathtt{RT}^p(\mathcal{G})$ is the same and we denote it by $\mathtt{MP}(\mathtt{RT}^p(\mathcal{G}))$. We denote the potential of v by $\mathrm{Pot}^p(v)$ and the strength of v by $\mathrm{St}^p(v)$, and we define them as follows.

$$\mathrm{Pot}^p(v) = p \cdot \mathrm{Pot}^p(v^+) + (1-p) \cdot \mathrm{Pot}^p(v^-) + w(v) - \mathtt{MP}(\mathtt{RT}^p(\mathcal{G})) \text{ and}$$
$$\mathrm{St}^p(v) = p \cdot (1-p) \cdot \big(\mathrm{Pot}^p(v^+) - \mathrm{Pot}^p(v^-)\big)$$

There are optimal strategies for which $\mathrm{Pot}^p(v^-) \leq \mathrm{Pot}^p(v') \leq \mathrm{Pot}^p(v^+)$, for every $v' \in N(v)$, which can be found, for example, using the strategy iteration algorithm. Note that $\mathrm{St}(v) \geq 0$, for every $v \in V$.

Consider a finite path $\pi = v_1, \ldots, v_n$ in $\mathcal{G}$. We intuitively think of π as a play, where for every $1 \leq i < n$, the bid of Max in v_i is $\mathrm{St}(v_i)$ and he moves to v_i^+ upon winning. Thus, if $v_{i+1} = v_i^+$, we say that Max won in v_i, and if $v_{i+1} \neq v_i^+$, we say that Max lost in v_i. Let $W(\pi)$ and $L(\pi)$ respectively be the indices in which Max wins and loses in π. We call Max wins *investments* and Max loses *gains*, where intuitively he *invests* in increasing the energy and *gains* a higher ratio of the budget whenever the energy decreases. Let $G(\pi)$ and $I(\pi)$ be the sum of gains and investments in π, respectively, thus $G(\pi) = \sum_{i \in L(\pi)} \mathrm{St}(v_i)$ and $I(\pi) = \sum_{i \in W(\pi)} \mathrm{St}(v_i)$. Recall that the energy of π is $E(\pi) = \sum_{1 \leq i < n} w(v_i)$. The following lemma, whose proof can be found in the full version, which generalizes a similar lemma in [5], connects the strength with the change in energy.

▶ **Lemma 11.** *Consider a strongly-connected mean-payoff game $\mathcal{G}$ and $p \in [0,1]$. For every finite path $\pi = v_1, \ldots, v_n$ in $\mathcal{G}$, we have $\mathit{Pot}^p(v_1) - \mathit{Pot}^p(v_n) + (n-1) \cdot \mathit{MP}(\mathit{RT}^p(\mathcal{G})) \leq E(\pi) + G(\pi)/(1-p) - I(\pi)/p$. In particular, when $p = \nu/(\mu+\nu)$ for $\nu, \mu > 0$, there is a constant $P = \min_v \mathit{Pot}^p(v) - \max_v \mathit{Pot}^p(v)$ such that $\frac{\nu \cdot \mu}{\nu + \mu} \cdot \big(E(\pi) - P - (n-1) \cdot \mathit{MP}(\mathit{RT}^{\frac{\nu}{\mu+\nu}}(\mathcal{G}))\big) \geq \mu \cdot I(\pi) - \nu \cdot G(\pi)$.*

4.3 Normalizing the bids

Whenever the game reaches a vertex v, Max's bid is obtained by carefully normalizing the strength of v. More formally, assuming an initial ratio r, in v, Max bids $r \cdot (1-r) \cdot \mathrm{St}(v) \cdot \beta_x$, where β_x is the normalization factor and $x \in \mathbb{R}_{\geq 1}$. In this section we show how to choose the normalization factor. We associate with every $x \geq 1$, two numbers: a ratio r_x and β_x both in $(0,1]$. We think of $(r_x)_{x \geq 1}$ as a sequence and a play gives rise to a walk on the sequence, which corresponds to the changes in energy in the bidding game. When the walk is in $x \geq 1$, Max uses the normalization factor β_x. If Max wins a bidding, we take a step up on the sequence, modeling the increase of energy, and when Min wins, we talk a step down. The size of the step depends on the strength of v. We prove existence of sequences with properties given in the following lemma and formally define Max's strategy after it.

▶ **Lemma 12.** *Consider a game $\mathcal{G}$, a finite set of non-negative strengths $S \subseteq \mathbb{R}_{\geq 0}$, a ratio $r \in (0,1)$, and a taxman parameter $\tau \in [0,1]$. For every $K > \frac{\tau r^2 + r(1-r)}{\tau(1-r)^2 + r(1-r)}$ there exist sequences $(r_x)_{x \geq 1}$ and $(\beta_x)_{x \geq 1}$ with the following properties.*

1. *Max's bid does not exceed his budget, thus, for each position $x \in \mathbb{R}_{\geq 1}$ and strength $s \in S$, we have $\beta_x \cdot s \cdot r \cdot (r-1) < r_x$.*
2. *Min cannot force the game beyond position 1, thus for every $s \in S \backslash \{0\}$ and $1 \leq x < 1+rs$, we have $\beta_x \cdot s \cdot r \cdot (r-1) > 1 - r_x$.*
3. *The ratios tend to r from above, thus for every $x \in \mathbb{R}_{\geq 1}$, we have $r_x \geq r$, and $\lim_{x \to \infty} r_x = r$.*
4. *No matter who wins a bidding, Max's ratio can only improve. Thus, in case of winning and in case of losing, we respectively have*
$$\frac{r_x - \beta_x \cdot s \cdot r \cdot (r-1)}{1 - (1-\tau) \cdot \beta_x \cdot s \cdot r \cdot (r-1)} \geq r_{x+(1-r) \cdot K \cdot s} \textit{ and } \frac{r_x + \tau \cdot \beta_x \cdot s \cdot r \cdot (r-1)}{1 - (1-\tau) \cdot \beta_x \cdot s \cdot r \cdot (r-1)} \geq r_{x - s \cdot r}$$

We first show how Lemma 12 implies Theorem 9.

Proof that Lemma 12 implies Lemma 10. Fix $\epsilon > 0$, we construct strategy for Max guaranteeing a payoff greater than $-\epsilon$, as wanted. Observe that

$$\frac{r}{r + (1-r)\frac{\tau r^2 + r(1-r)}{\tau(1-r)^2 + r(1-r)}} = \frac{r(\tau(1-r)+r)}{\tau r(1-r) + r^2 + \tau r^2 + r(1-r)} = \frac{r + \tau(1-r)}{1+\tau} = F(\tau, r).$$

Thus, since by assumption $\texttt{MP}(\texttt{RT}^{F(\tau,r)}(\mathcal{G})) = 0$ and $\texttt{MP}(\texttt{RT}^{p}(\mathcal{G}))$ is a continuous function in $p \in [0,1]$ [8, 22], we can pick $K > F(\tau, r)$ such that $\texttt{MP}(\texttt{RT}^{\frac{r}{r+(1-r)K}}(\mathcal{G})) > -\epsilon$.

We now describe Max's strategy. We think of the change in Max's ratio as a walk on $\mathbb{R}_{\geq 1}$. Each position $x \in \mathbb{R}_{\geq 1}$ is associated with a ratio r_x. The walk starts in a position x_0 such that Max's initial ratio is at least r_{x_0}. Let $\nu = r$ and $\mu = K(1-r)$. Suppose the token is placed on a vertex $v \in V$. Then, Max's bid is $r \cdot (1-r) \cdot \beta_x \cdot \mathrm{St}(v)$, where the ratios of Max and Min are normalized to sum up to 1, and he proceeds to v^+ upon winning. If Max wins, the walk proceeds up $\mu \cdot \mathrm{St}(v)$ steps to $x + \mu \mathrm{St}(v)$, and if he loses, the walk proceeds down to $x - \nu \mathrm{St}(v)$. Suppose Min fixes some strategy and let $\pi = v_1, \ldots, v_n$ be a finite prefix of the play that is generated by the two strategies. Suppose the walk following π reaches $x \in \mathbb{R}$. Then, using the terminology of the previous section, we have $x = x_0 - G(\pi) \cdot \nu + I(\pi) \cdot \mu$. Lemma 12 shows that the walk always stays above 1, thus $x \geq 1$. Combining with Lemma 11, we get $\frac{\nu+\mu}{\nu \cdot \mu}(1 - x_0) + P + (n-1) \cdot \texttt{MP}(\texttt{RT}^{\frac{\nu}{\nu+\mu}}(\mathcal{G})) \leq E(\pi)$. Thus, dividing both sides by n and letting $n \to \infty$, since x_0 and P are constants depending only on K we conclude that this strategy guarantees payoff at least $\texttt{MP}(\texttt{RT}^{\frac{\nu}{\nu+\mu}}(\mathcal{G})) > -\epsilon$. ◀

We continue to prove Lemma 12.

Proof of Lemma 12. Note that $\frac{\tau r^2 + r(1-r)}{\tau(1-r)^2 + r(1-r)}$ is well-defined for $r \in (0,1)$. Fix $\tau \in [0,1]$ and $r \in (0,1)$. Let $K > \frac{\tau r^2 + r(1-r)}{\tau(1-r)^2 + r(1-r)}$. Observe that the two inequalities in Point 4 are equivalent to:

$$\begin{aligned} r_{x-rs} - r_x &\leq \tau r(1-r)\beta_x s + (1-\tau) r(1-r)\beta_x s r_{x-rs}, \\ r_x - r_{x+K(1-r)s} &\geq r(1-r)\beta_x s - (1-\tau) r(1-r)\beta_x s r_{x+K(1-r)s}. \end{aligned}$$

Point 3 combined with monotonicity in the above expressions, implies that we can replace the last term in each of them by r in order to obtain stronger inequalities. Therefore, it suffices for $(r_x)_{x\ge 1}$ and $(\beta_x)_{x\ge 1}$ to satisfy

$$\begin{aligned} r_{x-rs} - r_x &\le \tau r(1-r)\beta_x s + (1-\tau)r(1-r)\beta_x s r,\\ r_x - r_{x+K(1-r)s} &\ge r(1-r)\beta_x s - (1-\tau)r(1-r)\beta_x s r, \end{aligned}$$

which is equivalent to

$$\begin{aligned} r_{x-rs} - r_x &\le r(1-r)\beta_x s[\tau + (1-\tau)r],\\ r_x - r_{x+K(1-r)s} &\ge r(1-r)\beta_x s[1 - (1-\tau)r]. \end{aligned} \tag{1}$$

We seek $(r_x)_{x\ge 1}$ and $(\beta_x)_{x\ge 1}$ in the form $r_x = \gamma^{x-1} + (1-\gamma^{x-1})r$ and $\beta_x = \beta\gamma^{x-1}$ for some $\gamma, \beta \in (0,1)$. Note that this choice ensures Points 1 and 3. Therefore, we just need to show that we can find $\gamma, \beta \in [0,1]$ for which the inequalities in (1) hold for any $s \in S$. Substituting r_x and β_x in terms of γ and β, the inequalities in (1) reduce to

$$\begin{aligned} r_{x-rs} - r_x &= \gamma^{x-1}(\gamma^{-rs} - 1)(1-r) \overset{?}{\le} \beta\gamma^{x-1} r(1-r)s[\tau + (1-\tau)r],\\ r_x - r_{x+K(1-r)s} &= \gamma^{x-1}(1 - \gamma^{K(1-r)s})(1-r) \overset{?}{\ge} \beta\gamma^{x-1} r(1-r)s[1 - (1-\tau)r]. \end{aligned}$$

First, when $s = 0$, both sides of both inequalities are equal to 0 so both inequalities clearly hold. Recall that S is a finite set of non-negative strengths. Thus, when $s > 0$, it takes values in $0 < s_1 \le \ldots \le s_n$, and the above inequalities are equivalent to

$$\begin{aligned} &\gamma \ge \big(1 + \beta rs[\tau + (1-\tau)r]\big)^{-\frac{1}{rs}},\\ &\gamma \le \big(1 - \beta rs[1 - (1-\tau)r]\big)^{\frac{1}{K(1-r)s}}. \end{aligned} \tag{2}$$

Since both of these expressions are in $(0,1)$, to conclude that $\gamma, \beta \in (0,1)$ exist, it suffices to show that there is some $\beta \in (0,1)$ such that

$$\max_{s\in\{s_1,\ldots,s_n\}} \big(1 + \beta rs[\tau + (1-\tau)r]\big)^{-\frac{1}{rs}} \le \min_{s\in\{s_1,\ldots,s_n\}} \big(1 - \beta rs[1 - (1-\tau)r]\big)^{\frac{1}{K(1-r)s}}. \tag{3}$$

Note that the LHS of (3) is monotonically increasing in $s > 0$ whereas the RHS is monotonically decreasing in $s > 0$, therefore it suffices to find $\beta \in (0,1)$ for which

$$\big(1 + \beta rs_n[\tau + (1-\tau)r]\big)^{-\frac{1}{rs_n}} \le \big(1 - \beta rs_1[1 - (1-\tau)r]\big)^{\frac{1}{K(1-r)s_1}}. \tag{4}$$

By Taylor's theorem $(1+y)^\alpha = 1 + \alpha y + O(y^2)$, so Taylor expanding both sides of (4) in $\beta > 0$ we get

$$\begin{aligned} &\big(1 + \beta rs_n[\tau + (1-\tau)r]\big)^{-\frac{1}{rs_n}} = 1 - \beta[\tau + (1-\tau)r] + O(\beta^2),\\ &\big(1 - \beta rs_1[1 - (1-\tau)r]\big)^{\frac{1}{K(1-r)s_1}} = 1 - \beta\frac{r}{K(1-r)}[1 - (1-\tau)r] + O(\beta^2). \end{aligned}$$

Therefore, if we show that $[\tau + (1-\tau)r] > \frac{r}{K(1-r)}[1 - (1-\tau)r]$, the linear coefficient of β on the LHS of (4) will be strictly smaller than the linear coefficient of β on the RHS. Thus, for sufficiently small $\beta > 0$, (4) will hold, which concludes the proof of the lemma. This condition is equivalent to

$$K > \frac{r[1 - (1-\tau)r]}{(1-r)[\tau + (1-\tau)r]} = \frac{r[\tau r + (1-r)]}{(1-r)[\tau(1-r) + r]} = \frac{\tau r^2 + r(1-r)}{\tau(1-r)^2 + r(1-r)},$$

which is true by assumption. Thus, Points 1, 3, and 4 hold. In the full version, we show that Point 2 holds. ◀

4.4 General mean-payoff taxman games

We extend the solution to general games. Recall that the threshold ratio in mean-payoff games is a necessary and sufficient initial ratio with which Max can guarantee a payoff of at least 0.

▶ **Theorem 13.** *Threshold ratios exist in mean-payoff taxman games.*

Proof. Consider a mean-payoff taxman game $\mathcal{G} = \langle V, E, w\rangle$ with taxman parameter τ. If $\mathcal{G}$ is strongly-connected, then by Theorem 9, the threshold ratio in all vertices in $\mathcal{G}$ is the same and is $r \in (0, 1)$ for r such that $\texttt{MP}(\texttt{RT}^{F(\tau,r)}(\mathcal{G})) = 0$. If no such r exists, then either $\texttt{MP}(\texttt{RT}^{F(\tau,1)}(\mathcal{G})) < 0$, in which case the threshold ratios are 1, or $\texttt{MP}(\texttt{RT}^{F(\tau,0)}(\mathcal{G})) > 0$, in which case the threshold ratios are 0. The proof for general games follows along the same lines as the proof for reachability games. For each bottom strongly-connected component S_i of $\mathcal{G}$ we find the threshold ratio $r_i \in (0, 1)$ as in the above. We play a "generalized" reachability game on $\mathcal{G}$ as follows. The game ends once the token reaches one of the BSCCs in $\mathcal{G}$. Max wins the game iff the first time the game enters a BSCC S_i, Max's ratio is greater than r_i. Showing existence of threshold ratios in the generalized game follows the same argument as for reachability games [13]. ◀

5 Computational Complexity

We show, for the first time, computational complexity results for taxman games. We study the following problem, which we call THRESH: given a taxman game $\mathcal{G}$ with taxman parameter τ and a vertex v_0 in $\mathcal{G}$, decide whether $\texttt{Th}(v_0) \geq 0.5$. The correspondence in Theorem 9 gives the second part of the following theorem, and for the first part, in the full version, we show a reduction from THRESH to the *existential theory of the reals* [7].

▶ **Theorem 14.** *For taxman reachability, parity, and mean-payoff games THRESH is in PSPACE. For strongly-connected mean-payoff games, THRESH is in NP ∩ coNP.*

6 Discussion

We study, for the first time, infinite-duration taxman-bidding games, which span the spectrum between Richman and poorman bidding. For qualitative objectives, we show that the properties of taxman coincide with these of Richman and poorman bidding. For mean-payoff games, where Richman and poorman bidding have an elegant though surprisingly different mathematical structure, we show a complete understanding of taxman games. Our study of mean-payoff taxman games sheds light on these differences and similarities between the two bidding rules. Unlike previous proof techniques, which were ad-hoc, we expect our technique to be easier to generalize beyond taxman games, where they can be used to introduce concepts like multi-players or partial information into bidding games.

Abstract

In the Cluster Deletion problem the goal is to remove the minimum number of edges of a given graph, such that every connected component of the resulting graph constitutes a clique. It is known that the decision version of Cluster Deletion is NP-complete on (P_5-free) chordal graphs, whereas Cluster Deletion is solved in polynomial time on split graphs. However, the existence of a polynomial-time algorithm of Cluster Deletion on interval graphs, a proper subclass of chordal graphs, remained a well-known open problem. Our main contribution is that we settle this problem in the affirmative, by providing a polynomial-time algorithm for Cluster Deletion on interval graphs. Moreover, despite the simple formulation of the algorithm on split graphs, we show that Cluster Deletion remains NP-complete on a natural and slight generalization of split graphs that constitutes a proper subclass of P_5-free chordal graphs. Although the later result arises from the already-known reduction for P_5-free chordal graphs, we give an alternative proof showing an interesting connection between edge-weighted and vertex-weighted variations of the problem. To complement our results, we provide faster and simpler polynomial-time algorithms for Cluster Deletion on subclasses of such a generalization of split graphs.

1 Introduction

In graph theoretic notions, *clustering* is the task of partitioning the vertices of the graph into subsets, called clusters, in such a way that there should be many edges within each cluster and relatively few edges between the clusters. In many applications, the clusters are restricted to induced cliques, as the represented data of each edge corresponds to a similarity value between two objects [18, 19]. Under the term cluster graph, which refers to a disjoint union of cliques, one may find a variety of applications that have been extensively studied [1, 5, 23]. Here we consider the Cluster Deletion problem which asks for a minimum number of edge deletions from an input graph, so that the resulting graph is a disjoint union of cliques. In the decision version of the problem, we are also given an integer k and we want to decide whether at most k edge deletions are enough to produce a cluster graph.

Although Cluster Deletion is NP-hard on general graphs [24], settling its complexity status restricted on graph classes has attracted several researchers. Regarding the maximum degree of a graph, Komusiewicz and Uhlmann [22] have shown an interesting dichotomy result: Cluster Deletion remains NP-hard on C_4-free graphs with maximum degree four, whereas it can be solved in polynomial time on graphs having maximum degree at most three. Quite recently, Golovach et al. [14] have shown that it remains NP-hard on planar graphs. For graph classes characterized by forbidden induced subgraphs, Gao et al. [11] showed that Cluster Deletion is NP-hard on $(C_5, P_5, \mathrm{bull}, \mathrm{fork}, \text{co-gem}, \text{4-pan}, \text{co-4-pan})$-free graphs and on $(2K_2, 3K_1)$-free graphs. Regarding H-free graphs, Grüttemeier et al. [16], showed a complexity dichotomy result for any graph H consisting of at most four vertices. In particular, for any graph H on four vertices with $H \notin \{P_4, \mathrm{paw}\}$, Cluster Deletion is NP-hard on H-free graphs, whereas it can be solved in polynomial time on P_4- or paw-free graphs [16]. Interestingly, Cluster Deletion remains NP-hard on P_5-free chordal graphs [3].

On the positive side, Cluster Deletion has been shown to be solved in polynomial time on cographs [11], proper interval graphs [3], split graphs [3], and P_4-reducible graphs [2]. More precisely, iteratively picking maximum cliques defines a clustering on the graph which actually gives an optimal solution on cographs (i.e., P_4-free graphs), as shown by Gao et al. in [11]. In fact, the greedy approach of selecting a maximum clique provides a 2-approximation algorithm, though not necessarily in polynomial-time [7]. As the problem is already NP-hard on chordal graphs [3], it is natural to consider subclasses of chordal graphs such as interval graphs and split graphs. Although for split graphs there is a simple polynomial-time algorithm, restricted to interval graphs only the complexity on proper interval graphs was determined by giving a solution that runs in polynomial-time [3]. Settling the complexity of Cluster Deletion on interval graphs, was left open [3, 2, 11].

For proper interval graphs, Bonomo et al. [3] characterized their optimal solution by consecutiveness of each cluster with respect to their natural ordering of the vertices. Based on this fact, a dynamic programming approach led to a polynomial-time algorithm. It is not difficult to see that such a consecutiveness does not hold on interval graphs, as potential clusters might require to break in the corresponding vertex ordering. Here we characterize an optimal solution of interval graphs whenever a cluster is required to break. In particular, we take advantage of their consecutive arrangement of maximal cliques and describe subproblems of maximal cliques containing the last vertex. One of our key observations is that the candidate clusters containing the last vertex can be enumerated in polynomial time given two vertex orderings of the graph. We further show that each such candidate cluster separates the graph in a recursive way with respect to optimal subsolutions, that enables to define our dynamic programming table to keep track about partial solutions. Thus, our algorithm for interval graphs suggests to consider a particular consecutiveness of a solution and apply a dynamic programming approach defined by two vertex orderings. The overall running time of our algorithm is $O(n^6)$ for an interval graph on n vertices.

Furthermore, we complement the previously-known NP-hardness of Cluster Deletion on P_5-free chordal graphs, by providing a proper subclass of such graphs for which we prove that the problem remains NP-hard. This result is inspired and motivated by the very simple characterization of an optimal solution on split graphs: either a maximal clique constitutes the only non-edgeless cluster, or there are exactly two non-edgeless clusters whenever there is a vertex of the independent set that is adjacent to all the vertices of the clique except one [3]. Due to the fact that true twins belong to the same cluster in an optimal solution, it is natural to consider true twins at the independent set, as they are expected not to influence the solution characterization. Surprisingly, we show that Cluster Deletion remains NP-complete even on such a slight generalization of split graphs. This is achieved by observing that the constructed graphs given in the reduction for P_5-free graphs [3], constitute such split-related graphs. However, here we give a different reduction that highlights an interesting connection between edge-weighted and vertex-weighted split graphs. We then study two different classes of such generalization of split graphs that can be viewed as the parallel of split graphs that admit disjoint clique-neighborhood and nested clique-neighborhood. For Cluster Deletion we provide polynomial-time algorithms on both classes of graphs. In particular, for the former case, a polynomial-time algorithm is already known and is achieved through computing a minimizer of submodular functions [3]. Here we provide a simpler and faster (linear-time) algorithm for Cluster Deletion on such graphs that avoids the usage of submodular functions minimization.

2 Preliminaries

All graphs considered here are simple and undirected. We refer to Diestel's classical book [8] for standard graph terminology that is undefined here. Two adjacent vertices u and v are called *true twins* if $N[u] = N[v]$, whereas two non-adjacent vertices x and y are called *false twins* if $N(u) = N(v)$. For a set of finite graphs $\mathcal{H}$, we say that a graph G is $\mathcal{H}$-free if G does not contain an induced subgraph isomorphic to any of the graphs of $\mathcal{H}$.

The problem of Cluster Deletion is formally defined as follows: given a graph $G = (V, E)$, the goal is to compute the minimum set $F \subseteq E(G)$ of edges such that every connected component of $G - F$ is a clique. A *cluster graph* is a P_3-free graph, or equivalently, any of its connected components is a clique. Thus, the task of Cluster Deletion is to turn the input graph G into a cluster graph by deleting the minimum number of edges. Let $S = C_1, \ldots, C_k$ be a solution of Cluster Deletion such that $G[C_i]$ is a clique. In such terms, the problem can be viewed as a vertex partition problem into $C_1, \ldots, C_k$. Each C_i is simple called *cluster*. Edgeless clusters, i.e., clusters containing exactly one vertex, are called *trivial clusters*. The edges of G are partitioned into *internal* and *external* edges: an internal edge uv has both its endpoints $u, v \in C_i$ in the same cluster C_i, whereas an external edge uv has its endpoints in different clusters $u \in C_i$ and $v \in C_j$, for $i \neq j$. Then, the goal of Cluster Deletion is to minimize the number of external edges which is equivalent to maximize the number of internal edges. We write $S(G)$ to denote an optimal solution for Cluster Deletion of the graph G, that is, a cluster subgraph of G having the maximum number of edges. Given a solution $S(G)$, the number of edges incident only to the same cluster, that is the number of internal edges, is denoted by $|S(G)|$.

For a clique C, we say that a vertex x is *C-compatible* if $C \setminus \{x\} \subseteq N(x)$. We start with few preliminary observations regarding twin vertices. Notice that for true twins x and y, if x belongs to any cluster C then y is C-compatible.

▶ **Lemma 1** ([3]). *Let x and y be true twins in G. Then, in any optimal solution x and y belong to the same cluster.*

The above lemma shows that we can contract true twins and look for a solution on a vertex-weighted graph that does not contain true twins. Notice, however, that the weights on the vertices imply weights on the edges of the graph, as they contribute to the total cost of external and internal edges in a solution. Even though false twins cannot be grouped into the same cluster as they are non-adjacent, we can actually disregard one of the false twins whenever their neighborhood forms a clique.

▶ **Lemma 2.** *Let x and y be false twins in G such that $N(x) = N(y)$ is a clique. Then, there is an optimal solution such that y constitutes a trivial cluster.*

Proof. Let C_x and C_y be the clusters of x and y, respectively, in an optimal solution such that $|C_x| \geq 2$ and $|C_y| \geq 2$. We construct another solution by replacing both clusters by $C_x \cup C_y \setminus \{y\}$ and $\{y\}$, respectively. To see that this indeed a solution, first observe that x is adjacent to all the vertices of $C_y \setminus \{y\}$ because $N(x) = N(y)$, and $C_x \cup C_y \setminus \{y\} \subseteq N[x]$ forms a clique by the assumption. Moreover, since $|C_x| \geq 2$ and $|C_y| \geq 2$, we know that $|C_x| + |C_y| \leq |C_x||C_y|$, implying that the number of internal edges in the constructed solution is at least as large as the number of internal edges of the optimal solution. ◀

Moreover, we prove the following generalization of Lemma 1.

▶ **Lemma 3.** *Let C and C' be two clusters of an optimal solution and let $x \in C$ and $y \in C'$. If y is C-compatible then x is not C'-compatible.*

Proof. Let S be an optimal solution such that $C, C' \in S$. Assume for contradiction that x is C'-compatible. We show that S is not optimal. Since y is C-compatible, we can move y to C and obtain a solution S_y that contains the clusters $C \cup \{y\}$ and $C' \setminus \{y\}$. Similarly, we construct a solution S_x from S, by moving x to C' so that $C \setminus \{x\}, C' \cup \{x\} \in S_x$. Notice that the S_x forms a clustering, since x is C'-compatible. We distinguish between the following cases, according to the values $|C|$ and $|C'|$.

- If $|C| \geq |C'|$ then $|S_y| > |S|$, because $\binom{|C|+1}{2} + \binom{|C'|-1}{2} > \binom{|C|}{2} + \binom{|C'|}{2}$.
- If $|C| < |C'|$ then $|S_x| > |S|$, because $\binom{|C|-1}{2} + \binom{|C'|+1}{2} > \binom{|C|}{2} + \binom{|C'|}{2}$.

In both cases we reach a contradiction to the optimality of S. Therefore, x is not C'-compatible. ◀

▶ **Corollary 4.** *Let C be a cluster of an optimal solution and let $x \in C$. If there is a vertex y that is C-compatible and $N[y] \subseteq N[x]$, then y belongs to C.*

3 Polynomial-time algorithm on interval graphs

Here we present a polynomial-time algorithm for the Cluster Deletion problem on interval graphs. A graph is an *interval graph* if there is a bijection between its vertices and a family of closed intervals of the real line such that two vertices are adjacent if and only if the two corresponding intervals intersect. Such a bijection is called an *interval representation* of the graph. We identify the intervals of the given representation with the vertices of the graph, interchanging these notions appropriately. Whether a given graph is an interval graph can be decided in linear time and if so, an interval representation can be generated in linear time [10, 13]. Notice that every induced subgraph of an interval graph is an interval graph.

Let G be an interval graph. Instead of working with the interval representation of G, we consider its sequence of maximal cliques. It is known that a graph G with p maximal cliques is an interval graph if and only if there is an ordering $K_1, \ldots, K_p$ of the maximal cliques of G, such that for each vertex v of G, the maximal cliques containing v appear consecutively in the ordering (see e.g., [10, 13]). A path $\mathcal{P} = K_1 \cdots K_p$ following such an ordering is called a *clique path* of G. Notice that a clique path is not necessarily unique for an interval graph. Also note that an interval graph with n vertices contains at most n maximal cliques. By definition, for every vertex v of G, the maximal cliques containing v form a connected subpath in $\mathcal{P}$.

Given a vertex v, we denote by $K_{a(v)}, \ldots, K_{b(v)}$ the maximal cliques containing v with respect to $\mathcal{P}$, where $K_{a(v)}$ and $K_{b(v)}$ are the *first* (*leftmost*) and *last* (*rightmost*) maximal cliques containing v. Notice that $a(v) \leq b(v)$ holds. Moreover, for every edge of G there is a maximal clique K_i of $\mathcal{P}$ that contains both endpoints of the edge. Thus, two vertices u and v are adjacent if and only if $a(v) \leq a(u) \leq b(v)$ or $a(v) \leq b(u) \leq b(v)$.

For a set of vertices $U \subseteq V$, we write $a\text{-}\min U$ and $a\text{-}\max U$ to denote the minimum and maximum value, respectively, among all $a(u)$ with $u \in U$. Similarly, $b\text{-}\min U$ and $b\text{-}\max U$ correspond to the minimum and maximum value, respectively, with respect to $b(u)$.

With respect to the Cluster Deletion problem, observe that for any cluster C of a solution, we know that $C \subseteq K_i$ where $K_i \in \mathcal{P}$, as C forms a clique. A vertex y is said to be *guarded* by two vertices x and z if $\min\{a(x), a(z)\} \leq a(y)$ and $b(y) \leq \max\{b(x), b(z)\}$ hold. For a clique C, observe that y is C-compatible if and only if there exists a maximal clique K_i such that $C \subseteq K_i$ with $a(y) \leq i \leq b(y)$. Observe that the following statement generalizes Corollary 4, in the sense that the neighborhood of the guarded vertex y is not necessarily contained in the neighborhood of x or z.

▶ **Lemma 5.** *Let x, y, z be three vertices of G such that y is guarded by x and z. If x and z belong to the same cluster C of an optimal solution and y is C-compatible then $y \in C$.*

Let $v_1, \ldots, v_n$ be an ordering of the vertices such that $b(v_1) \leq \cdots \leq b(v_n)$. For every v_i, v_j with $b(v_i) \leq b(v_j)$, we define the following set of vertices:

$$V_{i,j} = \{v \in V(G) : \min\{a(v_i), a(v_j)\} \leq a(v) \text{ and } b(v) \leq b(v_j)\}\,.$$

That is, $V_{i,j}$ contains all vertices that are guarded by v_i and v_j. We write $a(i,j)$ to denote the value of $\min\{a(v_i), a(v_j)\}$ and we simple write $K_{a(j)}$ and $K_{b(j)}$ instead of $K_{a(v_j)}$ and $K_{b(v_j)}$. Notice that for a neighbor u of v_j with $u \in V_{i,j}$, we have either $a(v_j) \leq a(u)$ or $a(v_i) \leq a(u) \leq a(v_j)$. This means that all neighbors of v_j that are totally included (i.e., all vertices u such that $a(v_j) \leq a(u) \leq b(u) \leq b(v_j)$) belong to $V_{i,j}$ for any v_i with $b(v_i) \leq b(v_j)$. To distinguish such neighbors of v_j, we define the following sets (see also Figure 1):

- $U(j)$ contains the neighbors $u \in V_{i,j}$ of v_j such that $a(u) < a(v_j) \leq b(u) \leq b(v_j)$ (neighbors of v_j in $V_{i,j}$ that partially overlap v_j).
- $M(j)$ contains the neighbors $w \in V_{i,j}$ of v_j such that $a(v_j) \leq a(w) \leq b(w) \leq b(v_j)$ (neighbors of v_j that are totally included within v_j).

In the forthcoming arguments, we restrict ourselves to the graph induced by $V_{i,j}$. It is clear that the first maximal clique that contains a vertex of $V_{i,j}$ is $K_{a(i,j)}$, whereas the last maximal clique is $K_{b(j)}$. For two vertices v_i, v_j with $b(v_i) \leq b(v_j)$, we define the following:

- $A_{i,j}$ is the value of an optimal solution for Cluster Deletion of the graph $G[V_{i,j}]$.

To ease the notation, when we say a cluster of $A_{i,j}$ we mean a cluster of an optimal solution of $G[V_{i,j}]$. Notice that $A_{1,n}$ is the desired value for the whole graph G, since $V_{1,n} = V(G)$.

Our task is to construct the values for $A_{i,j}$ by taking into account all possible clusters that contain v_j. To do so, we show that (i) the number of candidate clusters containing v_j in $A_{i,j}$ is polynomial and (ii) each such candidate cluster containing v_j separates the graph in a recursive way with respect to optimal subsolutions.

Observe that if $v_iv_j \in E(G)$ then $v_i \in U(j)$ if and only if $a(v_i) < a(v_j)$, whereas $v_i \in M(j)$ if and only if $a(v_j) \leq a(v_i)$; in the latter case, it is not difficult to see that $V_{i,j} = M(j) \cup \{v_j\}$. Thus, whenever $v_i \in M(j)$ holds, we have $V_{i,j} = V_{j,j}$. The candidates of a cluster of $A_{i,j}$ containing v_j lie among $U(j)$ and $M(j)$. Let us show with the next two lemmas that we can restrict ourselves into a polynomial number of such candidates. To avoid repeating ourselves, in the forthcoming statements we let v_i, v_j be two vertices with $b(v_i) \leq b(v_j)$.

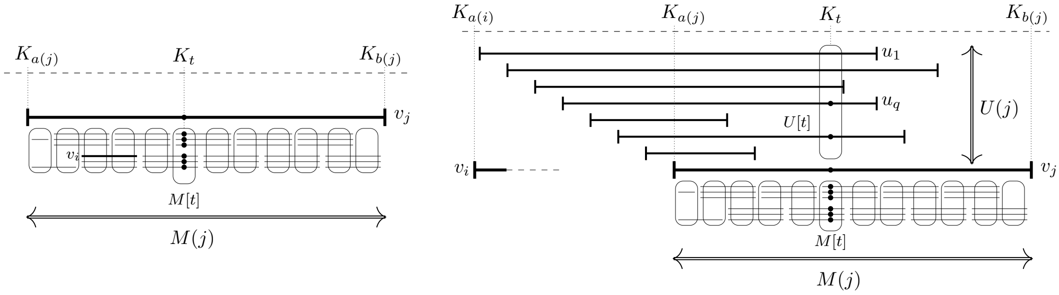

Figure 1 Illustrating the sets $M(j)$ and $U(j)$ for v_j. The left part shows the case in which $v_i \in M(j)$ (or, equivalently, $V_{i,j} = V_{j,j}$), whereas the right part corresponds to the case in which $a(v_i) < a(v_j)$.

▶ **Lemma 6.** *Let C be a cluster of $A_{i,j}$ containing v_j. If there is a vertex $w \in M(j)$ such that $w \in C$ then there is a maximal clique K_t with $a(v_j) \le t \le b(v_j)$ such that $K_t \cap M(j) \subseteq C$ and $C \cap M(j) \subseteq K_t$.*

Proof. Observe that $w \in M(j)$ implies $a(v_j) \le a(w) \le b(w) \le b(v_j)$. Since $v_j, w \in C$, we know that there is a maximal clique K_t for which $C \subseteq K_t$ with $a(v_j) \le a(w) \le t \le b(w) \le b(v_j)$. We show that all other vertices of $K_t \cap M(j)$ are guarded by v_j and w. Notice that for every vertex $y \in M(j)$ we already know that $a(v_j) \le a(y)$ and $b(y) \le b(v_j)$. Thus, for every vertex $y \in M(j)$ we have $a(v_j) = \min\{a(v_j), a(w)\} \le a(y)$ and $b(y) \le b(v_j) = \max\{b(v_j), b(w)\}$. This means that all vertices of $K_t \cap M(j) \setminus \{w\}$ are guarded by v_j and w. Moreover, since $C \subseteq K_t$, we know that all vertices of $K_t \cap M(j)$ are C-compatible. Therefore, we apply Lemma 5 to every vertex of $K_t \cap M(j)$, showing that $K_t \cap M(j) \subseteq C$. Furthermore, there is no vertex of $M(j) \setminus K_t$ that belongs to C, because $C \subseteq K_t$. ◀

By Lemma 6, we know that we have to pick the entire set $K_t \cap M(j)$ for constructing candidates to form a cluster that contains v_j and some vertices of $M(j)$. As there are at most n choices for K_t, we get a polynomial number of such candidate sets. We next show that we can construct a polynomial number of candidate sets that contain v_j and vertices of $U(j)$. For doing so, we consider the vertices of $U(j)$ increasingly ordered with respect to their first maximal clique. More precisely, let $U(j)_{\le a} = (u_1, \ldots, u_{|U(j)|})$ be an increasingly order of the vertices of $U(j)$ such that $a(u_1) \le \cdots \le a(u_{|U(j)|})$ (see the right part of Figure 1).

▶ **Lemma 7.** *Let C be a cluster of $A_{i,j}$ containing v_j and let $u_q \in U(j)_{\le a}$.If $u_q \in C$ then every vertex of $\{u_{q+1}, \ldots, u_{|U(j)|}\}$ that is C-compatible belongs to C.*

Proof. Let u be a vertex of $\{u_{q+1}, \ldots, u_{|U(j)|}\}$. We show that u is guarded by u_q and v_j. By the definition of $U(j)_{\le a}$, we know that $a(u_q) < a(u) < a(v_j)$. Moreover, observe that $b(u) \le b(v_j)$ holds by the fact that $u \in V_{i,j}$ and $b(u_q) \le b(v_j)$. Thus, we apply Lemma 5 to u, because $u_q, v_j \in C$ and u is C-compatible, showing that $u \in C$ as desired. ◀

For $a(v_j) \le t \le b(v_j)$, let $M[t] = K_t \cap M(j)$. Observe that each $M[t]$ may be an empty set. On the part $M(j)$, all vertices are grouped into the sets $M[a(v_j)], \ldots, M[b(v_j)]$. Similar to the group $M[t]$, let $U[t] = U(j) \cap K_t$. Then, all vertices of $U[t]$ are $\{v_j, M[t]\}$-compatible and all vertices of $M[t]$ are $\{v_j, U[t]\}$-compatible. Figure 1 depicts the corresponding sets.

▶ **Lemma 8.** *Let C be a cluster of $A_{i,j}$ containing v_j. Then, there is $a(v_j) \le t \le b(v_j)$ such that $M[t] \subseteq C$.*

All vertices of a cluster C containing v_j belong to $U(j) \cup M(j)$. Thus, $C \setminus \{v_j\}$ can be partitioned into $C \cap U(j)$ and $C \cap M(j)$. Also notice that $C \subseteq K_t$ for some $a(v_j) \leq t \leq b(v_j)$. Combined with the previous lemmas, we enumerate all such subsets C of $U(j) \cup M(j)$ in polynomial-time. In particular, we first build all candidates for $C \cap M(j)$, which are exactly the sets $M[t]$ by Lemmas 6 and 8. Then, for each of such candidate $M[t]$, we apply Lemma 7 to construct all subsets containing the last q vertices of $U[t]_{\leq a}$. Thus, there are at most n^2 candidate sets from the vertices of $U(j) \cup M(j)$ that belong to the same cluster with v_j.

3.1 Splitting into partial solutions

We further partition the vertices of $M(j)$. Given a pivot group $M[t]$, we consider the vertices that lie on the right part of $M[t]$. More formally, for $a(v_j) \leq t < b(v_j)$, we define the set $B_j(t) = \big((K_{t+1} \cup \cdots \cup K_{b(j)}) \setminus K_t\big) \cap M(j)$. The reason of breaking the vertices of the part $M(j)$ into sets $B_j(t)$ is the following.

▶ **Lemma 9.** *Let C be a cluster of $A_{i,j}$ such that $\{v_j\} \cup M[t] \subseteq C$, for $a(v_j) \leq t \leq b(v_j)$. Then, for any two vertices $x \in V_{i,j} \setminus B_j(t)$ and $y \in B_j(t)$, there is no cluster of $A_{i,j}$ that contains both of them.*

Proof. First observe that $y \in (M[t+1] \cup \cdots \cup M[b(j)]) \setminus M[t]$. We consider two cases for x, depending on whether $x \in M(j)$ or not. Assume that $x \in M(j)$. If $x \in M[t]$, then $x \in C$ by Lemma 6, which implies that $y \notin C$. If $x \in (M[a(v_j)] \cup \cdots \cup M[t-1]) \setminus M[t]$ then $xy \notin E(G)$. Now assume that $x \in U(j)$. If $x \in C$, then y does not belong to K_t, so that $y \notin C$. If $x \notin C$, then we show that x does not belong to a cluster with any vertex of $B_j(t)$. Assume for contradiction that x belongs to a cluster C' such that $C' \cap B_j(t) \neq \varnothing$. This means that $x \in K_{i'}$ with $t < i' \leq b(v_j)$ and $C' \subseteq K_{i'}$. Then v_j is C'-compatible and x is C-compatible, as both x and v_j belong to $K_t \cap K_{i'}$. Therefore, by Lemma 3 we reach a contradiction to x and v_j belonging to different clusters. ◀

For a non-empty set $S \subseteq V(G)$, we write $A(S)$ to denote the following solutions:

- $A(S) = A_{i',j'}$, where $v_{i'}$ is the vertex of S having the smallest $a(v_{i'})$ and $v_{j'}$ is the vertex of S having the largest $b(v_{j'})$.

Having this notation, observe that $A_{i,j} = A(V_{i,j})$, for any v_i, v_j with $b(v_i) \leq b(v_j)$. However, it is important to notice that $A(S)$ does not necessarily represent the optimal solution of $G[S]$, since the vertices of S may not be consecutive with respect to $V_{i',j'}$, so that S is only a subset of $V_{i',j'}$ in the corresponding solution $A_{i',j'}$ for $A(S)$. Under the following assumptions, with the next result we show that for the chosen sets we have $S = V_{i',j'}$.

▶ **Observation 10.** *Let $V_t = K_t \cap V_{i,j}$, for every $\min\{a(v_i), a(v_j)\} \leq t \leq b(v_j)$. If $S_L = \big(V_{a(i,j)} \cup \cdots \cup V_{t-1}\big) \setminus V_t$ then $S_L = V_{i',j'}$, where $i' = a\text{-}\min(S_L)$ and $j' = b\text{-}\max(S_L)$.*

Given the clique path $\mathcal{P} = K_1 \cdots K_p$, a *clique-index* t is an integer $1 \leq t \leq p$. Let $\ell(j), r(j)$ be two clique-indices such that $a(i,j) \leq \ell(j) \leq a(v_j)$ and $a(v_j) \leq r(j) \leq b(v_j)$. We denote by $\ell_r(j)$ the minimum value of $a(v)$ among all vertices of $v \in K_{r(j)} \cap V_{i,j}$ having $\ell(j) \leq a(v)$. Clearly, $\ell(j) \leq \ell_r(j) \leq r(j)$ holds. A pair of clique-indices $(\ell(j), r(j))$ is called *admissible pair* for a vertex v_j, if both $a(i,j) \leq \ell(j) \leq a(v_j)$ and $a(v_j) \leq r(j) \leq b(v_j)$ hold. Given an admissible pair $(\ell(j), r(j))$, we define the following set of vertices:

- $C(\ell(j), r(j)) = \{z \in V_{i,j} : \ell_r(j) \leq a(z) \text{ and } r(j) \leq b(z)\}$.

Observe that all vertices of $C(\ell(j), r(j))$ induce a clique in G, because $C(\ell(j), r(j)) \subseteq K_{r(j)}$. We say that a vertex u *crosses* the pair $(\ell(j), r(j))$ if $a(u) < \ell_r(j)$ and $r(j) \leq b(u)$. It is not difficult to see that for a vertex u that crosses $(\ell(j), r(j))$, we have $u \notin C(\ell(j), r(j))$. We prove the following properties of $C(\ell(j), r(j))$.

▶ **Lemma 11.** *Let $v_{i'}, v_{j'}$ be two vertices with $b(v_{i'}) \leq b(v_{j'})$ and let (ℓ, r) be an admissible pair for $v_{j'}$. Moreover, let v_i, v_j be the vertices of $V_{i',j'} \setminus C(\ell, r)$ having the smallest $a(v_i)$ and largest $b(v_j)$, respectively. If the vertices of $C(\ell, r)$ form a cluster in $A_{i',j'}$ then the following statements hold:*

1. *$V_{i,j} = V_{i',j'} \setminus C(\ell, r)$.*
2. *If $a(x) \leq r \leq b(x)$ holds for a vertex $x \in V_{i,j}$, then x crosses (ℓ, r).*
3. *Every vertex of $B_j(r)$ does not belong to the same cluster with any vertex of $V_{i,j} \setminus B_j(r)$.*
4. *Every vertex that crosses (ℓ, r) does not belong to the same cluster with any vertex $y \in V_{i,j}$ having $\ell_r \leq a(y)$.*

Notice that the number of admissible pairs $(\ell(j), r(j))$ for v_j is polynomial because there are at most n choices for each clique-index. Moreover, if $v_i \in M(j)$ then $\ell(j) = a(v_j)$. A pair of clique-indices (ℓ, r) with $\ell \leq r$ is called *bounding pair for v_j* if either $b(v_j) < r$ holds, or v_j crosses (ℓ, r). Given a bounding pair (ℓ, r) for v_j, we write $(\ell(j), r(j)) < (\ell, r)$ to denote the set of admissible pairs $(\ell(j), r(j))$ for v_j with the following restriction on $r(j)$:

- $r(j) \leq b(v_j)$, whenever $b(v_j) < r$ holds, and $r(j) < \ell$, whenever $b(v_j) \geq r$ holds.

Observe that if $b(v_j) < r$ holds, then $(\ell(j), r(j)) < (\ell, r)$ describes all admissible pairs for v_j with no restriction, regardless of ℓ. On the other hand, if $\ell < a(v_j)$ and $r \leq b(v_j)$ hold, then (ℓ, r) is not a bounding pair for v_j. In fact, we will show that the latter case will not be considered in our partial subsolutions. Intuitively, an admissible pair $(\ell(j), r(j))$ corresponds to the cluster containing v_j, whereas a bounding pair (ℓ, r) forbids v_j to select certain vertices as they have already formed a cluster that does not contain v_j (observe that $v_j \in C(\ell(j), r(j))$ and $v_j \notin C(\ell, r)$).

Our task is to construct subsolutions over all admissible pairs for v_j with the property that the vertices of $C(\ell(j), r(j))$ form a cluster. To do so, we consider a vertex $v_{j'}$ with $b(v_j) \leq b(v_{j'})$ and a cluster containing $v_{j'}$. Let (ℓ, r) be an admissible pair for $v_{j'}$ such that $a(v_j) \leq r \leq b(v_j)$. The previous results suggest to consider solutions in which the vertices of $C(\ell, r)$ form a cluster in an optimal solution. It is clear that if $\ell \leq a(v_j)$ then $v_j \in C(\ell, r)$. Moreover, if $b(v_j) < r$, then no vertex of $V_{i,j}$ belongs to $C(\ell, r)$. Thus, we need to construct solutions for $A_{i,j}$, whenever (ℓ, r) is a bounding pair for v_j and the vertices of $C(\ell, r)$ form a cluster. Such an idea is formally described as follows: Let (ℓ, r) be a bounding pair for v_j.

- $A_{i,j}[\ell, r]$ is the value of an optimal solution for Cluster Deletion of the graph $G[V_{i,j}] - (C(\ell, r) \cup B_j(r))$ such that the vertices of $C(\ell, r)$ form a cluster.

Hereafter, we assume that $B_j(t)$ with $t \geq b(v_j)$ corresponds to an empty set. Figure 2 illustrates a partition of the vertices with respect to $A_{i,j}[\ell, r]$. Notice that an optimal solution $A_{i,j}$ without any restriction is described in terms of $A_{i,j}[\ell, r]$ by $A_{i,j}[1, b(v_j) + 1]$, since no vertex of $V_{i,j}$ belongs to $C(1, b(v_j) + 1)$. Therefore, $A_{1,n}[1, n + 1]$ corresponds to the optimal solution of the whole graph G. As base cases, observe that if $V_{i,j}$ contains at most one vertex then $A_{i,j}[\ell, r] = 0$ for all bounding pairs (ℓ, r). For a set C, we write $|C|_2$ to denote the number $\binom{|C|}{2}$. With the following result, we describe a recursive formulation for the optimal solution $A_{i,j}[\ell, r]$, which is our central tool for our dynamic programming algorithm.

▶ **Lemma 12.** *Let (ℓ, r) be a bounding pair for v_j. Then,*

$$A_{i,j}[\ell, r] = \max_{(\ell(j), r(j)) < (\ell, r)} \left(A(V_L)[\ell(j), r(j)] + |C(\ell(j), r(j))|_2 + A(V_R)[\ell, r]\right),$$

where $V_L = V_{i,j} \setminus (C(\ell(j), r(j)) \cup B_j(r(j)))$ and $V_R = B_j(r(j)) \setminus (C(\ell, r) \cup B_j(r))$.

▶ **Theorem 13.** Cluster Deletion *is polynomial-time solvable on interval graphs.*

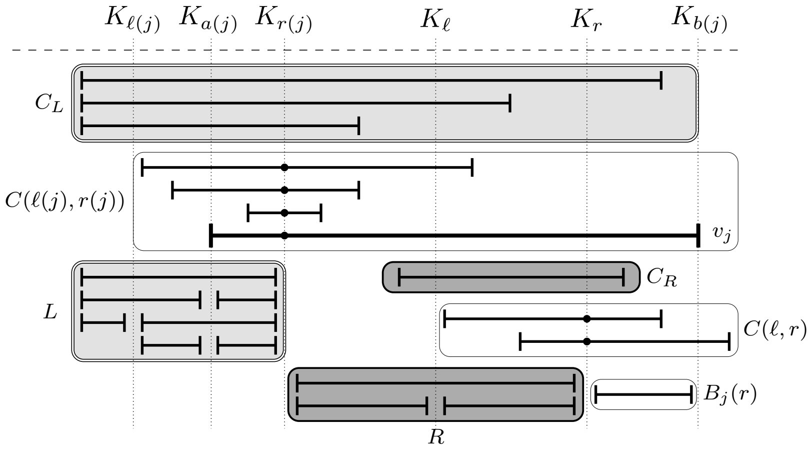

Figure 2 A partition of the set of vertices given in $A_{i,j}[\ell, r]$, where $V_L = C_L \cup L$ and $V_R = C_R \cup R$. Observe that $B_j(r(j)) = R \cup C_R \cup (C(\ell, r) \cap V_{i,j}) \cup B_j(r)$.

4 Cluster Deletion on a generalization of split graphs

A graph $G = (V, E)$ is a *split graph* if V can be partitioned into a clique C and an independent set I, where (C, I) is called a *split partition* of G. Split graphs are characterized as $(2K_2, C_4, C_5)$-free graphs [9]. They form a subclass of the larger and widely known graph class of *chordal graphs*, which are the graphs that do not contain induced cycles of length 4 or more as induced subgraphs. In general, a split graph can have more than one split partition and computing such a partition can be done in linear time [17].

Hereafter, for a split graph G, we denote by (C, I) a split partition of G in which C is a maximal clique. It is known that Cluster Deletion is polynomial-time solvable on split graphs [3]. In fact, the algorithm given in [3] is characterized by its simplicity due to the following elegant characterization of an optimal solution: if there is a vertex $v \in I$ such that $N(v) = C \setminus \{w\}$ and w has a neighbor v' in I then the non-trivial clusters of an optimal solution are $C \setminus \{w\} \cup \{v\}$ and $\{w, v'\}$; otherwise, the only non-trivial cluster of an optimal solution is C [3]. Here we study whether such a simple characterization can be extended into more general classes of split graphs. Due to Lemma 1, it is natural to consider true twins at the independent set, as they are grouped together in an optimal solution and they are expected not to influence the solution characterization. Surprisingly, we show that Cluster Deletion remains NP-complete even on such a slight generalization of split graphs. Before presenting our NP-completeness proof, let us first show that such graphs form a proper subclass of P_5-free chordal graphs. We start by giving the formal definition of such graphs.

▶ **Definition 14.** *A graph $G = (V, E)$ is called split-twin graph if its vertex set can be partitioned into C and I such that $G[C]$ is a clique and the vertices of each connected component of $G[I]$ form true twins in G.*

It is clear that in a split-twin graph G the following holds: (i) each connected component of $G[I]$ is a clique and forms a true-twin set in G, and (ii) contracting the connected components of $G[I]$ results in a split graph, denoted by G^*. Figure 3 illustrates the induced subgraphs that are forbidden in a split-twin graph.

▶ **Proposition 15.** *A graph G is split-twin if and only if it does not contain any of the graphs $C_4, C_5, P_5, 2P_3, \bar{A}, X$ as induced subgraphs.*

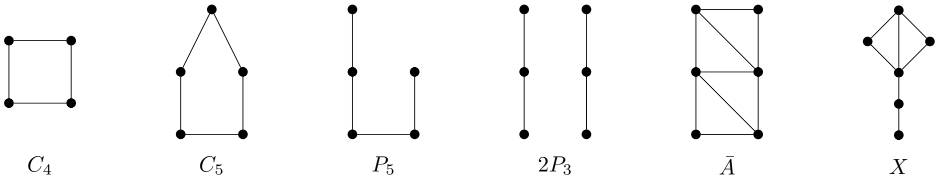

Figure 3 The list of forbidden induced subgraph characterization for split-twin graphs.

Thus by Proposition 15, split-twin graphs form a proper subclass of P_5-free chordal graphs, i.e., of (C_4, C_5, P_5)-free graphs. Now let us show that decision version of Cluster Deletion is NP-complete on split-twin graphs. This is achieved by observing that the constructed graphs given in the reduction for P_5-free graphs [3], constitute such split-related graphs. In particular, the reduction shown in [3] comes from the X3C problem: given a universe X of $3q$ elements and a collection $C = \{C_1, \ldots, C_{|C|}\}$ of 3-element subsets of X, asks whether there is a subset $C' \subseteq C$ such that every element of X occurs in exactly one member of C'. The constructed graph G is obtained by identifying the elements of X as a clique K_X and there are $|C|$ disjoint cliques $K_1, \ldots, K_{|C|}$ each of size $3q$ corresponding to the subsets of C and a vertex x of K_X is adjacent to all the vertices of K_i if and only if x belongs to the corresponding subset C_i of K_i. Then, it is not difficult to see that the vertices of each K_i are true twins and the contracted graph G^* is a split graph, showing that G is indeed a split-twin graph. Therefore, by the NP-completeness given in [3], we have:

▶ **Theorem 16.** Cluster Deletion *is NP-complete on split-twin graphs.*

However, here we give a different reduction that highlights an interesting connection between edge-weighted and vertex-weighted split graphs. In the Edge Weighted Cluster Deletion problem, each edge of the input graph is associated with a weight and the objective is to construct a clustered graph having the maximum total (cumulative) weight of edges. As already explained, we can contract true twins and obtain a vertex-weighted graph as input for the corresponding Cluster Deletion. Similarly, it is known that for edge-weighted graphs the corresponding Edge Weighted Cluster Deletion remains NP-hard even when restricted to particular variations on special families of graphs [3]. In fact, it is known that Edge Weighted Cluster Deletion remains NP-hard on split graphs even when (i) all edges inside the clique have weight one, (ii) all edges incident to a vertex $w \in I$ have the same weight q, and (iii) $q = |C|$ [3]. We abbreviate the latter problem by EWCD and denote by (C, I, k) an instance of the problem where (C, I) is a split partition of the vertices of G and k is the total weight of the edges in a cluster solution for G. With the following result, we show an interesting connection between the two variations of the problem when restricted to split-twin graphs.

▶ **Theorem 17.** *There exists a polynomial time algorithm that, given an instance (C, I, k) for EWCD, produces an equivalent instance for* Cluster Deletion *on split-twin graphs.*

Proof. From G, we build a split-twin graph $G' = (C' \cup I', E')$ by keeping the same clique $C' = C$, and for every vertex $w_j \in I$ we apply the following:

- We replace w_j by $q = |C|$ true twin vertices I'_j (i.e., by a q-clique) such that for any vertex $w' \in I'_j$ we have $N_{G'}(w') = N_G(w_j) \cup (I'_j \setminus \{w'\})$. That is, their neighbors outside I'_j are exactly $N_G(w_j)$. Moreover, the set of vertices $I'_1, \ldots, I'_{|I|}$ form I'.

By the above construction, it is not difficult to see that G' is a split-twin graph, since the graph induced by I' is a disjoint union of cliques and two adjacent vertices of I' are true twins in G'. Also observe that the construction takes polynomial time because q is at most $n = |V(G)|$. We claim that there is an edge weighted cluster solution for G with total weight at least k if and only if there is a cluster solution for G' having at least $k + |I| \cdot \binom{q}{2}$ edges.

Assume that there is a cluster solution S for G with total weight at least k. From S, we construct a solution S' for G'. There are three types of clusters in S:

(a) Cluster formed only by vertices of the clique C, i.e., $Y \in S$, where $Y \subseteq C$. We keep such clusters in S'. We denote by t_a the total weight of clusters of type (a). Notice that since the weight of edges having both endpoints in C are all equal to one, t_a corresponds to the number of edges in Y.

(b) Cluster formed only by one vertex $w_j \in I$, i.e., $\{w_j\} \in S$. In S' we replace such cluster by the corresponding clique I'_j having exactly $\binom{q}{2}$ edges. It is clear that the total weight of such clusters do not contribute to the value of S.

(c) Cluster formed by the vertices $y_1, \ldots, y_p, w_j$, where $y_i \in C$ and $w_j \in I$. As the weights of the edges between the vertices of y_i is one, the total number of weights in such a cluster is $\binom{p}{2} + p \cdot q$. Let t_c be the total weight of clusters of type (c). In S' we replace w_j by the vertices of I'_j and obtain a cluster S' having $\binom{p}{2} + p \cdot q + \binom{q}{2}$ number of edges.

Now observe that in S we have $t_a + t_c$ total weight, which implies $t_a + t_c \geq k$. Thus, in S' we have at least $t_a + t_c + |I| \cdot \binom{q}{2}$ edges, giving the desired bound.

For the opposite direction, assume that there is a solution S' in G' having at least $k + |I| \cdot \binom{q}{2}$ edges. All vertices of I'_j are true twins and, by Lemma 1, they belong to the same cluster in S'. Thus, any cluster of S' has one of the following forms: (i) Y', where $Y' \subseteq C'$, (ii) I'_j, (iii) $I'_j \cup \{y'_1, \ldots, y'_p\}$, where $y'_i \in C'$. This means that all internal edges having both endpoints in I' contribute to the value of S' by $|I| \cdot \binom{q}{2}$. Moreover, observe that for any internal edge of S' of the form $y'w'$ with $y' \in C'$ and $w' \in I'_j$, we know that there are exactly q internal edges incident to y' and the q vertices of I'_j. Thus, internal edges $y'w'$ of S' correspond to exactly one internal edge yw_j of S having weight q, where $y = y'$ (recall that $C = C'$) and w_j is the vertex of I associated with I_j. Hence, all internal edges outside each I'_j in S' correspond to either a weighted internal edge in S or to the same unweighted edge of C in S. Therefore, there is an edge weighted solution S having weight at least k. ◀

4.1 Polynomial-time algorithms on subclasses of split-twin graphs

Due to the hardness result given in Theorems 16 and 17, it is natural to consider subclasses of split-twin graphs related to their analogue subclasses of split graphs. We consider two such subclasses. The first one corresponds to the split-twin graphs such that the vertices of I have no common neighbor in the clique, unless they are true or false twins. The second subclass corresponds to threshold graphs (i.e., split graphs in which the vertices of the independent set have nested neighborhood) and form the split-twin graphs in which the vertices of I have a nested neighborhood. We formally define such graphs and give polynomial-time algorithms for Cluster Deletion. For a vertex $x \in I$ we write $N_C(x)$ to denote the set $N(x) \cap C$.

▶ **Definition 18.** *A split-twin graph G with partition (C, I) on its vertices is called 1-split-twin graph if for any two vertices $x, y \in I$, either $N_C(x) \cap N_C(y) = \varnothing$ or $N_C(x) = N_C(y)$.*

It is not difficult to see that in a 1-split-twin graph, any two vertices of I having a common neighbor in C have the same neighborhood in C. Close related to 1-split-twin graphs, are the *1-split graphs* which are the edge-weighted split graphs in which every vertex of the independent set is adjacent to exactly one vertex of the clique. It is known that the (edge-weighted) Cluster Deletion is solved in polynomial-time on 1-split graphs [3]. Let us explain how to use the algorithm on a 1-split graph to obtain a polynomial-time algorithm on a 1-split-twin graph $G = (C, I)$. Observe that the contracted graph G^* is 1-split. Let xy be an edge of G^*. Denote by $w(x)$ and $w(y)$ the weights assigned to x and y that correspond to the sizes of their true twins classes in G. From the vertex-weighted 1-split graph G^*, construct an edge-weighted 1-split graph H^* by removing the vertex weights and for each edge xy assign weight $w(x) \cdot w(y)$. Then, given a solution of the edge-weighted H^* taken from the algorithm of [3], we obtain a solution for Cluster Deletion on G by adding the internal edges corresponding to each contracted vertex.

Notice, however, that the running time is bounded by the polynomial-time algorithm of 1-split graphs. In particular the described algorithm of 1-split graphs is accomplished through a minimizer of a general submodular function provided a given oracle for evaluating the function value [3]. This means that through such an approach it is unlikely to achieve a better running time for 1-split-twin graphs, unless there is a faster algorithm with less number of oracle calls for finding a minimizer of a general submodular function. With our next result we provide a simpler and faster (linear-time) algorithm for Cluster Deletion on 1-split-twin graphs that avoids the usage of submodular functions minimization.

▶ **Theorem 19.** Cluster Deletion *is linear-time solvable on 1-split-twin graphs.*

Proof. Let G be a 1-split-twin graph with partition (C, I). First observe that if G is disconnected then I contains isolated cliques, i.e., true twins having no neighbor in C. Thus we can restrict ourselves to a connected graph G, since by Lemma 1 each isolated clique is contained in exactly one cluster of an optimal solution. We now show that all vertices of C that have a common neighbor in I are true twins. Let u and v be two vertices of C such that $x \in N(u) \cap N(v) \cap I$. All vertices of $C \setminus \{u, v\}$ are adjacent to both u and v. Assume that there is a vertex $y \in I$ that is adjacent to u and non-adjacent to v. If $xy \in E(G)$ then by the definition of split-twin graphs x and y are true twins which contradicts the assumption of $xv \in E(G)$ and $yv \notin E(G)$. Otherwise, x and y are non-adjacent and since $N_C(x) \cap N_C(y) \neq \varnothing$ we reach a contradiction to the definition of 1-split-twin graphs. Thus, all vertices of C that have a common neighbor in I are true twins.

We partition the vertices of C into true twin classes $C_1, \ldots, C_k$, such that each C_i contains true twins of C. From the previous discussion, we know that any vertex of I is adjacent to all the vertices of exactly one class C_i; otherwise, there are vertices of different classes in C that have common neighbor. For a class C_i, we partition the vertices of $N(C_i) \cap I$ into true twin classes $I_i^1, \ldots, I_i^q$ such that $|I_i^1| \geq \cdots \geq |I_i^q|$.

We claim that in an optimal solution S, the vertices of each class I_i^j with $j \geq 2$ constitute a cluster. To see this, observe first that the vertices of I_i^j, $1 \leq j \leq q$, are true twins, and by Lemma 1 they all belong to the same cluster of S. Also, by Lemma 1 we know that all the vertices of C_i belong to the same cluster of S. Moreover, all vertices between different classes I_i^j,$I_i^{j'}$ are non-adjacent and are C_i-compatible. Since every vertex of I_i^j is non-adjacent to all the vertices of $V(G) \setminus \{I_i^j \cup C_i\}$, we know that any cluster of S that contains I_i^j is of the form either $\{I_i^j \cup C_i\}$ or I_i^j. Assume that there is a cluster that contains $\{I_i^j \cup C_i\}$ with $j \geq 2$. Then, we substitute the vertices of I_i^j by the vertices of I_i^1 and obtain a solution of at least the same size, because $|I_i^1| \geq |I_i^j|$ implies $\binom{|C_i|+|I_i^1|}{2} \geq \binom{|C_i|+|I_i^j|}{2}$. Thus, all vertices of each class I_i^j with $j \geq 2$ constitute a cluster in an optimal solution S.

This means that we can safely remove the vertices of I_i^j with $j \geq 2$, by constructing a cluster that contains only I_i^j. Hence, we construct a graph G^* from G, in which there are only matched pair of k classes (C_i, I_i) such that (i) all sets C_i, I_i are non-empty except possibly the set I_k, (ii) $N(C_i) \cap I = I_i$, (iii) $N(I_i) = C_i$, (iv) $G^*[C_i \cup I_i]$ is a clique, and (v) $G^*[C_1 \cup \cdots \cup C_k]$ is a clique. Our task is to solve Cluster Deletion on G^*, since for the rest of the vertices we have determined their cluster. By Lemma 1, if the vertices of $C_i \cup C_j$ belong to the same cluster then the vertices of each I_i and I_j constitute two clusters. Thus, for each set of vertices I_i we know that either one of $C_i \cup I_i$ or I_i constitutes a cluster in S. This boils down to compute a set M of matched pairs (C_i, I_i), having the maximum value

$$\sum_{(C_i,I_i)\in M} \binom{|C_i|+|I_i|}{2} + \binom{\sum_{C_j \notin M} |C_j|}{2} + \sum_{I_j \notin M} \binom{|I_j|}{2}.$$

Let (C_i, I_i) and (C_j, I_j) be two pairs of classes such that $|C_i| + |I_i| \leq |C_j| + |I_j|$. We show that if $(C_j, I_j) \notin M$ then $(C_i, I_i) \notin M$. Assume for contradiction that $(C_j, I_j) \notin M$ and $(C_i, I_i) \in M$. Observe that $|I_j| < \sum_{C_t \notin M \setminus C_j} |C_t|$, because I_j is C_j-compatible. Similarly, we know that $\sum_{C_t \notin M \setminus C_j} |C_t| + |C_j| \leq |I_i|$. This however, shows that $|C_j| + |I_j| < |I_i|$, contradicting the fact that $|C_i| + |I_i| \leq |C_j| + |I_j|$. Thus $(C_j, I_j) \notin M$ implies $(C_i, I_i) \notin M$.

This means that we can consider the k pair of classes (C_i, I_i) in a decreasing order according to their number of vertices $|C_i| + |I_i|$. With a simple dynamic programming algorithm, starting from the largest ordered pair (C_1, I_1) we know that either (C_1, I_1) belongs to M or not. In the former, we add $\binom{|C_1|+|I_1|}{2}$ to the optimal value of $(C_2, I_2), \ldots, (C_k, I_k)$ and in the latter we know that no pair belongs to M giving a total value of $\binom{\sum |C_i|}{2} + \sum \binom{|I_i|}{2}$. By choosing the maximum between the two values, we construct a table of size k needed for the dynamic programming. Computing the twin classes and the partition (C, I) takes linear time in the size of G and sorting the pair of classes can be done $O(n)$ time, since $\sum(|C_i| + |I_i|)$ is bounded by n. Thus, the total running time is $O(n + m)$, as the dynamic programming for computing M requires $O(n)$ time. Therefore, all steps can be carried out in linear time for a 1-split-twin graph G. ◀

▶ **Definition 20.** *A split-twin graph G with partition (C, I) on its vertices is called threshold-twin graph if the vertices of I can be ordered $w_1, \ldots, w_{|I|}$ such that for any $w_i, w_j \in I$ with $i < j$, we have $N_C(w_i) \subseteq N_C(w_j)$.*

For the next result, we prove that there is no P_4 in a threshold-twin graph (P_4-free graphs are closed under true twins addition). Thus, by the algorithm given in [11], we have:

▶ **Theorem 21.** Cluster Deletion *is polynomial-time solvable on threshold-twin graphs.*

5 Concluding remarks

It is notable that our algorithm for interval graphs, heavily relies on the linear structure obtained from their clique paths. Such an observation, leads us to consider few open questions regarding two main directions. On the one hand, it seems tempting to adjust our algorithm for other vertex partitioning problems on interval graphs within a more general framework, as already have been studied for particular graph properties [4, 12, 20, 21, 25]. On the other hand, it is reasonable to ask whether our approach works for Cluster Deletion on graphs admitting similar linear structure such as permutation graphs, or graphs having bounded linear related parameter. Towards the latter direction, observe that Cluster Deletion as a vertex partitioning problem can be solved in linear time on graphs of bounded treewidth by using Courcelle's machinery [6].

Although for other structural parameters it seems rather difficult to obtain similar result, it is still interesting to settle the complexity of Cluster Deletion on distance hereditary graphs that admit constant clique-width [15]. In fact, we would like to settle the case in which from a given cograph we can append degree-one vertices. This comes in conjunction with the 1-split-twin graphs, as they can be seen as a degree-one extension of a clique.

Abstract

The square of a graph H, denoted H^2, is obtained from H by adding new edges between two distinct vertices whenever their distance in H is two. The half-squares of a bipartite graph $B = (X, Y, E_B)$ are the subgraphs of B^2 induced by the color classes X and Y, $B^2[X]$ and $B^2[Y]$. For a given graph $G = (V, E_G)$, if $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$, then B is a representation of G and W is the set of points in B. If in addition B is planar, then G is also called a map graph and B is a witness of G [Chen, Grigni, Papadimitriou. Map graphs. *J. ACM*, 49 (2) (2002) 127-138].

While Chen, Grigni, Papadimitriou proved that any map graph $G = (V, E_G)$ has a witness with at most $3|V| - 6$ points, we show that, given a map graph G and an integer k, deciding if G admits a witness with at most k points is NP-complete. As a by-product, we obtain NP-completeness of EDGE CLIQUE PARTITION on planar graphs; until this present paper, the complexity status of EDGE CLIQUE PARTITION for planar graphs was previously unknown.

We also consider half-squares of tree-convex bipartite graphs and prove the following complexity dichotomy: Given a graph $G = (V, E_G)$ and an integer k, deciding if $G = B^2[V]$ for some tree-convex bipartite graph $B = (V, W, E_B)$ with $|W| \leq k$ points is NP-complete if G is non-chordal dually chordal and solvable in linear time otherwise. Our proof relies on a characterization of half-squares of tree-convex bipartite graphs, saying that these are precisely the chordal and dually chordal graphs.

1 Introduction

Map graphs, introduced and investigated in [5, 6], are intersection graphs of simply-connected and interior-disjoint regions of the Euclidean plane; each region is homeomorphic to a closed disc. More precisely, a *map* of a graph $G = (V, E_G)$ is a function $\mathcal{M}$ taking each vertex $v \in V$ to a region $\mathcal{M}(v)$ in the plane, such that all $\mathcal{M}(v)$, $v \in V$, are interior-disjoint, and two distinct vertices v and v' of G are adjacent if and only if the boundaries of $\mathcal{M}(v)$ and $\mathcal{M}(v')$ intersect, even in a point. A *map graph* is one having a map. Map graphs are interesting as they generalize planar graphs in a very natural way. Some applications of map graphs have been addressed in [8]. Papers dealing with hard problems in map graphs include [4, 9, 10, 11, 13, 14].

In [5, 6], the notion of *half-squares* of bipartite graphs has been also introduced in order to give a combinatorial representation of map graphs. The square of a graph H, denoted H^2, is obtained from H by adding new edges between any two vertices at distance two in H. For a bipartite graph $B = (X, Y, E_B)$, the subgraphs of the square B^2 induced by the color classes X and Y, $B^2[X]$ and $B^2[Y]$, are called the two *half-squares* of B. For a given graph $G = (V, E_G)$, if $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$, then B is a *representation* or a *half-root* of G and W is the set of *points* in B. While every graph is a

half-square of some bipartite graph, it turns out that map graphs are exactly half-squares of *planar* bipartite graphs [5, 6]. If $G = (V, E_G)$ is a map graph and $B = (V, W, E_B)$ is a planar representation of G, then B is called a *witness* of G. See Figure 1 for an example.

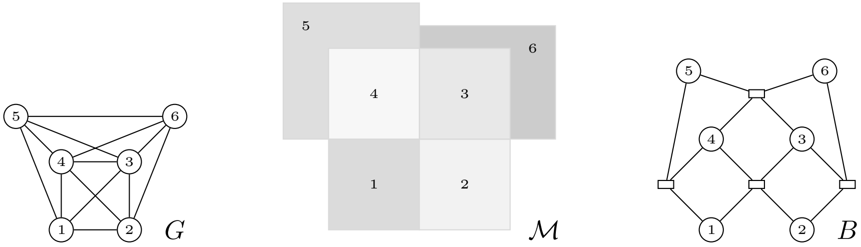

Figure 1 A map graph G, a map $\mathcal{M}$, and a witness B of G.

It is perhaps important to note at this place that one of the difficulties in recognizing map graphs is that we do not know the set of points of a witness we are looking for. It is shown in [5, 6] that an n-vertex graph $G = (V, E_G)$ is a map graph if and only if it has a witness $B = (V, W, E_B)$ with $|W| \leq 3n - 6$ points, implying that recognizing map graphs is in NP. Subsequently, Thorup [28] announced that recognizing map graphs is in P by giving an $\Omega(n^{120})$-time algorithm for n-vertex input graphs.[1] Thorup's algorithm is very complex and highly non-combinatorial. Given the very high polynomial degree in Thorup's running time, the most discussed problem concerning map graphs is whether there is a faster recognition algorithm with simpler arguments for map graphs.

One direction in attacking this problem is to consider map graphs with restricted witness. Structural results and more efficient recognition algorithms for map graphs with restricted witness will enhance our understanding on map graphs in whole. More generally, let $\mathcal{B}$ be a class of (not necessarily planar) bipartite graphs, the following problem has been discussed first by Le and Le [18].

$\mathcal{B}$ REPRESENTATION
Instance: A graph $G = (V, E_G)$.
Question: Does there exist a bipartite graph $B = (V, W, E_B)$ in $\mathcal{B}$ with $G = B^2[V]$?

Recall that in case $\mathcal{B}$ is the class of all planar bipartite graphs, PLANAR REPRESENTATION is the problem of recognizing map graphs, which admits an $\Omega(n^{120})$-time algorithm due to Thorup. Recall also that every map graph has a witness $B = (V, W, E_B)$ with $|W| \leq 3|V| - 6$ due to Chen *et al.* [5, 6]. This motivates considering the following problem.

POINT MINIMAL $\mathcal{B}$ REPRESENTATION
Instance: A graph $G = (V, E_G)$ and an integer k.
Question: Does there exist a bipartite graph $B = (V, W, E_B)$ in $\mathcal{B}$ with $G = B^2[V]$ and $|W| \leq k$?

In case $\mathcal{B}$ is the class of all bipartite graphs, we simply denote the problem by POINT MINIMAL REPRESENTATION.

This paper considers the cases where $\mathcal{B}$ is one of the classes of (planar) bipartite graphs of a given girth, of tree-convex bipartite graphs, and of tree-biconvex bipartite graphs. All terms used are given in the next section.

[1] Thorup did not give the running time explicitly, but it is estimated to be roughly $\Omega(n^{120})$ with n being the vertex number of the input graph; cf. [6].

Our contributions. We first consider map graphs with witness of large girth and, more generally, half-squares of bipartite graphs of large girth, and prove the following complexity dichotomy for MINIMAL POINT (PLANAR) GIRTH-g REPRESENTATION: Given a (map) graph $G = (V, E_G)$ and an integer k, deciding if $G = B^2[V]$ for some (planar) bipartite graph $B = (V, W, E_B)$ of girth at least g with $|W| \leq k$ points is NP-complete for $g \leq 6$ and polynomially solvable otherwise. The case $g \geq 8$ is based on our previous paper [19], and the case $g \leq 6$ is based on a close connection to the well-known NP-complete problems EDGE CLIQUE COVER and EDGE CLIQUE PARTITION. It is perhaps interesting to note that, while recognizing map graphs is in P due to Thorup, our hardness result in case $g = 4$ says that the problem becomes intractable if we ask for a witness with few points. In case $g = 6$, our result implies that EDGE CLIQUE PARTITION is NP-complete for planar graphs. (The complexity status of this problem for planar graphs was previously unknown.) We then consider half-squares of tree-convex bipartite graphs, and prove the following complexity dichotomy for MINIMAL POINT TREE-CONVEX REPRESENTATION: Given a graph $G = (V, E_G)$ and an integer k, deciding if $G = B^2[V]$ for some tree-convex bipartite graph $B = (V, W, E_B)$ with $|W| \leq k$ points is NP-complete for non-chordal dually chordal graphs G and solvable in linear time otherwise. We obtain this result by proving that half-squares of tree-convex bipartite graphs are exactly the chordal and dually chordal graphs. We also show that MINIMAL POINT TREE-BICONVEX REPRESENTATION can be solved in linear time by proving that half-squares of tree-biconvex bipartite graphs are precisely the double chordal graphs. Our results on half-squares of tree-(bi)convex bipartite graphs settle the question left open in [18].

Related work. The first restricted representations of map graphs have been considered in [5, 6] which lead to the so-called k-map graphs; k-map graphs are map graphs having a witness in which every point has at most k neighbors. It turns out that, for $k \leq 3$, k-map graphs are precisely the planar graphs. 4-map graphs can be recognized in cubic time [1], and are related to 1-planar graphs [1, 7], a relevant topic in graph drawing. Recognizing k-map graphs, $k \geq 5$, in polynomial time still remains open. (We remark that Thorup's algorithm cannot be used to recognize map graphs having witness with additional properties.)

Mnich et al. [25] considered map graphs with outerplanar witness and tree witness, and showed that such map graphs can be recognized in linear time. Map graphs with witness of a given girth and, more generally, half-squares of bipartite graphs of a given girth have been considered in the recent paper [19]. It is shown in that paper that half-squares of (planar) bipartite graphs of girth at least 8 admit good characterizations, leading to cubic time recognition algorithms. In [18], half-squares of classical bipartite graphs, such as biconvex, convex, and chordal bipartite graphs, have been studied. It turns out that half-squares of biconvex, convex, and chordal bipartite graphs (all are subclasses of tree-(bi)convex bipartite graphs) are exactly the proper interval, interval, and strongly chordal graphs, respectively.

The paper is organized as follows. All definitions and notion needed are provided in the next section. Section 3 first collects known results on half-squares of (planar) bipartite graphs of large girth, and then provides a dichotomy theorem for POINT MINIMAL GIRTH-g (PLANAR) REPRESENTATION. Section 4 deals with half-squares of tree-convex and tree-biconvex bipartite graphs, and provides a dichotomy theorem for POINT MINIMAL TREE-CONVEX REPRESENTATION. Section 5 concludes the paper with some open problems for future work.

2 Preliminaries

All graphs considered are simple and connected. Let $G = (V, E_G)$ be a graph with vertex set $V(G) = V$ and edge set $E(G) = E_G$. A *stable set* (a *clique*) in G is a set of pairwise non-adjacent (adjacent) vertices. The complete graph on n vertices and the cycle with n vertices are denoted K_n and C_n, respectively. A K_3 is also called a *triangle*. The *diamond*, denoted $K_4 - e$, is the graph obtained from the K_4 by deleting an edge.

The neighborhood of a vertex v in G, denoted $N_G(v)$, is the set of all vertices in G adjacent to v; if the context is clear, we simply write $N(v)$. A *universal vertex* v in G is one with $N(v) = V \setminus \{v\}$, i.e., v is adjacent to all other vertices in G.

Let F be a graph. *F-free graphs* are those having no induced subgraphs isomorphic to F. *Chordal graphs* are precisely the C_k-free graphs, $k \geq 4$. A *dually chordal graph* G is one in which every connected component H of G admits a spanning tree T such that every maximal clique of H induces a subtree in T.[2] Graphs that are both chordal and dually chordal are called *double chordal*. While chordal graphs are closed under taking induced subgraphs, dually chordal graphs and double chordal graphs are not. *Strongly chordal graphs* are those graphs G such that every induced subgraph of G is double chordal. See [15, 24, 27] for more information on these graph classes. Additional information on dually chordal graphs can be found in [2]. We will use the well-known facts that chordal and dually chordal graphs, hence double chordal graphs, can be recognized in linear time [15, 27, 2], and that any n-vertex chordal graph has at most n maximal cliques and all of them can be listed in linear time [15, 27].

For a subset $W \subseteq V$, $G[W]$ is the subgraph of G induced by W, and $G - W$ stands for $G[V \setminus W]$. For a vertex v, $G - v$ stands for $G - \{v\}$. We will consider map graphs with large-girth witness and, more generally, half-squares of bipartite graphs of large girth. Here, the *girth* of a graph is the minimum length of a cycle in that graph. (Thus, a graph has girth at least g if and only if it is C_k-free for all $k < g$.) We will also consider half-squares of tree-convex bipartite graphs, a problem left open in [18]. A bipartite graph $B = (X, Y, E_B)$ is *tree-convex on X* if there exists a tree $T = (X, E_T)$ such that, for each $y \in Y$, $N(y)$ induces a subtree in T. Being *tree-convex on Y* is defined similarly. B is *tree-convex* if it is tree-convex on X or tree-convex on Y. B is *tree-biconvex* if it is both tree-convex on X and tree-convex on Y. A well-known subclass of tree-biconvex bipartite graphs consists of the *chordal bipartite graphs*, i.e., bipartite graphs containing no induced cycle of length at least six. Liu [21] discusses relationships between tree-convex bipartite graphs and other classical classes of bipartite graphs.

POINT MINIMAL $\mathcal{B}$ REPRESENTATION is related to two well-studied problems. An *edge clique cover* of a graph G is a family of cliques $\mathcal{C}$ in G such that every edge of G is contained in one or more cliques in $\mathcal{C}$. An *edge clique partition* of G is an edge clique cover $\mathcal{C}$ of G such that every edge of G is contained in exactly one clique in $\mathcal{C}$. The two well-studied problems are:

EDGE CLIQUE COVER

Instance: A graph $G = (V, E_G)$ and an integer k.

Question: Does G have an edge clique cover of size k or less?

[2] Dually chordal graphs haven been studied under different names and admit various characterizations. The chosen definition is dependent on our purpose.

EDGE CLIQUE PARTITION
Instance: A graph $G = (V, E_G)$ and an integer k.
Question: Does G have an edge clique partition of size k or less?

EDGE CLIQUE COVER is NP-complete [26, 17], and remains NP-complete on planar graphs [3] and on complements of bipartite graphs [20]. We will use the fact that EDGE CLIQUE COVER is solvable in linear time on chordal graphs [23]. The monograph [24] provides more information on edge clique covers.

EDGE CLIQUE PARTITION is NP-complete [26, 16], and remains NP-complete on K_4-free graphs [22]. In contrast to EDGE CLIQUE COVER, EDGE CLIQUE PARTITION is NP-complete on chordal graphs, even on split graphs [30]. EDGE CLIQUE PARTITION on planar graphs has been considered in [12]; the complexity status of this problem on planar graphs was unknown until our present work.

Let $\mathcal{C}$ be an edge clique cover of a graph $G = (V, E_G)$. The *vertex-$\mathcal{C}$ incidence bipartite graph* of G is $B_{\mathcal{C}} = (V, \mathcal{C}, E_B)$ with $E_B = \{vC \mid v \in V, C \in \mathcal{C}, v \in C\}$. If $\mathcal{C} = \mathcal{C}(G)$, the set of all maximal cliques in G, then $B_{\mathcal{C}}$ is called the *vertex-clique incidence bipartite graph* of G and usually denoted by B_G.

▶ **Fact 1.**
(i) *For any graph $G = (V, E_G)$ and any edge clique cover $\mathcal{C}$ of G, $G = B^2_{\mathcal{C}}[V]$. If $\mathcal{C}$ is in addition an edge clique partition, then $B_{\mathcal{C}}$ is C_4-free.*
(ii) *For any graph $G = (V, E_G)$ and any bipartite graph $B = (V, W, E_B)$ with $G = B^2[V]$, $\mathcal{C} = \{N_B(w) \mid w \in W\}$ is an edge clique cover of G. If B is in addition C_4-free, then $\mathcal{C}$ is an edge clique partition of G.*

Proof. (i): For all vertices $x, y \in V$ we have $xy \in E_G \Leftrightarrow x, y \in C$ for some $C \in \mathcal{C} \Leftrightarrow xC$ and yC are edges of $B_{\mathcal{C}}$ for some $C \in \mathcal{C} \Leftrightarrow xy \in E(B^2_{\mathcal{C}}[V])$. If $\mathcal{C}$ is an edge clique partition, then, for any two distinct cliques $C, C' \in \mathcal{C}$, C and C' have at most one vertex in common. Hence, $B_{\mathcal{C}}$ is a C_4-free.

(ii): If $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$, then any edge of G is in a clique $N_B(w)$ for some $w \in W$, hence $\{N_B(w) \mid w \in W\}$ is an edge clique cover of G. If, in addition, B is C_4-free, then $|N_B(w) \cap N_B(w')| \leq 1$ for any two distinct points $w, w' \in W$. Hence $\{N_B(w) \mid w \in W\}$ is an edge clique partition of G. ◀

Thus,

- POINT MINIMAL REPRESENTATION and EDGE CLIQUE COVER, and
- POINT MINIMAL C_4-FREE REPRESENTATION and EDGE CLIQUE PARTITION

are computationally equivalent.

3 Girth-constrained representations

This section deals with half-squares of (planar) bipartite graphs of large girth. In [18], the following useful fact has been observed, and used in [19] in discussing half-squares of bipartite graphs with girth constraints.

▶ **Lemma 1** ([18]). *Let $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$. If B has no induced cycle of length six, then every maximal clique Q in G stems from a star in B, i.e., there is a point $w \in W$ such that $Q = N_B(w)$.*

We will also use this fact when considering point minimal representations of half-squares and map graphs.

3.1 Half-squares of girth-constrained bipartite graphs

Recall that *every* graph is a half-square of a girth-six bipartite graph (take its subdivision). Half-squares of bipartite graphs of large girth have been fully characterized as follows.

▶ **Theorem 2** ([19]). *Let $t \geq 4$ be an integer. The following statements are equivalent for every graph $G = (V, E_G)$.*

(i) *G is a half-square of a bipartite graph with girth at least $2t$;*
(ii) *G is diamond-free and C_ℓ-free for every $4 \leq \ell \leq t-1$;*
(iii) *The vertex-clique incidence bipartite graph B_G of G has girth at least $2t$.*

Theorem 2 implies that half-squares of bipartite graphs of large girth can be recognized in cubic time (cf. [19]).

By definition, *every* map graph is a half-square of a planar bipartite graph. Though map graphs can be recognized in polynomial time due to Thorup, no good characterization for map graphs is known so far. Map graphs of planar bipartite graphs of large girth have been fully characterized as follows.

▶ **Theorem 3** ([19]). *Let $t \geq 4$ be an integer. The following statements are equivalent for every graph $G = (V, E_G)$.*

(i) *G is a map graph having a witness of girth at least $2t$;*
(ii) *G is diamond-free and C_ℓ-free for every $4 \leq \ell \leq t-1$, and the vertex-clique incidence bipartite graph B_G of G is planar;*
(iii) *The vertex-clique incidence bipartite graph B_G of G is planar and has girth at least $2t$.*

Theorem 3 implies that map graphs with witness of large girth can be recognized in time $O(n^2m)$ (cf. [19]). No good characterization of map graphs with girth-six witness is known so far. It is also not known whether these map graphs can be recognized efficiently. Note that every planar graph has a girth-six witness, e.g., its subdivision.

3.2 Point minimal girth-constrained representations

This subsection deals with half-squares of (planar) bipartite graphs with girth constraints. We first consider the non-planar case.

Recall that, by Fact 1, POINT MINIMAL REPRESENTATION is equivalent to EDGE CLIQUE COVER, and thus is NP-complete. Also by Fact 1, POINT MINIMAL C_4-FREE REPRESENTATION is equivalent to EDGE CLIQUE PARTITION, and thus is NP-complete. Notice that C_4-free bipartite graphs and bipartite graphs of girth at least six coincide.

Now, let $t \geq 4$ be an integer and assume $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$ of girth at least $2t$. By Lemma 1, any maximal clique in G is a neighborhood of some $w \in W$, implying $|W| \geq |\mathcal{C}(G)|$. Thus, by Theorem 2, B_G is a minimal point girth-$2t$ representation for G. Note that, in this case, $\mathcal{C}(G)$ can be computed in polynomial time (cf. [19]), hence we obtain:

▶ **Theorem 4.** POINT MINIMAL GIRTH-AT-LEAST-$2t$ REPRESENTATION *is* NP-*complete for $t \leq 3$ and solvable in polynomial time otherwise.*

In the remainder of this subsection, we deal with the planar case. We first consider the girth-four witness case, i.e., no girth condition is made. Recall that any map graph with n vertices has a witness with at most $3n-6$ points. We are going to show that finding a witness with minimal number of points is hard. We will use the fact that EDGE CLIQUE COVER remains NP-complete on maximal planar graphs without triangle-separators. More precisely, it was shown in [3], that EDGE CLIQUE COVER remains NP-complete for plane triangulations in which every triangle is a face. Observe that such a triangulation does not contain any 4-clique K_4, unless the whole graph is a K_4. Thus, we may further assume that all plane triangulations considered are K_4-free.

▶ **Theorem 5.** POINT MINIMAL PLANAR REPRESENTATION *is* NP-*complete, even when restricted to planar graphs.*

Proof. Let $G = (V, E_G)$ be a plane triangulation in which every triangle is a face, and let k be an integer. We will argue that G has an edge clique cover of size k or less if and only if G has a witness $B = (V, W, E_B)$ with $|W| \leq k$.

First, assume G has an edge clique cover $\mathcal{C}$ with $|\mathcal{C}| \leq k$. Note that we can assume that every clique in $\mathcal{C}$ is a triangle. Then, as any triangle in G is a face of the plane triangulation G, the vertex-$\mathcal{C}$ incidence bipartite graph $B_{\mathcal{C}} = (V, \mathcal{C}, E_B)$ is planar. Indeed, $B_{\mathcal{C}}$ is obtained from G by

- inserting a point w_T in the face T, $T \in \mathcal{C}$, and
- connecting w_T with the three vertices of the triangle T, and
- deleting all edges of G.

See also Figure 2. By Fact 1, as $\mathcal{C}$ is an edge clique cover of G, $G = B^2_{\mathcal{C}}[V]$, and by construction, $B_{\mathcal{C}}$ has $|\mathcal{C}| \leq k$ points.

Next, assume that $G = H^2[V]$ for some (planar) bipartite graph $H = (V, W, E_H)$ with $|W| \leq k$. Then, by Fact 1, $N_H(w)$, $w \in W$, form an edge clique cover of G with $|W| \leq k$ cliques. (Notice that, in this direction, we do not use the fact that H is planar. Any half-root of G with at most k points works.) ◀

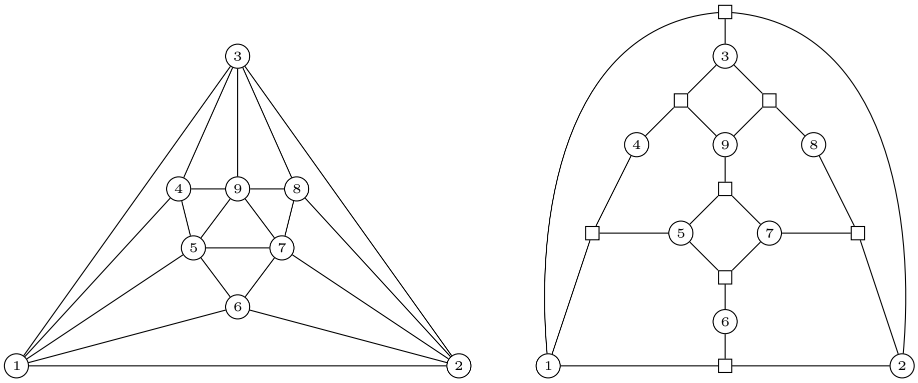

Figure 2 A triangulation G with the edge clique cover $\mathcal{C}$ consisting of the eight triangles 126, 278, 389, 349, 145, 567, 579, and 123, and the planar bipartite graph $B_{\mathcal{C}}$ obtained from G and $\mathcal{C}$.

We next consider the girth-six witness case. Recall that every planar graph has a witness of girth six. We are going to show that finding a witness of girth six with minimal number of points is hard. In a graph, a set of pairwise edge-disjoint triangles is called an independent triangle set. In [29], Uehara considered the following problem:

INDEPENDENT TRIANGLE SET
Instance: A graph $G = (V, E_G)$ and an integer k.
Question: Does G have k or more pairwise edge-disjoint triangles?

Uehara [29] proved that the INDEPENDENT TRIANGLE SET, restricted to plane triangulations, is NP-complete. Chang and Müller [3] observed that INDEPENDENT TRIANGLE SET is NP-complete even on plane triangulations in which every triangle is a face. (We leave the details to the full version.) Recall that we may further assume that all such plane triangulations are K_4-free.

▶ **Theorem 6.** POINT MINIMAL PLANAR GIRTH-6 REPRESENTATION *is* NP*-complete, even when restricted to planar graphs.*

Proof. Let $G = (V, E_G)$ be a plane triangulation without K_4 in which every triangle is a face, and let k be an integer. We will argue that G has k edge-disjoint triangles if and only if there is a C_4-free planar bipartite graph $B = (V, W, E_B)$ with $G = B^2[V]$ and $|W| \le m - 2k$. (As usual, m denotes the edge number of G.)

First, assume G has k edge-disjoint triangles $T_1, \ldots, T_k$. We construct a bipartite graph $B = (V, W, E_B)$ as follows; let F be the set of all edges of G not belonging to any triangle T_i, $1 \le i \le k$. For each $1 \le i \le k$, w_i is a point in W corresponding to T_i, and for each edge $e \in F$, w_e is a point in W corresponding to e. Then, B is the V-W incidence bipartite graph. Thus, $W = \{w_1, \ldots, w_k\} \cup \{w_e \mid e \in F\}$, and $E_B = \{vw_i \mid v \in V, v \in T_i, 1 \le i \le k\} \cup \{vw_e \mid v \in V, v \in e \in F\}$. Obviously, B is planar. Indeed, B is obtained from the plane triangulation G by

- inserting a point w_i in the face T_i, $1 \le i \le k$, and connecting w_i with the three vertices of T_i,
- subdividing each edge $e \in F$ by a point w_e, and
- deleting all edges in $T_1 \cup \ldots \cup T_k$.

Now, as each of the triangles T_i is a face of the plane triangulation G, B is clearly planar.

Since $\{T_1, \ldots, T_k\} \cup F$ is an edge clique cover of G, $G = B^2[V]$. Since the triangles T_i are edge-disjoint, $|N_B(w_i) \cap N_B(w_j)| \le 1$ for $1 \le i, j \le k$, $i \ne j$, and by definition of F, $|N_B(w_e) \cap N_B(w)| \le 1$ for all $e \in F$, $w \in W \setminus \{w_e\}$. That is, B is C_4-free. Moreover, B has $|W| = k + |F| = m - 2k$ points.

Next, assume that $G = H^2[V]$ for some (planar) C_4-free bipartite graph $H = (V, W, E_H)$ with $|W| \le m-2k$. Among all such bipartite graphs, let H have minimal number of points $|W|$. Since G is K_4-free, $|N_H(w)| \le 3$ for all $w \in W$. Since $|W|$ is minimal, $|N_H(w)| \ge 2$, and every two points have distinct neighborhoods. Let $w_1, \ldots, w_{k'}$ be the degree-3 points in W. Then, as H is C_4-free, $N_H(w_i)$, $1 \le i \le k'$, are k' edges-disjoint triangles in G. Since $G = H^2[V]$, G has $m = 3k' + (|W| - k') = |W| + 2k' \le m - 2k + 2k'$ edges. Therefore, $k' \ge k$. That is, G has at least k edges-disjoint triangles. ◀

Since, by Fact 1, POINT MINIMAL GIRTH-6 REPRESENTATION and EDGE CLIQUE PARTITION are equivalent, Theorem 6 implies:

▶ **Corollary 7.** EDGE CLIQUE PARTITION *is* NP*-complete on planar graphs.*

We remark that the complexity of EDGE CLIQUE PARTITION on planar graphs was previously unknown until this work (cf. [12]). Actually, the proof of Theorem 6 implies that EDGE CLIQUE PARTITION is NP-complete even for K_4-free maximal plane graphs in which every triangle is a face.

Now, let $t \ge 4$ be an integer, and assume that $G = B^2[V]$ for some planar bipartite graph $B = (V, W, E_B)$ of girth at least $2t$. By Lemma 1, any maximal clique in G is a neighborhood of some point $w \in W$, implying $|W| \ge |\mathcal{C}(G)|$. Thus, by Theorem 3, B_G is a minimal point planar girth-$2t$ representation for G. Note that, in this case, $\mathcal{C}(G)$ can be computed in polynomial time (cf. [19]), hence, by Theorems 5 and 6 we obtain:

▶ **Theorem 8.** POINT MINIMAL PLANAR GIRTH-AT-LEAST-$2t$ REPRESENTATION *is* NP*-complete for* $t \leq 3$ *and solvable in polynomial time otherwise.*

4 Tree-convex representations

Recall that a bipartite graph $B = (X, Y, E_B)$ is tree-convex on X (resp. Y) if there is a tree T on vertex set X (resp. Y) such that the neighborhood of any vertex $y \in Y$ (resp. $x \in X$) forms a subtree in T. B is tree-biconvex if it is both tree-convex on X and on Y. In this section we first characterize and recognize half-squares of tree-convex bipartite graphs and half-squares of tree-biconvex bipartite graphs. Characterizing and recognizing these half-squares have been left open in [18]. We then discuss the problem of determining such a representation with minimal number of points.

4.1 Half-squares of tree-convex bipartite graphs

In this section, we characterize half-squares of tree-convex bipartite graphs and of tree-biconvex bipartite graphs. It turns out that these are precisely the chordal and dually chordal graphs, and the double chordal graphs, respectively. We will use the following well known characterizations of chordal graphs which are classical by now (cf. [15, 24]).

▶ **Theorem 9.** *The following statements are equivalent for any graph* $G = (V, E)$*:*

(i) G *is chordal;*

(ii) G *is the vertex-intersection graph of subtrees in a tree: There are subtrees* T_v*,* $v \in V$*, of a tree* T *such that, for any pair of vertices* u, v *of* G*,* $uv \in E$ *if and only if* T_u *and* T_v *have a vertex in common;*

(iii) G *has a clique tree: There is a tree* T *on the maximal cliques of* G *with the property that, for any vertex* v *of* G*, the cliques containing* v *form a subtree of* T*.*

▶ **Lemma 10.** *Let* $B = (X, Y, E_B)$ *be a bipartite graph. If* B *is tree-convex on* Y*, then* $B^2[X]$ *is chordal and* $B^2[Y]$ *is dually chordal.*

Proof. Let B be tree-convex with an associated tree $T = (Y, E_T)$ such that, for each $v \in X$, $N_B(v)$ induces a subtree in T.

Then, by Theorem 9 (ii), $B^2[X]$ is chordal. We now show that $G = B^2[Y]$ is dually chordal. Note that we may assume that G is connected. Then T is a spanning tree of G. Indeed, consider an edge y_1y_2 of T, and let T_1 and T_2 be the two subtrees of $T - y_1y_2$ containing y_1 and y_2, respectively. Since $G = B^2[Y]$ is connected, some vertex $x \in X$ must have neighbors, in B, in both T_1 and T_2. Since $N_B(x)$ is a subtree of T, both y_1 and y_2 must be neighbors of such a vertex x. Therefore, y_1y_2 is an edge of $B^2[V] = G$, and hence T is a spanning tree of G as claimed. Now, consider an arbitrary maximal clique C of G, and suppose that $T[C]$ is not connected. Let $T_1, \ldots, T_q$ be the connected components of $T[C]$. Let $y \notin T[C]$ such that there is a connected component of $T - y$ contains only one of $T_1, \ldots, T_q$, say T_1. (As T is a tree, such vertex y exists.) Now, since C is a clique in G, for each $w \in T_1$ and $w' \in T_i$, $2 \leq i \leq q$, there is some $v \in X$ adjacent in B to both w and w'. Since $T[N(v)]$ is a subtree, v therefore must be adjacent in B to y. Thus, y is adjacent in G to every $w \in T_1$ and every $w' \in T_i$, $2 \leq i \leq q$. This contradicts the fact that C is a maximal clique in G. Thus, for any maximal clique C of G, $T[C]$ is a subtree in T, hence G is dually chordal. ◀

It follows from Lemma 10 that half-squares of tree-biconvex bipartite graphs are double chordal. The following lemma characterizes chordal graphs, dually chordal graphs and double chordal graphs in terms of their vertex-clique bipartite graphs.

▶ **Lemma 11.** *Let $G = (V, E_G)$ be a graph and let $B_G = (V, \mathcal{C}(G), E_B)$ the vertex-clique incidence bipartite graph of G. Then:*

(i) *G is chordal if and only if B_G is tree-convex on $\mathcal{C}(G)$.*

(ii) *G is dually chordal if and only if B_G is tree-convex on V.*

(iii) *G is double chordal if and only if B_G is tree-biconvex.*

Proof. (i): Let G be a chordal graph. By Theorem 9 (iii), G has a clique tree T. By definition of B_G and of T, for each $v \in V$, $N_{B_G}(v) = \{C \in \mathcal{C}(G) \mid v \in C\}$ induces a subtree in T. That is, B_G is tree-convex on $\mathcal{C}(G)$. The conserve follows from Lemma 10 with $B = B_G$, where $X = V$ and $Y = \mathcal{C}(G)$. (Recall that $G = B_G^2[V] = B^2[X]$.)

(ii): Let G be a (connected) dually chordal graph, and let $T = (V, E_T)$ be a spanning tree of G such that, for each maximal clique C of G, $T[C]$ is a subtree of T. Then, by definition of B_G, for each $w \in W$, $N_{B_G}(w)$ is a maximal clique in G, hence $N_{B_G}(w)$ induces a subtree in T. The converse follows from Lemma 10 with $B = B_G$, where $X = \mathcal{C}(G)$ and $Y = V$.

(iii): This part immediately follows from (i) and (ii). ◀

By Lemmas 10 and 11 we obtain:

▶ **Theorem 12.**

(i) *A graph is a half-square of a tree-convex bipartite graph if and only if it is chordal or dually chordal.*

(ii) *Half-squares of tree-biconvex bipartite graphs are exactly the double chordal graphs.*

Since chordal and dually chordal graphs, hence double chordal graphs, can be recognized in linear time, we obtain from Theorem 12:

▶ **Corollary 13.** *Deciding if a given graph is a half-square of a tree-(bi)convex bipartite graph can be done in linear time.*

4.2 Point minimal tree-convex representations

In the remainder of this section, we first show that POINT MINIMAL TREE-BICONVEX REPRESENTATION is solvable in linear time and then prove a complexity dichotomy theorem for POINT MINIMAL TREE-CONVEX REPRESENTATION.

We will show that, in fact, $\langle G, k \rangle$ is a yes-instance for POINT MINIMAL TREE-BICONVEX REPRESENTATION if and only if G is double chordal and k is at least the number of maximal cliques of G, $k \geq |\mathcal{C}(G)|$. If we ask for a tree-convex (not necessarily tree-biconvex) representation, k may be much smaller than $|\mathcal{C}(G)|$. See Figure 3 for an example.

The following fact will be useful in later discussions:

▶ **Lemma 14.** *Let $B = (X, Y, E_B)$ be tree-convex on Y. Then, for each maximal clique C of $B^2[X]$, there is some $y \in Y$ with $C = N_B(y)$.*

Proof. Let $T = (Y, E_T)$ be a tree such that, for any $x \in X$, $T[N_B(x)]$ is a subtree of T. Let C be a maximal clique in $B^2[X]$. Let $y \in T$ be a vertex with maximum $|N_B(y) \cap C|$. Suppose there is some $x \in C \setminus N_B(y)$. Let $w \in T$ be a neighbor of x in B that is closest to y in T, and let T_w be the connected component of $T - wy'$ containing w, where wy' is the w-edge on the w,y-path in T (possibly $y' = y$). Since B is tree-convex on Y with

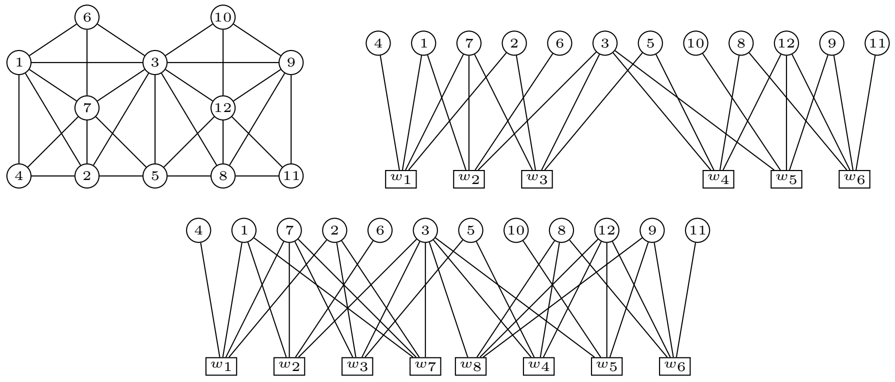

Figure 3 A double chordal graph G (top left), a point minimal tree-convex, not tree-biconvex, half-square root B (top right) and a point minimal tree-biconvex half-square root B_G of G (bottom).

tree T, $N_B(x) \subseteq T_w$. By the choice of y, there is some $x' \in N_B(y) \cap C \setminus N_B(w)$. As B is tree-convex on Y with tree T, we have $N_B(x') \subseteq T_y$ with T_y is the connected component of $T - yy''$ containing y, where yy'' is the y-edge on the y, w-path in T (possibly $y'' = w$). Since $T_w \cap T_y = \emptyset$, we have $N_B(x) \cap N_B(x') = \emptyset$. This contradicts the fact that x and x' are adjacent in $B^2[V]$.

Thus, $C \subseteq N_B(y)$, and by the maximality of the clique C, $C = N_B(y)$. ◀

Notice that tree-convex bipartite graphs need not be C_6-free, and C_6-free bipartite graphs need not be tree-convex. So, Lemma 14 and Lemma 1 are independent to each other.

▶ **Theorem 15.** POINT MINIMAL TREE-BICONVEX REPRESENTATION *is solvable in linear time.*

Proof. Let $\langle G, k \rangle$ be an instance for POINT MINIMAL TREE-BICONVEX REPRESENTATION. By Theorem 12 (ii) we may assume that $G = (V, E_G)$ is double chordal. Let $B = (V, W, E_G)$ be an arbitrary tree-biconvex bipartite graph with $G = B^2[V]$. By Lemma 14, every maximal clique C of G is the neighborhood $N_B(w)$ for some $w \in W$, implying $|W| \geq |\mathcal{C}(G)|$. Therefore, the vertex-clique incidence bipartite graph B_G of G (which is tree-biconvex by Lemma 11 (iii)) is a point optimal tree-biconvex half-root of G. That is, $\langle G, k \rangle$ is a yes-instance if and only if G is double chordal and $k \geq |\mathcal{C}(G)|$.

Finally, recall that double chordal graphs can be recognized in linear time, and that all maximal cliques of an n-vertex chordal graph (there are at most n) can be computed in linear time (and so B_G can be constructed in linear time, too). ◀

We now are providing a dichotomy for POINT MINIMAL TREE-CONVEX REPRESENTATION. We first begin with the hardness case.

▶ **Lemma 16.** POINT MINIMAL TREE-CONVEX REPRESENTATION *is* NP*-complete, when restricted to non-chordal dually chordal input graphs.*

Proof. Given an instance $\langle G = (V, E_G), k \rangle$ of POINT MINIMAL REPRESENTATION, construct an instance $\langle G', k' \rangle$ for POINT MINIMAL TREE-CONVEX REPRESENTATION as follows.

- G' is obtained from G by adding a new vertex u and all edges between u and all vertices of G, i.e., u is a universal vertex of G';
- $k' := k$.

Suppose that $G = B^2[V]$ for some bipartite graph $B = (V, W, E_B)$ with $|W| \leq k$. Consider $B' = (V', W', E_{B'})$ with $V' = V \cup \{u\}$, $W' = W$ and $E_{B'} = E_B \cup \{uw \mid w \in W\}$. Then it is easy to see that $G' = B'^2[V']$. Notice, moreover, that G' is dually chordal (as u is a universal vertex of G'), and B' is tree-convex (with a star $T = (V, \{uv \mid v \in V\})$).

Conversely, if $G' = H^2[V']$ for some bipartite graph $H = (V', W, E_H)$ with $|W| \leq k'$, regardless tree-convex or not, then clearly $G = B^2[V]$, where $B = H - u$ with at most $k = k'$ points.

Since POINT MINIMAL REPRESENTATION (viz., CLIQUE EDGE COVER) is NP-complete on non-chordal graphs, POINT MINIMAL TREE-CONVEX REPRESENTATION is NP-complete, when restricted to non-chordal dually chordal graphs. ◀

For the efficient solvable cases, we need the following characterization of dually chordal graphs which is slightly more flexible than the one stated in Lemma 11 (ii), and can be proved along the same line. (Notice that the characterization of chordal and double chordal graphs stated in Lemma 11 (i) and (iii), respectively, does not admit this flexibility.)

▶ **Lemma 17.** *Let $G = (V, E_G)$ be a graph and let $\mathcal{C}$ be an edge clique cover of G in which every member is a maximal clique. Let $B_{\mathcal{C}} = (V, \mathcal{C}, E_B)$ be the vertex-$\mathcal{C}$ incidence bipartite graph of G. Then G is dually chordal if and only if $B_{\mathcal{C}}$ is tree-convex on V.*

Notice that any edge clique cover can be modified in an obvious way to another one of the same size that consists of maximal cliques only.

▶ **Theorem 18.** POINT MINIMAL TREE-CONVEX REPRESENTATION *is* NP*-complete for non-chordal dually chordal inputs, and solvable in linear time otherwise.*

Proof. Let $\langle G, k\rangle$ be an instance for POINT MINIMAL TREE-CONVEX REPRESENTATION. By Theorem 12, we may assume that $G = (V, E_G)$ is chordal or dually chordal (otherwise, the output is 'no' as G does not have a tree-convex representation). Recall that chordal, as well as dually chordal graphs can be recognized in linear time.

By Lemma 16, it remains to consider the case in which G is chordal. The following procedure decides in linear time if G has a tree-convex representation with at most k points and, if so, outputs such one.

```
(1)  if $G$ is double chordal then
(2)      compute an optimal edge clique cover $\mathcal{C}$ of $G$ that consists of
(3)      maximal cliques only
(4)      if $k < |\mathcal{C}|$ then return 'no'
(5)      return the vertex-$\mathcal{C}$ incidence bipartite graph $B_{\mathcal{C}}$
(6)  else  // $G$ is chordal but not dually chordal
(7)      if $k < |\mathcal{C}(G)|$ then return 'no'
(8)      return the vertex-clique incidence bipartite graph $B_G$
```

Since G is chordal, an optimal edge clique cover $\mathcal{C}$ can be computed in linear time [23]. In fact, the optimal edge clique cover of a chordal graph computed in [23] consists of maximal cliques only. Also, recall that for any chordal graph $G = (V, E_G)$, $\mathcal{C}(G)$ consists of at most $|V|$ maximal cliques and all maximal cliques can be listed in linear time.

We now argue that the output of the procedure is a tree-convex representation with at most k points (if exists). Assume first that G is dually chordal (and hence G is double chordal). Then $B_{\mathcal{C}}$ is tree-convex (on V) by Lemma 17. Thus, by Fact 1, $B_{\mathcal{C}}$ is a point optimal tree-convex representation of G. So, the outputs at lines (4) and (5) are correct.

In the second case, let us assume that G is not dually chordal. Then, by Lemma 10, for any tree-convex representation $B = (V, W, E_B)$ of G, B must be tree-convex on W. Hence, by Lemma 14, every maximal clique of $G = B^2[V]$ is the neighborhood $N_B(w)$ for some $w \in W$, implying $|W| \geq |\mathcal{C}(G)|$. Therefore, the vertex-clique incidence bipartite graph B_G of G (which is, by Lemma 11 (i), tree-convex on $\mathcal{C}(G)$; recall that G is chordal) is a point optimal tree-convex half-root of G. Thus, the outputs at lines (7) and (8) are correct. ◀

5 Conclusion

Though the computational complexity of MINIMAL POINT PLANAR GIRTH-g REPRESENTATION is completely determined (Theorem 8), the problem of characterizing and recognizing map graphs with girth-6 witness is still open. Recall that, by definition, all map graphs have a witness of girth at least 4, and that all map graphs with witness of girth $g \geq 8$ admit good characterizations which lead to simple cubic time recognition algorithms [19]. Since any planar graph has a girth-six witness (e.g., its subdivision), it is natural to study map graphs with girth-six witness. Thus, recognizing and characterizing map graphs with girth-six witness are two interesting open problems.

In contrast to large-girth witnesses, maximal witnesses (i.e., maximal planar bipartite graphs) have girth four. Recognizing and characterizing map graphs with maximal witness are two other interesting open problems for further research.

Perhaps, another way to look for a simpler and more efficient algorithm than the one of Thorup is to consider restricted input graphs (rather than restricted witnesses). So, recognizing map graphs is trivial if the input graphs are planar. But it is not obvious for other restricted graph classes; especially for graphs with arbitrary large cliques. In particular, it seems that it is not easy to recognize chordal map graphs in polynomial time without using Thorup's algorithm.

Abstract

The Colouring problem is to decide if the vertices of a graph can be coloured with at most k colours for an integer k, such that no two adjacent vertices are coloured alike. A graph G is H-free if G does not contain H as an induced subgraph. It is known that Colouring is NP-complete for H-free graphs if H contains a cycle or claw, even for fixed $k \geq 3$. We examine to what extent the situation may change if in addition the input graph has bounded diameter.

1 Introduction

Graph colouring is one of the best studied concepts in Computer Science and Mathematics. This is mainly due to its many practical and theoretical applications and its many natural variants and generalizations. Over the years, numerous surveys and books on graph colouring were published (see, for example, [1, 4, 18, 21, 26, 28, 31]).

A *(vertex) colouring* of a graph $G = (V, E)$ is a mapping $c : V \to \{1, 2, \ldots\}$ that assigns each vertex $u \in V$ a *colour* $c(u)$ in such a way that $c(u) \neq c(v)$ whenever $uv \in E$. If $1 \leq c(u) \leq k$, then c is said to be a *k-colouring* of G and G is said to be *k-colourable*. The Colouring problem is to decide if a given graph G has a k-colouring for some given integer k. If k is *fixed*, that is, k is not part of the input, we denote the problem by k-Colouring. It is well known that even 3-Colouring is NP-complete [23].

In this paper we aim to increase our understanding of the computational hardness of Colouring. One way to do this is to consider inputs from families of graphs to learn more about the kind of graph structure that causes the hardness. This led to a highly extensive study of Colouring and k-Colouring for many special graph classes. The best-known result in this direction is due to Grötschel, Lovász, and Schrijver, who proved that Colouring is polynomial-time solvable for perfect graphs [13].

Perfect graphs form an example of a graph class that is closed under vertex deletion. Such graph classes are also called *hereditary*. Hereditary graph classes are ideally suited for a *systematic* study in the computational complexity of graph problems. Not only do they capture a very large collection of many well-studied graph classes, but they are also exactly the graph classes that can be characterized by a unique set $\mathcal{H}$ of minimal forbidden induced subgraphs. When solving an NP-hard problem under input restrictions, it is standard practice to consider, for example, first the case where $\mathcal{H}$ has small size, or where each $H \in \mathcal{H}$ has small size.

We note that the set $\mathcal{H}$ defined above may be infinite. If not, say $\mathcal{H} = \{H_1, \ldots, H_p\}$ for some positive integer p, then the corresponding hereditary graph class $\mathcal{G}$ is said to be *finitely defined*. Formally, a graph G is $(H_1, \ldots, H_p)$*-free* if for each $i \in \{1, \ldots, p\}$, G is H_i*-free*, where the latter means that G does not contain an induced subgraph isomorphic to H_i.

We emphasize that the borderline between NP-hardness and tractability is often far from clear beforehand and jumps in computational complexity can be extreme. In order to illustrate this behaviour of graph problems, we present the following example of a (somewhat artificial) graph problem related to vertex colouring.

Colouring-or-Subgraph
Instance: an n-vertex graph G
Question: is G $\lceil\sqrt{\log n}\rceil$-colourable or H-free for some graph H with $|V(H)| \leq \lceil\sqrt{\log n}\rceil$?

▶ **Theorem 1.** *The* Colouring-or-Subgraph *problem is* NP*-hard, but constant-time solvable for every hereditary graph class not equal to the class of all graphs.*

Proof. We reduce from 3-Colouring, which we recall is NP-complete [23]. Let G be an n-vertex graph. Set $k = \lceil\sqrt{\log n}\rceil$. Add $k - 3$ pairwise adjacent vertices to G. Make the new vertices also adjacent to every vertex of G. Add each possible graph on k vertices as a connected component to G. The resulting graph G' has $n + (k-3) + k \cdot 2^{\frac{k(k-1)}{2}} < 3n^2$ vertices. By construction, G' contains every graph on at most k vertices as an induced subgraph. Hence, G' is a yes-instance of Colouring-or-Subgraph if and only if G' is k-colourable, and the latter holds if and only if G is 3-colourable.

Now let $\mathcal{G}$ be a hereditary graph class for which there exist at least one graph H such that every graph $G \in \mathcal{G}$ is H-free. Let $\ell = |V(H)|$. We claim that Colouring-or-Subgraph is constant-time solvable for $\mathcal{G}$. Let $G \in \mathcal{G}$ be an n-vertex graph. If $n \leq 2^{|\ell|^2}$, then G has constant size and the problem is constant-time solvable. If $n > 2^{|\ell|^2}$, then $\ell = |V(H)| < \sqrt{\log n} \leq \lceil\sqrt{\log n}\rceil$. Hence G is a yes-instance of Colouring-or-Subgraph, as G is H-free and H has less than $\lceil\sqrt{\log n}\rceil$ vertices. ◀

In this paper, we consider the problems Colouring and k-Colouring. In order to describe known results and our new results we first give some terminology and notation.

1.1 Terminology and Notation

The *disjoint union* of two vertex-disjoint graphs F and G is the graph $G + F = (V(F) \cup V(G), E(F) \cup E(G))$. The disjoint union of s copies of a graph G is denoted sG. A *linear forest* is the disjoint union of paths. The *length* of a path or a cycle is the number of its edges. The *distance* $\text{dist}(u, v)$ between two vertices u, v in a graph G is the length of a shortest induced path between them. The *diameter* of a graph G is the maximum distance over all pairs of vertices in G. The *girth* of a graph G is the length of a shortest induced cycle of G. The graphs C_r, P_r and K_r denote the cycle, path and complete graph on r vertices, respectively.

A *polyad* is a tree where exactly one vertex has degree at least 3. We will use several special polyads in our paper. The graph $K_{1,r}$ denotes the $(r+1)$-vertex *star*, that is, the graph with vertices $x, y_1, \ldots, y_r$ and edges xy_i for $i = 1, \ldots, r$. The graph $K_{1,3}$ is also called the *claw*. The *subdivision* of an edge uw in a graph removes uw and replaces it with a new vertex v and edges uv, vw. We let $K_{1,r}^{\ell}$ denote the *ℓ-subdivided star*, which is the graph obtained from a star $K_{1,r}$ by subdividing one edge of $K_{1,r}$ exactly ℓ times. The graph $S_{h,i,j}$, for $1 \leq h \leq i \leq j$, denotes the *subdivided claw*, which is the tree with one vertex x of degree 3 and exactly three leaves, which are of distance h, i and j from x, respectively. Note that $S_{1,1,1} = K_{1,3}$. The graph $S_{1,1,2} = K_{1,3}^1$ is also known as the *chair*.

1.2 Known Results

The computational complexity of Colouring has been fully classified for H-free graphs: if H is an induced subgraph of $P_1 + P_3$ or of P_4, then Colouring for H-free graphs is polynomial-time solvable, and otherwise it is NP-complete [20]. In contrast, the complexity classification for k-Colouring restricted to H-free graphs is still incomplete. It is known that for every $k \geq 3$, k-Colouring for H-free graphs is NP-complete if H contains a cycle [10] or an induced claw [16, 22]. However, the remaining case where H is a linear forest has not been settled yet even if H consists of a single path. For P_t-free graphs, the cases $k \leq 2$, $t \geq 1$ (trivial), $k \geq 3$, $t \leq 5$ [14], $k = 3$, $6 \leq t \leq 7$ [2] and $k = 4$, $t = 6$ [6] are polynomial-time solvable and the cases $k = 4$, $t \geq 7$ [17] and $k \geq 5$, $t \geq 6$ [17] are NP-complete. The cases where $k = 3$ and $t \geq 8$ are still open. For further details, including for linear forests H of more than one connected component, see the survey paper [11] or some recent papers [5, 12, 19].

1.3 Our Focus

We consider H-free graphs where H contains a cycle or claw. In this case, k-Colouring restricted to H-free graphs is NP-compete for every $k \geq 3$, as mentioned above. However, we re-examine the situation after adding a diameter constraint to our input graphs. If the diameter is 1, then G is a complete graph, and Colouring becomes trivial. As such, our research question is:

To what extent does bounding the diameter help making Colouring *and* k-Colouring *tractable on H-free graphs?*

We remark that H-free graphs of diameter at most d for some integer d are no longer hereditary, which requires some care in the proof of our results. We also note that by a straightforward reduction from 3-Colouring one can show that k-Colouring is NP-complete for graphs of diameter d for all pairs (k, d) with $k \geq 3$ and $d \geq 2$ except for two cases, namely $(k, d) \in \{(3, 2), (3, 3)\}$. Mertzios and Spirakis [24] settled the case $(k, d) = (3, 3)$ by proving that 3-Colouring is NP-complete even for C_3-free graphs of diameter 3. The case $(k, d) = (3, 2)$ is still open.

1.4 Our Results

We complement the bounded diameter results of Mertzios and Spirakis [24] by presenting a set of new results for Colouring and k-Colouring for H-free graphs of bounded diameter when H contains a claw or a cycle. Results for the case where H has a cycle usually follow from stronger results for graphs of girth at least g for some fixed integer g. In particular, Emden-Weinert, Hougardy and Kreuter [10] proved that for all integers $k \geq 3$ and $g \geq 3$, k-Colouring is NP-complete for graphs with girth at least g and with maximum degree at most $6k^{13}$ (for more results on Colouring for graphs of maximum degree, see [3, 7, 25]).

First, in Section 3 we research the effect on bounding the diameter of k-Colouring and Colouring restricted to polyad-free graphs for various polyads. Our first result, which formed together with the result of [24] the starting point of our investigation, is that k-Colouring is constant-time solvable for $K_{1,r}$-free graphs of diameter d for any fixed integers $d \geq 1$, $k \geq 1$ and $r \geq 1$. We also show that this does not hold for Colouring (when k is part of the input). We then extend these results for larger polyads; see also Figure 1.

Second, in Section 4 we perform a similar study for graphs of bounded diameter and girth. We provide new polynomial-time and NP-hardness results for k-Colouring, identifying and

Colours	Diameter	H-free	Complexity	Theorem

Figure 2 The complexity of 3-Colouring for graphs of diameter at most d and girth at least g.

2 Preliminaries

In this section we complement Section 1.1 by giving some additional terminology and notation. We also recall some useful results from the literature.

Let $G = (V, E)$ be a graph. A vertex $u \in V$ is *dominating* if u is adjacent to every other vertex of G. For a set $S \subseteq V$, the graph $G[S]$ denotes the subgraph of G induced by S. The *neighbourhood* of a vertex $u \in V$ is the set $N(u) = \{v \mid uv \in E\}$ and the *degree* of u is the size of $N(u)$. For a set $U \subseteq V$, we write $N(U) = \bigcup_{u \in U} N(u) \setminus U$. For a set $U \subseteq V$ and a vertex $u \in U$, the *private neighbourhood* of u with respect to U is the set $N(u) \setminus (N(U \setminus \{u\}) \cup U)$ of *private neighbours* of u with respect to U, which is the set of neighbours of u outside U that are not a neighbour of any other vertex of U. If every vertex of G has degree p, then G is *(p)-regular*.

We will use the aforementioned results of Král' et al.; Holyer; Leven and Galil; Emden-Weinert, Hougardy and Kreuter; and Mertzios and Spirakis.

▶ **Theorem 2** ([20]). *Let H be a graph. If $H \subseteq_i P_4$ or $H \subseteq_i P_1 + P_3$, then* Colouring *restricted to H-free graphs is polynomial-time solvable, otherwise it is* NP*-complete.*

▶ **Theorem 3** ([16, 22]). *For every integer $k \geq 3$, k-*Colouring *is* NP*-complete for claw-free graphs.*

▶ **Theorem 4** ([10]). *For all integers $k \geq 3$ and $g \geq 3$, k-*Colouring *is* NP*-complete for graphs with girth at least g (and with maximum degree at most $6k^{13}$).*

▶ **Theorem 5** ([24]). 3-Colouring *is NP-complete for C_3-free graphs of diameter* 3.

A *list assignment* of a graph $G = (V, E)$ is a function L that prescribes a *list of admissible colours* $L(u) \subseteq \{1, 2, \ldots\}$ to each $u \in V$. A colouring c *respects* L if $c(u) \in L(u)$ for every $u \in V$. If $|L(u)| \leq 2$ for each $u \in V$, then L is also called a 2-*list assignment*. The 2-List Colouring problem is to decide if a graph G with a 2-list assignment L has a colouring that respects G. Our strategy for obtaining a polynomial-time algorithm for 3-Colouring is often to reduce the input to a polynomial number of instances of 2-List Colouring. The reason is that we can then apply the following well-known result of Edwards.

▶ **Theorem 6** ([9]). *The* 2-List Colouring *problem is linear-time solvable.*

We will also use the following result, which includes the Hoffman-Singleton Theorem, which provides a description of regular graphs of diameter 2 and girth 5.

▶ **Theorem 7** ([8, 15, 30]). *For every $d \geq 1$, every graph of diameter d and girth $2d + 1$ is p-regular for some integer p. Moreover, if $d = 2$, then there are only four such graphs (with $p = 2, 3, 7, 57$, respectively) and if $d \geq 3$, then such graphs are cycles (of length $2d + 1$).*

A *clique* in a graph is a set of pairwise adjacent vertices, and an *independent set* is a set of pairwise non-adjacent vertices. By Ramsey's Theorem [27], there exists a constant, which we denote by $R(k, r)$, such that any graph on at least $R(k, r)$ vertices contains either a clique of size k or an independent set of size r.

3 Polyad-Free Graphs of Bounded Diameter

In this section we prove, among other things, our results on Colouring and k-Colouring for polyad-free graphs of bounded diameter; see also Figure 1. We first make an observation.

▶ **Lemma 8.** *If G is a graph of diameter d that is not a tree, then G contains an induced cycle of length at most $2d + 1$.*

Proof. As G is not a tree and G is connected, G must contain a cycle C. Suppose that C has length at least $2d + 2$. Since G has diameter d, there exists a path of length at most d in G between any two vertices u and v at distance $d + 1$ in C. The vertices of this path, together with the vertices of the path of length $d + 1$ between u and v on C, induce a subgraph of G that contains an induced cycle C' of length at most $2d + 1$. ◀

We now state our first result, which forms the starting point of the research in this section.

▶ **Theorem 9.** *For all integers $d, k, r \geq 1$, k-*Colouring *is constant-time solvable for $K_{1,r}$-free graphs of diameter d.*

Proof. Let $G = (V, E)$ be a $K_{1,r}$-free graph of diameter d. We prove that if G has size larger than some constant $\beta(k, r)$, which we determine below, then G is not k-colourable. If $|V(G)| \leq \beta(k, r)$, we can solve k-Colouring in constant time.

As G is $K_{1,r}$-free, Ramsey's Theorem tells us that the neighbourhood of every vertex $u \in V$ with degree at least $R(k, r)$ contains a clique of size k. In that case $N(u) \cup \{u\}$ is a clique of size $k + 1$. Hence, to be k-colourable, every vertex of G must have degree less than $R(k, r)$, so G must have at most $\beta(k, r) = 1 + R(k, r) + R(k, r)^2 + \ldots + R(k, r)^d$ vertices. ◀

If k is not part of the input, Theorem 9 no longer holds. This is shown by the following more general theorem. In this theorem we assume that $H \not\subseteq_i P_1 + P_3$ and $H \not\subseteq_i P_4$, as in those cases Colouring is polynomial-time solvable for all H-free graphs due to Theorem 2. Note that Theorem 10 covers all remaining cases except the case where $H = K_{1,3}$.

▶ **Theorem 10.** *Let H be a graph with $H \not\subseteq_i P_1 + P_3$ and $H \not\subseteq_i P_4$ and d be an integer. Then* Colouring *for H-free graphs of diameter at most d is*

1. *NP-complete if H has no dominating vertex u such that $H - u \subseteq_i P_1 + P_3$ or $H - u \subseteq_i P_4$ and $d \geq 2$;*
2. *NP-complete if $H \neq K_{1,3}$ and H has a dominating vertex u such that $H - u \subseteq_i P_1 + P_3$ or $H - u \subseteq_i P_4$ and $d \geq 3$.*

Proof.

1. Let H have no dominating vertex u such that $H-u \subseteq_i P_1+P_3$ or $H-u \subseteq_i P_4$. We define H' as $H - u$ if H has a dominating vertex u and as H itself otherwise. By construction, $H' \not\subseteq_i P_1 + P_3$ and $H' \not\subseteq_i P_4$. Hence, Colouring is NP-complete for H'-free graphs due to Theorem 2. Let G be an H'-free graph. Add a dominating vertex to G. The new graph G' has diameter 2 and is H-free. Moreover, G is k-colourable if and only if G' is $(k + 1)$-colourable.
2. Let $H \neq K_{1,3}$ have a dominating vertex u such that $H - u \subseteq_i P_1 + P_3$ or $H - u \subseteq_i P_4$. Then H cannot be a forest, as in that case H would be in $\{P_1, P_2, P_3, K_{1,3}\}$. Hence, H has an induced cycle C_r for some $r \geq 3$. If $r = 3$, then 3-Colouring is NP-complete for H-free graphs of diameter 3, as it is so for C_3-free graphs of diameter 3 due to Theorem 5. If $r \geq 4$, then Colouring is NP-complete even for H-free graphs of diameter 2, as it is so for C_r-free graphs of diameter 2 due to **1**. ◀

It is a natural question whether we can extend Theorem 9 to H-free graphs of diameter d, where H is a slightly larger tree than a star. The first interesting case is where H is an ℓ-subdivided star $K_{1,r}^{\ell}$ for some integer $\ell \geq 1$ and $r \geq 3$. We prove a number of results for various values of d,k,ℓ. For one of our proofs and also for the proof of our next result we need the following theorem.

▶ **Theorem 11.** 3-Colouring *can be solved in polynomial time for C_5-free graphs of diameter at most* 2.

Proof. If G is bipartite, then G is 3-colourable. If G contains a K_4, then G is not 3-colourable. We check these properties in polynomial time, and from now on we assume that G is K_4-free and non-bipartite. The latter implies that G must have an odd induced cycle C_r for some odd integer r. As G has diameter 2, we find that $r \leq 5$ due to Lemma 8. As G is C_5-free, it follows that $r = 3$.

Let C be a triangle in G. We write $N_0 = V(C) = \{x_1, x_2, x_3\}$, $N_1 = N(V(C))$ and $N_2 = V(G) \setminus (N_0 \cup N_1)$. As G has diameter 2, for every $i \in \{1, 2, 3\}$, it holds that every vertex in N_2 has a neighbour in N_1 that is adjacent to x_i.

We let T consist of all vertices of N_2 that have a neighbour in N_1 that is adjacent to exactly two vertices of N_0. We claim that $N_2 = T$. In order to see this, let $u \in N_2$. If u has a neighbour $y \in N_1$ adjacent to every x_i, then G contains a K_4, a contradiction. Hence, u must have three distinct neighbour y_1, y_2, y_3, such that for $i \in \{1, 2, 3\}$, it holds that $N(y_i) \cap N_0 = \{x_i\}$. If $\{y_1, y_2, y_3\}$ is a clique, then G has a K_4 on vertices u, y_1, y_2, y_3, a contradiction. Hence, we may assume without loss of generality that y_1 and y_2 are non-adjacent. However, then $\{u, y_1, x_1, x_2, y_2\}$ induces a C_5 in G, another contradiction. We conclude that $T = N_2$.

If G has a 3-colouring c, then we may assume without loss of generality that $c(x_i) = i$ for $i \in \{1, 2, 3\}$. Hence, our algorithm assigns colours 1, 2, 3 to x_1, x_2, x_3, respectively. This reduces the list of admissible colours of the vertices of N_1 by at least one colour. In particular, vertices in N_1 that have two neighbours in N_0 can be coloured with only one colour. Our algorithm assigns this colour to such vertices. This means that any of their neighbours in $T = N_2$ can be coloured with at most two colours. So, after propagation, we have obtained either two adjacent vertices that are coloured alike, in which case G is not 3-colourable, or we have constructed an instance of 2-List Colouring. We can solve such an instance in linear time due to Theorem 6. ◀

We are now ready to state our results for $K_{1,r}^{\ell}$, where we exclude the cases that are tractable in general, namely where $d = 1$, or $k \leq 2$, or $r \leq 2$ (the latter case corresponds to the case where $H = K_{1,2}^{+} = P_4$, so we can use Theorem 2). Note that for $k \geq 4$ all interesting cases are NP-complete, whereas for $k = 3$ the situation is less clear.

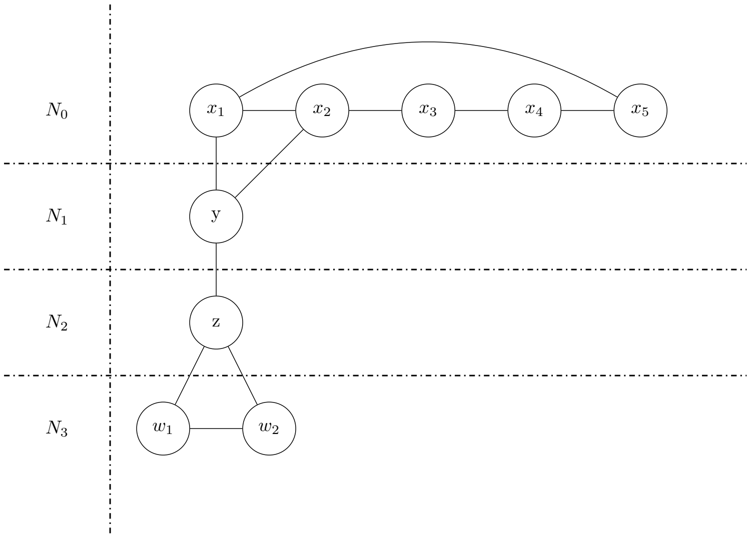

Figure 3 An example of a decomposition of a chair-free graph of diameter 3 into sets $N_0, \ldots, N_3$ where $p = 5$ and $y \in N_1$ has two “descendants” in N_3. To prevent an induced chair, y must be adjacent to exactly two (adjacent) vertices of N_0, and w_1 and w_2 must be adjacent to each other.

▶ **Theorem 12.** *Let d, k, ℓ, r be four integers with $d \geq 2$, $k \geq 3$, $\ell \geq 1$ and $r \geq 3$. Then k-Colouring for $K_{1,r}^{\ell}$-free graphs of diameter at most d is:*

1. *polynomial-time solvable if $d \geq 2$, $k = 3$, $\ell = 1$ and $r = 3$*
2. *polynomial-time solvable if $d = 2$, $k = 3$, $\ell = 2$ and $r \geq 3$*
3. *NP-complete if $d \geq 4$, $k = 3$, $\ell \geq 3$ and $r \geq 4$*
4. *NP-complete if $d \geq 2$, $k \geq 4$, $\ell \geq 1$ and $r \geq 3$.*

Proof.

1. Recall that $K_{1,3}^{1}$ is the chair $S_{1,1,2}$. Let G be a chair-free graph of diameter d. If G is a tree, then G is even 2-colourable. We check in $O(n^4)$ time if G has a K_4. If so, then G is not 3-colourable. From now on we assume that G is not a tree and that G is K_4-free. As G is not a tree and G is connected, G contains an induced cycle of length at most $2d + 1$ by Lemma 8. We can find a largest induced cycle C of length at most $2d + 1$ in $O(n^{2d+1})$ time. Let $|V(C)| = p$. We write $N_0 = V(C) = \{x_1, x_2, \ldots, x_p\}$ and for $i \geq 1$, $N_i = N(N_{i-1}) \setminus N_{i-2}$. So the sets N_i partition $V(G)$, and the distance of a vertex $u \in N_i$ to N_0 is i.

Case 1. $4 \leq p \leq 2d + 1$.

This case is illustrated in Figure 3. We consider every possible 3-colouring of C. Let c be such a 3-colouring. Every vertex with two differently coloured neighbours can only be coloured with one remaining colour. We assign this unique colour to such a vertex and apply this rule as long as possible. This takes polynomial time. The remaining vertices have a list of admissible colours that either consists of two or three colours, and vertices in the latter case belong to $V(G) \setminus (N_0 \cup N_1)$ (as $N(N_0) = N_1$).

If $N_2 = \emptyset$, then $V(G) = N_0 \cup N_1$. Then, we obtained an instance of 2-List Colouring, which we can solve in linear time due to Theorem 6. Now assume that $N_2 \neq \emptyset$. Let $z \in N_2$. Then z has a neighbour $y \in N_1$, which in turn has a neighbour $x \in N_0$. If y is adjacent to neither neighbour of x on N_0, then z, y, x and these two neighbours induce a chair in G, a contradiction. Hence, y must be adjacent to at least one neighbour of x on N_0, meaning that y must have received a colour by our algorithm. Consequently, z must have a list of admissible colours of size at most 2.

From the above we deduce that every vertex in N_2 has only two available colours in its list. We now consider the vertices of N_3. Let $z' \in N_3$. Then z' has a neighbour $z \in N_2$, which in turn has a neighbour $y \in N_1$, which in turn has a neighbour $x \in N_0$, say $x = x_1$. If y has two non-adjacent neighbours in N_0, then z', z, y and these two non-adjacent neighbours of y induce a chair in G, a contradiction. Combined with the fact deduced above, we conclude that y must have exactly two neighbours in N_0 and these two neighbours must be adjacent, say x_2 is the other neighbour of y in N_0.

Suppose x_1 and x_2 are both adjacent to a vertex $y' \in N_1 \setminus \{y\}$ that is adjacent to a vertex in N_2 that has a neighbour in N_3. Then, just as in the case of vertex y, the two vertices x_1 and x_2 are the only two neighbours of y' in N_0. If y and y' are not adjacent, this means that x_2, x_3, x_4, y, y' induce a chair in G, a contradiction. Hence y and y' must be adjacent. However, then x_1, x_2, y, y' form a K_4, a contradiction. This means that every pair of adjacent vertices of N_0 can have at most one common neighbour in N_1 that is adjacent to a vertex in N_2 with a neighbour in N_3. We already deduced that every vertex of N_1 with a "descendant" in N_3 has exactly two neighbours in N_0, which are adjacent. Hence, we conclude that the number of such vertices of N_1 is at most p.

We now observe that for $i \geq 2$, every vertex in N_i has at most two neighbours in N_{i+1}. This can be seen as follows. If $v \in N_i$ has two non-adjacent neighbours w_1, w_2 in N_{i+1}, then we pick a neighbour u of v in N_{i-1}, which has a neighbour t in N_{i-2}. Then v, u, t, w_1, w_2 induce a chair in G, a contradiction. Hence , the neighbourhood of every vertex in N_i in N_{i+1} is a clique, which must have size at most 2 due to the K_4-freeness of G. As the number of vertices in N_1 with a "descendant" in N_3 is at most p, this means that there are at most $2^{i-1}p$ vertices in N_i with a neighbour in N_{i+1}. Therefore the total number of vertices not belonging to any of the sets N_0, N_1 or N_2 is at most $\sum_{i=3}^{d} 2^{i-1}p$. This means the total number of vertices not belonging to N_1 or N_2 is at most $\beta(d) = \sum_{i=3}^{d} 2^{i-1}p + p \leq \sum_{i=3}^{d} 2^{i-1}(2d+1) + 2d + 1$. Let T_c be this set. We consider every possible 3-colouring of $G[T_c]$. As we already deduced that the vertices in $N_1 \cup N_2$ have a list of size at most 2, for each case we obtain an instance of 2-List Colouring, which we can solve in linear time due to Theorem 6. As the total number of instances we need to consider is at most $3^p \times 3^{\beta(d)} \leq 3^{2d+1} \times 3^{\beta(d)}$, our algorithm runs in polynomial time.

Case 2. $p = 3$.

As p was the size of a largest induced cycle of length at most $2d+1$ and $2d+1 \geq 5$, we find that G is C_4-free. As G is K_4-free, each vertex of N_1 is adjacent to at most two vertices of N_0. If a vertex $x \in N_0$ has two independent private neighbours u and v in N_1 with respect to N_0, then every neighbour w of u in N_2 must also be a neighbour of v and vice versa, since G is chair-free. However, this is not possible, as x, u, w, v induce a C_4.

We conclude that u and v must be adjacent. Therefore, as G is K_4-free, every vertex of N_0 has at most two private neighbours in N_1, with respect to N_0, that have a neighbour in N_2.

By the same arguments as above we deduce that every two vertices of N_0 have at most one common neighbour in N_1 that is adjacent to a vertex in N_2. Combined with the above, we find that there at most $6+3=9$ vertices in N_1 that have a neighbour in N_2. If a vertex in N_1 has two independent neighbours in N_2, then G contains an induced chair, which is not possible. Hence the neighbourhood of a vertex in N_1 in N_2 is a clique, which has size at most 2 due to the K_4-freeness of G. We conclude that $|N_2| \leq 9 \times 2 = 18$. Similarly, every vertex in N_i for $i \geq 3$ has at most two neighbours in N_{i+1}. Therefore the number of vertices in N_i for $i \geq 3$ is at most $18 \times 2^{i-2}$. This means that the total number of vertices outside $N_0 \cup N_1 \cup N_2$ is at most $\beta(d) = \sum_{i=3}^{d} 18 \times 2^{i-2}$. Let T be this set. We consider every possible 3-colouring of $G[T]$ and every possible 3-colouring of C. For each case we obtain an instance of 2-List Colouring, which we can solve in linear time due to Theorem 6. As the total number of instances we need to consider is at most $3^d \times 3^{\beta(d)}$, our algorithm runs in polynomial time.

2. Let G be a $K_{1,r}^2$-free graph of diameter at most 2. We first check in $O(n^4)$ time if G is K_4-free. If not, then G is not 3-colourable. We then check in $O(n^5)$ time if G has an induced C_5. If G is C_5-free, then we use Theorem 11. From now on, suppose that G is K_4-free and that G contains an induced cycle C of length 5, say on vertices $x_1, \ldots, x_5$ in that order. We write $N_0 = V(C) = \{x_1, \ldots, x_5\}$, $N_1 = N(V(C))$ and $N_2 = V(G) \setminus (N_0 \cup N_1)$. Let N_2' be the set of vertices in N_2 that are adjacent to some vertex in N_1 that is a private neighbour of some vertex in N_0 with respect to N_0. As G is K_4-free, the private neighbourhood $P(x_i)$ of each vertex $x_i \in N_0$ with respect to N_0 does not contain a clique of size 3. Moreover, if $P(x_i)$ contains an independent set I of size $r-1$ for some $i \in \{1, \ldots, 5\}$, then $I \cup \{x_i, x_{i+1}, x_{i+2}, x_{i+3}\}$ induces a $K_{1,r}^2$, which is not possible. Now let $v \in P(x_i)$ for some $i \in \{1, \ldots 5\}$, say $i = 1$. As G is K_4-free, the set $N(v) \cap N_2$ does not contain a clique of size 3. Moreover, if $N(v) \cap N_2$ contains an independent set I' of size $r-1$, then $I' \cup \{v, x_1, x_2, x_3, \}$ induces a $K_{1,r}^2$, which is not possible. Hence, $|N(v) \cap N_2| \leq R(3, r-1)$ by Ramsey's Theorem. We conclude that $|N_2'| \leq 5R(3, r-1)^2$.
We now consider all possible 3-colourings of C. Let c be such a 3-colouring. We assume without loss of generality that $c(x_1) = c(x_3) = 1$, $c(x_2) = c(x_4) = 2$ and $c(x_5) = 3$. Moreover, every vertex that has two differently coloured neighbours can only be coloured with one remaining colour. We assign this unique colour to such a vertex and apply this rule as long as possible. This takes polynomial time. The remaining vertices have a list of admissible colours that either consists of two or three colours, and vertices in the latter case must belong to N_2 (as $N(N_0) = N_1$).
Let T_c be the set of vertices in N_2 that still have a list of size 3. We will prove that $T_c \subseteq N_2'$. Let $u \in T_c$. As G has diameter 2, we find that u has a neighbour v adjacent to x_5. Then v cannot be adjacent to any of $x_1, \ldots, x_4$, as otherwise v would have a unique colour and u would not be in T_c. Hence, v is a private neighbour of x_5 with respect to N_0. We conclude that all vertices in T_c belong to N_2', which implies that $|T_c| \leq |N_2'| \leq 5R(3, r-1)^2$.
We now consider every possible 3-colouring of $G[T_c]$. Then all uncoloured vertices have a list of size at most 2. In other words, we created an instance of 2-List Colouring, which we solve in linear time using Theorem 6. As the number of 3-colourings of C is at most 3^5 and for each 3-colouring c of C the number of 3-colourings of $G[T_c]$ is at most $3^{5R(3,r-1)^2}$, the total running time of our algorithm is polynomial.

3. We consider the standard reduction from the NP-complete problem NAE 3-SAT [29], where each variable appears in at most three clauses and each literal appears in at most two. Given a CNF formula ϕ, we construct the graph G as follows:
   - Add a vertex v_{x_i} for each literal x_i.
   - Add an edge between each literal and its negation.
   - Add a vertex z adjacent to every literal vertex.
   - For each clause C_i add a triangle T_i with vertices $c_{i_1}, c_{i_2}, c_{i_3}$.
   - Fix an arbitrary order of the literals of C_i, $x_{i_1}, x_{i_2}, x_{i_3}$ and add an edge $x_{i_j}c_{i_j}$.

   Given a 3-colouring of G, assume z is assigned colour 1. Then each literal vertex is assigned either colour 2 or colour 3. If, for some clause C_i, the vertices x_{i_1}, x_{i_2} and $x_{i,3}$ are all assigned the same colour, then T_i cannot be coloured. Therefore, if we set literals whose vertices are coloured with colour 2 to be true and those coloured with colour 3 to be false, each clause must contain at least one true literal and at least one false literal.
   If ϕ is satisfiable then we can colour vertex z with colour 1, each true literal with colour 2 and each false literal with colour 3. Then, since each clause has at least one true literal and at least one false literal, each triangle has neighbours in two different colours. This implies that each triangle is 3-colourable. Therefore G is 3-colourable if and only if ϕ is satisfiable.
   We next show that G has diameter at most 4. First note that any literal vertex is adjacent to z and any clause vertex is adjacent to some literal vertex so any vertex is at distance at most 2 from z. Therefore any two vertices are at distance at most 4.
   Finally we show that G is $K_{1,4}^3$-free. Any literal vertex has degree at most 4 since it appears in at most two clauses. However it has at most 3 independent neighbours since its negation is adjacent to z. Each clause vertex has at most 3 neighbours so the only vertex with four independent neighbours is d. The longest induced path including z has length at most 4 since any such path contains at most one literal and at most two vertices of any triangle. Therefore G is $K_{1,4}^3$-free.
4. This follows from Theorem 3. Let $k^* \geq 3$. We take a claw-free graph G and add a dominating vertex to it. The new graph G' has diameter at most 2 and is $K_{1,3}^1$-free. Let $k = k^* + 1 \geq 4$. Then G is k^*-colourable if and only if G' is k-colourable. ◀

Subdividing two edges of the claw yields another interesting case, namely where $H = S_{1,2,2}$. For $k \geq 4$, Theorem 12 tells us that k-Colouring is NP-complete for $S_{1,2,2}$-free graphs of diameter 2. For $k = 3$, we could only prove polynomial-time solvability if $d = 2$.

▶ **Theorem 13.** 3-Colouring *can be solved in polynomial time for $S_{1,2,2}$-free graphs of diameter at most* 2.

Proof. Let G be an $S_{1,2,2}$-free graph of diameter at most 2. We first check in $O(n^5)$ time if G has an induced C_5. If G is C_5-free, then we use Theorem 11. Suppose G contains an induced cycle C of length 5, say on vertices $x_1, \ldots, x_5$ in that order. We write $N_0 = V(C) = \{x_1, \ldots, x_5\}$, $N_1 = N(V(C))$ and $N_2 = V(G) \setminus (N_0 \cup N_1)$. As G has diameter 2, for every $i \in \{1, 2, 3\}$, every vertex in N_2 has a neighbour in N_1 that is adjacent to x_i.

We let T consist of all vertices of N_2 that have a neighbour in N_1 that is adjacent to two adjacent vertices of N_0. So the colour of any vertex of T will be fixed in any 3-colouring after colouring the five vertices of N_0. We claim that $N_2 = T$. In order to see this, let $u \in N_2$. As G has diameter 2, we find that u must have a neighbour $v \in N_1$ adjacent to a vertex of N_0, say x_1. Then v is not adjacent to x_5 or x_2. If v is not adjacent to x_3 either, then the vertices x_1, x_5, x_2, x_3, v, u induce a $S_{1,2,2}$ with center x_1, a contradiction. So v must be adjacent to x_3, meaning v is not adjacent to x_4. However, now x_3, x_2, x_4, x_5, v, u induce a $S_{1,2,2}$ with center x_3, another contradiction.

We now "guess" the 3-colouring of C by considering all 3^5 possibilities if necessary. We then proceed as in the proof of Theorem 11. That is, we observe that every vertex of N_1 can only be coloured with two possible colours and that after propagation, every uncoloured vertex of N_2 can only be coloured with two possible colours as well (as $T = N_2$). Then it remains to solve an instance of 2-List Colouring, which takes linear time by Theorem 6. As we need to do this at most 3^5 times, the total running time of our algorithm is polynomial. ◀

4 Graphs of Bounded Diameter and Girth

In this section we will examine the trade-offs for k-Colouring between diameter and girth. Recall that Mertzios and Spirakis [24] proved that 3-Colouring is NP-complete for graphs of diameter 3 and girth 4 (Theorem 5). We extend their result in our next theorem, partially displayed in Figure 2. This theorem shows that there is still a large gap for which we do not know the computational complexity of 3-Colouring for graphs of diameter d and girth g.

▶ **Theorem 14.** *Let d, g, k be three integers with $d \geq 2$, $g \geq 3$ and $k \geq 3$. Then k-Colouring for graphs of diameter at most d and girth at least g is*

1. *polynomial-time solvable if $g \geq 2d + 1$*
2. *NP-complete if $d = 3$ and $g \leq 4$ and $k = 3$*
3. *NP-complete if $4p \leq d \leq 4p + 3$ and $g \leq 4p + 2$ for some integer $p \geq 1$ and $k = 3$.*

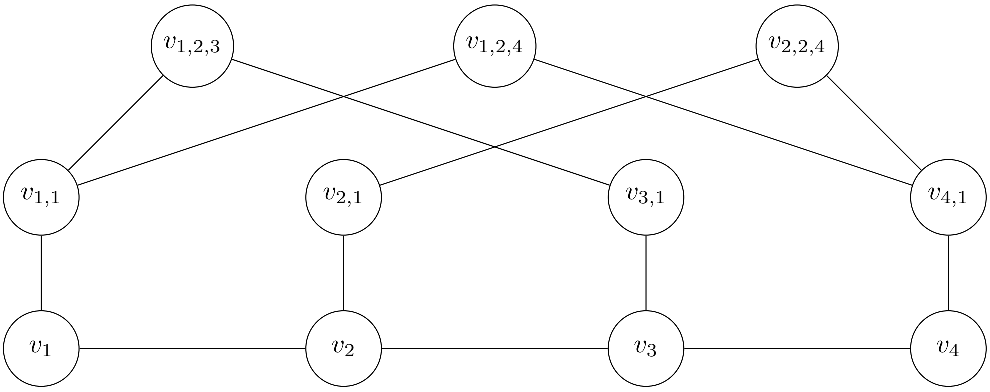

Figure 4 An example of a graph G', constructed in the proof of Theorem 14(3), for $p = 1$.

Proof.

1. This case follows from Theorem 7.
2. This case is Theorem 5 (proven in [24]).
3. We reduce 3-Colouring for graphs of girth at least $8p - 3$, which is NP-complete by Theorem 4, to 3-Colouring for graphs of diameter at most $4p$ and girth at least $4p + 2$. Construct the graph G' as follows (see Figure 4 for an example):
   - label the vertices of G v_1 to v_n;
   - for each vertex of G, add a new neighbour $v_{i,1}$;
   - for every two vertices v_i and v_j such that $\text{dist}(v_i, v_j) > l = 2p - 1$ add new vertices to form the path $v_{i,1}v_{i,2,j}...v_{i,p+1,j}v_{j,p,i}...v_{j,1}$.

First we show that G' has diameter at most $4p$. For any two vertices v_i and v_j of G either $\text{dist}(v_i, v_j) \leq l$ or we have the path $v_{i,1}v_{i,2,j}...v_{i,p+1,j}v_{j,p,i}...v_{j,1}$ and $\text{dist}(v_i, v_j) \leq 2p+2$. Similarly, $\text{dist}(v_i, v_{j,1}) \leq 2p+1$ and $\text{dist}(v_{i,1}, v_{j,1}) \leq 2p+1$. Now consider two vertices $v_{a,r,b}$ and $v_{c,q,d}$ for $2 \leq r \leq p+1$, $2 \leq q \leq p+1$. If $\text{dist}(v_a, v_c) \leq l$ then $\text{dist}(v_{a,r,b}, v_{c,q,d}) \leq r+q+l \leq (p+1)+(p+1)+(2p-1) \leq 4p+1$. Otherwise we have the path $v_{a,r,b}..v_{a,1}v_{a,2,c}...v_{a,p+1,c}v_{c,p,a}...v_{c,1}v_{c,2,d}...v_{c,q,d}$. This gives $\text{dist}(v_{a,r,b}, v_{c,q,d}) \leq (r-1)+p+p+(q-1) \leq 4p$. In fact, if $\text{dist}(v_{a,r,b}, v_{c,q,d}) = 4p+1$, then we must have $r = q = p+1$ and $\text{dist}(v_a, v_c) = \text{dist}(v_a, v_d) = \text{dist}(v_b, v_c) = \text{dist}(v_b, v_d) = 2p-1$. In this case we have two paths of length at most $4p-2$ between v_a and v_b, one containing v_c and the other containing v_d. These paths must be distinct since the existence of the vertex $v_{c,p+1,d}$ implies that $\text{dist}(v_c, v_d) > 2p-1$. Therefore we have a cycle in G of length at most $8p-4$ which contradicts the assumption that G has girth at least $8p-3$. This implies that the diameter of G' is at most $4p$.

Since G has girth at least $8p-3$, every cycle in G' of length less than $4p+2$ must contain at least one vertex of $V(G') \setminus V(G)$. Since all the vertices of $V(G') \setminus V(G)$ except the vertices $v_{i,1}$ have degree 2, any such cycle C must contain the path $v_{i,1}..v_{i,p+1,j}...v_j$ for some v_i, v_j at distance greater than l. This path has length $2p+1$. If C contains $v_{i,2,m}$ for some m different from j then it contains the path $v_{i,2,m}...v_{m,1}$ and has length at least $4p+2$. Similarly, this is the case if C contains $v_{j,2,m}$ for m different from i. Otherwise C contains v_i and v_j which are at distance at least l and has length at least $(2p+1)+2+(2p-1) = 4p+2$.

Finally, we show that G is 3-colourable if and only if G' is 3-colourable. The latter holds if and only if the subgraph G'' of G' induced by $V(G) \cup \{v_{i,1} \mid 1 \leq i \leq n\}$ is 3-colourable, since every other vertex of G' has degree 2. The graph G is 3-colourable if and only if G'' is 3-colourable, since G is an induced subgraph of G'' and each vertex of $V(G'') \setminus V(G)$ has degree 1. Therefore, G is 3-colourable if and only if G' is 3-colourable. ◀

5 Conclusions

We proved a number of new results for Colouring and k-Colouring for polyad-free graphs of bounded diameter and for graphs of bounded diameter and girth. In particular we identified and narrowed a number of complexity gaps. This leads us to some natural open problems. Our first two open problems follow from Theorem 10. The third open problem comes from Theorem 12; note that $K_{1,3}^2 = S_{1,1,3}$. Our fourth open problem stems from Theorem 13. Recall that determining the complexity of 3-Colouring for graphs of diameter 2 is still wide open. This question is covered by the fifth open problem.

▶ **Open Problem 1.** *Does there exist an integer d such that* Colouring *is* NP*-complete for $K_{1,3}$-free graphs of diameter d?*

▶ **Open Problem 2.** *What is the complexity of* Colouring *for C_3-free graphs of diameter 2, or equivalently, graphs of diameter 2 and girth 4?*

▶ **Open Problem 3.** *What are the complexities of* 3-Colouring *for $K_{1,4}^1$-free graphs of diameter 3 and for $K_{1,3}^2$-free graphs of diameter 3?*

▶ **Open Problem 4.** *Do there exist integers d, h, i, j such that* 3-Colouring *is* NP*-complete for $S_{h,i,j}$-free graphs of diameter d?*

▶ **Open Problem 5.** *What is the complexity of the open cases in Figure 2 and in particular of* 3-Colouring *for graphs of diameter 2 and for graphs of diameter 2 and girth 4?*

Abstract

Distance labeling schemes are schemes that label the vertices of a graph with short labels in such a way that the distance between any two vertices u and v can be determined efficiently by merely inspecting the labels of u and v, without using any other information. One of the important problems is finding natural classes of graphs admitting distance labeling schemes with labels of polylogarithmic size. In this paper, we show that the class of cube-free median graphs on n nodes enjoys distance labeling scheme with labels of $O(\log^3 n)$ bits.

1 Introduction

Classical network representations are usually global in nature. In order to derive a useful piece of information, one must access to a global data structure representing the entire network even if the needed information only concerns few nodes. Nowadays, with networks getting bigger and bigger, the need for locality is more important than ever. Indeed, in several cases, global representations are impractical and network representation must be distributed. The notion of (distributed) labeling scheme has been introduced [12, 32, 38, 39, 27] in order to meet this need. A *(distributed) labeling scheme* is a scheme maintaining global information on a network using local data structures (or labels) assigned to nodes of the network. Their goal is to locally store some useful information about the network in order to answer a specific query concerning a pair of nodes by only inspecting the labels of the two nodes. Motivation for such localized data structure in distributed computing is surveyed and widely discussed in [38]. The predefined queries can be of various types such as distance, adjacency, or routing. The quality of a labeling scheme is measured by the size of the labels of nodes and the time required to answer queries. Trees with n vertices admit adjacency and routing labeling schemes with size of labels and query time $O(\log n)$[1] and distance labeling schemes with size of labels and query time $O(\log^2 n)$, and this is asymptotically optimal. Finding natural classes of graphs admitting distance labeling schemes with labels of polylogarithmic size is an important and challenging problem.

A connected graph G is *median* if any triplet of vertices x, y, z contains a unique vertex simultaneously lying on shortest (x, y)-, (y, z)-, and (z, x)-paths. Median graphs constitute the most important class in metric graph theory [5]. This importance is explained by the bijections between median graphs and discrete structures arising and playing important roles in completely different areas of research in mathematics and theoretical computer science: in fact, median graphs, 1-skeletons of CAT(0) cube complexes from geometric group theory [30, 41], domains of event structures from concurrency [44], median algebras from universal algebra [7], and solution sets of 2-SAT formulae from complexity theory [36, 42] are all the same. In this paper, we design a distance labeling scheme for median graphs containing no cubes. In our scheme, the labels have $O(\log^3 n)$ bits and $O(1)$ query time. Our constant query time assumes the standard word-RAM model with word size $\Omega(\log n)$.

We continue with the idea of the labeling scheme. Let $G = (V, E)$ be a cube-free median graph with n vertices. First, the algorithm computes a median (centroid) vertex m of G. and the star $\mathrm{St}(m)$ of m (the union of all edges and squares of G incident to m). The star $\mathrm{St}(m)$ is gated, i.e., each vertex of G has an unique projection (nearest vertex) in $\mathrm{St}(m)$. Therefore, with respect to the projection function, the vertex-set of G is partitioned into fibers: the fiber $F(x)$ of $x \in \mathrm{St}(m)$ consists of all vertices $v \in V$ having x as the projection in $\mathrm{St}(m)$. Since m is a median of G, each fiber contains at most $\frac{n}{2}$ vertices. The fibers are also gated and are classified into panels and cones depending to the distance between their projections and m (one for panels and two for cones). Each cone has at most two neighboring panels however a panel may have an unbounded number of neighboring cones. Given two arbitrary vertices u and v of G, we show that $d_G(u, v) = d_G(u, m) + d_G(m, v)$ for all locations of u and v in the fibers of $\mathrm{St}(m)$ except the cases when u and v belong to neighboring cones and panels, or u and v belong to two cones neighboring the same panel, or u and v belong to the same fiber. If $d_G(u, v) = d_G(u, m) + d_G(m, v)$, then $d_G(u, v)$ can be retrieved by keeping $d_G(u, m)$ in the label of u and $d_G(v, m)$ in the label of v. If u and v belong to the same fiber $F(x)$, the computation of $d_G(u, v)$ is done by recursively partitioning the cube-free median graph $F(x)$ at a later stage of the recursion. In the two other cases, we show that $d_G(u, v)$ can be retrieved by keeping in the labels of vertices in all cones the distances to their projections on the two neighboring panels. It turns out (and this is the main technical contribution of the paper), that for each panel $F(x)$, the union of all projections of vertices from neighboring cones on $F(x)$ is included in an isometric tree of G and that the vertices of the panel $F(x)$ contain one or two projections in this tree. All such outward and inward projections are kept in the labels of respective vertices. Therefore, one can use distance labeling schemes for trees to deal with vertices u and v lying in neighboring fibers or in cones having a common neighboring panel. Consequently, the size of the label of a vertex u on each recursion level is $O(\log^2 n)$. Since the recursion depth is $O(\log n)$, the vertices of G have labels of size $O(\log^3 n)$. The distance $d_G(u, v)$ can be retrieved by finding the first time in the recursion when vertices u and v belong to different fibers of the partition. Consequently, the main result of the paper is the following theorem:

▶ **Theorem 1.** *There exists a distance labeling scheme that constructs in $O(n^2 \log n)$ time labels of size $O(\log^3 n)$ of the vertices of a cube-free median graph $G = (V, E)$. Given the labels of u and v of G, it computes in constant time the distance $d_G(u, v)$ between u and v.*

The remaining part of this note is organized in the following way. Section 2 introduces the notions used in this paper. In Section 3 we review the main results on distance labeling schemes and on median graphs. In Section 4 we recall or establish some properties of general median graphs used in our scheme. Section 5 presents the most important geometric and structural properties of cube-free median graphs, which are the essence of our distance scheme and which do not hold for general median graphs. Section 6 describes our distance labeling scheme for cube-free median graphs and proves Theorem 1. Due to page limits, the missing proofs and the pseudocodes are provided in the full version [22]. In the full version, we also describe a routing labeling scheme with similar performances.

2 Preliminaries

2.1 Basic notions

All graphs $G = (V, E)$ in this note are finite, undirected, simple, and connected. We will write $u \sim v$ if two vertices u and v are adjacent. The *distance* $d_G(u, v)$ between two vertices u and v is the length of a shortest (u, v)-path, and the *interval* $I(u, v) := \{x \in V : d_G(u, x) + d_G(x, v) = d_G(u, v)\}$ consists of all the vertices on shortest (u, v)–paths. A connected subgraph H of G is called *isometric* if $d_H(u, v) = d_G(u, v)$ for any two vertices u, v of H. A subgraph H of G is *gated* if for every vertex $v \notin V(H)$, there exists a vertex $v' \in V(H)$ such that for all $u \in V(H)$, $d_G(v, u) = d_G(v, v') + d_G(v', u)$ (v' is called the *gate* of v in H). For a vertex x of a gated subgraph H of G, the set $F(x) = \{v \in V : x \text{ is the gate of } v \text{ in } H\}$ is called the *fiber* of x with respect to H. The fibers $\{F(x) : x \in H\}$ define a partition of G. The *m-dimensional hypercube* Q_m has all subsets of $\{1, \ldots, m\}$ as the vertex-set and $A \sim B$ iff $|A \triangle B| = 1$.

A graph G is called *median* if the intersection $I(x, y) \cap I(y, z) \cap I(z, x)$ is a singleton for each triplet x, y, z of vertices; this unique intersection vertex is called the *median* of x, y, z. Median graphs are bipartite. Basic examples of median graphs are trees, hypercubes, rectangular grids, and Hasse diagrams of distributive lattices and of median semilattices [5]. The *star* $\mathrm{St}(z)$ of a vertex z of a median graph G is the union of all hypercubes of G containing z. The *dimension* $\dim(G)$ of a median graph G is the largest dimension of an hypercube subgraph of G. A *cube-free median graph* is a median graph G of dimension 2, see Figure 1 for illustrations. Even if cube-free median graphs are the skeletons of 2-dimensional CAT(0) cube complexes, their combinatorial structure is rather intricate. As an example, for $n, m \geq 5$, the Cartesian product $K_{1,n} \times K_{1,m}$ is a non-planar cube-free median graph. Moreover, for any n, one can construct a cube-free median graph containing K_n as a minor by gluing together $\binom{n}{2}$ grids of size $n \times n$ along a common horizontal side. Hence, this class is not a subset of any minor-closed graph family.

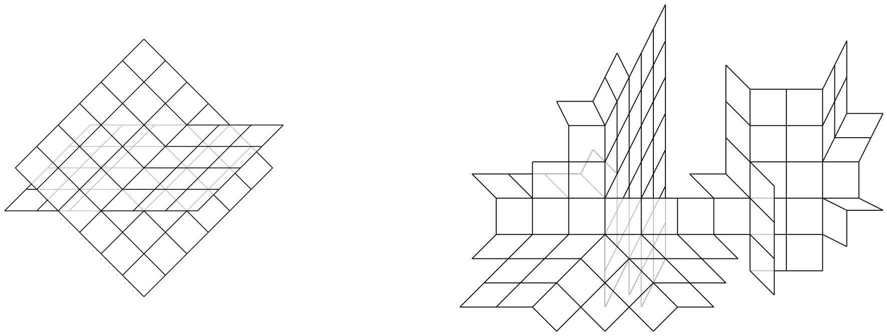

Figure 1 Cube-free median graphs.

2.2 Distance labeling schemes

A *labeling scheme* for a graph family $\mathcal{G}$ consists of an encoding function and a decoding function. These functions depend on the family $\mathcal{G}$ and on the type of queries: adjacency, distance, or routing queries. More formally, a *distance labeling scheme* on a graph family $\mathcal{G}$ consists of an *encoding function* $C_G : V(G) \to \{0,1\}^*$ that gives to every vertex of a graph G of $\mathcal{G}$ a label, and of a *decoding function* $D_G : \{0,1\}^* \times \{0,1\}^* \to \mathbb{N}$ that, given the labels of two vertices u and v of G, can compute efficiently the distance $d_G(u,v)$ between them.

3 Related work

3.1 Distance labeling schemes

Distance Labeling Schemes (DLS) have been introduced in a series of papers by Peleg et al. [38, 39, 27]. Before these works, some closely related notions already existed such as embeddings in a squashed cube [43] (equivalent to distance labeling schemes with labels of size $\log n$ times the dimension of the cube) or labeling schemes for adjacency requests [32]. One of the main results for DLS is that general graphs support distance labeling schemes with labels of size $O(n)$ bits [43, 27, 2]. This scheme is asymptotically optimal since $\Omega(n)$ bits labels are needed for general graphs. Another important result is that there exists a distance labeling scheme for the class of trees with $O(\log^2 n)$ bits labels [38, 3, 24]. Several classes of graphs containing trees also enjoy a distance labeling scheme with $O(\log^2 n)$ bit labels such as bounded tree-width graphs [27], distance-hereditary graphs [25], bounded clique-width graphs [23], and non-positively curved plane graphs [19]. A lower bound of $\Omega(\log^2 n)$ bits on the label length is known for trees [27, 3], implying that all the results mentioned above are optimal as well. Other families of graphs have been considered such as interval graphs, permutation graphs, and their generalizations [9, 26] for which an optimal bound of $\Theta(\log n)$ bits was given, and planar graphs for which there is a lower bound of $\Omega(n^{\frac{1}{3}})$ bits [27] and an upper bound of $O(\sqrt{n})$ bits [28].

3.2 Median graphs

Median graphs and related structures have an extensive literature; several surveys exist listing their numerous characterizations and properties [5, 33, 34]. These structures have been investigated in different contexts by quite a number of authors for more than half a century. In this subsection we briefly review the links between median graphs and CAT(0) cube complexes. We also recall some results, related to the subject of this paper, about the distance and shortest path problems in median graphs and CAT(0) cube complexes. For a survey of results on median graphs and their bijections with median algebras, median semilattices, CAT(0) cube complexes, and solution spaces of 2-SAT formulae, see [5]. For a comprehensive presentation of median graphs and CAT(0) cube complexes as domains of event structures, see the long version of [14].

It is not immediately clear from the definition, but median graphs are intimately related to hypercubes: median graphs can be obtained from hypercubes by amalgams and median graphs are themselves isometric subgraphs of hypercubes [8, 35]. Even more, median graphs are exactly the retracts of hypercubes [4]. Due to the abundance of hypercubes, to each median graph G one can associate a cube complex $X(G)$ obtained by replacing every hypercube of G by a solid unit cube. Then G can be recovered as the 1-skeleton of $X(G)$. The cube complex $X(G)$ can be endowed with several intrinsic metrics, in particular with the ℓ_2-metric. An important class of cube complexes studied in geometric group theory and combinatorics is the class of CAT(0) cube complexes. CAT(0) geodesic metric spaces are usually defined via the nonpositive curvature comparison axiom of Cartan–Alexandrov–Toponogov [13]. For cube complexes (and more generally for cell complexes) the CAT(0) property can be defined in a very simple and intuitive way by the property that *ℓ_2-geodesics between any two points are unique*. Gromov [30] gave a nice combinatorial characterization of CAT(0) cube complexes as *simply connected cube complexes with flag links*. It was also shown in [18, 40] that *median graphs are exactly the 1-skeletons of CAT(0) cube complexes.*

Previous characterizations can be used to show that several cube complexes arising in applications are CAT(0). Billera et al. [10] proved that the space of trees (encoding all tree topologies with a given set of leaves) is a CAT(0) cube complex. Abrams et al. [1, 29] considered the space of all possible positions of a reconfigurable system and showed that in many cases this state complex is CAT(0). Billera et al. [10] formulated the problem of computing the geodesic between two points in the space of trees. In the robotics literature, geodesics in state complexes correspond to the motion planning to get the robot from one position to another one with minimal power consumption. A polynomial-time algorithm for geodesic problem in the space of trees was provided in [37] and, very recently, [31] designed such an algorithm for all CAT(0) cube complexes.

Returning to median graphs, the following is known about the labeling schemes for them. First, the arboricity of any median graph G on n vertices is at most $\log n$, leading to adjacency schemes of $O(\log^2 n)$ bits per vertex. As noted in [21], one $\log n$ factor can be replaced by the dimension of G. Compact distance labeling schemes can be obtained for some subclasses of cube-free median graphs. One particular class is that of *squaregraphs*, i.e., plane graphs in which all inner vertices have degree ≥ 4. For squaregraphs, distance schemes with labels of size $O(\log^2 n)$ follow from a more general result of [19] for plane graphs of nonpositive curvature. Another such class of graphs is that of partial double trees [6]. Those are the median graphs which isometrically embed into a Cartesian product of two trees. The isometric embedding of partial double trees into a product of two trees immediately leads to distance schemes with labels of $O(\log^2 n)$ bits. Finally, with a technically involved proof, it was shown in [20] that there exists a constant M such that any cube-free median graph G with maximum degree Δ can be isometrically embedded into a Cartesian product of at most $\epsilon(\Delta) := M\Delta^{26}$ trees. This immediately shows that cube-free median graph admit distance labeling schemes with labels of length $O(\epsilon(\Delta)\log^2 n)$. Compared with the $O(\log^3 n)$-labeling scheme obtained in the current paper, the disadvantage of the $O(\epsilon(\Delta)\log^2 n)$-labeling scheme is the dependence from the maximum degree Δ of G. The situation is even worse for high dimensional median graphs: [20] presents an example of a 5-dimensional median graph/CAT(0) cube complex with constant degree which cannot be embedded into a Cartesian product of a finite number of trees. Therefore, for general finite median graphs the function $\epsilon(\Delta)$ does not exist. This in some sense explains the difficulty of designing polylogarithmic distance labeling schemes for general median graphs. Nevertheless, we do not have any indication to believe that such schemes do not exist.

4 Fibers in median graphs

In this section, we recall several useful properties of fibers of gated subgraphs of median graphs. From the definition, one can deduce that median graphs satisfy the following quadrangle condition: *For any vertices u, v, w, z such that $d_G(u, z) = k + 1$, $v, w \sim z$, and $d_G(u, v) = d_G(u, w) = k$, there is a unique vertex $x \sim v, w$ such that $d_G(u, x) = k - 1$.*

▶ **Lemma 1.** *[17]: A subgraph H of a median graph G is gated if and only if any vertex $v \notin V(H)$ is adjacent to at most one vertex of H.*

Combinatorially, the stars of median graphs may have quite an arbitrary structure: by a result of [8], there is a bijection (via the simplex graph operation) between the stars of median graphs and arbitrary graphs. However, from the metric point of view, stars $\mathrm{St}(z)$ have interesting properties:

▶ **Proposition 2.** *The stars $St(z)$ and their fibers $F(x), x \in St(z)$, are gated.*

Both properties of Proposition 2 are known for more general graphs: for gatedness of stars, see [15, Theorem 6.17]) and for gatedness of fibers of gated sets, see [16].

Let H be a gated subgraph of G and let $\mathcal{F}(H) = \{F(x) : x \in V(H)\}$ be the partition of V into fibers. We call two fibers $F(x)$ and $F(y)$ *neighboring* (notation $F(x) \sim F(y)$) if there exists an edge $x'y'$ of G with x' in $F(x)$ and y' in $F(y)$. If $F(x)$ and $F(y)$ are neighboring fibers of H, then denote by $\partial_y F(x)$ the set of all vertices $x' \in F(x)$ having a neighbor y' in $F(y)$ and call $\partial_y F(x)$ the *boundary of* $F(x)$ *relative to* $F(y)$. The following three results can be easily proved.

▶ **Lemma 2.** *Two fibers $F(x)$ and $F(y)$ of H are neighboring if and only if $x \sim y$. Moreover, if $F(x) \sim F(y)$, then $\partial_y F(x)$ induces a gated subgraph of G of dimension $\leq \dim(G) - 1$.*

For a vertex x of H and its fiber $F(x)$, the union of all boundaries $\partial_y F(x)$ over all $F(y) \sim F(x)$, $y \in V(H)$, is called the *total boundary* of the fiber $F(x)$ and is denoted by $\partial^* F(x)$. The boundaries $\partial_y F(x)$ constituting $\partial^* F(x)$ are called *branches* of $\partial^* F(x)$.

▶ **Lemma 3.** *The total boundary of any fiber of H is an isometric subgraph of G not containing* $\dim(G)$*-cubes.*

We conclude this section with an additional property of fibers of stars of *median vertices* of G, i.e., vertices minimizing the function $M(x) = \sum_{v \in V} d_G(x, v)$.

▶ **Lemma 4.** *Let m be a median vertex of a median graph G with n vertices. Then any fiber $F(x)$ of the star $St(m)$ of m has at most $n/2$ vertices.*

Unfortunately, the total boundary of a fiber does not always induce a median subgraph. Therefore, one cannot recursively apply the algorithm to the subgraphs induced by the total boundaries $\partial^* F(x)$. However, if G is cube-free, then the total boundaries of fibers are isometric subtrees of G and one can use for them distance schemes for trees. Even in this case, we still need an additional property of $\partial^* F(x)$. We establish it in the next section.

5 Fibers in cube-free median graphs

In this section, we establish additional properties of fibers and of their total boundaries in cube-free median graphs (for other properties of such graphs, see [11]). Using them we can show that for any pair u, v of vertices of G, the following trichotomy holds: the distance $d_G(u, v)$ either can be computed as $d_G(u, m) + d_G(m, v)$, or as the sum of distances from u, v to appropriate vertices u', v' of $\partial^* F(x)$ plus the distance between u', v' in $\partial^* F(x)$, or via a recursive call to the fiber containing u and v.

5.1 Classification of fibers

Let z be an arbitrary vertex of G and let $\mathcal{F}_z = \{F(x) : x \in \mathrm{St}(z)\}$ denote the partition of V into the fibers of $\mathrm{St}(z)$. We distinguish two types of fibers: the fiber $F(x)$ is called a *panel* if x is adjacent to z and $F(x)$ is called a *cone* if x has distance two to z. The interval $I(x,z)$ is the edge xz if $F(x)$ is a panel and is a square $Q_x := (x, y', z, y'')$ if $F(x)$ is a cone. In the second case, since y' and y'' are the only neighbors of x in $\mathrm{St}(z)$, by Lemma 2 we deduce that the cone $F(x)$ is adjacent to the panels $F(y')$ and $F(y'')$ and that $F(x)$ is not adjacent to any other panel or cone. By the same lemma, a panel $F(y)$ is not adjacent to any other panel, but $F(y)$ is adjacent to all cones $F(x)$ such that the square Q_x contains the edge yz.

5.2 Total boundaries of fibers are quasigated

For a set A, an *imprint* of a vertex $u \notin A$ on A is a vertex $a \in A$ such that $I(u,a) \cap A = \{a\}$. Denote by $\Upsilon(u,A)$ the set of all imprints of u on A. The most important property of imprints is that for any vertex $z \in A$, there exists a shortest (u,z)-path passing via an imprint. Therefore, if the set $\Upsilon(u,A)$ has constant size, one can store in the label of u the distances to the vertices of $\Upsilon(u,A)$. Using this, for any $z \in A$, one can compute $d_G(u,z)$ as $\min\{d_G(u,a) + d_G(a,z) : a \in \Upsilon(u,A)\}$. Note that A is gated iff any $u \notin A$ has a unique imprint on A. We will say that a set A is *quasigated* if $|\Upsilon(u,A)| \leq 2$ for any vertex $u \notin A$. The main goal of this subsection is to show that the total boundaries of fibers are quasigated.

Let T be a tree with a distinguished vertex r in G, called the *root* of T. We will say that a rooted tree T has *gated branches* if for any vertex x of T the unique path $P(x,r)$ of T connecting x to the root r is a gated subgraph of G. Lemma 3 implies:

▶ **Lemma 5.** *The total boundary of any fiber is an isometric tree with gated branches.*

By Lemma 5, $\partial^* F(x)$ has gated branches, however $\partial^* F(x)$ is not necessarily gated itself. Since a panel $F(x)$ may be adjacent to an arbitrary number of cones, one can think that the imprint-set $\Upsilon(u, \partial^* F(x))$ of a vertex u of $F(x)$ may have an arbitrarily large size. The following lemma shows that this is not the case, namely that $|\Upsilon(u, \partial^* F(x))| \leq 2$. This is one of the key ingredients in the design of the distance labeling scheme presented in Section 6. This property is no longer true for median graphs of dimension > 2.

▶ **Lemma 6.** *Any rooted (at r) tree T with gated branches of G is quasigated.*

Proof. Pick any $u \in V \setminus V(T)$ and suppose by way of contradiction that $\Upsilon(u,T)$ contains three distinct imprints x_1, x_2, and x_3. Since T has gated branches, none of the vertices x_1, x_2, x_3 belong to the path of T between r and another vertex from this triplet. In particular, r is different from x_1, x_2, x_3. Suppose additionally that among all rooted trees T' with gated branches of G and such that $|\Upsilon(u,T')| \geq 3$, the tree T has the minimal number of vertices. This minimality choice (and the fact that any subtree of T containing r is also a rooted tree with gated branches) implies that T is exactly the union of the three gated paths $P(r,x_1), P(r,x_2)$, and $P(r,x_3)$. Therefore, x_1, x_2 and x_3 are the leaves of T.

Let y_i be the neighbor of x_i in the path $P(r,x_i)$, $i = 1,2,3$. Since G is bipartite, either $x_i \in I(y_i,u)$ or $y_i \in I(x_i,u)$. Since $x_i \in \Upsilon(u,T)$, necessarily $x_i \in I(y_i,u)$. Let T'_i be the subtree of T obtained by removing the leaf x_i. From the minimality choice of T, we cannot replace T by the subtree T'_i. This means that $|\Upsilon(u,T'_i)| \leq 2$. Since $x_j, x_k \in \Upsilon(u,T'_i)$ for $\{i,j,k\} = \{1,2,3\}$, necessarily $I(y_i,u) \cap \{x_j,x_k\} \neq \varnothing$ holds.

First, notice that $x_1, x_2, x_3 \in I(u,r)$. Indeed, let z_i denote the median of the triplet x_i, u, r. If $z_i \neq x_i$, since $z_i \in I(x_i,r) = P(x_i,r) \subset T$ and $z_i \in I(u,x_i)$, we obtain a contradiction with the inclusion of x_i in $\Upsilon(u,T)$. Thus $z_i = x_i$, yielding $x_i \in I(u,z_i)$.

Now, suppose without loss of generality that $d_G(r, x_3) = \max\{d_G(r, x_i) : i = 1, 2, 3\} := k$. Since $I(y_3, u) \cap \{x_1, x_2\} \neq \varnothing$ as shown above, we can suppose that $x_2 \in I(y_3, u)$. Since $x_3 \in I(y_3, u)$, from these inclusions we obtain that $d_G(x_3, u) + 1 = d_G(y_3, x_2) + d_G(x_2, u)$. Then $d_G(x_3, u) \geq d_G(x_2, u)$, and we conclude that $d_G(x_3, u) = d_G(x_2, u)$ and $d_G(y_3, x_2) = 1$. Since $x_2, x_3 \in I(r, u)$, $d_G(x_3, r) = d_G(x_2, r)$. We distinguish two cases:

Case 1. $d_G(x_1, r) = k$.

Since x_1, x_2, x_3 have the same distance k to r, we can apply to x_1 the same analysis as to x_3 and deduce that the neighbor y_1 of x_1 in T coincides with one of the vertices y_2 or y_3. Since $y_2 = y_3 = y$, we conclude that the vertices x_1, x_2, x_3 have the same neighbor y in T. Since y is closer to r than each of the vertices x_1, x_2, x_3 and since $x_1, x_2, x_3 \in I(r, u)$, we conclude that $x_1, x_2, x_3 \in I(y, u)$. Applying the quadrangle condition three times, we can find three vertices $x_{i,j}, i, j \in \{1, 2, 3\}, i \neq j$, such that $x_{i,j} \sim x_i, x_j$ and $d_G(x_{i,j}, u) = k - 1$. If two of the vertices $x_{1,2}, x_{2,3}$, and $x_{3,1}$ coincide, then we will get a forbidden $K_{2,3}$. Thus $x_{1,2}, x_{2,3}$, and $x_{3,1}$ are pairwise distinct. Since G is bipartite, this implies that $d_G(x_i, x_{j,k}) = 3$ for $\{i, j, k\} = \{1, 2, 3\}$. Since $x_{1,2}, x_{2,3} \in I(x_2, u)$, by quadrangle condition there exists a vertex w such that $w \sim x_{1,2}, x_{2,3}$ and $d_G(w, u) = k - 2$. Since G is bipartite, $d_G(w, x_{3,1})$ equals to 3 or to 1. If $d_G(w, x_{3,1}) = 3 = d(y, w)$, then the triplet $y, w, x_{3,1}$ has two medians x_1 and x_3, which is impossible, because G is median. Thus $d_G(w, x_{3,1}) = 1$, i.e., $w \sim x_{3,1}$. Then one can easily see that the vertices $y, x_1, x_2, x_3, x_{1,2}, x_{2,3}, x_{3,1}, w$ define an isometric 3-cube of G, contrary to the assumption that G is cube-free. This finishes the analysis of Case 1.

Case 2. $d_G(x_1, r) < k$.

This implies that $d_G(r, x_1) \leq k-1 = d_G(r, y)$. Let r' be the neighbor of r in the (r, y)-path of T. Note that $r' \notin I(r, x_1) = P(r, x_1)$. Otherwise, $r' \in P(r, x_1) \cap P(r, x_2) \cap P(r, x_3)$ and we can replace T by the subtree T' rooted at r' and consisting of the subpaths of $P(r, x_i)$ between r' and x_i, $i = 1, 2, 3$. Clearly T' is a rooted tree with gated branches and $x_1, x_2, x_3 \in \Upsilon(u, T')$, contrary to the minimality choice of T. Thus $r' \notin P(r, x_1)$.

Let also $P(r, x_1) = (r, v_1, \ldots, v_{m-1}, v_m =: x_1)$. Note that r may coincide with y_1 and x_1 may coincide with v_1. Since $v_1, r' \in I(r, u)$, by quadrangle condition we will find $v'_2 \sim v_1, r'$ at distance $d_G(r, u) - 2$ from u. Since $r' \notin I(r, x_1)$, $v'_2 \neq v_2$. Since $v_2, v'_2 \in I(v_1, u)$, by quadrangle condition we will find $v'_3 \sim v_2, v'_2$ at distance $d_G(r, u) - 3$ from u. Again, since $r' \notin I(r, x_1)$, $v'_3 \neq v_3$. Continuing this way, we will find the vertices $v'_2, v'_3, \ldots, v'_m, v'_{m+1} =: x'_1$ forming an (r', x'_1)-path $P(r', x'_1)$ and such that $v'_{i+1} \sim v_i, v'_i$, $v'_{i+1} \neq v_{i+1}$, and v'_{i+1} is one step closer to u than v_i and v'_i. From its construction, $P(r', x'_1)$ is a shortest path. We assert that $P(r', x'_1)$ is gated. Otherwise, by Lemma 1, we can find two vertices v'_{i-1} and v'_{i+1} having a common neighbor z' different from v'_i. Let z be the median of the triplet z', v_{i-1}, v_{i+1}. Then z is a common neighbor of z', v_{i-1}, v_{i+1} and z is different from v_i (otherwise, we obtain a forbidden $K_{2,3}$). But then the vertices $v_{i-1}, v_i, v_{i+1}, v'_{i-1}, v'_i, v'_{i+1}, z, z'$ induce in G an isometric 3-cube, contrary to the assumption that G is cube-free. Consequently, $P(r', x'_1)$ is a gated path of G.

Let T'' be the tree rooted at r' and consisting of the gated path $P(r', x'_1)$ and the gated subpaths of $P(r, x_2)$ and $P(r, x_3)$ between r' and x_2, x_3, respectively. Clearly, T'' is a rooted tree with gated branches. Notice that $x'_1, x_2, x_3 \in \Upsilon(u, T'')$. Indeed, if x_2 or x_3 belonged to $I(x'_1, u)$, then $x'_1 \in I(x_1, u)$ and we would conclude that x_2 or x_3 belongs to $I(x_1, u)$, which is impossible because $x_1 \in \Upsilon(u, T)$. On the other hand, x'_1 cannot belong to $I(x_2, u)$ or to $I(x_3, u)$ because $d_G(x'_1, u) = d_G(x_1, u) - 1 \leq d_G(x_2, u) = d_G(x_3, u)$. Consequently, $|\Upsilon(u, T'')| \geq 3$. Since T'' contains less vertices than T, we obtain a contradiction with the minimality choice of T. This concludes the analysis of Case 2, thus T is quasigated. ◀

Applying Lemmas 5 and 6 to the subgraph of G induced by the fiber $F(x)$, we obtain:

▶ **Corollary 3.** *The total boundary $\partial^* F(x)$ of any fiber $F(x)$ is quasigated.*

5.3 Classification of pairs of vertices

In Subsection 5.1, we classified the fibers of $\mathrm{St}(z)$ into panels and cones. In this subsection, we use it to provide a classification of pairs of vertices of G with respect to the partition into fibers, which extends the one done in [19] for planar median graphs.

Let z be an arbitrary fixed vertex of G. Let $\mathcal{F}_z = \{F(x) : x \in \mathrm{St}(z)\}$ be the partition of V into the fibers of $\mathrm{St}(z)$. Let u, v be two arbitrary vertices of G and suppose that u belongs to the fiber $F(x)$ and v belongs to the fiber $F(y)$ of $\mathcal{F}_z$. We say that u and v are *roommates* if they belong to the same fiber, i.e., $x = y$. We say that u and v are *1-neighboring* if $F(x)$ and $F(y)$ are two neighboring fibers (then one of them is a panel and another is a cone). We say that u and v are *2-neighboring* if $F(x)$ and $F(y)$ are distinct cones neighboring with a common panel, i.e., there exists a panel $F(w) \sim F(x), F(y)$. Finally, we say that u and v are *separated* if the fibers $F(x)$ and $F(y)$ are distinct, are not neighboring, and if both $F(x)$ and $F(y)$ are cones, then they are not 2-neighboring. From the definition it follows that any two vertices u, v of G are either roommates, or separated, or 1-neighboring, or 2-neighboring.

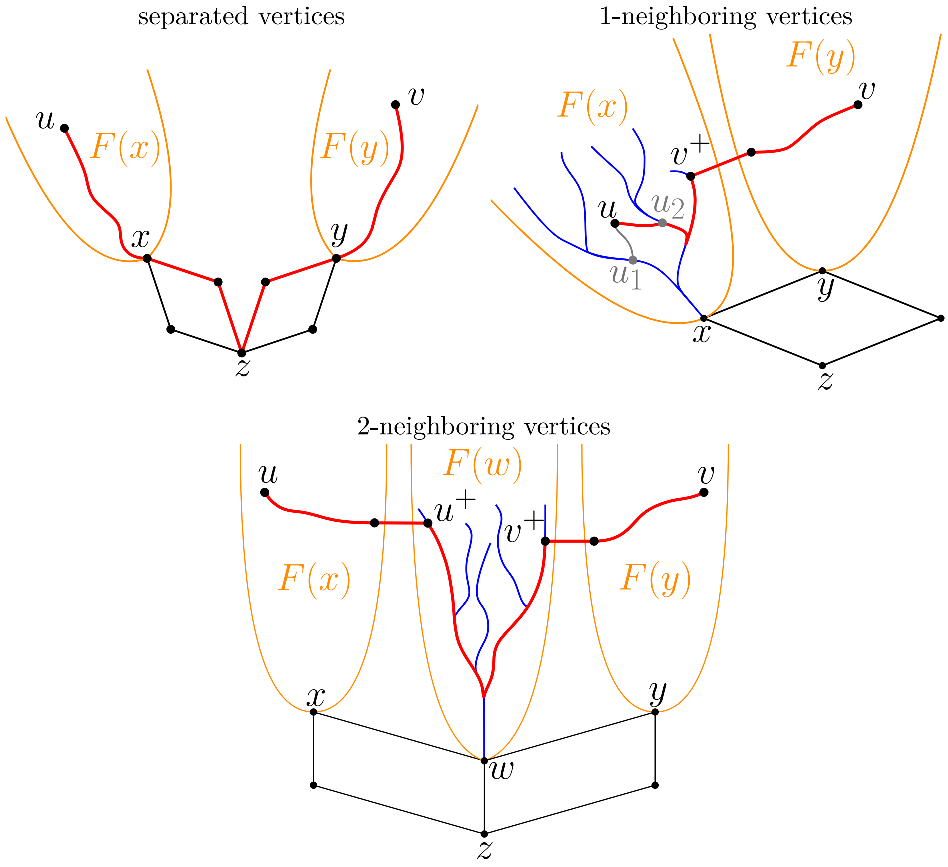

Figure 2 To Lemmas 7, 8 and 9: in red, shortest paths between separated, 1-neighboring, and 2-neighboring vertices u and v. The total boundaries of the panels appear in blue.

We continue with distance formulae for separated, 2-neighboring, and 1-neighboring vertices. The illustration of each of the formulae is provided in Figure 2.

▶ **Lemma 7.** *Two vertices u and v are separated if and only if $d_G(u,v) = d_G(u,z) + d_G(z,v)$.*

▶ **Lemma 8.** *Let u and v be two 1-neighboring vertices such that u belongs to the panel $F(x)$ and v belongs to the cone $F(y)$. Let u_1 and u_2 be the two imprints of u on the total boundary $\partial^* F(x)$ and let v^+ be the gate of v in $F(x)$. Then, $d_G(u,v) = \min\{d_G(u,u_1) + d_{\partial^* F(x)}(u_1,v^+), d_G(u,u_2) + d_{\partial^* F(x)}(u_2,v^+)\} + d_G(v^+,v)$.*

▶ **Lemma 9.** *Let u and v be two 2-neighboring vertices belonging to the cones $F(x)$ and $F(y)$, respectively, and let $F(w)$ be the panel neighboring $F(x)$ and $F(y)$. Let u^+ and v^+ be the gates of u and v in $F(w)$. Then $d_G(u,v) = d_G(u,u^+) + d_{\partial^* F(w)}(u^+,v^+) + d_G(v^+,v)$.*

6 Distance labeling scheme for cube-free median graphs

Let $G = (V,E)$ be a cube-free median graph with n vertices and let m be a median vertex of G. Let u,v be any pair of vertices of G for which we have to compute the distance $d_G(u,v)$. Applying Lemmas 7, 8, and 9 with m instead of z, the distance $d_G(u,v)$ can be computed once u and v are separated, 1-neighboring, or 2-neighboring and once u and v keep in their labels the distances to m, to the respective gates u^+ and v^+, and to the imprints u_1 and u_2 if u belongs to a panel. It also requires keeping in the labels of u and v the information necessary to compute each of the distances $d_{\partial^* F(x)}(u_1,v^+), d_{\partial^* F(x)}(u_2,v^+), d_{\partial^* F(w)}(u^+,v^+)$. Since the total boundaries are isometric trees, this can be done by keeping in the label of u the labels of u_1, u_2, and u^+ in a distance labeling scheme for trees, as well as keeping in the label of v such a label of v^+. This shows that $d_G(u,v)$ can be computed in all cases except when u and v are roommates. Since $F(x)$ is median, we can apply the same recursive procedure to each fiber $F(x)$ instead of G. Therefore, $d_G(u,v)$ is computed in the first recursive call when u and v will no longer belong to the same fiber of the current median vertex (we will sometimes refer at this median vertex as the *separator* of u and v). Since at each step the division into fibers is performed with respect to a median, $|F(x)| \leq n/2$ by Lemma 4, thus the tree of recursive calls has logarithmic depth.

In this section, we present the distance labeling scheme. The encoding scheme is described by the algorithm Dist_Enc presented in Subsection 6.1. Subsection 6.2 presents the algorithm Dist for answering distance queries. In Subsection 6.3, we briefly explain how a constant query time can be achieved by adding $O(\log^2 n)$ bits in head of each label.

6.1 Encoding

We describe now how Dist_Enc constructs for every vertex u of G a distance label $\mathrm{LD}(u)$. This is done recursively and every depth of the recursion is called a *step*. Initially, we suppose that every vertex u of G is given a unique identifier $\mathrm{id}(u)$. We define this naming step as Step 0 and denote the corresponding part of $\mathrm{LD}(u)$ by $\mathrm{LD}_0(u)$, i.e., $\mathrm{LD}_0(u) := \mathrm{id}(u)$. At Step 1, Dist_Enc computes a median vertex m of G, the star $\mathrm{St}(m)$ of m, and the partition $\mathcal{F}_m := \{F(x) : x \in \mathrm{St}(m)\}$ of V into fibers. Every vertex u of G receives the identifier $\mathrm{id}(m)$ of m and its distance $d_G(u,m)$ to m. After that, every vertex x of $\mathrm{St}(m)$ receives a special identifier $\mathrm{L}_{\mathrm{St}(m)}(x)$ of size $O(\log|V|)$ given by a distance labeling for the star $\mathrm{St}(m)$. Then, Dist_Enc computes the gate $u^{\downarrow}$ in $\mathrm{St}(m)$ of every vertex u of G and adds its identifier $\mathrm{L}_{\mathrm{St}(m)}(u^{\downarrow})$ to $\mathrm{LD}(u)$. The identifiers $\mathrm{L}_{\mathrm{St}(m)}(x)$ of the vertices of $\mathrm{St}(m)$ can also be used to distinguish the fibers of $\mathrm{St}(m)$. This triplet $(\mathrm{id}(m), d_G(u,m), \mathrm{L}_{\mathrm{St}(m)}(u^{\downarrow}))$ contains the necessary information relative to $\mathrm{St}(m)$ and is thus referred as the *part "star"* of the information $\mathrm{LD}_1(u)$ given to u at Step 1. We denote this part by $\mathrm{LD}_1^{\mathrm{St}}(u)$. We also set $\mathrm{LD}_1^{\mathrm{St[Med]}}(u) := \mathrm{id}(m)$, $\mathrm{LD}_1^{\mathrm{St[Dist]}}(u) := d_G(u,m)$ and $\mathrm{LD}_1^{\mathrm{St[gate]}}(u) := \mathrm{L}_{\mathrm{St}(m)}(u^{\downarrow})$ for the three components of the label $\mathrm{LD}_1^{\mathrm{St}}(u)$.

Afterwards, at Step 1, the algorithm considers each fiber $F(x)$ of $\mathcal{F}_m$. If $F(x)$ is a panel, then the algorithm computes the total boundary $\partial^* F(x)$ of $F(x)$. The vertices v of the quasigated tree $\partial^* F(x)$ are given special identifiers $\mathrm{LD}_{\partial^* F(x)}(v)$ of size $O(\log^2 |V|)$ consisting of a distance labeling scheme for trees (see [24]). For each vertex u of the panel $F(x)$, the algorithm computes the two imprints u_1 and u_2 of u in $\partial^* F(x)$ (it may happen that $u_1 = u_2$) and stores $(\mathrm{LD}_{\partial^* F(x)}(u_1), d_G(u, u_1))$ and $(\mathrm{LD}_{\partial^* F(x)}(u_2), d_G(u, u_2))$ in $\mathrm{LD}_1^{\mathrm{1st}}(u)$ and $\mathrm{LD}_1^{\mathrm{2nd}}(u)$. If $F(x)$ is a cone and $F(w_1)$ and $F(w_2)$ are the two panels neighboring $F(x)$, then for each vertex u of $F(x)$, the algorithm computes the gates u_1^+ and u_2^+ of u in $F(w_1)$ and $F(w_2)$, respectively. Since $u_i^+ \in \partial_x F(w_i) \subset \partial^* F(x), i = 1, 2$, the labels $\mathrm{LD}_{\partial^* F(w_1)}(u_1^+)$ and $\mathrm{LD}_{\partial^* F(w_2)}(u_2^+)$ in the distance labelings of trees $\partial^* F(w_1)$ and $\partial^* F(w_2)$ are well-defined. Therefore, the algorithm stores $(\mathrm{LD}_{\partial^* F(w_1)}(u_1^+), d_G(u, u_1^+))$ and $(\mathrm{LD}_{\partial^* F(w_2)}(u_2^+), d_G(u, u_2^+))$ in $\mathrm{LD}_1^{\mathrm{1st}}(u)$ and $\mathrm{LD}_1^{\mathrm{2nd}}(u)$. This ends Step 1.

Since $\mathcal{F}_m$ partitions V into gated median subgraphs, the label $\mathrm{LD}_2(u)$ added to $\mathrm{LD}(u)$ at Step 2 is constructed as $\mathrm{LD}_1(u)$ replacing G by the fiber $F(u^\downarrow)$ containing u, and so on. Since each fiber contains no more than half of the vertices of the current graph, at Step $\lceil \log |V| \rceil$, the fiber containing any vertex consists solely of this vertex, and the algorithm stops. Therefore, for each pair of vertices u and v of G, there exists a step of the recursion after which u and v are no longer roommates.

6.2 Distance queries

Let u and v be two vertices of G and let $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$ be their labels returned by Dist_Enc. Here we describe how the algorithm Dist computes the information about the relative positions of u and v with respect to each other and how, using it, computes $d_G(u, v)$. First, the algorithm has to detect if u and v coincide or not. If $u \neq v$, then Dist finds the largest integer i such that $\mathrm{LD}_i^{\mathrm{St[Med]}}(u) = \mathrm{LD}_i^{\mathrm{St[Med]}}(v)$. This corresponds to the first time the vertices u and v belong to different fibers in a partition. Let m be the median vertex of the current median graph that is the separator of u and v. Then, the algorithm Dist retrieves the distances $d := d_G(u^\downarrow, v^\downarrow)$, $d_u := d_G(u^\downarrow, m)$ and $d_v := d_G(v^\downarrow, m)$. This is done by using the identifiers $\mathrm{LD}_i^{\mathrm{St[gate]}}(u)$ and $\mathrm{LD}_i^{\mathrm{St[gate]}}(v)$ and the distance decoder for distance labeling in stars. With this information at hand, one can easily decide for each of the vertices u and v if it belongs to a cone or to a panel, and moreover decide if the vertices u and v are 1-neighboring, 2-neighboring, or separated. In each of these cases, a call to an appropriate function is done.

First suppose that the vertices u and v are 1-neighboring ($d = 1$ and one of d_u, d_v is 1 and the other is 2), i.e., one of the vertices u, v belongs to a cone, the other one belongs to a panel, and the cone and the panel are neighboring. The function `Dist_1-Neighboring` returns the distance $d_G(u, v)$ in the assumption that u belongs to a panel and v belongs to a cone (if v belongs to a panel and u to a cone, it suffices to swap the names of the vertices u and v before using `Dist_1-Neighboring`). The function finds the gate v^+ of v in the panel of u by looking at $\mathrm{LD}_i^{\mathrm{St[gate]}}(v)$ (it also retrieves the distance $d_G(v, v^+)$). It then retrieves the imprint u^* of u (and the distance $d_G(u, u^*)$) on the total boundary of the panel that minimizes the distance of u to one of the two imprints plus the distance from this imprint to the gate v^+ using their tree distance labeling scheme. Finally, `Dist_1-Neighboring` returns $d_G(u, u^*) + d_G(u^*, v^+) + d_G(v^+, v)$ as $d_G(v, u)$.

Now suppose that the vertices u and v are 2-neighboring (i.e., $d = d_u = d_v = 2$). Then both u and v belong to cones. By inspecting $\mathrm{LD}_i^{\mathrm{St[gate]}}(u)$ and $\mathrm{LD}_i^{\mathrm{St[gate]}}(v)$, the function `Dist_2-Neighboring` determines the panel $F(w)$ sharing a border with the cones $F(u^\downarrow)$ and $F(v^\downarrow)$. Then, the function retrieves the respective gates u^+ and v^+ of u and v in this panel $F(w)$ and the distances $d_G(u, u^+)$ and $d_G(v, v^+)$. The distance between the gates u^+ and v^+ is retrieved using the distance decoder for trees. The algorithm returns $d_G(u, u^+) + d_G(u^+, v^+) + d_G(v^+, v)$ as $d_G(u, v)$.

In the remaining cases, the vertices u and v are separated. By Lemma 7, $d_G(u, v) = d_G(u, m) + d_G(m, v)$. Both u and v have stored the median vertex m and their distances to m. Therefore, `Dist_Separated` simply returns the sum of those two distances.

6.3 Complexity analysis and improved query time

The correctness of DIST results from the following properties of G: stars and fibers are gated (Proposition 2); total boundaries of fibers are quasigated (Corollary 3) isometric trees with gated branches (Lemma 5); the formulae for computing the distance between separated, 1-neighboring, and 2-neighboring vertices (Lemmas 7, 8, and 9). At each step of the encoding, $O(\log^2 n)$ bits are added to the label of every vertex (due to the tree-distance labeling scheme they contain). Since there are $\lceil \log n \rceil$ steps, the total length of each label is $O(\log^3 n)$. For decoding the labels, it suffices to read them once to find when the vertices are no longer roommates. This is done in time $O(\log^2 n)$ assuming the *word-RAM model*. Then it might be necessary to decode the distance labels for trees. This can be done in constant time [24].

To sum up, the most costly part of decoding the labels $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$ is to read them up to find the (median) separator of u and v. But with an appropriate $O(\log^2 n)$ bits information concatenated to $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$, one can find this median vertex in $O(1)$ time and then directly jump to the corresponding part of $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$. For that, consider the tree T (of recursive calls) in which vertices at depth i are the median vertices chosen at step i and in which the children of a vertex x are the medians chosen at step $i + 1$ in the fibers generated by x at step i. We can observe that every vertex of G appears in this tree, that the separator m of any two vertices u and v of G is their nearest common ancestor in the tree T, and that its depth j in this tree corresponds to its position in $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$, i.e., $\mathrm{LD}_j^{\mathrm{St[Med]}}(u) = \mathrm{LD}_j^{\mathrm{St[Med]}}(v) = \mathrm{id}(m)$. As noticed in [39], any distance labeling for trees T can be modified to support *nearest common ancestor's depth (NCAD)* queries by adding the depth $\mathrm{depth}(u)$ of u in T to the label $L(u)$ given to each vertex $u \in V(T)$ by the distance labeling. Given two vertices u and v of T, the NCAD decoder then returns $\frac{1}{2}(\mathrm{depth}(u) + \mathrm{depth}(v) - d_T(u, v))$. So, during the execution of DIST_ENC, we can also construct the tree T of recursive calls and then give an NCAD label $L'(u)$ in T to every vertex of G. Now, the first step of DIST will consist in decoding $L'(u)$ and $L'(v)$. Then the algorithm directly reads the parts of $\mathrm{LD}(u)$ and $\mathrm{LD}(v)$ corresponding to the last common median they stored. This establishes Theorem 1.

7 Conclusion

In this paper we presented a distance labeling scheme for cube-free median graphs G with labels of size $O(\log^3 n)$. For that, we considered the partitioning of G into fibers (of size $\leq n/2$) of the star $\mathrm{St}(m)$ of a median vertex m. Each fiber is further recursively partitioned using the same algorithm. We classified the fibers into panels and cones and the pairs of vertices u, v of G into roommates, separated, 1-neighboring, and 2-neighboring pairs. If u and v are roommates, then $d_G(u, v)$ is taken at a later step of the recursion. Otherwise, we showed how to retrieve $d_G(u, v)$ by keeping in the labels of u and v some distances from those vertices to some gates/imprints. Our main ingredient is the fact that the total boundaries of fibers of cube-free median graphs are isometric quasigated trees.

This last property of fibers is an obstacle in generalizing our approach to all median graphs, or even to median graphs of dimension 3. The main problem is that the total boundary is no longer a median graph. Therefore, one cannot apply to this total boundary the distance scheme for cube-free median graphs. Nevertheless, a more brute-force approach works for arbitrary median graphs G of constant maximum degree Δ. In this case, all hypercubes of G have constant size. Thus, the star $\mathrm{St}(m)$ cannot have more than $O(2^{\Delta})$ vertices, i.e., $\mathrm{St}(m)$ has a constant number of fibers. Since every fiber is gated, at every step of the encoding algorithm, every vertex v can store in its label the distance from v to its gates in all fibers of $\mathrm{St}(m)$. Consequently, this leads to distance labeling scheme with labels of (polylogarithmic) length $O(2^{\Delta}\log^3 n)$ for all median graphs with constant maximum degree Δ. We would like to finish this paper with the following question: *Does there exist a polylogarithmic distance labeling scheme for general median graphs or for median graphs of constant dimension?*

One-Dimensional Guarded Fragments

Emanuel Kieroński
University of Wrocław, Poland
kiero@cs.uni.wroc.pl

Abstract

We call a first-order formula one-dimensional if every maximal block of existential (or universal) quantifiers in it leaves at most one variable free. We consider the one-dimensional restrictions of the guarded fragment, GF, and the tri-guarded fragment, TGF, the latter being a recent extension of GF in which quantification for subformulas with at most two free variables need not be guarded, and which thus may be seen as a unification of GF and the two-variable fragment, FO^2. We denote the resulting formalisms, resp., GF_1, and TGF_1. We show that GF_1 has an exponential model property and NExpTime-complete satisfiability problem (that is, it is easier than full GF). For TGF_1 we show that it is decidable, has the finite model property, and its satisfiability problem is 2-ExpTime-complete (NExpTime-complete in the absence of equality). All the above-mentioned results are obtained for signatures with no constants. We finally discuss the impact of their addition, observing that constants do not spoil the decidability but increase the complexity of the satisfiability problem.

2012 ACM Subject Classification Theory of computation → Logic

Keywords and phrases guarded fragment, two-variable logic, satisfiability, finite model property

1 Introduction

The *guarded fragment* of first-order logic, GF, is obtained by requiring all quantifiers to be appropriately relativised by atoms. It was introduced by Andréka, van Benthem and Németi [1] as a generalization of propositional modal logic and may be also seen as an extension of some standard description logics. GF has good algorithmic and model-theoretic properties. In particular, Grädel proved that its satisfiability problem is decidable, it has a tree-like model property and the finite model property [7]. The idea of GF turned out to be very fruitful and found numerous applications. In this paper we consider some modifications of the syntax of GF. Our aim is to check if in this way we can obtain interesting fragments with better complexity and/or attractive expressiveness.

The satisfiability problem for GF is 2-ExpTime-complete. This relatively high complexity can be lowered to ExpTime either by bounding the number of variables, or the arity of relation symbols [7]. We propose another way of decreasing the complexity without sacrificing either the number of variables or the arity of relations. The idea is to restrict formulas to be *one-dimensional*. We say that a formula is one-dimensional if every maximal block of existential (or universal) quantifiers in it leaves at most one variable free. We remark that the one-dimensional restriction of full first-order logic, F_1, is undecidable, as observed by Hella and Kuusisto [9]. We denote the intersection of F_1 and GF by GF_1 and call it the *one-dimensional guarded fragment*. While this variation decreases the expressive power of the logic, we believe that it is still quite interesting, as, in particular, it still embeds propositional modal logic, and most standard description logics embeddable in full GF. Thus, as GF, it may serve as an extension of modal/description logics to contexts with relations of arbitrary arity. We show that the satisfiability problem for GF_1 is NExpTime-complete and that it has an exponential model property, that is, its every satisfiable formula has a model of size bounded exponentially in its length. This is in contrast to full GF in which one can enforce doubly exponentially large models. Moreover, proving the finite model property for GF_1 is much easier than for full GF, in particular it does not need complicated combinatorial constructions used in the case of GF (in [7], and in Bárány, Gottlob and Otto [2]). We obtain a corresponding NExpTime-lower bound even for a weaker logic, *uniform* GF_1, that is the intersection of GF_1 and *uniform* F_1, UF_1, the latter being a decidable restriction of F_1 introduced in [9] as a canonical generalization of the two-variable fragment FO^2 (with equality) to scenarios involving relations of arity greater than two (see Kieroński, Kuusisto [13] where NExpTime-completeness of UF_1 is shown). This is slightly surprising, since in many aspects UF_1 behaves similarly to the two-variable fragment, FO^2, and the guarded version of the latter is ExpTime-complete [7].

We also consider an extension of GF called the *tri-guarded fragment*, TGF. In TGF quantification for subformulas with at most two free variables may be used freely, without guards. Hence, TGF unifies GF and the already-mentioned FO^2. We borrowed the term *tri-guarded fragment* from a recent work by Rudolph and Šimkus [15], but, actually, the idea behind TGF is not new and can be traced back already in Kazakov's PhD thesis [11] where the fragment $\mathrm{GF}|\mathrm{FO}^2$, essentially identical with TGF, was defined. A similar logic, GF *with binary cross product*, $\mathrm{GF}^{\times_2}$, is also considered by Bourhis, Morak and Pieris [4]. Both $\mathrm{GF}|\mathrm{FO}^2$ and $\mathrm{GF}^{\times_2}$ do not allow constant symbols. We remark that in our initial scenario we also assume that constants are not present in signature; however, we will discuss their addition later.

Similarly to GF, FO^2 is a seminal fragment of first-order logic, and its importance is justified, *inter alia*, by its close relationships to modal and description logics. Mortimer [14] demonstrated that it has the finite model property and Grädel, Kolaitis and Vardi [8] proved that its satisfiability problem is NExpTime-complete. Each of the logics GF, FO^2 has some advantages and drawbacks with respect to the other. We mention here the fact that GF allows only to express properties of a local character, *e.g.*, it cannot express $\forall xy(Px \wedge Qy \rightarrow Rxy)$, while FO^2 does not allow for a non-trivial use of relations of arity greater than two. TGF offers a substantial improvement in these aspects. Moreover, in TGF we can embed the Gödel class, that is the class of all prenex formulas of the form $\forall xy \exists \bar{z} \psi(x, y, \bar{z})$. Indeed, any such formula has an equisatisfiable TGF formula obtained just by an addition of a dummy guard, as follows, $\forall xy \exists \bar{z}(G(x, y, \bar{z}) \wedge \psi(x, y, \bar{z}))$, where G is a fresh relation symbol of the appropriate arity. Such embedding implies, however, that the satisfiability problem for TGF with equality is undecidable, since the Gödel class with equality is undecidable, as proved by Goldfarb [6]. The undecidability of TGF with equality is also shown in [15] by a direct grid encoding. On the positive side, it turns out that the satisfiability problem for TGF *without equality* is decidable and 2-ExpTime-complete. It was proved in [11] by a resolution method, and follows also from the decidability of $\mathrm{GF}^{\times}_{2}$, shown in [4] by a use of the database-theoretic concept of *chase*.[1]

[1] A footnote in [4] suggests that the decidability of GF with binary cross-product is retained in the presence of equality. This has however been later later refuted by the authors (private communication). GF with binary cross product with equality is undecidable by the same arguments we gave for TGF.

In this paper we consider a natural combination of GF_1 and TGF, the *one-dimensional triguarded fragment*, TGF_1, which, on the one hand, allows us to use unguarded quantification for subformulas with at most two free variables, but, on the other hand, requires to obey the one-dimensionality restriction. We show that this variant is decidable even in the presence of equality. The complexity, however, depends on the presence/absence of equality: The satisfiability problem is 2-ExpTime-complete with equality and NExpTime-complete without it. The logic has the finite model property (we remark that whether full TGF has the finite model property is an open question), and, again, a bound on the size of minimal models is doubly- or singly exponential, depending on whether equality is allowed or not. TGF_1 may be seen as a decidable generalization of FO^2 (with equality) to scenarios with relations of arity greater than two, alternative and orthogonal in the expressive power to the above-mentioned UF_1. We also remark that TGF_1 can express the concept of *nominals* from description logics, since the combination of equality and unguarded quantification for subformulas with two free variables allows us to say that some unary predicates hold for unique elements of a model. Thus we can embed in TGF_1, *e.g.*, the description logic $\mathcal{ALC}$ plus inverse roles ($\mathcal{I}$), nominals ($\mathcal{O}$), role hierarchies ($\mathcal{H}$), and any Boolean combination of roles (including their negations).

We then briefly consider applications of the ideas of one-dimensionality and tri-guardedness to two decidable extensions of GF, namely, the loosely guarded fragment, LGF, introduced by van Benthem [17], and the guarded negation fragment, GNFO, proposed by Bárány, ten Cate and Segoufin [3]. Regarding one-dimensionality, it helps in the case of LGF: one-dimensional LGF has an exponential model property and NExpTime-complete satisfiability problem (exactly as GF_1), but does not help in the case of GNFO, where the one-dimensional variant remains 2-ExpTime-hard. Regarding the tri-guardedness, the results are negative: both LGF and GNFO, even in their one-dimensional variants, become undecidable when unguarded quantification for subformulas with two free variables is allowed.

As remarked, all the results discussed above are obtained under the assumption that constants are not present in signatures. It turns out that all the decidability results are preserved in the presence of constants. However, interestingly, the computational complexity may change (we recall that for GF constants make no difference [7]). This is also the case for TGF with constants, without equality, which is shown in [15] to be 2-NExpTime-complete. Here we show that a 2-NExpTime-lower bound can be obtained even for TGF_1 with constants, without equality. We also observe that the presence of constants lifts the complexity of GF_1 to 2-ExpTime.

In Table 1 we summarize the above-discussed complexity results for the variations of GF. We point out an interesting status of TGF_1: it is NExpTime-complete without equality and constants, 2-ExpTime-complete with equality and without constants, and 2-NExpTime-complete with constants (with or without equality).

We finally remark that further pushing the concepts of one-dimensionality and tri-guardedness to, resp., *two*-dimensionality and *tetra*-guardedness does not lead to attractive results. Indeed, a 2-ExpTime lower bound for two-dimensional GF can be shown by a slight adaptation of the bound for full GF from [7]; allowing for unguarded quantification for subformulas with three free variables gives undecidability, as the resulting logic contains the undecidable three-variable fragment of FO (see, *e.g.*, Kahr, Moore and Wang [10]). Undecidability of the three-variable fragment can be easily shown even using only one-dimensional formulas.

Table 1 Complexities of the guarded fragments. If the presence of constants makes a difference, the complexity of the variant with constants is given in the brackets. All logics have the finite model property. Results of this paper are distinguished in bold.

logic	with =	without =
GF	2-ExpTime.	2-ExpTime
TGF	undecidable	2-ExpTime (2-NExpTime)
GF_1	**NExpTime (2-ExpTime)**	**NExpTime (2-ExpTime)**
TGF_1	**2-ExpTime (2-NExpTime)**	**NExpTime (2-NExpTime)**

2 Preliminaries

We mostly work with purely relational signatures with no constants and function symbols (only in Section 6 we consider signatures with constants). For convenience we also assume that there are no relation symbols of arity 0. We refer to structures using Fraktur capital letters, and to their domains using the corresponding Roman capitals. Given a structure $\mathfrak{A}$ and some $B \subseteq A$ we denote by $\mathfrak{A}{\restriction}B$ or just by $\mathfrak{B}$ the restriction of $\mathfrak{A}$ to its subdomain B.

We usually use $a, b, \ldots$ to denote elements from domains of structures, $\bar{a}$, $\bar{b}$, ... for tuples of elements, x, y, ... for variables and $\bar{x}$, $\bar{y}$, ... for tuples of variables; all of these possibly with some decorations. For a tuple of variables $\bar{x}$ we use $\psi(\bar{x})$ to denote a formula (or subformula) ψ, whose all free variables are in $\bar{x}$.

An *atomic l-type* β over a signature σ is a maximal consistent set of atomic or negated atomic formulas (including equalities/inequalities) over σ in l variables $x_1, \ldots, x_l$. We often identify a type with the conjunction of its elements, $\beta(x_1, \ldots, x_l)$. For an l-type β we denote by $\beta{\restriction}x_i$ $(i = 1, \ldots, l)$ the 1-type obtained by removing from β all the literals that use some x_j, with $j \neq i$, and then replacing all occurrences of x_i by x_1. We will be particularly interested in 1-types and 2-types over signatures σ consisting of the relation symbols used in some given formula. Observe that the number of 1-types is bounded by a function which is exponential in $|\sigma|$, and hence also in the length of the formula. This is because a 1-type just corresponds to a subset of σ. On the other hand, the number of 2-types may be doubly exponentially large. Indeed, using an n-ary predicate and two fixed variables one can build 2^n atoms which then can be used to form 2^{2^n} different 2-types.

Let $\mathfrak{A}$ be a structure, and let $a, b \in A$ be such that $a \neq b$. We denote by $\mathrm{tp}^{\mathfrak{A}}(a)$ the unique atomic 1-type *realized* in $\mathfrak{A}$ by the element a, *i.e.*, the 1-type $\alpha(x)$ such that $\mathfrak{A} \models \alpha(a)$; similarly by $\mathrm{tp}^{\mathfrak{A}}(a, b)$ we denote the unique atomic 2-type realized in $\mathfrak{A}$ by pair (a, b), *i.e.*, the 2-type $\beta(x, y)$ such that $\mathfrak{A} \models \beta(a, b)$. For $B \subseteq A$ we denote by $\boldsymbol{\alpha}[B]$ the set of all 1-types realized in $\mathfrak{A}$ by elements of B.

Below we define several fragments of first-order logic, FO, including two new fragments, GF_1 and TGF_1. Each of the fragments is defined as the least set of formulas (i) containing all atomic formulas (including equalities), (ii) closed under Boolean connectives, and (iii) satisfying appropriate (depending on the fragment) rules of using quantifiers, specified below ($\bar{x}$, $\bar{y}$ represent here any tuples of variables and x, y represent any variables):

- *Guarded fragment* of first-order logic, GF:
  - if $\psi(\bar{x}, \bar{y}) \in \mathrm{GF}$ then $\forall \bar{x}(\gamma(\bar{x}, \bar{y}) \rightarrow \psi(\bar{x}, \bar{y}))$ and $\exists \bar{x}(\gamma(\bar{x}, \bar{y}) \wedge \psi(\bar{x}, \bar{y}))$ belong to GF, where $\gamma(\bar{x}, \bar{y})$ is an atomic formula containing all the free variables of ψ, called a *guard* for ψ.
- *One-dimensional fragment* of first-order logic, F_1:
  - if $\psi(\bar{x}, y) \in \mathrm{F}_1$ then $\exists \bar{x} \psi(\bar{x}, y)$ and $\forall \bar{x} \psi(\bar{x}, y)$ belong to F_1.

- *One-dimensional guarded fragment*, GF_1:
  - if $\psi(\bar{x}, y) \in \mathrm{GF}_1$ then $\forall \bar{x}(\gamma(\bar{x}, y) \rightarrow \psi(\bar{x}, y))$ and $\exists \bar{x}(\gamma(\bar{x}, y) \wedge \psi(\bar{x}, y))$ belong to GF_1, where $\gamma(\bar{x}, y)$ is a guard for ψ.
- *Tri-guarded fragment*, TGF:
  - if $\psi(\bar{x}, \bar{y}) \in \mathrm{TGF}$ then $\forall \bar{x}(\gamma(\bar{x}, \bar{y}) \rightarrow \psi(\bar{x}, \bar{y}))$ and $\exists \bar{x}(\gamma(\bar{x}, \bar{y}) \wedge \psi(\bar{x}, \bar{y}))$ belong to TGF, where $\gamma(\bar{x}, \bar{y})$ is a guard for ψ,
  - if $\psi(x, y)$ is in TGF, then $\exists x \psi(x, y)$ and $\forall x \psi(x, y)$ belong to TGF.
- *One-dimensional tri-guarded fragment*, TGF_1:
  - if $\psi(\bar{x}, y) \in \mathrm{TGF}_1$ then $\forall \bar{x}(\gamma(\bar{x}, y) \rightarrow \psi(\bar{x}, y))$ and $\exists \bar{x}(\gamma(\bar{x}, y) \wedge \psi(\bar{x}, y))$ belong to TGF_1, where $\gamma(\bar{x}, y)$ is a guard for ψ,
  - if $\psi(x, y)$ is in TGF_1, then $\exists x \psi(x, y)$ and $\forall x \psi(x, y)$ belong to TGF_1.

Note that GF_1 is just the intersection of GF and F_1, TGF contains both GF and FO^2, and TGF_1 is the intersection of TGF and F_1, containing full FO^2.

We recall that the satisfiability problem for F_1 is undecidable [9]. To regain decidability its *uniform* restriction, UF_1, was introduced in [9]. Roughly speaking, a boolean combination of atoms is allowed in UF_1 if all of them use precisely the same set of variables; the exceptions are atoms with one free variable and equalities, which may be used freely. See [9] or [13] for a formal definition and more details on UF_1.

We will also be interested in the loosely guarded fragment, LGF, the guarded negation fragment, GNFO, and their one-dimensional and tri-guarded variations. They will be introduced in Section 5.

3 Finite model property

In this section we prove the finite model property for TGF_1 and obtain (essentially optimal) upper bounds on the size of minimal models of its satisfiable formulas, as well as of formulas of its interesting subfragments.

We introduce a Scott-type normal form for TGF_1. Given a TGF_1 formula φ we say that it is in *normal form* if it has the following shape

$$\bigwedge_{i \in I} \forall \bar{x}(\gamma_i(\bar{x}) \rightarrow \psi_i(\bar{x})) \wedge \bigwedge_{i \in I'} \forall x \exists \bar{y} \psi'_i(x, \bar{y}) \wedge \forall x y \psi''(x, y) \qquad (1)$$

where I, I' are some sets of indices, the ψ_i, ψ'_i, and ψ'' represent arbitrary quantifier-free formulas, and for every i, γ_i is a proper guard for ψ_i. We remark that we do not require guards in formulas of the form $\forall\exists$, even if they contain more than two variables, as their presence there is inessential (cf. Remark in [7], p. 1725). In a rather standard fashion one can show the following lemma.

▶ **Lemma 1.** *There is a polynomial nondeterministic procedure, taking as its input a* TGF_1 *formula* φ *and producing a normal form formula* φ' *(over an extended signature), such that*
(i) *if* $\mathfrak{A} \models \varphi$ *for some structure* $\mathfrak{A}$ *then there is a run of the procedure producing a normal form* φ' *such that* $\mathfrak{A}' \models \varphi'$ *for some expansion* $\mathfrak{A}'$ *of* $\mathfrak{A}$*,*
(ii) *if the procedure has a run producing* φ' *and* $\mathfrak{A}' \models \varphi'$*, for some* $\mathfrak{A}'$*, then* $\mathfrak{A}' \models \varphi$*.*
Moreover, if φ *is without equality then the procedure produces* φ' *without equality; if* φ *is in* GF_1 *then the last conjunct* $\forall x y \psi''(x, y)$ *is not present in* φ'*.*

Lemma 1 allows us, when dealing with decidability or complexity issues and when considering the size of minimal models of formulas in TGF_1, to restrict attention to normal form sentences. The part of this lemma starting with "moreover" will allow us to use it effectively for TGF_1 without equality and for GF_1.

Our normal form is similar to normal form for GF [7]. It adapts the latter to the one-dimensional setting and extends it by the last type of conjuncts. The conversion to normal form in [7] is deterministic, it however cannot be used directly in our case as it adds one free variable to every subformula, which spoils one-dimensionality and may lead to unguarded subformulas with three variables.

Let φ be a normal form formula and $\mathfrak{A}$ its model. Take $a \in A$ and a conjunct $\psi = \forall x \exists \bar{y} \psi_i'(x, \bar{y})$ of φ. Let $\bar{b}$ be a tuple of elements of $\mathfrak{A}$ such that $\mathfrak{A} \models \psi_i'(a, \bar{b})$. Then $\mathfrak{A}\restriction(\{a\} \cup \bar{b})$ is called a *witness structure* for a and ψ.

▶ **Theorem 2.** *Every satisfiable formula φ in*

(i) TGF_1 *(with equality) has a finite model of size bounded doubly exponentially in $|\varphi|$.*
(ii) TGF_1 *without equality has a finite model of size bounded exponentially in $|\varphi|$.*
(iii) GF_1 *(with or without equality) has a finite model of size bounded exponentially in $|\varphi|$.*

We concentrate on showing (i) and then obtain (ii) and (iii) as a corollary from the finite model construction presented. Let φ be a normal form TGF_1 formula as in (1), and denote $n = |\varphi|$. Let us fix an arbitrary model $\mathfrak{A}$ of φ. We construct a bounded model $\mathfrak{B} \models \varphi$. We mimic the scheme of the classical construction from [8] showing an exponential model property for FO^2, in particular we adapt the notions of *kings* and *court*. The details, however, are more complicated.

Court. We say that an element $a \in A$ is a *king* if $\mathrm{tp}^{\mathfrak{A}}(a)$ is realized in $\mathfrak{A}$ only by a; $\mathrm{tp}^{\mathfrak{A}}(a)$ is then called *royal*. As in the case of FO^2 kings are important as their duplication may be forbidden by formulas like $\forall xy(Px \wedge Py \rightarrow x = y)$. Let $K \subseteq A$ be the set of kings of $\mathfrak{A}$. For each $a \in K$ and each $i \in I'$ choose a witness structure $\mathfrak{W}_{a,i}$ for a and ψ_i' in $\mathfrak{A}$. Let $C = K \cup \bigcup_{a,i} W_{a,i}$. We call $\mathfrak{C}$ the *court* of $\mathfrak{A}$. The court will be retained in $\mathfrak{B}$. Note that the number of elements in C is bounded exponentially in n, and it that the structure $\mathfrak{C}$ can be described using exponentially many bits (the latter is true since the arity of all relation symbols is bounded by n). Note that K, and thus also C may be empty.

Pattern witness structures. For each non-royal element $a \in A \setminus K$ we say that the isomorphism type of the structure $\mathfrak{A}\restriction(K \cup \{a\})$ is the $\mathfrak{K}$-type of a. Note that from a $\mathfrak{K}$-type of an element one can infer its 1-type, and that the number of the $\mathfrak{K}$-types realized in $\mathfrak{A}$ is bounded doubly exponentially in n. Denote by $\boldsymbol{\alpha}^{\mathfrak{K}}$ the set of $\mathfrak{K}$-types realized in $\mathfrak{A}$ by the elements of $A \setminus K$. Later, we will allow ourselves to use the notion of a $\mathfrak{K}$-type in a natural way also for other structures with a distinguished substructure $\mathfrak{K}$. For each $\pi \in \boldsymbol{\alpha}^{\mathfrak{K}}$ choose an element a having $\mathfrak{K}$-type π in $\mathfrak{A}$ and for each $i \in I'$ choose a witness structure $\mathfrak{W}_{\pi,i}$ for a and ψ_i'. Let $\mathfrak{W}_{\pi,i}^* = \mathfrak{W}_{\pi,i}\restriction(W_{\pi,i} \setminus (K \cup \{a\}))$. For each $\pi \in \boldsymbol{\alpha}^{\mathfrak{K}}$, $i \in I'$ and $j = 0, 1, 2$ let $\mathfrak{W}_{\pi,i,j}^*$ be a fresh isomorphic copy of $\mathfrak{W}_{\pi,i}^*$.

Universe. We define the universe of $\mathfrak{B}$ as follows $B := C \cup \bigcup_{\pi,i,j} W_{\pi,i,j}^*$, where π ranges over $\boldsymbol{\alpha}^{\mathfrak{K}}$, i over I' and j over $\{0, 1, 2\}$. We emphasise that the sets $W_{\pi,i,j}^*$ are disjoint from C and from each other. We retain in $\mathfrak{B}$ the structure on C from $\mathfrak{A}$ and for each π, i, j we make $\mathfrak{B}\restriction(K \cup W_{\pi,i,j}^*)$ isomorphic to $\mathfrak{A}\restriction(K \cup W_{\pi,i}^*)$. This, in particular, makes the $\mathfrak{K}$-type in $\mathfrak{B}$ of each element b belonging to some $W_{\pi,i,j}^*$ identical with the $\mathfrak{K}$-type in $\mathfrak{A}$ of the counterpart of b from the original substructure $\mathfrak{W}_{\pi,i}$.

Witness structures for the court. Let us consider an element $c \in C \setminus K$, and denote by π its $\mathfrak{K}$-type in $\mathfrak{A}$. For every $i \in I'$ make $\mathfrak{B}\restriction(\{c\} \cup (W_{\pi,i} \cap K) \cup W_{\pi,i,0}^*)$ isomorphic to $\mathfrak{W}_{\pi,i}$. This provides a witness structure for c and ψ_i' in $\mathfrak{B}$. Note that a single such step (for fixed c

and i) consists in defining relations on tuples containing c, at least one element of $W^*_{\pi,i,0}$ and possibly some elements of K, since relations on other relevant tuples were defined in the desired way in step *Universe*. Note that no conflicts (attempts to set the same atom to both true and false) can arise, when we perform this step for some c and i and then for the same c and some $i' \neq i$, because in the first case we define truth-values of relations only on tuples containing some element from $W^*_{\pi,i,0}$, and in the second – only on tuples containing some element from $W^*_{\pi,i',0}$, and $W^*_{\pi,i,0}$ is disjoint from $W^*_{\pi,i',0}$. Finally, when we perform this step for some c, and then for some $c' \neq c$ no conflicts arise since in the first case we define relations only on tuples containing c but not c' and in the second – only on tuples containing c' but not c.

Witness structures for the other elements. Consider now any element $b \in B \setminus C$. Assume it belongs to $W^*_{\pi',i',j'}$ and that π is the $\mathfrak{K}$-type of b in $\mathfrak{B}\restriction(K \cup \{b\})$. For each $i \in I'$ make the structure on $\{b\} \cup (W_{\pi,i} \cap K) \cup W^*_{\pi,i,(j'+1 \mod 3)}$ isomorphic to $\mathfrak{W}_{\pi,i}$. This provides a witness structure for b and ψ'_i in $\mathfrak{B}$. Again, to do it we need to define relations on some tuples containing b and some element of $W^*_{\pi,i,(j'+1 \mod 3)}$, and, due to our strategy, this can be done without conflicts.

Completing the structure. For any pair of distinct elements $b, b' \in B$ whose 2-type has not yet been defined in $\mathfrak{B}$ choose a pair of distinct elements a, a' with $\text{tp}^{\mathfrak{A}}(a) = \text{tp}^{\mathfrak{B}}(b)$ and $\text{tp}^{\mathfrak{A}}(a') = \text{tp}^{\mathfrak{B}}(b')$, and set $\text{tp}^{\mathfrak{B}}(b, b') := \text{tp}^{\mathfrak{A}}(a, a')$. An appropriate pair a, a' exists even if $\text{tp}^{\mathfrak{B}}(b) = \text{tp}^{\mathfrak{B}}(b')$ since at least one of b, b' has a non-royal type. For any tuple $\bar{b}$ of elements of B containing at least three distinct elements, and any relation symbol R of arity $|\bar{b}|$, if the truth-value of $R(\bar{b})$ in $\mathfrak{B}$ has not yet been defined then set it to *false*.

This finishes the definition of $\mathfrak{B}$. Let us now estimate its size. We can bound the number and the arity of relation symbols by $n = |\varphi|$. Then the size of K is bounded by the number of possible 1-types, 2^n. The size of C is bounded by $2^n \cdot n(n-1)$, as each element a of K may need at most n witness structures each of them containing (besides a) at most $n-1$ elements. The number of possible relations of arity at most n on a a set of $2^n + 1$ elements is bounded by $2^{(2^n+1)^n} \leq 2^{2^{n^2+n}}$, thus the number of $\mathfrak{K}$-types is bounded by $(2^{2^{n^2+n}})^n = 2^{n \cdot 2^{n^2+n}} \leq 2^{2^{n^2+2n}} \leq 2^{2^{2n^2}}$ (for $n > 1$). Finally, we can bound the size of B by $2^n + 2^n \cdot n(n-1) + 3n(n-1) \cdot 2^{2^{2n^2}}$, doubly exponentially in n.

Presently, we explain that $\mathfrak{B} \models \varphi$. First note that for each $b \in B$ and each $i \in I'$ there is an appropriate witness structure: if $b \in K$ then this witness structure is provided in $\mathfrak{C}$ which is a substructure of $\mathfrak{B}$. If $b \in C \setminus K$ or $b \in B \setminus C$ then a proper witness structure is provided explicitly either in step *Witness structure for the court* or, resp., *Witness structures for the other elements*. Thus $\mathfrak{B}$ satisfies all conjuncts of φ of the form $\forall x \exists \bar{y} \psi'_i(x, \bar{y})$.

Consider any conjunct $\forall \bar{x}(\gamma_i(\bar{x}) \rightarrow \psi_i(\bar{x}))$ of φ and a tuple of elements $\bar{b}$ such that $\mathfrak{B} \models \gamma_i(\bar{b})$. If $\bar{b} \subseteq C$ or $\bar{b} \subseteq K \cup W^*_{\pi,i,j}$ for some π, i, j then the structure on $\bar{b}$ was made an isomorphic copy of some substructure of $\mathfrak{A}$ in step *Universe*. Otherwise $\bar{b}$ contains at least two distinct elements. In this case the structure on $\bar{b}$ was made an isomorphic copy of some substructure of $\mathfrak{A}$ either in one of the steps *Witness structures for the court*, *Witness structures for the other elements* or in step *Completing the structure* (in this last subcase $\bar{b}$ contains precisely two distinct elements). Thus $\mathfrak{B} \models \psi_i(\bar{b})$. Finally, consider the conjunct $\forall xy \psi''(x, y)$ and take any pair $b, b' \in B$. Again, the structure on $\{b, b'\}$ is an isomorphic copy of a substructure of $\mathfrak{A}$ defined (at the latests) in step *Completing the structure*.

This finishes the proof of (i). To see (ii) and (iii) we first observe that in both cases every satisfiable formula φ has a model without kings. Given a structure $\mathfrak{A}$ we define two new structures $2\mathfrak{A}$ and $2\mathfrak{A}^+$, each of them with universe $A \times \{0,1\}$ and the substructures on $A \times \{0\}$ and $A \times \{1\}$ isomorphic to $\mathfrak{A}$. In $2\mathfrak{A}$ we make these two copies of $\mathfrak{A}$ completely disjoint by setting the truth-value of $R(\bar{a})$ to *false* for any R and any tuple $\bar{a}$ (of the appropriate length) contained neither in $A \times \{0\}$ nor $A \times \{1\}$. In $2\mathfrak{A}^+$, for any tuple $\bar{a}$ contained neither in $A \times \{0\}$ nor $A \times \{1\}$ and for any relation symbol R of arity $|\bar{a}|$, if this tuple contains at least three distinct elements then we also define $R(\bar{a})$ to be *false*. If $\bar{a}$ contains just two distinct elements, say $(a,0)$ and $(a',1)$, then for any relation symbol R or arity $|\bar{a}|$ set $R(\bar{a})$ *true* iff $\mathfrak{A} \models R(\bar{a}{\restriction}1)$ where $\bar{a}{\restriction}1$ is the projection of the elements of $\bar{a}$ on their first position.

Observations that if φ is without equality and $\mathfrak{A} \models \varphi$ then $2\mathfrak{A}^+ \models \varphi$, and that if φ is in GF_1 (even with equality) and $\mathfrak{A} \models \varphi$ then $2\mathfrak{A} \models \varphi$ are routine. Of course our new models are without kings. Starting our small model construction from a model without kings we get $K = \emptyset$ and thus $\mathfrak{K}$-types trivialize to 1-types, which means that their number is bounded singly exponentially. Also $C = \emptyset$ and thus we construct $\mathfrak{B}$ out of the $W^*_{\pi,i,j}$ where π ranges over the set of 1-types, the number of possible i is linear in n and there are just three possible values of j. The size of each $\mathfrak{W}^*_{\pi,i,j}$ is linear in n. The size of the constructed models can be thus estimated by $3n(n-1) \cdot 2^n$. Hence part (ii) and (iii) of Thm. 2 hold.

4 Complexity

In this section we establish the complexity of the considered logics.

▶ **Theorem 3.** *The satisfiability problem (= finite satisfiability problem)*

(i) *for* TGF_1 *with equality is* 2-ExpTime*-complete.*

(ii) *for* TGF_1 *without equality is* NExpTime*-complete.*

(iii) *for* GF_1 *is* NExpTime*-complete.*

Upper bound in (i). We design an alternating satisfiability test for TGF_1 using only exponential space. A 2-ExpTime-upper bound follows then from the fact that AExpSpace=2-ExpTime (Chandra, Kozen, Stockmeyer [5]). The procedure takes as its input a TGF_1 formula φ and works as described below. For simplicity our description is slightly informal. In particular, we do not precisely specify how structures constructed during its execution are represented. We also allow ourselves to write “guess an object X such that Y” instead of more accurate “guess an object X; verify if X meets property Y; if it does not then **reject**”.

1. Nondeterministically compute a normal form φ' as in Lemma 1. Let $n := |\varphi'|$.
2. **Guess** a set of 1-types $\boldsymbol{\alpha} = \boldsymbol{\alpha}_r \dot{\cup} \boldsymbol{\alpha}_{nr}$ over the signature of φ' (royal and non-royal types), such that for any α_1, α_2 (possibly $\alpha_1 = \alpha_2$) such that $\alpha_1 \in \boldsymbol{\alpha}$ and $\alpha_2 \in \boldsymbol{\alpha}_{nr}$ there is a 2-type β such that $\beta{\restriction}x_1 = \alpha_1$ and $\beta{\restriction}x_2 = \alpha_2$, and β does not violate the universal conjuncts of φ'.
3. **Guess** structures $\mathfrak{K}$, $\mathfrak{C}$ of size at most 2^n and $2^n \cdot n^2$, resp., with $\mathfrak{K}$ being a substructure of $\mathfrak{C}$, such that (i) $\boldsymbol{\alpha}[K] = \boldsymbol{\alpha}_r$, (ii) $\boldsymbol{\alpha}[C \setminus K] \subseteq \boldsymbol{\alpha}_{nr}$, (iii) each element of K has all the required witness structures for $\forall\exists$ conjuncts of φ' in $\mathfrak{C}$, and (iv) universal conjuncts of φ' are not violated in $\mathfrak{C}$.
4. **Universally choose** an element $c \in C \setminus K$ and a conjunct ψ of φ' of type $\forall\exists$. Set $\mathfrak{F} := \mathfrak{C}{\restriction}(K \cup \{c\})$.
5. Set $\mathit{Counter} := 0$.

6. **Guess** an extension $\mathfrak{D}$ of $\mathfrak{F}$, with universe $D = K \cup \{c\} \cup \{a_1, \ldots, a_t\}$, such that (i) $\mathrm{tp}^{\mathfrak{D}}(a_i) \in \boldsymbol{\alpha}_{nr}$ for all i, (ii) for some $k_1, \ldots, k_s \in K$ the structure $\mathfrak{W} = \mathfrak{D} \restriction \{c, k_1, \ldots, k_s, a_1, \ldots, a_t\}$ is a witness structure for c and ψ, (iii) universal conjuncts of φ' are not violated in $\mathfrak{D}$. If $t = 0$ then **accept**.
7. **Universally choose** a new value for c from $\{a_1, \ldots, a_t\}$ and a conjunct ψ of φ' of the form $\forall\exists$. Set $\mathfrak{F} := \mathfrak{F}\restriction(K \cup \{c\})$.
8. $\mathit{Counter} := \mathit{Counter} + 1$
9. If $\mathit{Counter} < 2^{2^{2n^2}}$ then goto 6 else **accept**.

Let us first note that exponential space is sufficient to perform the above algorithm. By Lemma 1 we have that n is bounded polynomially in $|\varphi|$. The number of 1-types in $\boldsymbol{\alpha}$ is also bounded by 2^n, as a 1-type is determined by a subset of the signature. For some pairs of 1-types we need to guess a 2-type whose description is exponential (there are at most 2^n tuples of length not greater than n consisting of a pair of elements, and at most n relation symbols). The size of the structure $\mathfrak{C}$ guessed in Step 4 is explicitly required to be exponential in n. Also its description requires only exponentially many bits (recall that the arity of all relations is bounded by n). Analogously we can bound the size of structures $\mathfrak{D}$ guessed in Step 6. Finally, the value of $\mathit{Counter}$ is bounded doubly exponentially, so it also can be written using exponentially many bits.

Now we argue that the procedure accepts its input φ iff φ is satisfiable. Assume first that the procedure accepts φ. We show that then φ' (and thus, by Lemma 1, also φ) has a model. Consider an accepting run of the procedure. We may assume w.l.o.g. that this run is uniform, that is, when entering step 6, in configurations differing only in the values of $\mathit{Counter}$ (but with isomorphic $\mathfrak{F}$s) it makes the same (isomorphic) guesses of $\mathfrak{D}$. Then the modification of this procedure in which Step 9 is replaced just by 'Goto 6' can run infinitely (if necessary) without clashes. Indeed if the value $\mathit{Counter} = 2^{2^{2n^2}}$ is reached we have a guarantee that the $\mathfrak{K}$-type of the current c appeared before in the computation (cf. our estimations on the size of the small model constructed in the proof of Thm. 2, in particular on the number of $\mathfrak{K}$-types). We can construct a model for φ' starting from the substructure $\mathfrak{C}$ guessed in Step 4, and then providing witness structures for all conjuncts of the form $\forall\exists$ of φ' and elements c in accordance with guesses of $\mathfrak{D}$ is Step 6 (we add fresh copies of elements $a_1, \ldots, a_t$ and make the structure on the union of K, $\{c\}$ and the set of the newly added elements isomorphic to $\mathfrak{D}$). We complete the (usually infinite) structure as in Step *Completing the structure* of the small model construction from the proof of Thm. 2 using the 2-types guaranteed in Step 1. As in that proof we can also show that the constructed structure is a model of φ'.

Conversely, assume that φ has a model $\mathfrak{A}^*$. Nondeterministically compute its normal form φ' and let $\mathfrak{A} \models \varphi'$ be an expansion of $\mathfrak{A}^*$ guaranteed by Lemma 1. Let $\mathfrak{B}$ be a model of φ' constructed as in the proof of Thm. 2, starting from $\mathfrak{A}$. W can now make all the guesses of our procedure in accordance with $\mathfrak{B}$: denoting $K_{\mathfrak{B}}$ and $C_{\mathfrak{B}}$ the set of kings and a court of $\mathfrak{B}$, resp., we set $\boldsymbol{\alpha}_r := \boldsymbol{\alpha}[K_{\mathfrak{B}}]$, $\boldsymbol{\alpha}_{nr} := \boldsymbol{\alpha}[B \setminus K_{\mathfrak{B}}]$, $\mathfrak{K} := \mathfrak{K}_{\mathfrak{B}}$, $\mathfrak{C} := \mathfrak{C}_{\mathfrak{B}}$. Then in the loop 6-9, when a structure $\mathfrak{D}$ containing a witness structure for c and ψ is going to be guessed we choose an element $c' \in \mathfrak{B}$ such that the $\mathfrak{K}$-types of c' in $\mathfrak{B}$ and c in $\mathfrak{F}$ are identical and find a witness structure for c' and ψ in $\mathfrak{B}$. We set $\mathfrak{D}$ to be isomorphic to the restriction of $\mathfrak{B}$ to the union of $K_{\mathfrak{B}}$ and this witness structure. This strategy naturally leads to acceptance.

Lower bound in (i). We encode computations of an alternating Turing machine M working in exponential space on its input $\bar{a} = a_{i_0} \ldots a_{i_{n-1}}$.

The general idea of the proof is not far from the ideas used in the proofs of the 2-ExpTime-lower bound for GF [7] and 2-NExpTime-lower bound for TGF with constants [15]. We must, however, be careful to avoid quantification leaving more than one variable free, which happens in both the above-mentioned proofs. *E.g.*, in [7] configurations of a Turing machine are encoded by pairs of elements a_1, a_2; concretely, by the truth-values of some relations of arity $O(n)$ on tuples consisting of a_1, a_2. To enforce existence of successor configurations quantification leaving two free variables is needed there.

We assume that M has states $s_0, s_1, \ldots, s_k$, where s_0 is the initial state, s_{k-1} is the only accepting state, and s_k is the only rejecting state. The alphabet of M consists of letters $a_0, \ldots, a_l$ where a_0 represents *blank*. Without loss of generality we assume that M has precisely two possible moves in every configuration, that on its every computation path it enters the accepting or rejecting state no later than in 2^{2^n}-th step, and then, after reaching such final state, does not stop but works infinitely in a trivial way, without changing its configuration.

For $i = 0, \ldots, k$ we use a predicate S_i, for $i = 0, \ldots, l$ we use a predicate A_i and to describe the head position we use a predicate H. Each of the S_i, A_i and H is of arity $1 + n$.

We enforce the existence of two kings, called *zero* and *one*, marked, resp., by unary predicates Z and O. They will also be called *bits*, serve as binary digits and will be used to encode the numbers of tape cells.

$$\exists x(Z(x) \wedge \neg O(x)) \wedge \forall xy(Z(x) \wedge Z(y) \rightarrow x = y) \tag{2}$$

$$\exists x(O(x) \wedge \neg Z(x)) \wedge \forall xy(O(x) \wedge O(y) \rightarrow x = y) \tag{3}$$

The idea is that every element of a model encodes a configuration of M in its relation to tuples of bits of size n. Such a tuple of bits $\bar{b}$ can be naturally read as a number in the range $[0, \ldots, 2^n - 1]$. Let us think that $A_i(c, \bar{b})$ means that in the configuration encoded by c, tape cell $\bar{b}$ contains a_i, $H(c, \bar{b})$ denotes that this tape cell is scanned by the head and, for a cell observed by the head, $S_i(c, \bar{b})$ means that M is in state s_i.

To be able to speak about properties of configurations of M in TGF_1 we introduce a predicate C of arity $1 + 2n$, which will be made true at least for all tuples consisting of an arbitrary element of a model followed by $2n$ bits. We first say that, for any $0 \leq i < 2n$, C holds for some tuple consisting of i ones and $2n - i$ zeros, and then propagate C to all relevant tuples, using the fact that the pair of permutations $(2, 1, 3, \ldots, 2n)$ and $(2, 3, \ldots, 2n, 1)$ generates the whole permutation group S_{2n}. Below $\bar{z} = z_{2n-1}, z_{2n-2}, \ldots, z_1, z_0$.

$$\begin{aligned}\forall x \exists t_1 t_0 (O(t_1) \wedge Z(t_0) \wedge & C(x, t_0, t_0, t_0, \ldots, t_0) \wedge \\ & C(x, t_1, t_0, t_0 \ldots, t_0) \wedge \\ & C(x, t_1, t_1, t_0, \ldots, t_0) \wedge \ldots \wedge \\ & C(x, t_1, t_1, t_1, \ldots, t_1))\end{aligned} \tag{4}$$

$$\forall x \bar{z} (C(x, \bar{z}) \rightarrow C(x, z_{2n-2}, z_{2n-1}, z_{2n-3}, \ldots, z_0) \wedge C(x, z_{2n-2}, z_{2n-3}, \ldots, z_0, z_{n-1})) \tag{5}$$

We use a convention that $\bar{u}, \bar{v}, \bar{w}$ are tuples of variables of size n, $\bar{u} = u_{n-1}, \ldots, u_0$ and analogously for $\bar{v}$ and $\bar{w}$. We introduce abbreviations, $\lambda^{\neq}(\bar{u}, \bar{v})$ and $\lambda^{+1}(\bar{u}, \bar{v})$ for quantifier-free formulas of size polynomial in n. The former is intended to say that the numbers encoded by $\bar{u}$ and $\bar{v}$ differ, the latter – that the number encoded by $\bar{v}$ is greater by one than the number encoded by $\bar{u}$. *E.g.*, $\lambda^{+1}(\bar{u}, \bar{v})$ can be defined as

$$\bigvee_{0 \leq i < n} (Z(u_i) \wedge O(v_i) \wedge \bigwedge_{j<i} (O(u_j) \wedge Z(v_j)) \wedge \bigwedge_{j>i} (O(u_j) \leftrightarrow Z(v_j))) \tag{6}$$

Analogously, we use $\lambda^i(\bar{u})$ and $\lambda^{\geq i}(\bar{u})$ for formulas saying that the number encoded by $\bar{u}$ is, resp., equal to i and greater or equal i. Again, they can be defined in a standard way by quantifier-free, polynomially bounded formulas.

Now we ensure that every element properly encodes a configuration. The following formulas say that, resp., there is a tape cell scanned by the head, there is at most one such cell, this cell carries also information about the state, and every tape cell contains precisely a single letter. Below $\dot{\bigvee}_i \psi_i$ is an easily definable shorthand for "exactly one of the ψ_i holds".

$$\forall x \exists \bar{u} (H(x, \bar{u}) \wedge \bigwedge_i (O(u_i) \vee Z(u_i)) \tag{7}$$

$$\forall x \bar{u} \bar{v} (C(x, \bar{u}, \bar{v}) \to H(x, \bar{u}) \wedge \lambda^{\neq}(\bar{u}, \bar{v}) \to \neg H(x, \bar{v})) \tag{8}$$

$$\forall x \bar{u} (H(x, \bar{u}) \to \dot{\bigvee}_i S_i(x, \bar{u})) \tag{9}$$

$$\forall x \bar{u} (C(x, \bar{u}, \bar{u}) \to \dot{\bigvee}_i A_i(x, \bar{u})) \tag{10}$$

We then say that every element has two successors, and, using the trick with permutations prepare appropriate guards. Predicates $Succ_i$ are of arity $2 + 3n$. For $i = 1, 2$ we write:

$$\begin{aligned} \forall x \exists y t_1 t_0 (O(t_1) \wedge Z(t_0) \wedge & Succ_i(x, y, t_0, t_0, t_0, \ldots, t_0) \wedge \\ & Succ_i(x, y, t_1, t_0, t_0 \ldots, t_0) \wedge \\ & Succ_i(x, y, t_1, t_1, t_0, \ldots, t_0) \wedge \ldots \wedge \\ & Succ_i(x, y, t_1, t_1, t_1, \ldots, t_1)) \end{aligned} \tag{11}$$

$$\begin{aligned} & \forall x y \bar{t} (Succ_i(x, y, \bar{t}) \to \\ & \quad Succ_i(x, y, t_{3n-2}, t_{3n-1}, t_{3n-3}, \ldots, t_0) \wedge Succ_i(x, y, t_{3n-2}, t_{3n-3}, \ldots, t_0, t_{3n-1})) \end{aligned} \tag{12}$$

We next describe the computations of M on $\bar{a}$. First we say that the letter at a tape cell not scanned by the head does not change in the successor configurations. For $i = 1, 2$:

$$\forall x y \bar{u} ((Succ_i(x, y, \bar{u}, \bar{u}, \bar{u}) \to \neg H(x, \bar{u}) \to \bigwedge_i (A_i(x, \bar{u}) \to A_i(y, \bar{u}))) \tag{13}$$

Consider now existential moves. Assume that in an existential state s_i, reading a letter a_j the machine has two possible transitions: $(s_{i'}, a_{j'}, \to)$ and $(s_{i''}, a_{j''}, \leftarrow)$. Then we write:

$$\begin{aligned} & \forall x y \bar{u} \bar{v} \bar{w} (Succ_1(x, y, \bar{u}, \bar{v}, \bar{w}) \to H(x, \bar{u}) \wedge S_i(x, \bar{u}) \wedge A_j(x, \bar{u}) \wedge \lambda^{+1}(\bar{u}, \bar{v}) \wedge \lambda^{+1}(\bar{w}, \bar{u}) \to \\ & \quad (H(y, \bar{v}) \wedge S_{i'}(y, \bar{v}) \wedge A_{j'}(y, \bar{u})) \vee (H(y, \bar{w}) \wedge S_{i''}(y, \bar{w}) \wedge A_{j''}(y, \bar{u}))) \end{aligned} \tag{14}$$

Similarly, assume that M has moves as above in a universal state s_i. We write:

$$\begin{aligned} & \forall x y \bar{u} \bar{v} \bar{v} (Succ_1(x, y, \bar{u}, \bar{v}, \bar{v}) \to \\ & \quad H(x, \bar{u}) \wedge S_i(x, \bar{u}) \wedge A_j(x, \bar{u}) \wedge \lambda^{+1}(\bar{u}, \bar{v}) \to H(y, \bar{v}) \wedge S_{i'}(y, \bar{v}) \wedge A_{j'}(y, \bar{u})) \end{aligned} \tag{15}$$

$$\begin{aligned} & \forall x y \bar{u} \bar{w} \bar{w} (Succ_2(x, y, \bar{u}, \bar{w}, \bar{w}) \to \\ & \quad H(x, \bar{u}) \wedge S_i(x, \bar{u}) \wedge A_j(x, \bar{u}) \wedge \lambda^{+1}(\bar{w}, \bar{u}) \to H(y, \bar{w}) \wedge S_{i'}(y, \bar{w}) \wedge A_{j'}(y, \bar{u})) \end{aligned} \tag{16}$$

We finally say that a model does not contain a configuration with the rejecting state and impose the existence of an element encoding the initial configuration.

$$\neg \exists x S_k(x) \wedge \exists x Init(x) \tag{17}$$

$$\begin{aligned} \forall x \bar{u} (C(x, \bar{u}) \to Init(x) \to (& \lambda^{=0}(\bar{u}) \to H(x, \bar{u}) \wedge S_0(x, \bar{u}) \wedge A_{i_0}(x, \bar{u})) \wedge \\ & (\lambda^{=1}(\bar{u}) \to A_{i_1}(x, \bar{u})) \wedge \ldots \wedge \\ & (\lambda^{=n-1}(\bar{u}) \to A_{i_{n-1}}(x, \bar{u})) \wedge \\ & (\lambda^{\geq n}(\bar{u}) \to A_0(x, \bar{u}))) \end{aligned} \tag{18}$$

Showing that M accepts $\bar{a}$ iff the constructed formula has a model is routine.

Upper bounds in (ii) and (iii). In both cases we have proved an exponential model property. Thus, to test satisfiability it suffices to guess an exponentially bounded structure and verify that it indeed is a model. More precisely, given a formula φ we nondeterministically convert it into normal form φ'. We guess an exponentially bounded model $\mathfrak{B}$ of φ' (again we remark that not only the universe of $\mathfrak{B}$ is bounded exponentially, but also the description of $\mathfrak{B}$, since we are dealing only with at most $|\varphi'|$ relations of arity at most $|\varphi'|$), and verify that it is indeed a model. The last task can be carried out in an exhaustive way: for each $b \in B$ and each conjunct of φ' of the form $\forall x \exists \bar{y} \psi'_i(x, \bar{y})$ guess which elements form a witness structure for b and this conjunct and check that they indeed form a required witness structure; for each conjunct $\forall \bar{x}(\gamma_i(\bar{x}) \to \psi_i(\bar{x}))$ enumerate all tuples $\bar{b}$ of elements of B such that $|\bar{b}| = |\bar{x}|$ and check that $\mathfrak{B} \models \gamma_i(\bar{b}) \to \psi_i(\bar{b})$. Proceed analogously with the conjunct $\forall xy \psi''(x, y)$.

Lower bounds in (ii) and (iii). It suffices to show NExpTime-lower bound for GF$_1$ without equality. As advertised in the Introduction, we even strengthen this result using only uniform formulas, that is we show NExpTime-hardness of the *uniform* one-dimensional guarded fragment being the intersection of GF and UF$_1$. For our current purposes it is sufficient to say that conjunctions of sentences $\exists \bar{x} \psi(\bar{x})$ and $\forall \bar{x} \psi(\bar{x})$ with quantifier-free ψ are uniform if all atoms of φ use either all variables of $\bar{x}$ or just one of them. We use only formulas of such kind. For a general definition of UF$_1$ see [9] or [13]. Our proof goes by an encoding of an exponential tiling problem and is given in the full version of this paper.

5 Variations on extensions of the guarded fragment

Let us see what happens when the ideas of one-dimensionality, tri-guardedness and their combination are applied to two extensions of the guarded fragment: the loosely guarded fragment, LGF, introduced by van Benthem [17], and the guarded negation fragment, GNFO, introduced by Bárány, ten Cate and Segoufin [3]. LGF is defined similarly to GF, but the notion of the guard is more liberal: in subformulas of the form $\exists \bar{y}(\gamma(\bar{x}, \bar{y}) \wedge \varphi(\bar{x}, \bar{y}))$ and $\forall \bar{y}(\gamma(\bar{x}, \bar{y}) \to \varphi(\bar{x}, \bar{y}))$ we do not require that γ is atomic but allow it to be a conjunction of atoms such that for every variable from $\bar{y}$ and every variable from $\bar{y} \cup \bar{x}$ there is an atom in γ containing both of them. In GNFO (atomic) guards are required not for quantifiers but for negated subformulas. For a more detailed definition of GNFO see [3].

One-dimensionality. First, let us see that the one-dimensionality decreases the complexity of LGF, similarly as in the case of GF, but does not affect the complexity of GNFO.

▶ **Theorem 4.**

(i) *The satisfiability (= finite satisfiability) problem for the one-dimensional* LGF, LGF$_1$, *is* NExpTime*-complete.* LGF$_1$ *has an exponential model property.*

(ii) *The satisfiability (= finite satisfiability) problem for the one-dimensional* GNFO *is* 2-ExpTime*-complete.*

To prove (i) we adjust the small model construction from the proof of Thm. 2, by using more copies of witness structures and refining the strategy of providing witnesses. The construction from the proof of Thm. 2 cannot be applied without any changes to the current scenario, as it may accidentally form some cliques of cardinality greater than 2 in the Gaifmann graph of the constructed model which then could work as loose guards and lead to a violation of some universal conjuncts of the input formula.

To see (ii) note that GNFO contains the unary negation fragment, UNFO, whose satisfiability problem is already 2-ExpTime-hard. UNFO is not one-dimensional but can be polynomially translated to its equivalent UN-normal form (ten Cate, Segoufin [16]), which is one-dimensional. The upper bound is inherited from the upper bound for full GNFO [3].

Tri-guardedness. Unfortunately, allowing for unguarded binary subformulas leads to undecidability already in the case of one-dimensional variants of LGF and GNFO.

▶ **Theorem 5.** *The (finite) satisfiability problems for the one-dimensional* LGF *or* GNFO*, with unguarded subformulas with two variables, even without equality, are undecidable.*

In the case of LGF_1, unguarded binary subformulas give the power of full one-dimensional fragment F_1. Indeed by adding a conjunct $\forall xy G^*(x, y)$ we would be able to guard any tuple of variables $x_1, \ldots, x_k$ by the conjunction $\bigwedge_{i \neq j} G^*(x_i, x_j)$. (A similar observation is present also in [15].) As the satisfiability problem for F_1 is undecidable [9] this gives the undecidability of the considered variation of LGF. For the one-dimensional GNFO, using unguarded negations of binary atoms one can express transitivity of binary relations: $\neg\exists xyz(Rxy \wedge Ryz \wedge \neg Rxz)$. One-dimensional GNFO contains the two-variable guarded fragment which becomes undecidable when extended by transitive relations (Kieroński [12], Kazakov [11]). Thus the claim follows.

6 Adding constants

Finally, we study the satisfiability problem for GF_1 and TGF_1 with constants. It turns out that in the presence of constants we lose neither the decidability nor the finite model property, however, the complexity increases. The following theorem completes Table 1.

▶ **Theorem 6.**

(i) *Every satisfiable formula in* TGF_1 *with constants has a finite model of size bounded doubly exponentially in its length.*

(ii) *The satisfiability (= finite satisfiability) problem for* GF_1 *with constants (with or without equality) is 2-*ExpTime*-complete.*

(iii) *The satisfiability (= finite satisfiability) problem for* TGF_1 *with constants (with or without equality) is 2-*NExpTime*-complete.*

It is not difficult to see that Lemma 1 holds for formulas with constants. Thus, to show (i) we can use a minor adaptation of our small model construction from the proof of Thm. 2. Indeed, interpretations of constants may be treated as kings. The number of $\mathfrak{K}$-types remains doubly exponential. The construction works then essentially without changes, we only remark that in step *Completing the structure*, when a 2-type for a pair of elements is chosen, we need to define the truth-values of all relations on tuples built out of these elements and constants. This way we get a doubly exponential bound on the size of models.

The upper bound in (ii) follows from the fact that full GF with constants is in 2-ExpTime [7].

The upper bound in (iii) follows from the fact that full TGF with constants is in 2-NExpTime [15]. We remark, however, that this upper bound for TGF is obtained without proving the finite model property, thus to justify the upper bound for finite satisfiability of TGF_1 we must refer to part (i) of Thm. 6.

The corresponding lower bounds in (ii) and (iii) are proved in the full version of this paper.

Abstract

We show that the finite satisfiability problem for the unary negation fragment with an arbitrary number of transitive relations is decidable and 2-ExpTime-complete. Our result actually holds for a more general setting in which one can require that some binary symbols are interpreted as arbitrary transitive relations, some as partial orders and some as equivalences. We also consider finite satisfiability of various extensions of our primary logic, in particular capturing the concepts of nominals and role hierarchies known from description logic. As the unary negation fragment can express unions of conjunctive queries, our results have interesting implications for the problem of finite query answering, both in the classical scenario and in the description logics setting.

1 Introduction

Decidable fragments and unary negation. Searching for attractive fragments of first-order logic is an important theme in theoretical computer science. Successful examples of such fragments, with numerous applications, are modal and description logics. They have their own syntax, but naturally translate to first-order logic, via the *standard translation.* Several seminal decidable fragments of first-order logic were identified by preserving one particular restriction obeyed by this translation and dropping all the others. Important examples of such fragments are two-variable logic, FO^2, [25], the guarded fragment, GF, [2], and the fluted fragment, FF, [24, 22]. They restrict, respectively, the number of variables, the quantification pattern and the order of variables in which they appear as arguments of predicates. A more recent proposal [27] is the *unary negation fragment*, UNFO. This time we restrict the use of negations, allowing them only in front of subformulas with at most one free variable. UNFO turns out to retain many good algorithmic and model theoretic properties of modal logic, including the finite model property, a tree-like model property and the decidability of the satisfiability problem. We remark here that UNFO and GF have a common decidable generalization, *the guarded negation fragment*, GNFO, [5].

To justify the attractiveness of UNFO let us look at one of the crucial problems in database theory, open-world query answering. Given an (incomplete) set of facts $\mathfrak{D}$, a set of constraints $\mathcal{T}$ and a query q, check if $\mathfrak{D} \wedge \mathcal{T}$ entails q. Generally, this problem is undecidable, and to make it decidable one needs to restrict the class of queries and constraints. Widely investigated class of queries are (unions of) *conjunctive queries* – (disjunctions of) sentences of the form $\exists \bar{x}\psi(\bar{x})$ where ψ is a conjunction of atoms. An important class of constraints are *tuple generating dependencies*, TGDs, of the form $\forall \bar{x}\bar{y}(\psi(\bar{x},\bar{y}) \rightarrow \exists \bar{z}\psi'(\bar{y},\bar{z}))$, where ψ and ψ' are, again, conjunctions of atoms. Conjunctive query answering against arbitrary TGDs is still undecidable (see, e.g., [6]), so TGDs need to be restricted further. Several classes of TGDs making the problem decidable have been proposed. One interesting such class are *frontier-one* TGDs, in which the *frontier* of each dependency, $\bar{y}$, consists just of a single variable [4]. Frontier-one TGDs are a special case of frontier-guarded TGDs [3]. Checking whether $\mathfrak{D}$ and $\mathcal{T}$ entail q boils down to verifying (un)satisfiability of the formula $\mathfrak{D} \wedge \mathcal{T} \wedge \neg q$. It turns out that if $\mathcal{T}$ is a conjunction of frontier-one TGDs and q is a disjunction of conjunctive queries then the resulting formula belongs to UNFO.

Transitivity. A serious weakness of the expressive power of UNFO is that it cannot express transitivity of a binary relation, nor related properties like being an equivalence, a partial order or a linear order. This limitation becomes particularly important when database or knowledge representation applications are considered, as transitivity is a natural property in many real-life situations. Just consider relations like *greater-than* or *part-of*. This weakness is shared by FO^2, GF and FF. Thus, it is natural to think about their extensions, in which some distinguished binary symbols may be explicitly required to be interpreted as transitive relations. It turns out that FO^2, GF and FF do not cope well with transitivity, and the satisfiability problems for the obtained extensions are undecidable [15, 13, 23] (see also [10, 18, 17]). Some positive results were obtained for FO^2, GF and FF only when one transitive relation is available [21, 18, 23] or when some further syntactic restrictions are imposed [26].

UNFO is an exception here, since its satisfiability problem remains decidable in the presence of arbitrarily many transitive relations. This has been explicitly stated in [16], as a corollary from a stronger result that UNFO is decidable when extended by regular path expressions. Independently, the decidability of UNFO with transitivity, UNFO+$\mathcal{S}$, follows from [1], which deals with the decidability of a richer logic, the guarded negation fragment with transitive relations restricted to non-guard positions, which embeds UNFO+$\mathcal{S}$. From both papers the 2-ExpTime-completeness of UNFO+$\mathcal{S}$ can be inferred.

Our main results. A problem related to satisfiability is *finite satisfiability*, in which we ask about the existence of *finite* models. In computer science, the importance of decision procedures for finite satisfiability arises from the fact that most objects about which we may want to reason using logic, e.g., databases, are finite. Thus the ability of solving only general satisfiability may not be fully satisfactory. Both the above-mentioned decidability results implying the decidability of UNFO+$\mathcal{S}$ are obtained by employing tree-like model properties of the logics and then using automata techniques. Since tree-like unravelings of models are infinite, this approach works only for general satisfiability, and gives little insight into the decidability/complexity of finite satisfiability. In this paper we consider the finite satisfiability problem for UNFO+$\mathcal{S}$. Actually, we made a step in this direction already in our previous paper [7] (see [8] for its longer version) where we proved a related result that UNFO with equivalence relations, UNFO+EQ, has the finite model property and thus that its satisfiability and finite satisfiability problems coincide, both being 2-ExpTime-complete. Some ideas developed in [7] are extended and applied also here, even though UNFO+$\mathcal{S}$ does not have the finite model property which becomes evident when looking at the following formula with transitive T, $\forall x \exists y Txy \wedge \forall x \neg Txx$, satisfiable only in infinite models.

Our main contribution is demonstrating the decidability of finite satisfiability for UNFO+$\mathcal{S}$ and establishing its 2-ExpTime-completeness. En route we obtain a triply exponential bound on the size of minimal models of finitely satisfiable UNFO+$\mathcal{S}$ formulas. Actually, our results hold for a more general setting, in which some relations may be required to be interpreted as equivalences, some as partial orders, and some just as arbitrary transitive relations. Returning to database motivations, we get this way the decidability of the *finite* open-world query answering for unions of conjunctive queries against frontier-one TGDs with equivalences, partial orders and arbitrary transitive relations. By *finite open-world query answering* we mean the question if for given $\mathfrak{D}$, $\mathcal{T}$ and q, $\mathfrak{D}$ and $\mathcal{T}$ entail q over *finite* structures.

To the best of our knowledge, UNFO+$\mathcal{S}$ is the first logic which allows one to use arbitrarily many transitive relations, and, at the same time, to speak non-trivially about relations of arbitrary arities, whose finite satisfiability problem is shown decidable. In the case of related logics of this kind, like the guarded fragment with transitive guards [26], and the guarded negation fragment with transitive relations outside guards [1], the decidability was shown only for general satisfiability, and its finite version is open. (Finite satisfiability was shown decidable only for the *two-variable* guarded fragment with transitive guards [20]).

We believe that moving from UNFO+EQ from [7] to UNFO+$\mathcal{S}$ is an important improvement. Besides the fact that this requires strengthening our techniques and employing some new ideas, general transitive relations have stronger motivations than equivalences. In particular, it opens natural connections to the realm of description logics, DLs.

UNFO and expressive description logics. UNFO, via the above-mentioned standard translation, embeds the DL $\mathcal{ALC}$, as well as its extension by inverse roles ($\mathcal{I}$) and role intersections ($\sqcap$). Thus, having the ability of expressing conjunctive queries, we can use our results to solve the so-called *(finite) ontology mediated query answering* problem, (F)OMQA, for some DLs. This problem is a counterpart of (finite) open-world query answering: given a conjunctive query (or a union of conjunctive queries) and a knowledge base specified in a DL, check whether the query holds in every (finite) model of this knowledge base.

While there are quite a lot of results for OMQA, not much is known about FOMQA. In particular, for DLs with transitive roles ($\mathcal{S}$) the only positive results we are aware of are the ones obtained recently in [12], where the decidability and 2-ExpTime-completeness of FOMQA for the logics $\mathcal{SOI}$, $\mathcal{SIF}$ and $\mathcal{SOF}$ is shown. This is orthogonal to our results described above, since UNFO+$\mathcal{S}$ captures neither nominals ($\mathcal{O}$) nor functional roles ($\mathcal{F}$). On the other hand, we are able to express any positive boolean combinations of roles, including their intersection ($\sqcap$), which allows us to solve FOMQA, e.g., for the logic $\mathcal{SI}^{\sqcap}$. Moreover we can use non-trivially relations of arity greater than two.

It is an interesting question if our decidability result can be extended to capture some more expressive DLs. Unfortunately, we cannot hope for *number restrictions* ($\mathcal{Q}$ or $\mathcal{N}$) or even *functional roles* ($\mathcal{F}$), as satisfiability and finite satisfiability of UNFO (even without transitive relations) and two binary functional relations are undecidable. This is implicit in [27] (see the full version of this paper for an explicit proof). On the positive side, we show the decidability and 2-ExpTime-completeness of finite satisfiability of UNFO+$\mathcal{SOH}$, extending UNFO+$\mathcal{S}$ by constants (corresponding to *nominals* ($\mathcal{O}$)) and inclusions of binary relations (capturing *role hierarchies* ($\mathcal{H}$)). This is sufficient, in particular, to imply the decidability of FOMQA for the description logic $\mathcal{SHOI}^{\sqcap}$, which, up to our knowledge, is a new result.

Towards guarded negation fragment. We propose also another decidable extension of our basic logic, the *one-dimensional base-guarded negation fragment* with transitive relations on non-guard positions, BGNFO$_1$+$\mathcal{S}$. This is a non-trivial fragment of the already mentioned logic from [1]. After some rather easy adjustments, our constructions cover this bigger logic, however, it becomes undecidable when extended with inclusions of binary relations.

Organization of the paper. The rest of this paper is organized as follows. Section 2 contains definitions, basic facts and a high-level description of our decidability proof. As our constructions are rather complex, in the main body of the paper, Section 3, we explicitly process the restricted, two-variable case of our logic, for which our ideas can be presented more transparently. In Section 4 we just formulate the remaining results, leaving the details for the full version of this paper, which also contains the missing proofs from Sections 2 and 3. In Section 5 we conclude the paper.

2 Preliminaries

2.1 Logics, structures, types and functions

We employ standard terminology and notation from model theory. We refer to structures using Fraktur capital letters, and their domains using the corresponding Roman capitals. For a structure $\mathfrak{A}$ and $A' \subseteq A$ we use $\mathfrak{A}{\restriction}A'$ or $\mathfrak{A}'$ to denote the restriction of $\mathfrak{A}$ to A'.

The *unary negation fragment of first-order logic*, UNFO is defined by the following grammar [27]: $\varphi = B\bar{x} \mid x = y \mid \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \exists x \varphi \mid \neg\varphi(x)$, where, in the first clause, B represents any relational symbol, and, in the last clause, φ has no free variables besides (at most) x. An example formula not expressible in UNFO is $x \neq y$. We formally do not have universal quantification. However we allow ourselves to use $\forall \bar{x} \neg \varphi$ as an abbreviation for $\neg \exists \bar{x} \varphi$, for an UNFO formula φ. Note that frontier-one TGDs $\forall \bar{x} y(\psi(\bar{x}, y) \to \exists \bar{z} \psi'(y, \bar{z}))$ are in UNFO as they can be rewritten as $\neg \exists \bar{x} y(\psi(\bar{x}, y) \wedge \neg \exists \bar{z} \psi'(y, \bar{z}))$.

We mostly work with purely relational signatures (admitting constants only in some extensions of our main results) of the form $\sigma = \sigma_{\text{base}} \cup \sigma_{\text{dist}}$, where σ_{base} is the *base signature*, and σ_{dist} is the *distinguished signature*. We assume that $\sigma_{\text{dist}} = \{T_1, \ldots, T_{2k}\}$, with all the T_u binary, and intension that T_{2u} is interpreted as the inverse of T_{2u-1}. For every $1 \leq u \leq k$ we sometimes write T_{2u}^{-1} for T_{2u-1}, and T_{2u-1}^{-1} for T_{2u}. We say that a subset $\mathcal{E}$ of σ_{dist} is *closed under inverses* if, for every $1 \leq u \leq 2k$, we have $T_u \in \mathcal{E}$ iff $T_u^{-1} \in \mathcal{E}$. Note that $\mathcal{E}$ is closed under inverses iff $\sigma_{\text{dist}} \setminus \mathcal{E}$ is closed under inverses. Given a formula φ we denote by σ_φ the signature induced by φ, *i.e.*, the minimal signature, with its distinguished part closed under inverses, containing all symbols from φ.

The *unary negation fragment with transitive relations*, UNFO+$\mathcal{S}$, is defined by the same grammar as UNFO, however when satisfiability of its formulas is considered, we restrict the class of admissible models to those that interpret all symbols from σ_{dist} as transitive relations and, additionally, for each u, interpret T_{2u} as the inverse of T_{2u-1}. The latter condition is intended to simplify the presentation, and is imposed without loss of generality. In our constructions we sometimes consider some auxiliary structures in which symbols from σ_{dist} are not necessarily interpreted as transitive relations (but the pairs T_{2u-1}, T_{2u} are always interpreted as inverses of each other).

An *(atomic) k-type* over a signature σ is a maximal satisfiable set of literals (atoms and negated atoms) over σ with variables $x_1, \ldots, x_k$. We often identify a k-type with the conjunction of its elements. We are mostly interested in 1- and 2-types. Given a σ-structure $\mathfrak{A}$ and $a, b \in A$ we denote by $\text{atp}^{\mathfrak{A}}(a)$ the 1-type *realized* by a, that is the unique 1-type $\alpha(x_1)$ such that $\mathfrak{A} \models \alpha(a)$, and by $\text{atp}^{\mathfrak{A}}(a, b)$ the unique 2-type $\beta(x_1, x_2)$ such that $\mathfrak{A} \models \beta(a, b)$.

We use various functions in our paper. Given a function $f : A \to B$ we denote by $\text{Rng} f$ its range, by $\text{Dom} f$ its domain, and by $f{\restriction}A_0$ the restriction of f to $A_0 \subseteq A$.

2.2 Normal form, witnesses and basic facts

We say that an UNFO+$\mathcal{S}$ formula is in Scott-normal form if it is of the shape

$$\forall x_1, \ldots, x_t \neg\varphi_0(\bar{x}) \wedge \bigwedge_{i=1}^{m} \forall x \exists \bar{y} \varphi_i(x, \bar{y}) \tag{1}$$

where each φ_i is a UNFO+$\mathcal{S}$ quantifier-free formula and φ_0 is additionally in negation normal form (NNF). A similar normal form for UNFO was introduced in the bachelor's thesis [9]. By a straightforward adaptation of Scott's translation for FO^2 [25] one can translate in polynomial time any UNFO+$\mathcal{S}$ formula to a formula in normal form, in such a way that both are satisfiable over the same domains. This allows us, when dealing with decidability/complexity issues for UNFO+$\mathcal{S}$, or when considering the size of minimal finite models of formulas, to restrict attention to normal form formulas.

Given a structure $\mathfrak{A}$, a normal form formula φ as in (1) and elements $a, \bar{b}$ of A such that $\mathfrak{A} \models \varphi_i(a, \bar{b})$ we say that the elements of $\bar{b}$ are *witnesses* for a and φ_i and that $\mathfrak{A}\restriction\{a, \bar{b}\}$ is a *witness structure* for a and φ_i. Fix an element a. For every φ_i choose a witness structure $\mathfrak{W}_i$. Then the structure $\mathfrak{W} = \mathfrak{A}\restriction\{W_1 \cup \ldots \cup W_m\}$ is called a φ-*witness structure* for a.

We are going to present a construction which given an arbitrary finite model of a normal form UNFO+$\mathcal{S}$ formula φ builds a finite model of φ of a bounded size. The construction goes via several intermediate steps in which some tree-like models are produced. To argue that that they are still models of φ we use the following basic observation (we recall that t is the number of variables of the $\forall$-conjunct of φ).

▶ **Lemma 1.** *Let $\mathfrak{A}$ be a model of a normal form UNFO+$\mathcal{S}$ formula φ. Let $\mathfrak{A}'$ be a structure in which all symbols from σ_{dist} are interpreted as transitive relations, such that*

(a1) *for every $a' \in A'$ there is a φ-witness structure for a' in $\mathfrak{A}'$,*

(a2) *for every tuple $a'_1, \ldots, a'_t \in A'$ there is a homomorphism $\mathfrak{h} : \mathfrak{A}'\restriction\{a'_1, \ldots, a'_t\} \to \mathfrak{A}$ which preserves 1-types of elements.*

Then $\mathfrak{A}' \models \varphi$.

2.3 Plan of the small model construction

Our main goal is to show that finite satisfiability of UNFO+$\mathcal{S}$ formulas can be checked in 2-ExpTime. To this end we will introduce a natural notion of tree-like structures and a measure associating with transitive paths of such structures their so-called *ranks*. Intuitively, for a transitive relation T_i and a T_i-path π, the T_i-rank of π is the number of one-directional T_i-edges in π (a precise definition is given in Section 3.1). Then we show that having the following forms of models is equivalent for a normal form formula φ:

(f1) finite;

(f2) tree-like, with bounded ranks of transitive paths;

(f3) tree-like, with ranks of transitive paths bounded doubly exponentially in $|\varphi|$;

(f4) tree-like, with ranks of paths bounded doubly exponentially in $|\varphi|$, and regular (with doubly exponentially many non-isomorphic subtrees);

(f5) finite of size triply exponential in $|\varphi|$.

We will make the following steps: (f1) $\rightsquigarrow$ (f2), (f2) $\rightsquigarrow$ (f3), (f3) $\rightsquigarrow$ (f4), (f4) $\rightsquigarrow$ (f5). The step closing the circle, (f5) $\rightsquigarrow$ (f1) is trivial. In the two-variable case, we will omit the form (f4) and directly show (f3) $\rightsquigarrow$ (f5). Our 2-ExpTime-algorithm will look for models of the form (f3). Showing transitions leading from (f3) to (f5) justifies that its answers coincide indeed with the existence of *finite* models.

This scheme is similar to the one we used to show the finite model property for UNFO+EQ in [7]. In the main part of the construction from [7] we build bigger and bigger substructures in which some equivalence relations are total. The induction goes, roughly speaking, by the number of non-total equivalences in the substructure. Here we extend this approach to handle one-way transitive connections. It may be useful to briefly compare the case of UNFO+$\mathcal{S}$ and the case of UNFO+EQ.

First of all, if a given formula φ is from UNFO+EQ then we can start our constructions leading to a small finite model of φ from its arbitrary model, while if φ is in UNFO+$\mathcal{S}$ we start from a *finite* model of φ. A very simple step (f1) $\rightsquigarrow$ (f2) in both papers is, essentially, identical. The counterpart of step (f3) $\rightsquigarrow$ (f4) in the case of equivalences is slightly simpler, but the main differences lie in steps (f2) $\rightsquigarrow$ (f3) and (f4) $\rightsquigarrow$ (f5). The former, clearly, is not present at all in [7]. While the general idea in this step is quite standard, as we just use a kind of tree pruning, the details are rather delicate due to possible interactions among different transitive relations, and this step is, by no means, trivial. We refine here, in particular, the apparatus of *declarations* introduced in [7]. Regarding step (f4) $\rightsquigarrow$ (f5), the main construction there, in its single inductive step, has two phases: building the so-called *components* and then arranging them into a bigger structure. It is this first phase which is more complicated than in the corresponding step in [7]. Having components prepared we join them similarly as in [7].

3 The two-variable case

As in the case of unbounded number of variables we can restrict attention to normal form formulas, which in the two-variable case simplify to the standard Scott-normal form [25]:

$$\forall xy \neg\varphi_0(x,y) \wedge \bigwedge_{i=1}^{m} \forall x \exists y \varphi_i(x,y), \tag{2}$$

where all φ_i are quantifier-free UNFO^2+$\mathcal{S}$ formulas (in this restricted case it is not important whether φ_0 is in NNF or not). As is typical for two-variable logics we assume that formulas do not use relational symbols of arity greater than 2 (cf. [14]).

3.1 Tree pruning in the two-variable case

We use a standard notion of a (finite or infinite) rooted tree and related terminology. Additionally, any set consisting of a node and all its children is called a *family*. Any node b, except for the root and the leaves, belongs to two families: the one containing its parent, and the one containing its children, the latter called the *downward family of b*.

We say that a structure $\mathfrak{A}$ over a signature consisting of unary and binary symbols is a *light tree-like structure* if its nodes can be arranged into a rooted tree in such a way that if $\mathfrak{A} \models Baa'$ for some non-transitive relation symbol B then one of three conditions holds: $a = a'$, a is the parent of a' or a is a child of a', and if $\mathfrak{A} \models T_u aa'$ for some T_u then either $a = a'$ or there is a sequence of distinct nodes $a = a_0, a_1, \ldots, a_k = a'$ such that a_i and a_{i+1} are joined by an edge of the tree and $\mathfrak{A} \models T_u a_i a_{i+1}$. In other words, distant nodes in a light tree-like structure can be joined only by transitive connections, moreover, these transitive connections are just the transitive closures of connections inside families. For a light tree-like structure $\mathfrak{A}$ and $a \in A$ we denote by A_a the set of all nodes in the subtree rooted at a and by $\mathfrak{A}_a$ the corresponding substructure.

Let $\mathfrak{A}$ be a light tree-like structure. A sequence of nodes $a_1, \ldots, a_N \in A$ is a *downward path* in $\mathfrak{A}$ if for each i a_{i+1} is a child of a_i. A *downward-T_u-path* is a downward path such that for each i we have $\mathfrak{A} \models T_u a_i a_{i+1}$. The *$T_u$-rank* of a downward-$T_u$-path $\vec{a}$, $\mathfrak{r}_u^{\mathfrak{A}}(\vec{a})$, is the cardinality of the set $\{i : \mathfrak{A} \models \neg T_u a_{i+1} a_i\}$. The T_u-*rank* of an element $a \in A$ is defined as $\mathfrak{r}_u^{\mathfrak{A}}(a) = \sup\{\mathfrak{r}_u^{\mathfrak{A}}(\vec{a}) : \vec{a} = a, a_2, \ldots, a_N; \vec{a}$ is a downward-T_u-path$\}$. For an integer M, we say that $\mathfrak{A}$ has downward-T_u-paths *bounded by* M when for all $a \in A$ we have $\mathfrak{r}_u^{\mathfrak{A}}(a) \leq M$, and that $\mathfrak{A}$ has *transitive paths bounded by* M if it has downward-T_u-paths bounded by M for all u. Note that a downward-T_u-path bounded by M may have more than M nodes, as the symmetric T_u-connections do not increase the rank.

Given an arbitrary model $\mathfrak{A}$ of a normal form UNFO^2+$\mathcal{S}$ formula φ we can simply construct its light tree-like model of degree bounded by $|\varphi|$. We define a *light-φ-tree-like unraveling* $\mathfrak{A}'$ of $\mathfrak{A}$ and an associated function $\mathfrak{h} : A' \to A$ in the following way. $\mathfrak{A}'$ is divided into levels $L_0, L_1, \ldots$. Choose an arbitrary element $a \in A$ and add to level L_0 of A' an element a' such that $\text{atp}^{\mathfrak{A}'}(a') = \text{atp}^{\mathfrak{A}}(a)$; set $\mathfrak{h}(a') = a$. The element a' will be the only element of L_0 and will become the root of $\mathfrak{A}'$. Having defined L_i repeat the following for every $a' \in L_i$. For every j, if $\mathfrak{h}(a')$ is not a witness for φ_j and itself then choose in $\mathfrak{A}$ a witness b for $\mathfrak{h}(a')$ and φ_j. Add a fresh copy b' of b to L_{i+1}, make $\mathfrak{A}' \restriction \{a', b'\}$ isomorphic to $\mathfrak{A} \restriction \{\mathfrak{h}(a'), b\}$ and set $\mathfrak{h}(b') = b$. Complete the definition of $\mathfrak{A}'$ transitively closing all relations from σ_{dist}.

▶ **Lemma 2** ((f1) ⇝ (f2), light)**.** *Let $\mathfrak{A}$ be a finite model of a normal form UNFO^2+$\mathcal{S}$ formula φ. Let $\mathfrak{A}'$ be a light-φ-tree-like unraveling of $\mathfrak{A}$. Then $\mathfrak{A}' \models \varphi$ and $\mathfrak{A}'$ is a light tree-like structure of degree bounded by $|\varphi|$, and transitive paths bounded by $|A|$.*

Our next task is making the transition (f2) ⇝ (f3). For this purpose we introduce a notion of light declarations. It is closely related to a notion of declarations which will be used in the general case, but simpler than the latter. Fix a signature and let $\boldsymbol{\alpha}$ be the set of 1-types over this signature.

For $\mathcal{T} \subseteq \{T_1, \ldots, T_{2k}\}$ we write $\mathfrak{A} \models \mathcal{T}ab$ iff $\mathfrak{A} \models T_u ab$ for all $T_u \in \mathcal{T}$. A *light declaration* is a function of type $\mathcal{P}(\{T_1, \ldots, T_{2k}\}) \to \mathcal{P}(\boldsymbol{\alpha})$. Given a light tree-like structure $\mathfrak{A}$ and its node a we say that a *respects* a light declaration $\mathfrak{d}$ if for every $\mathcal{T}$, for every $\alpha \in \mathfrak{d}(\mathcal{T})$ there is **no** node $b \in A$ of 1-type α such that $\mathfrak{A} \models \mathcal{T}ab$. We denote by $\text{ldec}^{\mathfrak{A}}(a)$ the maximal light declaration respected by a. Formally, for every $\mathcal{T} \subseteq \{T_1, \ldots, T_{2k}\}$, $\text{ldec}^{\mathfrak{A}}(a)(\mathcal{T}) = \{\alpha :$ for every node b of type α we have $\neg\mathfrak{A} \models \mathcal{T}ab\}$. Intuitively, $\text{ldec}^{\mathfrak{A}}(a)$ says, for any combination of transitive relations, which 1-types have **no** realizations to which a is connected by this combination in $\mathfrak{A}$. Note that if a respects a light declaration $\mathfrak{d}$ then for any $\mathcal{T}$ we have $\mathfrak{d}(\mathcal{T}) \subseteq \text{ldec}^{\mathfrak{A}}(a)(\mathcal{T})$. We remark that it would be equivalent to define the light declarations without the negations, listing the 1-types that a given node **is** connected with, however we choose a version with negations to make them uniform with the corresponding (more complicated) notion in the general case, where negations are more convenient.

Now we define the *local consistency conditions (LCCs)* for a system of light declarations $(\mathfrak{d}_a)_{a \in A}$ assigned to all nodes of a tree-like structure $\mathfrak{A}$. Let F be the downward family of some node a. We say that the system *satisfies LCCs at* a if for every $a_1, a_2 \in F$ and for every $\mathcal{T}$ such that $\mathfrak{A} \models \mathcal{T}a_1a_2$ the following two conditions hold: **(ld1)** for every $\alpha \in \boldsymbol{\alpha}$, if $\alpha \in \mathfrak{d}_{a_1}(\mathcal{T})$ then $\alpha \in \mathfrak{d}_{a_2}(\mathcal{T})$, **(ld2)** $\text{atp}^{\mathfrak{A}}(a_2) \notin \mathfrak{d}_{a_1}(\mathcal{T})$. Given a light tree-like structure $\mathfrak{A}$ we say that a system of light declarations $(\mathfrak{d}_a)_{a \in A}$ is *locally consistent* if it satisfies LCCs at each $a \in A$ and is *globally consistent* if $\mathfrak{d}_a(\mathcal{T}) \subseteq \text{ldec}^{\mathfrak{A}}(a)(\mathcal{T})$ for each $a \in A$ and each $\mathcal{T}$. Note that the global consistency means that all nodes a respect their light declarations $\mathfrak{d}_a$. It is not difficult to see that local and global consistency play along in the following sense.

▶ **Lemma 3** (Local-global, light)**.** *Let $\mathfrak{A}$ be a light tree-like structure. Then, (i) if a system of light declarations $(\mathfrak{d}_a)_{a \in A}$ is locally consistent then it is globally consistent; and (ii) the* canonical *system of light declarations, $(\text{ldec}^{\mathfrak{A}}(a))_{a \in A}$, is locally consistent.*

Given a light tree-like structure $\mathfrak{A}$, by the *generalized type* of a node a of $\mathfrak{A}$ we will mean a pair $(\mathrm{ldec}^{\mathfrak{A}}(a), \mathrm{atp}^{\mathfrak{A}}(a))$, and denote it as $\mathrm{gtp}^{\mathfrak{A}}(a)$. We introduce a concept of top-down tree pruning. Let $\mathfrak{A}$ be a light tree-like structure. A *top-down tree pruning process* on $\mathfrak{A}$ has countably many steps $0, 1, 2, \ldots$, each of them producing a new light tree-like structure by removing some nodes from the previous one and naturally stitching together the surviving nodes. We emphasise that the universes of all structures build in this process are subsets of the universe of the original structure $\mathfrak{A}$. More specifically, we take $\mathfrak{A}_0 := \mathfrak{A}$, and having constructed $\mathfrak{A}_i$, $i \geq 0$ construct $\mathfrak{A}_{i+1}$ as follows. For every node a of $\mathfrak{A}_i$ of depth $i+1$ (we assume that the root has depth 0) either leave the subtree rooted at a untouched or replace it by a subtree rooted at some descendant b of a having in the original structure $\mathfrak{A}$ the same generalized type as a, and then transitively close all transitive relations. The result of the process is a naturally defined limit structure $\mathfrak{A}'$, in which the pair of elements a, b, of depth d_a and d_b respectively, has its 2-type taken from $\mathfrak{A}_{\max(d_a, d_b)}$. Note that this 2-type is not modified in the subsequent structures, so the definition is sound.

▶ **Lemma 4** (Tree-pruning, light). *Let $\mathfrak{A}$ be a light tree-like structure. Let $(\mathfrak{d}_a)_{a \in A}$ be the canonical system of light declarations on $\mathfrak{A}$, $\mathfrak{d}_a := \mathrm{ldec}^{\mathfrak{A}}(a)$. Let $\mathfrak{A}'$ be the result of a top-town tree pruning process on $\mathfrak{A}$. Then (i) the system of light declarations $(\mathfrak{d}_a)_{a \in A'}$ (the canonical declarations from $\mathfrak{A}$ of the nodes surviving the pruning process) in $\mathfrak{A}'$ is locally consistent, (ii) for any pair of elements $a, a' \in A'$ there is a homomorphism $\mathfrak{A} \restriction \{a, a'\} \to A$ preserving the 1-types; it also follows that (iii) for a normal form φ, if $\mathfrak{A}$ is a model of φ such that any node a has all its witnesses in its downward family then $\mathfrak{A}' \models \varphi$.*

It is not difficult to devise a strategy of top-down tree pruning leading to a model with short transitive paths in a simple scenario where only one transitive relation is present. With several transitive relations, however, a quite intricate strategy seems to be required. The main obstacle is that when decreasing the T_u-rank of an element a, for some u, we may accidentally increase the T_v-rank of a for some $v \neq u$. Nevertheless, an appropriate strategy exists (see the full version of this paper), which allows us to state:

▶ **Lemma 5** ((f2) ⇝ (f3), light). *Let φ be a normal form UNFO^2+$\mathcal{S}$ formula. Let $\mathfrak{A} \models \varphi$ be a light tree-like structure over signature σ_φ, with transitive paths bounded by some natural number M, such that each element has all the required witnesses in its downward family. Then φ has a light tree-like model with transitive paths bounded doubly exponentially in $|\varphi|$.*

3.2 Finite model construction in the two-variable case

In this section we show the following small model property. To this end, in particular, we will make the transition (f3) ⇝ (f5).

▶ **Theorem 6.** *Every finitely satisfiable two-variable UNFO+$\mathcal{S}$ formula φ has a finite model of size bounded triply exponentially in $|\varphi|$.*

Let us fix a finitely satisfiable normal form UNFO+$\mathcal{S}$ formula φ over a signature $\sigma_\varphi = \sigma_{\text{base}} \cup \sigma_{\text{dist}}$ for $\sigma_{\text{dist}} = \{T_1, \ldots, T_{2k}\}$. Denote by $\boldsymbol{\alpha}$ the set of 1-types over this signature. Fix a light tree-like model $\mathfrak{A} \models \varphi$, with linearly bounded degree and doubly exponentially bounded transitive paths (in this section we denote this bound by $\hat{M}_\varphi$), as guaranteed by Lemma 5. We show how to build a "small" finite model $\mathfrak{A}' \models \varphi$. For a set $\mathcal{E} \subseteq \sigma_{\text{dist}}$, closed under inverses, and $a \in A$ we denote by $[a]_{\mathcal{E}}$ the set consisting of a and all elements $b \in A$ such that $\mathfrak{A} \models T_u ab$ for all $T_u \in \mathcal{E}$. Note that $[a]_{\mathcal{E}}$ is either a singleton or each of the $T_u \in \mathcal{E}$ is total on $[a]_{\mathcal{E}}$, that is, for each $b_1, b_2 \in [a]_{\mathcal{E}}$ we have $\mathfrak{A} \models T_u b_1 b_2$ for all $T_u \in \mathcal{E}$. We note that $[a]_{\emptyset} = A$.

In our construction we inductively produce finite fragments of $\mathfrak{A}'$ corresponding to some (potentially infinite) classes $[a]_{\mathcal{E}}$ of $\mathfrak{A}$. Essentially, the induction goes downward on the size of $\mathcal{E}$. Intuitively, if a relation is total then it plays no important role, so we may forget about it during the construction. Every such fragment will be obtained by an appropriate arrangement of some number of basic building blocks, called *components*. Each of the components is obtained by some number of applications of the inductive assumption to situations in which a new pair of relations T_{2u-1}, T_{2u} is added to $\mathcal{E}$.

Let us formally state our inductive lemma. In this statement we do not explicitly include any bound on the size of promised finite models, but such a bound will be implicit in the proof and will be presented later. Recall that $\mathfrak{A}$ is the model fixed at the beginning of this subsection.

▶ **Lemma 7** (Main construction, light). *Let $a_0 \in A$ and let $\mathcal{E}_0 \subseteq \sigma_{dist}$ be closed under inverses, let $\mathcal{E}_{tot} := \sigma_{dist} \setminus \mathcal{E}_0$. Let $\mathfrak{A}_0 = \mathfrak{A}_{a_0} \restriction [a_0]_{\mathcal{E}_{tot}}$. Then there exist a finite structure $\mathfrak{A}'_0$, a function $\mathfrak{p} : A'_0 \to A_0$ and an element $a'_0 \in A'_0$, called the* origin *of $\mathfrak{A}'_0$, such that*

(b1) *A'_0 is a singleton or every symbol from $\mathcal{E}_{tot}$ is interpreted as the total relation on $\mathfrak{A}'_0$.*

(b2) *$\mathfrak{p}(a'_0) = a_0$.*

(b3) *For each $a' \in A'_0$ and each i, if $\mathfrak{p}(a')$ has a child being its witness for φ_i in $\mathfrak{A}_0$ then a' has a witness for φ_i in $\mathfrak{A}'_0$. Moreover, $\mathrm{atp}^{\mathfrak{A}'_0}(a') = \mathrm{atp}^{\mathfrak{A}_0}(\mathfrak{p}(a'))$.*

(b4) *For every pair $a', b' \in A'_0$ there exists a homomorphism $\mathfrak{h} : \mathfrak{A}'_0 \restriction \{a', b'\} \to \mathfrak{A}$ preserving* 1*-types such that $\mathfrak{h}(a') = \mathfrak{p}(a')$, and for any 1-type α and $\mathcal{T} \subseteq \{1, \ldots, 2k\}$, if $\mathfrak{A}'_0 \models \mathcal{T}a'b'$ and $\alpha \notin \mathrm{ldec}^{\mathfrak{A}}(\mathfrak{p}(b'))(\mathcal{T})$ then $\alpha \notin \mathrm{ldec}^{\mathfrak{A}}(\mathfrak{p}(a'))(\mathcal{T})$.*

Observe first that Lemma 7 indeed allows us to build a particular finite model of φ. Apply it to $\mathcal{E}_0 = \sigma_{\text{dist}}$ (which means that $\mathcal{E}_{tot} = \emptyset$ and $[a_0]_{\mathcal{E}_{tot}} = A$) and a_0 being the root of $\mathfrak{A}$ (which means that $\mathfrak{A}_0 = \mathfrak{A}$) and use Lemma 1 to see that the obtained structure $\mathfrak{A}'_0$ is a model of φ. Indeed, Condition (a1) of Lemma 1 follows directly from Condition (b3), as in this case $\mathfrak{p}(a')$ has all witnesses in $\mathfrak{A}_0$. Condition (a2) is directly implied by Condition (b4).

The proof of Lemma 7 goes by induction on l, where $l = |\mathcal{E}_0|/2$. In the base of induction, $l = 0$, we have $\mathcal{E}_{tot} = \sigma_{\text{dist}}$. Without loss of generality we may assume that the classes $[a]_{\mathcal{E}_{tot}}$ are singletons for all $a \in A$. (If this is not the case, we just add artificial transitive relations T_{2k+1} and T_{2k+2} both interpreted as the identity in $\mathfrak{A}$.) We simply take $\mathfrak{A}'_0 := \mathfrak{A}_0 = \mathfrak{A} \restriction \{a_0\}$ and set $\mathfrak{p}(a_0) = a_0$. It is readily verified that the conditions (b1)–(b4) are then satisfied.

For the inductive step assume that Lemma 7 holds for arbitrary $\mathcal{E}_0$ closed under inverses, of size $2(l-1) < 2k$. We show that then it holds for $\mathcal{E}_0$ of size $2l$. Take such $\mathcal{E}_0$, and assume, w.l.o.g., that $\mathcal{E}_0 = \{T_1, \ldots, T_{2l}\}$. In the next two subsections we present a construction of $\mathfrak{A}'_0$. We argue that it is correct in the full version of this paper. Finally we estimate the size of the produced models and establish the complexity of the finite satisfiability problem.

3.2.1 Pattern components

We plan to construct $\mathfrak{A}'_0$ out of basic building blocks called *components*. Each component will be an isomorphic copy of some pattern component.

Let $\boldsymbol{\gamma}[A_0]$ be the set of the generalized types realized in $\mathfrak{A}_0$. For every $\gamma \in \boldsymbol{\gamma}[A_0]$ we construct two pattern structures, a *pattern component* $\mathfrak{C}^\gamma$ and an *extended pattern component* $\mathfrak{G}^\gamma$. $\mathfrak{C}^\gamma$ is a finite structure whose universe is divided into $2l$ *layers* $L_1, \ldots, L_{2l}$. $\mathfrak{G}^\gamma$ extends $\mathfrak{C}^\gamma$ by an additional, *interface layer*, denoted L_{2l+1}. See the left part of Fig. 1. We now define $\mathfrak{G}^\gamma$, obtaining then $\mathfrak{C}^\gamma$ just by the restriction of $\mathfrak{G}^\gamma$ to non-interface layers.

Each non-interface layer L_i is further divided into *sublayers* $L_i^1, L_i^2, \ldots, L_i^{\hat{M}_\varphi+1}$. Additionally, in each sublayer L_i^j its initial part $L_i^{j,init}$ is distinguished. In particular, $L_1^{1,init}$ consists

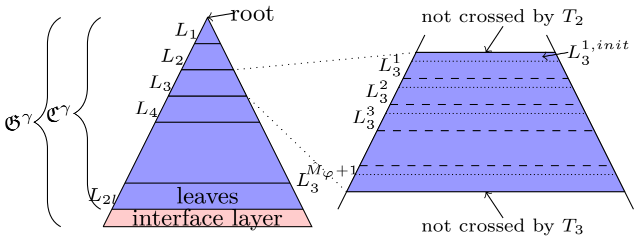

Figure 1 A schematic view of a component in the two-variable case.

of a single element called the *root*. The interface layer L_{2l+1} has no internal division but, for convenience, is sometimes referred to as $L_{2l+1}^{1,init}$. The elements of L_{2l} are called *leaves* and the elements of L_{2l+1} are called *interface elements*. See Fig. 1.

$\mathfrak{G}^\gamma$ will have a shape resembling a tree, with structures obtained by the inductive assumption as nodes, though it will not be tree-like in the sense of Section 3.1 (in particular, the internal structure of nodes may be complicated). All elements of $\mathfrak{G}^\gamma$, except for the interface elements, will have appropriate witnesses (those required by (b3)) provided. The crucial property we want to enforce is that the root of $\mathfrak{G}^\gamma$ will not be joined to its interface elements by any transitive path.

We remark that during the process of building a pattern component we do not yet apply the transitive closure to the distinguished relations. Postponing this step is not important from the point of view of the correctness of the construction, but will allow us for a more precise presentation of the proof of this correctness. Given a component $\mathfrak{C}$ (extended component $\mathfrak{G}$) we will sometimes denote by $\mathfrak{C}_+$ ($\mathfrak{G}_+$) the structure obtained from $\mathfrak{C}$ ($\mathfrak{G}$) by applying all the appropriate transitive closures.

The role of every non-interface layer L_u is, speaking informally, to *kill* T_u, that is to ensure that there will be no T_u-connections from L_u to L_{u+1}. See the right part of Fig. 1. The role of sublayers of L_u, on the other hand, is to decrease the T_u-rank of the patterns of elements. The purpose of the interface layer, L_{2l+1}, will be to connect the component with other components.

If γ is the generalized type of a_0 then take $a := a_0$; otherwise take as a any element of A_0 of generalized type γ. We begin the construction of $\mathfrak{G}^\gamma$ by defining $L_1^{1,init} = \{a'\}$ for a fresh a', setting $\text{atp}^{\mathfrak{G}^\gamma}(a') = \text{atp}^{\mathfrak{A}}(a)$ and $\mathfrak{p}(a') = a$.

Construction of a layer. Let $1 \le u \le 2l$. Assume we have defined layers $L_1, \ldots, L_{u-1}$, the initial part of sublayer L_u^1, $L_u^{1,init}$, and both the structure of $\mathfrak{G}^\gamma$ and the values of $\mathfrak{p}$ on $L_1 \cup \ldots \cup L_{u-1} \cup L_u^{1,init}$. We are going to kill T_u. We now expand $L_u^{1,init}$ to a full layer L_u.

Step 1: Subcomponents. Assume that we have defined sublayers $L_u^1, \ldots, L_u^{j,init}$, and both the structure of $\mathfrak{G}^\gamma$ and the values of $\mathfrak{p}$ on $L_1 \cup \ldots \cup L_{u-1} \cup L_u^1 \cup \ldots \cup L_u^{j,init}$. For each $b \in L_u^{j,init}$ perform independently the following procedure. Apply the inductive assumption to $\mathfrak{p}(b)$ and the set $\mathcal{E}_0 \setminus \{T_u, T_u^{-1}\}$ obtaining a structure $\mathfrak{B}_0$, its origin b_0 and a function $\mathfrak{p}_b : B_0 \to A_{\mathfrak{p}(b)} \cap [\mathfrak{p}(b)]_{\mathcal{E}_{tot} \cup \{T_u, T_u^{-1}\}} \subseteq A_0$ with $\mathfrak{p}_b(b_0) = \mathfrak{p}(b)$. Identify b_0 with b and add the remaining elements of $\mathfrak{B}_0$ to L_u^j, retaining the structure. Substructures $\mathfrak{B}_0$ of this kind will be called *subcomponents* (note that all appropriate relations are transitively closed in subcomponents). Extend $\mathfrak{p}$ so that $\mathfrak{p}{\restriction}B_0 = \mathfrak{p}_b$. This finishes the definition of L_u^j.

Step 2: Providing witnesses. For each $b \in L_u^j$ and $1 \leq s \leq m$ independently perform the following procedure. Let $\mathfrak{B}_0$ be the subcomponent created inductively in *Step 1*, such that $b \in B_0$. If $\mathfrak{p}(b)$ has a witness for $\varphi_s(x, y)$ in A_0 then we want to reproduce such a witness for b. Choose one such witness c (being a child of $\mathfrak{p}(b)$) for $\mathfrak{p}(b)$. Let us denote $\beta = \mathrm{atp}^{\mathfrak{A}}(\mathfrak{p}(b), c)$. If $\{T_u xy, T_u^{-1} xy\} \subseteq \beta$ then by Condition (b3) of the inductive assumption b already has an appropriate witness in the subcomponent $\mathfrak{B}_0$. So we do nothing in this case. If $T_u xy \in \beta$ and $T_u^{-1} xy \notin \beta$ then we add a copy c' of c to $L_u^{j+1,init}$; if $T_u xy \notin \beta$ then we add a copy c' of c to $L_{u+1}^{1,init}$. We join b with c' by β and set $\mathfrak{p}(c') = c$.

An attentive reader may be afraid that when adding witnesses for elements of the last sublayer $L_u^{\hat{M}_\varphi+1}$ of L_u we may want to add one of them to the non-existing layer $L_u^{\hat{M}_\varphi+2}$. There is however no such danger, which follows from the following claim.

▷ Claim 8. (i) Let $b \in L_u^{j,init}$ and let $\mathfrak{B}_0$ be the subcomponent created for b in *Step 1*. Then for all $b' \in \mathfrak{B}_0$ we have $\mathfrak{r}_u^{\mathfrak{A}}(\mathfrak{p}(b)) \geq \mathfrak{r}_u^{\mathfrak{A}}(\mathfrak{p}(b'))$. (ii) Let $b \in L_u^j$ and let $c' \in L_u^{j+1}$ be a witness created for b in *Step* 2. Then $\mathfrak{r}_u^{\mathfrak{A}}(\mathfrak{p}(b)) > \mathfrak{r}_u^{\mathfrak{A}}(\mathfrak{p}(c'))$.

Hence, when moving from L_u^j to L_u^{j+1} the T_u-ranks of pattern elements for the elements of these sublayers strictly decrease. Since these ranks are bounded by $\hat{M}_\varphi$, then, even if the T_u-ranks of the patterns of some elements of L_u^1 are equal to $\hat{M}_\varphi$, then, if $L_u^{\hat{M}_\varphi+1}$ is non-empty, the T_u-ranks of the patterns of its elements must be 0, which means that they cannot have witnesses connected to them one-directionally by T_u.

The construction of $\mathfrak{G}^\gamma$ is finished when layer L_{2l} is fully processed. We have added some elements to the interface layer, L_{2l+1}. Recall that it has only its "initial part".

3.2.2 Joining the components

In this section we take some number of copies of pattern components and arrange them into the desired structure $\mathfrak{A}'_0$, identifying interface elements of some components with the roots of some other. Some care is needed in this process in order to avoid any modifications of the internal structure of closures $\mathfrak{C}_+$ of components $\mathfrak{C}$, which could potentially result from the transitivity of relations. In particular we need to ensure that if for some u a pair of elements of a component $\mathfrak{C}$ is not connected by T_u inside $\mathfrak{C}$, then it will not become connected by a chain of T_u-edges external to $\mathfrak{C}$.

We create a pattern component $\mathfrak{C}^\gamma$ and its extension $\mathfrak{G}^\gamma$ for every $\gamma \in \boldsymbol{\gamma}[A_0]$. Let γ_{a_0} be the generalized type of a_0. Let *max* be the maximal number of interface elements across all the $\mathfrak{G}^\gamma$. For each $\mathfrak{G}^\gamma$ arbitrarily number its interface elements from 1 up to, maximally, *max*.

For each γ we take copies $\mathfrak{G}_{i,\gamma'}^{\gamma,g}$ of $\mathfrak{G}^\gamma$ for $g \in \{0, 1\}$, $1 \leq i \leq max$ and $\gamma' \in \boldsymbol{\gamma}[A_0]$. The parameter g is sometimes called a *color* (*red* or *blue*); it is convenient to think that the non-interface elements of $G_{i,\gamma'}^{\gamma,g}$ are of color g, but its interface elements have color $1-g$, cf. the left part of Fig. 1, as the latter will be later identified with the roots of some components of color $1 - g$. We import the numbering of the interface elements to these copies. We also take an additional copy $\mathfrak{G}_{\perp,\perp}^{\gamma_{a_0},0}$ of $\mathfrak{G}^{\gamma_{a_0}}$. Its root will become the origin of the whole $\mathfrak{A}'_0$. By $\mathfrak{C}_{i,\gamma'}^{\gamma,g}$ we denote the restriction of $\mathfrak{G}_{i,\gamma'}^{\gamma,g}$ to its non-interface elements.

For each γ, g consider extended components of the form $\mathfrak{G}_{\cdot,\cdot}^{\gamma,g}$, where the placeholders $\cdot$ can be substituted with any combination of proper indices. Perform the following procedure for each $1 \leq i \leq max$. Let b be the i-th interface element of any such extended component, let γ' be the generalized type of $\mathfrak{p}(b)$. Identify the i-th interface elements of all $\mathfrak{G}_{\cdot,\cdot}^{\gamma,g}$ with the root c_0 of $\mathfrak{G}_{i,\gamma}^{\gamma',1-g}$. Note that the values of $\mathfrak{p}(c_0)$ and $\mathfrak{p}(b)$ may differ. However, by construction, they have identical generalized types γ'. For the element c^* obtained in this identification step we define $\mathfrak{p}(c^*) = \mathfrak{p}(c_0)$.

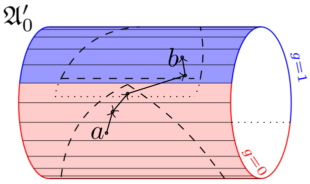

Figure 2 Viewing $\mathfrak{A}^0_0$ and $\mathfrak{A}'_0$ as placed on a cylindrical surface.

Define the graph of components used in the above construction, G^{comp}, by joining two components by an edge iff we identified an interface element of the extended version of one of them with the root of the other. Let A^0_0 be the union of the components accessible from $\mathfrak{C}^{\gamma_{a_0},0}_{\perp,\perp}$ in G^{comp} and let $\mathfrak{A}^0_0$ be the induced structure. Note that in $\mathfrak{A}^0_0$ we still do not take the transitive closures of relations. We define $\mathfrak{A}'_0$ by transitively closing all relations from $\sigma_{\rm dist}$ in $\mathfrak{A}^0_0$. Finally, we choose as the origin a'_0 of $\mathfrak{A}'_0$ the root of the pattern component $\mathfrak{C}^{\gamma_0,0}_{\perp,\perp}$.

We remark that it is sufficient to take as the universe of $\mathfrak{A}'_0$ the union of the universes of some components $\mathfrak{C}^{\cdot,\cdot}_{\cdot,\cdot}$, and not of their extended versions $\mathfrak{G}^{\cdot,\cdot}_{\cdot,\cdot}$ from which we started our construction, since the interface elements from these extended components were identified with some roots of other components.

For the correctness proof of our construction see the full version of this paper. In this proof it is helpful to think about $\mathfrak{A}^0_0$ and $\mathfrak{A}'_0$ as the structures placed on a cylindrical surface and divided into $4l$ *levels*, see Fig. 2. What is crucial, any transitive path in $\mathfrak{A}^0_0$ can cross at most one of the two borders between colors.

3.2.3 Size of models and complexity

By a rather routine calculation we can show that models produced in the proof of Lemma 7 are of size bounded triply exponentially in the length of input formulas. This finishes the proof of Thm. 6, which immediately gives the decidability of the finite satisfiability problem for UNFO^2+$\mathcal{S}$ and suggests a simple 3-NExpTime-procedure: guess a finite structure of size bounded triply exponentially in the size of input φ and verify that it is indeed a model of φ. We can however do better and show a doubly exponential upper bound matching the known complexity of the general satisfiability problem. For this we design an alternating exponential space algorithm searching for models of the form (f3). The lower bound can be obtained for the two-variable UNFO^2+$\mathcal{S}$ in the presence of one transitive relation by a straightforward adaptation of the lower bound proof for GF^2 with transitive guards [19].

▶ **Theorem 9.** *The finite satisfiability problem for UNFO^2+$\mathcal{S}$ is 2-*ExpTime*-complete.*

4 The general case and its further extensions

In the full version of this paper we generalize the ideas from Section 3 to show:

▶ **Theorem 10.** *The finite satisfiability problem for UNFO+$\mathcal{S}$ is 2-*ExpTime*-complete.*

We also obtain a triply exponential upper bound on the size of minimal finite models of finitely satisfiable formulas. The structure of the proofs is similar to the two-variable case, though some details are more complicated. In particular, we need to go through form (f4) of models: regular trees with bounded ranks of transitive paths. We also explain that in addition to general transitive relations we can use also equivalences and partial orders.

We further extend Thm. 10 by considering an extension, UNFO+$\mathcal{SOH}$, of UNFO+$\mathcal{S}$ by constants and inclusion of binary relations of the form $B_1 \subseteq B_2$, interpreted in a natural way: $\mathfrak{A} \models B_1 \subseteq B_2$ iff $\mathfrak{A} \models \forall xy(B_1xy \rightarrow B_2xy)$.

▶ **Theorem 11.** *The finite satisfiability problem for UNFO+$\mathcal{SOH}$ is 2-*ExpTime*-complete.*

As mentioned in the Introduction, UNFO+$\mathcal{SOH}$ captures several interesting description logics. This implies that we can solve FOMQA problem for them. In particular, we have the following corollary, which, up to our knowledge is the first decidability result for FOMQA in the case of a description logic with both transitive roles and role hierarchies.

▶ **Corollary 12.** *Finite ontology mediated query answering, FOMQA, for the description logic $\mathcal{SHOI}^{\sqcap}$ is decidable and 2-*ExpTime*-complete.*

$\mathcal{SHOI}^{\sqcap}$ and some related logics are considered, e.g., in [11]. For more about FOMQA for description logics with transitivity see [12]. For more about OMQA for description logics see, e.g., references in [12].

Somewhat orthogonally to the extensions motivated by description logics we consider the *base-guarded negation fragment with transitivity*, BGNFO+$\mathcal{S}$, for which the general satisfiability problem was shown decidable in [1]. We do not solve its finite satisfiability problem here, but, analogously to the extension with equivalence relations, UNFO+EQ [7], we are able to lift our results to its one-dimensional restriction, BGNFO$_1$+$\mathcal{S}$, admitting only formulas in which every maximal block of quantifiers leaves at most one variable free.

▶ **Theorem 13.** *The finite satisfiability problem for BGNFO$_1$+$\mathcal{S}$ is 2-*ExpTime*-complete.*

Surprisingly, in contrast to UNFO+$\mathcal{S}$, BGNFO$_1$+$\mathcal{S}$ becomes undecidable when extended by inclusions of binary relations.

5 Conclusions

We proved that the finite satisfiability problem for the unary negation fragment with transitive relations, UNFO+$\mathcal{S}$, is decidable and 2-ExpTime-complete, complementing this way the analogous result for the general satisfiability problem for this logic implied by two other papers. Further, we identified some decidable extensions of our base logic capturing the concepts of nominals and role hierarchies from description logics. We noted that our work has some interesting implications on the finite query answering problem both under the classical (open-world) database scenario as well as in the description logics setting.

One open question is the decidability of the finite satisfiability problem for the full logic BGNFO+$\mathcal{S}$ from [1]. We made a step in this direction here, by solving this problem for the one-dimensional restriction of that logic. Another question is if our techniques can be adapted to a setting in which we do not assert that some distinguished relations are transitive but where we can talk about the transitive closure of the binary relations, or, more generally, to the extension of UNFO with regular path expressions from [16].

We finally remark that we do not know if our small model construction, producing finite models of size bounded triply exponentially in the size of the input formulas, is optimal with respect to the size of models. The best we can do for the lower bound is to enforce models of doubly exponential size (actually, this can be done in UNFO even without transitive relations).

Abstract

We study the satisfiability problem for the fluted fragment extended with transitive relations. We show that the logic enjoys the finite model property when only one transitive relation is available. On the other hand we show that the satisfiability problem is undecidable already for the two-variable fragment of the logic in the presence of three transitive relations.

1 Introduction

The *fluted fragment*, here denoted $\mathcal{FL}$, is a fragment of first-order logic in which, roughly speaking, the order of quantification of variables coincides with the order in which those variables appear as arguments of predicates. The allusion is presumably architectural: we are invited to think of arguments of predicates as being "lined up" in columns. The following formulas are sentences of $\mathcal{FL}$

$$\begin{array}{l}\text{No student admires every professor}\\ \forall x_1(\text{student}(x_1) \rightarrow \neg\forall x_2(\text{prof}(x_2) \rightarrow \text{admires}(x_1, x_2)))\end{array} \tag{1}$$

$$\begin{array}{l}\text{No lecturer introduces any professor to every student}\\ \forall x_1(\text{lecturer}(x_1) \rightarrow \neg\exists x_2(\text{prof}(x_2) \wedge \forall x_3(\text{student}(x_3) \rightarrow \text{intro}(x_1, x_2, x_3)))),\end{array} \tag{2}$$

with the "lining up" of variables illustrated in Fig. 1. By contrast, none of the formulas

$$\forall x_1.r(x_1, x_1)$$
$$\forall x_1\forall x_2(r(x_1, x_2) \rightarrow r(x_2, x_1))$$
$$\forall x_1\forall x_2\forall x_3(r(x_1, x_2) \wedge r(x_2, x_3) \rightarrow r(x_1, x_3)),$$

expressing, respectively, the reflexivity, symmetry and transitivity of the relation r, is fluted, as the atoms involved cannot be arranged so that their argument sequences "line up" in the fashion of Fig. 1.

The history of this fragment is somewhat tortuous. The basic idea of *fluted logic* can be traced to a paper given by W.V. Quine to the 1968 *International Congress of Philosophy* [19], in which the author defined the *homogeneous m-adic formulas*. Quine later relaxed this

fragment, in the context of a discussion of predicate-functor logic, to what he called "fluted" quantificational schemata [20], claiming that the satisfiability problem for the relaxed fragment is decidable. The viability of the proof strategy sketched by Quine was explicitly called into question by Noah [12], and the subject then taken up by W.C. Purdy [17], who gave his own definition of "fluted formulas", proving decidability. It is questionable whether Purdy's reconstruction is faithful to Quine's intentions: the matter is clouded by differences in the definitions of predicate functors between between [12] and [20], both of which Purdy cites. In fact, Quine's original definition of "fluted" quantificational schemata appears to coincide with a logic introduced – apparently independently – by A. Herzig [6]. Rightly of wrongly, however, the name "fluted fragment" has now attached itself to Purdy's definition in [17]; and we shall continue to use it in that way in the present article. See Sec. 2 for a formal definition.

To complicate matters further, Purdy claimed in [18] that $\mathcal{FL}$ (i.e. the fluted fragment, in our sense, and his) has the exponential-sized model property: if a fluted formula φ is satisfiable, then it is satisfiable over a domain of size bounded by an exponential function of the number of symbols in φ. Purdy concluded that the satisfiability problem for $\mathcal{FL}$ is NExpTime-complete. These latter claims are false. It was shown in [14] that, although $\mathcal{FL}$ has the finite model property, there is no elementary bound on the sizes of the models required, and the satisfiability problem for $\mathcal{FL}$ is non-elementary. More precisely, define $\mathcal{FL}^m$ to be the subfragment of $\mathcal{FL}$ in which at most m variables (free or bound) appear. Then the satisfiability problem for $\mathcal{FL}^m$ is $\lfloor m/2 \rfloor$-NExpTime-hard for all $m \geq 2$ and in $(m-2)$-NExpTime for all $m \geq 3$ [15]. It follows that the satisfiability problem for $\mathcal{FL}$ is Tower-complete, in the framework of [21]. These results fix the exact complexity of satisfiability of $\mathcal{FL}^m$ for small values of m. Indeed, the satisfiability problem for FO^2, the two-variable fragment of first-order logic, is known to be NExpTime-complete [5], whence the corresponding problem for $\mathcal{FL}^2$ is certainly in NExpTime. Moreover, for $0 \leq m \leq 1$, $\mathcal{FL}^m$ coincides with the m-variable fragment of first-order logic, whence its satisfiability problem is NPTime-complete. Thus, taking 0-NExpTime to mean NPTime, we see that the satisfiability problem for $\mathcal{FL}^m$ is $\lfloor m/2 \rfloor$-NExpTime-complete, at least for $m \leq 4$.

The focus of the present paper is what happens when we add to the fluted fragment the ability to stipulate that certain designated binary relations are *transitive*, or are *equivalence relations*. The motivation comes from analogous results obtained for other decidable fragments of first-order logic. Consider basic propositional modal logic K. Under the standard translation into first-order logic (yielded by Kripke semantics), we can regard K as a fragment of first-order logic – indeed as a fragment of $\mathcal{FL}^2$. From basic modal logic K, we obtain the logic K4 under the supposition that the accessibility relation on possible worlds is transitive, and the logic S5 under the supposition that it is an equivalence relation: it is well-known that the satisfiability problems for K and K4 are PSpace-complete, whereas that for S5 is NPTime-complete [11]. (For analogous results on *graded* modal logic, see [7].) Closely related are also description logics (cf. [2]) with *role hierarchies* and *transitive roles*. In particular, the description logic $\mathcal{SH}$, which has the finite model property, is an ExpTime-complete fragment of $\mathcal{FL}$ with transitivity. Similar investigations have been carried out in respect of FO^2, which has the finite model property and whose satisfiability problem, as just mentioned, is NExpTime-complete. The finite model property is lost when one transitive relation or two equivalence relations are allowed. For equivalence, everything is known: the (finite) satisfiability problem for FO^2 in the presence of a single equivalence relation remains NExpTime-complete, but this increases to 2-NExpTime-complete in the presence of two equivalence relations [8, 9], and becomes undecidable with three. For transitivity, we have an incomplete picture: the *finite* satisfiability problem for FO^2 in the presence with a single transitive relation in decidable in 3-NExpTime [13], while the decidability of the satisfiability problem remains open (cf. [23]); the corresponding problems with two transitive relations are both undecidable [10].

Adding equivalence relations to the fluted fragment poses no new problems. Existing results on of FO^2 with two equivalence relations can be used to show that the satisfiability and finite satisfiability problems for $\mathcal{FL}$ (not just $\mathcal{FL}^2$) with *two* equivalence relations are decidable. Furthermore, the proof that the corresponding problems for FO^2 in the presence of *three* equivalence relations are undecidable can easily be seen to apply also to $\mathcal{FL}^2$. On the other hand, the situation with transitivity is much less clear.

We show in the sequel that $\mathcal{FL}$ in the presence of a single transitive relation has the finite model property. On the other hand, $\mathcal{FL}$ with three transitive relations admits axioms of infinity and the corresponding satisfiability problem is undecidable even for the intersection of $\mathcal{FL}^2$ with the *guarded fragment* [1] (and the same holds even when one of these transitive relations is the identity). The status of $\mathcal{FL}$ with just two transitive relations remains open. These can be contrasted with DLs where, to lose the finite model property, one needs to add to $\mathcal{S}$ either both *inverses* and *number restrictions*, or the *self* operator (none expressible in $\mathcal{FL}$). We also want to point to another paper in this volume [4] and the references therein where the impact of adding transitivity to the *unary negation fragment* is discussed.

2 Preliminaries

Unless explicitly stated to the contrary, the fragments of first-order logic considered here do not contain equality. We employ purely relational signatures, i.e. no individual constants or function symbols. We do, however, allow 0-ary relations (proposition letters).

Let $\bar{x}_\omega = x_1, x_2, \ldots$ be a fixed sequence of variables. We define the sets of formulas $\mathcal{FL}^{[m]}$ (for $m \geq 0$) by structural induction as follows: (i) any atom $\alpha(x_\ell, \ldots, x_m)$, where $x_\ell, \ldots, x_m$ is a contiguous subsequence of $\bar{x}_\omega$, is in $\mathcal{FL}^{[m]}$; (ii) $\mathcal{FL}^{[m]}$ is closed under boolean combinations; (iii) if φ is in $\mathcal{FL}^{[m+1]}$, then $\exists x_{m+1}\varphi$ and $\forall x_{m+1}\varphi$ are in $\mathcal{FL}^{[m]}$. The set of *fluted formulas* is defined as $\mathcal{FL} = \bigcup_{m\geq 0} \mathcal{FL}^{[m]}$. A *fluted sentence* is a fluted formula with no free variables. Thus, when forming Boolean combinations in the fluted fragment, all the combined formulas must have as their free variables some suffix of some prefix $x_1, \ldots, x_m$ of $\bar{x}_\omega$; and, when quantifying, only the last variable in this sequence may be bound. Note also that proposition letters (0-ary predicates) may be combined freely with formulas: if φ is in $\mathcal{FL}^{[m]}$, then so, for example, is $\varphi \wedge P$, where P is a proposition letter.

Denote by $\mathcal{FL}^m$ the sub-fragment of $\mathcal{FL}$ consisting of those formulas featuring at most m variables, free or bound. Do not confuse $\mathcal{FL}^m$ (the set of fluted formulas with at most m variables, free or bound) with $\mathcal{FL}^{[m]}$ (the set of fluted formulas with *free* variables $x_\ell, \ldots, x_m$).

These are, of course, quite different. For example, (1) is in $\mathcal{FL}^2$, and (2) is in $\mathcal{FL}^3$, but they are both in $\mathcal{FL}^{[0]}$. Note that $\mathcal{FL}^m$ cannot include predicates of arity greater than m.

For $m \geq 2$, denote by $\mathcal{FL}^m k\mathrm{T}$ the m-variable fluted fragment $\mathcal{FL}^m$ together with k distinguished transitive relations. In addition, denote by $\mathcal{FL}^2 k\mathrm{T}^u$ the sub-fragment of $\mathcal{FL}^2 k\mathrm{T}$ in which no binary predicates occur except the k distinguished transitive ones.

3 The decidability of fluted logic with one transitive relation

In this section, we show that the logic $\mathcal{FL}1\mathrm{T}$, the fluted fragment together with a single distinguished transitive relation $\mathfrak{t}$, has the finite model property. We proceed in stages. First, we show that $\mathcal{FL}^2 1\mathrm{T}^u$ has a doubly exponential-sized model property. Next, we show that $\mathcal{FL}^2 1\mathrm{T}$ has a triply exponential-sized model property, via an exponential-sized reduction to $\mathcal{FL}^2 1\mathrm{T}^u$. Finally, for $m \geq 2$, we provide an exponential-sized reduction of the satisfiability problem for $\mathcal{FL}^{m+1} 1\mathrm{T}$ to the corresponding problem for $\mathcal{FL}^m 1\mathrm{T}$, showing that, if the target of the reduction has a model of size N, then the source has a model of size $O(2^N)$. The satisfiability problems considered here will all have at least exponential complexity. Therefore, we may assume without loss of generality in this section that all signatures feature no 0-ary predicates, since their truth values can simply be guessed.

3.1 The logic $\mathcal{FL}^2 1\mathrm{T}^u$

Fix some signature Σ of unary predicates. We consider $\mathcal{FL}^2 1\mathrm{T}^u$-formulas over the signature $\Sigma \cup \{\mathfrak{t}\}$, where $\mathfrak{t}$ is the distinguished transitive predicate. (Thus, $\mathfrak{t} \notin \Sigma$.) By a 1-*type over* Σ, we mean a maximal consistent conjunction of literals $\pm p(x)$, where $p \in \Sigma$. If $\mathfrak{A}$ is a structure interpreting $\Sigma \cup \{\mathfrak{t}\}$, any element $a \in A$ satisfies a unique 1-type over Σ; we denote it $\mathrm{tp}^{\mathfrak{A}}[a]$. Since Σ will not vary, we typically omit reference to it when speaking of 1-types. We use the letters π and π' always to range over 1-types and μ always to range over arbitrary quantifier-free Σ-formulas involving just the variable x. We write $\pi(y)$ to indicate the result of substituting y everywhere for x in π, and similarly for π' and μ.

Call a $\mathcal{FL}^2 1\mathrm{T}^u$-formula over $\Sigma \cup \{\mathfrak{t}\}$ *basic* if it is of one of the forms

$$\exists x.\mu \qquad \forall x.\mu \qquad \forall x(\pi \to \exists y(\mu(y) \wedge \pm\mathfrak{t}(x,y))) \qquad \forall x(\pi \to \forall y(\pi'(y) \to \pm\mathfrak{t}(x,y))).$$

The following Lemma is a version of the familiar “Scott normal form” for $\mathcal{FL}^2$ from [22].

▶ **Lemma 1.** *Let φ be a $\mathcal{FL}^2 1\mathrm{T}^u$-sentence. There exists a set Ψ of basic $\mathcal{FL}^2 1\mathrm{T}^u$-formulas with the following properties: (i) $\models (\bigwedge \Psi) \to \varphi$; (ii) if φ has a model, then so has Ψ; (iii) $\|\Psi\|$ is bounded by a polynomial function of $\|\varphi\|$.*

We say that a *super-type over* Σ is a pair $\langle \pi, \Pi \rangle$, where π is a 1-type over Σ and Π a set of 1-types over Σ. If $\mathfrak{A}$ is a structure interpreting the signature $\Sigma \cup \{\mathfrak{t}\}$ and $a \in A$, the super-type of a in $\mathfrak{A}$, denoted $\mathrm{stp}^{\mathfrak{A}}[a]$, is the pair $\langle \mathrm{tp}^{\mathfrak{A}}[a], \Pi \rangle$, where $\Pi = \{\mathrm{tp}^{\mathfrak{A}}[b] \mid \mathfrak{A} \models \mathfrak{t}[a,b]\}$. Intuitively, a super-type is a description of an element in a structure specifying that element’s 1-type together with the 1-types of those elements to which it is related by $\mathfrak{t}$. If S is a set of super-types, we write $\mathrm{tp}(S) = \{\pi \mid \langle \pi, \Pi \rangle \in S \text{ for some } \Pi\}$. We usually omit Σ when speaking of super-types. By a *certificate*, we mean a pair $C = (S, \ll)$, where S is a set of super-types and $\ll$ is a transitive relation on $\mathrm{tp}(S)$ satisfying the following conditions:

(C1) if $\langle \pi, \Pi \rangle \in S$ and $\pi' \in \Pi$, then there exists $\langle \pi', \Pi' \rangle \in S$ with $\Pi' \subseteq \Pi$;

(C2) if $\pi \ll \pi'$, $\langle \pi, \Pi \rangle \in S$ and $\langle \pi', \Pi' \rangle \in S$, then $\{\pi'\} \cup \Pi' \subseteq \Pi$.

For a structure $\mathfrak{A}$, the *certificate of* $\mathfrak{A}$, denoted $C(\mathfrak{A})$, is the pair $(S, \ll)$, where $S = \{\mathrm{stp}^{\mathfrak{A}}[a] \mid a \in A\}$ is the set of super-types realized in $\mathfrak{A}$, and $\pi \ll \pi'$ if and only if π and π' are realized in $\mathfrak{A}$ and $\mathfrak{A} \models \forall x(\pi \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$. Intuitively, a certificate is a description of a structure listing the realized super-types and containing a partial order which specifies when all elements realizing one 1-type are related by $\mathfrak{t}$ to all elements realizing another 1-type.

▶ **Lemma 2.** *If $\mathfrak{A}$ is any structure interpreting $\Sigma \cup \{\mathfrak{t}\}$, $C(\mathfrak{A})$ is a certificate.*

Proof. Write $C(\mathfrak{A}) = (S, \ll)$. Obviously $\ll$ is transitive. We must check (**C1**) and (**C2**).
(**C1**): Suppose $\langle \pi, \Pi \rangle \in S$ and $\pi' \in \Pi$. Let a be such that $\mathrm{stp}^{\mathfrak{A}}[a] = \langle \pi, \Pi \rangle$. Then there exists a $b \in A$ such that $\mathrm{tp}^{\mathfrak{A}}[b] = \pi'$ and $\mathfrak{A} \models \mathfrak{t}[a,b]$. Let $\mathrm{stp}^{\mathfrak{A}}[b] = \langle \pi', \Pi' \rangle$.
(**C2**): Suppose $\langle \pi, \Pi \rangle \in S$ and $\langle \pi', \Pi' \rangle \in S$ with $\pi \ll \pi'$, and let $a, b \in A$ be such that $\mathrm{stp}^{\mathfrak{A}}[a] = \langle \pi, \Pi \rangle$ and $\mathrm{stp}^{\mathfrak{A}}[b] = \langle \pi', \Pi' \rangle$. Since $\pi \ll \pi'$, by construction of $C(\mathfrak{A})$, we have $\mathfrak{A} \models \forall x(\pi \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$, whence it is immediate that $\pi' \in \Pi$ and $\Pi' \subseteq \Pi$. ◀

If $C = (S, \ll)$ is a certificate, and ψ a basic $\mathcal{FL}^2 1\mathrm{T}^u$-formula, we define the relation $C \models \psi$ to hold provided the following six conditions are satisfied. The motivation for this definition is provided by Lemmas 3 and 4.

(i) if ψ is of the form $\forall x(\pi \to \exists y(\mu(y) \wedge \mathfrak{t}(x,y)))$, then, for all Π such that $\langle \pi, \Pi \rangle \in S$, there exists $\pi' \in \Pi$ such that $\models \pi' \to \mu$;
(ii) if ψ is of the form $\forall x(\pi \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$ and $\pi, \pi' \in \mathrm{tp}(S)$, then $\pi \ll \pi'$;
(iii) if ψ is of the form $\forall x(\pi \to \exists y(\mu(y) \wedge \neg\mathfrak{t}(x,y)))$, then, for all $\langle \pi, \Pi \rangle \in S$, there exists $\langle \pi', \Pi' \rangle \in S$ such that $\models \pi' \to \mu$ and there exists no $\alpha \in \{\pi\} \cup \Pi$ such that $\alpha \ll \pi'$;
(iv) if ψ is of the form $\forall x(\pi \to \forall y(\pi'(y) \to \neg\mathfrak{t}(x,y)))$, then, for all $\langle \pi, \Pi \rangle \in S$, $\pi' \notin \Pi$;
(v) if ψ is of the form $\exists x.\mu$, then there exists $\langle \pi, \Pi \rangle \in S$ such that $\models \pi \to \mu$;
(vi) if ψ is of the form $\forall x.\mu$, then, for all $\langle \pi, \Pi \rangle \in S$, $\models \pi \to \mu$.

▶ **Lemma 3.** *Let $\mathfrak{A}$ be a structure interpreting $\Sigma \cup \{\mathfrak{t}\}$ and let ψ be a basic $\mathcal{FL}^2 1\mathrm{T}^u$-formula over $\Sigma \cup \{\mathfrak{t}\}$. If $\mathfrak{A} \models \psi$, then $C(\mathfrak{A}) \models \psi$.*

Proof. We write $C(\mathfrak{A}) = (S, \ll)$ and consider the possible forms of ψ in turn.

- $\psi = \forall x(\pi \to \exists y(\mu(y) \wedge \mathfrak{t}(x,y)))$: Suppose $\langle \pi, \Pi \rangle \in S$. Then there exists $a \in A$ with $\mathrm{stp}^{\mathfrak{A}}[a] = \langle \pi, \Pi \rangle$. Since $\mathfrak{A} \models \psi$, choose $b \in A$ such that $\mathfrak{A} \models \mu[b]$ and $\mathfrak{A} \models \mathfrak{t}[a,b]$, and let $\mathrm{tp}^{\mathfrak{A}}[b] = \pi'$. Then $\models \pi' \to \mu$ and $\pi' \in \Pi$, as required.
- $\psi = \forall x(\pi \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$: It is immediate by the construction of $C(\mathfrak{A})$ that, if $\pi, \pi' \in \mathrm{tp}(S)$, then $\pi \ll \pi'$;
- $\psi = \forall x(\pi \to \exists y(\mu(y) \wedge \neg\mathfrak{t}(x,y)))$: Suppose $\langle \pi, \Pi \rangle \in S$. Then there exists $a \in A$ with $\mathrm{stp}^{\mathfrak{A}}[a] = \langle \pi, \Pi \rangle$. Since $\mathfrak{A} \models \psi$, choose $b \in A$ such that $\mathfrak{A} \models \mu[b]$ and $\mathfrak{A} \not\models \mathfrak{t}[a,b]$, and let $\mathrm{tp}^{\mathfrak{A}}[b] = \pi'$, so that $\models \pi' \to \mu$. We require only to show that there exists no $\alpha \in \{\pi\} \cup \Pi$ such that $\alpha \ll \pi'$. Suppose, for contradiction, that such an α exists. By (**C1**), $\alpha \in \mathrm{tp}(S)$. If $\alpha = \pi$, then, by the definition of $\ll$, we have $\mathfrak{A} \models \forall x(\pi \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$, which contradicts the supposition that $\mathfrak{A} \not\models \mathfrak{t}[a,b]$. If $\alpha \in \Pi$, then, by the definition of Π and $\ll$, we have an element $a' \in A$ such that $\mathrm{tp}^{\mathfrak{A}}[a'] = \alpha$, $\mathfrak{A} \models \mathfrak{t}[a,a']$ and $\mathfrak{A} \models \forall x(\alpha \to \forall y(\pi'(y) \to \mathfrak{t}(x,y)))$, which again contradicts the supposition that $\mathfrak{A} \not\models \mathfrak{t}[a,b]$.
- $\psi = \forall x(\pi \to \forall y(\pi'(y) \to \neg\mathfrak{t}(x,y)))$: Suppose $\langle \pi, \Pi \rangle \in S$ and let $a \in A$ be such that $\mathrm{stp}^{\mathfrak{A}}[a] = \langle \pi, \Pi \rangle$. Since $\mathfrak{A} \models \psi$, we have $\pi' \notin \Pi$.
- $\psi = \exists x.\mu$ or $\psi = \forall x.\mu$. Immediate by construction of S. ◀

▶ **Lemma 4.** *If $C = (S, \ll)$ is a certificate, then there exists a structure $\mathfrak{A}$ over a domain of cardinality $2|S|$ such that, for any basic $\mathcal{FL}^2 1\mathrm{T}^u$-formula ψ over Σ, $C \models \psi$ implies $\mathfrak{A} \models \psi$.*

Proof. Define $A^+ = \{a^+_{\pi,\Pi} \mid \langle \pi, \Pi \rangle \in S\}$ and $A^- = \{a^-_{\pi,\Pi} \mid \langle \pi, \Pi \rangle \in S\}$, where the various $a^+_{\pi,\Pi}$ and $a^-_{\pi,\Pi}$ are some objects (assumed distinct), and set $A = A^+ \cup A^-$. Define the binary relations $T_1 = \{\langle a^\pm_{\pi,\Pi}, a^+_{\pi',\Pi'} \rangle \mid \{\pi'\} \cup \Pi' \subseteq \Pi\}$ and $T_2 = \{\langle a^\pm_{\pi,\Pi}, a^\pm_{\pi',\Pi'} \rangle \mid \pi \ll \pi'\}$, and let T be the transitive closure of $T_1 \cup T_2$. Intuitively, we may think of the elements $a^+_{\pi',\Pi'}$ as witnessing existential formulas of the form $\exists y(\mu(y) \wedge \mathfrak{t}(x,y))$, where $\models \pi' \rightarrow \mu$, and of the elements $a^-_{\pi',\Pi'}$ as witnessing existential formulas of the form $\exists y(\mu(y) \wedge \neg\mathfrak{t}(x,y))$. Now define $\mathfrak{A}$ on the domain A by setting $\text{tp}^{\mathfrak{A}}[a^\pm_{\pi,\Pi}] = \pi$ for all $\langle \pi, \Pi \rangle \in S$, and by setting $\mathfrak{t}^{\mathfrak{A}} = T$.

We observe that if $a = a^\pm_{\pi,\Pi}$ and $b = a^\pm_{\pi',\Pi'}$ are elements of A such that a is related to b by either T_1 or T_2, then $\{\pi'\} \cup \Pi' \subseteq \Pi$. Indeed, for T_1, this is immediate by definition; and for T_2, it follows from property (**C2**) of certificates. It follows by induction that, if a is related to b by T, then $\{\pi'\} \cup \Pi' \subseteq \Pi$. To prove the lemma, we consider the possible forms of ψ in turn.

- $\psi = \forall x(\pi \rightarrow \exists y(\mu(y) \wedge \mathfrak{t}(x,y)))$: Suppose $a = a^\pm_{\pi,\Pi}$. Since $C \models \psi$, there exists $\pi' \in \Pi$ such that $\pi' \rightarrow \mu$. By (**C1**), there exists $\langle \pi', \Pi' \rangle \in S$ such that $\Pi' \subseteq \Pi$. Letting $b = a^+_{\pi',\Pi'}$, we have that a is related to b by T_1. But then $\mathfrak{A} \models \mathfrak{t}[a,b]$ and $\mathfrak{A} \models \mu[b]$ by construction of $\mathfrak{A}$.
- $\psi = \forall x(\pi \rightarrow \forall y(\pi'(y) \rightarrow \mathfrak{t}(x,y)))$: Since $C \models \psi$, we have $\pi \ll \pi'$. Suppose now $a = a^\pm_{\pi,\Pi}$ and $b = a^\pm_{\pi',\Pi'}$. Thus, a is related to b by T_2, and so by construction of $\mathfrak{A}$, $\mathfrak{A} \models \mathfrak{t}[a,b]$.
- $\psi = \forall x(\pi \rightarrow \exists y(\mu(y) \wedge \neg\mathfrak{t}(x,y)))$: Suppose $a = a^\pm_{\pi,\Pi}$. Since $C \models \psi$, there exists $\langle \pi', \Pi' \rangle \in S$ such that $\pi' \rightarrow \mu$, and such that there is no $\alpha \in \{\pi\} \cup \Pi$ with $\alpha \ll \pi'$. Now let $b = a^-_{\pi',\Pi'}$. By construction of $\mathfrak{A}$, $\mathfrak{A} \models \mu[b]$. It suffices to show that $\mathfrak{A} \not\models \mathfrak{t}[a,b]$. For otherwise, by the definition of T, there exists a chain of elements $a = a_1, \ldots, a_m = b$ with each related to the next by either T_1 or T_2 and with a_{m-1} related to a_m by T_2. (Notice that nothing can be related by T_1 to $b = a^-_{\pi',\Pi'}$.) Writing $a_{m-1} = a^\pm_{\alpha,\Pi''} \in S$, we see that $\alpha \ll \pi'$, and, moreover, that a is either identical to a_{m-1}, or related to it by T. As we observed above, if $a^\pm_{\pi,\Pi}$ is related to $a^\pm_{\alpha,\Pi''}$ by T, then $\alpha \in \Pi$. Thus, either way, $\alpha \in \{\pi\} \cup \Pi$. But we are supposing that no such α exists.
- $\psi = \forall x(\pi \rightarrow \forall y(\pi'(y) \rightarrow \neg\mathfrak{t}(x,y)))$: Suppose $a = a^\pm_{\pi,\Pi}$ and $b = a^\pm_{\pi',\Pi'}$ are elements of A. We observed above that, if a is related to b by T, then $\pi' \in \Pi$, contradicting the assumption that $C \models \psi$. Thus, by construction of $\mathfrak{A}$, $\mathfrak{A} \not\models \mathfrak{t}[a,b]$.
- $\psi = \exists x.\mu$ or $\psi = \forall x.\mu$. Immediate by construction of $\mathfrak{A}$. ◀

Since the number of super-types over Σ is bounded by $2^{(2^{|\Sigma|}+|\Sigma|)}$, and a structure $\mathfrak{A}$ can be guessed and verified to be a model of any m-variable first-order formula φ in time $O(|\varphi| \cdot |A|^m)$ [25], Lemmas 1–4 yield:

▶ **Lemma 5.** *If φ is a satisfiable formula of $\mathcal{FL}^2 1\mathrm{T}^u$, then φ has a model of size at most doubly exponential in $\|\varphi\|$. Hence the satisfiability problem for $\mathcal{FL}^2 1\mathrm{T}^u$ is in* 2-NExpTime.

3.2 The logics $\mathcal{FL}^m 1\mathrm{T}$ for $m \geq 2$

Let Σ be a signature of predicates of positive arity, excluding $\mathfrak{t}$. An atomic formula of $\mathcal{FL}^m 1\mathrm{T}$ involving a predicate from $\Sigma \cup \{\mathfrak{t}\}$ will be called a *fluted m-atom over* $\Sigma \cup \{\mathfrak{t}\}$. A *fluted m-literal* is a fluted m-atom or the negation thereof. A *fluted m-clause* is a disjunction of fluted m-literals. We allow the absurd formula $\bot$ (i.e. the empty disjunction) to count as a fluted m-clause. Thus, any literal of a fluted m-clause has arguments $x_h, \ldots, x_m$, in that order, for some h ($1 \leq h \leq m$). When writing fluted m-clauses, we silently remove bracketing, re-order literals and delete duplicated literals as necessary. A *fluted m-type* is a maximal consistent set of fluted m-literals; where convenient, we identify fluted m-types with their conjunctions. If $\mathfrak{A}$ is a structure interpreting $\Sigma \cup \{\mathfrak{t}\}$, any tuple $a_1, \ldots, a_m$ from A satisfies a unique fluted m-type; we denote it $\text{ftp}^{\mathfrak{A}}[a_1, \ldots, a_m]$. Note that a fluted 1-type over

$\Sigma \cup \{\mathfrak{t}\}$ coincides with what we earlier called a 1-type over Σ. Reference to the signature $\Sigma \cup \{\mathfrak{t}\}$ will as usual be suppressed when clear from context. Predicates in Σ will be referred to as *non-distinguished*. Our strategy will be to reduce the (finite) satisfiability problem for $\mathcal{FL}^m1\mathrm{T}$ to that for $\mathcal{FL}^21\mathrm{T}$ (Lemma 11), and thence to that for $\mathcal{FL}^21\mathrm{T}^u$ (Lemma 9), which we have already dealt with (Lemma 5).

A $\mathcal{FL}^m1\mathrm{T}$-formula φ $(m \geq 2)$ is in *clause normal form* if it is of the form

$$\forall x_1 \cdots x_m.\Omega \ \wedge \bigwedge_{i=1}^{s} \forall x_1 \cdots x_{m-1} \, (\alpha_i \rightarrow \exists x_m.\Gamma_i) \wedge \bigwedge_{j=1}^{t} \forall x_1 \cdots x_{m-1}(\beta_j \rightarrow \forall x_m.\Delta_j), \tag{3}$$

where $\Omega, \Gamma_1, \ldots, \Gamma_s, \Delta_1, \ldots, \Delta_t$ are sets of fluted m-clauses, and $\alpha_1, \ldots, \alpha_s$, $\beta_1, \ldots, \beta_t$ fluted $(m-1)$-atoms. We refer to $\forall x_1 \cdots x_m.\Omega$ as the *static conjunct* of φ, to conjuncts of the form $\forall x_1 \cdots x_{m-1} \, (\alpha_i \rightarrow \exists x_m \Gamma_i)$ as the *existential conjuncts* of φ, and to conjuncts of the form $\forall x_1 \cdots x_{m-1}(\beta_j \rightarrow \forall x_m.\Delta_j)$ as the *universal conjuncts* of φ.

Using the same techniques as for Lemma 1, we can transform any $\mathcal{FL}^m1\mathrm{T}$-formula into clause normal form.

▶ **Lemma 6.** *Let φ be an $\mathcal{FL}^m1\mathrm{T}$-formula, $m \geq 2$. There exists an $\mathcal{FL}^m1\mathrm{T}$-formula ψ in clause normal form such that: (i) $\models \psi \rightarrow \varphi$; and (ii) if φ has a model then so has ψ; (iii) $\|\psi\|$ is bounded by a polynomial function of $\|\varphi\|$.*

For fragments of first-order logic not involving equality, we are free to duplicate any element a in a structure $\mathfrak{A}$. More formally, we have the following lemma, which will be used as a step in the ensuing argument.

▶ **Lemma 7.** *Let $\mathfrak{A}$ be any structure, and let $z > 0$. There exists a structure $\mathfrak{B}$ such that (i) if φ is any first-order formula without equality, then $\mathfrak{A} \models \varphi$ if and only if $\mathfrak{B} \models \varphi$; (ii) $|B| = z \cdot |A|$; and (iii) if $\psi(x_1, \ldots, x_{m-1}) = \exists x_m.\chi(x_1, \ldots, x_m)$ is a first-order formula without equality, and $\mathfrak{B} \models \psi[b_1, \ldots, b_{m-1}]$, then there exist at least z distinct elements b of B such that $\mathfrak{B} \models \chi[b_1, \ldots, b_{m-1}, b]$.*

Keeping the signature Σ fixed, we employ the standard apparatus of resolution theorem-proving to eliminate non-distinguished predicates of arity 2 or more. Suppose $p \in \Sigma$ is a predicate of arity m, and let γ' and δ' be fluted m-clauses over Σ. Then, $\gamma = p(x_1, \ldots, x_m) \vee \gamma'$ and $\delta = \neg p(x_1, \ldots, x_m) \vee \delta'$ are also fluted m-clauses, as indeed is $\gamma' \vee \delta'$. In that case, we call $\gamma' \vee \delta'$ a *fluted resolvent* of γ and δ, and we say that $\gamma' \vee \delta'$ is *obtained by fluted resolution* from γ and δ *on* $p(x_1, \ldots, x_m)$. Thus, fluted resolution is simply a restriction of the familiar resolution rule from first-order logic to the case where the resolved-on literals have maximal arity, m, and (in the case $m = 2$) do not feature the distinguished predicate $\mathfrak{t}$. It may be helpful to note the following at this point: (i) if γ and δ resolve to form ϵ, then $\models \forall x_1 \cdots \forall x_m(\gamma \wedge \delta \rightarrow \epsilon)$; (ii) the fluted resolvent of two fluted m-clauses may or may not involve predicates of arity m; (iii) in fluted resolution, the arguments of the literals in the fluted m-clauses undergo no change when forming the resolvent; (iv) if the fluted m-clause γ involves no predicates of arity m, then it cannot undergo fluted resolution at all.

If Γ is a set of fluted m-clauses, denote by Γ^* the smallest set of fluted m-clauses including Γ and closed under fluted resolution. If $\Gamma = \Gamma^*$, we say that it is *closed under fluted resolution*. We further denote by Γ° the result of deleting from Γ^* any clause involving a *non-distinguished* predicate of arity m. Observe that, since all fluted m-atoms involving predicates of *non*-maximal arity are of the form $p(x_h, \ldots, x_m)$ for some $h \geq 2$, it follows that Γ° features the variable x_1 *only* in the case $m = 2$, and even then only in literals of the form $\pm\mathfrak{t}(x_1, x_2)$.

The following lemma is, in effect, nothing more than the familiar completeness theorem for (ordered) propositional resolution. The proof is omitted due to space limits.

▶ **Lemma 8.** *Let Γ be a set of fluted m-clauses over a signature $\Sigma \cup \{\mathfrak{t}\}$, let Σ' be the result of removing all predicates of maximal arity m from Σ, and let τ^- be a fluted m-type over $\Sigma' \cup \{\mathfrak{t}\}$. If τ^- is consistent with Γ°, then there exists a fluted m-type τ over the signature $\Sigma \cup \{\mathfrak{t}\}$ such that $\tau \supseteq \tau^-$ and τ is consistent with Γ.*

The following lemma employs a technique from [13] to eliminate binary predicates.

▶ **Lemma 9.** *Let φ be an $\mathcal{FL}^2 1\mathrm{T}$-formula in clause normal form over a signature $\Sigma \cup \{\mathfrak{t}\}$, and suppose that φ has s existential and t universal conjuncts. Then there exists a clause normal form $\mathcal{FL}^2 1\mathrm{T}^u$-formula φ' over a signature $\Sigma' \cup \{\mathfrak{t}\}$ such that: (i) φ' has at most $2^t s$ existential and 2^t universal conjuncts; (ii) $|\Sigma'| \leq |\Sigma| + 2^t(s+1)$; (iii) if φ has a model, so does φ'; and (iv) if φ' has a model of size M, then φ has a model of size at most sM.*

Proof. Let $\varphi = \forall x_1 x_2.\Omega \ \wedge \bigwedge_{i=1}^s \forall x_1 \left(p_i(x_1) \to \exists x_2.\Gamma_i\right) \wedge \bigwedge_{j=1}^t \forall x_1 (q_j(x_1) \to \forall x_2.\Delta_j)$, where $\Omega, \Gamma_1, \ldots, \Gamma_s, \Delta_1, \ldots, \Delta_t$ are sets of fluted 2-clauses, and $p_1, \ldots, p_s$, $q_1, \ldots, q_t$ unary predicates. Write $T = \{1, \ldots, t\}$. For all i $(1 \leq i \leq s)$ and all $J \subseteq T$, let $p_{i,J}$ and q_J be new unary predicates. The intended interpretation of $p_{i,J}(x_1)$ is "x_1 satisfies p_i, and also satisfies q_j for every $j \in J$;" and the intended interpretation of $q_J(x_1)$ is "x_1 satisfies q_j for every $j \in J$." Let φ' be the conjunction of the sentences:
(a) $\bigwedge_{i=1}^s \bigwedge_{J \subseteq T} \forall x_2((p_i(x_2) \wedge \bigwedge_{j \in J} q_j(x_2)) \to p_{i,J}(x_2))$,
(b) $\bigwedge_{J \subseteq T} \forall x_2((\bigwedge_{j \in J} q_j(x_2)) \to q_J(x_2))$,
(c) $\bigwedge_{i=1}^s \bigwedge_{J \subseteq T} \forall x_1 \left(p_{i,J}(x_1) \to \exists x_2 \left(\Gamma_i \cup \Omega \cup \bigcup\{\Delta_j \mid j \in J\}\right)^\circ\right)$, and
(d) $\bigwedge_{J \subseteq T} \forall x_1 \left(q_J(x_1) \to \forall x_2 \left(\Omega \cup \bigcup\{\Delta_j \mid j \in J\}\right)^\circ\right)$.
Observe that φ' contains no non-distinguished binary predicates, and hence is in $\mathcal{FL}^2 1\mathrm{T}^u$. Clearly, φ' satisfies properties (i) and (ii). To show (iii), suppose $\mathfrak{A} \models \varphi$, and let $\mathfrak{A}'$ be the structure obtained by interpreting the predicates $p_{i,J}$ and q_J as suggested above. To show (iv), suppose φ' has a model of size M. By Lemma 7, φ' has a model $\mathfrak{B}$ of size sM in which witnesses for all the conjuncts in (c) are duplicated s times. We need to show that $\mathfrak{B}$ can be expanded to a model of φ. Fix $a \in B$ and suppose a satisfies p_1. Let J be the set of indices j such that a satisfies q_j. By (a), putting $i = 1$, a satisfies $p_{1,J}$, whence, by (c), there exists b such that the pair $\langle a, b\rangle$ satisfies $(\Gamma_1 \cup \Omega \cup \bigcup\{\Delta_j \mid j \in J\})^\circ$. But Lemma 8 guarantees that we can expand $\mathfrak{B}$ by interpreting the non-distinguished binary predicates so that $\langle a, b\rangle$ satisfies $\Gamma_1 \cup \Omega \cup \bigcup\{\Delta_j \mid j \in J\}$. Because of the duplication of witnesses, we can repeat with $p_2, \ldots, p_s$, choosing a fresh witness each time, so as to avoid clashes. Do this for all elements a. At the end of the process, the partially defined expansion of $\mathfrak{B}$ satisfies all the existential conjuncts of φ, and violates none of the universal or static conjuncts. A precisely similar argument shows that we may complete the expansion so that no universal or static conjuncts of φ are violated. ◀

Thus, at the expense of an exponentially larger signature, we have reduced the (finite) satisfiability problem for $\mathcal{FL}^2 1\mathrm{T}$ to that for $\mathcal{FL}^2 1\mathrm{T}^u$. By Lemmas 5 and 9, we obtain

▶ **Lemma 10.** *Let φ be a $\mathcal{FL}^2 1\mathrm{T}$-formula. If φ is satisfiable, then φ has a model of size at most triply exponential in $\|\varphi\|$. Hence the satisfiability problem for $\mathcal{FL}^2 1\mathrm{T}$ is in 3-NExpTime.*

We now establish the finite model property for the whole of $\mathcal{FL}1\mathrm{T}$ by eliminating variables from $\mathcal{FL}^{m+1}1\mathrm{T}$, where $m \geq 2$, one at a time. The proof of the following Lemma is similar to the proof of Lemma 9 and is omitted due to space limits.

▶ **Lemma 11.** *Let φ be a clause normal form $\mathcal{FL}^{m+1}1\mathrm{T}$-formula $(m \geq 2)$ over a signature $\Sigma \cup \{\mathrm{t}\}$, and suppose that φ has s existential conjuncts and t universal conjuncts. Then there exists a clause normal form $\mathcal{FL}^{m}1\mathrm{T}$-formula φ' over a signature $\Sigma' \cup \{\mathrm{t}\}$ such that the following hold: (i) φ' has at most $2^t s$ existential and 2^t universal conjuncts; (ii) $|\Sigma'| \leq |\Sigma| + 2^t(s+1)$; (iii) if φ has a model, so does φ'; and (iv) if φ' has a model of size M, then φ has a model of size at most sM.*

▶ **Theorem 12.** *Let φ be a $\mathcal{FL}^{m}1\mathrm{T}$-formula for $m \geq 2$. If φ is satisfiable, then φ has a model of size at most $(m+1)$-tuply exponential in $\|\varphi\|$. Hence the satisfiability problem for $\mathcal{FL}^{m}1\mathrm{T}$ is in non-deterministic $(m+1)$-tuply exponential time.*

Proof. Induction on m. The case $m = 2$ is Lemma 10. The inductive step is Lemma 11. ◀

We mentioned in Sec. 1 that [14] establishes a lower bound of $\lfloor m/2 \rfloor$-NExpTime-hard for the satisfiability problem for $\mathcal{FL}^{m}$. For $m \geq 3$, this appears to be the best available lower bound on the corresponding problem for $\mathcal{FL}^{m}1\mathrm{T}$. Thus, a gap remains between the best available upper and lower complexity bounds. Certainly, it follows that the satisfiability problem for $\mathcal{FL}1\mathrm{T}$ is Tower-complete, as for $\mathcal{FL}$.

4 Fluted Logic with more Transitive Relations

In this section we show two undecidability results for the fluted fragment with two variables, $\mathcal{FL}^2$, extended with more transitive relations, that have been informally announced in [24]. We employ the apparatus of tiling systems.

A *tiling system* is a tuple $\boldsymbol{\mathcal{C}} = (\mathcal{C}, \mathcal{C}_H, \mathcal{C}_V)$, where $\mathcal{C}$ is a finite set of *tiles*, and $\mathcal{C}_H$, $\mathcal{C}_V \subseteq \mathcal{C} \times \mathcal{C}$ are the *horizontal* and *vertical* constraints.

Let S be any of the spaces $\mathbb{N} \times \mathbb{N}$, $\mathbb{Z} \times \mathbb{Z}$ or $\mathbb{Z}_t \times \mathbb{Z}_t$. A tiling system $\boldsymbol{\mathcal{C}}$ *tiles* S, if there exists a function $\rho : S \to \mathcal{C}$ such that for all $(p,q) \in S$: $(\rho(p,q), \rho(p+1,q)) \in \mathcal{C}_H$ and $(\rho(p,q), \rho(p,q+1)) \in \mathcal{C}_V$. The following problems are known to be undecidable (cf. e.g. [3]):

- Given a tiling system $\boldsymbol{\mathcal{C}}$ determine if $\boldsymbol{\mathcal{C}}$ tiles $\mathbb{Z} \times \mathbb{Z}$, or $\mathbb{N} \times \mathbb{N}$.
- Given a tiling system $\boldsymbol{\mathcal{C}}$ determine if $\boldsymbol{\mathcal{C}}$ tiles $\mathbb{Z}_t \times \mathbb{Z}_t$, for some $t \geq 1$.

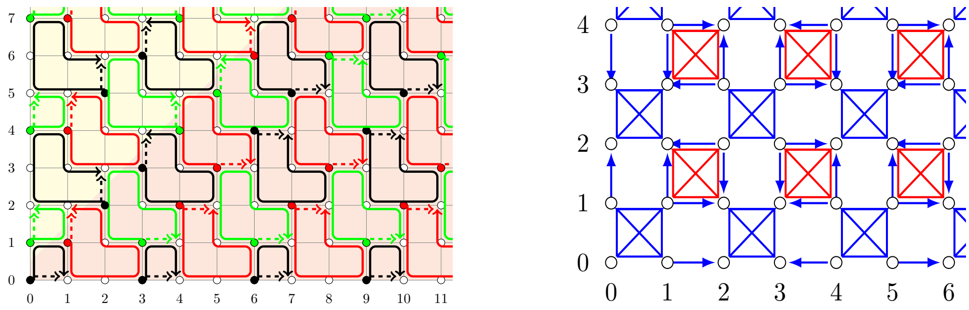
In this section we first prove the following theorem.

▶ **Theorem 13.** *The satisfiability problem for $\mathcal{FL}^2 3\mathrm{T}$, the two-variable fluted fragment with three transitive relations, is undecidable.*

Proof. Suppose the signature contains transitive relations b (black), g (green) and r (red), and additional unary predicates e, e', f, l, $c_{i,j}$ $(0 \leq i \leq 5,\ 0 \leq j \leq 2)$ and $d_{i,j}$ $(0 \leq i \leq 2,\ 0 \leq j \leq 5)$; we refer to the $c_{i,j}$'s and to the $d_{i,j}$'s as *colours.*

We reduce from the $\mathbb{N} \times \mathbb{N}$ tiling problem. We first write a formula φ_{grid} that captures several properties of the intended expansion of the $\mathbb{N} \times \mathbb{N}$ grid as shown in Fig. 2a. There the predicates $c_{i,j}$ and $d_{i,j}$ together define a partition of the universe as follows: an element (k,k') with $k' > k$ (i.e. in the yellow region, above the diagonal) satisfies $c_{i,j}$ with $i = k \mod 6$, $j = k' \mod 3$, and an element (k,k') with $k \geq k'$ (i.e. in the pink region, on or below the diagonal) satisfies $d_{i,j}$ with $i = k \mod 3, j = k' \mod 6$. Paths of the same transitive relation have length at most 7 and follow one of four designated patterns. Remaining unary predicates mark the following elements: l – left column, f – bottom row, e – main diagonal, and e' – elements with coordinates $(k, k+1)$.

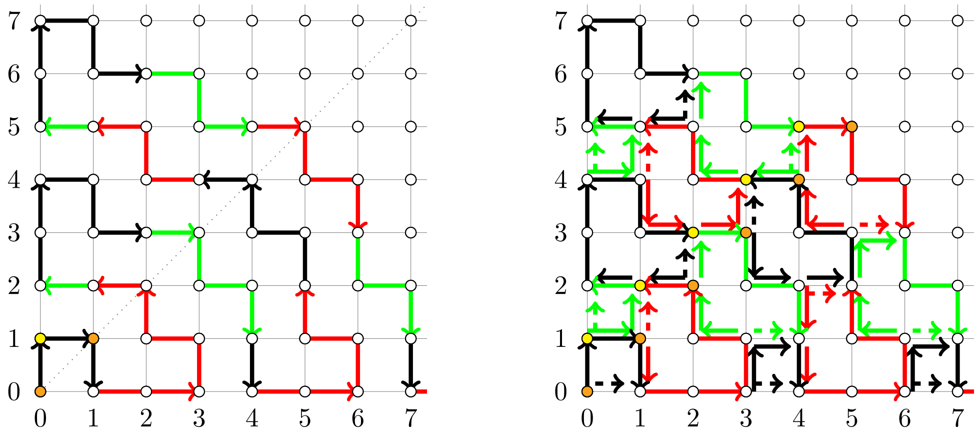
The formula φ_{grid} comprises a large number of conjuncts. We have organized these conjuncts into groups, each of which secures a particular property (or collection of properties) exhibited by its models. The first two properties are very simple:



(a) Three transitive relations: b, g and r. Filled nodes depict the beginning of a transitive path of the same colour; dotted lines connect the first element with the last element on such path.

(b) Two transitive relations: b and r. Edges without arrows depict connections in both direction.

Figure 2 Expansions of the $\mathbb{N} \times \mathbb{N}$ grid in the proofs of Theorem 13 (a) and Theorem 16 (b).



(a) Path starting with an initial element and generated by witnesses for conjuncts of group (3).

(b) Additional edges arising from conjuncts of group (4) (solid lines drawn inside grid cells) and transitivity (dashed lines). Nodes on the diagonals are marked orange (e) and yellow (e').

Figure 3 Construction of the intended model of φ_{grid} in the proof of Theorem 13.

(1) There is an "initial" element satisfying $d_{00}(x) \wedge e(x) \wedge l(x) \wedge f(x)$.

(2) The predicates $c_{i,j}$ and $d_{i,j}$ together partition the universe.

The third property generates the path shown in Fig. 3a:

(3) Each element has a b- r- or g- successor as shown in the path shown in Fig. 3a, and satisfying the appropriate predicates $c_{i,j}$ or $d_{i,j}$. Specifically, if a node in this path has coordinates (x, y) with $y > x$, then it satisfies $c_{i,j}$ where $i = x \mod 3$ and $j = y \mod 6$; and when $y \leq x$, then the node satisfies $d_{i,j}$ where $i = x \mod 3$ and $j = y \mod 6$.

The conjuncts enforcing this property have the form

$$\forall x\big(colour(x) \wedge diag(x) \wedge border(x) \rightarrow \exists y(t(x,y) \wedge colour'(y))\big), \tag{3a}$$

where $colour$ and $colour'$ stand for one of the predicate letters $c_{i,j}$ or $d_{i,j}$, $diag(x)$ stands for one of the literals $e'(x)$, $\neg e'(x)$, $e(x)$, $\neg e(x)$ or $\top$ (i.e. the logical constant true), $border(x)$ stands for one of the literals $l(x)$, $\neg l(x)$, $f(x)$, $\neg f(x)$ or $\top$, and t stands for one of the transitive predicate letters b, r or g. The precise combinations of the literals and predicate letters in these conjuncts can be read from Fig. 3a (cf. [16] for details).

To connect all pairs of elements that are neighbours in the standard grid we require a fourth property, which we give in schematic form as follows:

(4) *Certain* pairs of elements connected by *one* transitive relation are also connected by *another*, as indicated in Fig. 3b.

Here are some examples of the conjuncts enforcing this property:

$$\forall x(c_{01}(x) \rightarrow \forall y(b(x,y) \wedge (c_{11}(y) \vee d_{11}(y)) \rightarrow g(x,y))), \tag{4a}$$

$$\forall x(d_{11}(x) \rightarrow \forall y(b(x,y) \wedge d_{10}(y) \rightarrow r(x,y))), \tag{4b}$$

$$\forall x(d_{11}(x) \rightarrow \forall y(r(x,y) \wedge (c_{12}(y) \vee d_{12}(y)) \rightarrow g(x,y))), \tag{4c}$$

The role of these conjuncts can be explained referring to Fig. 3b. For example, employing (4b) for the element $(1,1)$ in the intended model $\mathfrak{G}$, we get $\mathfrak{G} \models r((1,1),(1,0))$; hence by transitivity of r, also $\mathfrak{G} \models r((1,1),(1,2))$. This, applying (4c), implies $\mathfrak{G} \models g((1,1),(1,2))$. By (4a), we get $\mathfrak{G} \models g((0,1),(1,1))$ and, by transitivity of g, $\mathfrak{G} \models g((0,1),(0,2))$. The process is illustrated in Fig. 3b; when carried on along the zig-zag path, it constructs a grid-like structure.

These conjuncts depend on having available the predicates marking the borders and the diagonals. Specifically, we require the following property:

(5) the predicates l, f, e and e' are distributed to mark the left-most column, the first row, the diagonal and the "super-diagonal" of the grid, as indicated above. To secure this property, we add to φ_{grid} several conjuncts, for instance:

$$\bigwedge_{0 \leq i \leq 2,\ 0 \leq j \leq 5} \forall x\big(d_{i,j}(x) \wedge \pm e(x) \rightarrow \forall y((b(x,y) \vee g(x,y) \vee r(x,y)) \wedge d_{i+1,j+1}(y) \rightarrow \pm e(y))\big), \tag{5a}$$

where $\pm e(x)$ denotes uniformly $e(x)$ or $\neg e(x)$. Similar conjuncts are added for the super-diagonal, left column and bottom row; and also for the connection with and between e and e'. The conjuncts ensuring properties (4) and (5) work in tandem. For instance, applying (5a) to (1,1) we get e is true at $(2,2)$; then, following the zig-zag path and applying more conjuncts from the group (4), we get that $g((2,2),(3,3))$ holds, so the node $(3,3)$ will be marked by e; this will propagate along the main diagonal.

The structure $\mathfrak{G}$ depicted in Fig. 2a is a model of φ_{grid}. In fact, φ_{grid} is an infinity axiom. To see this, let $\mathfrak{A} \models \varphi_{grid}$ and define an injective embedding ρ of the standard grid on $\mathbb{N} \times \mathbb{N}$ into $\mathfrak{A}$ as follows. Let $next : \mathbb{N} \times \mathbb{N} \mapsto \mathbb{N} \times \mathbb{N}$ be the successor function defined on $\mathbb{N} \times \mathbb{N}$ as depicted by the zig-zag path in the left-hand picture of Fig. 3 starting at $(0,0)$ (ignoring any colours). Denote $s_0 = (0,0)$, $s_n = next(s_{n-1})$ and $S_n = \{s_0, \ldots, s_n\}$. Let $a_0 \in A$ be an element such that $\mathfrak{A} \models d_{00}(a) \wedge e(a) \wedge l(a) \wedge f(a)$ that exists by condition (1). Define $\rho(s_0) = a_0$. Now, we proceed inductively: suppose $\rho(s_{n-1})$ has already been defined in step $n-1$ of the induction and $\rho(s_{n-1}) = a_{n-1}$. Let a_n be the witness of a_{n-1} for the appropriate conjunct from the group (3), i.e. where the unary literals for x agree with the unary literals satisfied by a_{n-1} in $\mathfrak{A}$. Define $\rho(s_n) = a_n$. Using induction one can prove that ρ is indeed injective: in the inductive step we assume that $\mathfrak{A} \restriction \{a_0, \ldots, a_{n-1}\}$ is isomorphic to $\mathfrak{G} \restriction S_{n-1}$, and we show that $a_n \notin \{a_0, \ldots, a_{n-1}\}$ and $\mathfrak{A} \restriction \{a_0, \ldots, a_n\}$ and $\mathfrak{G} \restriction S_n$ are again isomorphic. In the proof one considers several cases depending on the 1-type realized by a_n. The formula φ_{grid} ensures that $a_0, \ldots, a_{18}$ are all distinct, and any eight consecutive elements of the sequence $a_0, \ldots, a_n$ are always distinct. Consider $a_{18} = \rho(4,2)$ that requires a witness $b \in A$ for a conjunct from the group (3) such that $\mathfrak{A} \models r(a_{18}, b) \wedge d_{11}(b)$. Suppose, $b = a_2 = \rho(1,1)$, since $\mathfrak{A} \models d_{11}(a_2)$. Then, by transitivity of g, $\mathfrak{A} \models g(a_{18}, a_{10})$, which is a contradiction with $\mathfrak{G} \models \neg g((4,2),(1,1))$. Other cases are similar and due to page limits have been omitted.

We are now ready to define the horizontal and vertical successors in models of of φ_{grid}. In fact, instead of defining the horizontal grid successor h as one binary relation, we define two disjoint binary relations $\mathsf{rt}(x, y)$ and $\mathsf{lt}(x, y)$ such that rt and the inverse of lt together give the expected horizontal grid successor; they are defined respecting the "direction" of the transitive edges in the models. In the intended model $\mathsf{rt}((x_1, y_1), (x_2, y_2))$ holds if $x_2 = x_1 + 1$, $y_2 = y_1$ and (x_1, y_1) and (x_2, y_2) are connected by b, g or r; and for $\mathsf{lt}((x_1, y_1), (x_2, y_2))$ to hold we require $x_2 = x_1 - 1$ instead of $x_2 = x_1 + 1$. We present the definition of $\mathsf{rt}(x, y)$ in detail below[1]

$$\begin{aligned}\mathsf{rt}(x,y) :=& (b(x,y) \vee g(x,y) \vee r(x,y)) \quad \wedge \\ & (c_{01}(x) \wedge d_{11}(y)) \vee (c_{20}(x) \wedge d_{03}(y)) \vee (c_{42}(x) \wedge d_{25}(y)) \quad \vee \\ & \bigvee_{(i,j)\notin\{(0,2),(1,2),(2,1),(3,1),(4,0),(5,0)\}} (c_{ij}(x) \wedge c_{i+1,j}(y)) \quad \vee \bigvee_{(i,j)\notin\{(2,1),(1,3),(0,5)\}} (d_{ij}(x) \wedge d_{i+1,j}(y))\end{aligned}$$

The relation rt connects elements that are connected by b, g or r and satisfy one of the possible combinations of colours: in the second line the combinations for crossing the diagonal are listed, in the third line the left disjunction describes combinations when both elements are located above the diagonal, and in the right disjunction – when both elements are located on and below the diagonal. The definition of $\mathsf{lt}(x, y)$ complements that of rt. Analogously, we define relations up and dn that together define the vertical grid successor.

Now we are ready to write formulas that properly assign tiles to elements of the model. We do this with a formula φ_{tile}, which again features several conjuncts enforcing various properties of its models. Fortunately, the properties in question are much simpler this time:

(6) Each node encodes precisely one tile: $\forall x\big(\bigvee_{C\in\mathcal{C}} C(x) \wedge \bigwedge_{C\neq D}(\neg C(x) \vee \neg D(x))\big)$.

(7) Adjacent tiles respect $\mathcal{C}_H$. This is secured by the conjuct

$$\bigwedge_{C\in\mathcal{C}} \forall x\big(C(x) \to \forall y\big((\mathsf{rt}(x,y) \to \bigvee_{C':(C,C')\in\mathcal{C}_H} C'(y)) \quad \wedge \quad (\mathsf{lt}(x,y) \to \bigvee_{C':(C',C)\in\mathcal{C}_H} C'(y))\big)\big).$$

(8) Adjacent tiles respect $\mathcal{C}_V$ (written as above using up and dn).

We remark that these latter formulas are not strictly fluted but can be rewritten as fluted using classical tautologies.

Finally, let $\eta_{\boldsymbol{\mathcal{C}}}$ be the conjunction of φ_{grid} and φ_{tile}. We complete the proof showing

▷ Claim 14. $\eta_{\boldsymbol{\mathcal{C}}}$ is satisfiable iff $\boldsymbol{\mathcal{C}}$ tiles $\mathbb{N} \times \mathbb{N}$.

Proof. ($\Leftarrow$) If $\boldsymbol{\mathcal{C}}$ tiles $\mathbb{N} \times \mathbb{N}$ then to show that $\eta_{\boldsymbol{\mathcal{C}}}$ is satisfiable we can expand our intended model $\mathfrak{G}$ for φ_{grid} assigning to every element of the grid a unique $C \in \mathcal{C}$ given by the tiling.

($\Rightarrow$) Let $\mathfrak{A} \models \eta_{\boldsymbol{\mathcal{C}}}$. Let ρ be the embedding of the standard $\mathbb{N} \times \mathbb{N}$ grid into $\mathfrak{A}$ defined above. One can inductively show that ρ maps neighbours in the grid to elements connected by one of the relations $\mathsf{lt}, \mathsf{rt}, \mathsf{up}, \mathsf{dn}$ as follows ($i, j \geq 0$):

$$\mathfrak{A} \models \mathsf{rt}(\rho(i,j), \rho(i+1,j)) \dot\vee \mathsf{lt}(\rho(i+1,j), \rho(i,j)) \wedge \mathsf{up}(\rho(i,j), \rho(i,j+1)) \dot\vee \mathsf{dn}(\rho(i,j+1), \rho(i,j)).$$

(Here, $\dot\vee$ is exclusive disjunction.) So, we can define a tiling of the standard grid assigning to every node (i, j) the unique tile C such that $\mathfrak{A} \models C(\rho(i, j))$. Conditions (7) and (8) together with the above observation ensure that this assignment satisfies the tiling conditions. ◁

◀

[1] Addition in subscripts of the $c_{i,j}$'s is always understood modulo 6 in the first position, and modulo 3 in the second position, i.e. $c_{i+a,j+b}$ denotes $c_{(i+a) \bmod 6,(j+b) \bmod 3}$. Similarly, addition in subscripts of the $d_{i,j}$'s is understood modulo 3 in the first position, and modulo 6 in the second position.

We remark that the formula φ_{grid} in the proof of Theorem 13 is an axiom of infinity, hence the satisfiability and the finite satisfiability problems do not coincide. Moreover, all formulas used in the proof are either guarded or can easily be rewritten as guarded. Furthermore, in the proof it would suffice to assume that b, g and r are interpreted as equivalence relations. Hence, we can strengthen the above theorem as follows.

▶ **Corollary 15.** *The satisfiability problem for the intersection of the fluted fragment with the two-variable guarded fragment is undecidable in the presence of three transitive relations (or three equivalence relations).*

Now we improve the undecidability result to the case of $\mathcal{FL}^2$2T with equality.

▶ **Theorem 16.** *The (finite) satisfiability problem for the two-variable fluted fragment with equality is undecidable in the presence of two transitive relations.*

Proof. We write a formula φ_{grid} over a signature consisting of transitive relations b and r, and unary predicates $c_{i,j}$ $(0 \leq i, j \leq 3)$. The formula φ_{grid} captures several properties of the intended expansion of the $\mathbb{Z} \times \mathbb{Z}$ grid as shown Fig. 2b:

(1) there is an initial element: $\exists x.c_{00}(x)$.
(2) the predicates $c_{i,j}$ partition the universe.
(3) transitive paths do not connect distinct elements of the same colour: $\bigwedge_{0 \leq i,j \leq 3} \forall x(c_{ij}(x) \rightarrow \forall y((b(x, y) \vee r(x, y)) \wedge c_{ij}(y) \rightarrow x = y))$
(4) each element belongs to a 4-element blue clique and to a 4-element red clique.
(5) *certain* pairs of elements connected by r are also connected by b, and *certain* pairs of elements connected by b are also connected by r.

We have given property (5) only schematically, of course; its role is analogous to that of property (4) in the proof of Theorem 13. The remainder of the proof is similar to the one presented for Theorem 13 and is omitted due to space limits. We note that φ_{grid} has also finite models expanding a toroidal grid structure $\mathbb{Z}_{4m} \times \mathbb{Z}_{4m}$ $(m > 0)$ obtained by identifying elements from columns 0 and $4m$ and from rows 0 and $4m$. Hence, the proof gives undecidability for both the satisfiability and the finite satisfiability problems. ◀

Again, the formulas used in the above proof are guarded or can be rewritten as guarded. Also it suffices to assume that r is an equivalence relation. Hence we get the following

▶ **Corollary 17.** *The (finite) satisfiability problem for the intersection of the fluted fragment with equality with the two-variable guarded fragment is undecidable in the presence of two transitive relations (or one transitive and one equivalence relation).*

5 Conclusions

In this paper, we considered the (m-variable) fluted fragment in the presence of different numbers of transitive relations. We showed that $\mathcal{FL}$1T has the finite model property, but $\mathcal{FL}^2$3T admits axioms of infinity and the satisfiability problem for $\mathcal{FL}^2$3T is undecidable. This contrasts with known results for other decidable fragments, in particular, FO^2, where the satisfiability and finite satisfiability problems are undecidable in the presence of two transitive relations, and where the *finite* satisfiability problem is decidable in the presence of one transitive relation. It is open whether the (finite) satisfiability problem for $\mathcal{FL}$ in the presence of *two* transitive relations, $\mathfrak{t}_1$ and $\mathfrak{t}_2$, is decidable. We point out that Lemma 11 in Section 3 could be generalized to normal form formulas from $\mathcal{FL}^{m+1}$2T. Hence, the (finite) satisfiability problem for $\mathcal{FL}$ in the presence of two transitive relations is decidable if and only if the corresponding problem for $\mathcal{FL}^2$ with two transitive relations is decidable. Unfortunately neither the method of Sec. 3 (to show decidability) nor that of Sec. 4 (to show undecidability) appears to apply here. The barrier in the former case is that pairs of elements can be related by both $\mathfrak{t}_1$ and $\mathfrak{t}_2$ via divergent $\mathfrak{t}_1$- and $\mathfrak{t}_2$-chains, so that simple certificates of the kind employed for $\mathcal{FL}^2 1\mathrm{T}^u$ do not guarantee the existence of models. The barrier in the latter case is that the grid construction has to build models featuring transitive paths of *bounded* length, and this seems not to be achievable with just two transitive relations. Finally, we expect that the undecidability result for $\mathcal{FL}^2 3\mathrm{T}$ can be extended to get undecidability of the corresponding finite satisfiability problem.

Abstract

We study descriptive complexity of counting complexity classes in the range from #P to $\# \cdot \mathrm{NP}$. A corollary of Fagin's characterization of NP by existential second-order logic is that #P can be logically described as the class of functions counting satisfying assignments to free relation variables in first-order formulae. In this paper we extend this study to classes beyond #P and extensions of first-order logic with team semantics. These team-based logics are closely related to existential second-order logic and its fragments, hence our results also shed light on the complexity of counting for extensions of first-order logic in Tarski's semantics. Our results show that the class $\# \cdot \mathrm{NP}$ can be logically characterized by independence logic and existential second-order logic, whereas dependence logic and inclusion logic give rise to subclasses of $\# \cdot \mathrm{NP}$ and #P, respectively. We also study the function class generated by inclusion logic and relate it to the complexity class $\mathrm{TotP} \subsetneq \#\mathrm{P}$. Our main technical result shows that the problem of counting satisfying assignments for monotone Boolean Σ_1-formulae is $\# \cdot \mathrm{NP}$-complete with respect to Turing reductions as well as complete for the function class generated by dependence logic with respect to first-order reductions.

1 Introduction

The question of the power of counting arises in propositional and predicate logic in a number of contexts. Counting the number of satisfying assignments for a given propositional formula, #SAT, is complete for Valiant's class #P of functions counting accepting paths of nondeterministic polynomial-time Turing machines [32]. Valiant also proved that #SAT even remains complete when restricted to monotone 2CNF-formulae.

The class #P can be seen as the counting analogue of NP, which was shown by Fagin [11] to correspond to existential second order logic, where the quantified relation encodes accepting computation paths of NP-machines. Hence, if we define $\#\mathrm{FO}^{\mathrm{rel}}$ to count satisfying assignments to free relational variables in first-order (FO-) formulae, we obtain $\#\mathrm{FO}^{\mathrm{rel}} = \#\mathrm{P}$. This result has been refined to prefix classes of FO showing, e.g., that $\#\Pi_2^{\mathrm{rel}} = \#\mathrm{P}$ [30].

If we define $\#\mathrm{FO}^{\mathrm{func}}$ in the same fashion as $\#\mathrm{FO}^{\mathrm{rel}}$ except that we count assignments to function variables instead of relation variables, then obviously $\#\mathrm{FO}^{\mathrm{func}} = \#\mathrm{P}$. The situation changes for the prefix classes, though. In particular, unlike for $\#\Pi_1^{\mathrm{rel}}$, it holds that $\#\Pi_1^{\mathrm{func}} = \#\mathrm{P}$, and, remarkably, also arithmetic circuit classes like $\#\mathrm{AC}^0$ can be characterized in this context [7].

In this paper we consider a different model-theoretic approach to the study of counting processes using so-called team-based logics. In these logics, formulae with free variables are evaluated not for single assignments to these variables but for *sets* of such assignments (called *teams*). Logics with team semantics have been developed for the study of various dependence and independence concepts important in many areas such as (probabilistic) databases and Bayesian networks (see, e.g. [16, 5, 15]) for which model counting is an important inference task (see, e.g., [3, 27]). In addition, team-based logics have interesting connections to a wide range of areas such as formal semantics of natural language [4], social choice theory [28], and quantum information theory [18].

In team semantics, a first-order formula is satisfied by a team if and only if all its members satisfy the formula individually. Interest in teams stems from the introduction of different logical atoms describing properties of teams, called team atoms, such as the value of a variable being functionally dependent on other variables (characterized by the *dependence* atom $=\!(\bar{x}, y)$), a variable being independent from other variables (characterized by the *independence* atom $\bar{y}\perp_{\bar{x}}\bar{z}$), and the values of a variable occurring as values of some other variable (characterized by the *inclusion* atom $\bar{x} \subseteq \bar{y}$), etc. ([31, 14, 12]).

We initiate in this paper the study of counting for team-based logics. In our proofs we utilize the known correspondences between team-based logics and existential second-order logic (Σ_1^1) and its fragments (see Theorem 2). We want to stress that our results are also novel for existential second-order logic and its fragments, and that there is no natural way to carry out the study of the function class generated by inclusion logic, that is, FO extended by the inclusion atom, in Tarskian semantics.

We define $\#\mathrm{FO}^{\mathrm{team}}$ to be the class of functions counting teams that satisfy a given FO-formula, and similarly for extensions of FO by team atoms. Making use of different team atoms, we give a characterization of $\# \cdot \mathrm{NP}$. While it is relatively easy to see that with every finite set A of NP-definable team atoms, the class $\#\mathrm{FO}(A)^{\mathrm{team}}$ stays a subclass of $\# \cdot \mathrm{NP}$ (Toda's generalization of #P, see [17] for a survey of counting classes like these), we show that FO extended with the independence atom is actually sufficient to characterize the full class $\# \cdot \mathrm{NP}$:

$$\#\mathrm{FO}(\perp)^{\mathrm{team}} = \#\Sigma_1^1 = \# \cdot \mathrm{NP}.$$

The situation with inclusion logic and dependence logic is more complex due to their strong closure properties: satisfaction of formulae is closed under union for inclusion logic and is closed downwards for dependence logic. We show that $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ is a subclass of TotP, which is a class of counting problems with easy decision versions. Note that TotP is a strict subclass of #P unless P = NP and consequently the same holds for $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$. Furthermore, $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ is a subclass of $\#\cdot\mathrm{NP}$, which we believe to be strict as well. Interestingly, both classes contain complete problems from their respective superclasses. In establishing this result for dependence logic, we introduce an interesting class of monotone quantified Boolean formulae and show that the corresponding counting problem where the all-0-assignment is not counted, $\#\Sigma_1\mathrm{CNF}^-_*$, is $\#\cdot\mathrm{NP}$-complete. In order to prove $\#\cdot\mathrm{NP}$-completeness we also show that the more natural problem of counting all satisfying assignments of the same class of formulae is $\#\cdot\mathrm{NP}$-complete by introducing a new technique of simultaneous reductions between pairs of counting problems, which we hope will also be useful in other contexts.

For inclusion logic we show that the well-known #P-complete problem $\#2\mathrm{CNF}^+$ is in $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ and that the problem of counting assignments for existentially quantified dual-Horn formulae is hard for $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$.

In related previous work, so-called weighted logics have been used to logically characterize counting complexity classes [1], and the decision-problem analogue PP of #P and the counting hierarchy have been logically characterized in [21, 23, 6]. Counting classes from circuit complexity beyond $\#\mathrm{AC}^0$ have been logically characterized in [8].

Due to space restrictions, we only give proof sketches for some theorems, and detailed proofs for all results throughout the paper are deferred to the full version of this paper.

2 Definitions and Preliminaries

First-order Logic and Team Semantics

Let us start by recalling the syntax of first-order logic (FO). In this work, we only consider relational vocabularies (i.e., vocabularies with no function or constant symbols), and thus the only first-order terms are variables. Formulae of first-order logic are defined by the following grammar:

$$\varphi ::= \varphi \wedge \varphi \mid \varphi \vee \varphi \mid \exists x\varphi \mid \forall x\varphi \mid R(\overline{x}) \mid \neg R(\overline{x}) \mid x = y \mid x \neq y \qquad (\star)$$

where x, y are variables, R is a relation symbol, and $\overline{x}$ is a tuple of the appropriate number of variables.

The set of *free variables* of a formula φ is defined as usual, and we sometimes write $\varphi(x_1, \dots, x_k)$ to emphasize that the free variables of φ are among $x_1, \dots, x_k$. A formula with no free variable is called a *sentence*. For any k, the fragment Σ_k of FO consists of all formulae of the form $\exists\overline{x_1}\forall\overline{x_2}\dots Q\overline{x_k}\varphi$, where φ is quantifier-free and Q is either $\exists$ or $\forall$ depending on whether k is odd or even; similarly, the fragment Π_k is defined as the class of all formulae $\forall\overline{x_1}\exists\overline{x_2}\dots Q\overline{x_k}\varphi$ in prenex normal form with a quantifier prefix with k alternations starting with universal quantifiers.

We only consider finite structures with a finite relational vocabulary σ. Denote the class of all such structures by $\mathrm{STRUC}[\sigma]$, and let $\mathrm{dom}(\mathcal{A})$ denote the universe of a σ-structure $\mathcal{A}$. We will always use structures with universe $\{0, 1, \dots, n-1\}$ for some $n \in \mathbb{N} \setminus \{0\}$. We assume that our structures contain a *built-in binary relation* $\leq$ and *ternary relations* $+, \times$ with the usual interpretation, i.e., $\leq$ is interpreted in a model of any size as the "less than or equal to" relation on $\mathbb{N}$, $+$ is interpreted as addition and $\times$ as multiplication. We write $\mathrm{enc}_\sigma(\mathcal{A})$ for the standard binary encoding of a σ-structure $\mathcal{A}$ (see e.g., [20]): Relations are encoded row by row by listing their truth values as 0's and 1's. The whole structure is encoded by the concatenation of the encodings of its relations.

We assume that the reader is familiar with the usual Tarskian semantics for first-order formulae, in which formulae are evaluated with respect to single assignments of a structure. In this paper, we also consider so-called *team semantics* for first-order formulae, in which formulae are evaluated with respect to teams. A *team* is a *set* of assignments of a structure, that is, a set of functions $s\colon \{x_1, \dots, x_k\} \to \mathrm{dom}(\mathcal{A})$, where we call $\{x_1, \dots, x_k\}$ the domain of the team. Note that the empty set $\emptyset$ is a team, called *empty team*, and the singleton $\{\emptyset\}$ containing only the empty assignment is also a team. We denote by $\mathrm{team}(\mathcal{A}, (x_1, \dots, x_k))$ the set of all teams over a structure $\mathcal{A}$ with the domain $\{x_1, \dots, x_k\}$. Due to certain connections between team logics and second-order logic it is often helpful to view teams as relations. Let $\mathcal{A}$ be a structure and X a team of $\mathcal{A}$ with domain $\{x_1, \dots, x_k\}$. $\mathcal{A}$ and X induce the k-ary relation $\mathrm{rel}(X)$ on $\mathrm{dom}(\mathcal{A})$ defined as

$$\mathrm{rel}(X) := \{(s(x_1), \dots, s(x_n)) \mid s \in X\}.$$

Furthermore, for any subset $V \subseteq \{x_1, \dots, x_k\}$ of variables we define

$$X\big|_V := \{s\big|_V \mid s \in X\},$$

the restriction of team X to domain V.

We define inductively the notion of a team X with domain $\{x_1, \dots, x_k\}$ of a structure $\mathcal{A}$ with $A := \mathrm{dom}(\mathcal{A})$ satisfying an FO-formula $\varphi(x_1, \dots, x_k)$, denoted by $\mathcal{A} \models_X \varphi$, as follows:

- $\mathcal{A} \models_X \alpha$ for α an atomic formula if and only if for all $s \in X$, $\mathcal{A} \models_s \alpha$ in the usual Tarskian semantics sense.
- $\mathcal{A} \models_X \varphi \vee \psi$ if and only if there are teams $Y, Z \subseteq X$ such that $Y \cup Z = X$, $\mathcal{A} \models_Y \varphi$ and $\mathcal{A} \models_Z \psi$.
- $\mathcal{A} \models_X \varphi \wedge \psi$ if and only if $\mathcal{A} \models_X \varphi$ and $\mathcal{A} \models_X \psi$.
- $\mathcal{A} \models_X \exists x\varphi$ if and only if there exists a function $F\colon X \to \mathcal{P}(A) \setminus \{\emptyset\}$, called *supplementing function*, such that $\mathcal{A} \models_{X[F/x]} \varphi$, where

$$X[F/x] = \{s[a/x] \mid s \in X \text{ and } a \in F(s)\} \qquad \text{and} \quad s[a/x](y) = \begin{cases} a, & \text{if } x = y, \\ s(y), & \text{else.} \end{cases}$$

- $\mathcal{A} \models_X \forall x\varphi$ if and only if $\mathcal{A} \models_{X[A/x]} \varphi$, where $X[A/x] = \{s[a/x] \mid s \in X \text{ and } a \in A\}$.

A sentence φ is said to be *true* in $\mathcal{A}$, written $\mathcal{A} \models \varphi$, if $\mathcal{A} \models_{\{\emptyset\}} \varphi$.

FO-formulae φ are flat over team semantics, i.e., $\mathcal{A} \models_X \varphi$, if and only if $\mathcal{A} \models_s \varphi$ for all $s \in X$. In this sense, team semantics is conservative over FO-formulae. We now extend first-order logic by sets of atomic formulae which are not flat. For any sequence $\overline{x}$ of variables and variable y, the string $=\!(\overline{x}, y)$ is called a *dependence atom.* For any sequences $\overline{x}, \overline{y}, \overline{z}$ of variables, the string $\overline{y} \perp_{\overline{x}} \overline{z}$ is called an *independence atom.* For any two sequences $\overline{x}$ and $\overline{y}$ of variables of the same length, the string $\overline{x} \subseteq \overline{y}$ is called an *inclusion atom.* The team semantics of these atoms is defined as follows:

- $\mathcal{A} \models_X =\!(\overline{x}, y)$, if and only if for all $s, s' \in X$, if $s(\overline{x}) = s'(\overline{x})$, then $s(y) = s'(y)$.
- $\mathcal{A} \models_X \overline{y} \perp_{\overline{x}} \overline{z}$ if and only if for all $s, s' \in X$ such that $s(\overline{x}) = s'(\overline{x})$, there exists $s'' \in X$ such that $s''(\overline{x}) = s(\overline{x})$, $s''(\overline{y}) = s(\overline{y})$ and $s''(\overline{z}) = s'(\overline{z})$.
- $\mathcal{A} \models_X \overline{x} \subseteq \overline{y}$ if and only if for all $s \in X$ there is $s' \in X$ such that $s(\overline{x}) = s'(\overline{y})$.

For any subset $A \subseteq \{=(\dots), \perp, \subseteq\}$, we define $\mathrm{FO}(A)$ as first-order logic extended by the respective atoms, and refer to such a logic as *team-based logic*. More precisely we extend the grammar $(\star)$ by adding a rule for each atom in A. For example for $\mathrm{FO}(\{\subseteq\})$ we add the rule

$$\varphi ::= \overline{x} \subseteq \overline{y},$$

where $\overline{x}, \overline{y}$ are tuples of variables. For convenience, we often omit the curly brackets and write for example $\mathrm{FO}(\subseteq)$ instead of $\mathrm{FO}(\{\subseteq\})$.

The team-based logic $\mathrm{FO}(=(\dots))$ is known in the literature as *dependence logic* [31], $\mathrm{FO}(\perp)$ as *independence logic* [14] and $\mathrm{FO}(\subseteq)$ as *inclusion logic* [12]. We recall some basic properties of these logics from [31, 14, 12]: Formulae of $\mathrm{FO}(=(\dots))$ are *closed downwards*, i.e., $\mathcal{A} \models_X \varphi$ and $Y \subseteq X$ implies $\mathcal{A} \models_Y \varphi$, formulae of $\mathrm{FO}(\subseteq)$ are *closed under unions*, i.e., $\mathcal{A} \models_X \varphi$ and $\mathcal{A} \models_Y \varphi$ implies $\mathcal{A} \models_{X \cup Y} \varphi$, and formulae of any of these logics have the *empty team property*, i.e., $\mathcal{A} \models_\emptyset \varphi$ always holds.

The above atoms expressing team properties can be generalized, as we will do next. Let us first recall below the definition of generalized quantifiers, where we follow the notations from [22, 26].

▶ **Definition 1.** *Let $i_1, \dots, i_n$ $(n > 0)$ be a sequence of positive integers, and σ a vocabulary consisting of an i_j-ary relation symbol for each $1 \leq j \leq n$. A* generalized quantifier *of type $(i_1, \dots, i_n)$ is a class $\mathcal{C}$ of σ-structures $(A, B_1, \dots, B_n)$ such that the following conditions hold:*

1. *$A \neq \emptyset$ and for each $1 \leq j \leq n$, we have $B_j \subseteq A^{i_j}$.*
2. *$\mathcal{C}$ is closed under isomorphisms, that is, if $(A', B'_1, \dots, B'_n) \in \mathcal{C}$ is isomorphic to $(A, B_1, \dots, B_n)$, then $(A', B'_1, \dots, B'_n) \in \mathcal{C}$.*

Let Q be a generalized quantifier of type $(i_1, \dots, i_n)$. Let us extend the syntax of first-order logic with an expression $A_Q(\overline{x_1}, \dots, \overline{x_n})$, where each $\overline{x_j}$ is a tuple of variables of length i_j and $Vars(\overline{x_i})$ is the set of variables in x_i. We call A_Q a generalized (dependency) atom *(of type $(i_1, \dots, i_n)$), and its team semantics is defined as:*

$$\mathcal{A} \models_X A_Q(\overline{x_1}, \dots, \overline{x_n}) \textit{ if and only if} (\mathrm{rel}(X|_{Vars(\overline{x_1})}), \dots, \mathrm{rel}(X|_{Vars(\overline{x_n})})) \in Q^{\mathcal{A}},$$

where $Q^{\mathcal{A}} = \{(B_1, \dots, B_n) \mid (\mathrm{dom}(\mathcal{A}), B_1, \dots, B_n) \in Q\}$.

We say that a generalized dependency atom A_Q is NP-definable if there is an NP-algorithm that decides for a given structure $\mathcal{A}$ and a given team X whether $\mathcal{A} \models_X A_Q(\overline{x_1}, \dots, \overline{x_n})$ holds or not. A set A of generalized atoms is NP-definable if every $a \in A$ is NP-definable. For example, the set $A = \{=(\dots), \perp, \subseteq\}$ is NP-definable.

Many results in this paper are based on the expressive power of the logics defined above, that we shall now recall. We first recall some notions and notations. Existential second-order logic (Σ^1_1) consists of formulae of the form $\exists R_1 \dots \exists R_k \varphi$, where φ is an FO-formula. Let σ be a vocabulary. We write $\sigma(R)$ for the vocabulary that arises by adding a fresh relation symbol R to σ, and we sometimes write $\varphi(R)$ to emphasize that the relation symbol R occurs in the $\sigma(R)$-formula φ. If $\mathcal{A}$ is a σ-structure, we write $(\mathcal{A}, Q)$ for $\mathcal{A}$ expanded into a $\sigma(R)$-structure where the new k-relation symbol R is interpreted as $Q \subseteq \mathrm{dom}(\mathcal{A})^k$. A $\sigma(R)$-sentence $\varphi(R)$ of Σ^1_1 is said to be *downward monotone* with respect to R if $(\mathcal{A}, Q) \models \varphi(R)$ and $Q' \subseteq Q$ imply $(\mathcal{A}, Q') \models \varphi(R)$. It is known that $\varphi(R)$ is downward monotone with respect to R if and only if $\varphi(R)$ is equivalent to a sentence where R occurs only negatively (see e.g., [24]).

▶ **Theorem 2** (see [12, 24, 13]).

1. *For every σ-formula φ of* $\mathrm{FO}(\perp)$*, there is an $\sigma(R)$-sentence $\psi(R)$ of Σ^1_1 such that for all σ-structures $\mathcal{A}$ and teams X,*

$$\mathcal{A} \models_X \varphi \iff (\mathcal{A}, \mathrm{rel}(X)) \models \psi(R). \tag{1}$$

Conversely, for every $\sigma(R)$-sentence $\psi(R)$ of Σ^1_1, there is a σ-formula φ of $\mathrm{FO}(\perp)$ *such that (1) holds for all σ-structures $\mathcal{A}$ and* non-empty *teams X.*

2. *The same as the above holds for formulae of* $\mathrm{FO}(=\!(\dots))$ *as well, except that in both directions for* $\mathrm{FO}(=\!(\dots))$ *the relation symbol R is assumed to occur only negatively in the sentence $\psi(R)$.*
3. *In particular, over sentences both* $\mathrm{FO}(\perp)$ *and* $\mathrm{FO}(=\!(\dots))$ *are expressively equivalent to Σ^1_1, in the sense that every σ-sentence of* $\mathrm{FO}(\perp)$ *(or* $\mathrm{FO}(=\!(\dots))$*) is equivalent to a σ-sentence ψ of Σ^1_1, i.e., for any σ-structure $\mathcal{A}$,*

$$\mathcal{A} \models \varphi \iff \mathcal{A} \models \psi,$$

and vice versa. As a consequence of Fagin's Theorem (see [11]), over finite structures both $\mathrm{FO}(\perp)$ *and* $\mathrm{FO}(=\!(\dots))$ *capture* NP*.*

4. *For any σ-formula $\varphi(x_1, \dots, x_k)$ of* $\mathrm{FO}(\subseteq)$*, there exists a $\sigma(R)$-formula $\psi(R)$ of positive greatest fixed point logic (*posGFP*) such that for all σ-structures $\mathcal{A}$ and teams X,*

$$\mathcal{A} \models_X \varphi \iff \mathcal{A}, \mathrm{rel}(X) \models_s \psi(R) \text{ for all } s \in X;$$

and vice versa. In particular, over sentences $\mathrm{FO}(\subseteq)$ *is expressively equivalent to* posGFP*. As a consequence of Immerman's Theorem (see [19]), over finite structures,* $\mathrm{FO}(\subseteq)$ *is expressively equivalent to least fixed point logic (*LFP*). Thus, by [19, 34], over ordered finite structures,* $\mathrm{FO}(\subseteq)$ *captures* P*.*

5. *Let $\varphi(R)$ be a* myopic *σ-formula, that is, $\varphi(R) = \forall \overline{x}(R(\overline{x}) \to \psi(R, \overline{x}))$, where ψ is a first order σ-formula with only positive occurrences of R. Then there exists a σ-formula $\chi \in$* $\mathrm{FO}(\subseteq)$ *such that for all σ-structures $\mathcal{A}$ and all teams X:*

$$\mathcal{A} \models_X \chi(\overline{x}) \Leftrightarrow \mathcal{A}, \mathrm{rel}(X) \models \varphi(R).$$

Propositional and Quantified Boolean formulae

In this paper, we will also consider certain classes of propositional and quantified Boolean formulae. As usual, we use CNF to denote the class of propositional formulae in conjunctive normal form and k-CNF to denote the class of propositional formulae in conjunctive normal form where each clause contains at most k literals. A formula in CNF is in the class DualHorn if each of its clauses contains at most one negative literal.

For a class $\mathcal{C}$ of Boolean formulae, we denote by $\Sigma_1\mathcal{C}$ the class of quantified Boolean formulae in prenex normal form with only existential quantifiers where the quantifier-free part is an element of $\mathcal{C}$.

For a class $\mathcal{C}$ of quantified Boolean formulae we denote with $\mathcal{C}^+$(resp. $\mathcal{C}^-$) the class of formulae in $\mathcal{C}$ whose free variables occur only positively (resp. negatively). For example, $\Sigma_1 3\mathrm{CNF}^-$ consists of all quantified Boolean formulae in prenex normal form with only existential quantifiers, where the quantifier-free part is in 3CNF and the free variables occur only negatively. Note that in Boolean formulae all variables are free.

Counting Problems and Counting Classes

This paper aims to identify model-theoretic characterizations of counting classes in terms of team-based logics. Let us now recall relevant previous results on the descriptive complexity of counting problems. We begin by defining the most important complexity classes for counting problems.

▶ **Definition 3.** *A function $f\colon \{0,1\}^* \to \mathbb{N}$ is in* $\#\mathrm{P}$ *if there is a non-deterministic polynomial time Turing machine M such that for all inputs $x \in \{0,1\}^*$,*

$$f(x) \text{ is the number of the accepting computation paths of } M \text{ on input } x.$$

This definition can be generalized as follows.

▶ **Definition 4.** *Let $\mathcal{C}$ be a complexity class. A function $f\colon \{0,1\}^* \to \mathbb{N}$ is said to be in $\# \cdot \mathcal{C}$ if there are a language $L \in \mathcal{C}$ and a polynomial p such that for all $x \in \{0,1\}^*$:*

$$f(x) = |\{y \mid |y| \leq p(|x|) \text{ and } (x,y) \in L\}|.$$

Obviously $\#\mathrm{P} = \# \cdot \mathrm{P}$, and it is well known that $\#\mathrm{P} \subseteq \# \cdot \mathrm{NP} \subseteq \# \cdot \mathrm{coNP} = \#\mathrm{P}^{\mathrm{NP}}$, where, under reasonable complexity-theoretic assumptions, all these inclusions are strict; see [17] for a survey of these issues.

▶ **Definition 5.** *A function $f\colon \{0,1\}^* \to \mathbb{N}$ is in* TotP *if there is a non-deterministic polynomial time Turing machine M such that for all inputs $x \in \{0,1\}^*$,*

$$f(x) \text{ is the number of the computation paths of } M \text{ on input } x \text{ minus } 1.$$

Subtracting 1 from the number of computation paths is neccessary since otherwise TotP-functions could never map to 0. In [29] it was shown that TotP is the closure with respect to parsimonious reductions of self-reducible counting problems from $\#\mathrm{P}$ whose decision version is in P. It follows that $\mathrm{TotP} \subsetneq \#\mathrm{P}$ unless $\mathrm{P} = \mathrm{NP}$.

Next, we define the relevant logical counting classes.

▶ **Definition 6.** *A function $f\colon \{0,1\}^* \to \mathbb{N}$ is said to be in $\#\mathrm{FO}^{\mathrm{rel}}$ if there is a vocabulary σ with a built-in linear order $\leq$, and an* FO*-formula $\varphi(R_1, \ldots, R_k, x_1, \ldots, x_\ell)$ over σ with free relation variables $R_1, \ldots, R_k$ and free individual variables $x_1, \ldots, x_\ell$ such that for all σ-structures $\mathcal{A}$,*

$$f(\mathrm{enc}_\sigma(\mathcal{A})) = |\{(S_1, \ldots, S_k, c_1, \ldots, c_\ell) : \mathcal{A} \models \varphi(S_1, \ldots, S_k, c_1, \ldots, c_\ell\}|.$$

If the input of f is not of the appropriate form, we assume the output to be 0*.*

In the same fashion, subclasses of $\#\mathrm{FO}^{\mathrm{rel}}$, such as $\#\Sigma_k^{\mathrm{rel}}$ and $\#\Pi_k^{\mathrm{rel}}$ for arbitrary k, are defined by assuming that the formula φ in the above definition is in the corresponding fragments Σ_k and Π_k.

Recall the relationship between the above defined logical counting classes and $\#\mathrm{P}$:

▶ **Theorem 7** ([30])**.** $\#\Sigma_0^{\mathrm{rel}} = \#\Pi_0^{\mathrm{rel}} \subset \#\Sigma_1^{\mathrm{rel}} \subset \#\Pi_1^{\mathrm{rel}} \subset \#\Sigma_2^{\mathrm{rel}} \subset \#\Pi_2^{\mathrm{rel}} = \#\mathrm{FO}^{\mathrm{rel}} = \#\mathrm{P}$*. Furthermore, $\#\Sigma_0^{\mathrm{rel}} \subseteq \mathrm{FP}$.*

Complete problems (i.e., hardest problems) for counting classes have also been studied extensively. Let us now recall three reductions that are relevant in this study. Let f and h be counting problems. We say that f is *parsimoniously* reducible to h if there is a polynomial-time computable function g such that $f(x) = h(g(x))$ for all inputs x, f is *Turing* reducible to h if $f \in \mathrm{FP}^h$, and f is *metrically* reducible to h if there are polynomial-time computable functions g_1, g_2 such that $f(x) = g_2(h(g_1(x)), x)$ for all inputs x. Clearly, metric reductions are Turing reductions with one oracle query. Besides these three familiar reductions we now define another type of reductions, called *first-order reductions.* First recall that for any two vocabularies σ_1, σ_2, an *FO-interpretation* (or a *first-order query*) is a function $I : \mathrm{STRUC}[\sigma_1] \to \mathrm{STRUC}[\sigma_2]$, represented as a tuple $I = (\varphi_0, \varphi_{R_1}, \ldots, \varphi_{R_\ell})$ of FO-formulae over σ_1 with k free variables, that maps any structure $\mathcal{A} \in \mathrm{STRUC}[\sigma_1]$ to another structure $I(\mathcal{A}) \in \mathrm{STRUC}[\sigma_2]$, whose domain is a subset of $\mathrm{dom}(\mathcal{A})^k$ (i.e., a set of k-ary tuples of elements in $\mathcal{A}$) defined by φ_0 and relations R_i are defined by φ_{R_i} (see [20] for detailed discussion). In the team semantics case, we also need to define how teams are transformed by the interpretation I. The value $I(X)$ is defined in a straightforward way: individual elements from $\mathcal{A}^{k \cdot m}$ in X are mapped to elements from $I(\mathcal{A})^m$ in $I(X)$, where k is the arity of tuples in the domain of the structure $I(\mathcal{A})$, and m is the arity of the team $I(X)$. Now, we define first-order reductions via FO-interpretations as follows:

▶ **Definition 8.** *Let f_1, f_2 be two functions. We say f_1 is first-order reducible or FO-reducible to f_2 (denoted $f_1 \leq_{fo} f_2$) if there are vocabularies σ_1, σ_2 with $\sigma_2 = (R_1^{a_1}, \ldots, R_l^{a_l})$ and an FO-interpretation $I = (\varphi_0, \varphi_{R_1}, \ldots, \varphi_{R_\ell})$, where $\varphi_0, \varphi_{R_1}, \ldots, \varphi_{R_\ell}$ are* FO*-formulae over σ_1, such that for all $\mathcal{A}_1 \in \mathrm{STRUC}[\sigma_1]$, there are $k \in \mathbb{N}$ and $\mathcal{A}_2 \in \mathrm{STRUC}[\sigma_2]$ with*

$$dom(\mathcal{A}_2) = \{(x^1, \ldots, x^k) \mid \mathcal{A}_1 \models \varphi_0(x^1, \ldots, x^k)\}$$

and for all $i \leq k$

$$R_i((x_1^1, \ldots, x_1^k), \ldots, (x_{a_i}^1, \ldots, x_{a_i}^k)) \Leftrightarrow \mathcal{A}_1 \models \varphi_{R_i}(x_1^1, \ldots, x_1^k, \ldots, x_{a_i}^1, \ldots, x_{a_i}^k)$$

and $f_1(\mathrm{enc}_{\sigma_1}(\mathcal{A}_1)) = f_2(\mathrm{enc}_{\sigma_2}(\mathcal{A}_2))$.

It is often possible to find complete problems in counting classes by counting satisfying assignments for certain (quantified) Boolean formulae. Let $\mathcal{F}$ be a class of quantified Boolean formulae. Define the problem $\#\mathcal{F}$ as follows:

Problem:	$\#\mathcal{F}$
Input:	Formula $\varphi \in \mathcal{F}$
Output:	Number of satisfying assignments of φ

For example, #SAT, the function counting the number of satisfying assignments for propositional formulae, as well as its restriction #3CNF, are complete for #P under parsimonious reductions, while $\#2\mathrm{CNF}^+$ and $\#2\mathrm{CNF}^-$ are complete for #P under Turing reductions. Observe that for all Σ_1CNF-formulae φ it holds that the number of satisfying assignments is equal to that of the formula $\widetilde{\varphi}$ obtained by negating all literals in all clauses in φ. Thus, $\#\Sigma_1\mathrm{CNF}^+$ and $\#\Sigma_1\mathrm{CNF}^-$ are in a sense the same problem. In fact all our results for $\#\mathcal{C}^+$ (for a class of formulae $\mathcal{C}$) also hold for $\#\mathcal{C}^-$ and vice versa. This also holds for #Horn and #DualHorn. Note that Aziz et al [2] studied the problem $\#\Sigma_1\mathrm{SAT}$ under the name *projected model counting* and observed that it is contained in $\# \cdot \mathrm{NP}$.

Next we introduce the central class for this paper, a class of counting problems in the context of team-based logics. For any set A of generalized dependency atoms, we define $\#\mathrm{FO}(A)^{\mathrm{team}}$ to consist of those functions counting non-empty satisfying teams for $\mathrm{FO}(A)$-formulae. Note that by the empty team property of dependence, independence, and inclusion logic formulae any function that counts all satisfying teams (including the empty team) could not attain the value 0.

▶ **Definition 9.** *For any set A of generalized atoms, $\#\mathrm{FO}(A)^{\mathrm{team}}$ is the class of all functions $f\colon \{0,1\}^* \to \mathbb{N}$ for which there is a vocabulary σ with a built-in linear order $\leq$ and an $\mathrm{FO}(A)$-formula $\varphi(\overline{x})$ over σ with a tuple $\overline{x}$ of free first-order variables such that for all σ-structures $\mathcal{A}$,*

$$f(\mathrm{enc}_\sigma(\mathcal{A})) = |\{X \in \mathit{team}(\mathcal{A}, (\overline{x})) : X \neq \emptyset \text{ and } \mathcal{A} \models_X \varphi(\overline{x})\}|.$$

We denote by f_φ the function defined by φ.

▶ **Example 10.** As an example for how to work with team semantics in a counting context, we show that the #P-complete problem $\#2\mathrm{CNF}^+$ is contained in both $\#\mathrm{FO}(=\!(\dots))^{\mathrm{team}}$ and $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$. Let $\varphi(x_1,\dots,x_n) = \bigwedge C_i \in 2\mathrm{CNF}^+$, where each $C_i = \ell_{i,1} \vee \ell_{i,2}$ and $\ell_{i,j} \in \{x_1,\dots,x_n\}$. Consider the vocabulary $\tau_{2\mathrm{CNF}^+} = \{C^2\}$. We encode the formula $\varphi(x_1,\dots,x_n)$ by the structure $\mathcal{A} = (\{x_1,\dots,x_n\}, C^{\mathcal{A}})$, where $(x,y) \in C^{\mathcal{A}}$ if and only if the clause $x \vee y$ occurs in φ.

We show that $\#2\mathrm{CNF}^+$ can be defined by counting non-empty teams (which correspond to assignments mapping at least one variable to true) satisfying suitable formulae from $\mathrm{FO}(\subseteq)$ as well as $\mathrm{FO}(=\!(\dots))$. For this purpose, we encode Boolean assignments to the variables $x_1,\dots,x_n$ by teams over one variable t. Since the universe of our structures is exactly the set of variables of the formula $\varphi(x_1,\dots,x_k)$ in question, assignments to the variables can be encoded by inclusion of the values of the variables x_i in t in the team.

Now, the following $\mathrm{FO}(\subseteq)$-formula defines $\#2\mathrm{CNF}^+$:

$$\varphi_{\subseteq}(t) = \forall x \forall y (\neg C(x,y) \vee x \subseteq t \vee y \subseteq t).$$

Intuitively, this formula states that if a pair (x,y) of variables in φ occur in the same clause (i.e., $C(x,y)$ holds), then the value of one of the two variables x,y is contained in the team, or it is set to true.

To define the same problem in $\mathrm{FO}(=\!(\dots))$ where inclusion atoms are not any more available in the language, we need to encode assignments differently. We now encode variables x_i being set to 1 by not including them in the team over the variable t. The $\mathrm{FO}(=\!(\dots))$-formula that defines $\#2\mathrm{CNF}^+$ is the following:

$$\begin{aligned}\varphi_{=(\dots)}(t) =& \exists \min \forall z \min \leq z \wedge \\ & \quad \forall x \forall y \exists x' \exists y' \Big(=\!(x,x') \wedge =\!(y,y') \wedge (\neg x = y \vee x' = y') \wedge \\ & \qquad (x \neq t \vee x' = \min) \wedge (\neg C(x,y) \vee x' \neq \min \vee y' \neq \min) \Big).\end{aligned}$$

Intuitively, in the above formula we use existential quantifications together with dependence atoms to express that x' is a function of x, and this function f is guaranteed in the formula to be consistent with the assignment encoded by the team. We shall interpret a function mapping to the minimal element of the universe (encoded by the variable min in the formula) as an assignment to 0, and a function mapping to any other element as an assignment to 1. Now, the second last conjunct in our formula states that all variables that occur as values of t in the team (which correspond to those x_i set to 0) are mapped by our function f to the minimal element. Finally, the last conjunct in our formula checks whether the 2CNF-formula is satisfied by the assignment encoded by f. Note that in order to talk about the assignment to two variables simultaneously, in the above formula we actually use two (equivalent) functions to encode the same assignment.

3 A Characterization of the Class $\# \cdot \mathrm{NP}$

In this section, we characterize the class $\# \cdot \mathrm{NP}$ in terms of team-based logics. Our first result shows that $\# \cdot \mathrm{NP}$ is the largest class attainable by counting teams in team-based logics $\mathrm{FO}(A)$, as long as all generalized atoms in A are NP-definable.

▶ **Theorem 11.** *For any set A of* NP*-definable generalized atoms,* $\#\mathrm{FO}(A)^{\mathrm{team}} \subseteq \# \cdot \mathrm{NP}$.

Proof Sketch. Let $\varphi(\overline{x}) \in \#\mathrm{FO}(A)^{\mathrm{team}}$. To show that $f_\varphi \in \# \cdot \mathrm{NP}$ we note that f_φ can be computed by counting on input $\mathrm{enc}_\sigma(\mathcal{A})$ the number of teams X such that $\mathcal{A} \models_X \varphi(\overline{x})$. It is thus sufficient to show that the letter can be checked in NP on input $(\mathrm{enc}_\sigma(\mathcal{A}), X)$. In this proof, the only places that involve nondeterminism are disjunctions (guess the split), existential quantifiers (guess the supplementing function) and NP-definable generalized atoms (checkable in NP by definition). ◀

Next, we prove the converse inclusion of the above theorem by proving a stronger result: The whole class $\#{\cdot}\mathrm{NP}$ can actually be captured by a single generalized atom, the independence atom.

▶ **Theorem 12.** $\# \cdot \mathrm{NP} \subseteq \#\mathrm{FO}(\perp)^{\mathrm{team}}$

Proof Sketch. It is sufficient to show $\# \cdot \mathrm{NP} \subseteq \#\Sigma_1^1$ since by Theorem 2.1 we have $\#\Sigma_1^1 = \#\mathrm{FO}(\perp)^{\mathrm{team}}$.

Let $f \in \# \cdot \mathrm{NP}$. Then there are a polynomial p and $L \in \mathrm{NP}$ such that

$$f(x) = |\{y \mid |y| = p(|x|), (x, y) \in L\}|.$$

We encode tuples (x, y) of strings with $|y| = p(|x|)$ as structures $\mathcal{A}_{(x,y)}$ by encoding the string x as a structure $\mathcal{A}_x$ in the standard way, and y as a unique relation R_y over $\mathrm{dom}(\mathcal{A}_x)^k$ for some $k \in \mathbb{N}$. Finally, Fagin's theorem gives a Σ_1^1-sentence φ such that for all x,

$$|\{y \mid |y| = p(|x|), (x, y) \in L\}| = |\{y \mid \mathcal{A}_{(x,y)} \models \varphi\}| = |\{R \mid \mathcal{A}_x \models \varphi(R)\}|. \quad ◀$$

▶ Remark 13. The class $\#\mathrm{P}$ can also be characterized by counting teams. A variant $\mathcal{L}$ of dependence logic that defines exactly the first-order definable team properties in the sense of Theorem 2 was introduced in [25]. Since $\#\mathrm{P} = \#\mathrm{FO}$ (see [30]), this logic $\mathcal{L}$ captures $\#\mathrm{P}$. We do not present the details of $\mathcal{L}$ in this paper, but only note that $\mathcal{L}$ has weaker versions of quantifiers and disjunction instead of the standard ones as defined in Section 2.

4 Counting Teams in Dependence and Inclusion Logic

In this section, we study the smaller classes $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ and $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$. We begin by showing that the $\# \cdot \mathrm{NP}$-complete problem $\#\Sigma_1\mathrm{CNF}^-_*$, defined below, is contained in $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$. We will show $\# \cdot \mathrm{NP}$-completeness for $\#\Sigma_1\mathrm{CNF}^-_*$ in Theorem 26.

Problem:	$\#\Sigma_1\mathrm{CNF}^-_*$
Input:	Formula $\varphi(x_1, \dots, x_k) \in \mathrm{CNF}^-$
Output:	Number of satisfying assignments of φ, disregarding the all-0-assignment

Note that the *all-0-assignment* is the assignment mapping each variable to 0.

▶ **Theorem 14.** $\#\Sigma_1\mathrm{CNF}^-_* \in \#\mathrm{FO}(=(\dots))^{\mathrm{team}}$.

We will show that the above problem is actually complete for $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ with respect to first-order reductions. First-order reductions turn out to be particularly natural in our context, as all our classes are closed under these reductions.

▶ **Theorem 15.** *$\#\mathrm{FO}(A)^{\mathrm{team}}$ is closed under first-order reductions for $A \subseteq \{=(\dots), \perp, \subseteq\}$.*

Next we show that the problem $\#\Sigma_1\mathrm{CNF}^-_*$ is hard and thus complete for $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ under first-order reductions. Our proof technique is similar to that of [9], where the data complexity of inclusion logic is shown to be polynomial.

▶ **Theorem 16.** *$\#\Sigma_1\mathrm{CNF}^-_*$ is complete for $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ with respect to first-order reductions.*

Having proven our results for dependence logic $\mathrm{FO}(=(\dots))$, we now turn to inclusion logic $\mathrm{FO}(\subseteq)$. We first prove that $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ is a subclass of $\#\mathrm{P}$.

▶ **Theorem 17.** *$\#\mathrm{FO}(\subseteq)^{\mathrm{team}} \subseteq \#\mathrm{P}$.*

The above theorem naturally gives rise to the question whether $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ actually coincides with $\#\mathrm{P}$. However, we identify in the next lemma a particular property of $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ functions, making this equivalence unlikely to hold.

▶ **Lemma 18.** *Let $\varphi(\overline{x}) \in \mathrm{FO}(\subseteq)$ be a formula over a vocabulary σ. Then the language $L := \{w \mid f_\varphi(w) > 0\}$ is in P.*

▶ **Corollary 19.** *If $\mathrm{P} \neq \mathrm{NP}$, then $\#\mathrm{FO}(\subseteq)^{\mathrm{team}} \neq \#\mathrm{P}$.*

Theorem 17 and Corollary 19 indicate that $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ is most likely a strict subclass of $\#\mathrm{P}$. Nevertheless, we show in the next theorem that $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ contains the problem #DualHorn which is complete for $\#\mathrm{P}$ with respect to Turing reductions. It is unknown whether $\#\mathrm{DualHorn} \in \#\mathrm{FO}(=(\dots))$.

▶ **Theorem 20.** *$\#\mathrm{DualHorn} \in \#\mathrm{FO}(\subseteq)$.*

We continue by exhibiting a hard problem for the class $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$. It is an open question whether the problem is definable by an inclusion logic formula.

▶ **Theorem 21.** *$\#\Sigma_1\mathrm{DualHorn}$ is hard for $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ with respect to first-order reductions.*

It seems to us that $\#\mathrm{FO}(\subseteq)$ is a strict subclass of $\#\mathrm{P}$ and the decision versions of problems in $\#\mathrm{FO}(\subseteq)$ are in P. For this reason, we now investigate relationship between $\#\mathrm{FO}(\subseteq)$ and the subclass TotP. We show that $\#\mathrm{FO}(\subseteq)$ is a subclass of TotP and that TotP contains $\#\Sigma_1\mathrm{DualHorn}$. We conjecture that these classes do not coincide, but this question remains open.

▶ **Theorem 22.** *$\#\mathrm{FO}(\subseteq) \subseteq \mathrm{TotP}$*

▶ **Theorem 23.** *$\#\Sigma_1\mathrm{DualHorn} \in \mathrm{TotP}$*

5 Complete Problems for $\# \cdot \mathrm{NP}$

In this section we show that $\#\Sigma_1\mathrm{CNF}^-_*$ is $\# \cdot \mathrm{NP}$-complete. To this end, we first observe that $\#\Sigma_1\mathrm{CNF}$ is $\# \cdot \mathrm{NP}$-complete. Afterwards we show that the smaller class $\#\Sigma_1\mathrm{CNF}^-$ remains $\# \cdot \mathrm{NP}$-complete by adapting the proof for $\#\mathrm{P}$-completeness of $\#2\mathrm{CNF}^+$ given by Valiant [33]. We conclude this section with a reduction from $\#\Sigma_1\mathrm{CNF}^-$ to $\#\Sigma_1\mathrm{CNF}^-_*$ showing the $\# \cdot \mathrm{NP}$-completeness of the latter.

▶ **Lemma 24.** $\#\Sigma_1\mathrm{SAT}$ *and* $\#\Sigma_1\mathrm{CNF}$ *are* $\# \cdot \mathrm{NP}$*-complete under parsimonious reductions.*

▶ **Theorem 25.** $\#\Sigma_1\mathrm{CNF}^-$ *is* $\# \cdot \mathrm{NP}$*-complete under Turing reductions.*

Proof Sketch. Membership follows from 24, since $\#\Sigma_1\mathrm{CNF}^-$ is a special case of $\#\Sigma_1\mathrm{CNF}$. For the hardness proof, we show a chain of reductions adapted from the one used by Valiant [33] to show the #P-completeness of $\#2\mathrm{CNF}^+$. Recall that the main steps of Valiant's chain of reductions are:

$$\begin{aligned} \#3\mathrm{CNF} \leq \mathrm{PERMANENT} & \leq \#\mathrm{PERFECT\text{-}MATCHING} \\ \leq \#\mathrm{IMPERFECT\text{-}MATCHING} & \leq \#2\mathrm{CNF}^+. \end{aligned}$$

Our idea is to add a $\Sigma_1 3\mathrm{CNF}$-formula to the input of each problem in the above chain of reductions, and to express certain properties of the respective inputs in the added formula. We then count only the solutions to the input that also satisfy the added formula.

As part of the chain of reductions we will make use of the following problem:

Problem:	$\#(3\mathrm{CNF}, \Sigma_1 3\mathrm{CNF}^-)$
Input:	Formula $\varphi(x_1, \dots, x_k) \in 3\mathrm{CNF}$ and formula $\psi(x_1, \dots, x_k) \in \Sigma_1 3\mathrm{CNF}^-$
Output:	Number of satisfying assignments of $\varphi \wedge \psi$

We will reduce $\#\Sigma_1 3\mathrm{CNF}$ to $\#(3\mathrm{CNF}, \Sigma_1 3\mathrm{CNF}^-)$, and then apply the above chain of reductions (with added formulae, as described above). This results in a reduction to $\#(2\mathrm{CNF}^-, \Sigma_1 3\mathrm{CNF}^-)$, defined analogously to the above problem. Finally it is straightforward to show $\#(2\mathrm{CNF}^-, \Sigma_1 3\mathrm{CNF}^-) \leq \#\Sigma_1\mathrm{CNF}^-$ using the fact that for $\varphi \in 2\mathrm{CNF}^-$ and $\psi \in \Sigma_1 3\mathrm{CNF}^-$, the prenex normal form of $\varphi \wedge \psi$ is a $\Sigma_1 3\mathrm{CNF}^-$-formula. We conclude by sketching the first reduction.

$\underline{\#\Sigma_1 3\mathrm{CNF} \leq \#(3\mathrm{CNF}, \Sigma_1 3\mathrm{CNF}^-)}$: We construct for any $\varphi \in \Sigma_1 3\mathrm{CNF}$ two formulae $\varphi' \in 3\mathrm{CNF}$ and $\psi \in \Sigma_1 3\mathrm{CNF}^-$ such that $\#\Sigma_1 3\mathrm{CNF}(\varphi) = \#(3\mathrm{CNF}, \Sigma_1 3\mathrm{CNF}^-)(\varphi', \psi)$.

Assume $\varphi = \exists y_1 \dots \exists y_\ell \bigwedge C_i \wedge \bigwedge D_i \wedge \bigwedge E_i$, where clauses C_i only contain free variables of φ, clauses D_i contain only bound variables of φ, and clauses E_i contain at least one free and at least one bound variable of φ. We can now simply add all clauses C_i to φ' and all clauses D_i to ψ.

To handle the remaining clauses, we add for each E_i a new free variable e_i. We then express in φ' that e_i is true if and only if clause E_i is not satisfied by the assignment to the free variables, and express in ψ that E_i has to be satisfied by the assignment to the bound variables if e_i is true. The former does not involve any bound variables and for the latter, the only needed free variable is e_i, which only occurs negatively. ◀

Because of the special role of the empty team in the team logics we consider, we will also show the completeness for another version of $\#\Sigma_1\mathrm{CNF}^-$, denoted as $\#\Sigma_1\mathrm{CNF}^-_*$, for which the all-0-assignment is not counted.

▶ **Theorem 26.** *The problem* $\#\Sigma_1\mathrm{CNF}^-_*$ *is* $\# \cdot \mathrm{NP}$*-complete under Turing reductions.*

6 Conclusion

In this paper we have studied the following hierarchy of classes defined by counting problems for team-based logics:

$$\begin{array}{ccccc}
\mathrm{TotP} & \subseteq \#\mathcal{L}^{\mathrm{team}} = \#\mathrm{P} & \subseteq & \#\mathrm{FO}(\perp)^{\mathrm{team}} = \# \cdot \mathrm{NP} \\
\rotatebox[origin=c]{90}{$\subseteq$} & & & \rotatebox[origin=c]{90}{$\subseteq$} \\
\#\mathrm{FO}(\subseteq)^{\mathrm{team}} & & & \#\mathrm{FO}(=(\dots))^{\mathrm{team}}
\end{array}$$

We also showed that our classes are closed under first-order reductions and that $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$ and $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ contain complete problems from $\#\mathrm{P}$ and $\# \cdot \mathrm{NP}$, respectively. The latter problem is even complete for $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ under first-order reductions.

The connection between $\#\mathrm{FO}(=(\dots))^{\mathrm{team}}$ and the classes $\#\mathrm{P}$ and $\# \cdot \mathrm{NP}$ is not yet clear. While we know that a complete problem from $\# \cdot \mathrm{NP}$ is contained in it, it is open whether the class coincides with $\# \cdot \mathrm{NP}$, and (if not) whether it contains the class $\#\mathrm{P}$. We conjecture that the answer to both questions is negative, since the defining logic has closure properties that make it unlikely to contain counting versions of non-monotone problems from $\#\mathrm{P}$.

Regarding $\#\mathrm{FO}(\subseteq)^{\mathrm{team}}$, the search for a complete problem could be interesting. We have only showed that the problem #DualHorn is contained in this class and the problem $\#\Sigma_1$DualHorn is hard for this class, but neither of the problems is known to be complete.

The lower end of our hierarchy deserves further study as well. The class $\#\mathrm{FO}^{\mathrm{team}}$ (i.e., the class with no dependency atoms in the formulae) can be shown to be a subclass of FTC^0, the class of functions computable by families of polynomial size constant depth majority circuits (see [35]). The circuit-based counting class $\#\mathrm{AC}^0$, counting proof trees in polynomial size constant depth unbounded fan-in circuits [35], was characterized in a model-theoretic manner by counting assignments to free function symbols in certain quantifier-restricted FO-formulae [7]. A similar quantifier restriction for $\#\mathrm{FO}(A)^{\mathrm{team}}$, where A consists of the dependency atom plus a totality atom (that we did not study in the present paper), also leads to a characterization of $\#\mathrm{AC}^0$. This suggests that low level counting classes and circuit classes in the context of counting problems for team-based logics might be worth studying. Another natural question is to search for generalized dependency atoms that lead to interesting relations to complexity classes. Besides the aforementioned totality atom, the constancy or the exclusion [12] atom are worth examining. In particular, it is an open question to find an atom A such that $\#\mathrm{FO}(A)^{\mathrm{team}} = \#\mathrm{P}$. The logic $\mathcal{L}$ of [25], though it satisfies the equality, is not of this form.

In the context of counting complexity theory, an interesting question to study is the approximability of problems in different classes. In our case, it is unlikely that any of our classes is efficiently approximable (in the sense of FPRAS): In [10] it was shown that it is unlikely that the number of satisfying assignments of CSPs can be approximated by an FPRAS, unless all relations in the constraint language are affine. Since our classes contain counting problems for classes of formulae which do not admit this property, this result applies. Consequently, it would be interesting to study restrictions of our full classes to obtain, possibly, efficiently approximable fragments.

Our proof of the completeness of $\#\Sigma_1\mathrm{CNF}^-$ for $\# \cdot \mathrm{NP}$ introduces problems that arise from "pairing decision problems" and gives simultaneous reductions between such pairs. This idea might be helpful in other contexts as well; in particular it should lead to more interesting complete problems for $\# \cdot \mathrm{NP}$ or higher levels $\# \cdot \Sigma_k$ of the counting polynomial-time hierarchy.

Abstract

What approximation ratio can we achieve for the Facility Location problem if whenever a client u connects to a facility v, the opening cost of v is at most θ times the service cost of u? We show that this and many other problems are a particular case of the Activation Edge-Cover problem. Here we are given a multigraph $G = (V, E)$, a set $R \subseteq V$ of terminals, and thresholds $\{t^e_u, t^e_v\}$ for each uv-edge $e \in E$. The goal is to find an assignment $\mathbf{a} = \{a_v : v \in V\}$ to the nodes minimizing $\sum_{v \in V} a_v$, such that the edge set $E_{\mathbf{a}} = \{e = uv : a_u \geq t^e_u, a_v \geq t^e_v\}$ activated by $\mathbf{a}$ covers R. We obtain ratio $1 + \max\limits_{x \geq 1} \dfrac{\ln x}{1 + x/\theta} \approx \ln\theta - \ln\ln\theta$ for the problem, where θ is a problem parameter. This result is based on a simple generic algorithm for the problem of minimizing a sum of a decreasing and a sub-additive set functions, which is of independent interest. As an application, we get the same ratio for the above variant of Facility Location. If for each facility all service costs are identical then we show a better ratio $1 + \max\limits_{k \in \mathbb{N}} \dfrac{H_k - 1}{1 + k/\theta}$, where $H_k = \sum_{i=1}^k 1/i$. For the Min-Power Edge-Cover problem we improve the ratio 1.406 of [4] (achieved by iterative randomized rounding) to 1.2785. For unit thresholds we improve the ratio $73/60 \approx 1.217$ of [4] to $\frac{1555}{1347} \approx 1.155$.

1 Introduction

Let $G = (V, E)$ be an undirected multigraph where each edge $e \in E$ has an **activating function** f^e from some range $L^e \subseteq \mathbb{R}^2_+$ to $\{0, 1\}$. Given a non-negative **assignment** $\mathbf{a} = \{a_v : v \in V\}$ to the nodes, we say that a uv-edge $e \in E$ is **activated** by $\mathbf{a}$ if $f^e(a_u, a_v) = 1$. Let $E_{\mathbf{a}} = \{e \in E : f^e(a_u, a_v) = 1\}$ denote the set of edges activated by $\mathbf{a}$. The **value** of an assignment $\mathbf{a}$ is $\mathbf{a}(V) = \sum_{v \in V} a_v$. In Activation Network Design problems the goal is to find an assignment $\mathbf{a}$ of minimum value, such that the edge set $E_{\mathbf{a}}$ activated by $\mathbf{a}$ satisfies a prescribed property. We make the following two assumptions, which are standard in the literature; see the paper of Panigrahi [20] that introduced the problem, and a recent survey [19] on various activation problems.

Monotonicity Assumption. *For every $e \in E$, f^e is monotone non-decreasing, namely, $f^e(x_u, x_v) = 1$ implies $f^e(y_u, y_v) = 1$ if $y_u \geq x_u$ and $y_v \geq x_v$.*

Polynomial Domain Assumption. *Every $v \in V$ has a polynomial size in $n = |V|$ set L_v of "levels" and $L^e = L_u \times L_v$ for every uv-edge $e \in E$.*

Given a set $R \subseteq V$ of **terminals** we say that an edge set J is an **R-cover** or that J **covers** R if every $v \in R$ has some edge in J incident to it. In Edge-Cover problems we seek an R-cover J that minimizes a given value function, e.g., the edge cost of J. The min-cost Edge-Cover problem can be solved in polynomial time [9], and it is one of the most fundamental problems in Combinatorial Optimization, cf. [23].

We consider the Activation Edge-Cover problem. Since we consider multigraphs, $e = uv$ means that e is a uv-edge, namely, that u, v are the endnodes of e; $e = uv \in E$ means that e is a uv-edge that belongs to E. Under the two assumptions above, the problem can be formulated without activating functions. For this, replace each edge $e = uv$ by a set of at most $|L_u| \cdot |L_v|$ uv-edges $\{e(t_u, t_v) : (t_u, t_v) \in L_u \times L_v, f^e(t_u, t_v) = 1\}$. Then for any $J \subseteq E$ the optimal assignment $\mathbf{a}$ activating J is given by $a_u = \max\{t^e_u : e \in J \text{ is incident to } u\}$; here and everywhere a maximum or a minimum taken over an empty set is assumed to be zero. Consequently, the problem can be restated as follows.

Activation Edge-Cover
Input: A graph $G = (V, E)$, a set of terminals $R \subseteq V$, and thresholds $\{t^e_u, t^e_v\}$ for each uv-edge $e \in E$.
Output: An assignment $\mathbf{a}$ of minimum value $\mathbf{a}(V) = \sum_{v \in V} a_v$, such that the edge set $E_{\mathbf{a}} = \{e = uv \in E : a_u \geq t^e_u, a_v \geq t^e_v\}$ activated by $\mathbf{a}$ covers R.

As we will explain later, Activation Edge-Cover problems are among the most fundamental problems in network design, that include NP-hard problems such as Set-Cover, Facility Location, covering problems that arise in wireless networks (node weighted/min-power/installation problems), and many other problems. The Activation Edge-Cover problem admit ratio $O(\ln |R|)$ by a factor 2 reduction to the Facility Location problem.

To state our main result we define assignments $\mathbf{q}$ and $\mathbf{c}$, where $c_v = q_v = 0$ if $v \in V \setminus R$ and for $u \in R$:

- $q_u = \min\limits_{e=uv \in E} t^e_u$ is the minimum threshold at u of an edge in E incident to u.
- $c_u = \min\limits_{e=uv \in E} (t^e_u + t^e_v) - q_u$, so $c_u + q_u$ is the minimum value of an edge in E incident to u.

Following [19], the quantity $\max_{u \in R} c_u/q_u$ is called the **slope** of the instance. We say that an Activation Edge-Cover instance is **θ-bounded** if the instance slope is at most θ, namely if $c_u \leq \theta q_u$ for all $u \in R$; moreover, we assume by default that $\theta = \max_{u \in R} c_u/q_u$ is the instance slope. Let opt denote the optimal solution value of a problem instance at hand. For each $u \in R$ let e_u be some minimum value edge covering u. Then $\{e_u : u \in R\}$ is an R-cover of value at most $\sum_{u \in R}(c_u + q_u) = (\mathbf{c} + \mathbf{q})(R)$. From this and the definition of θ we get

$$0 \leq \mathsf{opt} - \mathbf{q}(R) \leq \mathbf{c}(R) \leq \theta \mathbf{q}(R) \leq \theta \mathsf{opt}$$

In particular, $(\mathbf{c} + \mathbf{q})(R) \leq (\theta + 1)\mathsf{opt}$. Using this, it is possible to design a greedy algorithm with ratio $1 + \ln(\theta + 1)$. We will show how to obtain a better ratio (the difference is quite significant when $\theta \leq 10^4$ – see Table 1). In what follows, let H_k denote the k-th harmonic number. Our approximation ratios are expressed in the terms of the following two functions $\omega(\theta)$ and $\bar{\omega}(\theta)$ defined for $\theta > 0$, where $\bar{\omega}$ can be viewed as a "discrete version" of ω:

$$\omega(\theta) = \max_{x \geq 1} \frac{\ln x}{1 + x/\theta} \qquad \bar{\omega}(\theta) = \max_{k \in \mathbb{N}} \frac{H_k - 1}{1 + k/\theta}$$

Table 1 Some numerical bounds on $1+\omega(\theta)$, $1+\bar{\omega}(\theta)$, $\ln\theta - \ln\ln\theta$, and $1+\ln(\theta+1)$.

θ	1	2	3	5	10	100	1000	10000	1000000
$1+\omega(\theta)$	1.2785	1.4631	1.6036	1.8146	2.1569	3.6360	5.4214	7.3603	11.4673
$1+\bar{\omega}(\theta)$	1.2167	1.3667	1.4834	1.6637	1.9645	3.3428	5.0808	6.9967	11.0820
$\ln\theta - \ln\ln\theta$	-	1.0597	1.0046	1.1336	1.4686	3.0780	4.9752	6.9901	11.1898
$1+\ln(\theta+1)$	1.6932	2.0987	2.3863	2.7918	3.3979	5.6152	7.9088	10.2105	14.8156

In Lemma 8 we show that $\omega(\theta) = W(\theta/e)$, where $W(z)$ is the **Lambert W Function** (a.k.a. ProductLog Function), which is the inverse function of $z(W) = We^W$, c.f. [7, 15]. We are not aware of any known formula for $\bar{\omega}(\theta)$, but since $H_k - 1 \leq \ln k$, $\bar{\omega}(\theta) < \omega(\theta)$ for $\theta > 0$. We also observe in Section 4 that in the definition of $\bar{\omega}(\theta)$ the maximum is attained for the smallest integer k such that $H_k \geq 2 + \frac{\theta-1}{k+1}$. It follows from [15] that $\lim_{\theta\to\infty}[1 + W(\theta/e) - (\ln\theta - \ln\ln\theta)] = 0$, so $1+\omega(\theta)$ (and it seems that also $1+\bar{\omega}(\theta)$) is close to $\ln\theta - \ln\ln\theta$ for large values of θ, although the convergence is very slow; see Table 1.

These functions were implicitly used before to bound approximation ratios. E.g., Robins & Zelikovsky [22] proved that their algorithm for the Steiner Tree problem in quasi-bipartite graph achieves ratio $1+\omega(1)+\epsilon < 1.2785$; this was improved to $1+\bar{\omega}(1)+\epsilon = \frac{73}{60}+\epsilon$ in [3]. See also [12] and a survey on the Steiner Tree problem in [13]. In [4] is established ratio $\frac{73}{60}$ for the Min-Power Edge-Cover problem in bipartite graphs and for unit thresholds.

Our main result is:

▶ **Theorem 1.** Activation Edge-Cover *admits ratio* $1+\omega(\theta)$ *for* θ*-bounded instances. The problem also admits ratio* $1+\ln(\Delta+1)$*, and ratio* $1+\ln\Delta$ *if* R *is an independent set in* G*, where* Δ *is the maximum number of terminal neighbors of a node in* G*.*

This result is based on a generic simple approximation algorithm for the problem of minimizing a sum of a decreasing and a sub-additive set functions, which is of independent interest; it is described in the next section. This result is inspired by the algorithm of Robins & Zelikovsky [22] for the Steiner Tree problem, and the analysis in [13] of this algorithm.

We note that Slavik [25] proved that the greedy algorithm for Set-Cover achieves ratio $\ln n - \ln\ln n + \Theta(1)$, while our ratio for Activation Edge-Cover is asymptotically $\ln\theta - \ln\ln\theta + \Theta(1)$; but we do not see an immediate relation between the two results.

Let us say that $v \in V$ is a **steady node** if the thresholds t_v^e of the edges e incident to v are all equal to the same number w_v, which we call the **weight of** v. Note that we may assume that all non-terminals are steady, by replacing each $v \in V \setminus R$ by L_v new nodes; see the so called "Levels Reduction" in [19]. This implies that no two parallel edges are incident to the same non-terminal. Clearly, we may assume that $V \setminus R$ is an independent set in G. Let Bipartite Activation Edge-Cover be the restriction of Activation Edge-Cover to instances when also R is an independent set, namely, when G is bipartite with sides $R, V \setminus R$. Note that in this case G is a simple graph and all non-terminals are steady.

We now mention some threshold types in Activation Edge-Cover problems, known problems arising from these types, and some implications of Theorem 1 for these problems.

Weighted Set-Cover.

This is a particular case of Bipartite Activation Edge-Cover when all nodes are steady and nodes in R have weight 0. Note that in this case θ is infinite, and we can only deduce from Theorem 1 the known ratio $1 + \ln \Delta$. Consider a modification of the problem, which we call θ-Bounded Weighted Set-Cover: when we pick a set $v \in V \setminus R$, we pay w_v for v, and also pay w_v/θ for each element in R covered by v that was not yet covered. Then the corresponding Activation Edge-Cover instance is θ-bounded.

Facility Location.

Here we have a bipartite graph with sides R (clients) and $V \setminus R$ (facilities), weights (opening costs) $\mathbf{w} = \{w_v : v \in V \setminus R\}$, and distances (service costs) $\mathbf{d} = \{d_{uv} : u \in R, v \in V \setminus R\}$. We need to choose $S \subseteq V \setminus R$ with $\mathbf{w}(S) + \sum_{u \in R} d(u, S)$ minimal, where $d(u, S) = \min_{v \in S} d_{uv}$ is the minimal distance from u to S. This is equivalent to Bipartite Activation Edge-Cover. Note however that if for some constant θ we have $w_v \leq \theta d_{uv}$ for all $uv \in E$ with $u \in R$ and $v \in V \setminus R$, then the corresponding Bipartite Activation Edge-Cover instance is θ-bounded, and achieves a low constant ratio even for large values of θ, by Theorem 1.

Installation Edge-Cover.

Suppose that the installation cost of a wireless network is proportional to the total height of the towers for mounting antennas. An edge uv is activated if the towers at u and v are tall enough to overcome obstructions and establish line of sight between the antennas. This is modeled as each pair $u, v \in V$ has a height demand h^{uv} and constants γ_{uv}, γ_{vu}, such that a uv-edge is activated by $\mathbf{a}$ if the scaled heights $\gamma_{uv} a_u, \gamma_{vu} a_v$ sum to at least h^{uv}. In the Installation Edge-Cover problem, we need to assign heights to the antennas such that each terminal can communicate with some other node, while minimizing the total sum of the heights. The problem is Set-Cover hard even for $0, 1$ thresholds and bipartite G [20]. But in a practical scenario, the quotient of the maximum tower height over the minimum tower height is a small constant; say, if possible tower heights are $5, 15, 20$, then $\theta = 4$.

Min-Power Edge-Cover.

This problem is a particular case of Activation Edge-Cover when $t_u^e = t_v^e$ for every edge $e = uv \in E$; note that $\theta = 1$ in this case (in fact, the case $\theta = 1$ is much more general). The motivation is to assign energy levels to the nodes of a wireless network while minimizing the total energy consumption, and enabling communication for every terminal. The Min-Power Edge-Cover problem is NP-hard even if $R = V$, or if R is an independent set in the input graph G and unit thresholds [14]. The problem admits ratio 2 by a trivial reduction to the min-cost case. This was improved to 1.5 in [17], and then to 1.406 in [4], which also establishes the ratio 73/60 for the bipartite case and for unit thresholds.

From Theorem 1 and the discussion above we get:

▶ **Corollary 2.** Min-Power Edge-Cover *admits ratio* $1 + \omega(1) < 1.2785$*, and the* θ*-bounded versions of each of the problems* Weighted Set-Cover, Facility Location*, and* Installation Edge-Cover*, admits ratio* $1 + \omega(\theta)$*.*

Let us illustrate this result on the Facility Location problem. One might expect a constant ratio for any $\theta > 0$, but our ratio $1+\omega(\theta)$ is surprisingly low. Even if $\theta = 100$ (service costs are at least 1% of opening costs) then we get a small ratio $1 + \omega(100) < 3.636$. Even for $\theta = 10^4$ we still get a reasonable ratio $1 + \omega(10^4) < 7.3603$. All previous results for the problem are usually summarized by just two observations: the problem is Set-Cover hard (so has a logarithmic approximation threshold by [21, 10]), and that it admits a matching logarithmic ratio $1 + \ln |R|$ [6]; see surveys on Facility Location problems by Vygen [26] and Shmoys [24]. Due to this, almost all work focused on the more tractable Metric Facility Location problem. Our Theorem 1 implies that many practical non-metric Facility Location instances admit a reasonable small constant ratio.

Note that our Theorem 1 ratio 1.2785 for $\theta = 1$ significantly improves the previous best ratio 1.406 of [4] for Min-Power Edge-Cover on general graphs achieved by iterative randomized rounding; we do not match the ratio 73/60 of [4] for the bipartite case, but note that the case $\theta = 1$ is much more general than the min-power case considered in [4].

For the case of "locally uniform" thresholds – when for each non-terminal (facility) all thresholds (service costs) are identical, we show a better ratio, see also Table 1.

▶ **Theorem 3.** Bipartite Activation Edge-Cover *with locally uniform thresholds admits ratio* $1 + \bar{\omega}(\theta)$.

In addition, we consider unit thresholds, and using some new ideas in addition to [4], improve the "natural" previous best ratio $73/60 \approx 1.217$ of [4] as follows.

▶ **Theorem 4.** Activation Edge-Cover *with unit thresholds admits ratio* $\frac{1555}{1347} < 1.155$.

We note that the proofs of some of our results are non-trivial, although we invested an effort to simplify matters. In any case, the focus in this paper is not technical, but rather conceptual. Our main contribution is giving a unified algorithm for a large class of problems that we identify – θ-Bounded Activation Edge-Cover problems, either substantially improving known ratios, or showing that many seemingly Set-Cover hard problems may be tractable in practice. Let us also point out that our main result is more general than the applications listed in Corollary 2. The generalization to θ-bounded Activation Edge-Cover problems is different from earlier results; besides finding a unifying algorithmic idea that generalizes and improves previous results, we are also able to find tractable special cases in a new direction.

The rest of this paper is organized as follows. In Section 2 we define the Generalized Min-Covering problem and analyze a greedy algorithm for it, see Theorem 5. In Section 3 we use Theorem 5 to prove Theorem 1. Theorems 3 and 4 are proved using a modified method in Sections 4 and 5, respectively.

2 The Generalized Min-Covering problem

A set function f is **increasing** if $f(A) \leq f(B)$ whenever $A \subseteq B$; f is **decreasing** if $-f$ is increasing, and f is **sub-additive** if $f(A \cup B) \leq f(A) + f(B)$ for any subsets A, B of the ground-set. Let us consider the following algorithmic problem:

Generalized Min-Covering
Input: Non-negative set functions ν, τ on subsets of a ground-set U such that ν is decreasing, τ is sub-additive, and $\tau(\emptyset) = 0$.
Output: $A \subseteq U$ such that $\nu(A) + \tau(A)$ is minimal.

The "ordinary" Min-Covering problem is $\min\{\tau(A) : \nu(A) = 0\}$; it is a particular case of the Generalized Min-Covering problem when we seek to minimize $M\nu(A) + \tau(A)$ for a large enough constant M. Under certain assumptions, the Min-Covering problem admits ratio $1 + \ln \nu(\emptyset)$ [16]. Various generic covering problems are considered in the literature, among them the Submodular Covering problem [27], and several other types, cf. [5].

The variant we consider is inspired by the algorithms of Robins & Zelikovsky [22] for the Steiner Tree problem, and the analysis in [13] of this algorithm; but, to the best of our knowledge, the explicit formulation of the Generalized Min-Covering problem given here is new. Interestingly, our ratio for Activation Edge-Cover with $\theta = 1$ is the same as that of [22] for Steiner Tree in quasi-bipartite graphs.

We call ν the **potential** and τ the **payment**. The idea behind this interpretation and the subsequent greedy algorithm is as follows. Given an optimization problem, the potential $\nu(A)$ is the value of some "simple" augmenting feasible solution for A. We start with an empty set solution, and iteratively try to decrease the potential by adding a set $B \subseteq U \setminus A$ of minimum "density" – the price paid for a unit of the potential. The algorithm terminates when the price ≥ 1, since then we gain nothing from adding B to A. The ratio of such an algorithm is bounded by $1 + \ln \frac{\nu(\emptyset)}{\mathsf{opt}}$ (assuming that during each iteration a minimum density set can be found in polynomial time). So essentially the greedy algorithm converts ratio $\alpha = \frac{\nu(\emptyset)}{\mathsf{opt}}$ into ratio $1 + \ln \alpha$. However, sometimes a tricky definition of the potential and the payment functions may lead to a smaller ratio.

Let opt be the optimal solution value of a problem instance at hand. Fix an optimal solution A^*. Let $\nu^* = \nu(A^*)$, $\tau^* = \tau(A^*)$, so $\mathsf{opt} = \tau^* + \nu^*$. The quantity $\frac{\tau(B)}{\nu(A)-\nu(A\cup B)}$ is called the **density** of B (w.r.t. A); this is the price paid by B for a unit of potential. The Greedy Algorithm (a.k.a. Relative Greedy Heuristic) for the problem starts with $A = \emptyset$ and while $\nu(A) > \nu^*$ repeatedly adds to A a non-empty augmenting set $B \subseteq U$ that satisfies the following condition, while such B exists:

Density Condition: $$\frac{\tau(B)}{\nu(A) - \nu(A \cup B)} \leq \min\left\{1, \frac{\tau^*}{\nu(A) - \nu^*}\right\}.$$

Note that since ν is decreasing $\nu(A) - \nu(A \cup A^*) \geq \nu(A) - \nu(A^*) = \nu(A) - \nu^*$; hence if $\nu(A) > \nu^*$, then $\frac{\tau(A^*)}{\nu(A)-\nu(A\cup A^*)} \leq \frac{\tau^*}{\nu(A)-\nu^*}$ and there exists an augmenting set B that satisfies the condition $\frac{\tau(B)}{\nu(A)-\nu(A\cup B)} \leq \frac{\tau^*}{\nu(A)-\nu^*}$, e.g., $B = A^*$. Thus if B^* is a minimum density set and $\frac{\tau(B^*)}{\nu(A)-\nu(A\cup B^*)} \leq 1$, then B^* satisfies the Density Condition; otherwise, the density of B^* is larger than 1 so no set can satisfy the Density Condition.

▶ **Theorem 5.** *The* Greedy Algorithm *achieves approximation ratio*

$$1 + \frac{\tau^*}{\mathsf{opt}} \ln \frac{\nu_0 - \nu^*}{\tau^*} = 1 + \frac{\tau^*}{\mathsf{opt}} \cdot \ln\left(1 + \frac{\nu_0 - \mathsf{opt}}{\tau^*}\right) .$$

Proof. Let ℓ be the number of iterations. Let $A_0 = \emptyset$ and for $i = 1, \ldots, \ell$ let A_i be the intermediate solution at the end of iteration i and $B_i = A_i \setminus A_{i-1}$. Let $\nu_i = \nu(A_i)$, $i = 0, \ldots, \ell$. Then:

$$\frac{\tau(B_i)}{\nu_{i-1} - \nu_i} \leq \min\left\{1, \frac{\tau^*}{\nu_{i-1} - \nu^*}\right\} \qquad i = 1, \ldots, \ell$$

Since ν is decreasing

$$\sum_{i=1}^{\ell} \tau(B_i) \leq \sum_{i=1}^{\ell} \min\left\{1, \frac{\tau^*}{\nu_{i-1} - \nu^*}\right\} (\nu_{i-1} - \nu_i)$$

This is the lower Darboux sum of the function $f(\nu) = \begin{cases} 1 & \text{if } \nu \leq \tau^* + \nu^* \\ \frac{\tau^*}{\nu - \nu^*} & \text{if } \nu > \tau^* + \nu^* \end{cases}$ in the interval $[\nu_\ell, \nu_0]$ w.r.t. the partition $\nu_\ell < \nu_{\ell-1} < \cdots < \nu_0$. We claim that $\tau^* + \nu^* \geq \nu_\ell$. Since the algorithm stopped with A_ℓ, at least one of the following holds: (i) $A_\ell = U$; (ii) $\nu_\ell \leq \nu^*$; (iii) A^* has density > 1. If (i) holds then (ii) holds (by the monotonicity of ν), but case (ii) is trivial. So assume that only (iii) holds. Then $\frac{\tau(A^*)}{\nu(A_\ell)-\nu(A_\ell \cup A^*)} > 1$, thus since ν is decreasing $\tau(A^*) \geq \nu_\ell - \nu(A \cup A^*) \geq \nu_\ell - \nu(A^*)$. Consequently, $\sum_{i=1}^{\ell} \tau(B_i)$ is bounded by

$$\int_{\nu_\ell}^{\nu_0} f(\nu)d\nu = \int_{\nu_\ell}^{\tau^*+\nu^*} 1d\nu + \int_{\tau^*+\nu^*}^{\nu_0} \frac{\tau^*}{\nu - \nu^*}d\nu = \tau^* + \nu^* - \nu_\ell + \tau^* \ln \frac{\nu_0 - \nu^*}{\tau^*}$$

Let $A = A_\ell = \bigcup_{i=1}^{\ell} B_i$ be the set computed by the algorithm. Since τ is sub-additive

$$\tau(A) \leq \sum_{i=1}^{\ell} \tau(B_i) \leq \tau^* + \nu^* - \nu(A) + \tau^* \ln \frac{\nu_0 - \nu^*}{\tau^*}$$

Thus the approximation ratio is bounded by $\frac{\tau(A)+\nu(A)}{\mathsf{opt}} \leq 1 + \frac{\tau^*}{\mathsf{opt}} \ln \frac{\nu_0 - \nu^*}{\tau^*}$. ◀

3 Algorithm for general thresholds (Theorem 1)

Given an instance $G = (V, E), \mathbf{t}, R$ of Activation Edge-Cover define the corresponding Generalized Min-Covering instance U, τ, ν as follows. We put at each node $u \in V$ a large set of "assignment units", and let U be the union of these sets of "assignment units". Note that to every $A \subseteq U$ naturally corresponds the assignment $\mathbf{a}$ where a_u is the number of units in A put at u. It would be more convenient to define ν and τ in terms of assignments, by considering instead of a set $A \subseteq U$ the corresponding assignment $\mathbf{a}$.

To define ν and τ, let us recall the assignments $\mathbf{q}$ and $\mathbf{c}$ from the Introduction. We have $c_v = q_v = 0$ if $v \in V \setminus R$ and for $u \in R$:

- $q_u = \min_{e=uv \in E} t_u^e$ is the minimum threshold at u of an edge in E incident to u.
- $c_u = \min_{e=uv \in E} (t_u^e + t_v^e) - q_u$, so $c_u + q_u$ is the minimum value of an edge in E incident to u.

We let $Q = \mathbf{q}(V) = \mathbf{q}(R)$ and $C = \mathbf{c}(R)$. Note that $\mathbf{c}(R') \leq \theta\mathbf{q}(R')$ for any $R' \subseteq R$; in particular, $C \leq \theta Q$. For an assignment $\mathbf{a}$ that "augments" $\mathbf{q}$ let $R_{\mathbf{q+a}}$ denote the set of terminals covered by the edge set $E_{\mathbf{q+a}}$ activated by the assignment $\mathbf{q}+\mathbf{a}$. A natural definition of the potential and the payment functions would be $\tau(\mathbf{a}) = \mathbf{a}(V)$ and $\nu(\mathbf{a}) = (\mathbf{c}+\mathbf{q})(R \setminus R_{\mathbf{q+a}})$ but this enable us to prove only ratio $1 + \ln(\theta + 1)$. We show a better ratio by adding to the potential in advance the "fixed" part Q. We define

$$\tau(\mathbf{a}) = \mathbf{a}(V) \qquad \nu(\mathbf{a}) = Q + \mathbf{c}(R \setminus R_{\mathbf{q+a}})$$

It is easy to see that ν is decreasing, τ is sub-additive, and $\tau(\mathbf{0}) = 0$.

The next lemma shows that the obtained Generalized Min-Covering instance is equivalent to the original Activation Edge-Cover instance.

▶ **Lemma 6.** *If $\mathbf{q}+\boldsymbol{a}$ is a feasible solution for* Activation Edge-Cover *then $\tau(\boldsymbol{a})+\nu(\boldsymbol{a}) = Q+\boldsymbol{a}(V)$. If $\mathbf{a}$ is a feasible solution for* Generalized Min-Covering *then one can construct in polynomial time a feasible solution for* Activation Edge-Cover *of value at most $\tau(\boldsymbol{a}) + \nu(\boldsymbol{a})$. In particular, both problems have the same optimal value, and* Generalized Min-Covering *has an optimal solution $\boldsymbol{a}^*$ such that $\nu(\boldsymbol{a}^*) = Q$ and thus $\mathsf{opt} = \tau(\boldsymbol{a}^*) + Q$.*

Proof. If $\mathbf{q} + \mathbf{a}$ is a feasible Activation Edge-Cover solution then $R_{\mathbf{q+a}} = R$ and thus $\nu(\mathbf{a}) = Q$. Consequently, $\tau(\mathbf{a}) + \nu(\mathbf{a}) = \mathbf{a}(V) + Q$.

Let now $\mathbf{a}$ be a Generalized Min-Covering solution. The assignment $\mathbf{q} + \mathbf{a}$ has value $Q + \mathbf{a}(V)$ and activates the edge set $E_{\mathbf{q+a}}$ that covers $R_{\mathbf{q+a}}$. To cover $R \setminus R_{\mathbf{q+a}}$, pick for every $u \in R \setminus R_{\mathbf{q}+\mathbf{a}}$ an edge uv with $t_u^{uv} + t_v^{uv}$ minimum. Let $\mathbf{b}$ be an assignment defined by $b_u = c_u$ if $u \in R \setminus R_{\mathbf{q}+\mathbf{a}}$ and $b_u = 0$ otherwise. The set of picked edges can be activated by an assignment $\mathbf{q}+\mathbf{b}$ that has value $Q + \mathbf{c}(R \setminus R_{\mathbf{q}+\mathbf{a}})$. The assignment $\mathbf{q}+\mathbf{a}+\mathbf{b}$ activates both edge sets and has value $Q + \mathbf{a}(V) + \mathbf{c}(R \setminus R_{\mathbf{q}+\mathbf{a}}) = \tau(\mathbf{a}) + \nu(\mathbf{a})$, as required. ◀

For the obtained Generalized Min-Covering instance, let us fix an optimal solution $\mathbf{a}^*$ as in Lemma 6, so $\nu^* = Q$ and $\mathsf{opt} = \tau^* + Q$. Denote $\nu_0 = \nu(\mathbf{0}) = Q + \mathbf{c}(R)$, and note that $\mathbf{c}(R) \le \theta Q$. To apply Theorem 5 we need several bounds given in the next lemma.

▶ **Lemma 7.** $\dfrac{\mathsf{opt}}{\tau^*} \ge 1 + \dfrac{1}{\theta}$, $\dfrac{\nu_0}{\tau^*} \le (\theta+1)\left(\dfrac{\mathsf{opt}}{\tau^*} - 1\right)$, *and* $\dfrac{\nu_0 - \nu^*}{\tau^*} \le \Delta + 1$.

Proof. Note that

$$\tau^* + Q = \mathsf{opt} \le \nu_0 \le (\theta+1)Q \ .$$

In particular, $\tau^* \le \theta Q$, and this implies the first bound of the lemma

$$\frac{\mathsf{opt}}{\tau^*} = 1 + \frac{Q}{\tau^*} \ge 1 + \frac{1}{\theta} \ .$$

The second bound of the lemma holds since $\nu_0 \le (\theta+1)Q = (\theta+1)(\mathsf{opt} - \tau^*)$.

The last bound of the lemma is equivalent to the bound $\mathbf{c}(R) \le \tau^*(\Delta+1)$. Let J be an inclusion minimal edge cover of R activated by $\mathbf{q}+\mathbf{a}^*$. Then J is a collection $\mathcal{S}$ of node disjoint rooted stars with leaves in R. Let $S \in \mathcal{S}$. By the definition of $\mathbf{c}$, $\mathbf{a}^*(S) \ge \max\limits_{u \in R \cap S} c_u$, thus $\mathbf{c}(R \cap S) \le |R \cap S|\mathbf{a}^*(S) \le (\Delta+1)\mathbf{a}^*(S)$. Consequently, $\mathbf{c}(R) = \sum\limits_{S \in \mathcal{S}} \mathbf{c}(R \cap S) \le (\Delta+1)\sum\limits_{S \in \mathcal{S}} \mathbf{a}^*(S) \le (\Delta+1)\mathbf{a}^*(V)$. ◀

We will show later that the Greedy Algorithm can be implemented to run in polynomial time; now we focus on showing that it achieves the approximation ratios stated in Theorem 1. Denote $x = \theta\left(\frac{\mathsf{opt}}{\tau^*} - 1\right)$ and $f(x) = \frac{\ln x}{1 + x/\theta}$. By Lemma 7 first bound, $x \ge 1$. Substituting Lemma 7 second bound in Theorem 5 second bound we get that the ratio is bounded by

$$1 + \frac{\tau^*}{\mathsf{opt}} \cdot \ln\left(1 + \frac{\nu_0}{\tau^*} - \frac{\mathsf{opt}}{\tau^*}\right) \le 1 + \frac{\ln x}{1 + x/\theta} = 1 + f(x)$$

Consequently, the ratio is bounded by $1 + \max\{f(x) : x \ge 1\} = 1 + \omega(\theta)$.

Substituting Lemma 7 third bound in Theorem 5 first bound and observing that $\tau^* \le \mathsf{opt}$ we get that the ratio is bounded by $1 + \ln(\Delta+1)$. In the case when R is an independent set in G, it is easy to see that the third bound in Lemma 7 improves to $\dfrac{\nu_0 - \nu^*}{\tau^*} \le \Delta$, and we get ratio $1 + \ln \Delta$ in this case.

In the next lemma we show that $\omega(\theta) = W(\theta/e)$, where $W(z)$ is the Lambert W Function, which is the inverse function of $z(W) = We^W$.

▶ **Lemma 8.** *For any $\theta > 0$, the equation $y + 1 = \ln(\theta/y)$ has a unique (real) root $y(\theta)$, and $0 < y(\theta) \le \theta$. Furthermore, $\omega(\theta) = y(\theta) = W(\theta/e)$ for any $\theta > 0$.*

Proof. Since the function $y+1$ is strictly increasing and the function $\ln(\theta/y)$ is strictly decreasing, the equation has at most one root; we claim that this root exists and is in the interval $(0, \theta]$. To see this consider the function $h(y) = y + 1 - \ln(\theta/y)$, and note that h is continuous and that $h(\theta) = \theta + 1 > 0$ while $h(\epsilon) = \epsilon + 1 - \ln(\theta/\epsilon) < 0$ for $\epsilon > 0$ small enough.

Let $f(x)=\frac{\ln x}{1+x/\theta}$. Since $f(1)=0$ and $\lim\limits_{x\to\infty} f(x)=0$ (by L'Hospital's Rule), $f(x)$ attains a maximum when

$$f'(x)=\frac{(1+x/\theta)/x-(\ln x)/\theta}{(1+x/\theta)^2}=\frac{1+x/\theta-(x/\theta)\ln x}{x(1+x/\theta)^2}=0\ .$$

So $f'(x)=0$ if and only if $1+x/\theta=(x/\theta)\ln x$, and then $f(x)=\theta/x$. Substituting $y\leftarrow\theta/x$ we get the equation $y+1=\ln(\theta/y)$, where $0<y\leq\theta$. Thus $\omega(\theta)=y(\theta)$.

To prove that $W(\theta/e)=y(\theta)$ we show that $W(\theta/e)+1=\ln(\theta/W(\theta/e))$, namely, that $W(\theta/e)$ is the root of the equation $y+1=\ln(\theta/y)$ that defines $y(\theta)$. We have $W(z)e^{W(z)}=z$ for any $z>0$ (c.f. Eq. 1.5 in [7]), which is equivalent to $W(z)+\ln W(z)=\ln z$. Thus $W(\theta/e)+\ln W(\theta/e)=\ln(\theta/e)$, which gives $W(\theta/e)+1=\ln(\theta/W(\theta/e))$, as claimed. ◀

Finally, we show that the Greedy Algorithm algorithm can be implemented in polynomial time. As was mentioned in Section 2 before Theorem 5, we just need to perform in polynomial time the following two operations for any assignment $\mathbf{a}$: to check the condition $\nu(\mathbf{a})>\nu^*$, and to find an augmenting assignment $\mathbf{b}$ of minimum density.

The assignments $\mathbf{q}$ and $\mathbf{c}$ can be computed in polynomial time, and thus the potential $\nu(\mathbf{a})=Q+\mathbf{c}(R\setminus R_{\mathbf{q}+\mathbf{a}})$ can be computed in polynomial time, for any $\mathbf{a}$. Let $\mathbf{a}^*$ be an optimal solution as in Lemma 6, and denote $\tau^*=\tau(\mathbf{a}^*)$ and $\nu^*=\nu(\mathbf{a}^*)=Q$. Then the condition $\nu(A)>\nu^*$ is equivalent to $\nu(\mathbf{a})\geq Q$ and thus can be checked in polynomial time.

Now we show how to find an augmenting assignment $\mathbf{b}$ of minimum density. Note that the density of an assignment $\mathbf{b}$ w.r.t. $\mathbf{a}$ is

$$\frac{\tau(\mathbf{b})}{\nu(\mathbf{a})-\nu(\mathbf{a}+\mathbf{b})}=\frac{\mathbf{b}(V)}{\mathbf{c}(R\setminus R_{\mathbf{q}+\mathbf{a}})-\mathbf{c}(R\setminus R_{\mathbf{q}+\mathbf{a}+\mathbf{b}})}=\frac{\mathbf{b}(V)}{\mathbf{c}(R_{\mathbf{q}+\mathbf{a}+\mathbf{b}}\setminus R_{\mathbf{q}+\mathbf{a}})}\ .$$

▶ **Lemma 9.** *There exists a polynomial time algorithm that given an instance of* Activation Edge-Cover *and an assignment* $\mathbf{a}$ *finds an assignment* $\mathbf{b}$ *of minimum density.*

Proof. A **star** is a rooted tree $S=(V_S,E_S)$ with at least one edge such that only its root s may have degree ≥ 2. We say that a star S is a **proper star** if all the leaves of S are terminals. We denote the terminals in S by $R_S=R\cap V_S$.

Since $\mathbf{q},\mathbf{a}$ are given assignments, we simplify the notation by assuming that $R\leftarrow R\setminus R_{\mathbf{q}+\mathbf{a}}$ is our set of terminals, and that $\mathbf{a}\leftarrow\mathbf{q}+\mathbf{a}$ is our given assignment. Then the density of $\mathbf{b}$ is just $\frac{\mathbf{b}(V)}{\mathbf{c}(R_{\mathbf{a}+\mathbf{b}})}$. Let $\mathbf{b}^*$ be an assignment of minimum density, and let $J^*\subseteq E_{\mathbf{a}+\mathbf{b}^*}$ be an inclusion minimal $R_{\mathbf{a}+\mathbf{b}^*}$-cover. Then J^* decomposes into a collection $\mathcal{S}$ of node disjoint proper stars that collectively cover $R_{\mathbf{a}+\mathbf{b}^*}$. For $S\in\mathcal{S}$ let $\mathbf{b}^S$ be the optimal assignment such that $\mathbf{a}+\mathbf{b}^S$ activates S. Since the stars in $\mathcal{S}$ are node disjoint

$$\sum_{S\in\mathcal{S}}\mathbf{b}^S(V)\leq\mathbf{b}^*(V)\quad\text{and}\quad\sum_{S\in\mathcal{S}}\mathbf{c}(R_S)=\mathbf{c}(R_{\mathbf{a}+\mathbf{b}^*})\ .$$

By an averaging argument, $\frac{\mathbf{b}^S(V)}{\mathbf{c}(R_S)}\leq\frac{\mathbf{b}^*(V)}{\mathbf{c}(R_{\mathbf{a}+\mathbf{b}^*})}$ holds for some $S\in\mathcal{S}$, and since $\mathbf{b}^*$ is a minimum density assignment, so is $\mathbf{b}^S$, and $\frac{\mathbf{b}^S(V)}{\mathbf{c}(R_S)}=\frac{\mathbf{b}^*(V)}{\mathbf{c}(R_{\mathbf{a}+\mathbf{b}^*})}$ holds. Consequently, it is sufficient to show how to find in polynomial time an assignment $\mathbf{b}$ such that $\mathbf{a}+\mathbf{b}$ activates a proper star S and $\frac{\mathbf{b}(V)}{\mathbf{c}(R_S)}$ is minimal.

We may assume that we know the root v and the value $w=b_v$ of an optimal density pair $S,\mathbf{b}$; there are at most $|V||E|$ choices and we can try all and return the best outcome. Let $R_w=\{u\in R:\text{there is a }uv\text{-edge }e\text{ with }t_v^e\leq a_v+w\}$. For $u\in R_w$ let b_u be the minimal non-negative number for which there is a uv-edge e with $a_v+w\geq t_v^e$ and $a_u+b_u\geq t_u^e$.

Then our problem is equivalent to finding $R_S \subseteq R_w$ with $\sigma(R_S) = \frac{w+\mathbf{b}(R_S)}{\mathbf{c}(R_S)}$ minimum. This problem can be solved in polynomial time, by starting with $R_S = \emptyset$ and while there is $u \in R_w \setminus R_S$ with $\sigma(R_S + u) < \sigma(R_S)$, adding $u \in R_w \setminus R_S$ to R_S with b_u/c_u minimum. ◀

The proof of Theorem 1 is complete.

4 Locally uniform thresholds (Theorem 3)

Here we consider the Bipartite Activation Edge-Cover problem with locally uniform thresholds. This means that each non-terminal $v \in V \setminus R$ has weight w_v and all edges incident to v have the same threshold t^v; in the θ-bounded version $w_v \leq \theta t^v$. We consider a natural greedy algorithm that repeatedly picks a star S that minimizes the average price paid for each terminal (the quotient of the optimal activation value of S over $|R_S|$), and then removes R_S. Each time we choose a star S we distribute its activation value uniformly among its terminals, paying in the computed solution the average price for each terminal of S.

We now apply a standard "set-cover" analysis, cf. [28]. In some optimal solution fix an inclusion maximal star S^* with center v and terminals R_{S^*} covered by the algorithm in the order $r_k, r_{k-1}, ..., r_1$, where r_k is covered first and r_1 last; we bound the algorithm payment for covering R_{S^*}. Note that $1 \leq k \leq \Delta$. Denote $w = w_v$ and let t be the threshold of the terminals in S^*. Let S^*_i be the substar of S^* with leaves $r_i, \ldots, r_1$. At the start of the iteration in which the algorithm covers r_i, the terminals of S^*_i are uncovered. Thus the algorithm pays for covering r_i at most the average price paid by S^*_i, namely $(w+it)/i = w/i + t$. Over all iterations, the algorithm pays for covering R_{S^*} at most $wH_k + kt$, while the optimum pays $w + kt$. Thus the quotient between them is bounded by

$$\frac{wH_k + kt}{w + kt} = \frac{w/tH_k + k}{w/t + k} \leq \frac{\theta H_k + k}{\theta + k} = 1 + \frac{\theta(H_k - 1)}{\theta + k} \leq 1 + \max_{1 \leq k \leq \Delta} \frac{H_k - 1}{1 + k/\theta} \leq 1 + \bar{\omega}(\theta) .$$

Since any optimal solution decomposes into node disjoint stars, the last term bounds the approximation ratio, concluding the proof of Theorem 3.

Let $g(k) = \frac{H_k - 1}{1 + k/\theta}$ where $k \in \mathbb{N}$, so $\bar{\omega}(\theta) = \max_{k \in \mathbb{N}} g(k)$. We have

$$g(k+1) - g(k) = \frac{\theta}{(k+\theta)(k+1+\theta)} \left(2 - H_k + \frac{\theta - 1}{k+1} \right) .$$

Thus $g(k+1) \geq g(k)$ if and only if $2 - H_k + \frac{\theta-1}{k+1} > 0$. Consequently, $\bar{\omega}(\theta) = g(k(\theta))$ where $k(\theta)$ be the smallest integer k such that $H_k \geq 2 + \frac{\theta-1}{k+1}$.

For $\theta = 1$ we have $k(\theta) = 4$, so $1 + \bar{\omega}(1) = 73/60$. The greedy algorithm cannot do better even for unit thresholds, as shows the example in Fig. 1. The instance has 48 terminals (in black), and two sets of covering nodes: the upper 12 nodes that form an optimal cover, and the bottom 13 nodes. The bottom nodes have 3 nodes of degree 4, 4 of degree 3, and 6 of degree 2. The algorithm may start taking all bottom nodes, and only then add the upper ones, thus creating a solution of value 73, instead of the optimum 60.

5 Unit thresholds (Theorem 4)

Here we consider the case of unit thresholds when $t^e_u = t^e_v = 1$ for every uv-edge e. By a reduction from [4], we may assume that the instance is bipartite. Specifically, for any optimal assignment $\mathbf{a}$ we have $a_u = 1$ for all $u \in R$, hence we can consider the residual instance obtained by removing the terminals covered by edges with both ends in R; in the new obtained instance R is an independent set, and recall that we may assume that $V \setminus R$ is an independent set.

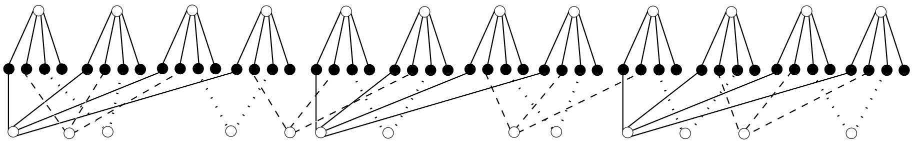

Figure 1 Tight example of ratio $\frac{73}{60}$ for unit thresholds.

One can observe that in the obtained bipartite instance, **a** is an optimal solution if and only if $a_v \in \{0,1\}$ for all $v \in V$, $a_v = 1$ for all $v \in R$, and the set $C = \{v \in V \setminus R : a_v = 1\}$ covers R, meaning that R is the set of neighbors of C. Namely, our problem is equivalent to $\min\{|C| + |R| : C \subseteq V \setminus R, C \text{ covers } R\}$. On the other hand the problem $\min\{|C| : C \subseteq V \setminus R, C \text{ covers } R\}$ is essentially the (unweighted) Set-Cover problem, and C is a feasible solution to this Set-Cover instance if and only if $C \cup R$ is the characteristic set of a feasible assignment for the Activation Edge-Cover instance. Note that both problems are equivalent w.r.t. their optimal solutions but may differ w.r.t. approximation ratios, since if C^* is an optimal Set-Cover solution then $\frac{|C|+|R|}{|C^*|+|R|}$ may be much smaller than $\frac{|C|}{|C^*|}$.

Recall that a standard greedy algorithm for Set-Cover repeatedly picks the center of a largest star and removes the star from the graph. This algorithm has ratio H_k for k-Set-Cover, where $k = \Delta$ is the maximum degree of a non-terminal (the maximum size of a set). However, the same algorithm achieves a much smaller ratio $\frac{73}{60}$ for Activation Edge-Cover with unit thresholds; the ratio $\frac{73}{60}$ was established in [4], and it also follows from the case $\theta = 1$ in Theorem 3. In what follows we denote by α_k the best known ratio for k-Set-Cover. We have $\alpha_1 = \alpha_2 = 1$ ($k = 2$ is the Edge-Cover problem) and $\alpha_3 = 4/3$ [8]. The current best ratios for $k \geq 4$ are due to [11] (see also [18, 1]). We summarize the current values of α_k for $k \leq 7$ in the following table.

Table 2 Current values of α_k for $k \leq 7$.

α_1	α_2	α_3	α_4	α_5	α_6	α_7
1	1	$\frac{4}{3}$	$\frac{73}{48}$	$\frac{26}{15}$	$\frac{28}{15}$	$\frac{212}{105}$

We now show how these ratios for k-Set-Cover can be used to approximate the Activation Edge-Cover problem with unit costs. We start by describing a simple algorithm with ratio $1\frac{67}{360} < \frac{73}{60}$, that uses only the $k = 2$ case.

Algorithm 1 ratio $1\frac{67}{360}$

```
$A \leftarrow \emptyset$
while there exists a star with at least 3 terminals do
    add to $A$ and remove from $G$ the node-set of a maximum size star
add to $A$ an optimal solution of the residual instance
```

We claim that the above algorithm achieves approximation ratio $1\frac{67}{360}$ for Activation Edge-Cover (a similar analysis implies ratio $H_k - \frac{1}{6}$ for Set-Cover). In some optimal solution fix a star S^* with terminals covered in the order $r_k, r_{k-1}, ..., r_1$, where r_k is covered first and r_1 last; we bound the algorithm payment to cover these terminals. Let S^*_i be the substar of S^* with leaves $r_i, \ldots, r_1$. At the start of the iteration when r_i is covered, the terminals of S^*_i are uncovered. Thus the algorithm pays for covering r_i at most the density of S^*_i, namely, $(i+1)i = 1 + 1/i$. Over all iterations, the algorithm pays for covering R_S at most $k + H_k$, while the optimum pays $k + 1$. If $k = 1$ then the algorithm pays at most the amount of the optimum. We claim that if $k \geq 2$ then in fact the payment is at most $k + H_k - 1/6$. If $k = 2$ then the payment is at most $3 < 3 + H_3 - 1/6$ (we pay 3 if the star "survives" all the iterations before the last). For $k \geq 3$, the pay for the last 3 terminals is either: $4/3$ for each of for r_3, r_2 and 2 for r_1 (a total of $14/3$), or $4/3$ for r_3 and 3 for r_2, r_1 (a total of $13/3$). The maximum is $14/3 = 3 + H_3 - 1/6$. Consequently, the ratio is bounded by

$$\max_{k \geq 2} \frac{k + H_k - 1/6}{k+1} = 1 + \max_{k \geq 2} \frac{H_k - 7/6}{k+1} = 1 + \max_{k \geq 2} g(k)$$

By fundamental computations we have $g(k+1) - g(k) = \frac{13/6 - H_k}{(k+1)(k+2)}$. Thus $g(k)$ is increasing if and only if $H_k < \frac{13}{6}$. Since $H_4 = \frac{23}{12} < \frac{13}{6}$ and $H_5 = \frac{137}{60} > \frac{13}{6}$, we get that $\max_{k \geq 2} g(k) = g(5) = \frac{67}{360}$, so we have ratio $1\frac{67}{360}$.

We now show ratio $\frac{8}{7} < \frac{1555}{1347} < \frac{7}{6}$. As in the greedy algorithm for Set-Cover, we repeatedly remove an inclusion maximal set of disjoint stars with maximum number of leaves and pick the set of roots of these stars. The difference is that each time stars with more than k leaves are exhausted, we compute an α_k-approximate solution A_k for the remaining k-Set-Cover instance; we let $A_0 = \emptyset$. This gives many Set-Cover solutions, each is a union of the centers of stars picked and A_k; we choose the smallest one, and together with R this gives a feasible Activation Edge-Cover solution. Formally, the algorithm is:

Algorithm 2 ratio $\rho = \frac{1555}{1347} < 1.1545$

```
1 for $k \leftarrow \Delta$ downto 0 do
2    remove from $G$ a maximal collection of node disjoint $(k+1)$-stars
     let $C_{k+1}$ be the set of the roots of the stars removed so far
3    compute an $\alpha_k$-approximate $k$-Set-Cover solution $A_k$ in $G$
4 return the smallest set $C_{k+1} \cup A_k$, $k \in \{\Delta, \dots, 0\}$
```

Since we claim ratio $\frac{1555}{1347} > 1.15 > \frac{8}{7}$, at iterations when $k \geq 7$ step 3 can be skipped, since then we can apply a standard "local ratio" analysis [2]. Indeed, when a star with $k \geq 7$ terminals is removed, the partial solution value increases by $k+1$ while the optimum decreases by at least k. Hence for $k \geq 7$ it is a $\frac{k+1}{k} \leq \frac{8}{7}$ local ratio step. Consequently, we may assume that $\Delta \leq 6$, provided that we do not claim ratio better than $8/7$.

Let $r = |R|$. Let τ be the optimal value to the initial Set-Cover instance. At iteration k the algorithm computes a solution of value at most $\alpha_k \tau + r + |C_{k+1}|$. Thus we get ratio ρ if $\rho(r + \tau) \geq \alpha_k \tau + r + |C_{k+1}|$ holds for some $k \leq 6$. Otherwise,

$$\begin{aligned}
\rho(r+\tau) &< \alpha_6 \tau + r \\
\rho(r+\tau) &< \alpha_5 \tau + r + |C_6| \\
\rho(r+\tau) &< \alpha_4 \tau + r + |C_5| \\
\rho(r+\tau) &< \alpha_3 \tau + r + |C_4| \\
\rho(r+\tau) &< \alpha_2 \tau + r + |C_3| \\
\rho(r+\tau) &< \alpha_1 \tau + r + |C_2| \\
\rho(r+\tau) &< \qquad\quad r + |C_1|
\end{aligned}$$

Denote $\sigma = \alpha_1 + \cdots + \alpha_5 = \frac{1581}{240}$. Note that $|C_1| + \cdots + |C_6| = r$, since in this sum the number of stars with k leaves is summed exactly k times, $k = 1, \dots, 6$. The first inequality, and the inequality obtained as the sum of the other six inequalities gives the following two inequalities:

$$\begin{aligned}\rho(r+\tau) &< \alpha_6\tau + r\\ 6\rho(r+\tau) &< \sigma\tau + 7r\end{aligned}$$

Dividing both inequalities by τ and denoting $x = r/\tau$ gives:

$$\begin{aligned}\rho(x+1) &< \alpha_6 + x\\ 6\rho(x+1) &< \sigma + 7x\end{aligned}$$

Since $\rho > 1$ and $7 > 6\rho$ this is equivalent to:

$$\frac{6\rho-\sigma}{7-6\rho} < x < \frac{\alpha_6-\rho}{\rho-1}$$

We obtain a contradiction if ρ is the solution of the equation $\frac{6\rho-\sigma}{7-6\rho} = \frac{\alpha_6-\rho}{\rho-1}$, namely

$$\rho = \frac{7\alpha_6-\sigma}{6\alpha_6-\sigma+1} = 1 + \frac{\alpha_6-1}{6\alpha_6-\sigma+1} = 1 + \frac{208}{1347} = \frac{1555}{1347} \ .$$

This concludes the proof of Theorem 4.

Abstract

We give deterministic distributed $(1+\varepsilon)$-approximation algorithms for Minimum Vertex Coloring and Maximum Independent Set on chordal graphs in the LOCAL model. Our coloring algorithm runs in $O(\frac{1}{\varepsilon}\log n)$ rounds, and our independent set algorithm has a runtime of $O(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon})\log^* n)$ rounds. For coloring, existing lower bounds imply that the dependencies on $\frac{1}{\varepsilon}$ and $\log n$ are best possible. For independent set, we prove that $\Omega(\frac{1}{\varepsilon})$ rounds are necessary.

Both our algorithms make use of the tree decomposition of the input chordal graph. They iteratively peel off interval subgraphs, which are identified via the tree decomposition of the input graph, thereby partitioning the vertex set into $O(\log n)$ layers. For coloring, each interval graph is colored independently, which results in various coloring conflicts between the layers. These conflicts are then resolved in a separate phase, using the particular structure of our partitioning. For independent set, only the first $O(\log \frac{1}{\varepsilon})$ layers are required as they already contain a large enough independent set. We develop a $(1+\varepsilon)$-approximation maximum independent set algorithm for interval graphs, which we then apply to those layers.

This work raises the question as to how useful tree decompositions are for distributed computing.

1 Introduction

The LOCAL Model. In the LOCAL model of distributed computation [31], the input graph $G = (V, E)$ with $n = |V|$ represents a communication network, where every network node hosts a computational entity. Nodes have unique IDs. A distributed algorithm is executed on all network nodes simultaneously and proceeds in discrete rounds. Initially, besides their own IDs, nodes only know their neighbors. Each round consists of a computation and a communication phase. In the computation phase, nodes are allowed to perform unlimited computations. In the communication phase, nodes can send individual messages of unbounded sizes to all their neighbors (and receive messages from them as well). The runtime of the algorithm is the total number of communication rounds, and the objective is to design algorithms that run in as few rounds as possible. The output is typically distributed: For

vertex colorings, it is required that upon termination of the algorithm, every node knows its own color, and for independent sets, every node knows whether it participates in the independent set.

Network Decompositions. Network decompositions (see for example [3, 35, 32]) are a widely employed tool in distributed computing. They allow us to partition the vertex set of a graph into connected clusters of bounded diameter such that the cluster graph, i.e., the graph obtained by contracting the clusters into vertices, has small chromatic number. The Linial-Saks network decomposition method [32] guarantees that the cluster graph can be colored with $\mathrm{O}(\log n)$ colors (and provides such a coloring), and no better method is known with regards to the number of colors. When employing a network decomposition algorithm for the Minimum Vertex Coloring (MVC) problem, the chromatic number of the cluster graph directly translates to the achieved approximation factor: Iterate through the color classes of the cluster graph and make each cluster color itself *optimally* using exponential time computations (recall that MVC is NP-hard) and using a color palette that is disjoint to the colors employed by already colored neighboring clusters. Indeed, this techniques yields the currently best known distributed algorithm for MVC (with approx. factor $\mathrm{O}(\log n)$) [4].

Tree Decompositions. Our objective is to obtain distributed coloring algorithms with improved approximation guarantees, i.e., sub-logarithmic in n. To this end, we follow a route that at a first glance is very similar to the approach outlined above. However, instead of employing network decompositions, we make use of the *tree decomposition* of the input graph. A tree decomposition is a decomposition of the vertex set into (not necessarily disjoint) bags that are arranged in a tree such that every edge of the input graph is contained in the induced subgraph of at least one bag, and all bags that contain a specific vertex form a subtree in the tree decomposition. The key advantage of employing tree decompositions rather than network decompositions is that trees have small chromatic number and can efficiently be colored distributively. There are however multiple obstacles: First, there are graphs whose tree decompositions necessarily contain at least one bag whose diameter (maximum distance in the original graph between any two nodes in the bag) is $\Omega(n)$ (e.g. on a ring [16]). In these graphs, network nodes thus cannot learn the set of bags they are contained in in a small number of rounds and it appears impossible that nodes can obtain a local view of a coherent global tree decomposition. Second, the fact that every node may appear in multiple bags renders the coloring process more difficult since we cannot simply color independent parts of the tree simultaneously as some nodes may appear in multiple parts.

Our Results. Despite these obstacles, in this paper we show that the tree decomposition route can successfully be taken for the class of *chordal graphs*. A graph is chordal, if every cycle on at least four nodes contains a *chord*, i.e., an edge different from the edges of the cycle connecting two nodes of the cycle. Chordal graphs admit a tree decomposition where every bag has diameter 1, i.e., every bag is a clique. We first show that the tree decomposition of a chordal graph can efficiently be computed in the distributed setting. We then employ a peeling process on the tree decomposition that partitions the chordal graph into *interval subgraphs*, which can be colored efficiently distributively using a line of work by Halldórsson and Konrad [24, 25]. Particular care needs to be taken where these subgraphs meet, and we employ a color rotation technique to correct the colors at their boundaries. Perhaps surprisingly, this approach allows us to obtain a $(1+\varepsilon)$-approximation algorithm on this graph class, which constitutes our main result (**Theorem 14**). Our algorithm runs in $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds and prior work shows that the dependencies on both $\frac{1}{\varepsilon}$ and $\log n$ are optimal.

We further adapt this approach to the Maximum Independent Set (MIS) problem. In general graphs, a $(1+\varepsilon)$-approximation to MIS can be obtained in $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds [11, 21]. We show that using the tree decomposition approach outlined above, a $(1+\varepsilon)$-approximation on chordal graphs can be obtained in $\mathrm{O}(\frac{1}{\varepsilon}\log(\frac{1}{\varepsilon})\log^* n)$ rounds (**Theorem 16**), and we prove that $\Omega(\frac{1}{\varepsilon})$ rounds are necessary (**Theorem 17**).

Related Work: Distributed Vertex Coloring. Distributed vertex coloring has been studied since more than 30 years (e.g. [14, 23]). Given a graph $G = (V, E)$, a *(legal) c-coloring* of G is an assignment $\gamma : V \rightarrow \{1, 2, \dots, c\}$ of at most c colors to the nodes of G such that every pair of adjacent nodes receives different colors. The algorithmic challenge lies in computing colorings with few colors. The *chromatic number* $\chi(G)$ is the smallest c such that there is a c-coloring. The MVC problem asks to find a $\chi(G)$-coloring. This is a difficult task, even in the centralized setting: In general graphs, MVC is NP-complete [27] and hard to approximate within a factor of $n^{1-\varepsilon}$, for any $\varepsilon > 0$ [39].

Most research papers on distributed vertex coloring address the problem of computing a $(\Delta + 1)$-coloring (e.g. [14, 38, 37, 5, 8, 26, 18, 12]) (other objectives, such as Δ-colorings [36, 20] and other degree-based objectives [1] have been studied as well). Only few research papers address the MVC problem in a distributed model itself. On general graphs, the best distributed algorithm computes a $\mathrm{O}(\log n)$-approximation in $\mathrm{O}(\log^2 n)$ rounds [4] and is based on the network decomposition of Linial and Saks [32]. This algorithm uses exponential time computations, which due to the computational hardness of MVC is necessary unless $P = NP$. Barenboim et al. [7] gave a $\mathrm{O}(n^{\varepsilon})$-approximation algorithm that runs in $\exp(\mathrm{O}(1/\varepsilon))$ rounds. Both the exponential time computations and the relatively large best known approximation factor of $\mathrm{O}(\log n)$ on general graphs motivate the study of special graph classes. Besides results on graph classes with bounded chromatic number (planar graphs [23] and graphs of bounded arboricity [6, 22]), the only natural graph class with unbounded chromatic number that has been addressed in the literature are *interval graphs*, which are the intersection graphs of intervals on the line. Halldórsson and Konrad gave a $(1 + \varepsilon)$-approximation algorithm for MVC on interval graphs that runs in $\mathrm{O}(\frac{1}{\varepsilon}\log^* n)$ rounds [25] (see also [24]). This work is the most relevant related work to our results.

Related Work: Distributed Independent Sets. An *independent set* in a graph $G = (V, E)$ is a subset of non-adjacent nodes $I \subseteq V$. Algorithms for independent sets are usually designed with one of the following two objectives in mind: (1) Compute a *maximal independent set*, i.e., an independent set I that cannot be enlarged by adding a node outside I to it, or (2) Compute a Maximum Independent Set (MIS) (or an approximation thereof), i.e., an independent set of maximum size, which is the variant studied in this paper. Similar to MVC, the MIS problem is NP-complete [27] and hard to approximate within a factor of $n^{1-\varepsilon}$, for every $\varepsilon > 0$ [39]. In the distributed setting, Luby [33] and independently Alon et al. [2] gave distributed $\mathrm{O}(\log n)$ rounds maximal independent set algorithms more than 30 years ago. Improved results are possible for graphs with bounded maximum degree ([8, 19]) or on specific graph classes (e.g. [14, 38]). Using exponential time computations, a $(1 + \varepsilon)$-approximation to MIS can be computed in general graphs in $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds [11] (see also [21]). Deterministic distributed MIS algorithms may be inferior to randomized ones: It is known that every deterministic MIS $\mathrm{O}(1)$-approximation algorithm on a path requires $\Omega(\log^* n)$ rounds [30, 15], while a simple randomized $\mathrm{O}(1)$-round $\mathrm{O}(1)$-approximation algorithm exists [15].

Outline. In Section 2, we give notation and definitions. We then discuss in Section 3 how network nodes can obtain coherent local views of the tree decomposition. A centralized $(1+\varepsilon)$-approximation MVC algorithm is then presented in Section 4, and distributed implementation of this algorithm is given in Section 5. Due to space restrictions, we only briefly sketch our results on MIS in Section 6 and defer a complete exposition to the full version of this paper [29]. Finally, we conclude in Section 7.

2 Preliminaries

Basic Notation and Definitions. Let $G = (V, E)$ be a graph. For a node $v \in V$, we denote by $\Gamma_G(v)$ the *neighborhood* of v in G. The *degree* of v in G is defined as $\deg_G(v) := |\Gamma_G(v)|$. By $\Gamma_G[v]$ we denote the set $\Gamma_G(v) \cup \{v\}$. Similarly, for a set of nodes $W \subseteq V$ we write $\Gamma_G(W) := (\bigcup_{v\in W} \Gamma_G(v)) \setminus W$, and $\Gamma_G[W] := \Gamma_G(W) \cup W$. The *distance-$k$ neighborhood* of v in G, i.e., the set of nodes at distance at most k from v in G, is denoted $\Gamma_G^k(v)$. The subgraph of G induced by a set of nodes U is denoted by $G[U]$. A set of pairwise adjacent (resp., non-adjacent) nodes in G is called a *clique* (resp., an *independent set*). A clique (resp., an independent set) S is *maximal* if $S \cup \{v\}$ is not a clique (resp., an independent set), for every $v \in V \setminus S$. A *maximum* independent set in G is an independent set of maximum size. The cardinality of a maximum independent set is called the *independence number* of G. A graph is *chordal* if every cycle of length at least four contains a chord, i.e., an edge that connects two non-consecutive nodes of the cycle. It is a well-known fact that an n-node chordal graph has at most n maximal cliques.

Tree Decomposition. A *tree decomposition* of an n-node graph $G = (V, E)$ is a forest $\mathcal{T} = (\mathcal{S}, \mathcal{E})$ whose vertex set $\mathcal{S} = \{S_1, S_2, \ldots, S_n\}$ is a family of subsets of V, and:

1. every node[1] $v \in V$ belongs to at least one subset in $\mathcal{S}$;
2. for every edge $uv \in E$, there is a subset $S_i \in \mathcal{S}$ containing both nodes u and v;
3. for every node $v \in V$ the family $\phi(\mathcal{T}, v) \subseteq \mathcal{S}$ of subsets containing v induces a tree in $\mathcal{T}$, which we denote $\mathcal{T}(v)$, i.e., $\mathcal{T}(v) := \mathcal{T}[\phi(\mathcal{T}, v)]$.

When the tree decomposition is clear from the context we will write $\phi(v)$ instead of $\phi(\mathcal{T}, v)$. It follows from the definition that G is a subgraph of the intersection graph of the trees $\mathcal{T}(v)$.

Tree Decomposition of Chordal Graphs. It is well known (see, e.g., [10]) that a graph G is chordal if and only if it has a tree decomposition $\mathcal{T} = (\mathcal{C}, \mathcal{E})$ whose vertex set $\mathcal{C}$ is the family of maximal cliques of G. We call such a tree decomposition a *clique forest* of chordal graph G. Since every vertex of the clique forest is a clique, G coincides with the intersection graph of the subtrees $\mathcal{T}(v)$ of clique forest $\mathcal{T}$. In other words, a clique forest of a chordal graph G is a forest $\mathcal{T} = (\mathcal{C}, \mathcal{E})$ whose vertex set $\mathcal{C}$ is the family of maximal cliques of G, such that $\mathcal{T}[\phi(v)]$ is a tree for every v. If a clique forest of a chordal graph is linear, i.e., a forest with every component being a path, then the graph is interval.

▶ **Theorem 1** ([17]). *A chordal graph G is interval iff its clique forest is a linear forest.*

[1] For convenience, throughout the paper, we say *node* when referring to a vertex of an underlying graph, and we say *vertex* when referring to a vertex of its tree decomposition.

Binary Paths. We say that a path $v_1, \ldots, v_k$ in G is *binary*, if $\deg_G(v_i) \leq 2$, for every $i \in [k]$ (note that this implies that $\deg_G(v_i) = 2$, for every $i \in \{2, 3, \ldots, k-1\}$). We say that a binary path $v_1, \ldots, v_k$ is a *pendant path*, if either $\deg_G(v_1) = 1$ or $\deg_G(v_k) = 1$ (or both). For convenience, we consider an isolated vertex as a pendant path. A binary path $v_1, \ldots, v_k$ is an *internal path*, if $\deg_G(v_i) = 2$, for every $i \in [k]$. A binary/pendant/internal path is *maximal* if it cannot be enlarged by adding a vertex outside the path to it.

Let $G = (V, E)$ be a chordal graph with clique forest $\mathcal{T} = (\mathcal{C}, \mathcal{E})$. Let $\mathcal{P} = C_1, \ldots, C_k$ be a binary path in $\mathcal{T}$. We define the *diameter* of $\mathcal{P}$ to be the maximum distance in G between nodes in $C_1 \cup \ldots \cup C_k$, that is, $diam(\mathcal{P}) = \max\limits_{u \in C_i, v \in C_j, i,j \in [k]} dist_G(u, v)$. Similarly, we define the *independence number* of $\mathcal{P}$ to be the independence number of $G[C_1 \cup \ldots \cup C_k]$.

Distributed Algorithms for Interval Graph. Halldórsson and Konrad [25] gave a deterministic distributed algorithm for coloring interval graphs. For every $\varepsilon \geq \frac{2}{\chi(G)}$, their algorithm computes a $(1+\varepsilon)$-approximation to MVC in $O(\frac{1}{\varepsilon} \log^* n)$ rounds. We will reuse this algorithm and denote it by $\textsc{ColIntGraph}(\varepsilon)$.

3 Computing Local Views of the Clique Forest

Our algorithms make use of the clique forest of the input chordal graph. For network nodes to obtain a coherent view of the clique forest, we make use of the following *maximum weight spanning forest* characterization: With a chordal graph G we associate the *weighted clique intersection graph* $\mathcal{W}_G$ whose vertex set is the family $\mathcal{C}$ of maximal cliques of G, and any two cliques $C_1, C_2 \in \mathcal{C}$ with a nonempty intersection are connected by an edge with weight $|C_1 \cap C_2|$. Then:

▶ **Theorem 2** ([9]). *A forest $\mathcal{T} = (\mathcal{C}, \mathcal{E})$ is a clique forest of a chordal graph G if and only if it is a maximum weight spanning forest of $\mathcal{W}_G$.*

Observe that while the vertex set of a clique forest is unique, i.e., the family of maximal cliques of G, the edge set is not necessarily unique as there may be multiple different maximum weight spanning forests in $\mathcal{W}_G$. To obtain coherent local views of a clique forest, it is thus necessary that nodes agree on a unique maximum weight spanning forest in $\mathcal{W}_G$. We achieve this by defining a linear order $<$ on the edges of $\mathcal{W}_G$ that respects the partial order given by the edge weights, and preferring edges that are larger with respect to $<$. To this end, we first assign to every maximal clique $C \in \mathcal{C}$ a word $\sigma(C)$ over the alphabet of the identifiers of nodes, where $\sigma(C)$ consists of the identifiers of the nodes in C listed in increasing order. Further, we associate with every edge $e = C_iC_j$ a triple (w_e, l_e, h_e), where w_e is the weight of e, i.e., $w_e = |C_i \cap C_j|$, $l_e = \text{lexmin}\{\sigma(C_i), \sigma(C_j)\}$, and $h_e = \text{lexmax}\{\sigma(C_i), \sigma(C_j)\}$. Now for two edges e and f we define $e < f$ if and only if either $w_e < w_f$, or $w_e = w_f$ and $l_e \prec l_f$, or $w_e = w_f$, $l_e = l_f$ and $h_e \prec h_f$, where $\prec$ is the lexicographical order. Clearly, $<$ orders the edges of $\mathcal{W}_G$ linearly while preserving the weight order.

In what follows, when we say that $\mathcal{T}$ is *the* clique forest of a chordal graph G, we implicitly assume that it is the clique forest uniquely specified by the above mechanism. Figure 2 demonstrates the weighted clique intersection graph and the clique forest of the chordal graph presented in Figure 1. A maximum weight spanning forest has the following easily verifiable local optimality property:

▶ **Lemma 3.** *Let $G = (V, E)$ be a weighted graph with a unique maximum weight spanning forest F, and let $U \subseteq V$ be a set of nodes inducing a tree T in F. Then $G[U]$ has a unique maximum weight spanning tree, which coincides with T.*

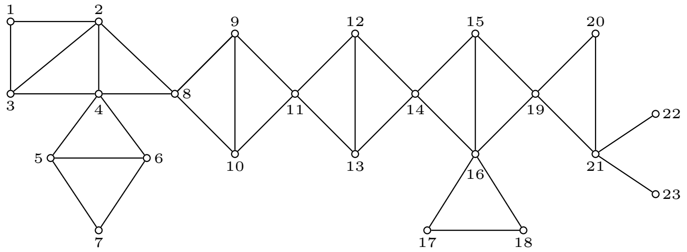

Figure 1 Chordal graph G.

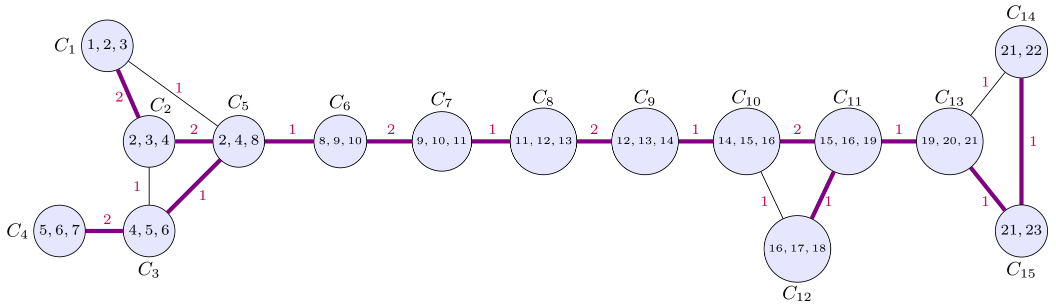

Figure 2 The weighted clique intersection graph $\mathcal{W}_G$ of chordal graph G presented in Fig. 1. The vertices of $\mathcal{W}_G$ are the maximal cliques of G, and two vertices C_i, C_j of $\mathcal{W}_G$ with a nonempty intersection are connected by an edge with weight $|C_1 \cap C_2|$. The bold edges are the edges of the clique forest $\mathcal{T}$ of G., i.e., the edges of the unique maximum weight spanning forest of $\mathcal{W}_G$ corresponding to the linear order of edges $<$.

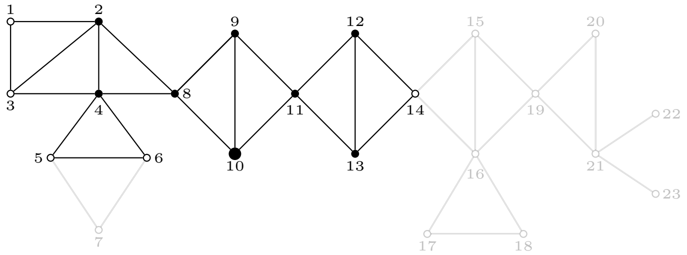

Figure 3 Local view of graph G from node 10. The non-gray nodes are the nodes in $\Gamma^3_G[10]$, and the black nodes are the nodes in $\Gamma^2_G[10]$.

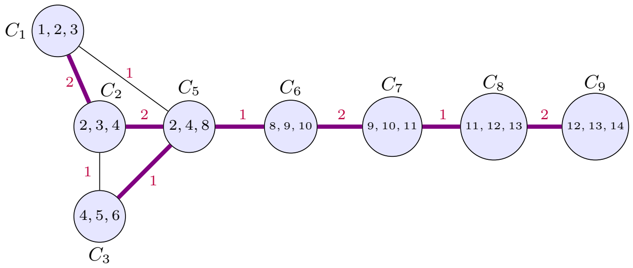

Figure 4 Local view of the graph $\mathcal{W}_G$ from node 10. The cliques in $\mathcal{C}' = \{C_1, C_2, C_3, C_5, C_6, C_7, C_8, C_9\}$ are exactly the maximal cliques of G that contain at least one node from $\Gamma^2_G[10]$. The bold edges are the edges of the unique maximum weight spanning forest of $\mathcal{W}_G[\mathcal{C}']$, which coincides with the subtree of $\mathcal{T}$ induced by $\mathcal{C}'$.

Applied to a chordal graph and its clique forest, we thus obtain:

▶ **Lemma 4.** *Let $G = (V, E)$ be a chordal graph and $\mathcal{T} = (\mathcal{C}, \mathcal{E})$ its clique forest. Then for any $v \in V$ the unique maximum weight spanning forest in $\mathcal{W}_G[\phi(v)]$ equals to tree $\mathcal{T}(v) = \mathcal{T}[\phi(v)]$.*

This suggests a method for a node $v \in V$ to compute a local view $\mathcal{T}'$ of clique forest $\mathcal{T}$: Suppose that v knows its distance d-neighborhood $\Gamma_G^d[v]$. For every $u \in \Gamma_G^{d-1}[v]$, v computes the family $\phi(u)$ of maximal cliques containing u (notice that a maximal clique that contains a node at distance $d-1$ from v may include nodes at distance d). Then, v computes the maximum weight spanning forest in every $\mathcal{W}_G[\phi(u)]$ and adds the edges of this forest to $\mathcal{T}'$. Figures 3 and 4 illustrate construction of a local view of the clique forest of the chordal graph presented in Figure 1.

4 Minimum Vertex Coloring: Centralized Algorithm

In this section, we give a centralized $(1+\varepsilon)$-approximation algorithm for MVC on chordal graphs. This algorithm will later be implemented in the LOCAL model in Section 5.

4.1 Algorithm

Algorithm 1 A centralized $(1+\varepsilon)$-approximation coloring algorithm for chordal graphs.

```
Input: $G = (V, E)$ is an $n$-node chordal graph with clique forest $\mathcal{T} = (\mathcal{C}, \mathcal{E})$; a parameter $\varepsilon > \frac{2}{\chi(G)}$.
   Set $k = 2/\varepsilon$.
(1) Pruning Phase.
   Let $\mathcal{T}_1 = \mathcal{T}$, $U_1 = V$.
   for $i = 1, 2, \ldots, \lceil \log n \rceil$ do:
      a. Let $\mathcal{L}_i$ be the set that contains all maximal pendant paths of $\mathcal{T}_i$, and all maximal internal paths of $\mathcal{T}_i$ of diameter at least $3k$.
      b. Let $V_i \subseteq U_i$ be such that for each $v \in V_i$, $\mathcal{T}(v)$ is a subpath of a path in $\mathcal{L}_i$.
      c. Let $U_{i+1} = U_i \setminus V_i$, and let $\mathcal{T}_{i+1}$ be the forest obtained from $\mathcal{T}_i$ by removing all paths in $\mathcal{L}_i$. As proved in Lemma 5, $\mathcal{T}_{i+1}$ is the clique forest of $G[U_{i+1}]$.
(2) Coloring Phase.
   for $i = 1, 2, \ldots, \lceil \log n \rceil$ do: Color $G[V_i]$ with at most $(1 + 1/k)\chi(G[V_i]) + 1$ colors.
(3) Color Correction Phase.
   for $i = \lceil \log n \rceil - 1, \lceil \log n \rceil - 2, \ldots, 1$ do:
      for each path $\mathcal{P} \in \mathcal{L}_i$ do:
         (a) Let $W \subseteq V_i$ be the set of nodes $w$ such that $\mathcal{T}(w)$ is a subpath of $\mathcal{P}$.
         (b) Let $W' \subseteq \bigcup_{l>i} V_l$ be the subset of nodes that have neighbors in $W$.
         (c) As we will show, $G[W \cup W']$ is an interval graph. Using Lemma 8, we recolor those nodes of $W$ that are at distance at most $k+3$ from a node in $W'$ using at most $(1 + 1/k)\chi(G[V_i]) + 1$ colors to resolve all coloring conflicts between $W$ and $W'$.
```

Our algorithm (Alg. 1) consists of the pruning, the coloring, and the color correction phases: In the pruning phase, the node set V is partitioned into at most $\lceil \log n \rceil$ *layers* $V_1, \ldots, V_{\lceil \log n \rceil}$ such that, for every $i \in [\lceil \log n \rceil]$, $G[V_i]$ constitutes an interval graph. In each step of the pruning phase, we remove every node $v \in U_i$ from the current graph $G[U_i]$ (we set $U_1 = V$ and hence $G[U_1] = G$) whose corresponding subtree $\mathcal{T}(v)$ in the clique forest $\mathcal{T}_i$ of $G[U_i]$ is a subpath of a pendant path or an internal path of diameter at least $3k$. The set of removed nodes is denoted V_i, and $G[V_i]$ forms an interval graph (which follows from Lemma 7, [29]). We prove in Lemma 5 that the clique forest $\mathcal{T}_{i+1}$ of the resulting graph $G[U_{i+1}]$, where

$U_{i+1} = U_i \setminus V_i$, can be obtained by removing all pendant paths and all internal paths of diameter at least $3k$ from $\mathcal{T}_i$. We also show in Lemma 6 that the pruning process ends after at most $\lceil \log n \rceil$ iterations and thus creates at most $\lceil \log n \rceil$ layers.

In the coloring phase, each interval graph $G[V_i]$ is colored with at most $(1+1/k)\chi(G[V_i])+1$ colors. In the centralized setting, it would be easy to color these interval graphs optimally. However, since we will implement the algorithm later in the distributed setting, and an optimal coloring on interval graphs cannot be computed distributively in few rounds, we impose a weaker quality guarantee that can be achieved distributively. The colorings of different layers are computed independently from each other and do not give a coherent coloring of the entire input graph.

In the color correction phase, these incoherences are corrected. To this end, the colors of $V_{\lceil \log n \rceil}$ remain unchanged and we correct the layers iteratively, starting with layer $\lceil \log n \rceil - 1$ and proceeding downwards to layer V_1. In a general step, for every path $\mathcal{P} \in \mathcal{L}_i$, we show that the subgraph induced by the nodes $W \subseteq V_i$ whose subtrees are subpaths of $\mathcal{P}$ forms an interval graph together with those nodes in $\bigcup_{j \geq i+1} V_j$ that have coloring conflicts towards W (Lemma 8, [29]). Notice that each path $\mathcal{P}$ connects to at most two maximal cliques in $\mathcal{T}_i$. The neighborhood of W thus consists of subsets of these (at most two) cliques, which further implies that all conflicting nodes in $\bigcup_{j \geq i+1} V_j$ are included in these cliques as well. We then reuse a recoloring result previously proved by Halldórsson and Konrad [25], which shows that we can resolve all conflicts by changing the colors of those nodes in W that are at distance at most $k+3$ from the (at most) two conflicting cliques.

4.2 Analysis

The analysis of our algorithm relies on various technical lemmas that are given in the full version of this paper [29]. We now give the most important lemmas that allow us to prove correctness of our algorithm. Concerning the pruning step, we show that $\mathcal{T}_i$ is indeed the clique forest of $G[U_i]$ in Lemma 5, and we prove that at most $\lceil \log n \rceil$ iterations are required to complete the pruning process[2] in Lemma 6.

▶ **Lemma 5.** *For every i, $\mathcal{T}_i$ is the clique forest of $G[U_i]$.*

▶ **Lemma 6.** *Phase 1 in Alg. 1 requires at most $\lceil \log n \rceil$ iterations, i.e., $\bigcup_{1 \leq i \leq \lceil \log n \rceil} V_i = V$.*

Next, we address the color correction phase. In each iteration of the phase we consider every path $\mathcal{P} \in \mathcal{L}_i$ independently. The subgraph induced by the set of nodes $W \subseteq V_i$ whose corresponding trees are subpaths of $\mathcal{P}$ is legally colored in the coloring phase. This coloring may be inconsistent with the coloring of subgraph $G[U_{i+1}]$. However, we prove in Lemma 8, [29], that the set $W' \subseteq \bigcup_{s>i} V_s = U_{i+1}$ of neighbors of W in $G[U_{i+1}]$ (i.e., the nodes in U_{i+1} that could potentially cause conflicts) is the union of at most two cliques, which are included in the end vertices of the clique forest of interval graph $G[W \cup W']$. In order to resolve these conflicts we carry out a recoloring process on interval graph $G[W \cup W']$ with fixed colorings of its "boundary" cliques. To this end, we reuse a result by Halldórsson and Konrad [25]:

▶ **Lemma 7** (Halldórsson and Konrad [25]). *Let $G = (V, E)$ be an interval graph with its clique forest $\mathcal{T} = (\mathcal{C}, \mathcal{E})$ being a path $\mathcal{P} = C_1, C_2, \ldots, C_k$ such that $\mathrm{dist}_G(u, v) \geq r$ for every pair of nodes $u \in C_1, v \in C_k$, for an integer $r \geq 5$. Suppose that cliques C_1 and C_k are legally colored using at most c colors. Then the coloring of $G[C_1 \cup C_k]$ can be extended to a legal coloring of G with at most $\max\{\lfloor (1 + \frac{1}{r-3})\chi(G) \rfloor + 1, c\}$ colors.*

[2] Recently, inspired by Miller and Reif's *parallel tree contraction* [34], a very similar procedure was developed by Chang and Pettie [13].

Equipped with Lemma 7, we now prove correctness of the color correction phase.

▶ **Lemma 8** (Recoloring Lemma). *Consider the color correction phase (Step 3) of Algorithm 1. Let $\mathcal{P} \in \mathcal{L}_i$ be a path and let $W \subseteq V_i$ be the subset of nodes whose corresponding subtrees are included in $\mathcal{P}$. Further, let $W' \subseteq \bigcup_{s>i} V_s = U_{i+1}$ be the nodes in U_{i+1} that have neighbors in W. Suppose that W' is colored using colors from the set $[\lfloor(1+1/k)\chi(G)+1\rfloor]$. Then, we can recolor those nodes of W that are at distance at most $k+4$ from W' in G with colors from the set $[\lfloor(1+1/k)\chi(G)+1\rfloor]$ so that $G[W \cup W']$ is legally colored.*

Proof. By Lemma 8, [29], $G[W \cup W']$ is an interval graph and its clique forest is a path. Let $\mathcal{P}' = C_1, C_2, \dots, C_r$ denote this path. The same lemma also states that $W' \subseteq C_1 \cup C_r$.

Let i be the minimum index such that $\mathrm{dist}(u,v) \geq k+3$, for every $u \in W' \cap C_1$ and $v \in C_i$. Then, by Lemma 7, the nodes of the cliques $C_2, \dots, C_{i-1}$ can be recolored using at most $\lfloor(1+1/k)\chi(G)\rfloor + 1$ colors to resolve the coloring conflicts between $W' \cap C_1$ and W. Similarly, let j be the maximum index such that $\mathrm{dist}(u,v) \geq k+3$, for every $u \in W' \cap C_r$ and $v \in C_j$. Then, by Lemma 7, the nodes of the cliques $C_{j+1}, \dots, C_{r-1}$ can be recolored using at most $\lfloor(1+1/k)\chi(G)\rfloor + 1$ colors to resolve the conflicts between $W' \cap C_r$ and W. ◀

▶ **Theorem 9.** *For any $\varepsilon > \frac{2}{\chi(G)}$, Algorithm 1 is a $(1+\varepsilon)$-approximation* MVC *algorithm on chordal graphs.*

Proof. First, we show by induction that the algorithm uses at most $(1+1/k)\chi(G)+1$ colors. This is clearly true for $G_{\lceil \log n \rceil}$. The induction step follows from Lemma 8. Now, using the assumption $\varepsilon > \frac{2}{\chi(G)}$, we obtain: $(1+1/k)\chi(G)+1 \leq (1+\varepsilon/2)\chi(G)+\varepsilon\chi(G)/2 = (1+\varepsilon)\chi(G)$, which proves the approximation factor of the algorithm. ◀

5 Minimum Vertex Coloring: Distributed Algorithm

We give now a LOCAL model implementation of Algorithm 1 that runs in $\mathrm{O}\left(\frac{1}{\varepsilon}\log n\right)$ rounds.

5.1 Algorithm

The global behavior of our distributed algorithm, Algorithm 2, is identical to that of our centralized Algorithm 1. The main challenge lies in the coordination of the network nodes. One particular difficulty stems from the fact that network nodes are not aware of n, the total number of nodes, and thus do not know when the $\lceil \log n \rceil$ iterations of the pruning phase have completed. For this reason, nodes execute the three phases of Algorithm 1 asynchronously.

We will first present the pseudocode of our distributed algorithm, which is executed independently on every node v. Then we will describe each of the three phases in detail.

Algorithm 2 A distributed $(1+\varepsilon)$-approximation algorithm, code for node v.

```
Input:  a parameter $\varepsilon$, let $k = \lceil 2/\varepsilon \rceil$
1. Pruning Phase. $(l_v, parent_v, children_v) \leftarrow$ PRUNETREE()
2. Coloring Phase. Run ColIntGraph($\frac{1}{k}$) on layer $l_v$ and store color in $c_v$
3. Color Correction Phase.
     if $parent_v \neq \bot$ then
         Wait until message SetColor($c$) received from $parent_v$;   Set $c_v \leftarrow c$;
     end if
     CorrectChildren($children_v, k$)
```

The Pruning Phase. In the pruning phase, the subroutine PruneTree is invoked and returns parameters l_v, $parent_v$, and $children_v$, where l_v is the layer of node v, and $parent_v$ and $children_v$ are variables necessary for the coordination of the color correction phase and are defined and explained later. The pseudocode of PruneTree is given in Algorithm 3.

Algorithm 3 PruneTree(), code for node v.

```
Initialization:
Let $i = 1$, $l_v = -1, children_v = \{\}$, and $parent_v = \perp$
while $l_v = -1$ do:
  1. Collect $\Gamma_G^{10k}(v)$ together with variables $l_u$ and $ID_u$, for every $u \in \Gamma_G^{10k}(v)$
  2. Compute local view of the clique forest $\mathcal{T}_i = (\mathcal{C}_i, \mathcal{E}_i)$ of the subgraph of $G$ induced by the
     nodes $u \in \Gamma_G^{10k}(v)$ with $l_u = -1$
  3. if $\mathcal{T}_i(v)$ is a subpath of a pendant path in $\mathcal{T}_i$, or $\mathcal{T}_i(v)$ is a subpath of a binary path in $\mathcal{T}_i$ of
     diameter at least $3k$ then
       $l_v = i$;    $parent_v$ = parent of $v$;
     else
       Add children in layer $i$ (if there are any) to $children_v[i]$
     end if
  4. $i = i + 1$
return $(l_v, parent_v, children_v)$
```

In each iteration of the while loop of PruneTree, one layer is removed from the clique forest of the input graph. To describe the global behavior of the algorithm, we will reuse the naming conventions already used in Algorithm 1. Let $U_1 = V$, and let $V_i \subseteq U_i$ be the set of nodes removed in iteration i, i.e., assigned layer index i. Let also $U_{i+1} = U_i \setminus V_i$, and let $\mathcal{L}_i$ be the set of maximal paths removed from the clique forest $\mathcal{T}_i$ of $G[U_i]$.

In each iteration i, first, each node v collects its distance-$10k$ neighborhood. Then, v computes its local view of the clique forest $\mathcal{T}_i$ of the graph induced by the nodes that have not yet been removed from the graph, i.e., of $G[U_i]$ (as in Section 3). Next, node v is removed from $G[U_i]$ and added to the current layer V_i if its corresponding subtrees $\mathcal{T}_i(v)$ is entirely contained in either a pendant path or a binary path of large enough diameter. This step is identical to Algorithm 1, and the exact same partitioning is computed. Node v that is removed in the current iteration stores its parent in $parent_v$, and nodes that remain in the graph potentially store some of the removed nodes as their children in $children_v$.

▶ **Definition 10** (Parent, Child). *Let $v \in V_i$ and let $\mathcal{P}$ be the maximal binary path in $\mathcal{T}_i$ that contains $\mathcal{T}_i(v)$. If $\mathcal{P}$ is a component of $\mathcal{T}_i$ then we define $parent_v := \perp$. Otherwise, let C be the vertex outside $\mathcal{P}$ in $\mathcal{T}_i$ such that C is adjacent to an end vertex of $\mathcal{P}$ and $dist_G(v, C)$ is minimal. Let c be the node with maximum ID in C. Then the* parent *of v is defined to be c, if $dist_G(v, C) \leq k + 3$, and $\perp$ otherwise. If c is the parent of v, then v is a* child *of c.*

The parent of node v is responsible for recoloring v in the color correction phase. Notice that a node v does not have a parent if the closest maximal clique outside v's path $\mathcal{P}$ is at least at distance $k + 4$ from v. In this case, the color that v will receive in the coloring phase is final and no color correction is needed for v. Recall that in the color correction phase of Algorithm 1, we only need to recolor nodes that are at distance at most $k + 3$ from the cliques that contain nodes with color conflicts. Finally, the subroutine returns the node's level l_v, its parent $parent_v$, and its children $children_v$.

The Coloring Phase. Notice that all nodes of layer i return from PruneTree in the same round. They can hence invoke the coloring phase simultaneously. They run the algorithm ColIntGraph of Halldórsson and Konrad [25] and compute a coloring on $G[V_i]$ that uses at most $\lfloor (1+\frac{1}{k})\chi(G[V_i]) + 1 \rfloor$ colors. This algorithm runs in $\mathrm{O}(k \log^* n)$ rounds.

While some nodes execute the coloring phase, others still execute PruneTree. These nodes repeatedly collect their distance-$10k$ neighborhood. This requires all other network nodes to continuously forward messages, which can be taken care of in the background.

The Color Correction Phase. In color correction phase, nodes with assigned parents (i.e., nodes v with $parent_v \neq \perp$) first wait until they received their final color from their parents. Only then they proceed and correct the colors of their children. To this end, each such node v runs subroutine CorrectChildren, which processes $children_v$ layer by layer, starting with layer $l_v - 1$ down to 1. If v has children in layer V_i, then it waits until all nodes adjacent to $children_v[i]$ which are contained in layers $> i$ have received their final colors. This can be done by repeatedly collecting its local distance-$(k+5)$ neighborhood and checking whether the colors of all nodes in $\Gamma_{G[U_i]}(children_v[i])$ are final. Then, v locally computes the color correction for $children_v[i]$ and notifies them about their new colors.

Algorithm 4 CorrectChildren($children_v, k$), code for node v.

```
for $l \leftarrow l_v - 1, l_v - 2, \ldots, 1$ do:
    if $children_v[l] \neq \{\}$ then
        a. Wait until all neighbors of $children_v[l]$ in $G[U_l]$ have received their final color
        b. Compute color correction as in Lemma 8
        c. For each $u \in children_v[l]$, send message SetColor($c$) to $u$, where $c$ is $u$'s new color
```

5.2 Analysis

To ensure correctness of our algorithm, we need to show that the parent of a node $v \in V_i$ is contained in a layer $j > i$. This is shown via the following lemma.

▶ **Lemma 11.** *Let $\mathcal{P} \in \mathcal{L}_i$, and let $W \subseteq V_i$ be the set of nodes whose corresponding subtrees are included in $\mathcal{P}$. Then every node $u \in \Gamma_{G[U_i]}(W)$ is contained in a layer V_j with $j > i$.*

It follows from the definition that the parent of a node $v \in V_i$ belongs to $\Gamma_{G[U_i]}(W)$. Hence:

▶ **Corollary 12.** *The parent of a node $v \in V_i$ is contained in a layer V_j with $j > i$.*

The following lemma demonstrates that Algorithm 2 mimics the behavior of our centralized algorithm and uses $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds. This establishes our main result, stated in Theorem 14.

▶ **Lemma 13.** *The global behavior of Algorithm 2 is identical to the behavior of Algorithm 1. Furthermore, Algorithm 2 runs in $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds.*

▶ **Theorem 14.** *For every $\varepsilon \geq \frac{2}{\chi(G)}$, there is a deterministic $(1+\varepsilon)$-approximation algorithm for* MVC *on chordal graphs that runs in $\mathrm{O}(\frac{1}{\varepsilon}\log n)$ rounds in the* LOCAL *model.*

6 Maximum Independent Set

Maximum Independent Set on Interval Graphs. Let $H = (V, E)$ be an interval graph, i.e., a chordal graph whose clique forest is a collection of paths. We first observe that the subset of nodes $V' \subseteq V$, with $u \in V'$ iff there exists a node $v \in V$ with $\Gamma_H[v] \subsetneq \Gamma_H[u]$, is not needed for the computation of a large maximum independent set: If a maximum independent set I^* in H contains a node $u \in V'$, then it can simply be replaced by a node v with $\Gamma_H[v] \subsetneq \Gamma_H[u]$. We thus only need to consider graph $H' := H[V \setminus V']$, which constitutes a unit interval graph. We first compute a distance-k maximal independent set I in $\mathrm{O}(k \log^* n)$ rounds, for some $k = \Theta(\frac{1}{\varepsilon})$, by simulating the maximal independent set $\mathrm{O}(\log^* n)$ rounds algorithm for bounded-independence graphs [38] on H'^k. Then, every $(v_1, v_2) \in P$, where P is the set of pairs of nodes of I that are of mutual distance at most $2k-1$, computes a maximum independent set I_{v_1,v_2} among the nodes *located between them* but outside of $\Gamma_{H'}(v_1) \cup \Gamma_{H'}(v_2)$ in $\mathrm{O}(k)$ rounds. Set $I \cup (\cup_{(v_1,v_2)\in P} I_{v_1,v_2})$ has the desired size.

▶ **Theorem 15.** *For every $\varepsilon > 0$, there is a deterministic $(1+\varepsilon)$-approximation algorithm for* MIS *on interval graphs that operates in $\mathrm{O}(\frac{1}{\varepsilon} \log^* n)$ rounds in the LOCAL model.*

Maximum Independent Set on Chordal Graphs. Our distributed MIS algorithm uses an adapted version of the peeling process used in our coloring algorithm. The key observation that allows us to obtain a runtime of $o(\log n)$ is the fact that the first $\mathrm{O}(\log \frac{1}{\varepsilon})$ layers computed by our peeling process already contain a large enough independent set. Our algorithm proceeds as follows: In each iteration $i = 1, \ldots, \mathrm{O}(\frac{1}{\varepsilon})$ of the peeling process, we remove set $\mathcal{L}_i$ of all pendant paths and all internal paths of large enough diameter from the clique forest $\mathcal{T}_i$ of the graph induced by the remaining nodes. Next, we compute large independent sets among the nodes whose trees are included in each path $\mathcal{P} \in \mathcal{L}_i$. If $\mathcal{P}$ has a large independence number then we run our $(1+\varepsilon)$-approximation algorithm for interval graphs in $\mathrm{O}(\frac{1}{\varepsilon} \log^* n)$ rounds. If $\mathcal{P}$ has small independence number we need to compute an optimal independent set in order to locally stay within a $(1+\varepsilon)$-approximation guarantee. This can be achieved using only $\mathrm{O}(\frac{1}{\varepsilon})$ rounds, since paths with small independence number necessarily have small diameter. The runtime is dominated by the product of the number of iterations $\mathrm{O}(\log \frac{1}{\varepsilon})$ and the $\mathrm{O}(\frac{1}{\varepsilon} \log^* n)$ runtime of our MIS algorithm for interval graphs.

▶ **Theorem 16.** *For any $\varepsilon \in (0, 1/2)$, there is a deterministic $(1+\varepsilon)$-approximation algorithm for* MIS *on chordal graphs that runs in $\mathrm{O}(\frac{1}{\varepsilon} \log(\frac{1}{\varepsilon}) \log^* n)$ rounds in the LOCAL model.*

When implementing this idea, care needs to be taken when combining the computed independent sets of different levels. Indeed, our algorithm bases the computation of the independent set in level i on the outcome of the computations of the independent sets of levels $< i$ and it seems difficult to avoid this. We therefore cannot execute the independent set computations of different levels simultaneously, which would reduce the runtime to $\mathrm{O}(\frac{1}{\varepsilon}(\log^* n + \log \frac{1}{\varepsilon}))$.

Lower Bound. Our lower bound is established on a path P_n of length n and uses an indistinguishability argument: Consider a k rounds MIS algorithm that operates on P_n, and let v be an arbitrary node that is not too close to an end point of the path. Suppose that v is selected into the independent set. Let u_1 be a node at distance $2k+1$ from v and let u_2 be the adjacent node to u_1 that is at distance $2k+2$ from v. Since the runtime of the algorithm is k, the outputs computed by u_1 and u_2 are independent from v. Since in average it is equally likely that u_1 or u_2 are selected, the expected size of an independent set in the subpath starting at v and ending at u_2 is thus strictly smaller than $k+2$, while a maximum independent set in this subpath is of size $k+2$. Based on this insight, we obtain

▶ **Theorem 17.** *For every $\varepsilon > 0$ and n large enough, every randomized algorithm in the LOCAL model with expected approximation factor at most $1+\varepsilon$ for* MIS *requires $\Omega(\frac{1}{\varepsilon})$ rounds.*

7 Conclusion

In this paper, we gave distributed $(1 + \varepsilon)$-approximation algorithms for MVC and MIS on chordal graphs. We showed that in chordal graphs network nodes can obtain coherent views of a global tree decomposition, which enabled us to exploit the tree structure of the input graph for the design of algorithms. How can we extend the class of graphs on which we can solve MVC and MIS within a small approximation factor even further? In particular, how can we handle graphs that contain longer induced cycles, such as k-chordal graphs (for some integer k)?

Abstract

Many systems have to be maintained while the underlying constraints, costs and/or profits change over time. Although the state of a system may evolve during time, a non-negligible transition cost is incured for transitioning from one state to another. In order to model such situations, Gupta et al. (ICALP 2014) and Eisenstat et al. (ICALP 2014) introduced a *multistage* model where the input is a sequence of instances (one for each time step), and the goal is to find a sequence of solutions (one for each time step) that simultaneously (i) have good quality on the time steps and (ii) as stable as possible. We focus on the *multistage* version of the KNAPSACK problem where we are given a time horizon $t = 1, 2, \dots, T$, and a sequence of knapsack instances $I_1, I_2, \dots, I_T$, one for each time step, defined on a set of n objects. In every time step t we have to choose a feasible knapsack S_t of I_t, which gives a *knapsack profit*. To measure the stability/similarity of two consecutive solutions S_t and S_{t+1}, we identify the objects for which the decision, to be picked or not, remains the same in S_t and S_{t+1}, giving a *transition profit*. We are asked to produce a sequence of solutions $S_1, S_2, \dots, S_T$ so that the total knapsack profit plus the overall transition profit is maximized.

We propose a PTAS for the MULTISTAGE KNAPSACK problem. This is the first approximation scheme for a combinatorial optimization problem in the considered multistage setting, and its existence contrasts with the inapproximability results for other combinatorial optimization problems that are even polynomial-time solvable in the static case (e.g.MULTISTAGE SPANNING TREE, or MULTISTAGE BIPARTITE PERFECT MATCHING). Then, we prove that there is no FPTAS for the problem even in the case where $T = 2$, unless $P = NP$. Furthermore, we give a pseudopolynomial time algorithm for the case where the number of steps is bounded by a fixed constant and we show that otherwise the problem remains NP-hard even in the case where all the weights, profits and capacities are 0 or 1.

1 Introduction

In a classical combinatorial optimization problem, given an instance of the problem we seek a feasible solution optimizing the objective function. However, in many systems the input may change over the time and the solution has to be adapted to the input changes. It is then necessary to determine a tradeoff between the optimality of the solutions in each time step and the stability/similarity of consecutive solutions. This is important since in many applications there is a significant transition cost for changing (parts of) a solution. Recently,

Gupta et al. [15] and Eisenstat et al. [11] introduced a *multistage* model in order to deal with such situations. They consider that the input is a sequence of instances (one for each time step), and the goal is to find a sequence of solutions (one for each time step) reaching such a tradeoff.

Our work follows the direction proposed by Gupta et al. [15] who suggested the study of more combinatorial optimization problems in their multistage framework. In this paper, we focus on the multistage version of the KNAPSACK problem. Consider a company owning a set $N = \{u_1, \dots, u_n\}$ of production units. Each unit can be used or not; if u_i is used, it spends an amount w_i of a given resource (energy, raw material,...), and generates a profit p_i. Given a bound W on the global amount of available resource, the static KNAPSACK problem aims at determining a feasible solution that specifies the chosen units in order to maximize the total profit under the constraint that the total amount of the resource does not exceed the bound of W. In a multistage setting, considering a time horizon $t = 1, 2, \dots, T$ of, let us say, T days, the company needs to decide a production plan for each day of the time horizon, given that data (such as prices, level of resources,...) usually change over time. This is a typical situation, for instance, in energy production planning (like electricity production, where units can be nuclear reactors, wind or water turbines,...), or in data centers (where units are machines and the resource corresponds to the available energy). Moreover, in these examples, there is an extra cost to turn ON or OFF a unit like in the case of turning ON/OFF a reactor in electricity production [25], or a machine in a data center [1]. Obviously, whenever a reactor is in the ON or OFF state, it is beneficial to maintain it at the same state for several consecutive time steps, in order to avoid the overhead costs of state changes. Therefore, the design of a production plan over a given time horizon has to take into account both the profits generated each day from the operation of the chosen units, as well as the potential transition profits from maintaining a unit at the same state for two consecutive days.

We formalize the problem as follows. We are given a time horizon $t = 1, 2, \dots, T$, and a sequence of knapsack instances $I_1, I_2, \dots, I_T$, one for each time step, defined on a set of n objects. In every time step t we have to choose a feasible knapsack S_t of I_t, which gives a *knapsack profit.* Taking into account transition costs, we measure the stability/similarity of two consecutive solutions S_t and S_{t+1} by identifying the objects for which the decision, to be picked or not, remains the same in S_t and S_{t+1}, giving a *transition profit.* We are asked to produce a sequence of solutions $S_1, S_2, \dots, S_T$ so that the total knapsack profit plus the overall transition profit is maximized.

Our main contribution is a polynomial time approximation scheme (PTAS) for the multistage version of the KNAPSACK problem. Up to the best of our knowledge, this is the first approximation scheme for a multistage combinatorial optimization problem and its existence contrasts with the inapproximability results for other combinatorial optimization problems that are even polynomial-time solvable in the static case (e.g. MULTISTAGE SPANNING TREE [15], or MULTISTAGE BIPARTITE PERFECT MATCHING [4]).

1.1 Problem definition

Formally, the MULTISTAGE KNAPSACK problem can be defined as follows.

▶ **Definition 1.** *In the* MULTISTAGE KNAPSACK *problem (MK) we are given:*

- *a time horizon $T \in \mathbb{N}^*$, a set $N = \{1, 2, \dots, n\}$ of objects;*
- *For any $t \in \{1, \dots, T\}$, any $i \in N$:*
  - *p_{ti} the profit of taking object i at time t*
  - *w_{ti} the weight of object i at time t*

- *For any $t \in \{1, \ldots, T-1\}$, any $i \in N$: $B_{ti} \in \mathbb{R}^+$ the bonus of the object i if we keep the same decision for i at time t and $t+1$.*
- *For any $t \in \{1, \ldots, T\}$: the capacity C_t of the knapsack at time t.*

We are asked to select a subset $S_t \subseteq N$ of objects at each time t so as to respect the capacity constraint: $\sum_{i \in S_t} w_{ti} \leq C_t$. To a solution $S = (S_1, \ldots, S_T)$ are associated:

- *A knapsack profit $\sum_{t=1}^{T} \sum_{i \in S_t} p_{ti}$ corresponding to the sum of the profits of the T knapsacks;*
- *A transition profit $\sum\limits_{t=1}^{T-1} \sum\limits_{i \in \Delta_t} B_{ti}$ where Δ_t is the set of objects either taken or not taken at both time steps t and $t+1$ in S (formally $\Delta_t = (S_t \cap S_{t+1}) \cup (\overline{S_t} \cap \overline{S_{t+1}})$).*

The value of the solution S is the sum of the knapsack profit and the transition profit, to be maximized.

1.2 Related works

Multistage combinatorial optimization. A lot of optimization problems have been considered in online or semi-online settings, where the input changes over time and the algorithm has to modify the solution by making as few changes as possible. Tradeoffs between modification costs and quality of solutions have been also studied in the reoptimization setting. We refer the reader to [3, 6, 10, 14, 22, 23, 26] and the references therein.

Multistage optimization has been studied for fractional problems by Buchbinder et al. [8] and Buchbinder, Chen and Naor [7]. The multistage model considered in this article is the one studied in Eisenstat et al. [11] and Gupta et al. [15]. Eisenstat et al. [11] studied the multistage version of facility location problems. They proposed a logarithmic approximation algorithm. An et al. [2] obtained constant factor approximation for some related problems. Gupta et al. [15] studied the Multistage Maintenance Matroid problem for both the offline and the online settings. They presented a logarithmic approximation algorithm for this problem, which includes as a special case a natural multistage version of Spanning Tree. The same paper also introduced the study of the Multistage Minimum Perfect Matching problem. They showed that the problem becomes hard to approximate even for a constant number of stages. Later, Bampis et al. [4] showed that the problem is hard to approximate even for bipartite graphs and for the case of two time steps. In the case where the edge costs are metric within every time step they first proved that the problem remains APX-hard even for two time steps. They also showed that the maximization version of the problem admits a constant factor approximation algorithm but is APX-hard. In another work [5], the Multistage Max-Min Fair Allocation problem has been studied in the offline and the online settings. This corresponds to a multistage variant of the Santa Klaus problem. For the off-line setting, the authors showed that the multistage version of the problem is much harder than the static one. They provided constant factor approximation algorithms for the off-line setting.

Knapsack variants. Our work builds upon the Knapsack literature [18]. It is well known that there is a simple 2-approximation algorithm as well as a fully polynomial time (FPTAS) for the static case [16, 20, 21, 17]. There are two variants that are of special interest for our work:

(i) The first variant is a generalization of the Knapsack problem known as the k-Dimensional Knapsack ($k - DKP$) problem:

▶ **Definition 2.** *In the k-*Dimensional Knapsack *problem ($k - DKP$), we have a set $N = \{1, 2, \dots, n\}$ of objects. Each object i has a profit p_i and k weights w_{ji}, $j = 1, \dots, k$. We are also given k capacities C_j. The goal is to select a subset $Y \subseteq N$ of objects such that:*

- *The capacity constraints are respected: for any j, $\sum_{i \in Y} w_{ji} \leq C_j$;*
- *The profit $\sum_{i \in Y} p_i$ is maximized.*

It is well known that for the usual Knapsack problem, in the continuous relaxation (variables in $[0, 1]$), at most one variable is fractional. Caprara et al. [9] showed that this can be generalized for $k - DKP$.

Let us consider the following ILP formulation ($ILP - DKP$) of the problem:

$$\begin{cases} \max \sum\limits_{i \in N} p_i y_i \\ s.t. \left| \begin{array}{lcll} \sum\limits_{i \in N} w_{ji} y_i & \leq & C_j & \forall j \in \{1, ..., k\} \\ y_i \in \{0, 1\} & & & \forall i \in N \end{array} \right. \end{cases}$$

▶ **Theorem 3.** *[9] In the continuous relaxation ($LP - DKP$) of ($ILP - DKP$) where variables are in $[0, 1]$, in any basic solution at most k variables are fractional.*

A basic solution is an extreme point (vertex) of the polytope of solutions. Note that with an easy affine transformation on variables, the same result holds when variable y_i is subject to $a_i \leq y_i \leq b_i$ instead of $0 \leq y_i \leq 1$: *in any basic solution at most k variables y_i are such that $a_i < y_i < b_i$.*

Caprara et al. [9] use the result of Theorem 3 to show that for any fixed constant k, $k - DKP$ admits a polynomial time approximation scheme (PTAS). Other PTASes have been presented in [24, 12]. Korte and Schrader [19] showed that there is no FPTAS for $k - DKP$ unless $P = NP$.

(ii) The second related variant is a simplified version of $k - DKP$ called Cardinality-2-KP, where the dimension is 2, all the profits are 1 and, given a K, we are asked if there is a solution of value at least K (decision problem). In other words, given two knapsack constraints, can we take K objects and verify the two constraints? The following result is shown in [18].

▶ **Theorem 4.** *[18]* Cardinality-2-KP *is NP-complete.*

1.3 Our contribution

As stated before, our main contribution is to propose a PTAS for the multistage Knapsack problem. Furthermore, we prove that there is no FPTAS for the problem even in the case where $T = 2$, unless $P = NP$. We also give a pseudopolynomial time algorithm for the case where the number of steps is bounded by a fixed constant and we show that otherwise the problem remains NP-hard even in the case where all the weights, profits and capacities are 0 or 1. The following table summarizes our main result pointing out the impact of the number T of time steps on the difficulty of the problem ("no FPTAS" means "no FPTAS unless P=NP").

$T = 1$	T fixed	any T
pseudopolynomial	pseudopolynomial	strongly NP-hard
FPTAS	PTAS	PTAS
-	no FPTAS	no FPTAS

We point out that the negative results (strongly NP-hardness and no FPTAS) hold even in the case of *uniform bonus*, i.e., when $B_{ti} = B$ for all $i \in N$ and all $t = 1, \dots, T - 1$.

2 ILP formulation

The Multistage Knapsack problem can be written as an ILP as follows. We define Tn binary variables x_{ti} equal to 1 if i is taken at time t ($i \in S_t$) and 0 otherwise. We also define $(T-1)n$ binary variables z_{ti} corresponding to the transition profit of object i between time t and $t+1$. The profit is 1 if i is taken at both time steps, or taken at none, and 0 otherwise. Hence, $z_{ti} = 1 - |x_{(t+1)i} - x_{ti}|$. Considering that we solve a maximization problem, this can be linearized by the two inequalities: $z_{ti} \leq -x_{(t+1)i} + x_{ti} + 1$ and $z_{ti} \leq x_{(t+1)i} - x_{ti} + 1$. We end up with the following ILP (called $ILP - MK$):

$$\begin{cases} \max \sum_{t=1}^{T} \sum_{i \in N} p_{ti} x_{ti} + \sum_{t=1}^{T-1} \sum_{i \in N} z_{ti} B_{ti} & \\ s.t. \left| \begin{array}{llll} \sum_{i \in N} w_{ti} x_{ti} & \leq & C_t & \forall t \in \{1, ..., T\} \\ z_{ti} & \leq & -x_{(t+1)i} + x_{ti} + 1 & \forall t \in \{1, ..., T-1\}, \forall i \in N \\ z_{ti} & \leq & x_{(t+1)i} - x_{ti} + 1 & \forall t \in \{1, ..., T-1\}, \forall i \in N \\ x_{ti} \in \{0,1\} & & & \forall t \in \{1, ..., T\}, \forall i \in N \\ z_{ti} \in \{0,1\} & & & \forall t \in \{1, ..., T-1\}, \forall i \in N \end{array} \right. \end{cases}$$

In devising the PTAS we will extensively use the linear relaxation $(LP - MK)$ of $(ILP - MK)$ where variables x_{ti} and z_{ti} are in $[0,1]$.

3 A polynomial time approximation scheme

In this section we show that Multistage Knapsack admits a PTAS. The central part of the proof is to derive a PTAS when the number of steps is a fixed constant (Sections 3.1 and 3.2). The generalization to an arbitrary number of steps is done in Section 3.3.

Building upon [9], our PTAS for a fixed number of time steps heavily relies on a property of the relaxed LP-formulation of Multistage Knapsack: we show that there are at most T^3 fractional variables in an optimal (basic) solution of the (relaxed) Multistage Knapsack problem. Based on this bound, the PTAS is built from a combination of (1) bruteforce search (to find the most profitable objects), (2) a preprocessing step and (3) a rounding of the fractional solution of the (relaxed) LP-formulation. The preprocessing step associated to the bound on the number of fractional variables allow to bound the global loss of the solution built by the algorithm.

We show how to bound the number of fractional variables in Section 3.1. We first illustrate the reasoning on the case of two time-steps, and then present the general result. In Section 3.2 we present the PTAS for a constant number of steps. For ease of notation, we will sometimes write a feasible solution as $S = (S_1, \ldots, S_T)$ (subsets of objects taken at each time step), or as $S = (x, z)$ (values of variables in $(ILP - MK)$ or $(LP - MK)$).

3.1 Bounding the number of fractional objects in $(LP - MK)$

3.1.1 Warm-up: the case of two time-steps

We consider in this section the case of two time-steps ($T = 2$), and focus on the linear relaxation $(LP - MK)$ of $(ILP - MK)$ with the variables x_{ti} and z_i in $[0,1]$ (we write z_i instead of z_{1i} for readability). We say that an object is *fractional* in a solution S if x_{1i}, x_{2i} or z_i is fractional.

Let us consider a (feasible) solution $\hat{S} = (\hat{x}, \hat{z})$ of $(LP - MK)$, where $\hat{z}_i = 1 - |\hat{x}_{2i} - \hat{x}_{1i}|$ (variables $\hat{z}_i$ are set to their optimal value w.r.t. $\hat{x}$). We show the following.

▶ **Proposition 5.** *If $\hat{S}$ is a basic solution of $(LP - MK)$, at most 4 objects are fractional.*

Proof. First note that since we assume $\hat{z}_i = 1 - |\hat{x}_{1i} - \hat{x}_{2i}|$, if $\hat{x}_{1i}$ and $\hat{x}_{2i}$ are both integers then $\hat{z}_i$ is an integer. So if an object i is fractional either $\hat{x}_{1i}$ or $\hat{x}_{2i}$ is fractional.

Let us denote:

- L the set of objects i such that $\hat{x}_{1i} = \hat{x}_{2i}$.
- $P = N \setminus L$ the set of objects i such that $\hat{x}_{1i} \neq \hat{x}_{2i}$.

We first show Fact 1.

Fact 1. In P there is at most one object i with $\hat{x}_{1i}$ fractional.

Suppose that there are two such objects i and j. Note that since $0 < |\hat{x}_{1i} - \hat{x}_{2i}| < 1$, $\hat{z}_i$ is fractional, and so is $\hat{z}_j$. Then, for a sufficiently small $\epsilon > 0$, consider the solution S_1 obtained from $\hat{S}$ by transfering at time 1 an amount ϵ of weight from i to j (and adjusting consequently z_i and z_j). Namely, in S_1:

- $x^1_{1i} = \hat{x}_{1i} - \frac{\epsilon}{w_{1i}}$, $z^1_i = \hat{z}_i - d_i \frac{\epsilon}{w_{1i}}$, where $d_i = 1$ if $\hat{x}_{2i} > \hat{x}_{1i}$ and $d_i = -1$ if $\hat{x}_{2i} < \hat{x}_{1i}$ (since i is in P $\hat{x}_{2i} \neq \hat{x}_{1i}$).
- $x^1_{1j} = \hat{x}_{1j} + \frac{\epsilon}{w_{1j}}$, $z^1_j = \hat{z}_i + d_j \frac{\epsilon}{w_{1j}}$, where $d_j = 1$ if $\hat{x}_{2j} > \hat{x}_{1j}$ and $d_j = -1$ otherwise.

Note that (for ϵ sufficiently small) S_1 is feasible. Indeed (1) $\hat{x}_{1i}, \hat{x}_{1j}, \hat{z}_i$ and $\hat{z}_j$ are fractional (2) the weight of the knapsack at time 1 is the same in S_1 and in $\hat{S}$ (3) if $\hat{x}_{1i}$ increases by a small δ, if $\hat{x}_{2i} > \hat{x}_{1i}$ then $|\hat{x}_{2i} - \hat{x}_{i1}|$ decreases by δ so $\hat{z}_i$ can increase by δ (so $d_i = 1$), and if $\hat{x}_{2i} < \hat{x}_{i1}$ then $\hat{z}_i$ has to decrease by δ (so $d_i = -1$), and similarly for $\hat{x}_{1j}$.

Similarly, let us define S_2 obtained from $\hat{S}$ with the reverse transfer (from j to i). In S_2:

- $x^2_{1i} = \hat{x}_{1i} + \frac{\epsilon}{w_{1i}}$, $z^2_i = \hat{z}_i + d_i \frac{\epsilon}{w_{1i}}$
- $x^2_{1j} = \hat{x}_{1j} - \frac{\epsilon}{w_{1j}}$, $z^2_j = \hat{z}_i - d_j \frac{\epsilon}{w_{1j}}$

As previously, S_2 is feasible. Then $\hat{S}$ is clearly a convex combination of S_1 and S_2 (with coefficient 1/2), so not a basic solution, and Fact 1 is proven.

In other words (and this interpretation will be important in the general case), for this case we can focus on variables at time one, and interpret *locally* the problem as a (classical, unidimensional) fractional knapsack problem. By locally, we mean that we consider as fixed the variables at time 2: for variables at time 1, if $\hat{x}_{1i} < \hat{x}_{2i}$ then x_{1i} must be in $[0, \hat{x}_{2i}]$ (in S^1, x^1_{1i} cannot be larger than $\hat{x}_{2i}$, otherwise the previous value of z^1_i would be erroneous); similarly if $\hat{x}_{1i} > \hat{x}_{2i}$ then x_{1i} must be in $[\hat{x}_{2i}, 1]$. The profit associated to object i is $p_{1i} + d_i B_{1i}$ (if x_{i1} increases/decreases by ϵ, then the knapsack profit increases/decreases by $p_{1i}\epsilon$, and the transition profit increases/decreases by $\epsilon d_i B_{1i}$, as explained above). Then we have at most one fractional variable, as in any fractional knapsack problem.

In P there is at most one object i with $\hat{x}_{1i}$ fractional. Similarly there is at most one object k with $\hat{x}_{2k}$ fractional. In P, for all but at most two objects, both $\hat{x}_{1i}$ and $\hat{x}_{2i}$, and thus $\hat{z}_i$, are integers.

Note that this argument would not hold for variables in L. Indeed if $\hat{x}_{1i} = \hat{x}_{2i}$, then $\hat{z}_i = 1$, and the transition profit decreases in *both* cases: when $\hat{x}_{1i}$ increases by $\delta > 0$ and when it decreases by δ. So, we cannot express $\hat{S}$ as a convex combination of S_1 and S_2 as previously.

However, let us consider the following linear program $2-DKP$ obtained by fixing variables in P to their values in $\hat{S}$, computing the remaining capacities $C'_t = C_t - \sum_{j \in P} w_{tj}\hat{x}_{tj}$, and "imposing" $x_{1i} = x_{2i}$:

$$\begin{cases} \max \sum\limits_{i\in L}(p_{1i}+p_{2i})y_i + \sum\limits_{i\in L} B_{1i} & & \\ \qquad\sum\limits_{i\in L} w_{1i}y_i & \leq & C'_1 \\ \qquad\sum\limits_{i\in L} w_{2i}y_i & \leq & C'_2 \\ \qquad y_i \in [0,1] & & \forall i \in L \end{cases}$$

Clearly, the restriction of $\hat{S}$ to variables in L is a solution of $2-DKP$. Formally, let $\hat{S}_L = (\hat{y}_j, j \in L)$ defined as $\hat{y}_j = \hat{x}_{1j}$. $\hat{S}_L$ is feasible for $2-DKP$. Let us show that it is basic: suppose a contrario that $\hat{S}_L = \frac{S^1_L+S^2_L}{2}$, with $S^1_L = (y^1_i, i \in L) \neq S^2_L$ two feasible solutions of $2-DKP$. Then consider the solution $S^1 = (x^1, y^1)$ of $(LP-MK)$ defined as:

- If $i \in L$ then $x^1_{1i} = x^1_{2i} = y^1_i$, and $z^1_{1i} = 1 = \hat{z}_{1i}$.
- Otherwise (for i in P) S^1 is the same as $\hat{S}$.

S^1 is clearly a feasible solution of MULTISTAGE KNAPSACK. If we do the same for S^2_L, we get a (different) feasible solution S^2, and $\hat{S} = \frac{S^1+S^2}{2}$, so $\hat{S}$ is not basic, a contradiction.

By the result of [9], $\hat{S}_L$ has at most 2 fractional variables. Then, in L, for all but at most 2 variables both $\hat{x}_{1i}$, $\hat{x}_{2i}$ and $\hat{z}_i$ are integers. ◀

3.1.2 General case

The case of 2 time steps suggests to bound the number of fractional objects by considering 3 cases:

- Objects with $\hat{x}_{1i}$ fractional and $\hat{x}_{1i} \neq \hat{x}_{2i}$. As explained in the proof of Proposition 5, this can be seen locally (as long as x_{1i} does not reach $\hat{x}_{2i}$) as a knapsack problem from which we can conclude that there is at most 1 such fractional object.
- Similarly, objects with $\hat{x}_{2i}$ fractional and $\hat{x}_{1i} \neq \hat{x}_{2i}$.
- Objects with $\hat{x}_{1i} = \hat{x}_{2i}$ fractional. As explained in the proof of Proposition 5, this can be seen as a $2-DKP$ from which we can conclude that there are at most 2 such fractional objects.

For larger T, we may have different situations. Suppose for instance that we have 5 time steps, and a solution (x, z) with an object i such that: $x_{1i} < x_{2i} = x_{3i} = x_{4i} < x_{5i}$. So we have x_{ti} fractional and constant for $t = 2, 3, 4$, and different from x_{1i} and x_{5i}. The idea is to say that we cannot have many objects like this (in a basic solution), by interpreting these objects on time steps $3, 4, 5$ as a basic optimal solution of a $3-DKP$ (locally, i.e. with a variable y_i such that $x_{1i} \leq y_i \leq x_{5i}$).

Then, roughly speaking, the idea is to show that for any pair of time steps $t_0 \leq t_1$, we can bound the number of objects which are fractional and constant on this time interval $[t_0, t_1]$ (but not at time $t_0 - 1$ and $t_1 + 1$). Then a sum on all the possible choices of (t_0, t_1) gives the global upper bound.

Let us state this rough idea formally. In all this section, we consider a (feasible) solution $\hat{S} = (\hat{x}, \hat{z})$ of $(LP-MK)$, where $\hat{z}_{ti} = 1 - |\hat{x}_{(t+1)i} - \hat{x}_{ti}|$ (variables $\hat{z}_{ti}$ are set to their optimal value w.r.t. $\hat{x}$).

In such a solution $\hat{S} = (\hat{x}, \hat{z})$, let us define as previously an object as *fractional* if at least one variable $\hat{x}_{ti}$ or $\hat{z}_{ti}$ is fractional. Our goal is to show the following result.

▶ **Theorem 6.** *If $\hat{S} = (\hat{x}, \hat{z})$ is a basic solution of $(LP - MK)$, it has at most T^3 fractional objects.*

Before proving the theorem, let us introduce some definitions and show some lemmas. Let t_0, t_1 be two time steps with $1 \leq t_0 \leq t_1 \leq T$.

▶ **Definition 7.** *The set $F(t_0, t_1)$ associated to $\hat{S} = (\hat{x}, \hat{z})$ is the set of objects i (called fractional w.r.t. (t_0, t_1)) such that*

- $0 < \hat{x}_{t_0 i} = \hat{x}_{(t_0+1)i} = \cdots = \hat{x}_{t_1 i} < 1$*;*
- *Either $t_0 = 1$ or $\hat{x}_{(t_0-1)i} \neq \hat{x}_{t_0 i}$;*
- *Either $t_1 = T$ or $\hat{x}_{(t_1+1)i} \neq \hat{x}_{t_1 i}$;*

In other words, we have $\hat{x}_{ti}$ fractional and constant on $[t_0, t_1]$, and $[t_0, t_1]$ is maximal w.r.t. this property.

For $t_0 \leq t \leq t_1$, we note C'_t the remaining capacity of knapsack at time t considering that variables outside $F(t_0, t_1)$ are fixed (to their value in $\hat{x}$):

$$C'_t = C_t - \sum_{i \notin F(t_0, t_1)} w_{ti} \hat{x}_{ti}.$$

As previously, we will see $x_{t_0 i}, \ldots, x_{t_1 i}$ as a single variable y_i. We have to express the fact that this variable y_i cannot "cross" the values $\hat{x}_{(t_0-1)i}$ (if $t_0 > 1$) and $\hat{x}_{(t_1+1)i}$ (if $t_1 < T$), so that everything remains locally (in this range) linear. So we define the lower and upper bounds a_i, b_i induced by Definition 7 as:

- Initialize $a_i \leftarrow 0$. If $\hat{x}_{(t_0-1)i} < \hat{x}_{t_0 i}$ then do $a_i \leftarrow \hat{x}_{(t_0-1)i}$. If $\hat{x}_{(t_1+1)i} < \hat{x}_{t_1 i}$ then do $a_i \leftarrow \max(a_i, \hat{x}_{(t_1+1)i})$.
- Similarly, initialize $b_i \leftarrow 1$. If $\hat{x}_{(t_0-1)i} > \hat{x}_{t_0 i}$ then do $b_i \leftarrow \hat{x}_{(t_0-1)i}$. If $\hat{x}_{(t_1+1)i} > \hat{x}_{t_1 i}$ then do $b_i \leftarrow \min(b_i, \hat{x}_{(t_1+1)i})$.

Note that with this definition $a_i < \hat{x}_{t_0,i} < b_i$. This allows us to define the polyhedron $P(t_0, t_1)$ as the set of $y = (y_i : i \in F(t_0, t_1))$ such that

$$\begin{cases} \sum\limits_{i \in F(t_0,t_1)} w_{ti} y_i & \leq & C'_t & \forall t \in \{t_0, ..., t_1\} \\ a_i \leq y_i \leq b_i & & & \forall i \in F(t_0, t_1) \end{cases}$$

▶ **Definition 8.** *The solution $\hat{y}$ associated to $\hat{S} = (\hat{x}, \hat{z})$ is defined as $\hat{y}_i = \hat{x}_{t_0 i}$ for $i \in F(t_0, t_1)$.*

▶ **Lemma 9.** *If $\hat{S} = (\hat{x}, \hat{z})$ is a basic solution, then the solution $\hat{y}$ associated to $(\hat{x}, \hat{z})$ is feasible of $P(t_0, t_1)$ and basic.*

Proof. Since $(\hat{x}, \hat{z})$ is feasible, then $\hat{y}$ respects the capacity constraints (remaining capacity), and $a_i < \hat{y}_i = \hat{x}_{t_0 i} < b_i$ so $\hat{y}$ is feasible.

Suppose now that $\hat{y} = \frac{y^1 + y^2}{2}$ for two feasible solutions $y^1 \neq y^2$ of $P(t_0, t_1)$. We associate to y^1 a feasible solution $S^1 = (x^1, z^1)$ as follows.

For any object i, we fix $x^1_{ti} = \hat{x}_i$ for $t \notin [t_0, t_1]$, and $x^1_{ti} = y^1_i$ for $t \in [t_0, t_1]$. We fix variables z^1_{it} to their maximal values, i.e. $z^1_{ti} = 1 - |x^1_{(t+1)i} - x^1_{ti}|$. This way, we get a feasible solution (x^1, z^1). Note that:

- $z^1_{ti} = \hat{z}_{ti}$ for $t \notin [t_0 - 1, t_1]$, since coresponding variables x are the same in S^1 and $\hat{S}$;
- $z^1_{ti} = 1 = \hat{z}_{ti}$ for $t \in [t_0, t_1 - 1]$, since variables x are constant on the interval $[t_0, t_1]$.

Then, for variables z, the only modifications between z^1 and $\hat{z}$ concern the "boundary" variables z^1_{ti} for $t = t_0 - 1$ and $t = t_1$.

We build this way two solutions $S^1 = (x^1, z^1)$ and $S^2 = (x^2, z^2)$ of $(LP - MK)$ corresponding to y^1 and y^2. By construction, S^1 and S^2 are feasible. They are also different provided that y^1 and y^2 are different. It remains to prove that $\hat{S} = (S^1 + S^2)/2$.

Let us first consider variables x:

- if $t \notin [t_0, t_1]$, $x^1_{ti} = x^2_{ti} = \hat{x}_{ti}$ so $\hat{x}_{ti} = \frac{x^1_{ti}+x^2_{ti}}{2}$.
- if $t \in [t_0, t_1]$, $x^1_{ti} = y^1_i$ and $x^2_{ti} = y^2_t$, so $\frac{x^1_{ti}+x^2_{ti}}{2} = \frac{y^1_i+y^2_i}{2} = \hat{y}_i = \hat{x}_{ti}$.

Now let us look at variables z: first, for $t \notin \{t_0 - 1, t_1\}$, $z^1_{ti} = z^2_{ti} = \hat{z}_{ti}$ so $\hat{z}_{ti} = \frac{z^1_{ti}+z^2_{ti}}{2}$. The last and main part concerns the last 2 variables $z_{(t_0-1)i}$ (if $t_0 > 1$) and $z_{t_1 i}$ (if $t_1 < T$).

We have $z^1_{(t_0-1)i} = 1 - |x^1_{t_0 i} - x^1_{(t_0-1)i}| = 1 - |x^1_{t_0 i} - \hat{x}_{(t_0-1)i}|$ and $\hat{z}_{(t_0-1)i} = 1 - |\hat{x}_{t_0 i} - \hat{x}_{(t_0-1)i}|$. The crucial point is to observe that thanks to the constraint $a_i \leq y_i \leq b_i$, and by definition of a_i and b_i, $x^1_{t_0,i}$, $x^2_{t_0,i}$ and $\hat{x}_{t_0,i}$ are either all greater than (or equal to) $\hat{x}_{(t_0-1)i}$, or all lower than (or equal to) $\hat{x}_{(t_0-1)i}$.

Suppose first that they are all greater than (or equal to) $\hat{x}_{(t_0-1)i}$. Then $z^1_{(t_0-1)i} - \hat{z}_{(t_0-1)i} = |\hat{x}_{t_0,i} - \hat{x}_{t_0-1,i}| - |x^1_{t_0,i} - \hat{x}_{t_0-1,i}| = \hat{x}_{t_0 i} - x^1_{t_0 i} = \hat{y}_i - y^1_i$.

Similarly, $z^2_{(t_0-1)i} - \hat{z}_{(t_0-1)i} = \hat{y}_i - y^2_i$. So $\frac{z^1_{(t_0-1)i}+z^2_{(t_0-1)i}}{2} = \frac{2\hat{z}_{(t_0-1)i}+2\hat{y}_i-y^1_i-y^2_i}{2} = \hat{z}_{(t_0-1)i}$.

Now suppose that they are all lower than (or equal to) $\hat{x}_{t_0-1,i}$. Then:

$$z^1_{(t_0-1)i} - \hat{z}_{(t_0-1)i} = |\hat{x}_{t_0 i} - \hat{x}_{(t_0-1)i}| - |x^1_{t_0 i} - \hat{x}_{(t_0-1)i}| = x^1_{t_0 i} - \hat{x}_{t_0 i} = y^1_i - \hat{y}_i$$

Similarly, $z^2_{(t_0-1)i} - \hat{z}_{(t_0-1)i} = y^2_i - \hat{y}_i$. So $\frac{z^1_{(t_0-1)i}+z^2_{(t_0-1)i}}{2} = \frac{2\hat{z}_{(t_0-1)i}-2\hat{y}_i+y^1_i+y^2_i}{2} = \hat{z}_{(t_0-1)i}$.

Then, in both cases, $\hat{z}_{(t_0-1)i} = \frac{z^1_{(t_0-1)i}+z^2_{(t_0-1)i}}{2}$.

With the very same arguments we can show that $\frac{z^1_{t_1 i}+z^2_{t_1 i}}{2} = \hat{z}_{t_1 i}$. Then, $\hat{S}$ is the half sum of S^1 and S^2, contradiction with the fact that $\hat{S}$ is basic. ◀

Now we can bound the number of fractional objects w.r.t. (t_0, t_1).

▶ **Lemma 10.** $|F(t_0, t_1)| \leq t_1 + 1 - t_0$.

Proof. $P(t_0, t_1)$ is a polyhedron corresponding to a linear relaxation of a $k - DLP$, with $k = t_1 + 1 - t_0$. Since $\hat{y}$ is basic, using Theorem 3 (and the note after) there are at most $k = t_1 + 1 - t_0$ variables $\hat{y}_i$ such that $a_i < \hat{y}_i < b_i$. But by definition of $F(t_0, t_1)$, for all $i \in F(t_0, t_1)$ $a_i < \hat{y}_i < b_i$. Then $|F(t_0, t_1)| \leq t_1 + 1 - t_0$. ◀

Now we can easily prove Theorem 6.

Proof. First note that if $\hat{x}_{ti}$ and $\hat{x}_{(t+1)i}$ are integral, then so is $\hat{z}_{ti}$. Then, if an object i is fractional at least one $\hat{x}_{ti}$ is fractional, and so i will appear in (at least) one set $F(t_0, t_1)$.

We consider all pairs (t_0, t_1) with $1 \leq t_0 \leq t_1 \leq T$. Thanks to Lemma 10, $|F(t_0, t_1)| \leq t_1 + 1 - t_0$. So, the total number of fractional objects is at most:

$$N_T = \sum_{t_0=1}^{T} \sum_{t_1=t_0}^{T} (t_1 + 1 - t_0) \leq T^3$$

Indeed, there are less than T^2 choices for (t_0, t_1) and at most T fractional objects for each choice. ◀

Note that with standard calculation we get $N_T = \frac{T^3+3T^2+2T}{6}$, so for $T = 2$ time steps $N_2 = 4$: we have at most 4 fractional objects, the same bound as in Proposition 5.

3.2 A PTAS for a constant number of time steps

Now we can describe the $PTAS$. Informally, the algorithm first guesses the ℓ objects with the maximum reward in an optimal solution (where ℓ is defined as a function of ϵ and T), and then finds a solution on the remaining instance using the relaxation of the LP. The fact that the number of fractional objects is small allows to bound the error made by the algorithm.

For a solution S (either fractional or integral) we define $g_i(S)$ as the reward of object i in solution S: $g_i(S) = \sum_{t=1}^{T} p_{ti}x_{ti} + \sum_{t=1}^{T-1} z_{ti}B_{ti}$. The value of a solution S is $g(S) = \sum_{i\in N} g_i(S)$.

Consider the algorithm A^{LP} which, on an instance of Multistage Knapsack:

- Finds an optimal (basic) solution $S^r = (x^r, z^r)$ of the relaxation $(LP - MK)$ of $(ILP - MK)$;
- Takes at step t an object i if and only if $x^r_{ti} = 1$.

Clearly, A^{LP} outputs a feasible solution, the value of which verifies:

$$g(A^{LP}) \geq g(S^r) - \sum_{i\in F} g_i(S^r) \tag{1}$$

where F is the set of fractional objects in S^r. Indeed, for each integral (i.e., not fractional) object the reward is the same in both solutions.

Now we can describe the algorithm **Algorithm $\boldsymbol{PTAS_{ConstantMK}}$**, which takes as input an instance of Multistage Knapsack and an $\epsilon > 0$, and works as follows.

1. Let $\ell := \min\left\{\left\lceil \frac{(T+1)T^3}{\epsilon}\right\rceil, n\right\}$.
2. For all $X \subseteq N$ such that $|X| = \ell$, $\forall X_1 \subseteq X, ..., \forall X_T \subseteq X$:
   If for all $t = 1, \ldots, T$ $w_t(X_t) = \sum_{j\in X_t} w_{tj} \leq C_t$, then:
   - Compute the rewards of object $i \in X$ in the solution $(X_1, \ldots, X_T)$, and find the smallest one, say k, with reward g_k.
   - On the subinstance of objects $Y = N \setminus X$:
     - For all $i \in Y$, for all $t \in \{1, \ldots, T\}$: if $p_{ti} > g_k$ then set $x_{ti} = 0$.
     - apply A^{LP} on the subinstance of objects Y, with the remaining capacity $C'_t = C_t - w_t(X_t)$, where some variables x_{ti} are set to 0 as explained in the previous step.
   - Let $(Y_1, ..., Y_T)$ be the sets of objects taken at time $1, \ldots, T$ by A^{LP}. Consider the solution $(X_1 \cup Y_1, ..., X_T \cup Y_T)$.
3. Output the best solution computed.

▶ **Theorem 11.** *The algorithm $PTAS_{ConstantMK}$ is a $(1-\epsilon)$-approximation algorithm running in time $O\left(n^{O(T^5/\epsilon)}\right)$.*

Proof. (sketch) Let us briefly argue why the claimed ratio holds. We consider the iteration of the algorithm where X equals the set of ℓ objects which have maximum reward in an optimal solution S^*. By exhaustive search, the algorithm considers the case where $X_1, \ldots, X_T$ are exactly as in S^*, so the reward of the algorithm is the same as S^* for these objects. For the remaining objects, we use the relaxation of the linear program to build an integer solution. The loss corresponds to the rewards generated by fractional objects (see Equation 1) in the *fractional solution.*

While these profits could be very high, the preprocessing step fixing some variables with high profit to 0 (x_{ti} is set to 0 if $p_{ti} > g_k$) allows to bound the loss as (roughly) the reward of these fractional objects *in* S^*. Since there is a bounded number of fractional objects, the loss induced by their rewards can be bounded by a fraction ϵ of the optimal value, by choosing a sufficiently large $\ell = |X|$. ◀

3.3 Generalization to an arbitrary number of time steps

We now devise a PTAS for the general problem, for an arbitrary (not constant) number of steps. We actually show how to get such a PTAS provided that we have a PTAS for (any) constant number of time steps. Let A_{ϵ,T_0} be an algorithm which, given an instance of Multistage Knapsack with at most T_0 time steps, outputs a $(1-\epsilon)$-approximate solution in time $O(n^{f(\epsilon,T_0)})$ for some function f.

The underlying idea is to compute (nearly) optimal solutions on subinstances of bounded sizes, and then to combine them in such a way that at most a small fraction of the optimal value is lost.

Let us first give a rough idea of our algorithm $PTAS_{MK}$.

Given an $\epsilon > 0$, let $\epsilon' = \epsilon/2$ and $T_0 = \lceil \frac{1}{\epsilon'} \rceil$. We construct a set of solutions $S^1, \dots, S^{T_0}$ in the following way:

In order to construct S^1, we partition the time horizon $1, \dots, T$ into $\lceil \frac{T}{T_0} \rceil$ consecutive intervals. Every such interval has length T_0, except possibly the last interval that may have a smaller length. We apply A_{ϵ,T_0} at every interval in this partition. S^1 is then just the concatenation of the partial solutions computed for each interval.

The partition used to build the solution S^i, $1 < i \leq T_0$, is made in a similar way. The only difference is that the first interval of the partition of the time horizon $1, \dots, T$ goes from time 1 to time $i-1$. For the remaining part of the time horizon, i.e. for $i, \dots T$, the partition is made as previously, i.e. starting at time step i, every interval will have a length of T_0, except possibly the last one, whose length may be smaller. Once the partition is operated, we apply A_{ϵ,T_0} to every interval of the partition. S^i, $1 < i \leq T_0$, is then defined as the concatenation of the partial solutions computed on each interval. Among the T_0 solutions $S^1, \dots, S^{T_0}$, the algorithm chooses the best solution.

The construction is illustrated on Figure 1, with 10 time steps and $T_0 = 3$. The first solution S^1 is built by applying 4 times A_{ϵ,T_0}, on the subinstances corresponding to time steps $\{1, 2, 3\}, \{4, 5, 6\}, \{7, 8, 9\}$, and $\{10\}$. The solution S^2 is built by applying 4 times A_{ϵ,T_0}, on the subinstances corresponding to time steps $\{1\}, \{2, 3, 4\}, \{5, 6, 7\}$, and $\{8, 9, 10\}$.

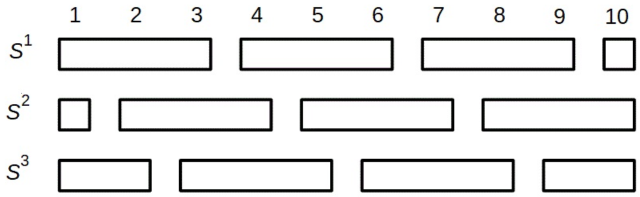

Figure 1 The three solutions for $T_0 = 3$ and $T = 10$.

▶ **Theorem 12.** *The algorithm $PTAS_{MK}$ is a polynomial time approximation algorithm.*

Let us give a rough idea of the proof. As we see from Figure 1, each solution S^t misses some potential transition profit between some time steps (as between 3 and 4, between 6 and 7, and between 9 and 10 for S^1). For each j, such loss between step j and $j+1$ appears in exactly one S^t, so in average we loose a fraction $1/T_0$ of the optimal transition profit (so a fraction at most ϵ'). Another loss is due to the fact that we use an approximation algorithm on the subinstances, inducing also a loss of at most a fraction ϵ' of the optimum value.

4 Pseudo-polynomiality and hardness results

We complement the previous result on approximation scheme by showing the following results for Multistage Knapsack. First, it does not admit an FPTAS (unless $P = NP$), as stated in the following Theorem.

▶ **Theorem 13.** *There is no FPTAS for* Multistage Knapsack *unless $P = NP$, even if there are only two time steps and the bonus is uniform.*

The reduction is from Cardinality-2-KP, and the idea of the proof is to take a sufficiently large (but polynomially bounded) bonus in the multistage instance in order to force the knapsacks of the two time steps to be the same.

The second result states that the problem is pseudo-polynomial for a constant number of time steps. More precisely, with a standard dynamic programming procedure, we have the following.

▶ **Theorem 14.** Multistage Knapsack *is solvable in time $O(T(2C_{max} + 2)^T n)$ where $C_{max} = \max\{C_i, i = 1, \dots, T\}$.*

As a final result, we show that the problem is strongly NP-hard (when the number of steps is not bounded), by showing the NP-hardness of the following subproblem.

▶ **Definition 15.** Binary Multistage Knapsack *is the sub-problem of* Multistage Knapsack *where all the weights, profits and capacities are all equal to 0 or* 1.

For the usual Knapsack problem, the binary case corresponds to a trivial problem. For the multistage case, we have the following:

▶ **Theorem 16.** Binary Multistage Knapsack *is NP-hard, even in the case of uniform bonus.*

Proof. (sketch) We prove the result by a reduction from the Independent Set problem where, given a graph G and an integer K, we are asked if there exists a subset of K pairwise non adjacent vertices (called an independent set). This problem is NP-hard, see [13].

Let (G, K) be an instance of the Independent Set problem, with $G = (V, E)$, $V = \{v_1, \dots, v_n\}$ and $E = \{e_1, \dots, e_m\}$. We build the following instance I' of Binary Multistage Knapsack:

- There are n objects $\{1, 2 \dots, n\}$, one object per vertex;
- There are $T = m$ time steps: each edge (v_i, v_j) in E corresponds to one time step;
- at the time step corresponding to edge (v_i, v_j): objects i and j have weight 1, while the others have weight 0, all objects have profit 1, and the capacity constraint is 1.
- The transition profit is $b_{ti} = B = 2nm$ for all i, t.

Roughly speaking, B is large enough to ensure that in an optimal solution there are no modifications of the knapsack over the time. Then we can show that there is an independent set of size (at least) K if and only if there is a solution for Binary Multistage Knapsack of value (at least) $n(m - 1)B + mK$. ◀

Since B is polynomially bounded in the proof, Multistage Knapsack is strongly NP-hard.

Abstract

This paper studies the expressive and computational power of discrete Ordinary Differential Equations (ODEs). It presents a new framework using discrete ODEs as a central tool for computation and algorithm design. We present the general theory of discrete ODEs for computation theory, we illustrate this with various examples of algorithms, and we provide several implicit characterizations of complexity and computability classes.

The proposed framework presents an original point of view on complexity and computation classes. It unifies several constructions that have been proposed for characterizing these classes including classical approaches in implicit complexity using restricted recursion schemes, as well as recent characterizations of computability and complexity by classes of continuous ordinary differential equations. It also helps understanding the relationships between analog computations and classical discrete models of computation theory.

At a more technical point of view, this paper points out the fundamental role of linear (discrete) ordinary differential equations and classical ODE tools such as changes of variables to capture computability and complexity measures, or as a tool for programming many algorithms.

1 Introduction

Since the beginning of its foundations, classification of the difficulty of problems, with various models of computation, either by their complexity or by their computability properties, is a thriving field of computer science. Nowadays, classical computer science problems also deal with continuous data coming from different areas and modeling involves the use of tools like numerical analysis, probability theory or differential equations. Thus new characterizations

related to theses fields have been proposed. On a dual way, the quest for new types of computers recently led to revisit the power of some models for analog machines based on differential equations, and to compare them to modern digital models. In both contexts, when discussing the related computability or complexity issues, one has to overcome the fact that today's (digital) computers are in essence discrete machines while the objects under study are continuous and naturally correspond to Ordinary Differential Equations (ODEs).

We consider here an original approach in between the two worlds: discrete oriented computation with differential equations.

ODEs appear to be a natural way of expressing properties and are intensively used, in particular in applied science. The theory of classical (continuous) ODEs has an abundant literature (see e.g. [1, 3, 9]) and is rather well understood under many aspects. We are interested here in a discrete counterpart of classical continuous ODEs: discrete ODEs. Its associated derivative notion, called *finite differences*, has been widely studied in numerical optimization for function approximation [12] and is reminiscent in *discrete calculus* [14, 13, 15, 20] for combinatorial analysis (remark that similarities between discrete and continuous statements have also been historically observed, under the terminology of *umbral* or *symbolic calculus* as early as in the 19th century). However, even if the underlying computational content of finite differences theory is clear and has been pointed out many times, no fundamental connections with algorithms and complexity have been exhibited so far.

In this article, our goal is to demonstrate that discrete ODEs is a very natural tool for algorithm design and to prove that complexity and computability notions can be elegantly and simply captured using discrete ordinary differential equations. We illustrate this by providing a characterization of **FPTIME**, the class of polynomial time computable functions, and of its non deterministic analog **FNP**. To this aim, we will also demonstrate how some notions from the analog world such as linearity of differential equations or derivatives along some particular functions (i.e. changes of variables) are representative of a certain computational hardness and can be used to solve efficiently some (classical, digital) problems.

As far as we know, this is the first time that computations with discrete ODEs and their related complexity aspects are considered. By contrast, complexity results have been recently obtained about classical (continuous) ODEs for various classes of functions, mostly in the framework of computable analysis. The hardness of solving continuous ODEs has been intensively discussed: for example [19] establishes some bases of the complexity aspects of ODEs and more recent works like [18] or [10] establish links between complexity or effective aspects of such differential equations. We believe that investigating the expressive power of discrete ODE, can help to better understand complexity of computation for both the discrete and continuous settings. Indeed, on the one hand, our results offers a new machine independent perspective on classical discrete computations, i.e. computations that deal with bits, words, or integers. And, on the other hand, it relates classical (discrete) complexity classes to analog computations, i.e. computations over the reals, as analog computation have been related in various ways to continuous ordinary differential equations, and as discrete ordinary differential equations provide clear hints about their continuous counterparts. A mid-term goal of this line of research is also to bring insights from complexity theory to the problem of solving ODE (discrete and, hopefully also, numerical). A descriptive approach such as the one initiated in the paper could help classifying large classes of ODE by their computational hardness and bring some uniformity to methods of this field.

From restricted recursion scheme to discrete differential equations

Recursion schemes constitutes a major approach of computability theory and to some extent of complexity theory. A foundational result in that spirit is due to Cobham, who gave in [8] a characterization of functions computable in polynomial time through the notion of *bounded recursion on notations* (BRN, for short). A function f is defined by BRN from g, h_0, h_1, k if $f(0, \mathbf{y}) = g(\mathbf{y})$; $f(\mathbf{0}(x), \mathbf{y}) = h_0(f(x, \mathbf{y}), x, \mathbf{y})$ for $x \neq 0$; $f(\mathbf{1}(x), \mathbf{y}) = h_1(f(x, \mathbf{y}), x, \mathbf{y})$ with, for all $x, \mathbf{y}$: $f(x, \mathbf{y}) \leq k(x, \mathbf{y})$. Here $\mathbf{0}(.)$ and $\mathbf{1}(.)$ denote the successor functions defined by $\mathbf{0}(x) = 2.x$ and $\mathbf{1}(x) = 2.x + 1$. In this approach, the number of steps is controlled through the use of the alternative successors $\mathbf{0}(.)$ and $\mathbf{1}(.)$ (which increase the size of their argument by one in each round) and the size of objects through an explicit upper bound by a given function k. Later, notions such as safe recursion [2] or ramification ([22, 21] have allowed syntactical characterizations of polynomial time or other classes [23] that do not require the use of an explicit bound but at the expense of rather sophisticated schemes. These works have therefore been at the origin of the very vivid field of *implicit complexity* at the interplay of logic and theory of programming.

A discrete function can also be described by its derivative i.e. the value $\mathbf{f}(x+1, \mathbf{y}) - \mathbf{f}(x, \mathbf{y})$. It is straightforward to rewrite primitive recursion in this setting, though one may have to cope with possibly negative values. To capture more fine grained time and space measures we come up in the proposed context of discrete ODEs with at least two original concepts which are very natural in the continuous setting:

- deriving along a function; when such a function is suitably chosen this allows to control the number of steps in the computation;
- linearity that permits to control object sizes.

By combining these two approaches, we provide a characterization of **FPTIME** that does not require to specify an explicit bound in the recursion, in contrast to Cobham's work, nor to assign a specific role or type to variables, in contrast to safe recursion or ramification. The characterization happens to be very simple from a syntactical point of view using only natural notions from the world of ODE.

This characterization is also a first step to convince the reader that deep connections between complexity and ODE solving do exist and that these connections are worth to be further studied.

Related works on analog computations

As many historical or even possibly futuristic analog machines are naturally described by (continuous) ODEs, the quest of understanding how the computational power of analog models compare to classical digital ones have led to several results relating classical complexity to various classes of continuous ODEs. In particular, a series of papers has been devoted to study various classes of the so-called $\mathbb{R}$-recursive functions, after their introduction in [25] as a theoretical model for computations over the reals. At the complexity level, characterizations of complexity classes such as **PTIME** and **NPTIME** using $\mathbb{R}$-recursive algebra have been obtained [27], motivated in particular by the idea of transferring classical questions from complexity theory to the context of real and complex analysis [24, 27, 26]. But this has been done with the addition of limit schemata and with a rather different settings.

More recently, revisiting the model of General Purpose Analog Computer of Claude Shannon, it is has been proved that polynomial differential equations can be considered as a very simple and elegant model in which computable functions over the reals and polynomial time computable functions over the reals can be defined without any reference to concepts from discrete computation theory [4, 29]. We believe the current work is a substantial step to understand the underlying power and theory of such analog models, by providing concepts, definitions and results relating the two worlds.

Refer to [5] for an up to date survey about various works on analog computations, in particular in a computation theory perspective.

Structure of the paper

In Section 2 a short introduction to discrete differentiability is given followed in Section 3 by an illustration, through examples, of the programming ability of discrete ODE. Formal definitions of discrete ODE schemas are given in Section 4 together with characterizations of classical computability classes. Our objective, from Section 2 to 4, is to expose in a simple way (using sometimes well-known concepts) the basics of the theory of discrete ODE and its computational content, before getting to more technical results. Section 5 introduces the notion of length-ODE which is central, together with the that of (essentially) linear differential equation, for the characterization of **FPTIME** (Section 6) and **FNP** (Sections 7). In Section 8 we discuss some extensions of the results.

2 Discrete differentiability and ODEs

In this section, we review some basic notions of discrete calculus to help intuition in the rest of the paper (refer to [16, 12] for a more complete review). Discrete derivatives are usually intended to concern functions over the integers of type $\mathbf{f}: \mathbb{N}^p \rightarrow \mathbb{Z}^d$, but the statements and concepts considered in our discussions are also valid more generally for functions of type $\mathbf{f}: \mathbb{Z}^p \rightarrow \mathbb{Z}^d$, for some integers p, d, or even functions $\mathbf{f}: \mathbb{R}^p \rightarrow \mathbb{R}^d$. The basic idea is to consider the following concept of derivative

▶ Remark 1. We first discuss the case where $p = 1$, i.e. functions $\mathbf{f}: \mathbb{N} \rightarrow \mathbb{Z}^d$. We will later on consider more general functions, with partial derivatives instead of derivatives.

▶ **Definition 2** (Discrete Derivative). *The discrete derivative of $\mathbf{f}(x)$ is defined as $\Delta\mathbf{f}(x) = \mathbf{f}(x+1) - \mathbf{f}(x)$. We will also write $\mathbf{f}'$ for $\Delta\mathbf{f}(x)$ to help to understand statements with respect to their classical continuous counterparts.*

Several results from classical derivatives generalize to this settings: this includes linearity of derivation $(a \cdot f(x) + b \cdot g(x))' = a \cdot f'(x) + b \cdot g'(x)$, formulas for products and division such as $(f(x) \cdot g(x))' = f'(x) \cdot g(x+1) + f(x) \cdot g'(x) = f(x+1)g'(x) + f'(x)g(x)$.

A fundamental concept is the following:

▶ **Definition 3** (Discrete Integral). *Given some function $\mathbf{f}(x)$, we write $\int_a^b \mathbf{f}(x)\delta x$ as a synonym for $\int_a^b \mathbf{f}(x)\delta x = \sum_{x=a}^{x=b-1} \mathbf{f}(x)$ with the convention that it takes value 0 when $a = b$ and $\int_a^b \mathbf{f}(x)\delta x = -\int_b^a \mathbf{f}(x)\delta x$ when $a > b$.*

The telescope formula yields the so-called Fundamental Theorem of Finite Calculus:

▶ **Theorem 4** (Fundamental Theorem of Finite Calculus). *Let $\mathbf{F}(x)$ be some function. Then, $\int_a^b \mathbf{F}'(x)\delta x = \mathbf{F}(b) - \mathbf{F}(a)$.*

As for classical functions, a given function has several primitives. These primitives are defined up to some additive constant. Several techniques from the classical settings generalize to the discrete settings: this includes the technique of integration by parts.

A classical concept in discrete calculus is the one of falling power defined as $x^{\underline{m}} = x \cdot (x-1) \cdot (x-2) \cdots (x-(m-1))$. This notion is motivated by the fact that it satisfies a derivative formula $(x^{\underline{m}})' = m \cdot x^{\underline{m-1}}$ similar to the classical one for powers in the continuous setting. In a similar spirit, we introduce the concept of falling exponential.

▶ **Definition 5** (Falling exponential). *Given some function $\mathbf{U}(x)$, the expression $\mathbf{U}$ to the falling exponential x, denoted by $\overline{2}^{\mathbf{U}(x)}$, stands for $\overline{2}^{\mathbf{U}(x)} = (1 + \mathbf{U}'(x-1)) \cdots (1 + \mathbf{U}'(1)) \cdot (1 + \mathbf{U}'(0)) = \prod_{t=0}^{t=x-1}(1 + \mathbf{U}'(t))$, with the convention that $\prod_0^0 = \mathbf{id}$, where $\mathbf{id}$ is the identity (sometimes denoted 1 hereafter)*

This is motivated by the remarks that $2^x = \overline{2}^x$, and that the discrete derivative of a falling exponential is given by $\left(\overline{2}^{\mathbf{U}(x)}\right)' = \mathbf{U}'(x) \cdot \overline{2}^{\mathbf{U}(x)}$ for all $x \in \mathbb{Z}$.

We will focus in this article on discrete Ordinary Differential Equations (ODE) on functions with several variables, that is to say for example on equations of the (possibly vectorial) form:

$$\frac{\partial \mathbf{f}(x, \mathbf{y})}{\partial x} = \mathbf{h}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}), \tag{1}$$

where $\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial x}$ stands as expected for the derivative of functions $\mathbf{f}(x, \mathbf{y})$ considered as a function of x, when $\mathbf{y}$ is fixed i.e. $\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial x} = \mathbf{f}(x+1, \mathbf{y}) - \mathbf{f}(x, \mathbf{y})$. When some initial value $\mathbf{f}(0, \mathbf{y}) = \mathbf{g}(\mathbf{y})$ is added, this is called an *Initial Value Problem (IVP)* or a *Cauchy Problem*. An IVP can always be put in integral form

$$\mathbf{f}(x, \mathbf{y}) = \mathbf{f}(0, \mathbf{y}) + \int_0^x \mathbf{h}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}) \delta x.$$

Our aim here is to discuss total functions whose domain and range is either of the form $\mathcal{D} = \mathbb{N}$, $\mathbb{Z}$, or possibly a finite product $\mathcal{D} = \mathcal{D}_1 \times \cdots \times \mathcal{D}_k$ where each $\mathcal{D}_i = \mathbb{N}$, $\mathbb{Z}$. By considering that $\mathbb{N} \subset \mathbb{Z}$, we assume that the range is always $\mathbb{Z}^d$ for some d. The concept of solution for such ODEs is as expected: given $h : \mathbb{Z}^d \times \mathbb{N} \times \mathbb{Z}^p \to \mathbb{Z}$ (or $h : \mathbb{Z}^d \times \mathbb{Z} \times \mathbb{Z}^p \to \mathbb{Z}$), a solution over $\mathcal{D}$ is a function $f : \mathcal{D} \times \mathbb{Z}^p \to \mathbb{Z}^d$ that satisfies the equations for all $x, \mathbf{y}$.

We will only consider well-defined ODEs such as above in this article (but variants with partially defined functions could be considered as well). Observe that an IVP of the form (1) always admits a (necessarily unique) solution over $\mathbb{N}$ since f can be defined inductively with $\mathbf{f}(0, \mathbf{y}) = \mathbf{g}(\mathbf{y})$ and $\mathbf{f}(x+1, \mathbf{y}) = \mathbf{f}(x, \mathbf{y}) + \mathbf{h}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y})$.

▶ Remark 6. Notice that this is not necessarily true over $\mathbb{Z}$: As an example, consider $f'(x) = -f(x) + 1$, $f(0) = 0$. By definition of $f'(x)$, we must have $f(x+1) = 1$ for all x, but if $x = -1$, $f(0) = 1 \neq 0$.

▶ Remark 7 (Sign function). It is very instructive to realize that the solution of this IVP over $\mathbb{N}$ is the sign $\mathsf{sg}_{\mathbb{N}}(x)$ function defined by $\mathsf{sg}_{\mathbb{N}}(x) = 1$ if $x > 0$ and $\mathsf{sg}_{\mathbb{N}}(x) = 0$ in the other case.

Linear (also called *Affine*) ODEs will play a very important role in what follows, i.e. discrete ordinary differential equations of the form $\mathbf{f}'(x) = \mathbf{A}(x) \cdot \mathbf{f}(x) + \mathbf{B}(x)$.

▶ Remark 8. Recall that the solution of $f'(x) = a(x)f(x) + b(x)$ for classical continous derivatives turns out to be given by (usually obtained using the method of variation of parameters): $f(x) = f(0)e^{\int_0^x a(t)dt} + \int_0^x b(u)e^{\int_u^x a(t)dt} du$. This generalizes with our definitions to discrete ordinary differential equations, and this works even vectorially:

▶ **Lemma 9** (Solution of linear ODE). *For matrices $\mathbf{A}$ and vectors $\mathbf{B}$ and $\mathbf{G}$, the solution of equation $\mathbf{f}'(x, \mathbf{y}) = \mathbf{A}(x, \mathbf{y}) \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}(x, \mathbf{y})$ with initial conditions $\mathbf{f}(0, \mathbf{y}) = \mathbf{G}(\mathbf{y})$ is $\mathbf{f}(x, \mathbf{y}) = \left(\overline{2}^{\int_0^x \mathbf{A}(t,\mathbf{y})\delta t}\right) \cdot \mathbf{G}(\mathbf{y}) + \int_0^x \left(\overline{2}^{\int_{u+1}^x \mathbf{A}(t,\mathbf{y})\delta t}\right) \cdot \mathbf{B}(u, \mathbf{y}) \delta u$.*

▶ Remark 10. Notice that this can be rewritten as $\sum_{u=-1}^{x-1}\left(\prod_{t=u+1}^{x-1}(1+\mathbf{A}(t,\mathbf{y}))\right)\cdot\mathbf{B}(u,\mathbf{y})$ with the conventions that for any function $\kappa(\cdot)$, $\prod_{x}^{x-1}\kappa(x)=1$ and $\mathbf{B}(-1,\mathbf{y})=\mathbf{G}(\mathbf{y})$. Such equivalent expressions both have a clear computational content. They can be interpreted as an algorithm unrolling the computation of $\mathbf{f}(x+1,\mathbf{y})$ from the computation of $\mathbf{f}(x,\mathbf{y}),\mathbf{f}(x-1,\mathbf{y}),\dots,\mathbf{f}(0,\mathbf{y})$. The next section will build on that remark through some examples.

3 Programming with discrete ODE

The computational dimension of calculus of finite differences has been widely stressed in mathematical analysis. However, no fundamental connection has been established with algorithmic and complexity. In this section, we show that several algorithms can actually be naturally expressed as discrete ODEs.

For now, we suppose that composition of functions, constant and the following basic functions can be used freely as functions from $\mathbb{Z}$ to $\mathbb{Z}$: arithmetic operations: $+$, $-$, $\times$; $\ell(x)$ returns the length of $|x|$ written in binary; $\mathsf{sg}(x):\mathbb{Z}\to\mathbb{Z}$ (respectively: $\mathsf{sg}_{\mathbb{N}}(x):\mathbb{N}\to\mathbb{Z}$) that takes value 1 for $x>0$ and 0 in the other case; From these basic functions, for readability, one may define useful functions as synonyms: $\bar{\mathsf{sg}}(x)$ stands for $\bar{\mathsf{sg}}(x)=(1-\mathsf{sg}(x))\times(1-\mathsf{sg}(-x))$: it tests if $x=0$ for $x\in\mathbb{Z}$; $\bar{\mathsf{sg}}_{\mathbb{N}}(x)$ stands for $\bar{\mathsf{sg}}_{\mathbb{N}}(x)=1-\mathsf{sg}_{\mathbb{N}}(x)$: it tests if $x=0$ for $x\in\mathbb{N}$. $\mathsf{if}(x,y,z)$ stands for $\mathsf{if}(x,y,z)=y+\bar{\mathsf{sg}}(x)\cdot(z-y)$ and $\mathsf{if}_{\mathbb{N}}(x,y,z)$ stands for $\mathsf{if}_{\mathbb{N}}(x,y,z)=y+\bar{\mathsf{sg}}_{\mathbb{N}}(x)\cdot(z-y)$. $\mathsf{if}(x<x',y,z)$ will be a synonym for $\mathsf{if}(\mathsf{sg}(x'-x+1),y,z)$ and $\mathsf{if}(x=x',y,z)$ will be a synonym for $\mathsf{if}(1-\bar{\mathsf{sg}}(x-x'),y,z)$.

First observe that discrete ODEs allow to express easily search functions:

▶ **Example 11** (Computing the minimum of a function)**.** The minimum of a function $\min f: x\mapsto min\{f(y):0\leq y\leq x\}$ is given by $F(x,x)$ where F is solution of the discrete ODE $F(0,x)=f(0)$; $\frac{\partial F(t,x)}{\partial t}=H(F(t,x),f(x),t,x)$, where $H(F,f,t,x)=0$ if $F<f$, $f-F$ if $F\geq f$. In integral form, we have: $F(x,y)=F(0)+\int_0^x H(F(t,y),t,y)\delta t$.

Conversely such an integral above (equivalently discrete ODE) can always be considered as a (recursive) algorithm: compute the integral from its definition as a sum. On this example, this corresponds basically to compute $F(x,x)$ recursively by $F(t+1,x)=\mathsf{if}(F(t,x)<f(x),F(t,x),f(x))$.

▶ Remark 12. Note that this algorithm is not polynomial in the length of its argument x, as it takes time x to compute $\min f$. Getting to polynomial algorithms will be at the heart of coming discussions in the two next examples and in Section 5.

As shown in the following two examples, discrete ODEs can express more sophisticated functions and turn out to be very natural in many other contexts, in particular non numerical ones, where they would probably not be expected.

▶ **Example 13** (Computing the integer part and divisions, going to Length-ODE)**.** Suppose that we want to compute $\lfloor\sqrt{x}\rfloor=\max\{y\leq x:y\cdot y\leq x\}$ and $\left\lfloor\frac{x}{y}\right\rfloor=\max\{z\leq x:z\cdot y\leq x\}$. It can be done by the following general method. Let f,h be some functions with h being non decreasing. We compute some_h with $\mathsf{some}_h(x)=y$ s.t. $|f(x)-h(y)|$ is minimal. When $h(x)=x^2$ and $f(x)=x$, it holds that: $\lfloor\sqrt{x}\rfloor=\mathsf{if}(\mathsf{some}_h(x)^2\leq x,\mathsf{some}_h(x),\mathsf{some}_h(x)-1)$. The function some_h can be computed (in non-polynomial time) as a solution of an ODE as in Example 11. However, there is a more efficient (polynomial time) way to do it based on what one usually does with classical ordinary differential equations: performing a change of variable so that the search becomes logarithmic in x. Indeed, we can write $\mathsf{some}_h(x)=G(\ell(x),x)$ for some function $G(t,x)$ that is a solution of $G(0,x)=x$; $\frac{\partial G(t,x)}{\partial t}=E(G(t,x),t,x)$ where $E(G,t,x)$ takes value $2^{\ell(x)-t-1}$ whenever $h(G>f(x))$, 0 whenever $h(G)=f(x)$ and $-2^{\ell(x)-t-1}$ whenever $h(G)<f(x)$.

▶ **Example 14** (Computing suffixes with discrete ODEs)**.** The suffix function, $\mathsf{suffix}(x, y)$ takes as input two integers x and y and outputs the $\ell(y) = t$ least significant bits of the binary decomposition of x. We describe below a way to compute a suffix working over a parameter t, that is logarithmic in x. Consider the following unusual algorithm that can be interpreted as a fix-point definition of the function: $\mathsf{suffix}(x, y) = F(\ell(x), y)$ where $F(0, x) = x$; $F(t + 1, x) = \mathsf{if}(\ell(F(t, x)) = 1, F(t, x), F(t, x) - 2^{\ell(F(t,x))-1})$.This can be interpreted as a differential equation, whose solution is converging fast again (i.e. in polynomial time) to what we want. In other words, $\mathsf{suffix}(x, y) = F(\ell(x), x)$ using the solution of the IVP: $F(0, y) = x$, $\frac{\partial F(T,y)}{\partial T} = \mathsf{if}(\ell(F(t, x)) = 1, 0, -2^{\ell(F(t,x))-1})$.

4 Computability and Discrete ODEs

Here, we consider functions defined by ODEsunder the prism of computability. It serves as an introductory illustration of the close relationship between discrete ODEs and recursive schemata before moving to efficient algorithms and complexity classes characterizations with a finer approach. This part is clearly inspired by ideas from [6, 7], but adapted here for our framework of discrete ODEs. We refer to [30, 28] for basic definitions from computability.

▶ **Definition 15** ((Scalar) Discrete ODE schemata)**.** *Given $g : \mathbb{N}^p \to \mathbb{N}$ and $h : \mathbb{Z} \times \mathbb{N}^{p+1} \to \mathbb{Z}$, we say that f is defined by discrete ODE solving from g and h, denoted by $f = \mathrm{ODE}(g, h)$, if $f : \mathbb{N}^{p+1} \to \mathbb{Z}$ corresponds to the (necessarily unique) solution of Initial Value Problem*

$$\frac{\partial f(x,\mathbf{y})}{\partial x} = h(f(x, \mathbf{y}), x, \mathbf{y}), \qquad f(0, \mathbf{y}) = g(\mathbf{y}). \tag{2}$$

▶ Remark 16. To be more general, we could take $g : \mathbb{N}^p \to \mathbb{Z}$. However, this would be of no use in the context of this paper. We could also consider vectorial equations as in what follows which are very natural in the context of ODEs, and we would get similar statements.

It is clear that primitive recursion schemes can be reformulated as discrete ODE schemata. The restriction to Linear ODEs is very natural, in particular as this class of ODEs has a highly developed theory for the continuous setting. It is very instructive to realize that the class of functions definable by Linear ODEs is exactly the well-known class of elementary functions [17] (we will see later how additional requirements lead to a characterization of polynomial time functions).

▶ **Definition 17** (Linear ODE schemata)**.** *Given a vector $\mathbf{G} = (G_i)_{1\leq i\leq k}$ matrix $\mathbf{A} = (A_{i,j})_{1\leq i,j\leq k}$, $\mathbf{B} = (B_i)_{1\leq i\leq k}$ whose coefficients corresponds to functions $g_i : \mathbb{N}^p \to \mathbb{N}^k$, and $a_{i,j} : \mathbb{N}^{p+1} \to \mathbb{Z}$ and $b_{i,j} : \mathbb{N}^{p+1} \to \mathbb{Z}$ respectively, we say that $\mathbf{f}$ is obtained by linear ODE solving from g, A and B, denoted by $\mathbf{f} = \mathrm{LI}(\mathbf{G}, \mathbf{A}, \mathbf{B})$, if $f : \mathbb{N}^{p+1} \to \mathbb{Z}^k$ corresponds to the (necessarily unique) solution of Initial Value Problem*

$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial x} = \mathbf{A}(x, \mathbf{y}) \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}(x, \mathbf{y}), \qquad \mathbf{f}(0, \mathbf{y}) = \mathbf{G}(\mathbf{y}). \tag{3}$$

▶ **Theorem 18** (A discrete ODE characterization of elementary functions)**.** *The set of elementary functions $\mathcal{E}$ is the intersection with $\mathbb{N}^{\mathbb{N}}$ of the smallest set of functions that contains the zero functions $\mathbf{0}$, the projection functions π_i^p, the successor function $\mathbf{s}$, addition $+$, subtraction $-$, and that is closed under composition and discrete linear ODE schemata (respectively: scalar discrete linear ODE schemata)* LI.

By adding suitable towers of exponential, the above result can be generalized to characterize the various levels of the Grzegorczyk hierarchy. We can also reexpress Kleene's minimization:

▶ **Theorem 19** (Discrete ODE computability and classical computability are equivalent). *A total function $f : \mathbb{N}^p \to \mathbb{N}$ is total recursive iff there exist some functions $h_1, h_2 : \mathbb{N}^{p+1} \to \mathbb{N}^2$ in the smallest set of functions that contains the zero functions $\mathbf{0}$, the projection functions π_i^p, the successor function $\mathbf{s}$, and that is closed under composition and discrete* ODE *schemata such that: for all $\mathbf{y}$, there exists some $T = T(\mathbf{y})$ with $h_2(T, \mathbf{y}) \neq 0$; $f(\mathbf{y}) = h_1(T, \mathbf{y})$ where T is the smallest such T.*

5 Restricted recursion and integration schemes

In order to talk about complexity instead of computability, we need to add some restrictions on the integration scheme. This follows from the following remark:

▶ **Example 20.** The solution of the (degree 2) polynomial ODE $y_1' = y_1$, $y_i' = y_{i-1}' y_i'$ for $i = 1, \ldots d$ is growing faster than a tower of falling exponentials. Consequently, it is not polynomial time computable as just outputting its value in binary cannot be done in polynomial time.

We consequently propose to introduce the following variation on the notion of derivation: derivation along some function $\mathcal{L}(x, \mathbf{y})$.

▶ **Definition 21** ($\mathcal{L}$-ODE). *Let $\mathcal{L} : \mathbb{N}^{p+1} \to \mathbb{Z}$. We write*

$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \mathcal{L}} = \frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \mathcal{L}(x,\mathbf{y})} = \mathbf{h}(\mathbf{f}(x,\mathbf{y}), x, \mathbf{y}), \tag{4}$$

as a formal synonym for $\mathbf{f}(x+1,\mathbf{y}) = \mathbf{f}(x,\mathbf{y}) + (\mathcal{L}(x+1,\mathbf{y}) - \mathcal{L}(x,\mathbf{y})) \cdot \mathbf{h}(\mathbf{f}(x,\mathbf{y}), x, \mathbf{y})$.

▶ Remark 22. This is motivated by the fact that the latter expression is similar to classical formula for classical continuous ODEs:

$$\frac{\delta f(x,\mathbf{y})}{\delta x} = \frac{\delta \mathcal{L}(x,\mathbf{y})}{\delta x} \cdot \frac{\delta f(x,\mathbf{y})}{\delta \mathcal{L}(x,\mathbf{y})}.$$

This will allow us to simulate suitable changes of variables using this analogy. We will talk about $\mathcal{L}$-IVP when some initial condition is added. An important special case is when $\mathcal{L}(x, \mathbf{y})$ corresponds to the length $\mathcal{L}(x, \mathbf{y}) = \ell(x)$ function: we will call this special case length-ODEs.

5.1 General theory

The main result of this part illustrates one key property of the $\mathcal{L}$-ODE scheme from a computational point of view: its dependence on the number of distinct values of function $\mathcal{L}$.

▶ **Definition 23** ($Jump_{\mathcal{L}}$). *Let $\mathcal{L} : \mathbb{N}^{p+1} \to \mathbb{Z}$ be some function. Fixing $\mathbf{y} \in \mathbb{N}^p$, let $Jump_{\mathcal{L}}(x, \mathbf{y}) = \{0 \leq i \leq x-1 | \mathcal{L}(i+1, \mathbf{y}) \neq \mathcal{L}(i, \mathbf{y})\}$ be the set of positive integers less than x after which the value of $\mathcal{L}$ changes.*

We also write: $J_{\mathcal{L}} = |Jump_{\mathcal{L}}(x, \mathbf{y})|$ for its cardinality; $\alpha : [0..J_{\mathcal{L}}-1] \to Jump_{\mathcal{L}}(x, \mathbf{y})$ for an increasing function enumerating the elements of $Jump_{\mathcal{L}}(x, \mathbf{y})$: If $i_0 < i_1 < i_2 < \cdots < i_{J_{\mathcal{L}}-1}$ denote all elements of $Jump_{\mathcal{L}}(x, \mathbf{y})$, then $\alpha(j) = i_j \in Jump_{\mathcal{L}}(x, \mathbf{y})$.

▶ **Lemma 24.** *Let $\mathbf{f} : \mathbb{N}^{p+1} \to \mathbb{Z}^d$ and $\mathcal{L} : \mathbb{N}^{p+1} \to \mathbb{Z}$ be some functions. Assume that (4) holds. Then $\mathbf{f}(x, \mathbf{y})$ is equal to:*

$$\mathbf{f}(0,\mathbf{y}) + \int_0^{J_{\mathcal{L}}} \Delta \mathcal{L}(\alpha(u), \mathbf{y}) \cdot \mathbf{h}(\mathbf{f}(\alpha(u), \mathbf{y}), \alpha(u), \mathbf{y}) \delta u.$$

▶ Remark 25. Note that the above result would still hold with $\mathcal{L}$ and h taking their images in $\mathbb{R}$.

Its proof is based on (and illustrates) some fundamental aspect of $\mathcal{L}$-ODE from their definition: for fixed $\mathbf{y}$, the value of $\mathbf{f}(x, \mathbf{y})$ only changes when the value of $\mathcal{L}(x, \mathbf{y})$ changes. If the previous hypotheses hold, there is then an alternative view to understand the integral, by using a change of variable, and by building a discrete ODE that mimics the computation of the integral.

▶ **Lemma 26** (Alternative view). *Let $k \in \mathbb{N}$, $f : \mathbb{N}^{p+1} \to \mathbb{Z}^d$, $\mathcal{L} : \mathbb{N}^{p+1} \to \mathbb{Z}$ be some functions and assume that* (4) *holds. Then $\mathbf{f}(x, \mathbf{y})$ is given by $\mathbf{f}(x, \mathbf{y}) = \mathbf{F}(\mathcal{L}(x, \mathbf{y}), \mathbf{y})$ where $\mathbf{F}$ is the solution of initial value problem*

$$\frac{\partial \mathbf{F}(t,\mathbf{y})}{\partial t} \quad = \quad \Delta\mathcal{L}(t, \mathbf{y}) \cdot \mathbf{h}(\mathbf{F}(t, \mathbf{y}), t, \mathbf{y}) \qquad \mathbf{F}(0, \mathbf{y}) \quad = \quad \mathbf{f}(\mathcal{L}(0, \mathbf{x}), \mathbf{y}).$$

Conversely, if there is such a function $\mathbf{F}$, then a discrete ODE of the type of (4) *can easily be derived.*

5.2 Linear length-ODEs

▶ Remark 27. In all previous reasonings, we considered that a function over the integers is polynomial time computable if it is in the length of all its arguments, as this is the usual convention. When not explicitly stated, this is our convention. As usual, we also say that some vectorial function (respectively: matrix) is polynomial time computable if all its components are. We need sometimes to consider also polynomial dependency directly in some of the variables and not on their length: This happens in the next fundamental lemma.

We write $\| \cdots \|$ for the sup norm: given some matrix $\mathbf{A} = (A_{i,j})_{1 \leq i \leq n, 1 \leq j \leq m}$, $\|A\| = \max_{i,j} A_{i,j}$.

▶ **Lemma 28** (Fundamental observation). *Consider the ODE*

$$\mathbf{f}'(x, \mathbf{y}) = \mathbf{A}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}) \cdot \mathbf{f}(x, \mathbf{y}) + \mathbf{B}(\mathbf{f}(x, \mathbf{y}), x, \mathbf{y}). \tag{5}$$

Assume:

1. *The initial condition $\mathbf{G}(\mathbf{y}) =^{def} \mathbf{f}(0, \mathbf{y})$, as well as Matrix $\mathbf{A}$ and vector $\mathbf{B}$ are polynomial time computable.*
2. *$\ell(\|\mathbf{A}(f, x, \mathbf{y})\|) \leq \ell(\|\mathbf{f}\|) + p_{\mathbf{A}}(x, \ell(\mathbf{y}))$ for some polynomial p_A*
3. *$\ell(\|\mathbf{B}(f, x, \mathbf{y})\|) \leq \ell(\|\mathbf{f}\|) + p_{\mathbf{B}}(x, \ell(\mathbf{y}))$ for some polynomial p_B*

Then its solution $\mathbf{f}(x, \mathbf{y})$ is polynomial time computable in x and the length of $\mathbf{y}$.

Proof sketch. This comes from the explicit form of solutions provided by Lemma 9, considered then as an algorithm (see Remark 10). The point is then to analyse the size of all the involved quantities in order to state that this remains indeed polynomial time feasible. ◀

We now go to specific forms of linear ODEs.

▶ **Definition 29.** *A* sg*-polynomial expression $P(x_1, ..., x_h)$ is an expression built-on $+, -, \times$ (often denoted $\cdot$) and* sg() *functions over a set of variables $V = \{x_1, ..., x_h\}$ and integer constants. The degree $\deg(x, P)$ of a term $x \in V$ in P is defined inductively as follows:*

- $\deg(x, x) = 1$ *and for $x' \in X \cup \mathbb{Z}$ such that $x' \neq x$,* $\deg(x, x') = 0$
- $\deg(x, P + Q) = \max\{\deg(x, P), \deg(x, Q)\}$
- $\deg(x, P \times Q) = \deg(x, P) + \deg(x, Q)$
- $\deg(x, \mathit{sg}(P)) = 0$

A sg*-polynomial expression P is essentially constant in x if* $\deg(x, P) = 0$.

Compared to the classical notion of degree in polynomial expression, all subterms that are within the scope of a sign function contributes 0 to the degree. A vectorial function (resp. a matrix or a vector) is said to be a sg-polynomial expression if all its coordinates (resp. coefficients) are. It is said to be *essentially constant* if all its coefficients are.

▶ **Definition 30.** *A (possibly vectorial) sg-polynomial expression $\mathbf{g}(\mathbf{f}(x,\mathbf{y}),x,\mathbf{y})$ is essentially linear in $\mathbf{f}(x,\mathbf{y})$ if it is of the form $\mathbf{g}(\mathbf{f}(x,\mathbf{y}),x,\mathbf{y}) = \mathbf{A}[\mathbf{f}(x,\mathbf{y}),x,\mathbf{y}] \cdot \mathbf{f}(x,\mathbf{y}) + \mathbf{B}[\mathbf{f}(x,\mathbf{y}),x,\mathbf{y}]$ where $\mathbf{A}$ and $\mathbf{B}$ are sg-polynomial expressions essentially constant in $\mathbf{f}(x,\mathbf{y})$.*

▶ **Example 31.** The expression $P(x,y,z) = x \cdot \mathsf{sg}((x^2-z)\cdot y) + y^3$ is linear in x, essentially constant in z and not linear in y. The expression $P(x, 2^{\ell(y)}, z) = \mathsf{sg}(x^2-z)\cdot z^2 + 2^{\ell(y)}$ is essentially constant in x, essentially linear in $2^{\ell(y)}$ (but not essentially constant) and not essentially linear in z. The expression: $\mathsf{if}(x,y,z) = y + \bar{\mathsf{sg}}(x)\cdot(z-y) = y + (1-\mathsf{sg}(x))\cdot(z-y)$ is essentially constant in x and linear in y and z.

▶ **Definition 32.** *Function $\mathbf{f}$ is linear $\mathcal{L}$-ODE definable (from $\mathbf{u}$, $\mathbf{g}$ and $\mathbf{h}$) if it corresponds to the solution of $\mathcal{L}$-IVP*

$$\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \mathcal{L}} = \mathbf{u}(\mathbf{f}(x,\mathbf{y}),\mathbf{h}(x,\mathbf{y}),x,\mathbf{y}) \qquad f(0,\mathbf{y}) = \mathbf{g}(\mathbf{y}) \tag{6}$$

where $\mathbf{u}$ is essentially linear in $\mathbf{f}(x,\mathbf{y})$. When $\mathcal{L}(x,\mathbf{y}) = \ell(x)$, such a system is called linear length-ODE.

The previous statements lead to the following:

▶ **Lemma 33** (Key Observation for linear $\mathcal{L}$-ODE). *Assume that $\mathbf{f}$ is the solution of (6) and that functions $\mathbf{g},\mathbf{h},\mathcal{L}$ and $Jump_{\mathcal{L}}$ are computable in polynomial time. Then, $\mathbf{f}$ is computable in polynomial time.*

6 A characterization of polynomial time

The above result shows that functions defined by linear length-ODE from functions computable in polynomial time, are indeed polynomial time. We are now ready to introduce a recursion scheme based on solving linear differential equations to capture polynomial time.

▶ Remark 34. Since the functions we define take their values in $\mathbb{N}$ and have output in $\mathbb{Z}$, composition is an issue. Instead of considering restrictions of these functions with output in $\mathbb{N}$ (which is always possible, even by syntactically expressible constraints), we simply admit that composition may not be defined in some cases. In other words, we consider that composition is a partial operator.

▶ **Definition 35** ($\mathbb{DL}$). *Let $\mathbb{DL}$ be the smallest subset of functions, that contains $\mathbf{0}$, $\mathbf{1}$, projections π_i^p, the length function $\ell(x)$, the addition function $x{+}y$, the subtraction function $x{-}y$, the multiplication function $x \times y$ (often denoted $x \cdot y$), the sign function $\mathsf{sg}(x)$ and closed under composition (when defined) and linear length-ODE scheme.*

▶ Remark 36. As our proofs show, the definition of $\mathbb{DL}$ would remain the same by considering closure under any kind of $\mathcal{L}$-ODE with $\mathcal{L}$ satisfying the hypothesis of Lemma 33.

▶ **Example 37.** A number of natural functions are in $\mathbb{DL}$. Functions $2^{\ell(x)}$, $2^{\ell(x)\cdot\ell(y)}$, $\mathsf{if}(x,y,z)$, $\mathsf{suffix}(x,y)$, $\lfloor\sqrt{x}\rfloor$, $\lfloor\frac{x}{y}\rfloor$, $2^{\lfloor\sqrt{x}\rfloor}$ all belong to $\mathbb{DL}$ by some linear length-ODE easy to establish.

▶ **Theorem 38.** $\mathbb{DL} = \mathbf{FPTIME}$

sketch. $\boxed{\subseteq}$ Consequence of Lemma 33, on the fact that arithmetic operations that are allowed can be computed in polynomial time and that **FPTIME** is closed under composition.

$\boxed{\supseteq}$ A register machine program is a finite sequence of ordered labeled instructions acting on a finite set of registers $R_0,...,R_k$. Such a machine is equipped with assignment instructions ($R_j := R_j + R_i$, $R_j := R_j - R_i$, $R_j := i$ for $i \in \{0,1\}$), control flow statement (if$R_j = 0$ goto p) and halt instruction.

Let $f : \mathbb{N}^p \longrightarrow \mathbb{N}$ be computable in polynomial time and M a k registers machine that computes f in time $\ell(\mathbf{x})^c$ for some $c \in \mathbb{N}$ (with $\mathbf{x}$ in registers $R_1, ..., R_p$, $p \leq k$, at startup and $f(\mathbf{x})$ in R_0 at the end). It is well known that polynomial time on register machines and on Turing machines is the same.

The computation of M is defined by simultaneous recursion scheme on length for functions $R_0(t,\mathbf{x}), ..., R_k(t,\mathbf{x})$ and $\mathsf{inst}(t,\mathbf{x})$: it gives, respectively, the values of each register and the label of the current instruction at time $\ell(t)$. It is shown to correspond to some length-linear ODE. As an example, we describe function $\mathsf{inst}(t,\mathbf{x})$ below.

Let next_l^I, next_l^h, $h \leq k$ describe the evolution of function inst and of register R_h between two instants of time after firing instruction with label l. If l is of the type $R_j := R_j - R_i$ (or is any assignment), then $\mathsf{next}_l^I = 1$ since $\mathsf{inst}(t+1,\mathbf{x}) = \mathsf{inst}(t,\mathbf{x}) + 1$. If l if of the type if $R_j = 0$ goto p, $\mathsf{next}_l^I = \mathsf{if}(R_j(t,\mathbf{x}), p - \mathsf{inst}(t,\mathbf{x}), 1)$ since, in case $R_j(t,\mathbf{x}) = 0$ instruction number goes from $\mathsf{inst}(t,\mathbf{x})$ to p. The definition of each next_l^h is similar.

The value of $\mathsf{inst}(t+1,\mathbf{x})$ can then be described from $\mathsf{inst}(t,\mathbf{x})$ and $R_h(t,\mathbf{x})$, $h \leq k$, by cases depending on the type of the current instruction. Expanded as an arithmetic expression, this gives:

$$\frac{\partial \mathsf{inst}}{\partial \ell}(t,\mathbf{x}) = \sum_{l=0}^{m} \Big(\prod_{i=0}^{l-1} \mathsf{sg}(\mathsf{inst}(t,\mathbf{x}) - i) \Big) \cdot \bar{\mathsf{sg}}(\mathsf{inst}(t,\mathbf{x}) - l) \cdot \mathsf{next}_l^I.$$

It is proved to be of the form

$$\frac{\partial R_j}{\partial \ell}(t,\mathbf{x}) = \sum_{l=0}^{m} \Big(\prod_{i=0}^{l-1} \mathsf{sg}(\mathsf{inst}(t,\mathbf{x}) - i) \Big) \cdot \bar{\mathsf{sg}}(\mathsf{inst}(t,\mathbf{x}) - l) \cdot \mathsf{next}_l^j$$

for some next_l^j encoding the various types of instructions.

The definition is similar (and easier) for each function $R_j(t,\mathbf{x})$. Observe that in the expression above, there is at most one occurrence of $\mathsf{inst}(t,\mathbf{x})$ and $R_j(t,\mathbf{x})$ that is not under the scope of an essentially constant function (i.e. the sign functions). Hence, the expressions are of the prescribed form.

We know M works in time $\ell(\mathbf{x})^c$ for some fixed $c \in \mathbb{N}$. Both functions $\ell(\mathbf{x}) = \ell(x_1) + \ldots + \ell(x_p)$ and $B(\mathbf{x}) = 2^{\ell(\mathbf{x}) \cdot \ell(\mathbf{x})}$ are in $\mathbb{DL}$. It is easily seen that : $\ell(\mathbf{x})^c \leq B^{(c)}(\ell(\mathbf{x})))$ where $B^{(c)}$ is the c-fold composition of function B. We conclude by setting $f(\mathbf{x}) = R_0(B^{(c)}(\max(\mathbf{x})), \mathbf{x})$. ◀

▶ **Definition 39** (Normal linear $\mathcal{L}$-ODE (N$\mathcal{L}$-ODE)). *Function $\mathbf{f}$ is definable by a normal linear $\mathcal{L}$-ODE if it corresponds to the solution of $\mathcal{L}$-IVP $\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \mathcal{L}} = \mathbf{u}(\mathbf{f}(x,\mathbf{y}), x, \mathbf{y})$, $\quad \mathbf{f}(0,\mathbf{y}) = \mathbf{v}(\mathbf{y})$ where $\mathbf{u}$ is essentially linear in $\mathbf{f}(x,\mathbf{y})$ and $\mathbf{v}$ is either the identity, a projection or a constant function.*

From the proof of Theorem 38 the result below can be easily obtained. It expresses that composition needs to be used only once as exemplified in the above definition.

▶ **Theorem 40** (Alternative characterization of **FPTIME**). *A function $\mathbf{f} : \mathbb{N}^p \to \mathbb{Z}$ is in* **FPTIME** *iff $f(\mathbf{y}) = \mathbf{g}(\ell(\mathbf{y})^c, \mathbf{y})$ for some integer c and some $\mathbf{g} : \mathbb{N}^{p+1} \to \mathbb{Z}^k$ solution of a normal linear length-ODE $\frac{\partial \mathbf{g}(x,\mathbf{y})}{\partial \ell(x)} = \mathbf{u}(\mathbf{g}(x,\mathbf{y}), x, \mathbf{y})$.*

▶ Remark 41. From similar arguments, **FPTIME** also corresponds to the class defined as $\mathbb{DL}$ but where linear length-ODE scheme is replaced by normal linear length-ode scheme: this forbids a function already defined with some ODE scheme to be used into some other ODE scheme.

7 A characterization of FNP

This can be extended to more general class such as **FNP**. A function can always seen by its graph Q: A relation Q is in **FNP** if and only if there is a deterministic time verifier, given an arbitrary input (x, y) determines whether $(x, y) \in Q$. Equivalently, Q is **FNP** if and only if there is a non deterministic polynomial time algorithm that, given an arbitrary input x, can find some y such that $(x, y) \in Q$. A function $w : \mathbb{N}^{p+1} \to \mathbb{Z}$ is bounded if for all $\mathbf{x} \in \mathbb{N}^p$, $w(\mathbf{x}) \leq \|\mathbf{x}\|$.

▶ **Definition 42** (Normal linear $\mathcal{L}$-ODE with parameter). *Let $\mathcal{L} : \mathbb{N}^{p+1} \to \mathbb{Z}$. Function $\mathbf{f} : \mathbb{N}^{p+1} \to \mathbb{Z}^k$ is definable by a $\mathcal{L}$-ODE with parameter if there exists a bounded function $w : \mathbb{N}^{p+1} \to \mathbb{Z}$ such that $\mathbf{f}$ is the solution of an equation $\frac{\partial \mathbf{f}(x,\mathbf{y})}{\partial \mathcal{L}} = \mathbf{u}(\mathbf{f}(x, \mathbf{y}), w(x, \mathbf{y}), x, \mathbf{y})$ $\mathbf{f}(0, \mathbf{y}) = \mathbf{v}(\mathbf{y})$, where $\mathbf{u}$ is essentially linear in $\mathbf{f}(x, \mathbf{y})$ and $\mathbf{v}$ is either the identity, a projection or a constant function.*

▶ **Theorem 43** (Characterization of **FNP**). *A function $\mathbf{f} : \mathbb{N}^p \to \mathbb{N}^k$ is in* **FNP** *iff $f(\mathbf{y}) = \mathbf{g}(2^{\ell(\mathbf{y})^c}, \mathbf{y})$ for some integer c and some $\mathbf{g} : \mathbb{N}^{p+1} \to \mathbb{N}^k$, solution of a normal linear length-ODE with parameter $\frac{\partial \mathbf{g}(x,\mathbf{y})}{\partial \ell(x)} = \mathbf{u}(\mathbf{g}(x, \mathbf{y}), w(x, \mathbf{y}), x, \mathbf{y})$ for some bounded $w : \mathbb{N}^{p+1} \to \mathbb{N}$.*

8 Discussions and further works

Our aim in this article was to give the basis of a presentation of complexity theory based on discrete Ordinary Differential Equations and their basic properties. We demonstrated the particular role played by affine ordinary differential equations in complexity theory, as well as the concept of derivation along some particular function (i.e. change of variable) to guarantee a low complexity.

Previous ideas used here for **FPTIME** can also be extended to provide a characterization of other complexity classes: This includes the possibility of characterizing the class $\mathbf{P}_{[0,1]}$ of functions computable in polynomial time over the reals in the sense of computable analysis, or more general classes of classical discrete complexity theory such as **FPSPACE**. For the clarity of the current exposition, as this would require to introduce other types of schemata of ODEs, we leave this characterization (and improvement of the corresponding schemata to "the most natural and powerful form") for future work, but we believe the current article basically provides the key types of arguments to conceive that this is indeed possible.

More generally, it is also very instructive to revisit classical algorithmic under this viewpoint, and for example one may realize that even inside class **PTIME**, the Master Theorem (see e.g. [11, Theorem 4.1] for a formal statement) can be basically read as a result on (the growth of) a particular class of discrete time length ODEs. Several recursive algorithms can then be reexpressed as particular discrete ODEs of specific type.

Abstract

We note that the coalgebra of formal power series in commutative variables is final in a certain subclass of coalgebras. Moreover, a system Σ of polynomial PDEs, under a coherence condition, naturally induces such a coalgebra over differential polynomial expressions. As a result, we obtain a clean coinductive proof of existence and uniqueness of solutions of initial value problems for PDEs. Based on this characterization, we give complete algorithms for checking equivalence of differential polynomial expressions, given Σ.

1 Introduction

The last two decades have seen an impressive growth of formal methods and tools for continuous and hybrid systems, centered around techniques for reasoning on ordinary differential equations (ODEs), see e.g. [29, 28, 21, 11, 15, 6] and references therein. On the other hand, formal methods for systems defined by *partial* differential equations (PDEs) have not undergone a comparable development. The present paper is meant as an initial contribution towards this development.

Like in our previous works on ODEs [5, 7], our starting point is a simple operational view of differential equations as programs for calculating the Taylor coefficients of a function. Taking a transition in such a program corresponds to taking a function's derivative. An output is returned as the result of evaluating the current state (function) at a fixed expansion point, for example the origin. This idea is certainly not new: it is for example at the root of classical methods to numerically solve ODEs.

We focus here on polynomial PDEs, which are expressive enough for the vast majority of problems arising in applications, and systematically pursue the above operational view in the framework of coalgebras. We first introduce a subclass of coalgebras that enjoy a commutativity property of transitions, then note that formal power series in commutative variables (CFPSs) are final for this subclass (Section 2). A system Σ of PDEs and a specification of initial data together form an initial value problem. Under a coherence condition (Section 3), an initial value problem induces a coalgebra structure over the set of differential polynomials. The solution of the initial value problem is therefore obtained as the unique coalgebra morphism from the set of such polynomials to the final coalgebra of CFPSs. This way, we obtain an elementary and clean proof of existence and uniqueness of solutions as CFPSs (Section 4). We also show that coherence is an essential requirement for this result. From a pragmatical point of view, we note that as solutions of PDEs, CFPSs may be viewed as a conservative extension of analytic functions: *if* an analytic solution of Σ exists, *then* its Taylor expansion from 0, seen as a formal power series, coincides with the unique solution in our sense.

This characterization is the basis of an algorithm to automatically check polynomial equalities – e.g. conservation laws – valid among the functions defined by given system Σ and a specification of initial data (Section 5). Just like in certain on-the-fly algorithms for bisimulation checking, the underlying idea is, based on the introduced transition structure, to incrementally build a relation until it "closes up", but working here modulo sum and product of polynomials. Concepts from algebraic geometry, notably Gröbner bases, are used to prove the termination and correctness of this algorithm. In fact, we are more general than this, and also give a method to automatically compute the weakest precondition (= set of initial data specifications) under which a given equality is valid in Σ. These algorithms are complete, under a certain finite-parameter condition. This way one can, for example, automatically check conservation laws of a given physical system. Relationship with our previous work on ODEs [5, 7], as well as with related work by other authors, is discussed in the concluding section (Section 6). Proofs omitted from the present version will appear in a forthcoming online version of the paper.

2 Commutative coalgebras

Let X be a finite nonempty set of *actions (or variables)*, ranged over by $x, y, ...$ and O a nonempty set. We recall that a *(Moore) coalgebra*[1] with actions in X and outputs in O is a triple $C = (\mathcal{S}, \delta, o)$ where: $\mathcal{S}$ is a set of *states*, $\delta : \mathcal{S} \times X \to \mathcal{S}$ is a *transition* function, and $o : \mathcal{S} \to O$ is an *output* function (see e.g. [27]). A *bisimulation* in C is a binary relation $R \subseteq \mathcal{S} \times \mathcal{S}$ such that whenever $s\, R\, t$ then: (a) $o(s) = o(t)$, and (b) for each x, $\delta(s, x)\, R\, \delta(t, x)$. It is an (easy) consequence of the general theory of bisimulation that a largest bisimulation over C, called bisimilarity and denoted by $\sim_C$, exists, is the union of all bisimulation relations, and is an equivalence relation over $\mathcal{S}$. Given two coalgebras with actions in X and outputs in O, C_1 and C_2, a *morphism* from C_1 to C_2 is a function $\mu : \mathcal{S}_1 \to \mathcal{S}_2$ that: (1) preserves outputs ($o_1(s) = o_2(\mu(s))$), and (2) preserves transitions ($\mu(\delta_1(s, x)) = \delta_2(\mu(s), x)$), for each state s and action x). It is an easy consequence of this definition that a morphism preserves bisimulation in both directions, that is: $s \sim_{C_1} t$ if and only if $\mu(s) \sim_{C_2} \mu(t)$.

We introduce now the subclass of Moore coalgebras we will focus on. We say a coalgebra C has *commutative actions* (or just that is *commutative*) if for each state s and actions x, y, it holds that $\delta(\delta(s, x), y) \sim_C \delta(\delta(s, y), x)$. We will introduce below an example of commutative coalgebra. In what follows, we let σ range over X^*, and, for any state s, let $s(\sigma)$ be defined inductively as: $s(\epsilon) \stackrel{\triangle}{=} s$ and $s(x\sigma) \stackrel{\triangle}{=} \delta(s, x)(\sigma)$.

▶ **Lemma 2.1.** *Let C be a commutative coalgebra. If $\sigma, \sigma' \in X^*$ are permutations of one another then for any state $s \in \mathcal{S}$, $s(\sigma) \sim_C s(\sigma')$.*

We now introduce the coalgebra of formal power series in commutative variables with outputs in $O = \mathbb{R}$. Let $X^{\otimes}$, ranged over by $\tau, \tau', ...$, be the set of *monomials*[2] that can be formed from $X = \{x_1, ..., x_n\}$, in other words, the commutative monoid freely generated by X.

▶ **Definition 2.2** (commutative formal power series). *Let X be a finite nonempty alphabet. A* commutative formal power series *(CFPS) with indeterminates in X and coefficients in $\mathbb{R}$ is a total function $f : X^{\otimes} \to \mathbb{R}$. The set of these CFPSs will be denoted by $\mathcal{F}(X)$, or simply $\mathcal{F}$ if X is understood from the context.*

[1] In the paper, we only consider Moore coalgebras. For brevity, we shall omit the qualification "Moore".

[2] In general, we shall adopt for monomials the same notation we use for strings, as the context is sufficient to disambiguate. In particular, we overload the symbol ϵ to denote both the empty string and the empty monomial.

In the rest of the section, we fix an arbitrary X. We will sometimes use the suggestive notation

$$\sum_\tau f(\tau) \cdot \tau$$

to denote a CFPS $f = \lambda\tau.f(\tau)$. By slight abuse of notation, for each $r \in \mathbb{R}$, we will denote the CFPS that maps ϵ to r and anything else to 0 simply as r; while x_i will denote the i-th identity, the CFPS that maps x_i to 1 and anything else to 0. In the sequel, $\delta(f,x) \stackrel{\triangle}{=} \frac{\partial f}{\partial x}$ denotes the CFPS obtained by the usual (formal) partial derivative of f along x. For a more workable formulation of this definition, let us introduce the following notation. Let us fix any total order $\mathbf{x} = (x_1, ..., x_n)$ of the variables in X. Given a vector $\boldsymbol{\alpha} = (\alpha_1, ..., \alpha_n)$ of nonnegative integers (a *multi-index*), we let $\mathbf{x}^{\boldsymbol{\alpha}}$ denote the monomial $x_1^{\alpha_1} \cdots x_n^{\alpha_n}$. Then $\frac{\partial f}{\partial x_i}$ is defined by the following, for each $\tau = \mathbf{x}^{(\alpha_1,\ldots,\alpha_n)}$

$$\frac{\partial f}{\partial x_i}(\tau) \quad \stackrel{\triangle}{=} \quad (\alpha_i + 1) f(x_i \tau) \,. \tag{1}$$

Finally, we define the coalgebra of CFPSs, $C_\mathcal{F}$

$$C_\mathcal{F} \quad \stackrel{\triangle}{=} \quad (\mathcal{F}, \delta_\mathcal{F}, o_\mathcal{F})$$

where $\delta_\mathcal{F}(f,x) = \frac{\partial f}{\partial x}$ and $o_\mathcal{F}(f) = f(\epsilon)$ (the constant term of f). Bisimilarity in $C_\mathcal{F}$, denoted by $\sim_\mathcal{F}$, coincides with equality. It is easily seen that for each x, y, $\frac{\partial}{\partial y}\frac{\partial f}{\partial x} = \frac{\partial}{\partial x}\frac{\partial f}{\partial y}$, so that $C_\mathcal{F}$ is a commutative coalgebra. Now fix any commutative coalgebra $C = (\mathcal{S}, \delta, o)$. We define the function $\mu : \mathcal{S} \to \mathcal{F}$ as follows. For each $\tau = \mathbf{x}^{\boldsymbol{\alpha}}$

$$\mu(s)(\tau) \quad \stackrel{\triangle}{=} \quad \frac{o(s(\tau))}{\boldsymbol{\alpha}!} \tag{2}$$

where $\boldsymbol{\alpha}! \stackrel{\triangle}{=} \alpha_1! \cdots \alpha_n!$. Here, abusing slightly notation, we let $o(s(\tau))$ denote $o(s(\sigma))$, for some string σ obtained by arbitrarily ordering the elements in τ: the specific order does not matter, in view of Lemma 2.1 and of condition (a) in the definition of bisimulation.

▶ **Lemma 2.3.** *Let C be a commutative coalgebra and $f = \mu(s)$. For each x, $\frac{\partial f}{\partial x} = \mu(\delta(s,x))$.*

Based on the above lemma and the fact that $\sim_\mathcal{F}$ is equality, we can prove the following corollary, saying that $C_\mathcal{F}$ is *final* in the class of *commutative* coalgebras.

▶ **Corollary 2.4** (coinduction and finality of $C_\mathcal{F}$)**.** *Let C be a commutative coalgebra. The function μ in (2) is the unique coalgebra morphism from C to $C_\mathcal{F}$. Moreover, the following* coinduction *principle is valid: $s \sim_C t$ if and only if $\mu(s) = \mu(t)$ in $\mathcal{F}$.*

Proof. We have: (1) $o(s) = \mu(s)(\epsilon)$ by the definition of μ, and (2) $\mu(\delta(s,x)) = \delta_\mathcal{F}(\mu(s), x)$, by Lemma 2.3. This proves that μ is a coalgebra morphism. Next, we prove that $\sim_\mathcal{F}$ coincides with equality in $\mathcal{F}$. More precisely, we prove that for each τ and for each f, g: $f \sim_\mathcal{F} g$ implies $f(\tau) = g(\tau)$. Proceeding by induction on the length of τ, we see that the base case is trivial, while for the induction step $\tau = x_i\tau'$ we have: $f \sim_\mathcal{F} g$ implies $\frac{\partial f}{\partial x_i} \sim_\mathcal{F} \frac{\partial g}{\partial x_i}$ (bisimilarity), which in turn implies $\frac{\partial f}{\partial x_i}(\tau') = \frac{\partial g}{\partial x_i}(\tau')$ (induction hypothesis); but by (1), $f(x_i\tau') = (\frac{\partial f}{\partial x_i}(\tau'))/(\alpha_i + 1)$ and $g(x_i\tau') = (\frac{\partial g}{\partial x_i}(\tau'))/(\alpha_i + 1)$, and this completes the induction step. From the coincidence of $\sim_\mathcal{F}$ with equality in $\mathcal{F}$, and the fact that any morphism preserves bisimilarity in both directions, the last part of the statement (coinduction) follows immediately. Finally, let ν be any morphism from C to $C_\mathcal{F}$. From the definitions of bisimulation and morphism it is easy to see that for each s, $\mu(s) \sim_\mathcal{F} \nu(s)$: this implies $\mu(s) = \nu(s)$ by coinduction, and proves uniqueness of μ. ◀

We end this section by recalling the sum and product operations on $\mathcal{F}$. For any $\xi = \mathbf{x}^{\boldsymbol{\alpha}}$ and $\tau = \mathbf{x}^{\boldsymbol{\beta}}$, let $\xi \leq \tau$ if for each $i = 1, ..., n$, $\alpha_i \leq \beta_i$; in this case τ/ξ denotes the monomial $\mathbf{x}^{(\beta_1-\alpha_1,...,\beta_n-\alpha_n)}$. We have the following definitions of sum and product. For each $\tau \in X^{\otimes}$:

$$(f+g)(\tau) \triangleq f(\tau)+g(\tau) \qquad\qquad (f\cdot g)(\tau) \triangleq \sum_{\xi\leq\tau} f(\xi)\cdot g(\tau/\xi)\,. \tag{3}$$

These operations correspond to the usual sum and product of functions, when (convergent) CFPS are interpreted as analytic functions. These operations enjoy associativity, commutativity and distributivity. Moreover, if $f(\epsilon) \neq 0$ there exists a unique CFPS $f^{-1} \in \mathcal{F}$ that is a multiplicative inverse of f, that is $f \cdot f^{-1} = 1$. Finally, the following familiar rules of differentiation are satisfied:

$$\frac{\partial(f+g)}{\partial x} \triangleq \frac{\partial f}{\partial x} + \frac{\partial g}{\partial x} \qquad\qquad \frac{\partial(f\cdot g)}{\partial x} \triangleq \frac{\partial f}{\partial x}\cdot g + f\cdot\frac{\partial g}{\partial x}\,. \tag{4}$$

If the *support* of f, $\mathrm{supp}(f) \triangleq \{\tau : f(\tau) \neq 0\}$, is finite, we will call f a *polynomial.* The set of polynomials, denoted by $\mathbb{R}[X]$, is closed under the above defined operations of partial derivative, sum and product (but in general not inverse). Moreover, note that, when confining to polynomials, these operations are well defined even in case the cardinality of the set X of indeterminates is infinite.

3 Coherent systems of PDEs

We first review some notation and terminology from the formal theory of PDEs; these are standard notions, see e.g. [23, 18]. Like in the previous section, assume we are given a finite nonempty set X, which we will call here the *independent* variables. Another nonempty, finite set U of *dependent* variables, disjoint from X, is given; U is ranged over by $u, v, ...$ $\mathcal{D} \triangleq \{u_\tau : u \in U, \tau \in X^{\otimes}\}$ is the set of the *derivatives*; here u_ϵ will be identified with u. $E, F, ...$ range over $\mathcal{P} \triangleq \mathbb{R}[X \cup \mathcal{D}]$, the set of *(differential, multivariate) polynomials* with coefficients in $\mathbb{R}$ and indeterminates in $X \cup \mathcal{D}$. Considered as formal objects, polynomials are just finite-support CFPSs in $\mathcal{F}(X \cup \mathcal{D})$ (see Section 2). As such, they inherit from CFPSs the operations of sum, product and partial derivative, along with the corresponding properties. Syntactically, we shall write polynomials as expressions of the form $\sum_{\alpha\in M} \lambda_\alpha \cdot \alpha$, for $0 \neq \lambda_\alpha \in \mathbb{R}$ and $M \subseteq_{\mathrm{fin}} (X \cup \mathcal{D})^{\otimes}$. For example, $E = v_z u_{xy} + v_y^2 + u + 5x$ is a polynomial[3]. For an independent variable $x \in X$, the *total derivative* of $E \in \mathcal{P}$ along x is just the derivative of E along x, taking into account that $\frac{\partial u_\tau}{\partial x} = u_{x\tau}$. Formally, we have the following.

▶ **Definition 3.1** (total derivative). *The operator $D_x : \mathcal{P} \to \mathcal{P}$ is defined by (note $\sum$ below has only finitely many nonzero terms)*

$$D_x E \triangleq \frac{\partial E}{\partial x} + \sum_{u,\tau} u_{x\tau} \cdot \frac{\partial E}{\partial u_\tau}$$

where $\frac{\partial E}{\partial a}$ denotes the partial derivative of polynomial E along $a \in X \cup \mathcal{D}$.

D_x inherits from partial derivatives rules for sum and product that are the analog of (4). As an example, for the polynomial E above, we have $D_x E = v_{xz} u_{xy} + v_z u_{xxy} + 2v_y v_{xy} + u_x + 5$.

[3] Real arithmetic expressions will be used as a meta-notation for polynomials: e.g. $(u+u_x+1)\cdot(x+u_y)$ denotes the polynomial $xu + uu_y + xu_x + u_x u_y + x + u_y$.

In particular, $D_x u_\tau = u_{x\tau}$ and $D_x x^k = kx^{k-1}$. Just as partial derivatives, total derivatives commute with each other, that is $D_x D_y F = D_y D_x F$. This suggests to extend the notation to monomials: for any monomial $\tau = x_1 \cdots x_m$, we let $D_\tau F$ be $D_{x_1} \cdots D_{x_m} F$, where the order of the variables is irrelevant.

▶ **Definition 3.2** (system of PDEs). *A* system of PDEs *is a nonempty set Σ of equations (pairs) of the form $u_\tau = E$, with $E \in \mathcal{P}$. The set of derivatives u_τ that appear as left-hand sides of equations in Σ is denoted* $\mathrm{dom}(\Sigma)$. *Based on Σ, the set $\mathcal{D}$ can be partitioned into two sets as follows:*

- $\mathcal{P}\mathrm{r}(\Sigma) \overset{\triangle}{=} \{u_\xi \,:\, \tau \leq \xi$ *for some τ s.t.* $u_\tau \in \mathrm{dom}(\Sigma)\}$ *is the set of* principal derivatives *of Σ;*
- $\mathcal{P}\mathrm{a}(\Sigma) \overset{\triangle}{=} \mathcal{D} \setminus \mathcal{P}\mathrm{r}(\Sigma)$ *is the set of* parametric derivatives *of* Σ.

We let $\mathcal{P}_0(\Sigma) \overset{\triangle}{=} \mathbb{R}[X \cup \mathcal{P}\mathrm{a}(\Sigma)]$.

The intuition of $\mathcal{P}\mathrm{a}(\Sigma)$ is that, once we fix the corresponding values, the rest of the solution, hence $\mathcal{P}\mathrm{r}(\Sigma)$, will be uniquely determined (see Example 3.4 below). Note that we do not require that each derivative occurs at most once as left-hand side in Σ. The *infinite prolongation* of a system Σ, denoted Σ^∞, is the system of PDEs of the form $u_{\xi\tau} = D_\xi F$, where $u_\tau = F$ is in Σ and $\xi \in X^\otimes$. Of course, $\Sigma^\infty \supseteq \Sigma$. Moreover, Σ and Σ^∞ induce the *same* sets of principal and parametric derivatives.

A *ranking* is a total order $\prec$ of $\mathcal{D}$ such that: (a) $u_\tau \prec u_{x\tau}$, and (b) $u_\tau \prec v_\xi$ implies $u_{x\tau} \prec v_{x\xi}$, for each $x \in X$, $\tau, \xi \in X^\otimes$ and $u, v \in U$. Dickson's lemma [10] implies that $\mathcal{D}$ with $\prec$ is a well-order, and in particular that there is no infinite descending chain in it. The system Σ is $\prec$*-normal* if, for each equation $u_\tau = E$ in Σ, $u_\tau \succ v_\xi$, for each v_ξ appearing in E. An easy but important consequence of condition (b) above is that if Σ is normal then also its prolongation Σ^∞ is normal.

Now, consider the equational theory over $\mathcal{P}$ induced by the equations in Σ^∞. More precisely, write $E \to_\Sigma F$ if F is the polynomial that is obtained from E by replacing one occurrence of u_τ with G, for some equation $u_\tau = G \in \Sigma^\infty$. Note, in particular, that $E \in \mathcal{P}$ cannot be rewritten if and only if $E \in \mathcal{P}_0(\Sigma)$. We let $=_\Sigma$ denote the reflexive, symmetric and transitive closure of $\to_\Sigma$. The following definition formalizes the key concepts of consistency and coherence of Σ. Basically, as we will show, under the syntactic requirement of normality, which is natural from an algorithmic point of view, consistency is a necessary and sufficient condition for Σ to admit a unique solution under *all* initial data specifications.

▶ **Definition 3.3** (consistency and coherence). *Let Σ be a system of PDEs.*

- *We say Σ is* consistent *if for each $E \in \mathcal{P}$ there is a unique $F \in \mathcal{P}_0(\Sigma)$ such that $E =_\Sigma F$.*
- *Let $\prec$ be a ranking. A system Σ is* $\prec$-coherent *if it is $\prec$-normal and consistent.*

For a consistent system, we can define a *normal form function*

$$S_\Sigma : \mathcal{P} \to \mathcal{P}_0(\Sigma)$$

by letting $S_\Sigma E = F$, for the unique $F \in \mathcal{P}_0(\Sigma)$ such that $E =_\Sigma F$. The term $S_\Sigma E$ will be often abbreviated as SE, if Σ is understood from the context. Deciding if a (finite) system Σ is coherent, for a suitable ranking $\prec$, is of course a nontrivial problem. In a *normal* system, since $\prec$ is a well-order, there are no infinite sequences of rewrites $E_1 \to_\Sigma E_2 \to_\Sigma E_3 \to_\Sigma \cdots$: therefore it is possible to rewrite any E into some $F \in \mathcal{P}_0(\Sigma)$ in a finite number of steps. Proving coherence in this case reduces basically to ensure that Σ contains "enough equations" to make $\to_\Sigma$ confluent. In fact, an even more general problem than checking coherence is completing a normal, non coherent system by new equations so as to make it coherent; or

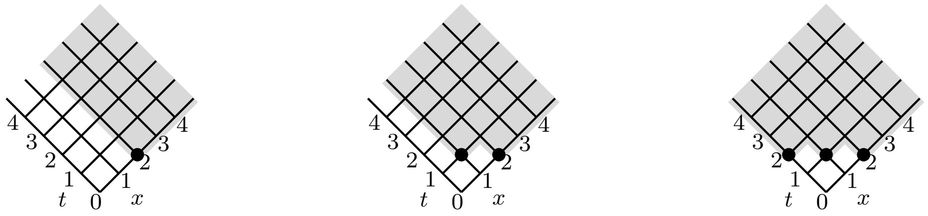

Figure 1 Lattices of u-derivatives, partially ordered by $u_\xi \leq u_\tau$ if and only if $\xi \leq \tau$. With reference to Example 3.4, black circles correspond to left-hand sides of equations, shaded regions to principal derivatives, and non-shaded regions to parametric derivatives.

deciding if this is impossible at all, because the system is intrinsically inconsistent. There is a rich literature on these problems, which we briefly review in the concluding section. The following simple example is enough to demonstrate these concepts for our purposes.

▶ **Example 3.4** (coherence). Consider the heat equation in one spatial dimension, where $X = \{x, t\}$, $U = \{u\}$ and Σ is given by the single equation (for a real parameter $a \neq 0$)

$$u_{xx} \;=\; au_t\,. \tag{5}$$

Here, the principal derivatives are $\mathcal{P}\mathrm{r}(\Sigma) = \{u_{xx\tau} : \tau \in X^{\otimes}\}$, and the parametric ones are $\mathcal{P}\mathrm{a}(\Sigma) = \{u_{t^j} : j \geq 0\} \cup \{u_{xt^j} : j \geq 0\}$ (see Figure 1, left). Since the system has just one equation, it is clearly consistent: indeed, its prolongation Σ^∞ has precisely one equation $u_{xx\tau} = D_\tau\,(au_t)$ for each principal derivative $u_{xx\tau}$. Concerning coherence, we consider the following ranking. Ordering the independent variables as $t < x$ induces a *graded* lexicographic order $\prec_{\mathrm{grlex}}$ over $X^{\otimes}$: that is, monomials are compared first by their total degree, and then lexicographically. We lift $\prec_{\mathrm{grlex}}$ to $\mathcal{D}$ as expected: explicitly, $u_\xi \prec u_\tau$ if, for $\xi = t^i x^j$ and $\tau = t^{i'} x^{j'}$, it holds that either $i + j < i' + j'$ or $(i + j = i' + j'$ and $j' > j)$. Σ is clearly $\prec$-normal.

Next, suppose we build a new system Σ_1 by adding the new equation (with no physical significance)

$$u_{tx} \;=\; u\,.$$

Now the parametric derivatives are u_{t^j} for $j \geq 0$ and u_x, while the remaining derivatives are principal (see Figure 1, center). The prolongation of the new system, Σ_1^∞, has both $u_{txx} = u_x$ and $u_{txx} = au_{tt}$ as equations, which implies $u_x =_{\Sigma_1} au_{tt}$. As $u_x, u_{tt} \in \mathcal{P}\mathrm{a}(\Sigma_1) \subseteq \mathcal{P}_0(\Sigma_1)$, we conclude that Σ_1 is *not* consistent, hence not coherent: indeed, there are two distinct but equivalent normal forms. This suggests that we can complete Σ_1 by inserting a third equation, a so-called *integrability condition*

$$u_{tt} \;=\; \frac{u_x}{a}\,.$$

In the resulting system Σ_2 the set of parametric derivatives has changed to $\{u, u_t, u_x\}$ (see Figure 1, right), and u_{txx} has the (only) normal form u_x. The system Σ_2 can be indeed checked to be consistent, hence coherent. Finally, consider adding to the original system Σ the two equations below, thus obtaining Σ_3

$$u_{tx} \;=\; t \qquad\qquad u_{tt} \;=\; 1\,.$$

Together with (5) these two equations imply $a =_{\Sigma_3} 0$: Σ_3 is not consistent, moreover there is no way of completing it so as to get a consistent system. That is, Σ_3 is (informally speaking) intrinsically inconsistent.

For our purposes, it is enough to know that completing a given system of equations to make it coherent, or deciding that this is impossible, can be achieved by one of many existing computer algebra algorithms. For example, there is a completion procedure by Marvan [18], for which a Maple implementation is also available. See also Reid et al.'s method of reduction to *reduced involutive form* [23], implemented in the Maple rif package. An alternative to these methods is applying a procedure similar to the Knuth-Bendix completion algorithm [13] to the given system. Further references are discussed in the concluding section. In practice, in many cases arising from applications (e.g. mathematical physics), transforming the system into a coherent form for an appropriate ranking can be accomplished manually, without much difficulty. We shall not further dwell on algorithms for coherence checking in the rest of the paper. We end the section with a technical result about normal forms in coherent systems that will be used in the next section.

▶ **Lemma 3.5.** *Let Σ be coherent. For each $x \in X$ and $F \in \mathcal{P}$, $SD_xSF = SD_xF$.*

4 Coalgebraic semantics of initial value problems

We will provide differential polynomials with a coalgebra structure depending on Σ: from this, existence and uniqueness of solutions of initial value problems will follow almost immediately by coinduction (Corollary 2.4). The essential point is that coherence allows for the definition of a transition function based on total derivatives. In the definition below, it is useful to bear in mind that, informally, for a parametric derivative u_τ, the initial data value $\rho(u_\tau)$ specifies the value of $\frac{\partial u}{\partial \tau}$ at the origin.

▶ **Definition 4.1** (initial value problem). *Let Σ be a system of PDEs. A* specification of initial data *for Σ is a mapping $\rho : \mathcal{P}\mathrm{a}(\Sigma) \to \mathbb{R}$. An* initial value problem *is a pair $\mathbf{B} = (\Sigma, \rho)$.*

In what follows, for any function $\psi : U \to \mathcal{F}$, we can consider its homomorphic extension $\mathcal{P} \to \mathcal{F}$, obtained by interpreting each expression E in the obvious way: replace u_τ by $\frac{\partial \psi(u)}{\partial \tau}$, and sum and product by the corresponding operations in $\mathcal{F}$ (see Section 2); an independent variable $x_i \in X$ is interpreted as the i-th identity CFPS. By slight abuse of notation, we will still denote by "ψ" the homomorphic extension of ψ. In part (a) below, recall that for a CFPS f, $f(\epsilon)$ represents, informally, the value of function f at the origin.

▶ **Definition 4.2** (solution of $\mathbf{B}$). *A* solution *of a initial value problem $\mathbf{B} = (\Sigma, \rho)$ is a mapping $\psi : U \to \mathcal{F}$ such that: (a) the initial data specifications are satisfied, that is $\psi(u_\tau)(\epsilon) = \rho(u_\tau)$ for each $u_\tau \in \mathcal{P}\mathrm{a}(\Sigma)$; and (b) all equations are satisfied, that is $\psi(u_\tau) = \psi(F)$ for each $u_\tau = F$ in Σ^∞.*

The following lemma about solutions will be used to prove uniqueness of the solution of $\mathbf{B}$.

▶ **Lemma 4.3.** *Let $\mathbf{B} = (\Sigma, \rho)$ and ψ a solution of $\mathbf{B}$. For each $E, F \in \mathcal{P}$, $E =_\Sigma F$ implies $\psi(E) = \psi(F)$.*

With any coherent (w.r.t. some ranking) Σ and initial data specification ρ, $\mathbf{B} = (\Sigma, \rho)$, we can associate a coalgebra as follows. The initial data specification $\rho : \mathcal{P}\mathrm{a}(\Sigma) \to \mathbb{R}$ can be extended homomorphically to $\mathcal{P}_0(\Sigma) \to \mathbb{R}$, by interpreting $+$ and $\cdot$ as the usual sum and product over $\mathbb{R}$, respectively, and by letting $\rho(x) \overset{\triangle}{=} 0$ for each independent variable $x \in X$. Now we define a coalgebra depending on $\mathbf{B}$:

$$C_{\mathbf{B}} \overset{\triangle}{=} (\mathcal{P}, \delta_\Sigma, o_\rho)$$

where $\delta_\Sigma(E,x) \stackrel{\triangle}{=} SD_xE$ and $o_\rho(E) \stackrel{\triangle}{=} \rho(SE)$. We will denote by $\sim_{\mathbf{B}}$ bisimilarity in $C_{\mathbf{B}}$. As an example of transition, for the heat equation $\Sigma = \{u_{xx} = au_t\}$, one has $\delta_\Sigma(u_{xx}, t) = au_{tt}$.

▶ Remark 4.4. An obvious alternative to the above definition of transition function of $C_{\mathbf{B}}$ would be just letting $\delta_\Sigma(E,x) = D_xE$: this definition in fact would work as well, but it has the computational disadvantage of making the order of the derivatives higher at each step, which would be inconvenient for the algorithms to be developed later on (Section 5).

As expected, $C_{\mathbf{B}}$ is a commutative coalgebra. Moreover, each expression is bisimilar to its normal form. This is the content of the following lemma.

▶ **Lemma 4.5.** *Let $\mathbf{B} = (\Sigma, \rho)$, with Σ coherent. Then: (1) $C_{\mathbf{B}}$ is commutative; and (2) For each $E \in \mathcal{P}$, $E \sim_{\mathbf{B}} SE$.*

Note that since $\delta_\Sigma(\delta_\Sigma(E,x),y) = \delta_\Sigma(\delta_\Sigma(E,y),x)$, for any monomial τ, the notation $\delta_\Sigma(E,\tau)$ is well defined. As a consequence of the previous lemma, part 1, and of Corollary 2.4, there exists a unique morphism from $C_{\mathbf{B}}$ to $C_{\mathcal{F}}$. This morphism is the unique solution of $\mathbf{B}$ we are after. We need a lemma, saying that the unique morphism ϕ from $C_{\mathbf{B}}$ to $C_{\mathcal{F}}$ is compositional.

▶ **Lemma 4.6.** *Let $\mathbf{B} = (\Sigma, \rho)$, with Σ coherent, and let $\phi_{\mathbf{B}}$ be the unique morphism from $C_{\mathbf{B}}$ to $C_{\mathcal{F}}$. Then $\phi_{\mathbf{B}}$ is a homomorphism over $\mathcal{P}$.*

▶ **Theorem 4.7** (coalgebraic semantics of PDEs). *Let $\mathbf{B} = (\Sigma, \rho)$, with Σ coherent. Let $\phi_{\mathbf{B}}$ denote the unique morphism from $C_{\mathbf{B}}$ to $C_{\mathcal{F}}$. Then $\phi_{\mathbf{B}}$ (restricted to U) is the unique solution of $\mathbf{B}$.*

Proof. By virtue of Lemma 4.6, $\phi_{\mathbf{B}}$ coincides with the homomorphic extension of $(\phi_{\mathbf{B}})_{|U}$. We first prove that that $\phi_{\mathbf{B}}$ respects the initial data specification. Let u_τ be parametric. By the definition of coalgebra morphism and of output functions in $C_{\mathcal{F}}$ and $C_{\mathbf{B}}$, we have

$$\phi_{\mathbf{B}}(u_\tau)(\epsilon) \quad = \quad o_{\mathcal{F}}(\phi_{\mathbf{B}}(u_\tau)) \quad = \quad o_\rho(u_\tau) \quad = \quad \rho(Su_\tau) \quad = \quad \rho(u_\tau)$$

which proves the wanted condition. Next, we have to prove that $\phi_{\mathbf{B}}$ satisfies the equations in Σ^∞. But for each such equation, say $u_\tau = F$, we have $Su_\tau =_\Sigma SF$ by the definition of $=_\Sigma$, hence $u_\tau \sim_{\mathbf{B}} F$ by Lemma 4.5(2), hence the thesis by coinduction (Corollary 2.4). We finally prove uniqueness of the solution. Assume ψ is a solution of $\mathbf{B}$, and consider the homomorphic extension of ψ to $\mathcal{P}$, still denoted by ψ. We prove that ψ is a coalgebra morphism from $C_{\mathbf{B}}$ to $C_{\mathcal{F}}$, hence $\psi = \phi_{\mathbf{B}}$ will follow by coinduction (Corollary 2.4). Let $E \in \mathcal{P}$. There are two steps in the proof.

- $\psi(E)(\epsilon) = \rho(SE) = o_\rho(E)$. This follows directly from Lemma 4.3, since $\psi(E) = \psi(SE)$.
- For each x, $\frac{\partial\psi(E)}{\partial x} = \psi(\delta_\Sigma(E,x))$. First, we note that $\frac{\partial\psi(E)}{\partial x} = \psi(D_xE)$. This is proven by induction on the size of E: in the base case when $E = u_\tau$, just use the fact that, by the definition of solution, $\frac{\partial\psi(u_\tau)}{\partial x} = \frac{\partial}{\partial x}\frac{\partial\psi(u)}{\partial\tau} = \frac{\partial\psi(u)}{\partial\tau x} = \psi(u_{\tau x}) = \psi(D_xu_\tau)$; in the induction step, use the fact that ψ is an homomorphism over $\mathcal{P}$, and the derivation rules of D_x and $\frac{\partial}{\partial x}$ for sum and product. Now applying Lemma 4.3, we get $\psi(D_xE) = \psi(SD_xE) = \psi(\delta_\Sigma(E,x))$, which is the wanted equality. ◀

▶ Remark 4.8 (analyticity). The previous theorem guarantees that formal power series solutions of a coherent system of PDEs always exist and are unique. In general, there is no guarantee of analyticity for such solutions. However, *if* a solution ψ of Σ in the usual sense exists that is analytic around the origin, *then* its Taylor expansion from the origin, seen as a CFPS, coincides with our solution $\phi_{\mathbf{B}}$: for each u and $f = \psi(u)$, we have that $f = \sum_{\boldsymbol{\alpha}}(\frac{\partial f}{\partial\tau})(0)\cdot\frac{\mathbf{x}^{\boldsymbol{\alpha}}}{\boldsymbol{\alpha}!} = \phi_{\mathbf{B}}(u)$. Riquier's theorem [24] gives sufficient syntactic conditions for the existence of analytic solutions; see [26, 16, 17] for further discussion of this point.

The computational content of Theorem 4.7 is twofold. One one hand, we can use coinduction as a technique to prove semantically valid identities $E = F$ for the initial value problem at hand, as bisimulations $E \sim_{\mathbf{B}} F$ (via Corollary 2.4). On the other hand, we can calculate mechanically the coefficients of the Taylor expansion of the solution. This will also be key to the algorithms presented in Section 5.

▶ **Corollary 4.9** (Taylor coefficients). *Let Σ be coherent, let ρ be an initial data specification and let $\phi_{\mathbf{B}}$ be the unique solution of $\mathbf{B} = (\Sigma, \rho)$. Then, for each $E \in \mathcal{P}$, $\phi_{\mathbf{B}}(E) = \sum_{\tau = \mathbf{x}^{\boldsymbol{\alpha}}} c_\tau \cdot \tau$ where*

$$c_\tau = \frac{\rho(\delta_\Sigma(E, \tau))}{\boldsymbol{\alpha}!} \,. \tag{6}$$

Proof. This follows immediately from Theorem 4.7 and from the definitions of unique morphism (2) and of the coalgebra $C_{\mathbf{B}}$. ◀

The terms $\frac{\delta_\Sigma(E,\tau)}{\boldsymbol{\alpha}!} \in \mathcal{P}_0(\Sigma)$ appearing in (6) provide a “symbolic” representation of the Taylor coefficients of solutions, independent of ρ.

▶ **Example 4.10.** Consider $U = \{f, g, i, j, h, k\}$, $X = \{x, y\}$ and $\Sigma = \{\, f_x = -g \,,\, f_y = -g \,,\, g_x = f \,,\, g_y = f \,,\, i_x = -j \,,\, i_y = 0 \,,\, j_x = i \,,\, j_y = 0 \,,\, h_x = 0 \,,\, h_y = -k \,,\, k_x = 0 \,,\, k_y = h \,\}$. Note that $\mathcal{P}\mathrm{a}(\Sigma) = U$. The system is consistent because Σ^∞ has just one equation for each $u_\tau \in \mathcal{P}\mathrm{r}(\Sigma)$. Moreover, it is normal, hence coherent, with respect to any graded ranking. Consider now the initial value problem $\mathbf{B} = (\Sigma, \rho)$ where ρ is defined by $\rho(f) = \rho(i) = \rho(h) = 1$ and $\rho(g) = \rho(j) = \rho(k) = 0$. Let $E \triangleq ih - jk$, $F \triangleq ik + jh$ and $R \subseteq \mathcal{P} \times \mathcal{P}$, $R \triangleq \{(f, E), (g, F), (-f, -E), (-g, -F)\}$: it is immediate to check that R is a bisimulation in $C_{\mathbf{B}}$. By coinduction and Theorem 4.7, we have therefore $\phi_{\mathbf{B}}(f) = \phi_{\mathbf{B}}(E)$ and $\phi_{\mathbf{B}}(g) = \phi_{\mathbf{B}}(F)$. Note that, in the given $\mathbf{B}$, the variables in U encode $\cos(x+y), \sin(x+y), \cos(x), \sin(x), \cos(y), \sin(y)$, respectively. Therefore e.g. $\phi_{\mathbf{B}}(f) = \phi_{\mathbf{B}}(E)$ actually proves that $\cos(x+y) = \cos(x)\cos(y) - \sin(x)\sin(y)$, a well-known trigonometric identity.

Finally, a more refined argument leads to a precise characterization of the systems that admit (unique) solutions for every initial data specification, under normality.

▶ **Theorem 4.11** (consistency, existence and uniqueness). *Let Σ be a normal system. Σ is coherent if and only if for each ρ, $\mathbf{B} = (\Sigma, \rho)$ has a solution. Moreover, for each such $\mathbf{B}$ the solution is unique.*

5 Equivalence checking

In this section, based on Theorem 4.7 and on an algebraic characterization of bisimilarity we shall discuss below, we will provide a decision algorithm for the equivalence problem $\phi_{\mathbf{B}}(E) = \phi_{\mathbf{B}}(F)$, limited to the following subclass of PDE systems.

▶ **Definition 5.1** (finite-parameter systems). *A system Σ is* finite-parameter *if $\mathcal{P}\mathrm{a}(\Sigma)$ is finite.*

For instance, with reference to Example 3.4, Σ_2 is finite-parameter, while Σ and Σ_1 are not. We need to introduce now some additional, mostly standard notation about polynomials. According to (6), the calculation of the Taylor coefficients of a solution of an initial value problem $\mathbf{B} = (\Sigma, \rho)$ involves evaluating expressions in $\mathcal{P}_0(\Sigma) = \mathbb{R}[X \cup \mathcal{P}\mathrm{a}(\Sigma)]$. As $k \triangleq |X \cup \mathcal{P}\mathrm{a}(\Sigma)| < +\infty$, elements of $\mathcal{P}_0(\Sigma)$ can be treated as usual multivariate polynomials in a finite number of indeterminates. In particular, we can identify initial data specifications

ρ with points in $\mathbb{R}^k$ that vanish in the x-coordinates ($x \in X$). In this section we will let ρ range over $\mathbb{R}^k$. Moreover, we let $\mathbb{R}^k_0 \stackrel{\triangle}{=} \{\rho \in \mathbb{R}^k \,:\, \rho(x) = 0$ for each $x \in X\}$ and, for polynomials $E \in \mathcal{P}_0(\Sigma)$ and initial data specifications $\rho \in \mathbb{R}^k_0$, write $\rho(E)$ as $E(\rho)$ – that is the value in $\mathbb{R}$ obtained by evaluating E at point ρ.

In what follows, we shall also make use a few elementary notions from algebraic geometry [10]. In particular, an *ideal* $J \subseteq \mathcal{P}_0(\Sigma)$ is a nonempty set of polynomials closed under addition, and under multiplication by polynomials in $\mathcal{P}_0(\Sigma)$. For $P \subseteq \mathcal{P}_0(\Sigma)$, $\langle\ P\ \rangle \stackrel{\triangle}{=} \{\sum_{i=1}^{m} G_i \cdot E_i \,:\, m \geq 0,\ G_i \in \mathcal{P}_0(\Sigma),\ E_i \in P\}$ denotes the smallest ideal which includes P, and $V(P) \subseteq \mathbb{R}^k$ the *(affine) variety* induced by P: $V(P) \stackrel{\triangle}{=} \{\rho \in \mathbb{R}^k \,:\, E(\rho) = 0$ for each $E \in P\} \subseteq \mathbb{R}^k$. For $W \subseteq \mathbb{R}^k$, $I(W) \stackrel{\triangle}{=} \{E \in \mathcal{P}_0(\Sigma) \,:\, E(\rho) = 0$ for each $\rho \in V\}$. We will use a few basic facts about ideals and varieties: (a) both $I(\cdot)$ and $V(\cdot)$ are inclusion reversing: $P_1 \subseteq P_2$ implies $V(P_1) \supseteq V(P_2)$ and $W_1 \subseteq W_2$ implies $I(W_1) \supseteq I(W_2)$; (b) any ascending chain of ideals $I_0 \subseteq I_1 \subseteq \cdots$ stabilizes in a finite number of steps (Hilbert's basis theorem); (c) for finite $P \subseteq \mathcal{P}_0(\Sigma)$, the problem of deciding if $E \in \langle\ P\ \rangle$ is decidable, by computing a Gröbner basis (a set of generators with special properties) of $\langle\ P\ \rangle$. See [10] for a comprehensive treatment.

Given a coherent, finite-parameter Σ and an initial data specification $\rho \in \mathbb{R}^k_0$, let us denote by $\phi_{\mathbf{B}}$ the unique solution of the initial value problem $\mathbf{B} = (\Sigma, \rho)$ (Theorem 4.7). Since by definition $\phi_{\mathbf{B}}$ is a homomorphism, for any given $E, F \in \mathcal{P}$, establishing that $\phi_{\mathbf{B}}(E) = \phi_{\mathbf{B}}(F)$ is equivalent to establish that $\phi_{\mathbf{B}}(E - F) = 0$. In other words, we can identify polynomial equations with polynomials, and valid polynomial equations under ρ with polynomials $E \in \mathcal{Z}_{\mathbf{B}} \subseteq \mathcal{P}$, where (below, 0 denotes the zero CFPS in $\mathcal{F}(X)$)

$$\mathcal{Z}_{\mathbf{B}} \stackrel{\triangle}{=} \phi_{\mathbf{B}}^{-1}(0)\,.$$

The equality problem reduces therefore to the *membership* problem for $\mathcal{Z}_{\mathbf{B}}$, for which we will now give an algorithm. In general terms, given $E \in \mathcal{P}$, suppose we want to decide if $E \in \mathcal{Z}_{\mathbf{B}}$. Note that, by virtue of Lemma 4.3, we can assume w.l.o.g. that $E \in \mathcal{P}_0(\Sigma)$. We shall rely mainly on Corollary 4.9. Consider now the chain of sets $A_0 \subseteq A_1 \subseteq \cdots \subseteq \mathcal{P}_0(\Sigma)$ defined as:

$$A_0 \stackrel{\triangle}{=} \{E\} \qquad\qquad A_{i+1} \stackrel{\triangle}{=} A_i \cup \{\delta_\Sigma(F, x) \,:\, F \in A_i,\, x \in X\}\,. \tag{7}$$

Let $m \geq 0$ be the least integer such that either: (a) there exists $F \in A_m$ s.t. $F(\rho) \neq 0$; or (b) no such $F \in A_m$ exists, but $A_{m+1} \subseteq I_m$, where, for each $i \geq 0$, $I_i \stackrel{\triangle}{=} \langle\ A_i\ \rangle$ is the ideal in $\mathcal{P}_0(\Sigma)$ generated by A_i. The algorithm returns "No" if (a) occurs, and "Yes" if (b) occurs. Note that the I_i's, $i \geq 0$, form an ascending chain of ideals in $\mathcal{P}_0(\Sigma)$, which must stabilize in a finite numbers of steps (by Hilbert's basis theorem). Moreover, the inclusion $A_{m+1} \subseteq I_m$ is decidable (by Gröbner basis construction). This ensures termination and effectiveness of the outlined algorithm. Concerning its correctness, we premise the following lemma, which implies that we can effectively detect stabilization of the sequence of the ideals I_i s.

▶ **Lemma 5.2.** *Let Σ be coherent and finite-parameter. Suppose $A_{m+1} \subseteq I_m$. Then $I_m = I_{m+j}$ for each $j \geq 1$.*

▶ **Corollary 5.3** (membership checking). *Let Σ be coherent and finite-parameter, ρ an initial data specification for Σ and $E \in \mathcal{P}_0(\Sigma)$. Then $\phi_{\mathbf{B}}(E) = 0$ if and only if the above algorithm returns "Yes".*

Proof. "No" is returned in case (a) occurs: as A_m consists precisely of all $\delta_\Sigma(E, \tau)$ such that $|\tau| \leq m$, this implies that $\phi_{\mathbf{B}}(E) \neq 0$, by virtue of (6). Assume on the other hand "Yes" is returned, that is case (b) of the algorithm occurs. Then by Lemma 5.2, $I_0 \subseteq \cdots \subseteq I_m =$

$I_{m+1} = I_{m+2} = \cdots$: therefore I_m contains in effect *every* $\delta_\Sigma(E, \tau)$ such that $\tau \in X^\otimes$. As ρ makes all polynomials in A_m vanish, by the definition of ideal ρ also makes all polynomials in $I_m = \langle\ A_m\ \rangle$ vanish. As a consequence, $(\delta_\Sigma(E, \tau))(\rho) = 0$ for all $\tau \in X^\otimes$, which, from Corollary 4.9, implies that $\phi_{\mathbf{B}}(E) = 0$. ◀

▶ **Example 5.4** (Burgers' equation)**.** Consider the following system, which is a special case of Burgers' equation [1, 9]

$$u_t \ = \ -u \cdot u_x \qquad u_x \ = \ \frac{1}{t+1}\,.$$

To code up this system, we fix $X = \{t, x\}$ and $U = \{u, v\}$, where v represents $1/(t+1)$, and let

$$\Sigma \ = \ \{u_t = -u \cdot u_x,\ u_x = v,\ v_t = -v^2,\ v_x = 0\}\,. \tag{8}$$

As $\mathcal{P}\mathrm{a}(\Sigma) = \{u, v\}$, the system is finite-parameter. Σ can be checked to be consistent – in particular there is a unique equation in Σ^∞ for u_{tx}, that is $u_{tx} = -v^2$. Moreover, with the lexicographic order induced by $u > v$ and $t > x$, Σ is coherent. Now fix $\rho(u) = \rho(v) = 1$ as an initial data specification and let $E \triangleq u - (x+1)v$. We check that $E = 0$ is a valid equation for the initial value problem $\mathbf{B} = (\Sigma, \rho)$, that is $E \in \mathcal{Z}_{\mathbf{B}}$, applying the above algorithm. We have: $A_0 = \{E\}$ and $A_1 = \{E\} \cup \{\delta_\Sigma(E, t), \delta_\Sigma(E, x)\} = \{E\} \cup \{-v \cdot E, 0\}$. As trivially $\{0, -v \cdot E\} \subseteq \langle\ \{E\}\ \rangle = I_0$, and $E(\rho) = (-v \cdot E)(\rho) = 0$, the algorithm returns "Yes". Note that the validity of $E = 0$ implies that $u = (x+1)v = \frac{x+1}{t+1}$, $v = \frac{1}{t+1}$ yield a solution of $\mathbf{B}$.

Finally, relying on the ascending chain (7), we devise a complete algorithm to compute the set of initial data specifications under which a given equation E is valid in Σ – so to speak, the weakest precondition of E.

▶ **Corollary 5.5** (weakest precondition)**.** *Let Σ be coherent and finite-parameter, $E \in \mathcal{P}_0(\Sigma)$. Let $I_{m+1} = I_m$. Then $\{\rho \in \mathbb{R}_0^k : \phi_{(\Sigma,\rho)}(E) = 0\} = V(X \cup A_m)$.*

▶ **Example 5.6** (Burgers' equation, continued)**.** Consider again the system Σ in (8) and $E = u - v \cdot (x+1)$. As $I_1 = I_0 = \langle\ \{E\}\ \rangle$, we see that the set of ρ's under which E is valid is $V(X \cup \{E\})$; that is, those ρ's such that $\rho(t) = \rho(x) = 0$ and $\rho(u) = \rho(v)$.

▶ Remark 5.7 (complexity). Procedures for computing Gröbner bases, such as Buchberger's algorithm, have a very high *worst*-case time and space complexity – exponential in the number of variables and the degree of the involved polynomials, see [10]. The number of steps m before the chain (7) stabilizes can also depend super-exponentially on the number of variables and their degrees, see [19]. This theoretical complexity is of course inherited by our algorithms. On the other hand, Gröbner basis algorithms have shown to behave well in many practical cases: this suggests that an assessment of our algorithms based on concrete case studies might be more informative than a purely complexity theoretical one. We leave a systematic exploration of this more pragmatical aspect for future work.

6 Conclusion, further and related work

We have put forward a coalgebraic framework for PDEs, that yields a clean proof of existence and uniqueness of solutions of initial value problems, and complete algorithms for checking equivalence of differential polynomial expressions, under a finite-parameters assumption. To the best of our knowledge, no such characterization and completeness results for PDEs exist in the literature. As for future work, we plan to explore extensions of the present results to *postconditions*: computing at once the most general, in a precise sense, consequences of a given algebraic set of initial data specifications. This would also permit to automatically discover valid equations, rather than just check given ones.

Conceptually, the present development parallels in part our previous work on polynomial ODEs [5, 7]. Technically, the case of PDEs is by far more challenging, for the following reasons. (a) Existence of solutions, and of the transition structure itself, depends now on coherence, which is trivial in ODEs. (b) In PDEs, differential polynomials live in the infinite-indeterminates space $\mathcal{P}$, which requires reduction to $\mathcal{P}_0(\Sigma)$ via S and a finiteness assumption on parametric derivatives; in ODEs, $\mathcal{P} = \mathcal{P}_0(\Sigma)$ always has finitely many indeterminates.

An operational view of functions and differential equations similar to ours has been considered elsewhere in the literature on coalgebras [20, 27]. In particular, it is at the basis of Rutten's calculus of *behavioural differential equations* [27]. In this calculus, neither PDEs nor equivalence algorithms are considered, though. Algorithms for equivalence checking are presented in [4, 3], limited to linear *weighted automata*: in terms of differential equations, these basically correspond to linear ODEs.

In the field of formal methods, we are aware of the work by Boldo et al. [2], who apply theorem proving to the formal verification of a numerical PDE integrator written in C. Platzer, in his work on differential hybrid games [22], relies on certain Hamilton-Jacobi type PDEs in order to define a solution concept for differential games. These works pursue goals rather different from ours, though.

Our work is also related to the field of Differential Algebra. In the classical exposition, coherent systems correspond to Riquier-Janet's *orthonomic passive* systems [24, 12], further developed by Thomas [30]. A modern presentation of orthonomic passive systems is in Marvan's [18]. A more geometrical approach is followed by Reid et al. [23, 26]. The work of Riquier, Janet and Thomas is the root of what is nowadays known as Ritt-Kolchin's Differential Algebra (DA) [25, 14]. Recent developments of DA include the work by the French school, especially Boulier et al., see e.g. [8, 16]. The relationship of our coalgebraic framework with DA is not yet entirely clear and deserves further investigation.

Abstract

This paper introduces and studies a notion of *algorithmic randomness* for subgroups of rationals. Given a randomly generated additive subgroup $(G, +)$ of rationals, two main questions are addressed: first, what are the model-theoretic and recursion-theoretic properties of $(G, +)$; second, what learnability properties can one extract from G and its subclass of finitely generated subgroups? For the first question, it is shown that the theory of $(G, +)$ coincides with that of the additive group of integers and is therefore decidable; furthermore, while the word problem for G with respect to any generating sequence for G is not even semi-decidable, one can build a generating sequence β such that the word problem for G with respect to β is co-recursively enumerable (assuming that the set of generators of G is limit-recursive). In regard to the second question, it is proven that there is a generating sequence β for G such that every non-trivial finitely generated subgroup of G is recursively enumerable and the class of all such subgroups of G is behaviourally correctly learnable, that is, every non-trivial finitely generated subgroup can be semantically identified in the limit (again assuming that the set of generators of G is limit-recursive). On the other hand, the class of non-trivial finitely generated subgroups of G cannot be syntactically identified in the limit with respect to any generating sequence for G. The present work thus contributes to a recent line of research studying algorithmically random infinite structures and uncovers an interesting connection between the arithmetical complexity of the set of generators of a randomly generated subgroup of rationals and the learnability of its finitely generated subgroups.

2012 ACM Subject Classification Theory of computation → Pseudorandomness and derandomization; Theory of computation → Inductive inference

1 Introduction

The concept of *algorithmic randomness*, particularly for strings and infinite sequences, has been extensively studied in recursion theory and theoretical computer science [6, 15, 19]. It has also been applied in a wide variety of disciplines, including formal language and automata theory [14], machine learning [29], and recently even quantum theory [20]. An interesting and long open question is whether the well-established notions of randomness for infinite sequences have analogues for infinite structures such as graphs and groups. Intuitively, it might be reasonable to expect that a collection of random infinite structures possesses the following characteristics: (1) randomness should be an isomorphism invariant property; in particular, random structures should not be computable; (2) the collection of random structures (of any type of algebraic structure) should have cardinality equal to that of the continuum. The standard random infinite graph thus does not qualify as an algorithmically random structure; in particular, it is isomorphic to a computable graph and has a countable categorical theory. Very recently, Khoussainov [12, 13] defined algorithmic randomness for infinite structures that are akin to graphs, trees and finitely generated structures.

This paper addresses the following three open questions in algorithmic randomness: (A) is there a reasonable way to define algorithmically random structures for standard algebraic structures such as groups; (B) can one define algorithmic randomness for groups that are not necessarily finitely generated; (C) what are the model-theoretic properties of algorithmically random structures? The main contribution of the present paper is to answer the first two questions positively for a fundamental and familiar algebraic structure, the *additive group of rationals*, denoted $(\mathbb{Q}, +)$, and to answer the third question with respect to this structure. Prior to this work, question (A) was answered for structures such as *finitely generated* universal algebras, connected graphs, trees of bounded degree and monoids [12]. Concerning question (C), it is still unknown whether the first order theory of algorithmically random graphs (or trees) is decidable. In fact, it is not even known whether any two algorithmically random graphs (of the same bounded degree) are elementarily equivalent [12].

As mentioned earlier, one goal of this work is to formulate a notion of randomness for subgroups of $(\mathbb{Q}, +)$. This is a fairly natural class of groups to consider, given that the isomorphism types of its subgroups have been completely classified, as opposed to the current limited state of knowledge about the isomorphism types of even rank 2 groups. As has been known since the work of Baer [1], the subgroups of $(\mathbb{Q}, +)$ coincide, up to isomorphism, with the torsion-free Abelian groups of rank 1. Moreover, the group $(\mathbb{Q}, +)$ is robust enough that it has uncountably many algorithmically random subgroups (according to our definition of algorithmically random subgroups of $(\mathbb{Q}, +)$), which contrasts with the fact that there is a unique standard random graph up to isomorphism. At the same time, the algorithmically random subgroups of $(\mathbb{Q},+)$ are not too different from one other in the sense that they are all elementarily equivalent (a fact that will be proven later), which is similar to the case of standard random graphs being elementarily equivalent.

The properties of the subgroups of $(\mathbb{Q},+)$ were first systematically studied by Baer [1] and then later by Beaumont and Zuckerman [3]. Later, the group $(\mathbb{Q},+)$ was studied in the context of automatic structures [28]. An early definition of a random group is due to Gromov [10]. According to this definition, random groups are those obtained by first fixing a set of generators, and then randomly choosing (according to some probability distribution) the relators specifying the quotient group. An alternative definition of a general random infinite structure was proposed by Khoussainov [12, 13]; this definition is based on the notion of a *branching class*, which is in turn used to define Martin-Löf tests for infinite structures entirely in analogy to the definition of a Martin-Löf test for sequences. An infinite structure is then said to be Martin-Löf random if it passes every Martin-Löf test in the preceding sense.

Like Gromov's definition of a random group, the one adopted in the present work is syntactic, in contrast to the semantic and algebraic definition due to Khoussainov. However, rather than selecting the relators at random according to a prescribed probability distribution for a fixed set of generators, our approach is to directly encode a Martin-Löf random binary sequence into the generators of the subgroup. More specifically, we fix any binary sequence R, and define the group G_R as that generated by all rationals of the shape $p_i^{-n_i}$, where p_i denotes the $(i+1)$-st prime and n_i is the number of ones occurring between the i-th and $(i+1)$-st occurrences of zero in R; n_0 is the number of starting ones, and if there is no $(i+1)$-st zero then n_j is defined to be zero for all j greater than i and G_R is generated by all $p_{i'}^{-n_{i'}}$ with i' less than i and all $p_i^{-n'}$ such that n' is any positive integer. G_R is then said to be *randomly generated* if and only if R is Martin-Löf random. In order to derive certain computability properties, it will always be assumed in the present paper that any Martin-Löf random sequence associated to a randomly generated subgroup of $(\mathbb{Q},+)$ is also limit-recursive. It may be observed that no finitely generated subgroup of $(\mathbb{Q},+)$ is randomly generated in the sense adopted here; this corresponds to the intuition that in any "random" infinite binary sequence R, the fraction of zeroes in the first n bits should tend to a number strictly smaller than one as n grows to infinity.

The first main part of this work is devoted to the study of the model-theoretic and recursion-theoretic properties of randomly generated subgroups of $(\mathbb{Q},+)$. It is shown that the theory of any randomly generated subgroup coincides with that of the integers with addition (denoted $(\mathbb{Z},+)$), and is therefore decidable[1]. Next, we define the notion of a *generating sequence* for a randomly generated group G_R; this is an infinite sequence β such that G_R is generated by the terms of β. We then consider the word problem for G_R with respect to β: this is the problem of determining, given any two finite integer sequence representations σ and τ of elements of G_R with respect to β, whether or not σ and τ represent the same element of G_R. We show that the word problem for G_R with respect to *any* generating sequence β is never recursively enumerable (r.e.); on the other hand, one can construct a generating sequence β' for G_R such that the corresponding word problem for G_R is co-r.e. Moreover, one can build a generating sequence β'' for G_R such that the word problem for the quotient group of G_R by $\mathbb{Z}$ with respect to β'' is r.e.

The second main part of this paper investigates the learnability of non-trivial finitely generated subgroups of randomly generated subgroups of $(\mathbb{Q},+)$ from positive examples, also

[1] For a proof of the decidability of the theory of $(\mathbb{Z},+)$, often known as *Presburger Arithmetic*, see [16, pages 81–84].

known as learning from text. Stephan and Ventsov [25] examined the learnability of classes of substructures of algebraic structures; the study of more general classes of structures was undertaken in the work of Martin and Osherson [17, Chapter III]. The general objective is to understand how semantic knowledge of a class of concepts can be exploited to learn the class; in the context of the present problem, semantic knowledge refers to the properties of every finitely generated subgroup of any randomly generated subgroup of rationals, such as being generated by a single rational [1]. It may be noted that the present work considers learning of the actual representations of finitely generated subgroups, as opposed to learning their structures up to isomorphism, as is considered in the learning framework of Martin and Osherson [17]. Various positive learnability results are obtained: it will be proven, for example, that for any randomly generated subgroup G_R of $(\mathbb{Q}, +)$, there is a generating sequence β for G_R such that the set of representations of every non-trivial finitely generated subgroup of G_R with respect to β is r.e.; furthermore, the class of all such representations can be identified in the limit up to semantic equivalence. On the other hand, it will be seen that the class of all such representations can never be learnable in the limit. Similar results hold for the class of non-trivial finitely generated subgroups of the quotient group of G_R by $\mathbb{Z}$. Thus this facet of our work implies a connection between the limit-recursiveness of the set of generators of a randomly generated subgroup of $(\mathbb{Q}, +)$ and the learnability of its non-trivial finitely generated subgroups.

2 Preliminaries

Any unexplained recursion-theoretic notation may be found in [22, 24, 21]. For background on algorithmic randomness, we refer the reader to [6, 19]. We use $\mathbb{N} = \{0, 1, 2, \ldots\}$ to denote the set of all natural numbers and $\mathbb{Z}$ to denote the set of all integers. The $(i+1)$-st prime will be denoted by p_i. $\mathbb{Z}^{<\omega}$ denotes the set of all finite sequences of integers. Throughout this paper, $\varphi_0, \varphi_1, \varphi_2, \ldots$ is a fixed acceptable programming system of all partial recursive functions and $W_0, W_1, W_2, \ldots$ is a fixed *acceptable numbering of all recursively enumerable* (abbr. r.e.) *sets* of natural numbers. We will occasionally work with objects belonging to some countable class X different from $\mathbb{N}$; in such a case, by abuse of notation, we will use the same symbol W_e to denote the set of objects obtained from W_e by replacing each member x with $F(x)$ for some fixed bijection F between $\mathbb{N}$ and X.

Given any set S, S^* denotes the set of all finite sequences of elements from S. By $D_0, D_1, D_2, \ldots$ we denote any fixed *canonical indexing of all finite sets* of natural numbers. Cantor's pairing function $\langle \cdot, \cdot \rangle \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ is given by $\langle x, y \rangle = \frac{1}{2}(x+y)(x+y+1) + y$ for all $x, y \in \mathbb{N}$. The symbol K denotes the *diagonal halting problem*, i.e., $K = \{e \mid e \in \mathbb{N},\ \varphi_e(e) \text{ converges}\}$. The *jump* of K, that is, the relativised halting problem $\{e \mid e \in \mathbb{N}; \varphi_e^K(e)\downarrow\}$, will be denoted by K'.

For $\sigma \in (\mathbb{N} \cup \{\#\})^*$ and $n \in \mathbb{N}$ we write $\sigma(n)$ to denote the element in the n-th position of σ. Further, $\sigma[n]$ denotes the sequence $\sigma(0), \sigma(1), \ldots, \sigma(n-1)$. Given a number $a \in \mathbb{N}$ and some fixed $n \in \mathbb{N}$, $n \geq 1$, we denote by a^n the finite sequence $a, \ldots, a$, where a occurs exactly n times. Moreover, we identify a^0 with the empty string ε. For any finite sequence σ we use $|\sigma|$ to denote the length of σ. The concatenation of two sequences σ and τ is denoted by $\sigma \circ \tau$; for convenience, and whenever there is no possibility of confusion, this is occasionally denoted by $\sigma\tau$. For any sequence β (infinite or otherwise) and $s < |\beta|$, $\beta\restriction_s$ denotes the initial segment of β of length $s+1$. For any $m \geq 1$ and $p \in \mathbb{Z}$, $I_m(p)$ denotes the vector of length m whose first $m-1$ coordinates are 0 and whose last coordinate is p. Furthermore, given two vectors $\alpha = (a_i)_{0 \leq i \leq m}$ and $\beta = (b_i)_{0 \leq i \leq m}$ of equal length, $\alpha \cdot \beta$ denotes the scalar product of α and β, that is, $\alpha \cdot \beta := \sum_{i=0}^{m} a_i b_i$. For any $c \in \mathbb{Z}$ and $\sigma := (b_i)_{0 \leq i \leq m} \in \mathbb{Z}^{<\omega}$, $c\sigma$ denotes the vector obtained from σ by coordinatewise multiplication with c, that is, $c\sigma := (cb_0, cb_1, \ldots, cb_m)$. For any non-empty $S \subseteq \mathbb{Q}$, $\langle S \rangle$ denotes $\{\sum_{i=0}^{k} c_i s_i \mid k \in \mathbb{N} \wedge c_i \in \mathbb{Z} \wedge s_i \in S\}$.

Cantor space, the set of all infinite binary sequences, will be denoted by 2^ω. The set of finite binary strings will be denoted by $2^{<\omega}$. For any binary string σ, $[\sigma]$ denotes the cylinder generated by σ, that is, the set of infinite binary sequences with prefix σ. For any $U \subseteq 2^{<\omega}$, the open set generated by U is $[U] := \bigcup_{\sigma \in U} [\sigma]$. The Lebesgue measure on 2^ω will be denoted by λ; that is, for any binary string σ, $\lambda([\sigma]) = 2^{-|\sigma|}$. By the Carathéodory Theorem, this uniquely determines the Lebesgue measure on the Cantor space.

3 Randomly Generated Subgroups of Rationals

We first review some basic definitions and facts in algorithmic randomness which in our setting is always understood w.r.t the Lebesgue measure. An *r.e. open set* R is an open set generated by an r.e. set of binary strings. Regarding W_e as a subset of $2^{<\omega}$, one has an enumeration $[W_0], [W_1], [W_2], \ldots$ of all r.e. open sets. A *uniformly r.e. sequence* $(G_m)_{m<\omega}$ *of open sets* is given by a recursive function f such that $G_m = [W_{f(m)}]$ for each m. As infinite binary sequences may be viewed as characteristic functions of subsets of $\mathbb{N}$, we will often use the term "set" interchangeably with "infinite binary sequence"; in particular, the subsequent definitions apply equally to subsets of $\mathbb{N}$ and infinite binary sequences.

Martin-Löf [18] defined randomness based on tests. A *Martin-Löf test* is a uniformly r.e. sequence $(G_m)_{m<\omega}$ of open sets such that $(\forall m < \omega)[\lambda(G_m) \leq 2^{-m}]$. A set $Z \subseteq \mathbb{N}$ *fails* the test if $Z \in \bigcap_{m<\omega} G_m$; otherwise Z *passes* the test. Z is *Martin-Löf random* if Z passes each Martin-Löf test. Schnorr [23] showed that Martin-Löf random sets can be described via martingales. A *martingale* is a function $\mathrm{mg} : 2^{<\omega} \to \mathbb{R}^+ \cup \{0\}$ that satisfies for every $\sigma \in 2^{<\omega}$ the equality $\mathrm{mg}(\sigma \circ 0) + \mathrm{mg}(\sigma \circ 1) = 2\mathrm{mg}(\sigma)$. For a martingale mg and a set Z, the martingale mg *succeeds* on Z if $\sup_n \mathrm{mg}(Z(0) \ldots Z(n)) = \infty$.

▶ **Theorem 1.** *[23] For any set Z, Z is Martin-Löf random iff no r.e. martingale succeeds on Z.*

The following characterisation of all subgroups of $(\mathbb{Q}, +)$ forms the basis of our definition of a random subgroup.

▶ **Theorem 2.** *[3] Let G be any subgroup of $(\mathbb{Q}, +)$. Then there is an integer z, as well as a sequence $(n_i)_{i<\omega}$ with $n_i \in \mathbb{N} \cup \{\infty\}$ such that $G = \left\{ \frac{a \cdot z}{\Pi_{i=0}^{k} p_i^{m_i}} \mid a \in \mathbb{Z} \wedge k \in \mathbb{N} \wedge (\forall i \leq k)[m_i \in \mathbb{N} \wedge m_i < n_i] \right\}$.*

▶ **Definition 3.** *Let $R \in 2^\omega$ be a real in the Cantor space, i.e. an infinite sequence of 0's and 1's. Then the group G_R is the subgroup of the rational numbers $(\mathbb{Q}, +)$ generated by $a_0, a_1, \ldots$ with $a_i = \frac{1}{p_i^{n_i}}$ for all $i \in \mathbb{N}$, where for each $i \in \mathbb{N}$, by p_i we denote the $(i+1)$-st prime and by n_i the number of consecutive 1's in R between the i-th and $(i+1)$-st zero in R, with which we let n_0 count the number of starting 1's. If there is no $(i+1)$-st zero, we let $n_i := \infty$, meaning that for all n the fraction $\frac{1}{p_i^n}$ is in G_R.*

Clearly, $(\mathbb{Z}, +)$ is always a subgroup of G_R and $\frac{1}{p_i} \notin G_R$ if and only if the i-th and $(i+1)$-st zero in R are consecutive. Thus, if R ends with infinitely many zeros, then G_R is isomorphic to $(\mathbb{Z}, +)$. Moreover, there is a prime p_i such that $\frac{1}{p_j} \notin G_R$ for all $j > i$ and $\frac{1}{p_i^n} \in G_R$ for all $n \in \mathbb{N}$, for short p_i infinitely divides G_R, if and only if R ends with an infinite sequence of 1's.

▶ **Lemma 4.** *If $R \in 2^\omega$ is Martin-Löf random, then n_i is finite for every $i \in \mathbb{N}$, where n_i is defined as in Definition 3. In other words, the group G_R is not infinitely divisible by any prime.*

Proof. This is an easy observation, as in no Martin-Löf random w.r.t the Lebesgue measure only finitely many 0's occur. ◀

A similar argument shows that for Martin-Löf random R there are infinitely many primes occurring as basis of a denominator of a generator.

▶ **Definition 5.** *Fix a probability distribution μ on the natural numbers and let $X = (X_i)_{i\in\mathbb{N}}$ be a sequence of iid random variables taking values in $\mathbb{N}$ with distribution $X_i \sim \mu$ for all $i \in \mathbb{N}$. Denote by H_X the subgroup of $(\mathbb{Q}, +)$ generated by $\{p_i^{-X_i} \mid i \in \mathbb{N}\}$, where p_i denotes the $(i+1)$-st prime.*

The so obtained random group might follow a more uniform process.

▶ **Lemma 6.** *If μ is the distribution on $\mathbb{N}$ assigning 0 probability $\frac{1}{2}$, 1 probability $\frac{1}{4}$, 2 probability $\frac{1}{8}$ and n probability 2^{-n-1}, then with probability 1 holds $H_X = G_R$ for some Martin-Löf random R.*

Proof. This follows immediately, as the set of ML-randoms has measure 1 with respect to the Lebesgue measure. From $X_0 = n_0$, $X_1 = n_1$, …, $X_i = n_i$, … we obtain an infinite binary sequence $R \in 2^\omega$ by recursively appending $1^{n_i}0$ in step i to the already established initial segment of R, starting with the empty string. By definition the Lebesgue measure assigns probability $\frac{1}{2^{n+1}}$ to having the (intermediate) subsequence 1^n0 in R. This is exactly the probability of the event $X_i = n$. ◀

A *generating sequence for G_R* is an infinite sequence $(b_i)_{i<\omega}$ such that $\langle b_i \mid i < \omega\rangle = G_R$. We will often deal with generating sequences rather than minimal generating sets for G_R, mainly due to the fact that if the terms of a sequence β are carefully chosen based on a limiting recursive programme for R (so that β itself is limiting recursive), then, as will be seen later, the set of representations of elements of G_R with respect to β can have certain desirable computability properties, such as equality being co-r.e.

▶ **Proposition 7.** *Suppose $R \leq_T K$ is Martin-Löf random. Then there does not exist any strictly increasing recursive enumeration $i_0, i_1, i_2, \ldots$ such that for each j, there is some $n_{i_j} \geq 1$ with $p_{i_j}^{-n_{i_j}} \in G_R$.*

▶ **Theorem 8.** *If $R \leq_T K$ is Martin-Löf random, then $(G_R, +)$ is co-r.e., meaning that $+$ is recursive and there is a generating sequence with respect to which equality is co-r.e.*

Proof. For a fixed generating sequence $(q_i)_{i<\omega}$ of G_R there is an epimorphism from the set of finite sequences of integers $\mathbb{Z}^{<\omega}$ to G_R by identifying $\sigma = (\sigma(0), \ldots, \sigma(|\sigma|-1))$ with $x = \sum_{i=0}^{|\sigma|-1} \sigma(i)q_i$. We call σ a representation of x w.r.t. $(q_i)_{i<\omega}$ or $(q_i)_{i<n+1}$.

Obviously, for any generating sequence of G_R addition is recursive as only the components of the representations have to be added as integers.

In order to prove that equality is co-r.e., we construct a specific generating sequence $(b_i)_{i<\omega}$. Based on the result R^s of the computation of R after s steps, we are going to define finite sequences β_s of rational numbers recursively, such that $|\beta_s| = s+1$ and inequality on $\{-s-1, \ldots, s+1\}^{s+1} \subseteq \mathbb{Z}^{s+1}$, interpreted as representations w.r.t. β_s, is decided and extends the inequalities on $\{-s, \ldots, s\}^s$, even though they originate from an interpretation as representations according to β_{s-1}. With this in the limit we obtain a generating sequence of G_R, meaning that for every i there is some $s_i > i$ such that for all $s \geq s_i$ the i-th element of β_s is the same as the i-th element of β_{s_i}, which we denote by b_i. Further, $(b_i)_{i\in\mathbb{N}}$ generates G_R and for this generating sequence equality will be co-r.e.

In the following we write $n_{i,s}$ for n_i according to R^s, i.e. the number of 1's between the i-th and $(i+1)$-st zero in R^s, as introduced in Definition 3. As R^s does not end with infinitely many 1's, $n_{i,s}$ can be computed in finitely many steps for every i and s.

$s = 0$. Let $\beta_0 = (1)$.

$s \rightsquigarrow s+1$. Check for every $i \leq s$ whether $n_{i,s} = n_{i,s+1}$. If $n_{i,s} = n_{i,s+1}$ let $\beta_{s+1}(i) = \beta_s(i)$. Replace all $\frac{1}{p_i^{n_{i,s}}}$ occurring in β_s with $n_{i,s} \neq n_{i,s+1}$ by some respective integer, for which existence we argue below, such that

$$\Delta_{(q_i)_{i<s+1}} = \{\, (\sigma_0, \sigma_1) \in (\,\{-s-1, \ldots, s+1\}^{s+1}\,)^2 \mid \\ \sigma_0, \sigma_1 \text{ represent different elements w.r.t. } (q_i)_{i<s+1} \,\}$$

stays the same or enlarges if $(q_i)_{i<s+1}$ equals the first $s+1$ entries of β_{s+1} instead of β_s. Further, let

$$\beta_{s+1}(s+1) = \frac{1}{p_j^{n_{j,s+1}}},$$

where $j \leq s+1$ is minimal such that $\frac{1}{p_j^{n_{j,s+1}}}$ is an element of $G_{R^{s+1}}$ and does not yet occur in $\beta_{s+1}\restriction(s+1)$. If there is no such j, let $\beta_{s+1}(s+1) = 1$.

For example, if the tape after stage $s = 2$ started with $1111010\ldots$, after 3 steps contained $1101010\ldots$ and $\beta_2 = (1, \frac{1}{2^4}, \frac{1}{3})$, then in β_3 we would have to replace $\frac{1}{2^4}$ by an integer w such that for arbitrary integers $u_0, u_1, u_2, v_0, v_1, v_2$ between -3 and 3 we have

$$u_0 + u_1\frac{1}{2^4} + u_2\frac{1}{3} \neq v_0 + v_1\frac{1}{2^4} + v_2\frac{1}{3} \quad \Rightarrow \quad u_0 + u_1 w + u_2\frac{1}{3} \neq v_0 + v_1 w + v_2\frac{1}{3}$$

and $\beta_3(3)$ would be $\frac{1}{2^2}$.

We proceed by showing that there is always such an integer w.

▷ Claim 9. For every $s \in \mathbb{N}$ in step $s+1$ it is possible to alter finitely many entries of β_s to obtain $\beta_{s+1}\restriction(s+1)$ such that $\Delta_{\beta_s} \subseteq \Delta_{\beta_{s+1}\restriction(s+1)}$.

Proof of the Claim. Let $s \in \mathbb{N}$. It suffices to show that one entry can be replaced in this desired way. As the argument does not depend on the position, we further assume that it is the last entry. For all $(\sigma_0, \sigma_1) \in \Delta_{\beta_s}$ we want to prevent

$$\sum_{i=0}^{s-1} \sigma_0(i)\beta_s(i) + \sigma_0(s)w = \sum_{i=0}^{s-1} \sigma_1(i)\beta_s(i) + \sigma_1(s)w.$$

This is a linear equation having zero or one solution in $\mathbb{Q}$. As there are only finitely many choices for the pair (σ_0, σ_1), an integer not fulfilling any of these equations can be found in a computable way. ◁

We continue by proving that the entries of the β_s stabilize, such that in the limit we obtain a sequence $(b_i)_{i<\omega}$ of elements of G_R.

▷ Claim 10. For every $i \in \mathbb{N}$ there is some $s_i \geq i$ such that for all $s \geq s_i$ we have $\beta_s(i) = b_i$, with $b_i = \beta_{s_i}(i)$.

Proof of the Claim. Let $i \in \mathbb{N}$. If there is $s_i > i$ such that the entry $\beta_{s_i-1}(i)$ had to be changed, then $\beta_{s_i}(i)$ is an integer and thus, it will never be changed lateron. In case this does not happen, we obtain $\beta_s(i) = \beta_i(i)$ for all $s \geq i$ and therefore $s_i = i$. ◁

By the next claim the just constructed sequence generates the random group.

▷ Claim 11. The sequence $(b_i)_{i<\omega}$ generates G_R.

Proof of the Claim. Let $i \in \mathbb{N}$ and a_i as in Definition 3. We argue that there is some j with $a_i = b_j$. Let m_i be the position of the $(i+1)$-st zero in the Martin-Löf random R. Then there is s' such that after s' computation steps $R \upharpoonright (m_i + 1)$ is not changed any more. Thus, after at most i additional steps all generators of G_R having one of the first i primes as denominator are in the range of $\beta_{s'+i}$. ◁

Finally, we observe that w.r.t. the generating sequence $(b_i)_{i<\omega}$ all pairs of unequal elements of G_R can be recursively enumerated.

▷ Claim 12. Equality in $(G_R, +)$ is co-r.e.

Proof of the Claim. We run the algorithm generating $(b_i)_{i<\omega}$ and in step s return all elements of the finite set Δ_{β_s}. As inequalities w.r.t β_s yield inequalities w.r.t. $(b_i)_{i<\omega}$, we only enumerate correct information. Further, for every two elements x, y of G_R fix representations w.r.t. $(b_i)_{i<\omega}$ and s' large enough such that not more than the first s' of the b_i occur in these representations, all of these have stabilized up to stage s' and all coefficients in the representations take values between $-s' - 1$ and $s' + 1$. Then $x \neq y$ if and only if the tuple of their representations is in $\Delta_{\beta_{s'}}$. ◁

This finishes the proof of the theorem. ◀

As there are K-recursive Martin-Löf random reals, we obtain the following corollary.

▶ **Corollary 13.** *There exists a co-r.e. random subgroup of the rational numbers.*

▶ Remark 14. Proposition 7 implies, in particular, that if $R \leq_T K$ is Martin-Löf random, then there cannot exist any generating sequence for G_R with respect to which equality of members of G_R is r.e. Indeed, suppose that such a generating sequence β did exist, so that $E := \{(\sigma, \tau) \in \mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega} \mid \sigma \cdot \beta \upharpoonright_{|\sigma|-1} = \tau \cdot \beta \upharpoonright_{|\tau|-1}\}$ is r.e. Fix any $\sigma_0 \in \mathbb{Z}^{<\omega}$ such that $\sigma_0 \cdot \beta_{|\sigma_0|-1} = 1$ (since $1 \in G_R$, such a σ_0 must exist). Then there is a strictly increasing recursive enumeration $i_0, i_1, i_2, \dots$ such that for all j, i_j is the first ℓ found for which the following hold: (i) $\ell > i_{j'}$ whenever $j' < j$; (ii) there are $n_\ell \geq 1$ and relatively prime positive integers q, r with $p_\ell \nmid q$ and $p_\ell \nmid r$ such that for some m, $(q\sigma_0, I_m(rp_\ell^{n_\ell})) \in E$. Note that

$$\begin{aligned}(q\sigma_0, I_m(rp_\ell^{n_\ell})) \in E \Leftrightarrow q = (q\sigma_0) \cdot \beta_{|\sigma_0|-1} = I_m(rp_\ell^{n_\ell}) \cdot \beta_{m-1} = rp_\ell^{n_\ell} b_{m-1} \\ \Leftrightarrow b_{m-1} = qp_\ell^{-n_\ell} r^{-1}.\end{aligned}$$

The Martin-Löf randomness of R implies that β contains infinitely many terms of the form $\frac{q'}{r' p_{\ell'}^{n'_{\ell'}}}$ with $n'_{\ell'} \geq 1$, q' and r' relatively prime and positive, $p_{\ell'} \nmid q'$ and $p_{\ell'} \nmid r'$. Thus i_j is defined for all j, and by Proposition 7 this contradicts the Martin-Löf randomness of R.

Further, a variation of the algorithm yields that equality of the proper rational part is r.e. on random groups.

▶ **Theorem 15.** *If $R \leq_T K$ is Martin-Löf random, then equality modulo 1 on $(G_R, +)$ is r.e. with respect to some generating sequence.*

The next main result is concerned with the model-theoretic properties of random subgroups of rationals. We recall that two structures (in the model-theoretic sense) M and N with the same set σ of non-logical symbols are *elementarily equivalent* (denoted $M \equiv N$) iff they satisfy the same first-order sentences over σ; the *theory* of a structure M (denoted $\mathrm{Th}(M)$) is the set of all first-order sentences (over the set of non-logical symbols of M) that are satisfied by M. The reader is referred to [16] for more background on model theory. We will prove a result that may appear a bit surprising: even though Martin-Löf random subgroups of $(\mathbb{Q}, +)$ (viewed as classes of integer sequence representations) are not computable, any such subgroup is elementarily equivalent to $(\mathbb{Z}, +)$ - the additive group of integers - and thus has a decidable theory. In other words, the incomputability of a random subgroup of rationals, at least according to the notion of "randomness" adopted in the present work, has little or no bearing on the decidability of its first-order properties. We begin by showing that the theory of any subgroup G of rationals reduces to that of the subgroup of $(\mathbb{Q}, +)$ generated by the set of all rationals either equal to 1 or of the shape p^{-n}, where p is a prime infinitely dividing G and $n \in \mathbb{N}$. Our proof of this fact rests on a sufficient criterion due to Szmielew [27] for the elementary equivalence of two groups; this result will be stated as it appears in [11].

▶ **Theorem 16.** *([27], as cited in [11]) Let p be a prime number and G be a group. For all $n \geq 1$, $k \geq 1$ and elements $g_1, \ldots, g_k \in G$, define $G[p^n] := \{x \in G \mid p^n x = 0\}$ and the following predicate $C(p; g_1, \ldots, g_k)$:*

$C(p; g_1, \ldots, g_k) \Leftrightarrow$ the images $g'_1, \ldots, g'_k$ of $g_1, \ldots, g_k$ in the factor group $\overline{G} := G/G[p^n]$are such that $g'_1 + p\overline{G}, \ldots, g'_k + p\overline{G}$ are linearly independent in $\overline{G}/p\overline{G}$.

Define the parameters $\alpha_{p,n}(G), \beta_p(G)$ and $\gamma_p(G)$ as follows.

$$\begin{aligned} \alpha_{p,n}(G) &:= \sup\{k \in \mathbb{N} \mid G \text{ contains } \mathbb{Z}^k_{p^n} \text{ as a pure subgroup}\}, \\ \beta_p(G) &:= \inf\{\sup\{k \in \mathbb{N} \mid \mathbb{Z}^k_{p^n} \text{ is a subgroup of } G\} \mid n \in \mathbb{N}\}, \\ \gamma_p(G) &:= \inf\{\sup\{k \in \mathbb{N} \mid (\exists x_1, \ldots, x_k) C(p; x_1, \ldots, x_k)\} \mid n \in \mathbb{N}\}. \end{aligned}$$

(Here $pG := \{pg \mid g \in G\}$ and $\mathbb{Z}^k_{p^n}$ is the k-th power of the primary cyclic group on p^n elements, that is, it consists of all elements $(a_0, \ldots, a_{k-1})$ such that $a_0, \ldots, a_{k-1} \in \mathbb{Z}_{p^n}$.) Then any two groups H and L are elementarily equivalent iff $\alpha_{q,m}(H) = \alpha_{q,m}(L)$, $\beta_q(H) = \beta_q(L)$ and $\gamma_q(H) = \gamma_q(L)$ for all primes q and all $m \geq 1$.

The definition of a *pure* subgroup will not be used in the proof of the subsequent theorem; it will be observed that if G is a subgroup of the rationals, then for $k \geq 1$ and $n \geq 1$, it cannot contain $\mathbb{Z}^k_{p^n}$ as a subgroup in any case, so that $\alpha_{p,n}(G) = \beta_p(G) = 0$.

▶ **Theorem 17.** *Let G be a subgroup of $(\mathbb{Q}, +)$. Then $G \equiv [\mathbb{Z}]_{P(G)}$, where $P(G) := \{i \in \mathbb{N} \mid (\forall x \in G)(\forall n \in \mathbb{N})[\frac{x}{p_i^n} \in G]\}$ denotes the set of all primes infinitely dividing G and for a set of primes P we write $[\mathbb{Z}]_P$ for the subgroup of $(\mathbb{Q}, +)$ generated by $\{1\} \cup \{\frac{1}{p^k} \mid p \in P, k \in \mathbb{N}\}$.*

Note that $\mathrm{Th}([\mathbb{Z}]_K, +)$ is undecidable; in contrast, for R Martin-Löf random we have $P(G_R) = \varnothing$, so the promised corollary follows.

▶ **Corollary 18.** *Let $R \in 2^\omega$ be Martin-Löf random. Then $(G_R, +)$ and $(\mathbb{Z}, +)$ have the same theories.*

One may ask whether this still holds for richer structures. This is not the case, as for example the theory of $(G, +, <)$ is different from $\mathrm{Th}(\mathbb{Z}, +, <)$, as in the latter $x = 1$ is a satisfying assignment for the formula $x + x > x \wedge \forall y < x \neg y + y > y$. There does not exist an $x \in G_R$ with this property for a ML-random R.

4 Learning Finitely Generated Subgroups of a Random Subgroup of Rationals

In this section, we investigate the learnability of non-trivial finitely generated subgroups of any group G_R generated by a Martin-Löf random sequence R such that $R \leq_T K$. First, we introduce some additional notation.

▶ **Notation 19.** *Let $R \leq_T K$ be Martin-Löf random and let $\beta := (b_i)_{i<\omega}$ be any generating sequence of G_R. For any subgroup F of G_R, F_β denotes the set of all representations of elements of F with respect to β, that is, $F_\beta := \{\sigma \in \mathbb{Z}^{<\omega} \mid \sum_{i=0}^{|\sigma|-1} \sigma(i) b_i \in F\}$. Furthermore, define $\mathcal{F}_\beta := \{F_\beta \mid F$ is a non-trivial finitely generated subgroup of $G_R\}$.*

We will consider learning from *texts*, where a text is an infinite sequence that contains all elements of F_β for the F to be learnt and may contain the symbol #, which indicates a pause in the data presentation and thus no new information. For any text T and $n \in \mathbb{N}$, $T(n)$ denotes the $(n+1)$-st term of T and $T[n]$ denotes the finite sequence $T(0), \ldots, T(n-1)$, i.e., the *initial segment* of length n of T; $\mathrm{content}(T[n])$ denotes the set of non-pause elements occurring in $T[n]$. A *learner* M is a recursive function mapping $(\mathbb{Z}^{<\omega} \cup \{\#\})^*$ into $\mathbb{N} \cup \{?\}$; the ? symbol permits M to abstain from conjecturing at any stage. A learner is fed successively with growing initial segments of the text and it produces a sequence of conjectures $e_0, e_1, e_2, \ldots$, which are interpreted with respect to a fixed *hypothesis space*. In the present paper, we stick to the standard hypothesis space, a fixed Gödel numbering $W_0, W_1, W_2, \ldots$ of all r.e. subsets of $\mathbb{Z}^{<\omega}$. In our setting from the generator $\frac{q}{m}$ of F we can immediately derive an index e for F_β and therefore in the proofs we argue for learning q and m. The learner is said to *behaviourally correctly* (denoted **Bc**) learn the representation F_β of a finitely generated subgroup F with respect to a fixed generating sequence β for G_R iff on every text for F_β, the sequence of conjectures output by the learner converges to a correct hypothesis; in other words, the learner almost always outputs an r.e. index for F_β [7, 5, 2]. If almost all of the learner's hypotheses on the given text are equal in addition to being correct, then the learner is said to *explanatorily* (denoted **Ex**) learn F_β (or it learns F_β *in the limit*) [9].

A useful notion that captures the idea of the learner converging on a given text is that of a *locking sequence*, or more generally that of a *stabilising sequence*. A sequence $\sigma \in (\mathbb{N} \cup \{\#\})^*$ is called a *stabilising sequence* [8] for a learner M on some set L if $\mathrm{content}(\sigma) \subseteq L$ and for all $\tau \in (L \cup \{\#\})^*$, $M(\sigma) = M(\sigma \circ \tau)$. A sequence $\sigma \in (\mathbb{N} \cup \{\#\})^*$ is called a *locking sequence* [4] for a learner M on some set L if σ is a stabilising sequence for M on L and $W_{M(\sigma)} = L$.

The following proposition due to Blum and Blum [4] will be occasionally useful.

▶ **Proposition 20.** *[4] If a learner M explanatorily learns some set L, then there exists a locking sequence for M on L. Furthermore, all stabilising sequences for M on L are also locking sequences for M on L.*

Clearly, also a **Bc**-version of Proposition 20 holds.

It is not clear in the first place whether or not every finitely generated subgroup of a randomly generated subgroup of $(\mathbb{Q}, +)$ can even be represented as an r.e. set. This will be clarified in the next series of results. We recall that a *finitely generated subgroup* F of G_R is any subgroup of G_R that has some *finite generating set* S, which means that every element of F can be written as a linear combination of finitely many elements of S and the inverses of elements of S. F is *trivial* if it is equal to $\{0\}$; otherwise it *non-trivial.* Furthermore, if G_R is a subgroup of $(\mathbb{Q}, +)$, then any finitely generated subgroup F of G_R is *cyclic*, that is, $F = \left\langle \frac{q}{m} \right\rangle$ for some $q \in \mathbb{N}$ and $m \in \mathbb{N}$ with $\gcd(q, m) = 1$ (see, for example, [26, Theorem 8.1]). The latter fact will be used freely throughout this paper. For any generating sequence β for G_R and any finitely generated subgroup F of G_R, the set of representations of elements of F with respect to β will be denoted by F_β.

▶ **Theorem 21.** *Let $R \leq_T K$ be Martin-Löf random. Then there is a generating sequence $(b_i)_{i<\omega}$ of G_R such that for every non-trivial finitely generated subgroup F of G_R the set F_β is r.e.*

▶ Remark 22. The statement of Theorem 21 excludes the trivial subgroup because for any generating sequence $\beta := (b_i)_{i<\omega}$ for G_R, $\langle 0 \rangle_\beta$ cannot be r.e. To see this, suppose, by way of contradiction, that $\langle 0 \rangle_\beta$ were r.e. Given any $\sigma, \sigma' \in \mathbb{Z}^{<\omega}$, set $\ell = \max(\{|\sigma| - 1, |\sigma'| - 1\})$, and for all $i \in \{0, \ldots, \ell\}$, $w_i = \sigma(i)$ if $i \leq |\sigma| - 1$ and 0 otherwise, and $v_i = \sigma'(i)$ if $i \leq |\sigma'| - 1$ and 0 otherwise. Then $\sigma \cdot \beta \restriction_{|\sigma|-1} = \sigma' \cdot \beta \restriction_{|\sigma'|-1} \Leftrightarrow \sigma \cdot \beta \restriction_{|\sigma|-1} - \sigma' \cdot \beta \restriction_{|\sigma'|-1} = 0 \Leftrightarrow \sum_{i=0}^{\ell} (w_i - v_i) b_i = 0 \Leftrightarrow (w_0 - v_0, w_1 - v_1, \ldots, w_\ell - v_\ell) \in \langle 0 \rangle_\beta$. Thus if $\langle 0 \rangle_\beta$ were r.e., then equality with respect to β would also be r.e., which, as was shown earlier, is impossible.

We note that there cannot be any generating sequence β for G_R such that there are finitely generated subgroups F, F' of G_R with F_β r.e. and F'_β co-r.e.

▶ **Theorem 23.** *Let $R \leq_T K$ be Martin-Löf random. Let β be any generating sequence for G_R. Then for any finitely generated subgroups F and F' of G_R, one of the following holds: (i) both F_β and F'_β are r.e., (ii) both F_β and F'_β are co-r.e., or (iii) at least one of F_β and F'_β is neither r.e. nor co-r.e.*

▶ **Theorem 24.** *Let $R \leq_T K$ be Martin-Löf random. Then there is a generating sequence β of G_R such that F_β is r.e. for every non-trivial finitely generated subgroup F of G_R and $\mathcal{F}_\beta$ is* **Bc***-learnable.*

The next result shows, in contrast to Theorem 24, that if $R \leq_T K$ is Martin-Löf random, then, given *any* generating sequence β for G_R such that F_β is r.e. for every non-trivial finitely generated subgroup F of G_R, the class $\mathcal{F}_\beta$ is not explanatorily learnable.

▶ **Theorem 25.** *Let $R \leq_T K$ be Martin-Löf random. Suppose $\beta := (b_i)_{i<\omega}$ is a generating sequence for G_R such that for any non-trivial finitely generated subgroup F of G_R, F_β is r.e. Then $\mathcal{F}_\beta$ is not* **Ex***-learnable.*

The next theorem considers the learnability of the set of representations of any finitely generated subgroup F of the quotient group $G_R/\mathbb{Z}$ with respect to the generating sequence for $G_R/\mathbb{Z}$ constructed in the proof of Theorem 15. Slightly abusing the notation defined in Notation 19, for any generating sequence β for $G_R/\mathbb{Z}$, F_β will denote the set of representations of any subgroup F of $G_R/\mathbb{Z}$ with respect to β, and $\mathcal{F}_\beta$ will denote $\{F_\beta \mid F \text{ is a finitely generated subgroup of } G_R/\mathbb{Z}\}$.

▶ **Theorem 26.** *Suppose $R \leq_T K$ is Martin-Löf random. Let $G_R/\mathbb{Z}$ be the quotient group of G_R by $\mathbb{Z}$. Then there is a generating sequence β for $G_R/\mathbb{Z}$ such that F_β is r.e. for all finitely generated subgroups of $G_R/\mathbb{Z}$ and $\mathcal{F}_\beta$ is* **Bc***-learnable.*

As in the case of the collection of non-trivial finitely generated subgroups of G_R, the class $\mathcal{F}_\beta$ is not explanatorily learnable with respect to any generating sequence β for $G_R/\mathbb{Z}$. The proof is entirely analogous to that of Theorem 25.

▶ **Theorem 27.** *Let $R \leq_T K$ be Martin-Löf random. Suppose $\beta := (b_i)_{i<\omega}$ is a generating sequence for $G_R/\mathbb{Z}$ such that for any finitely generated subgroup F of $G_R/\mathbb{Z}$, F_β is r.e. Then $\mathcal{F}_\beta$ is not* $\mathbf{Ex}$*-learnable.*

A natural question is whether the learnability or non-learnability of a class of representations for a collection of subgroups of G_R is independent of the choice of the generating sequence for G_R. We have seen in Theorem 25, for example, that the non explanatory learnability of the class of non-trivial finitely generated subgroups of G_R holds for *any* generating sequence for G_R such that F_β is r.e. whenever F is a finitely generated subgroup. The next theorem gives a positive learnability result that is to some extent independent of the choice of the generating sequence: for any generating sequence β for G_R such that equality with respect to β is K-recursive and F_β is r.e. whenever F is a finitely generated subgroup of G_R, the class $\mathcal{F}_\beta$ is explanatorily learnable relative to oracle K.

▶ **Theorem 28.** *Let $R \leq_T K$ be Martin-Löf random. Then for any generating sequence β for G_R such that equality with respect to β is K-recursive (in other words, the set $E_\beta := \{(\sigma, \sigma') \in \mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega} \mid \sigma \cdot \beta_{|\sigma|-1} = \sigma' \cdot \beta_{|\sigma'|-1}\}$ is K-recursive) and F_β is r.e. for all finitely generated subgroups of G_R, $\mathcal{F}_\beta$ is* $\mathbf{Ex}[K]$*-learnable.*

We recall from Theorem 15 that there is a generating sequence $\beta := (b_i)_{i<\omega}$ for G_R such that equality modulo 1 with respect to β is r.e.; in other words, the set $\{(\sigma, \sigma') \in \mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega} \mid \sigma \cdot \beta_{|\sigma|-1} \equiv \sigma' \cdot \beta_{|\sigma|'-1}\ (mod\ 1)\}$ is r.e. The next result considers the learnability of a class that is in some sense “orthogonal” to the class $\mathbb{Z}_\beta$: the class of all sets of representations of $\mathbb{Z}$ with respect to *any* generating sequence β' for G_R such that $\mathbb{Z}_{\beta'}$ is r.e. In the statement and proof of the next theorem, for any generating sequence β for G_R, let E_β denote the set $\{(\sigma, \sigma') \in \mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega} \mid \sigma \cdot \beta_{|\sigma|-1} = \sigma' \cdot \beta_{|\sigma'|-1}\ (mod\ 1)\}$.

▶ **Theorem 29.** *Let $R \leq_T K$ be Martin-Löf random. Let $\mathcal{G}_0$ be the collection of all generating sequences β for G_R such that E_β is r.e., and define $\mathcal{E}_0 := \{E_\beta \mid \beta \in \mathcal{G}_0\}$. Then $\mathcal{E}_0$ is not* $\mathbf{Bc}$*-learnable.*

In contrast to Theorem 29, we present a positive learnability result for the collection of all E_β such that E_β is co-r.e. The learnability is with respect to a hypothesis space which uses co-r.e. indices. That is to say, given any text T, the learner will on T always output an r.e. index for sets of the form $(\mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega}) \setminus E_{\beta'}$, where $E_{\beta'}$ is some co-r.e. set. In the statement and proof of the next theorem, given any generating sequence β for G_R such that equality with respect to β is co-r.e., E_β will denote the set $\{(\sigma, \sigma') \in \mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega} \mid \sigma \cdot \beta_{|\sigma|-1} = \sigma' \cdot \beta_{|\sigma'|-1}\}$.

▶ **Theorem 30.** *Let $R \leq_T K$ be Martin-Löf random. Let $\mathcal{G}_1$ be the collection of all generating sequences β for G_R such that E_β is co-r.e., and define $\mathcal{E}_1 := \{E_\beta \mid \beta \in \mathcal{G}_1\}$. Then $\mathcal{E}_1$ is explanatorily learnable relative to oracle K using co-r.e. indices. That is to say, there is a K-recursive learner M such that for any $E_\beta \in \mathcal{E}_1$ and any text T for E_β, M on T will output an r.e. index for $(\mathbb{Z}^{<\omega} \times \mathbb{Z}^{<\omega}) \setminus E_\beta$ in the limit.*

5 Conclusion and Possible Future Research

This paper introduced a method of constructing random subgroups of rationals, whereby Martin-Löf random binary sequences are directly encoded into the generators of the group.

It was shown that if the Martin-Löf random sequence associated to a randomly generated subgroup G is limit-recursive, then one can build a generating sequence β for G such that the word problem for G is co-r.e. with respect to β, as well as another generating sequence β' such that the word problem for $G/\mathbb{Z}$ with respect to β' is r.e. We also showed that every non-trivial finitely generated subgroup of G has an r.e. representation with respect to a suitably chosen generating sequence for G; moreover, the class of all such r.e. representations is behaviourally correctly learnable but never explanatorily learnable. We did not, however, extend the definition of algorithmic randomness to *all* Abelian groups; we suspect that such a general definition might be out of reach of current methods due to the fact that the isomorphism types of even rank 2 groups (subgroups of $(\mathbb{Q}^2, +)$) are still unknown.

Abstract

We study the problem #IndSub(Φ) of counting all induced subgraphs of size k in a graph G that satisfy the property Φ. This problem was introduced by Jerrum and Meeks and shown to be #W[1]-hard when parameterized by k for some families of properties Φ including, among others, connectivity [JCSS 15] and even- or oddness of the number of edges [Combinatorica 17]. Very recently [IPEC 18], two of the authors introduced a novel technique for the complexity analysis of #IndSub(Φ), inspired by the "topological approach to evasiveness" of Kahn, Saks and Sturtevant [FOCS 83] and the framework of graph motif parameters due to Curticapean, Dell and Marx [STOC 17], allowing them to prove hardness of a wide range of properties Φ. In this work, we refine this technique for graph properties that are non-trivial on edge-transitive graphs with a prime power number of edges. In particular, we fully classify the case of monotone bipartite graph properties: It is shown that, given *any* graph property Φ that is closed under the removal of vertices and edges, and that is non-trivial for bipartite graphs, the problem #IndSub(Φ) is #W[1]-hard and cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f, unless the Exponential Time Hypothesis fails. This holds true even if the input graph is restricted to be bipartite and counting is done modulo a fixed prime. A similar result is shown for properties that are closed under the removal of edges only.

1 Introduction

The study of the computational complexity of counting problems was initiated by Valiant's seminal work about the complexity of computing the permanent [22]. In contrast to a decision problem which requires to *verify* the existence of a solution, a counting problem asks to compute the *number* of solutions. Counting complexity theory is particularly interesting for problems whose decision versions are solvable efficiently but whose counting versions are intractable. One such example is the problem of finding/counting perfect matchings, whose decision version is solvable in polynomial time [7] and whose counting version is as least as hard as every problem in the Polynomial Hierarchy PH with respect to polynomial-time Turing reductions [22, 21]. In this work, we consider the following problem which was first introduced by Jerrum and Meeks [11]: Fix a graph property Φ, given a graph G and a positive integer k, compute the number of all induced subgraphs of G with k vertices that satisfy Φ. We denote this problem by #IndSub(Φ) and remark that, strictly speaking, #IndSub(Φ) is the *unlabeled* version of p-#InducedSubgraphWithProperty(Φ) as defined in [12, Section 1.3.1]. In particular, our properties only depend on the isomorphism type of a graph and not on any labeling of the vertices.

We study the *parameterized complexity* of #IndSub(Φ) depending on the property Φ. The underlying framework, known as *parameterized counting complexity theory*, was introduced independently by Flum and Grohe [8] and McCartin [16], and constitutes a hybrid of (classical) computational counting and parameterized complexity theory. Here, the method of parameterization allows us to perform a multivariate analysis of the complexity of #IndSub(Φ): Instead of the distinction between polynomial-time solvable and NP-hard cases, we search for properties Φ for which the problem is solvable in time $f(k) \cdot n^{O(1)}$, where n is the number of vertices of the graph and f can be any computable function. If this is the case, the problem is called *fixed-parameter tractable.* Unfortunately, the only known cases of Φ for which #IndSub(Φ) is fixed-parameter tractable are trivial in the sense that there are only finitely many k such that Φ is neither true nor false on the set of all graphs with k vertices. On the contrary, it is easy to see that #IndSub(Φ) is most likely not fixed-parameter tractable if Φ encodes a problem whose decision version is already known to be hard. An example of the latter is the property of being a complete graph. In this case, the problem #IndSub(Φ) is identical to the problem of counting cliques of size k, for which even the decision version, that is, *finding* a clique of size k in a graph with n vertices, cannot be done in time $f(k) \cdot n^{o(k)}$, unless the Exponential Time Hypothesis fails [3, 4].

The first non-trivial hardness result of #IndSub(Φ) was given by Jerrum and Meeks for Φ the property of being connected [11]. Note that, in this case, the decision version of the problem can be solved efficiently as, on input G and k, one only has to decide whether there exists a connected component of G of size at least k. This result initiated a line of research in which Jerrum and Meeks proved fixed-parameter tractability of #IndSub(Φ) to be unlikely for the property of having an even (or odd) number of edges [12], for properties that induce low edge densities [10] and for properties that are closed under the addition of edges and whose (edge-)minimal elements have large treewidth [17]. More precisely, all of those results established hardness for the parameterized complexity class #W[1], which can be seen as the parameterized counting equivalent of NP. In a recent breakthrough result [5], Curticapean, Dell and Marx have shown, that for every graph property Φ, the problem #IndSub(Φ) is either fixed-parameter tractable or hard for #W[1], that is, there are no cases of intermediate difficulty. On the downside, they did not provide an explicit criterion for #W[1]-hardness that allows to pin down the complexity of #IndSub(Φ), given a concrete property Φ.

However, combining the framework of [5] with tools from the "topological approach to evasiveness" by Kahn, Saks and Sturtevant [13], two of the authors of the current paper established #W[1]-hardness for a wide range of properties, including, for example, all non-trivial properties that are closed under the removal of edges and false on odd cycles [20]. Taken together, the above results suggest the following conjecture.

▶ **Conjecture 1.** *Let Φ be a computable graph property satisfying that there are infinitely many positive integers k such that Φ is neither true nor false on all graphs with k vertices. Then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard.*

Unfortunately, a proof of this conjecture seems to be a long way off. In this work however, building up on [5, 20], we introduce an algebraic approach that allows us to resolve the above conjecture in case of *all* non-trivial monotone properties on bipartite graphs. In particular, we obtain a matching lower bound under the Exponential Time Hypothesis.

Results and techniques

We call a graph property *monotone* if it is closed under the removal of vertices and edges and *edge-monotone* if it is closed under the removal of edges only. Furthermore, we write IS_k for the graph consisting of k isolated vertices and $K_{t,t}$ for the complete bipartite graph with t vertices on each side. Our main theorems read as follows.

▶ **Theorem 2.** *Let Φ be a computable graph property and let $\mathcal{K}$ be the set of all prime powers t such that $\Phi(\mathsf{IS}_{2t}) \neq \Phi(K_{t,t})$. If $\mathcal{K}$ is infinite then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$ hard. If additionally $\mathcal{K}$ is dense then it cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f unless ETH fails. This holds true even if the input graphs to $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

In the previous theorem, a set $\mathcal{K}$ is *dense* if there exists a constant c such that for every $m \in \mathbb{N}$, there exists a $k \in \mathcal{K}$ such that $m \leq k \leq cm$. While the hypotheses of Theorem 2 sound technical, the theorem applies in many situations. In particular, it is applicable to properties that are neither (edge-) monotone nor the complement thereof: Let Φ be the property of being Eulerian. The graph $K_{t,t}$ contains an Eulerian cycle if $t = 2^s$ for $s \geq 1$. Hence we can apply Theorem 2 with $\mathcal{K} = \{2^s \mid s \geq 1\}$, which is infinite and dense.

▶ **Corollary 3.** *Let Φ be the property of being Eulerian. Then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard and cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f unless the ETH fails. This holds true even if the input graphs to $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

In case Φ is edge-monotone, the condition $\Phi(\mathsf{IS}_{2t}) \neq \Phi(K_{t,t})$ is equivalent to non-triviality and if Φ is monotone, we obtain the following, more concise statement of the hardness result.

▶ **Theorem 4.** *Let Φ be a computable monotone graph property such that Φ and $\neg\Phi$ hold on infinitely many bipartite graphs. Then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard and cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f unless the Exponential Time Hypothesis fails. This holds true even if the input graphs to $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

Let us illustrate further consequences of the previous theorems with respect to (edge-) monotone properties. First of all, most of the prior hardness results ([11, 10, 17, 12, 20]) are shown to hold in the restricted case of bipartite graphs. We provide three examples:

▶ **Corollary 5.** *The problem $\#\textsc{IndSub}(\Phi)$, restricted to* bipartite input graphs, *is $\#\mathsf{W}[1]$-hard and cannot be solved in time $f(k) \cdot |V(G)|^{o(k)}$ for any computable function f unless ETH fails, if Φ is one of the properties of being disconnected, planar or non-hamiltonian.*

One example of a monotone property Φ for which the complexity of $\#\textsc{IndSub}(\Phi)$ was unknown, even for general graphs, is given by the following corollary of Theorem 4.

▶ **Corollary 6.** *Let F be a fixed bipartite graph with at least one edge and define $\Phi(G) = 1$ if G does not contain a subgraph isomorphic to F. Then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard and cannot be solved in time $f(k) \cdot |V(G)|^{o(k)}$ for any computable function f unless ETH fails. This holds true even if the input graphs of $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

As the number of induced subgraphs of size k that satisfy Φ equals $\binom{|V(G)|}{k}$ minus the number of induced subgraphs of size k that satisfy $\neg\Phi$, *all of the previous result remain true for the complementary properties* $\neg\Phi$.

In proving the previous theorems we build up on the approach in [5, 20], where it was shown that, given a graph property Φ and a positive integer k, the number of induced subgraphs of size k in a graph G that satisfy Φ can equivalently be expressed as the following sum over all (isomorphism types of) graphs H:

$$\sum_H a_\Phi(H) \cdot \#\mathsf{Hom}(H \to G)\,, \tag{1}$$

where a_Φ is a function from graphs to integers with finite support and $\#\mathsf{Hom}(H \to G)$ is the number of graph homomorphisms from H to G. It is known that computing a linear combination of homomorphism numbers, as in the above expression, is *precisely as hard as* computing its hardest term with a non-zero coefficient ([5], also implicitly proved in [2]). We refer to this property as *complexity monotonicity.* In [20] two of the authors of the current paper used a topological approach to analyze the coefficient $a_\Phi(K_k)$ of the complete graph on k vertices. If this coefficient is non-zero then complexity monotonicity implies that computing the number of induced subgraphs of size k in a graph G that satisfy Φ is at least as hard as computing the number $\#\mathsf{Hom}(K_k \to G)$. This, in turn, is equivalent to computing the number of cliques of size k in G, the canonical $\#\mathsf{W}[1]$-complete problem [8]. While this approach led to hardness proofs for a wide range of properties Φ, it seems that resolving Conjecture 1, even restricted to monotone properties, requires a significant amount of new ideas. Without going too much into the details[1] of [20], our analysis of $a_\Phi(K_k)$ is complicated by the fact that the number of edges of the complete graph on $k \geq 4$ vertices is not a prime power. In this work, we hence focus on the coefficient of $a_\Phi(H)$ for graphs H that have a prime power number of edges and for which computing $\#\mathsf{Hom}(H \to G)$ is hard. One example of such graphs is the biclique $K_{t,t}$ for some prime power t. Here a biclique $K_{t,t}$, also called a complete bipartite graph, has t vertices on each side and contains every edge from a vertex on the left side to a vertex to the right side. Hence the number of edges is t^2 which is a prime power if t is.

In analyzing the coefficient $a_\Phi(K_{t,t})$ of the complete bipartite graph, we invoke the results of Rivest and Vuillemin [19] who considered transitive boolean functions over a domain of prime power cardinality to resolve the asymptotic version of what is known as *Karp's evasiveness conjecture* (we recommend Miller's survey [18] for an excellent overview).

[1] Readers familiar with [20] might recall that fixed points of group actions have been used to derive a simpler formula to compute the number $a_\Phi(K_t)$ modulo a prime p for positive powers t of p. This formula would simplify greatly if the group had a p-power number of elements *and* acted transitively on the edges of K_t. Unfortunately, this can never happen for $t \geq 4$, since the number of edges of K_t is not itself a p-power.

Given a property Φ and a graph H, the *alternating enumerator* of Φ and H is defined to be

$$\hat{\chi}(\Phi, H) := \sum_{S \subseteq E(H)} \Phi(H[S]) \cdot (-1)^{\#S},$$

where $H[S]$ is the graph with vertices $V(H)$ and edges S. Roughly speaking, it will turn out that the value of $a_\Phi(H)$ is closely related to $\hat{\chi}(\Phi, H)$. We furthermore point out that, in case Φ is closed under the removal of edges, the alternating enumerator $\hat{\chi}(\Phi, H)$ equals what is called the reduced Euler characteristic of the simplicial complex on $E(H)$ associated to Φ [18, 20]. In Section 3 we study the alternating enumerator in case of edge-transitive graphs, that is, graphs whose automorphism groups act transitively on the set of edges. We give a self-contained proof of the following fact, which implicitly follows from [19].

▶ **Lemma 7.** *Let Φ be a graph property and let H be an edge-transitive graph with p^k edges such that p is a prime and $\Phi(H[\emptyset]) \neq \Phi(H)$. Then it holds that $\hat{\chi}(\Phi, H) = (\pm 1) \mod p$.*

Now, intuitively, Lemma 7 induces a strategy towards proving hardness of #IndSub(Φ): Assume a family of edge-transitive graphs $\mathcal{H}$ can be found such that $\#E(H)$ is a prime power and $\Phi(H[\emptyset]) \neq \Phi(H)$ for every $H \in \mathcal{H}$. Then #IndSub(Φ) is at least as hard as counting homomorphisms from graphs in $\mathcal{H}$, the latter of which is fully understood [6]. This observation gives a strong motivation for the study of edge-transitive graphs with a prime power number of edges. In the second part of Section 3, we fully classify those graphs as subgraphs of bipartite graphs or vertex-transitive subgraphs of wreath graphs; consult Section 3 for the formal definitions. The proof of the following theorem, which might be of independent interest, relies on a non-trivial application of Sylow's theorems.

▶ **Theorem 8.** *Let G be a connected edge-transitive graph with p^t edges for some prime p and positive integer t. Then either G is bipartite or G is vertex-transitive and can be obtained from the wreath graph W_{p^k} for $k \geq 1$ by removing edges (or both).*

With the analysis of $\hat{\chi}$ and edge-transitive graphs completed, we turn to the reduction from counting homomorphisms in Section 4. More precisely, given a class $\mathcal{H}$ of edge-transitive graphs with a prime power number of edges and a graph property Φ such that for every $H \in \mathcal{H}$ we have that $\Phi(H[\emptyset]) \neq \Phi(H)$, we construct a parameterized Turing reduction from #Hom($\mathcal{H}$) to #IndSub(Φ). Here, the problem #Hom($\mathcal{H}$) is defined as follows: Given as input a graph $H \in \mathcal{H}$ and a graph G, compute the number of homomorphisms from H to G. For technical reasons, we cannot immediately transform the number of induced subgraphs that satisfy Φ to a linear combination of homomorphism numbers as in Equation (1). We solve this technical issue by introducing color-prescribed variants of those problems in an intermediate step. In this context we consider H-colored graphs. Recall that a graph G is H-colored if it comes with a homomorphism c from G to H. A homomorphism from H to G is then called color-prescribed if it maps every vertex v of H to a vertex u of G satisfying that $c(u) = v$. We demonstrate that, given an H-colored graph G and oracle access to #IndSub(Φ), the following linear combination can be computed in time $f(|V(H)|) \cdot |V(G)|^{O(1)}$.

$$\sum_{S \subseteq E(H)} \hat{a}_\Phi(S) \cdot \#\mathsf{cp\text{-}Hom}(H[S] \to G). \tag{2}$$

Here $\mathsf{cp\text{-}Hom}(H[S] \to G)$ denotes the set of color-prescribed homomorphisms from $H[S]$ to G and $\hat{a}_\Phi$ is a function of finite support only depending in Φ. In particular, $\hat{a}_\Phi(E(H))$ and $\hat{\chi}(\Phi, H)$ are proved to agree up to a factor of -1. Finally, we establish complexity monotonicity for linear combinations of color-prescribed homomorphisms as in Equation (2), which in combination with Lemma 7 yields the desired reduction.

Combining the previous results, we invoke the reduction on graph properties that are non-trivial on bipartite graphs and prove Theorem 2 and Theorem 4, in Section 5. Furthermore, we illustrate that our algebraic approach readily extends to modular counting by proving that both, Theorem 2 and Theorem 4 remain true in case counting is done modulo a fixed prime. Due to space constraints, the formal statement and proof of the modular counting version, as well as some proofs of Sections 3 and 4, are deferred to the full version.

2 Preliminaries

Given a positive integer k, we write $[k]$ for the set $\{1,\dots,k\}$ and given a set A we write $\binom{A}{k}$ for the set of all subsets of size k of A. Furthermore, assuming that A is finite, we write $\#A$ or $|A|$ for its cardinality. Given a function $g : A \times B \to C$ and an element $a \in A$, we write $g(a,\star)$ for the function which maps $b \in B$ to $g(a,b)$. Some of our proofs rely on (elementary) group theory; due to the space constraints we refrain from an introduction and refer the reader to e.g. Chapter 1 in the standard textbook of Lang [14].

2.1 Graph theory

Graphs in this work are considered simple, undirected and without self-loops. More precisely, a graph G is a pair of a finite set $V(G)$ of vertices and a symmetric and irreflexive relation $E(G) \subseteq V(G)^2$. If a graph H is obtained from G by deleting a set of edges and a set of vertices of G, including incident edges, then H is called a *subgraph* of G. Given a subset $\hat{V}$ of $V(G)$ we write $G[\hat{V}]$ for the graph with vertices $\hat{V}$ and edges $E \cap \hat{V}^2$. The resulting graph is called an *induced subgraph* of G. An *edge-subgraph* of a graph H is a graph obtained from H by deleting edges. Given a set $S \subseteq E(H)$ we write $H[S]$ for the edge-subgraph $(V(H), S)$ of H.

Homomorphisms and embeddings

A *homomorphism* from a graph H to a graph G is a mapping $h : V(H) \to V(G)$ that preserves adjacencies. In other words, for every edge $\{u,v\} \in E(H)$ it holds that $\{h(u),h(v)\} \in E(G)$. We write $\mathsf{Hom}(H \to G)$ for the set of all homomorphisms from H to G. A homomorphism inducing a bijection of vertices and satisfying $\{u,v\} \in E(H)$ if and only if $\{f(u),f(v)\} \in E(G)$ is called an *isomorphism* and we say that two graphs H and $\hat{H}$ are *isomorphic* if there exists an isomorphism from H to $\hat{H}$. We write $\mathsf{Sub}(H \to G)$ and $\mathsf{IndSub}(H \to G)$ for the sets of all subgraphs and induced subgraphs of G, respectively, that are isomorphic to H.

An isomorphism from a graph to itself is called an *automorphism.* The set of automorphisms of a graph, together with the operation of functional composition constitutes a group, called the *automorphism group* of a graph. Slightly abusing notation, we will write $\mathsf{Aut}(H)$ for both the set of automorphisms of a graph H as well as for the automorphism group of H.

An *embedding* is an injective homomorphism and we write $\mathsf{Emb}(H \to G)$ for the set of embeddings from H to G. If an embedding h from H to G additionally satisfies that $\{h(u),h(v)\} \in E(G)$ implies $\{u,v\} \in E(H)$, we call it a *strong embedding.* We write $\mathsf{StrEmb}(H \to G)$ for the set of strong embeddings from H to G. Observe that the images of embeddings and strong embeddings from H to G are precisely the subgraphs and induced subgraphs of G that are isomorphic to H.

Colored variants

Given graphs G and H, we say that G is *H-colored* if G comes with a homomorphism c from G to H, called an *H-coloring*. Note that, in particular, every edge-subgraph of H can be H-colored by the identity function on $V(H)$, which is assumed to be the given coloring whenever we consider H-colored edge-subgraphs of H in this paper. Given an edge-subgraph F of H and a homomorphism h from F to a H-colored graph G, we say that h is *color-prescribed* if for all $v \in V(F) = V(H)$ it holds that $c(h(v)) = v$. We write $\mathsf{cp\text{-}Hom}(F \to G)$ for the set of all color-prescribed homomorphisms from F to G. $\mathsf{cp\text{-}StrEmb}(F \to G)$ is defined similarly for color-prescribed strong embeddings. We point out that a definition of $\mathsf{cp\text{-}Emb}$ is obsolete as every color-prescribed homomorphism is injective by definition and hence an embedding. Furthermore, we write $\mathsf{cp\text{-}Sub}(F \to G)$ and $\mathsf{cp\text{-}IndSub}(F \to G)$ for the sets of images of color-prescribed embeddings and strong embeddings from F to G, respectively. Elements of $\mathsf{cp\text{-}Sub}(F \to G)$ and $\mathsf{cp\text{-}IndSub}(F \to G)$ are referred to as color-prescribed subgraphs and induced subgraphs.[2]

Graph properties and the alternating enumerator

A *graph property* is a function Φ from graphs to $\{0, 1\}$ such that for any pair of isomorphic graphs H and $\hat{H}$ we have that $\Phi(H) = \Phi(\hat{H})$. Adapting the notation of Rivest and Vuillemin [19], we define the *alternating enumerator* of a property Φ and a graph H to be the function

$$\hat{\chi}(\Phi, H) := \sum_{S \subseteq E(H)} \Phi(H[S]) \cdot (-1)^{\# S} .$$

A graph property Φ is called *edge-monotone* if it is closed under the removal of edges. It is called *monotone* if it is closed under the removal of edges *and* vertices.[3] Given a graph property Φ, a positive integer k and a graph G, we write $\mathsf{IndSub}(\Phi, k \to G)$ for the set of all induced subgraphs of size k of G that satisfy Φ. Furthermore, given a graph property Φ and an H-colored graph G, we write $\mathsf{cp\text{-}IndSub}(\Phi \to G)$ for the set of all color-prescribed induced subgraphs of size $|V(H)|$ in G that satisfy Φ.

2.2 Parameterized counting complexity

The field of parameterized counting was introduced independently by McCartin [16] and Flum and Grohe [8] and constitutes a hybrid of classical computational counting and parameterized complexity theory. A *parameterized counting problem* is a pair of a function $P : \Sigma^* \to \mathbb{N}$ and a computable parameterization $\kappa : \Sigma^* \to \mathbb{N}$. It is called *fixed-parameter tractable* (FPT) if there exists a computable function f and a deterministic algorithm that computes $P(x)$ in time $f(\kappa(x)) \cdot |x|^{O(1)}$ for every $x \in \Sigma^*$. A *parameterized Turing reduction* from (P, κ) to $(\hat{P}, \hat{\kappa})$ is a deterministic FPT algorithm with respect to κ that is given oracle access to $\hat{P}$ and that on input x computes $P(x)$ with the additional restriction that there exists a computable function g such that for any oracle query y it holds that $\hat{\kappa}(y) \leq g(\kappa(x))$. We write $(P, \kappa) \leq^{\mathrm{fpt}}_{\mathrm{T}} (\hat{P}, \hat{\kappa})$ if a parameterized Turing reduction exists.

[2] The observant reader might have noticed that the sets $\mathsf{cp\text{-}Sub}(F \to G)$ and $\mathsf{cp\text{-}Hom}(F \to G)$ as well as $\mathsf{cp\text{-}IndSub}(F \to G)$ and $\mathsf{cp\text{-}StrEmb}(F \to G)$ are essentially the same as a color-prescribed homomorphism is uniquely identified by its image. However, we decided to distinguish those notions in order to make the combinatorial arguments in Section 4 more accessible.

[3] To avoid confusion, we remark that in some literature, e.g. in [17] a property is called monotone if it is closed under *addition* of vertices and edges.

Given a graph G and a positive integer k, the parameterized counting problem #Clique asks to compute the number of complete subgraphs of size k in G and is parameterized by k, that is $\kappa(G,k) := k$. It is complete for the class #W[1], which can be seen as a parameterized counting equivalent of NP [8]. Evidence for the fixed-parameter intractability of #W[1]-hard problems is given by the *Exponential Time Hypothesis* (ETH), which asserts that 3-SAT cannot be solved[4] in time $\mathsf{exp}(o(m))$ where m is the number of clauses of the input formula. Assuming ETH, #Clique cannot be solved in time $f(k) \cdot n^{o(k)}$ for any function f [3, 4] and hence #W[1]-hard problems are not fixed-parameter tractable.

Given a recursively enumerable class of graphs $\mathcal{H}$, the problem #Hom($\mathcal{H}$) asks, given a graph $H \in \mathcal{H}$ and an arbitrary graph G, to compute $\#\mathsf{Hom}(H \to G)$. Its parameterization is given by $\kappa(H,G) := |V(H)|$. The problems #cp-Hom($\mathcal{H}$) and #cp-IndSub($\mathcal{H}$) are defined similarly. Note that the inputs of the latter two problems are of the form (H,G) where $H \in \mathcal{H}$ and G comes with an explicitly given H-coloring.

Given a computable graph property Φ, the problem #IndSub(Φ) asks, given a graph G and a positive integer k, to compute $\#\mathsf{IndSub}(\Phi, k \to G)$ and the parameterization is given by $\kappa(G,k) := k$. Furthermore, we define #cp-IndSub(Φ) to be the problem of, given a graph G that is H-colored for some graph H, computing $\#\mathsf{cp}\text{-}\mathsf{IndSub}(\Phi \to G)$ and parameterize it by $\kappa(G) := |V(H)|$. We emphasize that, similarly to #cp-Hom($\mathcal{H}$), the input graph G comes with an explicitly given H-coloring, from which H can be constructed and thus the parameterization is well-defined.

3 Alternating enumerators and p-edge-transitive graphs

In this part of the paper we will provide a rough exposition of the work of Rivest and Vuillemin [19] who studied transitive boolean functions to resolve the asymptotic version of Karp's evasiveness conjecture. We will then apply their result to graphs H that are both edge-transitive and have p^ℓ many edges for some prime p. This will enable us to conclude that the alternating enumerator of Φ and H is (± 1) modulo p whenever $\Phi(H[\emptyset]) \neq \Phi(H)$. We start by introducing some required notions from algebraic graph theory.
The automorphism group of a graph H induces a group action on the edges of H, given by $h\{u,v\} := \{h(u), h(v)\}$. A group action is *transitive* if there exists only one orbit and a graph H is called *edge-transitive* if the group action on the edges is transitive, that is, if for every pair of edges $\{u,v\}$ and $\{\hat{u},\hat{v}\}$ there exists an automorphism $h \in \mathsf{Aut}(H)$ such that $h\{u,v\} = \{\hat{u},\hat{v}\}$. If additionally the number of edges of an edge-transitive graph is a prime power p^ℓ we call the graph *p-edge-transitive*.

▶ **Lemma 9** (Lemma 7 restated). *Let Φ be a graph property and let H be a p-edge-transitive graph such that $\Phi(H[\emptyset]) \neq \Phi(H)$. Then it holds that $\hat{\chi}(\Phi, H) = (\pm 1) \mod p$.*

Lemma 9 is implicitly proven in [19, Theorem 4.3], but for completeness we will include a short and self-contained proof, demonstrating a first application of the machinery of Sylow subgroups that we will need later.

For the proofs in this section, let us recall some key results from group theory. Given a prime number p, a finite group Γ' is called a *p-group* if the order $\#\Gamma'$ is a power of p. The following is a well-known and central result from the theory of finite groups.

[4] We point out that this includes deterministic and randomized algorithms.

▶ **Theorem 10** (Sylow theorems). *Let Γ be a finite group of order $\#\Gamma = p^k m$ for a prime p and an integer $m \geq 1$ coprime to p. Then Γ contains a subgroup Γ' of order p^k. Moreover, every other subgroup Γ'' of Γ of order p^k is conjugate to Γ', that is there exists $g \in \Gamma$ with $\Gamma'' = g\Gamma' g^{-1}$. In particular, the groups Γ', Γ'' are isomorphic (via the conjugation by g).*

Finally, every subgroup $\tilde{\Gamma} \subseteq \Gamma$ which is a p-group is actually contained in some conjugate $g\Gamma' g^{-1}$ of the group Γ'.

A subgroup $\Gamma' \subseteq \Gamma$ as above is called a *p-Sylow subgroup* of Γ.

The following result is a first important application of the Sylow theorems. It can be found as Exercise (E28) in [1]; for completeness we include a proof in the full version.

▶ **Lemma 11.** *Let Γ be a finite group acting transitively on a set T such that $\#T = p^l$ for some $l \geq 0$. Then the induced action of any p-Sylow subgroup $\Gamma' \subseteq \Gamma$ on T is still transitive.*

This result allows us to give a short proof of Lemma 9 above. We sketch the proof here and provide the details in the full version of the paper.

Proof sketch of Lemma 9. Let Γ' be a p-Sylow subgroup of $\mathsf{Aut}(H)$, then by Lemma 11 it acts transitively on $E(H)$. This action on the edges of H induces an action on the set of subsets $S \subseteq E(H)$ and by the Orbit-Stabilizer Theorem, for any S which is not invariant under Γ', the size of its orbit by Γ' is a positive power of p. Then in the sum

$$\hat{\chi}(\Phi, H) = \sum_{S \subseteq E(H)} \Phi(H[S]) \cdot (-1)^{\#S},$$

we group together summands belonging to S in the same Γ'-orbit. The contribution of any orbit of positive size is divisible by p and can be left out modulo p. Since Γ' acts transitively on $E(H)$, the only invariant sets S are $S = \emptyset$ and $S = E(H)$, so we have

$$\hat{\chi}(\Phi, H) = \Phi(H[\emptyset]) + \Phi(H[E(H)]) \cdot (-1)^{\#E(H)} = \Phi(H[\emptyset]) - \Phi(H) \mod p.$$

Note that we use the fact that for $p > 2$ we have that $\#E(H)$ is odd since it is a prime power and for $p = 2$ we have $-1 = 1$ modulo p. Now, the condition $\Phi(H[\emptyset]) \neq \Phi(H)$ exactly gives us $\Phi(H[\emptyset]) - \Phi(H) = \pm 1 \mod p$. ◀

There are two main examples for p-edge-transitive graphs. The first example is the class of the complete, bipartite graphs K_{p^l,p^m} with $l, m \geq 0$. The graph K_{p^l,p^m} has p^{l+m} edges and the automorphism group clearly acts transitively on the edges of that graph. The second example is the class of wreath graphs W_{p^k} for $k \geq 1$. The graph W_{p^k} has p^k vertices that can be decomposed in disjoint sets $V_0, \ldots, V_{p-1}$ of order p^{k-1} each, and edges $\{v_i, v_{i+1}\}$ for each $i = 0, \ldots, p-1$ and vertices $v_i \in V_i, v_{i+1} \in V_{i+1}$ (where it is understood that $V_p = V_0$). Thus in total, W_{p^k} has p^{2k-1} edges, except for $p = 2$ where it has 2^{2k-2} edges. The graph W_{p^k} can be seen as the lexicographical product of a p-cycle with a graph consisting of p^{k-1} disjoint vertices. For $k = 1$ we exactly obtain the p-cycle. To see that W_{p^k} is edge-transitive, we observe that on the one hand, for fixed i we can apply an arbitrary permutation on V_i leaving the graph invariant. On the other hand, there exists a “rotational action” sending V_j to V_{j+1} for $j = 0, \ldots, p-1$, which also leaves the graph invariant. Using these two types of automorphisms, we can map every edge to every other edge.

The following result tells us that in a certain sense the graphs K_{p^l,p^m} and W_{p^k} are the maximal p-edge-transitive graphs. A graph G is called *vertex-transitive* if its automorphism group $\mathsf{Aut}(G)$ acts transitively on its set of vertices $V(G)$.

▶ **Theorem 12** (Theorem 8 restated). *Let G be a connected p-edge-transitive graph. Then either G is bipartite (and thus a subgraph of a graph of the form K_{p^l,p^m} for some $l,m \geq 0$) or G is vertex-transitive and an edge-subgraph of W_{p^k} for $k \geq 1$ (or both).*

Due to the space constraints the proof is deferred to the full version of the paper.

4 The main reduction: From homomorphisms to induced subgraphs

In what follows we will construct a sequence of reductions, starting from $\#\textsc{Hom}(\mathcal{H})$ and ending in $\#\textsc{IndSub}(\Phi)$. Here, $\mathcal{H}$ is a recursively enumerable set of p-edge-transitive graphs and Φ is a graph property such that for every graph $H \in \mathcal{H}$ we have that $\Phi(H[\emptyset]) \neq \Phi(H)$. More precisely, we will prove that

$$\#\textsc{Hom}(\mathcal{H}) \leq^{\mathrm{fpt}}_{\mathrm{T}} \#\textsc{cp-Hom}(\mathcal{H}) \overset{\text{Lemma 17}}{\leq^{\mathrm{fpt}}_{\mathrm{T}}} \#\textsc{cp-IndSub}(\Phi) \leq^{\mathrm{fpt}}_{\mathrm{T}} \#\textsc{IndSub}(\Phi) \qquad (3)$$

In particular, all of those reductions will be tight in the sense that conditional lower bounds on the fine-grained complexity of $\#\textsc{Hom}(\mathcal{H})$ immediately transfer to $\#\textsc{IndSub}(\Phi)$. For the hardness results we rely on a result of Dalmau and Jonsson [6] stating that the problem $\#\textsc{Hom}(\mathcal{H})$ is known to be #W[1]-hard whenever $\mathcal{H}$ is recursively enumerable and of unbounded treewidth.[5] Here a class of graphs is said to have unbounded treewidth if for every $b \in \mathbb{N}$ there exists a graph in the class with treewidth at least b. Due to space constraints, the remainder of this section is concerned with proving Lemma 17, that is, the second step of the reduction sequence; the first and the third step are deferred to the full version.

Reducing color-prescribed homomorphisms to color-prescribed induced subgraphs

The reduction from color-prescribed homomorphisms to color-prescribed induced subgraphs requires the introduction of an H-colored variant of the framework of graph motif parameters, which was explicitly introduced in [5] and implicitly used in [2]. More precisely, given an H-colored graph G and a property Φ, we will express $\#\mathsf{cp\text{-}IndSub}(\Phi \to G)$ as a linear combination of color-prescribed homomorphisms, that is, terms of the form $\#\mathsf{cp\text{-}Hom}(H[S] \to G)$. In a first step, we show complexity monotonicity for linear combinations of color-prescribed homomorphisms. While this property allows a quite simple proof, a second step, in which we study the coefficient of $\#\mathsf{cp\text{-}Hom}(H \to G)$ requires a thorough understanding of the alternating enumerator of Φ and H. In case of p-edge-transitive graphs, the latter is provided by Lemma 9.

We start by introducing a colored variant of the tensor product of graphs (see e.g. Chapter 5.4.2 in [15]). Given two H-colored graphs G and $\hat{G}$ with colorings c and $\hat{c}$ we define their *color-prescribed* tensor product $G \times_H \hat{G}$ as the graph with vertices $V = \{(v,\hat{v}) \in V(G) \times V(\hat{G}) \mid c(v) = \hat{c}(\hat{v})\}$ and edges between two vertices $(v,\hat{v})$ and $(u,\hat{u})$ if and only if $\{v,u\} \in E(G)$ and $\{\hat{v},\hat{u}\} \in E(\hat{G})$. The next lemma states that $\#\mathsf{cp\text{-}Hom}$ is linear with respect to $\times_H$, a short proof of which can be found in the full version of the paper.

▶ **Lemma 13.** *Let H be a graph, let F be an edge-subgraph of H and let G and $\hat{G}$ be H-colored. Then we have that*

$$\#\mathsf{cp\text{-}Hom}(F \to G \times_H \hat{G}) = \#\mathsf{cp\text{-}Hom}(F \to G) \cdot \#\mathsf{cp\text{-}Hom}(F \to \hat{G})\,.$$

[5] We remark that the graph parameter of treewidth is not used explicitly in this work. Hence we omit the definition and refer the interested reader e.g. to Chapter 11 in [9].

We are now prepared to prove the color-prescribed variant of complexity monotonicity.

▶ **Lemma 14** (Complexity monotonicity). *Let H be a graph and let a be a function from edge-subgraphs of H to rationals. There exists an algorithm $\mathbb{A}$ that is given an H-colored graph G as input and has oracle access to the function*

$$\sum_{S\subseteq E(H)} a(H[S])\cdot \#\textsf{cp-Hom}(H[S]\to \star)\,,$$

and computes $\#\textsf{cp-Hom}(H[S]\to G)$ for all S such that $a(H[S])\neq 0$ in time $f(|H|)\cdot|V(G)|$ where f is a computable function. Furthermore, every oracle query $\hat{G}$ satisfies $|V(\hat{G})|\leq f(|H|)\cdot|V(G)|$.

Proof. Using Lemma 13 we have that for every H-colored graph F it holds that

$$\sum_{S\subseteq E(H)} a(H[S])\cdot \#\textsf{cp-Hom}(H[S]\to (G\times_H F)) \tag{4}$$

$$= \sum_{S\subseteq E(H)} a(H[S])\cdot \#\textsf{cp-Hom}(H[S]\to G)\cdot \#\textsf{cp-Hom}(H[S]\to F)\,, \tag{5}$$

which we can evaluate for $F = H[\emptyset],\dots,H[E(H)]$. This induces a system of linear equations which can easily be shown to have a unique solution; the proof that the corresponding matrix is non-singular can be found in the full version of the paper. Consequently, the numbers $a(H[S])\cdot\#\textsf{cp-Hom}(H[S]\to G)$ are uniquely determined and can be computed by solving the system using Gaussian elimination. Finally, we obtain the numbers $\#\textsf{cp-Hom}(H[S]\to G)$ by multiplying with $a(H[S])^{-1}$ whenever $a(H[S])\neq 0$. ◀

It remains to express the number of color-prescribed induced subgraphs that satisfy a property Φ as a linear combination of color-prescribed homomorphisms. We only sketch the proof of the following lemma and defer the details to the full version of the paper.

▶ **Lemma 15.** *Let H be a graph, let Φ be a graph property and let G be an H-colored graph. Then it holds that*

$$\#\textsf{cp-IndSub}(\Phi\to G) = \sum_{S\subseteq E(H)} \Phi(H[S]) \sum_{J\subseteq E(H)\setminus S} (-1)^{\#J}\cdot \#\textsf{cp-Hom}([H[S\cup J]\to G)\,.$$

Moreover, the absolute values of the coefficient of $\#\textsf{cp-Hom}(H\to G)$ and $\hat{\chi}(\Phi,H)$ are equal.

Proof sketch. We rely on the following claim which follows by inclusion-exclusion.

▷ Claim 16. Let H be graph, let $S\subseteq E(H)$ and let G be an H-colored graph. Then we have that

$$\#\textsf{cp-IndSub}(H[S]\to G) = \sum_{J\subseteq E(H)\setminus S} (-1)^{\#J}\cdot \#\textsf{cp-Sub}(H[S\cup J]\to G)\,.$$

Now summing up over all S for which $\Phi(H[S])=1$ and applying Claim 16 yields

$$\#\textsf{cp-IndSub}(\Phi\to G) = \sum_{S\subseteq E(H)} \Phi(H[S]) \sum_{J\subseteq E(H)\setminus S} (-1)^{\#J}\cdot \#\textsf{cp-Hom}(H[S\cup J]\to G)\,. \tag{6}$$

Finally, we collect for the coefficient of $\#\textsf{cp-Hom}(H\to G)$ and obtain

$$\sum_{S\subseteq E(H)} \Phi(H[S])\cdot(-1)^{\#E(H)-\#S} = (-1)^{\#E(H)}\cdot\hat{\chi}(\Phi,H)\,. \tag{7}$$

◀

The application of the complexity monotonicity property for color-prescribed homomorphisms (Lemma 14) requires non-zero coefficients. However, this can be guaranteed for the coefficient of interest in case of p-edge-transitive graphs as shown in Section 3. Formally, the reduction is constructed as follows.

▶ **Lemma 17.** *Let Φ be a graph property and let H be a p-edge-transitive graph such that $\Phi(H[\emptyset]) \neq \Phi(H)$. There exists an algorithm $\mathbb{A}$ that is given an H-colored graph G as input and has oracle access to the function $\#\textsf{cp-IndSub}(\Phi \to \star)$ and computes $\#\textsf{cp-Hom}(H \to G)$ in time $f(|H|) \cdot |V(G)|$ where f is a computable function. Furthermore, every oracle query $\hat{G}$ is H-colored as well and satisfies $|V(\hat{G})| \leq f(|H|) \cdot |V(G)|$.*

Proof. Using Lemma 15 we can express $\#\textsf{cp-IndSub}(\Phi \to \star)$ as a linear combination of color-prescribed homomorphisms. In particular, the coefficient of $\#\textsf{cp-Hom}(H \to \star)$ is $(\pm 1) \cdot \hat{\chi}(\Phi, H)$ and by Lemma 9 we have that this number is non-zero whenever H is p-edge-transitive and $\Phi(H[\emptyset]) \neq \Phi(H)$. Hence we can use the algorithm from Lemma 14 to compute $\#\textsf{cp-Hom}(H \to G)$ in the desired running time. ◀

5 Non-trivial monotone properties on bipartite graphs

In the last part of the paper, we apply the algebraic approach which was laid out in the preceding sections to bipartite graph properties. This will allow us to prove our main result. To this end, we say that a set $\mathcal{K} \subseteq \mathbb{N}$ is *dense* if there exists a constant c such that for every $k' \in \mathbb{N}$ there exists $k \in \mathcal{K}$ such that $k' \leq k \leq ck'$. Furthermore, we write $\textsf{IS}_k$ for the graph with k isolated vertices. The following theorem is obtained by invoking the reduction sequence (3) to complete bipartite graphs $K_{t,t}$ for prime powers $t = p^k$, which are p-edge-transitive (see Section 3). Due to the space constraints, the details, as well as the case of modular counting, are deferred to the full version of the paper.

▶ **Theorem 18** (Theorem 2 restated). *Let Φ be a computable graph property and let $\mathcal{K}$ be the set of all prime powers t such that $\Phi(\textsf{IS}_{2t}) \neq \Phi(K_{t,t})$. If $\mathcal{K}$ is infinite then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$ hard. If additionally $\mathcal{K}$ is dense then it cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f unless ETH fails. This holds true even if the input graphs to $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

Note that, in case Φ or its complement is edge-monotone, we only have to find infinitely many prime powers t for which Φ is neither true nor false on the set of all edge-subgraphs of $K_{t,t}$, which is the case for all sensible, non-trivial properties that do not rely on the number of vertices in some way. If Φ (or its complement) is monotone, that is, not only closed under the removal of edges, but also under the removal of vertices, then such artificial properties do not exist and we can state the result more clearly as follows.

▶ **Corollary 19** (Theorem 4 restated). *Let Φ be a computable monotone graph property such that Φ and $\neg\Phi$ hold on infinitely many bipartite graphs. Then $\#\textsc{IndSub}(\Phi)$ is $\#\mathsf{W}[1]$-hard and cannot be solved in time $f(k) \cdot n^{o(k)}$ for any computable function f unless ETH fails. This holds true even if the input graphs to $\#\textsc{IndSub}(\Phi)$ are restricted to be bipartite.*

Proof. If Φ is monotone and Φ and $\neg\Phi$ hold on infinitely many bipartite graphs, then $\Phi(\textsf{IS}_k) = 1$ for all positive integers k and $\Phi(K_{t,t}) = 0$ for all but finitely many t. Hence we can apply Theorem 18 and, in particular, the set $\mathcal{K}$ will contain all but finitely many prime powers and is therefore dense. ◀

Conclusion

We have established hardness for #IndSub(Φ) for *any* (edge-)monotone property Φ that is non-trivial on bipartite graphs. In particular, this holds true even if we count modulo a prime and restrict the input graphs to be bipartite as well. Hence, we did not only significantly extend the set of graph properties Φ for which the (parameterized) complexity of #IndSub(Φ) is understood, but we also generalized many of the prior results, such as [11], [17] and parts of [20] to the cases of bipartite input graphs and modular counting.

As a next step towards a proof of Conjecture 1, we suggest the study of properties that are defined by forbidden induced subgraphs, for which the complexity of #IndSub(Φ) is only partially resolved at this point.

Abstract

A tournament is a directed graph in which there is a single arc between every pair of distinct vertices. Given a tournament T on n vertices, we explore the classical and parameterized complexity of the problems of determining if T has a cycle packing (a set of pairwise arc-disjoint cycles) of size k and a triangle packing (a set of pairwise arc-disjoint triangles) of size k. We refer to these problems as Arc-disjoint Cycles in Tournaments (ACT) and Arc-disjoint Triangles in Tournaments (ATT), respectively. Although the maximization version of ACT can be seen as the linear programming dual of the well-studied problem of finding a minimum feedback arc set (a set of arcs whose deletion results in an acyclic graph) in tournaments, surprisingly no algorithmic results seem to exist for ACT. We first show that ACT and ATT are both NP-complete. Then, we show that the problem of determining if a tournament has a cycle packing and a feedback arc set of the same size is NP-complete. Next, we prove that ACT and ATT are fixed-parameter tractable, they can be solved in $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$ time and $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$ time respectively. Moreover, they both admit a kernel with $\mathcal{O}(k)$ vertices. We also prove that ACT and ATT cannot be solved in $2^{o(\sqrt{k})} n^{\mathcal{O}(1)}$ time under the Exponential-Time Hypothesis.

1 Introduction

Given a (directed or undirected) graph G and a positive integer k, the Disjoint Cycle Packing problem is to determine whether G has k (vertex or arc/edge) disjoint (directed or undirected) cycles. Packing disjoint cycles is a fundamental problem in Graph Theory and Algorithm Design with applications in several areas. Since the publication of the classic Erdős-Pósa theorem in 1965 [21], this problem has received significant scientific attention in various algorithmic realms. In particular, Vertex-Disjoint Cycle Packing in undirected graphs is one of the first problems studied in the framework of parameterized complexity. In this framework, each problem instance is associated with a non-negative integer k called *parameter*, and a problem is said to be *fixed-parameter tractable* (FPT) if it can be solved in $f(k)n^{\mathcal{O}(1)}$ time for some computable function f, where n is the input size. For convenience, the running time $f(k)n^{\mathcal{O}(1)}$ is denoted as $\mathcal{O}^\star(f(k))$. A *kernelization algorithm* is a polynomial-time algorithm that transforms an arbitrary instance of the problem to an equivalent instance of the same problem whose size is bounded by some computable function g of the parameter of the original instance. The resulting instance is called a *kernel* and if g is a polynomial function, then it is called a *polynomial kernel.* A decidable parameterized problem is FPT if and only if it has a kernel (not necessarily of polynomial size). Kernelization typically involves applying a set *reduction rules* to the given instance to produce another instance. A reduction rule is said to be *safe* if it is sound and complete, i.e., applying it to the given instance produces an equivalent instance. In order to classify parameterized problems as being FPT or not, the W-hierarchy is defined: FPT $\subseteq$ W[1] $\subseteq$ W[2] $\subseteq \cdots \subseteq$ XP. It is believed that the subset relations in this sequence are all strict, and a parameterized problem that is hard for some complexity class above FPT in this hierarchy is said to be fixed-parameter intractable. Further details on parameterized algorithms we refer to recent books [16, 19, 24, 26].

Vertex-Disjoint Cycle Packing in undirected graphs is FPT with respect to the solution size k [10, 36] but has no polynomial kernel unless NP $\subseteq$ coNP/poly [11]. In contrast, Edge-Disjoint Cycle Packing in undirected graphs admits a kernel with $\mathcal{O}(k \log k)$ vertices (and is therefore FPT) [11]. On directed graphs, these problems have many practical applications (for example in biology [12, 18]) and they have been extensively studied [7, 34]. It turns out that Vertex-Disjoint Cycle Packing and Arc-Disjoint Cycle Packing are equivalent and are W[1]-hard [33, 42]. Therefore, studying these problems on a subclass of directed graphs is a natural direction of research. Tournaments form a mathematically rich subclass of directed graphs with interesting structural and algorithmic properties [6, 38]. Tournaments have several applications in modeling round-robin tournaments and in the study of voting systems and social choice theory [29, 31].

Feedback Vertex Set and Feedback Arc Set are two well-explored algorithmic problems on tournaments. A *feedback vertex (arc) set* is a set of vertices (arcs) whose deletion results in an acyclic graph. Given a tournament, MinFAST and MinFVST are the problems of obtaining a feedback arc set and feedback vertex set of minimum size, respectively. We refer to the corresponding decision version of the problems as FAST and FVST. The optimization problems MinFAST and MinFVST have numerous practical applications in the areas of voting theory [17], machine learning [15], search engine ranking [20] and have been intensively studied in various algorithmic areas. MinFAST and MinFVST are NP-hard [3, 13] while FAST and FVST are FPT when parameterized by the solution size k [4, 23, 25, 31]. Further, FAST has a kernel with $\mathcal{O}(k)$ vertices and FVST has a kernel with $\mathcal{O}(k^{1.5})$ vertices [9, 35]. Surprisingly, the duals (in the linear programming sense) of MinFAST and MinFVST have not been considered in the literature until recently. Any tournament that has a cycle also has a triangle [7]. Therefore, if a tournament has k vertex-disjoint cycles, then it also has k vertex-disjoint triangles. Thus, Vertex-Disjoint Cycle Packing in tournaments is just packing vertex-disjoint triangles. This problem is NP-hard [8]. A straightforward application of the *colour coding* technique [5] shows that this problem is FPT and a kernel with $\mathcal{O}(k^2)$ vertices is an immediate consequence of the quadratic element kernel known for 3-Set Packing [1]. Recently, a kernel with $\mathcal{O}(k^{1.5})$ vertices was shown for this problem using interesting variants and generalizations of the popular *expansion lemma* [35].

A tournament that has k arc-disjoint cycles need not necessarily have k arc-disjoint triangles. This observation hints that packing arc-disjoint cycles could be significantly harder than packing vertex-disjoint cycles. It also hints that packing arc-disjoint cycles and arc-disjoint triangles in tournaments could be problems of different complexities. This is the starting point of our study. Subsequently, we refer to a set of pairwise arc-disjoint cycles as a *cycle packing* and a set of pairwise arc-disjoint triangles as a *triangle packing*. Given a tournament, MaxACT and MaxATT are the problems of obtaining a maximum set of arc-disjoint cycles and triangles, respectively. We refer to the corresponding decision version of the problems as ACT and ATT. Formally, given a tournament T and a positive integer k, ACT (resp. ATT) is the task of determining if T has k arc-disjoint cycles (resp. triangles). From a structural point of view, the problem of partitioning the arc set of a directed graph into a collection of triangles has been studied for regular tournaments [44], almost regular tournaments [2] and complete digraphs [28]. In this work, we study the classical complexity of MaxACT and MaxATT and the parameterized complexity of ACT and ATT with respect to the solution size (i.e. the number k of cycles/triangles) as parameter.

Our main contributions.

- We prove that MaxATT and MaxACT are NP-hard (Theorems 5 and 7). As a consequence, we also show that ACT and ATT do not admit algorithms with $\mathcal{O}^\star(2^{o(\sqrt{k})})$ running time under the Exponential-Time Hypothesis (Theorem 10). Moreover, deciding if a tournament has a cycle packing and a feedback arc set of the same size is NP-complete (Theorem 9).
- A tournament T has k arc-disjoint cycles if and only if T has k arc-disjoint cycles each of length at most $2k + 1$ (Theorem 11).
- ACT can be solved in $\mathcal{O}^\star(2^{\mathcal{O}(k \log k)})$ time (Theorem 17) and admits a kernel with $\mathcal{O}(k)$ vertices (Theorem 16).
- ATT can be solved in $\mathcal{O}^\star(2^{\mathcal{O}(k)})$ time and admits a kernel with $\mathcal{O}(k)$ vertices (Theorem 18).

2 Preliminaries

We denote the set $\{1, 2, \ldots, n\}$ of consecutive integers from 1 to n by $[n]$.

Directed Graphs. A *directed graph* D (or *digraph*) is a pair consisting of a finite set $V(D)$ of *vertices* of D and a set $A(D)$ of *arcs* of D, which are ordered pairs of elements of $V(D)$. For a vertex $v \in V(D)$, its *out-neighbourhood*, denoted by $N^+(v)$, is the set $\{u \in V(D) \colon vu \in A(D)\}$ and its *out-degree*, denoted by $d^+(x)$, is $|N^+(v)|$. For a set F of arcs, $V(F)$ denotes the union of the sets of endpoints of arcs in F. Given a digraph D and a subset X of vertices, we denote by $D[X]$ the digraph induced by the vertices in X. Moreover, we denote by $D \setminus X$ the digraph $D[V(D) \setminus X]$ and say that this digraph is obtained by *deleting* X *from* D.

Paths and Cycles. A *path* P in a digraph D is a sequence $(v_1, \dots, v_k)$ of distinct vertices such that for each $i \in [k-1]$, $v_i v_{i+1} \in A(D)$. The set $\{v_1, \dots, v_k\}$ is denoted by $V(P)$ and the set $\{v_i v_{i+1} \colon i \in [k-1]\}$ is denoted by $A(P)$. A *cycle* C in D is a sequence $(v_1, \dots, v_k)$ of distinct vertices such that $(v_1, \dots, v_k)$ is a path and $v_k v_1 \in A(D)$. The length of a path or cycle X is the number of vertices in it. A cycle on three vertices is called a *triangle*. A digraph is called a *directed acyclic graph* if it has no cycles. A *feedback arc set* (FAS) is a set of arcs whose deletion results in an acyclic graph. For a digraph D, let $\mathrm{minfas}(D)$ denote the size of a minimum FAS of D. Any directed acyclic graph D has an ordering $\sigma(D) = (v_1, \dots, v_n)$ called *topological ordering* of its vertices such that for each $v_i v_j \in A(D)$, $i < j$ holds. Given an ordering σ and two vertices u and v, we write $u <_\sigma v$ if u is before v in σ.

Tournaments. A *tournament* T is a digraph in which for every pair u, v of distinct vertices either $uv \in A(T)$ or $vu \in A(T)$ but not both. In other words, a tournament T on n vertices is an orientation of the complete graph K_n. A tournament T can alternatively be defined by an ordering $\sigma(T) = (v_1, \dots, v_n)$ of its vertices and a set of *backward arcs* $\overleftarrow{A}_\sigma(T)$ (which will be denoted $\overleftarrow{A}(T)$ as the considered ordering is not ambiguous), where each arc $a \in \overleftarrow{A}(T)$ is of the form $v_{i_1} v_{i_2}$ with $i_2 < i_1$. Indeed, given $\sigma(T)$ and $\overleftarrow{A}(T)$, we define $V(T) = \{v_i : i \in [n]\}$ and $A(T) = \overleftarrow{A}(T) \cup \overrightarrow{A}(T)$ where $\overrightarrow{A}(T) = \{v_{i_1} v_{i_2} : (i_1 < i_2) \text{ and } v_{i_2} v_{i_1} \notin \overleftarrow{A}(T)\}$ is the set of *forward arcs* of T in the given ordering $\sigma(T)$. The pair $(\sigma(T), \overleftarrow{A}(T))$ is called a *linear representation* of the tournament T. A tournament is called *transitive* if it is a directed acyclic graph and a transitive tournament has a unique topological ordering. Given two tournaments T_1, T_2 defined by $\sigma(T_l)$ and $\overleftarrow{A}(T_l)$ with $l \in \{1, 2\}$, we denote by $T = T_1 T_2$ the tournament called the *concatenation of* T_1 *and* T_2, where $V(T) = V(T_2) \cup V(T_2)$, $\sigma(T) = \sigma(T_1)\sigma(T_2)$ is the concatenation of the two sequences, and $\overleftarrow{A}(T) = \overleftarrow{A}(T_1) \cup \overleftarrow{A}(T_2)$.

3 NP-hardness of MaxACT and MaxATT

This section contains our main results. We prove the NP-hardness of MaxATT using a reduction from 3-SAT(3). Here, 3-SAT(3) denotes the specific case of 3-SAT where each clause has at most three literals, and each literal appears at most two times positively and exactly one time negatively. In the following, denote by F the input formula of an instance of 3-SAT(3). Let n be the number of its variables and m be the number of its clauses. We may suppose that $n \equiv 3 \pmod 6$. If it is not the case, we can add up to 5 unused variables x with the trivial clause $x \vee \overline{x}$. This operation guarantees us we keep the hypotheses of 3-SAT(3). We can also assume that $m + 1 \equiv 3 \pmod 6$. Indeed, if it not the case, we add 6 new unused variables $x_1, \dots, x_6$ with the 6 trivial clauses $x_i \vee \overline{x_i}$, and the clause $x_1 \vee x_2$. This padding process keep both the 3-SAT(3) structure and $n \equiv 3 \pmod 6$. From F we construct a tournament T which is the concatenation of two tournaments T_v and T_c defined below.

In the following, let f be the reduction that maps an instance F of 3-SAT(3) to a tournament T we describe now.

The variable tournament T_v. For each variable v_i of F, we define a tournament V_i of order 6 as follows: $\sigma_i(V_i) = (r_i, \bar{x}_i, x_i^1, s_i, x_i^2, t_i)$ and $\overleftarrow{A}_\sigma(V_i) = \{s_i r_i, t_i x_i^1\}$. Figure 1 is a representation of one variable gadget V_i. One can notice that the minimum FAS of V_i corresponds exactly to the set of its backward arcs. We now define $V(T_v)$ be the union of the vertex sets of the V_is and we equip T_v with the order $\sigma_1 \sigma_2 \dots \sigma_n$. Thus, T_v has $6n$

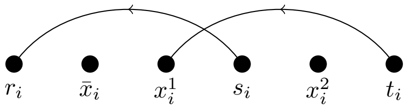

Figure 1 The variable gadget V_i. Only backward arcs are depicted, so all the remaining arcs are forward arcs.

vertices. We also add the following backward arcs to T_v. Since $n \equiv 3 \pmod 6$, there is an edge-disjoint (undirected) triangle packing of K_n covering all its edges with triangles that can be computed in polynomial time [32]. Let $\{u_1, \ldots, u_n\}$ be an arbitrary enumeration of the vertices of K_n. Using a perfect triangle packing Δ_{K_n} of K_n, we create a tournament T_{K_n} such that $\sigma'(T_{K_n}) = (u_1, \ldots, u_n)$ and $\overleftarrow{A}_{\sigma'}(T_{K_n}) = \{u_k u_i : (u_i, u_j, u_k) \text{ is a triangle of } \Delta_{K_n} \text{ with } i < j < k\}$. Now we set $\overleftarrow{A}_\sigma(T_v) = \{xy : x \in V(V_i), y \in V(V_j) \text{ for } i \neq j \text{ and } u_j u_i \in \overleftarrow{A}_{\sigma'}(T_{K_n})\} \cup \bigcup_{i=1}^{n} \overleftarrow{A}_\sigma(V_i)$. In some way, we "blew up" every vertex u_i of T_{K_n} into our variable gadget V_i.

The clause tournament T_c. For each of the m clauses c_j of F, we define a tournament C_j of order 3 as follows: $\sigma(C_j) = (c_j^1, c_j^2, c_j^3)$ and $\overleftarrow{A}_\sigma(C_j) = \emptyset$. In addition, we have a $(m+1)^{th}$ tournament denoted by C_{m+1} and defined by $\sigma(C_{m+1}) = (c_{m+1}^1, c_{m+1}^2, c_{m+1}^3)$ and $\overleftarrow{A}_\sigma(C_{m+1}) = \{c_{m+1}^3 c_{m+1}^1\}$, that is C_{m+1} is a triangle. We call this triangle the *dummy triangle* , and its vertices the *dummy vertices*. We now define T_c such that $\sigma(T_c)$ is the concatenation of each ordering $\sigma(C_j)$ in the natural order, that is $\sigma(T_c) = (c_1^1, c_1^2, c_1^3, \ldots, c_m^1, c_m^2, c_m^3, c_{m+1}^1, c_{m+1}^2, c_{m+1}^3)$. So T_c has $3(m+1)$ vertices. Since $m + 1 \equiv 3 \pmod 6$, we use the same trick as above to add arcs to $\overleftarrow{A}_\sigma(T_c)$ coming from a perfect packing of undirected triangles of K_{m+1}. Once again, we "blew up" every vertex u_j of $T_{K_{m+1}}$ into our clause gadget C_j.

The tournament T. To define our final tournament T let us begin with its ordering σ defined by $\sigma(T) = \sigma(T_v)\sigma(T_c)$. Then we construct $\overleftarrow{A}^{vc}(T)$ the backward arcs between T_c and T_v. For any $j \in [m]$, if the clause c_j in F has three literals, that is $c_j = \ell_1 \vee \ell_2 \vee l_3$, then we add to $\overleftarrow{A}^{vc}(T)$ the three backward arcs $c_j^3 z_u$ where $u \in [3]$ and such that $z_u = \bar{x}_{i_u}$ when $\ell_u = \bar{v}_{i_u}$, and $z_u \in \{x_{i_u}^1, x_{i_u}^2\}$ when $\ell_u = v_{i_u}$ in such a way that for any $i \in [n]$, there exists a unique arc $a \in \overleftarrow{A}^{vc}(T)$ with $h(a) = x_i^1$. Informally, in the previous definition, if $x_{i_u}^1$ is already "used" by another clause, we chose $z_u = x_{i_u}^2$. Such an orientation will always be possible since each variable occurs at most two times positively and once negatively in F. If the clause c_j in F has only two literals, that is $c_j = \ell_1 \vee \ell_2$, then we add in $\overleftarrow{A}^{vc}(T)$ the two backward arcs $c_j^2 z_u$ where $u \in [2]$ and such that $z_u = \bar{x}_{i_u}$ when $\ell_u = \bar{v}_{i_u}$ and $z_u \in \{x_{i_u}^1, x_{i_u}^2\}$ when $\ell_u = v_{i_u}$ in such a way that for any $i \in [n]$, there exists a unique arc $a \in \overleftarrow{A}^{vc}(T)$ with $h(a) = x_i^1$. Finally, we add in $\overleftarrow{A}^{vc}(T)$ the backward arcs $c_{m+1}^u \bar{x}_i$ for any $u \in [3]$ and $i \in [n]$. These arcs are called *dummy arcs*. We set $\overleftarrow{A}_\sigma(T) = \overleftarrow{A}_\sigma(T_v) \cup \overleftarrow{A}_\sigma(T_c) \cup \overleftarrow{A}^{vc}(T)$. Notice that each $\bar{x}_i$ has exactly four arcs $a \in \overleftarrow{A}_\sigma(T)$ such that $h(a) = \bar{x}_i$ and $t(a)$ is a vertex of T_c. To finish the construction, notice also that T has $6n+3(m+1)$ vertices and can be computed in polynomial time. Figure 2 is an example of the tournament obtained from a trivial 3-SAT(3) instance.

Now, we move on to proving the correctness of the reduction. First of all, observe that in each variable gadget V_i, there are only four triangles: let δ_i^1, δ_i^2, δ_i^3 and δ_i^4 be the triangles $(r_i, \bar{x}_i, s_i)$, (r_i, x_i^1, s_i), (x_i^1, s_i, t_i) and (x_i^1, x_i^2, t_i), respectively. Moreover, notice that there are only three maximal triangle packings of V_i which are $\{\delta_i^1, \delta_i^3\}$, $\{\delta_i^1, \delta_i^4\}$ and $\{\delta_i^2, \delta_i^4\}$. We call these packings $\Delta_i^\top$, $\Delta_i^{\top'}$ and $\Delta_i^\perp$, respectively.

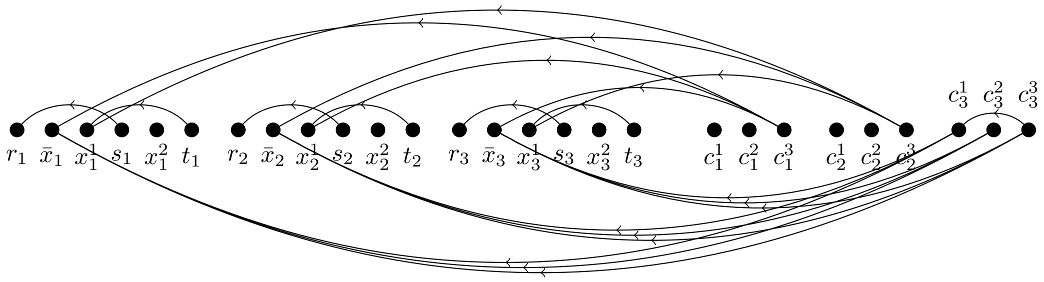

Figure 2 Example of reduction obtained when $F = \{c_1, c_2\}$ where $c_1 = \bar{v}_1 \vee v_2 \vee \bar{v}_3$ and $c_2 = v_1 \vee \bar{v}_2 \vee v_3$. Forward arcs are not depicted. In addition to the depicted backward arcs, we have the 36 backward arcs from V_3 to V_1, and the 9 backward arcs from C_3 to C_1.

Given a triangle packing Δ of T and a subset X of vertices, we define for any $x \in X$ the Δ-local out-degree of the vertex x, denoted $d^+_{X\setminus\Delta}(x)$, as the remaining out-degree of x in $T[X]$ when we remove the arcs of the triangles of Δ. More formally, we set: $d^+_{X\setminus\Delta}(x) = |\{xa\colon a \in X, xa \in A[X], xa \notin A(\Delta)\}|$.

▶ Remark 1. Given a variable gadget V_i, we have:

(i) $d^+_{V_i\setminus\Delta_i^\top}(x_i^1) = d^+_{V_i\setminus\Delta_i^\top}(x_i^2) = 1$ and $d^+_{V_i\setminus\Delta_i^\top}(\bar{x}_i) = 3$,

(ii) $d^+_{V_i\setminus\Delta_i^{\top\prime}}(x_i^1) = 1$, $d^+_{V_i\setminus\Delta_i^{\top\prime}}(x_i^2) = 0$ and $d^+_{V_i\setminus\Delta_i^{\top\prime}}(\bar{x}_i) = 3$,

(iii) $d^+_{V_i\setminus\Delta_i^\perp}(x_i^1) = d^+_{V_i\setminus\Delta_i^\perp}(x_i^2) = 0$ and $d^+_{V_i\setminus\Delta_i^\perp}(\bar{x}_i) = 4$,

(iv) none of $\bar{x}_i x_i^1$, $\bar{x}_i x_i^2$, $\bar{x}_i t_i$ belongs to $\Delta_i^\top$ or $\Delta_i^\perp$.

Informally, we want to set the variable x_i to true (resp. false) when one of the locally-optimal $\Delta_i^{\top\prime}$ or $\Delta_i^\top$ (resp. $\Delta_i^\perp$) is taken in the variable gadget V_i in the global solution. Now given a triangle packing Δ of T, we partition Δ into the following sets:

- $\Delta_{V,V,V} = \{(a,b,c) \in \Delta : a \in V_i,\ b \in V_j,\ c \in V_k$ with $i < j < k\}$,
- $\Delta_{V,V,C} = \{(a,b,c) \in \Delta : a \in V_i,\ b \in V_j,\ c \in C_k$ with $i < j\}$,
- $\Delta_{V,C,C} = \{(a,b,c) \in \Delta : a \in V_i,\ b \in C_j,\ c \in C_k$ with $j < k\}$,
- $\Delta_{C,C,C} = \{(a,b,c) \in \Delta : a \in C_i,\ b \in C_j,\ c \in C_k$ with $i < j < k\}$,
- $\Delta_{2V,C} = \{(a,b,c) \in \Delta : a,\ b \in V_i,\ c \in C_j\}$,
- $\Delta_{V,2C} = \{(a,b,c) \in \Delta : a \in V_i, b,\ c \in C_j\}$,
- $\Delta_{3V} = \{(a,b,c) \in \Delta : a,\ b,\ c \in V_i\}$,
- $\Delta_{3C} = \{(a,b,c) \in \Delta : a,\ b,\ c \in C_i\}$.

Notice that in T, there is no triangle with two vertices in a variable gadget V_i and its third vertex in a variable gadget V_j with $i \neq j$ since all the arcs between two variable gadgets are oriented in the same direction. We have the same observation for clauses.
In the two next lemmas, we prove some properties concerning the solution Δ, which imply the result of Lemma 4.

▶ **Lemma 2.** *There exists a triangle packing Δ^v (resp. Δ^c) which uses exactly the arcs between distinct variable gadgets (resp. clause gadgets). Therefore, we have $|\Delta_{V,V,V}| \leq 6n(n-1)$ and $|\Delta_{C,C,C}| \leq 3m(m+1)/2$ and these bounds are tight.*

Proof. First recall that the tournament T_v is constructed from a tournament T_{K_n} which admits a perfect packing of $n(n-1)/6$ triangles. Then we replaced each vertex u_i in T_{K_n} by the variable gadget V_i and kept all the arcs between two variable gadgets V_i

and V_j in the same orientation as between u_i and u_j. Let $u_iu_ju_k$ be a triangle of the perfect packing of T_{K_n}. We temporally relabel the vertices of V_i, V_j and V_k respectively by $\{f_i, i \in [6]\}$, $\{g_i, i \in [6]\}$ and $\{h_i, i \in [6]\}$ and consider the tripartite tournament $K_{6,6,6}$ given by $V(K_{6,6,6}) = \{f_i, g_i, h_i, i \in [6]\}$ and $A(K_{6,6,6}) = \{f_ig_j, g_ih_j, h_if_j : i, j \in [6]\}$. Then it is easy to check that $\{(f_i, g_j, h_{i+j \pmod 6}) : i, j \in [6]\}$ is a perfect triangle packing of $K_{6,6,6}$. Since every triangle of T_{K_n} becomes a $K_{6,6,6}$ in T_v, we can find a triangle packing Δ^v which use all the arcs between disjoint variable gadgets. We use the same reasoning to prove that there exists a triangle packing Δ^c which use all the arcs available in T_c between two distinct clause gadget. ◀

▶ **Lemma 3.** *For any triangle packing Δ of the tournament T, we have:*
(i) $|\Delta_{V,V,V}| + |\Delta_{C,C,C}| \leq 6n(n-1) + 3m(m+1)/2,$
(ii) $|\Delta_{2V,C}| + |\Delta_{V,2C}| + |\Delta_{V,C,C}| + |\Delta_{V,V,C}| \leq |\overleftarrow{A}^{vc}(T)|,$
(iii) $|\Delta_{3V}| \leq 2n,$
(iv) $|\Delta_{3C}| \leq 1.$
Therefore in total we have $|\Delta| \leq 6n(n-1) + 3m(m+1)/2 + 2n + |\overleftarrow{A}^{vc}(T)| + 1.$

Proof. Let Δ be a triangle packing of T. Recall that we have: $|\Delta| = |\Delta_{V,V,V}| + |\Delta_{V,V,C}| + |\Delta_{V,C,C}| + |\Delta_{C,C,C}| + |\Delta_{2V,C}| + |\Delta_{V,2C}| + |\Delta_{3V}| + |\Delta_{3C}|$. First, inequality (i) comes from Lemma 2. Then, we have $|\Delta_{2V,C}| + |\Delta_{V,2C}| + |\Delta_{V,C,C}| + |\Delta_{V,V,C}| \leq |\overleftarrow{A}^{vc}(T)|$ since every triangle of these sets consumes one backward arc from T_c to T_v. We have $|\Delta_{3V}| \leq 2n$ since we have at most 2 disjoint triangles in each variable gadget. Finally we also have $|\Delta_{3C}| \leq 1$ since the dummy triangle is the only triangle lying in a clause gadget. ◀

▶ **Lemma 4.** *F is satisfiable if and only if there exists a triangle packing Δ of size $6n(n-1) + 3m(m+1)/2 + 2n + |\overleftarrow{A}^{vc}(T)| + 1$ in the tournament T.*

As 3-SAT(3) is NP-hard [39, 43], this implies the following theorem.

▶ **Theorem 5.** MaxATT *is NP-hard.*

As mentioned in the introduction, packing arc-disjoint cycles is not necessarily equivalent to packing arc-disjoint triangles. Thus, we need to establish the following lemma to transfer the previous NP-hardness result to MaxACT.

▶ **Lemma 6.** *Given a* 3-SAT(3) *instance F, and T the tournament constructed from F with the reduction f, we have a triangle packing Δ of T of size* $6n(n-1) + 3m(m+1)/2 + 2n + |\overleftarrow{A}^{vc}(T)| + 1$ *if and only if there is a cycle packing O of the same size.*

The previous lemma and Theorem 5 imply the following theorem.

▶ **Theorem 7.** MaxACT *is NP-hard.*

Let us now define two special cases Tight-ATT (resp. Tight-ACT) where, given a tournament T and a linear ordering σ with k backward arcs, where $k = \text{minfas}(T)$, the goal is to decide if there is a triangle (resp. cycle) packing of size k. We call these special cases the "tight" versions of the classical packing problems because as the input admits an FAS of size k, any triangle (or cycle) packing has size at most k. We have the following result, directly implying the NP-hardness of Tight-ATT and Tight-ACT.

▶ **Lemma 8.** *Let T be a tournament constructed by the reduction f, and k be the threshold value defined in Lemma 4. Then, we have $k = \text{minfas}(T)$ and we can construct (in polynomial time) an ordering of T with k backward arcs.*

▶ **Theorem 9.** Tight-ATT *and* Tight-ACT *are NP-hard.*

Finally, the size s of the required packing in Lemma 4 satisfies $s = \mathcal{O}((n+m)^2)$. Under the Exponential-time Hypothesis, the problem 3-SAT cannot be solved in $2^{o(n+m)}$ [16, 30]. Then, using the linear reduction from 3-SAT to 3-SAT(3) [43], we also get the following result.

▶ **Theorem 10.** *Under the Exponential-time Hypothesis,* ATT *and* ACT *cannot be solved in* $\mathcal{O}^\star(2^{o(\sqrt{k})})$ *time.*

In the framework of parameterizing above guaranteed values [37], the above results imply that ACT parameterized below the guaranteed value of the size of a minimal feedback arc set is fixed-parameter intractable.

4 Parameterized Complexity of ACT

The classical Erdős-Pósa theorem for cycles in undirected graphs states that for each non-negative integer k, every undirected graph either contains k vertex-disjoint cycles or has a feedback vertex set consisting of $f(k) = \mathcal{O}(k \log k)$ vertices [21]. An interesting consequence of this theorem is that it leads to an FPT algorithm for Vertex-Disjoint Cycle Packing (see [36] for more details).

Analogous to these results, we prove an Erdős-Pósa type theorem for tournaments and show that it leads to an $\mathcal{O}^\star(2^{\mathcal{O}(k \log k)})$ time algorithm and a linear vertex kernel for ACT. First we obtain the following result.

▶ **Theorem 11.** *Let k and r be positive integers such that $r \leq k$. A tournament T contains a set of r arc-disjoint cycles if and only if T contains a set of r arc-disjoint cycles each of length at most $2k+1$.*

Proof. The reverse direction of the claim holds trivially. Let us now prove the forward direction. Let $\mathcal{C}$ be a set of r arc-disjoint cycles in T that minimizes $\sum_{C \in \mathcal{C}} |C|$. If every cycle in $\mathcal{C}$ is a triangle, then the claim trivially holds. Otherwise, let C be a longest cycle in $\mathcal{C}$ and let ℓ denote its length. Let v_i, v_j be a pair of non-consecutive vertices in C. Then, either $v_iv_j \in A(T)$ or $v_jv_i \in A(T)$. In any case, the arc e between v_i and v_j along with $A(C)$ forms a cycle C' of length less than ℓ with $A(C') \setminus \{e\} \subset A(C)$. By our choice of $\mathcal{C}$, this implies that e is an arc in some other cycle $\widehat{C} \in \mathcal{C}$. This property is true for the arc between any pair of non-consecutive vertices in C. Therefore, we have $\binom{\ell}{2} - \ell \leq \ell(k-1)$ leading to $\ell \leq 2k+1$. ◀

This result essentially shows that it suffices to determine the existence of k arc-disjoint cycles in T each of length at most $2k+1$ in order to determine if (T,k) is an yes-instance of ACT. This immediately leads to a quadratic Erdős-Pósa bound. That is, for every non-negative integer k, every tournament T either contains k arc-disjoint cycles or has an FAS of size $\mathcal{O}(k^2)$. Next, we strengthen this result to arrive at a linear bound.

We will use the following lemma known from [14] in order to prove Theorem 13[1]. For a digraph D, let $\Lambda(D)$ denote the number of non-adjacent pairs of vertices in D. That is, $\Lambda(D)$ is the number of pairs u, v of vertices of D such that neither $uv \in A(D)$ nor $vu \in A(D)$.

[1] The authors would like to thank F. Havet for pointing out that Lemma 12 was a consequence of a result by Chudnovsky et al. [14], as well for an improvement of the constant in Theorem 13.

▶ **Lemma 12.** [14] *Let D be a triangle-free digraph in which for every pair u, v of distinct vertices, at most one of uv or vu is in $A(D)$. Then, we can compute an FAS of size at most $\Lambda(D)$ in polynomial time.*

▶ **Theorem 13.** *For every non-negative integer k, every tournament T either contains k arc-disjoint triangles or has an FAS of size at most $5(k-1)$ that can be obtained in polynomial time.*

Proof. Let $\mathcal{C}$ be a maximal set of arc-disjoint triangles in T (that can be obtained greedily in polynomial time). If $|\mathcal{C}| \geq k$, then we have the required set of triangles. Otherwise, let D denote the digraph obtained from T by deleting the arcs that are in some triangle in $\mathcal{C}$. Clearly, D has no triangle and $\Lambda(D) \leq 3(k-1)$. Let F be an FAS of D obtained in polynomial time using Lemma 12. Then, we have $|F| \leq 3(k-1)$. Next, consider a topological ordering σ of $D - F$. Each triangle of $\mathcal{C}$ contains at most 2 arcs which are backward in this ordering. If we denote by F' the set of all the arcs of the triangles of $\mathcal{C}$ which are backward in σ, then we have $|F'| \leq 2(k-1)$ and $(D-F)-F'$ is acyclic. Thus $F^* = F \cup F'$ is an FAS of T satisfying $|F^*| \leq 5(k-1)$. ◀

Next, we show how to obtain a linear kernel for ACT. This kernel is inspired by the linear kernelization described in [9] for FAST and uses Theorem 13. Let T be a tournament on n vertices. First, we apply the following reduction rule.

▶ **Reduction Rule 4.1.** *If a vertex v is in no cycle, then delete v from T.*

This rule is clearly safe as our goal is to find k cycles and v cannot be in any of them. To describe our next rule, we need to state a result by Bessy et al. [9]. An *interval* is a consecutive set of vertices in a linear representation $(\sigma(T), \overleftarrow{A}(T))$ of a tournament T.

▶ **Lemma 14** ([9])**.** *Let $T = (\sigma(T), \overleftarrow{A}(T))$ be a tournament on which Reduction Rule 4.1 is not applicable. If $|V(T)| \geq 2|\overleftarrow{A}(T)| + 1$, then there exists a partition $\mathcal{J}$ of $V(T)$ into intervals (that can be computed in polynomial time) such that there are $|\overleftarrow{A}(T) \cap E| > 0$ arc-disjoint cycles using only arcs in E where E denotes the set of arcs in T with endpoints in different intervals.*

Our reduction rule that is based on this lemma is as follows.

▶ **Reduction Rule 4.2.** *Let $T = (\sigma(T), \overleftarrow{A}(T))$ be a tournament on which Reduction Rule 4.1 is not applicable. Let $\mathcal{J}$ be a partition of $V(T)$ into intervals satisfying the properties specified in Lemma 14. Reverse all arcs in $\overleftarrow{A}(T) \cap E$ and decrease k by $|\overleftarrow{A}(T) \cap E|$ where E denotes the set of arcs in T with endpoints in different intervals.*

▶ **Lemma 15.** *Reduction Rule 4.2 is safe.*

Proof. Let T' be the tournament obtained from T by reversing all arcs in $\overleftarrow{A}(T) \cap E$. Suppose T' has $k - |\overleftarrow{A}(T) \cap E|$ arc-disjoint cycles. Then, it is guaranteed that each such cycle is completely contained in an interval. This is due to the fact that T' has no backward arc with endpoints in different intervals. Indeed, if a cycle in T' uses a forward (backward) arc with endpoints in different intervals, then it also uses a back (forward) arc with endpoints in different intervals. It follows that for each arc $uv \in E$, neither uv nor vu is used in these $k - |\overleftarrow{A}(T) \cap E|$ cycles. Hence, these $k - |\overleftarrow{A}(T) \cap E|$ cycles in T' are also cycles in T. Then, we can add a set of $|\overleftarrow{A}(T) \cap E|$ cycles obtained from the second property of Lemma 14 to these $k - |\overleftarrow{A}(T) \cap E|$ cycles to get k cycles in T. Conversely, consider a set of k cycles in

T. As argued earlier, we know that the number of cycles that have an arc that is in E is at most $|\overleftarrow{A}(T) \cap E|$. The remaining cycles (at least $k - |\overleftarrow{A}(T) \cap E|$ of them) do not contain any arc that is in E, in particular, they do not contain any arc from $\overleftarrow{A}(T) \cap E$. Therefore, these cycles are also cycles in T'. ◀

Thus, we have the following result.

▶ **Theorem 16.** ACT *admits a kernel with* $\mathcal{O}(k)$ *vertices.*

Proof. Let (T, k) denote the instance obtained from the input instance by applying Reduction Rule 4.1 exhaustively. From Lemma 13, we know that either T has k arc-disjoint triangles or has an FAS of size at most $5(k-1)$ that can be obtained in polynomial time. In the first case, we return a trivial yes-instance of constant size as the kernel. In the second case, let F be the FAS of size at most $5(k-1)$ of T. Let $(\sigma(T), \overleftarrow{A}(T))$ be the linear representation of T where $\sigma(T)$ is a topological ordering of the vertices of the directed acyclic graph $T - F$. As $V(T-F) = V(T)$, $|\overleftarrow{A}(T)| \leq 5(k-1)$. If $|V(T)| \geq 10k - 9$, then from Lemma 14, there is a partition of $V(T)$ into intervals with the specified properties. Therefore, Reduction Rule 4.2 is applicable (and the parameter drops by at least 1). When we obtain an instance where neither of the Reduction Rules 4.1 and 4.2 is applicable, it follows that the tournament in that instance has at most $10k$ vertices. ◀

Finally, we show that ACT can be solved in $\mathcal{O}^\star(2^{\mathcal{O}(k \log k)})$ time. The idea is to reduce the problem to the following Arc-Disjoint Paths problem in directed acyclic graphs: given a digraph D on n vertices and k ordered pairs $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices of D, do there exist arc-disjoint paths $P_1, \ldots, P_k$ in D such that P_i is a path from s_i to t_i for each $i \in [k]$? On directed acyclic graphs, Arc-Disjoint Paths is known to be NP-complete [22], W[1]-hard [42] with respect to k as parameter and solvable in $n^{\mathcal{O}(k)}$ time [27]. Despite its fixed-parameter intractability, we will show that we can use the $n^{\mathcal{O}(k)}$ algorithm and Theorems 13 and 16 to describe an FPT algorithm for ACT.

▶ **Theorem 17.** ACT *can be solved in* $\mathcal{O}^\star(2^{\mathcal{O}(k \log k)})$ *time.*

Proof. Consider an instance (T, k) of ACT. Using Theorem 16, we obtain a kernel $\mathcal{I} = (\widehat{T}, \widehat{k})$ such that $\widehat{T}$ has $\mathcal{O}(k)$ vertices. Further, $\widehat{k} \leq k$. By definition, (T, k) is an yes-instance if and only if $(\widehat{T}, \widehat{k})$ is an yes-instance. Using Theorem 13, we know that $\widehat{T}$ either contains $\widehat{k}$ arc-disjoint triangles or has an FAS of size at most $5(\widehat{k} - 1)$ that can be obtained in polynomial time. If Theorem 13 returns a set of $\widehat{k}$ arc-disjoint triangles in $\widehat{T}$, then we declare that (T, k) is an yes-instance.

Otherwise, let $\widehat{F}$ be the FAS of size at most $5(\widehat{k} - 1)$ returned by Theorem 13. Let D denote the (acyclic) digraph obtained from $\widehat{T}$ by deleting $\widehat{F}$. Observe that D has $\mathcal{O}(k)$ vertices. Suppose $\widehat{T}$ has a set $\mathcal{C} = \{C_1, \ldots, C_{\widehat{k}}\}$ of $\widehat{k}$ arc-disjoint cycles. For each $C \in \mathcal{C}$, we know that $A(C) \cap \widehat{F} \neq \emptyset$ as $\widehat{F}$ is an FAS of $\widehat{T}$. We can guess that subset F of $\widehat{F}$ such that $F = \widehat{F} \cap A(\mathcal{C})$. Then, for each cycle $C_i \in \mathcal{C}$, we can guess the arcs F_i from F that it contains and also the order π_i in which they appear. This information is captured as a partition $\mathcal{F}$ of F into $\widehat{k}$ sets, F_1 to $F_{\widehat{k}}$ and the set $\{\pi_1, \ldots, \pi_{\widehat{k}}\}$ of permutations where π_i is a permutation of F_i for each $i \in [\widehat{k}]$. Any cycle C_i that has $F_i \subseteq F$ contains a (v, x)-path between every pair (u, v), (x, y) of consecutive arcs of F_i with arcs from $A(D)$. That is, there is a path from $\mathrm{h}(\pi_i^{-1}(j))$ and $\mathrm{t}(\pi_i^{-1}((j+1) \mod |F_i|))$ with arcs from D for each $j \in [|F_i|]$. The total number of such paths in these $\widehat{k}$ cycles is $\mathcal{O}(|F|)$ and the arcs of these paths are contained in D which is a (simple) directed acyclic graph.

The number of choices for F is $2^{|\widehat{F}|}$ and the number of choices for a partition $\mathcal{F} = \{F_1, \ldots, F_{\widehat{k}}\}$ of F and a set $X = \{\pi_1, \ldots, \pi_{\widehat{k}}\}$ of permutations is $2^{\mathcal{O}(|\widehat{F}| \log |\widehat{F}|)}$. Once such a choice is made, the problem of finding $\widehat{k}$ arc-disjoint cycles in $\widehat{T}$ reduces to the problem of finding $\widehat{k}$ arc-disjoint cycles $\mathcal{C} = \{C_1, \ldots, C_{\widehat{k}}\}$ in $\widehat{T}$ such that for each $1 \leq i \leq \widehat{k}$ and for each $1 \leq j \leq |F_i|$, C_i has a path P_{ij} between $\mathrm{h}(\pi_i^{-1}(j))$ and $\mathrm{t}(\pi_i^{-1}((j+1) \mod |F_i|))$ with arcs from $D = \widehat{T} - \widehat{F}$. This problem is essentially finding $r = \mathcal{O}(|\widehat{F}|)$ arc-disjoint paths in D and can be solved in $|V(D)|^{\mathcal{O}(r)}$ time using the algorithm in [27]. Therefore, the overall running time of the algorithm is $\mathcal{O}^\star(2^{\mathcal{O}(k \log k)})$ as $|V(D)| = \mathcal{O}(k)$ and $r = \mathcal{O}(k)$. ◀

5 Parameterized Complexity of ATT

It is easy to obtain an $\mathcal{O}^\star(2^{\mathcal{O}(k)})$ time algorithm using the classical colour coding technique [5] for packing subgraphs of bounded size, and in particular for ATT. Moreover, using matching techniques, we also provide a kernel with a linear number of vertices.

In this section, we provide an FPT algorithm and a linear vertex kernel for ATT. First, it is easy to obtain an $\mathcal{O}^\star(2^{\mathcal{O}(k)})$ time algorithm using the classical colour coding technique [5] for packing subgraphs of bounded size.

▶ **Theorem 18.** ATT *can be solved in* $\mathcal{O}^\star(2^{\mathcal{O}(k)})$ *time.*

Proof. Consider an instance $\mathcal{I} = (T, k)$ of ATT. Let n denote $|V(T)|$ and m denote $|A(T)|$. Let $\mathcal{F}$ denote the family of colouring functions $c : A(T) \to [3k]$ of size $2^{\mathcal{O}(k)} \log^2 m$ that can be computed in $\mathcal{O}^\star(2^{\mathcal{O}(k)})$ time using $3k$-perfect family of hash functions [41]. For each colouring function c in $\mathcal{F}$, we colour $A(T)$ according to c and find a triangle packing of size k whose arcs use different colours. We use a standard dynamic programming routine to finding such a triangle packing. Clearly, if $\mathcal{I}$ is an yes-instance and $\mathcal{C}$ is a set of k arc-disjoint triangles in T, there is a colouring function in $\mathcal{F}$ that colours the $3k$ arcs in these triangles with distinct colours and our algorithm will find the required triangle packing. Given a colouring $c \in \mathcal{F}$, we first compute for every set of 3 colours $\{a, b, c\}$ whether the arcs coloured with a, b or c induce a triangle using 3 different colours or not. Then, for every set S of $3(p+1)$ colours with $p \in [k-1]$, we recursively test if the arcs coloured with the colours in S induce $p+1$ arc-disjoint triangles whose arcs use all the colours of S. This is achieved by iterating over every subset $\{a, b, c\}$ of S and checking if there is a triangle using colours a, b and c and a collection of p arc-disjoint triangles whose arcs use all the colours of $S \setminus \{a, b, c\}$. For a given S, we can find this collection of triangles in $\mathcal{O}(p^3) = \mathcal{O}(k^3)$ time. Therefore, the overall running time of the algorithm is $\mathcal{O}^\star(2^{\mathcal{O}(k)})$. ◀

Next, we show that ATT has a linear vertex kernel.

▶ **Theorem 19.** ATT *admits a kernel with* $\mathcal{O}(k)$ *vertices.*

Proof. Let $\mathcal{X}$ be a maximal collection of arc-disjoint triangles of a tournament T obtained greedily. Let $V_\mathcal{X}$ denote the vertices of the triangles in $\mathcal{X}$ and $A_\mathcal{X}$ denote the arcs of $V_\mathcal{X}$. Let U be the remaining vertices of $V(T)$, i.e., $U = V(T) \setminus V_\mathcal{X}$. If $|\mathcal{X}| \geq k$, then (T, k) is an yes-instance of ATT. Otherwise, $|\mathcal{X}| < k$ and $|V_\mathcal{X}| < 3k$. Moreover, notice that $T[U]$ is acyclic and T does not contain a triangle with one vertex in $V_\mathcal{X}$ and two in vertices in U (otherwise $\mathcal{X}$ would not be maximal).

Let B be the (undirected) bipartite graph defined by $V(B) = A_\mathcal{X} \cup U$ and $E(B) = \{au\colon a \in A_\mathcal{X}, u \in U$ such that $(t(a), h(a), u)$ forms a triangle in $T\}$. Let M be a maximum matching of B and A' (resp. U') denote the vertices of $A_\mathcal{X}$ (resp. U) covered by M. Define $\overline{A'} = A_\mathcal{X} \setminus A'$ and $\overline{U'} = U \setminus U'$.

We now prove that $(V_{\mathcal{X}} \cup U', k)$ is a linear kernel of (T, k). Let $\mathcal{C}$ be a maximum sized triangle packing that minimizes the number of vertices of $\overline{U'}$ belonging to a triangle of $\mathcal{C}$. By previous remarks, we can partition $\mathcal{C}$ into $C_{\mathcal{X}} \cup F$ where $C_{\mathcal{X}}$ are the triangles of $\mathcal{C}$ included in $T[V_{\mathcal{X}}]$ and F are the triangles of $\mathcal{C}$ containing one vertex of U and two vertices of $V_{\mathcal{X}}$. It is clear that F corresponds to a union of vertex-disjoint stars of B with centres in U. Denote by $U[F]$ the vertices of U clause gadget g to a triangle of F. If $U[F] \subseteq U'$ then $(V_{\mathcal{X}} \cup U', k)$ is immediately a kernel. Suppose there exists a vertex x_0 such that $x_0 \in U[F] \cap \overline{U'}$.

We will build a tree rooted in x_0 with edges alternating between F and M. For this let $H_0 = \{x_0\}$ and construct recursively the sets H_{i+1} such that

$$H_{i+1} = \begin{cases} N_F(H_i) \text{ if } i \text{ is even,} \\ N_M(H_i) \text{ if } i \text{ is odd,} \end{cases}$$

where, given a subset $S \subseteq U$, $N_F(S) = \{a \in A_{\mathcal{X}} : \exists s \in S \text{ s.t. } (t(a), h(a), s) \in F \text{ and } as \notin M\}$ and given a subset $S \subseteq A_{\mathcal{X}}$, $N_M(S) = \{u \in U : \exists a \in A_{\mathcal{X}} \text{ s.t. } au \in M\}$. Notice that $H_i \subseteq U$ when i is even and that $H_i \subseteq A_{\mathcal{X}}$ when i is odd, and that all the H_i are distinct as F is a union of disjoint stars and M a matching in B. Moreover, for $i \geq 1$ we call T_i the set of edges between H_i and H_{i-1}. Now we define the tree T such that $V(T) = \bigcup_i H_i$ and $E(T) = \bigcup_i T_i$. As T_i is a matching (if i is even) or a union of vertex-disjoint stars with centres in H_{i-1} (if i is odd), it is clear that T is a tree.

For i being odd, every vertex of H_i is incident to an edge of M otherwise B would contain an augmenting path for M, a contradiction. So every leaf of T is in U and incident to an edge of M in T and T contains as many edges of M than edges of F. Now for every arc $a \in A_{\mathcal{X}} \cap V(T)$ we replace the triangle of $\mathcal{C}$ containing a and corresponding to an edge of F by the triangle $(t(a), h(a), u)$ where $au \in M$ (and au is an edge of T). This operation leads to another collection of arc-disjoint triangles with the same size as $\mathcal{C}$ but containing a strictly smaller number of vertices in $\overline{U'}$, yielding a contradiction.

Finally $V_{\mathcal{X}} \cup U'$ can be computed in polynomial time and we have $|V_{\mathcal{X}} \cup U'| \leq |V_{\mathcal{X}}| + |M| \leq 2|V_{\mathcal{X}}| \leq 6k$, which proves that the kernel has $\mathcal{O}(k)$ vertices. ◀

6 Concluding Remarks

In this work, we studied the classical and parameterized complexity of packing arc-disjoint cycles and triangles in tournaments. We showed NP-hardness, fixed-parameter tractability and linear kernelization results. An interesting problem could be to find subclasses of tournaments where these problems are polynomial-time solvable. For instance, we show in the full version of the paper that it is the case for sparse tournaments, that is for tournaments which admit an FAS that is a matching. This class of tournaments is worthy of attention for these packing problems as packing vertex-disjoint triangles (and hence cycles) in sparse tournaments is NP-complete [8]. To conclude, observe that very few problems on tournaments are known to admit an $\mathcal{O}^\star(2^{\sqrt{k}})$-time algorithm when parameterized by the standard parameter k [40] - FAST is one of them [4, 23]. To the best of our knowledge, outside bidimensionality theory, there are no packing problems that are known to admit such subexponential algorithms. In light of the $2^{o(\sqrt{k})}$ lower bound shown for ACT and ATT, it would be interesting to explore if these problems admit $\mathcal{O}^\star(2^{\mathcal{O}(\sqrt{k})})$ algorithms.

Abstract

Given an n-vertex digraph D and a non-negative integer k, the Minimum Directed Bisection problem asks if the vertices of D can be partitioned into two parts, say L and R, such that $|L|$ and $|R|$ differ by at most 1 and the number of arcs from R to L is at most k. This problem, in general, is W-hard as it is known to be NP-hard even when $k = 0$. We investigate the parameterized complexity of this problem on semicomplete digraphs. We show that Minimum Directed Bisection on semicomplete digraphs is one of a handful of problems that admit sub-exponential time fixed-parameter tractable algorithms. That is, we show that the problem admits a $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ time algorithm on semicomplete digraphs. We also show that Minimum Directed Bisection admits a polynomial kernel on semicomplete digraphs. To design the kernel, we use (n, k, k^2)-splitters. To the best of our knowledge, this is the first time such pseudorandom objects have been used in the design of kernels. We believe that the framework of designing kernels using splitters could be applied to more problems that admit sub-exponential time algorithms via chromatic coding. To complement the above mentioned results, we prove that Minimum Directed Bisection is NP-hard on semicomplete digraphs, but polynomial time solvable on tournaments.

1 Introduction

A bisection of a graph is a partition of its vertex set into two (almost) equal parts. In the Minimum Bisection problem, given an undirected graph G and a non-negative integer k, the task to check whether the vertex set of G can be partitioned into two parts, say A and B, such that $||A| - |B|| \leq 1$ and the number of edges with one endpoint in A and the other endpoint in B is at most k. This problem has been studied extensively, resulting in a large volume of literature [7, 11, 12, 19, 20, 27, 28]. In particular, it has been shown that Minimum Bisection is NP-hard [19], but admits a fixed-parameter tractable algorithm (with k as the parameter) [11]. We study the directed counterpart of this problem in the

44th International Symposium on Mathematical Foundations of Computer Science (MFCS 2019).

framework of parameterized complexity. In the Minimum Directed Bisection problem, the input consists of a digraph D and an integer k, and the question is to determine whether the vertices of D can be partitioned into two parts, say L and R, such that $||L| - |R|| \leq 1$, and there are at most k arcs with their tails in R and heads in L (i.e. arcs directed from R to L). The problem is formally defined below.

Minimum Directed Bisection **Parameter:** k
Input: A digraph D and a non-negative integer k.
Question: Can the vertex set of D be partitioned into two parts, say L and R, such that $||L| - |R|| \leq 1$ and there are at most k arcs (u, v) with $u \in R$ and $v \in L$?

Feige and Yahalom [16] showed that this problem is NP-hard even for $k = 0$, which implies that the Minimum Directed Bisection problem has no polynomial time approximation unless P = NP. Their result also implies that Minimum Directed Bisection is para-NP-hard on general digraphs and hence, it is W-hard when parameterized by k. We study the complexity of this problem on restricted classes of digraphs such as tournaments and semicomplete digraphs.

Our results. Our contribution is threefold.

1. We show that Minimum Directed Bisection is polynomial time solvable on tournaments.
2. On semicomplete digraphs, Minimum Directed Bisection is NP-hard, but admits an algorithm running in time $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$.
3. We also show that Minimum Directed Bisection on semicomplete digraphs admits a polynomial kernel.

A *tournament* is a digraph D such that for every distinct pair of vertices u and v of D, *exactly one* of the arcs (u, v) or (v, u) is present in D. A *semicomplete digraph* is a digraph D such that for every pair of distinct vertices u and v of D, *at least one* of the arcs (u, v) or (v, u) is present in D. Note that both the arcs (u, v) and (v, u) may be present in a semicomplete digraph. Tournaments and semicomplete digraphs form two interesting and well-studied classes of digraphs. See, for example, the monograph by Bang-Jensen and Gutin [3] for an overview. In recent years, tournaments and semicomplete digraphs received a great deal of attention, in part, due to the many structural results for these classes that are similar to the theory of minors for undirected graphs. In particular, it has been shown that tournaments are well-quasi ordered under strong minors [23] and strong immersions [9]. Similarly, semicomplete digraphs have been shown to be well-quasi ordered under strong minors, butterfly immersions [22] and strong immersions [5].

Due to the extremely rigid structure of tournaments, a number of problems that are NP-hard on general digraphs become polynomial time solvable on tournaments. Examples include classic problems such as Hamiltonian path [29] and Hamiltonian Cycle [8]. Although semicomplete digraphs are a slight generalization of tournaments, the flexibility in the definition allowing for the presence of anti-parallel arcs makes them distinctly dissimilar to tournaments when it comes to tractability of algorithmic problems. This contrast in behavior is perhaps best illustrated by problems such as Cutwidth and Optimal Linear Arrangement (OLA), which are polynomial time solvable on tournaments, but NP-hard on semicomplete digraphs [4]. Our work reinforces this pattern. We show that while Minimum Directed Bisection is polynomial time solvable on tournaments (Lemma 4), it is NP-hard on semicomplete digraphs (Lemma 16). The polynomial time solvability of Minimum Directed Bisection on tournaments follows from a polynomial time algorithm due to Fradkin [18] for computing the cutwidth of a tournament. Barbero et al. [4] showed that Fradkin's approach in [18] yields a polynomial time algorithm for the Optimal Linear Arrangement problem on tournaments as well. We rely on the analysis of Barbero et al. in [4] to conclude that Fradkin's approach works for Minimum Directed Bisection on tournaments as well. We establish the NP-hardness of Minimum Directed Bisection on semicomplete digraphs by a reduction from the Maximum Bisection problem on directed acyclic graphs.

Tournaments and semicomplete digraphs found favor with the parameterized complexity community mainly because of the possibility that several problems might admit sub-exponential time parameterized algorithms on these classes of digraphs. In the field of parameterized complexity, problems that admit sub-exponential time algorithms (except those on planar graphs, using the bidimensionality approach) are something of a rarity. In fact, the first such sub-exponential time algorithm was designed by Alon, Lokshtanov and Saurabh [1] for the Feedback Arc Set problem on tournaments (FAST). They developed the technique of chromatic coding to design a $2^{\mathcal{O}(\sqrt{k}\log^2 k)}$ algorithm for this problem. This running time has since been improved, independently by Feige [15], Karpinski and Schudy [21], and Fomin and Pilipczuk [17], to $2^{\mathcal{O}(\sqrt{k})}$. Fomin and Pilipczuk's [17] algorithm for FAST was in fact a by-product of their work on the Cutwidth and Optimal Linear Arrangement (OLA) problems on semicomplete digraphs. They showed that both Cutwidth and OLA admit sub-exponential FPT algorithms on semicomplete digraphs. Later, Barbero et al. [4] showed that these problems are indeed NP-hard on semicomplete digraphs. We show that Minimum Directed Bisection on semicomplete digraphs admits a sub-exponential time algorithm that runs in time $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ (Theorem 21).

Both our algorithm and kernel for Minimum Directed Bisection build on a crucial observation that in any bisection (L, R) of a semicomplete digraph, every vertex v has a "preferred position" (either L or R), which we call the "canonical position" of v (denoted by $\mathtt{can}(v)$). In particular, if (L, R) is a bisection of size at most k, then we show that in (L, R), no more than $2k$ vertices can deviate from their canonical positions. Note that with just this information one can easily design an $n^{\mathcal{O}(k)}$ algorithm for the problem. In order to achieve sub-exponential FPT running time, we use the technique of chromatic coding to identify a small set of vertices that contain these $2k$ vertices that can deviate from their canonical positions. More precisely, we color the vertex set with $\mathcal{O}(\sqrt{k})$ colors such that all the k arcs in a k-sized bisection (if it exists) are properly colored. Then, to identify the desired set of vertices, we exploit the fact that no arc within a color class can be directed from R to L. The crucial point in chromatic coding is that it is sufficient to try out $2^{\mathcal{O}(\sqrt{k}\log k)}\log n$ different coloring functions so as to ensure that we find a coloring with the required property.

The kernelization complexity of problems on tournaments and semicomplete digraphs has proved to be even more diverse, requiring a wide array of techniques specific to individual problems. For instance, it is now textbook knowledge that the Feedback Arc Set problem on tournaments admits a simple kernel with $\mathcal{O}(k^2)$ vertices [10, 14]. There has been a line of work on this front that improved the size of the kernel, the current best being a linear kernel by Bessy et al. [6]. Barbero et al. [4] showed that while Cutwidth on semicomplete digraphs does not admit a polynomial kernel unless $\mathsf{NP} \subseteq \mathsf{coNP}/\text{poly}$, OLA does admit a kernel with $2k$ vertices. In addition, by using the submodularity property of directed cuts, Barbero et al. [4] showed that Cutwidth admits a Turing kernel on semicomplete digraphs.

We employ a family of hash functions called (n, k, k^2)-splitters, introduced by Naor et al. [26], to design a polynomial kernel for Minimum Directed Bisection on semicomplete digraphs (Theorem 22). Splitters are a well-known combinatorial tool often used to derandomize algorithms. To the best of our knowledge, this is the first occurrence of splitters' being used to design polynomial kernels. Our kernelization algorithm for Minimum Directed Bisection on semicomplete digraphs has two main steps. In the first step, we reduce the given instance (D, k) of the Minimum Directed Bisection problem to $k^{\mathcal{O}(1)}$ many instances of a weighted variant of the problem, with the guarantee that the sizes of the reduced instances is $k^{\mathcal{O}(1)}$ and at least one of the reduced instances is equivalent to the original instance (D, k). Then, in the second step, we apply a polynomial time reduction from the reduced instances to Minimum Directed Bisection to obtain the desired kernel. To elaborate a little about the first step, like in the design of our algorithm, we want a coloring function that properly colors the k arcs of the bisection. But unlike in the algorithm where we have to use $\mathcal{O}(\sqrt{k})$ colors to ensure sub-exponential runtime, for the kernel, it is enough to have such a coloring using $\mathcal{O}(k^2)$ colors. This increase in the number of colors from $\mathcal{O}(\sqrt{k})$ to $\mathcal{O}(k^2)$ allows us to bring down the size of the coloring family that guarantees the existence of the good coloring that we want, to a polynomial in k. This is where we use (n, k, k^2)-splitters: we construct a reduced instance for each of the $k^{\mathcal{O}(1)}$ coloring functions. The one corresponding to the good coloring function is the one that is always a yes-instance if the input instance is a yes-instance.

Related work on Minimum Bisection. As mentioned earlier, the Minimum Bisection problem, (the undirected counterpart of our problem) is an extensively-studied problem in algorithmic graph theory. Being a natural variant of the well-known Min Cut problem, Minimum Bisection has already been known to be NP-hard since the 1970s [19]. However, the parameterized complexity of the problem had been open for a long time, until it was finally settled by Cygan et al. [11] in 2014, who showed that the problem is fixed-parameter tractable. Before that, Jansen et al. [20] had shown that the problem is fixed-parameter tractable when parameterized by the treewidth of the input graph. The best known approximation algorithm for Minimum Bisection, to the best of our knowledge, is due to Räcke [28], with an approximation factor of $\mathcal{O}(\log n)$. While Minimum Bisection on planar graphs admits a single-exponential parameterized algorithm [7], it remains open whether the problem is NP-hard. On the related (but incomparable) class of unit disk graphs, Minimum Bisection is known to be NP-hard [12], but was recently shown to admit a single-exponential parameterized algorithm [27]. The Minimum Vertex Bisection problem (the vertex-deletion variant of Minimum Bisection) asks the following question. Given an undirected graph G and a non-negative integer k, is it possible to partition the vertex set of G into three parts A, S and B such that $|S| \leq k$, $|A| = |B|$ and there are no edges between A and B? This problem is W[1]-hard: as observed in [11], the W[1]-hardness of Minimum Vertex Bisection follows from a more general result due to Marx [25].

2 Preliminaries

For a natural number $n \in \mathbb{N}$, $[n]$ denotes the set $\{1, 2, \ldots, n\}$. For $z \in \mathbb{N}$, $|z|$ denotes the number of bits in the binary representation of z.

Splitters. Consider two finite sets A and B and a function $f : A \to B$. For a subset $S \subseteq A$, we say that f *splits S evenly* if for every $b_1, b_2 \in B$, $|f^{-1}(b_1) \cap S|$ and $|f^{-1}(b_2) \cap S|$ differ by at most 1. Notice that if $|B| > |S|$, then f splits S evenly if and only if f is injective on S.

▶ **Definition 1** ([26]). *For positive integers n, k and ℓ, an (n, k, ℓ)-*splitter *is a family $\mathcal{F}$ of functions from $[n]$ to $[\ell]$ such that for every subset $S \subseteq [n]$ of size at most k, there exists a function $f \in \mathcal{F}$ that splits S evenly.*

▶ **Proposition 2** ([2, 26]). *There is an algorithm that, given positive integers n and k, runs in time $k^{\mathcal{O}(1)} n \log n$ and constructs an (n, k, k^2)-splitter of size $k^{\mathcal{O}(1)} \log n$.*

Digraphs. For a digraph D, we denote by $V(D)$ and $A(D)$ the vertex set and arc set of D, respectively. For sets $X, Y \subseteq V(D)$, $A(X, Y) = \{(x, y) \in A(D) \mid x \in X \text{ and } y \in Y\}$. (Whenever dealing with multiple digraphs on the same vertex set, we may write $A_D(X, Y)$ instead of $A(X, Y)$ to emphasize that we mean the set of arcs from X to Y *in* D.) For a vertex $v \in V(D)$, $A(v)$ denotes the set of arcs incident with v. For an arc $a \in A(D)$, $V(a)$ denotes the set of endpoints of a. That is, if $a = (u, v) \in A(D)$, then $V(a) = \{u, v\}$. More generally, for a set of arcs $A \subseteq A(D)$, $V(A) = \cup_{a \in A} V(a)$. The *complement* of D, denoted by $\overline{D}$, is the digraph defined as follows: $V(\overline{D}) = V(D)$ and $A(\overline{D}) = (V^2 \setminus \{(u, u) \mid u \in V(D)\}) \setminus A(D)$. (We assume that D has no self-loops.) Note that for vertices $u, v \in V(D)$, if $(u, v) \notin A(D)$, then $(u, v), (v, u) \in A(\overline{D})$. For a digraph D, $\texttt{rev}(D)$ denotes the digraph obtained by reversing all arcs of D, i.e. $V(\texttt{rev}(D)) = V(D)$ and $A(\texttt{rev}(D)) = \{(u, v) \mid (v, u) \in A(D)\}$.

Consider a digraph D. Throughout this paper, we use (L_D, R_D) to denote a bipartition of D. That is $V(D) = L_D \cup R_D$ and $L_D \cap R_D = \emptyset$. We may drop the subscript D and simply write (L, R) when D is clear from the context. A bipartition (L_D, R_D) is a *bisection* of D if $||L_D| - |R_D|| \leq 1$; we refer to the value $|A(R_D, L_D)|$ as the *size of the bipartition* (L_D, R_D). Moreover, we say that (L_D, R_D) is a *one way partition* if $A(R_D, L_D) = \emptyset$, i.e. if (L_D, R_D) is a bipartition of size 0.

3 Some Observations and Simple Lemmas

Throughout this paper, whenever dealing with an instance (D, k) of Minimum Directed Bisection, we assume that $|V(D)|$ is even. This assumption about $V(D)$ is made without loss of generality since if $|V(D)|$ is odd, then we may construct two instances (D_1, k) and (D_2, k) of Minimum Directed Bisection such that at least one of them will be equivalent to (D, k) and $|V(D_1)| = |V(D_2)| = |V(D)| + 1$. The following lemma shows that it is safe to make this assumption.

▶ **Lemma 3** ($\star$[1]). *Given an instance (D, k) of* Minimum Directed Bisection *where $|V(D)|$ is odd, it is possible to construct two instances (D_1, k) and (D_2, k) of* Minimum Directed Bisection *in polynomial time such that* (i) *$|V(D_1)|$ and $|V(D_2)|$ are even,* (ii) *D_1 and D_2 are semicomplete digraphs (tournaments) if D is a semicomplete digraph (tournament), and* (iii) *(D, k) is a yes-instance if and only if either (D_1, k) or (D_2, k) is a yes-instance.*

The following lemma deals with Minimum Directed Bisection on tournaments.

▶ **Lemma 4** ($\star$). Minimum Directed Bisection *is polynomial time solvable on tournaments.*

Proof Sketch. The algorithm for Minimum Directed Bisection on tournaments works as follows. Given a tournament T on n vertices, sort the vertices in non-decreasing order by their in-degrees. Take L_T to be the set of the first $n/2$ vertices in the sorted list, and $R_T = V(T) \setminus L_T$. Then, our claim is that (L_T, R_T) is a minimum bisection of T, i.e. $|A(R_T, L_T)| \leq |A(Y, X)|$ for every bisection (X, Y) of T. The correctness of this algorithm follows from Lemma 1 in [4]. ◀

[1] Due to paucity of space, proofs of statements marked with a $\star$ have been omitted.

We now state two observations about semicomplete digraphs. These observations are considered to be folklore, so we omit their proofs. Specifically, the first observation is immediate, and the second can be found in [13].

▶ **Observation 5.** *Let D be a semicomplete digraph on n vertices, where n is even. For every $v \in V(D)$, we have $d^+(v) \geq n/2$ or $d^-(v) \geq n/2$.*

▶ **Observation 6.** *Every semicomplete digraph contains a Hamiltonian path. Moreover, there is a polynomial time algorithm that, given a semicomplete digraph D as input, finds a Hamiltonian path in D.*

We now develop some preliminary results that will be used in the design and analysis of our algorithm and kernel.

Canonical Position. A crucial idea behind our algorithm and kernel is that every vertex has a "preferred position" in a bisection (either L or R). In particular, if a vertex v deviates from its preferred position, then at least one of the arcs incident with v would have to belong to $A(R, L)$. Therefore, in a bisection of size at most k, no more than $\mathcal{O}(k)$ vertices can deviate from their preferred positions. Next, we formalize this idea.

▶ **Definition 7.** *Let D be a semicomplete digraph on n vertices, where n is even. The partition (L^c_D, R^c_D) (not necessarily a bisection) of $V(D)$ defined as $L^c_D = \{v \in V(D) \mid d^+(v) \geq n/2\}$ and $R^c_D = V(D) \setminus L^c_D$ is called the* canonical partition *of D. For a vertex $v \in L^c_D$, we say that L^c_D is the* canonical position of v *and write* $\texttt{can}(v) = L^c_D$. *Similarly, for a vertex $v \in R^c_D$, we say that R^c_D is the* canonical position of v *and write* $\texttt{can}(v) = R^c_D$.

▶ **Definition 8.** *Let D be a semicomplete digraph with a bipartition (L, R). For a vertex $v \in V(D)$, we say that (L, R)* respects the canonical position of v *if $v \in L$ and* $\texttt{can}(v) = L^c_D$ *or if $v \in R$ and* $\texttt{can}(c) = R^c_D$. *Otherwise, we say that (L, R)* violates the canonical position of v.

The following lemma follows directly from the definition of the canonical position of a vertex. It shows that if a bisection (L, R) violates the canonical position of a vertex v, then at least one of the arcs incident with v must belong to $A(R, L)$.

▶ **Lemma 9** ($\star$). *Consider a semicomplete digraph D on n vertices, where n is even. Let (L, R) be a bisection of D. Let $v \in V(D)$ be such that (L, R) violates the canonical position of v. Then, $A(R, L) \cap A(v) \neq \emptyset$.*

An immediate consequence of Lemma 9 is that any bisection of size at most k of a semicomplete digraph can violate the canonical positions of at most $2k$ vertices.

▶ **Corollary 10.** *Let (D, k) be an yes-instance of* Minimum Directed Bisection, *and let (L, R) be a bisection of D of size at most k. Let $X = \{v \in V(D) \mid (L, R)$ violates the canonical position of $v\}$. Then, $|X| \leq 2k$.*

Proof. As Lemma 9 shows, for every $v \in X$, $A(R, L)$ contains an arc incident with v. Since each arc in $A(R, L)$ can be incident with at most two vertices in X, and $|A(R, L)| \leq k$, it follows that $|X| \leq 2k$. ◀

Consider a bisection (L, R) of D, and a subset of vertices $Z \subseteq V(D)$ such that no arc of $D[Z]$ belongs to $A(R, L)$. The following lemma identifies the vertices in Z whose canonical positions can possibly be violated by (L, R). Moreover, it shows that there can be at most $4k$ such vertices in Z, and that (L, R) must respect the canonical position of every other vertex.

▶ **Lemma 11.** *Let D be a semicomplete digraph with a bisection (L, R) of size at most k. Let $Z \subseteq V(D)$ be such that no arc of $D[Z]$ belongs to $A_D(R, L)$. That is, $(L \cap Z, R \cap Z)$ is a one way partition of Z. Let P be a Hamiltonian path in $D[Z]$ from a vertex α to a vertex β for some $\alpha, \beta \in Z$. Let $X = \{x \in Z \mid \texttt{can}(x) = R^c_D\}$ and $Y = \{y \in Z \mid \texttt{can}(y) = L^c_D\}$. For $1 \leq j \leq |X|$, let x_j be the j^{th} vertex of P that belongs to X as we traverse P from α to β, and for $1 \leq p \leq |Y|$, let y_p be the p^{th} vertex of P that belongs to Y as we traverse $\texttt{rev}(P^i)$ from β to α. Then, if $|X| > 2k$, then for every $x_j \in X$ with $j > 2k$, $x_j \in R$. Similarly, if $|Y| > 2k$, then for every $y_p \in Y$ with $p > 2k$, $y_p \in L$. (In other words, (L, R) respects the canonical positions of x_j and y_p for $j > 2k$ and $p > 2k$.)*

Proof. Note first that for any arc $(z, z') \in A(P)$, it cannot be the case that $z \in R$ and $z' \in L$, as $(L \cap Z, R \cap Z)$ is a one way partition of Z. More generally, this property holds for any two distinct vertices $z, z' \in Z$ such that z appears before z' as we traverse P from α to β. To see this, suppose by way of contradiction that $z \in R$ and $z' \in L$. Then, consider the subpath of P from z to z'. This subpath must have an arc from a vertex in R to a vertex in L, which we have already argued to be impossible.

Now, suppose that $|X| > 2k$ and consider a vertex $x_j \in X$ with $j > 2k$. Then, $\texttt{can}(x_j) = R^c_D$. We need to show that $x_j \in R$. Assume for contradiction that $x_j \in L$, i.e. (L, R) violates the canonical position of x_j. Then, for every $j' \leq j$, we must have $x_{j'} \in L$ as well, as otherwise, we obtain a pair $\{x_{j'}, x_j\}$ such that $x_{j'}$ appears before x_j as we traverse P from α to β while $x_{j'} \in R$ and $x_j \in L$, which by the preceding argument, is not possible. Having $x_{j'} \in L$ for every $j' \leq j$ means that (L, R) violates the canonical position of $x_{j'}$ for every $j' \leq j$. Thus, (L, R) violates the canonical positions of more than $2k$ vertices. However, as (L, R) is a bisection of D of size at most k, by Corollary 10, (L, R) can violate the canonical positions of at most $2k$ vertices.

Using symmetric arguments, we also derive that $y_p \in L$ for every $p > 2k$. ◀

▶ Remark 12. In the above proof, it is actually shown that for any $j \leq |X|$ such that (L, R) violates the canonical position of $x_j \in X$, (L, R) must violate the canonical position of $x_{j'}$ for every $j' < j$ as well. Similarly, for any $p \leq |Y|$ such that (L, R) violates the canonical position of $y_p \in Y$, (L, R) must violate the canonical position of $y_{p'}$ for every $p' < p$ as well.

Tools for Our Kernel. We now develop some tools that will be used to design our kernel. Consider a vertex-weighted digraph D, where the weights are given by a function $w : V(D) \to \mathbb{N}$. For a subset $X \subseteq V(D)$ of vertices, the weight of X is defined as $w(X) = \sum_{x \in X} w(x)$. We say that a partition (L, R) of $V(D)$ is a *w-bisection* of D (or simply a *bisection* when w is clear from the context) if $|w(L) - w(R)| \leq 1$, and $|A(R, L)|$ is called the size of the bisection. So, given (D, w, k), the Weighted Minimum Bisection (WMB) problem asks whether D has a w-bisection of size at most k. We now define a "composition" of this problem, where the input consists of multiple pairs (D, w), and at least one is required to have a bisection of size at most k.

At Least One Weighted Minimum Bisection (ALO-WMB)
Input: A collection $D_1, D_2, \ldots, D_r$ of vertex-weighted semicomplete digraphs, a weight function $w_i : V(D_i) \to \mathbb{N}$ for every $i \in [r]$, and a non-negative integer k.
Question: Does there exist $i \in [r]$ such that D_i has a w_i-bisection of size at most k?

It is not difficult to see that this problem belongs to the class NP: a polynomial-sized certificate for the problem would be a partition (L, R) of $V(D_i)$ for some i, and it can be verified whether (L, R) is indeed a bisection of size at most k in time polynomial in $\sum_{j \in [r]} (|V(D_j)| + \sum_{v \in V(D_j)} |w_j(v)|)$. For future reference, we record this observation below.

▶ **Observation 13.** ALO-WMB *belongs to the class NP.*

$\mathcal{P}$-Contraction of a Digraph. Consider a digraph D. Let $\mathcal{P} = \{V_1, V_2, \ldots, V_p\}$ be a partition of $V(D)$ (i.e. $V_i \cap V_j = \emptyset$ for every distinct $i, j \in [p]$ and $\bigcup_{i \in [p]} V_i = V(D)$). The *$\mathcal{P}$-contraction* of D is the digraph $\mathcal{P}(D)$ obtained by "contracting" every part V_i into a single vertex, formally defined as follows. The digraph $\mathcal{P}(D)$ has p vertices, one corresponding to every part $V_i \in \mathcal{P}$. For each $i \in [p]$, let z_i deonte the vertex of $\mathcal{P}(D)$ corresponding to the part V_i. For distinct $i, j \in [p]$, the arc (z_i, z_j) is present in $\mathcal{P}(D)$ if and only if there exist $v_i \in V_i$ and $v_j \in V_j$ such that $(v_i, v_j) \in A(D)$. (Note that $\mathcal{P}(D)$ has no self-loops.) For a vertex $z_i \in V(\mathcal{P}(D))$, we refer to the part V_i as the *parent-part of z_i* (or simply *part of z_i*), and write $\texttt{part}(z_i) = V_i$. Moreover, we define the *$\mathcal{P}$-weighted-contraction* of D to be the digraph $\mathcal{P}(D)$, where weights are assigned to its vertices by a weight function $w_{\mathcal{P}}$, which is given by $w_{\mathcal{P}}(z_i) = |V_i|$ for every vertex z_i of $\mathcal{P}(D)$.

▶ **Lemma 14** (⋆). *Let D be an unweighted (not necessarily semicomplete) digraph and (L, R) a bipartition (not necessarily a bisection) of D. Consider a pair of partitions $\mathcal{L} = \{V_1, V_2, \ldots, V_p\}$ and $\mathcal{R} = \{V_{p+1}, V_{p+2}, \ldots, V_q\}$ of L and R, respectively. Let $\mathcal{P}$ be the partition of $V(D)$ that is the union of $\mathcal{L}$ and $\mathcal{R}$, i.e. $\mathcal{P} = \mathcal{L} \cup \mathcal{R}$. Let $H = \mathcal{P}(D)$ be the $\mathcal{P}$-weighted-contraction of D. (Thus, for each $V_i \in \mathcal{P}$, H has a vertex z_i, with weight $w_{\mathcal{P}}(z_i) = |V_i|$.) Let $L_H = \{z_1, z_2, \ldots, z_p\}$, and $R_H = \{z_{p+1}, z_{p+2}, \ldots, z_q\}$. Then, (L, R) is a bisection of D if and only if (L_H, R_H) is a $w_{\mathcal{P}}$-bisection of H.*

4 NP-hardness of Minimum Directed Bisection on Semicomplete Digraphs

In this section, we show that Minimum Directed Bisection is NP-hard on semicomplete digraphs by a reduction from Maximum Directed Bisection on directed acyclic graphs (DAGs). (Recall that in the Maximum Directed Bisection problem, the input consists of a digraph D and an integer k, and the task is to determine whether D admits a bisection (L, R) such that $|A(R, L)| \geq k$.) The NP-hardness of Maximum Directed Bisection on DAGs easily follows from the fact that Directed Max-Cut is NP-hard on DAGs, shown by Lampis et al. [24] (Theorem 4 in [24]).

▶ **Observation 15** (⋆). Maximum Directed Bisection *is NP-complete on DAGs.*

▶ **Lemma 16** (⋆). Minimum Directed Bisection *is NP-complete on semicomplete digraphs.*

Proof Sketch. It is easy to see that Minimum Directed Bisection belongs to NP. Now, for the proof of hardness, we give a reduction from the Maximum Directed Bisection problem on DAGs. To this end, consider an instance (D, k) of Maximum Directed Bisection where D is a DAG. Let $|V(D)| = n$. Without loss of generality, assume that n is even. (Add an isolate vertex to D if n is odd.) We construct an instance (D', k') of Minimum Directed Bisection as follows. Take $D' = \overline{D}$ and $k' = n^2/4 - k$. Note first that $\overline{D}$ is a semicomplete digraph, and that D' can be constructed in polynomial time. It can be verified that (D, k) is a yes-instance if and only if (D', k') is a yes-instance. ◀

▶ Remark 17. By Observation 13, the problem At Least One Weighted Minimum Bisection belongs to the class NP. Moreover, we have just shown that Minimum Directed Bisection is NP-complete on semicomplete digraphs. Thus, we can conclude that there is a polynomial time reduction from ALO-WMB to Minimum Directed Bisection on semicomplete digraphs.

Figure 1 An example of a Hamiltonian path P_i in D_i, with the canonical positions of its vertices. We have $V(D_i) = X_i \cup Y_i$. The vertices of X_i are indexed from left to right, while the vertices of Y_i are indexed from right to left.

5 FPT Algorithm for Minimum Directed Bisection on Semicomplete Digraphs

In this section, we design an algorithm for Minimum Directed Bisection on semicomplete digraphs that runs in time $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$. Our algorithm is based on a technique called chromatic coding, introduced by Alon et al. [1]. The basic idea behind this technique is to color the vertices of the input digraph by $\mathcal{O}(\sqrt{k})$ colors so that all the k arcs in a k-sized bisection (if one exists) are properly colored, i.e. have their endpoints in different color classes. As stated below, it was shown that there is a coloring family of size $2^{\mathcal{O}(\sqrt{k}\log k)}\log n$ that does this job.

▶ **Proposition 18** (Chromatic coding [1]). *For positive integers n and k, there exists a family $\mathcal{F}$ of functions from $[n]$ to $[2\lceil\sqrt{k}\rceil]$ with the following property: for every graph G with $V(G) = [n]$ and with at most k edges, there exists a function $f \in \mathcal{F}$ that properly colors $E(G)$ (i.e. for every $uv \in E(G)$, $f(u) \neq f(v)$). Moreover, there is an algorithm that runs in time $2^{\mathcal{O}(\sqrt{k}\log k)}n\log n$ and constructs such a family $\mathcal{F}$ of size $2^{\mathcal{O}(\sqrt{k}\log k)}\log n$.*

The family $\mathcal{F}$ in Proposition 18 is called a *coloring family*, and the elements of $\mathcal{F}$ are called *coloring functions*. For a coloring function $f \in \mathcal{F}$, we refer to the set of all vertices that have been assigned the color i by f as the i^{th} color class.

Informally, our algorithm for Minimum Directed Bisection is as follows. Suppose that (D, k) is a yes-instance, and let (L, R) be a bisection of D of size at most k. We would like to color the vertices of D using $\mathcal{O}(\sqrt{k})$ colors so that all arcs of $A(R, L)$ are properly colored (of course, without knowing (L, R)). Proposition 18 guarantees such a coloring function f. For any color i, let D_i be the subgraph of D induced by vertices in the i^{th} color class. Because all arcs of $A(R, L)$ are properly colored, no arc of D_i can belong to $A(R, L)$. Thus, we "guess" the vertices of D_i whose canonical positions are violated by (L, R), and define a partition of $V(D_i)$ accordingly. Due to Lemma 11 and Remark 12, there are at most $4k$ vertices in D_i whose canonical positions can be violated by (L, R). Thus we would need to consider only $k^{\mathcal{O}(\sqrt{k})} = 2^{\mathcal{O}(\sqrt{k}\log k)}$ guesses, which gives rise to an algorithm with the claimed running time. We present a formal description of our algorithm in Algorithm 1.

In the next two lemmas, we establish the correctness of Algorithm 1, and analyse its runtime.

▶ **Lemma 19** (⋆). *Algorithm 1 is correct.*

Proof Sketch. Observe first that if Algorithm 1 returns yes, then D has a bisection of size at most k (that is (L^f_t, R^f_t) for some f and t). Therefore, in order to show that Algorithm 1 returns the correct answer, we shall prove the following. If (D, k) is a yes-instance with a k-sized bisection (L, R), then for some $f \in \mathcal{F}$ and for some tuple t defined in Step 2 of the algorithm, we will have $(L, R) = (L^f_t, R^f_t)$ where L^f_t and R^f_t are as defined in Step 2-(ii)-(a) of the algorithm. ◀

▶ **Lemma 20** (⋆). *Algorithm 1 runs in time $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$.*

Algorithm 1 Input: (D, k) where D is a semicomplete digraph on n vertices.

```
1. Run the algorithm in Proposition 18 and construct a coloring family $\mathcal{F}$.
2. For each $f \in \mathcal{F}$, perform the following steps:
      (i). For each $i \in [2\lceil\sqrt{k}\rceil]$, consider $D_i$, the subgraph of $D$ induced by $f^{-1}(i)$, and perform the following steps.
            (a). Find a Hamiltonian path $P_i$ in $D_i$. Then, $P_i$ is a path from $\alpha_i$ to $\beta_i$ for some $\alpha_i, \beta_i \in V(D_i)$.
            (b). Let $X_i = \{x \in V(D_i) \mid \texttt{can}(x) = R^{c}_{D}\}$ and $Y_i = \{y \in V(D_i) \mid \texttt{can}(y) = L^{c}_{D}\}$. For $1 \leq j \leq |X_i|$, let $x_j$ be the $j^{\text{th}}$ vertex of $P_i$ that belongs to $X_i$ as we traverse $P_i$ from $\alpha_i$ to $\beta_i$. For $1 \leq p \leq |Y_i|$, let $y_p$ be the $p$th vertex of $P_i$ that belongs to $Y_i$ as we traverse $\texttt{rev}(P_i)$ from $\beta_i$ to $\alpha_i$ (see Figure 1).
            (c). For each pair $(\ell_i, q_i)$, where $0 \leq \ell_i \leq \min\{|X_i|, 2k\}$ and $0 \leq q_i \leq \min\{|Y_i|, 2k\}$, construct a partition $(L_{\ell_i,q_i}, R_{\ell_i,q_i})$ of $V(D_i)$ as follows. For every $j \leq \ell_i$, assign $x_j$ to $L_{\ell_i,q_i}$, and for every $p \leq q_i$, assign $y_p$ to $R_{\ell_i,q_i}$. For every other vertex $z \in V(D_i)$, assign $z$ to $L_{\ell_i,q_i}$ if $\texttt{can}(z) = L^{c}_{D}$, and assign $z$ to $R_{\ell_i,q_i}$ otherwise.
      (ii). For each tuple $t = (t_1, t_2, \ldots, t_{2\lceil\sqrt{k}\rceil})$, $t_i = (\ell_i, q_i)$ for some $0 \leq \ell_i \leq \min\{|X_i|, 2k\}$ and $0 \leq q_i \leq \min\{|Y_i|, 2k\}$ such that $(L_{\ell_i,q_i} R_{\ell_i,q_i})$ is a one way partition of $V(D_i)$, perform the following step.
            (a). Construct a partition $(L^f_t, R^f_t)$ of $V(D)$ as follows: $L^f_t = \bigcup_i L_{\ell_i,q_i}$ and $R^f_t = \bigcup_i R_{\ell_i,q_i}$. If $(L^f_t, R^f_t)$ is a bisection of $D$ of size at most $k$, then return that $(D, k)$ is a yes-instance and terminate.
3. Return that $(D, k)$ is a no-instance.
```

We have thus proved the following theorem.

▶ **Theorem 21.** Minimum Directed Bisection *on semicomplete digraphs admits a* $2^{\mathcal{O}(\sqrt{k}\log k)} n^{\mathcal{O}(1)}$ *time algorithm.*

6 Polynomial Kernel for Minimum Directed Bisection on Semicomplete Digraphs

In this section, we design a polynomial kernel for the Minimum Directed Bisection problem on semicomplete digraphs. Specifically, we prove the following theorem.

▶ **Theorem 22.** *There is a polynomial time algorithm that, given an instance* (D, k) *of* Minimum Directed Bisection *where* D *is a semicomplete digraph, produces an equivalent instance* (D', k') *of* Minimum Directed Bisection *such that* $\max\{|V(D')|, k'\} \leq k^{\mathcal{O}(1)}$.

Throughout this section, D denotes a semicomplete digraph on n vertices and k a non-negative integer. Given an instance (D, k) of Minimum Directed Bisection, our kernel proceeds as follows. In the first step, we reduce the instance (D, k) to an equivalent instance of ALO-WMB (defined in Section 2), whose size is bounded by $k^{\mathcal{O}(1)}$. As ALO-WMB belongs to the class NP (see Remark 13), and Minimum Directed Bisection is NP-complete (see Lemma 16), we know that ALO-WMB admits a polynomial time reduction to Minimum Directed Bisection. In the second step, we apply this reduction to the $k^{\mathcal{O}(1)}$-sized ALO-WMB instance to obtain an equivalent instance of Minimum Directed Bisection of size $k^{\mathcal{O}(1)}$. And in order to reduce Minimum Directed Bisection to ALO-WMB in the first step, we use an $(n, 2k, 4k^2)$-splitter. Using such a splitter, we construct $k^{\mathcal{O}(1)}$ many instances of Weighted Minimum Bisection (WMB) such that each one of these instances has size $k^{\mathcal{O}(1)}$, and at least one of them is equivalent to our original instance (D, k).

▶ Remark 23 (Assumption about k). In this section, given an instance (D, k) of Minimum Directed Bisection, we assume that $\log n \leq k$. Otherwise, if $\log n > k$, then we have $n > 2^k > 2^{\sqrt{k}\log k}$. But this implies that Algorithm 1 runs in time polynomial in n. That is, if $\log n > k$, then we can solve Minimum Directed Bisection on semicomplete digraphs in polynomial time.

Terminology. In what follows, we use the following definitions and notations. Consider an instance (D, k) of Minimum Directed Bisection. Let (L, R) be a bisection of D. Let S be the set of endpoints of the arcs in $A(R, L)$, i.e. $S = V(A(R, L))$. For some positive integer $\ell \geq |S|$, let $f : V(D) \to [\ell]$ be a function that splits S evenly. For each $i \in [\ell]$ such that $f^{-1}(i) \neq \emptyset$, let $D_i, P_i, \alpha_i, \beta_i, X_i, Y_i, x_j$ and y_p be as defined in Algorithm 1. Since f splits S evenly, and $\ell \geq |S|$, the function f is injective on S. Therefore, no arc of D_i belongs to $A(R, L)$. Moreover, note that $V(D_i)$ is the disjoint union of X_i and Y_i.

Fix $i \in [\ell]$. We say that a vertex $z \in V(D_i)$ is *marked* if $z = x_j$ for some $x_j \in X_i$ with $j \leq 2k$, or if $z = y_p$ for some $y_p \in Y_i$ with $p \leq 2k$. Otherwise, we say that z is *unmarked*. That is, the first $2k$ of vertices of P_i that belong to X_i, and the last $2k$ vertices of P_i that belong to Y_i are marked. All other vertices are unmarked. (Here, first and last are defined with respect to the traversal of P_i from α_i to β_i.) Therefore, in light of Lemma 11, if (L, R) is of size at most k, and (L, R) violates the canonical position of a vertex $v \in V(D_i)$, then v is a marked vertex. In other words, every bisection of D of size at most k, if such a bisection exists, respects the canonical position of every unmarked vertex. Let M_i denote the set of all marked vertices in $V(D_i)$.

Let $n_i = |V(D_i)|$. For $r \in [n_i]$, let v_r be the r^{th} vertex of P_i as we traverse P_i from α_i to β_i. That is, $P_i = (\alpha_i =)v_1 v_2 \dots v_{n_i} (= \beta_i)$.

▶ **Observation 24.** *We have $|M_i| = |M_i \cap X_i| + |M_i \cap Y_i| \leq 2k + 2k = 4k$. If $v_r \in X_i \cap M_i$, then for every $v_s \in X_i$ with $s \leq r$, we have $v_s \in M_i$. Similarly, if $v_r \in Y_i \cap M_i$, then for every $v_s \in Y_i$ with $s \geq r$, we have $v_s \in M_i$.*

For $r, s \in [n_i], r \leq s$, let $P_i^{r,s}$ denote the subpath of P_i from vertex v_r to vertex v_s. Also, we say that the subpath $P_i^{r,s}$ is *monochromatic* if for every $r \leq j \leq s$, the vertex v_j is unmarked, and $\texttt{can}(v_j) = \texttt{can}(v_r)$. And we say that a monochromatic subpath $P_i^{r,s}$ is a *maximal monochromatic subpath* if there is no monochromatic subpath of P_i that strictly contains $P_i^{r,s}$. That is, a maximal monochromatic subpath is a maximal subpath of P_i such that all its vertices are unmarked and have the same canonical positions.

▶ **Lemma 25** ($\star$). *Assume that (D, k) is a yes-instance and that (L, R) is a bisection of D of size at most k. Then for every i, the path P_i has at most $4k + 2$ maximal monochromatic subpaths.*

The above lemma shows that $V(D_i) \setminus M_i$ can be partitioned into at most $4k+2$ maximal monochromatic subpaths. Additionally, $V(D_i)$ contains at most $4k$ marked vertices. Let $\mathcal{P}_{f,i}$ denote this partition of $V(D_i)$ into $4k + 2 + 4k = 8k + 2$ parts. That is, every part in $\mathcal{P}_{f,i}$ is either the set of vertices of a maximal monochromatic subpath of P_i or a singleton set consisting of a marked vertex. We call $\mathcal{P}_{f,i}$ the *monochromatic partition* of $V(D_i)$.

▶ **Lemma 26** ($\star$). *Assume that (D, k) is a yes-instance and that (L, R) is a bisection of D of size at most k. Then, for every part $Z \in \mathcal{P}_{f,i}$, either $Z \subseteq L$ or $Z \subseteq R$.*

Kernel. Our kernelization algorithm works as follows. Given (D,k), we begin by using Proposition 2 to construct an $(n,2k,4k^2)$-splitter $\mathcal{F}'$ in time $k^{\mathcal{O}(1)}n\log n$. By Proposition 2 and Remark 23, we get that $|\mathcal{F}'| = k^{\mathcal{O}(1)}$. For each function $f \in \mathcal{F}'$, we do as follows. For each $i \in [4k^2]$ such that $f^{-1}(i) \neq \emptyset$, we find a Hamiltonian path P_i in D_i. We say that $f \in \mathcal{F}$ is a *good function* if for every $i \in [4k^2]$ such that $f^{-1}(i) \neq \emptyset$, the path P_i has at most $4k+2$ maximal monochromatic subpaths. Let $\mathcal{F} \subseteq \mathcal{F}'$ be the collection of good functions in $\mathcal{F}$. We now compute the monochromatic partition $\mathcal{P}_{f,i}$ of $V(D_i)$. Note that $|\mathcal{P}_{f,i}| \leq 8k+2$. Let $\mathcal{P}_f$ be the partition of $V(D)$ obtained by taking the union of $\mathcal{P}_i$ for all i, that is, $\mathcal{P}_f = \bigcup_{i\in[4k^2]} \mathcal{P}_{f,i}$. We have $|\mathcal{P}_f| \leq 4k^2 \cdot (8k+2) = k^{\mathcal{O}(1)}$. This completes the first step our kernelizaition algorithm. Observe that this step can be executed in time $k^{\mathcal{O}(1)}n^{\mathcal{O}(1)}$.

Now, construct the $\mathcal{P}_f$-weighted contraction of D, (with weight function $w_{\mathcal{P}_f}$), and denote it by H_f. Note that $|V(H_f)| = |\mathcal{P}_f| = k^{\mathcal{O}(1)}$. As every vertex $v \in V(H_f)$ corresponds to a part of $\mathcal{P}_f$ of size at most n, we have $w_{\mathcal{P}_f}(v) = |\texttt{part}(v)| \leq n$ for every vertex $v \in V(H_f)$. Hence, $|w_{\mathcal{P}_f}(v)| \leq \log n \leq k$ for every $v \in V(H_f)$ (by Remark 23). Thus, H_f is a vertex-weighted semicomplete digraph with $k^{\mathcal{O}(1)}$ vertices and further, the weight of each vertex in $V(H_f)$ can be encoded using $k^{\mathcal{O}(1)}$ bits. This is the second step of our kernel. Observe that this step also runs in time polynomial in n.

Now, consider the instance $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ of ALO-WMB. Note that the size of the ALO-WMB instance $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ is bounded by $k^{\mathcal{O}(1)}$. The following lemma shows the equivalence of this instance to (D,k).

▶ **Lemma 27** ($\star$). *The instance (D,k) is a yes-instance of* Minimum Directed Bisection *if and only if $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ is a yes-instance of* ALO-WMB.

Note that the first two steps of the kernel – up to the construction of the ALO-WMB instance $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ – runs in polynomial time. Finally, we use the polynomial time reduction in Remark 17 to reduce the instance $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ of ALO-WMB to an equivalent instance (D', k') of Minimum Directed Bisection on semicomplete digraphs. As the size of the instance $(\{(H_f, w_{\mathcal{P}_f}) \mid f \in \mathcal{F}\}, k)$ is bounded by $k^{\mathcal{O}(1)}$, this reduction runs in time polynomial in k. We thus conclude that the size of the instance (D', k') is also bounded by $k^{\mathcal{O}(1)}$. This completes the proof of Theorem 22.

7 Conclusion

We studied the Minimum Directed Bisection problem from the parameterized complexity perspective. In particular, we gave an algorithm with running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ and a polynomial kernel for Minimum Directed Bisection on semicomplete digraphs. Some natural questions that arise from this work are: can the $\log k$ dependence on the exponent in the running time be removed? How far can we reach in improving the size of the kernel? In particular, can one prove a lower bound/existence of a linear/quadratic kernel for Minimum Directed Bisection on semi-complete digraphs? We also believe that our technique of employing splitters can be generalized for the design of kernels for many problems, especially the ones that admit algorithms crucially using chromatic coding. At least, for such problems, the use of splitters can "simulate" the effects of chromatic coding that are sufficient for kernelization.

Abstract

The class of synchronous relations, also known as automatic or regular, is one of the most studied subclasses of rational relations. It enjoys many desirable closure properties and is known to be logically characterized: the synchronous relations are exactly those that are defined by a first-order formula on the structure of all finite words, with the prefix, equal-length and last-letter predicates. Here, we study the quantifier alternation hierarchy of this logic. We show that it collapses at level Σ_3 and that all levels below admit decidable characterizations. Our results reveal the connections between this hierarchy and the well-known hierarchy of first-order defined languages of finite words.

1 Introduction

We study classes of relations on finite words, within the class of rational relations. Synchronous relations [8] – also studied as *regular relations* [3] and *automatic relations* [5] – form a subclass of rational relations which is well-behaved from many standpoints. Contrary to rational relations, they enjoy crucial effective properties such as closure under intersection and complement. As a consequence, most paradigmatic problems are decidable for synchronous relations, in the same way as they are for regular languages. Further, they admit clean characterizations both in terms of automata and logic, providing yet more evidence of the connections between logic, formal languages and automata. Due to this good behavior, this class finds various applications in verification [6, 1], automatic structures [5], the theory of transducers and database theory [2].

Synchronous relations contain natural relations such as equality, prefix, or equal-length. In fact, any letter-to-letter transduction, alphabetic morphism or length-preserving rational relation lies within synchronous relations [4].

Synchronous relations are those that are accepted by multi-tape finite automata. A k-tape automaton over an alphabet $\mathbb{A}$ can be naturally seen as an NFA over the alphabet of

k-tuples $\hat{\mathbb{A}} = (\mathbb{A} \cup \{\perp\})^k$ that reads k input words $w_1, \ldots, w_k \in \mathbb{A}^*$ simultaneously, from left to right, the i-th transition reading the tuple from $\hat{\mathbb{A}}$ composed of the i-th letters of each word w_j (or $\perp$ if $i > |w_j|$). Synchronous relations can also be described as finite unions of the componentwise concatenation of a length-preserving rational relation with a recognizable relation – two other well-studied classes of relations [4].

On the other hand, relations can be defined by logical formulæ interpreted on words in $\mathbb{A}^*$: a formula φ with free variables $z_1, \ldots, z_k$ defines the k-ary relation of all tuples $(w_1, \ldots, w_k)$ such that φ holds with the interpretation $z_i \mapsto w_i$ $(1 \leq i \leq k)$. Eilenberg, Elgot and Shepherdson [9] showed that a relation is synchronous if, and only if, it can be defined in this way by a first-order formula using the prefix, equal-length and last letter predicates.

This characterization opens the possibility of exploring classes of synchronous relations specified by fragments of first-order logic. In the present work, we study the quantifier alternation hierarchy in this logic, that is, the classes of relations defined by formulæ with a bounded number of alternations of existential and universal quantifier blocks. This is a natural way of providing small, well-behaved classes (closed under boolean combinations) of synchronous relations. We show that the hierarchy collapses at level Σ_3 and we give clean combinatorial characterizations for its different layers, namely Σ_1, its boolean closure $\mathcal{B}\Sigma_1$, Σ_2 and $\mathcal{B}\Sigma_2$. These characterizations reveal strong links with the classical Σ_1- and Σ_2- fragments of the first-order theory on finite words with the order $<$ relation and letter predicates. Interestingly, the notion of *subwords*, which plays a central role in the characterization of $\Sigma_1[<]$ and $\mathcal{B}\Sigma_1[<]$, must be replaced here by the more subtle notion of *synchronized subwords*.

We also show that these characterizations are decidable: given a synchronous relation, one can decide whether it is defined by a formula in Σ_1 (resp. $\mathcal{B}\Sigma$, Σ_2, $\mathcal{B}\Sigma_2$). Our results provide therefore a complete decision procedure for the alternation hierarchy of synchronous relations.

Section 2 introduces technical preliminaries. Our main results are all stated in Section 3, and their proofs are given in the ensuing sections: Section 4 for the collapse of the hierarchy, Section 5 for what concerns the Σ_1- and $\mathcal{B}\Sigma_1$-fragments and Section 6 for the Σ_2- and $\mathcal{B}\Sigma_2$-fragments.

2 Preliminaries

For any set A and $\bar{a} \in A^k$, we denote by $\bar{a}(i)$ its i-th component, an element of A. If $w \in A^*$ is a word, we denote by $|w|$ its length and, for any $1 \leq i \leq j \leq |w|$, by $w[i]$ the letter of w in i-th position, and by $w[i..j]$ the factor $w[i] \cdots w[j]$ of w between positions i and j. To simplify notation, we let $w[i..j] = \varepsilon$ (the empty word) whenever $1 \leq i \leq j \leq |w|$ does not hold. If u, v are words, we let $u \sqcap v$ be the longest common prefix of u and v.

We will consider relations of a fixed arity $k \geq 2$, over a fixed alphabet $\mathbb{A}$ with at least two letters. Let $\perp$ be a symbol not in $\mathbb{A}$, and let $\mathbb{A}_\perp = \mathbb{A} \cup \{\perp\}$. We will often work with the alphabet $\mathbb{A}_\perp^k$, the direct product of k copies of $\mathbb{A}_\perp$.

Synchronous relations

Given $w_1, \ldots, w_k \in \mathbb{A}^*$, we define the *synchronized word* $\bar{w}$ of the tuple $(w_1, \ldots, w_k)$, written $\bar{w} = w_1 \otimes \cdots \otimes w_k$, to be the word in $(\mathbb{A}_\perp^k)^*$ such that:

- $|\bar{w}| = \max(|w_1|, \ldots, |w_k|)$; and
- for every $i \in \{1, \ldots, |\bar{w}|\}$ and $j \in \{1, \ldots, k\}$, we have $\bar{w}[i](j) = w_j[i]$ if $i \leq |w_j|$, and $\bar{w}[i](j) = \perp$ otherwise.

For example, $abba \otimes c \otimes de = (a, c, d)(b, \perp, e)(b, \perp, \perp)(a, \perp, \perp)$. We let SW_k be the set of all k-synchronized words, that is, $SW_k = \{w_1 \otimes \cdots \otimes w_k : w_1, \ldots, w_k \in \mathbb{A}^*\}$. For $S = \{s_1, \ldots, s_n\} \subseteq \{1, \ldots, k\}$ such that $s_1 < \cdots < s_n$, we define the *projection* $\pi_S \colon SW_k \to (\mathbb{A}^n_\perp)^*$ as $\pi_S(w_1 \otimes \cdots \otimes w_k) = w_{s_1} \otimes \cdots \otimes w_{s_n}$. In the case of a singleton $S = \{i\}$, note that $\pi_S : SW_k \to \mathbb{A}^*$, and we simply write π_i. If $R \subseteq (\mathbb{A}^*)^k$ is a k-ary relation, the *synchronized language of* R, denoted by L_R, is the language $\{w_1 \otimes \cdots \otimes w_k \colon (w_1, \ldots, w_k) \in R\} \subseteq (\mathbb{A}^k_\perp)^*$. The relation R is said to be *synchronous* if L_R is regular. The set of synchronous relations, of arbitrary arity, is denoted by **Sync**.

MSO over finite words

In the classical setting introduced by Büchi (see [21]), languages over an alphabet $\mathbb{A}$ are described by formulæ interpreted over the set of positions of a finite word, using the binary word ordering predicate $<$ and the unary letter predicates a ($a \in \mathbb{A}$) – where $a(i)$ holds if the word carries letter a in position i. Büchi's Theorem [7, 21] states that a language is regular if and only if it is definable by a closed monadic second order formula in this logic, written $\mathbf{MSO}[<, \{a\}_{a \in \mathbb{A}}]$, or $\mathbf{MSO}[<]$ if $\mathbb{A}$ is understood. If φ is a closed formula in $\mathbf{MSO}[<]$, we let $|\varphi|$ be the language in $\mathbb{A}^*$ it defines, and if $\mathcal{F}$ is a set of formulæ, $|\mathcal{F}|$ denotes the class $\{|\varphi| : \varphi \in \mathcal{F}\}$.

First-order formulæ in Büchi's logic define a strict subclass of regular languages, that of *star-free* languages (see [19, 12, 21, 22]). The quantifier alternation hierarchy within $\mathbf{FO}[<]$ forms a strict infinite hierarchy, and it has been the object of intense study (see [17, 18] for an overview). In the sequel, we will only use results regarding the $\mathbf{\Sigma}_1$, $\mathcal{B}\mathbf{\Sigma}_1$, $\mathbf{\Sigma}_2$ and $\mathcal{B}\mathbf{\Sigma}_2$ fragments of $\mathbf{FO}[<]$, possibly enriched with the constant predicate **max**, which stands for the last position in a word (see below in this section and Section 6). Recall that $\mathcal{B}$ designates the boolean closure; that $\mathbf{\Sigma}_1$ is the set of existential formulæ, of the form $\exists z_1 \cdots \exists z_n\ \varphi$ with φ quantifier-free; and that $\mathbf{\Sigma}_2$ consists in the formulæ of the form $\exists z_1 \cdots \exists z_n\ \varphi$ with φ in $\mathcal{B}\mathbf{\Sigma}_1$. The $\mathbf{\Pi}_i$ fragment consists of the negations of the formulæ in $\mathbf{\Sigma}_i$ (e.g., $\mathbf{\Pi}_1$ are all formulæ of the form $\forall z_1 \cdots \forall z_n\ \varphi$ with φ quantifier-free). We will sometimes write $\mathbf{FO}[<](\mathbb{A}^*)$ (or fragments thereof) when we want to make explicit the alphabet $\mathbb{A}$ we work with.

FO over the structure of all finite words

We now turn to the signature introduced by Eilenberg *et al.* [9] to discuss synchronous relations over $\mathbb{A}^*$, namely $\sigma = [\preceq, \mathsf{eq}, (\ell_a)_{a \in \mathbb{A}}]$. These predicates are interpreted as follows:

- $(w_1, w_2) \models x \preceq y$ if and only if w_1 is a *prefix* of w_2;
- $(w_1, w_2) \models \mathsf{eq}(x, y)$ if and only if w_1 and w_2 have *equal length*;
- $w \models \ell_a(x)$ if and only if the *last letter* of w is a.

Every formula φ with free variables $z_1, \ldots, z_k$ defines a k-ary relation written $\|\varphi\|$, namely:

$$\|\varphi\| = \{(w_1, \ldots, w_k) \in (\mathbb{A}^*)^k : (w_1, \ldots, w_k) \models \varphi\}.$$

Let $\mathbf{FO}[\sigma]$ denote the set of first order formulæ with signature σ, and for any $\mathcal{F} \subseteq \mathbf{FO}[\sigma]$ let $\|\mathcal{F}\|$ denote the set of relations definable by formulæ in $\mathcal{F}$. For convenience, we write $x \prec y$ for $(x \preceq y) \wedge \neg(y \preceq x)$, and L_φ for $L_{\|\varphi\|}$. For example, $\varphi(x_1, x_2, x_3) = (x_3 \preceq x_1) \wedge (x_3 \preceq x_2) \wedge \forall z\ (x_3 \prec z \to \neg(z \preceq x_1 \wedge z \preceq x_2))$ defines the set $\|\varphi\|$ of all triples (w_1, w_2, w_3) such that $w_3 = w_1 \sqcap w_2$.

Types and type sequences

For a letter $\bar{a} = (a_1, \ldots, a_k) \in \mathbb{A}_\perp^k$, the *type of* $\bar{a}$ is the subset of $\{1, \ldots, k\}^2$ $\mathsf{type}(\bar{a}) = \{(i,j) : a_i = a_j \neq \perp\}$. The *type* of a synchronized word $\bar{w} = \bar{a}_1 \cdots \bar{a}_n$ is given by $\mathsf{type}(\bar{w}) = \bigcap_{1 \leq i \leq n} \mathsf{type}(\bar{a}_i)$. For example, $\mathsf{type}((a, \perp, a, b)) = \{(1,3), (3,1), (1,1), (3,3), (4,4)\}$ and $\mathsf{type}((a, \perp, a, b)(\perp, \perp, b, b)) = \{(3,3), (4,4)\}$.

In particular, if $\bar{w} \in SW_k$, the successive values $T_1 \supsetneq T_2 \cdots \supsetneq T_n$ taken by the types of the prefixes of $\bar{w}$ form the *type sequence* of $\bar{w}$, written $\mathsf{type\text{-}seq}(\bar{w})$. In such a sequence, we say that T_i is an *end type* if either $i = n$, or $(j,j) \in T_i \setminus T_{i+1}$ for some $j \leq k$ – that is, if $\bar{w} = w_1 \otimes \cdots \otimes w_k$, T_i is an end type in $\mathsf{type\text{-}seq}(\bar{w})$ if the length of the longest prefix of $\bar{w}$ of type T_i is equal to $|w_j|$ for some j. If T is a type, we let $\mathbb{A}_T$ be the set of T-*compatible letters*, $\mathbb{A}_T = \{\bar{a} \in \mathbb{A}_\perp^k : T \subseteq \mathsf{type}(\bar{a}) \subseteq T^\star\}$, where $T^\star = \{(i,j) : (i,i), (j,j) \in T\}$; and let $\mathbb{A}_{-,T} = \{\bar{a} \in \mathbb{A}_\perp^k : T = \mathsf{type}(\bar{a})\}$. If T' is a type such that $T \subsetneq T'$, we also let $\mathbb{A}_{T',T} = \{\bar{a} \in \mathbb{A}_\perp^k : T = T' \cap \mathsf{type}(\bar{a})\}$. Hence, if $\bar{w}\bar{a} \in SW_k$ and $\bar{w}$ has type T (resp. T'), then $\mathsf{type}(\bar{w}\bar{a}) = T$ if and only if $\bar{a} \in \mathbb{A}_T$ (resp. $T \subsetneq T'$ and $\bar{a} \in \mathbb{A}_{T',T}$).

It follows that, if $\bar{T} = (T_1, \ldots, T_n)$ is a type sequence and $K(\bar{T})$ is the set of synchronized words $\bar{w}$ such that $\mathsf{type\text{-}seq}(\bar{w}) = \bar{T}$, then

$$K(\bar{T}) = \mathbb{A}_{-,T_1} \mathbb{A}_{T_1}^* \mathbb{A}_{T_1,T_2} \mathbb{A}_{T_2}^* \cdots \mathbb{A}_{T_{n-1},T_n} \mathbb{A}_{T_n}^*. \tag{1}$$

Note that this product of languages is *deterministic*, that is, given $\bar{w}$, we can determine $\mathsf{type\text{-}seq}(\bar{w})$ and its unique factorization in the product (1) by reading $\bar{w}$ from left to right: the first letter determines T_1, the next factor is the longest written in $\mathbb{A}_{T_1}$, the first letter not in $\mathbb{A}_{T_1}$ (together with T_1) determines T_2, etc.

If $\bar{w} = \bar{w}_1 \cdots \bar{w}_n$ is this factorization, with $\bar{w}_i \in \mathbb{A}_{T_{i-1},T_i} \mathbb{A}_{T_i}^*$ for each i ($\mathbb{A}_{T_-,T_i} \mathbb{A}_{T_i}^*$ for $i = 1$), we say that $\bar{w}_i$ is the *i-th type factor* of $\bar{w}$, written $\mathsf{type\text{-}factor}_i(\bar{w})$.

Synchronized subwords

We denote by $\sqsubseteq$ the (*scattered*) *subword relation* on $\mathbb{A}^*$ (sometimes called *subsequence*): if $u, v \in \mathbb{A}^*$, we have $u \sqsubseteq v$ if there exists a strictly increasing function $p \colon \{1, \ldots, |u|\} \to \{1, \ldots, |v|\}$, called the *witness function*, such that, for all $i \in \{1, \ldots, |u|\}$, $u[i] = v[p(i)]$.

Given $\bar{w} = w_1 \otimes \cdots \otimes w_k$ and $\bar{w}' = w'_1 \otimes \cdots \otimes w'_k$, we say that $\bar{w}$ is a *synchronized subword* of $\bar{w}'$, denoted by $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$ if and only if $\bar{w} \sqsubseteq \bar{w}'$, with a witness function p which is

- *type preserving*: $\mathsf{type}(\bar{w}[1..i]) = \mathsf{type}(\bar{w}'[1..p(i)])$ for all $1 \leq i \leq |\bar{w}|$; and
- *end preserving*: $p(|w_j|) = |w'_j|$ for all $j \in \{1, \ldots, k\}$.

▶ **Lemma 1.** *For $\bar{u}, \bar{u}' \in SW_k$ with type sequences $\bar{T}$ and $\bar{T}'$, we have $\bar{u} \sqsubseteq_{\mathsf{s}} \bar{u}'$ if and only if $\bar{T}$ is a subsequence of $\bar{T}'$ with a witness function $t \colon \{1, \ldots, |\bar{T}|\} \to \{1, \ldots, |\bar{T}'|\}$ such that, for every i, the i-th type factor of $\bar{u}$ is a subword of the $t(i)$-th type factor of $\bar{u}'$, and they further have the same last letter if $\bar{T}_i$ is an end type of $\bar{T}$.*

Proof. Suppose first that $\bar{u} \sqsubseteq_{\mathsf{s}} \bar{u}'$ and let $p \colon \{1, \ldots, |\bar{u}|\} \to \{1, \ldots, |\bar{u}'|\}$ be a witness function. Let $\bar{T}$ and $\bar{T}'$ be the type sequences of $\bar{u}$ and $\bar{u}'$ and let $\bar{u} = \bar{u}_1 \cdots \bar{u}_n$, $\bar{u}' = \bar{u}'_1 \cdots \bar{u}'_m$ be the type factorizations of $\bar{u}$ and $\bar{u}'$. For each $1 \leq i \leq n$, if $\bar{v}_i = \bar{u}_1 \cdots \bar{u}_i$, then $T_i = \mathsf{type}(\bar{v}_i) = \mathsf{type}(\bar{u}'[1..p(|\bar{v}_i|)])$, so $\bar{T}$ is a subsequence of $\bar{T}'$. Let $t(i)$ be such that $T'_{t(i)} = T_i$. Since p is type-preserving, the factor $\bar{u}_i$ is a subword of $\bar{u}'_{t(i)}$. Both have the same last letter if T_i is an end type for $\bar{u}$, since p is end-preserving.

Conversely, suppose that $T_i = T'_{t(i)}$ and that $\bar{u}_i \sqsubseteq \bar{u}'_{t(i)}$, with witness function p_i (with domain $\{1, \ldots, |\bar{u}_i|\}$). Let p be the function on $\{1, \ldots, |\bar{u}|\}$ obtained by "concatenating" the p_i: $p(|\bar{u}_1 \cdots \bar{u}_{i-1}| + h) = |\bar{u}'_1 \cdots \bar{u}'_{t(i)-1}| + p_i(h)$. It is directly verified that p witnesses $\bar{u} \sqsubseteq_{\mathsf{s}} \bar{u}'$. ◀

Given a quasi-order $\preceq$ over a domain X, the $\preceq$-*upward closure* of an element $x \in X$ is the set $\uparrow_{\preceq} x = \{x' \in X : x \preceq x'\}$. If $S \subseteq X$, we also let $\uparrow_{\preceq} S = \bigcup_{x \in S} \uparrow_{\preceq} x$. Finally, S is $\preceq$-*upward closed* if $S = \uparrow_{\preceq} S$. Henceforward, we write $\uparrow w$ and $\uparrow S$ as short for $\uparrow_{\sqsubseteq} w$ and $\uparrow_{\sqsubseteq} S$; and we write $\uparrow_{\mathsf{s}} \bar{w}$ and $\uparrow_{\mathsf{s}} S$ as short for $\uparrow_{\sqsubseteq_{\mathsf{s}}} w$ and $\uparrow_{\sqsubseteq_{\mathsf{s}}} S$.

A *well-quasi-order* (*wqo*) is a quasi-order $(X, \preceq)$ such that for every infinite sequence $(x_i)_{i \in \mathbb{N}}$ of elements of X, there exist $i < j$ such that $x_i \preceq x_j$. A crucial observation is that, if $\preceq$ is a wqo, then any set has a finite number of $\preceq$-minimal elements.

It is a classical result (Higman's lemma [10], see also [11, chap. 6]) that the subword order on $\mathbb{A}^*$ is a wqo. Unsurprisingly, the same holds for the synchronized subword order.

▶ **Proposition 2.** *For every k, $(SW_k, \sqsubseteq_{\mathsf{s}})$ is a well-quasi-order.*

Proof. If $(\bar{w}_n)_n$ is an infinite sequence of elements of SW_k, we can extract an infinite subsequence of elements with the same type sequence $\bar{T} = (T_1, \ldots, T_n)$ (since there are only finitely many type sequences). Similarly, we can further extract an infinite subsequence where, for each end type T_i, all the i-th type factors end with the same letter.

On this subsequence, $\sqsubseteq_{\mathsf{s}}$ coincides with the intersection of the subword order applied to each of the n type factors. The result follows since the subword order is a wqo and wqo's are closed under intersection. ◀

Bounded subword and synchronized subword classes

It is well-known [21] that $|\mathbf{\Sigma}_1[<]|$ is the set of languages of the form $\uparrow \mathcal{S}$, where $\mathcal{S}$ is a set of words (which can be assumed to be finite by the wqo property). Similarly, $|\mathcal{B}\mathbf{\Sigma}_1[<]|$ is the set of finite unions of languages of the form $\uparrow \mathcal{S} \setminus \uparrow \mathcal{S}'$, where $\mathcal{S}, \mathcal{S}'$ are finite sets of words. For $h \in \mathbb{N}$, let $\sim_h$ be the equivalence relation on $\mathbb{A}^*$ defined by $w_1 \sim_h w_2$ if and only if w_1 and w_2 have the same subwords of length at most h. Then we also know [13, 21] that $|\mathcal{B}\mathbf{\Sigma}_1[<]|$ is the set of finite unions of $\sim_h$-classes, also known as the set of *piecewise testable* languages.

We introduce analogous definitions for synchronized subwords. If $h \in \mathbb{N}$, we let $\approx_h$ be the equivalence relation on synchronized words defined by $\bar{w}_1 \approx_h \bar{w}_2$ if $\bar{w}_1$ and $\bar{w}_2$ have the same set of synchronized subwords of length less than or equal to h. We let $\mathcal{V}_h$ be the set of equivalence classes of $\approx_h$ and $\bar{\mathcal{V}}_h$ be its Boolean closure. Finally, we let $\bar{\mathcal{V}} = \bigcup_{h \in \mathbb{N}} \bar{\mathcal{V}}_h$.

3 Summary of results

We start with an overview of our main results. Their proofs are discussed in the next sections. Theorem 3 refines the already mentioned 1969 result of Eilenberg *et al.* [9], which states that the relations definable in $\|\mathbf{FO}[\sigma]\|$ are exactly the synchronous relations.

▶ **Theorem 3.** *For any alphabet having at least two letters,*

$$\|\mathbf{\Sigma}_1[\sigma]\| \subsetneq \|\mathcal{B}\mathbf{\Sigma}_1[\sigma]\| \subsetneq \|\mathbf{\Sigma}_2[\sigma]\| \subsetneq \|\mathcal{B}\mathbf{\Sigma}_2[\sigma]\| \subsetneq \|\mathbf{\Sigma}_3[\sigma]\| = \|\mathbf{FO}[\sigma]\| = \mathbf{Sync}.$$

The characterizations of the $\mathbf{\Sigma}_1[\sigma]$- and the $\mathcal{B}\mathbf{\Sigma}_1[\sigma]$-fragments are in terms of synchronized subwords, rather than ordinary subwords as in the case of word languages.

▶ **Theorem 4.** *For any relation R, $R \in \|\mathbf{\Sigma}_1[\sigma]\|$ if and only if $L_R = \uparrow_{\mathsf{s}} L_R$.*

▶ **Theorem 5.** *For any relation R, $R \in \|\mathcal{B}\mathbf{\Sigma}_1[\sigma]\|$ if and only if $L_R \in \bar{\mathcal{V}}$.*

We note the following corollary of Theorem 4, which follows from the wqo property of the synchronized subword order (Proposition 2).

▶ **Corollary 6.** *For every formula $\varphi \in \mathbf{\Sigma}_1[\sigma]$ with k free variables, there exists a finite set $S \subseteq SW_k$ such that $L_\varphi = \uparrow_s S$.*

In contrast, the characterizations of the $\mathbf{\Sigma}_2[\sigma]$- and the $\mathcal{B}\mathbf{\Sigma}_2[\sigma]$-fragments reduce to the corresponding logical fragments for word languages.

▶ **Theorem 7.** *For any relation R, $R \in \|\mathbf{\Sigma}_2[\sigma]\|$ if and only if $L_R \in |\mathbf{\Sigma}_2[<]|$.*

▶ **Corollary 8.** *For any relation R, $R \in \|\mathcal{B}\mathbf{\Sigma}_2[\sigma]\|$ if and only if $L_R \in |\mathcal{B}\mathbf{\Sigma}_2[<]|$.*

These characterizations can then be used to prove the decidability of the membership problems for the different fragments of $\mathbf{FO}[\sigma]$.

▶ **Theorem 9.** *Given a fragment $\mathcal{F} \in \{\mathbf{\Sigma}_1[\sigma], \mathcal{B}\mathbf{\Sigma}_1[\sigma], \mathbf{\Sigma}_2[\sigma], \mathcal{B}\mathbf{\Sigma}_2[\sigma]\}$ and a synchronous relation R (say, an automaton accepting L_R), it is decidable whether $R \in \|\mathcal{F}\|$.*

▶ Remark 10. The decidability of membership in $\|\mathbf{\Sigma}_2[\sigma]\|$ and $\|\mathcal{B}\mathbf{\Sigma}_2[\sigma]\|$ follows directly from the decidability of $|\mathbf{\Sigma}_2[<]|$ [15] and $|\mathcal{B}\mathbf{\Sigma}_2[<]|$ [16], see also [17].

4 Collapse of the alternation hierarchy

Here we prove Theorem 3. The equality $\|\mathbf{FO}[\sigma]\| = \mathbf{Sync}$ was proved in [9]. The collapse at level Σ_3 is established by a folklore argument, in which the runs of a classical (1-tape) automaton are first-order encoded using additional tapes.

Specifically, let R be a k-ary synchronous relation and let $\mathcal{A}$ be a DFA accepting the language L_R, with state set Q. We fix $0, 1$, two distinct letters of $\mathbb{A}$, which will be used to encode the runs of $\mathcal{A}$. If $\bar{w} \in SW_k$ and if $q \in Q$, we let u_q be the word of length $|\bar{w}|$ which carries the letter 1 at each position i such that $\mathcal{A}$ is in state q after reading the i first letters of $\bar{w}$, and carries letter 0 everywhere else.

A $\mathbf{\Sigma}_3[\sigma]$-formula φ with free variables $z_1, \ldots, z_k$ defining R is obtained as follows. A tuple of variables $Y = (y_q)_{q \in Q}$ is quantified existentially, and the rest of the formula, in $\mathcal{B}\mathbf{\Sigma}_2[\sigma]$, verifies that the words u_q ($q \in Q$) assigned to these variables encode the run of $\mathcal{A}$ as above. More precisely, each of these words must have length $|\bar{w}|$ (verified in $\mathbf{\Pi}_2[\sigma]$) and at every position, exactly one of them carries a 1 (verified in $\mathbf{\Pi}_1[\sigma]$). Moreover, the first letter of each u_q must be 1 exactly when q is the state reached from the initial state when reading the tuple of first letters of the words assigned to $z_1, \ldots, z_k$; the notion of first letter, or rather of length 1 prefix is $\mathbf{\Pi}_2[\sigma]$-definable. Similarly, the last state must be one of the final states of $\mathcal{A}$, which is readily verified using (without any quantifier) the last letter predicates ℓ_a. Finally, the compatibility of the u_q's with the transitions of the run of $\mathcal{A}$ on $\bar{w}$ can be encoded with a $\mathbf{\Pi}_2[\sigma]$-formula. Thus $\mathbf{Sync}$ is contained in $\|\mathbf{\Sigma}_3[\sigma]\|$

We now turn to the proof of the strictness of containments in Theorem 3. We observe that a unary relation on $\mathbb{A}$ is nothing but a language in $\mathbb{A}^*$. In that case, the notion of type is trivial, and $w \sqsubseteq_{\mathsf{s}} w'$ if and only if $w \sqsubseteq w'$ and they have the same last letter. In view of Theorems 4 and 5, it follows that a^* is in $\|\mathcal{B}\mathbf{\Sigma}_1[\sigma]\|$ but not in $\|\mathbf{\Sigma}_1[\sigma]\|$. The other containments are strict because they are in the classical framework. This completes the proof of Theorem 3.

5 $\Sigma_1[\sigma]$ and its boolean closure

We prove Theorems 4 and 5, and we exhibit a decision procedure for membership in $(\mathcal{B})\mathbf{\Sigma}_1[\sigma]$.

5.1 Characterization of $\Sigma_1[\sigma]$

The proof of Theorem 4 is a consequence of the following three properties:

- if φ is a formula of $\mathbf{\Sigma}_1[\sigma]$, then L_φ is $\sqsubseteq_{\mathsf{s}}$-upward closed (Lemma 12 below);
- the relation defined by the $\sqsubseteq_{\mathsf{s}}$-upward closure of any synchronized word is $\mathbf{\Sigma}_1[\sigma]$-definable (Lemma 13 below);
- $\sqsubseteq_{\mathsf{s}}$ is a well-quasi-order on SW_k (Proposition 2 above).

We first show how these three properties imply Theorem 4.

Proof of Theorem 4. If R is $\mathbf{\Sigma}_1[\sigma]$-definable, then $L_R = \uparrow_{\mathsf{s}} L_R$ by Lemma 12. Conversely, suppose that $L_R = \uparrow_{\mathsf{s}} L_R$ and let S be a $\sqsubseteq_{\mathsf{s}}$-minimal subset of L_R, such that $\uparrow_{\mathsf{s}} S = \uparrow_{\mathsf{s}} L_R$. Since $\sqsubseteq_{\mathsf{s}}$ is a wqo by Proposition 2, S is finite, say, $S = \{\bar{w}_1, \ldots, \bar{w}_m\}$. By Lemma 13, for every $1 \leq i \leq m$, there exists a formula $\varphi_i \in \mathbf{\Sigma}_1[\sigma]$ such that $L_{\varphi_i} = \uparrow_{\mathsf{s}} \bar{w}_i$. Letting $\varphi = \bigvee_{1 \leq i \leq m} \varphi_i$, we see that $L_\varphi = \bigcup_{1 \leq i \leq m} \uparrow_{\mathsf{s}} \bar{w}_i = \uparrow_{\mathsf{s}} S = \uparrow_{\mathsf{s}} L_R = L_R$, and hence $R = \|\varphi\| \in \|\mathbf{\Sigma}_1[\sigma]\|$. ◀

Before we prove Lemma 12, we establish the following technical lemma.

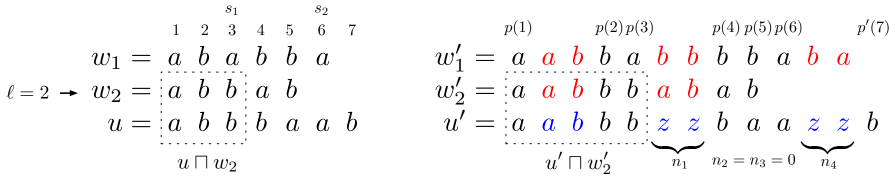
▶ **Lemma 11.** *Let $\bar{w} = w_1 \otimes \cdots \otimes w_k$, and $\bar{w}' = w_1' \otimes \cdots \otimes w_k'$ such that $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$. For all $u \in \mathbb{A}^*$, there exists $u' \in \mathbb{A}^*$ such that $\bar{w} \otimes u \sqsubseteq_{\mathsf{s}} \bar{w}' \otimes u'$.*

Proof. Let $p\colon \{1, \ldots, |\bar{w}|\} \to \{1, \ldots, |\bar{w}'|\}$ be the witness function for $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$. Let $s_1 = \max_{i \leq k} |u \sqcap w_i|$ and $\ell \leq k$ be such that $|u \sqcap w_\ell| = s_1$. Finally, let $s_2 = \min(|\bar{w}|, |u|)$, and $u[s_1{+}1..s_2] = a_1 \cdots a_m$. That is, $u = (u \sqcap w_\ell)\ (a_1 \cdots a_m)\ u[s_2{+}1..|u|]$, with the understanding that $u[s_2 + 1..|u|] = \varepsilon$ if $|u| \leq |\bar{w}|$.

For $1 \leq i \leq m$, let $n_i = p(s_1 + i) - p(s_1) - 1$, and $n_{m+1} = |\bar{w}'| - p(s_2)$. Let also z be an arbitrary letter of $\mathbb{A}$. We then define

$$u' = w_\ell'[1..p(s_1)]\ z^{n_1}\, a_1 \cdots z^{n_m}\, a_m\, z^{n_{m+1}}\ u[s_2 + 1..|u|].$$

Example. Let $\bar{w} = w_1 \otimes w_2$, $\bar{w}' = w_1' \otimes w_2'$ and u be defined as follows.



Now let p' be the function defined on $\{1, \ldots, \max(|\bar{w}|, |u|)\}$, which extends p by letting $p'(|\bar{w}| + j) = |\bar{w}'| + j$ for $1 \leq j \leq |u| - |\bar{w}|$. We show that p' is a witness for $\bar{w} \otimes u \sqsubseteq_{\mathsf{s}} \bar{w}' \otimes u'$.

By construction, p' is increasing and $(\bar{w} \otimes u)[i] = (\bar{w}' \otimes u')[p'(i)]$ for every $i \leq \max(|\bar{w}|, |u|)$ $= |\bar{w} \otimes u|$. We must now show that, for each such i, $\mathsf{type}((\bar{w} \otimes u)[1..i]) = \mathsf{type}((\bar{w}' \otimes u)[1..p'(i)])$, and that $p'(|u|) = |u'|$. For convenience, we write $\bar{w}_u$ for $\bar{w} \otimes u$ and $\bar{w}'_{u'}$ for $\bar{w}' \otimes u'$.

- If $1 \leq i \leq s_1$, then $p'(i) = p(i)$, the u-component of each letter of $\bar{w}_u[1..i]$ coincides with its w_ℓ-component, and the u'-component of each letter of $\bar{w}'_{u'}[1..p(i)]$ coincides with its w'_ℓ-component. It follows that $\mathsf{type}(\bar{w}_u[1..i])$ is the symmetric transitive closure of $\mathsf{type}(\bar{w}[1..i]) \cup \{(\ell, k + 1)\}$. Similarly, $\mathsf{type}(\bar{w}'_{u'}[1..p(i)])$ is the symmetric transitive closure of $\mathsf{type}(\bar{w}'[1..p(i)]) \cup \{(\ell, k + 1)\}$. Since $\mathsf{type}(\bar{w}[1..i]) = \mathsf{type}(\bar{w}'[1..p(i)])$, we have $\mathsf{type}(\bar{w}_u[1..i]) = \mathsf{type}(\bar{w}'_{u'}[1..p'(i)])$. In particular, we have $u[i] = w_\ell[i] = w'_\ell[p'(i)] = u'[p'(i)]$. If $i = |u|$, then $s_1 = i$ and, by definition, $u' = w'_\ell[1..p(i)]$. It follows that $|u'| = p(i) = p'(i)$.

- If $s_1 < i \leq s_2$, again we have $p'(i) = p(i)$. Moreover, $\mathsf{type}(\bar{w}_u[1..i]) = \mathsf{type}(\bar{w}[1..i]) \cup \{(k+1, k+1)\}$ since the u-component differs from any other component on at least one position less than or equal to i. For the same reason, $\mathsf{type}(\bar{w}'_{u'}[1..p'(i)]) = \mathsf{type}(\bar{w}'[1..p(i)]) \cup \{(k+1, k+1)\} = \mathsf{type}(\bar{w}_u[1..i])$. Also, by definition of the n_j, we get $u[i] = u'[p(i)]$ and, as above, if $i = |u|$, we find that $p(i) = p(|u'|)$.
- If $s_2 < i \leq |u|$, then $p'(i) - |\bar{w}'| = i - |\bar{w}| = |u[s_2+1..i]|$. In particular, $p'(|u|) = |\bar{w}'| + |u[s_2+1..i]| = |u'|$. Moreover, $\mathsf{type}(\bar{w}_u[1..i]) = \{(k+1, k+1)\} = \mathsf{type}(\bar{w}'_{u'}[1..p'(i)])$. ◀

▶ **Lemma 12.** *If φ is a formula in $\mathbf{\Sigma}_1[\sigma]$, then L_φ is $\sqsubseteq_s$-upward closed.*

Proof. First observe that if the synchronized words $\bar{w} = w_1 \otimes \cdots \otimes w_k$ and $\bar{w}' = w'_1 \otimes \cdots \otimes w'_k$ satisfy $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$, then, for all $i, j \in \{1, \ldots, k\}$, we have:

- $w_i \preceq w_j$ if and only if $w'_i \preceq w'_j$;
- $|w_i| = |w_j|$ if and only if $|w'_i| = |w'_j|$;
- if $|w_i| = |w'_i| > 0$, then w_i and w'_i have the same last letter.

We now proceed by induction on the number of quantified variables of φ. If φ is quantifier-free, these three properties show that L_φ is $\sqsubseteq_{\mathsf{s}}$-upward closed.

If φ is not quantifier-free, we have $\varphi(y_1, \ldots, y_k) = \exists x\ \psi(y_1, \ldots, y_k, x)$ for some $\psi \in \mathbf{\Sigma}_1[\sigma]$. Let $\bar{w}, \bar{w}' \in SW_k$ such that $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$ and $\bar{w} \models \varphi$. Then there is $u \in \mathbb{A}^*$ such that $\bar{w} \otimes u \models \psi$. By Lemma 11, there also exists $u' \in \mathbb{A}^*$ such that $\bar{w} \otimes u \sqsubseteq_{\mathsf{s}} \bar{w}' \otimes u'$. Since $\|\psi\|$ is $\sqsubseteq_{\mathsf{s}}$-upward closed by induction, $\bar{w}' \otimes u' \models \psi$, and hence $\bar{w}' \models \varphi$. This completes the proof. ◀

▶ **Lemma 13.** *If $\bar{w}$ is a synchronized word, then the relation defined by $\uparrow_{\mathsf{s}}\bar{w}$ is $\mathbf{\Sigma}_1[\sigma]$-definable.*

Proof. Let $\bar{w} = w_1 \otimes \cdots \otimes w_k \in SW_k$. We define a formula $\varphi(z_1, \ldots, z_k)$ (dependent on $\bar{w}$) whose synchronized language is $\uparrow_{\mathsf{s}}\bar{w}$, using existential quantification on a set consisting of one variable for each w_i and one for each position within w_i. Formally, let $X = \{x_{i,j} : 1 \leq i \leq k, 1 \leq j \leq |w_i|\}$. Then $\varphi(z_1, \ldots, z_k) = \exists X.\psi(z_1, \ldots, z_k, X)$, where ψ is the conjunction of the following formulæ for every $i \in \{1, \ldots, k\}$:

(1) $z_i = x_{i,|w_i|}$;
(2) for every $1 \leq j < |w_i|$: $x_{i,j} \prec x_{i,j+1}$;
(3) for every $1 \leq j \leq |w_i|$: $\ell_{w_i[j]}(x_{i,j})$;
(4) for every $1 \leq i' \leq k$ and $j \leq \min\{|w_i|, |w_{i'}|\}$: $\mathsf{eq}(x_{i,j}, x_{i',j})$;
(5) for every $1 \leq i' \leq k$ and $j \leq \min\{|w_i|, |w_{i'}|\}$ such that $w_i[1..j] = w_{i'}[1..j]$: $x_{i,j} = x_{i',j}$.

Let $\bar{w}' = w'_1 \otimes \cdots \otimes w'_k$. First assume that $\bar{w}' \in \uparrow_{\mathsf{s}}\bar{w}$: we want to show that $\bar{w}' \in L_\varphi$. Let p be a witness function for $\bar{w} \sqsubseteq_{\mathsf{s}} \bar{w}'$. For each $1 \leq i \leq k$ and $1 \leq j \leq |w_i|$, let the word $w'_i[1..p(j)]$ be assigned to variable $x_{i,j}$. It is readily verified that $(w'_1, \ldots, w'_k)$ satisfies $\varphi(z_1, \ldots, z_k)$ and hence $\bar{w} \in \|\varphi\|$.

Conversely, suppose that $\bar{w}' \in L_\varphi$. There exists an assignment α for the variables in φ such that $(\bar{w}, \alpha) \vDash \varphi$. We define a function $p\colon \{1, \ldots, |\bar{w}|\} \to \{1, \ldots, |\bar{w}'|\}$ as follows.

If $1 \leq j \leq |\bar{w}|$, there exists $1 \leq i \leq k$ such that $j \leq |w_i|$, and we let $p(j) = |\alpha(x_{i,j})|$. Condition (4) in the definition of φ shows that p is well-defined. Condition (2) shows that it is increasing and Condition (3) shows that $\bar{w}[j] = \bar{w}'[p(j)]$, so that p is a witness function for $\bar{w} \sqsubseteq \bar{w}'$. Finally, Conditions (5) and (1) show that p is type- and end-preserving, thus establishing that it is a witness for $\bar{w} \sqsubseteq_s \bar{w}'$. ◀

5.2 Characterization of $\mathcal{B}\Sigma_1[\sigma]$

The following lemma establishes one of the implications of Theorem 5.

▶ **Lemma 14.** *For every $\varphi \in \mathcal{B}\mathbf{\Sigma}_1[\sigma]$, $L_\varphi \in \bar{\mathcal{V}}$.*

Proof. By a standard transformation, φ is logically equivalent to a formula $\bigvee_{i=1}^{n} \psi_i \wedge \psi_i'$ in disjunctive normal form, where $\psi_i \in \mathbf{\Sigma}_1[\sigma]$ and $\psi_i' \in \mathbf{\Pi}_1[\sigma]$ for every i. By Corollary 6, there exist finite sets $\mathcal{S}_i$ and $\mathcal{S}_i'$ $(1 \leq i \leq n)$ of synchronized words such that $L_{\psi_i} = \uparrow_{\mathsf{s}}\mathcal{S}_i$ and $L_{\neg\psi_i'} = \uparrow_{\mathsf{s}}\mathcal{S}_i'$. Let $\mathcal{S} = \bigcup_{i=1}^{n} \mathcal{S}_i \cup \mathcal{S}_i'$ and let $h = \max\{|\bar{u}| : \bar{u} \in \mathcal{S}\}$.

If $\bar{w}, \bar{w}'$ are synchronized words such that $\bar{w} \approx_h \bar{w}'$, then $\bar{w}$ and $\bar{w}'$ have the same synchronized subwords of length at most h, and hence the same synchronized subwords in each $\mathcal{S}_i$ and each $\mathcal{S}_i'$ (since these sets contain only words of length at most h). If $\bar{w} \in L_\varphi$, then for some i, $\bar{w}$ contains a synchronized subword in $\mathcal{S}_i$ and none in $\mathcal{S}_i'$. The same holds therefore for $\bar{w}'$, and $\bar{w}' \in L_{\varphi_i \wedge \psi_i'}$. Thus $\bar{w}' \in L_\varphi$, which completes the proof. ◀

To establish the converse implication, we consider $h \in \mathbb{N}$ and $L \in \bar{\mathcal{V}}_h$, such that L is a finite union of $\approx_h$-classes $[\bar{w}_1]_h, \ldots, [\bar{w}_n]_h$, and we show that $L = L_\varphi$ for some $\varphi \in \mathcal{B}\mathbf{\Sigma}_1[\sigma]$.

For each $1 \leq i \leq n$, let $\mathcal{S}_i$ be the set of synchronized subwords of $\bar{w}_i$ of length at most h, and $\mathcal{S}_i'$ be the complement of $\mathcal{S}_i$ within the set of synchronized words of length at most h. Both are finite and, by Lemma 13, there exist $\mathbf{\Sigma}_1[\sigma]$-formulæ ψ_i and ψ_i' such that $L_{\psi_i} = \uparrow_{\mathsf{s}}\mathcal{S}_i$ and $L_{\psi_i'} = \uparrow_{\mathsf{s}}\mathcal{S}_i'$. Then, for each $1 \leq i \leq n$, $[\bar{w}_i]_h = \uparrow_{\mathsf{s}}\mathcal{S}_i \setminus \uparrow_{\mathsf{s}}\mathcal{S}_i' = L_{\psi_i \wedge \neg\psi_i'}$ and hence, $L = L_\varphi$ with $\varphi = \bigvee_i \psi_i \wedge \neg\psi_i'$. This completes the proof of Theorem 5, since $\varphi \in \mathcal{B}\mathbf{\Sigma}_1[\sigma]$.

5.3 Deciding membership in $\|\mathbf{\Sigma}_1[\sigma]\|$

In view of Theorem 4 and of the properties of regular languages (namely the decidability of equality), membership decidability for $\|\mathbf{\Sigma}_1[\sigma]\|$ reduces to proving the following proposition.

▶ **Proposition 15.** *Given a regular language $L \subseteq SW_k$, its upward-closure $\uparrow_{\mathsf{s}}L$ is regular and computable.*

We begin with some preliminary definitions, which will also be used in the next section. For $\mathcal{S} \subseteq SW_k$, let $\uparrow^{\ell} \mathcal{S} = \{\bar{w} \in SW_k : \exists \bar{u} \in \mathcal{S}\ \bar{u} \sqsubseteq \bar{w}$ and $\bar{u}, \bar{w}$ have the same last letter$\}$. Let $\mathcal{A}$ be a deterministic automaton accepting L, with state set Q and initial state q_0. For $p, r \in Q$, we let $\mathcal{A}(p, r)$ be the same as $\mathcal{A}$, with p as initial state and $\{r\}$ as final states, and denote by $\mathsf{Lang}(\mathcal{A}(p, r))$ the language accepted by $\mathcal{A}(p, r)$.

We say that a state sequence $\bar{q} = (q_1, \ldots, q_n) \in Q^n$ is *$\bar{T}$-compatible* in $\mathcal{A}$ if q_1 is reachable from q_0 by reading a word in $\mathbb{A}_{-,T_1}\mathbb{A}_{T_1}^*$, q_2 is reachable from q_1 by reading a word in $\mathbb{A}_{T_1,T_2}\mathbb{A}_{T_2}^*$, etc. In addition, we require q_n to be a final state of $\mathcal{A}$. Observe that, given $\bar{T}$, the set of $\bar{T}$-compatible state sequences is finite and computable.

If $\bar{q}$ is $\bar{T}$-compatible, we let $L(\bar{T}, \bar{q}, i)$ be the intersection of the language accepted by $\mathcal{A}(q_{i-1}, q_i)$ with $\mathbb{A}_{T_{i-1},T_i}\mathbb{A}_{T_i}^*$ ($\mathbb{A}_{-,T_1}\mathbb{A}_{T_1}^*$ if $i = 1$). In particular, if $\bar{w} \in SW_k$ and $\mathsf{type\text{-}seq}(\bar{w}) = \bar{T}$, then $\bar{w} \in L$ if and only if there exists a $\bar{T}$-compatible sequence $\bar{q}$ such that $\bar{w} \in L(\bar{T}, \bar{q}, 1) \cdots L(\bar{T}, \bar{q}, n)$ (uniquely determined, due to determinism). Note that the n factors of $\bar{w}$ thus determined are its type factors. In particular, $L = \bigcup L(\bar{T}, \bar{q}, 1) \cdots L(\bar{T}, \bar{q}, n)$, where the union runs over all type sequences $\bar{T}$ and all $\bar{T}$-compatible state sequences $\bar{q}$ of $\mathcal{A}$. This is a finite union, all of whose terms are explicitly computable.

Proof of Proposition 15. For L, $\mathcal{A}$, $\bar{T}$, $\bar{q}$, i as above, let $\widehat{L}(\bar{T}, \bar{q}, i)$ be $\widehat{L}(\bar{T}, \bar{q}, i) = \uparrow L(\bar{T}, \bar{q}, i) \cap \mathbb{A}_{T_i}^*$ if T_i is not an end type or $\widehat{L}(\bar{T}, \bar{q}, i) = \uparrow^{\ell} L(\bar{T}, \bar{q}, i) \cap \mathbb{A}_{T_i}^*$ otherwise. We now show that

$$\uparrow_{\mathsf{s}}L = \bigcup \widehat{L}(\bar{T}, \bar{q}, 1) \cdots \widehat{L}(\bar{T}, \bar{q}, n).$$

Note that the closure $\uparrow K$ of a regular language K is regular and computable (by adding self loops to the states of an automaton accepting K), and the operation $L(\bar{T}, \bar{q}, i) \mapsto \widehat{L}(\bar{T}, \bar{q}, i)$ is therefore computable, implying Proposition 15.

The proof is essentially an application of Lemma 1. Suppose first that $\bar{w} \in {\uparrow_{\mathsf{s}}} L$, that is, there exists $\bar{u} \in L$ such that $\bar{u} \sqsubseteq_{\mathsf{s}} \bar{w}$. Let $\bar{T} = \mathsf{type\text{-}seq}(\bar{u}) = (T_1, \dots, T_n)$ and let $\bar{q}$ be the $\bar{T}$-compatible state sequence determined by reading $\bar{u}$ in $\mathcal{A}$. By Lemma 1, $\bar{T} \sqsubseteq \mathsf{type\text{-}seq}(\bar{w})$, with a witness function t such that, for each $1 \leq i \leq n$, the i-th type factor $\bar{u}_i$ of $\bar{u}$ is a subword of $\bar{w}_{t(i)}$, the $t(i)$-th type factor of $\bar{w}$ (with an additional last letter condition if T_i is an end type). Therefore $\bar{u}_i$ is also a subword of $\bar{w}_{t(i-1)+1} \cdots \bar{w}_{t(i)}$, with the same last letter condition in the case of end types. Since $\bar{u}_i \in L(\bar{T}, \bar{q}, i)$, this means that $\bar{w}_{t(i-1)+1} \cdots \bar{w}_{t(i)} \in \widehat{L}(\bar{T}, \bar{q}, i)$ and hence $\bar{w} \in \widehat{L}(\bar{T}, \bar{q}, 1) \cdots \widehat{L}(\bar{T}, \bar{q}, n)$.

Conversely, suppose that $\bar{w} \in \widehat{L}(\bar{T}, \bar{q}, 1) \cdots \widehat{L}(\bar{T}, \bar{q}, n)$ for some type sequence $\bar{T}$ and $\bar{T}$-compatible state sequence $\bar{q}$. For each $1 \leq i \leq n$, let $\bar{u}_i \in L(\bar{T}, \bar{q}, i)$ be such that $\bar{u}_i \sqsubseteq \bar{w}_i$, with witness function p_i (and such that $p_i(|u_i|) = |w_i|$ if T_i is an end type). By construction of the $L(\bar{T}, \bar{q}, i)$'s, the word $\bar{u} = \bar{u}_1 \cdots \bar{u}_n$ is in L, with type factors $\bar{u}_1, \dots, \bar{u}_n$. Moreover $\bar{u} \sqsubseteq_{\mathsf{s}} \bar{w}$ for the witness function obtained by "concatenating" the functions p_i: $p(i) = p_1(i)$ for $i \leq |\bar{u}_1|$, and $p(|\bar{u}_1 \cdots \bar{u}_{i-1}| + h) = |\bar{w}_1 \cdots \bar{w}_{i-1}| + p_i(h)$ for every $1 < i \leq n$ and $1 \leq h \leq |\bar{u}_i|$. ◀

5.4 Deciding membership in $\|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$

As a first step, we note the following.

▶ **Lemma 16.** *If $\bar{T}$ is a type sequence, then $K(\bar{T})$ is $\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]$-definable.*

Proof. Let $S_{\bar{T}}$ be the set of $\sqsubseteq_s$-minimal elements of $K(\bar{T})$, a finite set by Proposition 2. Then $K(\bar{T}) \subseteq {\uparrow_{\mathsf{s}}} S_{\bar{T}}$. Moreover, if $\bar{u} \in {\uparrow_{\mathsf{s}}} S_{\bar{T}}$, then $\bar{T} \sqsubseteq \mathsf{type\text{-}seq}(\bar{u})$ by Lemma 1. It follows that $K(\bar{T}) = {\uparrow_{\mathsf{s}}} S_{\bar{T}} \setminus \bigcup \{{\uparrow_{\mathsf{s}}} S_{\bar{T}'} : \bar{T} \sqsubseteq \bar{T}', \bar{T} \neq \bar{T}'\}$. The statement then follows from Theorem 4. ◀

Since there are finitely many type sequences $\bar{T}$ and each $K(\bar{T})$ is computable, membership of a language L in $\|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$ is equivalent to the membership of each $L \cap K(\bar{T})$ in $\|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$.

We now fix a type sequence $\bar{T} = (T_1, \dots, T_n)$. Our next step is a technical characterization of $\|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$ for languages within $K(\bar{T})$. For each $1 \leq i \leq n$, let $\mathcal{F}_i = \mathcal{B}\boldsymbol{\Sigma}_1[<, \mathbf{max}](\mathbb{A}^*_{T_i})$ if T_i is an end type in $\bar{T}$, and $\mathcal{F}_i = \mathcal{B}\boldsymbol{\Sigma}_1[<](\mathbb{A}^*_{T_i})$ otherwise. Let also $\mathcal{G}_1 = \{\mathbb{A}_{-,T_1} \mathbb{A}^*_{T_1} \cap H \colon H \in |\mathcal{F}_1|\}$ and, for $i \geq 2$, $\mathcal{G}_i = \{\mathbb{A}_{T_{i-1},T_i} \mathbb{A}^*_{T_i} \cap H \colon H \in |\mathcal{F}_i|\}$.

▶ **Lemma 17.** *A regular language $L \subseteq K(\bar{T})$ is in $\|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$ if and only if, for each $\bar{T}$-compatible state sequence $\bar{q}$ and $1 \leq i \leq n$, $L(\bar{T}, \bar{q}, i) \in \mathcal{G}_i$.*

Proof. For convenience, we write $L(\bar{q}, i)$ for $L(\bar{T}, \bar{q}, i)$. First assume that every $L(\bar{q}, i) \in \mathcal{G}_i$, that is, there exists a $\mathcal{B}\boldsymbol{\Sigma}_1[<]$-definable language $H(\bar{q}, i) \subseteq \mathbb{A}^*_{T_i}$ such that $L(\bar{q}, i) = \mathbb{A}_{T_{i-1},T_i} \mathbb{A}^*_{T_i} \cap H(\bar{q}, i)$ (or, if $i = 1$, $L(\bar{q}, 1) = \mathbb{A}_{-,T_1} \mathbb{A}^*_{T_1} \cap H(\bar{q}, 1)$). Then $H(\bar{q}, i)$ is the finite union of languages of the form $H(\bar{q}, i, j) = {\uparrow} S(\bar{q}, i, j) \setminus {\uparrow} S'(\bar{q}, i, j)$ (or ${\uparrow^\ell} S(\bar{q}, i, j) \setminus {\uparrow^\ell} S'(\bar{q}, i, j)$ if T_i is an end type), for $1 \leq j \leq n_{\bar{q},i}$, where the $S(\bar{q}, i, j)$'s and $S'(\bar{q}, i, j)$'s are finite sets. Then $L(\bar{q}, i)$ is the union of the $L(\bar{q}, i, j) = \mathbb{A}_{T_{i-1},T_i} \mathbb{A}^*_{T_i} \cap H(\bar{q}, i, j)$ (or, if $i = 1$, $L(\bar{q}, 1, j) = \mathbb{A}_{-,T_1} \mathbb{A}^*_{T_1} \cap H(\bar{q}, 1, j)$). If $\bar{\jmath} = (j_1, \dots, j_n)$ is such that $1 \leq j_i \leq n_{\bar{q},i}$ for each $1 \leq i \leq n$, let $L(\bar{q}, \bar{\jmath}) = L(\bar{q}, 1, j_1) \cdots L(\bar{q}, n, j_n)$. Then L is the (finite) union of the $L(\bar{q}, \bar{\jmath})$. Now let

- $\mathcal{S}(\bar{q}, \bar{\jmath}) = \{\bar{w} \in K(\bar{T}) \colon$ for all $i \in \{1, \dots, n\}, \mathsf{type\text{-}factor}_i(\bar{w}) \in S(\bar{q}, i, j_i)\}$ and
- $\mathcal{S}'(\bar{q}, \bar{\jmath}) = \{\bar{w} \in K(\bar{T}) \colon$ for some $i \in \{1, \dots, n\}, \mathsf{type\text{-}factor}_i(\bar{w}) \in S'(\bar{q}, i, j_i)\}$.

Then, $L(\bar{q}, \bar{\jmath}) = K(\bar{T}) \cap ({\uparrow} \mathcal{S}(\bar{q}, \bar{\jmath}) \setminus {\uparrow} \mathcal{S}'(\bar{q}, \bar{\jmath})) \in \|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$. It follows that $L \in \|\mathcal{B}\boldsymbol{\Sigma}_1[\sigma]\|$.

Conversely, suppose that for some $\bar{q}$ and some i, $L(\bar{q}, i) \notin \mathcal{G}_i$. In view of Theorem 5, we want to show that L is not a union of $\approx_r$-classes for any $r \geq 1$. Let r be now fixed. We only need to exhibit words $\bar{w} \in L$ and $\bar{w}' \notin L$ such that $\bar{w} \approx_r \bar{w}'$.

Let $\sim_r^i$ be the relation on $\mathbb{A}_{T_i}^*$ given by $\bar{u} \sim_r^i \bar{v}$ if $\bar{u} \sim_r \bar{v}$ and, either the first letters of $\bar{u}$ and $\bar{v}$ are both in $\mathbb{A}_{T_{i-1}}$ or neither is. By means of contradiction, suppose $L(\bar{q}, i)$ is the finite union of the $\sim_r^i$ classes $[\bar{u}_1], \ldots, [\bar{u}_m]$. Then each $\bar{u}_j \in \mathbb{A}_{T_{i-1},T_i}\mathbb{A}_{T_i}^*$ and, by definition of $\sim_r^i$, $[\bar{u}_j] = \mathbb{A}_{T_{i-1},T_i}\mathbb{A}_{T_i}^* \cap [\![\bar{u}_j]\!]$, where $[\![\bar{u}_j]\!]$ denotes the $\sim_r$-class of $\bar{u}_j$. Therefore $L(\bar{q}, i) = \mathbb{A}_{T_{i-1},T_i}\mathbb{A}_{T_i}^* \cap M$, where M is the union of the $[\![\bar{u}_j]\!]$'s. Since $M \in |\mathcal{B}\mathbf{\Sigma}_1[<](\mathbb{A}_{T_i})|$, this shows that $L(\bar{q}, i) \in \mathcal{G}_i$, a contradiction. (In the case where T_i is an end type, we need to reason with the intersection of $\sim_r^i$ with the same-last-letter equivalence.)

Now, since $L(\bar{q}, i)$ is not a union of $\sim_r^i$-classes, there exist words $\bar{u}_i, \bar{u}'_i \in \mathbb{A}_{T_{i-1},T_i}\mathbb{A}_{T_i}^*$ such that $\bar{u}_i \sim_r \bar{u}'_i$ (and if T_i is an end type they have the same last letter) and exactly one of them is in $L(\bar{q}, i)$. Say $\bar{u}_i \in L(\bar{q}, i)$, such that $\bar{u}_i \in \mathsf{Lang}(\mathcal{A}(q_{i-1}, q_i))$ and $\bar{u}'_i \in \mathsf{Lang}(\mathcal{A}(q_{i-1}, q'_i))$ for some $q_i \neq q'_i$. Assuming wlog that $\mathcal{A}$ is minimal for L, there exist a word $\bar{y}$ and states p, p' of which exactly one is accepting, such that $\bar{y} \in \mathsf{Lang}(\mathcal{A}(q_i, p)) \cap \mathsf{Lang}(\mathcal{A}(q'_i, p'))$. Let $\bar{x} \in L(\bar{q}, 1) \cdots L(\bar{q}, i-1)$, $\bar{w} = \bar{x}\bar{u}_i\bar{y}$ and $\bar{w}' = \bar{x}\bar{u}'_i\bar{y}$. Then exactly one of $\bar{w}$, $\bar{w}'$ is in L. Since $L \subseteq K(\bar{T})$, this implies that $\bar{y} \in \mathbb{A}_{T_i}^*\mathbb{A}_{T_i,T_{i+1}}\mathbb{A}_{T_{i+1}}^* \cdots \mathbb{A}_{T_{n-1},T_n}\mathbb{A}_{T_n}^*$ ($\mathbb{A}_{T_n}^*$ if $i = n$). Consequently, $\bar{w}$ and $\bar{w}'$ have the same type sequence $\bar{T}$, with the same type factors except for the i-th one. Moreover, $\mathsf{type\text{-}factor}_i(\bar{w}) = \bar{u}_i\bar{u}'$ and $\mathsf{type\text{-}factor}_i(\bar{w}') = \bar{u}'_i\bar{u}'$, where $\bar{u}'$ is the longest $\mathbb{A}_{T_i}^*$ prefix of $\bar{u}$. Since $\bar{u}_i \sim_r \bar{u}'_i$, $\bar{u}_i\bar{u}' \sim_r \bar{u}'_i\bar{u}'$. Then $\bar{w} \approx_r \bar{w}'$ is a consequence of Lemma 1. ◀

In view of Lemma 17 and since each $L(\bar{T}, \bar{q}, i)$ is computable (Section 5.3), the decidability of $\|\mathcal{B}\mathbf{\Sigma}_1[\sigma]\|$ will be established if we show that membership in each $\mathcal{G}_i$ is decidable, which is the object of the following lemma.

▶ **Lemma 18.** *Let A be an alphabet and $B \subseteq A$. Then, it is decidable whether a regular language is in $\mathcal{W}_B = \{BA^* \cap L \colon L \in \mathcal{B}\mathbf{\Sigma}_1[<](A)\}$.*

Proof. We will prove the following characterization of $\mathcal{W}_B$: a regular language $K \in \mathcal{W}_B$ if and only if $K \subseteq BA^*$ and for every $b \in B$, $b^{-1}K = \{u \in A^* \colon bu \in K\} \in |\mathcal{B}\mathbf{\Sigma}_1[<](A)|$. Since $\mathcal{B}\mathbf{\Sigma}_1[<]$ membership is decidable [20], the result follows directly.

If $K \in \mathcal{W}_B$, then $K = BA^* \cap L$ for some $L \in |\mathcal{B}\mathbf{\Sigma}_1[<](A)|$. Therefore, $K \subseteq BA^*$ and, for every $b \in B$, $b^{-1}K = b^{-1}L \in |\mathcal{B}\mathbf{\Sigma}_1[<]|$ (since $\mathcal{B}\mathbf{\Sigma}_1[<$ is closed under left quotients).

Conversely, suppose that each $b^{-1}K$ ($b \in B$) is a $\mathcal{B}\mathbf{\Sigma}_1[<]$-language. Then there exists r such that each of these languages is a union of $\sim_r$-classes. Say that $u \sim_{r+1}^B v$ if $u \sim_{r+1} v$ and, either u, v have the same first letter in B or both their first letters are in $A \setminus B$. Suppose there exist words u, v such that $u \sim_{r+1}^B v$ and $u \in K$. Then $u \in BA^*$ and v has same first letter as u, say b, so that $u = bu'$ and $v = bv'$. In particular, $u' \sim_r v'$. Since $u' \in b^{-1}K$ and $b^{-1}K$ is a union of $\sim_r$-classes, it follows that $v' \in b^{-1}K$ and hence $v \in K$. Therefore, K is the union of the $\sim_{r+1}^B$-classes of a finite set of words $u_1, \ldots, u_n$ and if L is the union of the $\sim_{r+1}$-classes of the same words, then $L \in |\mathcal{B}\mathbf{\Sigma}_1[<]|$ and $L \cap BA^* = K$. That is, $K \in \mathcal{W}_B$. ◀

6 $\Sigma_2[\sigma]$ and its boolean closure

For any alphabet A, an *A-monomial* is a language of the form $A_1^*a_1A_2^*a_2 \cdots A_n^*a_nA_{n+1}^*$, where $A_1, A_2, \ldots, A_{n+1} \subseteq A$ and $a_1, a_2, \ldots, a_n \in A$. An *$A$-polynomial* is a finite union of A-monomials.

▶ Remark 19. It is known [14] that $\Sigma_2[<](A)$ sentences define exactly the set of A-polynomials. A non-trivial consequence is that the set of A-polynomials is closed under intersection.

Not every $\mathbb{A}_\perp^k$-polynomial respects the structural properties (on the positions of $\perp$) of synchronized words. For example $(a,\perp)^*(b,b)(a,a)^*$ is a polynomial over $\mathbb{A}_\perp^k$ for $\mathbb{A} = \{a,b\}$ and $k = 2$ but it does not define a relation. In order to characterize subsets of SW_k which are polynomials, we introduce the notion of $\perp$-*consistency.*

If $\bar{a} = a_1 \otimes \cdots \otimes a_k$ is a synchronized letter in $\mathbb{A}_\perp^k$, we denote by $\tau(\bar{a})$ the set $\{i \in \{1,\ldots,k\} \colon a_i = \perp\}$. A non-empty subset $\bar{A} \subseteq \mathbb{A}_\perp^k$ is said to be $\perp$-*consistent* if all the $\tau(\bar{a})$ ($\bar{a} \in \bar{A}$) take the same value. If that is the case, we let $\tau(\bar{A}) = \tau(\bar{a})$ (for any $\bar{a} \in \bar{A}$). Finally we say that a monomial $\bar{A}_0^*\bar{a}_1\bar{A}_1^* \ldots \bar{a}_n\bar{A}_n^*$ (over $\mathbb{A}_\perp^k$) is $\perp$-*consistent* if and only if every non-empty $\bar{A}_i$ is $\perp$-consistent and the sequence $\tau(\bar{A}_0), \tau(\bar{a}_1), \tau(\bar{A}_1), \ldots, \tau(\bar{a}_n), \tau(\bar{A}_n)$ is $\subseteq$-increasing (where the term $\tau(\bar{A}_i)$ is skipped if $\bar{A}_i = \emptyset$).

We denote by $\bar{\mathcal{P}}$ the set of all $\perp$-*consistent polynomials*, that is, of finite unions of $\perp$-consistent monomials. The following statement follows directly from this definition.

▶ **Lemma 20.** *Let $L = \bar{A}_0^*\bar{a}_1\bar{A}_1^* \ldots \bar{a}_n\bar{A}_n^*$ be an $\mathbb{A}_\perp^k$-monomial. Then $L \subseteq SW_k$ if and only if $L \in \bar{\mathcal{P}}$. Moreover, if L is $\perp$-consistent and $S \subseteq \{1,\ldots,k\}$, then $\pi_S(L)$ is a $\perp$-consistent monomial as well.*

We can now proceed with the proof of Theorem 7. We first show that a $\mathbf{\Sigma}_2[\sigma]$-definable k-ary relation R satisfies $L_R \in \bar{\mathcal{P}}$. Indeed, without loss of generality, R is defined by a $\mathbf{\Sigma}_2[\sigma]$-formula φ with free variables $S = \{z_1,\ldots,z_k\}$, of the form $\varphi = \exists x_1 \ldots \exists x_n\ \psi(x_1,\ldots,x_n,z_1,\ldots,z_k)$, with $\psi \in \mathbf{\Pi}_1[\sigma]$. In particular, $\|\psi\|$ is a $(n+k)$-ary relation and $R = \pi_S(\|\psi\|)$. Lemmas 20 and 21 therefore establish that $L_R \in \bar{\mathcal{P}}$.

▶ **Lemma 21.** *If $R \in \|\mathbf{\Pi}_1[\sigma]\|$ then $L_R \in \bar{\mathcal{P}}$.*

Proof. Since $R \in \|\mathbf{\Pi}_1[\sigma]\|$, it is the complement of a $\mathbf{\Sigma}_1[\sigma]$-definable relation. By Corollary 6, we have $L_R = SW_k \setminus {\uparrow_{\mathsf{s}}}\mathcal{S}$ for some finite set $\mathcal{S}$. Since $\bar{\mathcal{P}}$ is closed under intersection (see Remark 19), we only need to show that $SW_k \setminus {\uparrow_{\mathsf{s}}}\bar{w} \in \bar{\mathcal{P}}$ for a single synchronized word $\bar{w}$.

Let $\bar{T} = (T_1,\ldots,T_n) = \mathsf{type\text{-}seq}(\bar{w})$. By Lemma 1, we see that $\bar{u} \in L_R$ if and only either (1) $\bar{T} \not\sqsubseteq \mathsf{type\text{-}seq}(\bar{u})$, or (2) $\bar{T} \sqsubseteq \mathsf{type\text{-}seq}(\bar{u})$, with witness function t and $\bar{w}_i \not\sqsubseteq \bar{u}_{t(i)}$ for some $1 \leq i \leq n$ or, (3) again $\bar{T} \sqsubseteq \mathsf{type\text{-}seq}(\bar{u})$ with witness t, where $\bar{w}_i$ and $\bar{u}_{t(i)}$ do not have the same last letter for some i such that T_i is an end-type for $\bar{w}$.

The first condition means that $\bar{u} \in \bigcup K(\bar{T}')$, where the union runs over type sequences $\bar{T}'$ such that $\bar{T} \not\sqsubseteq \bar{T}'$. We saw in Section 2 that this union is in $\bar{\mathcal{P}}$. The second condition places $\bar{u}$ in $C_i = \mathbb{A}_{-,T_1}\mathbb{A}_{T_1}^* \cdots \mathbb{A}_{T_{i-2},T_{i-1}}\mathbb{A}_{T_{i-1}}^*\ L_i\ \mathbb{A}_{T_i,T_{i+1}}\mathbb{A}_{T_{i+1}}^* \cdots \mathbb{A}_{T_{n-1},T_n}\mathbb{A}_{T_n}^*$, where L_i is the set of words in $\mathbb{A}_{T_i-1T_i}\mathbb{A}_{T_i}^*$ that do not have $\bar{w}_i$ as a subword. Then L_i is $\mathbf{\Pi}_1[<]$-, and hence $\mathbf{\Sigma}_2[<]$-definable. As a consequence, $L_i \in \bar{\mathcal{P}}$ and, by associativity, $C_i \in \bar{\mathcal{P}}$. Finally, the third condition places $\bar{u}$ in $C_i' = \mathbb{A}_{-,T_1}\mathbb{A}_{T_1}^* \cdots \mathbb{A}_{T_{i-2},T_{i-1}}\mathbb{A}_{T_{i-1}}^*\ L_i'\ \mathbb{A}_{T_i,T_{i+1}}\mathbb{A}_{T_{i+1}}^* \cdots \mathbb{A}_{T_{n-1},T_n}\mathbb{A}_{T_n}^*$, where $L_i' = (\mathbb{A}_{T_i} \setminus \mathbb{A}_{T_{i-1}})\mathbb{A}_{T_i}^* \cap \mathbb{A}_{T_i}^* B_i$, with B_i the set of letters of $\mathbb{A}_{T_i}$ different from the last letter of $\bar{w}_i$. Here too, $L_i' \in \bar{\mathcal{P}}$ and hence $C_i' \in \bar{\mathcal{P}}$. ◀

The following lemma then concludes the proof of Theorem 7.

▶ **Lemma 22.** *If R is a relation such that L_R is a $\perp$-consistent polynomial, then $R \in \|\mathbf{\Sigma}_2[\sigma]\|$.*

Proof. By definition of $\bar{\mathcal{P}}$, the proof reduces to the case where L_R is a $\perp$-consistent monomial, say $L_R = \bar{A}_0^*\bar{a}_1\bar{A}_1^* \cdots \bar{a}_n\bar{A}_n^*$. We now construct a $\mathbf{\Sigma}_2[\sigma]$-formula φ, with set of free variables $Z = \{z_1,\ldots,z_k\}$, which defines R.

Let $w_1,\ldots,w_k \in \mathbb{A}^*$ be such that $\bar{w} = w_1 \otimes \cdots \otimes w_k = \bar{a}_1 \cdots \bar{a}_n$ (they exist due to $\perp$-consistency). Let $X = \{x_{i,j} : 1 \leq i \leq k, 1 \leq j \leq |w_i|\}$ and $Y = \{y_1,\ldots,y_k\}$ be sets of variables. We first let $\psi_1(X,Z)$ be the conjunction of the following formulæ for $1 \leq i \leq k$:

(1) for every $1 \leq j < |w_i|$: $x_{i,j} \prec x_{i,j+1}$; (2) $x_{i,|w_i|} \preceq z_i$; (3) for every $1 \leq j \leq |w_i|$: $\ell_{w_i[j]}(x_{i,j})$; (4) for every $1 \leq i' \leq k$ and $j \leq \min\{|w_i|, |w_{i'}|\}$: $\mathsf{eq}(x_{i,j}, x_{i',j})$. Notice that $\bar{u} \in SW_k$ satisfies $\exists X\ \psi_1(X, Z)$ if and only if $\bar{w}$ is a subword of $\bar{x}$ with witness function given by $p(j) = |x_{h,j}|$ for any $1 \leq h \leq k$.

The variables in Y are meant to represent the k components of a prefix of $\bar{u}$, which is expressed by $\psi_2(X, Y)$, the disjunction over all subsets H of $\{1, \ldots, k\}$ (H represents the components of $\bar{u}$ which are shorter than that prefix) of the formulæ

$$\bigwedge_{h \in H} (y_h \preceq z_h \wedge \mathsf{eq}(y_h, z_h)) \wedge \bigwedge_{h, i \notin H} (y_h \prec z_h) \wedge \mathsf{eq}(y_h, y_i)) \wedge \bigwedge_{h \in H, i \notin H} \exists r (r \preceq y_i \wedge \mathsf{eq}(r, y_h)).$$

Next, for $\bar{a} \in \mathbb{A}_{\perp}^{k}$ and $\bar{A} \subseteq \mathbb{A}_{\perp}^{k}$, and recalling that $\tau(\bar{a}) = \{h : \pi_h(\bar{a}) = \perp\}$, we define $\psi_{\bar{a}}(Y) = \bigwedge_{h \notin \tau(\bar{a})} \ell_{\pi_h(\bar{a})}(y_h)$ and $\psi_{\bar{A}}(Y) = \bigvee_{\bar{a} \in \bar{A}} \psi_{\bar{a}}(Y)$. Once $\bar{y}$ is a prefix of $\bar{u}$ and $\bar{w}$ is a subword of $\bar{u}$ with witness function p, if for some $1 \leq j \leq n$, we have $|\bar{y}| = p(j)$, then $\bar{y}$ satisfies $\psi_{\bar{a}_j}$. We now only need to verify that if $|\bar{y}|$ sits between $p(j)$ and $p(j+1)$ (for some $0 \leq j \leq n$), then $\bar{y}$ satisfies $\psi_{\bar{A}_j}$. This is done by the formula $\psi_3(X, Y) = \bigwedge_{j=0}^{n} \chi_j$, where $\chi_0(X, Y) = \left(\bigwedge_{h \notin \tau(\bar{A}_0)} y_h \prec x_{h,1}\right) \to \psi_{\bar{A}_0}(Y)$, $\chi_n(X, Y) = \left(\bigwedge_{h \notin \tau(\bar{A}_n)} x_{h,n} \prec y_h\right) \to \psi_{\bar{A}_n}(Y)$, and for every $0 < j < n$,

$$\chi_j(X, Y) = \left(\bigwedge_{h \notin \tau(\bar{A}_j)} (x_{h,j} \prec y_h) \wedge (y_h \prec x_{h,j+1}) \right) \to \psi_{\bar{A}_j}(Y).$$

Finally, R is defined by the $\mathbf{\Sigma}_2[\sigma]$ formula $\varphi(Z) = \exists X \psi_1(X, Z) \wedge \forall Y\ (\psi_2(X, Y) \wedge \psi_3(X, Y))$. ◀

Abstract

Term modal logics (TML) are modal logics with unboundedly many modalities, with quantification over modal indices, so that we can have formulas of the form $\exists y \forall x\ (\Box_x P(x, y) \supset \Diamond_y P(y, x))$. Like First order modal logic, TML is also "notoriously" undecidable, in the sense that even very simple fragments are undecidable. In this paper, we show the decidability of one interesting fragment, that of two variable TML. This is in contrast to two-variable First order modal logic, which is undecidable.

1 Introduction

Propositional multi-modal logics (ML) are extensively used in many areas of computer science and artifical intelligence ([2, 9]). ML is built upon propositional logic by adding modal operators $\Box_i$ and $\Diamond_i$ for every index i in a fixed finite set Ag which is often interpreted as a set of agents (or reasoners). Typically, the satisfiability problem is decidable for most instances of ML.

A natural question arises when we wish the set of modalities to be unbounded. This is motivated by a range of applications such as client-server systems, dynamic networks of processes, games with unboundedly many players, etc. In such systems, the number of agents is not fixed a priori. For some cases, the agent set can vary not only across models, but also from state to state (ex. when new clients enter the system or old clients exit the system).

Term Modal logic (TML) introduced by Fitting, Voronkov and Thalmann [6] addresses this requirement. TML is built upon first order logic, but the variables now range over modalities: so we can index the modality by terms ($\Box_x \alpha$) and these terms can be quantified over. State assertions describe properties of these "agents". Thus we can write formulas of the form: $\forall x(\Box_x P(x) \supset \exists y\ \Box_y \Diamond_x R(x, y))$. In [15] we have advocated PTML, the propositional fragment of TML, as a suitable logical language for reasoning about systems with unboundedly many agents. TML has been studied in dynamic epistemic contexts in [11] and in modelling situations where the identity of agents is not common knowledge among the agents [22].

The following examples illustrate the flavour of properties that can be expressed in TML.

- For every agent x there is some agent y such that $P(x,y)$ holds at all x-successors or there is some y-successor where $\neg P(x,y)$ holds.
  $\forall x \exists y\ \big(\Box_x P(x,y) \vee \Diamond_y(\neg P(x,y))\big)$
- Every agent of type A has a successor where some agent of type B exists.
  $\forall x\big(A(x) \supset \Diamond_x \exists y\ B(y)\big)$.
- There is some agent x such that for all agents y if there are no y successors then in all successors of x, there is a y successor.
  $\exists x \forall y\ \big(\Box_y \bot \supset \Box_x \Diamond_y \top\big)$.

Since TML contains first order logic, its satisfiability is clearly undecidable. We are then led to ask: can we build term modal logics over decidable fragments of first order logic? Natural candidates are the monadic fragment, the two-variable fragment and the guarded fragment [13, 1].

TML itself can be seen as a fragment of first order modal logic (FOML) [5] which is built upon first order logic by adding modal operators. There is a natural translation of TML into FOML by inductively translating $\Box_x \alpha$ into $\Box(P(x) \supset \alpha)$ and $\Diamond_x \alpha$ into $\Diamond(P(x) \wedge \alpha)$ to get an equi-satisfiable formula, where P is a new unary predicate. Sadly, this does not help much, since FOML is notorious for undecidability. The modal extension of many simple decidable fragments of first order logic become undecidable. For instance, the monadic fragment[12] or the two variable fragment [10] of FOML are undecidable. In fact FOML with two variables and a single unary predicate is already undecidable [18]. Analogously, in [15] we show that the satisfiability problem for TML is undecidable even when the atoms are restricted to propositions. In the presence of equality (even without propositions), this result can be further strengthened to show "Trakhtenbrot" like theorem of mutual recursive inseparability.

On the other hand, as we show in [15], the monodic fragment of PTML (the propositional fragment) is decidable (a formula φ is monodic if each of its modal subformulas of the form $\Box_x \psi$ or $\Diamond_x \psi$ has a restriction that the free variables of ψ is contained in $\{x\}$). Further, via the FOML translation above, we can show that the monodic restriction of TML based on the guarded fragment of first order logic and monadic first order logic are decidable [23].

In a different direction, Wang ([21]) considered a fragment of FOML in which modalities and quantifiers are bound to each other. In particular he considered the fragment with $\exists\Box$ and showed it to be decidable in PSPACE. In [17] it is proved that this technique of bundling quantifiers and modalities gives us interesting decidable fragments of FOML, and as a corollary, the bundled fragment of TML is decidable where quantifiers and modalities always occur in bundled form: $\forall x \Box_x \alpha, \exists x \Box_x \alpha$ and their duals. However, more general bundled fragments of TML (such as those based on the guarded fragment of first order logic) have been shown to be decidable by Orlandelli and Corsi ([14]), and by Shtakser ([19]). From all these results, it is clear that the one variable fragment of TML is decidable, and that the three variable fragment of PTML is undecidable.

In this paper, we show that the two variable fragment of TML (TML^2) is decidable. This is in contrast with FOML, for which the two variable fragment is undecidable [10]. Quoting Wolter and Zakharyaschev from [23], where they discuss the root of undecidability of FOML fragments:

> All undecidability proofs of modal predicate logics exploit formulas of the form $\Box\ \psi(x,y)$ in which the necessity operator applies to subformulas of more than one free variable; in fact, such formulas play an essential role in the reduction of undecidable problems to those fragments ...

Note that this is not expressible in TML^2 where there is no "free" modality; every modality is bound an index (x or y). With a third variable z, we could indeed encode $\Box P(x,y)$ as $\forall z \Box_z P(x,y)$, but we do not have it. The decidability of the two variable fragment of TML, *without constants or equality*, hinges crucially on this lack of expressiveness. Thus, TML^2 provides a decidable fragment of FOML^2. From FO^2 view point, Gradel and Otto[8] show that most of the natural extensions of FO^2 (like transitive closure, lfp) are undecidable except for the counting quantifiers. In this sense, 2-variable TML can be seen as another rare extension of FO^2 that still remains decidable. Note that in this paper we consider the two variable fragment of TML without the bundling or guarded or monodic restriction. Also, there is no natural translation of two variable TML to any known decidable fragment of FO such as the two variable fragment of FO with 2 equivalence relations etc (cf [20]).

Thus, the contribution of this paper is technical, mainly in the identification of a decidable fragment of TML. As is standard with two variable logics, we first introduce a normal form which is a combination of Fine's normal form for modal logics ([4]) and the Scott normal form ([7]) for FO^2. We then prove a bounded agent property using an argument that can be construed as modal depth induction over the "classical" bounded model construction for FO^2.

2 TML syntax and semantics

We consider relational vocabulary with no constants or function symbols, and without equality.

▶ **Definition 1** (TML syntax). *Given a countable set of variables* Var *and a countable set of predicate symbols $\mathcal{P}$, the syntax of* TML *is defined as follows:*

$$\varphi ::= P(\overline{x}) \mid \neg\varphi \mid (\varphi \wedge \varphi) \mid (\varphi \vee \varphi) \mid \exists x\ \varphi \mid \forall x\ \varphi \mid \Box_x\varphi \mid \Diamond_x\varphi$$

where $x \in$ Var, $\overline{x}$ is a vector of length n over Var and $P \in \mathcal{P}$ of arity n.

The *free* and *bound* occurrences of variables are defined as in FO with $\mathsf{Fv}(\Box_x\varphi) = \mathsf{Fv}(\varphi) \cup \{x\}$. We write $\varphi(\overline{x})$ if all the free variables in φ are included in $\overline{x}$. Given a TML formula φ and $x, y \in \mathsf{Var}$, if $y \notin \mathsf{Fv}(\varphi)$ then we write $\varphi[y/x]$ for the formula obtained by replacing every occurrence of x by y in φ. A formula φ is called a *sentence* if $\mathsf{Fv}(\varphi) = \emptyset$. The notion of modal depth of a formula φ (denoted by $\mathsf{md}(\varphi)$) is also standard, which is simply the maximum number of nested modalities occurring in φ. The length of a formula φ is denoted by $|\varphi|$ and is simply the number of symbols occurring in φ.

In the semantics, the number of accessibility relations is not fixed, but specified along with the structure. Thus the Kripke frame for TML is given by (W, D, R) where W is a set of worlds, D is the potential set of agents and $R \subseteq (W \times D \times W)$. The agent dynamics is captured by a function ($\delta : W \to 2^D$ below) that specifies, at any world w, the set of agents *live* (or meaningful) at w. The condition that whenever $(u, d, v) \in R$, we have that $d \in \delta(u)$ ensures only an agent alive at u can consider v accessible.

A *monotonicity* condition is imposed on the accessibility relation as well: whenever $(u, d, v) \in R$, we have that $\delta(u) \subseteq \delta(v)$. This is required to handle interpretations of free variables (cf [3, 6, 5]). Hence the models are called "increasing agent" models.

▶ **Definition 2** (TML structure). *An increasing agent model for* TML *is defined as the tuple $M = (W, D, \delta, R, \rho)$ where W is a non-empty countable set of worlds, D is a non-empty countable set of agents, $R \subseteq (W \times D \times W)$ and $\delta : W \to 2^D$. The map δ assigns to each $w \in W$ a non-empty local domain such that whenever $(w, d, v) \in R$ we have $d \in \delta(w) \subseteq \delta(v)$ and $\rho : (W \times \mathcal{P}) \to \bigcup_{n\in\omega} 2^{D^n}$ is the valuation function where for all $P \in \mathcal{P}$ of arity n we have $\rho(w, P) \subseteq [\delta(w)]^n$.*

For a given model M, we use $W^M, D^M, \delta^M, R^M, \rho^M$ to refer to the corresponding components. We drop the superscript when M is clear from the context. We often write D_w for $\delta(w)$. A *constant agent* model is one where $D_w = D$ for all $w \in W$. To interpret free variables, we need a variable assignment $\sigma : \mathsf{Var} \to D$. Call σ *relevant* at $w \in W$ if $\sigma(x) \in \delta(w)$ for all $x \in \mathsf{Var}$. The increasing agent condition ensures that if σ is relevant at w and $(w, d, v) \in R$ then σ is relevant at v as well. In a constant agent model, every assignment σ is relevant at all the worlds.

▶ **Definition 3** (TML semantics). *Given a* TML *structure $M = (W, D, \delta, R, \rho)$ and a* TML *formula φ, for all $w \in W$ and σ relevant at w, define $M, w, \sigma \vDash \varphi$ inductively as follows:*

$M, w, \sigma \vDash P(x_1, \ldots, x_n)$	$\Leftrightarrow$	$(\sigma(x_1), \ldots, \sigma(x_n)) \in \rho(w, P)$
$M, w, \sigma \vDash \neg\varphi$	$\Leftrightarrow$	$M, w, \sigma \nvDash \varphi$
$M, w, \sigma \vDash (\varphi \wedge \psi)$	$\Leftrightarrow$	$M, w, \sigma \vDash \varphi$ *and* $M, w, \sigma \vDash \psi$
$M, w, \sigma \vDash \exists x\ \varphi$	$\Leftrightarrow$	*there is some* $d \in \delta(w)$ *such that* $M,\ w,\ \sigma_{[x \mapsto d]} \vDash \varphi$
$M, w, \sigma \vDash \Box_x\ \varphi$	$\Leftrightarrow$	$M, v, \sigma \vDash \varphi$ *for all* v *s.t.* $(w, \sigma(x), v) \in R$

where $\sigma_{[x \mapsto d]}$ denotes another assignment that is the same as σ except for mapping x to d.

The semantics for $\varphi \vee \psi, \forall x\ \varphi$ and $\Diamond_x\ \varphi$ are defined analogously. Note that $M, w, \sigma \vDash \varphi$ is inductively defined only when σ is relevant at w. We often abuse notation and say “for all w and for all interpretations σ”, when we mean “for all w and for all interpretations σ relevant at w” (and we will ensure that relevant σ are used in proofs). In general, when considering the truth of φ in a model, it suffices to consider $\sigma : \mathsf{Fv}(\varphi) \mapsto D$, assignment restricted to the variables occurring free in φ. When $\mathsf{Fv}(\varphi) \subseteq \{x_1, \ldots, x_n\}$ and $\overline{d} \in [D_w]^n$ is a vector of length n over D_w, we write $M, w \vDash \varphi[\overline{d}]$ to denote $M, w, \sigma \vDash \varphi(\overline{x})$ where for all $i \leq n,\ \sigma(x_i) = d_i$. When φ is a sentence, we simply write $M, w \models \varphi$. A formula φ is *valid*, if φ is true in all models M at all w for all interpretations σ (relevant at w). A formula φ is *satisfiable* if $\neg\varphi$ is not valid.

Now we take up the satisfiability problem which is the central theme of this paper. First we observe that the satisfiability problem is equally hard for constant and increasing agent models for TML.

▶ **Proposition 4.** *For any* TML *formula φ, there is a corresponding formula $\hat{\varphi} \in$* TML *such that φ is satisfiable in an increasing agent model with agent set D iff $\hat{\varphi}$ is satisfiable in a constant agent model with agent set D.*

To see why the proposition is true, if φ is satisfiable in an increasing agent model, then we can turn the model into constant agent model as follows. We introduce a new unary predicate E and ensure that $E(d)$ is true at w if d is a member of $\delta(w)$ in the given increasing agent model. But now, all quantifications have to be relativized with respect to the new predicate E. Thus, the syntactic translation is defined as follows:

▶ **Definition 5.** *Let φ be any* TML *formula amd let E be a new unary predicate not occurring in φ. The translation is defined inductively as follows:*

- $\mathit{Tr}_1(P(x_1, \ldots, x_n)) = P(x_1, \ldots, x_n)$
- $\mathit{Tr}_1(\neg\varphi) = \neg\mathit{Tr}_1(\varphi)$ *and* $\mathit{Tr}_1(\varphi \wedge \psi) = \mathit{Tr}_1(\varphi) \wedge \mathit{Tr}_1(\psi)$
- $\mathit{Tr}_1(\Box_x\varphi) = \Box_x(\mathit{Tr}_1(\varphi))$
- $\mathit{Tr}_1(\exists x\ \varphi) = \exists x\ (E(x) \wedge \mathit{Tr}_1(\varphi))$

With this translation, we also need to ensure that the predicate E respects monotonicity. Hence we have $\gamma_\varphi = \bigwedge\limits_{i+j \leq \mathsf{md}(\varphi)} (\forall y \Box_y)^i \big(\forall x\ E(x) \supset (\forall y \Box_y)^j E(x)\big)$. Now, we can prove that φ is satisfiable in an increasing model M with agent set D iff $\mathsf{Tr}_1(\varphi) \wedge \gamma_\varphi$ is satisfiable in a constant agent model M' with agent set D. This translation is similar in approach to the one for FOML[23]. The formal proof of Prop. 4 is provided in [16].

The propositional term modal logic (PTML) is a fragment of TML where the atoms are restricted to propositions. Note that the variables still appear as index of modalities. For PTML, the valuation function can be simply written as $\rho : W \mapsto 2^{\mathcal{P}}$ where $\mathcal{P}$ is the set of propositions. Now we prove that the satisfiability problem for PTML is as hard as that for TML.

▶ **Proposition 6.** *Any* TML *formula* φ *has a corresponding formula* $\hat{\varphi} \in$ PTML*, such that* φ *is satisfiable in an increasing (constant) agent model with agent set* D *iff* $\hat{\varphi}$ *is satisfiable in an increasing (constant) agent model with agent set* D*.*

The reduction is based on the translation of an arbitrary atomic predicate $P(x_1, \ldots, x_n)$ to $\Diamond_{x_1} \ldots \Diamond_{x_n} p$ where p is a new proposition which represents the predicate P. However, this cannot be used always[1]. Thus, we use a new proposition q, to distinguish the "real worlds" from the ones that are added because of the translation. But now, the modal formulas have to be relativized with respect to the proposition q. The formal translation is given as follows:

▶ **Definition 7.** *Let* φ *be any* TML *formula where* $P_1, \ldots, P_k$ *are the predicates that occur in* φ*. Let* $\{p_1, \ldots, p_n\} \cup \{q\}$ *be a new set of propositions not occurring in* φ*. The translation with respect to* q *is defined inductively as follows:*

- $Tr_2(P_i(x_1, \ldots, x_n); q) = \Diamond_{x_1}(\neg q \wedge \Diamond_{x_2}(\ldots \neg q \wedge \Diamond_{x_n}(\neg q \wedge p_i)\ldots))$
- $Tr_2(\neg\varphi; q) = \neg Tr_2(\varphi; q)$ *and* $Tr_2(\varphi \wedge \psi; q) = Tr_2(\varphi; q) \wedge Tr_2(\psi; q)$
- $Tr_2(\Box_x \varphi; q) = \Box_x(q \supset Tr_2(\varphi; q))$
- $Tr_2(\exists x\ \varphi; q) = \exists x\ Tr_2(\varphi; q)$

Using this translation, we can prove that φ is satisfiable iff $q \wedge \mathsf{Tr}_2(\varphi; q)$ is satisfiable, over the same D. The proof details of Prop 6 are given in [16].

3 Two variable fragment

Note that all the examples discussed in the introduction section use only 2 variables. Thus, TML can express interesting properties even when restricted to two variables. We now consider the satisfiability problem of TML^2. The translation in Def. 7 preserves the number of variables. Therefore it suffices to consider the satisfiability problem for the two variable fragment of PTML.

Let PTML^2 denote the two variable fragment of PTML. We first consider a normal form for the logic. In [4], Fine introduces a normal form for propositional modal logics which is a disjunctive normal form (DNF) with every clause of the form $(\bigwedge\limits_i (s_i) \wedge \Box\alpha \wedge \bigwedge\limits_j \Diamond\beta_j)$ where s_i are literals and α, β_j are again in the normal form. For FO^2, we have Scott normal form [7] where every FO^2 sentence has an equi-satisfiable formula of the form $\forall x \forall y\ \varphi \wedge \bigwedge\limits_i \forall x \exists y\ \psi_i$ where φ and ψ_i are all quantifier free. For PTML^2, we introduce a combination of these two

[1] for instance, this translation will not work for the formula $\exists x\ P(x) \wedge \forall y\ \Box_y \bot$

normal forms, which we call the *Fine Scott Normal form* given by a DNF, where every clause is of the form:

$$\bigwedge_{i\leq a} s_i \wedge \bigwedge_{z\in\{x,y\}} (\Box_z\alpha \wedge \bigwedge_{j\leq m_z} \Diamond_z\beta_j) \wedge \bigwedge_{z\in\{x,y\}} (\forall z\ \gamma \wedge \bigwedge_{k\leq n_z} \exists z\ \delta_k) \wedge \forall x\forall y\ \varphi \wedge \bigwedge_{l\leq b} \forall x\exists y\ \psi_l$$

where $a, m_x, m_y, n_x, n_y, b \geq 0$ and s_i denotes literals. Further, α, β_j are recursively in the normal form and $\gamma, \delta_k, \varphi, \psi_l$ do not have quantifiers at the outermost level and all modal subformulas occurring in these formulas are (recursively) in the normal form. The normal form is formally defined in the next subsection.

Note that the first two conjuncts mimic the modal normal form and the last two conjuncts mimic the FO^2 normal form. The additional conjuncts handle the intermediate step where only one of the variable is quantified and the other is free.

We now formally define the normal form and prove that every PTML^2 formula has a corresponding equi-satisfiable formula in the normal form. After this we prove the bounded agent property for formulas in the normal form using an inductive FO^2 type model construction.

3.1 Normal form

We use $\{x, y\} \subseteq \mathsf{Var}$ as the two variables of PTML^2. We use z to refer to either x or y and refer to variables z_1, z_2 to indicate the variables x, y in either order. We use Δ_z to denote any modal operator $\Delta \in \{\Box, \Diamond\}$ and $z \in \{x, y\}$. A literal is either a proposition or its negation. Also, we assume that the formulas are given in negation normal form(NNF) where the negations are pushed in to the literals.

▶ **Definition 8** (FSNF normal form). *We define the following terms to introduce the* Fine Scott normal form *(FSNF) for* PTML^2*:*

- *A formula φ is a module if φ is a literal or φ is of the form $\Delta_z\alpha$.*
- *For any formula φ, the outer most components of φ given by $\mathsf{C}(\varphi)$ is defined inductively where for any φ which is a module, $\mathsf{C}(\varphi) = \{\varphi\}$ and $\mathsf{C}(Qz\ \varphi) = \{Qz\ \varphi\}$ where $z \in \{x, y\}$ and $Q \in \{\forall, \exists\}$. Finally $\mathsf{C}(\varphi \odot \psi) = \mathsf{C}(\varphi) \cup \mathsf{C}(\psi)$ where $\odot \in \{\wedge, \vee\}$.*
- *A formula φ is quantifier-safe if every $\psi \in \mathsf{C}(\varphi)$ is a module.*
- *We define Fine Scott normal form(FSNF) normal form (*DNF *and conjunctions) inductively as follows:*
  - *Any conjunction of literals is an FSNF conjunction.*
  - *φ is said to be in FSNF* DNF *if φ is a disjunction where every clause is an FSNF conjunction.*
  - *Suppose φ is quantifier-safe and for every $\Delta_z\psi \in \mathsf{C}(\varphi)$ if ψ is in FSNF* DNF *normal form then we call φ a quantifier-safe normal formula.*
  - *Let $a, b, m_x, m_y, n_x, n_y \geq 0$.*
    Suppose $s_1, \ldots, s_a$ are literals, $\alpha^x, \alpha^y, \beta^x_1, \ldots, \beta^x_{m_x}, \beta^y_1, \ldots, \beta^y_{m_y}$ are formulas in FSNF DNF *and $\gamma^x, \gamma^y, \delta^x_1, \ldots, \delta^x_{n_x}, \delta^y_1, \ldots, \delta^y_{n_y}, \varphi, \psi_1, \ldots, \psi_b$ are quantifier-safe normal formulas then:*

$$\bigwedge_{i\leq a} s_i \wedge \bigwedge_{z\in\{x,y\}} (\Box_z\alpha^z \wedge \bigwedge_{j\leq m_z} \Diamond_z\beta^z_j) \wedge \bigwedge_{z_1\in\{x,y\}} (\forall z_2\ \gamma^{z_1} \wedge \bigwedge_{k\leq n_z} \exists z_2\ \delta^{z_1}_k) \wedge \forall x\forall y\ \varphi \wedge \bigwedge_{l\leq b} \forall x\exists y\ \psi_l$$

is an FSNF conjunction.

Quantifier-safe formulas are those in which no quantifiers occur outside the scope of modalities. Note that the superscripts in α^x, α^y etc only indicate which variable the formula is associated with, so that it simplifies the notation. For instance, α^x does not say anything about the free variables in α^x. In fact there is no restriction on free variables in any of these formulas.

Further, note that by setting the appropriate indices to 0, we can have FSNF conjunctions where one or more of the components corresponding to $s_i, \beta^x, \beta^y, \delta^x, \delta^y, \psi_l$ are absent. We also consider the conjunctions where one or more of the components corresponding to $\Box_x\alpha^x, \Box_y\alpha^y, \varphi$ are also absent. As we will see in the next lemma, for any sentence $\varphi \in \mathsf{PTML}^2$, we can obtain an equi-satisfiable sentence, which at the outer most level, is a DNF where every clause is of the form $\bigwedge_{i\leq a} s_i \ \wedge\ \forall x\forall y\ \varphi \wedge \bigwedge_{l\leq b} \forall x\exists y\ \psi_l$.

▶ **Lemma 9.** *For every formula $\varphi \in \mathsf{PTML}^2$ there is a corresponding formula ψ in FSNF* DNF *such that φ and ψ are equi-satisfiable.*

Proof (Sketch). To get the formula in the normal form, we introduce some new unary predicates in the intermediate steps and finally get rid of them using the translation in Def. 7. The proof essentially follows that of reducing an FO^2 formula into its equi-satisfiable Scott normal form.

For the given formula φ, first observe that we can get an equivalent DNF over $\mathsf{C}(\varphi)$ using propositional validities. If φ is modal free, then we can simply ignore the quantifiers, since valuations of propositions do not depend on the quantifiers and the agent set is always non-empty. Thus we get a propositional DNF by erasing the quantifiers and this is in the required form.

If φ contains modal formulas, then we need to reduce every clause of the DNF to an FSNF conjunction. We first translate the formulas at the outer most level to the required form. This is the classical Scott-normal form construction which can be obtained by introducing new unary predicates appropriately to get rid of the nested quantifiers at the outer most level. Then, using the translation in Def 7, we get an equi-satisfiable PTML formula after replacing the newly introduced unary predicates by corresponding propositional translations. Further, replace conjuncts of the form $\Box_z\alpha$ and $\Box_z\beta$ by $\Box_z(\alpha \wedge \beta)$ for $z \in \{x, y\}$ to obtain the resulting formula which has at most one subformula of the from $\Box_x\alpha^x$ and $\Box_y\alpha^y$.

Note that after this translation, the resulting formula is in the required form at the outermost level. We now only need to repeat the entire process for every sub-formula inside the scope of modalities. The lemma is formally proved in [16]. ◀

Since we repeatedly convert the formula into DNF (inside the scope of every modality), if we start with a formula of length n, the final translated formula has length $2^{O(n^2)}$. However, observe that the number of modules in the translated formula is linear in the size of the given formula φ. Furthermore, the given formula is satisfiable in a model M iff the translation is satisfiable in M with appropriate modification of the ρ (valuation function).

3.2 Bounded agent property

Now we prove that any formula $\theta \in \mathsf{PTML}^2$ in FSNF DNF is satisfiable iff θ is satisfiable in a model M where the size of D is bounded. Note that for any PTML formula θ, if $M, w, \sigma \models \theta$ then $M^T, w, \sigma \models \theta$ where M^T is the standard tree unravelling of M with w as root [15]. Further, M^T can be restricted to be of height at most $\mathsf{md}(\theta)$. Hence, we restrict our attention to tree models of finite depth.

First we define the notion of types for agents at every world. In classical FO^2 the 2-types are defined on atomic predicates. In PTML^2 we need to define the types with respect to $\mathsf{modules}$. In any given tree model M rooted at r, for any $w \in W$ and $c, d \in D_w$ the $\mathsf{2\text{-}type}$ of (c, d) at w is simply the set of all $\mathsf{modules}$ that are true at w where the two variables are assigned c, d in either order. The $\mathsf{1\text{-}type}$ of c at w includes the set of all $\mathsf{modules}$ that are true at w when both x, y are assigned c. Further, for every non-root node w, suppose $(w' \xrightarrow{a} w)$ then the $\mathsf{1\text{-}type}$ of any $c \in D_w$ should capture how c behaves with respect to a and the $\mathsf{1\text{-}type}(w, c)$ should also include the information of how c acts with respect to d, for every $d \in D_w$. Thus the $\mathsf{1\text{-}type}$ of c at w is given by a 3-tuple where the first component is the set of all $\mathsf{modules}$ that are true when both x, y are assigned c, the second component captures how c behaves with respect to the incoming edge of w and the third component is a set of subsets of formulas such that for each $d \in D_w$ there is a corresponding subset of formulas capturing the $\mathsf{2\text{-}type}$ of c, d. To ensure that the type definition also carries the information of the height of the world w, if w is at height h then we restrict $\mathsf{1\text{-}type}$ and $\mathsf{2\text{-}type}$ at w to $\mathsf{modules}$ of modal depth at most $\mathsf{md}(\varphi) - h$.

For any formula φ, let $\mathsf{SF}(\varphi)$ be the set of all subformulas of φ closed under negation. We always assume[2] that $\top \in \mathsf{SF}(\varphi)$. Let $\mathsf{SF}^h(\varphi) \subseteq \mathsf{SF}(\varphi)$ be the set of all subformulas of modal depth at most $\mathsf{md}(\varphi) - h$. Thus we have $\mathsf{SF}(\varphi) = \mathsf{SF}^0(\varphi) \supseteq \mathsf{SF}^1(\varphi) \supseteq \ldots \supseteq \mathsf{SF}^{\mathsf{md}(\varphi)}(\varphi)$.

▶ **Definition 10** (PTML type). *For any* PTML^2 *formula* φ *and for any tree model* M *rooted at* r *with height at most* $\mathsf{md}(\varphi)$*, for all* $w \in W$ *at height* h*:*

- *For all* $c, d \in \delta(w)$*, define* 2-type$(w, c, d) = (\Gamma_{xy}; \Gamma_{yx})$ *where* $\Gamma_{xy} = \{\psi(x, y) \in \mathsf{SF}^h(\varphi) \mid M, w \models \psi(c, d)\}$ *and* $\Gamma_{yx} = \{\psi(x, y) \in \mathsf{SF}^h(\varphi) \mid M, w \models \psi(d, c)\}$.
- *If* w *is a non root node, (say* $w' \xrightarrow{a} w$*) then for all* $c \in \delta(w)$ *define* $1\text{-}\mathsf{type}(w, c) = (\Lambda_1; \Lambda_2; \Lambda_3)$ *where* $\Lambda_1 = 2\text{-}\mathsf{type}(w, c, c)$ *and* $\Lambda_2 = 2\text{-}\mathsf{type}(w, c, a)$ *and* $\Lambda_3 = \{2\text{-}\mathsf{type}(w, c, d) \mid d \in \delta(w)\}$.
- *For the root node* r*, for all* $c \in \delta(r)$ *define* $1\text{-}\mathsf{type}(w, c) = (\Lambda_1; \{\top\}; \Lambda_3)$ *where* $\Lambda_1 = 2\text{-}\mathsf{type}(w, c, c)$ *and* $\Lambda_3 = \{2\text{-}\mathsf{type}(w, c, d) \mid d \in \delta(w)\}$.

The second component of $\mathsf{1\text{-}type}(r, c)$ is added to maintain uniformity. For all $w \in W$ define $\mathsf{1\text{-}type}(w) = \{\mathsf{1\text{-}type}(w, c) \mid c \in D_w\}$ and $\mathsf{2\text{-}type}(w) = \{\mathsf{2\text{-}type}(w, c, d) \mid c, d \in D_w\}$. We use Λ, Π to represent elements of $\mathsf{1\text{-}type}(w)$ and Λ_1, Π_2 etc for the respective components.

If a formula θ is satisfiable in a tree model, the strategy is to inductively come up with bounded agent models for every subtree of the given tree (based on types), starting from leaves to the root. While doing this, when we add new type based agents to a world at height h, to maintain monotonicity, we need to propagate the newly added agents throughout its descendants. For this, we define the notion of extending any tree model by addition of some new set of agents.

Suppose in a tree model M, world w has local agent set D_w and we want to extend D_w to $D_w \cup C$, then first we have $\Omega : C \mapsto D_w$ which assigns every new agent to some already existing agent. The intended meaning is that the newly added agent $c \in C$ at w mimics the "type" of $\Omega(c)$. If w is a leaf node, we can simply extend $\delta(w)$ to $D_w \cup C$. If w is at some arbitrary height, along with *adding the new agents to the live agent set* to w, we also need to create successors for every $c \in C$, one for each successor subtree of $\Omega(c)$ and inductively add C to all the successor subtrees.

[2] Let p_0 be some proposition occurring in φ, then $\top$ is defined as $p_0 \vee \neg p_0$.

▶ **Definition 11** (Model extension). *Suppose M is a tree model rooted at r with finite agent set D and for every $w \in W$ let M^w be the subtree rooted at w. Let C be some finite set such that $C \cap D = \emptyset$ and for any $w \in W$ let $\Omega : C \mapsto D_w$ be a function mapping C to agent set live at w. Define the operation of "adding C to M^w guided by Ω" by induction on the height of w to obtain a new subtree rooted at w (denoted by $M^w_{(C,\Omega)}$ and the components denoted by δ', ρ' etc).*

- *If w is a leaf, then $M^w_{(C,\Omega)}$ is a tree with a single node w with new $\delta'(w) = \delta(w) \cup C$ and $\rho'(w) = \rho(w)$.*
- *If w is at height h then the new tree $M^w_{(C,\Omega)}$ is obtained from M^w rooted at w with new $\delta'(w) = \delta(w) \cup C$ and $\rho'(w) = \rho(w)$ and replacing all the subtrees M^u rooted at every successor u of w by $M^u_{(C,\Omega)}$. Furthermore, for every $c \in C$ and every $(w, \Omega(c), u) \in R$ create a new copy of $M^u_{(C,\Omega)}$ and rename its root as u^c and add an edge (w, c, u^c) to R'.*

Since we do not have *equality* in the language, this transformation will still continue to satisfy the same formulas.

▶ **Lemma 12.** *Let M be any tree model of finite depth rooted at r with finite agent set D and let $w \in W$. Let $M^w_{(C,\Omega)}$ (rooted at w) be an appropriate model extension of M^w (rooted at w). For any interpretation $\sigma : \mathsf{Var} \mapsto (C \cup D_w)$ let $\hat{\sigma} : \mathsf{Var} \mapsto D_w$ where $\hat{\sigma}(x) = \Omega(\sigma(x))$ if $\sigma(x) \in C$ and $\hat{\sigma}(x) = \sigma(x)$ if $\sigma(x) \in D_w$. Then for all $u \in W$ which is a descendant of w in M and for all $\sigma : \mathsf{Var} \mapsto (C \cup D_w)$ and for all* PTML *formula φ, we have $M^w_{(C,\Omega)}, u, \sigma \models \varphi$ iff $M, u, \hat{\sigma} \models \varphi$.*

To see why the lemma holds, first note that both models agree on literals since the valuation function remains the same. Further, since every new agent mimics some old agent, all the modal and the universal formulas continue to hold. Witnesses for $\exists$ formulas can still be picked from the old agent set (D_u). The lemma is formally proved in [16].

For any formula in the normal form, we use the same notations as in Def. 8. For a given formula $\theta \in \mathsf{PTML}^2$ in FSNF DNF form, let $\boldsymbol{\delta}^x_\theta = \{\exists y\ \delta^x \in \mathsf{SF}(\theta)\}$. Similarly we have $\boldsymbol{\delta}^y_\theta = \{\exists x\ \delta^y \in \mathsf{SF}(\theta)\}$ and $\boldsymbol{\psi}_\theta = \{\forall x \exists y\ \psi \in \mathsf{SF}(\varphi)\}$.

For any tree model M, let $\# \notin D$. For every $w \in W$ and for all $\exists y\ \delta \in \boldsymbol{\delta}^x_\theta$ let the function $g^w_\delta : D_w \mapsto D_w \cup \{\#\}$ be a mapping such that $M, w \models \delta(c, g^w_\delta(c))$ and $g^w_\delta(c) = \#$ only if there is no $d \in D_w$ such that $M, w \models \delta(c, d)$. Similarly for all $\exists x\ \delta \in \boldsymbol{\delta}^y_\theta$ let $h^w_\delta : D_w \mapsto D_w \cup \{\#\}$ such that $M, w \models \delta(h^w_\delta(c), h)$ and $h^w_\delta(c) = \#$ only if there is no $d \in D_w$ such that $M, w \models \delta(d, c)$. Again for all $\forall x \exists y\ \psi \in \boldsymbol{\psi}_\theta$ let $f^w_\psi : D_w \mapsto D_w \cup \{\#\}$ such that $M, w \models \psi(c, f^w_\psi(c))$ and $f^w_\psi(c) = \#$ only if there is no $d \in D_w$ such that $M, w \models \psi(c, d)$.

The functions g, h, f provide the witnesses at a world for every agent (if it exists) for the existential formulas respectively.

▶ **Theorem 13.** *Let $\theta \in \mathsf{PTML}^2$ be in an FSNF* DNF *sentence. Then θ is satisfiable iff θ is satisfiable in a model with bounded number of agents.*

Proof. It suffices to prove ($\Rightarrow$). Let M be a tree model of height at most $\mathsf{md}(\theta)$ rooted at r such that $M, r \models \theta$.

Let $E_\theta = \boldsymbol{\delta}^x_\theta \cup \boldsymbol{\delta}^y_\theta \cup \boldsymbol{\psi}_\theta$ and hence $|\mathsf{E}_\theta| \leq |\theta|$ (say q). Let $\mathsf{E}_\theta = \{\chi_1, \dots \chi_q\}$ be some enumeration. For every $w \in W$ and $a \in \delta(w)$ let $\mathsf{Wit}(a) = \{b_1 \dots b_q\}$ be the witnesses for a where $b_i = g^w_\delta(c)$ if χ_i is of the form $\exists y\ \delta \in \boldsymbol{\delta}^x_\theta$ (similarly $b_i = h^w_\delta(c)$ or $b_i = f^w_\psi(c)$ corresponding to χ_i of the from $\exists x\ \delta^y$ and $\forall x \exists y\ \psi$ respectively). If $b_i = \#$ then set $b_i = b$ for some arbitrary but fixed $b \in \delta(w)$.

For all $w \in W$ and $\Lambda \in$ 1-$\mathsf{type}(w)$ fix some $a^w_\Lambda \in \delta(w)$ such that 1-$\mathsf{type}(w, a^w_\Lambda) = \Lambda$. Furthermore, if c is the incoming edge of w and 1-$\mathsf{type}(w, c) = \Lambda$ then let $a^w_\Lambda = c$. Let $A^w = \{a^w_\Lambda \mid \Lambda \in$1-$\mathsf{type}(w)\}$.

Now we define the bounded agent model. For every $w \in W$ let M^w be the subtree model rooted at $w \in W$. For every such M^w, we define a corresponding *type based model* with respect to θ (denoted by T^w_θ with components denoted by $\delta^w_\theta, \rho^w_\theta$ etc) inductively as follows:

- If w is a leaf then T^w_θ is a tree with a single node w with $\delta^w_\theta(w) =$ 1-$\mathsf{type}(w) \times [1 \dots q] \times \{0, 1, 2\}$ and $\rho^w_\theta(w) = \rho(w)$.
- If w is at height h, T^w_θ is a tree rooted at w with $\delta^w_\theta(w) =$ 1-$\mathsf{type}(w) \times [1 \dots q] \times \{0, 1, 2\}$ and $\rho^w_\theta(w) = \rho(w)$.
  Before defining the successors of w in T^w_θ note that for every $(w, a, u) \in R$ we have T^u_θ which is the inductively constructed type based model rooted at u. Also, inductively we have $\delta^u_\theta(u) =$1-$\mathsf{type}(u) \times [1 \dots q] \times \{0, 1, 2\}$.

  Now for every $a^w_\Lambda \in A^w$ let $\{b_1 \dots b_q\}$ be the corresponding witnesses as described above. For every successor $(w, a^w_\Lambda, u) \in R$ and for every $1 \leq e \leq q$ and $f \in \{0, 1, 2\}$, create a new copy of T^u_θ (call it $N^{(\Lambda,e,f)}$) and name its root as $u^{(\Lambda,e,f)}$. Now add $\delta^w_\theta(w)$ to $N^{(\Lambda,e,f)}$ at $u^{(\Lambda,e,f)}$ guided by Ω where Ω is defined as follows:
  - For all $\Pi \in$ 1-$\mathsf{type}(w)$ we have $a^w_\Pi \in A^w$. Define $\Omega((\Pi, e, f)) = ($1-$\mathsf{type}(u, a^w_\Pi), e, f)$.
  - for all $k \leq q$ if 1-$\mathsf{type}(u, b_k) = \Pi$ then $\Omega((\Pi, k, f')) = ($1-$\mathsf{type}(u, b_k), e, f)$ where $f' = f + 1 \mod 3$.
  - Let $f' = f - 1 \mod 3$. For all $\Pi \in$ 1-$\mathsf{type}(w)$ let the witness set of a^w_Π be $\{d_1 \dots d_q\}$. For all $l \leq q$ if 1-$\mathsf{type}(w, d_l) = \Lambda$ then by Λ_3 component, there is some $a \in \delta(w)$ such that 2-$\mathsf{type}(w, d_l, a^w_\Pi) =$ 2-$\mathsf{type}(w, a^w_\Lambda, a)$. Define $\Omega((\Pi, l, f')) = ($1-$\mathsf{type}(u, a), e, f)$.
  - For all $(\Pi, e', f') \in \delta^w_\theta(w)$ if $\Omega(\Pi, e', f')$ is not yet defined, then set $\Omega(\Pi, e', f') = ($1-$\mathsf{type}(u, a^w_\Pi), e, f)$.

  Add an edge $(w, (\Lambda, e, f), u^{(\Lambda,e,f)})$ to R^w_θ.

Note that Ω is well defined since the first three steps are defined for the indices f, (f+1 mod 3) and (f-1 mod 3) respectively, which are always distinct. Also note that T^r_θ is a model that satisfies bounded agent property. Thus, it is sufficient to prove that $T^r_\theta, r \models \theta$.

Claim. For every $w \in W$ at height h and for all $\lambda \in \mathsf{SF}^h(\theta)$ the following holds:

1. Suppose λ is a sentence and $M, w \models \lambda$ then $T^w_\theta, w \models \lambda$.
2. If $\mathsf{Fv}(\lambda) \subseteq \{x, y\}$ and for all $\Lambda, \Pi \in$ 1-$\mathsf{type}(w)$ if $M, w, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \lambda$ then for all $1 \leq e \leq q$ and $f \in \{0, 1, 2\}$ we have $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi, e, f)] \models \lambda$.

Note that the theorem follows from claim (1), since θ is sentence and $M, r \models \theta$.

The proof of the claim is by reverse induction on h. In the base case $h = \mathsf{md}(\theta)$ which implies λ is modal free and hence is a DNF over $\mathsf{literals}$. Thus, both the claims follow since $\rho(w) = \rho^w_\theta(w)$.

For the induction step, let w be at height h. Now we induct on the structure of λ. Again if λ is a $\mathsf{literal}$ then both the the claims follow since $\rho(w) = \rho^w_\theta(w)$. The case of $\wedge$ and $\vee$ are standard.

For the case $\Box_x \lambda$, we only need to prove claim(2). Now suppose $M, w, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \Box_x \lambda$. Pick arbitrary e and f. We need to prove that $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi, e, f)] \models \Box_x \lambda$. Pick any $(w, (\Lambda, e, f), u^{(\Lambda,e,f)}) \in R^w_\theta$, then by construction we have $(w, a^w_\Lambda, u) \in R$ and since $M, w, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \Box_x \lambda$, we have $M, u, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \lambda$. Let $a^u_{\Pi'} \in A^u$ such that 1-$\mathsf{type}(u, a^u_{\Pi'}) =$1-$\mathsf{type}(u, a^w_\Pi)$ and since a^w_Λ is the incoming edge of u, by Π_2 component, we have 2-type$(u, a^w_\Pi, a^w_\Lambda)$ =2-type$(u, a^u_{\Pi'}, a^w_\Lambda)$ and also $a^w_\Lambda \in A^u$. Hence $M, u, [x \mapsto a^w_\Lambda, y \mapsto a^u_{\Pi'}] \models \lambda$ and by induction hypothesis $T^u_\theta, u, [x \mapsto ($1-type$(u, a^w_\Lambda), e, f), y \mapsto ($1-type$(u, a^u_{\Pi'}), e, f)] \models \lambda$. Now by construction, at $u^{(\Lambda,e,f)}$ we have $\Omega(\Lambda, e, f) = ($1-type$(w, a^w_\Lambda), e, f)$ and $\Omega(\Pi, e, f) = ($1-type$(u, a^u_{\Pi'}), e, f)$. Thus, by Lemma 12, $T^w_\theta, u^{(\Lambda,e,f)}, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi, e, f)] \models \lambda$. Hence, we have $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi, e, f)] \models \Box_x\lambda$. The case for $\Box_y\lambda$ is analogous.

For the case $\Diamond_y\lambda$, again only claim(2) applies. Suppose $M, w, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \Diamond_y\lambda$. Now pick e and f appropriately. We need to prove that $T^w_\theta, w, [x \mapsto (\Gamma, e, f), y \mapsto (\Pi, e, f)] \models \Diamond_y\lambda$. By supposition, there is some $w \xrightarrow{a^w_\Pi} u$ such that $M, u, [x \mapsto a^w_\Lambda, y \mapsto a^w_\Pi] \models \lambda$. Using the argument similar to the previous case, we can prove that $T^w_\theta, u^{(\Lambda,e,f)}, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi, e, f)] \models \lambda$ and hence $T^w_\theta, w, [x \mapsto (\Gamma, e, f), y \mapsto (\Pi, e, f)] \models \Diamond_y\lambda$. The case of $\Diamond_x\lambda$ is symmetric.

For the case $\exists y\ \lambda$ (where x is free at the outer most level), for claim (2) first note that since θ is in the normal form, λ is quantifier-safe. Also note that $\exists y\ \lambda = \chi_i$ for some $\chi_i \in E_\theta$. Now, suppose $M, w, [x \mapsto a^w_\Lambda] \models \exists y\ \lambda$ then we need to prove that $T^w_\theta, w, [x \mapsto (\Lambda, e, f)] \models \exists y\ \lambda$. Let the i^{th} witness of a^w_Λ be b_i and hence $M, w, [x \mapsto a^w_\Lambda, y \mapsto b_i] \models \lambda$. Let 1-type$(w, b_i) = \Pi'$, we claim that $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \lambda$ where $f' = f + 1 \mod 3$. Suppose not, then $\wedge$ and $\vee$ can be broken down and we get some module such that $M, w, [x \mapsto a^w_\Lambda, y \mapsto b_i] \models \Delta_z\lambda'$ and $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \not\models \Delta_z\lambda'$ where $\Delta \in \{\Box, \Diamond\}$ and $z \in \{x, y\}$. Assume $\Delta = \Box$ and $z = x$ (other cases are analogous). This implies $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \Diamond_x\neg\lambda'$ and hence there is some $w \xrightarrow{(\Lambda,e,f)} u^{(\Lambda,e,f)}$ such that $T^w_\theta, u^{(\Lambda,e,f)}, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \neg\lambda'(*)$. By construction, there is a corresponding $w \xrightarrow{a^w_\Lambda} u$ in M. Now since $M, w, [x \mapsto a^w_\Lambda, y \mapsto b_i] \models \Box_x\lambda'$, we have $M, u, [x \mapsto a^w_\Lambda, y \mapsto b_i] \models \lambda'$. Let $b'_i \in A^u$ such that 1-type(u, b_i) =1-type(u, b'_i). Since a^w_Λ is the incoming edge to u by Π'_2 component, we have 2-type(u, b_i, a^w_Λ) =2-type(u, b'_i, a^w_Λ) and $a^w_\Lambda \in A^u$. Thus, $M, u, [x \mapsto a^w_\Lambda, y \mapsto b'_i] \models \lambda'$ and by induction hypothesis, $T^u_\theta, u, [x \mapsto (\Lambda, e, f), y \mapsto ($1-type$(u, b'_i), e, f)] \models \lambda'$. Again by construction, at u we have $\Omega((\Lambda, e, f)) = (\Lambda, e, f)$ and $\Omega((\Pi', i, f')) = ($1-type$(u, b'_i), e, f)$ and hence by Lemma 12, $T^w_\theta, u^{(\Lambda,e,f)}, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \lambda'$ which is a contradiction to (*). The case of $\exists y\ \lambda$ is analogous.

For the case of $\forall x\ \lambda$ (where y is free at the outer most level), suppose $M, w, [y \mapsto a^w_\Pi] \models \forall x\ \lambda$. We need to prove that $T^w_\theta, w, [y \mapsto (\Pi, e, f)] \models \forall x\ \lambda$. Pick any $(\Lambda', e', f') \in \delta^w_\theta(w)$, now we claim $T^w_\theta, w, [x \mapsto (\Lambda', e', f'), y \mapsto (\Pi, e, f)] \models \lambda$ (otherwise, like in the previous case, since λ is quantifier-safe, we can reach a module where they differ and obtain a contradiction). The case $\forall y\ \lambda$ is analogous.

Finally we come to sentences which are relevant for claim (1). Note that in the normal form, at the outermost level, a sentence will have only literals or formulas of the form $\forall x \exists y\ \psi_l$ or $\forall x \forall y\ \varphi$.

For the case $M, w \models \forall x \exists y\ \psi_l$, let $\forall x \exists y\ \psi_l$ be i^{th} formula in E_θ. We need to prove $T^w_\theta, w \models \forall x \exists y\ \psi_l$. Pick any $(\Lambda, e, f) \in \delta^w_\theta(w)$ and we have $a^w_\Lambda \in A^w$. Let the i^{th} witness for a^w_Λ be b_i. Thus we have $M, w, [x \mapsto a_\Gamma, y \mapsto b_i] \models \psi_l$. Let 1-type$(w, b_i) = \Pi'$. Again we claim that $T^w_\theta, w, [x \mapsto (\Gamma, e, f), y \mapsto [\Pi', e, f')] \models \psi_l$ where $f' = f + 1 \mod 3$. Suppose not, again $\wedge$ and $\vee$ can be broken down and we get some module such that $M, w, [x \mapsto a^w_\Lambda, y \mapsto b_i] \models \Delta_z\lambda'$ and $T^w_\theta, w, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \not\models \Delta_z\lambda'$ where $\Delta \in \{\Box, \Diamond\}$ and $z \in \{x, y\}$. Assume $\Delta = \Diamond$ and $z = y$ (other cases are analogous). This implies $T^w_\theta, w, [x \mapsto$

$(\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \Box_y \neg\lambda'$ (*). Now let $a^w_{\Pi'} \in A^w$ such that 1-type$(w, a^w_{\Pi'})$ = 1-type$(w, b_i) = \Pi'$. Thus by Π'_3 component, there is some $d \in \delta^w_\theta$ such that 2-type$(w, a^w_{\Pi'}, d)$ = 2-type(w, b_i, a^w_Λ) and hence $M, w, [x \mapsto d, y \mapsto a^w_{\Pi'}] \models \Diamond_y \lambda'$. Hence there is some $w \xrightarrow{a^w_{\Pi'}} u$ such that $M, u, [x \mapsto d, y \mapsto a^w_{\Pi'}] \models \lambda'$. Now let 1-type$(u, d)$ = 1-type(u, d') such that $d' \in A^u$ and since $a^w_{\Pi'}$ is the incoming edge, we have $M, u, [x \mapsto d', y \mapsto a^w_{\Pi'}] \models \lambda'$ and by induction hypothesis, $T^u_\theta, u, [x \mapsto$ (1-type$(u, d'), i, f'), y \mapsto$ (1-type$(u, a^w_{\Pi'}), i, f')] \models \lambda'$ and while constructing $u^{(\Pi', i, f')}$ (case 3 applies for a^w_Λ since its i^{th} witness has same 1-type as $a^w_{\Pi'}$) we have $\Omega((\Lambda, e, f' - 1))$ = (1-type$(u, d'), i, f')$. Thus by Lemma 12 (since $f' - 1 = f$), $T^w_\theta, u^{(\Pi', i, f')}, [x \mapsto (\Lambda, e, f), y \mapsto (\Pi', i, f')] \models \lambda'$ which contradicts (*).

Finally, for the case $\forall x \forall y\ \varphi$ suppose $M, w \models \forall x \forall y\ \varphi$, then for any (Γ, e, f), $(\Delta, e', f') \in \delta^w_\theta(w)$ we claim that $T^w_\theta, w, [x \mapsto (\Gamma, e, f), y \mapsto (\Delta, e', f')] \models \varphi$ (else again, go to the smallest module and prove contradiction). ◀

Note that in the type based model, at any world w we have $|\delta^w_\theta| = 2^{2^{O(|\mathsf{SF}(\theta)|)}}$. Now if we start with a PTML^2 formula φ, then though its corresponding equi-satisfiable formula θ is exponentially larger, the number of distinct subformulas in θ is still linear in the size of φ.

▶ **Corollary 14.** TML^2 *satisfiability is in 2-EXPSPACE.*

Proof. Any TML^2 formula α is satisfiable iff (by Prop.6) its corresponding PTML^2 translation φ is satisfiable iff (by Theorem 13) the corresponding normal form θ of φ is satisfiable over agent set D of size $2^{2^{O(|\varphi|)}}$ iff (by Prop. 4) $\hat{\theta} \in$ PTML^2 is satisfiable in a constant domain model over D.

Thus we can expand the quantifiers of $\hat{\theta}$ by corresponding $\bigwedge$ and $\bigvee$ for $\forall$ and $\exists$ respectively and we get a propositional multi-modal formula. This satisfiability is in PSPACE. But in terms of the size of the formulas, $|\hat{\theta}| = 2^{2^{|\alpha|^2}}$. Thus we have a 2-EXPSPACE algorithm. ◀

3.3 Example

We illustrate the construction of *type based models* with an example. Consider the PTML^2 sentence $\theta := \forall x\ \Box_x \Box_x \bot \wedge \forall x \exists y\ (\Box_x(\Diamond_y(\neg p) \wedge \exists y\ \Diamond_y p))$ which is in FSNF DNF. Let M be the model described in Fig. 1 where

- $W = \{r\} \cup \{u^i, v^i, w^i \mid i \in \mathcal{N}\}$
- $D = \mathcal{N}$
- $\delta(r) = \{2i \mid i \in \mathcal{N}\}$ (all even numbers) and
  $\delta(w^i) = \delta(u^i) = \delta(v^i) = \mathcal{N}$
- $R = \{(r, 2i, w^i), (w^i, 2i + 1, u^i), (w^i, 2i + 2, v^i) \mid i \in \mathcal{N}\}$
- $\rho(r) = \rho(w^i) = \rho(v^i) = \emptyset$ and $\rho(u^i) = p$ for all $i \in \mathcal{N}$.

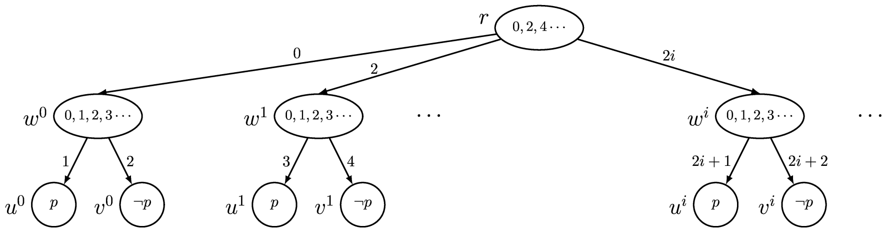

Figure 1 Given model such that $M, r \models \theta$.

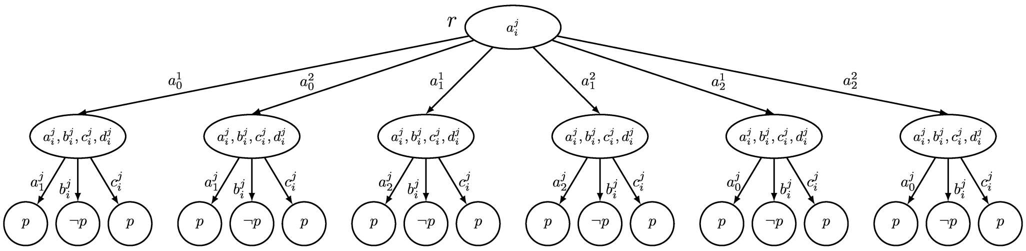

Figure 2 Corresponding bounded agent model with $M', r \models \theta$. a_i^j, b_i^j, c_i^j corresponds to agents with $1 \leq j \leq 2$ and $i \in \{0, 1, 2\}$. The edge a_i^j, b_i^j, c_i^j indicate one successor for every $1 \leq j \leq 2$ and $i \in \{0, 1, 2\}$.

Clearly, $M, r \models \theta$. Let $f^r : D_r \mapsto D_r$ be defined by $f^r(2i) = 2i + 2$ and at all w^i, $g^i(j) = 2i + 1$ for all $i \in \mathcal{N}$ be the two (relevant) witness functions. The one and two types at every world are described as follows:

At leaf nodes u^i and v^i there is only one distinct one type and two types. At w^i, note that $r \xrightarrow{2i} w_i$ is the incoming edge and only $2i + 1$ and $2i + 2$ have outgoing edges. Thus, there are 3 distinct 1-type members at w^i, each for $(2i + 1), (2i + 2)$ and [the rest]. Let b, c, d be the respective types. Finally at the root again we have only a single distinct type (call it a).

Since there are 2 existential formulas, the root of the type based model has $(1 \times 2 \times 3) = 6$ agents let it be $\{a_f^e \mid 1 \leq e \leq 2,\ 0 \leq f \leq 2\}$ and 0 be the representative. At w^0 we have $(3 \times 2 \times 3) = 18$ agents. Let the representatives be $1, 2, 0$ for b, c, d respectively. Note that we cannot pick any other representative for [the rest] other than 0 since 0 is the incoming edge to w^0. Let the bounded agent set be $\{b_f^e,\ c_f^e,\ d_f^e \mid 1 \leq e \leq 2,\ 0 \leq f \leq 2\}$. The corresponding bounded model M' is described in Figure 2. It can be verified that $M', r \models \theta$.

4 Discussion

We have proved that the two variable fragment of PTML^2 (and hence TML^2) is decidable. The upper bound shown is in 2-EXPSPACE. A NEXPTIME lower bound follows since FO^2 satisfiability can be reduced to PTML^2 satisfiability. We believe that by careful management of the normal form, space can be reused and the upper bound can in fact be brought down by one exponent. That would still leave a significant gap between lower and upper bounds to be addressed in future work.

We can also prove that addition of constants makes PTML^2 undecidable. In fact, with the addition of a single constant $\mathbf{c}$ we can use $\Box_{\mathbf{c}}$ to simulate the "free" $\Box$ of FOML^2, thus yielding undecidability. When it comes to equality, the situation is more tricky: note that we can no longer use model extension (Def.11 and Lemma 12) since equality might restrict the number of agents at every world.

The most important issue is expressiveness. What kind of accessibility relations or model classes can be characterized by 2-variable TML? This is unclear, but there are sufficiently intriguing examples and applications making the issue an interesting challenge.

Abstract

One of the most important open problems in finite model theory is the question whether there is a logic characterising efficient computation. While this question usually concerns PTIME, it can also be applied to other complexity classes, and in particular to LOGSPACE which can be seen as a formalisation of efficient computation for big data. One of the strongest candidates for a logic capturing PTIME is Choiceless Polynomial Time (CPT). It is based on the idea of choiceless algorithms, a general model of symmetric computation over abstract structures (rather than their encodings by finite strings). However, there is currently neither a comparably strong candidate for a logic for LOGSPACE, nor a logic transferring the idea of choiceless computation to LOGSPACE.

We propose here a notion of Choiceless Logarithmic Space which overcomes some of the obstacles posed by LOGSPACE as a less robust complexity class. The resulting logic is contained in both LOGSPACE and CPT, and is strictly more expressive than all logics for LOGSPACE that have been known so far. Further, we address the question whether this logic can define all LOGSPACE-queries, and prove that this is not the case.

1 Introduction

The probably most fundamental problem of finite model theory concerns the question whether there exist logics that precisely characterise the efficiently computable queries on finite structures. Usually this problem is called the *quest for a logic for polynomial time* [15], a problem originally posed by Chandra and Harel [5] and later made more precise by Gurevich [19]. But PTIME is just one, although certainly the most common, complexity class to capture the intuitive notion of efficient computability. Another important such class is LOGSPACE, which formalises efficient computation over large data sets with significantly smaller working memory, and may thus be viewed as a notion of efficient computability for big data. When Chandra and Harel [5] enquired about a logical characterization of the PTIME-queries, they already asked about LOGSPACE as well, and since then, a number of logics have been proposed that capture relevant parts of LOGSPACE. We briefly compare the state of the art on the quests for logics for PTIME and LOGSPACE, respectively.

Logics for polynomial time. For PTIME, the logic of reference is *fixed-point logic with counting* (FPC), which has first been proposed informally by Immerman [20] and then made precise in [11]. It extends first-order logic by fixed-point operators and counting terms and actually comes rather close to being a logic for polynomial time. It is strong enough to express many of the algorithmic techniques leading to polynomial-time procedures and it captures PTIME on many interesting classes of structures, including planar graphs, structures of bounded tree width, and actually all classes of graphs with an excluded minor [16]. For

a recent survey on FPC, see [6]. Nevertheless there are important problems that separate PTIME from FPC. The first of these, which still is an interesting benchmark problem for logics in PTIME, has been the CFI-query due to [4]. Other examples are efficiently solvable variants of the graph isomorphism problem or problems from linear algebra such as solving linear equation systems over finite fields or rings [2]. To handle such examples, several more powerful logics than FPC have been proposed, including for instance rank logic [7, 12].

However, the most promising candidate for a logic for PTIME is Choiceless Polynomial Time (CPT), introduced by Blass, Gurevich, and Shelah [3]. There are several different presentations of CPT (see e.g. [9, 10, 22, 25]). The original intention was to explore a model for efficient computations on finite structures which preserve symmetries at every step in the computation. This prohibits the explicit introduction of an ordering or, equivalently, arbitrary choices between indistinguishable elements of the input structure or of the current state. Such choices appear in many algorithms of fundamental importance, including depth-first search, Gaussian elimination, and many more. CPT is based on a computation model that avoids symmetry breaking choices, but allows essentially everything else, including parallelism and "fancy data structures", as long as all operations can be carried out in polynomial time. It works, given a finite structure, on its extension by all hereditarily finite sets over its universe, which may be seen as a powerful higher-order data structure. Choiceless Polynomial Time is the restriction of this model to polynomial-time resources. It is known that CPT is strictly more powerful than fixed-point logic with counting. In particular, CPT can express several variants of the CFI-queries that are not expressible in FPC and, more generally, CPT captures polynomial time over interesting classes of structures over which FPC fails to do so [1, 8, 23]. Nevertheless it is still open whether CPT captures PTIME on arbitrary finite structures. We refer to [9, 22, 26] for more information on CPT.

Logics for logarithmic space. The state of the art concerning logics for LOGSPACE is less advanced than for PTIME. On ordered structures, LOGSPACE can be captured by DTC, the extension of first-order logic by deterministic transitive closures [21]. A more elegant variant is the symmetric transitive closure logic STC, whose evaluation in LOGSPACE however depends on the highly non-trivial algorithm by Reingold [24] for undirected graph reachability. But even with an added counting operation, STC does not capture LOGSPACE on arbitrary structures, and again this can be proved by the CFI-query. Some of the shortcomings of transitive closure logics are elegantly countered by the logic LREC (short for L-recursion), especially in its stronger variant, called $\text{LREC}_=$ in the literature [17, 18]. The core of LREC is an elaborate recursion operator, augmented by a mechanism defining symmetric transitive closures to obtain closure under interpretations. However, although LREC captures LOGSPACE on a larger class of structures than transitive closure logics, it is still contained in FPC and thus does not capture LOGSPACE on arbitrary finite structures.

There has, up to now, not really emerged a convincing logspace-analogue of Choiceless Polynomial Time, and also no other really serious candidate for a logic for LOGSPACE. So some natural questions arise: *"What is Choiceless Logspace? What expressive power does it have, and could it actually capture all of* LOGSPACE*?"* Addressing these questions, we propose a notion of Choiceless Logspace. We prove that this provides a logic that is indeed contained in both CPT and LOGSPACE. Moreover, it is strictly more powerful than all LOGSPACE-logics known so far, including (the strong variant of) LREC. However, it turns out that even this logic fails to capture all LOGSPACE queries, which leads to the more general question of what would be a suitable notion of efficient choiceless computation for big data.

Sets of logarithmic size. Towards such a definition, we first note that the obvious, but naïve attempt fails. Since CPT permits polynomially many computation steps using only sets whose transitive closures contain polynomially many objects, the naïve approach would simply discard the time bound and allow sets with a transitive closure of logarithmically many objects. But this would make it possible to define sets containing logarithmically many atoms, which admits no straightforward evaluation in LOGSPACE: to represent such a set, one would store every atom as a number with logarithmically many bits, so one would actually have to represent logarithmically many numbers of logarithmic size. Unless LOGSPACE = NC^2, this should not be possible.

The central question is thus what it means that a set is of logarithmic size. Even though choiceless computation is invariant under encodings, already the size of an atom depends on its encoding. On an ordered encoding of a structure, every atom can be referenced by a binary string with logarithmically many bits. On the basis of this straightforward encoding, a logspace algorithm could only store constantly many atoms at a time, so a set of logarithmic size would be a set whose transitive closure is bounded by a constant. In fact, many standard logspace algorithms operate with a bounded number of storage locations, each of which can store an object with logarithmically many bits, typically an element of the input structure or a number that is polynomially bounded by the size of the input structure. A previous approach to defining choiceless logarithmic space [13, 27] has operated on exactly these "bounded sets". It corresponds to a logic, denoted here BDTC, that provides an operator for deterministic transitive closures over bounded sets. In its original version, BDTC lacks the ability to count, but besides that it has more fundamental deficiencies. Indeed, the assumption that a set of logarithmic size can only contain constantly many atoms does not take into account that there are alternative ways to represent atoms, and logspace algorithms that operate in a more sophisticated manner, using an unbounded number of storage locations such as the algorithm for tree isomorphism or Reingold's algorithm for undirected graph reachability. It is, for instance, possible to store the unique root of a tree in constant space by just storing its defining property. In a structure with a unary predicate P, every atom in P can be represented as "the kth element of P", so the size of the atom representation is logarithmic in $|P|$ instead of the size of the whole structure. The size of an atom with respect to LOGSPACE-algorithms can hence vary depending on its representation.

Towards Choiceless Logspace. This observation leads to the main idea behind CLogspace, the logic we shall introduce: When evaluating formulae with logarithmic bounds, we do not assume a fixed size for every atom. Therefore, the sizes of atoms are part of the semantics and, consequently, the logic is evaluated over *size-annotated hereditarily finite sets.*

Atoms can be represented using logical formulae. We introduce terms "$\mathrm{Atoms}\,.\varphi$" in our logic to make sure that, whenever a set of atoms is defined, that definition is guarded by a formula. The size of the atoms in that set will then be defined assuming that every atom is represented as "the ith entry of the kth tuple satisfying φ". So the size of every hereditarily finite object will depend on the terms of the form $\mathrm{Atoms}\,.\varphi$ generating the atoms in its transitive closure. However, this way of defining atoms does not allow unbounded recursion. We therefore add (a modified version of) the recursion operator from LREC to our logic. But, just like in CPT, iterated *creation* of sets is necessary to obtain a formalism that is stronger than common logics. Consequently, our logic also incorporates CPT-style iteration with some modifications mimicking the behaviour of LOGSPACE-algorithms.

In a nutshell, Choiceless LOGSPACE in our sense means iteration and recursion over hereditarily finite sets of logarithmic size, where the size of each atom is derived from its representation through a formula.

2 Choiceless Logarithmic Space and Choiceless Polynomial Time

In this section we present the precise definition of CLogspace. Readers familiar with Choiceless Polynomial Time will recall that it is evaluated with the data structure of all *hereditarily finite objects* over the given input structure.

The elements of the universe A of an input structure $\mathbf{A}$ are assumed to be *atoms*, i. e. not sets, and an *object* is an atom or a set. A set a is *transitive* if $\in$ is a transitive relation on a, which means that all elements of a are either subsets of a or atoms. The transitive closure $\mathrm{tc}(a)$ of an object a is the smallest transitive set b with $a \in b$. An object a is hereditarily finite if $\mathrm{tc}(a)$ is finite. Given a set A of atoms, $\mathrm{HF}(A)$ is the collection of hereditarily finite objects over A, i. e. the set of all objects x such that $x \in A$ or x is a hereditarily finite set such that all atoms in $\mathrm{tc}(x)$ are elements of A.

Choiceless Logspace is evaluated over *size-annotated hereditarily finite sets* where a size annotation is a function assigning (in a consistent way) a size to every element of the transitive closure of the given set. The definition of sizes guarantees that a set of logarithmic size can be represented in LOGSPACE in a straightforward way.

▶ **Definition 1.** *Let $\mathbf{A}$ be a σ-structure and $a \in \mathrm{HF}(A)$. A function $s\colon \mathrm{tc}(a) \to \mathbb{N}$ is a* size annotation of *a if, for each set $b \in \mathrm{tc}(a)$, $s(b) = 1+\sum_{c\in b} s(c)$. The set of* size-annotated hereditarily finite objects *is $\mathrm{SHF}(A) := \{(a, s_a) : a \in \mathrm{HF}(A)$ and s_a is a size annotation of $a\}$. For size annotations $(a, s_a), (b, s_b)$, we say that $(b, s_b) \in (a, s_a)$ if $b \in a$ and $s_b = s_a{\restriction}\mathrm{tc}(b)$.*

Note that a size annotation is completely determined by the values it assigns to the atoms. In particular, for a *pure set* $a \in \mathrm{HF}(A)$, with $\mathrm{tc}(a) \cap A = \emptyset$, there is a unique size annotation, which we denote by ann_a. Further, the size annotation yields an upper bound for the size of the transitive closure. As atoms may have size 0, conclude that $|\,\mathrm{tc}(a) \setminus A| \leq s(a)$ for any size annotation s of a.

We now formulate a high-level definition of the logic CLogspace, and then proceed to make precise, and explain, its ingredients step by step.

▶ **Definition 2** (Choiceless Logarithmic Space)**.** *The logic* CLogspace *is defined by rules for ordinary terms and formulae, iteration terms and recursion formulae as follows. If t is a term and φ is a formula according to these rules, and f is a function $f\colon n \mapsto c \log n$ for $c \in \mathbb{N}$, then (t, f) is a* CLogspace*-term, and (φ, f) is a* CLogspace*-formula.*

The function f only plays a role in defining the semantics of iteration terms. Otherwise the semantics is just given by the semantics of t and φ, respectively.

We first explain ordinary terms and formulae which provide the basic operations for constructing sets.

▶ **Definition 3** (Syntax)**.** *Ordinary terms and formulae over a vocabulary σ are defined inductively as follows:*

- *$\emptyset$ is a term, and every variable x is a term,*
- *if $\varphi \in \mathrm{FO}[\sigma]$ with at least one free variable, then $\mathrm{Atoms}\,.\varphi$ is a term,*
- *if t_1, t_2 are terms, then $\mathrm{Union}(t_1)$, $\mathrm{Unique}(t_1)$, $\mathrm{Pair}(t_1, t_2)$, and $\mathrm{Card}(t_1)$ are terms,*
- *for $R \in \sigma$ and terms $t_1, \dots, t_k$, the expressions $t_1 = t_2$, $t_1 \in t_2$, and $Rt_1 \dots t_k$ are formulae,*
- *Boolean combinations of formulae are formulae,*
- *if p and q are terms and φ is a formula, then $\{p : x \in q : \varphi\}$ is a (comprehension) term.*

The free variables $\mathrm{free}(t)$ of a term or formula t are defined as usual, where, in the term $t := \{p : x \in q : \varphi\}$, x occurs free in p and φ and bound in t. We therefore write $\{p(x) : x \in q : \varphi(x)\}$.

Counting. The terms $\mathrm{Card}(t)$ define cardinalities of sets. Since the cardinality of sets of polynomial size can be computed in LOGSPACE, von Neumann ordinals, which represent cardinalities in Choiceless Polynomial Time, are in general too large for our purposes. Therefore cardinalities will be denoted by a set encoding of their binary representation. For this purpose, we assume the short form $\langle a, b\rangle = \{a, \{a, b\}\}$ of Kuratowski pairs. This will make sure that every word of length two is represented by a set with two elements and can thus be distinguished from $\mathrm{bitset}(0)$ and $\mathrm{bitset}(1)$.

▶ **Definition 4.** *We define the function* $\mathrm{bitset}\colon \{0,1\}^+ \to \mathrm{HF}(\emptyset)$ *by setting* $\mathrm{bitset}(0) := \emptyset$, $\mathrm{bitset}(1) := \{\emptyset\}$, *and* $\mathrm{bitset}(bw) = \langle \mathrm{bitset}(b), \mathrm{bitset}(w)\rangle$ *for* $b \in \{0,1\}$ *and* $w \in \{0,1\}^+$.

If $n \in \mathbb{N}$, *let* $\mathrm{bitset}(n)$ *denote* $\mathrm{bitset}(\mathrm{bin}(n))$, *where* $\mathrm{bin}(n)$ *is the binary representation of* n, *with* 2^0 *as the right-most bit and without leading zeroes.*

It follows from the definition that the function bitset is injective. This representation of numbers keeps their size logarithmic with respect to their unique size annotation. More precisely, a simple induction on $|w|$ shows:

▶ **Lemma 5.** *Let* $s\colon \mathrm{tc}(\mathrm{bitset}(w)) \to \mathbb{N}$ *be a size annotation for* $w \in \{0,1\}^+$. *Then* $s(\mathrm{bitset}(w)) \leq 6|w|$.

Semantics of ordinary terms and formulae. Evaluation over size-annotated objects means that the value of every term is equipped with a size annotation. Hence, also the values of free variables have to incorporate size annotations. Recall that a size annotation defines a size for every element of the transitive closure of an object, which is uniquely determined by the sizes associated with the atoms. Unless the size of an atom is given externally through a free variable, its size originates from the term defining it. The only way to define atoms directly will be with terms of the form $\mathrm{Atoms}\,.\varphi$.

We assume every atom to be represented as "the ith entry of the kth tuple satisfying φ". Both φ and i are of constant size, since φ is a part of the term. So we can assume that, up to an additive constant, such an atom can be written as a number with $\log k$ bits where k is bounded by the number of tuples satisfying φ. This number is the size we assign to every atom defined that way. If an atom occurs in the values of multiple subterms, it may have multiple sizes that contribute to the value of the term. In that case, the minimal size is picked, which is formalised as follows:

▶ **Definition 6.** *Let* $S \subseteq \mathrm{SHF}(A)$ *be a set of size-annotated hereditarily finite sets. We denote by* S_{SHF} *the pair* (s, ann_s) *where* $s = \{s' : (s', \mathrm{ann}_{s'}) \in S\}$ *and* ann_s *is the unique size annotation of* s *with* $\mathrm{ann}_s(a) = \min\{\mathrm{ann}_{s'}(a) : (s', \mathrm{ann}_{s'}) \in S\}$ *for every atom* $a \in \mathrm{tc}(s)$.

▶ **Definition 7** (Semantics of ordinary terms). *Let* $\mathbf{A}$ *be a* σ*-structure and let* $\beta\colon X \to \mathrm{SHF}(A)$ *be a variable assignment. For* $\alpha \in \mathrm{SHF}(A)$, *we write* $\beta[x \mapsto \alpha]\colon X \cup \{x\} \to \mathrm{SHF}(A)$ *to denote the function that behaves like* β *on* $X \setminus \{x\}$ *and maps* x *to* α. *For an ordinary* σ*-term* t *(with* $\mathrm{free}(t) \subseteq X$*), we define the value* $t^{\mathbf{A},\beta} = ([\![t]\!]^{\mathbf{A},\beta}, \mathrm{ann}_t^{\mathbf{A},\beta}) \in \mathrm{SHF}(A)$ *as follows:*

- $\emptyset^{\mathbf{A},\beta} = (\emptyset, \emptyset \mapsto 1)$, *and* $x^{\mathbf{A},\beta} = \beta(x)$ *for any variable* x.
- *For* $t = \mathrm{Atoms}\,.\varphi$ *with* $\varphi \in \mathrm{FO}[\sigma]$, *let* $[\![t]\!]^{\mathbf{A},\beta} = \{a : \mathbf{A} \models \varphi(a)\}$ *if* $|\mathrm{free}(\varphi)| = 1$, *and* $[\![t]\!]^{\mathbf{A},\beta} = \{\{\langle \mathrm{bitset}(1), a_1\rangle, \dots, \langle \mathrm{bitset}(k), a_k\rangle\} : \mathbf{A} \models \varphi(a_1, \dots, a_k)\}$ *otherwise. In both cases* $\mathrm{ann}_t^{\mathbf{A},\beta}$ *is generated by mapping every occurring atom* a *to* $\log|[\![t]\!]^{\mathbf{A},\beta}|$.
- *If* $t = \mathrm{Pair}(t_1, t_2)$, *then* $t^{\mathbf{A},\beta} = \{{t_1}^{\mathbf{A},\beta}, {t_2}^{\mathbf{A},\beta}\}_{\mathrm{SHF}}$.
- *If* $t = \mathrm{Unique}(t')$, *then* $t^{\mathbf{A},\beta} = (a, \mathrm{ann}_{t'}^{\mathbf{A},\beta} \restriction \mathrm{tc}(a))$ *if* $[\![t']\!]^{\mathbf{A},\beta} = \{a\}$ *and* $t^{\mathbf{A},\beta} = (\emptyset, \emptyset \mapsto 1)$ *otherwise.*

- *If* $t = \mathrm{Union}(t')$, *then* $[\![t]\!]^{\mathbf{A},\beta} = \bigcup_{b\in[\![t']\!]^{\mathbf{A},\beta}} b$ *and* $\mathrm{ann}_t^{\mathbf{A},\beta} = \mathrm{ann}_{t'}^{\mathbf{A},\beta} \upharpoonright [\![t]\!]^{\mathbf{A},\beta}$.
- *If* $t = \mathrm{Card}(t')$, *then* $[\![t]\!]^{\mathbf{A},\beta} = \mathrm{bitset}\left(\left|[\![t']\!]^{\mathbf{A},\beta}\right|\right)$, *and* $\mathrm{ann}_t^{\mathbf{A},\beta} = \mathrm{ann}_{[\![t]\!]^{\mathbf{A},\beta}}$.
- *If* $t = \{p : x \in q : \varphi\}$, *then* $t^{\mathbf{A},\beta} = \{p^{\mathbf{A},\beta[x\mapsto a]} : a \in q^{\mathbf{A},\beta} : \mathbf{A},\beta[x \mapsto a] \models \varphi\}_{\mathrm{SHF}}$.

For a σ*-formula* φ*, the truth value of* $\mathbf{A},\beta \models \varphi$ *is defined in the obvious way.*

We denote the size $\mathrm{ann}_t^{\mathbf{A},\beta}([\![t]\!]^{\mathbf{A},\beta})$ assigned to the value of a term t by $\|t\|^{\mathbf{A},\beta}$. Further, we write true^k to denote a tautology with k free variables, true for true^1 and Atoms instead of Atoms . true. Then Atoms . true^k defines the set of all k-tuples over the input structure.

Iteration terms. Ordinary terms and formulae cannot define arbitrarily nested sets. This is achieved by constructing sets using fixed-point iteration.

▶ **Definition 8** (Syntax of iteration terms). *If* u *and* x *are variables and* t *is a term, then* $[t_u]^*(x)$ *is an* iteration term *with free variables* $\{x\} \cup \mathrm{free}(t) \setminus \{u\}$.

The fixed-point iteration starts with the object given by the free variable x, and the variable u is usually a free variable of t, whose value is the previous stage of the iteration. To ensure Logspace-computability, the fixed point is computed only if the logarithmic bound given as part of the term is satisfied by all intermediate stages. The value of an iteration term is not the fixed point itself, but the set of all stages up to that point.

▶ **Definition 9** (Semantics of iteration terms). *The* i*-fold iteration of a term* s *with free variable* u *is defined by induction as* $s^0 = s[u/x]$ *and* $s^{i+1} = s[u/s^i]$*, where* $s[u/t]$ *results from replacing every occurrence of* u *in* s *by the term* t*.*

Now let $t = [s_u]^*(x)$ *be an iteration term, let* $\mathbf{A}$ *be a structure and* $\beta\colon \mathrm{free}(t) \to \mathrm{SHF}(A)$ *a variable assignment. Then*

$$[\![t]\!]^{\mathbf{A},\beta} = \begin{cases} \{(s^i)^{\mathbf{A},\beta} : i \leq \ell\}_{\mathrm{SHF}}, & \text{for the least } \ell \text{ with } s^\ell = s^{\ell+1} \\ & \text{and } \|s^i\|^{\mathbf{A},\beta} \leq f(|A|) \text{ for all } i \leq \ell \\ & \text{if such an } \ell \text{ exists,} \\ (\emptyset, \emptyset \mapsto 1), & \text{otherwise.} \end{cases}$$

The differences between this definition and iteration in CPT are explained by two important properties of Logspace-algorithms: Firstly, a Logspace-algorithm can be sequentially executed for different input values, e.g. in a `forall`-loop. Iteration terms allow to do this in parallel for different values of the free variable x using suitable comprehension terms. Secondly, defining the value of the iteration term as the aggregation of all intermediate stages allows to generate outputs of polynomial size, which can be the input for other iteration terms.

Recursion formulae. With recursion formulae, we basically add to our logic the lrec-operator from [17, 18]. This operator permits a restricted kind of recursion over a graph interpretable in the input structure. Since our logic operates on hereditarily finite sets, we modify the interpretation such that the domain of the interpreted structure can be any definable set. Recursion formulae contain a term t_δ that restricts the domain to finitely many objects and defines their size annotations. Further, the vertices of the graph are labelled by sets of natural numbers, which we represent as bitsets instead of elements of a distinct number sort.

▶ **Definition 10** (Syntax of recursion formulae). *If* t_δ *and* t_C *are terms and* φ_E *and* $\varphi_=$ *are formulae, then* $[\mathsf{lrec}_{u,v} t_\delta, \varphi_=, \varphi_E, t_C](x, y)$ *is a* recursion formula*.*

For the definition of the semantics, fix a σ-structure $\mathbf{A}$, a variable assignment β, and a recursion formula $\varphi = [\mathsf{lrec}_{u,v} t_\delta, \varphi_=, \varphi_E, t_C](x,y)$. We first describe how t_δ, $\varphi_=$, φ_E and t_C define a labelled graph $G = (V, E, C)$ interpreted in the input structure. The formulae $\varphi_=$ and φ_E will be evaluated for pairs of elements from $[\![t_\delta]\!]^{\mathbf{A},\beta}$. For that purpose, we define the extension $\beta_{a,b} := \beta[u \mapsto (a, \mathrm{ann}^{\mathbf{A},\beta}_{t_\delta} \restriction \mathrm{tc}(a)), v \mapsto (b, \mathrm{ann}^{\mathbf{A},\beta}_{t_\delta} \restriction \mathrm{tc}(b))]$ of β for $a, b \in [\![t_\delta]\!]^{\mathbf{A},\beta}$.

The vertex set V consists of the equivalence classes of the reflexive, symmetric, transitive closure of the relation $\{(a,b) \in [\![t_\delta]\!]^{\mathbf{A},\beta} \times [\![t_\delta]\!]^{\mathbf{A},\beta} : \mathbf{A}, \beta_{a,b} \models \varphi_=\}$. Let $[a]$ denote the equivalence class of a. The edge set of G is $E := \{([a],[b]) : \mathbf{A}, \beta_{a,b} \models \varphi_E\}$. Further, the label of $[a] \in V$ is the set $C([a]) = \{c :$ there exists $a' \in [a]$ with $\mathrm{bitset}(c) \in [\![t_C]\!]^{\mathbf{A},\beta_{a'}}\}$, where $\beta_{a'} = \beta[u \mapsto (a', \mathrm{ann}^{\mathbf{A},\beta}_{t_\delta} \restriction \mathrm{tc}(a'))]$.

The truth value of the recursion formula depends on a recursive property X of vertices of a DAG unfolding of G. This unfolding is obtained by augmenting every vertex $[a] \in V$ with a resource $\ell \in \mathbb{N}$ restricting the space necessary to process paths through the DAG (for a detailed explanation, see [17, 18]). Then $([a], \ell) \in X \subseteq V \times \mathbb{N}$ if, and only if,

$$\ell > 0 \text{ and } \mathrm{bitset}\left(\left|\left\{[b] \in [a]E : \left([b], \left\lfloor \frac{\ell - 1}{|E[b]|} \right\rfloor\right) \in X\right\}\right|\right) \in C([a]),$$

If the values of the free variables x, y define a pair in $V \times \mathbb{N}$ (i.e. a vertex of the DAG), then the membership of that pair in X determines the truth value of the recursion formula:

▶ **Definition 11** (Semantics of recursion formulae). *Let $\varphi, \mathbf{A}, \beta$ and X as above. Then $\mathbf{A}, \beta \models \varphi$, where $\beta(x) = (a, \mathrm{ann}^{\mathbf{A},\beta}_{t_\delta} \restriction \mathrm{tc}(a))$ and $\beta(y) = (\mathrm{bitset}(\ell), \mathrm{ann}_{\mathrm{bitset}(\ell)})$ for $\ell \in \mathbb{N}$, if, and only if, $([a], \ell) \in X$.*

This completes the definition of CLogspace. We illustrate it with two short examples.

▶ **Example 12** (Size annotations). To see that the size annotation of a term can map the atoms to different values, consider the term $\mathrm{Union}(\mathrm{Pair}(\mathrm{Atoms}\,.\,\mathrm{true}, \mathrm{Atoms}\,.Px))$. The value of that term in a structure $\mathbf{A}$ is its whole domain. But the size annotation maps every element of $P^{\mathbf{A}}$ to $\log |P^{\mathbf{A}}|$, and the other atoms to $\log |A|$.

To demonstrate the use of iteration terms, we construct a formula $\varphi_{\mathrm{dtc}}(x,y)$ defining that there is a deterministic path from x to y.

▶ **Example 13** (Deterministic paths). The core of the formula is an iteration term $[t_u]^*(x)$ progressing along the deterministic path starting from x:

$$t(u) = \mathrm{Unique}\left(\{z : z \in \mathrm{Atoms}\,.\,\mathrm{true} : Euz\}\right).$$

Note that the free variable x determines the value of the first stage. So, by definition of Unique, the ith stage of $[t_u]^*(x)$ is the ith element on the deterministic path starting at x. Every stage is added to the value of the term, so the desired formula is $\varphi_{\mathrm{dtc}}(x,y) = y \in [t_u]^*(x)$. Since every atom is initially defined with the term $\mathrm{Atoms}\,.\,\mathrm{true}$, it is mapped to $\log |A|$ by the size annotation for the structure $\mathbf{A}$. Thus $n \mapsto \log n$ is a suitable bound for the formula.

Choiceless Polynomial Time. The newly introduced features that distinguish Choiceless Logspace from Choiceless Polynomial Time are size annotations, the addition of recursion formulae and the semantics of iteration terms. Further, CPT-formulae clearly possess polynomial instead of logarithmic bounds.

Consequently, the definition of CPT-formulae can be recovered from our definition of CLogspace by the following modifications: The terms of the form "$\mathrm{Atoms}\,.\varphi$" are replaced by an atomic term "Atoms", defining the full set of atoms from the input structure. The rule for recursion formulae is omitted. In terms (t, f) and formulae (φ, f), the function f is a polynomial.

In the definition of the semantics, the size annotations are eliminated completely. The polynomial bound for iteration terms is applied to the cardinality of the transitive closure of the current stage. For the computation to remain within polynomial time, the number of stages is also bounded by the polynomial. The value of an iteration term is the stage inducing the fixed-point instead of the accumulation of all intermediate stages. For more detailed definitions of Choiceless Polynomial Time, we refer to, for instance, [25, 9].

3 Inclusion in Logspace and CPT

We next prove the two essential properties of our logic that justify it to be called Choiceless Logspace: Firstly, every formula in our logic can be evaluated in logarithmic space. Secondly, it is choiceless in the sense that every formula can be translated to Choiceless Polynomial Time, the prototypical model of choiceless computation.

▶ **Theorem 14.** *Every query definable in* CLogspace *is* LOGSPACE*-computable.*

The explicit logarithmic bound in CLogspace-sentences is intended to enable evaluation in LOGSPACE. It ensures that every value occurring during an iterated computation has a sufficiently small size annotation. The size annotations induced by the semantics of terms and formulae are defined with a certain encoding of hereditarily finite sets in mind. We first define this encoding, which is the core of our evaluation algorithm.

Recall that elements of the input structure are always defined by means of terms $\mathrm{Atoms}\,.\varphi$. Since the algorithm will take as input string encodings of structures, we now operate on ordered structures. Hence one can represent an atom as "the ith entry of the kth tuple satisfying φ" using the linear order on the input structure. We denote the set of k-tuples from a structure $\mathbf{A}$ satisfying an FO-formula φ with k free variables by $\varphi^{\mathbf{A}}$.

▶ **Definition 15** (Representations)**.** *Let $\Phi \subseteq \mathrm{FO}[\sigma]$ for some vocabulary σ. The alphabet Σ_Φ consists of 0,1, "(", ")", "{", "}", "," and an alphabet symbol for each $\varphi \in \Phi$, which we also denote by φ. A* Φ-representation *is a word in the alphabet Σ_Φ that is either a set representation or an atom representation:*

- *An* atom representation *is a word (φ, i, m), where $\varphi \in \Phi$ with $k \geq 1$ free variables, and i and m are binary encodings of natural numbers $\leq k$ and $\leq |\varphi^{\mathbf{A}}|$, respectively. If $|\varphi^{\mathbf{A}}| = 0$, then m is the empty string.*
- *If $r_1, \dots, r_k$ are representations, then the word $\{r_1, \dots, r_k\}$ is a* set representation*.*

Let $\mathbf{A}$ be the expansion of a σ-structure $\mathbf{A}'$ by a linear order $<^{\mathbf{A}}$. The value *$r^{\mathbf{A}}$ of a representation r is defined as*

- *$(\varphi, i, m)^{\mathbf{A}} = a_i$ where $(a_1, \dots, a_k)$ is the m-th tuple (w.r.t. the lexicographical order extending $<$) in $\varphi^{\mathbf{A}}$.*
- *$\{r_1, \dots, r_k\}^{\mathbf{A}} = \{r_1^{\mathbf{A}}, \dots, r_k^{\mathbf{A}}\}$.*

A representation r is $\mathbf{A}$-minimal if

1. *for every atom a in $\mathrm{tc}(r^{\mathbf{A}})$, there is a unique atom representation of a that occurs as a substring of r,*
2. *if $r = \{r_1, \dots, r_k\}$, then $r_1, \dots, r_k$ are minimal representations and the values $r_i^{\mathbf{A}}$ are pairwise distinct.*

For an $\mathbf{A}$*-minimal representation* r*, we define the size annotation* $\mathrm{ann}_r^{\mathbf{A}}$ *by induction on the representation* r*:*

- $\mathrm{ann}^{\mathbf{A}}_{(\varphi,i,m)} \colon (\varphi, i, m)^{\mathbf{A}} \mapsto \log |\varphi^{\mathbf{A}}|$,
- $\mathrm{ann}^{\mathbf{A}}_{\{r_1 \dots r_k\}}$ *is the size annotation of* $\{(r_1^{\mathbf{A}}, \mathrm{ann}^{\mathbf{A}}_{r_1}), \dots, (r_k^{\mathbf{A}}, \mathrm{ann}^{\mathbf{A}}_{r_k})\}_{\mathrm{SHF}}$.

We say that r *is a representation of* $(r^{\mathbf{A}}, \mathrm{ann}_r^{\mathbf{A}}) \in \mathrm{SHF}(A)$*.*

We omit the structure $\mathbf{A}$ and speak about minimal representations if $\mathbf{A}$ can be inferred from the context. Note that there are representations that are not minimal, since the same set may be listed twice or an atom may occur encoded by different atom representations throughout the transitive closure of the value. Thus minimal representations ensure that the size annotation is well-defined. Note further that the size annotation does not agree with the word length of the representation. It does, however, provide an upper bound on the word length up to constant factors. Since the size annotation does not depend on the specific numbers i and m, this upper bound is independent of the linear order. Moreover, the size annotation of any given minimal representation is Logspace-computable.

Towards the evaluation algorithm, we show how to check whether two representations have the same value and, using the former as a subroutine, how to compute minimal representations.

▶ **Lemma 16.** *There is an algorithm that, given a* $\sigma \cup \{<\}$*-structure* $\mathbf{A}$ *(where* $<^{\mathbf{A}}$ *is obtained from the string representation of* $\mathbf{A}$*) and* $\mathbf{A}$*-minimal representations* r_1, r_2*, decides in logarithmic space whether* $r_1^{\mathbf{A}} = r_2^{\mathbf{A}}$*.*

Proof. We reduce equality of representations to isomorphism of coloured trees, where the colours are numbers $1, \dots, |A|$. An atom representation is encoded by a single node coloured by its value, and a set representation is encoded by a tree where the subtrees below the root encode the elements of the set representation. Note that, since the representations are minimal, every node has at most one child of any isomorphism type, so equality of the representations indeed implies isomorphism of the corresponding trees. ◀

▶ **Lemma 17.** *There is an algorithm that, given a* $\sigma \cup \{<\}$*-structure* $\mathbf{A}$ *(where* $<^{\mathbf{A}}$ *is obtained from the encoding of* $\mathbf{A}$*) and* $\mathbf{A}$*-minimal representations* $r_1, \dots, r_k$*, computes in logarithmic space a minimal representation* r *of the size-annotated set* $\{(r_1^{\mathbf{A}}, \mathrm{ann}^{\mathbf{A}}_{r_1}), \dots, (r_k^{\mathbf{A}}, \mathrm{ann}^{\mathbf{A}}_{r_k})\}_{\mathrm{SHF}}$*.*

Proof. We sequentially execute two Logspace-algorithms. The first one copies those representations to the output tape whose value did not occur before (using the algorithm from the previous lemma). The second algorithm replaces every atom representation by the shortest representation of its value occurring in the original string. ◀

With these subroutines, the evaluation of terms and formulae becomes rather straightforward. To simplify the statement of the following lemma, we do not distinguish between terms and formulae, but assume formulae to be terms with values $\emptyset$ and $\{\emptyset\}$.

▶ **Lemma 18.** *For every term* t *with free variables* $x_1, \dots, x_k$ *and every function* $f \colon n \mapsto c \log n$*, there is a* Logspace *algorithm that, given a* σ*-structure* $\mathbf{A}$ *and representations* $r_1, \dots, r_k$ *of* $\alpha_1, \dots, \alpha_k \in \mathrm{SHF}(A)$*, computes a representation of* $(t, f)^{\mathbf{A}, \beta \colon x_i \mapsto \alpha_i}$*.*

Proof. We proceed by induction on the construction of terms. Evaluation of atomic terms $\emptyset$ and x is trivial. For terms of the form $\mathrm{Atoms}\,.\varphi$, it suffices to compute the number n of tuples satisfying the FO-formulae φ and enumerate all tuples with entries (φ, i, m) for $0 \le m \le n$.

In the induction step, most cases follow directly from the induction hypothesis, using the fact that LOGSPACE is closed under sequential execution and thus the output of previous computations can be processed further regardless of its size. For Pair, Union and comprehension, the results of the subcomputations can be converted to a minimal representation with the algorithm from Lemma 17. Formulae $t_1 = t_2$ and $t_1 \in t_2$ can be evaluated using the algorithm from Lemma 16. For recursion formulae, the lemma follows from inclusion of LREC in LOGSPACE.

Let $[t_u]^*$ be an iteration term with free variable x_j. In its ith iteration, the algorithm computes a representation of $(t^i)^{\mathbf{A},\beta}$ from $(t^{i-1})^{\mathbf{A},\beta}$ (which is possible by induction hypothesis) and checks whether it satisfies the size bound. This is again possible using sequential execution. The new stage is compared to the previous one. Whenever a new value has been produced, it is additionally written to the output tape. A postprocessing step converts the result to a minimal representation and replaces it by the empty set if the bound has been exceeded at some point.

The bound on the size of each stage induces a logarithmic bound on the word length of the representations that are written to the work tape. In particular, this implies that the number of possible representations occurring as stages is polynomial. This ensures termination, since a counter can track the number of values that have been produced. ◀

We have established that CLogspace is a fragment of LOGSPACE. To verify that this fragment is *choiceless*, we embed it in CPT.

▶ **Theorem 19.** CLogspace $\leq$ CPT.

The straightforward way to prove the theorem is to inductively translate CLogspace-formulae to CPT. But the translation of formulae with free variables bears two technical difficulties: Firstly, CLogspace is evaluated over size-annotated hereditarily finite set. Secondly, standard definitions of CPT do not allow free variables in iteration terms.

We can, however, assume a non-standard variant of CPT where iteration terms may have free variables. This does not increase its expressive power because iteration terms can be simulated for all possible values of the free variables at once without exceeding the polynomial bound.

We address the first difficulty by the key concept of the translation to CPT: Expressing size annotations as hereditarily finite sets.

▶ **Definition 20.** *Let $\mathbf{A}$ be a σ-structure, and let $(a, s) \in \mathrm{SHF}(A)$. The* set representation $\mathrm{set}((a, s)) \in \mathrm{HF}(A)$ *is the set $\langle a, \{\langle b, [s(b)]\rangle : b \in \mathrm{tc}(a) \cap A\}\rangle$, where $[s(b)]$ is the ordinal corresponding to $s(b)$. We say that $\{\langle b, s(b)\rangle : b \in \mathrm{tc}(a) \cap A\}$* represents the size annotation s.

Proof of Theorem 19. Set representations of size annotations induce a translation between variable assignments, and thus a meaningful definition of translation between formulae with free variables. It remains to show that every CLogspace-formula can be (inductively) translated to CPT in that sense.

Most cases follow directly from the induction hypothesis, using CPT-terms that define combinations of size annotations. Size annotations are combined by using the minimal known size for every atom, which is definable in CPT.

In case a size annotation is not derived from the subterms, it originates from a term of the form "Atoms $.\varphi$". So the corresponding CPT-term has to define the size annotation that assigns the value $\log |\varphi^{\mathbf{A}}|$ to every atom from the structure $\mathbf{A}$ occurring in the value of the term. This is possible since logarithms are CPT-definable.

Further, CPT can check the logarithmic bound of iteration terms using the size annotation at each stage. Finally, recursion formulae can be translated to CPT because LREC $\leq$ FPC $\leq$ CPT. This concludes the proof of Theorem 19. ◀

4 The expressive power of CLogspace

To substantiate the idea that the rich syntax of CLogspace leads to greater expressive power, we compare it to known logics below LOGSPACE. As classical benchmarks, we consider the logics DTC and STC, which augment FO by deterministic and symmetric transitive closure operators. For precise definitions, we refer to [14, Sect. 3.5.2]. These logics are known [17] to be included in LREC, which is the strongest logic inside LOGSPACE known so far. Hence our main theorem of this kind is:

▶ **Theorem 21.** CLogspace $\gneq$ LREC.

LREC is a logic with counting terms, so it features a linearly ordered number sort and terms defining the cardinality of definable sets of tuples. Its core is the recursion operator, a modified version of which appears in our logic. We describe the lrec-operator in terms of the differences to our version, and refer to [17] for the full definition. Recall that the recursion operator interprets a graph in the input structure. In the original version, the elements of that graph are k-tuples from the input structure instead of hereditarily finite sets. Consequently, the domain term t_δ does not occur, and the subformulae can have multiple free variables. Further, the labels of the graph are defined as tuples over the number sort instead of bitsets. Both for counting of tuples and defining the labels of the graph, LREC uses a LOGSPACE-computable encoding of numbers polynomial in the size of the input structure by fixed-size tuples over the number sort. To verify that the LOGSPACE-computable arithmetic operations used in LREC are CLogspace-definable, we show:

▶ **Proposition 22.** *Let $R \subseteq \{0, \dots, |A|^k\}^\ell$ be any* LOGSPACE*-computable relation. Then there is a* CLogspace*-term defining* $\{\langle \mathrm{bitset}(n_1), \dots, \mathrm{bitset}(n_\ell)\rangle : (n_1, \dots, n_\ell) \in R\}$.

Proof. By implementing basic bit operations in CLogspace, the successor of any natural number is definable in the bitset encoding. This makes it possible to define a linear order on all bitsets up to any definable number. The elements of the linear order are bitsets of logarithmic size, so DTC-formulae can be simulated on that order analogously to Example 13. As DTC captures LOGSPACE on ordered structures, the proposition follows. ◀

The different encodings of numbers also pose a difficulty when translating formulae with free variables, since these variables can be domain or number variables. Defining a translation between variable assignments, inclusion of LREC in CLogspace can be made precise on the level of formulae with free variables. The translation to CLogspace is then rather straightforward. In particular, the only necessary iteration terms are those defining the operations on the number sort, so there exists an appropriate logarithmic bound.

So LREC is included in CLogspace. The inclusion is strict because of a property that CLogspace shares with CPT but not with traditional logics such as FPC and LREC: It benefits from padding of the input structure, i.e. it can define all LOGSPACE-properties of sufficiently small, definable substructures.

▶ **Definition 23.** *A $\sigma \cup \{U\}$-structure* $\mathbf{A}$ *is a* padded σ-structure *if $U \notin \sigma$ is a unary predicate. The* underlying structure *of* $\mathbf{A}$ *is the σ-reduct of $U^{\mathbf{A}}$.*

▶ **Theorem 24.** *Let $\mathcal{C}$ be the class of padded structures such that $2^{u!(u^2(6\log u+2)+1)} \leq n$ for every structure in $\mathcal{C}$ of size n with underlying structure of size u. For every* Logspace*-computable property $\mathcal{P}$, there is a* CLogspace*-sentence (φ, f) such that any structure in $\mathcal{C}$ satisfies (φ, f) if, and only if, the underlying structure satisfies $\mathcal{P}$.*

Proof. We define the set of all linear orders on the underlying structure. Then, since DTC $\leq$ LREC $\leq$ CLogspace and DTC captures Logspace on ordered structures, every Logspace-computable property can be defined on the resulting ordered structures.

Initially, all linear orders on two elements are created, defining pairs of atoms with the term $\text{Atoms}\,.(Ux \wedge Uy \wedge x \neq y)$. Then an iteration term extends every linear order by every atom that does not occur yet, defined by $\text{Atoms}\,.Uy$. It remains to show that there is a logarithmic bound for the iteration term. Its value in the ith stage is the set of all orders of the form $\{\langle a, b\rangle : a, b \in V : a < b\}$ for subsets $V \subseteq U$ of size $i + 2$. All atoms are defined by the terms $\text{Atoms}\,.Ux$ and $\text{Atoms}\,.(Ux \wedge Uy \wedge x \neq y)$, so every atom is annotated with a size $\leq 2\log|U|$. Then the pair $\langle a, b\rangle = \{a, \{a, b\}\}$ is mapped to $6\log|U| + 2$. Every linear order contains $< |V|^2 \leq |U|^2$ many pairs of that form, and there are $|V|! \leq |U|!$ many linear orders in the ith iteration. So $\|t^i\|^{\mathbf{A},\beta} \leq (|U|^2 \cdot (6\log|U| + 2) + 1) \cdot |U|! + 1$. By assumption, this is logarithmic in the size of the full input structure. ◀

Since the CFI-query is in Logspace, it is CLogspace-definable on padded structures. But LREC is included in FPC [18], so it cannot define this query even in the presence of padding. Thus Theorem 24 implies that CLogspace is strictly more expressive than LREC. It follows that also DTC and STC, and their extensions with counting, are strictly included in CLogspace. The same holds for all models of choiceless computation with a constant bound on the number of objects in the transitive closure of a set.

Even though our results demonstrate that CLogspace is stronger than all previously studied logics for Logspace, we can show that it does not capture all of Logspace. To establish this result we use a technique for proving inexpressibility results for fragments of CPT that is based on *supports* of hereditarily finite objects (see e.g. [3, 8, 26]).

▶ **Definition 25.** *Let $\text{Aut}(\mathbf{A})$ be the automorphism group of a finite structure $\mathbf{A}$. For $a \in \text{HF}(A)$, let $\text{Stab}(a)$ be the stabiliser of a with respect to $\text{Aut}(\mathbf{A})$, and let $\text{Stab}^\bullet(a)$ be its point-wise stabiliser. An object $s \in \text{HF}(A)$ is a* support *of a if $\text{Stab}^\bullet(s) \subseteq \text{Stab}(a)$.*

Every CPT-formula can be translated to an FPC-formula over a substructure of $\text{HF}(\mathbf{A})$ containing the sets *activated* by the formula. For general CPT-formulae, this can be an arbitrary substructure of $\text{HF}(\mathbf{A})$, depending on both the CPT-formula and the input structure. But for some fragments of CPT, the substructure can be over-approximated by those hereditarily finite objects that have a sufficiently small support. In particular, CLogspace-formulae can be translated to FPC-formulae that are evaluated over hereditarily finite sets with a support of logarithmic size.

▶ **Lemma 26.** *For a structure $\mathbf{A}$ and $f : \mathbb{N} \to \mathbb{N}$, let $\text{HF}_f(\mathbf{A})$ be the substructure of $\text{HF}(\mathbf{A})$ containing exactly those sets that have a support of size $f(n)$, where n is the size of the domain of $\mathbf{A}$. For every* CLogspace*-formula (φ, f), there is an* FPC*-formula ψ such that, for every structure $\mathbf{A}$, $\mathbf{A} \models (\varphi, f)$ if, and only if, $\text{HF}_f(\mathbf{A}) \models \psi$.*

Proof. Since the stages of all iteration terms are of size at most $f(n)$ with respect to their size annotations, they are elements of $\text{HF}_f(\mathbf{A})$. Analogously to the translation of CPT-terms to interpretations in an extension of FO in [10], every ordinary term or formula in CLogspace can be translated to an LREC-interpretation. Iteration terms can be translated to FPC-interpretations that create new objects representing the value of the iteration term, i.e. the aggregation of all stages. The element relation between that new element and the stages can then be defined by a fixed-point formula, maintaining the size annotations as a separate relation. ◀

By the same arguments as used in the proof of Theorem 40 in [8], this implies that the Cai-Fürer-Immerman query cannot be defined in CLogspace. As a consequence we get

▶ **Theorem 27.** CLogspace *is a strict fragment of* LOGSPACE.

5 Discussion

We have introduced Choiceless Logarithmic Space formalising the notion of symmetric, choiceless computations using only logarithmic workspace. Through the notion of size-annotated hereditarily finite sets, our logic takes into account that sizes of objects in LOGSPACE are sensitive to their encoding. The logic is a fragment of both Choiceless Polynomial Time and LOGSPACE, and it captures LOGSPACE on certain classes of structures with padding. This demonstrates the similarity to CPT, and, more importantly, makes it stronger than all previously known logics in LOGSPACE, in particular LREC.

However, we have seen that CLogspace does not capture LOGSPACE because it can only define sets with a support of logarithmic size, which, as shown in [8], makes it impossible to define the Cai-Fürer-Immerman query. It remains open whether the concepts used in CLogspace can be used to obtain a stronger logic that could capture all queries in LOGSPACE.

Of course, our definition can be tuned in several ways, addressing issues such as closure under interpretations, or trying to avoid the use of two different kinds of recursion operators (iteration terms and recursion formulae). Even for the current definition of CLogspace, it is open whether the lrec-operator can be eliminated without losing expressive power. It can, however, be shown that iteration terms are necessary (see [26]). However, contrary to polynomial time, logspace complexity is a much less robust notion, and the conflicting goals of providing sufficient power for choiceless computation and remaining inside LOGSPACE necessarily seem to result in a rather involved construction of CLogspace. It seems difficult to overcome, with further tunings of the definition, the barrier that the definable sets in CLogspace have a (far too) small support. In the light of the research carried out here, we therefore consider it improbable that some variant of choiceless computation can capture precisely all (symmetry-invariant) LOGSPACE-queries.

We may take a step back, and reconsider our general objectives. One of the reasons why we are looking for a logic that captures logspace complexity on arbitrary finite structures is that LOGSPACE, other than being a well-studied complexity class for standard computation models on ordered objects, is a reasonable formalisation of efficient computation for big data. But there are also other, less restrictive, complexity classes that can serve a similar purpose, for instance on the basis of polylogarithmic space bounds. Such variants may be more robust and make it possible to assume a standard encoding of atoms with small space and might grant more freedom in defining tree-like recursion using only iteration terms. Rather than trying to tune the definition of CLogspace to find stronger notions of choiceless computation inside LOGSPACE, we may thus also go beyond the logspace bound and ask more generally: *"What is efficient choiceless computation for big data?"*.

Abstract

The problem of d-Path Vertex Cover, d-PVC lies in determining a subset F of vertices of a given graph $G = (V, E)$ such that $G \setminus F$ does not contain a path on d vertices. The paths we aim to cover need not to be induced. It is known that the d-PVC problem is NP-complete for any $d \geq 2$. When parameterized by the size of the solution k, 5-PVC has direct trivial algorithm with $\mathcal{O}(5^k n^{\mathcal{O}(1)})$ running time and, since d-PVC is a special case of d-Hitting Set, an algorithm running in $\mathcal{O}(4.0755^k n^{\mathcal{O}(1)})$ time is known. In this paper we present an iterative compression algorithm that solves the 5-PVC problem in $\mathcal{O}(4^k n^{\mathcal{O}(1)})$ time.

1 Introduction

The problem of d-Path Vertex Cover, d-PVC lies in determining a subset F of vertices of a given graph $G = (V, E)$ such that $G \setminus F$ does not contain a path on d vertices (even not a non-induced one). The problem was first introduced by Brešar et al. [1], but its NP-completeness for any $d \geq 2$ follows already from the meta-theorem of Lewis and Yannakakis [11]. The 2-PVC problem corresponds to the well known Vertex Cover problem and the 3-PVC problem is also known as Maximum Dissociation Set. The d-PVC problem is motivated by the field of designing secure wireless communication protocols [12] or in route planning and speeding up shortest path queries [9].

Since the problem is NP-hard, any algorithm solving the problem exactly is expected to have exponential running time. If one measures the running time solely in terms of the input size, then several efficient (faster than trivial enumeration) exact algorithms are known for 2-PVC and 3-PVC. In particular, 2-PVC (Vertex Cover) can be solved in $\mathcal{O}(1.1996^n)$ time and polynomial space due to Xiao and Nagamochi [20] and 3-PVC can be solved in $\mathcal{O}(1.4656^n)$ time and polynomial space due to Xiao and Kou [18].

In this paper we aim on the parameterized analysis of the problem, that is, to confine the exponential part of the running time to a specific parameter of the input, presumably much smaller than the input size. Algorithms achieving running time $f(k)n^{O(1)}$ are called *parameterized*, *fixed-parameter tractable*, or *FPT*. See Cygan et al. [3] for a broader introduction to parameterized algorithms.

When parameterized by the size of the solution k, the d-PVC problem is directly solvable by a trivial FPT algorithm that runs in $\mathcal{O}^*(d^k)$ time.[1] However, since d-PVC is a special case of d-Hitting Set, it was shown by Fomin et al. [6] that for any $d \geq 4$ we have an algorithm solving d-PVC in $\mathcal{O}^*((d-0.9245)^k)$. In order to find more efficient solutions, the problem has been extensively studied in a setting where d is a small constant. For the 2-PVC (Vertex Cover) problem, the algorithm of Chen, Kanj, and Xia [2] has the currently best known running time of $\mathcal{O}^*(1.2738^k)$. For 3-PVC, Tu [16] used iterative compression to achieve a running time $\mathcal{O}^*(2^k)$. This was later improved by Katrenič [10] to $\mathcal{O}^*(1.8127^k)$, by Xiao and Kou [19] to $\mathcal{O}^*(1.7485^k)$ by using a branch-and-reduce approach and it was further improved by Tsur [15] to $\mathcal{O}^*(1.713^k)$. For the 4-PVC problem, Tu and Jin [17] again used iterative compression and achieved a running time $\mathcal{O}^*(3^k)$ and Tsur [14] claims to have an algorithm with running time $\mathcal{O}^*(2.619^k)$.

We present an algorithm that solves the 5-PVC problem parameterized by the size of the solution k in $\mathcal{O}^*(4^k)$ time by employing the iterative compression technique. Using the result of Fomin et al. [7] this also yields $\mathcal{O}(1.7501^n)$ time algorithm improving upon previously known $\mathcal{O}(1.7547^n)$ time algorithm.

Organization of this paper. We introduce the notation and define the 5-PVC problem in section 2. Our disjoint compression routine for iterative compression is exposed in section 3. We conclude this paper with a few open questions. Due to space constraints most proofs were deferred to the full version of this paper. However, to showcase our technique of proving the correctness of our algorithm, we included the proofs of correctness for Rules (R10) and (R13.1), and proofs of Lemmata 18 and 21.

2 Preliminaries

We use the $\mathcal{O}^*$ *notation* as described by Fomin and Kratsch [8], which is a modification of the big-$\mathcal{O}$ notation suppressing all polynomially bounded factors. We use the notation of parameterized complexity as described by Cygan et al. [3]. We use standard graph notation and consider simple and undirected graphs unless otherwise stated. Vertices of graph G are denoted by $V(G)$, edges by $E(G)$. By $G[X]$ we denote the subgraph of G induced by vertices of $X \subseteq V(G)$. By $N(v)$ we denote the set of neighbors of $v \in V(G)$ in G. Analogically, $N(X) = \bigcup_{x \in X} N(x)$ denotes the set of neighbors of vertices in $X \subseteq V(G)$. The degree of vertex v is denoted by $deg(v) = |N(v)|$. For simplicity, we write $G \setminus v$ for $v \in V(G)$ and $G \setminus X$ for $X \subseteq V(G)$ as shorthands for $G[V(G) \setminus \{v\}]$ and $G[V(G) \setminus X]$, respectively.

A *k-path*, denoted as an ordered k-tuple $P_k = (p_1, p_2, \ldots, p_k)$, is a path on k vertices $\{p_1, p_2, \ldots, p_k\}$. A path P_k *starts* at vertex x when $p_1 = x$. A *k-cycle* is a cycle on k vertices. A *triangle* is a 3-cycle. A P_5*-free* graph is a graph that does not contain a P_5 as a subgraph (the P_5 need not to be induced). The 5-Path Vertex Cover problem is formally defined as follows:

5-Path Vertex Cover, 5-PVC	
Input:	A graph $G = (V, E)$, an integer $k \in Z_0^+$.
Output:	A set $F \subseteq V$, such that $\lvert F \rvert \leq k$ and $G \setminus F$ is a P_5-free graph.

[1] The $\mathcal{O}^*()$ notation suppresses all factors polynomial in the input size.

▶ **Definition 1.** *A star is a graph S with vertices $V(S) = \{s\} \cup \{l_1, \ldots, l_k\}$, $k \geq 3$ and edges $E(S) = \{\{s, l_i\} \mid i \in \{1, \ldots, k\}\}$. Vertex s is called a center, vertices $L = \{l_1, \ldots, l_k\}$ are called leaves.*

▶ **Definition 2.** *A star with a triangle is a graph $S^{\triangle}$ with vertices $V(S^{\triangle}) = \{s, t_1, t_2\} \cup \{l_1, \ldots, l_k\}$, $k \geq 1$ and edges $E(S^{\triangle}) = \{\{s, t_1\}, \{s, t_2\}, \{t_1, t_2\}\} \cup \{\{s, l_i\} \mid i \in \{1, \ldots, k\}\}$. Vertex s is called a center, vertices $T = \{t_1, t_2\}$ are called triangle vertices and vertices $L = \{l_1, \ldots, l_k\}$ are called leaves.*

▶ **Definition 3.** *A di-star is a graph D with vertices $V(D) = \{s, s'\} \cup \{l_1, \ldots, l_k\} \cup \{l'_1, \ldots, l'_m\}$, $k \geq 1, m \geq 1$ and edges $E(D) = \{\{s, s'\}\} \cup \{\{s, l_i\} \mid i \in \{1, \ldots, k\}\} \cup \{\{s', l'_j\} \mid j \in \{1, \ldots, m\}\}$. Vertices s, s' are called centers, vertices $L = \{l_1, \ldots, l_k\}$ and $L' = \{l'_1, \ldots, l'_m\}$ are called leaves.*

▶ **Lemma 4.** *If a connected graph is P_5-free and has more than 5 vertices, then it is a star, a star with a triangle, or a di-star.*

3 5-PVC with P_5-free bipartition

We employ the generic iterative compression framework as described by Cygan et al. [3, pages 80–81]. We skip the generic steps and only present the disjoint compression routine (see the full version of the paper for a brief discussion of the whole iterative compression algorithm). That is, we assume that we are given a solution to the problem and search for another solution which is strictly smaller than and disjoint from the given one. Moreover, if the graph induced by the given solution contains a P_5, then we can directly answer no. Hence our routine DISJOINT_R restricts itself to a problem called 5-PVC WITH P_5-FREE BIPARTITION and we need it to run in $\mathcal{O}^*(3^k)$ time.

A *P_5-free bipartition* of graph $G = (V, E)$ is a pair (V_1, V_2) such that $V = V_1 \cup V_2$, $V_1 \cap V_2 = \emptyset$ and $G[V_1], G[V_2]$ are P_5-free. The 5-PVC WITH P_5-FREE BIPARTITION problem is formally defined as follows:

5-PVC WITH P_5-FREE BIPARTITION, 5-PVCWB	
INPUT:	A graph $G = (V, E)$ with P_5-free bipartition (V_1, V_2), an integer $k \in Z_0^+$.
OUTPUT:	A set $F \subseteq V_2$, such that $\lvert F \rvert \leq k$ and $G \setminus F$ is a P_5-free graph.

Throughout this paper the vertices from V_1 will be also referred to as “red” vertices and vertices from V_2 will be also refereed to as “blue” vertices.

3.1 Algorithm

Our algorithm is a recursive procedure DISJOINT_R(G, V_1, V_2, F, k), where G is the input graph, V_1, V_2 are the partitions of the P_5-free bipartition of G, F is the solution being constructed, and k is the maximum number of vertices we can still add to F. The procedure repeatedly tries to apply a series of rules with a condition that a rule (RI) can be applied only if all rules that come before (RI) cannot be applied. It is paramount that in every call of DISJOINT_R at least one rule can be applied. The main work is done in rules of two types: *reduction rules* and *branching rules*. To make it easier for the reader we also use rules called *context rules*, which only describe the configuration we are currently in and serve as some sort of a parent rules for their subrules.

A *reduction rule* is used to simplify a problem instance, i.e. remove some vertices or edges from G and possibly add some vertices to a solution, or to halt the algorithm. A *branching rule* splits the problem instance into at least two subinstances. The branching is based on subsets of vertices that we try to add to a solution and by adding them to the solution we also remove them from G.

The notation we use to denote the individual branches of a branching rule is as follows: $\langle\, X_1 \mid X_2 \mid \ldots \mid X_l \,\rangle$. Such a rule has l branches and $X_1, X_2, \ldots, X_l$ are subsets of V_2 which we try to add to the solution. This rule is translated into the following l calls of the procedure:

$$\text{DISJOINT\_R}(G \setminus X_i, V_1, V_2 \setminus X_i, F \cup X_i, k - |X_i|) \text{ for } i \in \{1, \ldots, l\}$$

A rule is *applicable* if the conditions of the rule are satisfied and none of the previous rules is applicable. If a context rule is not applicable, it means that none of its subrules is applicable.

A reduction rule is *correct* if it satisfies that the problem instance has a solution if and only if the simplified problem instance has a solution. A branching rule is *correct* if it satisfies that the problem instance has a solution if and only if at least one of the branches of the rule will return a solution.

When we say we *delete* a vertex, we mean that we remove it from G and also add it to the solution F. When we say we *remove* a vertex, we mean that we remove it from G and *do not* add it to the solution F.

For the rest of this paper assume that the parameters of the current call of DISJOINT_R are G, V_1, V_2, F, k.

3.2 Preprocessing

▶ **Reduction rule (R0).** This rule stops the recursion of DISJOINT_R. It has three stopping conditions:

1. If $k < 0$, return *no solution*;
2. else if G is P_5-free, return F;
3. else if $k = 0$, return *no solution.*

▶ **Reduction rule (R1).** Let $v \in V(G)$ be a vertex such that there is no P_5 in G that uses v. Then remove v from G.

▶ **Branching rule (R2).** Let P be a P_5 in G with $X = V(P) \cap V_2$ such that $|X| \le 3$. Then branch on $\langle\, x_1 \mid x_2 \mid \ldots \rangle, x_i \in X$, i.e. branch on the blue vertices of P.

▶ **Lemma 5.** *Assume that Rules (R0) – (R2) are not applicable. Then for each vertex $v \in V(G)$ there exists a P_5 in G that uses v; every P_5 in G uses exactly one red vertex; and there are only isolated vertices in $G[V_1]$.*

3.3 Dealing with isolated vertices in $G[V_2]$

▶ **Lemma 6.** *Assume that Rules (R0) – (R2) are not applicable. Let v be an isolated vertex in $G[V_2]$ and let F be a solution to* 5-PVCwB *which uses vertex v. Then there exists a solution F' that does not use vertex v and $|F'| \le |F|$.*

▶ **Branching rule (R3).** Let v be an isolated vertex in $G[V_2]$ and let $P = (v, w, x, y, z)$ be a P_5 where w is a red vertex. Then branch on $\langle\, x \mid y \mid z \,\rangle$.

▶ **Lemma 7.** *Assume that Rules (R0) – (R3) are not applicable. Then there are no isolated vertices in $G[V_2]$.*

3.4 Dealing with isolated edges in $G[V_2]$

▶ **Lemma 8.** *Assume that Rules (R0) – (R3) are not applicable. Let v be a blue vertex to which at least two red vertices are connected and let C_v be a connected component of $G[V_2]$ which contains v. Then for each red vertex w connected to v we have that $N(w) \subseteq V(C_v)$.*

▶ **Lemma 9.** *Assume that Rules (R0) – (R3) are not applicable. Let $e = \{u, v\}$ be a blue edge to which at least two red vertices are connected in a way that to both u and v there is at least one red vertex connected. Let C_e be a connected component of $G[V_2]$ which contains e. Then for each red vertex w connected to e we have that $N(w) \subseteq V(C_e)$.*

▶ **Lemma 10.** *Let X be a subset of V_2 such that $N(X) \cap V_1 = \emptyset$ and $|N(X) \cap V_2| = 1$. If there exists a solution F such that $F \cap X \neq \emptyset$, then there exists a solution F' such that $F' \cap X = \emptyset$ and $|F'| \leq |F|$.*

▶ **Definition 11.** *We say that two nodes x, y are twins if $N(x) \setminus \{y\} = N(y) \setminus \{x\}$.*

▶ **Lemma 12.** *Let x, y be blue vertices that are twins. Let F be a solution and $x \in F$. Then at least one of the following holds:*
(1) $y \in F$,
(2) $F' = (F \setminus \{x\}) \cup \{y\}$ is a solution.

▶ **Branching rule (R4).** Let $e = \{u, v\}$ be an isolated edge in $G[V_2]$. We know from Lemmata 8 and 9 that there is only one red vertex w connected to e, because if there were at least two red vertices connected to e, then there would be no P_5 that uses vertices from e. Let there be a red vertex w connected to at least one vertex in e. If w is connected only to one vertex in e, let that vertex be v. Assume that x is some vertex to which w connects outside e and let y be a neighbor of x in $G[V_2]$. Then branch on $\langle\, v \mid x \mid y \,\rangle$.

▶ **Lemma 13.** *Assume that Rules (R0) – (R4) are not applicable. Then there are no isolated edges in $G[V_2]$.*

3.5 Dealing with isolated P_3 paths in $G[V_2]$

▶ **Context rule (R5).** Let P be a $P_3 = (t, u, v)$ that forms a connected component in $G[V_2]$. From Lemmata 5, 8 and 9 we know that there is only one red vertex w connected to P. We further know that w must be connected to some component of $G[V_2]$ other than P, otherwise no P_5 could be formed. Assume that x is some vertex to which w connects outside P and let y be a neighbor of x in $G[V_2]$. This rule is split into four subrules (R5.1), (R5.2), (R5.3) and (R5.4) based on how w is connected to P.

▶ **Branching rule (R5.1).** Vertex w is connected only to v in P. Then branch on $\langle\, v \mid x \,\rangle$.

▶ **Branching rule (R5.2).** Vertex w is connected only to u, v in P. Then branch on $\langle\, u \mid v \mid x \,\rangle$.

▶ **Branching rule (R5.3).** Vertex w is connected only to u in P. Then branch on $\langle\, u \mid x \mid y \,\rangle$.

▶ **Branching rule (R5.4).** Vertex w is connected to t, v in P and w can be also connected to u in P. Then branch on $\langle\, u \mid v \mid x \,\rangle$.

▶ **Lemma 14.** *Assume that Rules (R0) – (R5) are not applicable. Then there are no isolated P_3 paths in $G[V_2]$.*

3.6 Dealing with isolated triangles in $G[V_2]$

▶ **Context rule (R6).** Let T be a $K_3 = \{t, u, v\}$ that forms a connected component in $G[V_2]$. From Lemmata 5 and 8 we know that there is only one red vertex w connected to T. We further know that w must be connected to some component of $G[V_2]$ other than T, otherwise no P_5 could be formed. Assume that x is some vertex to which w connects outside T and let y be a neighbor of x in $G[V_2]$. This rule is split into three subrules (R6.1), (R6.2) and (R6.3) based on how w is connected to T.

▶ **Branching rule (R6.1).** Vertex w is connected only to one vertex in T, let that vertex be v. Then branch on $\langle\, v \mid x \,\rangle$.

▶ **Branching rule (R6.2).** Vertex w is connected to exactly two vertices in T, let those vertices be u, v. Then branch on $\langle\, t \mid v \mid x \,\rangle$.

▶ **Branching rule (R6.3).** Vertex w is connected to all vertices in T. Then branch on $\langle\, v \mid x \,\rangle$.

▶ **Lemma 15.** *Assume that Rules (R0) – (R6) are not applicable. Then there are no isolated triangles in $G[V_2]$.*

3.7 Dealing with 4-cycles in $G[V_2]$

▶ **Lemma 16.** *Let C be a connected component of $G[V_2]$ and $X = V(C) \cap N(V_1)$. Let F be a solution that deletes at least $|X|$ vertices in C. Then $F' = (F \setminus V(C)) \cup X$ is also a solution and $|F'| \leq |F|$.*

▶ **Context rule (R7).** Let Q be a connected component in $G[V_2]$ such that Q is a subgraph of K_4 and a 4-cycle is a subgraph of Q, label the vertices of the 4-cycle (v_1, v_2, v_3, v_4). We will call pairs of vertices $\{v_1, v_3\}$ and $\{v_2, v_4\}$ *diagonal*, all other pairs will be called *non-diagonal*. Edges corresponding to diagonal (non-diagonal) pairs are called diagonal (non-diagonal) edges, respectively. This rule is split into two subrules (R7.1), (R7.2) based on the number of red vertices connected to Q.

▶ **Reduction rule (R7.1).** Assume that there are at least two red vertices connected to Q. Then delete any vertex v_i in Q and add it to the solution F.

▶ **Context rule (R7.2).** Assume that there is only one red vertex w connected to Q and $X = V(Q) \cap N(w)$. This rule is split into five subrules (R7.2a), (R7.2b), (R7.2c), (R7.2d) and (R7.2e) based on how w is connected to Q and whether w is connected to other components.

▶ **Reduction rule (R7.2a).** Vertex w is connected only to one vertex in Q, let it be v_1. Then delete v_1 and add it to the solution F.

▶ **Branching rule (R7.2b).** Set X contains at least one diagonal pair, let that pair be $\{v_1, v_3\}$. Then branch on $\langle\, v_1 \mid v_2 \mid v_4 \,\rangle$.

▶ **Branching rule (R7.2c).** Set X contains exactly one non-diagonal pair, let that pair be $\{v_1, v_2\}$, and case *(a)* either both diagonal edges are in Q , or case *(b)* none of them is. Then branch on $\langle\, v_1 \mid v_3 \mid v_4 \,\rangle$

▶ **Reduction rule (R7.2d).** Set X contains exactly one non-diagonal pair, let that pair be $\{v_1, v_2\}$ and exactly one diagonal edge is in Q, let that edge be $\{v_1, v_3\}$. Furthermore, w is connected only to Q, i.e. $N(w) \subseteq V(Q)$. Then delete any vertex v_i in Q and add it to the solution F.

▶ **Branching rule (R7.2e).** Set X contains exactly one non-diagonal pair, let that pair be $\{v_1, v_2\}$ and exactly one diagonal edge is in Q, let that edge be $\{v_1, v_3\}$. Furthermore, w is connected to at least one more component of $G[V_2]$ other than Q, label the vertex to which w connects outside Q as x and let y be a neighbor of x in $G[V_2]$. Then branch on $\langle\, \{v_1, v_2\} \mid x \mid y \,\rangle$.

▶ **Lemma 17.** *Assume that Rules (R0) – (R7) are not applicable. Then there is no component of $G[V_2]$ that contains a 4-cycle as a subgraph.*

3.8 Dealing with stars in $G[V_2]$

In this subsection we consider a connected component of $G[V_2]$ which is isomorphic to a star. Through this subsection we denote it by S and label its vertices as in Definition 1. We remark that, as none of the Rules (R0) – (R7) is applicable, there is exactly one red vertex connected to S.

▶ **Context rule (R8).** Let S be a star in $G[V_2]$ and let w be a red vertex connected to S. This rule is divided into three subrules (R8.1), (R8.2) and (R8.3) based on how w is connected to S.

▶ **Branching rule (R8.1).** A red vertex w is connected to at least two leaves of S, let those two leaves be l_1, l_2. Then branch on $\langle\, l_1 \mid s \mid L \setminus \{l_1, l_2\} \,\rangle$.

▶ **Branching rule (R8.2).** A red vertex w is connected only to s in S and w is connected to some other vertex x in $G[V_2]$ outside S and y is a neighbor of x in $G[V_2]$. Then branch on $\langle\, s \mid x \mid y \,\rangle$.

▶ **Branching rule (R8.3).** A red vertex w is connected to l_1 in S, w can be connected also to s in S, and w is connected to some other vertex x in $G[V_2]$ outside S. Then branch on $\langle\, s \mid l_1 \mid x \,\rangle$.

▶ **Lemma 18.** *Assume that Rules (R0) – (R8) are not applicable. Then there are no stars in $G[V_2]$.*

Proof. For contradiction assume that Rules (R0) – (R8) are not applicable and there is a star S in $G[V_2]$.

If there is no P_5 that uses vertices from S, then Rule (R1) is applicable on S. Suppose there are at least two red vertices connected to S. If the red vertices are not connected to a single vertex or a single edge in S, then Rule (R2) is applicable, since there is a P_5 that uses at least two red vertices. So suppose the red vertices are connected to a single vertex or a single edge in S. Then from Lemmata 8 and 9 we know that those red vertices are not connected to any other vertices outside S. Consequently, there cannot be a P_5 that uses vertices from S and again Rule (R1) is applicable on S.

So suppose that there is a P_5 that uses vertices from S and there is only one red vertex w connected to S. If w is connected to two leaves, then Rule (R8.1) is applicable. So suppose that w is not connected to two leaves. There are three not mutually isomorphic possibilities how w can be connected to S: $\{l_1\}$, $\{s\}$, and $\{l_1, s\}$. In those cases we apply Rules (R8.3), (R8.2), and (R8.3), respectively. ◀

3.9 Dealing with stars with a triangle in $G[V_2]$

In this subsection we consider a connected component of $G[V_2]$ which is isomorphic to a star with a triangle. Through this subsection we denote it by $S^{\triangle}$ and label its vertices as in Definition 2.

▶ **Context rule (R9).** Let $S^{\triangle}$ be a star with a triangle in $G[V_2]$ and let w be a red vertex connected to $S^{\triangle}$. This rule is divided into four subrules (R9.1), (R9.2), (R9.3) and (R9.4) based on how w is connected to $S^{\triangle}$.

▶ **Branching rule (R9.1).** There is a red vertex w such that $\{t_1, t_2\} \subseteq N(w)$. Then branch on $\langle\, t_1 \mid s \mid L \,\rangle$.

▶ **Branching rule (R9.2).** There is a red vertex w such that $|\{t_1, t_2\} \cap N(w)| = 1$, assume that w is connected to t_1. Then branch on $\langle\, t_1 \mid s \mid L \,\rangle$.

▶ **Lemma 19.** *Assume that Rules (R0) – (R9.1) are not applicable and the assumptions of Rule (R9.2) are satisfied. If F is a solution that contains t_2, then at least one of the following holds:*
(1) $t_1 \in F$,
(2) $F' = (F \setminus \{t_2\}) \cup \{t_1\}$ *is a solution.*

▶ **Branching rule (R9.3).** There is a red vertex w connected to a leaf of $S^{\triangle}$, let that leaf be l_1. Then branch on $\langle\, l_1 \mid s \,\rangle$.

▶ **Branching rule (R9.4).** A red vertex w is connected only to s in $S^{\triangle}$. Then w must be also connected to some component of $G[V_2]$ other than $S^{\triangle}$, otherwise no P_5 would occur in the component containing $S^{\triangle}$. Label the vertex to which w connects outside $S^{\triangle}$ as x. Then branch on $\langle\, s \mid x \,\rangle$.

▶ **Lemma 20.** *Assume that Rules (R0) – (R9) are not applicable. Then there are no stars with a triangle in $G[V_2]$.*

3.10 Dealing with di-stars in $G[V_2]$

In this subsection we consider a connected component of $G[V_2]$ which is isomorphic to a di-star. Through this subsection we denote it by D and label its vertices as in Definition 3.

▶ **Branching rule (R10).** Let D be a di-star in $G[V_2]$ and let there be a red vertex w connected to at least two leaves on the same side of the di-star, i.e. $|N(w) \cap L| \geq 2$ or $|N(w) \cap L'| \geq 2$. Assume that those leaves are from L and l_1, l_2 are among them. Observe that there is no other red vertex connected to l_1, l_2. Then branch on $\langle\, l_1 \mid s \mid s' \,\rangle$.

Proof of correctness. We have to delete something in $\{l_1, l_2, s, s'\}$ and since l_1, l_2 are twins, from Lemma 12 we know that we have to try only one of them, thus branching on $\langle\, l_1 \mid s \mid s' \,\rangle$ is correct. ◀

▶ **Context rule (R11).** Let D be a di-star in $G[V_2]$ and let w be the only red vertex connected to D such that $\{s, s'\} \subseteq N(w)$. This rule is split into three subrules (R11.1), (R11.2), and (R11.3) based on the degrees of s and s'.

▶ **Context rule (R11.1).** Assume that both s, s' have degree two in $G[V_2]$, i.e. the di-star D is actually a P_4. This rule is split into four subrules (R11.1a), (R11.1b), (R11.1c), and (R11.1d) based on how w is connected to D and whether w is connected to other components.

▶ **Branching rule (R11.1a).** Vertex w is connected only to s, s' in D. Then branch on $\langle\, s \mid s' \,\rangle$.

▶ **Branching rule (R11.1b).** Vertex w is connected to s, s' and to one leaf in D, let that leaf be l_1. Then branch on $\langle\, l_1 \mid s \mid s' \,\rangle$.

▶ **Branching rule (R11.1c).** Vertex w is connected to l_1, l'_1, s, s' in D and to at least one other component of $G[V_2]$, label the vertex w connects to outside D as x and the neighbor of x in $G[V_2]$ as y. Then branch on $\langle\, x \mid y \mid \{l_1, s'\} \mid \{s, l'_1\} \mid \{s, s'\}\,\rangle$.

▶ **Reduction rule (R11.1d).** Vertex w is connected only to l_1, l'_1, s, s' in D and to no other component of $G[V_2]$. Then delete any vertex v in D and add it to the solution F.

▶ **Context rule (R11.2).** Assume that exactly one of s, s' has degree at least 3 in $G[V_2]$, let it be s. This rule is split into four subrules (R11.2a), (R11.2b), (R11.2c), and (R11.2d) based on how w is connected to D.

▶ **Branching rule (R11.2a).** Vertex w is connected only to s, s' in D. Then branch on $\langle\, s \mid s'\,\rangle$.

▶ **Branching rule (R11.2b).** Vertex w is connected to s, s' and exactly one leaf from L in D, let that leaf be l_1. Then branch on $\langle\, l_1 \mid s \mid s'\,\rangle$.

▶ **Branching rule (R11.2c).** Vertex w is connected to s, s', l'_1 in D. Then branch on $\langle\, l'_1 \mid s \mid s'\,\rangle$.

▶ **Branching rule (R11.2d).** Vertex w is connected to s, s', l'_1 and exactly one leaf from L in D, let that leaf be l_1. Then branch on $\langle\, l_1 \mid s \mid s'\,\rangle$.

▶ **Branching rule (R11.3).** Assume that both s, s' in D have degree at least 3 in $G[V_2]$. Then branch on $\langle\, L \mid s \mid s' \mid L'\,\rangle$.

▶ **Context rule (R12).** Let D be a di-star in $G[V_2]$ and let w be the only red vertex connected to D such that w is connected to D by exactly two edges. We know that w is connected to a subset of $\{l_1, s, s', l'_1\}$, but not to both s and s'. This rule is split into three subrules (R12.1), (R12.2), and (R12.3) based on how w is connected to D.

▶ **Branching rule (R12.1).** Vertex w is connected to a center and its leaf in D, let them be s and l_1. Then branch on $\langle\, l_1 \mid s\,\rangle$.

▶ **Branching rule (R12.2).** Vertex w is connected to a center and to a leaf of the other center in D, let them be s' and l_1. Then branch on $\langle\, l_1 \mid s \mid s'\,\rangle$.

▶ **Context rule (R12.3).** Vertex w is connected to two opposite leaves in D, let them be l_1 and l'_1. This rule is split into four subrules (R12.3a), (R12.3b), (R12.3c), and (R12.3d) based on the degrees of s and s' and whether w is connected to other components.

▶ **Branching rule (R12.3a).** Both s, s' in D have degree 2 in $G[V_2]$ and w is connected to a component of $G[V_2]$ other than D, let x be the vertex w connects to outside D and let y be a neighbor of x in $G[V_2]$. Then branch on $\langle\, x \mid y \mid \{l_1, l'_1\}\,\rangle$.

▶ **Reduction rule (R12.3b).** Both s, s' in D have degree 2 in $G[V_2]$ and w is not connected to a component of $G[V_2]$ other than D. Then delete any vertex v in D and add it to the solution F.

▶ **Branching rule (R12.3c).** Exactly one of s, s' in D has degree at least 3 in $G[V_2]$, let it be s. Then branch on $\langle\, l_1 \mid s \mid l'_1\,\rangle$.

▶ **Branching rule (R12.3d).** Both s, s' in D have degree at least 3 in $G[V_2]$. Then branch on $\langle\, s \mid s' \mid \{l_1, l'_1\}\,\rangle$.

▶ **Context rule (R13).** Let D be a di-star in $G[V_2]$ and let w be the only red vertex connected to D such that w is connected to D by exactly three edges. We know that w is connected to a subset of $\{l_1, s, s', l'_1\}$, but not to both s and s'. Assume that w is connected to l_1, s, l'_1. This rule is split into four subrules (R13.1), (R13.2), (R13.3) and (R13.4) based on the degrees of s and s' and whether w is connected to other components.

▶ **Branching rule (R13.1).** Both s, s' in D have degree 2 in $G[V_2]$ and w is connected to at least one other component of $G[V_2]$, label the vertex w connects to outside D as x and the neighbor of x in $G[V_2]$ as y. Then branch on $\langle\, x \mid y \mid \{l_1, s'\} \mid \{s, l'_1\} \,\rangle$.

Proof of correctness. If none of the vertices x, y is deleted, then we have to delete at least two and, by Lemma 16, at most three vertices in D. Suppose we wanted to delete exactly two vertices. Out of six possible pairs, only $\{l_1, s'\}, \{s, s'\}, \{s, l'_1\}$ lead to a solution. We do not have to try $\{s, s'\}$, since if we delete s, then Lemma 10 becomes applicable and we may delete l'_1 instead of s'. Finally, if we wanted to delete three vertices, then by Lemma 16 those vertices would be $\{l_1, s, l'_1\}$, but this is already covered by branching on $\{s, l'_1\}$. Thus branching on $\langle\, x \mid y \mid \{l_1, s'\} \mid \{s, l'_1\} \,\rangle$ is correct. ◀

▶ **Reduction rule (R13.2).** Both s, s' in D have degree 2 in $G[V_2]$ and w is not connected to other component of $G[V_2]$. Then delete any vertex v in D and add it to the solution F.

▶ **Branching rule (R13.3).** Vertex s in D has degree at least 3 in $G[V_2]$. Then branch on $\langle\, l_1 \mid s \mid l'_1 \,\rangle$.

▶ **Branching rule (R13.4).** Vertex s' in D has degree at least 3 in $G[V_2]$. Then branch on $\langle\, l_1 \mid s' \mid l'_1 \,\rangle$.

▶ **Context rule (R14).** There is exactly one red vertex w connected to D by one edge. This rule is split into two subrules (R14.1) and (R14.2) based on how w is connected to D.

▶ **Reduction rule (R14.1).** Vertex w is connected to a leaf in D, let it be l_1. Then delete l_1 and add it to the solution F.

▶ **Branching rule (R14.2).** Vertex w is connected to a center in D, let it be s, and w is connected to at least one component of $G[V_2]$ other than D, label the vertex w connects to outside D as x. Then branch on $\langle\, s \mid x \,\rangle$.

▶ **Reduction rule (R15).** There are at least two red vertices connected to D by exactly one edge and they are connected to a single vertex. From Lemma 8 we know, that the red vertices are not connected to a component of $G[V_2]$ other than D and hence the single vertex must be a leaf, let it be l_1, otherwise no P_5 would be formed and Rule (R1) would be applicable. Then delete l_1 and add it to the solution F.

▶ **Branching rule (R16).** There are at least two red vertices connected to D by exactly one edge and they are connected to two opposite leaves, let those leaves be l_1, l'_1. Assume that there is at least one red vertex connected to each one of them. Further assume that the red vertices connected to l_1 are not connected to a component of $G[V_2]$ other than D. Then branch on $\langle\, s' \mid l'_1 \,\rangle$.

▶ **Branching rule (R17).** Let there be a di-star D and the two red vertices w, w' connected to D are connected to leaves l_1, l'_1, respectively, and at least one of the centers has degree at least three, let it be s. Then branch on $\langle\, s \mid s' \mid l'_1 \,\rangle$.

▶ **Branching rule (R18).** Let there be a di-star D and the two red vertices w, w' connected to D are connected to leaves l_1, l_1', respectively, and both centers have degree exactly two. Then branch on $\langle\, l_1 \mid l_1' \,\rangle$.

▶ **Lemma 21.** *Assume that Rules (R0) – (R9) are not applicable. Then at least one of Rules (R10) – (R18) is applicable.*

Proof. From Lemma 4 together with Lemmata 7, 13, 14, 15, 17, 18 and 20 we are now in the situation in which all components of $G[V_2]$ are di-stars and there must be a di-star D in $G[V_2]$ such that there is a P_5 that uses the vertices of D which implies there is at least one red vertex connected to D. For contradiction assume that Rules (R10) – (R18) are not applicable, i.e. no rules are applicable.

Let w be some red vertex connected to D. If $|N(w) \cap L| \geq 2$ or $|N(w) \cap L'| \geq 2$, then Rule (R10) is applicable. If there there is a red vertex w connected to l_i and a red vertex w' connected to l_j, $j \neq i$, then Rule (R2) applies. Similarly with vertices connected to l_i' and l_j'. So for the rest of this proof assume that each red vertex can be connected only to vertices l_1, s, s', or l_1'.

Firstly, assume that there is only one red vertex w connected to D. In Table 1 we list all possibilities (omitting several isomorphic cases) based on how w is connected to D, on the degrees of s and s', and whether w is connected only to D ($N(w) \subseteq V(D)$) or w is also connected outside D ($N(w) \nsubseteq V(D)$).

Observe that if there were at least two red vertices connected to D and w was connected to D by at least two edges, then Rule (R2) would be applicable with the only exception in case where w is connected to $\{l_1, s\}$ or $\{s', l_1'\}$ and the other red vertices to s or s', respectively. But this exception is resolved by Rule (R1) since vertices connected only to s or s' in this configuration are not used by any P_5. With this in mind, if there are at least two red vertices connected to D, then they are connected to D by only one edge.

Secondly, assume that there are at least two red vertices connected to D by exactly one edge. Let $X \subseteq V(D)$ be the vertices to which the red vertices are connected in D. Again, if $|X \cap L| \geq 2$ or $|X \cap L'| \geq 2$, then Rule (R2) applies. So suppose that $X \subseteq \{l_1, s, s', l_1'\}$. If $\{l_1, s'\} \subseteq X$ or $\{s, l_1'\} \subseteq X$ (which covers also cases where $|X| \geq 3$), then again Rule (R2) is applicable. If the vertices are connected to a single edge, then at least one of the vertices of such edge is a center, the vertices connected to it are not used by any P_5, and Rule (R1) applies. We conclude that the red vertices may be connected only to a single vertex or to two opposite leaves in D.

Thirdly, assume that the red vertices are connected to a single vertex. If that vertex is a leaf, then Rule (R15) is applicable, otherwise Rule (R1) is applicable.

Fourthly, assume that the red vertices are connected to two opposite leaves, let them be l_1 and l_1', and let W be the set of red vertices connected to l_1 and W' be the set of red vertices connected to l_1'. If the vertices in W or in W' (or both) are not connected to any component other than D, then Rule (R16) is applicable. This is the case whenever $|W| \geq 2$ or $|W'| \geq 2$ by Lemma 8.

Observe that now we are in situation in which there are exactly two red vertices w and w' connected to D by exactly one edge and these vertices are connected to l_1 and l_1', assume that w is connected to l_1 and w' is connected to l_1'. Furthermore, vertices w and w' are connected to at least one other di-star in $G[V_2]$. If at least one of L, L' has size at least two, then Rule (R17) is applicable, otherwise all di-stars in $G[V_2]$ are actually a P_4 paths and Rule (R18) is applicable.

Finally, there is no di-star remaining in $G[V_2]$ which together with Lemmata 4, 7, 13, 14, 15, 17, 18 and 20 implies that $G[V_2] = \emptyset$ and since V_1, V_2 is a P_5-free bipartition, there is no P_5 path remaining in G and Rule (R0) is applicable. ◀

Table 1 Possible configurations of single red vertex w and D in Lemma 21.

	$N(w) \not\subseteq V(D)$			$N(w) \subseteq V(D)$

3.11 Final remarks

From Lemma 21 we know that there is always at least one rule applicable. It remains to analyze the running time of the disjoint compression routine DISJOINT_R.

▶ **Theorem 22.** *The* DISJOINT_R *procedure solves the* 5-PVCWB *problem in* $\mathcal{O}^*(3^k)$ *time.*

By standard arguments (see Cygan et al. [3, pages 80–81]) we get the following corollary.

▶ **Corollary 23.** *The iterative compression algorithm solves the* 5-PVC *problem and runs in* $\mathcal{O}^*(4^k)$ *time.*

4 Conclusion

We conclude this paper with a few open questions.

Firstly, we see the trend of solving 3-PVC, 4-PVC and now 5-PVC with the iterative compression technique, so it is natural to ask whether this approach can be further used for 6-PVC or even to d-PVC in general. However, given the complexity (number of rules) of the algorithm presented in this paper, it seems more reasonable to first try to find a simpler algorithm for 5-PVC.

Secondly, motivated by the work of Orenstein et al. [13], we ask whether known algorithms for 3-PVC, 4-PVC, 5-PVC can be generalized to work with directed graphs.

Finally, due to Fafianie and Kratsch [5] we know that d-PVC problem has a kernel with $\mathcal{O}(k^d)$ vertices and edges. Dell and van Melkebeek [4] showed that there is no $\mathcal{O}(k^{d-\epsilon})$ kernel for any $\epsilon > 0$ for general d-HITTING SET unless coNP is in NP/poly, which would imply a collapse of the polynomial-time hierarchy. However, for 3-PVC problem, Xiao and Kou [19] presented a kernel with $5k$ vertices. To our knowledge, it is not known whether there exists a linear kernel for 4-PVC or any d-PVC with $d \geq 5$.

Abstract

A prototypical graph problem is centered around a graph-theoretic property for a set of vertices and a solution to it is a set of vertices for which the desired property holds. The task is to decide whether, in the given graph, there exists a solution of a certain quality, where we use size as a quality measure. In this work, we are changing the measure to the fair measure (cf. Lin and Sahni [27]). The fair measure of a set of vertices S is (at most) k if the number of neighbors in the set S of any vertex (in the input graph) does not exceed k. One possible way to study graph problems is by defining the property in a certain logic. For a given objective, an evaluation problem is to find a set (of vertices) that simultaneously minimizes the assumed measure and satisfies an appropriate formula. More formally, we study the MSO Fair Vertex Evaluation, where the graph-theoretic property is described by an MSO formula.

In the presented paper we show that there is an FPT algorithm for the MSO Fair Vertex Evaluation problem for formulas with one free variable parameterized by the twin cover number of the input graph and the size of the formula. One may define an extended variant of MSO Fair Vertex Evaluation for formulas with ℓ free variables; here we measure a maximum number of neighbors in each of the ℓ sets. However, such variant is W[1]-hard for parameter ℓ even on graphs with twin cover one.

Furthermore, we study the Fair Vertex Cover (Fair VC) problem. Fair VC is among the simplest problems with respect to the demanded property (i.e., the rest forms an edgeless graph). On the negative side, Fair VC is W[1]-hard when parameterized by both treedepth and feedback vertex set of the input graph. On the positive side, we provide an FPT algorithm for the parameter modular width.

1 Introduction

A prototypical graph problem is centered around a fixed property for a set of vertices. A solution is any set of vertices for which the given property holds. In a similar manner, one can define the solution as a set of vertices such that the given property holds when we remove this set of vertices from the input graph. This leads to the introduction of deletion problems – a standard reformulation of some classical problems in combinatorial optimization introduced by Yannakakis [37]. Formally, for a graph property π we formulate a *vertex deletion problem*. That is, given a graph $G = (V, E)$, find a smallest possible set of vertices W such that $G \setminus W$ satisfies the property π. Many classical problems can be formulated in this way such as Minimum Vertex Cover (π describes an edgeless graph) or Minimum Feedback Vertex Set (π is valid for forests).

Clearly, the complexity of a graph problem is governed by the associated property π. We can either study one particular problem or a broader class of problems with related graph-theoretic properties. One such relation comes from logic, for example, two properties are related if it is possible to express both by a first order (FO) formula. Then, it is possible to design a *model checking algorithm* that for any property π expressible in the fixed logic decides whether the input graph with the vertices from W removed satisfies π or not.

Undoubtedly, Courcelle's Theorem [4] for graph properties expressible in the monadic second-order logic (MSO) on graphs of bounded treewidth plays a prime role among model checking algorithms. In particular, Courcelle's Theorem provides for an MSO sentence φ an algorithm that given an n-vertex graph G with treewidth k decides whether φ holds in G in time $f(k, |\varphi|)n$, where f is some computable function and $|\varphi|$ is the quantifier depth of φ. In terms of parameterized complexity, such an algorithm is called *fixed-parameter tractable* (the problem belongs to the class FPT for the combined parameter $k + |\varphi|$). We refer the reader to monographs [7, 8] for background on parameterized complexity theory and algorithm design. There are many more FPT model-checking algorithms, e.g., an algorithm for (existential counting) modal logic model checking on graphs of bounded treewidth [33], MSO model checking on graphs of bounded neighborhood diversity [24], or MSO model checking on graphs of bounded shrubdepth [14] (generalizing the previous result). First order logic (FO) model checking received recently quite some attention as well and algorithms for graphs with bounded degree [34], nowhere dense graphs [16], and some dense graph classes [11] were given.

Fair Objective. Fair deletion problems, introduced by Lin and Sahni [27], are such modifications of deletion problems where instead of minimizing the size of the deleted set we change the objective. The Fair Vertex Deletion problem is defined as follows. For a given graph $G = (V, E)$ and a property π, the task is to find a set $W \subseteq V$ which minimizes the maximum number of neighbors in the set W over all vertices, such that the property π holds in $G \setminus W$. Intuitively, the solution should not be concentrated in a neighborhood of any vertex. In order to classify (fair) vertex deletion problems we study the associated decision version, that is, we are interested in finding a set W of size at most k, for a given number k. Note that this can introduce only polynomial slowdown, as the value of our objective is bounded by 0 from below and by the number of vertices of the input graph from above (provided a solution exists). Since we are about to use a formula with a free variable X to express the desired property π, we naturally use X to represent the set of deleted vertices in the formula. The *fair cost of a set* $W \subseteq V$ is defined as $\max_{v \in V} |N(v) \cap W|$. We refer to the function that assigns each set $W \subseteq V$ its fair cost as to the *fair objective function*. Here, we give a formal definition of the computational problem when the property π is defined in some logic L.

Fair L Vertex Deletion
Input: An undirected graph $G = (V, E)$, an L sentence φ, and a positive integer k.
Question: Is there a set $W \subseteq V$ of fair cost at most k such that $G \setminus W \models \varphi$?

Let $\varphi(X)$ be a formula with one free variable and let $G = (V, E)$ be a graph. For a set $W \subseteq V$ by $\varphi(W)$ we mean that we substitute W for X in φ. The definition below can be naturally generalized to contain ℓ free variables. We would like to point out one crucial difference between deletion and evaluation problems, namely that in evaluation problems we have access to the variable that represents the solution. This enables evaluation problems to impose some conditions on the solution, e.g., we can ensure that the graph induced by the solution has diameter at most 2 or is triangle-free.

Fair L Vertex Evaluation[1]
Input: An undirected graph $G = (V, E)$, an L formula $\varphi(X)$ with one free variable, and a positive integer k.
Question: Is there a set $W \subseteq V$ of fair cost at most k such that $G \models \varphi(W)$?

Minimizing the fair cost arises naturally for edge problems in many situations as well, e.g., in defective coloring [6], which has been substantialy studied from the practical network communication point of view [17, 19]. A graph $G = (V, E)$ is (k, d)-colorable if every vertex can be assigned a color from the set $[k]$ in such a way that every vertex has at most d neighbors of the same color. This problem can be reformulated in terms of fair deletion; we aim to find a set of edges F such that graph $G' = (V, F)$ has maximum degree d and $G \setminus F$ can be partitioned into k independent sets.

Related Results. There are several possible research directions once a model checking algorithm is known. One possibility is to broaden the result either by enlarging the class of graphs it works for or by extending the expressive power of the concerned logic, e.g., by introducing a new predicate [23]. Another obvious possibility is to find the exact complexity of the general model checking problem by providing better algorithms (e.g., for subclasses [24]) and/or lower-bounds for the problem [9, 25]. Finally, one may instead of deciding a sentence turn attention to finding a set satisfying a formula with a free variable that is optimal with respect to some objective function [1, 5, 15]. In this work, we take the last presented approach – extending a previous work on MSO model checking for the fair objective function.

When extending a model checking result to incorporate an objective function or a predicate, we face two substantial difficulties. On the one hand, we are trying to introduce as strong extension as possible, while on the other, we try not to worsen the running time too much. Of course, these two are in a clash. One evident possibility is to sacrifice the running time and obtain an XP algorithm, that is, an algorithm running in time $f(k)|G|^{g(k)}$. For example there is an XP algorithm for the Fair MSO_2 Vertex Evaluation problems parameterized by treewidth (and the size of the formula) by Kolman et al. [21] running in time $f(|\varphi|, \mathrm{tw}(G))|G|^{g(\mathrm{tw}(G))}$. An orthogonal extension is due to Szeider [35] for the so-called local cardinality constraints (MSO-LCC) who gave an XP algorithm parameterized by treewidth. If we decide to keep the FPT running time, such a result is not possible for treedepth (consequently for treewidth), as we give W[1]-hardness result for a very basic

[1] This problem is called Generalized Fair L Vertex-Deletion in [29] and in the respective conference version [28]. However, we believe that evaluation is a more suitable expression and coincides with standard terminology in logic.

Fair $\mathsf{L}_\emptyset$ Vertex Deletion problem[2] in this paper. A weaker form of this hardness was already known for FO logic [29]. Ganian and Obdržálek [15] study CardMSO and provide an FPT algorithm parameterized by neighborhood diversity. Recently, Masařík and Toufar [29] examined fair objective and provide an FPT algorithm for the Fair MSO_1 Vertex Evaluation problem parameterized by neighborhood diversity. See also [20] for a discussion of various extensions of the MSO.

We want to turn a particular attention to the Fair Vertex Cover (Fair VC) problem which, besides its natural connection with Vertex Cover, has some further interesting properties. For example, we can think about classical vertex cover as having several crossroads (vertices) and roads (edges) that we need to monitor. However, people could get uneasy if they will see too many policemen from one single crossroad. In contrast, if the vertex cover has low fair cost, it covers all roads while keeping a low number of policemen in the neighborhood of every single crossroad.

1.1 Our Results

We give a metatheorem for graphs having bounded twin cover. Twin cover (introduced by Ganian [12]; see also [13]) is one possible generalization of the vertex cover number. Here, we measure the number of vertices needed to cover all edges that are not twin-edges; an edge $\{u, v\}$ is a *twin-edge* if $N(u) \setminus \{v\} = N(v) \setminus \{u\}$. Ganian introduced twin cover in the hope that it should be possible to extend algorithms designed for parameterization by the vertex cover number to a broader class of graphs.

▶ **Theorem 1.** *The* Fair MSO_1 Vertex Evaluation *problem parameterized by the twin cover number and the quantifier depth of the formula admits an* FPT *algorithm.*

We want to point out here that in order to obtain this result we have to reprove the original result of Ganian [12] for MSO_1 model checking on graphs of bounded twin cover. For this, we extend arguments given by Lampis [24] in the design of an FPT algorithm for MSO_1 model checking on graphs of bounded neighborhood diversity. We do this to obtain better insight into the structure of the graph (a kernel) on which model checking is performed (its size is bounded by a function of the parameter). This, in turn, allows us to find a solution minimizing the fair cost and satisfying the MSO_1 formula. The result by Ganian in version [12] is based on the fact that graphs of bounded twin cover have bounded shrubdepth and so MSO_1 model checking algorithm on shrubdepth ([14, 10]) can be used.

When proving hardness results it is convenient to show the hardness result for a concrete problem that is expressible by an MSO_1 formula, yet as simple as possible. Therefore, we introduce a key problem for Fair Vertex Deletion – the Fair VC problem.

Fair Vertex Cover (Fair VC)	
Input:	An undirected graph $G = (V, E)$, and a positive integer k.
Question:	Is there a set $W \subseteq V$ of fair cost at most k such that $G \setminus W$ is an edgeless graph?

The Fair VC problem can be expressed in any logic that can express an edgeless graph (we denote such logic $\mathsf{L}_\emptyset$) which is way weaker than FO. Therefore, we propose a systematic study of the Fair VC problem which, up to our knowledge, have not been considered before.

▶ **Theorem 2.** *The* Fair VC *problem parameterized by treedepth* $\operatorname{td}(G)$ *and feedback vertex set* $\operatorname{fvs}(G)$ *combined is* W[1]*-hard.*

[2] Here, $\mathsf{L}_\emptyset$ stands for any logic that can express an edgeless graph.

Table 1 The table summarize some related (with a citation) and all the presented (with a reference) results on the studied parameters. Green cells denote FPT results, and red cells represent hardness results. Logic L in metatheorems is specified by a logic used in the respective theorem. Symbol $*$ denotes implied results from previous research and symbol ✓denotes new implied results. A question mark (?) indicates that the complexity is unknown.

	vc	fvs + td	tc	nd	cvd	mw
Fair VC	$*$	T2	✓	$*$	?	T3
FV L Del	MSO$_2$ $*$	L$_\emptyset$ ✓	MSO$_1$ ✓	MSO$_1$ $*$	?	?
FV L Eval	MSO$_2$ [29]	L$_\emptyset$ ✓	MSO$_1$ T1	MSO$_1$ $*$	?	?
ℓ-FV L Eval	MSO$_1$ $*$	L$_\emptyset$ ✓	MSO$_1$ T5	MSO$_1$ [20]	MSO$_1$ ✓	MSO$_1$ ✓

Note that this immediately yields W[1]-hardness and $f(w)n^{o(\sqrt{w})}$ lower bound for Fair L$_\emptyset$ Vertex Evaluation. Previously, an $f(w)n^{o(w^{1/3})}$ lower bound was given for FO logic by Masařík and Toufar [29]. Thus our result is stronger in both directions, i.e., the lower bound is stronger, and the logic is less powerful. On the other hand, we show that Fair VC can be solved efficiently in dense graph models.

▶ **Theorem 3.** *The* Fair VC *problem parameterized by modular width* $\mathrm{mw}(G)$ *admits an* FPT *algorithm with running time* $2^{\mathrm{mw}(G)} \cdot \mathrm{mw}(G) \cdot n^3$*, where n is the number of vertices in G.*

We point out that the Fair VC problem is (rather trivially) AND-compositional and thus it does not admit a polynomial kernel for parameterization by modular width.

▶ **Lemma 4.** *The* Fair VC *problem parameterized by the modular width of the input graph does not admit a polynomial kernel, unless* NP $\subseteq$ coNP/ poly.

Moreover, an analog to Theorem 3 cannot hold for parameterization by shrubdepth of the input graph. This is a consequence of Theorem 2 and the fact that if a class of graphs has bounded treedepth, then it has bounded shrubdepth (cf. [14, Proposition 3.4]).

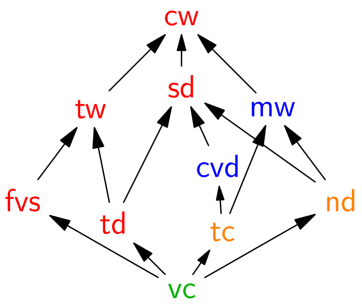
Another limitation in a rush for extensions of Theorem 1 is given when aiming for more free variables. More formally, the problem ℓ-Fair L Vertex Evaluation has formula $\varphi(X_1, \ldots, X_\ell)$ with ℓ free variables as an input and $W_1, \ldots, W_\ell$ are the corresponding sets in G of fair cost at most k. The *fair cost* of $W_1, \ldots, W_\ell$ is defined as $\max_{v \in V} \max_{i \in [\ell]} |N(v) \cap W_i|$. It is very surprising that such a generalization is not possible for parameterization by twin cover, since the same extension is possible for parameterization by neighborhood diversity [20]. In fact, they prove something even stronger, i.e., an FPT algorithm parameterized by neighborhood diversity in the context of $\mathsf{MSO}^{\mathsf{L}}_{\mathsf{lin}}$ is given in [20]. In $\mathsf{MSO}^{\mathsf{L}}_{\mathsf{lin}}$ one can specify both lower- and upper-bound for each vertex and each free variable (i.e., a feasibility interval is given for every vertex).

▶ **Theorem 5** (★[3]). *The* ℓ-Fair FO Vertex Evaluation *problem is* W[1]*-hard for parameter ℓ even on graphs with twin cover of size one.*

The reduction is done from the Unary ℓ-Bin Packing problem; the lower-bound and W[1]-hardness of Unary ℓ-Bin Packing was given by Jansen et al. [18].

For an overview of the results, please refer to Table 1 and to Figure 1 for the hierarchy of classes.

[3] We mark a result by ★ if the proof is omitted and deferred to the full version (available on arXiv).



🟨 **Figure 1** Hierarchy of graph parameters with depicted complexity of the Fair L Vertex Evaluation problem. An arrow indicates that a graph parameter upper-bounds the other. Thus, hardness results are implied in the direction of arrows, and FPT algorithms are implied in the reverse direction. Green colors indicate FPT results for MSO_2, orange are FPT for MSO_1, blue are open, and red are hardness results. We denote treewidth by tw, shrubdepth by sd, and clique width by cw. We refer to book [7] for definitions. Other parameters and their respective abbreviations are defined in Subsection 1.2.

1.2 Preliminaries

For a positive integer n we denote $[n]$ the set $\{1, \ldots, n\}$. We deal with simple undirected graphs, for further standard notation we refer to monographs: graph theory [30] and parameterized complexity [7]. For a vertex v by $N(v)$ we denote the neighborhood of v and by $N[v]$ we denote the closed neighborhood of vertex v, i.e., $N(v) \cup \{v\}$.

A parameter closely related to twin cover is *cluster vertex deletion* ($\mathrm{cvd}(G)$), that is, the smallest number of vertices one has to delete from a graph in order to get a collection of (disjoint) cliques. *Treedepth* of a graph G ($\mathrm{td}(G)$) is the minimum height of a rooted forest whose transitive closure contains the graph G [31]. *Feedback vertex set* ($\mathrm{fvs}(G)$) is the minimum number of vertices of a graph G whose removal leaves the graph without cycles. *Neighborhood diversity* ($\mathrm{nd}(G)$) is the smallest integer r such that the the vertex set of G can be partitioned into r sets $V_1, \ldots, V_r$ in such a way that the graph $G[V_i]$ is either a clique or an edgeless graph for all $i \in [r]$ and the bipartite graph $G[V_i, V_j]$ is either a complete bipartite graph or an edgeless graph for all distinct $i, j \in [r]$. *Modular width* of a graph G ($\mathrm{mw}(G)$), is the smallest positive integer r such that G can be obtained from an algebraic expression of width at most r, defined as follows. The *width of an expression* A is the maximum number of operands used by any occurrence of the substitution operation in A, where A is an algebraic expression that uses the following operations:

1. Create an isolated vertex.
2. The *substitution operation* with respect to a template graph T with vertex set $[r]$ and graphs $G_1, \ldots, G_r$ created by algebraic expression. The substitution operation, denoted by $T(G_1, \ldots, G_r)$, results in the graph on vertex set $V = V_1 \cup \cdots \cup V_r$ and edge set $E = E_1 \cup \cdots \cup E_r \cup \bigcup_{\{i,j\} \in E(T)} \big\{\{u, v\} : u \in V_i, v \in V_j\big\}$, where $G_i = (V_i, E_i)$ for all $i \in [r]$.

An algebraic expression of width $\mathrm{mw}(G)$ can be computed in linear time [36].

We stick with standard definitions and notation in logic. For a comprehensive summary, please consult a book by Libkin [26].

2 Metatheorems for Fair Evaluation

We show an FPT algorithm as it is stated in Theorem 1. We give a more detailed statement that implies the promised result straigthforwardly.

We split the proof into two parts. First, we show an algorithm for MSO_1 model checking parameterized by twin cover of the graph (Proposition 8). In the second part, we prove that we can even compute the optimal fair cost (Proposition 12) and so derive the promised result.

Overview of the Algorithm. For the model checking algorithm, we closely follow the approach of Lampis [24]. The idea is that if there is a large set of vertices with the same closed neighborhood, then some of them are irrelevant, i.e., we can delete them without affecting the truthfulness of the given formula φ. For graphs of bounded neighborhood diversity using this rule alone can reduce the number of vertices below a bound that depends on $\mathrm{nd}(G)$ and $|\varphi|$ only, thus providing an FPT model checking algorithm. For the graphs of bounded twin cover, this approach can be used to reduce the size of all (twin) cliques, yet their number can still be large. We take the approach one step further and describe the deletion of irrelevant cliques in a similar manner; these rules together yield a model checking algorithm for graphs of bounded twin cover.

The reduction rules also lead to a notion of *shape* of a set $W \subseteq V$. The motivation behind shapes is to partition all subsets of V such that if two sets W, W' have the same shape, then $G \models \varphi(W)$ if and only if $G \models \varphi(W')$. This allows us to consider only one set of each shape for the purposes of model checking. Since the number of all distinct shapes is bounded by some function of parameters, we can essentially brute force through all possible shapes.

A final ingredient is an algorithm that for a given shape outputs a subset of vertices with this shape that minimizes the fair cost. This algorithm uses ILP techniques, in particular minimizing quasiconvex function subject to linear constraints.

Notation. In what follows $G = (V, E)$ is a graph and K is its twin cover of size k. An MSO_1 formula φ contains q_S set quantifiers and q_v element (vertex) quantifiers. Given a twin cover K and $A \subseteq K$, we say that A is the *cover set* of a set $S \subseteq V \setminus K$ if every $v \in S$ has $N(v) \cap K = A$. Note that, by the definition of twin cover, for all $u, v \in V \setminus K$ with $\{u, v\} \in E$ we have that A is a cover set for u if and only if A is a cover set for v. We say that two cliques have the same *type* if they have the same size and the same cover set. Clearly, if the cover set is fixed, two cliques agree on type if and only if their sizes are the same. We define a *labeled graph*, that is, a graph and a collection of labels on the vertices. We say that two cliques have the *same labeled type* if all of them have the same size, the same cover set and the same labels on vertices.

2.1 Model checking

▶ **Proposition 6** ([24, Lemma 5 and Theorem 4]). *Let ϕ be an MSO_1 formula and let G be a labeled graph. If there is a set S of more than $2^{q_S} q_v$ vertices having the same closed neighborhood and the same labels, then for any $v \in S$ we have $G \models \varphi$ if and only if $G \setminus v \models \varphi$.*

In particular, if G is a graph with just one label, then for any clique C where each vertex has exactly the same closed neighborhood in G the following holds. Either there is a vertex $v \in C$ such that $G \models \phi$ if and only if $G \setminus v \models \phi$ or the size of C is bounded by $2^{q_S+1} q_v$.

Proposition 6 bounds the size of a maximum clique in $G \setminus K$ because we can apply it repeatedly for each clique that is bigger than the threshold $2^{q_S+1} q_v$. Now, we need to bound the number of cliques of each type. For this, we establish the following technical lemma.

▶ **Lemma 7** (★)**.** *Let G be a labeled graph with twin cover K. Let φ be an MSO_1 formula with q_v element quantifiers and q_S set quantifiers. Suppose the size of a maximum clique in $G \setminus K$ is bounded by r. If there are strictly more than*

$$\alpha(q_S, q_v) = 2^{rq_S}(q_v + 1)$$

cliques of the same labeled type $\mathcal{T}$, then there exists a clique C of the labeled type $\mathcal{T}$ such that $G \models \varphi$ if and only if $G \setminus C \models \varphi$.

From this, we can derive a model checking algorithm.

▶ **Proposition 8** (★ Model checking on graphs of bounded twin cover)**.** *Let G be a graph with twin cover K of size k and the size of the maximum clique in $G \setminus K$ bounded by $2^{q_S}q_v$ and φ is an MSO_1 sentence then either there exists a clique $C \in G \setminus K$ such that $G \models \phi$ if and only if $G \setminus C \models \varphi$ or the size of G is bounded by*

$$k + (q_v + 1)q_v^2 2^{k+2q_S+2^{q_S}q_Sq_v} = 2^{\mathcal{O}(k+2^{q_S}q_Sq_v)}\,.$$

2.2 Finding a Fair Solution

In the upcoming proof we follow the ideas of Masařík and Toufar [29]. They define, for a given formula $\varphi(X)$, a so-called shape of a set $W \subseteq V$ in G. The idea behind a shape is that in order to do the model checking we have deleted some vertices from G that cannot change the outcome of $\varphi(X)$, however, we have to derive a solution of minimal cost in the whole graph G. Thus the shape characterizes a set under which $\varphi(X)$ holds and we have to be able to find a set $W \subseteq V(G)$ for which $\varphi(W)$ holds and W minimizes the fair cost among sets having this shape.

Shape. Let $G = (V, E)$ be a graph, $\varphi(X)$ an MSO formula, $K \subseteq V$ a twin cover of G, $A \subseteq K$, and let $r = 2^{q_S+2}q_v$ and $\alpha = 2^{r(q_S+1)}(q_v + 1)$. Let $\mathcal{C}$ be the collection of all cliques in G such that A is their cover set. We define an A-*shape.* An A-shape of size r is a two dimensional table S_A of dimension $(r + 2) \times (r + 2)$ indexed by $\{0, 1, \dots, r + 1\} \times \{0, 1, \dots, r + 1\}$. Each entry $S_A(i, j) \in \{0, \dots, \alpha + 1\}$. The interpretation of $S_A(i, j)$ is the minimum of $\alpha + 1$ and of the number of cliques C with $N(C) = A$ such that

$$\min(\alpha + 1, |C \cap W|) = i \text{ and } \min(\alpha + 1, |C \setminus W|) = j.$$

Finally, the shape of X in G is a collection of A-shapes for all $A \subseteq K$.

A solution for $\mathcal{C}$ with cover set A can be formally described by a function sol: $\mathcal{C} \to \mathbb{N} \times \mathbb{N}$. The solution sol is *valid* if for every $C \in \mathcal{C}$ with $\mathrm{sol}(C) = (i, j)$ either $i + j = |C|$ or $|C| \geq r$, $i = r + 1$ (or equivalently $j = r + 1$), and $i + j < |C|$. For an illustration of a valid assignment please refer to Figure 2. We say that a valid solution sol is *compatible* with the shape S_A if $S(i, j) = \left|\mathrm{sol}^{-1}(i, j)\right|$, whenever $S(i, j) \leq \alpha$ and $\left|\mathrm{sol}^{-1}(i, j)\right| \geq \alpha + 1$ if $S(i, j) = \alpha + 1$. The A-shape S_A is said to be valid if there exists a valid solution for S_A. Note that such a solution does not exist if the shape specifies too many (or too few) cliques of certain sizes. The shape S is *valid* if all its A-shapes are valid.

The following lemma is a key observation about shapes.

▶ **Lemma 9.** *Let φ be an MSO_1 formula with one free variable, G a graph and W, W' two subsets of vertices having the same shape. Then $G \models \varphi(W)$ if and only if $G \models \varphi(W')$.*

Figure 3 An example of uncertainty in computation of objective function. The value in the last row depends on the size of the clique we are assigning to those cells. The value in the cell is how much we pay for any compatible clique assigned to this cell.

Proof. The proof follows using Proposition 6 and Lemma 7. Indeed, if we take the graph G with one label corresponding to set W and apply the reduction rules given by Proposition 6 and Lemma 7 and repeat the same process with W', we obtain two isomorphic labeled graphs. ◀

Lemma 9 allows us to say that a formula with one free variable holds under a shape since it is irrelevant which subset of vertices of this particular shape is assigned to the free variable. Also note that deciding whether the formula holds under the shape can be done in FPT time by simply picking arbitrary assignment of the given shape and running a model checking algorithm.

Lemma 11 computes a solution of minimal cost for an A-shape. We do this by reducing the task to integer linear programming (ILP) while using non-linear objective. A fuction $f : \mathbb{R}^p \to \mathbb{R}$ is *separable convex* if there exist convex functions $f_i : \mathbb{R} \to \mathbb{R}$ for $i \in [p]$ such that $f(x_1, \dots, x_p) = \sum_{i=1}^{p} f_i(x_i)$.

▶ **Theorem 10** ([32] – simplified). *Integer linear programming with objective minimization of a separable convex function in dimension p is* FPT *with respect to p and space exponential in L the length of encoding of the ILP instance.*

▶ **Lemma 11.** *Let $G = (V, E)$ be a graph, K be a twin cover of G, and $\emptyset \neq A \subseteq K$. There is an algorithm that given an A-shape S_A of size r computes a valid solution for S_A of minimal cost in time $f(|K|, r) \cdot |G|^{O(1)}$ or reports that S_A is not valid.*

Proof. Let $\mathcal{C}$ be the collection of all cliques such that A is their cover set. We split the task of finding a minimal solution to S_A into two independent parts depending on the size of cliques assigned in the phase.

The first phase is for cliques in $\mathcal{C}$ with sizes at most r. Observe that these can be assigned deterministically in a greedy way. This is because no cell of S_A is shared by two sizes and we can see that if there are more cells with value α on the corresponding diagonal we can always prefer the top one as this minimizes the cost (see Figure 3). However, this is not possible for larger cliques as they may in general share some cells of S_A and thus we defer them to the second phase.

Now observe that the most important vertices for computing the cost are the vertices constituting the set A. To see this just note that all other vertices see only A and their neighborhood (a clique) which is at least as large as for the vertices in A. It follows that we should only care about the number of selected vertices such that A is their cover set. Thus if the size of all cliques in $\mathcal{C}$ is bounded in terms of k we are done. Alas, this is not the case.

We split the set $\mathcal{C}$ into sets $\mathcal{C}_1, \dots, \mathcal{C}_{2r}$, and $\mathcal{C}_{\max}$. A clique $C \in \mathcal{C}$ belongs to $\mathcal{C}_{|C|}$ if $1 \le |C| \le 2r$ and belongs to $\mathcal{C}_{\max}$ otherwise. Note that cliques from $\mathcal{C}_{\max}$ may be assigned only to cells having at least one index $r+1$. As mentioned we are about to design an ILP with a non-linear objective function. This ILP has variables $x_{i,j}^q$ that express the number of cliques from the set $\mathcal{C}_q$ assigned to the cell (i,j) of S_A (that is, $1 \le i,j \le r+1$ and $q \in Q = \{1, \dots, 2r\} \cup \{\max\}$). The obvious conditions are the following (the $\trianglerighteq$ symbol translates to $=$ if $S(i,j) \le \alpha$ while it translates to $\ge$ if $S(i,j) = \alpha + 1$).

$$\sum_{q \in Q} x_{i,j}^q \trianglerighteq S_A(i,j) \qquad 0 \le i,j \le r+1$$

$$\sum_{0 \le i,j \le r+1} x_{i,j}^q = |\mathcal{C}_q| \qquad \forall q \in Q$$

$$x_{i,j}^q \ge 0 \qquad 0 \le i,j \le r+1, \forall q \in Q$$

We are about to minimize the following objective

$$\sum_{0 \le i \le r+1; 0 \le j \le r} \sum_{1 \le q \le 2r} (q-j) x_{i,j}^q + \sum_{0 \le i \le r+1} \sum_{\forall q} i \cdot x_{i,r+1}^q + g\left(x_{r+1,0}^{\max}, \dots, x_{r+1,r}^{\max}\right),$$

where $g \colon \mathbb{N}^r \to \mathbb{N}$ is a function that has access to sizes of all cliques in $\mathcal{C}_{\max}$ and computes the minimum possible assignment. We claim that the function g is a separable convex function in variables $x_{r+1,0}^{\max}, \dots, x_{r+1,r}^{\max}$. The first summand of the objective function describes the cliques of size at most $2r$. Their price corresponds to the number of vertices in the clique q minus the number of vertices that are not selected j. The second summand corresponds to the last row, where the cheapest price is always the number of selected vertices i. The last summand, discussed in the following paragraph, describes the assignment to the last row. The result then follows from Theorem 10 as the number of integral variables is $O(r^3)$.

Observe that the value of $g\left(x_{r+1,0}^{\max}, \dots, x_{r+1,r}^{\max}\right)$ is equal to sum of sizes of cliques "assigned to the last row" minus $\sum_{j=0}^r j \cdot x_{r+1,j}^{\max}$. Now, $g\left(x_{r+1,0}^{\max}, \dots, x_{r+1,r}^{\max}\right) = g'\left(\sum_{j=0}^r x_{r+1,j}^{\max}\right) - \sum_{j=0}^r j \cdot x_{r+1,j}^{\max}$. Since all cliques in $\mathcal{C}_{\max}$ are eligible candidates to be assigned to the last row and since it is always cheaper to assign there those of the smallest size among them, we can define g' based only on the number of cliques that are assigned to the last row. This finishes the proof since g' is a convex function. We defer the details on polynomial space to the full version of the paper. ◀

Now we are ready to prove the main result of this section. It essentially follows by the exhaustive search among all possible shapes S such that φ is true under S and application of Lemma 11.

▶ **Proposition 12.** *Let $G = (V,E)$ be a graph with twin cover K of size k. For an* MSO$_1$ *formula $\varphi(X)$ with one free variable that represents the set to be deleted it is possible to find a set $W \subseteq V$ such that*

- *$\varphi(W)$ holds in G and*
- *the cost of W is minimized among all subset of V satisfying $\varphi(X)$*

in time $f(k, |\varphi|)|V|^{O(1)}$ for some computable function f.

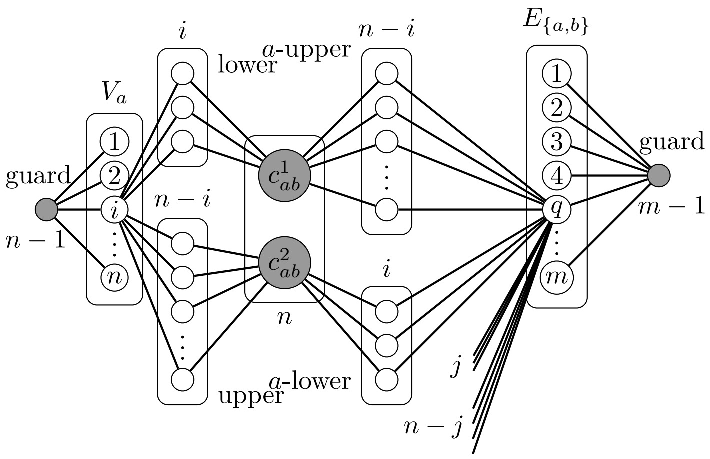

Figure 4 An overview of the reduction in the proof of Theorem 2. The gray vertices are enforced to be a part the fair vertex cover. If a vertex fair objective was lowered, then the resulting threshold is beneath the vertex (the group of vertices).

Proof sketch. We proceed as follows. For every possible selection of $K \cap W$ we generate all possible shapes and check whether $\varphi(X)$ evaluates to true under shape S and if so, we compute W for S having the minimal fair-cost. ◀

3 The Fair VC problem

3.1 Hardness for Treedepth and Feedback Vertex Set

We observe substantial connection between Fair VC and Target Set Selection (TSS). It is worth mentioning that Vertex Cover can be formulated in the language of TSS by setting the threshold to $\deg(v)$ for every vertex v. As a result, our reduction given here is, in certain sense, dual to the one given by Chopin et al. [3] for the TSS problem. However, we will show that the structure of the solution for Fair VC is, in fact, the complement of the structure of the solution for TSS given therein. The archetypal W[1]-hard problem is the ℓ-Multicolored Clique problem [7]:

ℓ-Multicolored Clique *Parameter:* ℓ
Input: An ℓ-partite graph $G = (V_1 \cup \cdots \cup V_\ell, E)$, where V_c is an independent set for every $c \in [\ell]$ and they are pairwise disjoint.
Question: Is there a clique of the size ℓ in G?

Proof sketch of Theorem 2. Refer to figure 4. Observe that we can enforce a vertex v to be a part of the fair vertex cover by attaching $k+1$ degree 1 vertices to v. Notice further that we may adjust (lower) the global budget k for individual vertex v by attaching vertices to v and then attaching k new leaves to the newly added vertices.

There are three types of gadgets in our reduction, namely the vertex selection gadget, the edge selection gadget, and the incidence check gadget. We start by enumerating the vertices in each color class by numbers from $[n]$ and edges by numbers in $[m]$. Now, we construct a graph H in which we are going to look for a vertex cover of small fair cost. Throughout the proof a, b are distinct numbers from $[\ell]$.

A selection gadget consists of z *choice* vertices (representing either the color class V_a with $z = n$ or $E_{\{a,b\}}$ in which case $z = m$), a special vertex called *guard*, and a group of n^2 *enumeration* vertices. The guard vertex is connected to all choice vertices, it is enforced to be a part of the fair vertex cover, and its budget is lowered so that at most $z - 1$ choice vertices can be in any fair vertex cover. The i-th choice vertex is connected to n private enumeration vertices. We further divide these vertices into two parts – the *lower part* consists of q vertices and the *upper part* consists of $n - q$ vertices, where q refers to the vertex number. That is, $q = i$ in case of a vertex choice gadget and for an edge choice gadget, we let $q = v_i$, where v_i is the number of the vertex incident to i-th edge in the corresponding colorclass.

The ab-incidence check gadget consist of two vertices c^1_{ab} and c^2_{ab}. Both c^1_{ab} and c^2_{ab} are enforced to be a part of the solution and with a lowered budget in a way that at most n vertices in the neighborhood of each of them can be part of any fair vertex cover. The vertex c^1_{ab} is connected to every lower part vertex in the selection gadget for V_a and to every upper a-part vertex in the selection gadget for $E_{\{a,b\}}$. For c^2_{ab} we exchange the role of upper- and lower- parts.

▷ Claim 13. Suppose (G, ℓ) is a yes-instance then there is a vertex cover in H with fair cost at most $k = \max(m - 1, 2n)$.

Let $K \subseteq V_1 \times \cdots \times V_\ell$ be a clique in G. We now construct a vertex cover C_K of H having $|N(w) \cap C_K| \le k$ for all $w \in W$. The set C_K contains the following:

1. all enforced vertices (including all guard and check vertices),
2. if $v \in V_a \cap K$ is the i-th vertex of V_a, then all selection vertices of V_a but the vertex i are in C_K and lower and upper enumeration vertices of i are in C_K, and
3. if $v \in V_a \cap K$ and $u \in V_b \cap K$ are adjacent through q-th edge of $E_{\{a,b\}}$, then all selection vertices of $E_{\{a,b\}}$ but the vertex q are in C_K and q's enumeration vertices are in C_K.

The proof of the reverse direction is deferred to the full version due to space limitations.

It remains to discuss the ETH based lower-bound. This follows immediately from our reduction and the result of Chen et al. [2] who proved that there is no $f(k)n^{o(\ell)}$ algorithm for ℓ-Multicolored Clique unless ETH fails. Since we have $\mathrm{td}(G) + \mathrm{fvs}(G) = O(\ell^2)$ in our reduction, the lower-bound follows. ◀

3.2 FPT algorithm for Modular Width

Since an algebraic expression A of width $\mathrm{mw}(G)$ can be computed in linear time [36], we can assume that we have A on the input. We construct the rooted ordered tree $\mathcal{T}$ corresponding to A. Each node $t \in \mathcal{T}$ is assigned a graph $G^t \subseteq G$, that is, the graph constructed by the subexpression of A rooted at t. Suppose we are performing substitution operation at node t with respect to template graph T and graphs $G_1, \dots, G_r$. Denote the resulting graph G^t and denote by n_i the size of $V(G_i)$.

Proof sketch of Theorem 3. The computation will be carried out recursively from the bottom of the tree $\mathcal{T}$. We first describe the structure of all vertex covers C in G^t. Observe that if $ij \in E(T)$, then at least one of $V(G_i), V(G_j)$ must be a subset of C. Thus, the set $C_T := \{i : V(G_i) \subseteq C\}$ is a vertex cover of the template graph T. We call the C_T the *type of the vertex cover* C. Furthermore, every set $C \cap V(G_i)$ must be a vertex cover of G_i. Since there are at most 2^r vertex covers of T, we try all of these. Furthermore, every set $C \cap V(G_i)$ must be a vertex cover of G_i.

We now describe the fair cost of the cover C in terms of fair costs and sizes of the sets $C \cap V(G_i)$. Let $c_i = |C \cap V(G_i)|$ and let f_i denote the fair cost of $C \cap V(G_i)$ in G_i. The *fair cost of* C *in* $W \subseteq V(G)$ is defined as $\max_{v \in W} |C \cap N(v)|$. For $i \in [r]$ the fair cost of C in $V(G_i)$ can be expressed as $f_i + \sum_{j : ij \in E(T)} c_j$. If we know the type C_T of the cover C, this expression can be simplified based on whether i lies in C_T or not. If $i \in C_T$, then f_i is $\Delta(G_i)$ (the maximal degree of G_i). If, on the other hand, $i \notin C_T$, then all its neighbors j are in C_T and in this case $c_j = n_j$. Combining these observations together we get

$$\text{fair cost of } C \text{ in } G_i = \begin{cases} \Delta(G_i) + \sum_{j \notin C_T : ij \in E(T)} c_j + \sum_{j \in C_T : ij \in E(T)} n_j & i \in C_T, \\ f_i + \sum_{j : ij \in E(T)} n_j & i \notin C_T. \end{cases}$$

From this we can design a dynamic program that computes the solution. ◀

4 Conclusions

Fair Edge L Deletion problems. One can define *edge deletion problems* in a similar way as vertex deletion problems.

FAIR L EDGE DELETION	
Input:	An undirected graph $G = (V, E)$, an L sentence φ, and a positive integer k.
Question:	Is there a set $F \subseteq E$ such that $G \setminus F \models \varphi$ and for every vertex v of G, it holds that $|\{e \in F : e \ni v\}| \le k$?

Recall, in dense graph classes one cannot obtain an MSO_2 model checking algorithm running in FPT-time [25]. This is the reason why evaluation problems do not make sense in this context. In sparse graph classes, this problem was studied in [29] where W[1]-hardness was obtained for Fair FO Edge Deletion on graphs of bounded treedepth and FPT algorithm was derived for Fair MSO_2 Edge Evaluation on graphs of bounded vertex cover.

The crucial open problem is to resolve the parameterized complexity of the FAIR FO EDGE DELETION problems for parameterization by neighborhood diversity and twin cover. To motivate the study we prove the following hardness result for parameterization by the cluster vertex deletion number. Recall that for any graph its cluster vertex deletion number is upper-bounded by the size of its twin cover.

▶ **Theorem 14** (★). *The* FAIR FO EDGE DELETION *problem is* W[1]*-hard when parameterized by the cluster vertex deletion number of the input graph.*

Generalization of parameters. Another open problem is to resolve the parameterized complexity of the FAIR MSO_1 VERTEX EVALUATION problems with respect to graph parameters generalizing neighborhood diversity or twin cover (e.g., modular width or cluster vertex deletion number respectively).

MSO with Local Linear Constraints. Previously, an FPT algorithm for evaluation of a fair objective was given for parameter neighborhood diversity [29]. That algorithm was extended [20] to a so-called *local linear constraints* again for a formula $\varphi(\cdot)$ with one free variable that is defined as follows. Every vertex $v \in V(G)$ is accompanied with two positive integers $\ell(v), u(v)$, the lower and the upper bound, and the task is to find a set X that not only $G \models \varphi(X)$ but for each $v \in V(G)$ it holds that $\ell(v) \le |N(v) \cap X| \le u(v)$. Note that this is a generalization as fair objective of value t can be tested in this framework by setting $\ell(v) = 0$ and $u(v) = t$ for every $v \in V(G)$. Is this extension possible for parameterization by the twin cover number?

Towards new fair problems. As we proposed the examination of Fair VC already, we would like to turn an attention to exploring fair versions of other classical and well-studied Vertex Deletion problems. In contrast, certain Fair Edge Deletion problems have got some attention before, namely Fair Feedback Edge Set [27] or Fair Edge Odd Cycle Transversal [22]. Besides Fair VC we propose a study of Fair Dominating Set and Fair Feedback Vertex Set. In particular, it would be really interesting to know whether fair variants of Vertex Cover and Dominating Set admit a similar behavior as in the classical setting.

Furthemore, We would like to ask whether there is an NP-hard Fair Vertex Deletion problem that admits an FPT algorithm for parameterization by treedepth (and feedback vertex set) of the input graph.

Abstract

A *b-coloring* of a graph G is a proper coloring of its vertices such that each color class contains a vertex that has at least one neighbor in all the other color classes. The b-Coloring problem asks whether a graph G has a b-coloring with k colors. The *b-chromatic number* of a graph G, denoted by $\chi_b(G)$, is the maximum number k such that G admits a b-coloring with k colors. We consider the complexity of the b-Coloring problem, whenever the value of k is close to one of two upper bounds on $\chi_b(G)$: The maximum degree $\Delta(G)$ plus one, and the m-degree, denoted by $m(G)$, which is defined as the maximum number i such that G has i vertices of degree at least $i-1$. We obtain a dichotomy result for all fixed $k \in \mathbb{N}$ when k is close to one of the two above mentioned upper bounds. Concretely, we show that if $k \in \{\Delta(G)+1-p, m(G)-p\}$, the problem is polynomial-time solvable whenever $p \in \{0,1\}$ and, even when $k = 3$, it is NP-complete whenever $p \geq 2$. We furthermore consider parameterizations of the b-Coloring problem that involve the maximum degree $\Delta(G)$ of the input graph G and give two FPT-algorithms. First, we show that deciding whether a graph G has a b-coloring with $m(G)$ colors is FPT parameterized by $\Delta(G)$. Second, we show that b-Coloring is FPT parameterized by $\Delta(G) + \ell_k(G)$, where $\ell_k(G)$ denotes the number of vertices of degree at least k.

1 Introduction

Given a set of colors, a *proper coloring* of a graph is an assignment of a color to each of its vertices in such a way that no pair of adjacent vertices receive the same color. In the deeply studied Graph Coloring problem, we are given a graph and the question is to determine the smallest set of colors with which we can properly color the input graph. This problem is among Karp's famous list of 21 NP-complete problems [14] and since it often arises in practice, heuristics to solve it are deployed in a wide range of applications. A very natural such heuristic is the following. We greedily find a proper coloring of the graph, and then try to *suppress* any of its colors in the following way: say we want to suppress color c. If there is a vertex v that has received color c, and there is another color $c' \neq c$ that does not appear in the neighborhood of v, then we can safely recolor the vertex v with color c' without

making the coloring improper. We terminate this process once we cannot suppress any color anymore.

To predict the worst-case behavior of the above heuristic, Irving and Manlove defined the notions of a *b-coloring* and the *b-chromatic number* of a graph [12]. A b-coloring of a graph G is a proper coloring such that in every color class there is a vertex that has a neighbor in all of the remaining color classes, and the b-chromatic number of G, denoted by $\chi_b(G)$, is the maximum integer k such that G admits a b-coloring with k colors. We observe that in a b-coloring with k colors, there is no color that can be suppressed to obtain a proper coloring with $k-1$ colors, hence $\chi_b(G)$ describes the worst-case behavior of the previously described heuristic on the graph G. We consider the following two computational problems associated with b-colorings of graphs.

b-Coloring

Input:	Graph G, integer k
Question:	Does G admit a b-coloring with k colors?

b-Chromatic Number

Input:	Graph G, integer k
Question:	Is $\chi_b(G) \geq k$?

We would like to point out an important distinction from the "standard" notion of proper colorings of graphs: If a graph G has a b-coloring with k colors, then this implies that $\chi_b(G) \geq k$. However, if $\chi_b(G) \geq k$ then we can in general not conclude that G has a b-coloring with k colors. A graph for which the latter implication holds as well is called *b-continuous*. This notion is mostly of structural interest, since the problem of determining if a graph is b-continous is NP-complete even if an optimal proper coloring and a b-coloring with $\chi_b(G)$ colors are given [2].

Besides observing that $\chi_b(G) \leq \Delta(G)+1$ where $\Delta(G)$ denotes the maximum degree of G, Irving and Manlove [12] defined the *m-degree* of G as the largest integer i such that G has i vertices of degree at least $i-1$. It follows that $\chi_b(G) \leq m(G)$. Since the definition of the b-chromatic number originated in the analysis of the worst-case behavior of graph coloring heuristics, graphs whose b-chromatic numbers take on *critical* values, i.e. values that are close to these upper bounds, are of special interest. In particular, identifying them can be helpful in structural investigations concerning the performance of graph coloring heuristics.

In terms of computational complexity, Irving and Manlove showed that both b-Coloring and b-Chromatic Number are NP-complete [12] and Sampaio observed that b-Coloring is NP-complete even for every fixed integer $k \geq 3$ [17]. Panolan et al. [16] gave an exact exponential algorithm for b-Chromatic Number running in time $\mathcal{O}(3^n n^4 \log n)$ and an algorithm that solves b-Coloring in time $\mathcal{O}(\binom{n}{k} 2^{n-k} n^4 \log n)$. From the perspective of parameterized complexity [6, 8], it has been shown that b-Chromatic Number is W[1]-hard parameterized by k [16] and that the dual problem of deciding whether $\chi_b(G) \geq n-k$, where n denotes the number of vertices in G, is FPT parameterized by k [11].

Since the above mentioned upper bounds $\Delta(G)+1$ and $m(G)$ on the b-chromatic number are trivial to compute, it is natural to ask whether there exist efficient algorithms that decide whether $\chi_b(G) = \Delta(G)+1$ or $\chi_b(G) = m(G)$. It turns out both these problems are NP-complete as well [10, 12, 15]. However, it is known that the problem of deciding whether a graph G admits a b-coloring with $k = \Delta(G)+1$ colors is FPT parameterized by k [16, 17].

The Dichotomy Result. One of the main contributions of this paper is a complexity dichotomy of the b-Coloring problem for fixed k, whenever k is close to either $\Delta(G)+1$ or $m(G)$. In particular, for fixed $k \in \{\Delta(G)+1-p, m(G)-p\}$, we show that the problem is polynomial-time solvable when $p \in \{0,1\}$ and, even in the case $k=3$, NP-complete for all fixed $p \geq 2$. More specifically, we give XP time algorithms for the cases $k=m(G)$, $k=\Delta(G)$, and $k=m(G)-1$ which together with the FPT algorithm for the case $k=\Delta(G)+1$ [16, 17] and the aforementioned NP-hardness result for $k=3$ complete the picture. We now formally state this result.

▶ **Theorem 1.** *Let G be a graph, $p \in \mathbb{N}$ and $k \in \{\Delta(G)+1-p, m(G)-p\}$. The problem of deciding whether G has a b-coloring with k colors is*

(i) NP*-complete if k is part of the input and $p \in \{0,1\}$,*
(ii) NP*-complete if $k=3$ and $p \geq 2$, and*
(iii) *polynomial-time solvable for any fixed positive k and $p \in \{0,1\}$.*

Maximum Degree Parameterizations. The positive results in our dichotomy theorem provide XP-algorithms to decide whether a graph has a b-coloring with a number of colors that either *precisely meets* or is *one below* one of two upper bounds on the b-chromatic number, with the parameter being the number of colors in each of the cases. Towards more "flexible" tractability results, we consider parameterized versions of b-Coloring that involve the maximum degree $\Delta(G)$ of the input graph G, but ask for the existence of b-colorings with a number of colors that in general is different from $\Delta(G)+1$ or $\Delta(G)$.

▶ **Theorem 2.** *Let G be a graph. The problem of deciding whether G has a b-coloring with $m(G)$ colors is* FPT *parameterized by $\Delta(G)$.*

One of the crucially used facts in the algorithm of the previous theorem is that if we ask whether a graph G has a b-coloring with $k=m(G)$ colors, then the number of vertices of degree at least k is at most k. We generalize this setting and parameterize b-Coloring by the maximum degree plus the number of vertices of degree at least k.

▶ **Theorem 3.** *Let G be a graph. The problem of deciding whether G has a b-coloring with k colors is* FPT *parameterized by $\Delta(G)+\ell_k(G)$, where $\ell_k(G)$ denotes the number of vertices of degree at least k in G.*

We now argue that parameterizing by only one of the two invariants used in Theorem 3 is not sufficient to obtain efficient parameterized algorithms. From the result of Kratochvíl et al. [15], stating that b-Coloring is NP-complete for $k=\Delta(G)+1$, it follows that b-Coloring is NP-complete when $\Delta(G)$ is unbounded and $\ell_k(G)=0$. On the other hand, Theorem 1(ii) implies that b-Coloring is already NP-complete when $k=3$ and $\Delta(G)=4$. Together, this rules out the possibility of FPT- and even of XP-algorithms for parameterizations by one of the two parameters alone, unless P $=$ NP.

Parameterizations of graph coloring problems by the number of high degree vertices have previously been considered for vertex coloring [1] and edge coloring [9]. Throughout the text, proofs of statements marked with "♣" are deferred to the full version [13].

2 Preliminaries

We use the following notation: For $k \in \mathbb{N}$, $[k] := \{1, \ldots, k\}$. For a function $f\colon X \to Y$ and $X' \subseteq X$, we denote by $f|_{X'}$ the restriction of f to X' and by $f(X')$ the set $\{f(x) \mid x \in X'\}$. For a set X and an integer n, we denote by $\binom{X}{n}$ the set of all size-n subsets of X.

Graphs. Throughout the paper a graph G with vertex set $V(G)$ and edge set $E(G) \subseteq \binom{V(G)}{2}$ is finite and simple. We often denote an edge $\{u, v\} \in E(G)$ by the shorthand uv. For graphs G and H we denote by $H \subseteq G$ that H is a subgraph of G, i.e. $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We often use the notation $n \coloneqq |V(G)|$. For a vertex $v \in V(G)$, we denote by $N_G(v)$ the *open neighborhood* of v in G, i.e. $N_G(v) = \{w \in V(G) \mid vw \in E(G)\}$, and by $N_G[v]$ the *closed neighborhood* of v in G, i.e. $N_G[v] \coloneqq \{v\} \cup N_G(v)$. For a set of vertices $X \subseteq V(G)$, we let $N_G(X) \coloneqq \bigcup_{v \in X} N_G(v) \setminus X$ and $N_G[X] \coloneqq X \cup N_G(X)$. When G is clear from the context, we abbreviate "N_G" to "N". The *degree* of a vertex $v \in V(G)$ is the size of its open neighborhood, and we denote it by $\deg_G(v) \coloneqq |N_G(v)|$ or simply by $\deg(v)$ if G is clear from the context. For an integer k, we denote by $\ell_k(G)$ the number of vertices of degree at least k in G.

For a vertex set $X \subseteq V(G)$, we denote by $G[X]$ the subgraph *induced* by X, i.e. $G[X] \coloneqq (X, E(G) \cap \binom{X}{2})$. We furthermore let $G - X \coloneqq G[V(G) \setminus X]$ be the subgraph of G obtained from removing the vertices in X and for a single vertex $x \in V(G)$, we use the shorthand "$G - x$" for "$G - \{x\}$".

A graph G is said to be *connected* if for any 2-partition (X, Y) of $V(G)$, there is an edge $xy \in E(G)$ such that $x \in X$ and $y \in Y$, and *disconnected* otherwise. A *connected component* of a graph G is a maximal connected subgraph of G. A *path* is a connected graph of maximum degree two, having precisely two vertices of degree one, called its *endpoints*. The *length* of a path is its number of edges. Given a graph G and two vertices u and v, the *distance* between u and v, denoted by $dist_G(u, v)$ (or simply $dist(u, v)$ if G is clear from the context), is the length of the shortest path in G that has u and v as endpoints.

A graph G is a *complete graph* if every pair of vertices of G is adjacent. A set $C \subseteq V(G)$ is a *clique* if $G[C]$ is a complete graph. A set $S \subseteq V(G)$ is an *independent set* if $G[S]$ has no edges. A graph G is a *bipartite graph* if its vertex set can be partitioned into two independent sets. A bipartite graph with bipartition (A, B) is a *complete bipartite graph* if all pairs consisting of one vertex from A and one vertex from B are adjacent, and with $a = |A|$ and $b = |B|$, we denote it by $K_{a,b}$. A *star* is the graph $K_{1,b}$, with $b \geq 2$, and we call *center* the unique vertex of degree b and *leaves* the vertices of degree one.

Colorings. Given a graph G, a map $\gamma \colon V(G) \to [k]$ is called a *coloring of G with k colors*. If for every pair of adjacent vertices, $uv \in E(G)$, we have that $\gamma(u) \neq \gamma(v)$, then the coloring γ is called *proper*. For $i \in [k]$, we call the set of vertices $u \in V(G)$ such that $\gamma(u) = i$ the *color class i*. If for all $i \in [k]$, there exists a vertex $x_i \in V(G)$ such that

(i) $\gamma(x_i) = i$, and

(ii) for each $j \in [k] \setminus \{i\}$, there is a neighbor $y \in N_G(x_i)$ of x_i such that $\gamma(y) = j$,

then γ is called a *b-coloring* of G. For $i \in [k]$, we call a vertex x_i satisfying the above two conditions a *b-vertex for color i*.

Parameterized Complexity. Let Σ be an alphabet. A *parameterized problem* is a set $\Pi \subseteq \Sigma^* \times \mathbb{N}$. A parameterized problem Π is said to be *fixed-parameter tractable*, or contained in the complexity class FPT, if there exists an algorithm that for each $(x, k) \in \Sigma^* \times \mathbb{N}$ decides whether $(x, k) \in \Pi$ in time $f(k) \cdot |x|^c$ for some computable function f and fixed integer $c \in \mathbb{N}$. A parameterized problem Π is said to be contained in the complexity class XP if there is an algorithm that for all $(x, k) \in \Sigma^* \times \mathbb{N}$ decides whether $(x, k) \in \Pi$ in time $f(k) \cdot n^{g(k)}$ for some computable functions f and g.

A *kernelization algorithm* for a parameterized problem $\Pi \subseteq \Sigma^* \times \mathbb{N}$ is a polynomial-time algorithm that takes as input an instance $(x, k) \in \Sigma^* \times \mathbb{N}$ and either correctly decides whether

$(x,k) \in \Pi$ or outputs an instance $(x',k') \in \Sigma^* \times \mathbb{N}$ with $|x'| + k' \leq f(k)$ for some computable function f for which $(x,k) \in \Pi$ if and only if $(x',k') \in \Pi$. We say that Π *admits a kernel* if there is a kernelization algorithm for Π.

3 Hardness Results

In this section we prove the hardness results of our complexity dichotomy. First, we show that b-Chromatic Number and b-Coloring are NP-complete for $k = m(G) - 1 = \Delta(G)$, based on a reduction for the case $k = m(G)$ due to Havet et al. [10].

▶ **Theorem 4 (♣).** *b-Chromatic Number and b-Coloring are NP-complete, even when $k = m(G) - 1 = \Delta(G)$.*

The previous theorem, together with the result that b-Coloring is NP-complete when $k = \Delta(G) + 1$ [15] and when $k = m(G)$ [10], proves Theorem 1(i). We now turn to the proof of Theorem 1(ii), that is, we show that b-Coloring remains NP-complete for $k = 3$ if $k = \Delta(G) + 1 - p$ or $k = m(G) - p$ for any $p \geq 2$, based on a reduction due to Sampaio [17]. Note that the following proposition indeed proves Theorem 1(ii) as for fixed $p \geq 2$, we have that $3 \in \{\Delta(G) + 1 - p, m(G) - p\}$ if and only if $\Delta(G) = p + 2$ or $m(G) = p + 3$.

▶ **Proposition 5 (♣).** *For every fixed integer $p \geq 2$, the problem of deciding whether a graph G has a b-coloring with 3 colors is NP-complete when $\Delta(G) = p + 2$ or $m(G) = p + 3$.*

Since b-Chromatic Number and b-Coloring are known to be NP-complete when $k = \Delta(G) + 1$ [15], we make the following observation which is of relevance to us since in Section 5.2, we show that b-Coloring is FPT parameterized by $\Delta(G) + \ell_k(G)$.

▶ **Observation 6.** *b-Chromatic Number and b-Coloring are NP-complete on graphs with $\ell_k(G) = 0$, where k is the integer associated with the respective problem.*

4 Dichotomy Algorithms

In this section we give the algorithms in our dichotomy result, proving Theorem 1(iii). We show that for fixed $k \in \mathbb{N}$, the problem of deciding whether a graph G admits a b-coloring with k colors is polynomial-time solvable when $k = m(G)$ (Sect. 4.2), when $k = \Delta(G)$ (Sect. 4.3), and when $k = m(G) - 1$ (Sect. 4.4), by providing XP-algorithms for each case.

A natural way of solving the b-Coloring problem is to first try to identify a set of k b-vertices, color them bijectively with colors from $[k]$, and for each vertex in the set a set of $k - 1$ neighbors that can be colored in such a way that the vertex becomes a b-vertex for its color. Then try to extend the resulting coloring to the remainder of the graph. We enumerate all such sets and colorings, and show that the extension problem is solvable in polynomial time in each of the above cases.

The strategy of identifying the set of b-vertices and subsets of their neighbors that make them b-vertices was (for instance) also used to give polynomial-time algorithms to compute the b-chromatic number of trees [12] and graphs with large girth [4]. We capture it by defining the notion of a *b-precoloring* in the next subsection.

4.1 b-Precolorings

All algorithms in this section are based on guessing a proper coloring of several vertices in the graph, for which we now introduce the necessary terminology and establish some preliminary results.

▶ **Definition 7** (Precoloring). *Let G be a graph and $k \in \mathbb{N}$. A* precoloring *with k colors of a graph G is an assignment of colors to a subset of its vertices, i.e. for $X \subseteq V(G)$, it is a map $\gamma_X : X \to [k]$. We call γ_X* proper*, if it is a proper coloring of $G[X]$. We say that a coloring $\gamma : V(G) \to [k]$* extends *γ_X, if $\gamma|_X = \gamma_X$.*

We use the following notation. For two precolorings γ_X and γ_Y with $X \cap Y = \emptyset$, we denote by $\gamma_X \cup \gamma_Y$ the precoloring that colors the vertices in X according to γ_X and the vertices in Y according to Y, i.e. the precoloring $\gamma_{X\cup Y} \coloneqq \gamma_X \cup \gamma_Y$ defined as follows: for all $v \in X \cup Y$, if $v \in X$, then $\gamma_{X\cup Y}(v) = \gamma_X$, and if $v \in Y$ then $\gamma_{X\cup Y}(v) = \gamma_Y(v)$.

Next, we define a special type of precoloring with the property that any proper coloring that extends it is a b-coloring of the graph.

▶ **Definition 8** (b-Precoloring). *Let G be a graph, $k \in \mathbb{N}$, $X \subseteq V(G)$ and γ_X a precoloring. We call γ_X a* b-precoloring with k colors *if γ_X is a b-coloring of $G[X]$. A b-precoloring γ_X is called* minimal *if for any $Y \subset X$, $\gamma_X|_Y$ is not a b-precoloring.*

It is immediate that any b-coloring can be obtained by extending a minimal b-precoloring, a fact that we capture in the following observation.

▶ **Observation 9.** *Let G be a graph, $k \in \mathbb{N}$, and γ a b-coloring of G with k colors. Then, there is a set $X \subseteq V(G)$ such that $\gamma|_X$ is a minimal b-precoloring.*

The next observation captures the structure of minimal b-precolorings with k colors. Roughly speaking, each such precoloring only colors a set of k b-vertices and for each b-vertex a set of $k-1$ of its neighbors that make that vertex the b-vertex of its color. We will use this property in the enumeration algorithm in this section to guarantee that we indeed enumerate all minimal b-precolorings with a given number of colors.

▶ **Observation 10.** *Let γ_X be a minimal b-precoloring with k colors. Then, $X = B \cup Z$, where*

(i) *$B = \{x_1, \ldots, x_k\}$ and for $i \in [k]$, $\gamma_X(x_i) = i$, and*
(ii) *$Z = \bigcup_{i\in[k]} Z_i$, where $Z_i \in \binom{N(x_i)}{k-1}$ and $\gamma_X(Z_i) = [k] \setminus \{i\}$.*

We are now ready to give the enumeration algorithm for minimal b-precolorings.

▶ **Lemma 11** (♣). *Let G be a graph on n vertices and $k \in \mathbb{N}$. The number of minimal b-precolorings with k colors of G is at most*

$$\beta(k) \coloneqq n^k \cdot \Delta^{k(k-1)} \cdot (k-1)!^k, \tag{1}$$

where $\Delta \coloneqq \Delta(G)$ and they can be enumerated in time $\beta(k) \cdot k^{\mathcal{O}(1)}$.

4.2 Algorithm for $k = m(G)$

Our first application of Lemma 11 is to solve the b-Coloring problem in the case when $k = m(G)$ in time XP parameterized by k. It turns out that in this case, we are dealing with a Yes-instance as soon as we found a b-precoloring in the input graph that also colors all high-degree vertices (see Claim 12.1).

▶ **Theorem 12.** *Let G be a graph. There is an algorithm that decides whether G has a b-coloring with $k = m(G)$ colors in time $n^{k^2} \cdot 2^{\mathcal{O}(k^2 \log k)}$.*

Proof. Let $D \subseteq V(G)$ denote the set of vertices in G that have degree at least k. Note that by the definition of $m(G)$, we have that $|D| \leq k$.

▶ **Claim 12.1** (♣). *G has a b-coloring with k colors if and only if G has a b-precoloring γ_X such that $D \subseteq X$ and there exists $S \subseteq D$ such that $\gamma_X|_{(X \setminus S)}$ is a minimal b-precoloring.*

The algorithm enumerates all minimal b-precolorings with k colors and for each such precoloring, it enumerates all colorings of the vertices D. If combining one such pair of precolorings gives a b-precoloring, it returns a greedy extension of it; otherwise it reports that there is no b-coloring with k colors, see Algorithm 1.

Algorithm 1 Algorithm for b-Coloring with $k = m(G)$.

```
Input   : A graph $G$
Output : A $b$-coloring with $m(G)$ colors if it exists, No otherwise.
foreach minimal $b$-precoloring $\gamma_X : X \to [k]$ do
    foreach precoloring $\gamma_{D \setminus X} : (D \setminus X) \to [k]$ do
        if $\gamma_{X \cup D} := \gamma_X \cup \gamma_{D \setminus X}$ is proper then return a greedy extension of $\gamma_{X \cup D}$;
return No;
```

The correctness of the algorithm follows from the fact that it enumerates all precolorings that can satisfy Claim 12.1. We discuss its runtime. By Lemma 11, we can enumerate all minimal b-precolorings with k colors in time $\beta(k) \cdot k^{\mathcal{O}(1)}$. For each such minimal b-precoloring, we also enumerate all colorings of D. Since $|D| \le k$, this gives an additional factor of k^k to the runtime which (with $\Delta \le n$) then amounts to $\beta(k) \cdot k^k \cdot k^{\mathcal{O}(1)} \le n^{k^2} \cdot 2^{\mathcal{O}(k^2 \log k)}$. ◀

4.3 Algorithm for $k = \Delta(G)$

Next, we turn to the case when $k = \Delta(G)$. Here the strategy is to again enumerate all minimal b-precolorings, and then for each such precoloring we check whether it can be extended to the remainder of the graph. Formally, we use an algorithm for the following problem as a subroutine.

Precoloring Extension (PrExt)

Input: A graph G, an integer k, and a precoloring $\gamma_X : X \to [k]$ of a set $X \subseteq V(G)$

Question: Does G have a proper coloring with k colors extending γ_X?

Naturally, Precoloring Extension is a hard problem, since it includes Graph Coloring as the special case when $X = \emptyset$. However, when $\Delta(G) \le k - 1$, then the problem is trivially solvable: we simply check if the precoloring at the input is proper and if so, we compute an extension of it greedily. Since each vertex has degree at most $k - 1$, there is always at least one color available. The case when $k = \Delta(G)$ has also been shown to be solvable in polynomial time.

▶ **Theorem 13** (Thm. 3 in [5], see also [7]). *There is an algorithm that solves* Precoloring Extension *in polynomial time whenever $\Delta(G) \le k$.*

▶ **Theorem 14.** *There is an algorithm that decides whether a graph G has a b-coloring with $\Delta(G)$ colors in time $n^{k+\mathcal{O}(1)} \cdot 2^{\mathcal{O}(k^2 \log k)}$.*

Proof (sketch). For each minimal b-precoloring γ_X, we apply the algorithm for PrExt of Theorem 13. If it finds a proper coloring extending γ_X, we return it, and if there is no successful run of the algorithm for PrExt, we return No. The details are given in the full version [13]. ◀

4.4 Algorithm for $k = m(G) - 1$

Before we proceed to describe the algorithm for b-Coloring when $k = m(G) - 1$, we show that the algorithm of Theorem 13 can be used for a slightly more general case of Precoloring Extension, namely the case when all high-degree vertices in the input instance are precolored.

▶ **Lemma 15** (♣). *There is an algorithm that solves an instance (G, k, γ_X) of* Precoloring Extension *in polynomial time whenever $\max_{v \in V(G) \setminus X} \deg(v) \leq k$.*

▶ **Theorem 16.** *There is an algorithm that decides whether a graph G has a b-coloring with $k = m(G) - 1$ colors in time $n^{k^2 + \mathcal{O}(1)} \cdot 2^{k^2 \log k}$.*

Proof (sketch). Let D denote the set of vertices of degree at least $k + 1$ in G. By the definition of $m(G)$, we have that $|D| \leq k + 1$. We first enumerate all minimal b-precolorings of G, and for each such precoloring, we enumerate all precolorings of D. Since given a b-precoloring γ_X with $D \subseteq X$, we have that every vertex in $V(G) \setminus X$ has degree at most k, we can apply the algorithm of Lemma 15 to verify whether there is a proper coloring of G that extends γ_X. If so, we output that extension. If no such precoloring can be found, then we conclude that we are dealing with a No-instance. We give the details of the algorithm and its correctness proof in the full version [13].

It remains to argue the runtime. We enumerate $\beta(k)$ (see (1)) minimal b-precolorings in time $\beta(k) \cdot k^{\mathcal{O}(1)}$ using Lemma 11. For each such precoloring, we enumerate all precolorings of $D \setminus X$. Since $|D| \leq k + 1$, there are at most k^{k+1} such colorings. Finally, we run the algorithm for PrExt due to Lemma 15 which takes time $n^{\mathcal{O}(1)}$. The total runtime becomes $\beta(k) \cdot k^{\mathcal{O}(1)} \cdot k^{k+1} \cdot n^{\mathcal{O}(1)} \leq n^{k^2 + \mathcal{O}(1)} \cdot 2^{k^2 \log k}$. ◀

5 Maximum Degree Parameterizations

In this section we consider parameterizations of b-Coloring that involve the maximum degree $\Delta(G)$ of the input graph G. In Section 5.1 we show that we can solve b-Coloring when $k = m(G)$ in time FPT parameterized by $\Delta(G)$ and in Section 5.2 we show that b-Coloring is FPT parameterized by $\Delta(G) + \ell_k(G)$.

Both algorithms presented in this section make use of the following reduction rule, which has already been applied in [16, 17] to obtain the FPT algorithm for the problem of deciding whether a graph G has a b-coloring with $k = \Delta(G) + 1$ colors, parameterized by k.

▶ **Reduction Rule 17** ([16, 17]). *Let (G, k) be an instance of* b-Coloring. *If there is a vertex $v \in V(G)$ such that every vertex in $N[v]$ has degree at most $k - 2$, then reduce (G, k) to $(G - v, k)$.*

5.1 FPT Algorithm for $k = m(G)$ parameterized by $\Delta(G)$

Sampaio [17] and Panolan et al. [16] independently showed that parameterized by $\Delta(G)$, it can be decided in FPT time whether a graph G has a b-coloring with $\Delta(G) + 1$ colors. In this section we show that in the same parameterization, it can be decided in FPT time whether a graph has a b-coloring with $m(G)$ colors.

▶ **Theorem** (Thm. 2, restated). *There is an algorithm that given a graph G on n vertices decides whether G has a b-coloring with $k = m(G)$ colors in time $2^{\mathcal{O}(k^4 \cdot \Delta)} + n^{\mathcal{O}(1)} < 2^{\mathcal{O}(\Delta^5)} + n^{\mathcal{O}(1)}$, where $\Delta := \Delta(G)$.*

Proof. We apply Reduction Rule 17 exhaustively to G and consider the following 3-partition (D, T, R) of $V(G)$, where D contains the vertices of degree at least k, T the vertices of degree precisely $k-1$ and R the remaining vertices, i.e. $R := V(G) \setminus (D \cup T)$. Since we applied Reduction Rule 17 exhaustively, we make

▶ **Observation 2.1.** *Every vertex in R has at least one neighbor in $D \cup T$.*

We pick an inclusion-wise maximal set $B \subseteq D \cup T$ such that for each pair of distinct vertices $b_1, b_2 \in B$, we have that $dist(b_1, b_2) \geq 4$.

Case 1 ($|B \cap T| < k$).[1] We show that for any vertex in $u \in V(G) \setminus B$, there is a vertex $v \in B$ such that $dist(u, v) \leq 4$. Suppose $u \in D \cup T$. Since we did not include u in B, it immediately follows that there is some $v \in B$ such that $dist(u, v) < 4$. Now suppose $u \in R$. By Observation 2.1, u has a neighbor w in $D \cup T$ and by the previous argument, there is a vertex $v \in B$ such that $dist(w, v) < 4$. We conclude that $dist(u, v) \leq 4$. Using this observation, we now show that in this case, the number of vertices in G is polynomial in k and Δ.

▶ **Claim 2.2.** *If $|B \cap T| < k$, then $|V(G)| \leq \mathcal{O}(k^4 \cdot \Delta)$.*

Proof. Note that $(B \cup D, S_1, \ldots, S_4)$ constitutes a partition of $V(G)$, where S_i is the set of vertices of $V(G) \setminus (B \cup D)$ that are at distance exactly i from B. Since $|B \cap T| < k$ and $|D| \leq k$, we have that $|B \cup D| < 2k$, and therefore $|S_1| < 2k \cdot \Delta$. By the definition of $m(G)$, all the vertices in $S_1 \cup \ldots \cup S_4$ have degree at most $k-1$. This implies that $|S_i| < (k-1)^{i-1} \cdot 2k \cdot \Delta$. We conclude that the number of vertices in G is at most $2k + 2k \cdot \Delta \cdot \sum_{i=1}^{4} (k-1)^{i-1} = \mathcal{O}(k^4 \cdot \Delta)$. ◁

By Claim 2.2, we can solve the instance in Case 1 in time $2^{\mathcal{O}(k^4 \cdot \Delta)}$ using the algorithm of Panolan et al. [16].

Case 2 ($|B \cap T| \geq k$). Let $B' \subseteq B \cap T$ with $|B'| = k$ and denote this set by $B' = \{x_1, x_2, \ldots, x_k\}$. We show that we can construct a b-coloring $\gamma \colon V(G) \to [k]$ of G such that for $i \in [k]$, x_i is the b-vertex of color i. For $i \in [k]$, we let $\gamma(x_i) := i$. Next, we color the vertices in D. Recall that $|D| \leq k$, so we can color the vertices in D injectively with colors from $[k]$, ensuring that this will not create a conflict on any edge in $G[D]$. Furthermore, consider $i, j \in [k]$ with $i \neq j$. Since $dist(x_i, x_j) \geq 4$, we have that $N(x_i) \cap N(x_j) = \emptyset$. In particular, there is no vertex in D that has two or more neighbors in B'. To summarize, we can conclude that we can let γ color the vertices of D in such a way that:

(i) γ is injective on D, and

(ii) γ is a proper coloring of $G[B' \cup D]$.

These two items imply that for each x_i ($i \in [k]$), its neighbors $N(x_i) \cap D$ receive distinct colors which are also different from i. Let $\ell := |N(x_i) \cap D|$. It follows that we can let γ color the remaning $(k-1) - \ell$ neighbors of x_i in an arbitrary bijective manner with the $(k-1) - \ell$ colors that do not yet appear in the neighborhood of x_i.

After this process, x_i is a b-vertex for color i. We proceed in this way for all $i \in [k]$. Since for $i, j \in [k]$ with $i \neq j$ we have that $dist(x_i, x_j) \geq 4$, it follows that there are no edges between $N[x_i]$ and $N[x_j]$ in G. Hence, we did not introduce any coloring conflict in the previous step. Now, all vertices in G that have not yet received a color by γ have degree at most $k-1$, so we can extend γ to a proper coloring of G in a greedy fashion.

We summarize the whole procedure in Algorithm 2. We now analyze its runtime. Clearly,

[1] This case is almost identical to [16, Case II in the proof of Theorem 2].

Algorithm 2 An algorithm that either constructs a b-coloring of a graph G with $m(G)$ colors, or reports that there is none, and runs in FPT time parameterized by $\Delta(G)$.

```
Input  : A graph $G$ with $k = m(G)$ // More generally, graph $G$ with
         $\ell_k(G) \leq k$
Output : A $b$-coloring with $k$ colors of $G$ if it exists, and No otherwise.
Apply Reduction Rule 17 exhaustively;
Let $(D, T, R)$ be a partition of $V(G)$ such that for all $x \in D$, $\deg_G(x) \geq k$, for all
  $x \in T$, $\deg_G(x) = k - 1$, and $R = V(G) \setminus (D \cup T)$;
Let $B \subseteq D \cup T$ be a maximal set such that for distinct $b_1, b_2 \in B$, $dist(b_1, b_2) \geq 4$;
if $|B \cap T| < k$ then // Case 1
    Solve the instance in time $2^{\mathcal{O}(k^4 \cdot \Delta)}$ using the $b$-Coloring algorithm [16];
    if the algorithm of [16] returned a $b$-coloring $\gamma$ then return $\gamma$;
    else return No;
else // Case 2, i.e. $|B \cap T| \geq k$
    Pick a size-$k$ subset of $B \cap T$, say $B' := \{x_1, \ldots, x_k\}$;
    Initialize a $k$-coloring $\gamma \colon V(G) \to [k]$;
    For $i \in [k]$, let $\gamma(x_i) := i$;
    Let $\gamma$ color the vertices of $D$ injectively such that $\gamma$ remains proper on $G[B' \cup D]$;
    For $i \in [k]$, let $\gamma$ color $N(x_i) \cap D$ such that $x_i$ is the $b$-vertex of color $i$;
    Extend the coloring $\gamma$ greedily to the remainder of $G$;
    return $\gamma$;
```

exhaustively applying Reduction Rule 17 can be done in time $n^{\mathcal{O}(1)}$. As mentioned above, Case 1 can be solved in time $2^{\mathcal{O}(k^4 \cdot \Delta)}$. In Case 2, the coloring of $G[B' \cup D]$ can be found in time $\mathcal{O}(k^2)$, and extending the coloring to the remainder of G can be done in time $n^{\mathcal{O}(1)}$. The claimed bound follows. ◀

▶ Remark 18 (♣). Algorithm 2 solves the problem of deciding whether G admits a b-coloring with k colors in time $2^{\mathcal{O}(k^4 \cdot \Delta)} + n^{\mathcal{O}(1)}$ whenever $\ell_k(G) \leq k$.

Furthermore, in the proof of Theorem 2, we provide a polynomial kernel for the problem: In Case 1, we have a kernelized instance on $\mathcal{O}(k^4 \cdot \Delta)$ vertices (see Claim 2.2) and in Case 2, we always have a Yes-instance.

▶ **Corollary 19.** *The problem of deciding whether a graph G has a b-coloring with $k = m(G)$ colors admits a kernel on $\mathcal{O}(k^4 \cdot \Delta) = \mathcal{O}(\Delta^5)$ vertices.*

5.2 FPT Algorithm Parameterized by $\Delta(G) + \ell_k(G)$

The next parameterization of b-Coloring involving the maximum degree that we consider is by $\Delta(G) + \ell_k(G)$. We show that in this case, the problem is FPT. By Observation 6 we know that b-Coloring is NP-complete on graphs with $\ell_k(G) = 0$, and by Theorem 1, it is NP-complete even when $k = 3$ and $\Delta(G) = 4$. Hence, there is no FPT- nor XP-algorithm for a parameterization using only one of the two above mentioned parameters unless P = NP. Note that the algorithm we provide in this section can be used to solve the case of $k = m(G)$ for which we gave a separate algorithm in Section 5.1, see Algorithm 2. However, Algorithm 2 is much simpler than the algorithm presented in this section, and simply applying the following algorithm for the case $k = m(G)$ results in a runtime of $2^{\mathcal{O}(k^{k+3} \cdot \Delta)} + n^{\mathcal{O}(1)}$ which is far worse than the runtime of $2^{\mathcal{O}(k^4 \cdot \Delta)} + n^{\mathcal{O}(1)}$ of Theorem 2.

▶ **Theorem** (Thm. 3, restated). *There is an algorithm that given a graph G on n vertices decides whether G has a b-coloring with k colors in time $2^{\mathcal{O}(\ell \cdot \Delta \cdot \min\{\ell, \Delta\}^{\ell+2})} + n^{\mathcal{O}(1)}$, where $\Delta := \Delta(G)$ and $\ell := \ell_k(G)$.*

Proof. The overall strategy of the algorithm is similar to Algorithm 2. We can make the following assumptions. First, if $\ell \le k$, then we can apply Algorithm 2 directly to solve the instance at hand, see Remark 18. Hence we can assume that $k < \ell$. Furthermore, $k \le \Delta + 1$, otherwise we are dealing with a trivial No-instance; we have that $k \le \min\{\ell - 1, \Delta + 1\}$. Furthermore, we can assume that $k > 2$, otherwise the problem is trivially solvable in time polynomial in n.

We consider a partition (D, T, R) of $V(G)$, where the vertices in D have degree at least k, the vertices in T have degree $k - 1$ and the vertices in R have degree less than $k - 1$. We assume that Reduction Rule 17 has been applied exhaustively, so Observation 2.1 holds, i.e. every vertex in R has at least one neighbor in $D \cup T$.

Now, we pick an inclusion-wise maximal set $B \subseteq D \cup T$ such that for each pair of distinct vertices $b_1, b_2 \in B$, $dist_G(b_1, b_2) \ge \ell + 3$.

Case 1 ($|B \cap T| < k$). By the same argument given in Case 1 of the proof of Theorem 2, we have that any vertex in $T \cup R$ is at distance at most $\ell + 3$ from a vertex in B. We now give a bound on the number of vertices in G in terms of ℓ and Δ.

▶ **Claim 3.1** (♣). *If $|B \cap T| < k$, then $|V(G)| = \mathcal{O}(\ell \cdot \Delta \cdot \min\{\ell, \Delta\}^{\ell+2})$.*

By the previous claim, we can solve the instance in time $2^{\mathcal{O}(\ell \cdot \Delta \cdot \min\{\ell, \Delta\}^{\ell+2})}$ in this case, using the exact exponential time algorithm for b-Coloring due to Panolan et al. [16].

Case 2 ($|B \cap T| \ge k$). Let $B' \subseteq B \cap T$ be of size k and denote it by $B' := \{x_1, \ldots, x_k\}$. The strategy in this case is as follows: We compute a proper coloring of $G[D]$, and then modify it so that can be extended to a b-coloring of G. In this process we will be able to guarantee for each $i \in [k]$, that either x_i can be the b-vertex for color i, or we will have found another vertex in D that can serve as the b-vertex of color i. The difficulty here arises from the following situation: Suppose that in the coloring we computed for $G[D]$, a vertex x_i has two neighbors in D that received the same color. Then, x_i cannot be the b-vertex of color i in any extension of that coloring, since $\deg(x_i) = k - 1$, and $k - 1$ colors need to appear the neighborhood of x_i for it to be a b-vertex. However, recoloring a vertex in $N(x_i) \cap D$ might create a conflict in the coloring of $G[D]$. These potential conflicts can only appear in the connected component of $G[D \cup B']$ that contains x_i. We now show that each component of $G[D \cup B']$ can contain at most one such vertex, by our choice of the set B.

▶ **Claim 3.2** (♣). *Let C be a connected component of $G[D \cup B']$. Then, C contains at most one vertex from B'.*

Throughout the following, for $i \in [k]$, we denote by C_i the connected component of $G[D \cup B']$ that contains x_i, and by ℓ_i the number of vertices of C_i, i.e. $\ell_i := |V(C_i)|$. By Claim 3.2, $C_i \ne C_j$, for all $i, j \in [k], i \ne j$. We now show that each neighbor of x_i has no neighbor in $D \cap N[B']$ outside of $V(C_i) \cup N[x_i]$.

▶ **Claim 3.3** (♣). *Let $i \in [k]$, and $y \in N(x_i) \setminus D$. Then, $N_G[y] \cap (D \cup N[B']) \subseteq V(C_i) \cup N[x_i]$.*

Let $\mathcal{C}_\emptyset$ be the set of connected components of $G[D \cup B']$ that do not contain any vertex from B'. We observe that any proper coloring of $G[D \cup B']$ can be obtained from independently coloring the vertices in $C_1, \ldots, C_k$, and $\mathcal{C}_\emptyset$. If for some $i \in [k]$, C_i is a trivial[2] component,

[2] We call a connected component of a graph *trivial* if it contains only one vertex.

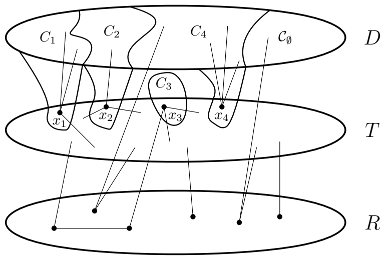

Figure 1 Illustration of the structure of a graph G in the proof of Theorem 3 where $k = 4$. Here, $B' = \{x_1, \dots, x_4\}$ and $C_1, \dots, C_4$ are the components of $G[D \cup B']$ containing $x_1, \dots, x_4$, respectively. Note that all vertices in T are of degree 3, all vertices in R of degree at most 2 and all vertices in R have a neighbor in $D \cup T$.

then $N(x_i) \cap D = \emptyset$. Hence, we can assign x_i any color without creating any conflict with the remaining vertices in $G[D \cup B']$. On top of that, Claim 3.3 ensures that assigning a color to a neighbor of any x_i (that is not contained in D) cannot create a coloring conflict with any vertex in $D \cup N[B']$ that is not contained in $V(C_i) \cup N[x_i]$. We illustrate the structure of G in Figure 1.

▶ **Claim 3.4 (♣).** *Let $i \in [k]$ and let $\gamma \colon V(C_i) \to [k]$ be a proper coloring of C_i. Then, one can find in time $\mathcal{O}(k^2 \cdot \ell_i^2)$ a set $Y_i \subseteq N_G(x_i) \setminus D$ and a proper coloring $\delta \colon V(C_i) \cup Y_i \to [k]$ of $G[V(C_i) \cup Y_i]$ that has a b-vertex for color i.*

We now wrap up the treatment of this case. We compute a proper k-coloring γ of $G[D \cup B']$ using standard methods [3]. We derive from γ another k-coloring δ of some induced subgraph of $G[D \cup N_G[B']]$ containing $D \cup B'$. For each $i \in [k]$, we do the following. With input $\gamma|_{V(C_i)}$ we compute a proper k-coloring δ_i of $G[V(C_i) \cup Y_i]$ using Claim 3.4, where Y_i is the set returned by its algorithm, and we let $\delta|_{V(C_i) \cup Y_i} := \delta_i$. Finally, we let $\delta|_{V(\mathcal{C}_\emptyset)} := \gamma|_{V(\mathcal{C}_\emptyset)}$. As for $i \neq j$, C_i and C_j are distinct connected components of $G[D \cup B']$ and by Claim 3.3, this construction is well-defined and there is no color conflict between any pair of vertices z_i, z_j where $z_i \in V(C_i) \cup Y_i$ and $z_j \in V(C_j) \cup Y_j$ for $i \neq j$. Since for each $i \in [k]$ we applied Claim 3.4, δ is a b-precoloring of G. All vertices in G that have not received a color so far (recall that δ colors all vertices in D) have degree at most $k - 1$, so we can extend the coloring δ greedily to the remainder of G and eventually obtain a b-coloring of G. The runtime of $2^{\mathcal{O}(\ell \cdot \Delta \cdot \min\{\ell, \Delta\}^{\ell+2})} + n^{\mathcal{O}(1)}$ is argued for in the full version [13]. ◀

Similar to above, we obtained a kernel for the problem. While this result does not provide a polynomial kernel for the parameterization $\Delta + \ell$, it does give a polynomial kernel if we consider the problem for *fixed* values of ℓ and parameter Δ.

▶ **Corollary 20.** *The problem of deciding whether a graph G admits a b-coloring with k colors admits a kernel on $\mathcal{O}(\ell \cdot \Delta \cdot \min\{\ell, \Delta\}^{\ell+2})$ vertices, where $\Delta := \Delta(G)$ and $\ell := \ell_k(G)$.*

6 Conclusion

We have presented a complexity dichotomy for b-Coloring with respect to two upper bounds on the b-chromatic number, in the following sense: We have shown that given a graph G and for fixed $k \in \{\Delta(G) + 1 - p, m(G) - p\}$, it can be decided in polynomial time whether G has a b-coloring with k colors whenever $p \in \{0, 1\}$ and the problem remains NP-complete whenever $p \geq 2$, already for $k = 3$.

The most immediate question left open in this work is the parameterized complexity of the b-Coloring problem when $k \in \{m(G), \Delta(G), m(G) - 1\}$. In all of these cases, we have provided XP-algorithms, and it would be interesting to see whether these problems are FPT or W[1]-hard. We showed that b-Coloring is FPT parameterized by $\Delta(G) + \ell_k(G)$, where $\ell_k(G)$ denotes the number of vertices of degree at least k in G, and this is optimal in the sense that there is no FPT nor XP algorithm for the problem parameterized by only one of the two invariants. It would be interesting to see if one could devise an FPT-algorithm for the parameterization that replaces the maximum degree by the number of colors.

Abstract

An input to a conflict-free variant of a classical problem Γ, called CONFLICT-FREE Γ, consists of an instance I of Γ coupled with a graph H, called the *conflict graph*. A solution to CONFLICT-FREE Γ in (I, H) is a solution to I in Γ, which is also an independent set in H. In this paper, we study conflict-free variants of MAXIMUM MATCHING and SHORTEST PATH, which we call CONFLICT-FREE MATCHING (CF-MATCHING) and CONFLICT-FREE SHORTEST PATH (CF-SP), respectively. We show that both CF-MATCHING and CF-SP are W[1]-hard, when parameterized by the solution size. Moreover, W[1]-hardness for CF-MATCHING holds even when the input graph where we want to find a matching is itself a matching, and W[1]-hardness for CF-SP holds for conflict graph being a unit-interval graph. Next, we study these problems with restriction on the conflict graphs. We give FPT algorithms for CF-MATCHING when the conflict graph is chordal. Also, we give FPT algorithms for both CF-MATCHING and CF-SP, when the conflict graph is d-degenerate. Finally, we design FPT algorithms for variants of CF-MATCHING and CF-SP, where the conflicting conditions are given by a (representable) matroid.

1 Introduction

In the recent years, conflict-free variant of classical combinatorial optimization problems have gained attention from the viewpoint of algorithmic complexity. A typical input to a conflict-free variant of a classical problem Γ, which we call Conflict-Free Γ, consists of an instance I of Γ coupled with a graph H, called the *conflict graph*. A solution to Conflict-Free Γ in (I, H) is a solution to I in Γ, which is also an independent set in H. Notice that conflict-free version of the problem introduces the constraint of "impossible pairs" in the solution that we seek for. Such a constraint of "impossible pairs" in a solution arises, for example, in the context of program testing and validation [16, 23]. Gabow et al. [16] studied the conflict-free version of paths in a graph, which they showed to be NP-complete.

Conflict-free variants of several classical problems such as, Bin Packing [10, 18, 20], Knapsack [35, 32], Minimum Spanning Tree [5, 6], Maximum Matching [6], Maximum Flow [33, 34], Shortest Path [6] and Set Cover [11] have been studied in the literature from the viewpoint of algorithmic complexity, approximation algorithms, and heuristics. It is interesting to note that most of these problems are NP-hard even when their classical counterparts are polynomial time solvable. Recently, Jain et al. [19] and Agrawal et al. [2, 1] initiated the study of conflict-free problems in the realm of parameterized complexity. In particular, they studied Conflict-Free $\mathcal{F}$-Deletion problems for various families $\mathcal{F}$, of graphs such as the family of forests, independent sets, bipartite graphs, interval graphs, etc.

Maximum Matching and Shortest Path are among the classical graph problems which are of very high theoretical and practical interest. The Maximum Matching problem takes as input a graph G, and the objective is to compute a maximum sized subset $Y \subseteq E(G)$ such that no two edges in Y have a common vertex. Maximum Matching is known to be solvable in polynomial time [12, 28]. The Shortest Path problem takes as input a graph G and vertices s and t, and the objective is to compute a path between s and t in G with the minimum number of vertices. The Shortest Path problem, together with its variants such as all-pair shortest path, single-source shortest path, weighted shortest path, etc. are known to be solvable in polynomial time [7, 3].

Darmann et al. [6] (among other problems) studied the conflict-free variants of Maximum Matching and Shortest Path. They showed that the conflict-free variant of Maximum Matching is NP-hard even when the conflict graph is a disjoint union of edges (matching). Moreover, for the conflict-free variant of Shortest Path, they showed that the problem is APX-hard, even when the conflict graph belongs to the family of 2-ladders.

In this paper, we study the conflict-free versions of matching and shortest path from the viewpoint of parameterized complexity. A parameterized problem Π is a subset of $\Sigma^* \times \mathbb{N}$, where Σ is a fixed, finite alphabet. An instance of a parameterized problem is a pair (I, k), where I is a classical problem instance and k is an integer, which is called the *parameter*. One of the central notions in parameterized complexity is *fixed-parameter tractability*, where given an instance (I, k) of a parameterized problem Π, the goal is to design an algorithm that runs in time $f(k)n^{\mathcal{O}(1)}$, where, $n = |I|$ and $f(\cdot)$ is some computable function, whose value depends only on k. An algorithm with running time as described above, is called an FPT algorithm. A parameterized problem that admits an FPT algorithm is said to be in FPT. Not every parameterized problem admits an FPT algorithm, under reasonable complexity-theoretic assumptions. Similar to the notion of NP-hardness and NP-hard reductions in classical Complexity Theory, there are notions of W[t]-hardness, where $t \in \mathbb{N}$ and parameterized reductions in parameterized complexity. A parameterized problem which is W[t]-hard, for some $t \in \mathbb{N}$ is believed not to admit an FPT algorithm. For more details on parameterized complexity we refer to the books of Downey and Fellows [9], Flum and Grohe [13], Niedermeier [30], and Cygan et al. [4].

Our Results. We study conflict-free (parameterized) variants of Maximum Matching and Shortest Path, which we call Conflict Free Maximum Matching (CF-MM, for short) and Conflict Free Shortest Path (CF-SP, for short), respectively. These problems are formally defined below.

Conflict Free Maximum Matching (CF-MM) **Parameter:** k
Input: A graph $G = (V, E)$, a conflict graph $H = (E, E')$, and an integer k.
Question: Is there a matching M of size at least k in G, such that M is an independent set in H?

Conflict Free Shortest Path (CF-SP) **Parameter:** k
Input: A graph $G = (V, E)$, a conflict graph $H = (E, E')$, two special vertices s and t, and an integer k.
Question: Is there an st-path P of length at most k in G, such that $E(P)$ is an independent set in H?

We show that both CF-MM and CF-SP are W[1]-hard, when parameterized by the solution size. The W[1]-hardness for CF-MM is obtained by giving an appropriate reduction from Independent Set, which is known to be W[1]-hard, when parameterized by the solution size [4, 8]. In fact, our W[1]-hardness result for CF-MM holds even when the graph where we want to compute a matching is itself a matching. We show the W[1]-hardness of CF-SP by giving an appropriate reduction from a multicolored variant of the problem Unit 2-Track Independent Set (which we prove to be W[1]-hard). We note that Unit 2-Track Independent Set is known to be W[1]-hard, which is used to establish W[1]-hardness of its multicolored variant. We note that our W[1]-hardness result of CF-SP holds even when the conflict graph is a unit interval graph.

Having shown the W[1]-hardness results, we then restrict our attention to having conflict graphs belonging to some families of graphs, where the Independent Set problem is either polynomial time solvable or solvable in FPT time. Two of the very well-known graph families that we consider are the family of chordal graphs and the family of d-degenerate graphs. For the CF-MM problem, we give an FPT algorithm, when the conflict graph belongs to the family of chordal graphs. Our algorithm is based on a dynamic programming over a "structured" tree decomposition of the conflict graph (which is chordal) together with "efficient" computation of representative families at each step of our dynamic programming routine. Notice that we cannot obtain an FPT algorithm for the CF-SP problem when the conflict graph is a chordal graph. This holds because unit-interval graphs are chordal, and the problem CF-SP is W[1]-hard, even when the conflict graph is a unit-interval graph.

For conflict graphs being d-degenerate, we obtain FPT algorithms for both CF-MM and CF-SP. These algorithms are based on the computation of an independence covering family, a notion which was recently introduced by Lokshtanov et al. [25]. We note that even for nowhere dense graphs, such an independence covering family can be computed efficiently [25]. Since our algorithms are based on computation of independence covering families, hence, our results hold even when the conflict graph is a nowhere dense graph.

Finally, we study a variant of CF-MM and CF-SP, where instead of conflicting conditions being imposed by independent sets in a conflict graph, they are imposed by independence constraints in a (representable) matroid. We give FPT algorithms for the above variant of both CF-MM and CF-SP.

Due to space limitations, many proofs have been omitted from the extended abstract.

2 Preliminaries

Sets and graph notations. For $n \in \mathbb{N}$, by $[n]$ and $[0,n]$, we denote the sets $\{1,2,\cdots,n\}$ and $\{0,1,2,\cdots,n\}$, respectively. For a set U and $p \in \mathbb{N}$, a p-family (over U) is a family of subsets of U of size p. We let ω denote the exponent in the running time of algorithm for matrix multiplication, the current best known bound for it is $\omega < 2.373$ [36]. Consider a graph G. For $X \subseteq V(G)$, $G[X]$ denotes the subgraph of G with vertex set X and edge set $\{uv \in E(G) \mid u,v \in X\}$. For $Y \subseteq E(G)$, $G[Y]$ denotes the subgraph of G with vertex set $\cup_{uv\in Y}\{u,v\}$ and edge set Y.

We define a structured tree decomposition that will be used in our algorithm.

▶ **Definition 1** ([4, 22]). Let (T,X) be a tree decomposition of a graph H with r as the root node. That is, T is a tree rooted at r and $X = \{X_t \mid t \in V(T)\}$. Then, (T,X) is a *nice tree decomposition* if for each each leaf ℓ in T and the root r, we have that $X_\ell = X_r = \emptyset$, and each non-leaf node $t \in V(T)$ is of one of the following types: **Introduce node:** t has exactly one child, say t', and $X_t = X_{t'} \cup \{v\}$, where $v \notin X_{t'}$. We say that v is *introduced* at t; **Forget node:** t has exactly one child, say t', and $X_t = X_{t'} \setminus \{v\}$, where $v \in X_{t'}$. We say that v is *forgotten* at t; **Join node:** t has exactly two children, say t_1 and t_2, and $X_t = X_{t_1} = X_{t_2}$.

A tree decomposition (T,X) of a graph H, where for each $t \in V(T)$, the graph $H[X_t]$ is a clique, is called a *clique-tree*. The result below follows from existence of clique-tree for chordal graphs [17] and an algorithm for computation of a nice tree decomposition [4, 22].

▶ **Proposition 2.** *Given an n vertex chordal graph H, in polynomial time we can construct a nice tree decomposition which is also a clique-tree (nice clique-tree), (T,X) of H with $\mathcal{O}(n^2)$ nodes.*

Matroids and representative sets. In the following we state some definitions related to matroids used in the paper. We refer the reader to [31] for more details. We also state the definition of representative families and state some results related to them.

▶ **Definition 3** ([4, 31]). A matroid $\mathcal{M} = (U,\mathcal{I})$ is a *partition* matroid if the ground set U is partitioned into sets $U_1, U_2, \cdots, U_k$, and for each $i \in [k]$, there is an integer a_i associated with U_i. A set $S \subseteq U$ is an independent in $\mathcal{M}$ if and only if for each $i \in [k]$, $|S \cap U_i| \le a_i$.

▶ **Proposition 4** ([15, 31, 26]). *A representation of a partition matroid over $\mathbb{Q}$ (the field of rationals) can be computed in polynomial time.*

▶ **Definition 5.** Let $\mathcal{M}_1 = (U_1,\mathcal{I}_1), \mathcal{M}_2 = (U_2,\mathcal{I}_2) \cdots, \mathcal{M}_t = (U_t,\mathcal{I}_t)$ be t matroids with $U_i \cap U_j = \emptyset$, for all $1 \le i \ne j \le t$. The *direct sum* $\mathcal{M}_1 \oplus \cdots \oplus \mathcal{M}_t$, of $\mathcal{M}_1, \mathcal{M}_2, \cdots, \mathcal{M}_t$ is the matroid with ground set $U = \cup_{i\in[t]} U_i$ and $X \subseteq U$ is independent in $\mathcal{M}$ if and only if for each $i \in [t]$, $X \cap U_i \in \mathcal{I}_i$.

▶ **Proposition 6** ([27, 31]). *Given matrices $A_1, A_2, \cdots, A_t$ (over $\mathbb{F}$) representing matroids $\mathcal{M}_1, \mathcal{M}_2, \cdots, \mathcal{M}_t$, respectively, we can compute a representation of their direct sum, $\mathcal{M}_1 \oplus \cdots \oplus \mathcal{M}_t$, in polynomial time.*

Next, we state the definition of representative families.

▶ **Definition 7.** Let $\mathcal{M} = (U,\mathcal{I})$ be a matroid, and $\mathcal{A}$ be a p-family of U. We say that $\mathcal{A}' \subseteq \mathcal{A}$ is a q-representative for $\mathcal{A}$ if for every set $Y \subseteq U$ of size q, if there is a set $X \in \mathcal{A}$, such that $X \cap Y = \emptyset$ and $X \cup Y \in \mathcal{I}$, then there is a set $X' \in \mathcal{A}'$ such that $X' \cap Y = \emptyset$ and $X' \cup Y \in \mathcal{I}$. If $\mathcal{A}' \subseteq \mathcal{A}$ is a q-representative for $\mathcal{A}$ then we denote it by $\mathcal{A}' \subseteq^q_{rep} \mathcal{A}$.

▶ **Theorem 8** ([4, 14]). *Given a matrix M (over field $\mathbb{F}$) representing a matroid $\mathcal{M} = (U, \mathcal{I})$ of rank k, a p-family $\mathcal{A}$ of independent sets in $\mathcal{M}$, and an integer q such that $p+q=k$, there is an algorithm which computes a q-representative family $\mathcal{A}' \subseteq^q_{rep} \mathcal{A}$ of size at most $\binom{p+q}{p}$ using at most $\mathcal{O}\big(|\mathcal{A}|\big(\binom{p+q}{p}p^\omega + \binom{p+q}{p}^{\omega-1}\big)\big)$ operations over $\mathbb{F}$.*

Let $\mathcal{A}_1$ and $\mathcal{A}_2$ be two families of sets over U and $\mathcal{M} = (U, \mathcal{I})$ be a matroid. We define their convolution as: $\mathcal{A}_1 \star \mathcal{A}_2 = \{A_1 \cup A_2 \mid A_1 \in \mathcal{A}_1, A_2 \in \mathcal{A}_2, A_1 \cap A_2 = \emptyset \text{ and } A_1 \cup A_2 \in \mathcal{I}\}$.

Universal sets and their computation. An (n, k)-*universal set* is a family $\mathcal{F}$ of subsets of $[n]$ such that for any set $S \subseteq [n]$ of size k, the family $\{A \cap S \mid A \in \mathcal{F}\}$ contains all 2^k subsets of S.

▶ **Proposition 9** ([4, 29]). *For any $n, k \geq 1$, we can compute an (n, k)-universal set of size $2^k k^{\mathcal{O}(\log k)} \log n$ in time $2^k k^{\mathcal{O}(\log k)} n \log n$.*

3 W[1]-hardness Results

In this section, we show that Conflict Free Maximum Matching and Conflict Free Shortest Path are W[1]-hard, when parameterized by the solution size.

W[1]-hardness of CF-MM. We show that CF-MM is W[1]-hard, when parameterized by the solution size, even when the graph where we want to find a matching, is itself a matching (disjoint union of edges). To prove our result, we give an appropriate reduction from Independent Set to CF-MM. It is known that Independent Set is W[1]-hard, when parameterized by the size of an independent set [4, 8]. Given an instance $(G^\star, k)$ of Independent Set, we construct an equivalent instance (G, H, k) of CF-MM as follows. We first describe the construction of G. For each $v \in V(G^\star)$, we add an edge vv' to G. Notice that G is a matching. This completes the description of G. Next, we move to the construction of H. We have $V(H) = \{e_v = vv' \mid v \in V(G^\star)\}$. Moreover, for $e_u, e_v \in V(H)$, we add the edge $e_u e_v$ to $E(H)$ if and only if $uv \in E(G^\star)$. We note that H is exactly the same as $G^\star$, with vertices being renamed. This completes the description of the reduction. We obtain the following theorem from the equivalence of instances $(G^\star, k)$ of Independent Set and (G, H, k) of CF-MM.

▶ **Theorem 10.** CF-MM *is W[1]-hard, when parameterized by the solution size.*

W[1]-hardness of CF-SP. We show that CF-SP is W[1]-hard, when parameterized by the solution size, even when the conflict graph is a proper interval graph. We refer to this restricted variant of the problem as Unit Interval CF-SP. To prove our result, we give an appropriate reduction from a multicolored variant of the problem Unit 2-Track Independent Set, which we call Unit 2-Track Multicolored IS. In the following, we define the problem Unit 2-Track Multicolored IS.

Unit 2-Track Multicolored IS (Unit 2-Track MIS) **Parameter:** k
Input: Two unit-interval graphs $G_1 = (V, E_1)$ and $G_2 = (V, E_2)$, and a partition $V_1, V_2, \cdots, V_k$ of V.
Question: Is there a set $S \subseteq V$, such that S is an independent set in both G_1 and G_2, and for each $i \in [k]$, we have $|S \cap V_i| = 1$?

It is known that Unit 2-Track IS is W[1]-hard, when parameterized by the solution size [21]. We can show that the problem Unit 2-Track MIS is W[1]-hard, when parameterized by the number of sets in the partition by giving an appropriate (Turing) reduction from Unit 2-Track IS. We give a reduction from Unit 2-Track MIS to Unit Interval CF-SP, and hence obtaining the desired result.

We now give a parameterized reduction from Unit 2-Track MIS to Unit Interval CF-SP. Let $(G_1, G_2, V_1, \cdots, V_k)$ be an instance of Unit 2-Track MIS. We construct an instance (G', H, s, t, k') of Unit Interval CF-SP as follows. For each $v \in V(G_1)$, we add a path on 3 vertices namely, (v_1, v_2, v_3) in G'. For notational convenience, for $v \in V(G_1)$, by $e_{12}(v)$ and $e_{23}(v)$ we denote the edges v_1v_2 and v_2v_3, respectively. Consider $i \in [k-1]$. For $u \in V_i$ and $v \in V_{i+1}$, we add the edge $z_{uv} = u_3v_1$ to $E(G')$. Moreover, by Z_i, we denote the set $\{z_{uv} \mid u \in V_i, v \in V_{i+1}\}$. We add two new vertices s and t to $V(G')$, and add all the edges in $Z_0 = \{sv_1 \mid v \in V_1\}$ and $Z_k = \{v_3t \mid v \in V_k\}$ to $E(G')$. Next, we move to the construction of H. Note that H must be a unit-interval graph on the vertex set $E(G') = (\cup_{i\in[0,k]} Z_i) \cup (\cup_{v \in V(G_1)}\{e_{12}(v), e_{23}(v)\})$. In H, each vertex in $\cup_{i\in[0,k]} Z_i$ is an isolated vertex. Let $E_{12} = \{e_{12}(v) \mid v \in V(G_1)\}$ and $E_{23} = \{e_{23}(v) \mid v \in V(G_1)\}$. For $e_{12}(u), e_{12}(v) \in E_{12}$, we add the edge $e_{12}(u)e_{12}(v)$ to $E(H)$ if and only if $uv \in E(G_1)$. Similarly, for $e_{23}(u), e_{23}(v) \in E_{23}$, we add the edge $e_{23}(u)e_{23}(v)$ to $E(H)$ if and only if $uv \in E(G_2)$. Observe that $H[E_{12}]$ is isomorphic to G_1, with bijection $\phi_1 : V(G_1) \to E_{12}$ with $\phi_1(v) = e_{12}(v)$. Similarly, $H[E_{23}]$ is isomorphic to G_2 with bijection $\phi_2 : V(G_2) \to E_{23}$ with $\phi_2(v) = e_{23}(v)$. By construction, H is a disjoint union of unit-interval graphs, and hence is a unit-interval graph. Finally, we set $k' = 3k+1$. This completes the description of the reduction. We obtain the following theorem from the equivalence of instances $(G_1, G_2, V_1, \cdots, V_k)$ of Unit 2-Track MIS and (G', H, s, t, k') of Unit Interval CF-SP.

▶ **Theorem 11.** Unit Interval CF-SP *is* W[1]-hard*, when parameterized by the solution size.*

4 FPT Algorithm for CF-MM with Chordal Conflict

In this section, we show that CF-MM is FPT, when the conflict graph is a chordal graph. We call this restricted version of CF-MM as Chordal Conflict Matching. Towards designing an algorithm for Chordal Conflict Matching, we first give an FPT algorithm for a restricted version of Chordal Conflict Matching, where the graph where we want to compute a matching is a bipartite graph. We call this variant of Chordal Conflict Matching as Chordal Conflict Bipartite Matching (CCBM). We then employ the algorithm for CCBM to design an FPT algorithm for Chordal Conflict Matching.

4.1 FPT algorithm for CCBM

We design an FPT algorithm for the problem CCBM, where the conflict graph is chordal and the graph where we want to compute a matching is a bipartite graph. The problem CCBM is formally defined below.

Chordal Conflict Bipartite Matching (CCBM) **Parameter:** k
Input: A bipartite graph $G = (V, E)$ with vertex bipartition L, R, a conflict graph $H = (E, E')$, and an integer k.
Question: Is there a matching $M \subseteq E$ of size k in G, such that M is an independent set in H?

The FPT algorithm for CCBM is based on a dynamic programming routine over tree decomposition of the conflict graph H and representative sets on the graph G. Let (G, L, R, H, k) be an instance of CF-MM, where G is a bipartite graph on n vertices, with vertex bipartition L, R, and H is a chordal graph with $V(H) = E(G)$.

In the following, we construct three matroids $\mathcal{M}_L = (E, \mathcal{I}_L), \mathcal{M}_R = (E^c, \mathcal{I}_R)$, and $\mathcal{M} = (E \cup E^c, \mathcal{I})$. Matroids $\mathcal{M}_L$ and $\mathcal{M}_R$ are partition matroids and the matroid $\mathcal{M}$ is the direct sum of $\mathcal{M}_L$ and $\mathcal{M}_R$. The ground set of $\mathcal{M}_L$ is $E = E(G)$. The set E^c contains a copy of edges in E, i.e., $E^c = \{e^c \mid e \in E\}$. We create two (disjoint) sets E and E^c, because $\mathcal{M}$ is the direct sum of $\mathcal{M}_L$ and $\mathcal{M}_R$, and we want their ground sets to be disjoint. Next, we describe the partition $\mathcal{E}$ of E into $|L|$ sets and $|L|$ integers, one for each set in the partition, for the partition matroid $\mathcal{M}_L$. For $u \in L$, let $E_u = \{uv \mid uv \in E\}$. Notice that for $u, v \in L$, where $u \neq v$, we have $E_u \cap E_v = \emptyset$. Moreover, $\cup_{u \in E} E_u = E$. We let $\mathcal{E} = \{E_u \mid u \in L\}$, and for each $u \in L$, we set $a_u = 1$. Similarly, we define the partition $\mathcal{E}^c$ of E^c with respect to set R. That is, we let $\mathcal{E}^c = \{E^c_u = \{(uv)^c \mid uv \in E(G)\} \mid u \in R\}$. Furthermore, for $u \in R$, we let $a_{u^c} = 1$. We define the following notation, which will be used later. For $Z \subseteq E$, we let $Z^c = \{e^c \mid e \in Z\} \subseteq E^c$.

To capture the independence property on the conflict graph, we rely on the fact that a chordal graph admits a nice clique-tree (Proposition 2). This allows us to do dynamic programming over a nice clique-tree. At each step of our dynamic programming routine, using representative sets, we ensure that we store a family of sets which are enough to recover (some) independent set in $\mathcal{M}$, if a solution exists.

We now move to the formal description of the algorithm. The algorithm starts by computing a nice clique-tree (T, X) of H in polynomial time, using Proposition 2. Let $r \in V(T)$ be the root of the (rooted) tree T. For $X_t \in X$, we let $\mathcal{X}_t = \{\emptyset\} \cup \{\{v\} \mid v \in X_t\}$.For a node $t \in V(T)$, by $\mathsf{desc}(t)$ we denote the set descendant of t in T (including t). For $t \in V(T)$, H_t is the graph $H[V_t]$, where $V_t = \cup_{d \in \mathsf{desc}(t)} X_d$.

In the following, we state some notations, which will be used in the algorithm. For each $t \in V(T)$, $Y \in \mathcal{X}_t$, and an integer $p \in [0, k]$ we define a family $\mathcal{P}^p_{t,Y}$ as: $\mathcal{P}^p_{t,Y} = \{Z \cup Z^c \mid Z \subseteq V(H_t)(\subseteq E), |Z| = p, Z \cap X_t = Y, Z \cup Z_c \in \mathcal{I}$ and $H_t[Z]$ is edgeless$\}$. For a family $\mathcal{F}$ of subsets of $E \cup E^c$, $\mathcal{F}$ is called a *paired-family* if for each $F \in \mathcal{F}$, there is $Z \subseteq E$, such that $F = Z \cup Z^c$. Next, we state the entries in our dynamic programming routine.

▶ **Definition 12.** *For each $t \in V(T)$, $Y \in \mathcal{X}_t$ and $p \in [0, k]$, we have an entry $c[t, Y, p]$, which stores a paired-family $\mathcal{F}(t, Y, p)$ of subsets of $E \cup E^c$ of size $2p$, such that for each $F = Z \cup Z^c \in \mathcal{F}$, the following conditions are satisfied: $|Z| = p$; $Z \cap X_t = Y$; Z is a matching in G, i.e., Z and Z^c are independent sets in $\mathcal{M}_L$ and $\mathcal{M}_R$, respectively; Z is an independent set in H_t. Moreover, $\mathcal{F} \neq \emptyset$ if and only if $\mathcal{P}^p_{t,Y} \neq \emptyset$.*

Consider $t \in V(T)$, $Y \in \mathcal{X}_t$ and $p \in [0, k]$. Observe that $\mathcal{P}^p_{t,Y}$ is a valid candidate for $c[t, Y, p]$, which also implies that (G, H, k) is a yes instance of CCBM if and only if $c[r, \emptyset, k] \neq \emptyset$. However, we cannot set $c[t, Y, p] = \mathcal{P}^p_{t,Y}$ as the size of $\mathcal{P}^p_{t,Y}$ could be exponential in n, and the goal here is to obtain an FPT algorithm. Hence, we will store a much smaller subfamily (of size at most $\binom{2k}{2p}$) of $\mathcal{P}^p_{t,Y}$ in $c[t, Y, p]$, which will be computed using representative sets. Moreover, as we have a structured form of a tree decomposition (nice clique-tree) of H, we compute the entries of the table based on the entries of its children, which will be given by recursive formulae. For leaf nodes, which form base cases for recursive formulae, we compute all entries directly.

Next, we give (recursive) formulae for the computation of the table entries. Consider $t \in V(T)$, $Y \in \mathcal{X}_t$ and $p \in [0, k]$. We compute the entry $c[t, Y, k]$ based on the following cases.

Leaf node. t is a leaf node. In this case, we have $X_t = \emptyset$, and hence $\mathcal{X}_t = \{\emptyset\}$. If $p = 0$, then $\mathcal{P}^p_{t,\emptyset} = \{\emptyset\}$, and $\mathcal{P}^p_{t,\emptyset} = \emptyset$, otherwise. Since, $\mathcal{P}^p_{t,\emptyset}$ is a valid candidate for $c[t, Y, p]$, we set $c[t, Y, p] = \mathcal{P}^p_{t,\emptyset}$. Note that $c[t, Y, p]$ has size at most $1 \leq \binom{2k}{2p}$, and we can compute $c[t, Y, p]$ in polynomial time.

Introduce node. Suppose t is an introduce node with child t' such that $X_t = X_{t'} \cup \{e\}$, where $e \notin X_{t'}$. If $Y \neq \emptyset$ and $p < 1$, then we set $c[t, Y, p] = \emptyset$. Otherwise, we compute the entry as described below. Before computing the entry $c[t, Y, p]$, we first compute a set $\widetilde{\mathcal{P}}^p_{t,Y}$ as follows. If $Y \neq \{e\}$, then we set $\widetilde{\mathcal{P}}^p_{t,Y} = c[t', Y, p]$, and otherwise, $\widetilde{\mathcal{P}}^p_{t,Y} = c[t', \emptyset, p-1] \star \{\{e, e^c\}\}$.

Next, we compute $\widehat{\mathcal{P}}^p_{t,Y} \subseteq^{2k-2p}_{\mathsf{rep}} \widetilde{\mathcal{P}}^p_{t,Y}$ of size $\binom{2k}{2p}$, using Theorem 8. Finally, we set $c[t, Y, p] = \widehat{\mathcal{P}}^p_{t,Y}$.

Forget node. Suppose t is a forget node with child t' such that $X_t = X_{t'} \setminus \{e\}$, where $e \in X_{t'}$. Before computing the entry $c[t, Y, p]$, we first compute a set $\widetilde{\mathcal{P}}^p_{t,Y}$ as follows. If $Y \neq \emptyset$, we set $\widetilde{\mathcal{P}}^p_{t,Y} = c[t', Y, p]$, and otherwise, $\widetilde{\mathcal{P}}^p_{t,Y} = c[t', \emptyset, p]$.

Next, we compute $\widehat{\mathcal{P}}^p_{t,Y} \subseteq^{2k-2p}_{\mathsf{rep}} \widetilde{\mathcal{P}}^p_{t,Y}$ of size $\binom{2k}{2p}$, using Theorem 8. Finally, we set $c[t, Y, p] = \widehat{\mathcal{P}}^p_{t,Y}$.

Join node. Suppose t is a join node with children t_1 and t_2, such that $X_t = X_{t_1} = X_{t_2}$. If $Y \neq \emptyset$ and $p < 1$, then we set $c[t, Y, p] = \emptyset$. Otherwise, we compute the entry as described below. Before computing the entry $c[t, Y, p]$, we first compute a set $\widetilde{\mathcal{P}}^p_{t,Y}$ as follows. If $Y = \emptyset$, we set $\tilde{\mathcal{P}}^p_{t,Y} = \cup_{i \in [0,p]}(c[t_1, \emptyset, i] \star c[t_2, \emptyset, p-i])$, and otherwise, $\tilde{\mathcal{P}}^p_{t,Y} = \cup_{i \in [p]}(c[t_1, Y, i] \star c[t_2, \emptyset, p-i])$.

Next, we compute $\widehat{\mathcal{P}}^p_{t,Y} \subseteq^{2k-2p}_{\mathsf{rep}} \widetilde{\mathcal{P}}^p_{t,Y}$ of size $\binom{2k}{2p}$, using Theorem 8. Finally, we set $c[t, Y, p] = \widehat{\mathcal{P}}^p_{t,Y}$.

This completes the description of the (recursive) formulae for computing all entries of the table. The correctness of the algorithm follows from the correctness of the (recursive) formulae, and the fact that (G, H, k) is a yes instance of CCBM if and only if $c[r, \emptyset, k] \neq \emptyset$. From the above, we obtain the following theorem.

▶ **Theorem 13.** CCBM *admits an FPT algorithm running in time* $\mathcal{O}(2^{\mathcal{O}(\omega k)} n^{\mathcal{O}(1)})$.

4.2 FPT algorithm for Chordal Conflict Matching

We design an FPT algorithm for Chordal Conflict Matching, using the algorithm for CCBM (Theorem 13). Let (G, H, k) be an instance of CF-MM, where H is a chordal graph and G is a graph on n vertices. We assume that G is a graph on vertex set $[n]$, which can easily be achieved by renaming vertices.

The algorithm starts by computing an $(n, 2k)$-universal set $\mathcal{F}$, using Proposition 9. For each set $A \in \mathcal{F}$, the algorithm constructs an instance $I_A = (G_A, L_A, R_A, H_A, k)$ of CCBM as follows. We have $V(G_A) = V(G)$, $L_A = A$, $R = V(G) \setminus A$, $E(G_A) = \{uv \in E(G) \mid u \in L_A, v \in R_A\}$, and $H_A = H[E(G_A)]$. Note that H_A is a chordal graph because chordal graphs are closed under induced subgraphs and disjoint unions. The algorithm decides the instance I_A using Theorem 13, for each $A \in \mathcal{F}$. The algorithm outputs yes if and only if there is $A \in \mathcal{F}$, such that I_A is a yes instance of CCBM.

▶ **Theorem 14.** *The algorithm presented for* CF-MM *is correct, Moreover, it runs in time* $2^{\mathcal{O}(\omega k)}k^{\mathcal{O}(\log k)}n^{\mathcal{O}(1)}$*, where* $\omega < 2.373$ *is the exponent of matrix multiplication and* n *is the number of vertices in the input graph.*

Proof. Let (G, H, k) be an instance of CF-MM, where H is a chordal graph and G is a graph on vertex set $[n]$. Clearly, if the algorithm outputs yes, then indeed (G, H, k) is a yes instance of CF-MM. Next, we argue that if (G, H, k) is a yes instance of CF-MM then the algorithm returns yes. Suppose there is a solution $M \subseteq E(G)$ to CF-MM in (G, H, k). Let $S = \{i, j \mid ij \in M\}$, and $L = \{i \mid \text{there is } j \in [n] \text{ such that } ij \in M \text{ and } i < j\}$. Observe that $|S| = 2k$. Since $\mathcal{F}$ is an $(n, 2k)$-universal set, there is $A \in \mathcal{F}$ such that $A \cap S = L$. Note that S is a solution to CCBM in I_A. This together with Theorem 13 implies that the algorithm will return yes as output.

Next, we prove the claimed running time of the algorithm. The algorithm computes $(n, 2k)$-universal set of size $\mathcal{O}(2^{2k}k^{\mathcal{O}(\log k)} \log n)$, in time $\mathcal{O}(2^{2k}k^{\mathcal{O}(\log k)}\ n \log n)$, using Proposition 9. Then for each $A \in \mathcal{F}$, the algorithm creates an instance I_A of CCBM in polynomial time. Furthermore, it resolves the I_A of CCBM in time $\mathcal{O}(2^{\mathcal{O}(\omega k)}n^{\mathcal{O}(1)})$ using Theorem 13. Hence, the running time of the algorithm is bounded by $2^{\mathcal{O}(\omega k)}k^{\mathcal{O}(\log k)}n^{\mathcal{O}(1)}$. ◀

5 FPT algorithms for CF-MM and CF-SP with matroid constraints

In this section, we study the problems CF-MM and CF-SP, where the conflicting condition is being an independent set in a (representable) matroid. Due to technical reasons we only consider the case when the matroid is representable over $\mathbb{Q}$ (the field of rationals).

5.1 FPT algorithm for Matroid CF-MM

We study a variant of the problem CF-MM, where the conflicting condition is being an independent set in a matroid representable over $\mathbb{Q}$. We call this variant of CF-MM as Rational Matroid CF-MM (Rat Mat CF-MM, for short), which is formally defined below.

Rational Matroid CF-MM (Rat Mat CF-MM)	**Parameter:** k
Input: A graph G, a matrix $A_{\mathcal{M}}$ (representing a matroid $\mathcal{M}$ over $\mathbb{Q}$) with columns indexed by $E(G)$, and an integer k.	
Question: Is there a matching $M \subseteq E(G)$ of size at most k, such that the set of columns in M are linearly independent (over $\mathbb{Q}$)?	

We design an FPT algorithm for Rat Mat CF-MM. Towards designing an algorithm for Rat Mat CF-MM, we first give an FPT algorithm for a restricted version of Rat Mat CF-MM, where the graph in which we want to compute a matching is a bipartite graph. We call this variant of Rat Mat CF-MM as Rat Mat CF-Bipartite Matching (Rat Mat CF-BM). We then employ the algorithm for Rat Mat CF-BM to design an FPT algorithm for Rat Mat CF-MM.

5.1.1 FPT algorithm for Rat Mat CF-BM

We design an FPT algorithm for the problem Rat Mat CF-BM, where the conflicting condition is being an independent set in a matroid (representable over $\mathbb{Q}$) and the graph where we want to compute a matching is a bipartite graph.

Our algorithm takes an instance of Rat Mat CF-BM and generates an instance of 3-Matroid Intersection, and then employs the known algorithm for 3-Matroid

Intersection to resolve the instance. In the following, we formally define the problem 3-Matroid Intersection.

> 3-Matroid Intersection **Parameter:** k
> **Input:** Matrices $A_{\mathcal{M}_1}, A_{\mathcal{M}_2}$, and $A_{\mathcal{M}_3}$ over $\mathbb{F}$ (representing matroids $\mathcal{M}_1, \mathcal{M}_2$, and $\mathcal{M}_3$, respectively, on the same ground set E) with columns indexed by E, and an integer k.
> **Question:** Is there a set $M \subseteq E$ of size k, such that M is independent in each $\mathcal{M}_i$, for $i \in [3]$?

Before moving further, we briefly explain why we needed an additional constraint that the input matrix is representable over $\mathbb{Q}$. Firstly, we will be using partition matroids which are representable only on fields of large enough size, and we want all the matroids, i.e. the one which is part of the input and the ones that we create, to be representable over the same field. Secondly, the algorithmic result (with the desired running time) we use for 3-Matroid Intersection works only for certain types of fields.

Next, we state an algorithmic result regarding 3-Matroid Intersection [24], which is be used by the algorithm. We note that we only state a restricted form of the algorithmic result for 3-Matroid Intersection in [24], which is enough for our purpose.

▶ **Proposition 15** (Proposition 4.8 [24] (partial)). 3-Matroid Intersection *can be solved in $\mathcal{O}(2^{3\omega k}\|A_M\|^{\mathcal{O}(1)})$ time, when the matroids are represented over $\mathbb{Q}$.*

We are now ready to prove the desired result.

▶ **Theorem 16.** Rat Mat CF-BM *can be solved in $\mathcal{O}(2^{3\omega k}\|A_M\|^{\mathcal{O}(1)})$ time.*

Proof. Let $(G = (V, E), L, R, A_{\mathcal{M}}, k)$ be an instance of Rat Mat CF-BM, where the matrix $A_{\mathcal{M}}$ represents a matroid $\mathcal{M} = (E, \mathcal{I})$ over $\mathbb{Q}$ and L, R is a partition of V into independent sets. Let $\mathcal{M}_L = (E, \mathcal{I}_L), \mathcal{M}_R = (E, \mathcal{I}_R)$ be the partition matroids as defined in Section 4. Next we compute matrix representations $A_{\mathcal{M}_L}$ and $A_{\mathcal{M}_R}$ of matroids $\mathcal{M}_L, \mathcal{M}_R$, respectively, using Proposition 4. Now, we solve 3-Matroid Intersection on the instance $(\mathcal{M}, A_{\mathcal{M}_L}, A_{\mathcal{M}_R}, k)$ (over $\mathbb{Q}$) using Proposition 15, and return the same answer, as returned by the algorithm in it. The correctness follows directly from the following. $S \subseteq E$ is a matching in G if and only if S is an independent set in $\mathcal{M}_L$ and $\mathcal{M}_R$, that is $S \in \mathcal{I}_L \cap \mathcal{I}_R$. The claimed running time follows from Proposition 4 and Proposition 15. ◀

5.1.2 FPT algorithm for Rat Mat CF-MM

We design an FPT algorithm for Rat Mat CF-MM, using the algorithm for Rat Mat CF-BM (Theorem 13). Let $(G, A_{\mathcal{M}}, k)$ be an instance of Rat Mat CF-MM, where the matrix $A_{\mathcal{M}}$ represents a matroid $\mathcal{M} = (E, \mathcal{I})$ over $\mathbb{Q}$. We assume that G is a graph with the vertex set $[n]$, which can easily be achieved by renaming vertices.

The algorithm starts by computing an $(n, 2k)$-universal set $\mathcal{F}$, using Proposition 9. For each set $X \in \mathcal{F}$, the algorithm constructs an instance $I_X = (G_X, L_X, R_X, A_{\mathcal{M}}, k)$ of Rat Mat CF-BM as follows. We have $V(G_X) = V(G)$, $L_X = X$, $R = V(G) \setminus X$, $E(G_X) = \{uv \in E(G) \mid u \in L_X, v \in R_X\}$. The algorithm decides the instance I_X using Theorem 16, for each $X \in \mathcal{F}$. The algorithm outputs yes if and only if there is $X \in \mathcal{F}$, such that I_X is a yes instance of Rat Mat CF-BM.

▶ **Theorem 17.** *The algorithm presented for* Rat Mat CF-MM *is correct. Moreover, it runs in time $\mathcal{O}(2^{(3\omega+2)k}k^{\mathcal{O}(\log k)}\|A_M\|^{\mathcal{O}(1)}n^{\mathcal{O}(1)})$.*

Proof. Let $(G, A_{\mathcal{M}}, k)$ be an instance of Rat Mat CF-MM, where matrix $A_{\mathcal{M}}$ represent a matroid $\mathcal{M} = (E, \mathcal{I})$ over field $\mathbb{F}$. Clearly, if the algorithm outputs yes, then indeed $(G, A_{\mathcal{M}}, k)$ is a yes instance of Rat Mat CF-MM. Next, we argue that if $(G, A_{\mathcal{M}}, k)$ is a yes instance of Rat Mat CF-MM then the algorithm returns yes. Suppose there is a solution $M \subseteq E(G)$ to Rat Mat CF-MM in $(G, A_{\mathcal{M}}, k)$. Let $S = \{i, j \mid ij \in M\}$, and $L = \{i \mid \text{there is } j \in [n] \text{ such that } ij \in M \text{ and } i < j\}$. Observe that $|S| = 2k$. Since $\mathcal{F}$ is an $(n, 2k)$-universal set, there is $X \in \mathcal{F}$ such that $X \cap S = L$. Note that S is a solution to Rat Mat CF-BM in I_X. This together with Theorem 16 implies that the algorithm will return yes as the output.

Next, we prove the claimed running time of the algorithm. The algorithm computes $(n, 2k)$-universal set of size $\mathcal{O}(2^{2k}k^{\mathcal{O}(\log k)} \log n)$, in time $\mathcal{O}(2^{2k}k^{\mathcal{O}(\log k)}\ n \log n)$, using Proposition 9. Then for each $X \in \mathcal{F}$, the algorithm creates an instance I_X of Rat Mat CF-BM in polynomial time. Furthermore, it resolves the I_X of Rat Mat CF-BM in time $\mathcal{O}(2^{3\omega k}\|A_M\|^{\mathcal{O}(1)})$ using Theorem 16. Hence, the running time of the algorithm is bounded by $\mathcal{O}(2^{(3\omega+2)k}k^{\mathcal{O}(\log k)}\|A_M\|^{\mathcal{O}(1)}n^{\mathcal{O}(1)})$. ◀

5.2 FPT algorithm for Matroid CF-SP

In this section, we design an FPT algorithm for Matroid CF-SP. The algorithm is based on dynamic programming over representative families. Let $(G, s, t, A_{\mathcal{M}}, k)$ be an instance of Matroid CF-SP. Before moving to the description of the algorithm, we need to define some notations. For distinct vertices $u, v \in V(G)$ and an integer p, we define: $\mathcal{P}^p_{uv} = \{X \subseteq E(G) \mid |X| = p, \text{ there is a } u - v \text{ path in } G[X] \text{ containing all edges in } X, \text{ and } X \in \mathcal{I}\}$.

By the definition of convolution of sets, it is easy to see that $\mathcal{P}^p_{uv} = \bigcup_{wv \in E(G)} \mathcal{P}^{p-1}_{uw} \star \{\{wv\}\}$. Now we are ready to describe our algorithm for Matroid CF-SP. We aim to store, for each $v \in V(G) \setminus \{s\}$, $p \leq k$, and $q \leq k - p$, a q-representative set $\widehat{\mathcal{P}}^{pq}_{sv}$, of $\mathcal{P}^p_{sv}$, of size $\binom{p+q}{q}$. Notice that for each $v \in V(G) \setminus \{s\}$, we can compute $\mathcal{P}^1_{sv}$ in polynomial time, since $\mathcal{P}^1_{sv} = \{sv\}$ if $sv \in E(G)$, and is empty otherwise. Moreover, since $|\mathcal{P}^1_{sv}| \leq 1$, therefore, we can set $\widehat{\mathcal{P}}^{1q}_{sv} = \mathcal{P}^1_{sv}$, for each $q \leq k - 1$. Next, we iteratively compute, for each $p \in \{2, 3, \cdots, k\}$, in increasing order, for each $q \leq k - p$, a q-representative $\widehat{\mathcal{P}}^{pq}_{sv}$, of $\mathcal{P}^p_{sv}$. From the above discussions, we obtain the following theorem.

▶ **Theorem 18.** *The algorithm Alg-Mat-CF-SP is correct, and runs in time* $\mathcal{O}(2^{\mathcal{O}(\omega k)}n^{\mathcal{O}(1)})$.

6 FPT Algorithm for d-degenerate Conflict Graphs

In this section, we show that CF-MM and CF-SP both are in FPT, when the conflict graph H is a d-degenerate graphs. These algorithms are based on the notion of independence covering family, which was introduced in [25], defined below.

▶ **Definition 19** ([25]). For a graph $H^\star$ and an integer k, a *k-independence covering family*, $\mathscr{I}(H^\star, k)$, is a family of independent sets in $H^\star$ such that for any independent set I' in $H^\star$ of size at most k, there is a set $I \in \mathscr{I}(H^\star, k)$ such that $I' \subseteq I$.

Our algorithms rely on the construction of k-independence covering family, for a family of graphs. We first design an algorithm for an annotated version of the CF-MM and CF-SP problems, which we call Annotated CF-MM and Annotated CF-SP, respectively. In the Annotated CF-MM (Annotated CF-SP) problem, the input to CF-MM (CF-SP) is annotated with a k-independence covering family $\mathcal{F}$ of H.

Algorithm 1 Alg-CF-MM (Alg-CF-SP).

```
Input: A graph $G$,((distinct) vertices $s, t \in V(G)$), a conflict graph $H$, an integer $k$,
       and a $k$-independence covering family $\mathcal{F}$ of $H$.
Output: If there a set $M \subseteq E$ of size $k$ in $G$ such that $M$ is a matching in $G$ (there
        is an $s - t$ path in $G[M]$) and $M$ is an independent set in $H$, then yes, and
        no otherwise.
for each $I \in \mathcal{F}$ do
    Let $G_I$ be the graph with $V(G_I) = V(G)$ and $E(G_I) = I$ ;
    if $G_I$ has a matching (path) of size $k$ then
        return yes;
end
return no ;
```

6.1 Algorithms for Annotated CF-MM and Annotated CF-SP

In this section, we study the problems Annotated CF-MM and Annotated CF-SP. The algorithm that we design for them run in time polynomial in the size of the input. We give the algorithm Alg-CF-MM (Alg-CF-SP) (Algorithm 1) for Annotated CF-MM (Annotated CF-SP).

In the following lemma we prove the correctness of Alg-CF-MM (Alg-CF-SP).

▶ **Lemma 20.** *The algorithm Alg-CF-MM (Alg-CF-SP) is correct. Moreover, the algorithm runs in time polynomial in the size of the input.*

We use Alg-CF-MM (Alg-CF-SP) together with Independence Covering Lemma of [25] to obtain algorithms for CF-MM (CF-SP) when the conflict graph is d-degenerate or nowhere dense graph. Towards this we state some lemmata from [25] that we use in our algorithms.

▶ **Proposition 21.** [25, Lemma 1.1] *There is a randomized algorithm running in polynomial time, that given a d-degenerate graph $H^\star$ and an integer k as input, outputs an independent set I, such that for every independent set I' of size at most k in graph $H^\star$, the probability that $I' \subseteq I$ is at least $(\binom{k(d+1)}{k} \cdot k(d+1))^{-1}$.*

▶ **Proposition 22.** [25, Lemmas 3.2 and 3.3] *There are two deterministic algorithms $\mathcal{A}_1$ and $\mathcal{A}_2$, which given a d-degenerate graph $H^\star$ and an integer k, output independence covering families $\mathscr{I}_1(H^\star, k)$ and $\mathscr{I}_2(H^\star, k)$, respectively, such that the following conditions are satisfied: i) $\mathcal{A}_1$ runs in time $\mathcal{O}(|\mathscr{I}_1(H^\star, k)| \cdot (n+m))$, where $|\mathscr{I}_1(H^\star, k)| = \binom{k(d+1)}{k} \cdot 2^{o(k(d+1))} \cdot \log n$ and ii) $\mathcal{A}_2$ runs in time $\mathcal{O}(|\mathscr{I}_2(H^\star, k)| \cdot (n+m))$, where $|\mathscr{I}_2(H^\star, k)| = \binom{k^2(d+1)^2}{k} \cdot (k(d+1))^{\mathcal{O}(1)} \cdot \log n$.*

Next, using Proposition 21 and 22, together with Alg-CF-MM (Alg-CF-SP), we obtain randomized and deterministic algorithms, respectively for CF-MM (CF-SP), when the conflict graph is a d-degenerate graph.

▶ **Theorem 23.** *There is a randomized algorithm, which given an instance (G, H, k) of* CF-MM(CF-SP)*, where H is a d-degenerate graph, in time $\binom{k(d+1)}{k} \cdot k(d+1) \cdot n^{\mathcal{O}(1)}$, either reports a failure or correctly outputs that the input is a* yes *instance of* CF-MM(CF-SP)*. Moreover, if the input is a* yes *instance of* CF-MM(CF-SP)*, then the algorithm outputs correct answer with a constant probability.*

Proof. Let $(G,(s,t),H,k)$ be an instance CF-MM (CF-SP), where H is a d-degenerate graph. We repeat the following procedure $(\binom{k(1+d)}{k} \cdot k(d+1))$ many times: i) the algorithm computes an independent set I in (H,k) using Proposition 21, and ii) the algorithm calls Alg-CF-MM (Alg-CF-SP) with input $(G,(s,t)H,k,\{I\})$.

The algorithm outputs yes, if in one of the calls to Alg-CF-MM (Alg-CF-SP), it receives a yes. Otherwise, the algorithm outputs no. The running time analysis of the above procedure follows from Proposition 21 and Lemma 20. Also, given a yes instance, the guarantee on success probability follows from Proposition 21, the number of repetitions, and Lemma 20. Moreover, from Lemma 20 the yes output returned by the algorithm is indeed the correct output to CF-MM(CF-SP)for the given instance. This concludes the proof. ◀

▶ **Theorem 24.** CF-MM (CF-SP) *admits a deterministic algorithm running in time* $\min\left\{\binom{k(d+1)}{k} \cdot 2^{o(k(d+1))} \cdot \log n, \binom{k^2(d+1)^2}{k} \cdot (k(d+1))^{\mathcal{O}(1)} \cdot \log n\right\} \cdot n^{\mathcal{O}(1)}$, *when the conflict graph is a d-degenerate graph.*

Proof. Let $(G,(s,t),H,k)$ be an instance CF-MM (CF-SP), where H is a d-degenerate graph. The algorithm starts by computing a k-independence covering family $\mathscr{I}(H,k)$ of H, using Proposition 22. Next, we call Alg-CF-MM (Alg-CF-SP) with the input $(G,(s,t),H,k,\mathscr{I}(H,k))$. The correctness and running time analysis of the above procedure follows from Proposition 22 and Lemma 20. This completes the proof. ◀

7 Conclusion

We studied conflict-free (parameterized) variants of Maximum Matching (CF-MM) and Shortest Path (CF-SP). We showed that both CF-MM and CF-SP are W[1]-hard, when parameterized by the solution size. In fact, our W[1]-hardness result for CF-MM holds even when the graph where we want to compute a matching is itself a matching and W[1]-hardness result of CF-SP holds even when the conflict graph is a unit interval graph. Then, we restricted our attention to having conflict graphs belonging to some families of graphs, where the Independent Set problem is either polynomial time solvable or solvable in FPT time. In particular, we considered the family of chordal graphs and the family of d-degenerate graphs. For the CF-MM problem, we gave an FPT algorithm, when the conflict graph belongs to the family of chordal graphs. We observed that, we cannot obtain an FPT algorithm for the CF-SP problem when the conflict graph is a chordal graph. This holds because unit-interval graphs are chordal, and the problem CF-SP is W[1]-hard, even when the conflict graph is a unit-interval graph. For conflict graphs being d-degenerate, we obtained FPT algorithms for both CF-MM and CF-SP. Our results hold even when the conflict graph is a nowhere dense graph. Finally, we studied a variant of CF-MM and CF-SP, where instead of conflicting conditions being imposed by independent sets in a conflict graph, they are imposed by independence constraints in a (representable) matroid. We gave FPT algorithms for the above variant of both CF-MM and CF-SP.

An interesting question is to obtain (parameterized) dichotomy results for CF-MM and CF-SP, based on the families of graphs where the input graphs belong to. Another direction could be studying kernelization complexity for different families of graphs, and also to see what all FPT problems remain FPT with the conflicting constraints.

Abstract

Uniqueness quantification ($\exists!$) is a quantifier in first-order logic where one requires that exactly one element exists satisfying a given property. In this paper we investigate the strength of uniqueness quantification when it is used in place of existential quantification in conjunctive formulas over a given set of relations Γ, so-called *primitive positive definitions* (pp-definitions). We fully classify the Boolean sets of relations where uniqueness quantification has the same strength as existential quantification in pp-definitions and give several results valid for arbitrary finite domains. We also consider applications of $\exists!$-quantified pp-definitions in computer science, which can be used to study the computational complexity of problems where the number of solutions is important. Using our classification we give a new and simplified proof of the trichotomy theorem for the unique satisfiability problem, and prove a general result for the unique constraint satisfaction problem. Studying these problems in a more rigorous framework also turns out to be advantageous in the context of lower bounds, and we relate the complexity of these problems to the *exponential-time hypothesis*.

1 Introduction

A *primitive positive definition* (pp-definition) over a relational structure $\mathcal{A} = (A; R_1, \ldots, R_k)$ is a first-order formula $\exists y_1, \ldots, y_m \colon \varphi(x_1, \ldots, x_n, y_1, \ldots, y_m)$ with free variables $x_1, \ldots, x_n$ where $\varphi(x_1, \ldots, x_n, y_1, \ldots, y_m)$ is a conjunctive formula. Primitive positive definitions have been extremely influential in the last decades due to their one-to-one correspondence with term algebras in universal algebra, making them a cornerstone in the *algebraic approach* for studying computational complexity [1, 10]. In short, pp-definitions can be used to obtain classical "gadget reductions" between problems by replacing constraints by their pp-definitions, which in the process might introduce fresh variables viewed as being existentially quantified. This approach has successfully been used to study the complexity of e.g. the *constraint satisfaction problem* (CSP) which recently led to a dichotomy between tractable and NP-complete CSPs [6, 28]. However, these reductions are typically not sufficient for optimisation problems and other variants of satisfiability, where one needs reductions preserving the number of models, so-called *parsimonious* reductions. Despite the tremendous advances in the algebraic approach there is currently a lack of methods for studying problems requiring parsimonious reductions, and in this paper we take the first step in developing such a framework. The requirement of parsimonious reductions can be realised by restricting existential quantification

to *unique quantification* ($\exists!$), where we explicitly require that the variable in question can be expressed as a unique combination of other variables. That is, $\mathcal{A} \models \exists! x_i \colon \varphi(x_1, \ldots, x_i, \ldots, x_n)$ if and only if there exists a function f such that $f(a_1, \ldots, a_{i-1}, a_{i+1}, \ldots, a_n) = a_i$, for all $a_1, \ldots, a_{i-1}, a_i, a_{i+1}, \ldots, a_n \in A$ where $\mathcal{A} \models \varphi(a_1, \ldots, a_{i-1}, a_i, a_{i+1}, \ldots, a_n)$. This notion of unique quantification is not the only one possible and we discuss an alternative viewpoint in Section 5. As a first step in understanding the applicability of uniqueness quantification in complexity classifications we are interested in studying the expressive power of unique existential quantification when used in place of existential quantification in pp-definitions, which we call *upp-definitions*. Any variables introduced by the resulting gadget reductions are then uniquely determined and do not affect the number of models.

Our main question is then: for which relational structures $\mathcal{A}$ is it the case that for every pp-formula $\varphi(x_1, \ldots, x_n)$ there exists a upp-formula $\vartheta(x_1, \ldots, x_n)$ such that $\mathcal{A} \models \varphi(a_1, \ldots, a_n) \Leftrightarrow \mathcal{A} \models \vartheta(a_1, \ldots, a_n)$ for all $a_1, \ldots, a_n \in A$? If this holds over $\mathcal{A}$ then uniqueness quantification has the same expressive power as existential quantification. The practical motivation for studying this is that if upp-definitions are as powerful as pp-definitions in $\mathcal{A}$, then, intuitively, any gadget reduction between two problems can be replaced with a parsimonious reduction. Given the generality of this question a complete answer for arbitrary relational structures is well out of reach, and we begin by introducing simplifying concepts. First, pp-definitions can be viewed as a closure operator over relations, and the resulting closed sets of relations are known as *relational clones*, or *co-clones* [21]. For each universe A the set of co-clones over A then forms a lattice when ordered by set inclusion, and given a set of relations Γ we write $\langle \Gamma \rangle$ for the smallest co-clone over A containing Γ. Similarly, closure under upp-definitions can also be viewed as a closure operator, and we write $\langle \Gamma \rangle_{\exists!}$ for the smallest set of relations over A containing Γ and which is closed under upp-definitions. Using these notions the question of the expressive strength of upp-definitions can be stated as: for which sets of relations Γ is it the case that $\langle \Gamma \rangle = \langle \Gamma \rangle_{\exists!}$? The main advantage behind this viewpoint is that a co-clone $\langle \Gamma \rangle$ can be described as the set of relations *invariant* under a set of operations F, $\mathrm{Inv}(F)$, such that the operations in F describe all permissible combinations of tuples in relations from Γ. An operation $f \in F$ is also said to be a *polymorphism* of Γ and if we let $\mathrm{Pol}(\Gamma)$ be the set of polymorphisms of Γ then $\mathrm{Pol}(\Gamma)$ is called a *clone*. This relationship allows us to characterise the cases that need to be considered by using known properties of $\mathrm{Pol}(\Gamma)$, which is sometimes simpler than working only on the relational side.

Our Results

Our main research question is to identify Γ such that $\langle \Delta \rangle_{\exists!} = \langle \Gamma \rangle$ for each Δ such that $\langle \Delta \rangle = \langle \Gamma \rangle$. If this holds we say that $\langle \Gamma \rangle$ is $\exists!$-*covered*. The main difficulty for proving this is that it might not be possible to directly transform a pp-definition into an equivalent upp-definition. To mitigate this we analyse relations in co-clones using *partial polymorphisms*, which allows us to analyse their expressibility in a very nuanced way. In Section 3.1 we show how partial polymorphisms can be leveraged to prove that a given co-clone is $\exists!$-covered. Most notably, we prove that $\langle \Gamma \rangle$ is $\exists!$-covered if $\mathrm{Pol}(\Gamma)$ consists only of projections of the form $\pi(x_1, \ldots, x_i, \ldots, x_n) = x_i$, or of projections and constant operations. As a consequence, Γ pp-defines all relations over A if and only if Γ upp-defines all relations over A. One way of interpreting this result is that if Γ is "sufficiently expressive" then pp-definitions can always be turned into upp-definitions. However, there also exists $\exists!$-covered co-clones where the reason is rather that Γ is "sufficiently weak". For example, if Γ is invariant under the affine operation $x - y + z \pmod{|A|}$, then existential quantification does not add any expressive power over unique existential quantification, since any existentially quantified variable occurring in a pp-definition can be expressed via a linear equation, and is therefore uniquely determined by other arguments. In Section 3.2 we then turn to the Boolean domain, and obtain a full classification of the ∃!-covered co-clones. Based on the results in Section 3.1 it is reasonable to expect that the covering property holds for sufficiently expressive languages and sufficiently weak languages, but that there may exist cases in between where unique quantification differs from existential quantification. This is indeed true, and we prove that the Boolean co-clones corresponding to non-positive Horn clauses, implicative and positive clauses, and their dual cases, are not ∃!-covered. Last, in Section 4 we demonstrate how the results from Section 3 can be used for obtaining complexity classifications of computational problems. One example of a problem requiring parsimonious reductions is the *unique satisfiability problem* over a Boolean set of relations Γ (U-SAT(Γ)) and its multi-valued generalization the *unique constraint satisfaction problem* (U-CSP(Γ)), where the goal is to determine if there exists a unique model of a given conjunctive Γ-formula. The complexity of U-SAT(Γ) was settled by Juban [15] for finite sets of relations Γ, essentially using a large case analysis. Using the results from Section 3.2 this complexity classification can instead be proved in a succinct manner, and we are also able to extend the classification to infinite Γ and large classes of non-Boolean Γ. This systematic approach is also advantageous for proving lower bounds, and we relate the complexity of U-SAT(Γ) to the highly influential *exponential-time hypothesis* (ETH) [12], by showing that none of the intractable cases of U-SAT(Γ) admit subexponential algorithms without violating the ETH.

Related Work

Primitive positive definitions with uniqueness quantification appeared in Creignou & Hermann [7] in the context of "quasi-equivalent" logical formulas, and in the textbook by Creignou et al. [8] under the name of *faithful implementations*. Similarly, upp-definitions were utilised by Kavvadias & Sideri [16] to study the complexity of the *inverse satisfiability problem*. A related topic is *frozen quantification*, which can be viewed as uniqueness quantification restricted to variables that are constant in any model [22].

2 Preliminaries

2.1 Operations and Relations

In the sequel, let $D \subseteq \mathbb{N}$ be a finite domain of values. A k-ary function $f \colon D^k \to D$ is sometimes referred to as an *operation* over D and we write $\mathrm{ar}(f)$ to denote the arity k. Similarly, a *partial operation* over D is a map $f \colon \mathrm{dom}(f) \to D$ where $\mathrm{dom}(f) \subseteq D^k$ is called the *domain* of f, and we let $\mathrm{ar}(f) = k$ be the arity of f. If f and g are k-ary partial operations such that $\mathrm{dom}(f) \subseteq \mathrm{dom}(g)$ and $f(t) = g(t)$ for each $t \in \mathrm{dom}(f)$ then f is said to be a *suboperation* of g. For $k \geq 1$ and $1 \leq i \leq k$ we let π^k_i be the ith *projection*, i.e., $\pi^k_i(x_1, \ldots, x_i, \ldots, x_k) = x_i$ for all $x_1, \ldots, x_i, \ldots, x_k \in D$. We write OP_D for the set of all operations over D and pOP_D for the set of all partial operations over D. As a notational shorthand we for $k \geq 1$ write $[k]$ for the set $\{1, \ldots, k\}$. For $d \in D$ we by $\mathbf{d}^n$ denote the constant n-ary tuple $(d, \ldots, d)$. Say that a k-ary $f \in \mathsf{OP}_D$ is *essentially unary* if there exists unary $g \in \mathsf{OP}_D$ and i such that $f(x_1, \ldots, x_i, \ldots, x_n) = g(x_i)$ for all $x_1, \ldots, x_i, \ldots, x_n \in D$.

Given an n-ary relation $R \subseteq D^n$ we write $\mathrm{ar}(R)$ to denote its arity n. If $t = (x_1, \ldots, x_n)$ is an n-ary tuple we write $t[i]$ to denote the ith element x_i, and $\mathrm{Proj}_{i_1, \ldots, i_{n'}}(t) = (t[i_1], \ldots, t[i_{n'}])$ to denote the *projection* on the coordinates $i_1, \ldots, i_{n'} \in \{1, \ldots, n\}$. Similarly, if R is an n-ary relation we let $\mathrm{Proj}_{i_1, \ldots, i_{n'}}(R) = \{\mathrm{Proj}_{i_1, \ldots, i_{n'}}(t) \mid t \in R\}$. The ith argument of a relation R is said to be *redundant* if there exists $j \neq i$ such that $t[i] = t[j]$ for each $t \in R$, and is said to be *fictitious* if for all $t \in R$ and $d \in D$ have $t' \in R$ where $t'[i] = d$ and $\mathrm{Proj}_{1,\ldots,i-1,i+1,\ldots,n}(t) = \mathrm{Proj}_{1,\ldots,i-1,i+1,\ldots,n}(t')$.

We write Eq_D for the equality relation $\{(x,x) \mid x \in D\}$ over D. We often represent relations by their defining first-order formulas, and if $\varphi(x_1,\ldots,x_n)$ is a first-order formula with n free variables we write $R(x_1,\ldots,x_n) \equiv \varphi(x_1,\ldots,x_n)$ to define the relation $R = \{(f(x_1),\ldots,f(x_n)) \mid f \text{ is a model of } \varphi(x_1,\ldots,x_n)\}$. We let REL^n_D be the set of all n-ary relations over D, $\mathsf{REL}^{\leq n}_D = \bigcup_{i=1}^{n} \mathsf{REL}^n_D$, and $\mathsf{REL}_D = \bigcup_{i=1}^{\infty} \mathsf{REL}^i_D$. A set $\Gamma \subseteq \mathsf{REL}_D$ will sometimes be called a *constraint language*.

2.2 Primitive Positive Definitions and Determined Variables

We say that an n-ary relation R has a *primitive positive definition* (pp-definition) over a set of relations Γ over a domain D if $R(x_1,\ldots,x_n) \equiv \exists y_1,\ldots,y_{n'} \colon R_1(\mathbf{x}_1) \wedge \ldots \wedge R_m(\mathbf{x}_m)$ where each $\mathbf{x}_i$ is a tuple of variables over $x_1,\ldots,x_n,y_1,\ldots,y_{n'}$ of length $\mathrm{ar}(R_i)$ and each $R_i \in \Gamma \cup \{\mathrm{Eq}_D\}$. Hence, R can be defined as a (potentially) existentially quantified conjunctive formula over $\Gamma \cup \{\mathrm{Eq}_D\}$. We will occasionally be interested in pp-definitions not making use of existential quantification, and call pp-definitions of this restricted type *quantifier-free primitive positive definitions* (qfpp-definitions).

▶ **Definition 1.** *Let R be an n-ary relation over a domain D. We say that $1 \leq i \leq n$ is* uniquely determined*, or just* determined*, if there exists $i_1,\ldots,i_k \in [n]$ and a function $h : D^k \to D$ such that $h(t[i_1],\ldots,\ldots,t[i_k]) = t[i]$ for each $t \in R$.*

When defining relations in terms of logical formulas we will occasionally also say that the ith variable is uniquely determined, rather than the ith index.

▶ **Definition 2.** *An n-ary relation R has a* unique primitive positive definition *(upp-definition) over a set of relations Γ if there exists a pp-definition*

$$R(x_1,\ldots,x_n) \equiv \exists y_1,\ldots,y_{n'} \colon R_1(\mathbf{x}_1) \wedge \ldots \wedge R_m(\mathbf{x}_m)$$

of R over Γ where each y_i is uniquely determined by $x_1,\ldots,x_n$.

We typically write $\exists! y_1,\ldots,y_{n'}$ for the existentially quantified variables in a upp-definition. Following Nordh & Zanuttini [22] we refer to unique existential quantification over constant arguments as *frozen existential quantification* ($i \in [\mathrm{ar}(R)]$ is constant if there exists $d \in D$ such that $t[i] = d$ for each $t \in R$). If R is upp-definable over Γ via a upp-definition only making use of frozen existential quantification then we say that R is *freezingly pp-definable* (fpp-definable) over Γ. Let us define the following closure operators over relations.

▶ **Definition 3.** *Let Γ be a set of relations. Then we define (1) $\langle \Gamma \rangle = \{R \mid R$ has a pp-definition over $\Gamma\}$, (2), $\langle \Gamma \rangle_{\exists!} = \{R \mid R$ has a upp-definition over $\Gamma\}$, (3), $\langle \Gamma \rangle_{\mathrm{fr}} = \{R \mid R$ has an fpp-definition over $\Gamma\}$, and (4), $\langle \Gamma \rangle_{\nexists} = \{R \mid R$ has a qfpp-definition over $\Gamma\}$.*

In all cases Γ is called a *base*. If $\Gamma = \{R\}$ is singleton then we write $\langle R \rangle$ instead of $\langle \Gamma \rangle$, and similarly for the other operators. Sets of relations of the form $\langle \Gamma \rangle$ are usually called *relational clones*, or *co-clones*, sets of the form $\langle \Gamma \rangle_{\nexists}$ *weak systems*, or *weak partial co-clones*, and sets of the form $\langle \Gamma \rangle_{\mathrm{fr}}$ are known as *frozen partial co-clones.* Note that $\langle \Gamma \rangle \supseteq \langle \Gamma \rangle_{\exists!} \supseteq \langle \Gamma \rangle_{\mathrm{fr}} \supseteq \langle \Gamma \rangle_{\nexists}$ for any $\Gamma \subseteq \mathsf{REL}_D$. Co-clones and weak systems can be described via algebraic invariants known as *polymorphisms* and *partial polymorphism.* More precisely, if $R \in \mathsf{REL}^n_D$ and $f \in \mathsf{OP}_D$ is a k-ary operation, then for $t_1,\ldots,t_k \in R$ we let

$f(t_1, \ldots, t_k) = (f(t_1[1], \ldots, t_k[1]), \ldots, f(t_1[n], \ldots, t_k[n]))$. We then say that a k-ary partial operation f *preserves* an n-ary relation R if $f(t_1, \ldots, t_k) \in R$ or there exists $i \in [n]$ such that $(t_1[i], \ldots, t_k[i]) \notin \mathrm{dom}(f)$, for each sequence of tuples $t_1, \ldots, t_k \in R$. If f preserves R then R is also said to be *invariant* under f. Note that if f is total then the condition is simply that $f(t_1, \ldots, t_k) \in R$ for each sequence $t_1, \ldots, t_k \in R$. We then let $\mathrm{pPol}(R) = \{f \in \mathsf{pOP}_D \mid f \text{ preserves } R\}$, $\mathrm{Pol}(R) = \mathrm{pPol}(R) \cap \mathsf{OP}_D$, $\mathrm{pPol}(\Gamma) = \bigcap_{R \in \Gamma} \mathrm{pPol}(R)$, and $\mathrm{Pol}(\Gamma) = \bigcap_{R \in \Gamma} \mathrm{Pol}(R)$. Similarly, if F is a set of (partial) operations we let $\mathrm{Inv}(F)$ be the set of relations invariant under F, and write $\mathrm{Inv}(f)$ if $F = \{f\}$ is singleton. It is then known that $\mathrm{Inv}(F)$ is a co-clone if $F \subseteq \mathsf{OP}_D$ and that $\mathrm{Inv}(F)$ is a weak system if $F \subseteq \mathsf{pOP}_D$. More generally, $\langle \Gamma \rangle = \mathrm{Inv}(\mathrm{Pol}(\Gamma))$ and $\langle \Gamma \rangle_{\nexists} = \mathrm{Inv}(\mathrm{pPol}(\Gamma))$, resulting in the following *Galois connections*.

▶ **Theorem 4** ([3, 4, 11, 26]). *Let Γ and Δ be two sets of relations. Then $\Gamma \subseteq \langle \Delta \rangle$ if and only if $\mathrm{Pol}(\Delta) \subseteq \mathrm{Pol}(\Gamma)$ and $\Gamma \subseteq \langle \Delta \rangle_{\nexists}$ if and only if $\mathrm{pPol}(\Delta) \subseteq \mathrm{pPol}(\Gamma)$.*

Last, we remark that sets of the form $\mathrm{Pol}(\Gamma)$ and $\mathrm{pPol}(\Gamma)$ are usually called *clones*, and *strong partial clones*, respectively, and form lattices when ordered by set inclusion. Boolean clones are particularly well understood and the induced lattice is known as *Post's lattice* [24]. If $F \subseteq \mathsf{OP}_D$ then we write $[F]$ for the intersection of all clones over D containing F. Hence, $[F]$ is the smallest clone over D containing F.

2.3 Weak and Plain Bases of Co-Clones

In this section we introduce two special types of bases of a co-clone, that are useful for understanding the expressibility of upp-definitions.

▶ **Definition 5** (Schnoor & Schnoor [27]). *Let $\langle \Gamma \rangle$ be a co-clone. A base Γ_w of $\langle \Gamma \rangle$ with the property that $\langle \Gamma_w \rangle_{\nexists} \subseteq \langle \Delta \rangle_{\nexists}$ for every base Δ of $\langle \Gamma \rangle$ is called a* weak base *of $\langle \Gamma \rangle$.*

Although not immediate from Definition 5, Schnoor & Schnoor [27] proved that a weak base exists whenever $\langle \Gamma \rangle$ admits a finite base, by the following relational construction.

▶ **Definition 6.** *For $s \geq 1$, let $U^s_D = \{t_1, \ldots, t_s\}$ where $t_1, \ldots, t_s$ is the sequence of $|D|^s$-ary tuples where $(t_1[1], \ldots, t_s[1]), \ldots, (t_1[|D|^s], \ldots, t_s[|D|^s])$ is a lexicographic enumeration of D^s.*

For $R \in \mathsf{REL}_D$ and $F \subseteq \mathsf{OP}_D$ we let $F(R) = \bigcap_{R' \in \mathrm{Inv}(F), R \subseteq R' \in \mathsf{REL}_D} R'$. We typically write U^s instead of U^s_D if the domain D is clear from the context, and say that a co-clone $\mathrm{Inv}(\mathsf{C})$ has *core-size* s if there exist relations R, R' such that $\mathrm{Pol}(R) = \mathsf{C}$, $R = \mathsf{C}(R')$, and $s = |R'|$. Weak bases can then be described via core-sizes as follows (a clone C is finitely related if there exists a finite base of $\mathrm{Inv}(\mathsf{C})$).

▶ **Theorem 7** (Schnoor & Schnoor [27]). *Let C be a finitely related clone where $\mathrm{Inv}(\mathsf{C})$ has core-size s. Then $\mathsf{C}(U^t)$ is a weak base of $\mathrm{Inv}(\mathsf{C})$ for every $t \geq s$.*

See Table 2 for a list of weak bases for the Boolean co-clones of interest in this paper [17, 18]. Here, and in the sequel, we use the co-clone terminology developed by Reith & Wagner [25] and Böhler et al. [5], where a Boolean co-clone $\mathrm{Inv}(\mathsf{C})$ is typically written as IC. Many relations in Table 2 are provided by their defining logical formulas; for example, $x_1 \rightarrow x_2$ is the binary relation $\{(0,0), (0,1), (1,1)\}$. See Table 1 for definitions of the remaining relations. As a convention we use c_0 to indicate a variable which is constant 0 in any model, and c_1 for a variable which is constant 1. On the functional side we use the bases by Böhler et al. [5] and let $\mathsf{I}_2 = [\pi^1_1], \mathsf{I}_0 = [0], \mathsf{I}_1 = [1], \mathsf{I} = [\{0,1\}]$, $\mathsf{N}_2 = [\overline{x}]$, $\mathsf{N} = [\{\overline{x}, 0, 1\}]$, $\mathsf{E}_2 = [\wedge]$,

$\mathsf{E}_0=[\{\wedge,0\}]$, $\mathsf{E}_1=[\{\wedge,1\}]$, $\mathsf{E}=[\{\wedge,0,1\}]$, $\mathsf{L}_2=[x\oplus y\oplus z]$, and $\mathsf{S}_{11}=[\{x\wedge(y\vee z),0\}]$, where $\overline{x}=1-x$ and where $0,1$ are shorthands for the two constant Boolean operations. We conclude this section by defining the dual notion of a weak base.

▶ **Definition 8** (Creignou et al. [9]). *Let $\langle\Gamma\rangle$ be a co-clone. A base Γ_p of $\langle\Gamma\rangle$ with the property that $\langle\Delta\rangle_{\nexists}\subseteq\langle\Gamma_p\rangle_{\nexists}$ for every base Δ of $\langle\Gamma\rangle$ is called a* plain base *of $\langle\Gamma\rangle$.*

Clearly, every co-clone is a trivial plain base of itself, but the question remains for which co-clones more succinct plain bases can be found. For arbitrary finite domains little is known but in the Boolean domain succinct plain bases have been described [9] (see Table 2).

2.4 Duality

Many questions concerning Boolean co-clones can be simplified by only considering parts of Post's lattice. If $f\in\mathsf{OP}_{\{0,1\}}$ is k-ary then the *dual* of f, $\mathrm{dual}(f)$, is the operation $\mathrm{dual}(f)(x_1,\ldots,x_k)=\overline{f(\overline{x_1},\ldots,\overline{x_k})}$, and we let $\mathrm{dual}(F)=\{\mathrm{dual}(f)\mid f\in F\}$ for a set $F\subseteq\mathsf{OP}_{\{0,1\}}$. Each Boolean clone C can then be associated with a dual clone $\mathrm{dual}(\mathsf{C})$. Similarly, for $R\in\mathsf{REL}_{\{0,1\}}$ we let $\mathrm{dual}(R)=\{\overline{t}\mid t\in R\}$ and $\mathrm{dual}(\Gamma)=\{\mathrm{dual}(R)\mid R\in\Gamma\}$ for $\Gamma\subseteq\mathsf{REL}_{\{0,1\}}$. It is then known that $\mathrm{Inv}(\mathrm{dual}(\mathsf{C}))=\mathrm{dual}(\mathrm{Inv}(\mathsf{C}))$.

3 The Expressive Power of Unique Existential Quantification

The main goal of this paper is to understand when the expressive power of unique existential quantification coincides with existential quantification in primitive positive formulas. Let us first consider an example where a pp-definition can be rewritten into a upp-definition.

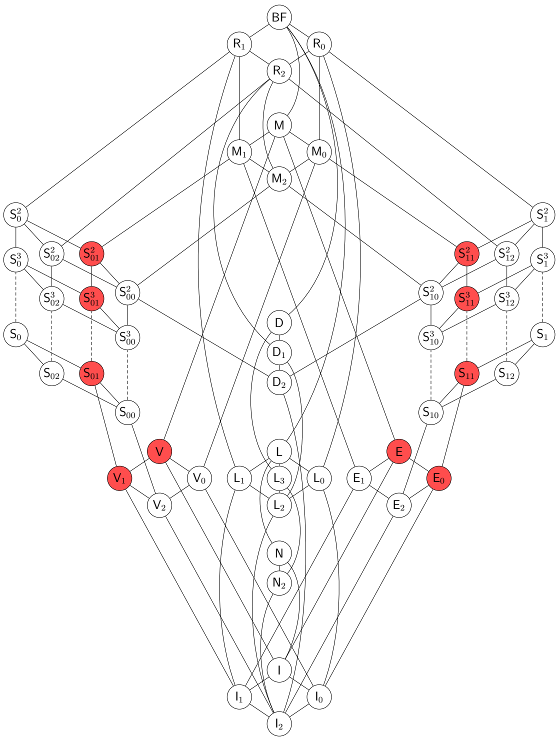

Figure 1 The lattice of Boolean clones. Inv(C) is coloured in red if and only if Inv(C) is not ∃!-covered.

▶ **Example 9.** Consider the canonical reduction from k-SAT to $(k-1)$-SAT via pp-definitions of the form $(x_1 \vee \ldots \vee x_k) \equiv \exists y \colon (x_1 \vee \ldots \vee x_{k-2} \vee y) \wedge (x_{k-1} \vee x_k \vee \neg y)$. In this pp-definition the auxiliary variable y is *not* uniquely determined since, for example, $y = 0$ and $y = 1$ are both consistent with $x_1 = 1, \ldots x_{k-2} = 1, x_{k-1} = 1, x_k = 1$. On the other hand, if we instead take the pp-definition $(x_1 \vee \ldots \vee x_k) \equiv \exists y \colon (x_1 \vee \ldots \vee x_{k-2} \vee y) \wedge (y \leftrightarrow (x_{k-1} \vee x_k))$, which can be expressed by $(k-1)$-SAT, it is easily verified that y is determined by x_{k-1} and x_k.

Using the algebraic terminology from Section 2 this property can be phrased as follows.

▶ **Definition 10.** *A co-clone $\langle \Gamma \rangle$ is* ∃!-covered *if $\langle \Gamma \rangle = \langle \Delta \rangle_{\exists!}$ for every base Δ of $\langle \Gamma \rangle$.*

Thus, we are interested in determining the ∃!-covered co-clones, and since every constraint language Γ belongs to a co-clone, namely $\langle \Gamma \rangle$, Definition 10 precisely captures the aforementioned question concerning the expressive strength of uniqueness quantification in primitive positive formulas. The remainder of this section will be dedicated to proving covering results of this form, with a particular focus on proving a full classification for the Boolean domain. See Figure 1 for a visualisation of this dichotomy. We begin in Section 3.1 by outlining some of the main ideas required to prove that a co-clone is ∃!-covered, and consider covering results applicable for arbitrary finite domains. In Section 3.2 we turn to the Boolean domain where we prove the classification in Figure 1. Throughout, the missing proofs can be found in the extended preprint [19], and the affected statements are marked with an asterisk $(*)$.

3.1 General Constructions

Given an arbitrary constraint language Γ it can be difficult to directly reason about the strength of upp-definitions over Γ. Fortunately, there are methods to mitigate this difficulty. Recall from Definition 5 that a weak base of a co-clone $\langle\Gamma\rangle$ is a base which is qfpp-definable by any other base of $\langle\Gamma\rangle$, and that a plain base is a base with the property that it can qfpp-define every relation in the co-clone. We then have the following useful lemma.

▶ **Lemma 11.** *Let $\langle\Gamma\rangle$ be a co-clone with a weak base Γ_w and a plain base Γ_p. If $\Gamma_p \subseteq \langle\Gamma_w\rangle_{\exists!}$ then $\langle\Gamma\rangle$ is $\exists!$-covered.*

Proof. Let Δ be a base of $\langle\Gamma\rangle$ and R an n-ary relation from $\langle\Gamma\rangle$, with a qfpp-definition $R(x_1,\ldots,x_n) \equiv \varphi(x_1,\ldots,x_n)$ over Γ_p. By assumption, Γ_w can upp-define every relation in Γ_p, and it follows that $R(x_1,\ldots,x_n) \equiv \exists! y_1,\ldots,y_m \colon \varphi'(x_1,\ldots,x_n,y_1,\ldots,y_m)$ for a Γ_w-formula $\varphi'(x_1,\ldots,x_n,y_1,\ldots,y_m)$ since each constraint in $\varphi(x_1,\ldots,x_n)$ can be replaced by its upp-definition over Γ_w. Last, since Δ can qfpp-define Γ_w, we obtain a upp-definition of R by replacing each constraint in $\varphi'(x_1,\ldots,x_n,y_1,\ldots,y_m)$ by its qfpp-definition over Δ. ◀

Although not difficult to prove, Lemma 11 offers the advantage that it is sufficient to prove that $\Gamma_p \subseteq \langle\Gamma_w\rangle_{\exists!}$ for two constraint languages Γ_w and Γ_p. Let us now illustrate some additional techniques for proving that $\langle\Gamma\rangle$ is $\exists!$-covered. Theorem 7 in Section 2.3 shows that the relation $\mathsf{C}(U^s)$ is a weak base of $\mathrm{Inv}(\mathsf{C})$ for s larger than or equal to the core-size of $\mathrm{Inv}(\mathsf{C})$. For s smaller than the core-size we have the following description of $\mathsf{C}(U^s)$.

▶ **Theorem 12 (*).** *Let C be a finitely related clone over a finite domain D. Then, for every $s \geq 1$, $\mathsf{C}(U^s) \in \langle\Gamma\rangle_{\nexists}$ for every base Γ of $\mathrm{Inv}(\mathsf{C})$.*

The applications of Theorem 12 in the context of upp-definitions might not be immediate. However, observe that each argument $i \in [|D|^s]$ of U^s is determined by at most s other arguments, and if C is sufficiently simple, this property can be proved to hold also for $\mathsf{C}(U^s)$. This intuition can then be formalised into the following general theorem.

▶ **Theorem 13.** *Let $\mathrm{Pol}(\Gamma)$ be a clone over a finite domain D such that each $f \in \mathrm{Pol}(\Gamma)$ is a constant operation or a projection. Then $\langle\Gamma\rangle$ is $\exists!$-covered.*

Proof. Let F be a set of operations such that $[F] = \mathrm{Pol}(\Gamma)$. We may without loss of generality assume that $F = \{f_1,\ldots,f_k\}$ for unary operations f_l such that $f_l(x) = d_l$ for some $d_l \in D$. Take an arbitrary n-ary relation $R \in \langle\Gamma\rangle$. Let $s = |R|$ and consider the relation $F(U^s)$ from Definition 6. Our aim is to prove that $F(U^s)$ can upp-define R, which is sufficient since $F(U^s) \in \langle\Gamma\rangle_{\nexists}$ via Theorem 12. Let $i_1,\ldots,i_n \in [|D|^s]$ denote the indices satisfying $\mathrm{Proj}_{i_1,\ldots,i_n}(F(U^s)) = R$. If $k = 0$, and $\mathrm{Pol}(\Gamma)$ consists only of projections, then $F(U^s) = U^s$, and each argument in $[|D|^s] \setminus \{i_1,\ldots,i_n\}$ is already determined by $i_1,\ldots,i_n$, and by the preceding remark $R \in \langle F(U^s)\rangle_{\exists!}$. Therefore, assume that $k \geq 1$. For each $f_l \in F$ then observe that $(d_l,\ldots,d_l) \in F(U^s)$ and that $(d_l,\ldots,d_l) \in \mathrm{Proj}_{i_1,\ldots,i_n}(U^s)$. Choose $j_1, j_2 \in [|D|^s]$ such that $t[j_1] \neq t[j_2]$ for $t \in U^s$ if and only if $\mathrm{Proj}_{i_1,\ldots,i_n}(t) = (d_l,\ldots,d_l)$, for a d_l such that $f_l(x) = d_l$. Thus, we choose a pair of indices differing in U^s if and only if the projection on $i_1,\ldots,i_n$ is constant. Such a choice is always possible since the arguments of U^s enumerate all s-ary tuples over D. Then construct the relation $R'(x_1,\ldots,x_{|D|^s}) \equiv F(U^s)(x_1,\ldots,x_{|D|^s}) \wedge \mathrm{Eq}(x_{j_1},x_{j_2})$. It follows that $\mathrm{Proj}_{i_1,\ldots,i_n}(R') = R$, and that every argument $l \in [|D|^s] \setminus \{i_1,\ldots,i_n\}$ is determined by $i_1,\ldots,i_n$. Hence, $R \in \langle F(U^s)\rangle_{\exists!}$. ◀

Theorem 13 implies that $\langle\Gamma\rangle$ is $\exists!$-covered if Γ is sufficiently powerful, and in particular implies that REL_D is $\exists!$-covered for every finite D. Hence, Γ pp-defines every relation if and only if Γ upp-defines every relation. However, as we will now illustrate, this is not the only possible case when a co-clone is $\exists!$-covered.

▶ **Lemma 14** (∗). *Let F be a set of operations over a finite domain D. If each argument $i \in [\mathrm{ar}(R)]$ is either fictitious or determined for every $R \in \mathrm{Inv}(F)$, then $\mathrm{Inv}(F)$ is $\exists!$-covered.*

▶ **Theorem 15.** *Let D be a finite domain such that $|D|$ is prime, and let $f(x, y, z) = x - y + z \pmod{|D|}$. Then, for any constraint language Γ over D such that $\langle\Gamma\rangle \subseteq \mathrm{Inv}(f)$, $\langle\Gamma\rangle$ is $\exists!$-covered.*

Proof. We will prove that the preconditions of Lemma 14 are satisfied for $\mathrm{Inv}(f)$, which is sufficient to prove the claim. Let R be invariant under f. Then it is known that R is the solution space of a system of linear equations modulo $|D|$ [14], from which it follows that each argument is either determined, since it can be written as a unique combination of other arguments, or is fictitious. ◀

3.2 Boolean Constraint Languages

In this section we use the techniques developed so far to prove that the classification in Figure 1 is correct. Note first that $\mathrm{Inv}(\mathsf{C})$ is $\exists!$-covered if and only if $\mathrm{Inv}(\mathrm{dual}(\mathsf{C}))$ is $\exists!$-covered, since a upp-definition $\exists! y_1, \ldots, y_{n'} \colon R_1(\mathbf{x}_1) \wedge \ldots \wedge R_m(\mathbf{x}_m)$ of n-ary $R \in \mathrm{Inv}(\mathsf{C})$ immediately yields a upp-definition $\exists! y_1, \ldots, y_{n'} \colon \mathrm{dual}(R_1)(\mathbf{x}_1) \wedge \ldots \wedge \mathrm{dual}(R_m)(\mathbf{x}_m)$ of $\mathrm{dual}(R) \in \mathrm{Inv}(\mathrm{dual}(\mathsf{C}))$. Thus, to simplify the presentation we omit the case when $\mathsf{C} \supseteq \mathsf{V}_2$ in Figure 1. Let us begin with the cases following directly from Section 3.1 or from existing results (recall that IC is a shorthand for $\mathrm{Inv}(\mathsf{C})$).

▶ **Lemma 16.** *Let IC be a Boolean co-clone. Then IC is $\exists!$-covered if $\mathsf{IC} \subseteq \mathsf{IM}_2$, $\mathsf{IC} \subseteq \mathsf{IL}_2$, $\mathsf{IC} \subseteq \mathsf{IS}_{12}$, $\mathsf{IC} = \mathsf{IS}_{10}$, $\mathsf{IC} = \mathsf{IS}^n_{10}$ for some $n \geq 2$, $\mathsf{IC} = \mathsf{IS}_1$, or $\mathsf{IC} = \mathsf{IS}^n_1$ for some $n \geq 2$.*

Proof. The case when $\mathsf{IC} \subseteq \mathsf{IL}_2$ follows from Theorem 15 since $\mathsf{L}_2 = [x \oplus y \oplus z]$. For each case when C belongs to the infinite chains in Post's lattice, or if $\mathsf{IC} \subseteq \mathsf{IM}_2$, it is known that $\mathsf{IC} = \langle\Gamma\rangle_{\mathrm{fr}}$ for any base Γ of IC [22], which is sufficient since $\langle\Gamma\rangle_{\mathrm{fr}} \subseteq \langle\Gamma\rangle_{\exists!}$. ◀

We now move on to the more interesting cases, and begin with the case when $\mathrm{Pol}(\Gamma)$ is essentially unary, i.e., consists of essentially unary operations. This covers $\mathsf{I}_2, \mathsf{I}_0, \mathsf{I}_1, \mathsf{I}, \mathsf{N}_2, \mathsf{N}$ from Figure 1.

▶ **Theorem 17** (∗). *Let Γ be a Boolean constraint language such that $\mathrm{Pol}(\Gamma)$ is essentially unary. Then $\langle\Gamma\rangle$ is $\exists!$-covered.*

Next, we consider ID_2, consisting of all relations pp-definable by binary clauses.

▶ **Lemma 18** (∗). *ID_2 is $\exists!$-covered.*

We now tackle the cases when $\mathrm{Inv}(\{\wedge, 0, 1\}) \subseteq \mathsf{IC} \subseteq \mathrm{Inv}(\{\wedge\})$ (E, E_0, E_1, and E_2 in Figure 1). First, we describe the determined arguments of relations in E_0.

▶ **Lemma 19.** *Let $R \in \mathsf{IE}_0$ be an n-ary relation. If $i \in [n]$ is determined in R then either (1) there exists $i_1, \ldots, i_k \in [n]$ distinct from i such that $t[i] = t[i_1] \wedge \ldots \wedge t[i_k]$ for every $t \in R$, or (2) $t[i] = 0$ for every $t \in R$.*

Proof. Assume that $i \in [n]$ is determined in R. Let $R_1 = \{t_1, \ldots, t_m\} = \{t \in R \mid t[i] = 1\}$ and $R_0 = \{s_1, \ldots, s_{m'}\} = \{s \in R \mid t[i] = 0\}$. Note first that $R_0 = \emptyset$ cannot happen since R is preserved by 0, and if $R_1 = \emptyset$ then we end up in case (2). Hence, in the remainder of the proof we assume that R_0 and R_1 are both non-empty.

Consider the tuple $t_1 \wedge \ldots \wedge t_m = t$ (applied componentwise), and observe that $t \in \{t_1, \ldots, t_m\}$ since R is preserved by $\wedge$, and that $t[i] = 1$ since $t_1[i] = \ldots = t_m[i] = 1$.

Furthermore, if $t[j] = 1$ for some $j \in [n]$ then it must also be the case that $t_1[j] = \ldots = t_m[j] = 1$. Let $i_1, \ldots, i_l \in [n] \setminus \{i\}$ denote the set of indices such that $t[i_j] = 1$. Then $t'[i] = t'[i_1] \wedge \ldots \wedge t'[i_l]$ for every $t' \in R_1$, and we also claim that $s[i] = s[i_1] \wedge \ldots \wedge s[i_l]$ for every $s \in R_0$, thus ending up in case (1). Note that $l > 0$, as otherwise every argument distinct from i is constantly 0 in t, which is not consistent with the fact that $\mathbf{0}^n \in R_0$, since it contradicts the assumption that i is determined. Assume that there exists $s \in R_0$ such that $s[i] = 0 \neq s[i_1] \wedge \ldots \wedge s[i_l]$. Then, clearly, $s[i_1] = \ldots = s[i_l] = 1$. But then $t \wedge s \in R$ implies that i is not determined, since $\text{Proj}_{1,\ldots,i-1,i+1,\ldots,n}(t \wedge s) = \text{Proj}_{1,\ldots,i-1,i+1,\ldots,n}(t)$ but $(t \wedge s)[i] \neq t[i]$. Hence, $s[i] = s[i_1] \wedge \ldots \wedge s[i_l]$ for every $s \in R$, which concludes the proof. ◀

Lemma 19 also shows that if $R \in \mathsf{IE}$ with a determined argument i then there exists $i_1, \ldots, i_k \in [\text{ar}(R)]$ such that $t[i] = t[i_1] \wedge \ldots \wedge t[i_k]$ for every $t \in R$, since the constant relation $\{(0)\} \notin \mathsf{IE}$. Before we use Lemma 19 to show the non-covering results for IE and IE_0, we will need the following lemma, relating the existence of a upp-definition to a qfpp-definition of a special form. The proof essentially follows directly from the statement of the lemma and is therefore omitted.

▶ **Lemma 20.** *Let Γ be a constraint language. Then an n-ary relation $R \in \langle \Gamma \rangle_{\exists!}$ has a upp-definition $R(x_1, \ldots, x_n) \equiv \exists! y_1, \ldots, y_m \colon \varphi(x_1, \ldots, x_n, y_1, \ldots, y_m)$ if and only if there exists an $(n+m)$-ary relation $R' \in \langle \Gamma \rangle_{\nexists}$ such that $\text{Proj}_{1,\ldots,n}(R') = R$ where each $n < i \leq n+m$ is determined by $1, \ldots, n$.*

Say that a partial operation f is *$\wedge$-closed* if $\text{dom}(f)$ is preserved by $\wedge$ and that it is *0-closed* if $\mathbf{0}^{\text{ar}(f)} \in \text{dom}(f)$. We may now describe partial polymorphisms of $\langle \Gamma \rangle_{\exists!}$ using $\wedge$-closed and 0-closed partial polymorphisms of Γ.

▶ **Lemma 21 (∗).** *Let Γ be a constraint language such that $\langle \Gamma \rangle = \mathsf{IE}_0$. If $f \in \text{pPol}(\Gamma)$ is $\wedge$- and 0-closed then $f \in \text{pPol}(\langle \Gamma \rangle_{\exists!})$.*

We now have all the machinery in place to prove that IE_0 and IE are not $\exists!$-covered.

▶ **Theorem 22.** *Let R_w be the weak base of IE_0 from Table 2. Then $\langle R_w \rangle_{\exists!} \subset \mathsf{IE}_0$.*

Proof. We prove that the relation $R(x_1, x_2, x_3) \equiv x_1 \leftrightarrow x_2 x_3$ is not upp-definable over R_w, which is sufficient since $R \in \mathsf{IE}_0$, as evident in Table 2. Furthermore, using Lemma 20, we only have to prove that any $(3+n)$-ary R' where $\text{Proj}_{1,2,3}(R') = R$, and where each other argument is determined by the three first, is not included in $\langle R_w \rangle_{\nexists}$. Assume, without loss of generality, that R' does not contain any redundant arguments. Define the binary partial operation f such that $f(0,0) = 0$, $f(0,1) = f(1,0) = 1$. By construction, f is both 0-closed and $\wedge$-closed, and it is also readily verified that f preserves R_w, which via Lemma 21 then implies that $f \in \text{pPol}(\langle R_w \rangle_{\exists!})$. To finish the proof we also need to show that $f \notin \text{pPol}(R')$, which is sufficient since it implies that $R' \notin \langle R_w \rangle_{\exists!}$. Take two tuples $s, t \in R'$ such that $\text{Proj}_{1,2,3}(s) = (0,0,1)$, and $\text{Proj}_{1,2,3}(t) = (0,1,0)$. From Lemma 19, for each $3 < i \leq n+3$, either i is constant 0 in R' or there exists $i_1, \ldots, i_k \in \{1,2,3\}$, $k \leq 3$, such that $t[i] = t[i_1] \wedge \ldots t[i_k]$ for each $t \in R'$. But then $(s[i], t[i]) \in \text{dom}(f)$ for each $3 < i \leq n+3$, since either $(s[i], t[i]) = (0,0) \in \text{dom}(f)$ or $(s[i], t[i])$ is a conjunction over $(0,0,1)$ and $(0,1,0)$. However, this implies that $f(s,t) = u \notin R'$ since $\text{Proj}_{1,2,3}(u) = (0,1,1)$. Hence, f does not preserve R', and $R' \notin \langle R_w \rangle_{\nexists}$ via Theorem 4. ◀

The proof for IE uses the same construction and we omit the details. Surprisingly, as we will now see, IE_1 and IE_2 behave entirely differently and are in fact $\exists!$-covered.

▶ **Lemma 23 (∗).** IE_1 *and* IE_2 *are $\exists!$-covered.*

The natural generalisation of the Boolean operations $\wedge$ and $\vee$ are so-called *semilattice operations*; binary operations that are idempotent, associative, and commutative. It is then tempting to conjecture that Lemma 19 can be generalized to arbitrary semilattice operations, i.e., that every determined argument can be described as a semilattice combination of other arguments, whenever a relation is preserved by a given semilattice operation. This, however, is not true. For a simple counterexample define the semilattice operation $s\colon \{0,1,2\}^2 \to \{0,1,2\}$ as $s(x,x) = x$ and $s(x,y) = 0$ otherwise. If we then consider the relation $R = \{(0,0),(1,1),(2,0)\}$ it is easily verified that s preserves R, and that the second argument is uniquely determined by the first argument but cannot be described via the operation s.

The only co-clones remaining are IS_{11} and IS_{11}^n (for $n \geq 2$). As we will see, unique existential quantification is only as powerful as frozen quantification for these co-clones. We state the following lemma only for IS_{11} but the same construction is valid also for IS_{11}^n.

▶ **Lemma 24** (∗). *Let Γ be a constraint language such that $\langle\Gamma\rangle = \mathsf{IS}_{11}$. Then $\langle\Gamma\rangle_{\exists!} = \langle\Gamma\rangle_{\mathrm{fr}}$.*

It thus only remains to prove that IS_{11} and IS_{11}^n do not collapse into a single frozen co-clone. Here, we state the lemma only for IS_{11}^n, but the same argument works for IS_{11}.

▶ **Lemma 25** (∗). *Let Γ_p denote the plain base and Γ_w the weak base of IS_{11}^n ($n \geq 2$) from Table 2. Then $\langle\Gamma_w\rangle_{\mathrm{fr}} \subset \langle\Gamma_p\rangle_{\mathrm{fr}}$.*

Combining the results in this section we can now finally prove our dichotomy theorem.

▶ **Theorem 26.** *Let $\langle\Gamma\rangle$ be a Boolean co-clone. Then $\langle\Gamma\rangle$ is not $\exists!$-covered if and only if*

1. $\langle\Gamma\rangle \in \{\mathsf{IE},\mathsf{IE}_0,\mathsf{IV},\mathsf{IV}_1\}$, *or*
2. $\langle\Gamma\rangle \in \{\mathsf{IS}_{01}^n,\mathsf{IS}_{11}^n \mid n \geq 2\} \cup \{\mathsf{IS}_{01},\mathsf{IS}_{11}\}$ *(where, in addition, $\langle\Gamma\rangle_{\exists!} = \langle\Gamma\rangle_{\mathrm{fr}}$).*

Proof. Each negative case either follows immediately from Lemma 22, Lemma 24, Lemma 25, or is the dual of one of those cases. Each $\exists!$-covered co-clone is proved in Lemma 16, Theorem 17, Lemma 18, and Lemma 23. ◀

4 Applications in Complexity

In this section we apply Theorem 26 to study the complexity of computational problems not compatible with pp-definitions. Let us begin by defining the *constraint satisfaction problem* over a constraint language Γ (CSP(Γ)).

INSTANCE: A tuple (V,C) where V is a set of variables and C a set of constraints of the form $R_i(x_{i_1},\ldots,x_{i_{\mathrm{ar}(R)}})$ for $R_i \in \Gamma$.
QUESTION: Does (V,C) have at least one model? That is, a function $f\colon V \to D$ such that $f(x_{i_1},\ldots,x_{i_{\mathrm{ar}(R_i)}}) \in R_i$ for each $R_i(x_{i_1},\ldots,x_{i_{\mathrm{ar}(R_i)}}) \in C$?

For Boolean constraint languages Γ we write SAT(Γ) instead of CSP(Γ). If $\Delta \subseteq \langle\Gamma\rangle$ (or, equivalently, $\mathrm{Pol}(\Gamma) \subseteq \mathrm{Pol}(\Delta)$) then CSP($\Delta$) is polynomial-time reducible to CSP(Γ) [13]. However, there exist many natural variants of CSPs not compatible with pp-definitions, but compatible with more restricted closure operators such as upp-definitions. One such example is the *unique satisfiability problem* over a Boolean constraint language Γ (U-SAT(Γ)).

Instance: A SAT(Γ) instance I.
Question: Does I have a unique model?

The unrestricted U-SAT problem, i.e., the U-SAT problem where all possible constraints are allowed, can be seen as the intersection of satisfiability (in NP), and the satisfiability problem of checking if a given instance does not admit two distinct models (in co-NP). Hence, U-SAT is included in the second level of the Boolean hierarchy, BH_2, but is not believed to be complete for this class [23]. This unclear status motivated Blass and Gurevich [2] to introduce the complexity class *unique polynomial-time*, US, the set of decision problems solvable by a non-deterministic polynomial-time Turing machine where an instance is a yes-instance if and only if there exists a unique accepting path. Blass and Gurevich then quickly observed that U-SAT is US-complete and that $\mathrm{US} \subseteq \mathrm{BH}_2$.

We will present a simple, algebraic proof of Juban's trichotomy theorem for U-SAT(Γ) [15], showing that U-SAT(Γ) for finite Γ is either tractable, co-NP-complete, or US-complete. Using our machinery we will also be able to generalise this result to arbitrary infinite constraint languages. However, for infinite Γ we first need to specify a method of representation. We assume that the elements $R_1, R_2, \ldots$ of Γ are recursively enumerable by their arity, are represented as lists of tuples, and that there exists a computable function $f\colon \mathbb{N} \to \mathbb{N}$ such that for every $k \geq 1$ and every k-ary relation R, $R \in \langle \Gamma \rangle_{\exists !}$ if and only if $R \in \langle \Gamma \cap \mathsf{REL}^{\leq f(k)}_{\{0,1\}} \rangle_{\exists !}$. Thus, if a relation is upp-definable it is always possible to bound the arities of the required relations in the definition. The complexity of U-SAT(Γ) is then determined by $\langle \Gamma \rangle_{\exists !}$ in the following sense.

▶ **Theorem 27.** *Let Γ and Δ be Boolean constraint languages. If $\Delta \subseteq \langle \Gamma \rangle_{\exists !}$ is finite then* U-SAT(Δ) *is polynomial-time many-one reducible to* U-SAT(Γ).

Proof. By assumption every $R \in \Delta$ is upp-definable over Γ. First let $k = \max\{f(\mathrm{ar}(R)) \mid R \in \Delta\}$. We then begin by computing a upp-definition of R over $\Gamma \cap \mathsf{REL}^{\leq k}_{\{0,1\}}$, and store this upp-definition in a table. Since Δ is finite this can be done in constant time. Next, given an instance $I = (V, C)$ of U-SAT(Δ), we similar to the ordinary CSP case simply replace each constraint in C by its upp-definition over Γ, and identify any potential variables occurring in equality constraints. This procedure might introduce additional variables, but since they are all determined by V, the existence of a unique model is preserved. ◀

▶ **Theorem 28 (∗).** *Let Γ be a Boolean constraint language. Then* U-SAT(Γ) *is co-NP-complete if $\langle \Gamma \rangle \in \{\mathsf{II}_0, \mathsf{II}_1\}$, US-complete if $\langle \Gamma \rangle = \mathsf{II}_2$, and is tractable otherwise.*

A complexity classification akin to Theorem 28 is useful since it clearly separates tractable from intractable cases. However, in the last decade, a significant amount of research has been devoted to better understanding the "fine-grained" complexity of intractable problems, with a particular focus on ruling out algorithms running in $O(c^{|V|})$ time for every $c > 1$, so-called *subexponential time.* This line of research originates from Impagliazzo et al. [12] who conjectured that 3-SAT is not solvable in subexponential time; a conjecture known as the *exponential-time hypothesis* (ETH). Lower bounds for U-SAT(Γ) can then be proven using the ETH and the results from Section 3.

▶ **Theorem 29 (∗).** *Let Γ be a Boolean constraint language such that* U-SAT(Γ) *is US-complete or co-NP-complete. Then* U-SAT(Γ) *is not solvable in subexponential time, unless the ETH is false.*

Using our algebraic framework, hardness results can effortlessly be proven for the CSP generalisation of U-SAT, i.e., the problem U-CSP(Γ) of answering yes if and only if the given instance of CSP(Γ) admits a unique model.

▶ **Theorem 30** (∗). *Let Γ be a constraint language over a finite domain D. If $\langle \Gamma \rangle = \mathsf{REL}_D$ then* U-CSP(Γ) *is US-complete, and if* $\mathrm{Pol}(\Gamma) = [\{f\}]$ *for a constant operation f, then* U-CSP(Γ) *is co-NP-complete.*

5 Concluding Remarks and Future Research

We have studied unique existential quantification in pp-definitions, with a particular focus on finding constraint languages where existential quantification and unique existential quantification coincide. In general, this question appears highly challenging, but we have managed to find several broad classes of languages where this is true, and established a complete dichotomy theorem in the Boolean domain. We also demonstrated that upp-definitions can be applied to obtain complexity theorems for problems in a more systematic manner than what has earlier been possible. Many interesting open question hinge on the possibility of finding an algebraic characterisation of upp-closed sets of relations. For example, it would be interesting to determine the cardinality of the set $\{\langle \Gamma \rangle_{\exists !} \mid \Gamma \subseteq \mathsf{II}_2\}$, and hopefully describe all such upp-closed sets. By our classification theorem it suffices to investigate the Boolean co-clones that are not $\exists!$-covered, but even this question appears difficult to resolve using only relational tools. Similarly, a continued description of the $\exists!$-covered co-clones over finite domains would be greatly simplified by an algebraic characterisation. Thus, given a set of relations Γ, what is the correct notion of a "polymorphism" of a upp-definable relation over Γ? This question also has a strong practical motivation: essentially all complexity classifications for CSP related problems over non-Boolean domain require stronger algebraic tools than pp-definitions, and this is likely the case also for problems that can be studied with upp-definitions.

Another interesting topic is the following computational problem concerning upp-definability. Fix a constraint language Γ, and let R be a relation. Is it the case that R is upp-definable over Γ? The corresponding problem for pp-definitions is tractable for Boolean constraint languages Γ [9] while the corresponding problem for qfpp-definitions is co-NP-complete [16, 20]. Note that if $\langle \Gamma \rangle$ is $\exists!$-covered (which can be checked in polynomial time) then $R \in \langle \Gamma \rangle_{\exists !}$ can be answered by checking whether $R \in \langle \Gamma \rangle$. Thus, only the co-clones that are not $\exists!$-covered would need to be investigated in greater detail.

Last, it is worth remarking that our notion of uniqueness quantification in pp-definitions is not the only one possible. Assume that we in $\exists ! x_i \colon R(x_1, \ldots, x_i, \ldots, x_n)$ over a domain D do not require that x_i is determined by $x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n$ but instead simply obtain the relation $\{(d_1, \ldots, d_{i-1}, d_{i+1}, \ldots, d_n) \mid \exists ! d_i \in D \text{ such that } (d_1, \ldots, d_{i-1}, d_i, d_{i+1}, \ldots, d_n) \in R)\}$. This notion of unique existential quantification is in general *not* comparable to existential quantification, since if we e.g. let $R = \{(0,0), (0,1), (1,0)\}$ then $T(x) \equiv \exists ! y \colon R(y, x)$ even though $T \notin \langle R \rangle$, i.e., is not even pp-definable by R (where $T = \{(1)\}$). Thus, it would be interesting to determine the resulting closed classes of relations and see in which respect they differ from the ordinary co-clone lattice.

Resolution Lower Bounds for Refutation Statements

Michal Garlík

Abstract

For any unsatisfiable CNF formula we give an exponential lower bound on the size of resolution refutations of a propositional statement that the formula has a resolution refutation. We describe three applications. (1) An open question in [2] asks whether a certain natural propositional encoding of the above statement is hard for Resolution. We answer by giving an exponential size lower bound. (2) We show exponential resolution size lower bounds for reflection principles, thereby improving a result in [1]. (3) We provide new examples of CNFs that exponentially separate Res(2) from Resolution (an exponential separation of these two proof systems was originally proved in [10]).

1 Introduction

Proving lower bounds on the size of propositional proofs is the central task of proof complexity theory. After Cook and Reckhow [4] motivated this line of research as an approach towards establishing NP $\neq$ coNP, some initial success for weak proof systems followed, e.g., the first exponential size lower bound for Resolution was proved by Haken [6]. Nevertheless, many important open problems from the 1980s and 1990s remain unsolved, and it seems that proving nontrivial lower bounds on the size of propositional proofs is hard. If it is hard for people, it is natural to ask if it is also hard for the proof systems themselves. In trying to formalize this question so that it makes sense to a proof system, we must say what we mean by "proving is hard". It can be "there are no short proofs", a statement which appears in a propositional formalization of reflection principles. By "short" we mean polynomial in the size of the formula being proven or refuted. The negation of the *reflection principle* for a proof system P is a conjunction of the statement "y is a P-refutation of length s of formula x of length n" and the statement "z is a satisfying assignment of formula x". In a propositional formulation of the principle, P, s, n are fixed parameters and x, y, z are disjoint sets of variables. A possible way to formalize the above question is then to take the first conjunct of the negation of the reflection principle and plug in for the x-variables some formula F of length n. The resulting formula was discussed and utilized by Pudlák [9]; we denote it by $\mathrm{REF}^F_{P,s}$ and call it a *refutation statement* for P. We may now ask whether some proof system Q can shortly refute $\mathrm{REF}^F_{P,s}$, and if it can not, we can interpret this to mean that lower bounds for P-refutations of F are hard for Q.

Pudlák [9] found connections between the reflection principles and automatizability, and these were elaborated on in [1]. Following [3], a proof system P is *automatizable* if there is a deterministic algorithm that when given as input an unsatisfiable CNF formula F outputs a P-refutation of F in time polynomial in the size of the shortest P-refutation of F. Recently, Atserias and Müller [2] showed that Resolution is not automatizable unless P = NP. Refutation statements for Resolution play a prominent role in their proof. They show that strong enough resolution size lower bounds for $\mathrm{REF}^F_{\mathrm{Res},s}$ with an unsatisfiable F imply their result. However, they leave the lower bound problem for $\mathrm{REF}^F_{\mathrm{Res},s}$ as an open question, and in place of $\mathrm{REF}^F_{\mathrm{Res},s}$ they use in the proof a different formulation of the refutation statement, obtained by a *relativization* of $\mathrm{REF}^F_{\mathrm{Res},s}$, for which lower bounds are easier to get. In this paper we focus mainly on giving an answer to the question.

1.1 Results in This Paper

The result that requires the most work is the following lower bound.

▶ **Theorem 1.** *For each $\epsilon > 0$ there is $\delta > 0$ and an integer t_0 such that if n, r, s, t are integers satisfying $t \geq s \geq n + 1$, $r \geq n \geq 2$, $t \geq r^{3+\epsilon}$, $t \geq t_0$, and F is an unsatisfiable CNF consisting of r clauses $C_1, \dots, C_r$ in n variables $x_1, \dots, x_n$, then any resolution refutation of $\mathrm{REF}^F_{s,t}$ has length greater than 2^{t^δ}.*

We then show that this theorem implies an exponential resolution size lower bound for the encoding of the refutation statement for which the lower bound question in [2] is originally asked.

The formula $\mathrm{REF}^F_{s,t}$ in the theorem is a variant of the refutation statement insisting that the resolution refutation it describes has the form of a levelled graph. A similar simplifying assumption, making it more practical to design random restrictions, is used in [11] for a propositional version of the coloured polynomial local search principle. Our proof proceeds with defining a random restriction tailored to $\mathrm{REF}^F_{s,t}$ and to an adversary argument. The nature of the refutation statement and the fact that the relations between refutation lines are encoded in unary, rather than in binary, necessitate a more complicated adversary argument than in [8] or [11], and this in turn poses more requirements on the random restriction. We discuss these details after the proof, in Remarks 20 and 21.

We see two reasons for working with the unary encoding of $\mathrm{REF}^F_{s,t}$. First, $\mathrm{REF}^F_{s,t}$ is weaker than refutation statements encoded in binary or relativized refutation statements. Hence lower bounds for $\mathrm{REF}^F_{s,t}$ imply lower bounds for the other encodings. Second, researchers who dealt with propositional encodings of reflection principles or refutation statements opted for the unary encoding [1, 7, 9].

Besides these two reasons, we need to work with the unary encoding to give an answer to the above mentioned lower bound question from [2]. Our answer is stated in the following theorem, the proof of which (an easy reduction to Theorem 1) is in the full version of this paper [5]. Below, $\mathrm{REF}(F, \tilde{s})$ denotes the encoding of the resolution refutation statement in [2]. We can assume that the formula $\mathrm{REF}^F_{\mathrm{Res},s}$ is the same as $\mathrm{REF}(F, s)$.

▶ **Theorem 2.** *For each $\epsilon > 0$ there is $\delta > 0$ and an integer t_0 such that if $n, r, \tilde{s}$ are integers satisfying $r \geq n \geq 2$, $\left\lfloor \frac{\tilde{s}}{n+1} \right\rfloor \geq r^{3+\epsilon}$, $\left\lfloor \frac{\tilde{s}}{n+1} \right\rfloor \geq t_0$, and F is an unsatisfiable CNF consisting of r clauses $C_1, \dots, C_r$ in n variables $x_1, \dots, x_n$, then any resolution refutation of $\mathrm{REF}(F, \tilde{s})$ has length greater than $2^{\lfloor \frac{\tilde{s}}{n+1} \rfloor^\delta}$.*

Our next result is that the negation of the reflection principle for Resolution, expressed by the formula $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$, exponentially separates the system Res(2) from Resolution. It was shown by Atserias and Bonet [1] that a similar encoding of the negation of the reflection principle separates the two theories almost-exponentially (giving a $2^{\Omega(2^{\log^\epsilon n})}$ resolution lower bound and a polynomial Res(2) upper bound). The exponential separation of Res(2) from Resolution was originally proved in [10] using a variation of the graph ordering principle. Our lower bound is stated in Theorem 3 below.

▶ **Theorem 3.** *For every $c > 4$ there is $\delta > 0$ and an integer n_0 such that if n, r, s, t are integers satisfying $t \geq s \geq n + 1$, $r \geq n \geq n_0$, $n^c \geq t \geq r^4$, then any resolution refutation of* $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ *has length greater than 2^{n^δ}.*

The proof of the theorem also yields new examples of CNFs exponentially separating Res(2) from Resolution.

▶ **Theorem 4.** *Let $\delta_1 > 0$ and let $\{A_n\}_{n\geq 1}$ be a family of unsatisfiable CNFs such that A_n is in n variables, has the number of clauses polynomial in n, and has no resolution refutations of length at most $2^{n^{\delta_1}}$. Then there is $\delta > 0$ and a polynomial p such that $A_n \wedge \mathrm{REF}^{A_n}_{n+1,p(n)}$ has no resolution refutations of length at most 2^{n^δ} and has polynomial size* Res(2) *refutations.*

A Res(2) upper bound for $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$, needed for completing the separation by this formula as well as by the formulas in Theorem 4, is stated in the following theorem.

▶ **Theorem 5.** *The negation of the reflection principle for Resolution expressed by the formula* $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ *has Res*(2) *refutations of size $O(trn^2 + tr^2 + st^2n^3 + st^3n)$.*

A polynomial size Res(2) upper bound on a similar encoding of the negation of the reflection principle for Resolution was proved in [1]. We simplify the proof and adapt it to $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ (see the full version [5]).

1.2 Outline of This Paper

The rest of the paper is organized as follows.

In Section 2 we give the necessary preliminaries.

In Section 3, Resolution of s levels of t clauses is introduced, and the clauses of the refutation statement $\mathrm{REF}^F_{s,t}$ for this refutation system are listed. We also state here a quadratic simulation of Resolution by this system.

In Section 4 we prove Theorem 1.

In Section 5 we define the formula $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ and we prove Theorems 3 and 4.

2 Preliminaries

For an integer s, the set $\{1, \ldots, s\}$ is denoted by $[s]$. We write $\mathrm{dom}(f), \mathrm{im}(f)$ for the domain and image of a funciton f. If x is a propositional variable, the *positive literal of* x, denoted by x^1, is x, and the *negative literal of* x, denoted by x^0, is $\neg x$. A *clause* is a set of literals. A clause is written as a disjunction of its elements. A *term* is a set of literals, and is written as a conjunction of the literals. A *CNF* is a set of clauses, written as a conjunction of the clauses. A k*-CNF* is a CNF whose every clause has at most k literals. A *DNF* is a set of terms, written as a disjunction of the terms. A k*-DNF* is a DNF whose every term has at most k literals. We will identify 1-DNFs with clauses. A clause is *non-tautological* if it does not contain both the positive and negative literal of the same variable. A clause C is a *weakening* of a clause D if $D \subseteq C$. A clause D is the *resolvent of* clauses C_1 and C_2 *on* a variable x if $x \in C_1, \neg x \in C_2$ and $D = (C_1 \setminus \{x\}) \cup (C_2 \setminus \{\neg x\})$. If E is a weakening of the resolvent of C_1 and C_2 on x, we say that E is obtained by the *resolution rule* from C_1 and C_2, and we call C_1 and C_2 the *premises* of the rule.

Let F be a CNF and C a clause. A *resolution derivation of C from F* is a sequence of clauses $\Pi = (C_1, \dots, C_s)$ such that $C_s = C$ and for all $u \in [s]$, C_u is a weakening of a clause in F, or there are $v, w \in [u-1]$ such that C_u is obtained by the resolution rule from C_v and C_w. The *length* of the derivation Π is s. For $u \in [s]$, the *height of u in* Π is the maximum h such that there is a subsequence $(C_{u_1}, \dots, C_{u_h})$ of Π in which $u_h = u$ and for each $i \in [h-1]$, C_{u_i} is a premise of a resolution rule by which $C_{u_{i+1}}$ is obtained in Π. The *height* of Π is the maximum height of u in Π for $u \in [s]$. A *resolution refutation of F* is a resolution derivation of the empty set from F.

A *partial assignment* to the variables $x_1, \dots, x_n$ is a partial map from $\{x_1, \dots, x_n\}$ to $\{0,1\}$. Let σ be a partial assignment. The CNF $F \restriction \sigma$ is formed from F by removing every clause containing a literal satisfied by σ, and removing every literal falsified by σ from the remaining clauses. If $\Pi = (C_1, \dots, C_s)$ is a sequence of clauses, $\Pi \restriction \sigma$ is formed from Π by the same operations. Note that if Π is a resolution refutation of F, then $\Pi \restriction \sigma$ is a resolution refutation of $F \restriction \sigma$.

The Res(k) refutation system is a generalization of Resolution. Its lines are k-DNFs and it has the following inference rules (A, B are k-DNFs, $j \in [k]$, and $l, l_1, \dots, l_j$ are literals):

$$\frac{A \vee l_1 \qquad B \vee (l_2 \wedge \dots \wedge l_j)}{A \vee B \vee (l_1 \wedge \dots \wedge l_j)}\ \wedge\text{-introduction} \qquad\qquad \frac{}{x \vee \neg x}\ \text{Axiom}$$

$$\frac{A \vee (l_1 \wedge \dots \wedge l_j) \qquad B \vee \neg l_1 \vee \dots \vee \neg l_j}{A \vee B}\ \text{Cut} \qquad\qquad \frac{A}{A \vee B}\ \text{Weakening}$$

Let F be a CNF. A *Res(k) derivation from F* is a sequence of k-DNFs $(D_1, \dots, D_s)$ so that each D_i either belongs to F or follows from the preceding lines by an application of one of the inference rules. The *size* of a Res(k) derivation is the number of symbols in it.

3 Resolution Refutations of s Levels of t Clauses

We introduce a variant of Resolution in which the clauses forming a refutation are arranged in layers.

▶ **Definition 6.** Let F be a CNF of r clauses in n variables $x_1, \dots, x_n$. We say that F has a *resolution refutation of s levels of t clauses* if there is a sequence of clauses $C_{i,j}$ indexed by all pairs $(i,j) \in [s] \times [t]$, such that each clause $C_{1,j}$ on the first level is a weakening of a clause in F, each clause $C_{i,j}$ on level $i \in \{2, \dots, s\}$ is a weakening of the resolvent of two clauses from level $i-1$ on a variable, and the clause $C_{s,t}$ is empty.

The following proposition shows that this system quadratically simulates Resolution and preserves the refutation height. The proof (in the full version [5] of the paper) uses a simple self-replicating pattern both to transport a premise of the resolution rule to the required level and to fill in all clauses $C_{i,j}$ that do not directly participate in the simulation.

▶ **Proposition 7.** *If a $(n-1)$-CNF F in n variables has a resolution refutation of height h and length s, then F has a resolution refutation of h levels of $3s$ clauses.*

We proceed to our formalization of the refutation statement for this refutation system. Let n, r, s, t be integers. Let F be a CNF consisting of r clauses $C_1, \dots, C_r$ in n variables $x_1, \dots, x_n$. We define a propositional formula $\mathrm{REF}^F_{s,t}$ expressing that F has a resolution refutation of s levels of t clauses.

We first list the variables of $\mathrm{REF}^F_{s,t}$. *D-variables* $D(i,j,k,b)$, $i \in [s]$, $j \in [t], k \in [n], b \in \{0,1\}$, encode clauses $C_{i,j}$ as follows: $D(i,j,k,1)$ (resp. $D(i,j,k,0)$) means that the literal x_k (resp. $\neg x_k$) is in $C_{i,j}$. *L-variables* $L(i,j,j')$ (resp. *R-variables* $R(i,j,j')$),

$i \in \{2,\dots,s\}, j, j' \in [t]$, say that $C_{i-1,j'}$ is a premise of the resolution rule by which $C_{i,j}$ is obtained, and it is the premise containing the positive (resp. negative) literal of the resolved variable. *V-variables* $V(i,j,k)$, $i \in \{2,\dots,s\}, j \in [t], k \in [n]$, say that $C_{i,j}$ is obtained by resolving on x_k. *I-variables* $I(j,m)$, $j \in [t], m \in [r]$, say that $C_{1,j}$ is a weakening of C_m.

$\mathrm{REF}^F_{s,t}$ is the union of the following fifteen sets of clauses:

$$\neg I(j,m) \vee D(1,j,k,b) \qquad j \in [t], m \in [r], b \in \{0,1\}, x_k^b \in C_m, \tag{1}$$

clause $C_{1,j}$ contains the literals of C_m assigned to it by $I(j,m)$,

$$\neg D(i,j,k,1) \vee \neg D(i,j,k,0) \qquad i \in [s], j \in [t], k \in [n], \tag{2}$$

no clause $C_{i,j}$ contains x_k and $\neg x_k$ at the same time,

$$\neg L(i,j,j') \vee \neg V(i,j,k) \vee D(i-1,j',k,1) \qquad i \in \{2,\dots,s\}, j, j' \in [t], k \in [n], \tag{3}$$

$$\neg R(i,j,j') \vee \neg V(i,j,k) \vee D(i-1,j',k,0) \qquad i \in \{2,\dots,s\}, j, j' \in [t], k \in [n], \tag{4}$$

clause $C_{i-1,j'}$ used as the premise given by $L(i,j,j')$ (resp. $R(i,j,j')$) in resolving on x_k must contain x_k (resp. $\neg x_k$),

$$\neg L(i,j,j') \vee \neg V(i,j,k) \vee \neg D(i-1,j',k',b) \vee D(i,j,k',b)$$
$$i \in \{2,\dots,s\}, j, j' \in [t], k, k' \in [n], b \in \{0,1\}, (k',b) \neq (k,1), \tag{5}$$

$$\neg R(i,j,j') \vee \neg V(i,j,k) \vee \neg D(i-1,j',k',b) \vee D(i,j,k',b)$$
$$i \in \{2,\dots,s\}, j, j' \in [t], k, k' \in [n], b \in \{0,1\}, (k',b) \neq (k,0), \tag{6}$$

clause $C_{i,j}$ derived by resolving on x_k must contain each literal different from x_k (resp. $\neg x_k$) from the premise given by $L(i,j,j')$ (resp. $R(i,j,j')$),

$$\neg D(s,t,k,b) \qquad k \in [n], b \in \{0,1\}, \tag{7}$$

clause $C_{s,t}$ is empty,

$$V(i,j,1) \vee V(i,j,2) \vee \ldots \vee V(i,j,n) \qquad i \in \{2,\dots,s\}, j \in [t], \tag{8}$$

$$I(j,1) \vee I(j,2) \vee \ldots \vee I(j,r) \qquad j \in [t], \tag{9}$$

$$L(i,j,1) \vee L(i,j,2) \vee \ldots \vee L(i,j,t) \qquad i \in \{2,\dots,s\}, j \in [t], \tag{10}$$

$$R(i,j,1) \vee R(i,j,2) \vee \ldots \vee R(i,j,t) \qquad i \in \{2,\dots,s\}, j \in [t], \tag{11}$$

$$\neg V(i,j,k) \vee \neg V(i,j,k') \qquad i \in \{2,\dots,s\}, j \in [t], k, k' \in [n], k \neq k', \tag{12}$$

$$\neg I(j,m) \vee \neg I(j,m') \qquad j \in [t], m, m' \in [r], m \neq m', \tag{13}$$

$$\neg L(i,j,j') \vee \neg L(i,j,j'') \qquad i \in \{2,\dots,s\}, j, j', j'' \in [t], j' \neq j'', \tag{14}$$

$$\neg R(i,j,j') \vee \neg R(i,j,j'') \qquad i \in \{2,\dots,s\}, j, j', j'' \in [t], j' \neq j'', \tag{15}$$

the V, I, L, R-variables define functions with the required domains and ranges.

4 A Lower Bound on Lengths of Resolution Refutations of $\mathrm{REF}^F_{s,t}$

We restate Theorem 1 from the Introduction.

▶ **Theorem 8.** *For each $\epsilon > 0$ there is $\delta > 0$ and an integer t_0 such that if n, r, s, t are integers satisfying*

$$t \geq s \geq n+1, \qquad r \geq n \geq 2, \qquad t \geq r^{3+\epsilon}, \qquad t \geq t_0, \tag{16}$$

and F is an unsatisfiable CNF consisting of r clauses $C_1, \dots, C_r$ in n variables $x_1, \dots, x_n$, then any resolution refutation of $\mathrm{REF}^F_{s,t}$ has length greater than 2^{t^δ}.

The rest of this section is devoted to a proof of the theorem. We argue by contradiction. Fix $\epsilon > 0$ and assume that for each $\delta > 0$ and t_0 there are integers n, r, s, t satisfying (16), an unsatisfiable CNF F, and a resolution refutation Π of $\mathrm{REF}^F_{s,t}$, such that F consists of r clauses $C_1, \ldots, C_r$ in n variables $x_1, \ldots, x_n$, and Π has length at most 2^{t^δ}.

The forthcoming distribution on partial assignments to the variables of $\mathrm{REF}^F_{s,t}$ employs in its definition and analysis two important parameters, p and w. We choose them as function of t and ϵ as follows:

$$p = t^{-a} \text{ with } a = \min\left\{\frac{2+\epsilon/2}{3+\epsilon/2}, \frac{3}{4}\right\}, \qquad w = t^{4/5}.$$

We now fix values of t_0, δ for which we will get the desired contradiction. Take t_0 so large and $\delta > 0$ so small that the inequalities

$$\max\left\{e^{-\frac{pw}{3}} + 2s \cdot e^{-\frac{pt}{3}}, e^{-\frac{pt}{8r}}\right\} \cdot 2^{t^\delta} + 3s \cdot e^{-\frac{pt}{3}} + 3p + 67p^3st < 1, \tag{17}$$

$$10pt + 4w < \frac{t}{4}, \tag{18}$$

$$e^{e^{\ln(t) - \frac{pt}{3}}} < 2, \tag{19}$$

hold for any n, r, s, t satisfying (16).

▶ **Definition 9.** For $i \in [s], j, j' \in [t], k \in [n], b \in \{0,1\}, m \in [r]$, we say that (i,j) is the *home pair* of the variable $D(i,j,k,b)$ (resp. $R(i,j,j')$; $L(i,j,j')$; $V(i,j,k')$; $I(j,m)$ if $i = 1$).

We write $V(i,j,\cdot)$ to stand for the set $\{V(i,j,k) : k \in [n]\}$. Similarly, we write $I(j,\cdot), L(i,j,\cdot), R(i,j,\cdot)$ to stand for the corresponding sets of variables, and we denote by $D(i,j,\cdot,\cdot)$ the set of variables $\{D(i,j,k,b) : k \in [n], b \in \{0,1\}\}$.

Let σ be a partial assignment. We say that $V(i,j,\cdot)$ is *set to* k *by* σ if $\sigma(V(i,j,k)) = 1$ and $\sigma(V(i,j,k')) = 0$ for all $k' \in [n], k' \neq k$. Similarly for $I(j,\cdot), L(i,j,\cdot), R(i,j,\cdot)$. We say that $D(i,j,\cdot,\cdot)$ is *set to* a clause $C_{i,j}$ *by* σ if for all $k \in [n], b \in \{0,1\}$, $\sigma(D(i,j,k,b)) = 1$ if $x_k^b \in C_{i,j}$ and $\sigma(D(i,j,k,b)) = 0$ if $x_k^b \notin C_{i,j}$.

For $Y \in \{D(i,j,\cdot,\cdot), V(i,j,\cdot), I(j,\cdot), R(i,j,\cdot), L(i,j,\cdot),\}$, we say that Y is *set by* σ if Y is set to v by σ for some value v. We will often omit saying "by σ" if σ is clear from the context.

▶ **Definition 10.** A *random restriction* ρ is a partial assignment to the variables of $\mathrm{REF}^F_{s,t}$ given by the following experiment:

1. For each pair $(i,j) \in [s] \times [t]$, with independent probability p include (i,j) in a set A_D. Then for each $(i,j) \in A_D$ and for each $k \in [n]$, independently, with probability $1/2$ choose between including the literal x_k or $\neg x_k$ in a clause $C_{i,j}$. Set $D(i,j,\cdot,\cdot)$ to $C_{i,j}$.
2. For each $j \in [t]$, with independent probability p include the pair $(1,j)$ in a set A_I. Then for each $(1,j) \in A_I \setminus A_D$, independently, choose at random $m \in [r]$ and set $I(j,\cdot)$ to m.
3. For each pair $(i,j) \in \{2,\ldots,s\} \times [t]$, with independent probability p include (i,j) in a set A_V. Then for each $(i,j) \in A_V$, independently, choose at random $k \in [n]$ and set $V(i,j,\cdot)$ to k.
4. For each pair $(i,j) \in \{2,\ldots,s\} \times [t]$, with independent probability p include the pair (i,j) in a set A_{RL}. Then, for each $i \in \{2,\ldots,s\}$, define $A_i := A_{RL} \cap (\{i\} \times [t])$ and do the following. If $|A_i| > 2pt$, define $h_i := \emptyset$, $B_{i-1} := \emptyset$. Otherwise, choose at random an injection h_i from $\{L(i,j,\cdot) : (i,j) \in A_i\} \cup \{R(i,j,\cdot) : (i,j) \in A_i\}$ to $[t]$. Define $B_{i-1} := \{(i-1,j) : j \in \mathrm{im}(h_i)\}$. Set $L(i,j,\cdot)$ to $h_i(L(i,j,\cdot))$ and $R(i,j,\cdot)$ to $h_i(R(i,j,\cdot))$ for all $(i,j) \in A_i$.

▶ **Lemma 11.** *With probability at least $1 - 3s \cdot e^{-pt/3}$, all of the following are satisfied.*

(i) *For each $i \in [s]$, the cardinality of $A_D \cap (\{i\} \times [t])$ is at most $2pt$.*

(ii) *For each $i \in \{2, \dots, s\}$, the cardinality of A_i is at most $2pt$ and the cardinality of $A_V \cap (\{i\} \times [t])$ is at most $2pt$.*

(iii) *The cardinality of A_I is at most $2pt$.*

Proof. By the Chernoff bound and the union bound it follows that item i is false with probability at most $s \cdot e^{-pt/3}$. Similarly for the remaining items. ◀

▶ **Definition 12.** Denote by G_ρ the graph with vertices $A_D \cup A_V \cup A_I \cup A_{RL} \cup \bigcup_{i\in[s-1]} B_i$, and with edges only between vertices on neighboring levels, such that (i, j) is connected by an edge to $(i-1, j')$ if and only if $h_i(L(i, j, \cdot)) = j'$ (then $(i-1, j')$ is called the *left child* of (i, j)) or $h_i(R(i, j, \cdot)) = j'$ (then $(i-1, j')$ is the *right child* of (i, j)).

The following lemma will be used later to show that a random restriction likely does not falsify any clause of $\mathrm{REF}^F_{s,t}$.

▶ **Lemma 13.** *With probability at least $1 - 3p - 67p^3st$, the following are satisfied.*

(i) *$(s, t) \notin (A_D \cup A_{RL} \cup A_V)$.*

(ii) *There is no triple $((i_1, j_1), (i_2, j_2), (i_3, j_3))$ of elements of $[s] \times [t]$, such that all the following hold:*

- **(a)** *For each $u \in [3]$ there is $X \in \{D, V, I, RL\}$ with $(i_u, j_u) \in A_X$,*
- **(b)** *$|\{(i_u, j_u, X) : u \in [3], X \in \{D, V, I, RL\}, (i_u, j_u) \in A_X\}| \geq 3$,*
- **(c)** *the subgraph of G_ρ consisting of the vertices that are in the triple and their children and all edges that go from a vertex of the triple to its children, is connected.*

Proof. The probability that item i is true is $(1 - p)^3 \geq 1 - 3p$.

Regarding item ii, we distinguish several cases based on the relative positions of the elements in a triple $((i_1, j_1), (i_2, j_2), (i_3, j_3))$. Note that the order in which the elements of the triple are listed does not matter in what we are proving, but some of the elements may coincide. When considering the cases, recall that due to our choice of the function h_i in the definition of ρ, two vertices in G_ρ cannot share a child.

In case all the elements of the triple are the same, iib is satisfied only if the element is chosen to A_X for three distinct values of X. This cannot happen on level 1, and on the other levels it happens with probability p^3. There are st many triples considered in the present case, so by the union bound the probability that there is any such triple satisfying all conditions in ii is at most p^3st.

In case $(i_1, j_1) \neq (i_2, j_2) = (i_3, j_3)$, condition iic is satisfied only if $i_1 = i_2 + 1$ or $i_2 = i_1 + 1$. In each of these two subcases, there are at most st^2 such triples. In the former subcase, we must have $(i_1, j_1) \in A_{RL}$ and at the same time $h_{i_1}(R(i_1, j_1, \cdot)) = j_2$ or $h_{i_1}(L(i_1, j_1, \cdot)) = j_2$. This happens with probability at most $2p/t$. Also, (i_2, j_2) has to be in A_X and $A_{X'}$ for distinct X, X', which happens with probability at most $3p^2$. So, the probability that any triple considered in this subcase satisfies iia - iic is at most $st^2 \cdot 6p^3/t = 6p^3st$. In the latter subcase, (i_2, j_2) has to be in A_{RL}, connected to (i_1, j_1), and additionally it has to be in A_D or A_V, while (i_1, j_1) has to be in arbitrary possible A_X. This happens with probability at most $2p/t \cdot 2p \cdot 3p = 12p^3/t$, so the probability that any such triple satisfies iia - iic is at most $12p^3st$.

In case all the elements of the triple are distinct, we again consider two subcases: first, $i_1 = i_2 + 1 = i_3 + 2$, and second, $i_1 - 1 = i_2 = i_3$. Each subcase concerns at most st^3 triples. In the first subcase, (i_3, j_3) has to be a child of (i_2, j_2), which in turn has to be a child of (i_1, j_1), and (i_3, j_3) also has to be in arbitrary possible A_X. This happens with probability at most $12p^3/t^2$. Hence the probability that any such triple satisfies iia - iic is at most $12p^3st$. In the second subcase, (i_1,j_1) has to have children (i_2,j_2) and (i_3,j_3), and each child has to be in some A_X for any suitable X. This happens with probability at most $2p/(t(t-1)) \cdot (3p)^2 = 18p^3/(t(t-1)) \leq 36p^3/t^2$. Hence the probability that any such triple satisfies iia - iic is at most $36p^3st$. ◀

We now define some specific ways to measure a clause and we use them in the next lemma to describe how a clause simplifies under a restriction.

▶ **Definition 14.** Let E be a clause in $\Pi{\restriction}\rho$, and let $(i,j) \in [s] \times [t]$. If E contains a literal of a variable from $D(i,j,\cdot,\cdot)$ (resp. $R(i,j,\cdot)$; $L(i,j,\cdot)$; $V(i,j,\cdot)$; $I(j,\cdot)$ and $i = 1$), we say that the pair (i,j) is *D-mentioned* (resp. *R-mentioned*; *L-mentioned*; *V-mentioned*; *I-mentioned*) *in E*.

We say that (i,j) is *V-important* (resp. *L-important*; *R-important*; *I-important*) *in E* if E contains the negative literal of a variable in $V(i,j,\cdot)$ (resp. $L(i,j,\cdot); R(i,j,\cdot); I(j,\cdot)$ and $i=1$) or if E contains at least $n/2$ (resp. $t/2$; $t/2$; $r/2$) positive literals of variables in $V(i,j,\cdot)$ (resp. $L(i,j,\cdot)$; $R(i,j,\cdot)$; $I(j,\cdot)$ and $i = 1$). A pair is *D-important in E* if it is D-mentioned in E.

▶ **Lemma 15.** *With probability at least* $1 - \max\left\{e^{-\frac{pw}{3}} + 2s \cdot e^{-\frac{pt}{3}}, e^{-\frac{pt}{8r}}\right\} \cdot 2^{t^\delta}$, *for every clause E in $\Pi{\restriction}\rho$ all of the following are satisfied.*

(i) *At most w many pairs (i,j) are D-mentioned in E.*
(ii) *At most w many pairs $(1,j)$ are I-important in E.*
(iii) *At most w many pairs (i,j) are V-important in E.*
(iv) *At most w many pairs (i,j) are L-important in E.*
(v) *At most w many pairs (i,j) are R-important in E.*
(vi) *For each $m \in [r]$, $|\{j : I(j,m) \in E\}| \leq \frac{t}{4}$.*
(vii) *For each $i \in \{s-n+1,\dots,s-1\}$ and $k \in [n]$, $|\{j : V(i,j,k) \in E\}| \leq \frac{t}{4}$.*

Proof. It is sufficient to prove that if E' is a clause in Π that violates any of i - vii, then with probability at least $1 - \max\left\{e^{-\frac{pw}{3}} + 2s \cdot e^{-\frac{pt}{3}}, e^{-\frac{pt}{8r}}\right\}$, E' is satisfied by ρ. Since Π has length at most 2^{t^δ}, the lemma then follows by the union bound.

Regarding item i, assume that E' in Π D-mentions more than w pairs (i,j). This means that a literal of a variable in $D(i,j,\cdot,\cdot)$ is in E' for more than w many pairs (i,j). For each such (i,j), such a literal is satisfied by ρ with probability at least $p/2$. So the probability that none of these literals in E' is satisfied is at most $(1-p/2)^w < e^{-pw/2}$.

Regarding item ii, suppose that more than w pairs $(1,j)$ are I-important in E'. For each such $(1,j)$, the probability that $(1,j) \in A_I \setminus A_D$ is $p(1-p)$, and provided this happens, the probability that ρ satisfies a literal in E' of a variable in $I(j,\cdot)$ is at least $\min\{(r-1)/r, 1/2\} = 1/2$. Hence the probability that E' is not satisfied by ρ is at most $(1-p(1-p)/2)^w < (1-p/3)^w < e^{-pw/3}$ (the first inequality follows from (18)).

Regarding item iii, a calculation similar to that for ii gives that a clause E' in Π with more than w many V-important pairs (i,j) is not satisfied by ρ with probability at most $(1-p/2)^w < e^{-pw/2}$.

Regarding item iv, suppose that more than w many pairs (i,j) from $\{2,\dots,s\} \times [t]$ are L-important in E'. For each $i \in \{2,\dots,s\}$, assume without loss of generality that the set of pairs (i,j) that are L-important in E' is the set $\{(i,1),\dots,(i,w_i)\}$; denote it by W_i. Note that the distribution of ρ does not change if we choose A_i and h_i in t many steps as follows. Start with $A_{i,0} = h_{i,0} = \emptyset$. At step $j = 1,2,\dots,t$, first add (i,j) to $A_{i,j-1}$ with probability p to get $A_{i,j}$. Then, if $|A_{i,j}| \leq 2pt$ and $(i,j) \in A_{i,j}$, choose at random two distinct elements j', j'' from $[t] \setminus \mathrm{im}(h_{i,j-1})$, and define $h_{i,j} := h_{i,j-1} \cup \{(L(i,j,\cdot), j'), (R(i,j,\cdot), j'')\}$. If $|A_{i,j}| \leq 2pt$ and $(i,j) \notin A_{i,j}$, define $h_{i,j} := h_{i,j-1}$. If $|A_{i,j}| > 2pt$ define $h_{i,j} := \emptyset$. This finishes step j. Finally, define $A_i := A_{i,t}$ and $h_i := h_{i,t}$.

For $i \in \{2, \dots, s\}$, let H_i be the set of literals in E' of a variable in $L(i,j,\cdot)$ for some $(i,j) \in W_i$. Also, for $(i,j) \in W_i$, let $T_{i,j}$ be the set of those $j' \in [t]$ such that the partial assignment given by setting $L(i,j,\cdot)$ to j' satisfies some literal in H_i. We know that $|T_{i,j}| \geq t/2$ for each $(i,j) \in W_i$.

The event that no literal in H_i is satisfied by ρ is a subset of the union of events (a) $|A_{i,t}| > 2pt$, and (b) $|A_{i,w_i}| \leq 2pt$ and for each $(i,j) \in A_{i,w_i}$, $h_{i,j}(L(i,j,\cdot)) \notin T_{i,j}$. Event (a) happens with probability at most $e^{-pt/3}$ by the Chernoff bound. We bound the probability of event (b). For each $j \in [w_i]$, if $(i,j) \in A_{i,j}$ and $|A_{i,j}| \leq 2pt$, then the probability that $h_{i,j}(L(i,j,\cdot)) \in T_{i,j}$ is at least $(|T_{i,j} \setminus \mathrm{im}(h_{i,j-1})|)/t \geq (t/2 - 4pt)/t = (1-8p)/2 \geq 1/3$ (the last inequality follows from (18)). Therefore, denoting $\ell := \min\{2pt, w_i\}$, the probability of event (b) is at most

$$\sum_{k=0}^{\ell} \binom{w_i}{k} p^k (1-p)^{w_i-k} \left(\frac{2}{3}\right)^k \leq \sum_{k=0}^{w_i} \binom{w_i}{k} \left(\frac{2p}{3}\right)^k (1-p)^{w_i-k} = (1-p/3)^{w_i}.$$

Thus, the probability that no literal in H_i is satisfied by ρ is at most $e^{-pt/3} + e^{-pw_i/3}$, and, denoting $S := \{i \in \{2, \dots, s\} : w_i \neq 0\}$, the probability that no literal in $\bigcup_{i \in S} H_i$ is satisfied by ρ is at most

$$\begin{aligned}\prod_{i \in S} \left(e^{-\frac{pw_i}{3}} + e^{-\frac{pt}{3}}\right) &\leq e^{-\frac{pw}{3}} + \sum_{k=1}^{|S|} \binom{|S|}{k} e^{-\frac{ptk}{3}} \\ &\leq e^{-\frac{pw}{3}} + |S| \cdot e^{-\frac{pt}{3}} \sum_{k=1}^{|S|} \binom{|S|-1}{k-1} e^{-\frac{pt(k-1)}{3}} \\ &= e^{-\frac{pw}{3}} + |S| \cdot e^{-\frac{pt}{3}} \cdot \left(1 + e^{-\frac{pt}{3}}\right)^{|S|-1} \\ &\leq e^{-\frac{pw}{3}} + s \cdot e^{-\frac{pt}{3}} \cdot e^{e^{\ln(t) - \frac{pt}{3}}} \leq e^{-\frac{pw}{3}} + 2s \cdot e^{-\frac{pt}{3}},\end{aligned}$$

where the penultimate inequality follows from $|S| - 1 \leq s \leq t$, and the last inequality follows from (19).

Item v is handled in the same way as iv.

Regarding item vi, suppose that for some $m \in [r]$ there are more than $t/4$ of $I(j,m)$ in E'. Similarly to the case ii, each such $I(j,m)$ is satisfied by ρ with independent probability at least $p(1-p)/r > p/(2r)$, so E' is not satisfied with probability at most $(1-p/(2r))^{t/4} < e^{-pt/(8r)}$.

Item vii is treated similarly to vi, with the resulting probability of not satisfying E' being $(1-p/n)^{t/4} < e^{-pt/(4n)} < e^{-pt/(8r)}$, where the last inequality follows from (16). ◀

By (17) and by Lemmas 11, 13, and 15, there is a restriction ρ satisfying all the assertions of the lemmas. Fix any such ρ.

▶ **Definition 16.** A partial assignment σ to the variables of $\mathrm{REF}^F_{s,t}$ is called an *admissible assignment* if it extends ρ and satisfies all the following conditions.

(C1) For each $(i,j) \in [s] \times [t]$, $D(i,j,\cdot,\cdot)$ (resp. $V(i,j,\cdot)$, $I(j,\cdot)$, $L(i,j,\cdot)$, $R(i,j,\cdot)$) either is set to some clause (resp. some $k \in [n]$, some $m \in [r]$, some $j' \in [t]$, some $j' \in [t]$) by σ or contains no variable that is in $\mathrm{dom}(\sigma)$.

(C2) For each $(i,j) \in [s] \times [t]$, if $L(i,j,\cdot)$ or $R(i,j,\cdot)$ is set to some $j' \in [t]$, then both $D(i,j,\cdot,\cdot)$ and $D(i-1,j',\cdot,\cdot)$ are set.

(C3) For each $(i,j) \in [s] \times [t]$, if $D(i,j,\cdot,\cdot)$ is set, then $V(i,j,\cdot)$ is set (if $i \in \{2,\ldots,s\}$) or $I(j,\cdot)$ is set (if $i=1$).

(C4) For each $(i,j) \in [s] \times [t]$, if $D(i,j,\cdot,\cdot)$ is set to a clause $C_{i,j}$, then $C_{i,j}$ is non-tautological and has at least $\min\{s-i,n\}$ many literals. If $D(i,j,\cdot,\cdot)$ is set to a clause $C_{i,j}$ with less than n literals and $V(i,j,\cdot)$ is set to some $k \in [n]$, then none of the literals of x_k is in $C_{i,j}$.

(C5) If $D(s,t,\cdot,\cdot)$ is set, it is set to the empty clause.

(C6) For each $j \in [t]$, if $D(1,j,\cdot,\cdot)$ and $I(j,\cdot)$ are set, then σ satisfies all clauses in (1) with this j.

(C7) For each $i \in \{2,\ldots,s\}, j,j' \in [t]$, if $L(i,j,\cdot)$ (resp. $R(i,j,\cdot)$) is set to j' and both $V(i,j,\cdot)$, $D(i-1,j',\cdot,\cdot)$ are set, then σ satisfies all clauses in (3) (resp. (4)) with these i,j,j'.

(C8) For each $i \in \{2,\ldots,s\}, j,j' \in [t]$, if $L(i,j,\cdot)$ (resp. $R(i,j,\cdot)$) is set to j' and $V(i,j,\cdot)$, $D(i,j,\cdot,\cdot)$, $D(i-1,j',\cdot,\cdot)$ are set, then σ satisfies all clauses in (5) (resp. (6)) with these i,j,j'.

(C9) For each $i \in \{2,\ldots,s\}$, the binary relation $h_{\sigma,i} := \{(Z(i,j,\cdot),j') : j,j' \in [t], Z \in \{L,R\}, \text{and } Z(i,j,\cdot) \text{ is set to } j' \text{ by } \sigma\}$ is a partial injection from $\{Z(i,j,\cdot) : j \in [t], Z \in \{L,R\}\}$ to $[t]$.

For the proofs of the following three lemmas, see the full version [5].

▶ **Lemma 17.** *No clause in* $\mathrm{REF}^F_{s,t}\lceil\rho$ *is falsified by any admissible assignment.*

▶ **Lemma 18.** *There is an admissible assignment.*

▶ **Lemma 19.** *Suppose that a clause E in $\Pi\lceil\rho$ is obtained by the resolution rule from clauses E_0 and E_1. Suppose further that there is an admissible assignment σ which satisfies both conditions*

(i) *every literal in E of a variable in* $\mathrm{dom}(\sigma)$ *is falsified by σ,*

(ii) *for each $Z \in \{D,V,I,R,L\}$, each Z-variable with a home pair Z-important in E is in* $\mathrm{dom}(\sigma)$.

Then there is an admissible assignment τ and $b \in \{0,1\}$ such that i and ii hold with τ in place of σ and E_b in place of E.

These three lemmas easily imply a contradiction, which concludes the proof of Theorem 8.

▶ Remark 20. If we assume $s = n+1$ in Theorem 8 (instead of assuming only $s \geq n+1$) then we can allow t to be smaller: it is enough to assume that $t \geq r^{2+\epsilon}$. This can be useful if one wants to reduce the number of variables of $\mathrm{REF}^F_{s,t}$ while keeping the lower bound of the theorem valid. The latter can be shown by making only the following modification in the proof of Theorem 8: change the definition of p to $p = s^{-1/3}t^{-a'}$ with $a' = \min\left\{\frac{1+\epsilon}{3+\epsilon}, \frac{1}{2}\right\}$, and change the definition of w to $w = s^{1/3}t^{3/5}$.

We note that if in the definition of $\mathrm{REF}^F_{s,t}$ we encode the functions determined by V- and I-variables in binary instead of in unary, the assumption $t \geq r^{3+\epsilon}$ in Theorem 8 is not necessary (and the proof of the theorem simplifies somewhat), and, in addition, the L- and R-variables can be encoded in binary too (with some further simplifications of the proof). This reduces the number of variables of $\mathrm{REF}^F_{s,t}$ in two ways, by allowing a smaller t and by using a more efficient encoding.

▶ Remark 21. Most of the obstacles our proof has to overcome are caused by the nature of the object described by $\mathrm{REF}^F_{s,t}$ and by the fact that the functions determined by V, I, L, R-variables are encoded in unary, rather than in binary. This forces us to work with several notions of width of two kinds, and we cannot keep as an invariant of the maintained partial assignment that it falsifies all literals of a clause as we traverse the refutation (as is the case e.g. in [11]). Moreover, keeping falsified just the literals with important indices and adding some simple conditions about not directly falsifying an axiom (a method which works e.g. in [8] for the pigeonhole principle) is not enough either, because we need to be prepared to consistently answer the prover's questions about clauses situated at remote parts of the same not too small component (learnt through the L- and R-variables). This is further complicated by the need to respond by adding a fresh literal to a clause that has too few literals to make sure its width grows fast enough (such clauses originate in the component of the empty clause), and by the necessity to arrive to a weakening of a clause in F when asked how a clause on level 2 is derived; both are more difficult to meet under the unary encoding and pose specific requirements on random restrictions. Our strategy stores some useful information in the form of negating some other literals than just those with important indices in a clause, as can be seen in the hierarchy of setting of variables of different kinds in Definition 16.

5 Reflection Principle for Resolution

We express the negation of the reflection principle for Resolution by a CNF in the form of a conjunction $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$. The only shared variables by the formulas $\mathrm{SAT}^{n,r}$ and $\mathrm{REF}^{n,r}_{s,t}$ encode a CNF with r clauses in n variables. The meaning of $\mathrm{SAT}^{n,r}$ is that the encoded CNF is satisfiable, while the meaning of $\mathrm{REF}^{n,r}_{s,t}$ is that it has a resolution refutation of s levels of t clauses. A formal definition is given next.

Formula $\mathrm{SAT}^{n,r}$ has the following variables. Variables $C(m,k,b)$, $m \in [r], k \in [n], b \in \{0,1\}$, encode clauses C_m as follows: $C(m,k,1)$ (resp. $C(m,k,0)$) means that the literal x_k (resp. $\neg x_k$) is in C_m. Variables $T(k)$, $k \in [n]$, and variables $T(m,k,b)$, $m \in [r], k \in [n], b \in \{0,1\}$, encode that an assignment to variables $x_1, \ldots, x_n$ satisfies the CNF $\{C_1, \ldots, C_r\}$. The meaning of $T(k)$ is that the literal x_k is satisfied by the assignment. The meaning of $T(m,k,1)$ (resp. $T(m,k,0)$) is that clause C_m is satisfied through the literal x_k (resp. $\neg x_k$).

We list the clauses of $\mathrm{SAT}^{n,r}$:

$$T(m,1,1) \vee T(m,1,0) \vee \ldots \vee T(m,n,1) \vee T(m,n,0) \qquad m \in [r], \tag{20}$$

$$\neg T(m,k,1) \vee T(k) \qquad m \in [r], k \in [n], \tag{21}$$

$$\neg T(m,k,0) \vee \neg T(k) \qquad m \in [r], k \in [n], \tag{22}$$

$$\neg T(m,k,b) \vee C(m,k,b) \qquad m \in [r], k \in [n], b \in \{0,1\}, \tag{23}$$

The meaning of (20) is that clause C_m is satisfied through at least one literal. The meaning of (21) and (22) is that if C_m is satisfied through a literal, then the literal is satisfied. The meaning of (23) is that if C_m is satisfied through a literal, then it contains the literal.

Variables of $\mathrm{REF}^{n,r}_{s,t}$ are the variables $C(m,k,b)$ of $\mathrm{SAT}^{n,r}$ together with all the variables of $\mathrm{REF}^{F}_{s,t}$ for some (and every) F of r clauses in n variables. That is, $\mathrm{REF}^{n,r}_{s,t}$ has the following variables:

$$\begin{array}{ll} C(m,k,b) & m \in [r], k \in [n], b \in \{0,1\}, \\ D(i,j,k,b) & i \in [s], j \in [t], k \in [n], b \in \{0,1\}, \\ R(i,j,j') \text{ and } L(i,j,j') & i \in \{2,\ldots,s\}, j,j' \in [t], \\ V(i,j,k) & i \in \{2,\ldots,s\}, j \in [t], k \in [n], \\ I(j,m) & j \in [t], m \in [r]. \end{array}$$

The clauses of $\mathrm{REF}^{n,r}_{s,t}$ are (2) - (15) of $\mathrm{REF}^{F}_{s,t}$ together with the following clauses (to replace clauses (1)):

$$\neg I(j,m) \vee \neg C(m,k,b) \vee D(1,j,k,b) \qquad j \in [t], m \in [r], k \in [n], b \in \{0,1\}, \tag{24}$$

saying that if clause $C_{1,j}$ is a weakening of clause C_m, then the former contains each literal of the latter.

We now prove the lower bound for $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ stated in the Introduction as Theorem 3 and restated below as Theorem 22.

▶ **Theorem 22.** *For every $c > 4$ there is $\delta > 0$ and an integer n_0 such that if n, r, s, t are integers satisfying*

$$t \geq s \geq n+1, \qquad r \geq n \geq n_0, \qquad n^c \geq t \geq r^4, \tag{25}$$

then any resolution refutation of $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ has length greater than 2^{n^δ} (which is exponential in the size of the formula).

Proof. Fix $c > 4$. We first observe that if Π is a resolution refutation of $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{s,t}$ and σ is a partial assignment such that its domain are all C-variables, then $\Pi \restriction \sigma$ is either a refutation of $\mathrm{REF}^{n,r}_{s,t} \restriction \sigma$, or a refutation of $\mathrm{SAT}^{n,r} \restriction \sigma$. This is because $\Pi \restriction \sigma$ is a resolution refutation and the two restricted formulas do not share any variables.

Let F be a CNF with r clauses in n variables, and let σ_F be a partial assignment such that its domain are all C-variables and σ_F evaluates them so that they describe the clauses of F. Notice that $\mathrm{REF}^{n,r}_{s,t} \restriction \sigma_F$ is $\mathrm{REF}^{F}_{s,t}$, since σ_F turns the clauses (24) into the clauses (1) (and removes the satisfied clauses). Therefore, in the case that $\Pi \restriction \sigma_F$ is a refutation of $\mathrm{REF}^{n,r}_{s,t} \restriction \sigma_F$ and F is unsatisfiable, the lower bound of Theorem 8 applies (setting $\epsilon = 1$ in that theorem, there is n_0 such that conditions (16) on n, r, s, t follow from (25)): the theorem yields some $\delta_1 > 0$ such that the length of $\Pi \restriction \sigma_F$ is at least $2^{n^{\delta_1}}$.

Let us now consider the case that $\Pi \restriction \sigma_F$ is a refutation of $\mathrm{SAT}^{n,r} \restriction \sigma_F$. Let SAT^F stand for $\mathrm{SAT}^{n,r} \restriction \sigma_F$. There is a substitution τ to the variables of SAT^F that turns the clauses of SAT^F into all the clauses of F together with some tautological clauses. It is defined as follows. If $\sigma_F(C(m,k,b)) = 0$, then $\tau(T(m,k,b)) = 0$. This satisfies (21) - (23) and deletes $T(m,k,b)$ from (20). If $\sigma_F(C(m,k,b)) = 1$, then (23) has been satisfied and we define $\tau(T(m,k,b)) = x_k^b$ and $\tau(T(k)) = x_k$. This choice turns (21) - (22) into a tautological clause and correctly substitutes the remaining literals of (20) to yield the m-th clause of F. Thus, if $\Pi \restriction \sigma_F$ is a refutation of $\mathrm{SAT}^{n,r} \restriction \sigma_F$, the substitution τ takes it into a not larger resolution refutation of F (since tautological clauses can be removed from any resolution refutation).

It remains to take any unsatisfiable formula F whose number of clauses is polynomially related to the number of variables and that requires resolution refutations of exponential length, e.g. the pigeonhole principle [6]. A trivial modification of F to serve also in the extreme case $r = n$ allowed by (25) will yield $\delta_2 > 0$ such that any resolution refutation of F has length greater than $2^{n^{\delta_2}}$, where n is the number of variables of F.

Setting δ to the minimum of δ_1 and δ_2 concludes the proof of the theorem. ◀

A similar proof gives Theorem 4. We restate the theorem below for convenience.

▶ **Theorem 23.** *Let $\gamma > 0$ and let $\{A_n\}_{n \geq 1}$ be a family of unsatisfiable CNFs such that A_n is in n variables, has the number of clauses polynomial in n, and has no resolution refutations of length at most 2^{n^γ}. Then there is $\delta > 0$ and a polynomial p such that $A_n \wedge \mathrm{REF}^{A_n}_{n+1,p(n)}$ has no resolution refutations of length at most 2^{n^δ} and has polynomial size* Res(2) *refutations.*

Proof. Let $p(n) \geq \max\{r^4, t_0\}$, where r is the maximum of the number of clauses of A_n and n, and t_0 is given by Theorem 8 for $\epsilon = 1$. This theorem and the assumptions on A_n give the required lower bound. To get the upper bound, start with the Res(2) refutation of $\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{n+1,p(n)}$ given by Theorem 5. Define substitutions σ_{A_n} and τ like in the proof of Theorem 22 with A_n in place of F, and observe again that $((\mathrm{SAT}^{n,r} \wedge \mathrm{REF}^{n,r}_{n+1,p(n)}) \restriction \sigma_{A_n}) \restriction \tau$ is $A_n \wedge \mathrm{REF}^{A_n}_{n+1,p(n)}$ together with some tautological clauses. ◀

Tangles and Single Linkage Hierarchical Clustering

Eva Fluck
RWTH Aachen University, Germany
fluck@cs.rwth-aachen.de

Abstract

We establish a connection between tangles, a concept from structural graph theory that plays a central role in Robertson and Seymour's graph minor project, and hierarchical clustering. Tangles cannot only be defined for graphs, but in fact for arbitrary connectivity functions, which are functions defined on the subsets of some finite universe, which in typical clustering applications consists of points in some metric space.

Connectivity functions are usually required to be submodular. It is our first contribution to show that the central duality theorem connecting tangles with hierarchical decompositions (so-called branch decompositions) also holds if submodularity is replaced by a different property that we call maximum-submodular.

We then define a natural, though somewhat unusual connectivity function on finite data sets in an arbitrary metric space and prove that its tangles are in one-to-one correspondence with the clusters obtained by applying the well-known single linkage clustering algorithms to the same data set.

The idea of viewing tangles as clusters has first been proposed by Diestel and Whittle [5] as an approach to image segmentation. To the best of our knowledge, our result is the first that establishes a precise technical connection between tangles and clusters.

1 Introduction

Connectivity in graphs and connectivity systems is a widely studied topic in theoretical computer science, e.g. [11, 8, 6, 7, 5]. On the other hand similarity, especially clustering, is an important and well studied topic in Data Science, e.g. [2, 4, 3, 10, 12]. We study the connection between both concepts by interpreting similarity as connectivity, thus two points are highly connected if their data is very similar and two sets are highly connected if they contain similar data points. Both communities will benefit from such a connection, as it opens up a basis for a wide range of new results. For example connectivity systems provide us with witnesses for the absence of highly connected regions, which is not yet established for clusters, as well as tree like representations of all those highly connected regions. Additionally there is large variety of efficient algorithms to compute or approximate different kind of clusters, which can possibly be used to find algorithms for computing highly connected regions in connectivity systems.

The concept of connectivity systems is based on the notion of connectivity in graphs. Such systems consist of a universe U of usually finitely many elements and some set function on subsets of U describing the connectivity between a set and its complement. These so called connectivity functions are symmetric and submodular. In this context two complementary questions are of interest [9]:

1. What are the highly connected regions of the universe?
2. How can we decompose the universe along low order separations?

An answer to the first question can be given by tangles, which describe highly connected regions in a non-rigorous way. For every low order separation the tangle describes on which side of the separation the large part of the region can be found. Nevertheless, a separation may cut off small parts of the region. In this way, for any single point it is not clearly defined whether it is part of the region or not. On the other hand, the orientation has to be consistent, meaning that all orientations have to point towards the same region.

The second question is addressed by branch decompositions. They contain a ternary tree and a mapping of the elements to the leafs of the tree. Then, the edges of the tree represent separations of the universe. The width of such a decomposition is the largest value of any separation induced by the tree. Both concepts have been introduced on graphs by Robertson and Seymour [11]. An overview on both branch decompositions and tangles for integer-valued functions, as well as their connection can be found in a survey of Grohe [9], which can be translated to real-valued functions. Branch decompositions and tangles address contrary questions, but they are dual. There is a tangle of a certain value if and only if there is no branch decomposition of smaller value. This duality result has first been shown on graphs in [11]. There have been other set functions, that are not submodular, for which duality has been shown. For example Adler et al. [1] have shown duality up to a constant factor for so called hypertangle number and hyperbranch width in hypergraphs. Diestel and Oum [6] developed a general duality theorem in combinatorial structures.

Besides tangles, there is another approach to identify highly similar (connected) regions, called clustering (e.g. [2, 4, 3, 10, 12]). Clustering is the umbrella term for different techniques to define sets of data points that are very similar to each other and not so similar to the data points contained in other sets. Thus, a question arises: How do clustering and tangles relate? A first approach towards this question was done by Diestel and Whittle [5], where they analyzed tangles in digital images as a way to describe the meaningful parts of the image. We consider hierarchical clustering algorithms as introduced by Carlson and Mémoli [2]. The basis of such an algorithm is a function that describes the distance between two sets. Single linkage clustering for example considers the distance of two sets to be the smallest distance between any element from one set to any element from the other set. The hierarchical clustering algorithm then merges the sets with the smallest distance, assigning the resulting partition said value. We allow more than one merge at once, if the distances are equal. The resulting sequence of partitions is represented by a so called dendogram.

1.1 Results

To find a correspondence between tangles and clustering one of the main goals is to find connectivity functions, or functions with similar properties, that represent the different clustering methods. Our main result is, that we are able to specify a function that is correspondent to hierarchical clustering using single linkage. For an arbitrary metric $\mathrm{d}\colon U \times U \to \mathbb{R}$, the set function corresponding to single linkage is the *minimum distance function* $\delta_{\mathrm{d}}\colon 2^U \to \mathbb{R}$, defined by

$$\delta_{\mathrm{d}}(X) = \max_{x \in X, y \notin X} \exp(-\mathrm{d}(x,y)),$$

for all $X \in 2^U \setminus \{\emptyset, U\}$ and $\delta_{\mathrm{d}}(\emptyset) = \delta_{\mathrm{d}}(U) = 0$. An introduction of this function is given in Section 3.

We show that this function is not a classical connectivity function, since it is not submodular. Therefore we define a different property, that we call maximum-submodularity. Our first theorem proves duality between branch decompositions and tangles of functions with this property.

▶ **Theorem 1.** *Let U be a finite set and let ϕ be a maximum-submodular connectivity function. The maximum order of a tangle of ϕ equals the minimum order of a branch decomposition of ϕ. The existence of one is witness to the non-existence of the other.*

A formal version of this theorem and its proof are shown in Section 4. This duality is a key result in the theory of tangles of connectivity systems and suggests that the chosen property on the functions results in a similarly deep theory. It allows us to use maximum-submodular connectivity functions to establish a connection between tangles and clustering.

Our second main result says that the tangles of the minimum distance function are in one-to-one correspondence with the resulting dendogram of single linkage hierarchical clustering. The technical notions appearing in the statement of the theorem will be explained later in this paper.

▶ **Theorem 2.** *Let (U, d) be a metric space.*

1. *For every $r \in \mathbb{R}$ and every cluster $\mathcal{B}$ of the dendogram resulting from single linkage with $|\mathcal{B}| > 1$,*

   $$\mathcal{T} := \{X \subseteq U \mid \delta_{\mathrm{d}}(X) < \exp(-r),\ \mathcal{B} \subseteq X\}$$

   is a δ_{d}-tangle of U of order $\exp(-r)$.
2. *For every δ_{d}-tangle $\mathcal{T}$ of U of order k we can identify a cluster $\mathcal{B}$ of the dendogram resulting from single linkage with $|\mathcal{B}| > 1$ such that*

   $$\mathcal{T} = \{X \subseteq U \mid \delta_{\mathrm{d}}(X) < k,\ \mathcal{B} \subseteq X\}.$$

For every non-singular set contained in a partition of the dendogram we find a distinct δ_{d}-tangle and vice versa. This is to the best of our knowledge the first precise technical connection between tangles and clusters.

2 Preliminaries and Definitions

In our definitions we follow [9]. Our goal is to describe connectivity within some data set U. Therefore we define set functions κ, that aim to describe how strong the connection is between a set and its complement. We say κ is *normalized* if $\kappa(\emptyset) = 0$, κ is *symmetric* if $\kappa(X) = \kappa(\overline{X})$, for all $X \subseteq U$ and κ is *submodular* if $\kappa(X) + \kappa(Y) \geq \kappa(X \cap Y) + \kappa(X \cup Y)$, for all $X, Y \subseteq U$. A set function that is normalized, symmetric and submodular is called *submodular connectivity function.*

▶ **Example 3** (see [9]). Let $G = (V, E)$ be a graph with edge weights $w_E \colon E \to \mathbb{R}$. The weighted edge-connectivity function $\nu \colon 2^V \to \mathbb{R}$, defined as

$$\nu(X) := \sum_{u \in X, v \in V \setminus X, (u,v) \in E} w_E(u, v),$$

is a submodular connectivity function.

We introduce a different type of function, that also describes connectivity. To show that this type has similar properties, we first take a look at basic concepts from the theory of connectivity systems. Most of these concepts have only been studied for integer-valued functions, but for our needs all properties are translatable to real-valued functions. We start with a formal definition of tangles, which are a way to describe highly connected regions.

▶ **Definition 4.** *Let κ be a symmetric set function on the universe U. A κ-*tangle *of order* $\mathrm{ord}(\mathcal{T}) = k \geq 0$ *is a set $\mathcal{T} \subseteq 2^U$ such that:*
T.0 *$\kappa(X) < k$ for all $X \in \mathcal{T}$,*
T.1 *for all $X \subseteq U$ with $\kappa(X) < k$, either $X \in \mathcal{T}$ or $\overline{X} \in \mathcal{T}$ holds,*
T.2 *$X_1 \cap X_2 \cap X_3 \neq \emptyset$ for all $X_1, X_2, X_3 \in \mathcal{T}$ and*
T.3 *$\{x\} \notin \mathcal{T}$ for all $x \in U$.*

We define the *tangle number* $\mathrm{tn}(\kappa)$ of a symmetric set function κ to be the largest possible order for which we can still define a κ-tangle.

We use the following well-known lemma, which states that tangles are in a way closed under intersection and supersets.

▶ **Lemma 5** (see [9]). *Let $\mathcal{T}$ be a κ-tangle of order k. Then it holds that*
1. *for all $X \in \mathcal{T}$ and all $Y \supseteq X$, if $\kappa(Y) < k$ then $Y \in \mathcal{T}$ and*
2. *for all $X, Y \in \mathcal{T}$, if $\kappa(X \cap Y) < k$ then $X \cap Y \in \mathcal{T}$.*

A different way to describe connectivity in a universe is given by branch decompositions. Here we do not look for highly connected regions, but ask ourselves how we can separate the universe into its single elements, using only separations of small value.

▶ **Definition 6.** *Let U be a finite set.*

- *A* pre-decomposition *of U is a pair (T, γ) consisting of a ternary (undirected) tree T and a mapping $\gamma\colon \overrightarrow{E}(T) \to 2^U$, from the directed edges of T to subsets of U, such that*
  - *$\gamma(t, u) = \overline{\gamma(u, t)}$, for all $(t, u) \in \overrightarrow{E}(T)$, and*
  - *$\gamma(s, u_1) \cup \gamma(s, u_2) \cup \gamma(s, u_3) = U$, for all internal nodes $s \in V(T)$ with $N(s) = \{u_1, u_2, u_3\}$.*
- *For leaves $\ell \in L(T)$ with neighbor $N(\ell) = \{u\}$, we write $\gamma(\ell)$ instead of $\gamma(u, \ell)$. We call the $\gamma(\ell)$* atoms *and define $\mathrm{At}(T, \gamma) \coloneqq \{\gamma(\ell) \mid \ell \in L(T)\}$.*
- *A pre-decomposition is* complete *if $|\gamma(\ell)| = 1$, for all leaves $\ell \in L(T)$.*
- *A pre-decomposition is* exact *at an internal node $t \in V(T)$ with $N(t) = \{u_1, u_2, u_3\}$ if all $\gamma(t, u_i)$ are mutually disjoint.*
- *A* decomposition *is a pre-decomposition that is exact at all internal nodes.*
- *A* branch decomposition *is a complete decomposition.*
- *Let κ be a set function on U. The* width *of a pre-decomposition (T, γ) is*

$$\mathrm{wd}(T, \gamma) \coloneqq \max\{\kappa(\gamma(t, u)) \mid (t, u) \in \overrightarrow{E}(T)\}.$$

We define the *branch width* $\mathrm{bw}(\kappa)$ of a symmetric set function κ to be the smallest possible width $\mathrm{wd}(T, \gamma)$ of any branch decomposition (T, γ) on U. For submodular connectivity functions duality between branch decompositions and tangles has been proven. The first to find this duality in graphs were Robertson and Seymour [11]. Duality between branch decompositions and tangles states that a branch decomposition of a certain width is a witness for the non-existence of a tangle of any larger order and vice versa. It follows that for any submodular connectivity function κ it holds that

$$\mathrm{tn}(\kappa) = \mathrm{bw}(\kappa).$$

3 The Minimum Distance Function

▶ **Definition 7** (Minimum Distance). *Let* $\mathrm{d}\colon U \times U \to \mathbb{R}$ *be an arbitrary metric. For a finite data set* U*, the* minimum distance function $\delta_{\mathrm{d}}\colon 2^U \to \mathbb{R}$*, is defined as follows:*

$$\delta_{\mathrm{d}}(X) := \begin{cases} 0 & \text{if } X = \emptyset \text{ or } \overline{X} = \emptyset, \\ \max_{x \in X, x' \in \overline{X}} \exp(-\,\mathrm{d}(x, x')) & \text{otherwise.} \end{cases}$$

This definition yields that X has a high value if there is a point outside of X very close to a point in X. The transformation $\exp(-c \cdot \mathrm{f}(x, y))$, for some constant c and some function f, is often used in clustering applications to transform a dissimilarity function f like a metric into a similarity function. The minimum distance function is in general not submodular, as can be seen with a small example. For an arbitrary $x \in \mathbb{R}^+$ define a one-dimensional universe containing only the following four points $a_1 = x$, $a_2 = x + 1$, $a_3 = -x$ and $a_4 = -x - 1$. Let $X = \{a_1, a_2\}$, $Y = \{a_1, a_3\}$ and the metric $d(u, v) = |u - v|$ is the absolute of the difference. Then $\delta_{\mathrm{d}}(X) = \exp(-2x) < \delta_{\mathrm{d}}(Y) = \delta_{\mathrm{d}}(X \cap Y) = \delta_{\mathrm{d}}(X \cup Y) = \exp(-1)$, for all $x > \frac{1}{2}$

We define a new property, that is similar to submodularity, which allows us to develop similar theories as for submodular connectivity functions.

▶ **Definition 8.** *A set function* κ *on a finite set* U *is* maximum-submodular *if, for all* $X, Y \subseteq U$*,*

$$\max(\kappa(X), \kappa(Y)) \geq \max(\kappa(X \cap Y), \kappa(X \cup Y)).$$

This property is neither a generalization of submodularity nor a specialization. For instance ν as in Example 3 is submodular but not maximum-submodular and in the next lemma we see that the minimum distance function, which in general is not submodular, is maximum-submodular. We call a normalized, symmetric and maximum-submodular set function *maximum-submodular connectivity function.*

▶ **Lemma 9.** *The minimum distance function is a maximum-submodular connectivity function.*

Proof. The minimum distance function is normalized by definition and symmetric since metrics are symmetric. If X or Y are equal to $\emptyset$ or U, maximum-submodularity trivially holds as $\{X, Y\} = \{X \cup Y, X \cap Y\}$ in these cases. Otherwise, we choose $u \in X \cap Y$ and $v \in \overline{X \cap Y}$ such that $\mathrm{d}(u, v) = \delta_{\mathrm{d}}(X \cap Y)$. Analogously we choose $u' \in \overline{X \cup Y} = \overline{X} \cap \overline{Y}$ and $v' \in X \cup Y$. Then w.l.o.g. we distinguish four cases, depending on v and v'.

Case 1: $v \in \overline{X} \cap \overline{Y}$ and $v' \in X \cap Y$ hold: Then w.l.o.g. $v = u'$ and $u = v'$ hold. Therefore $\delta_{\mathrm{d}}(X \cap Y) = \delta_{\mathrm{d}}(X \cup Y)$ and thus $\delta_{\mathrm{d}}(X) \geq \delta_{\mathrm{d}}(X \cap Y)$ and $\delta_{\mathrm{d}}(Y) \geq \delta_{\mathrm{d}}(X \cup Y)$ hold.

Case 2: $v \in \overline{X} \cap \overline{Y}$ and $v' \in \overline{X} \cap Y$ hold: It follows that $\delta_{\mathrm{d}}(X) \geq \delta_{\mathrm{d}}(X \cap Y)$ and $\delta_{\mathrm{d}}(Y) \geq \delta_{\mathrm{d}}(X \cup Y)$ hold.

Case 3: $v, v' \in \overline{X} \cap Y$ holds: It follows that $\delta_{\mathrm{d}}(X) \geq \delta_{\mathrm{d}}(X \cap Y)$ and $\delta_{\mathrm{d}}(Y) \geq \delta_{\mathrm{d}}(X \cup Y)$ hold.

Case 4: $v \in X \cap \overline{Y}$ and $v' \in \overline{X} \cap Y$ hold: In this case it holds that $\delta_{\mathrm{d}}(Y) \geq \delta_{\mathrm{d}}(X \cap Y)$ and $\delta_{\mathrm{d}}(Y) \geq \delta_{\mathrm{d}}(X \cup Y)$. Therefore we have $\delta_{\mathrm{d}}(Y) \geq \max(\delta_{\mathrm{d}}(X \cap Y), \delta_{\mathrm{d}}(X \cup Y))$ and the inequality holds.

As all other cases are symmetric to the four cases shown above, the inequality holds for all $X, Y \subseteq U$. ◀

Next, we consider tangles of the Minimum Distance Function. Firstly, we give an example of such a tangle.

▶ **Example 10.** Let $U \subset \mathbb{R}^n$ be a finite set of points. Let $x_1, x_2 \in U$ be two points such that $\mathrm{d}(x_1, x_2) = \min\{\mathrm{d}(x, y) \mid x, y \in U, x \neq y\}$. Then, for every $k \leq \exp(-\mathrm{d}(x_1, x_2))$,

$$\mathcal{T} := \{X \subseteq U \mid \delta_{\mathrm{d}}(X) < k,\ x_1, x_2 \in X\}$$

is a δ_{d}-tangle of order k.

$\mathcal{T}$ satisfies (T.0), (T.2) and (T.3) by construction. To see that (T.1) is satisfied note that if $x_1 \in X$ and $x_2 \in \overline{X}$ holds then $\delta_{\mathrm{d}}(X) = \exp(-\mathrm{d}(x_1, x_2)) \geq k$ holds.

Having this example we realize that the tangles described are the only δ_{d}-tangles.

▶ **Lemma 11.** *Every δ_{d}-tangle of order k is of the form described as in Example 10. That is, we can identify two points $u, v \in U$ such that $\exp(-\mathrm{d}(u, v)) \geq k$ and for all $X \in \mathcal{T}$ we have $u, v \in X$.*

Proof. To prove this we define the relation ${\delta_{\mathrm{d}}}^k := \{(u, v) \mid \exp(-\mathrm{d}(u, v)) \geq k\}$ and consider the graph $G_k := (U, {\delta_{\mathrm{d}}}^k)$. For every set $X \subseteq U$ with $\delta_{\mathrm{d}}(X) < k$ and every connected component C of G_k, holds either $V(C) \subseteq X$ or $V(C) \subseteq \overline{X}$ by definition. Thus for every δ_{d}-tangle $\mathcal{T}$ of order $\leq k$ it holds that all $X \in \mathcal{T}$ are disjoint unions of connected components of G_k. Additionally, using Lemma 5 (2) every such $\mathcal{T}$ is closed under intersection, as for two sets $X, Y \in \mathcal{T}$ and all connected components C of G_k either $V(C) \subseteq X \cap Y$ or $V(C) \cap X \cap Y = \emptyset$ and thus $\delta_{\mathrm{d}}(X \cap Y) < k$. Suppose for contradiction there is a δ_{d}-tangle $\mathcal{T}$ of order k such that there is no connected component of G_k, of size at least two, that is contained in all $X \in \mathcal{T}$. Let $C_0, \ldots, C_n$ be an enumeration of all connected components of G_k with $|C_i| \geq 2$. Then we can identify a sequence $X_0, \ldots, X_n \in \mathcal{T}$ such that $V(C_i) \nsubseteq X_i$, thus $V(C_i) \cap X_i = \emptyset$. We set $Y_1 := X_0 \cap X_1$ and $Y_{i+1} := Y_i \cap X_{i+1}$. Since $\mathcal{T}$ is closed under intersection, we get $Y_1, \ldots, Y_n \in \mathcal{T}$. As $\mathcal{T}$ is a tangle, $|Y_n| > 1$ has to hold. For every subset $Y \subseteq Y_n$ we have $\kappa(Y) < k$ as $Y_n \cap \bigcup_{i=0}^{n} C_i = \emptyset$. Take an enumeration of all elements $y_1, \ldots, y_m \in Y_n$ and construct a series of sets $Z_1, \ldots, Z_\ell \in \mathcal{T}$ such that $|Z_\ell| = 1$. Clearly this contradicts the existence of $\mathcal{T}$. If $\{y_1\} \in \mathcal{T}$ set $Z_1 := \{y_1\}$, else set $Z_1 := Y_n \setminus \{y_1\} = Y_n \cap \overline{\{y_1\}} \in \mathcal{T}$. If $|Z_i| = 1$ set $\ell = i$ and stop the construction. Otherwise if $\{y_{i+1}\} \in \mathcal{T}$ set $Z_{i+1} := \{y_{i+1}\}$, else set $Z_{i+1} := Z_i \setminus \{y_{i+1}\} = Z_i \cap \overline{\{y_{i+1}\}} \in \mathcal{T}$. As $|Z_i| > |Z_{i+1}|$ this construction terminates and yields the desired contradiction. ◀

From this lemma an important corollary follows. In Section 5 we use this to identify for each tangle a cluster resulting from single linkage hierarchical clustering.

▶ **Corollary 12.** *Let $\mathcal{T}$ be a δ_{d}-tangle of order k over the universe U. There is a unique connected component C of the graph $G = (U, {\delta_{\mathrm{d}}}^k)$, with ${\delta_{\mathrm{d}}}^k := \{(u, v) \mid \exp(-\mathrm{d}(u, v)) \geq k\}$, such that $C \subseteq X$, for all $X \in \mathcal{T}$.*

Proof. We already showed that there exists some component C such that $C \subseteq X$, for all $X \in \mathcal{T}$. Assume there is some component $C' \neq C$ such that $C' \subseteq X$, for all $X \in \mathcal{T}$. Then we have $C' \in \mathcal{T}$ and thus $C \subseteq C'$ which contradicts $C' \neq C$. ◀

4 Duality for Submodular Bounded Functions

Now we prove duality for all maximum-submodular connectivity functions, thus also for the minimal distance function. We achieve a result similar to the theory for submodular connectivity functions, first shown in [11]. To formulate the Duality Theorem we first need a definition.

▶ **Definition 13.** *Let κ be a symmetric set function on U and $\mathcal{A} \subseteq 2^U$.*

- *A pre-decomposition (T, γ) is* over *$\mathcal{A}$ if $At(T, \gamma) \subseteq \mathcal{A}$.*
- *A κ-tangle $\mathcal{T}$* avoids *$\mathcal{A}$ if $\mathcal{T} \cap \mathcal{A} = \emptyset$.*

The Duality Theorem states that there can not be any decomposition over a family of sets, if there is a tangle avoiding this family and vice versa. The proof yields a construction of such a decomposition. The following theorem is a precise formulation of Theorem 1.

▶ **Theorem 14** (Duality Theorem of Submodular Bounded Functions). *Let κ be a maximum-submodular connectivity function on U. Let $\mathcal{A} \subseteq 2^U$ such that $\mathcal{A}$ is closed under taking subsets and $\mathrm{Sing}(U) \subseteq \mathcal{A}$, where $\mathrm{Sing}(U)$ is the set of all singletons from U. Then there is a decomposition of width less than k over $\mathcal{A}$ if and only if there is no κ-tangle of order k that avoids $\mathcal{A}$.*

Assuming the theorem holds, we can directly derive the following corollary using that every branch decomposition of U is complete, thus is over $\mathrm{Sing}(U)$ and every κ-tangle avoids $\mathrm{Sing}(U)$ by definition.

▶ **Corollary 15.** *Let κ be a maximum-submodular connectivity function on U. It holds that*

$$\mathrm{tn}(\kappa) = \mathrm{bw}(\kappa).$$

Looking at the proof of duality for submodular connectivity functions as it is presented in [9], we see that they do not use any properties of the set function, besides symmetry and a transformation from a pre-decomposition into a decomposition of equal width. Therefore, we can adapt that proof if we are able to do a similar transformation. The following lemma shows how to achieve exactness at every node of a pre-decomposition.

▶ **Lemma 16** (Exactness Lemma). *Let κ be a maximum-submodular connectivity function on U and (T, γ) be a pre-decomposition of U. Then there is a mapping $\gamma' \colon \vec{E}(T) \to 2^U$ such that (T, γ') is a decomposition of U satisfying*

- *$\mathrm{wd}(T, \gamma') \leq \mathrm{wd}(T, \gamma)$ and*
- *$\gamma'(\ell) \subseteq \gamma(\ell)$, for all leaves $\ell \in L(T)$.*

Proof. We iteratively construct γ' from γ, keeping the invariants

- $\mathrm{wd}(T, \gamma') \leq \mathrm{wd}(T, \gamma)$ and
- $\gamma'(\ell) \subseteq \gamma(\ell)$, for all leaves $\ell \in L(T)$.

We pick an arbitrary leaf $\ell_{start} \in L(T)$ and set $\gamma'(\ell_{start}, s) \coloneqq \gamma(\ell_{start}, s)$ and $\gamma'(s, \ell_{start}) \coloneqq \gamma(s, \ell_{start})$ for $s \in N(\ell_{start})$. If T only consists of at most two nodes we are done, since (T, γ') is already a decomposition. Otherwise, we traverse the tree with breadth-first search starting at ℓ_{start}. If we reach a node $s \in V(T) \backslash L(T)$ with predecessor $t \in V(T)$, we do the following. Let $u_1, u_2 \in N(s)$ be the successors of s and define $X \coloneqq \gamma'(s, t)$ and $Y_i \coloneqq \gamma(s, u_i)$, for $i = 1, 2$.

If $X \cap (Y_1 \cup Y_2) \neq \emptyset$ we update Y_i to $Y_i \cap \overline{X}$, for $i = 1, 2$. This step is consistent with the invariants as $\kappa(Y_i \cap \overline{X}) \leq \max(\kappa(Y_i \cap \overline{X}), \kappa(Y_i \cup \overline{X})) \leq \max(\kappa(Y_i), \kappa(X))$, where the second inequality holds due to maximum-submodularity, and $Y_i \cap \overline{X} \subseteq \gamma(s, u_i)$, for $i = 1, 2$.

If $Y_1 \cap Y_2 \neq \emptyset$, update Y_1 to $Y_1 \cap \overline{Y_2}$. This step is again consistent with the invariants as $\kappa(Y_1 \cap \overline{Y_2}) \leq \max(\kappa(Y_1 \cap \overline{Y_2}), \kappa(Y_1 \cup \overline{Y_2})) \leq \max(\kappa(Y_1), \kappa(Y_2))$, where the second inequality holds due to maximum-submodularity, and $Y_1 \cap \overline{Y_2} \subseteq \gamma(s, u_1)$.

Set $\gamma'(s, u_i) \coloneqq Y_i$ and $\gamma'(u_i, s) \coloneqq \overline{\gamma'(s, u_i)}$, for $i = 1, 2$. After these steps we know that γ' is exact at s and we do not change γ' for any predecessor of s.

When we reach a leaf $\ell \in L(T)$, we do not change γ' and continue with the next node in the breadth-first search.

This construction yields the desired mapping. ◀

The construction above may result in a tree with empty leafs. But such a leaf can be easily removed by deleting it and its neighbor, connecting the resulting open edges.

Now, we are ready to prove the Duality Theorem for Submodular Bounded Functions.

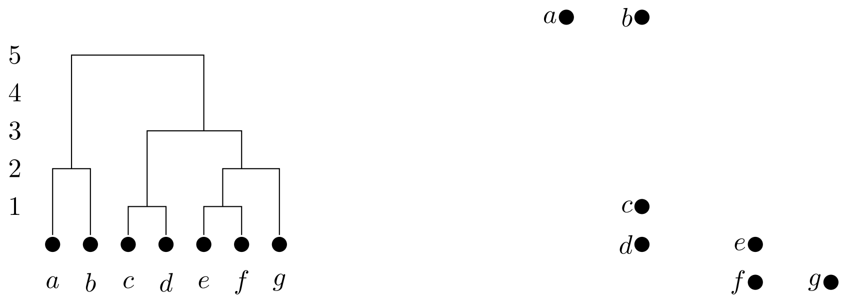
Proof of Theorem 14, see [9]. For the forward direction, we let (T, γ) be a decomposition of U over $\mathcal{A}$ of width less than k. Suppose, for contradiction, $\mathcal{T}$ is a κ-tangle of order k that avoids $\mathcal{A}$. We orient the edges $E(T)$ such that they point in the direction of the set that is contained in the tangle. Such a set always exists as the width is less then k. Thus, formally we orient $(s,t) \in E(T)$ towards t if $\gamma(s,t) \in \mathcal{T}$, and towards s if $\gamma(t,s) = \overline{\gamma(s,t)} \in \mathcal{T}$. As in every oriented tree, there is at least one node $t \in V(T)$ such that all edges incident to t are oriented towards t. If $t \in L(T)$ then $\gamma(t) \in \mathcal{A}$ and $\gamma(t) \in \mathcal{T}$ which contradicts the assumption that $\mathcal{T}$ avoids $\mathcal{A}$. Thus, t is an internal node with $N(t) = \{u_1, u_2, u_3\}$. But since all $\gamma(t, u_i)$ are mutually disjoint and all $\gamma(u_1, t) \in \mathcal{T}$ this contradicts (T.2) as $\gamma(t, u_1) \cup \gamma(t, u_2) \cup \gamma(t, u_3) = U$ and thus $\gamma(u_1, t) \cap \gamma(u_2, t) \cap \gamma(u_3, t) = \emptyset$. It follows that such a κ-tangle can not exist and the forward direction holds.

For the backward direction assume there is no κ-tangle of order k that avoids $\mathcal{A}$. We will construct a pre-decomposition (T, γ) of U over $\mathcal{A}$ of width less than k. Using the Exactness Lemma and since $\mathcal{A}$ is closed under taking subsets it follows that a decomposition of U over $\mathcal{A}$ exists.

We construct such a pre-decomposition (T, γ) inductively on the number of sets $X \subseteq U$ with $\kappa(X) < k$ and neither $X \in \mathcal{A}$ nor $\overline{X} \in \mathcal{A}$.

In the base case, for all $X \subseteq U$ with $\kappa(X) < k$, holds $X \in \mathcal{A}$ or $\overline{X} \in \mathcal{A}$. We define $\mathcal{Y} := \{\overline{X} \mid X \in \mathcal{A} \text{ with } \kappa(X) < k\}$. We know that $\mathcal{Y}$ can not be a tangle, as we assumed that there is no tangle of order k. Since (T.0) and (T.1) hold by assumption on $\mathcal{A}$, either (T.2) or (T.3) have to be false. If $\mathcal{Y}$ violates (T.2) there are three sets $Y_1, Y_2, Y_3 \in \mathcal{Y}$ such that $Y_1 \cap Y_2 \cap Y_3 = \emptyset$. Then $\overline{Y_1}, \overline{Y_2}, \overline{Y_3} \in \mathcal{A}$ and $\overline{Y_1} \cup \overline{Y_2} \cup \overline{Y_3} = U$. We set $T := (\{\ell_1, \ell_2, \ell_3, t\}, \{(\ell_i, t) \mid i = 1,2,3\})$, $\gamma(t, \ell_i) := \overline{Y_i} \in \mathcal{A}$ and $\gamma(\ell_i, t) := Y_i$. Then, (T, γ) is a pre-decomposition of U over $\mathcal{A}$. If $\mathcal{Y}$ violates (T.3) there is some $x \in U$ such that $\{x\} \in \mathcal{Y}$ and thus $\overline{\{x\}} \in \mathcal{A}$. Since $\mathrm{Sing}(U) \subseteq \mathcal{A}$ we have $\{x\} \in \mathcal{A}$. We take $T := (\{s,t\}, \{(s,t)\})$ and $\gamma(s,t) := \{x\}$, $\gamma(t,s) := \overline{\{x\}}$. Then (T, γ) is a pre-decomposition of U over $\mathcal{A}$.

In the inductive step, we have some $X \subseteq U$ with $\kappa(X) < k$ and neither $X \in \mathcal{A}$ nor $\overline{X} \in \mathcal{A}$. We chose X' such that $|X'|$ is minimal with respect to the conditions above. We set $\mathcal{A}^1 := \mathcal{A} \cup 2^{X'}$ and $\mathcal{A}^2 := \mathcal{A} \cup 2^{\overline{X'}}$. By the induction hypothesis there are pre-decompositions (T^1, γ^1) over $\mathcal{A}^1$ and (T^2, γ^2) over $\mathcal{A}^2$. If $\mathrm{At}(T_i, \gamma_i) \subseteq \mathcal{A}$ than (T_i, γ_i) is a pre-decomposition over $\mathcal{A}$ and we are done. Otherwise, we can assume that (T^1, γ^1) is a decomposition, due to the Exactness Lemma 16, thus the $\gamma^1(\ell)$ for all $\ell \in L(T^1)$ are unique. There is some $\ell^1 \in L(T^1)$ such that $\gamma^1(\ell^1) \notin \mathcal{A}$. As the width of (T^1, γ^1) is less than k and no true subset $X'' \subset X'$ fulfills $\kappa(X'') < k$ and neither $X'' \in \mathcal{A}$ nor $\overline{X''} \in \mathcal{A}$, we know that $\gamma^1(\ell^1) = X'$ and that it is the only leaf with this condition. We denote its neighbor by s^1. Let us now consider all $\ell_1^2, \dots, \ell_m^2 \in L(T^2)$ with $\gamma^2(\ell_i^2) \notin \mathcal{A}$. We know that, for all ℓ_i^2, we have $\gamma^2(\ell_i^2) \subseteq \overline{X'}$. We consider all s_i^2 with $N(\ell_i^2) = \{s_i^2\}$. We modify γ^2 by setting $\gamma^2(s_i^2, \ell_i^2) := \overline{X'}$ and $\gamma^2(\ell_i^2, s_i^2) := X'$. The result will still be a pre-decomposition. Then, we construct a pre-decomposition (T, γ) of U over $\mathcal{A}$. We take m disjoint copies (T_i^1, γ_i^1) of (T^1, γ^1). We



(a) The dendogram corresponding to the data points using single linkage.

(b) Data points used to compute the dendogram.

Figure 1 An example of a dendogram. The distance function used is $\ell_{SL}(X,Y) := \min_{x\in X,y\in Y} \|x-y\|$, where $\|\cdot\|$ is the Euclidean norm. This distance function is used in single linkage.

define

$$V(T) := \bigcup_{1\leq i\leq m} V(T_i^1)\backslash\{\ell_i^1\} \cup V(T^2)\backslash\{\ell_1^2,\dots,\ell_m^2\}$$

and take the union of all edge sets where ℓ_i^1 is replaced by s_i^2 and ℓ_i^2 is replaced by s_i^1. Then, we define $\gamma\colon E(T)\to 2^U$ by

$$\gamma(s,t) := \begin{cases} X' & \text{if } (s,t) = (s_i^1, s_i^2) \text{ for some } 1\leq i\leq m, \\ \overline{X'} & \text{if } (s,t) = (s_i^2, s_i^1) \text{ for some } 1\leq i\leq m, \\ \gamma^1(s,t) & \text{if } s,t\in V(T_i^1) \text{ for some } 1\leq i\leq m, \\ \gamma^2(s,t) & \text{if } s,t\in V(T^2). \end{cases}$$

Then, (T,γ) is a pre-decomposition of U over $\mathcal{A}$ of width less than k. ◀

5 Minimum Distance Function and Hierarchical Clustering

To establish the connection between the δ_{d}-tangles and hierarchical clustering, we use Agglomerative Hierarchical Clustering via single linkage on dissimilarity inputs. A dissimilarity input is an instance, where a small function value describes a large similarity between the points. The result of a hierarchical clustering algorithm is a dendogram. For an arbitrary set U, $\mathcal{P}(U)$ denotes the *set of all partitions* of U.

▶ **Definition 17** ([2]). *A* dendogram *over a finite set* $U = \{x_1,\dots,x_n\}$ *is a function* $\theta\colon [0,\infty)\to\mathcal{P}(U)$*, satisfying the following conditions:*

1. $\theta(0) = \{\{x_1\},\dots,\{x_n\}\}$*,*
2. *there exists* t_0 *such that* $\theta(t) = \{U\}$ *for all* $t\geq t_0$*,*
3. *if* $r\leq s$ *then* $\theta(r)$ *is a* refinement *of* $\theta(s)$*, that is for every* $\mathcal{B}\in\theta(r)$ *there is some* $\mathcal{B}'\in\theta(s)$ *such that* $\mathcal{B}\subseteq\mathcal{B}'$*, and*
4. *for all* r *there exists* $\epsilon>0$ *such that* $\theta(r)=\theta(t)$ *for all* $t\in[r,r+\epsilon]$.

The first and second condition ensure that the trivial partitions are part of the dendogram, with the single elements having the smallest possible value and the whole set giving an upper bound. The third condition states that every partition results from a merge of sets contained in a more refined partition. The last condition is a bit technical, and ensures that θ is right continuous. An example of a dendogram can be seen in Figure 1. We allow more than one cluster to merge in one step, as introduced and analyzed by Carlson and Mémoli [2]. The single linkage clustering in this framework works as follows.

▶ **Definition 18** ([2]). *Let (U, d) be a metric space and let $\ell_{SL}\colon 2^U \times 2^U \to \mathbb{R}$ be the single linkage function on U defined by*

$$\ell_{SL}(\mathcal{A}, \mathcal{B}) := \min_{a \in \mathcal{A}, b \in \mathcal{B}} \mathrm{d}(a, b).$$

Define a sequence of distances $R_0, R_1, R_2, \ldots \in [0, \infty)$ and a corresponding sequence of partitions $\Theta_0, \Theta_1, \Theta_2, \ldots \in \mathcal{P}(U)$ by:

- *$R_0 = 0$ and $\Theta_0 = \{\{x_1\}, \ldots, \{x_n\}\}$, with $U = \{x_1, \ldots, x_n\}$,*
- *$R_{i+1} := \min_{\mathcal{B}, \mathcal{B}' \in \Theta_i} \ell_{SL}(\mathcal{B}, \mathcal{B}')$*
- *$\Theta_{i+1} := \Theta_i / \sim_{R_{i+1}}$, where $\mathcal{B} \sim_{R_{i+1}} \mathcal{B}'$ if there exists a sequence of blocks of distance at most R_{i+1}, thus $\mathcal{B} = \mathcal{B}_1, \ldots, \mathcal{B}_s = \mathcal{B}' \in \Theta_i$ with $\ell_{SL}(\mathcal{B}_k, \mathcal{B}_{k+1}) \leq R_{i+1}$, for $k = 1, \ldots, s-1$.*

Then the dendogram for single linkage *is defined by*

$$\theta^{\ell_{SL}}(r) := \Theta_{i(r)},$$

where $i(r) := \max\{i \mid R_i \leq r\}$.

A less technical way to describe this is, that we start with distance $R_0 = 0$ and the partition into single elements. Then we inductively compute the smallest pairwise distance of any two points separated by the partition Θ_i, store this as the next distance value R_{i+1} and merge the corresponding sets to achieve a new partition Θ_{i+1}. We repeat this step until all sets are merged. The resulting dendogram can be interpreted as a decomposition of the universe into its δ_{d}-tangles, where the non-singular blocks of the dendogram correspond to the tangles. The following theorem is a precise formulation of Theorem 2.

▶ **Theorem 19.** *Let (U, d) be a metric space.*

1. *For every $r \in \mathbb{R}$ and every block $\mathcal{B} \in \theta^{\ell_{SL}}(r)$ with $|\mathcal{B}| > 1$,*

   $$\mathcal{T} := \{X \subseteq U \mid \delta_{\mathrm{d}}(X) < \exp(-r),\ \mathcal{B} \subseteq X\}$$

   is a δ_{d}-tangle of U of order $\exp(-r)$*.*
2. *For every δ_{d}-tangle $\mathcal{T}$ of U of order k we can identify a block $\mathcal{B} \in \theta^{\ell_{SL}}(-\log(k))$ with $|\mathcal{B}| > 1$ such that*

   $$\mathcal{T} = \{X \subseteq U \mid \delta_{\mathrm{d}}(X) < k,\ \mathcal{B} \subseteq X\}.$$

Proof. Using the same arguments as in Example 10 the first statement holds. For the second statement one needs the equivalence relation $\sim_r$ on U, where $x \sim_r y$ if and only if there is a sequence of elements $x = x_1, \ldots, x_s = y \in U$ such that $\mathrm{d}(x_i, x_{i+1}) \leq r$. Carlson and Mémoli [2] have shown that the blocks of $\theta^{\ell_{SL}}(r)$ are exactly the equivalence classes $U/{\sim_r}$.

Let $\mathcal{T}$ be a δ_{d}-tangle of order k. Using Corollary 12 we can find a connected component C in the graph $G = (U, {\delta_{\mathrm{d}}}^k)$ such that $C \subseteq X$, for all $X \in \mathcal{T}$. Looking at the definition ${\delta_{\mathrm{d}}}^k := \{(u, v) \mid \exp(-\mathrm{d}(u, v)) \geq k\}$ we see that two elements $u, v \in U$ are connected in G if and only if for their distance holds $\mathrm{d}(u, v) \leq -\log(k)$, thus $u \sim_{-\log(k)} v$. It follows that the equivalence classes of $U/{\sim_{-\log(k)}}$ are exactly the same as the connected components of G. Thus, there is a block $C = \mathcal{B} \in \theta^{\ell_{SL}}(-\log(k))$ that fulfills the requirement. ◀

▶ Remark 20. Let us consider two popular hierarchical clustering algorithms, average linkage and complete linkage. The algorithm is the same as in Definition 18, but the linkage function ℓ changes. The distance of two sets for complete linkage equals the maximum distance of any point from one set to any point from the other set, thus $\ell_{CL}(X,Y) := \max_{x\in X, y\in Y} \mathrm{d}(x,y)$. Using the same trick as for single linkage, a natural related connectivity function is $\kappa_{\mathrm{d}}(X) := \min_{x\in X, y\in \overline{X}} \exp(-\mathrm{d}(x,y))$, for $X \in 2^U \setminus \{\emptyset, U\}$, and $\kappa_{\mathrm{d}} = 0$, otherwise. This function is maximum-submodular and using the Manhattan distance it is even submodular. But in general, for an arbitrary partition P, it holds that

$$\min_{X,Y\in P} \max_{x\in X, y\in Y} \mathrm{d}(x,y) \neq -\log(\max_{X\in P} \min_{x\in X, x'\in \overline{X}} \exp(-\mathrm{d}(x,x'))),$$

as $\ell_{CL}(X,\overline{X}) = \max_{Y\in P} \ell_{CL}(X,Y)$, for arbitrary $X \in P$. This is different for single linkage. It holds that for any partition P of the universe we have

$$\min_{X,Y\in P} \ell_{SL}(X,Y) = -\log(\max_{X\in P} \delta_{\mathrm{d}}(X)),$$

as $\ell_{SL}(X,\overline{X}) = \min_{Y\in P} \ell_{SL}(X,Y)$, for arbitrary $X \in P$. Thus in contrast to single linkage, the optimum of complete linkage ℓ_{CL} used to compute R_{i+1} does not correspond to the optimum according to the connectivity function κ_{d}. For average linkage ($\ell_{AL}(X,Y) := \sum_{x\in X, y\in Y} \frac{\mathrm{d}(x,y)}{|X||Y|}$), a corresponding set function could be $\varphi_{\mathrm{d}}(X) := \sum_{x\in X, y\in \overline{X}} \frac{\exp(-\mathrm{d}(x,y))}{|X||\overline{X}|}$, for $X \in 2^U \setminus \{\emptyset, U\}$, and $\varphi_{\mathrm{d}} = 0$, otherwise. It is neither submodular nor maximum-submodular. Additionally in general $\ell_{AL}(X,\overline{X})$ is not directly computable from $\ell_{AL}(X,Y)$, for $X, Y \in P$ with P an arbitrary partition. To compute $\ell_{AL}(X,\overline{X})$, also the size of all $Y \in P$ is needed. We have

$$\ell_{AL}(X,\overline{X}) = \frac{\sum_{Y\in P, X\neq Y} |Y| \ell_{AL}(X,Y)}{\sum_{Y\in P, X\neq Y} |Y|}.$$

This makes it even harder to find a suitable connectivity function.

6 Conclusion

We establish a precise technical connection between tangles and hierarchical clustering. We can specify this connection for the minimum distance function and single linkage clustering. It is still an open question if there are other clustering algorithms for which we can find corresponding set functions. One of the main obstacles here is, that tangles and the corresponding set functions only look at global connectivity of some set to its converse whereas hierarchical clustering looks at local connectivity between two sets. For single linkage these two notions turned out to be the same.

Our second contribution is to show duality between tangles and branch decompositions for a new class of functions. In our view, the key transformation in the proof of the Duality Theorem is the Exactness Lemma (related to „shifting“ in [6]); this is where submodularity or maximum-submodularity comes in. To broaden the theory, it will be essential to understand under which general conditions such a transformation is possible.

Approximating the Orthogonality Dimension of Graphs and Hypergraphs

Ishay Haviv
School of Computer Science, The Academic College of Tel Aviv-Yaffo, Tel Aviv 61083, Israel

Abstract

A t-dimensional orthogonal representation of a hypergraph is an assignment of nonzero vectors in $\mathbb{R}^t$ to its vertices, such that every hyperedge contains two vertices whose vectors are orthogonal. The orthogonality dimension of a hypergraph H, denoted by $\overline{\xi}(H)$, is the smallest integer t for which there exists a t-dimensional orthogonal representation of H. In this paper we study computational aspects of the orthogonality dimension of graphs and hypergraphs. We prove that for every $k \geq 4$, it is NP-hard (resp. quasi-NP-hard) to distinguish n-vertex k-uniform hypergraphs H with $\overline{\xi}(H) \leq 2$ from those satisfying $\overline{\xi}(H) \geq \Omega(\log^{\delta} n)$ for some constant $\delta > 0$ (resp. $\overline{\xi}(H) \geq \Omega(\log^{1-o(1)} n)$). For graphs, we relate the NP-hardness of approximating the orthogonality dimension to a variant of a long-standing conjecture of Stahl. We also consider the algorithmic problem in which given a graph G with $\overline{\xi}(G) \leq 3$ the goal is to find an orthogonal representation of G of as low dimension as possible, and provide a polynomial time approximation algorithm based on semidefinite programming.

1 Introduction

A t-dimensional *orthogonal representation* of a hypergraph $H = (V, E)$ is an assignment of a nonzero real vector $u_v \in \mathbb{R}^t$ to every vertex $v \in V$, such that every hyperedge $e \in E$ contains two vertices $v, v' \in e$ whose vectors u_v and $u_{v'}$ are orthogonal. The *orthogonality dimension* of H, denoted by $\overline{\xi}(H)$, is the smallest integer t for which there exists a t-dimensional orthogonal representation of H.[1] The notion of orthogonal representations was introduced for graphs by Lovász [38] in the study of the Shannon capacity and was later involved in a geometric characterization of connectivity properties of graphs by Lovász, Saks, and Schrijver [40]. The orthogonality dimension over the complex field was used by de Wolf [15] in a characterization of the quantum one-round communication complexity of promise equality problems and by Cameron et al. [11] in the study of the quantum chromatic number of graphs (see also [43, 7, 8]). An extension of orthogonal representations, called orthogonal bi-representations, was introduced by Haemers [26] and has found several further applications to information theory and to theoretical computer science.

[1] Orthogonal representations of *graphs* are sometimes defined in the literature as orthogonal representations of the complement, namely, the definition requires vectors associated with *non-adjacent* vertices to be orthogonal. In this paper we have decided to use the other definition because it is extended more naturally to hypergraphs. For a graph G, one can view the notation $\overline{\xi}(G)$ as standing for $\xi(\overline{G})$.

Orthogonal representations can be viewed as a generalization of hypergraph vertex colorings, one of the most fundamental and extensively studied topics in graph theory. Recall that a hypergraph H is said to be c-colorable if one can assign one of c colors to every vertex of H such that no hyperedge is monochromatic. The chromatic number of H, denoted by $\chi(H)$, is the smallest integer c for which H is c-colorable. Obviously, every c-coloring of H induces a c-dimensional orthogonal representation of H by assigning the ith unit vector $e_i \in \mathbb{R}^c$ to every vertex colored by the ith color. On the other hand, given a t-dimensional orthogonal representation $(u_v)_{v \in V}$ of H one can assign to every vertex v the vector in $\{-1, 0, +1\}^t$ that consists of the signs of the entries of u_v, and since nonzero orthogonal vectors have distinct sign vectors it follows that H is 3^t-colorable. We conclude that every hypergraph H satisfies

$$\log_3 \chi(H) \leq \overline{\xi}(H) \leq \chi(H). \tag{1}$$

The upper bound in (1) can clearly be tight (take, e.g., a complete graph), and it turns out that there exist graphs whose orthogonality dimension is exponentially smaller than their chromatic number (see Proposition 7).

The current work studies the problem of approximating the orthogonality dimension of graphs and hypergraphs. This research direction was already suggested in the late eighties by Lovász et al. [40], who remarked that computing the orthogonality dimension of graphs seems to be a difficult task (see also [39]). Nevertheless, the only hardness result we are aware of for this graph parameter is the one of Peeters [42], who proved that for every $t \geq 3$ it is NP-hard to decide whether an input graph G satisfies $\overline{\xi}(G) \leq t$ (see also [7]). Before stating our hardness and algorithmic results, we overview related previous work on graph and hypergraph coloring.

1.1 Graph and Hypergraph Coloring

It is well known that the problem of deciding whether an input graph is c-colorable can be easily solved in polynomial time for $c \in \{1, 2\}$ and is NP-hard for every $c \geq 3$ [30].

In 1976, Garey and Johnson [21] have discovered an interesting connection between hardness of graph coloring and the multichromatic numbers of Kneser graphs. For integers $d \geq 2s$, the *Kneser graph* $K(d, s)$ is the graph whose vertices are all the s-subsets of $[d]$, where two sets are adjacent if they are disjoint. A *k-tuple coloring* f of a graph $G = (V, E)$ is an assignment $f(v)$ of a set of k colors to every vertex $v \in V$ such that $f(v) \cap f(v') = \emptyset$ whenever v and v' are adjacent in G. The *kth multichromatic number* of G, denoted by $\chi_k(G)$, is the smallest integer c for which G has a k-tuple coloring with c colors. Equivalently, $\chi_k(G)$ is the smallest integer c for which there exists a homomorphism from G to the Kneser graph $K(c, k)$. Note that $\chi_1(G)$ is simply the standard chromatic number $\chi(G)$. In the seventies, Stahl [45] has made the following conjecture regarding the multichromatic numbers of Kneser graphs (see also [19]).

▶ **Conjecture 1** ([45]). *For all integers k and $d \geq 2s$,*

$$\chi_k(K(d, s)) = \left\lceil \frac{k}{s} \right\rceil \cdot (d - 2s) + 2k.$$

More than forty years later, Conjecture 1 is still widely open. While the right-hand side in the conjecture is known to form an upper bound on $\chi_k(K(d, s))$ for all values of k, d and s, the conjecture was confirmed only for a few special cases. For $k = 1$, the conjecture was proved by Lovász [37] in a breakthrough application of algebraic topology confirming a conjecture by Kneser [33]. Stahl [45] proved that the conjecture holds whenever $1 \leq k \leq s$,

$d = 2s + 1$, or k is divisible by s. Garey and Johnson [21] proved the case of $s = 3$ and $k = 4$, namely, that $\chi_4(K(d,3)) = 2d - 4$, and used it in the analysis of a reduction from 3-colorability to prove that for every $c \geq 6$, it is NP-hard to distinguish between graphs G that satisfy $\chi(G) \leq c$ and those that satisfy $\chi(G) \geq 2c - 4$.

In 1993, Khanna, Linial, and Safra [32] proved that it is NP-hard to decide whether an input graph G satisfies $\chi(G) \leq 3$ or $\chi(G) \geq 5$ (see also [25]). As observed in [6], combining this result with the proof technique of [21] and the case of $s = 3$ and $k = 5$ in Conjecture 1 proved by Stahl [46] (who confirmed there the conjecture for $s \leq 3$ and all integers k and d), it follows that for every $c \geq 6$ it is NP-hard to distinguish between the cases $\chi(G) \leq c$ and $\chi(G) \geq 2c - 2$. Brakensiek and Guruswami [6] improved this result using different techniques and proved the NP-hardness of deciding whether a given graph G satisfies $\chi(G) \leq c$ or $\chi(G) \geq 2c - 1$ for all $c \geq 3$. In a recent work of Bulín, Krokhin, and Opršal [10], the latter condition was further improved to $\chi(G) \geq 2c$. We note that Dinur, Mossel, and Regev [16] proved that assuming a certain variant of the unique games conjecture, deciding whether a given graph G satisfies $\chi(G) \leq 3$ or $\chi(G) \geq c$ is NP-hard for every $c \geq 4$.

We next consider, for any constant $k \geq 3$, the problem of deciding whether an input k-uniform hypergraph (i.e., a hypergraph each of its hyperedges contains exactly k vertices) is c-colorable. While the problem can clearly be solved in polynomial time for $c = 1$, it was shown to be NP-hard for $c = 2$ and $k = 3$ by Lovász [36], motivating the study of the following gap problem: Given an n-vertex k-uniform hypergraph H, decide whether $\chi(H) \leq 2$ or $\chi(H) \geq c$. Guruswami, Håstad, and Sudan [24] proved that the problem is NP-hard for $k \geq 4$ and every constant $c \geq 3$. By combining their proof with the later PCP theorem of Moshkovitz and Raz [41], this result also follows for the super-constant $c = \Omega(\frac{\log\log n}{\log\log\log n})$. For $k = 3$, the NP-hardness was proved for every constant $c \geq 3$ by Dinur, Regev, and Smyth [17]. Their proof approach was extended in a recent work of Bhangale [3], who obtained NP-hardness for every $k \geq 4$ with the improved super-constant $c = \Omega(\log^{\delta} n)$ where $\delta > 0$ is some constant. Under the complexity assumption $\mathsf{NP} \not\subseteq \mathsf{DTIME}(2^{\mathrm{poly}(\log n)})$, several stronger hardness results are known. This includes the case of $k = 3$ and $c = \Omega(\sqrt[3]{\log\log n})$ proved in [17] and the case of $k \geq 4$ and $c = \Omega(\frac{\log n}{\log\log n})$ proved in [3]. For additional related results see, e.g., [3, Table 1] and the references therein.

On the algorithmic side, significant efforts have been made in the literature to obtain polynomial time algorithms for coloring n-vertex 3-colorable graphs using as few colors as possible. This line of research was initiated by a simple algorithm of Wigderson [47] that used $O(\sqrt{n})$ colors. In a series of increasingly sophisticated combinatorial algorithms, Blum [4] improved the number of colors to $\widetilde{O}(n^{3/8})$. Then, Karger, Motwani, and Sudan [29] introduced an algorithm based on a semidefinite relaxation and improved the number of colors to $\widetilde{O}(n^{1/4})$. Combining the combinatorial approach of [4] and the semidefinite relaxation of [29], Blum and Karger [4, 5] improved it to $\widetilde{O}(n^{3/14})$, which was later improved by Arora, Chlamtac, and Charikar [2] and by Chlamtac [13] to $\widetilde{O}(n^{0.2111})$ and $\widetilde{O}(n^{0.2072})$ respectively. The combinatorial component of these algorithms was recently improved by Kawarabayashi and Thorup [31], who reduced the number of colors to $\widetilde{O}(n^{0.19996})$. Halperin et al. [27] have obtained analogue results for coloring n-vertex c-colorable graphs for all constants $c \geq 4$, e.g., for $c = 4$ there exists an efficient algorithm that uses $\widetilde{O}(n^{7/19})$ colors.

For hypergraphs, there exists a simple combinatorial algorithm that given an n-vertex k-uniform 2-colorable hypergraph finds in polynomial time a coloring with $\widetilde{O}(n^{1-1/k})$ colors, as was shown independently by Alon et al. [1] and by Chen and Frieze [12]. For $k = 3$, this algorithm was combined in [1, 12] with the semidefinite programming approach of [29] to obtain a better bound of $\widetilde{O}(n^{2/9})$, which was later improved to $\widetilde{O}(n^{1/5})$ by Krivelevich, Nathaniel, and Sudakov [35]. We note, however, that Alon et al. [1] have provided evidence that the powerful semidefinite approach cannot be applied to coloring k-uniform hypergraphs for $k \geq 4$.

1.2 Our Contribution

The present paper offers hardness and algorithmic results on the orthogonality dimension of graphs and hypergraphs. We first mention that known hardness results on the chromatic number can be used to derive hardness results for the orthogonality dimension. Indeed, the inequalities given in (1) yield that for every integers t_1 and t_2, NP-hardness of deciding whether an input k-uniform hypergraph H satisfies $\chi(H) \leq t_1$ or $\chi(H) \geq t_2$ immediately implies the NP-hardness of deciding whether it satisfies $\overline{\xi}(H) \leq t_1$ or $\overline{\xi}(H) \geq \log_3 t_2$. In particular, the hardness results of [17, 25] imply that for all constants $k \geq 3$ and $t \geq 3$, it is NP-hard to decide whether an input k-uniform hypergraph H satisfies $\overline{\xi}(H) \leq 2$ or $\overline{\xi}(H) \geq t$. For $k = 2$, such a result follows from [16] under a variant of the unique games conjecture. However, for super-constant hardness gaps this implication leads to an exponential loss. In particular, it follows from [3] that for every $k \geq 4$ it is NP-hard to distinguish n-vertex k-uniform hypergraphs H with $\overline{\xi}(H) \leq 2$ from those satisfying $\overline{\xi}(H) \geq \Omega(\log \log n)$. We prove that this exponential loss can be avoided.

▶ **Theorem 2.** *Let $k \geq 4$ be a fixed integer.*

1. *There exists a constant $\delta > 0$ for which it is NP-hard to decide whether an input n-vertex k-uniform hypergraph H satisfies $\overline{\xi}(H) \leq 2$ or $\overline{\xi}(H) \geq \log^{\delta} n$.*
2. *Assuming $\mathsf{NP} \nsubseteq \mathsf{DTIME}(n^{O(\log \log n)})$, for every constant $c > 0$ there is no polynomial time algorithm that decides whether an input n-vertex k-uniform hypergraph H satisfies $\overline{\xi}(H) \leq 2$ or $\overline{\xi}(H) \geq c \cdot \frac{\log n}{\log \log n}$.*

We next consider the hardness of approximating the orthogonality dimension of *graphs*. Our result involves a generalization of orthogonal representations of graphs defined as follows. A t-dimensional *orthogonal k-subspace representation* of a graph $G = (V, E)$ is an assignment of a subspace $U_v \subseteq \mathbb{R}^t$ with $\dim(U_v) = k$ to every vertex $v \in V$, such that the subspaces U_v and $U_{v'}$ are orthogonal whenever v and v' are adjacent in G. For a graph G, let $\overline{\xi}_k(G)$ denote the smallest integer t for which there exists a t-dimensional orthogonal k-subspace representation of G. Note that $\overline{\xi}_1(G) = \overline{\xi}(G)$ for every graph G. We prove the following result.

▶ **Theorem 3.** *For every graph F, it is NP-hard to decide whether an input graph G satisfies $\overline{\xi}(G) \leq \overline{\xi}_3(F)$ or $\overline{\xi}(G) \geq \overline{\xi}_4(F)$.*

With Theorem 3 in hand, it is of interest to find graphs F for which $\overline{\xi}_4(F)$ is large compared to $\overline{\xi}_3(F)$. We consider here, in light of Conjecture 1, the behavior of the $\overline{\xi}_k$ parameters on the Kneser graphs $K(d, s)$. For $k = 1$, it was recently shown that the orthogonality dimension and the chromatic number coincide on Kneser graphs [28]. We further observe, as an application of a result of Bukh and Cox [9], that the values of χ_k and $\overline{\xi}_k$ coincide on the Kneser graphs $K(d, s)$ for every k divisible by s (that is, for all integers $\ell \geq 1$ and $d \geq 2s$, $\overline{\xi}_{\ell \cdot s}(K(d, s)) = \chi_{\ell \cdot s}(K(d, s)) = \ell \cdot d$, and in particular $\overline{\xi}_3(K(d, 3)) = d$; see Corollary 17). It would be natural to ask whether this is also the case for $k = 4$ and $s = 3$.

▶ **Question 4.** *Is it true that for every $d \geq 6$, $\overline{\xi}_4(K(d, 3)) = 2d - 4$?*

A positive answer to Question 4 would imply that for every $t \geq 6$, it is NP-hard to decide whether an input graph G satisfies $\overline{\xi}(G) \leq t$ or $\overline{\xi}(G) \geq 2t-4$, analogously to the hardness result of [21] for the chromatic number.[2]

We finally consider the algorithmic problem in which given an n-vertex k-uniform hypergraph H with constant orthogonality dimension, the goal is to find an orthogonal representation of H of as low dimension as possible. It is not difficult to show that a hypergraph H satisfies $\overline{\xi}(H) \leq 2$ if and only if it is 2-colorable. Hence, by the algorithm of Krivelevich et al. [35], given an n-vertex 3-uniform hypergraph H with $\overline{\xi}(H) \leq 2$ it is possible to efficiently find a coloring of H that uses $\widetilde{O}(n^{1/5})$ colors, and, in particular, to obtain an orthogonal representation of H of this dimension. For graphs, the first nontrivial case is where we are given as input an n-vertex graph G with $\overline{\xi}(G) \leq 3$, for which we prove the following result.

▶ **Theorem 5.** *There exists a randomized polynomial time algorithm that given an n-vertex graph G satisfying $\overline{\xi}(G) \leq 3$, finds a coloring of G that uses at most $\widetilde{O}(n^{0.2413})$ colors. In particular, the algorithm finds an orthogonal representation of G of dimension $\widetilde{O}(n^{0.2413})$.*

In fact, we prove a stronger statement than that of Theorem 5, allowing the input graph G to satisfy $\overline{\xi}_k(G) \leq 3k$ for some integer k (rather than the special case $k = 1$; see Theorem 23).

1.3 Overview of Proofs

Hardness of Approximating the Orthogonality Dimension of Hypergraphs

Theorem 2 is proved in two steps. In the first, we show that approximating the orthogonality dimension of k-uniform hypergraphs becomes harder as the uniformity parameter k grows, and in the second we prove the hardness result for 4-uniform hypergraphs. By combining the two, Theorem 2 follows. We elaborate below on each of these two steps.

The uniformity reduction

Our goal is to show that for every $k_1 \leq k_2$, one can efficiently transform a given k_1-uniform hypergraph H_1 to a k_2-uniform hypergraph H_2 so that $\overline{\xi}(H_1) = \overline{\xi}(H_2)$. We borrow a reduction used in [24] for hypergraph coloring and prove that it preserves the orthogonality dimension. For simplicity of presentation, let us consider here the case of $k_1 = 2$ and $k_2 = 4$. Given an n-vertex graph $G = (V, E)$ we construct a 4-uniform hypergraph H whose vertex set consists of ℓ copies $V_1, \ldots, V_\ell$ of V. For $i \in [\ell]$, let E_i denote the collection of 2-subsets of V_i that correspond to the edges of G. The hyperedges of H are defined as all possible unions of pairs of sets picked from distinct collections E_i and E_j.

As a warm-up, we observe that for a sufficiently large ℓ, say $\ell = n+1$, we have $\chi(G) = \chi(H)$. Indeed, if G is c-colorable then the c-coloring of G applied to each of the copies of V in H implies that H is c-colorable. On the other hand, if G is not c-colorable then for every coloring of H by c colors, every graph (V_i, E_i) contains a monochromatic edge. By $\ell > c$, there are $i \neq j$ and sets $e_1 \in E_i$ and $e_2 \in E_j$ such that all vertices of $e_1 \cup e_2$ share the same color. This implies the existence of a monochromatic hyperedge in H, hence H is not c-colorable.

We next show that for a sufficiently large ℓ we have $\overline{\xi}(G) = \overline{\xi}(H)$. The first direction is equally easy, namely, if G has a t-dimensional orthogonal representation then by assigning its vectors to every copy of V in H we get a t-dimensional orthogonal representation of

[2] It can be shown, using a result of [9], that every $d \geq 6$ satisfies $\overline{\xi}_4(K(d,3)) \geq \lceil 4d/3 \rceil$ (see Lemma 16). Combining this bound with Theorem 3, it follows that for every $t \geq 6$ it is NP-hard to decide whether an input graph G satisfies $\overline{\xi}(G) \leq t$ or $\overline{\xi}(G) \geq \lceil 4t/3 \rceil$.

H. For the other direction, assume that G satisfies $\overline{\xi}(G) > t$, and suppose for the sake of contradiction that $\overline{\xi}(H) \leq t$, i.e., there exists a t-dimensional orthogonal representation $(u_v)_{v \in V(H)}$ of H. By $\overline{\xi}(G) > t$, for every $i \in [\ell]$ there are two vertices $a_i, b_i \in V_i$ adjacent in G whose vectors are not orthogonal, that is, $\langle u_{a_i}, u_{b_i} \rangle \neq 0$. Now, it suffices to show that for some $i \neq j$ the four vectors $u_{a_i}, u_{b_i}, u_{a_j}, u_{b_j}$ are pairwise non-orthogonal, as this would imply a contradiction to the fact that $\{a_i, b_i, a_j, b_j\}$ is a hyperedge of H. It is not difficult to see that for some $i \neq j$ the vectors u_{a_i} and u_{b_j} are not orthogonal. Indeed, let $M_1 \in \mathbb{R}^{\ell \times t}$ be the matrix whose rows are the vectors u_{a_i} for $i \in [\ell]$, and let $M_2 \in \mathbb{R}^{\ell \times t}$ be the matrix whose rows are the vectors u_{b_i} for $i \in [\ell]$. Consider the matrix $M \in \mathbb{R}^{\ell \times \ell}$ defined by $M = M_1 \cdot M_2^T$, and notice that its diagonal entries are all nonzero (because $\langle u_{a_i}, u_{b_i} \rangle \neq 0$ for every i) and that its rank is at most t. Assuming that $\ell > t$, the matrix M must have some nonzero non-diagonal entry (otherwise its rank is ℓ), implying that $\langle u_{a_i}, u_{b_j} \rangle \neq 0$ for some $i \neq j$. This, however, still does not complete the argument, since it might be the case that for these indices i and j, one of the inner products $\langle u_{a_i}, u_{a_j} \rangle$, $\langle u_{b_i}, u_{a_j} \rangle$, and $\langle u_{b_i}, u_{b_j} \rangle$ is zero, avoiding the contradiction.

To overcome this difficulty, we use a symmetrization argument showing that the assumption $\overline{\xi}(H) \leq t$ implies that H has some t'-dimensional orthogonal representation $(w_v)_{v \in V(H)}$, where t' is not too large, with the following symmetry property: For every i and j, if $\langle w_{a_i}, w_{b_j} \rangle \neq 0$ then the inner products $\langle w_{a_i}, w_{a_j} \rangle$, $\langle w_{b_i}, w_{a_j} \rangle$, and $\langle w_{b_i}, w_{b_j} \rangle$ are all nonzero. With such an orthogonal representation, applying the above argument with $\ell > t'$ would certainly imply a contradiction and complete the proof. We achieve the symmetry property for $t' = t^4$ using vector tensor products. Namely, we assign to every vertex a_i the vector $w_{a_i} = u_{a_i} \otimes u_{b_i} \otimes u_{a_i} \otimes u_{b_i}$, to every vertex b_i the vector $w_{b_i} = u_{a_i}^{\otimes 2} \otimes u_{b_i}^{\otimes 2}$, and to every other vertex v the vector $w_v = u_v^{\otimes 4}$. It is straightforward to verify that $(w_v)_{v \in V(H)}$ forms a t'-dimensional orthogonal representation of H. Moreover, by standard properties of tensor products we have

$$\langle w_{a_i}, w_{b_j} \rangle = \langle u_{a_i}, u_{a_j} \rangle \cdot \langle u_{b_i}, u_{a_j} \rangle \cdot \langle u_{a_i}, u_{b_j} \rangle \cdot \langle u_{b_i}, u_{b_j} \rangle,$$

which can be used to obtain that if $\langle w_{a_i}, w_{b_j} \rangle \neq 0$ then the other three inner products $\langle w_{a_i}, w_{a_j} \rangle$, $\langle w_{b_i}, w_{a_j} \rangle$, and $\langle w_{b_i}, w_{b_j} \rangle$ are nonzero as well. This completes the proof sketch for $k_1 = 2$ and $k_2 = 4$. For the proof of the general case, we generalize the tensor-based argument to k-tuples of vertices and extend the matrix reasoning applied above using bounds on off-diagonal Ramsey numbers.

Hardness for 4-uniform hypergraphs

We next consider the hardness of approximating the orthogonality dimension of 4-uniform hypergraphs. A significant difficulty in proving such a result lies at the challenge of proving strong lower bounds on the orthogonality dimension. For the sake of comparison, in most hardness proofs for hypergraph coloring the lower bound on the chromatic number of the hypergraph H constructed by the reduction is shown by an upper bound on its independence number $\alpha(H)$ and the standard inequality $\chi(H) \geq \frac{|V(H)|}{\alpha(H)}$. This approach cannot be used for the orthogonality dimension, which in certain cases can be exponentially smaller than this ratio (see Proposition 7). Exceptions of this approach, where the lower bound on the chromatic number is not proved via the independence number, are the works of Dinur et al. [17] and Bhangale [3] on which we elaborate next.

A standard technique in proving hardness of approximation results is to reduce from the Label Cover problem, in which given a collection of constraints over a set of variables the goal is to decide whether there exists an assignment that satisfies all the constraints or any assignment satisfies only a small fraction of them. In such reductions, every variable over a domain $[R]$ is encoded via an error-correcting code known as the long code, and the constraints are replaced by "inner" constraints designed for the specific studied problem. One way to view the long code is as the graph whose vertices are all subsets of $[R]$ where two sets are adjacent if they are disjoint [18]. In the hardness proof of [17] for the chromatic number of 3-uniform hypergraphs, this graph was replaced by the induced subgraph that consists only of subsets of a given size (i.e., a Kneser graph), where a label $\alpha \in [R]$ is encoded by the 2-coloring of the vertices according to whether the sets contain α or not. The analysis of [17] is crucially based on the large chromatic number of Kneser graphs [37] and on the property that every coloring of Kneser graphs with number of colors smaller than their chromatic number enforces a large color class that includes a monochromatic edge. The latter property was proved in [17] using the chromatic number of the Schrijver graph [44], a vertex-critical subgraph of the Kneser graph. The approach of [17] was recently extended by Bhangale [3], who used in his long code construction only the vertices of the Schrijver graph. The fact that this subgraph has much fewer vertices and yet large chromatic number has led to improved hardness factors. However, for the analysis to work the "inner" constraints had to include four vertices, and this is the reason that the result was obtained for 4-uniform hypergraphs (and not for 3-uniform hypergraphs as in [17]).

In the current work we prove the hardness of approximating the orthogonality dimension of 4-uniform hypergraphs using the reduction applied in [3] for hypergraph coloring. While we achieve the same hardness factors as in [3], the analysis relies on several different ideas and tools. This includes the aforementioned symmetrization argument for orthogonal representations, a lower bound of Golovnev et al. [23] on the sparsity of low rank matrices with nonzero entries on the diagonal, and the orthogonality dimension of Schrijver graphs determined in [28] (see Theorem 8).

Hardness of Approximating the Orthogonality Dimension of Graphs

Theorem 3 relates the hardness of approximating the orthogonality dimension of graphs to orthogonal subspace representations. Our starting point is the NP-hardness of deciding whether an input graph G satisfies $\overline{\xi}(G) \leq 3$ [42]. Following an approach of Garey and Johnson [21], our reduction constructs a graph G' defined as the lexicographic product of some fixed graph F and the input graph G. Namely, we replace every vertex of F by a copy of G and replace every edge of F by a complete bipartite graph between the vertex sets associated with its endpoints (see Definition 11). We then show that if $\overline{\xi}(G) \leq 3$ then G' has a $\overline{\xi}_3(F)$-dimensional orthogonal representation, whereas if $\overline{\xi}(G) \geq 4$ the orthogonality dimension of G' is at least $\overline{\xi}_4(F)$. It would be interesting to figure out the best hardness factors that Theorem 3 can yield (see Question 4). We note, though, that our approach is limited to multiplicative hardness gaps bounded by 2, as it is easy to see that every graph F satisfies $\overline{\xi}_4(F) \leq \overline{\xi}_3(F) + \overline{\xi}_1(F) \leq 2 \cdot \overline{\xi}_3(F)$.

Coloring Graphs with Orthogonality Dimension Three

Consider the problem in which given an n-vertex graph G satisfying $\overline{\xi}(G) \leq 3$, the goal is to find an orthogonal representation of G of as low dimension as possible. Employing an approach of [14], we attempt to find a coloring of G with a small number of colors, as this in particular gives an orthogonal representation of the same dimension. As mentioned before, for every $c \geq 3$ there are known efficient algorithms for coloring n-vertex c-colorable graphs, however, our only guarantee on G is that its orthogonality dimension is at most 3.

Interestingly, it follows from a theorem of Kochen and Specker [34] (see also [22]) that the largest possible chromatic number of such a graph is 4. It follows that given an n-vertex graph G with $\overline{\xi}(G) \leq 3$, one can simply apply the efficient algorithm of [27] for coloring 4-colorable graphs to obtain a coloring of G by $\widetilde{O}(n^{\gamma})$ colors where $\gamma = 7/19 \approx 0.368$.

To improve on this bound, we show an efficient algorithm that finds a large independent set in a given graph G satisfying $\overline{\xi}(G) \leq 3$. We consider two cases according to the maximum degree in the graph. If G has a vertex of large degree then the algorithm finds a large independent set in its neighborhood. This can be done since the assumption $\overline{\xi}(G) \leq 3$ implies that the neighborhood of every vertex of G is 2-colorable (just as for 3-colorable graphs). Otherwise, in case that all the degrees in G are small, we use an algorithm of Karger et al. [29] based on a semidefinite relaxation of the chromatic number, called the *vector chromatic number*. Our analysis relies on a result by Lovász [38] relating the (strict) vector chromatic number of graphs to their orthogonality dimension. Now, by repeatedly omitting independent sets in G, we obtain a coloring that uses $\widetilde{O}(n^{1/4})$ colors. This can be slightly improved to $\widetilde{O}(n^{0.2413})$ by applying the refined analysis of Arora et al. [2] for the rounding algorithm of [29].

As already mentioned, our algorithm can handle any graph G that satisfies $\overline{\xi}_k(G) \leq 3k$ for some integer k, rather than for $k = 1$ (see Theorem 23). The generalized analysis involves a connection, recently proved by Bukh and Cox [9], between the (strict) vector chromatic number and the graph parameters $\overline{\xi}_k$.

1.4 Outline

The rest of the paper is organized as follows. In Section 2, we provide some background on the orthogonality dimension and on the Kneser and Schrijver graphs. In Section 3, we prove our hardness and algorithmic results on the orthogonality dimension of graphs, confirming Theorems 3 and 5. The analysis of the uniformity reduction and the proof of Theorem 2 can be found in the full version of the paper.

2 Preliminaries

2.1 Orthogonality Dimension

We define the orthogonality dimension of hypergraphs over a general field.

▶ **Definition 6.** *A t-dimensional* orthogonal representation *of a hypergraph $H = (V, E)$ over a field $\mathbb{F}$ is an assignment of a vector $u_v \in \mathbb{F}^t$ with $\langle u_v, u_v \rangle \neq 0$ to every vertex $v \in V$, such that for every hyperedge $e \in E$ there are two vertices $v, v' \in e$ satisfying $\langle u_v, u_{v'} \rangle = 0$. The* orthogonality dimension *of a hypergraph $H = (V, E)$ over $\mathbb{F}$, denoted by $\overline{\xi}(H, \mathbb{F})$, is the smallest integer t for which there exists a t-dimensional orthogonal representation of H over $\mathbb{F}$. For the real field $\mathbb{R}$, we let $\overline{\xi}(H)$ stand for $\overline{\xi}(H, \mathbb{R})$.*

The following proposition shows that there are graphs whose orthogonality dimension is exponentially smaller than their chromatic number.

▶ **Proposition 7.** *There exists an explicit family of graphs G_t such that $\overline{\xi}(G_t) \leq t$ and $\chi(G_t) \geq 2^{\Omega(t)}$.*

Proof. Let t be an integer divisible by 4. Consider the graph $G_t = (V, E)$ whose vertices are all the $\frac{t}{2}$-subsets of $[t]$ where two sets $A, B \in V$ are adjacent if their intersection size satisfies $|A \cap B| = \frac{t}{4}$. Notice that by $|A| = |B| = \frac{t}{2}$, this condition is equivalent to $|A \triangle B| = \frac{t}{2}$.

Assign to every vertex A the vector $u_A \in \{\pm 1\}^t$ where $(u_A)_i = +1$ if $i \in A$ and $(u_A)_i = -1$ otherwise. We claim that $(u_A)_{A \in V}$ is an orthogonal representation of G_t. Indeed, for every adjacent vertices $A, B \in V$ we have

$$\langle u_A, u_B \rangle = (-1) \cdot |A \triangle B| + (t - |A \triangle B|) = t - 2 \cdot |A \triangle B| = 0.$$

This implies that $\overline{\xi}(G_t) \leq t$. On the other hand, by a celebrated result of Frankl and Rödl [20], $\alpha(G_t) \leq 2^{c \cdot t}$ for some $c < 1$, implying that

$$\chi(G_t) \geq \frac{|V|}{\alpha(G_t)} \geq \frac{\binom{t}{t/2}}{2^{c \cdot t}} \geq 2^{(1-c-o(1)) \cdot t},$$

completing the proof. ◀

2.2 Kneser and Schrijver Graphs

For integers $d \geq 2s$, the *Kneser graph* $K(d,s)$ is the graph whose vertices are all the s-subsets of $[d]$, where two sets are adjacent if they are disjoint.

A set $A \subseteq [d]$ is said to be *stable* if it does not contain two consecutive elements modulo d (that is, if $i \in A$ then $i+1 \notin A$, and if $d \in A$ then $1 \notin A$). In other words, a stable subset of $[d]$ is an independent set in the cycle C_d with the numbering from 1 to d along the cycle. For integers $d \geq 2s$, the *Schrijver graph* $S(d,s)$ is the graph whose vertices are all the stable s-subsets of $[d]$, where two sets are adjacent if they are disjoint.

The orthogonality dimension of the Kneser and Schrijver graphs was determined in [28] using topological methods.

▶ **Theorem 8** ([28]). *For every $d \geq 2s$, $\overline{\xi}(K(d,s)) = \overline{\xi}(S(d,s)) = d - 2s + 2$.*

The number of vertices in $K(d,s)$ is clearly $\binom{d}{s}$. We need the following simple bound, given in [17], on the number of vertices in $S(d,s)$.

▶ **Lemma 9** ([17]). *For every $d \geq 2s$, the number of vertices in $S(d,s)$ is at most $\binom{d}{d-2s}$.*

3 The Orthogonality Dimension of Graphs

In this section we focus on the orthogonality dimension of graphs and prove Theorems 3 and 5.

3.1 Orthogonal Subspace Representations

We generalize the notion of orthogonal representations over the real field by assigning to every vertex a subspace of a given dimension, so that adjacent vertices are assigned to orthogonal subspaces.

▶ **Definition 10.** *A t-dimensional* orthogonal k-subspace representation *of a graph $G = (V,E)$ is an assignment of a subspace $U_v \subseteq \mathbb{R}^t$ with $\dim(U_v) = k$ to every vertex $v \in V$, such that the subspaces U_v and $U_{v'}$ are orthogonal whenever v and v' are adjacent in G. For a graph G, let $\overline{\xi}_k(G)$ denote the smallest integer t for which there exists a t-dimensional orthogonal k-subspace representation of G.*

Clearly, $\overline{\xi}(G) = \overline{\xi}_1(G)$ for every graph G. It is also easy to see that the multichromatic numbers of graphs, defined in Section 1.1, bound the parameters $\overline{\xi}_k$ from above, namely, $\overline{\xi}_k(G) \leq \chi_k(G)$ for every G and k.

3.2 Hardness

In this section we prove Theorem 3, namely that for every graph F, it is NP-hard to decide whether an input graph G satisfies $\overline{\xi}(G) \leq \overline{\xi}_3(F)$ or $\overline{\xi}(G) \geq \overline{\xi}_4(F)$. The proof employs the notion of lexicographic product of graphs, defined as follows.

▶ **Definition 11.** *The* lexicographic product *of the graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, denoted by $G_1 \bullet G_2$, is the graph whose vertex set is $V_1 \times V_2$ where two vertices (x_1, y_1) and (x_2, y_2) are adjacent if either $\{x_1, x_2\} \in E_1$ or $x_1 = x_2$ and $\{y_1, y_2\} \in E_2$.*

One can view the graph $G_1 \bullet G_2$ as the graph obtained from G_1 by replacing every vertex by a copy of G_2 and replacing every edge by a complete bipartite graph between the vertex sets associated with its endpoints. We need the following property of the orthogonality dimension of lexicographic products of graphs.

▶ **Lemma 12.** *For every two graphs G_1 and G_2, $\overline{\xi}(G_1 \bullet G_2) = \overline{\xi}_k(G_1)$ where $k = \overline{\xi}(G_2)$.*

Proof. Let $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ be two graphs and denote $k = \overline{\xi}(G_2)$.

We first prove that $\overline{\xi}(G_1 \bullet G_2) \geq \overline{\xi}_k(G_1)$. Denote $t = \overline{\xi}(G_1 \bullet G_2)$, then there exists a t-dimensional orthogonal representation $(u_{(x,y)})_{(x,y) \in V_1 \times V_2}$ of $G_1 \bullet G_2$. For every $x \in V_1$, let U_x denote the subspace of $\mathbb{R}^t$ spanned by all vectors $u_{(x,y)}$ with $y \in V_2$. By the definition of $G_1 \bullet G_2$, the subspaces U_x and $U_{x'}$ are orthogonal whenever x and x' are adjacent in G_1. Further, for every $x \in V_1$, the restriction of the given orthogonal representation to the copy of G_2 associated with x forms an orthogonal representation of G_2, so by $k = \overline{\xi}(G_2)$ it follows that $\dim(U_x) \geq k$. This implies that there exists a t-dimensional orthogonal k-subspace representation of G_1, hence $\overline{\xi}_k(G_1) \leq t$, as required.

We next prove that $\overline{\xi}(G_1 \bullet G_2) \leq \overline{\xi}_k(G_1)$. Denote $t = \overline{\xi}_k(G_1)$, then there exists a t-dimensional orthogonal k-subspace representation $(U_x)_{x \in V_1}$ of G_1. By $k = \overline{\xi}(G_2)$, there exists a k-dimensional orthogonal representation $(u_y)_{y \in V_2}$ of G_2. For every $x \in V_1$, the fact that $\dim(U_x) = k$ implies that there exists an orthogonal linear transformation T_x from $\mathbb{R}^k$ onto U_x. We assign to every vertex $(x, y) \in V_1 \times V_2$ of $G_1 \bullet G_2$ the nonzero vector $w_{(x,y)} = T_x(u_y) \in \mathbb{R}^t$. We claim that this is a t-dimensional orthogonal representation of $G_1 \bullet G_2$. To see this, let (x_1, y_1) and (x_2, y_2) be two adjacent vertices in $G_1 \bullet G_2$. If x_1 and x_2 are adjacent in G_1 then the subspaces U_{x_1} and U_{x_2} are orthogonal, hence the vectors $w_{(x_1,y_1)} \in U_{x_1}$ and $w_{(x_2,y_2)} \in U_{x_2}$ are orthogonal as well. Otherwise, $x_1 = x_2$ and the vertices y_1 and y_2 are adjacent in G_2. This implies that the vectors u_{y_1} and u_{y_2} are orthogonal, and since T_{x_1} preserves inner products it follows that $T_{x_1}(u_{y_1})$ and $T_{x_1}(u_{y_2})$ are orthogonal, and we are done. ◀

Equipped with Lemma 12, we are ready to prove Theorem 3.

Proof of Theorem 3. Fix a graph F. We reduce from the NP-hard problem of deciding whether an input graph G satisfies $\overline{\xi}(G) \leq 3$ [42]. The reduction maps an input graph G to the lexicographic product $G' = F \bullet G$ of F and G. The graph G' can clearly be constructed in polynomial time. The correctness of the reduction follows from Lemma 12. Indeed, we have $\overline{\xi}(G') = \overline{\xi}_k(F)$ for $k = \overline{\xi}(G)$, so if $\overline{\xi}(G) \leq 3$ then $\overline{\xi}(G') \leq \overline{\xi}_3(F)$ and if $\overline{\xi}(G) \geq 4$ then $\overline{\xi}(G') \geq \overline{\xi}_4(F)$. ◀

3.3 Algorithm

Before presenting our algorithm, we provide some background on the vector chromatic number of graphs.

3.3.1 Vector Chromatic Number

Consider the following two relaxations of the chromatic number of graphs, due to Karger, Motwani, and Sudan [29].

▶ **Definition 13.** *For a graph $G = (V, E)$ the* vector chromatic number *of G, denoted by $\chi_{\mathrm{v}}(G)$, is the minimal real value of $\kappa > 1$ for which there exists an assignment of a unit real vector u_v to every vertex $v \in V$ such that $\langle u_v, u_{v'} \rangle \leq -\frac{1}{\kappa-1}$ whenever v and v' are adjacent in G.*

▶ **Definition 14.** *For a graph $G = (V, E)$ the* strict vector chromatic number *of G, denoted by $\chi_{\mathrm{v}}^{(\mathrm{s})}(G)$, is the minimal real value of $\kappa > 1$ for which there exists an assignment of a unit real vector u_v to every vertex $v \in V$ such that $\langle u_v, u_{v'} \rangle = -\frac{1}{\kappa-1}$ whenever v and v' are adjacent in G.*

It is well known and easy to verify that for every graph G, $\chi_{\mathrm{v}}(G) \leq \chi_{\mathrm{v}}^{(\mathrm{s})}(G) \leq \chi(G)$. Karger et al. [29] have obtained the following algorithmic result.

▶ **Theorem 15** ([29]). *There exists a randomized polynomial time algorithm that given an n-vertex graph G with maximum degree at most Δ and $\chi_{\mathrm{v}}(G) \leq \kappa$ for some $\kappa \geq 2$, finds an independent set of size $\widetilde{\Omega}(\frac{n}{\Delta^{1-2/\kappa}})$.*

Note that the well-known Lovász ϑ-function, introduced in [38], is known to satisfy $\vartheta(G) = \chi_{\mathrm{v}}^{(\mathrm{s})}(\overline{G})$ for every graph G [29]. Combining this with a result of [38], it follows that the orthogonality dimension forms an upper bound on the strict vector chromatic number, that is, $\overline{\xi}(G) \geq \chi_{\mathrm{v}}^{(\mathrm{s})}(G)$ for every graph G. This was recently generalized by Bukh and Cox as follows (see [9, Proposition 23]).

▶ **Lemma 16** ([9]). *For every graph G and an integer k, $\overline{\xi}_k(G) \geq k \cdot \chi_{\mathrm{v}}^{(\mathrm{s})}(G)$.*

We derive that the graph parameters $\overline{\xi}_k$ and χ_k coincide on Kneser graphs $K(d, s)$ whenever k is divisible by s.

▶ **Corollary 17.** *For all integers $\ell \geq 1$ and $d \geq 2s$, $\overline{\xi}_{\ell \cdot s}(K(d, s)) = \ell \cdot d$.*

Proof. For the upper bound on $\overline{\xi}_{\ell \cdot s}(K(d, s))$, recall that Conjecture 1 was confirmed for $k = \ell \cdot s$ in [45], hence $\overline{\xi}_{\ell \cdot s}(K(d, s)) \leq \chi_{\ell \cdot s}(K(d, s)) = \ell \cdot d$. For the lower bound, combine Lemma 16 with the fact that $\chi_{\mathrm{v}}^{(\mathrm{s})}(K(d, s)) = \frac{d}{s}$ (see [38]), to get that $\overline{\xi}_{\ell \cdot s}(K(d, s)) \geq \ell \cdot d$. ◀

3.3.2 The Algorithm

We present an efficient algorithm that given a graph G that satisfies $\overline{\xi}(G) \leq 3$ (or, more generally, $\overline{\xi}_k(G) \leq 3k$ for some k), finds a coloring of G with relatively few colors. We use the following simple claim of Blum [4] which reduces the algorithmic task of coloring a graph to the algorithmic task of finding a large independent set in it.

▶ **Claim 18** ([4]). *Let $\mathcal{G}$ be a graph family which is closed under taking induced subgraphs, let $c_1, c_2 > 1$ be arbitrary fixed constants, and let $f : \mathbb{N} \to \mathbb{N}$ be any non-decreasing function satisfying $c_1 \cdot f(n) \leq f(2n) \leq c_2 \cdot f(n)$ for all sufficiently large n. Then if there exists a (randomized) polynomial time algorithm which finds an independent set of size $f(n)$ in any n-vertex graph $G \in \mathcal{G}$, then there exists a (randomized) polynomial time algorithm which finds an $O(\frac{n}{f(n)})$-coloring of any n-vertex graph $G \in \mathcal{G}$.*

We need the following two simple lemmas.

▶ **Lemma 19.** *Let $G = (V, E)$ be a graph such that $\overline{\xi}_k(G) \leq 2k$ for some integer k. Then G is 2-colorable.*

Proof. Let $G = (V, E)$ be a graph satisfying $\overline{\xi}_k(G) \leq 2k$, and let $(U_v)_{v \in V}$ be a $2k$-dimensional orthogonal k-subspace representation of G. It suffices to prove that every connected component of G is 2-colorable. Fix a vertex v in some connected component of G, and observe that there exists a unique subspace of $\mathbb{R}^{2k}$ of dimension k orthogonal to U_v. This implies that the orthogonal subspace representation of G provides a 2-coloring of the connected component of v, where the vertices of even distance from v are assigned to U_v and the vertices of odd distance from v are assigned to its orthogonal complement $U_v^{\perp}$, so we are done. ◀

For a graph G and a vertex v, let $N(v)$ denote the neighborhood of v in G and let $G[N(v)]$ denote the subgraph of G induced by $N(v)$.

▶ **Lemma 20.** *Let $G = (V, E)$ be a graph such that $\overline{\xi}_k(G) \leq 3k$ for some integer k. Then for every vertex $v \in V$ the subgraph $G[N(v)]$ is 2-colorable.*

Proof. Let $G = (V, E)$ be a graph satisfying $\overline{\xi}_k(G) \leq 3k$, and let $(U_v)_{v \in V}$ be a $3k$-dimensional orthogonal k-subspace representation of G. Let $v \in V$ be a vertex in G. The subspace U_v is orthogonal to all subspaces $U_{v'}$ with $v' \in N(v)$. By $\dim(U_v) = k$, the orthogonal complement of U_v in $\mathbb{R}^{3k}$ has dimension $2k$. It follows that $G[N(v)]$ admits a $2k$-dimensional orthogonal k-subspace representation, hence by Lemma 19 it is 2-colorable, as required. ◀

We are ready to prove the following result.

▶ **Theorem 21.** *There exists a randomized polynomial time algorithm that given an n-vertex graph G that satisfies $\overline{\xi}_k(G) \leq 3k$ for some k, finds a coloring of G that uses at most $\widetilde{O}(n^{1/4})$ colors. In particular, the algorithm finds an orthogonal representation of G of dimension $\widetilde{O}(n^{1/4})$.*

Proof. By Claim 18 it suffices to show that there exists a randomized polynomial time algorithm that given an n-vertex graph $G = (V, E)$ with $\overline{\xi}_k(G) \leq 3k$ for some k, finds in G an independent set of size $\widetilde{\Omega}(n^{3/4})$. We consider two possible cases. Suppose first that there exists a vertex $v \in V$ in G whose degree is at least $\Delta = n^{3/4}$. Then by Lemma 20 the subgraph $G[N(v)]$ is 2-colorable, so we can find an independent set in G of size at least $\frac{\Delta}{2}$ by finding in polynomial time a 2-coloring of $G[N(v)]$ and taking a largest color class. Otherwise, the maximum degree of G is at most Δ. By Lemma 16 we have

$$\chi_{\mathrm{v}}(G) \leq \chi_{\mathrm{v}}^{(\mathrm{s})}(G) \leq \frac{\overline{\xi}_k(G)}{k} \leq 3,$$

so by Theorem 15 we can find in polynomial time an independent set of size $\widetilde{\Omega}(\frac{n}{\Delta^{1/3}}) \geq \widetilde{\Omega}(n^{3/4})$, and we are done. ◀

To improve the number of used colors, we employ the following result that stems from the analysis by Arora et al. [2] of the semidefinite relaxation of [29]. (For an explicit statement, see [14, Lemma 4.12], applied with $\sigma = 0.5$, $c \approx 0.04843726$, and $\delta \approx 0.7587$.)

▶ **Theorem 22** ([2]). *There exists a randomized polynomial time algorithm that given an n-vertex graph G with maximum degree at most $\Delta = n^{0.7587}$ and $\chi_{\mathrm{v}}(G) \leq 3$, finds an independent set in G of size at least $\widetilde{\Omega}(n \cdot \Delta^{-0.3179}) \geq \widetilde{\Omega}(n^{0.7587})$.*

By applying Theorem 22 instead of Theorem 15 in the proof of Theorem 21, we obtain the following slight improvement, confirming Theorem 5.

▶ **Theorem 23.** *There exists a randomized polynomial time algorithm that given an n-vertex graph G that satisfies $\overline{\xi}_k(G) \leq 3k$ for some k, finds a coloring of G that uses at most $\widetilde{O}(n^{0.2413})$ colors.*

Domination Above r-Independence: Does Sparseness Help?

Abstract

Inspired by the potential of improving tractability via gap- or above-guarantee parametrisations, we investigate the complexity of Dominating Set when given a suitable lower-bound witness. Concretely, we consider being provided with a maximal r-independent set X (a set in which all vertices have pairwise distance at least $r+1$) along the input graph G which, for $r \geq 2$, lower-bounds the minimum size of any dominating set of G. In the spirit of gap-parameters, we consider a parametrisation by the size of the "residual" set $R := V(G) \setminus N[X]$.

Our work aims to answer two questions: How does the constant r affect the tractability of the problem and does the restriction to sparse graph classes help here? For the base case $r = 2$, we find that the problem is paraNP-complete even in apex- and bounded-degree graphs. For $r = 3$, the problem is W[2]-hard for general graphs but in FPT for nowhere dense classes and it admits a linear kernel for bounded expansion classes. For $r \geq 4$, the parametrisation becomes essentially equivalent to the natural parameter, the size of the dominating set.

Introduction

The research of *above/below guarantee* parameters as first used by Mahajan and Raman [22] was an important step towards studying problems whose natural parameters provided only trivial and unsatisfactory answers. Case in point, the motivation for Mahajan and Raman was the observation that every CNF-SAT formula with m clauses trivially has an assignment that satisfies $\geq \lceil m/2 \rceil$ clauses, thus question for the maximum number of satisfied clauses is only interesting if $k > \lceil m/2 \rceil$, which of course renders the parametrised approach unnecessary. They therefore proposed to study parametrisations "above guarantee": going with the previous example, we would ask to satisfy $\lceil m/2 \rceil + k$ clauses or 'k above guarantee'. After some isolated results in that direction (e.g. [15, 17]) the programme took up steam after Mahajan *et al.* presented several results and pointers in new directions [23] (e.g. [3, 16, 18, 17]). In particular, Cygan *et al.* broke new ground for Multiway Cut and Vertex Cover with algorithms that run in $O^*(4^k)$ time, where k is the *gap parameter* between an appropriate LP-relaxation and the integral optimum [5]. Lokshtanov *et al.* improved the Vertex Cover case to $O^*(2.3146^k)$ using a specialized branching algorithm [21].

The latter result highlights an important realization: these alternative, smaller parameters might not only provide the means to investigate problems without "good" natural parameters, it might also provide us with faster algorithms in practise! Gap- and above-guarantee parameters are attractive because there is a reasonable chance that they are small in real-world scenarios, something we often cannot expect from natural parameters.

To the best of our knowledge, so far no gap-parameter results are known for domination problems and an above/below-guarantee result is only known in bounded-degree graphs [23]. This is probably due to the fact that there are no simple "natural" upper/lower bounds and in the case of gap-parameters the LP-dualities do not provide much purchase. We therefore explore this topic under the most basic assumptions: we are provided with a witness for a lower bound on the domination number *as input* and consider parametrisations that arise from this additional information. In the case of Dominating Set, the witness takes the form of a 2*-independent set*, that is, a set in which all vertices have pairwise distance at least three. Note that this approach also captures a form of duality: the LP-dual of dominating set describes a 2-independent set, however, in general the two optima are arbitrarily far apart. Recently, Dvořák highlighted this connection [7] and proved that in certain sparse classes the gap between the dual optima is bounded by a constant.

Thus, assume we are given a maximal 2-independent set X alongside the input graph G. A parametrisation by $|X|$ would go against the spirit of gap-parameters, instead we parametrise by the size of *residual set* $R := V(G) \setminus N[X]$, that is, all vertices that lie at distance two from X (since X is maximal, no vertex can have distance three or more). We choose this particular parameter for two reasons:

(i) For $|R| = 0$ the problem is decidable in polynomial time since the domination number of the graph is precisely $|X|$.

(ii) The set $X \cup R$ is a dominating set of G.

The first property is of course an important pre-requisite for the problem to be in FPT under this parametrisation, while the second property guarantees us that the dominating set size lies in-between $|X|$ and $|X| + |R|$.

Our first investigatory dimension is the constant $r = 2$ in the 2-independent set: intuitively, increasing the minimum distance between vertices in X increases the size of the parameter $|R|$ and imposes more structure on the input instance. Our second dimension encompasses an approach that has been highly successful in improving tractability of domination problems: restricting the inputs to sparse graphs. While Dominating Set is W[2]-complete in general graphs, Alber *et al.* showed that it is fpt in planar graphs [1]; Alon and Gutner later proved that assuming degeneracy is sufficient [4]. Philip, Raman, and Sikdar extended this result yet further to graphs excluding a fixed bi-clique and also proved that it admits a polynomial kernel [25]. A related line of research was the hunt for *linear* kernels in sparse classes. Beginning with such a kernel on planar graphs by Alber, Fellows, and Niedermeier [2], results on apex-minor free graphs [10], graphs excluding a minor [11] and classes excluding a topological minor [12] were soon proven. Recently, a linear kernel for graphs of bounded expansion [6] (and an almost-linear kernel for nowhere dense graphs [9]) has subsumed all previous results.

Our investigation of Dominating Set parametrised above an r-independent set, for $r \geq 2$, led us to the following results. For $r = 2$, the problem is paraNP-complete already for $|R| = 1$, squashing all hope for an FPT or even XP algorithm. This also holds true if the inputs are restricted to sparse graph classes (apex-graphs/graphs of maximum degree six).

For $r = 3$, the problem is W[2]-hard in general graphs but admits an XP-algorithm. In nowhere dense and bounded expansion classes, it is fixed-parameter tractable. We further show, in the probably most technical part of this paper, that it admits a linear kernel in bounded expansion classes.

Finally, for $r \geq 4$ the problem remains W[2]-hard in general graphs and essentially degenerates to Dominating Set (hence, all the above mentioned results in sparse classes translate in the parametrisation above r-independence).

1 Preliminaries

A set $X \subseteq V(G)$ is *r-independent* if each pair of distinct vertices in X have distance at least $r{+}1$, thus an independent set is 1-independent. We write $N(v)$ and $N[v]$, respectively, for the neighbourhood and the closed neighbourhood of a vertex v. We extend this notation to sets as follows: for $X \subseteq V(G)$ we let $N(X)$ be all vertices not in X that have a neighbour in X and $N[X] := X \cup N(X)$. We let $N^i(X)$ be all vertices not in X that are at most distance i from any vertex in X and we let $N^i[X] = X \cup N^i(X)$. A vertex set $Z \subseteq V(G)$ is *dominated* by a set $D \subseteq V(G)$ if for every vertex $z \in Z$ we have $N[z] \cap D \neq \emptyset$, D is then called a *Z-dominator*. We let $\mathbf{ds}(G)$ denote the size of a minimum dominating set of G.

Dominating Set above r-independence

Input: A graph G, a maximal r-independent set $X \subseteq V(G)$, an integer p.
Parameter: The size of the residual set $R := V(G) \setminus N[X]$.
Problem: Does G have a dominating set of size p?

Note that $X \cup R$ is trivially a dominating set and that, for $r \geq 2$, it holds that $\mathbf{ds}(G) \geq |X|$, thus we will tacitly assume in the following that $|X| \leq p \leq |X| + |R|$ since all other instances are trivial.

We will frequently invoke the terms *bounded expansion* and *nowhere dense* to describe graph classes. The definitions of these terms requires the introduction of several concepts which will not be useful for the remainder of the paper, we refer the reader to the book by Nešetřil and Ossona de Mendez [24]. In this context, it is important to know that bounded expansion classes generalize most structurally sparse classes (planar, bounded genus, bounded degree, H-minor free, H-topological minor free) and nowhere dense classes contain bounded expansion classes in turn. The following lemma and propositions for those two sparse graph classes will be needed in the remainder of this paper:

▶ **Lemma 1** (Twin class lemma [13, 26]). *For every bipartite nowhere dense class there exists a constant ω and a function $f(s) = O(s^{o(1)})$ such that for every member $G = (X, Y, E)$ of the class it holds that*

1. $|\{u \mid \deg(u) > 2\tau\}_{u \in Y}| \leq 2\tau \cdot |X|$, *and*
2. $|\{N(u)\}_{u \in Y}| \leq (\min\{4^\tau, \omega(e\tau)^\omega\} + 2\tau) \cdot |X|$.

where $\tau = f(|X|) = O(|X|^{o(1)})$. If G is from a bounded expansion class, τ can be assumed a constant as well.

We will also frequently invoke the following result regarding first-order (FO) model checking in bounded expansion and nowhere dense classes:

▶ **Proposition 2** (Dvořák, Král, and Thomas [8]). *For every bounded expansion class, the first-order model checking problem is solvable in linear fpt-time parametrised by the size of the input formula.*

This result has since been extended to nowhere dense classes as well. Here, *almost linear fpt-time* means running time of the form $O(f(k) \cdot n^{1+o(1)})$ for some function f.

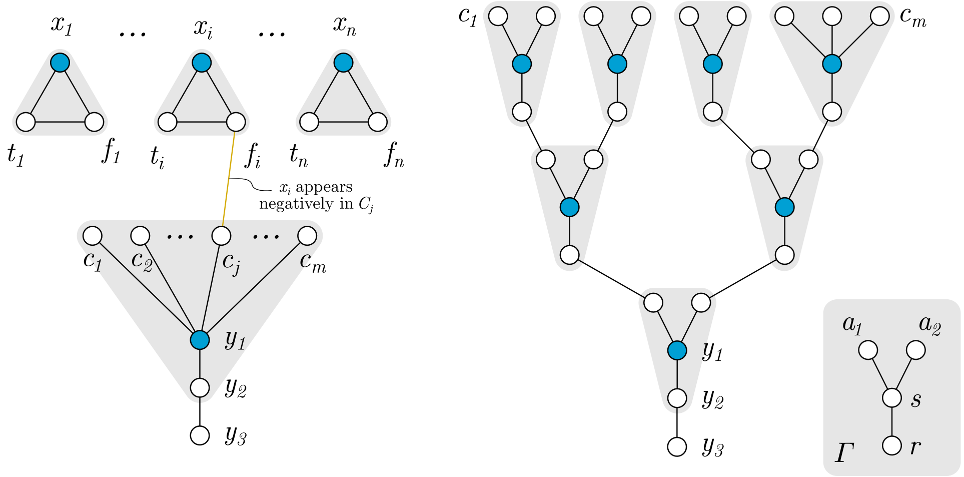

Figure 1 Sketch of reduction from 3SAT to Dominating Set above 2-independent set. The left side shows the basic reduction, the right side shows the bounded-degree replacement gadget for the clause part, with the tree-gadget Γ highlighted on the bottom right. The 2-independent set X is coloured blue and $N[X]$ is shaded in grey. In both constructions the set R consists only of y_3.

▶ **Proposition 3** (Grohe, Kreutzer, and Siebertz [14]). *For every nowhere dense class, he first-order model checking problem is solvable in almost linear fpt-time parametrised by the size of the input formula.*

2 Above 2-independence: hard as nails

In this section we will show that when we let $r = 2$, we find that the problem is paraNP-complete for $|R| = 1$, hence this parametrisation does not even admit an XP-algorithm. In the following we first present a reduction from 3SAT and then discuss how to modify it to reduce into sparse graph classes.

Since X is a (maximal) 2-independent set, we know that each vertex in R is a neighbour of some vertex in $N(X)$, otherwise we could add this vertex to X. Let us now describe the reduction. Let ϕ be 3SAT-instance with variables $x_1, \dots, x_n$ and clauses $C_1, \dots, C_m$. We construct G as follows (*cf.* Figure 1):

1. For each variable x_i, add a triangle with vertices x_i, t_i, f_i.
2. For each clause C_j add a vertex c_j. If the variable x_i occurs positively in C_j, add the edge $c_j t_i$; if it occurs negatively, add the edge $c_j f_i$.
3. Add a single vertex y_1 to the graph and connect it to each clause variable c_i. Add two further vertices y_2, y_3 and add the edges $y_1 y_2$ and $y_2 y_3$.

We further set $X := \{x_1, \dots, x_n, y_1\}$ as our 2-independent set; notice that the only vertex not contained in $N[X]$ is y_3. Hence, $R := \{y_3\}$.

▶ **Lemma 4.** *ϕ is satisfiable iff G has a dominating set of size $|X|$.*

Proof. Assume ϕ is satisfiable and fix one satisfying assignment I. We construct a dominating set D as follows: if x_i is true under I, add t_i to D; otherwise add f_i. Since I satisfies every clause of ϕ the dominating set so far dominates every clause vertex and, of course, every variable gadget. The remaining undominated vertices are y_1, y_2, y_3, thus adding y_2 to D yields a dominating set of G of size $|X|$.

In the other direction, assume that D is a dominating set of G of size $|X|$. Since y_3 is a pendant vertex we can assume that $y_2 \in D$ (if y_3 would be in D we could exchange it for y_2). That leaves $|X| - 1 = n$ vertices in D, precisely the number of variable-gadgets. Since every variable gadget must include at least one vertex of D, we conclude the every such gadget contains precisely one dominating vertex. Since that depletes our budget, no other vertex is contained in D.

By the usual exchange argument we may assume that the dominating vertex in each variable gadget is either f_i or t_i and not x_i for $1 \leq i \leq n$; hence the dominating vertices inside the variable gadgets encode a variable assignment I_D of ϕ. Finally, note that the clause vertices are not dominated by y_2 and y_1 is not contained in D. Hence, they must be completely dominated by vertices contained in the variable gadgets. Then, by construction, the assignment I_D satisfies ϕ and the claim follows. ◀

We conclude that 3SAT many-one reduces to Dominating Set above 2-independence already with $|R| = 1$. We obtain the following two corollaries that demonstrate that sparseness cannot help tractability here:

▶ **Corollary 5.** Dominating Set *above* 2-*independence is* paraNP-*complete in apex-graphs.*

Proof. We use the above construction but reduce from a planar variant of 3SAT. To ensure that we can construct variable-gadgets without edge crossings, we choose to reduce from Lichtenstein's Planar 3SAT variant [20] which ensures that the following graph G' derived from the Planar 3SAT instance ϕ is planar:

1. Every variable x_i of ϕ is represented by two literal vertices t_i, f_i with the edge $t_i f_i \in G'$
2. Each clause C_j is represented by a vertex c_j. If the variable x_i occurs positively in C_j, the edge $c_j t_i$ exits; if it occurs negatively, the edge $c_j f_i$ exists.

To complete G' to G we have to add the vertices x_i and connect them to t_i, f_i. This is clearly possible without breaking planarity (picture placing x_i on the middle of the line segment $f_i t_i$ and moving it perpendicular by a small amount, then the edges $x_i f_i$ and $x_i t_i$ can be embedded without crossing other edges). The vertices y_2, y_3 can be placed anywhere; finally the vertex y_1 will break planarity (the embedding does not guarantee that the clause vertices lie on the outer face of the graph) and we conclude that G is indeed an apex-graph. ◀

▶ **Corollary 6.** Dominating Set *above* 2-*independence is* paraNP-*complete in graphs of maximum degree six.*

Proof. We reduce from (3,4)SAT (NP-hardness shown in [27]) in which every clause has size three and every variable occurs in at most four clauses. We use the above construction with one modification. Instead of connecting all clause vertices to one vertex we create a bounded-degree tree with the clause-vertices as its leaves.

We begin by partitioning the clause vertices in pairs P_i; if there is an odd number of vertices the last group will have three vertices. Then, for each group $P_i = \{c, c'\}$, we add two vertices s^i, r^i, connect the clause-vertices c and c' to s^i, and add the edge $s^i r^i$. We further add each s^i to our 2-independent set X and then create a set L_1 consisting of each r^i. Now we iteratively construct the next level of the tree, starting with $L := L_1$:

1. If $L = \{r^1\}$, create a single vertex y_3, connect it to r^1 and finish, otherwise proceed with the next step.
2. Partition the vertices in L into ℓ groups $\{l_i, r_i\}$ of pairs. If $|L|$ is odd, the last group will be a triple $\{l_i, c_i, r_i\}$ instead.
3. For each group, create a tree-gadget Γ^i, with vertices $\{a_1, a_2, s^i, r^i\}$ (and a_3 if the group contains a third vertex), and edges $l_i a_1, r_i a_2$, $(c_i a_3)$, $a_1 s^i$, $a_2 s^i$, $(a_3 s^i)$, and $s^i r^i$.
4. Add each s^i to X, let L now be the set of all r^i (for $1 \leq i \leq \ell$) and continue with Step 1.

Figure 1, on the right side, shows an example of this construction. We note that, in the last tree-gadget, s^i and r^i are the same vertices as y_1 and y_2 respectively in the figure. We conclude the construction by adding each x_i from the variable-gadgets to X and setting $p := |X|$. Notice that the only vertex not contained in $N[X]$ is y_3 and thus $R := \{y_3\}$.

Since each variable in (3,4)SAT can be in up to four clauses, the maximum degree for t_i and f_i is six. All clause-vertices have degree at most four and all other types of vertices have a degree not higher than that, hence the claimed degree-bound holds. It is left to show that ϕ is satisfiable iff there is a dominating set of size $p = |X|$ in the graph.

Let us assume that ϕ is satisfiable and fix one satisfying assignment I. We construct a dominating set as follows, beginning in the same way as in Lemma 4: if x_i is true under I, add t_i to D, otherwise add f_i. Since I satisfies every clause of ϕ the dominating set so far dominates every clause vertex and every variable gadget. Now, the remaining undominated vertices are the tree-vertices, and our remaining budget is $|X| - n$ which is equal to the amount of tree-gadgets. Since every clause vertex is already dominated we can, for each tree-gadget $\Gamma^i = \{a_1, a_2, s^i, r^i\}$, add r^i to the dominating set. This will dominate s^i and the corresponding a_1 or a_2 in the tree-gadget below it, hence we can dominate all vertices of the graph within the budget $|X|$.

In the other direction, assume that D is a dominating set of G of size $|X|$. Since y_3 is a pendant vertex we can assume that $y_2 \in D$. Thus, in the last tree-gadget r^i (y_2) is in the dominating set. This means that in order for a_1 and a_2 to be dominated, r^i in both tree-gadgets above has to be in the dominating set. This holds for all tree-gadgets, all the way up to the clause vertices. Since we now have one vertex per tree-gadget in the dominating set this leaves n vertices. Just as in Lemma 4, we note that, for each variable gadget, either t_i or f_i is in the dominating set. We know that the clause variables are not dominated by anything in the tree gadgets and thus must be dominated by the variable vertices. As stated in Lemma 4, the dominating vertices inside the variable gadgets encode a variable assignment I_D that satisfies ϕ and the claim follows. ◀

3 Above 3-independence: sparseness matters

3.1 W[2]-hardness in general graphs

In the following we present a result for Dominating Set above 3-independence, namely that it is W[2]-hard in general graphs. We show this by reduction from Colourful Dominating Set parametrised by the number of colours k:

Colourful Dominating Set parametrised by k

Input: A graph G with a vertex partition $C_0, C_1, \dots, C_k$.

Problem: Is there a set that dominates C_0 and uses exactly one vertex from each set $C_1, \dots, C_k$?

It is easy to verify that Colourful Dominating Set is W[2]-hard by reducing from Red-Blue Dominating Set: we copy the blue set k times and make each copy a colour set C_i, $1 \leq i \leq k$, and let C_0 be the red set.

▶ **Lemma 7.** Dominating Set *above r-independence is* W[2]*-hard for $r \geq 2$.*

Proof. Let $I = (G, C_0, C_1, \dots, C_k)$ be an instance of Colourful Dominating Set. We construct an instance (G', X, k) of Dominating Set above r-independence as follows (*cf.* Figure 2):

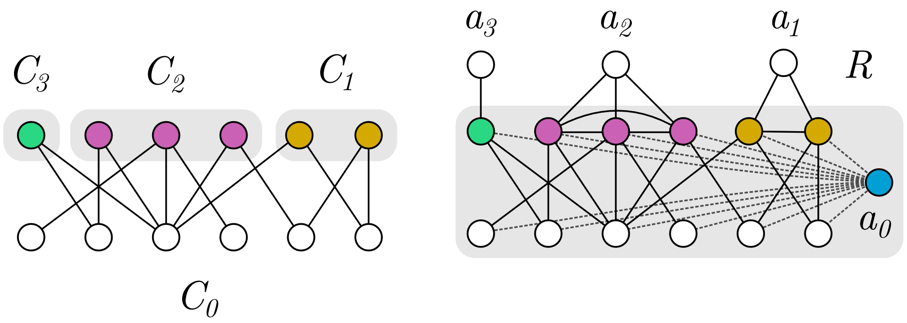

Figure 2 Sketch of reduction from Colourful Dominating Set to Dominating Set above r-independent set for $r \geq 2$. The set X contains only the vertex a_0, the remaining vertices a_i are all contained in the residual R.

1. Begin with G' equal to G; then
2. for each block C_i, $i \geq 1$, add edges to make $G[C_i]$ a complete graph and add an additional vertex a_i with neighbourhood C_i; then
3. add a vertex a_0 and connect it to all vertices in $C_0 \cup C_1 \cup \dots C_k$.

Let $X = \{a_0\}$ be the r-independent set (which it clearly is for any r) and thus $R = \{a_1, \dots, a_k\}$. Note that the graph G' trivially has a dominating set of size $k+1$; the set $\{a_0, a_1, \dots, a_k\}$. We now claim that I has a colourful dominating set of size k iff G' has a dominating set of size k.

Assume that I has a solution of size k and fix one such colourful dominating set D. Note that D in G' a) dominates all of C_0 (because it dominates C_0 in G) and b) dominates each set $C_i \cup \{a_i\}$, $i \geq 1$ (because D intersects each such C_i), and of course the vertex a_0. Hence, D is a dominating set of G' as well.

In the other direction, assume that D is a dominating set of G' of size k. Since each a_i, $i \geq 1$, is only connected to vertices in the corresponding set C_i, at least one vertex from each set $C_i \cup \{a_i\}$ needs to be in D. Since there are k such sets we conclude that D intersects each set $C_i \cup \{a_i\}$ in precisely one vertex. We can further modify any such solution to not take the a_i-vertices by taking an arbitrary vertex from C_i instead, thus assume that D has this form in the following. But then D is of course also a dominating set of size k for G, as claimed. ◀

3.2 Tractability in sparse graphs

In the following we present two positive results, namely that Dominating Set above 3-independence is fpt in nowhere dense classes and that it admits a polynomial kernel in bounded expansion classes. The algorithm further implies an XP algorithm in general graphs. The following annotated domination problem will occur as a subproblem:

Annotated Dominating Set

Input: A graph G, a subset $Y \subseteq V(G)$, a collection of vertex sets $R_1, \dots, R_\ell$, and an integer k.

Problem: Is there a set of size k that dominates $V(G) \setminus Y$ and contains at least one vertex in each R_i?

In the following algorithm we will group vertices of $N(X)$ according to their neighbourhood in R (or a subset of R). We will call those groups *R-neighbourhood classes*. We will write $\gamma(G, Y, \{R_1, \dots, R_\ell\})$ to denote the size of an optimal solution of Annotated Dominating Set.

▶ **Lemma 8.** Dominating set *above* 3*-independence can be solved in linear fpt-time in any graph class of bounded expansion.*

Proof. First we guess the intersection D_R of an optimal solution (should it exist) with R in $O(2^{|R|})$ time. Let $R' \subseteq R$ be those vertices of R that are not dominated by D_R. Define

$$\mathcal{R} := \{N(v) \cap R'\}_{v \in N(X)}$$

as the neighbourhoods induced in R' by vertices in $N(X)$. By Lemma 1, we have that $|\mathcal{R}| = O(|R'|)$ since G is from a class with bounded expansion (note that the partition into such neighbourhoods is computable in linear time using the partition-refinement data structure [19]). Accordingly, in time $O(2^{|\mathcal{R}|}) = 2^{O(|R'|)}$, we can guess a subset $\mathcal{R}' \subseteq \mathcal{R}$ such that an optimal solution covers exactly the neighbourhoods $\mathcal{R}'$ (if $\mathcal{R}'$ does not cover R' we abort this branch of the computation). We are now left with the task of choosing vertices from $N[X]$ to a) cover the neighbourhoods $\mathcal{R}'$ and b) dominate the vertices in $N[X]$ which are not dominated by D_R.

We introduce the following notation to ease our task: for a collection of R-neighbourhoods $\mathcal{S} \subseteq \mathcal{R}'$ and a set $Y \subseteq N(X)$, let $\mathcal{S}^{-1}(Y) := \{Y_i \subseteq Y \mid N(y) = S \text{ for all } y \in Y_i\}_{S \in \mathcal{S}}$. That is, $\mathcal{S}^{-1}(Y)$ contains those R'-neighbourhood classes in Y whose neighbourhood is contained in $\mathcal{S}$. Let $x_1, \ldots, x_\ell$ be an ordering of X and let $H_i := G[N[x_i]]$; we will describe a dynamic-programming algorithm over the ordering $x_1, \ldots, x_\ell$. Let $T_i[\mathcal{S}]$ be the minimum size of a partial solution in $N[\{x_1, \ldots, x_i\}]$ that covers the neighbourhoods $\mathcal{S} \subseteq \mathcal{R}'$ and together with D_R dominates all of $G[\bigcup_{1 \leq j \leq i} N[x_j]]$. We initialize $T_0[\mathcal{S}] := \infty$ for all $\emptyset \neq \mathcal{S} \subseteq \mathcal{R}'$ and $T_0[\emptyset] := 0$, then compute the following entries with the recurrence[1]

$$T_{i+1}[\mathcal{S}] := \min_{\mathcal{S}_1 \cup \mathcal{S}_2 = \mathcal{S}} \Big(T_i[\mathcal{S}_1] + \gamma\big(H_{i+1}, N(D_R) \cap N[x_{i+1}], \mathcal{S}_2^{-1}(N(x_{i+1}))\big)\Big).$$

Note that $\gamma(\ldots)$ is the minimum size of a set that dominates $N[x_i] \setminus N(D_R)$ while choosing at least one vertex from each member of $S_2^{-1}(N(x_i))$ (if $\emptyset \in S_2^{-1}(N(x_i)$ we assume that $\gamma(\ldots) = \infty$). The latter constraint corresponds to dominating the neighbourhoods of $\mathcal{S}_2$ in R' by using vertices from $N[x_i]$. Once the DP table T_ℓ has been computed, the size of an optimal solution is the value in $T_\ell[\mathcal{R}']$.

It remains to be noted that every neighbourhood graph H_i admits a dominating set of size one, hence the annotated dominating set has size at most $|\mathcal{S}_2| + 1 = O(|R|)$. Thus, the problem of finding an annotated dominating set is FO-expressible by a formula of size $O(|R|)$ and we can solve the subproblem of computing $\gamma(\ldots)$ in time $O(f(|R|) \cdot |N[x_i]|)$ for some function f using Proposition 2. As a result, we obtain a linear dependence on the input size (note that $|E| = O(|V|)$) in the running time and thus the problem is solvable in linear fpt-time. ◀

The same proof works for nowhere dense classes by applying Proposition 3 instead of Proposition 2:

▶ **Corollary 9.** Dominating set *above* 3*-independence can be solved in almost linear fpt-time in any nowhere dense class.*

We finally note that the algorithm described in the proof of Lemma 8 only needs a black-box fpt-algorithm for Annotated Dominating Set to run in fpt time, thus it is very likely that Dominating set above 3-independence is in FPT for other highly structured but not

[1] A proof for the correctness of the recurrence can be found in the full version available at `https://arxiv.org/abs/1906.09180`

necessarily sparse graph classes. We can run the same algorithm on general graphs to obtain an XP-algorithm using the bound $|\mathcal{R}| \leq 2^{|R'|}$ and a simple brute-force in XP-time on the Annotated Dominating Set subinstance during the DP.

▶ **Corollary 10.** Dominating set *above* 3*-independence is in* XP*.*

3.3 Kernelization in sparse graphs

Let us now set up the necessary machinery for the kernelization. A *boundaried graph* $^\circ G$ is a tuple (G, R) where G is a graph and $R \subseteq V(G)$ is the *boundary.* We also write $\partial^\circ G$ to denote the boundary. For a graph G and an induced subgraph H, the boundary $\partial_G H \subseteq V(H)$ are those vertices of H that have neighbours in $V(G) \setminus V(H)$. Thus for every subgraph H of G there is a naturally associated boundaried graph $\partial H = (H, \partial_G H)$.

For a boundaried graph $^\circ H$ and subsets $A, B \subseteq \partial^\circ H$ a set $D \subseteq V(^\circ H)$ is an (A,B)-dominator of $^\circ H$ if $D \cap \partial^\circ H = A$ and D dominates the set $(V(^\circ H) \setminus \partial^\circ H) \cup B$. We let $\mathbf{ds}(^\circ H, A, B)$ denote the size of a minimum (A,B)-dominator of $^\circ H$. A *replacement* for H is a boundaried graph (H', B) with $H[B] = H'[B]$. The operation of *replacing* H *by* H' *in* G, written as $G[H \to H']$, consist of removing the vertices $V(H) \setminus B$ from G, then adding H' to G with B in H' identified with B in G (we assume that the vertices $V(H') \setminus B$ do not occur in G).

▶ **Lemma 11.** *Let* (G, X, p) *be an instance of* Dominating Set *above* 3*-independence where* G *is from a bounded expansion class. Let* $x \in X$*,* $H_x = G[N^2[x]]$ *and* $R' = N^2[x] \cap R$*. Then, in fpt-time with parameter* $|R'|$*, we can compute a replacement* H'_x *for* H_x *of size* $O(4^{|R'|}|R'|)$ *such that* $\mathbf{ds}(G[H_x \to H'_x]) = \mathbf{ds}(G)$*. Moreover, the replacement* H'_x *is a subgraph of* H_x *and contains* x*.*

Proof. For every pair of subsets $A, B \in R'$ we compute a minimal (A,B)-dominator $S_{A,B}$ for $^\circ H_x = (H_x, R')$. Since this problem is expressible by an FO-formula of size $O(|R'|)$, we can employ Proposition 2 to compute the set $S_{A,B}$ in linear fpt-time with parameter $|R'|$. Note that $S_{A,B}$ will, besides the vertices in A, contain at most $|B|+1$ additional vertices, since $|B|$ vertices suffice to dominate B and the vertex x dominates all of $V(H_x) \setminus R$.

Let $S = \bigcup_{A,B \subseteq R'} S_{A,B} \cup R' \cup \{x\}$ be the union of all such computed solutions and the boundary. By construction, $|S| \leq (4^{|R'|}+1)|R'|+1$. Since all (A,B)-dominators live inside S, we can safely remove the edges from H_x that do not have any endpoint in S, call the resulting graph $\tilde{H}_x$. Let $Y := V(\tilde{H}_x) \setminus S$ and let $Y_1, \ldots, Y_t$ be a partition of Y into S-twin classes (thus all vertices in Y_i have the same neighbourhood in S and no other class has this neighbourhood). Note that Y is an independent set in $\tilde{H}_x$.

Let H'_x be obtained from $\tilde{H}_x$ by removing all but two representatives from every twin-class, denote those by $Y'_i \subseteq Y_i$. Clearly, every (A,B)-dominator of $\tilde{H}_x$ is still an (A,B)-dominator of H'_x, we need to proof the other direction. Let D' be an (A,B)-dominator of H'. If $D' \subseteq S$ then D' is still an (A,B)-dominator for H. The same holds if D' intersects every twin-class in at most one vertex: each such class either has size one, in which case it has size one in $\tilde{H}_x$ as well, or it has size two and the vertex not contained in D' is dominated by a vertex in S. In either case, D' dominates all of Y and thus is an (A,B)-dominator of $\tilde{H}_x$ and therefore of H_x. Thus, assume that D' fully contains some class Y'_i. Clearly, only one vertex of Y'_i is enough to dominate $N(Y'_i)$ (and potentially vertices in B), thus we can modify D' by picking the central vertex x instead to dominate the other vertex of Y'_i (which of course also dominates all of Y_i in $\tilde{H}_x$). This can, of course, only happen once, otherwise we would reduce the size of the supposedly minimal set D'. This leads us back to the previous case and we conclude that there exists an (A,B)-dominator of $\tilde{H}_x$ and thus H_x of equal size.

We conclude that $\mathbf{ds}({}^{\circ}H_x, A, B) = \mathbf{ds}({}^{\circ}H'_x, A, B)$ for every choice of $A, B \subseteq R'$; which implies that $\mathbf{ds}(G[H_x \to H'_x]) = \mathbf{ds}(G)$. Finally, by the twin-class lemma, $|H'_x| = O(|S|) = O(4^{|R'|}|R'|)$ since τ is a constant in bounded expansion classes. ◀

▶ **Lemma 12.** *Let (G, X, p) be an instance of* Dominating Set *above 3-independence where G is from a bounded expansion class. Let $R' \subseteq R$ be a subset and let $X' \subseteq X$ be those vertices $x \in X$ with $N^2(x) \cap R = R'$. Let H be the induced subgraph on $R' \cup \bigcup_{x \in X'} N[x]$. Assuming X' is not empty we can, in fpt-time with parameter $|R'|$, compute a replacement H' for H of size $O(|R'|^{2|R'|+2}4^{|R'|})$ alongside an offset c such that $\mathbf{ds}(G[H' \to H]) = \mathbf{ds}(G) - c$. Moreover, the replacement H' is a subgraph of H.*

Proof. Let $X' := \{x_1, \ldots, x_\ell\}$ and define the graphs $H_i := G[N^2[x_i]]$ for $1 \le i \le \ell$. We first we apply Lemma 11 to replace every subgraph H_i by a subgraph H'_i of size $O(4^{|R'|}|R'|)$ in linear fpt-time with parameter R'. For simplicity, let us call the resulting graph G and relabel the graphs H'_i to H_i (note that Lemma 11 ensures that dominating set size does not change and that X is still a 3-independent set of the resulting graph).

For every $x_i \in X'$ we compute a *characteristic vector* χ_i indexed by pairs of subsets of R' with the following semantic: for $A, B \subseteq R'$ we set $\chi_i[A, B] = \mathbf{ds}({}^{\circ}H_i, A, B)$. If $\chi_i[A, B]$ is larger than $|A| + |B| + 1$ we simply set $\chi_i[A, B] = \infty$.

Note that the constraint subproblem to compute $\chi_i[A, B]$ is FO-expressible, by a formula of size $O(|R'|)$, thus we can compute the vectors χ_i for $1 \le i \le \ell$ in linear time fpt-time with parameter $O(|R'|)$ using Proposition 2. Let $\equiv_\chi$ be the equivalence relation over the graphs H_i defined as $H_i \equiv_\chi H_j \iff \chi_i = \chi_j$ and let $\mathcal{H} := \{H_i\}_{1 \le i \le \ell} / \equiv_\chi$ be the corresponding partition into equivalence classes under $\equiv_\chi$. Note that $|\mathcal{H}| \le (|R'| + 1)^{2|R'|}$ since that is the number of possible characteristic vectors.

The construction of H' is now simple: in every equivalence class $\mathcal{C} \in \mathcal{H}$ we select $\min\{|\mathcal{C}|, |R|\}$ subgraphs and remove the rest; clearly H' is a subgraph of H of the claimed size. We let the offset c to be equal to the number of subgraphs removed in this way.

We are left to show that $\mathbf{ds}(G[H' \to H]) = \mathbf{ds}(G) - c$. Consider any minimal dominating set D for G. We call a graph H_i *interesting* under D if D intersects H_i in any vertex besides x_i.

▷ Claim 13. There exists a solution D' of size equal to D under which at most $|R'|$ graphs per equivalence class $\mathcal{C} \in \mathcal{H}$ are interesting.

Proof. Consider any such class $\mathcal{C} \in \mathcal{H}$. If $|\mathcal{C}| \le |R'|$ we are done, so assume otherwise. Let $R'' \subseteq R'$ be the set of vertices that are dominated through vertices in graphs contained in $\mathcal{C}$ and select up to $|R''|$ many graphs that together already dominate R''; we let D' to be equivalent to D on these graphs. Any graph $H \in \mathcal{C}$ *not* selected in this way only needs to dominate itself and we add its centre vertex $V(H) \cap X$ to D'. Since every graph needs to intersect any dominating set in at least one vertex, $|D'| \le |D|$ and since D is minimal we must have $|D'| = |D|$. Finally, only the $|R''| \le |R'|$ selected graphs are interesting under D', as claimed. ◁

Thus, let us assume in the following that D is such a minimal solution under which at most $|R'|$ graphs per class $\mathcal{C} \in \mathcal{H}$ are interesting. For such a solution D of H, we construct a solution D' of H' of size $|D| - c$ as follows. For a class $\mathcal{C} \in \mathcal{H}$, let $\mathcal{C}' \subseteq \mathcal{C}$ be those graphs that are contained in H' and let $\mathcal{I} \subseteq \mathcal{C}$ be the graphs that are interesting under D. Since $|\mathcal{C}| \le |\mathcal{C}'|$, we can pair every graph $H_i \in \mathcal{C}$ with a graph $H_{i'} \in \mathcal{C}'$. Fix such a pair $H_i, H_{i'}$, let $A = R' \cap D$ and let B be those vertices of R' that are exclusively dominated vertices in H_i. Since $\chi_i[A, B] = \chi_{i'}[A, B]$, there must exist a set of $|D \cap V(H_i)|$ vertices in $H_{i'}$ that dominate $H_{i'}$ and B. If we repeat this construction for every graph $H_i \in \mathcal{C}$ with their respective pair in $\mathcal{C}'$ and then pick the centre vertex $X \cap V(H_j)$ for all $H_j \in \mathcal{C}' \setminus \mathcal{C}$, then the resulting set D' has size $\leq |D| - c$ and dominates all of H'.

The same proof works in reverse if we start with a dominating set D' of H' to construct a dominating set D of H with $|D| \leq |D'| + c$; thus we conclude that $\mathbf{ds}(G[H' \to H]) = \mathbf{ds}(G) - c$ and the claim follows. ◀

▶ **Theorem 14.** Dominating Set *above* 3*-independence has a linear kernel in bounded expansion graphs.*

Proof. Let (G, X, p) be the input instance and let $x_1, \ldots, x_\ell$ be the members of the 3-independent set X. We define the graphs $H_i := G[N^2[x_i]]$ and their respective R-neighbours $R_i := N^2[x_i] \cap R$ for $1 \leq i \leq \ell$. Let τ be as in Lemma 1. We partition the graphs $\{H_i\}_{1 \leq i \leq \ell}$ into two sets $\mathcal{L}$, $\mathcal{S}$ where $H_i \in \mathcal{L}$ iff $|R_i| > 2\tau$; and $\mathcal{S}$ contains all remaining graphs.

Let us first reduce $\mathcal{S}$. Let $\mathcal{R} := \{R_i \mid H_i \in \mathcal{S}\}$ be the R-neighbourhoods of the graphs collected in $\mathcal{S}$. By the twin class lemma, $|\mathcal{R}| \leq (4^\tau + 2\tau)|R|$, however, for each member $R' \in \mathcal{R}$ we might have many graphs in $\mathcal{S}$ that intersect R in precisely this set R'.

Fix $R' \in \mathcal{R}$ for now and let $\mathcal{S}[R']$ be those graphs of $\mathcal{S}$ that intersect R in R'. Let $H_{R'} := G[\bigcup_{H \in \mathcal{S}[R']} V(H)]$ be the joint graph of the subgraphs in $\mathcal{S}[R']$. Since $|R'| \leq 2\tau$, and τ is a constant depending only on the graph class, we can apply Lemma 12 to compute a replacement $H'_{R'}$ of size $O(|R'|^{2|R'|+2} 4^{|R'|})$ with offset c in polynomial time. We apply the replacement $G[H_{R'} \to H'_{R'}]$ and decrease p by c. Repeating this procedure for all $R' \in \mathcal{R}$ yields a graph G_1 (a subgraph of G) in which the small graphs $\mathcal{S}$ in total contain at most $|\mathcal{R}| \cdot O(|\tau|^{2\tau+2} 4^\tau) = O(|R|)$ vertices, a 3-independent set $X' \subseteq X$ of G_1, and a new input p'. This concludes our reduction for $\mathcal{S}$.

Let us now deal with $\mathcal{L}$ in G_1. By the twin class lemma, $|\mathcal{L}| \leq 2\tau|R|$. But then $|X'|$ has size bounded in $O(|R|)$ and we conclude that the size of a minimal dominating set for G_1 is bounded by $O(|R|)$, hence we assume that p' is bounded by $O(|R|)$ (otherwise the instance is positive and we can output a trivial instance). We now apply the existing linear kernel [6] for Dominating Set to G_1. The output of the kernelization is a subgraph of the original graph, hence we collect the remaining vertices of the 3-independent set $X'' \subseteq X'$ in order to output a well-formed instance (G'', X'', p''). This concludes the proof. ◀

4 Above 4-independence: simple domination

In the case where the lower-bound set X is 4-independent we now have that for distinct $x, x' \in X$ it holds that $N^2(x) \cap N^2(x') = \emptyset$, thus for each $x \in X$ the set $N^2(x) \cap R$ can only be dominated from R and $N(x)$. Let us call an instance (G, X) *reduced* if for every $x \in X$ the intersection $N^2(x) \cap R$ is non-empty. We can easily pre-process our input instance to enforce this property: if such an x would exist we can simply remove $N[x]$ from G to obtain an equivalent instance. In a reduced instance the parameter $|R|$ is necessarily big compared to $|X|$:

▶ **Observation 15.** *For every reduced instance* (G, X) *of* Dominating Set *above* 4*-independence it holds that* $|R| \geq |X|$.

▶ **Corollary 16.** *Let* $\mathcal{G}$ *be a graph class for which* Dominating Set *is in* FPT*. Then* Dominating Set *above* 4*-independence is in* FPT *for* $\mathcal{G}$ *as well.*

▶ **Corollary 17.** *Let $\mathcal{G}$ be a graph class for which* Dominating Set *admits a polynomial kernel. Then* Dominating Set *above 4-independence admits a polynomial kernel for $\mathcal{G}$ as well.*

On the other hand, we showed in Section 3.1 that the problem remains W[2]-hard for any $r \geq 2$ in general graphs.

5 Conclusion

We considered Dominating Set parametrised by the residual of a given r-independent set and investigated how the value of r and the choice of input graph classes affect its tractability. We observed that the tractability does improve from $r = 2$ to $r = 3$ as it goes from being paraNP-complete to 'merely' W[2]-hard and at least admits an XP-algorithm. Larger values of r, however, do not increase the tractability as the problem becomes essentially equivalent to Dominating Set.

If we consider sparse classes (bounded expansion and nowhere dense), the improvement in tractability from $r = 2$ to $r = 3$ is much more pronounced; changing from paraNP-complete to FPT and even admitting a linear kernel in bounded expansion classes. We very much believe that the kernel can be extended to nowhere dense classes, but leave that quite technical task as an open question.

Abstract

In this paper, we study the following problem: given a connected graph G, can we reduce the domination number of G by at least one using k edge contractions, for some fixed integer $k \geq 0$? We show that for $k \leq 2$, the problem is coNP-hard. We further prove that for $k = 1$, the problem is W[1]-hard parameterized by the size of a minimum dominating set plus the mim-width of the input graph, and that it remains NP-hard when restricted to P_9-free graphs, bipartite graphs and $\{C_3, \dots, C_\ell\}$-free graphs for any $\ell \geq 3$. Finally, we show that for any $k \geq 1$, the problem is polynomial-time solvable for P_5-free graphs and that it can be solved in FPT-time and XP-time when parameterized by tree-width and mim-width, respectively.

1 Introduction

In a graph modification problem, we are usually interested in modifying a given graph G, via a small number of operations, into some other graph G' that has a certain desired property. This property often describes a certain graph class to which G' must belong. Such graph modification problems allow to capture a variety of classical graph-theoretic problems. Indeed, if for instance only k vertex deletions are allowed and G' must be a stable set or a clique, we obtain the Stable Set or Clique problem, respectively.

Now, instead of specifying a graph class to which G' should belong, we may ask for a specific graph parameter π to decrease. In other words, given a graph G, a set $\mathcal{O}$ of one or more graph operations and an integer $k \geq 1$, the question is whether G can be transformed into a graph G' by using at most k operations from $\mathcal{O}$ such that $\pi(G') \leq \pi(G) - d$ for some *threshold* $d \geq 0$. Such problems are called *blocker problems* as the set of vertices or edges involved can be viewed as "blocking" the parameter π. Notice that identifying such sets may provide important information about the structure of the graph G.

Blocker problems have been well studied in the literature (see for instance [1, 2, 3, 4, 6, 9, 14, 15, 16, 17, 19]) and their relations to other well-known graph problems have been presented (see for instance [9, 15]). So far, the literature mainly focused on the following graph parameters: the chromatic number, the independence number, the clique number, the matching number and the vertex cover number. Furthermore, the set $\mathcal{O}$ consisted of a single graph operation, namely either vertex deletion, edge contraction, edge deletion or edge

addition. Since these blocker problems are usually NP-hard in general graphs, a particular attention has been paid to their computational complexity when restricted to special graph classes.

In this paper, we focus on another parameter, namely the domination number γ, and we restrict $\mathcal{O}$ to a single graph operation, the edge contraction. More specifically, let $G = (V, E)$ be a graph. The *contraction* of an edge $uv \in E$ removes vertices u and v from G and replaces them by a new vertex that is made adjacent to precisely those vertices that were adjacent to u or v in G (without introducing self-loops nor multiple edges). We say that a graph G can be *k-contracted* into a graph G', if G can be transformed into G' by a sequence of at most k edge contractions, for an integer $k \geq 1$ (note that contracting an edge cannot increase the domination number). We will be interested in the following problem, where $k \geq 1$ is a fixed integer.

k-Edge Contraction(γ)
Instance: A connected graph $G = (V, E)$
Question: Can G be k-edge contracted into a graph G' such that $\gamma(G') \leq \gamma(G) - 1$?

In other words, we are interested in a blocker problem with parameter γ, graph operations set $\mathcal{O}$ = {edge contraction} and threshold $d = 1$. Notice that if $\gamma(G) = 1$, that is, G contains a dominating vertex, then G is always a No-instance for k-Edge Contraction(γ). Reducing the domination number using edge contractions was first considered in [13]; given a graph $G = (V, E)$, the authors denote by $ct_\gamma(G)$ the minimum number of edge contractions required to transform G into a graph G' such that $\gamma(G') \leq \gamma(G) - 1$ and prove that for a connected graph G such that $\gamma(G) \geq 2$, we have $ct_\gamma(G) \leq 3$. It follows that a connected graph G with $\gamma(G) \geq 2$ is always a Yes-instance of k-Edge Contraction(γ), if $k \geq 3$. The authors [13] further give necessary and sufficient conditions for $ct_\gamma(G)$ to be equal to 1, respectively 2.

▶ **Theorem 1** ([13]). *For a connected graph G, the following holds.*

(i) $ct_\gamma(G) = 1$ *if and only if there exists a minimum dominating set in G that is not a stable set.*

(ii) $ct_\gamma(G) = 2$ *if and only if every minimum dominating set in G is a stable set and there exists a dominating set D in G of size $\gamma(G) + 1$ such that $G[D]$ contains at least two edges.*

To the best of our knowledge, a systematic study of the computational complexity of k-Edge Contraction(γ) has not yet been attempted in the literature. We here initiate such a study as it has been done for other parameters and several graph operations. Our paper is organised as follows[1]. In Section 2, we present definitions and notations that are used throughout the paper. In Section 3, we prove the (co)NP-hardness of k-Edge Contraction(γ) for $k = 1, 2$. We further show that 1-Edge Contraction(γ) is W[1]-hard parameterized by the size of a minimum dominating set plus the mim-width of the input graph, and that it remains NP-hard when restricted to P_9-free graphs, bipartite graphs and $\{C_3, \ldots, C_l\}$-free graphs for any $l \geq 3$. Finally, we present in Section 4 some positive results; in particular, we show that for any $k \geq 1$, k-Edge Contraction(γ) is polynomial-time solvable for P_5-free graphs and that it can be solved in FPT-time and XP-time when parameterized by tree-width and mim-width, respectively.

[1] Proofs marked by ♠ are omitted due to space constraints.

2 Preliminaries

Throughout the paper, we only consider finite, undirected, connected graphs that have no self-loops or multiple edges. We refer the reader to [8] for any terminology and notation not defined here and to [7] for basic definitions and terminology regarding parameterized complexity.

Let $G = (V, E)$ be a graph and let $u \in V$. We denote by $N_G(u)$, or simply $N(u)$ if it is clear from the context, the set of vertices that are adjacent to u i.e., the *neighbors* of u, and let $N[u] = N(u) \cup \{u\}$. Two vertices $u, v \in V$ are said to be *true twins* (resp. *false twins*), if $N[u] = N[v]$ (resp. if $N(u) = N(v)$).

For a family $\{H_1, \dots, H_p\}$ of graphs, G is said to be $\{H_1, \dots, H_p\}$*-free* if G has no induced subgraph isomorphic to a graph in $\{H_1, \dots, H_p\}$; if $p = 1$ we may write H_1-free instead of $\{H_1\}$-free. For a subset $V' \subseteq V$, we let $G[V']$ denote the subgraph of G *induced* by V', which has vertex set V' and edge set $\{uv \in E \mid u, v \in V'\}$.

We denote by $d_G(u, v)$, or simply $d(u, v)$ if it is clear from the context, the length of a shortest path from u to v in G. Similarly, for any subset $V' \subseteq V$, we denote by $d_G(u, V')$, or simply $d(u, V')$ if it is clear from the context, the minimum length of a shortest path from u to some vertex in V' i.e., $d(u, V') = \min_{v \in V'} d(u, v)$.

For a vertex $v \in V$, we write $G - v = G[V \setminus \{v\}]$ and for a subset $V' \subseteq V$ we write $G - V' = G[V \setminus V']$. For an edge $e \in E$, we denote by $G \backslash e$ the graph obtained from G by contracting the edge e. The k*-subdivision* of an edge uv consists in replacing it by a path u-v_1-…-v_k-v, where $v_1, \dots, v_k$ are new vertices.

For $n \geq 1$, the path and cycle on n vertices are denoted by P_n and C_n respectively. A graph is *bipartite* if every cycle contains an even number of vertices.

A subset $S \subseteq V$ is called a *stable set* of G if any two vertices in S are nonadjacent; we may also say that S is *stable*. A subset $D \subseteq V$ is called a *dominating set*, if every vertex in $V \setminus D$ is adjacent to at least one vertex in D; the *domination number* $\gamma(G)$ is the number of vertices in a minimum dominating set. For any $v \in D$ and $u \in N[v]$, v is said to *dominate* u (in particular, v dominates itself); furthermore, u is a *private neighbor of* v *with respect to* D if u has no neighbor in $D \backslash \{v\}$. We say that D *contains an edge* (or more) if the graph $G[D]$ contains an edge (or more). The Dominating Set problem is to test whether a given graph G has a dominating set of size at most ℓ, for some given integer $\ell \geq 0$.

3 Hardness results

In this section, we present hardness results for the k-Edge Contraction(γ) problem. Recall that for $k \geq 3$, the problem is trivial; we show that for $k = 1, 2$, it becomes (co)NP-hard. To this end, we introduce the following problem.

Contraction Number(γ,k)

Instance: A connected graph $G = (V, E)$.

Question: Is $ct_\gamma(G) = k$?

▶ **Theorem 2.** Contraction Number(γ,3) *is* NP*-hard.*

Proof. We reduce from 1-in-3 Positive 3-Sat, where each variable occurs only positively, each clause contains exactly three positive literals, and we want a truth assignment such that each clause contains exactly one true variable. This problem is known to be NP-complete [11]. Given an instance Φ of this problem, with variable set X and clause set C, we construct an equivalent instance G_Φ of Contraction Number(γ,3) as follows. For any variable $x \in X$, we introduce a copy of C_3, which we denote by G_x, with two distinguished *truth vertices* T_x and F_x (see Fig. 1); in the following, the third vertex of G_x is denoted by u_x. For any clause $c \in C$ containing variables x_1, x_2 and x_3, we introduce the gadget G_c depicted in Fig. 1 (where it is connected to the corresponding variable gadgets). The vertex set of the clique K_c corresponds to the set of subsets of size 1 of $\{x_1, x_2, x_3\}$ (hence the notation); for any $i \in \{1,2,3\}$, the vertex x_i (resp. x'_i) is connected to every vertex $v_S \in K_c$ such that $x_i \notin S$ (resp. $x_i \in S$). Finally, for $i = 1,2,3$, we add an edge between t_i (resp. x'_i) and the truth vertex T_{x_i} (resp. F_{x_i}). Our goal now is to show that Φ is satisfiable if and only if $ct_\gamma(G_\Phi) = 3$. In the remainder of the proof, given a clause $c \in C$, we denote by x_1, x_2 and x_3 the variables occuring in c and thus assume that t_i (resp. x'_i) is adjacent to T_{x_i} (resp. F_{x_i}) for $i \in \{1,2,3\}$. Let us first start with some easy observations.

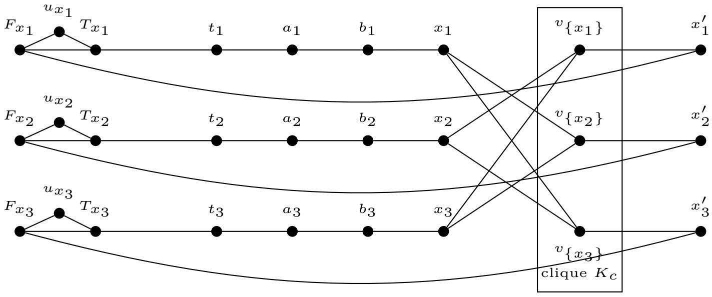

Figure 1 The gadget G_c together with G_{x_i}, $i = 1,2,3$, for a clause $c \in C$ containing variables x_1, x_2 and x_3 (the rectangle indicates that the corresponding set of vertices induces a clique).

▶ **Observation 1.** *Let D be a dominating set of G_Φ. Then for any $x \in X$, $|D \cap V(G_x)| \geq 1$ and for any $c \in C$, $|D \cap V(G_c)| \geq 4$. In particular, $|D| \geq |X| + 4|C|$.*

Clearly, for any $x \in X$, $|D \cap V(G_x)| \geq 1$ since u_x must be dominated. Also, in order to dominate vertices a_1, a_2, a_3 and $v_{\{x_1\}}$ in some gadget G_c, we need at least 4 distinct vertices, since their neighborhoods are pairwise disjoint and so, $|D \cap V(G_c)| \geq 4$, for any $c \in C$.

▶ **Observation 2.** *Let D be a dominating set of G_Φ. For any clause gadget G_c and $i \in \{1,2,3\}$, $D \cap \{a_i, b_i, x_i\} \neq \emptyset$.*

This immediately follows from the fact that every vertex b_i needs to be dominated and its neighbors are a_i and x_i for $i \in \{1,2,3\}$.

▶ **Observation 3.** *Let D be a dominating set of G_Φ. For any clause gadget G_c, if $|D \cap V(G_c)| = 4$, then $D \cap \{t_i, x'_i\} = \emptyset$ and $|D \cap \{a_i, b_i, x_i\}| = 1$, for any $i \in \{1,2,3\}$.*

If $t_i \in D$ for some $i \in \{1,2,3\}$, then it follows from Observation 2 that $|D \cap \{a_j, b_j, x_j\}| = 1$ for any $j \in \{1,2,3\}$. This implies that at least two vertices among x_1, x_2 and x_3 belong to D for otherwise there would exist $j \in \{1,2,3\}$ such that $v_{\{x_j\}}$ is not dominated. In particular, there must exist $j \neq i$ such that $x_j \in D$; but then, a_j is not dominated. Similarly, if $x'_i \in D$ for some $i \in \{1,2,3\}$, it follows from Observation 2 that $|D \cap \{a_j, b_j, x_j\}| = 1$ for any $j \in \{1,2,3\}$. But then, in order to dominate the vertices of K_c, either $x_i \in D$ in which case a_i is not dominated; or $\{x_j, j \neq i\} \subset D$ and a_j with $j \neq i$, is not dominated.

Now suppose that $|D \cap \{a_i, b_i, x_i\}| \geq 2$ for some $i \in \{1,2,3\}$. Then by Observation 2, we conclude that $|D \cap \{a_k, b_k, x_k\}| = 1$ for $k \neq i$ and $|D \cap \{a_i, b_i, x_i\}| = 2$. This implies that

$D \cap V(K_c) = \emptyset$ for otherwise we would have $|D \cap V(G_c)| \geq 5$. But then, since $x'_i \notin D$, D must contain at least two vertices among x_1, x_2 and x_3 in order to dominate the vertices of K_c; in particular, there exists $j \neq i$ such that $x_j \in D$ and so, a_j is not dominated.

▶ **Observation 4.** *Let D be a minimum dominating set of G_Φ and suppose that $ct_\gamma(G_\Phi) = 3$. Then for any vertices $u, v \in D$, we have $d(u, v) \geq 3$.*

Indeed, if u, v are adjacent, we conclude by Theorem 1(i) that $ct_\gamma(G_\Phi) = 1$; and if u, v are at distance 2 then $D \cup \{w\}$, where w is the vertex on a shortest path from u to v, contains two edges and we conclude by Theorem 1(ii) that $ct_\gamma(G_\Phi) = 2$.

▶ **Observation 5.** *Let D be a minimum dominating set of G_Φ and suppose that $ct_\gamma(G_\Phi) = 3$. Then for any clause gadget G_c and $i \in \{1, 2, 3\}$, $a_i \in D$ if and only if $T_{x_i} \notin D$.*

This readily follows from Observation 4. Further note that we may assume that for any $i \in \{1, 2, 3\}$, $a_i \in D$ if and only if $F_{x_i} \in D$; $T_{x_i} \notin D$ is equivalent to $\{F_{x_i}, u_{x_i}\} \cap D \neq \emptyset$ and if $T_{x_i} \notin D$, we may always replace D by $(D \backslash \{u_{x_i}\}) \cup \{F_{x_i}\}$.

▶ **Observation 6.** *Let D be a minimum dominating set of G_Φ and suppose that $ct_\gamma(G_\Phi) = 3$. Then for any clause gadget G_c, $|D \cap \{a_1, a_2, a_3\}| \leq 2$.*

If it weren't the case then, by Observation 4, no x_i or b_i $(i = 1, 2, 3)$ would belong to D. But since x_1, x_2 and x_3 must be dominated, it follows that $D \cap V(K_c) \neq \emptyset$ and by Observation 5, we conclude that D contains two vertices at distance two (namely, $v_{\{x_i\}} \in D \cap V(K_c)$ and F_{x_i} for some $i \in \{1, 2, 3\}$), which contradicts Observation 4.

▶ **Observation 7.** *Let D be a minimum dominating set of G_Φ and suppose that $ct_\gamma(G_\Phi) = 3$. Then for any clause gadget G_c, $|D \cap \{b_1, b_2, b_3\}| \leq 1$.*

Indeed, if we assume, without loss of generality, that $b_1, b_2 \in D$, then by Observation 4, $D \cap V(K_c) = \emptyset$. It then follows from Observation 4 that $x'_3 \in D$ for otherwise $V_{\{x_3\}}$ would not be dominated. But then $D \cap V(G_{x_3}) = \emptyset$ by Observation 4, which contradicts Observation 1.

▶ **Claim 1.** *$\gamma(G_\Phi) = |X| + 4|C|$ if and only if $ct_\gamma(G_\Phi) = 3$.*

Assume that $\gamma(G_\Phi) = |X| + 4|C|$ and consider a minimum dominating set D of G_Φ. We first show that D is a stable set which would imply that $ct_\gamma(G_\Phi) > 1$ (see Theorem 1(i)). First note that Observation 1 implies that $|D \cap V(G_x)| = 1$ and $|D \cap V(G_c)| = 4$, for any variable $x \in X$ and any clause $c \in C$. It then follows from Observation 3 that no truth vertex is dominated by some vertex t_i or x'_i in some clause gadget G_c with $i \in \{1, 2, 3\}$; in particular, this implies that there can exist no edge in D having one endvertex in some gadget G_x $(x \in X)$ and the other in some gadget G_c $(c \in C)$. Hence, it is enough to show that for any $c \in C$, $D \cap V(G_c)$ is a stable set.

Now consider a clause gadget G_c. It follows from Observation 3 that if there exists $i \in \{1, 2, 3\}$ such that $a_i \notin D$ then $b_i \in D$ since a_i must be dominated (also note that by Observation 3, if $a_i \in D$ then $b_i \notin D$). Hence, for any $i \in \{1, 2, 3\}$, exactly one of a_i and b_i belongs to D. But then, by Observation 3 and since $|D \cap V(G_c)| = 4$, we immediately conclude that $D \cap V(G_c)$ is a stable set and so, D is a stable set.

Now, suppose to the contrary that $ct_\gamma(G_\Phi) = 2$ i.e., there exists a dominating set D' of G_Φ of size $\gamma(G_\Phi) + 1$ containing two edges e and e' (see Theorem 1(ii)). First assume that there exists $x \in X$ such that $|D' \cap V(G_x)| = 2$. Then, for any $x' \neq x$, $|D' \cap V(G_{x'})| = 1$; and for any $c \in C$, $|D' \cap V(G_c)| = 4$ which by Observation 3 implies that $\{t_i, x'_i\} \cap D' = \emptyset$ for any $i \in \{1, 2, 3\}$. Since as shown previously, $D' \cap V(G_c)$ is then a stable set, it follows that D' contains at most one edge, a contradiction.

Thus, there must exist some $c \in C$ such that $|D' \cap V(G_c)| = 5$. We then claim that $\{a_1, a_2, a_3\} \not\subset D'$. Indeed, since $x_1, x_2, x_3, v_{\{x_1\}}, v_{\{x_2\}}$ and $v_{\{x_3\}}$ must be dominated, $D' \cap V(K_c) \neq \emptyset$ (otherwise, at least three additional vertices of G_c would be required to dominate x_1, x_2 and x_3), say $v_{\{x_1\}} \in D'$ without loss of generality. But then, $|N[x_1] \cap D'| = 1$ as x_1 must be dominated and $|D' \cap V(G_c)| = 5$ and so, D' contains at most one edge. Therefore, there must exist $i \in \{1,2,3\}$ such that $a_i \notin D'$, say $a_1 \notin D'$ without loss of generality. Then, since a_1 must be dominated, either $t_1 \in D'$ or $b_1 \in D'$.

Assume first that t_1 belongs to D' (note that $\{b_1, x_1\} \cap D' \neq \emptyset$ by Observation 2). We then claim that either e or e' has an endvertex in $\{a_j, b_j, x_j\}$ for some $j \neq 1$. Indeed, if it weren't the case, then t_1 would be an endvertex of neither e nor e' for otherwise $T_{x_1} \in D'$ which implies that $D' \cap \{v_{\{x_1\}}, x'_1\} \neq \emptyset$ as $|D' \cap V(G_{x_1})| = 1$ and x'_1 should be dominated. But then, D' contains at most one edge as $5 = |D' \cap V(G_c)| \geq |\{t_1\}| + |D' \cap \{b_1, x_1\}| + |D' \cap \{v_{\{x_1\}}, x'_1\}| + |D' \cap \{a_j, b_j, x_j, j \neq 1\}| \geq 1 + 1 + 1 + 2$ and neither e nor e' has an endvertex in $\{a_j, b_j, x_j\}$ for some $j \neq 1$ by assumption, a contradiction. Since e and e' have at most one common endvertex, it then follows that $|D' \cap V(G_c)| \geq |\{t_1\}| + |D' \cap \{a_j, b_j, x_j, j \neq 1\}| + 3 \geq 1 + 2 + 3$, a contradiction. Thus, either e or e' has an endvertex in $\{a_j, b_j, x_j\}$ for some $j \neq 1$, say $j = 2$ without loss of generality. Suppose that x_2 is an endvertex of e. Then the other endvertex of e should be b_2 for otherwise it belongs to K_c and thus, a_2 would not be dominated. But then, we conclude by Observation 2 and the fact that $|D' \cap V(G_c)| = 5$, that D' contains only one edge. Thus, $e = a_2 b_2$ or $e = a_2 t_2$ and since $v_{\{x_1\}}$ must be dominated, necessarily $x_3 \in D'$; but then, a_3 is not dominated. Therefore, it must be that b_1 belongs to D'; and we conclude similarly that if a_2 (resp. a_3) is not in D' then b_2 (resp. b_3) belongs to D'.

Now, since $t_1, a_1 \notin D'$, it follows that $T_{x_1} \in D'$ for otherwise t_1 would not be dominated. But $|D' \cap V(G_x)| = 1$ and so, $F_{x_1} \notin D'$; thus, $D' \cap \{x'_1, v_{\{x_1\}}\} \neq \emptyset$ as x'_1 must be dominated and we may assume, without loss of generality, that in fact, $v_{\{x_1\}} \in D'$. Then, if $D' \cap \{v_{\{x_2\}}, v_{\{x_3\}}\} = \emptyset$, necessarily $F_{x_2}, F_{x_3} \in D'$; indeed, since $|D' \cap V(G_c)| = 5$, at least one among x'_2 and x'_3 does not belong to D', say x'_2 without loss of generality. But if $x'_3 \in D'$, then exactly one of a_j and b_j, for $j \neq 1$ belongs to D' (recall that if $a_j \notin D'$ then $b_j \in D'$) and therefore, D' contains at most one edge. Thus, $F_{x_2}, F_{x_3} \in D'$ which implies that $D' \cap \{t_j, a_j\} \neq \emptyset$ for $j \neq 1$ as t_j must be dominated. But by Observation 2 and the fact that $|D' \cap V(G_c)| = 5$, we have that $|D' \cap \{t_2, t_3\}| \leq 1$ and so, D' contains at most one edge. Thus, $D' \cap \{v_{\{x_2\}}, v_{\{x_3\}}\} \neq \emptyset$ and since by Observation 2 $|D' \cap V(K_c)| \leq 2$, we conclude that in fact $|D' \cap V(K_c)| = 2$. But then, exactly one among a_j and b_j belongs to D' for $j \neq 1$ and so, D' contains only one edge. Consequently, no such dominating set D' exists and thus, $ct_\gamma(G_\Phi) = 3$.

Conversely, assume that $ct_\gamma(G_\Phi) = 3$ and consider a minimum dominating set D of G_Φ. It readily follows from Observations 1 and 4 that for any variable $x \in X$, $|D \cap V(G_x)| = 1$. Now consider a clause gadget G_c. Then, by Observation 4, we obtain that $t_i \notin D$ (resp. $x'_i \notin D$) for $i \in \{1,2,3\}$, as otherwise it would be within distance at most 2 from the vertex in D belonging to the gadget G_{x_i}.

Now since for any $i \in \{1,2,3\}$, $t_i \notin D$, if $a_i \notin D$ then $b_i \in D$ as a_i must be dominated (also note that by Observation 4, if $a_i \in D$ then $b_i \notin D$). Thus, by Observations 6 and 7, we conclude that for any clause gadget G_c, $|D \cap \{a_1, a_2, a_3\}| = 2$ and $|D \cap \{b_1, b_2, b_3\}| = 1$, say $a_1, a_2, b_3 \in D$ without loss of generality. But then, $v_{\{x_3\}}$ must belong to D; indeed, since $b_3 \in D$, it follows that $T_{x_3} \in D$ for otherwise t_3 is not dominated. Observation 4 then implies that $x'_3 \notin D$ and thus, it can only be dominated by $v_{\{x_3\}}$. But then, it follows from Observation 5 that every vertex in G_c is dominated and we conclude that $|D \cap V(G_c)| = 4$ by minimality of D. Consequently, $|D| = |X| + 4|C|$ which concludes the proof of Claim 1.

▶ **Claim 2.** $\gamma(G_\Phi) = |X| + 4|C|$ *if and only if* Φ *is satisfiable.*

Assume first that $\gamma(G_\Phi) = |X| + 4|C|$ and consider a minimum dominating set D of G_Φ. We construct a truth assignment from D satisfying Φ as follows. For any $x \in X$, if $T_x \in D$, set x to true; otherwise, set x to false. We claim that each clause $c \in C$ has exactly one true variable. Indeed, it follows from Observation 1 that $|D \cap V(G_c)| = 4$ for any $c \in C$, and from Claim 1 that $ct_\gamma(G_\Phi) = 3$. But then, by Observation 3, for any $i \in \{1,2,3\}$, $a_i \notin D$ if and only if $b_i \in D$ (a_i would otherwise not be dominated). It then follows from Observations 6 and 7 that $|D \cap \{a_1,a_2,a_3\}| = 2$ and $|D \cap \{b_1,b_2,b_3\}| = 1$ for any $c \in C$; but by Observation 5 we conclude that $b_i \in D$ if and only if $T_{x_i} \in D$, which proves our claim.

Conversely, assume that Φ is satisfiable and consider a truth assignment satisfying Φ. We construct a dominating set D of G_Φ as follows. If variable x is set to true, we add T_x to D; otherwise, we add F_x to D. For any clause $c \in C$ and $i \in \{1,2,3\}$, if $T_{x_i} \in D$, then add b_i to D; otherwise, add a_i to D. Since every clause has exactly one true variable, it follows that $|D \cap \{b_1,b_2,b_3\}| = 1$ and $|D \cap \{a_1,a_2,a_3\}| = 2$; finally add $v_{\{x_i\}}$ to D where $b_i \in D$. Now clearly $|D \cap V(G_c)| = 4$ and every vertex in G_c is dominated. Thus, $|D| = |X| + 4|C|$ and so by Observation 1, $\gamma(G_\Phi) = |X| + 4|C|$, which concludes this proof.

Now combining Claims 1 and 2, we have that Φ is satisfiable if and only if $ct_\gamma(G_\Phi) = 3$ which completes the proof of Theorem 2. ◀

By observing that for any graph G, G is a YES-instance for CONTRACTION NUMBER(γ,3) if and only if G is a NO-instance for 2-EDGE CONTRACTION(γ), we deduce the following corollary from Theorem 2.

▶ **Corollary 3.** 2-EDGE CONTRACTION(γ) *is* coNP*-hard.*

It is thus coNP-hard to decide whether $ct_\gamma(G) \leq 2$ for a graph G; and in fact, it is NP-hard to decide whether equality holds, as stated in the following.

▶ **Theorem 4 (♠).** CONTRACTION NUMBER(γ,2) *is* NP*-hard.*

We finally consider the case $k = 1$.

▶ **Theorem 5.** 1-EDGE CONTRACTION(γ) *is* NP*-hard even when restricted to* P_t*-free graphs, with* $t \geq 9$.

Proof. We reduce from DOMINATING SET: given an instance (G,ℓ) of this problem, we construct an equivalent instance G' of 1-EDGE CONTRACTION(γ) as follows. We denote by $\{v_1,\dots,v_n\}$ the vertex set of G. The graph G' consists of $\ell+1$ copies of G, denoted by $G_0,\dots,G_\ell$, connected in such a way that for any $1 \leq i \leq \ell$ and $1 \leq k \leq n$, the copies $v_k^i \in V(G_i)$ and $v_k^0 \in V(G_0)$ of a vertex v_k of G are true twins in the subgraph of G' induced by $V(G_0) \cup V(G_i)$; and for any $1 \leq i,j \leq \ell$ and $1 \leq k \leq n$, the copies $v_k^i \in V(G_i)$ and $v_k^j \in V(G_j)$ of a vertex v_k of G are false twins in the subgraph of G' induced by $\bigcup_{1 \leq p \leq \ell} V(G_p)$. Next, we add $\ell+1$ pairwise nonadjacent vertices $x_1,\dots,x_{\ell+1}$, which are made adjacent to every vertex in G_0; x_i is further made adjacent to every vertex in G_i, for all $1 \leq i \leq \ell$. Finally, we add a vertex y adjacent to only $x_{\ell+1}$ (see Fig. 2). Note that the fact that for all $1 \leq k \leq n$ and $1 \leq i,j \leq \ell$, v_k^i and v_k^j (resp. v_k^i and v_k^0) are false (resp. true) twins within the graph induced by $\bigcup_{1 \leq p \leq \ell} V(G_p)$ (resp. $V(G_0) \cup V(G_i)$) is not made explicit on Fig. 2 for the sake of readability. In the following, we denote by $X = \{x_1,\dots,x_{\ell+1}\}$ and $V = \bigcup_{0 \leq p \leq \ell} V(G_p)$. We now claim the following.

▶ **Claim 3.** $\gamma(G') = \min\{\gamma(G)+1, \ell+1\}$.

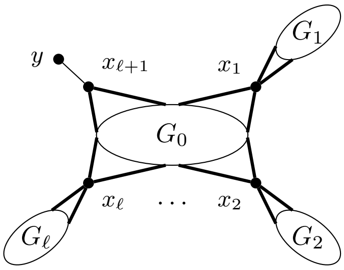

Figure 2 The graph G' (thick lines indicate that the vertex x_i is adjacent to every vertex in G_0 and G_i, for $i = 1, \dots, \ell + 1$).

It is clear that $\{x_1, \dots, x_{\ell+1}\}$ is a dominating set of G'; thus, $\gamma(G') \leq \ell + 1$. If $\gamma(G) \leq \ell$ and $\{v_{i_1}, \dots, v_{i_k}\}$ is a minimum dominating set of G, it is easily seen that $\{v^0_{i_1}, \dots, v^0_{i_k}, x_{\ell+1}\}$ is a dominating set of G'. Thus, $\gamma(G') \leq \gamma(G) + 1$ and so, $\gamma(G') \leq \min\{\gamma(G) + 1, \ell + 1\}$. Now, suppose to the contrary that $\gamma(G') < \min\{\gamma(G) + 1, \ell + 1\}$ and consider a minimum dominating D' set of G'. We first make the following simple observation.

▶ **Observation 8.** *For any dominating set D of G', $D \cap \{y, x_{\ell+1}\} \neq \emptyset$.*

Now, since $\gamma(G') < \ell + 1$, there exists $1 \leq i \leq \ell$ such that $x_i \notin D'$ (otherwise, $\{x_1, \dots, x_\ell\} \subset D'$ and combined with Observation 8, D' would be of size at least $\ell + 1$). But then, $D'' = D' \cap V$ must dominate every vertex in G_i, and so $|D''| \geq \gamma(G)$. Since $|D''| \leq |D'| - 1$ (recall that $D' \cap \{y, x_{\ell+1}\} \neq \emptyset$), we then have $\gamma(G) \leq |D'| - 1$, a contradiction. Thus, $\gamma(G') = \min\{\gamma(G) + 1, \ell + 1\}$.

We now show that (G, ℓ) is a Yes-instance for Dominating Set if and only if G' is a Yes-instance for 1-Edge Contraction(γ).

First assume that $\gamma(G) \leq \ell$. Then, $\gamma(G') = \gamma(G) + 1$ by the previous claim, and if $\{v_{i_1}, \dots, v_{i_k}\}$ is a minimum dominating set of G, then $\{v^0_{i_1}, \dots, v^0_{i_k}, x_{\ell+1}\}$ is a minimum dominating set of G' which is not stable. Hence, by Theorem 1(i), G' is a Yes-instance for 1-Edge Contraction(γ).

Conversely, assume that G' is a Yes-instance for 1-Edge Contraction(γ) i.e., there exists a minimum dominating set D' of G' which is not stable (see Theorem 1(i)). Then, Observation 8 implies that there exists $1 \leq i \leq \ell$ such that $x_i \notin D'$; indeed, if it weren't the case, then by Claim 3 we would have $\gamma(G') = \ell + 1$ and thus, D' would consist of $x_1, \dots, x_\ell$ and either y or $x_{\ell+1}$. In both cases, D' would be stable, a contradiction. It follows that $D'' = D' \cap V$ must dominate every vertex in G_i and thus, $|D''| \geq \gamma(G)$. But $|D''| \leq |D'| - 1$ (recall that $D' \cap \{y, x_{\ell+1}\} \neq \emptyset$) and so by Claim 3, $\gamma(G) \leq |D'| - 1 \leq (\ell + 1) - 1$ that is, (G, ℓ) is a Yes-instance for Dominating Set.

▷ Claim 6 (♠). If G is a $2K_2$-free graph, then G' is a P_9-free graph.

Since Dominating Set is NP-complete on $2K_2$-free graphs [5], the above claim concludes the proof of Theorem 5. ◀

Given the NP-hardness of 1-Edge Contraction(γ) and its close relation to Dominating Set, it is natural to consider the complexity of the problem when parameterized by the size of a minimum dominating set of the input graph. In the following, we show that 1-Edge Contraction(γ) is W[1]-hard when parameterized by $\gamma + mimw$, where $mimw$ denotes the maximum induced matching-width parameter (in short, mim-width). For a formal definition and basic properties of this width measure we refer the reader to [18]. We first state two simple facts regarding the mim-width of a graph.

▶ **Observation 9.** *Let G be a graph and $u, v \in V(G)$ be two vertices that are true (resp. false) twins in G. Then $mimw(G - v) = mimw(G)$.*

▶ **Observation 10.** *Let G be a graph and $v \in V(G)$. Then $mimw(G) \leq mimw(G - v) + 1$.*

▶ **Theorem 7.** 1-Edge Contraction(γ) *is* W[1]*-hard parameterized by $\gamma + mimw$.*

Proof. We give a parameterized reduction from Dominating Set parameterized by solution size plus mim-width, which is a problem that was recently shown to be W[1]-hard by Fomin et al. [10]. Given an instance (G, ℓ) of Dominating Set, the construction of the equivalent instance G' for 1-Edge Contraction(γ) is the same as the one introduced in the proof of Theorem 5; and it is there shown that G is a Yes-instance for Dominating Set if and only if G' is a Yes-instance for 1-Edge Contraction(γ). Now, note that G' can be obtained from G by the addition of true twins (the set $V(G_1)$), the addition of false twins (the sets $V(G_2), \ldots, V(G_\ell)$), and the addition of $\ell + 2$ vertices $(x_1, \ldots, x_{\ell+1}, y)$. By Observation 9, the addition of true (resp. false) twins does not increase the mim-width of a graph and, by Observation 10, the addition of a vertex can only increase the mim-width of G by one; thus, $mimw(G') \leq mimw(G) + \ell + 2$ and since $\gamma(G') \leq \ell + 1$ by Claim 3, we conclude that $mimw(G') + \gamma(G') \leq mimw(G) + 2\ell + 3$. ◀

In order to obtain complexity results for further graph classes, let us now consider subdivisions of edges.

▶ **Lemma 8 (♠).** *Let G be a graph and let G' be the graph obtained by 3-subdividing every edge of G. Then G is a* Yes*-instance for* 1-Edge Contraction(γ) *if and only if G' is a* Yes*-instance for* 1-Edge Contraction(γ)*.*

By 3-subdividing every edge of a graph G sufficiently many times, we deduce the following two corollaries from Lemma 8.

▶ **Corollary 9.** 1-Edge Contraction(γ) *is* NP*-hard when restricted to bipartite graphs.*

▶ **Corollary 10.** *For any $\ell \geq 3$,* 1-Edge Contraction(γ) *is* NP*-hard when restricted to $\{C_3, \ldots, C_\ell\}$-free graphs.*

We finally observe that, even if an edge is given, deciding whether contracting this particular edge decreases the domination number is unlikely to be solvable in polynomial time as shown in the following result.

▶ **Theorem 11.** *There exists no polynomial-time algorithm deciding whether contracting a given edge decreases the domination number, unless* P = NP*.*

Proof. We denote by Edge Contraction(γ) the problem that takes as an input a graph $G = (V, E)$ and an edge $e \in E$, and asks whether $\gamma(G \backslash e) \leq \gamma(G) - 1$. We show that if Edge Contraction(γ) can be solved in polynomial time, then Dominating Set can also be solved in polynomial time. Since Dominating Set is a well-known NP-complete problem, the result follows.

Let (G, ℓ) be an instance for Dominating Set and let e be an edge of G. We run the polynomial time algorithm for Edge Contraction(γ) to determine if $\gamma(G \setminus e) = \gamma(G) - 1$; we then have two possible scenarios.

Case 1. (G, e) is a YES-instance for EDGE CONTRACTION(γ). Since $\gamma(G \setminus e) = \gamma(G) - 1$, we know that G has a dominating set of size ℓ if and only if $G \setminus e$ has a dominating set of size $\ell - 1$. Hence, we obtain that $(G \setminus e, \ell - 1)$ is an equivalent instance for DOMINATING SET.

Case 2. (G, e) is a NO-instance for EDGE CONTRACTION(γ). Since $\gamma(G \setminus e) = \gamma(G)$, we know that G has a dominating set of size ℓ if and only if $G \setminus e$ has a dominating set of size ℓ. In this case, we obtain that $(G \setminus e, \ell)$ is an equivalent instance for DOMINATING SET.

In both cases, the ensuing equivalent instance has one less vertex. Thus, by applying the polynomial-time algorithm for EDGE CONTRACTION(γ) at most n times, we obtain a trivial instance for DOMINATING SET and can therefore correctly determine its answer. ◀

4 Algorithms

We now deal with cases in which k-EDGE CONTRACTION(γ) is tractable, for $k = 1, 2$. A first simple approach to the problem, from which we obtain Proposition 12, is based on brute force.

▶ **Proposition 12.** *For $k = 1, 2$, k-*EDGE CONTRACTION(γ) *can be solved in polynomial time for a graph class $\mathcal{C}$, if either*

(a) *$\mathcal{C}$ is closed under edge contractions and* DOMINATING SET *can be solved in polynomial time on $\mathcal{C}$; or*

(b) *for every $G \in \mathcal{C}$, $\gamma(G) \leq q$, where q is some fixed constant; or*

(c) *$\mathcal{C}$ is the class of $(H + K_1)$-free graphs, where $|V_H| = q$ is a fixed constant and k-*EDGE CONTRACTION(γ) *is polynomial-time solvable on H-free graphs.*

Proof. In order to prove item (a), it suffices to note that if we can compute $\gamma(G)$ and $\gamma(G \setminus e)$, for any edge e of G, in polynomial time, then we can determine whether a graph G is a YES-instance for 1-EDGE CONTRACTION(γ) in polynomial time (we may proceed in a similar fashion for 2-EDGE CONTRACTION(γ)).

For item (b), we proceed as follows. Given a graph G of $\mathcal{C}$, we first check whether G has a dominating vertex. If it is the case, then G is a NO-instance for k-EDGE CONTRACTION(γ) for both $k = 1, 2$. Otherwise, we may consider any subset $S \subset V(G)$ with $|S| \leq q$ and check whether it is a dominating set of G. Since there are at most $\mathcal{O}(n^q)$ possible such subsets, we can determine the domination number of G and check whether the conditions given in Theorem 1 (i) or (ii) are satisfied in polynomial time.

Finally, so as to prove item (c), we provide the following algorithm that works similarly for $k = 1$ and $k = 2$. Let H and q be as stated and let G be an instance of k-EDGE CONTRACTION(γ) on $(H + K_1)$-free graphs. We first test whether G is H-free (note that this can be done in time $\mathcal{O}(n^q)$). If this is the case, we use the polynomial-time algorithm for k-EDGE CONTRACTION(γ) on H-free graphs. Otherwise, G has an induced subgraph isomorphic to H; but since G is a $(H+K_1)$-free graph, $V(H)$ must then be a dominating set of G and so, $\gamma(G) \leq q$. We then conclude by Proposition 12(b) that k-EDGE CONTRACTION(γ) is also polynomial-time solvable in this case. ◀

Proposition 12(b) provides an algorithm for 1-EDGE CONTRACTION(γ) parameterized by the size of a minimum dominating set of the input graph running in XP-time. Note that this result is optimal as 1-EDGE CONTRACTION(γ) is W[1]-hard with such parameterization from Theorem 7.

We further show that even though simple, this brute force method provides polynomial-time algorithms for a number of relevant classes of graphs, such as graphs of bounded tree-width and graphs of bounded mim-width. We first state the following result and observation.

▶ **Theorem 13.** [18] *Given a graph G and a decomposition of width t,* Dominating Set *can be solved in time $\mathcal{O}^*(3^t)$ when parameterized by tree-width, and in time $\mathcal{O}^*(n^{3t})$ when parameterized by mim-width.*

▶ **Observation 11.** $mimw(G \setminus e) \leq mimw(G) + 1$.

Indeed, note that the graph $G \setminus e$ can be obtained from G by the removal of the vertices u and v where $e = uv$, and the addition of a new vertex whose neighborhood is $N_G(u) \cup N_G(v)$. The result then follows from Observation 10 and the fact that vertex deletion does not increase the mim-width of a graph.

▶ **Proposition 14.** *Given a decomposition of width t, k-*Edge Contraction*(γ) can be solved in time $\mathcal{O}^*(3^t)$ in graphs of tree-width at most t and in time $\mathcal{O}^*(n^{3t})$ in graphs of mim-width at most t, for $k = 1, 2$.*

Proof. We use the above-mentioned brute force approach and Theorem 13. That is, for $k = 1$, the algorithm first computes $\gamma(G)$ and then computes $\gamma(G \setminus e)$ for every $e \in E(G)$. For $k = 2$, the algorithm proceeds similarly for every pair of edges. We next show that the width parameters increase by a constant when contracting at most two edges. It is a well-known fact that $tw(G \setminus e) \leq tw(G)$ and so, $tw(G \setminus \{e, f\}) \leq tw(G)$. By Observation 11, $mimw(G \setminus e) \leq mimw(G) + 1$ which implies that $mimw(G \setminus \{e, f\}) \leq mimw(G) + 2$. Also note that, given a tree (resp. mim) decomposition of width t for G, we can construct in polynomial time decompositions of width t (resp. at most $t + 2$) for $G \setminus e$ and $G \setminus \{e, f\}$. This implies that $\gamma(G \setminus e)$ and $\gamma(G \setminus \{e, f\})$ can also be computed in time $\mathcal{O}^*(3^t)$ if G is a graph of tree-width at most t, and in time $\mathcal{O}^*(n^{3t})$ if G is a graph of mim-width at most t. ◀

Proposition 14 provides an algorithm for 1-Edge Contraction(γ) parameterized by mim-width running in XP-time; this result is optimal as 1-Edge Contraction(γ) is W[1]-hard parameterized by mim-width from Theorem 7.

Since Dominating Set is polynomial-time solvable in P_4-free graphs (see [12]), it follows from Proposition 12(a) that k-Edge Contraction(γ) can also be solved efficiently in this graph class. However, Dominating Set is NP-complete for P_5-free graphs (see [5]) and thus, it is natural to examine the complexity of k-Edge Contraction(γ) for this graph class. As we next show, k-Edge Contraction(γ) is in fact polynomial-time solvable on P_5-free graphs, for $k = 1, 2$.

▶ **Lemma 15.** *If G is a P_5-free graph with $\gamma(G) \geq 3$, then $ct_\gamma(G) = 1$.*

Proof. Let $G = (V, E)$ be a P_5-free graph and D be a minimum dominating set of G. Suppose that D is a stable set and consider $u, v \in D$ such that $d(u, v) = \max_{x,y \in D} d(x, y)$. Since G is P_5-free, $d(u, v) \leq 3$ and, since D is stable, $d(u, v) \geq 2$. We distinguish two cases depending on this distance.

Case 1. $d(u, v) = 3$. Let x (resp. y) be the neighbor of u (resp. v) on a shortest path from u to v. Then, $N(u) \cup N(v) \subseteq N(x) \cup N(y)$; indeed, if a is a neighbor of u, then a is nonadjacent to v (recall that $d(u, v) = 3$) and thus, a is adjacent to either x or y for otherwise a, u, x, y and v would induce a P_5 in G. The same holds for any neighbor of v. Consequently, $(D\backslash\{u, v\}) \cup \{x, y\}$ is a minimum dominating set of G which is not stable; the result then follows from Theorem 1(i).

Case 2. $d(u, v) = 2$. Since D is stable and $d(u, v) = \max_{x,y \in D} d(x, y) = 2$, it follows that every $w \in D\backslash\{u, v\}$ is at distance two from both u and v. Let x (resp. y) be the vertex on a shortest path from u (resp. v) to some vertex $w \in D\backslash\{u, v\}$.

Suppose first that $x = y$. If every private neighbor of w with respect to D is adjacent to x then $(D\backslash\{w\}) \cup \{x\}$ is a minimum dominating set of G which is not stable; the result then follows from Theorem 1(i). We conclude similarly if every private neighbor of u or v with respect to D is adjacent to x. Thus, we may assume that w (resp. u; v) has a private neighbor t (resp. r; s) with respect to D which is nonadjacent to x. Since G is P_5-free, it then follows that r, s and t are pairwise adjacent. But then, t, r, u, x and v induce a P_5, a contradiction.

Finally, suppose that $x \neq y$ (we may also assume that $uy, vx \notin E$ as we otherwise fall back in the previous case). Then, $xy \in E$ for u, x, w, y and v would otherwise induce a P_5. Now, if a is a private neighbor of u with respect to D then a is adjacent to either x or y (a, u, x, y and v otherwise induce a P_5); we conclude similarly that any private neighbor of v with respect to D is adjacent to either x or y. If b is adjacent to both u and v but not w, then it is adjacent to x (and y) as v, b, u, x and w (u, b, v, y and w) would otherwise induce a P_5. But then, $(D\backslash\{u, v\}) \cup \{x, y\}$ is a minimum dominating set of G which is not stable; thus, by Theorem 1(i), $ct_\gamma(G) = 1$ which concludes the proof. ◀

▶ **Theorem 16.** k-Edge Contraction(γ) *is polynomial-time solvable on* P_5*-free graphs, for* $k = 1, 2$.

Proof. If G has a dominating vertex, then G is clearly a No-instance for both $k = 1, 2$. Now, for every $uv \in E(G)$, we check whether $\{u, v\}$ is a dominating set. If it is the case, then by Theorem 1(i), G is a Yes-instance for k-Edge Contraction(γ) for $k = 1, 2$. If no edge of G is dominating, we consider all the pairs of nonadjacent vertices of G. If there exists such a pair dominating G and $k = 1$ then by Theorem 1(i), we have a No-instance for 1-Edge Contraction(γ) since this implies that every minimum dominating set of G is stable. For the case $k = 2$, if G has two nonadjacent vertices dominating G, we then consider all triples of vertices of G to check whether there exists one which is dominating and contains at least two edges (see Theorem 1(ii)). Finally, both for $k = 1$ and $k = 2$, if G has no dominating set of size at most two, then by Lemma 15, G is a Yes-instance for k-Edge Contraction(γ). ◀

5 Conclusion

In this paper, we studied the k-Edge Contraction(γ) problem and provided the first complexity results. In particular, we showed that 1-Edge Contraction(γ) is NP-hard for P_t-free graphs, $t \geq 9$, but polynomial-time solvable for P_5-free graphs; it would be interesting to determine the complexity status for P_ℓ-free graphs, for $\ell \in \{6, 7, 8\}$. Similarly, the complexity of 2-Edge Contraction(γ) for P_t-free graphs, with $t \geq 6$, remains an interesting open problem.

Abstract

We develop a framework for applying treewidth-based dynamic programming on graphs with "hybrid structure", i.e., with parts that may not have small treewidth but instead possess other structural properties. Informally, this is achieved by defining a refinement of treewidth which only considers parts of the graph that do not belong to a pre-specified tractable graph class. Our approach allows us to not only generalize existing fixed-parameter algorithms exploiting treewidth, but also fixed-parameter algorithms which use the size of a modulator as their parameter. As the flagship application of our framework, we obtain a parameter that combines treewidth and rank-width to obtain fixed-parameter algorithms for Chromatic Number, Hamiltonian Cycle, and Max-Cut.

1 Introduction

Over the past decades, the use of structural properties of graphs to obtain efficient algorithms for NP-hard computational problems has become a prominent research direction in computer science. Perhaps the best known example of a structural property that can be exploited in this way is the tree-likeness of the inputs, formalized in terms of the decomposition-based structural parameter *treewidth* [35]. It is now well known that a vast range of fundamental problems admit so-called *fixed-parameter* algorithms parameterized by the treewidth of the input graph – that is, can be solved in time $f(k) \cdot n^{\mathcal{O}(1)}$ on n-vertex graphs of treewidth k (for some computable function f). We say that such problems are FPT parameterized by treewidth.

LIPICS Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

On the other hand, dense graphs are known to have high treewidth and hence require the use of different structural parameters; the classical example of such a parameter tailored to dense graphs is *clique-width* [8]. Clique-width is asymptotically equivalent to the structural parameter *rank-width* [34], which is nowadays often used instead of clique-width due to a number of advantages (rank-width is much easier to compute [26] and can be used to design more efficient fixed-parameter algorithms than clique-width [21, 22]). While rank-width (or, equivalently, clique-width) dominates[1] treewidth and can be used to "lift" fixed-parameter algorithms designed for treewidth to well-structured dense graphs for a number of problems, there are also important problems which are FPT parameterized by treewidth but W[1]-hard (and hence probably not FPT) parameterized by rank-width. The most prominent examples of such problems are Chromatic Number [18], Hamiltonian Cycle [18], and Max-Cut [19].

Another generic type of structure used in algorithmic design is based on measuring the size of a *modulator* (i.e., a vertex deletion set) [5] to a certain graph class. Basic examples of parameters based on modulators include the vertex cover number (a modulator to edgeless graphs) [16] and the feedback vertex set number (a modulator to forests)[3]. For dense graphs, modulators to graphs of rank-width 1 have been studied [13, 30], and it is known that for every constant c one can find a modulator of size at most k to graphs of rank-width c (if such a modulator exists) in time $f(k) \cdot n$ [29]. However, the algorithmic applications of such modulators have remained largely unexplored up to this point.

Our Contribution. We develop a class of *hybrid parameters* which combines the foremost advantages of treewidth and modulators to obtain a "best-of-both-worlds" outcome. In particular, instead of measuring the treewidth of the graph itself or the size of a modulator to a graph class $\mathcal{H}$, we consider the treewidth of a (torso of a) modulator to $\mathcal{H}$. This parameter, which we simply call $\mathcal{H}$-treewidth, allows us to lift previously established tractability results for a vast number of problems from treewidth and modulators to a strictly more general setting. As our first technical contribution, we substantiate this claim with a meta-theorem that formalizes generic conditions under which a treewidth-based algorithm can be generalized to $\mathcal{H}$-treewidth; the main technical tool for the proof is an adaptation of *protrusion replacement* techniques [2, Section 4].

As the flagship application of $\mathcal{H}$-treewidth, we study the case where $\mathcal{H}$ is the class $\mathcal{R}_c$ of graphs of rank-width at most c (an arbitrary constant). $\mathcal{R}_c$-treewidth hence represents a way of lifting treewidth towards dense graphs that lies "between" treewidth and rank-width. We note that this class of parameters naturally incorporates a certain scaling trade-off: $\mathcal{R}_c$-treewidth dominates $\mathcal{R}_{c-1}$-treewidth for each constant c, but the runtime bounds for algorithms using $\mathcal{R}_c$-treewidth are worse than those for $\mathcal{R}_{c-1}$-treewidth.

Our first result for $\mathcal{R}_c$-treewidth is a fixed-parameter algorithm for computing the parameter itself. We then develop fixed-parameter algorithms for Chromatic Number, Hamiltonian Cycle and Max-Cut parameterized by $\mathcal{R}_c$-treewidth; moreover, in 2 out of these 3 cases the parameter dependencies of our algorithms are essentially tight. These algorithms represent generalizations of:

1. classical fixed-parameter algorithms parameterized by treewidth [12],
2. polynomial-time algorithms on graphs of bounded rank-width [22], and
3. (not previously known) fixed-parameter algorithms parameterized by modulators to graph classes of bounded rank-width.

[1] Parameter α dominates parameter β if for each graph class with bounded β, α is also bounded.

The main challenge for all of these problems lies in dealing with the fact that some parts of the graph need to be handled using rank-width based techniques, while for others we use treewidth-based dynamic programming. We separate these parts from each other using the notion of *nice $\mathcal{H}$-tree decompositions.* The algorithm then relies on enhancing the known dynamic programming approach for solving the problem on treewidth with a subroutine that not only solves the problem on the part of the graph outside of the modulator, but also serves as an interface by supplying appropriate records to the treewidth-based dynamic programming part of the algorithm. At its core, each of these subroutines boils down to solving an "extended" version of the original problem parameterized by the size of a modulator to $\mathcal{R}_c$; in particular, each subroutine immediately implies a fixed-parameter algorithm for the respective problem when parameterized by a modulator to constant rank-width. To give a specific example for such a subroutine, in the case of Chromatic Number one needs to solve the problem parameterized by a modulator to $\mathcal{R}_c$ where the modulator is furthermore precolored.

To avoid any doubt, we make it explicitly clear that the runtime of all of our algorithms utilizing $\mathcal{R}_c$-treewidth has a polynomial dependency on the input where the degree of this polynomial depends on c (as is necessitated by the W[1]-hardness of the studied problems parameterized by rank-width).

Related Work. Previous works have used a combination of treewidth with *backdoors*, a notion that is closely related to modulators, in order to solve non-graph problems such as Constraint Satisfaction [25], Boolean Satisfiability [24] and Integer Programming [23]. Interestingly, the main technical challenge in all of these papers is the problem of computing the parameter, while using the parameter to solve the problem is straightforward. In the algorithmic results presented in this contribution, the situation is completely reversed: the main technical challenge lies in developing the algorithms (and most notably the subroutines) for solving our targeted problems. Moreover, while the aforementioned three papers focus on solving a single problem, here we aim at identifying and exploiting structural properties that can be used to solve a wide variety of graph problems.

Other parameters which target inputs with hybrid structure include *sm-width* [36] and well-structured modulators [14]. It is not difficult to show that these are different (both conceptually and factually) from $\mathcal{R}_c$-treewidth.

2 Preliminaries

For $i \in \mathbb{N}$, let $[i]$ denote the set $\{1, \dots, i\}$. All graphs in this paper are simple and undirected. We refer to the standard textbook [11] for basic graph terminology. For $S \subseteq V(G)$, let $G[S]$ denote the subgraph of G induced by S. For $v \in V(G)$, the set of neighbors of v in G is denoted by $N_G(v)$ (or $N(v)$ when G is clear from the context). For $A \subseteq V(G)$, let $N_G(A)$ denote the set of vertices in $G - A$ that have a neighbor in A. For a vertex set A, an *A-path* is a path whose endpoints are contained in A and all the internal vertices are contained in $G - A$.

A set M of vertices in a graph G is called a *modulator* to a graph class $\mathcal{H}$ if $G - M \in \mathcal{H}$. The operation of *collapsing* a vertex set X, denoted $G \circ X$, deletes X from the graph and adds an edge between vertices $u, v \in V(G - X)$ if $uv \notin E(G)$ and there is an u-v path with all internal vertices in $G[X]$. We assume that the reader is familiar with *parameterized complexity* [9, 12], notably with notions such as FPT, W[1], treewidth and Courcelle's Theorem.

Rank-width. For a graph G and $U, W \subseteq V(G)$, let $\boldsymbol{A}_G[U, W]$ denote the $U \times W$-submatrix of the adjacency matrix over the two-element field GF(2), i.e., the entry $a_{u,w}$, $u \in U$ and $w \in W$, of $\boldsymbol{A}_G[U, W]$ is 1 if and only if $\{u, w\}$ is an edge of G. The *cut-rank* function ρ_G of a graph G is defined as follows: For a bipartition (U, W) of the vertex set $V(G)$, $\rho_G(U) = \rho_G(W)$ equals the rank of $\boldsymbol{A}_G[U, W]$.

A *rank-decomposition* of a graph G is a pair (T, μ) where T is a tree of maximum degree 3 and $\mu : V(G) \to \{t \mid t \text{ is a leaf of } T\}$ is a bijective function. For an edge e of T, the connected components of $T - e$ induce a bipartition (X, Y) of the set of leaves of T. The *width* of an edge e of a rank-decomposition (T, μ) is $\rho_G(\mu^{-1}(X))$. The *width* of (T, μ) is the maximum width over all edges of T. The *rank-width* of G, $\mathbf{rw}(G)$ in short, is the minimum width over all rank-decompositions of G. We denote by $\mathcal{R}_i$ the class of all graphs of rank-width at most i. A *rooted* rank-decomposition is obtained from a rank-decomposition by subdividing an arbitrarily chosen edge, and the newly created vertex is called the *root*.

Unlike clique-width, rank-width can be computed exactly by a fixed-parameter algorithm (which also outputs a corresponding rank-decomposition) [26].

Monadic Second-Order Logic. Counting Monadic Second-Order Logic (CMSO$_1$) is a basic tool to express properties of vertex sets in graphs. The syntax of CMSO$_1$ includes logical connectives $\wedge, \vee, \neg, \Leftrightarrow, \Rightarrow$, variables for vertices and vertex sets, quantifiers $\exists, \forall$ over these variables, and the relations $a \in A$ where a is a vertex variable and A is a vertex set variable; $\mathrm{adj}(a, b)$, where a and b are vertex variables and the interpretation is that a and b are adjacent; equality of variables representing vertices and sets of vertices; $\mathrm{Parity}(A)$, where A is a vertex set variable and the interpretation is that $|A|$ is even.

The CMSO$_1$ Optimization problem is defined as follows:

CMSO$_1$-OPT

Instance: A graph G, a CMSO$_1$ formula $\phi(A)$ with a free set variable A, and opt $\in \{\min, \max\}$.

Task: Find an interpretation of the set A in G such that G models $\phi(A)$ and A is of minimum/maximum (depending on opt) cardinality.

From the fixed-parameter tractability of computing rank-width [26], the equivalence of rank-width and clique-width [34] and Courcelle's Theorem for graphs of bounded clique-width [7] it follows that:

▶ **Fact 1** ([21]). CMSO$_1$-OPT *is* FPT *parameterized by* $\mathbf{rw}(G) + |\phi|$*, where* G *is the input graph and* ϕ *is the* CMSO$_1$ *formula.*

3 $\mathcal{H}$-Treewidth

The aim of $\mathcal{H}$-treewidth is to capture the treewidth of a modulator to the graph class $\mathcal{H}$. However, one cannot expect to obtain a parameter with reasonable algorithmic applications by simply measuring the treewidth of the graph *induced* by a modulator to $\mathcal{H}$ – instead, one needs to measure the treewidth of a so-called *torso*, which adds edges to track how the vertices in the modulator interact through $\mathcal{H}$. To substantiate this, we observe that Hamiltonian Cycle would become NP-hard even on graphs with a modulator that (1) induces an edgeless graph, and (2) is a modulator to an edgeless graph, and where (3) each connected component outside the modulator has boundedly many neighbors in the modulator [1].

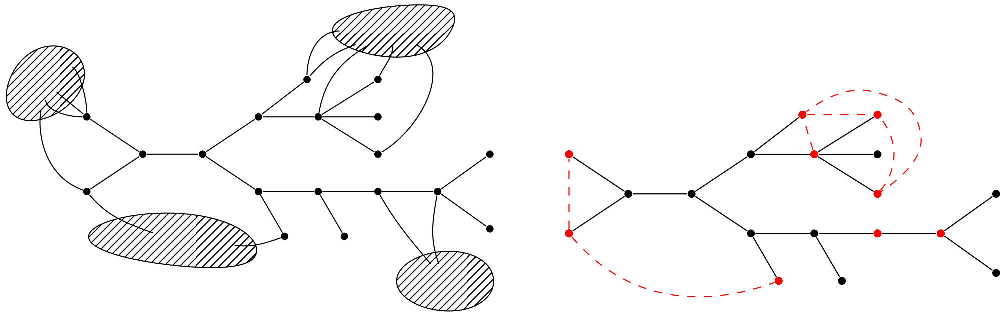

Figure 1 *Left:* A graph G with a tree as a modulator to $\mathcal{H}$ (the part in $\mathcal{H}$ is depicted hatched). *Right:* The corresponding $\mathcal{H}$-torso.

The notion of a *torso* has previously been algorithmically exploited in other settings [23, 25, 33], and its adaptation is our first step towards the definition of $\mathcal{H}$-treewidth (see also Figure 1).

▶ **Definition 1** ($\mathcal{H}$-Torso). *Let G be a graph and $X \subseteq V(G)$. For a graph class $\mathcal{H}$, $G \circ X$ is an* $\mathcal{H}$-torso *of G if each connected component C of $G[X]$ satisfies $C \in \mathcal{H}$.*

▶ **Definition 2** ($\mathcal{H}$-Treewidth). *The $\mathcal{H}$-treewidth of a graph G is the minimum treewidth of an $\mathcal{H}$-torso of G. We denote the $\mathcal{H}$-treewidth of G by $\mathbf{tw}_{\mathcal{H}}(G)$.*

Typically, we will want to consider a graph class $\mathcal{H}$ for which certain problems are polynomial-time tractable. Hence, we will assume w.l.o.g. that $(\emptyset, \emptyset) \in \mathcal{H}$. From the definition we easily observe that $\mathbf{tw}_{\mathcal{H}}(G) \leq \mathbf{tw}(G)$ for every G and $\mathcal{H}$.

3.1 Nice $\mathcal{H}$-Tree-Decompositions

Just like for tree decompositions, we can also define a canonical form of decompositions which has properties that are convenient when formulating dynamic programs using $\mathcal{H}$-treewidth. Intuitively, a *nice $\mathcal{H}$-tree decomposition* behaves like a nice tree decomposition on the torso graph (see points 1-3), with the exception that the neighborhoods of the collapsed parts must occur as special *boundary* leaves (see points 4-5).

▶ **Definition 3** (Nice $\mathcal{H}$-Tree-Decomposition). *A nice $\mathcal{H}$-tree decomposition of a graph G is a triple $(X, T, \{B_t \mid t \in V(T)\})$ where $X \subseteq V(G)$ such that $G \circ X$ is an $\mathcal{H}$-torso, $(T, \{B_t \mid t \in V(T)\})$ is a rooted tree decomposition of $G \circ X$, and:*

1. *Every node in T has at most two children.*
2. *If a node t has children $t_1 \neq t_2$, then $B_t = B_{t_1} = B_{t_2}$ and we call t a* join node*.*
3. *If a node t has exactly one child t', then either (a) there exists $x \in V(G) \setminus B_{t'}$ such that $B_t = B_{t'} \cup \{x\}$ and we call t an* introduce node*, or (b) there exists $x \in V(G) \setminus B_t$ such that $B_{t'} = B_t \cup \{x\}$ and we call t a* forget node*.*
4. *If a node t is a leaf, then (a) $|B_t| = 1$ and we call t a* simple leaf*, or (b) $B_t = N(C)$ for some connected component C of $G[X]$ and we call t a* boundary leaf*.*
5. *For each connected component C of $G[X]$ there is a unique leaf t with $B_t = N(C)$.*

An illustration of a nice $\mathcal{H}$-tree decomposition showcasing how it differs from a nice tree decomposition is provided in Figure 2; in line with standard terminology for treewidth, we call the sets B_t *bags*. The width of a nice $\mathcal{H}$-tree decomposition is simply the width of $(T, \{B_t \mid t \in V(T)\})$. Given a node t in a nice $\mathcal{H}$-tree decomposition T, we let Y_t be the set of all vertices

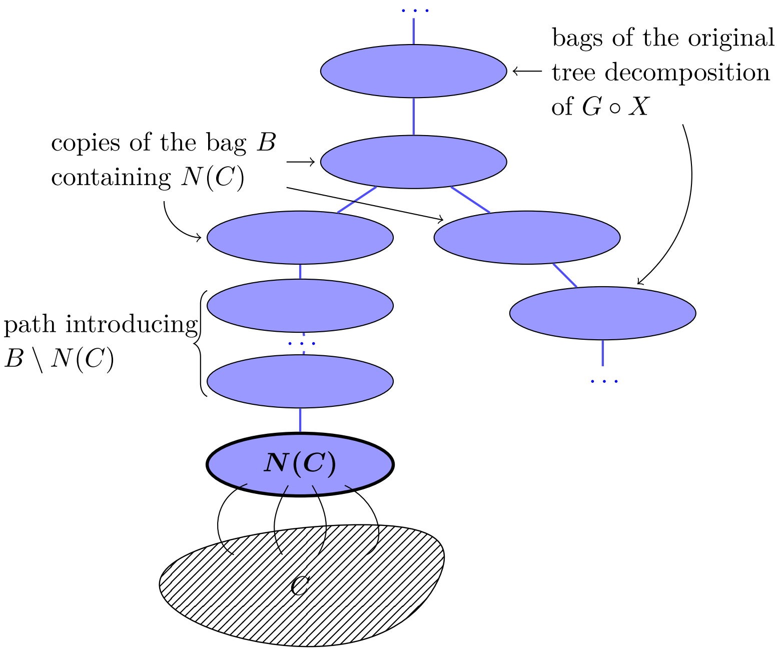

Figure 2 Part of a nice $\mathcal{H}$-tree-decomposition (blue) including a boundary leaf (bold) and a connected component C (hatched) of X.

contained in the bags of the subtree rooted at t, i.e., $Y_t = B_t \cup \bigcup_{p \text{ is separated from the root by } t} B_p$. It is possible to show that computing a nice $\mathcal{H}$-tree decomposition of bounded width can be reduced to finding an appropriate $\mathcal{H}$-torso (this is because a nice $\mathcal{H}$-tree decomposition can be obtained straightforwardly from a nice tree decomposition of the torso).

Hence, we can state the problem of computing a decomposition as follows:

$\mathcal{H}$-TREEWIDTH *Parameter: k*
Instance: A graph G, an integer k.
Task: Find an $\mathcal{H}$-torso U of G such that $\mathbf{tw}(U) \le k$, or correctly determine that no such $\mathcal{H}$-torso exists.

An Algorithmic Meta-Theorem. Before proceeding to the flagship application of $\mathcal{H}$-treewidth where $\mathcal{H}$ is the class of graphs of bounded rank-width, here we give a generic set of conditions that allow fixed-parameter algorithms for problems parameterized by $\mathcal{H}$-treewidth. Specifically, we consider graph problems that are *finite-state* [6] or have *finite integer index* [2, 4, 20]. Informally speaking, such problems only transfer a limited amount of information across a small separator in the input graph and hence can be solved "independently" on both sides of such a separator. Since these notions are only used in this section, we provide concise definitions below.

First of all, we will need the notion of boundaried graphs and gluing. A graph $\bar{G}$ is called *t-boundaried* if it contains t distinguished vertices identified as $b_1^G, \ldots, b_t^G$. The *gluing operation* $\oplus$ takes two t-boundaried graphs $\bar{G}$ and $\bar{H}$, creates their disjoint union, and then alters this disjoint union by identifying the boundaries of the two graphs (i.e. by setting $b_i^G = b_i^H$ for each $i \in [t]$).

Consider a decision problem $\mathcal{P}$ whose input is a graph. We say that two t-boundaried graphs $\bar{C}$ and $\bar{D}$ are *equivalent*, denoted by $\bar{C} \sim_{\mathcal{P},t} \bar{D}$, if for each t-boundaried graph $\bar{H}$ it holds that $\bar{C} \oplus \bar{H} \in \mathcal{P}$ if and only if $\bar{D} \oplus \bar{H} \in \mathcal{P}$. We say that $\mathcal{P}$ is *finite-state* (or *FS*, in brief) if, for each $t \in \mathbb{N}$, $\sim_{\mathcal{P},t}$ has a finite number of equivalence classes.

Next, consider a decision problem $\mathcal{Q}$ whose input is a graph and an integer. In this case we say that two t-boundaried graphs $\bar{C}$ and $\bar{D}$ are equivalent (denoted by $\bar{C} \sim_{\mathcal{Q},t} \bar{D}$) if there exists an *offset* $\delta(\bar{C}, \bar{D}) \in \mathbb{Z}$ such that for each t-boundaried graph $\bar{H}$ and each $q \in \mathbb{Z}$: $(\bar{C} \oplus \bar{H}, q) \in \mathcal{Q}$ if and only if $(\bar{D} \oplus \bar{H}, q + \delta(\bar{C}, \bar{D})) \in \mathcal{Q}$. We say that $\mathcal{Q}$ has *finite integer index* (or is *FII*, in brief) if, for each $t \in \mathbb{N}$, $\sim_{\mathcal{Q},t}$ has a bounded number of equivalence classes.

We note that a great number of natural graph problems are known to be FS or FII. For instance, all problems definable in Monadic Second Order logic are FS [2, Lemma 3.2], while examples of FII problems include Vertex Cover, Independent Set, Feedback Vertex Set, Dominating Set, to name a few [20]. We say that a FS or FII problem $\mathcal{P}$ is *efficiently extendable* on a graph class $\mathcal{H}$ if there is a fixed-parameter algorithm (parameterized by t) that takes as input a t-boundaried graph $\bar{G}$ such that the boundary is a modulator to $\mathcal{H}$ and outputs the equivalence class of $\bar{G}$ w.r.t. $\sim_{\mathcal{P},t}$.

▶ **Theorem 4.** *Let $\mathcal{P}$ be a FS or FII graph problem and $\mathcal{H}$ be a graph class such that (1) $\mathcal{P}$ is efficiently extendable on $\mathcal{H}$, (2) $\mathcal{P}$ is* FPT *parameterized by treewidth, and (3) $\mathcal{H}$-*treewidth *is* FPT*. Then $\mathcal{P}$ is* FPT *parameterized by $\mathcal{H}$-treewidth.*

Proof Sketch. We can solve $\mathcal{P}$ as follows. First of all, we use Point (3) to compute an $\mathcal{H}$-torso $G \circ X$ of treewidth k, where k is the $\mathcal{H}$-treewidth. Next, for each connected component C of $G[X]$, we use the fact that $C \in \mathcal{H}$ and Point (1) to compute the equivalence class of the boundaried graph $\bar{H} = \overline{G[C \cup N(C)]}$ where the boundary is $N(C)$. Note that since $\mathbf{tw}(G \circ X) \leq k$ and $N(C)$ forms a clique in $G \circ X$, $|N(C)| \leq k$ and hence this step takes only fixed-parameter time. Next, we use a brute-force enumeration argument to compute a bounded-size representative of the equivalence class of $\bar{H}$, and replace $\bar{H}$ with this representative. After doing this exhaustively, we obtain a graph G' of bounded treewidth, for which we can invoke Point (2). ◀

4 $\mathcal{R}_c$-Treewidth

This section focuses on the properties of $\mathcal{R}_c$-treewidth, a hierarchy of graph parameters that represent our flagship application of the generic notion of $\mathcal{H}$-treewidth.

Comparison to Known Parameters. It follows from the definition of $\mathcal{H}$-treewidth that $\mathcal{R}_c$-treewidth dominates treewidth (for every $c \in \mathbb{N}$). Similarly, it is obvious that $\mathcal{R}_c$-treewidth dominates the size of a modulator to $\mathcal{R}_c$ (also for every $c \in \mathbb{N}$). The following lemma shows that, for every fixed c, $\mathcal{R}_c$-treewidth is dominated by rankwidth.

▶ **Lemma 5.** *Let $c \in \mathbb{N}$. If $\mathbf{tw}_{\mathcal{R}_c}(G) = k$ then $\mathbf{rw}(G) \leq c + k + 1$.*

Proof. Let the $\mathcal{R}_c$-treewidth of G be witnessed by some nice $\mathcal{R}_c$-tree-decomposition $(X, T, \{B_t \mid t \in V(T)\})$ of width k.

We can obtain a rank-decomposition (T', μ) of G from $(X, T, \{B_t \mid t \in V(T))\}$ as follows:

For vertices v of $G \circ X$ such that there is no leaf node $t \in V(T)$ with $B_t = \{v\}$, let $t \in V(T)$ be a forget node with child t' such that $B_t \cup \{v\} = B_{t'}$. Turn t' into a join node by introducing t_1, t_2 with $B_{t_1} = B_{t_2} = B_{t'}$ as children of t', attaching the former child of t' to t_1 and a new leaf node t_v with $B_{t_v} = \{v\}$ below t_2. Note that this preserves the fact that for any $v \in V(G) \setminus X$, $T[\{u \in V(T) \mid v \in B_u\}]$ is a tree. Now we can choose for each $v \in V(G \circ X)$ some $\mu(v) \in V(T)$ such that $B_t = \{v\}$. This defines an injection from $V(G \circ X)$ to the leaves of T. However not every leaf of T is mapped to by μ. On one hand there are the boundary leaf nodes, below which we will attach subtrees to obtain a rank-decomposition of G. On the other hand there may be $v \in V(G \circ X)$ for which the choice of $\mu(v)$ was not unique, i.e. there is $t \neq \mu(v)$ with $B_t = \{v\}$. For all such v and t we delete all nodes on the root-t-path in T that do not lie on a path from the root to a vertex in $\{\mu(w) \mid w \in V(G \circ X)\} \cup \{t' \mid t' \text{ boundary leaf node}\}$. This turns μ into an injection from $V(G \circ X)$ to the leaves of T, that is surjective on the non-boundary leaf nodes.

Next, we extend (T, μ) to a rank-decomposition of G by proceeding in the following way for each connected component C of $G[X]$:
Let $t_C \in V(T)$ be the boundary leaf node with $B_t = N(C)$. Since $\mathbf{rw}(C) \leq c$, we find a rank-decomposition (T_C, μ_C) of C with width at most c. Attach T_C below t_C.
Let T' be the tree obtained by performing these modifications for all connected components C. Consider the rank-decomposition of G given by

$$\left(T', v \mapsto \begin{cases} \mu(v) & \text{if } v \in V(G \circ X) \\ \mu_C(v) & \text{if } v \in C \text{ for some } C \text{ as above} \end{cases}\right).$$

We show that its width is at most $c + k + 1$. Any edge e of T' is of one of the following types:

- e corresponds to an edge already contained in T: Then e induces a bipartition (X_G, Y_G) of $V(G)$. Fix $t \in V(T)$ to be the vertex in which e starts.
  Let $x \in X_G$ and $y \in Y_G$ be such that $xy \in E(G)$. Observe that e does not separate neighbors in X as these lie within the same connected component of $G[X]$ whose rank-decomposition is, by construction, attached completely within one of the two subtrees of T' separated by e. So, we consider $x \in V(G \circ X)$. If $y \in V(G \circ X)$ then x and y occur together in some bag of the original tree of the tree decomposition, and as remarked earlier this is still the case modified tree. This implies that at least one of $\{x, y\}$ must be present in B_t. If $y \notin V(G \circ X)$, by the construction of T', y corresponds to a leaf $t_y \in V(T')$ in a subtree attached to T rooted at $t_C \in V(T)$ with $B_{t_C} = N(C) \ni x$ and t_C and t_y are not separated by the removal of e. Also, x corresponds to a leaf $t_x \in V(T)$ which is in the subtree of $T' - e$ not containing t_y, i.e. the subtree not containing t_C. This means any subtree containing t_C and t_x also contains t, and since $(T, \{B_t \mid t \in V(T)\})$ is a tree-decomposition and $x \in B_{t_x} \cap B_{t_C}$ this means $x \in B_t$.
  In both cases at least one of $\{x, y\}$ is in B_t. Since this argument applies for every edge crossing the bipartition (X_G, Y_G), it follows that $\boldsymbol{A}_G[X_G, Y_G]$ may only contain "1" entries in rows and columns that correspond to the vertices in B_t. Since $|B_t| \leq k + 1$, it holds that $\boldsymbol{A}_G[X_G, Y_G]$ can be converted into a zero matrix by deleting at most $k + 1$ rows plus columns, which is a sufficient condition for $\boldsymbol{A}_G[X_G, Y_G]$ having rank at most $k + 1$.
- e corresponds to an edge in a rank-decomposition of some connected component C of $G[X]$: Then e induces a bipartition (X_G, Y_G) of $V(G)$ and a bipartition (X_C, Y_C), where $X_C = X_G \cap C$ and $Y_C = Y_G \cap C$, of C. Since vertices of C are only connected to vertices in $N(C)$ outside of C and $N(C) \subseteq B_t$ for some $t \in V(T)$, we have $\rho_G(X_G) \leq \rho_C(X_C) + |N(C)| \leq c + k + 1$.
- e corresponds to an edge connecting the rank-decomposition of some connected component C of $G[X]$ to T: Then the bipartition induced is $(C, V(G) \setminus C)$ and as $N(C) \subseteq B_t$ for some $t \in V(T)$ $\rho_G(C) \leq |N(C)| \leq k + 1$. ◀

Next, we compare $\mathcal{R}_c$-treewidth to Telle and Saether's *sm-width* [36].

▶ **Lemma 6.** *$\mathcal{R}_c$-treewidth and sm-width are incomparable.*

Computing $\mathcal{R}_c$-Treewidth. Our aim here is to determine the complexity of computing our parameters, i.e., finding a torso of small treewidth. Obtaining such a torso is a base prerequisite for our algorithms. We formalize the problem below.

$\mathcal{R}_c$-Treewidth *Parameter:* k
Instance: A graph G, an integer k.
Task: Find a $\mathcal{R}_c$-torso U of G such that $\mathbf{tw}(U) \leq k$, or correctly determine that no such $\mathcal{R}_c$-torso exists.

▶ **Lemma 7.** *$\mathcal{R}_c$-Treewidth is* FPT*.*

5 Algorithms Exploiting Modulators to $\mathcal{R}_c$

For a problem $\mathcal{P}$ to be FPT parameterized by $\mathcal{R}_c$-treewidth, $\mathcal{P}$ must necessarily be FPT parameterized by treewidth and also FPT parameterized by the size of a modulator to $\mathcal{R}_c$. However, it is important to note that the latter condition is not sufficient; indeed, one can easily invent artificial problems that are defined in a way which make them trivial in both of the cases outlined above, but become intractable (or even undecidable) once parameterized by $\mathcal{R}_c$-treewidth. That is, after all, why we need the notion of *efficient extendability* in Theorem 4.

Hence, in order to develop fixed-parameter algorithms for Chromatic Number, Hamiltonian Cycle and Max-Cut parameterized by $\mathcal{R}_c$-treewidth, we first need to show that they are not only FPT parameterized by the size of a modulator to $\mathcal{R}_c$, but they are also efficiently extendable. Such a result would be sufficient to employ Theorem 4 together with Lemma 7 in order to establish the desired fixed-parameter tractability results. That is also our general aim in this section, with one caveat: in order to give explicit and tight upper bounds on the parameter dependency of our algorithms, we provide algorithms that solve generalizations of Chromatic Number, Hamiltonian Cycle and Max-Cut parameterized by the size of a modulator to $\mathcal{R}_c$, whereas it will become apparent in the next section that these generalizations precisely correspond to the records required by the treewidth-based dynamic program that will be used in the torso. In other words, the efficient extendability of our problems on $\mathcal{R}_c$ is not proved directly but rather follows as an immediate consequence of our proofs in this section and the correctness of known treewidth-based algorithms.

Chromatic Number. In Chromatic Number, we are given a graph G and asked for the smallest number $\chi(G)$ such that the vertex set of G can be properly colored using $\chi(G)$ colors, i.e., the smallest number $\chi(G)$ such that $V(G)$ can be partitioned into $\chi(G)$ independent sets. Our aim in this section is to solve a variant of Chromatic Number on graphs with a k-vertex modulator X to $\mathcal{R}_c$ where X is precolored:

$\mathcal{R}_c$-Precoloring Extension *Parameter:* k
Instance: A graph G, a k-vertex modulator $X \subseteq V(G)$ to $\mathcal{R}_c$ and a coloring of X.
