Task: Compute the smallest number of colors required to extend the coloring of X to a proper coloring of G.

▶ **Theorem 8.** *$\mathcal{R}_c$-Precoloring Extension can be solved in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$.*

Proof Sketch. Let G be a graph together with a k-vertex modulator X to $\mathcal{R}_c$ and a proper coloring of X by colors $[k]$; let col_X be the set of colors assigned to at least one vertex in X. For disjoint vertex sets S and Q of G, two vertices v and w in S are *twins* with respect to Q if $N(v) \cap Q = N(w) \cap Q$. A *twin class* of S with respect to Q is a maximal subset of S that consists of pairwise twins w.r.t. Q.

Our starting point is a rooted rank-decomposition (T, μ) of $G - X$ of width at most c, which may be computed in time $\mathcal{O}(n^3)$ [26]. On a high level, our algorithm will apply dynamic programming along (T, μ) where it will group colors together based on which twin classes they occur in (analogously as in the XP algorithm for Chromatic Number parameterized by clique-width, due to Kobler and Rotics [31]), but keep different (more detailed) records about the at most k colors used in X.

For each $t \in V(T)$, let S_t be the set of all vertices that are assigned to the descendants of t, and let $G_t := G[S_t \cup X]$. By our definition of (T, μ), recall that $\rho_{G-X}(S_t) \leq c$ and that there are at most $z = 2^c$ twin classes of S_t w.r.t. $V(G) \setminus (X \cup S_t)$. We will refer to these twin classes as $R^t_1, R^t_2, \ldots, R^t_z$.

We are now ready to formally define the dynamic programming table M_t that stores the information we require at a node t of T. For $b_1, b_2, \ldots, b_k \subseteq [z]$ and $\{\, d_Z \in [n] \mid Z \subseteq [z] \,\}$, we let $M_t(b_1, b_2, \ldots, b_k, \{\, d_Z \mid Z \subseteq [z] \,\}) = 1$ if there is a proper coloring of G_t such that (1) for every $i \in [k]$, the color i appears in twin classes in $\{R^t_j : j \in b_i\}$ and does not appear in other twin classes, and (2) for every $Z \subseteq [z]$, d_Z is the number of colors from $\{k+1, k+2, \ldots, n\}$ that appear in twin classes of $\{R^t_j : j \in Z\}$ and do not appear in other twin classes. On the other hand, if no such proper coloring exists then we let $M_t(b_1, b_2, \ldots, b_k, \{\, d_Z \mid Z \subseteq [z] \,\}) = 0$.

The table M_t will be filled in a leaf-to-root fashion. Observe that by definition of d_Z's, for distinct subsets Z_1, Z_2 of $[z]$, d_{Z_1} and d_{Z_2} count disjoint sets of colors. This provides an easy way to count the total number of colors used. Since all vertices in $G - X$ appear below the root node r, the minimum number of colors required for a proper coloring of G will be the minimum value of $\left|\mathrm{col}_X \cup \{\, i \in [k] \mid b_i \neq \emptyset \,\}\right| + \sum_{Z \subseteq [z]} d_Z$, over all tuples $(b_1, b_2, \ldots, b_k, \{\, d_Z \mid Z \subseteq [z] \,\})$ whose M_r value is 1. ◀

Hamiltonian Cycle. In Hamiltonian Cycle, we are given an n-vertex graph G and asked whether G contains a cycle of length n as a subgraph. Note that if we restrict G to some subset of vertices $Y \subseteq V(G)$, then what remains from a Hamiltonian Cycle in G is a set of paths that start and end in the neighborhood of $V(G) \setminus Y$. Hence, the aim of this section is to solve the following generalization of Hamiltonian Cycle:

$\mathcal{R}_c$-Disjoint Paths Cover	*Parameter: k*
Instance:	A graph G, a k-vertex modulator $X \subseteq V(G)$ to $\mathcal{R}_c$, and $m \leq k$ pairs $(s_1, t_1), \ldots, (s_m, t_m)$ of vertices from X with $s_i \neq t_i$ for all $i \in [m]$.
Task:	Decide whether there are internally vertex-disjoint paths $P_1, P_2, \ldots, P_m$ in G such that P_i is a path from s_i to t_i and every vertex in $G - X$ belongs to precisely one path in $P_1, P_2, \ldots, P_m$.

▶ **Theorem 9.** $\mathcal{R}_c$-Disjoint Paths Cover *can be solved in time* $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$.

Proof Sketch. Let G be a graph, X be a k-vertex modulator to $\mathcal{R}_c$, and $(s_1, t_1), \ldots, (s_m, t_m)$ be m pairs of vertices from X. Our starting point is once again a rooted rank-decomposition (T, μ) of $G - X$ of width at most c, which may be computed in time $\mathcal{O}(n^3)$ [26]. We will obtain a fixed-parameter algorithm for checking the existence of such paths $P_1, \ldots, P_m$ in G by expanding the records used in Espelage, Gurski and Wanke's algorithm [15] for computing Hamiltonian Cycle parameterized by clique-width.

To follow partial solutions on each subgraph G_t, we consider certain generalizations of path-partitions of subgraphs of G. For a subgraph H of G, an *X-lenient path-partition* $\mathcal{P}$ of H is a collection of paths in H that are internally vertex-disjoint and share only endpoints in X such that $\bigcup_{P \in \mathcal{P}} V(P) = V(H)$. For convenience, we consider a path as an ordered sequence of vertices, and for a path $P = v_1 v_2 \cdots v_x$, we define $\ell(P) = v_1$ and $r(P) = v_x$.

We proceed by introducing our dynamic programming table. For each node t of T, we use the following tuples (D, SP) as indices of the table. Let $D = \{d_{b_1,b_2} \in \{0, 1, \ldots, n\} \mid (b_1, b_2) \in [z] \times [z]\}$. The integer d_{b_1,b_2} will represent the number of paths in an X-lenient path-partition of G_t that are fully contained in $G_t - X$ and whose endpoints are contained in $R^t_{b_1}$ and $R^t_{b_2}$. Let SP be a set such that

- for each $i \in \{1, \ldots, m\}$, $(i, 0, x)$, $(0, i, x)$, (i, i) with some $x \in [z]$ are the only possible tuples in SP,
- each integer in $\{1, \ldots, m\}$ appears at most once as an ℓ among all tuples $(\ell, 0, p)$ or (ℓ, ℓ) in SP, and similarly, each integer in $\{1, \ldots, m\}$ appears at most once as an r among all tuples $(0, r, p)$ or (r, r) in SP.

In short, the tuple $(i, 0, t)$ indicates the existence of a path starting in s_i and ending at a vertex in R^t_x. Similarly, $(0, i, t)$ indicates the existence of a path starting in t_i and ending in R^t_x. The tuple (i, i) indicates the existence of a path starting in s_i and ending in t_i. Note that there are at most $(n+1)^{z^2}$ possibilities for D. For an element of SP, there are $2mz + 1$ possible elements in SP, and thus there are at most 2^{2kz+1} possibilities for SP. This implies that the number of possible tuples (D, SP) is bounded by $(n+1)^{z^2} 2^{2kz+1}$.

We define a DP table M_t such that $M_t(D, SP) = 1$ if there is an X-lenient path-partition $\mathcal{P} = \mathcal{P}_1 \uplus \mathcal{P}_2$ of G_t such that

- $\mathcal{P}_1$ is the subset of $\mathcal{P}$ that consists of all paths fully contained in $G_t - X$,
- for every $d_{b_1,b_2} \in D$, there are exactly d_{b_1,b_2} distinct paths in $\mathcal{P}_1$ with endpoints in $R^t_{b_1}$ and $R^t_{b_2}$,
- for every (ℓ, r, p) or $(\ell, r) \in SP$, there is a unique path $P \in \mathcal{P}_2$ such that
  - if $\ell = i > 0$, then $\ell(P) = s_i$, and if $r = i > 0$, then $r(P) = t_i$,
  - if $\ell = 0$, then $\ell(P) \in R^t_p$, and if $r = 0$, then $r(P) \in R^t_p$,

In this case, we say that the X-lenient path-partition $\mathcal{P}$ is a partial solution with respect to (D, SP), and also (D, SP) is a characteristic of $\mathcal{P}$. We define $\mathcal{Q}_t$ as the set of all tuples (D, SP) where $M_t(D, SP) = 1$.

The table M_t is filled in a leaf-to-root fashion. Since all vertices in $G - X$ appear below the root node ro, to decide whether there is a desired X-lenient path-partition, it suffices to confirm that there are D and SP such that $M_{ro}(D, SP) = 1$, for every $d_{b_1,b_2} \in D$, $d_{b_1,b_2} = 0$, and for every $i \in \{1, 2, \ldots, m\}$, $(i, i) \in SP$.

The proof can be completed by describing a dynamic program to fill in the table M_t for each node $t \in V(T)$ in a leaf-to-root fashion. ◀

Max-Cut. The third problem we consider is Max-Cut, where we are given an integer ℓ together with an n-vertex graph G and asked whether $V(G)$ can be partitioned into sets V_1 and V_2 such that the number of edges with precisely one endpoint in V_1 (called the *cut size*) is at least ℓ.

$\mathcal{R}_c$-Max-Cut Extension *Parameter:* k

Instance: A graph G, a k-vertex modulator $X \subseteq V(G)$ to $\mathcal{R}_c$, $s \subseteq X$, and $\ell \in \mathbb{N}$.

Task: Is there a partition of $V(G)$ into sets V_1 and V_2 such that $X \cap V_1 = s$ and the number of edges between V_1 and V_2 is at least ℓ.

▶ **Theorem 10.** *$\mathcal{R}_c$-Max-Cut Extension can be solved in polynomial time.*

6 Algorithmic Applications of $\mathcal{R}_c$-Treewidth

In this section, we show that Chromatic Number, Hamiltonian Cycle and Max-Cut are FPT parameterized by $\mathcal{R}_c$-treewidth. As our starting point, recall that each of these problems admits a fixed-parameter algorithm when parameterized by treewidth which is based on leaf-to-root dynamic programming along the nodes of a nice tree decomposition. Notably, the algorithms are based on defining a certain *record* $\delta(P, Q)$ (for vertex sets P, Q) such that $\delta(B_t, Y_t)$ captures all the relevant information required to solve the problem on $G[Y_t]$ and to propagate this information from a node t to its parent. The algorithms compute these records on the leaves of the tree decomposition by brute force, and then dynamically update these records while traversing a nice tree decomposition towards the root; once the record $\delta(B_r, Y_r)$ is computed for the root r of the decomposition, the algorithm outputs the correct answer.

Our general strategy for solving these problems will be to replicate the records employed by the respective dynamic programming algorithm $\mathbb{A}$ used for treewidth, but *only for the nice $\mathcal{R}_c$-tree decomposition of the torso* of the input graph G. Recall that aside from the "standard" simple leaf nodes, nice $\mathcal{R}_c$-tree decompositions also contain boundary leaf nodes, which serve as separators between the torso and a connected component C with rank-width at most c. For $\mathbb{A}$ to work correctly with the desired runtime, we need to compute the record for each boundary leaf node using a subprocedure that exploits the bounded rank-width of C; in particular, we will see that this amounts to solving the problems defined in Section 5. Before proceeding to the individual problems, we provide a formalization and proof for the general ideas outlined above.

▶ **Lemma 11.** *Let $\mathcal{P}$ be a graph problem which can be solved via a fixed-parameter algorithm $\mathbb{A}$ parameterized by treewidth, where $\mathbb{A}$ runs in time $f(k') \cdot n'^a$ and operates by computing a certain record δ in a leaves-to-root fashion along a provided nice width-k' tree decomposition of the n'-vertex input graph.*

Let $\mathcal{Q}$ be obtained from $\mathcal{P}$ by receiving the following additional information in the input: (1) a nice $\mathcal{R}_c$-tree decomposition $(X, T, \{B_t \mid t \in V(T)\})$ of width k for the input n-vertex graph G, and (2) for each boundary leaf node t corresponding to the neighborhood of a connected component C of $G[X]$, the record $\delta(B_t, B_t \cup C)$.

Then, $\mathcal{Q}$ can be solved in time $f(k) \cdot n^a$.

Chromatic Number. Chromatic Number is W[1]-hard parameterized by rank-width [17] but can be solved in time $2^{\mathcal{O}(\mathbf{tw}(G) \cdot \log \mathbf{tw}(G))} \cdot n$ on n-vertex graphs when a minimum-width tree-decomposition is provided with the input [28]; moreover, it is known that this runtime is essentially tight [32].

It is well known that the chromatic number is at most $\mathbf{tw}(G) + 1$. One possible way of defining records in order to achieve a runtime of $2^{\mathcal{O}(\mathbf{tw}(G) \cdot \log \mathbf{tw}(G))} \cdot n$ is to track, for each proper coloring of vertices in a bag B_t, the minimum number of colors required to extend such a coloring to Y_t [28]. Formally, let S_t be the set of all colorings of B_t with colors $[\mathbf{tw}(G) + 1]$, and let $\alpha(B_t, Y_t) : S_t \to \mathbb{Z}$ be defined as follows:

- $\alpha(B_t, Y_t)(s) = -1$ if s is not a proper coloring of $G[B_t]$.
- $\alpha(B_t, Y_t)(s) = q$ if q is the minimum number of colors used by any proper coloring of $G[Y_t]$ which extends s.

Using Theorem 8, we can compute such $\alpha(B_t, Y_t)(s)$ for every proper coloring s of B_t. Hence, combining Lemma 11 and Theorem 8, we obtain:

▶ **Theorem 12.** Chromatic Number *can be solved in time* $2^{\mathcal{O}(k\log(k))} \cdot n^{\mathcal{O}(1)}$ *if a nice* $\mathcal{R}_c$*-tree decomposition of width* k *is provided on the input.*

Hamiltonian Cycle. Hamiltonian Cycle is W[1]-hard parameterized by rank-width [17] but can be solved in time $2^{\mathcal{O}(\mathbf{tw}(G)\cdot\log\mathbf{tw}(G))} \cdot n$ on n-vertex graphs when a minimum-width tree-decomposition is provided with the input via standard dynamic programming. This algorithm can be improved to run in time $2^{\mathcal{O}(\mathbf{tw}(G))} \cdot n$) by applying the advanced *rank-based approach* of Cygan, Kratsch and Nederlof [10] to prune the number of records. To simplify our exposition, here we focus on extending the standard dynamic programming algorithm which yields a slightly super-exponential runtime.

One possibility for defining the records for Hamiltonian Cycle is to track all possible ways one can cover Y_t by paths that start and end in B_t (intuitively, this corresponds to what remains of a hypothetical solution if we "cut off" everything above Y_t) [12]. Formally, let ${B_t}^\diamond$ be defined as follows:

- if $|B_t| > 2$, then ${B_t}^\diamond$ is the set of graphs with at most $|B_t|$ edges and degree at most 2 over vertex set B_t;
- if $|B_t| = 2$, then ${B_t}^\diamond$ contains three (multi)graphs over vertex set B_t: the edgeless graph, the graph with one edge, and the multigraph with two edges and no loops;
- if $|B_t| = 1$, then ${B_t}^\diamond$ contains an edgeless graph and a graph with a single loop, both over the single vertex in B_t;
- if $|B_t| = 0$, then ${B_t}^\diamond = \{\text{YES}, \text{NO}\}$.

We let $\beta(B_t, Y_t) : {B_t}^\diamond \to \{0, 1\}$, where for $Q \in {B_t}^\diamond$ we set $\beta(B_t, Y_t)(Q) = 1$ if and only if there exists a set P of paths in $G[Y_t]$ and a bijection that maps each $(v_1, \dots, v_\ell) \in P$ to an edge $(v_1, v_\ell) \in E(Q)$ such that each vertex $v \in G[Y_t \setminus B_t]$ is contained in precisely one path in P. In the special case where $B_t = \emptyset$, our records explicitly state whether $G[Y_t]$ contains a Hamiltonian cycle or not.

As before, we can now shift our attention to the problem of computing our records in boundary leaf nodes. We do so by looping over all of the at most k^{2k}-many graphs $Q \in {B_t}^\diamond$; for each such Q we check whether $G[Y_t] - B_t$ can be covered by internally vertex-disjoint paths connecting the pairs of vertices in B_t that form the endpoints of the edges in Q. Hence, we are left with the $\mathcal{R}_c$-Disjoint Paths Cover problem. From Theorem 9 and Lemma 11, we obtain:

▶ **Theorem 13.** Hamiltonian Cycle *can be solved in time* $2^{\mathcal{O}(k\log(k))} \cdot n^{\mathcal{O}(1)}$ *if a nice* $\mathcal{R}_c$*-tree decomposition of width* k *is provided on the input.*

Max-Cut. Max-Cut is another problem that is W[1]-hard parameterized by rank-width [19] but admits a simple fixed-parameter algorithm parameterized by treewidth – notably, it can be solved in time $2^{\mathcal{O}(\mathbf{tw}(G))} \cdot n$ on n-vertex graphs when a minimum-width tree-decomposition is provided with the input via standard dynamic programming [9, 12].

The simplest way of defining the records for Max-Cut is to keep track of all possible ways the bag B_t can be partitioned into V_1 and V_2, and for each entry in our table we keep track of the maximum number of crossing edges in Y_t compatible with that entry. Formally, let $\gamma(B_t, Y_t) : 2^{B_t} \to \mathbb{N}_0$, where for each $s \in 2^{B_t}$ it holds that $\gamma(B_t, Y_t)(s)$ is the maximum cut size that can be achieved in $G[Y_t]$ by any partition (V_1, V_2) satisfying $V_1 \cap B_t = s$. As before, from Theorem 10 and Lemma 11, we obtain:

▶ **Theorem 14.** Max-Cut *can be solved in time* $2^k \cdot n^{\mathcal{O}(1)}$, *if a nice* $\mathcal{R}_c$*-tree decomposition of width* k *is provided on the input.*

7 Concluding Remarks

While the technical contribution of this paper mainly focused on $\mathcal{R}_c$-treewidth, a parameter that allows us to lift fixed-parameter algorithms parameterized by treewidth to well-structured dense graph classes, it is equally viable to consider $\mathcal{H}$-treewidth for other choices of $\mathcal{H}$. Naturally, one should aim at graph classes where problems of interest become tractable, but it is also important to make sure that a (nice) $\mathcal{H}$-tree decomposition can be computed efficiently (i.e., one needs to obtain analogues to our Lemma 7). Examples of graph classes that may be explored in this context include split graphs, interval graphs, and more generally graphs of bounded mim-width [27].

The Power Word Problem

Markus Lohrey
Universität Siegen, Germany

Armin Weiß
Universität Stuttgart, Germany

Abstract

In this work we introduce a new succinct variant of the word problem in a finitely generated group G, which we call the power word problem: the input word may contain powers p^x, where p is a finite word over generators of G and x is a binary encoded integer. The power word problem is a restriction of the compressed word problem, where the input word is represented by a straight-line program (i.e., an algebraic circuit over G). The main result of the paper states that the power word problem for a finitely generated free group F is AC^0-Turing-reducible to the word problem for F. Moreover, the following hardness result is shown: For a wreath product $G \wr \mathbb{Z}$, where G is either free of rank at least two or finite non-solvable, the power word problem is complete for coNP. This contrasts with the situation where G is abelian: then the power word problem is shown to be in TC^0.

1 Introduction

Algorithmic problems in group theory have a long tradition, going back to the work of Dehn from 1911 [9]. One of the fundamental group theoretic decision problems introduced by Dehn is the *word problem* for a finitely generated group G (with a fixed finite generating set Σ): does a given word $w \in \Sigma^*$ evaluate to the group identity? Novikov [34] and Boone [8] independently proved in the 1950's the existence of finitely presented groups with undecidable word problem. On the positive side, in many important classes of groups the word problem is decidable, and in many cases also the computational complexity is quite low. Famous examples are finitely generated linear groups, where the word problem belongs to deterministic logarithmic space (L for short) [22] and hyperbolic groups where the word problem can be solved in linear time [17] as well as in LOGCFL [23].

In recent years, also compressed versions of group theoretical decision problems, where input words are represented in a succinct form, have attracted attention. One such succinct representation are so-called straight-line programs, which are context-free grammars that produce exactly one word. The size of such a grammar can be much smaller than the word it produces. For instance, the word a^n can be produced by a straight-line program of size $\mathcal{O}(\log n)$. For the *compressed word problem* for the group G the input consists of a straight-line program that produces a word w over the generators of G and it is asked whether w evaluates to the identity element of G. This problem is a reformulation of the circuit evaluation problem for G. The compressed word problem naturally appears when one tries to solve the word problem in automorphism groups or semidirect products [25, Section 4.2]. For the following classes of groups, the compressed word problem is known to be solvable in polynomial time: finite groups (where the compressed word problem is either P-complete or in NC^2 [6]), finitely generated nilpotent groups [20] (where the complexity is even in NC^2), hyperbolic groups [18] (in particular, free groups), and virtually special groups (i.e, finite extensions of subgroups of right-angled Artin groups) [25]. The latter class covers for instance Coxeter groups, one-relator groups with torsion, fully residually free groups and fundamental groups of hyperbolic 3-manifolds. For finitely generated linear groups there is still a randomized polynomial time algorithm for the compressed word problem [26, 25]. Simple examples of groups where the compressed word problem is intractable are wreath products $G \wr \mathbb{Z}$ with G a non-abelian group: for every such group the compressed word problem is coNP-hard [25] (this includes for instance Thompson's group F); on the other hand, if, in addition, G is finite, then the (ordinary) word problem for $G \wr \mathbb{Z}$ is in NC^1 [37].

In this paper, we study a natural variant of the compressed word problem, called the *power word problem.* An input for the power word problem for the group G is a tuple $(p_1, x_1, p_2, x_2, \dots, p_n, x_n)$ where every p_i is a word over the group generators and every x_i is a binary encoded integer (such a tuple is called a *power word*); the question is whether $p_1^{x_1} p_2^{x_2} \cdots p_n^{x_n}$ evaluates to the group identity of G.

From a power word $(p_1, x_1, p_2, x_2, \dots, p_n, x_n)$ one can easily (e.g. by an AC^0-reduction) compute a straight-line program for the word $p_1^{x_1} p_2^{x_2} \cdots p_n^{x_n}$. In this sense, the power word problem is at most as difficult as the compressed word problem. On the other hand, both power words and straight-line programs achieve exponential compression in the best case; so the additional difficulty of the the compressed word problem does not come from a higher compression rate but rather because straight-line programs can generate more "complex" words.

Our main results for the power word problem are the following; in each case we compare our results with the corresponding results for the compressed word problem:

- The power word problem for every finitely generated nilpotent group is in $\mathsf{DLOGTIME}$-uniform TC^0 and hence has the same complexity as the word problem (or the problem of multiplying binary encoded integers). The proof is a straightforward adaption of a proof from [33]. There, the special case, where all words p_i in the input power word are single generators, was shown to be in $\mathsf{DLOGTIME}$-uniform TC^0. The compressed word problem for every finitely generated nilpotent group belongs to the class $\mathsf{DET} \subseteq \mathsf{NC}^2$ and is hard for the counting class $\mathsf{C_{=}L}$ in case of a torsion-free nilpotent group [20].
- The power word problem for a finitely generated group G is NC^1-many-one-reducible to the power word problem for any finite index subgroup of G. An analogous result holds for the compressed word problem as well [20].
- The power word problem for a finitely generated free group is AC^0-Turing-reducible to the word problem for F_2 (the free group of rank two) and therefore belongs to L. In contrast, it was shown in [24] that the compressed word problem for a finitely generated free group of rank at least two is P-complete.
- The power word problem for a wreath product $G \wr \mathbb{Z}$ with G finitely generated abelian belongs to $\mathsf{DLOGTIME}$-uniform TC^0. For the compressed word problem for $G \wr \mathbb{Z}$ with G finitely generated abelian only the existence of a randomized polynomial time algorithm for the complement is known [21].
- The power word problem for the wreath products $F_2 \wr \mathbb{Z}$ and every wreath product $G \wr \mathbb{Z}$, where G is finite and non-solvable, is coNP-complete. For these groups this sharpens the corresponding coNP-hardness result for the compressed word problem [25].

Table 1 Our results on the power word problem compared to previous results on the (compressed) word problem. Here WP stands for “word problem”.

class of groups	PowerWP	CompressedWP	WP
nilpotent groups	TC^0	DET, $\mathsf{C}_=\mathsf{L}$-hard [20]	TC^0 [35]
Grigorchuk group G	L[a)]	PSPACE	L [13]
non-abelian f.g. free	L[b)]	P-complete [24]	L [22]
$G \wr \mathbb{Z}$ for G f.g. abelian	TC^0	coRP [21]	TC^0 [30]
$G \wr \mathbb{Z}$ for G finite non-solvable	coNP-complete	PSPACE, coNP-hard [25]	NC^1 [37]
$F_2 \wr \mathbb{Z}$	coNP-complete	PSPACE, coNP-hard [25]	L[b)] [37]
finite extension of a f.g. group H	NC^1-many-one-reducible to PowerWP(H) (resp. CompressedWP(H) [20], resp. WP(H) [37])		

a) AC^0-many-one-reducible to the word problem of G.
b) AC^0-Turing-reducible to the word problem of F_2.

- The power word problem for the Grigorchuk group is uAC^0-many-one-reducible to the word problem. The word problem for the Grigorchuk group is in L [13], which implies that the compressed word problem is in PSPACE. However, there is no non-trivial lower-bound known for the compressed word problem for the Grigorchuk group.

Table 1 summarizes the above results. Due to space constraints we present only short proof skteches for our main theorems; proofs of all lemmas can be found in the full version [27].

Related work. Implicitly, (variants of) the power word problem have been studied before. In the commutative setting, Ge [14] has shown that one can verify in polynomial time an identity $\alpha_1^{x_1}\alpha_2^{x_2}\cdots\alpha_n^{x_n} = 1$, where the α_i are elements of an algebraic number field and the x_i are binary encoded integers.

Another problem related to the power word problem is the knapsack problem [12, 28, 31] for a finitely generated group G (with generating set Σ): for a given sequence of words $w, w_1, \ldots, w_n \in \Sigma^*$, the question is whether there exist $x_1, \ldots, x_n \in \mathbb{N}$ such that $w = w_1^{x_1}\cdots w_n^{x_n}$ holds in G. For many groups G one can show that if such $x_1, \ldots, x_n \in \mathbb{N}$ exist, then there exist such numbers of size $2^{\mathrm{poly}(N)}$, where $N = |w| + |w_1| + \cdots + |w_n|$ is the input length. This holds for instance for right-angled Artin groups (also known as graph groups). In this case, one nondeterministically guesses the binary encodings of numbers $x_1, \ldots, x_n$ and then verifies, using an algorithm for the power word problem, whether $w_1^{x_1}\cdots w_n^{x_n}w^{-1} = 1$ holds. In this way, it was shown in [28] that for every right-angled Artin group the knapsack problem belongs to NP (using the fact that the compressed word problem and hence the power word problem for a right-angled Artin group belongs to P).

In [16], Gurevich and Schupp present a polynomial time algorithm for a compressed form of the subgroup membership problem for a free group F, where group elements are represented in the form $a_1^{x_1}a_2^{x_2}\cdots a_n^{x_n}$ with binary encoded integers x_i. The a_i must be standard generators of the free group F. This is the same input representation as in [33] and is more restrictive then our setting, where we allow powers of the form w^x for w an arbitrary word over the group generators (on the other hand, Gurevich and Schupp consider the subgroup membership problem, which is more general than the word problem).

2 Preliminaries

Words. An *alphabet* is a (finite or infinite) set Σ; an element $a \in \Sigma$ is called a *letter*. The free monoid over Σ is denoted by Σ^*, its elements are called *words*. The multiplication of the monoid is concatenation of words. The identity element is the empty word 1. The length of a word w is denoted by $|w|$. If w, p, x, q are words such that $w = pxq$, then we call x a *factor* of w, p a *prefix* of w, and q a *suffix* of w. We write $v \leq_{\mathrm{pref}} w$ (resp. $v <_{\mathrm{pref}} w$) if v is a (strict) prefix of w and $v \leq_{\mathrm{suff}} w$ (resp. $v <_{\mathrm{suff}} w$) if v is a (strict) suffix of w.

String rewriting systems. Let Σ be an alphabet and $S \subseteq \Sigma^* \times \Sigma^*$ be a set of pairs, called a *string rewriting system*. We write $\ell \to r$ if $(\ell, r) \in S$. The corresponding *rewriting relation* $\xRightarrow[S]{}$ over Σ^* is defined by: $u \xRightarrow[S]{} v$ if and only if there exist $\ell \to r \in S$ and words $s, t \in \Sigma^*$ such that $u = s\ell t$ and $v = srt$. We also say that u can be rewritten to v in one step. We write $u \xRightarrow[S]{k} v$ if u can be rewritten to v in exactly k steps, i.e., if there are $u_0, \dots, u_k$ with $u = u_0$, $v = u_k$ and $u_i \xRightarrow[S]{} u_{i+1}$ for $0 \leq i \leq k-1$. We denote the transitive closure of $\xRightarrow[S]{}$ by $\xRightarrow[S]{+} = \bigcup_{k \geq 1} \xRightarrow[S]{k}$ and the reflexive and transitive closure by $\xRightarrow[S]{*} = \bigcup_{k \geq 0} \xRightarrow[S]{k}$. Moreover $\xLeftrightarrow[S]{*}$ is the reflexive, transitive, and symmetric closure of $\xRightarrow[S]{}$; it is the smallest congruence containing S. The set of *irreducible word* with respect to S is $\mathrm{IRR}(S) = \{w \in \Sigma^* \mid \text{there is no } v \text{ with } w \xRightarrow[S]{} v\}$.

Free groups. Let X be a set and $X^{-1} = \left\{ a^{-1} \;\middle|\; a \in X \right\}$ be a disjoint copy of X. We extend the mapping $a \mapsto a^{-1}$ to an involution without fixed points on $\Sigma = X \cup X^{-1}$ by $(a^{-1})^{-1} = a$ and finally to an involution without fixed points on Σ^* by $(a_1 a_2 \cdots a_n)^{-1} = a_n^{-1} \cdots a_2^{-1} a_1^{-1}$. For an integer $z < 0$ and $w \in \Sigma^*$ we write w^z for $(w^{-1})^{-z}$. The string rewriting system $S = \left\{ aa^{-1} \to 1 \;\middle|\; a \in \Sigma \right\}$ is strongly confluent and terminating meaning that for every word $w \in \Sigma^*$ there exists a unique word $\mathrm{red}(w) \in \mathrm{IRR}(S)$ with $w \xRightarrow[S]{*} \mathrm{red}(w)$ (for precise definitions see e.g. [7, 19]). Words from $\mathrm{IRR}(S)$ are called *freely reduced*. The system S defines the free group $F_X = \Sigma^*/S$ with basis X. More concretely, elements of F_X can be identified with freely reduced words, and the group product of $u, v \in \mathrm{IRR}(S)$ is defined by $\mathrm{red}(uv)$. With this definition $\mathrm{red} : \Sigma^* \to F_X$ becomes a monoid homomorphism that commutes with the involution $\cdot^{-1}$: $\mathrm{red}(w)^{-1} = \mathrm{red}(w^{-1})$ for all words $w \in \Sigma^*$. If $|X| = 2$, we write F_2 for F_X. It is known that for every countable set X, F_2 contains an isomorphic copy of F_X.

Finitely generated groups and the power word problem. A group G is called *finitely generated* if there exist a finite a finite set X and a surjective group homomorphism $h : F_X \to G$. In this situation, the set $\Sigma = X \cup X^{-1}$ is called a finite (symmetric) generating set for G. For words $u, v \in \Sigma^*$ we usually say that $u = v$ in G or $u =_G v$ in case $h(\mathrm{red}(u)) = h(\mathrm{red}(v))$. The *word problem* for the finitely generated group G, $\mathrm{WP}(G)$ for short, is defined as follows:

- input: a word $w \in \Sigma^*$.
- question: does $w =_G 1$ hold?

A *power word* (over Σ) is a tuple $(p_1, x_1, p_2, x_2, \dots, p_n, x_n)$ where $p_1, \dots, p_n \in \Sigma^*$ are words over the group generators (called the periods of the power word) and $x_1, \dots, x_n \in \mathbb{Z}$ are integers that are given in binary notation. Such a power word represents the word $p_1^{x_1} p_2^{x_2} \cdots p_n^{x_n}$. Quite often, we will identify the power word $(p_1, x_1, p_2, x_2, \dots, p_n, x_n)$ with the word $p_1^{x_1} p_2^{x_2} \cdots p_n^{x_n}$. Moreover, if $x_i = 1$, then we usually omit the exponent 1 in a power word. The *power word problem* for the finitely generated group G, PowerWP(G) for short, is defined as follows:

- input: a power word $(p_1, x_1, p_2, x_2, \dots, p_n, x_n)$.
- question: does $p_1^{x_1} p_2^{x_2} \cdots p_n^{x_n} =_G 1$ hold?

Due to the binary encoded exponents, a power word can be seen as a succinct description of an ordinary word. Hence, a priori, the power word problem for a group G could be computationally more difficult than the word problem. We will see examples of groups G, where PowerWP(G) is indeed more difficult than WP(G) (under standard assumptions from complexity theory), as well as examples of groups G, where PowerWP(G) and WP(G) are equally difficult.

Wreath products. Let G and H be groups. Consider the direct sum $K = \bigoplus_{h \in H} G_h$, where G_h is a copy of G. We view K as the set $G^{(H)}$ of all mappings $f \colon H \to G$ such that $\mathrm{supp}(f) := \{h \in H \mid f(h) \neq 1\}$ is finite, together with pointwise multiplication as the group operation. The set $\mathrm{supp}(f) \subseteq H$ is called the *support* of f. The group H has a natural left action on $G^{(H)}$ given by $hf(a) = f(h^{-1}a)$, where $f \in G^{(H)}$ and $h, a \in H$. The corresponding semidirect product $G^{(H)} \rtimes H$ is the (restricted) *wreath product* $G \wr H$. In other words:

- Elements of $G \wr H$ are pairs (f, h), where $h \in H$ and $f \in G^{(H)}$.
- The multiplication in $G \wr H$ is defined as follows: Let $(f_1, h_1), (f_2, h_2) \in G \wr H$. Then $(f_1, h_1)(f_2, h_2) = (f, h_1 h_2)$, where $f(a) = f_1(a) f_2(h_1^{-1} a)$.

Complexity. We assume that the reader is familiar with the complexity classes P, NP, and coNP and many-one reductions; see e.g. [2] for details. We use circuit complexity for classes below deterministic logspace (L for short).

A language $L \subseteq \{0,1\}^*$ is AC^0-Turing-reducible to $K \subseteq \{0,1\}^*$ if there is a family of constant-depth, polynomial-size Boolean circuits with oracle gates for K deciding L. More precisely, $L \subseteq \{0,1\}^*$ belongs to $\mathsf{AC}^0(K)$ if there exists a family $(C_n)_{n \geq 0}$ of circuits which, apart from the input gates $x_1, \dots, x_n$ are built up from *not*, *and*, *or*, and *oracle gates* for K (which output 1 if and only if their input is in K). All gates may have unbounded fan-in, but there is a polynomial bound on the number of gates and wires and a constant bound on the depth (length of a longest path from an input gate x_i to the output gate o). Finally, C_n accepts exactly the words from $L \cap \{0,1\}^n$, i.e., if each input gate x_i receives the input $a_i \in \{0,1\}$, then a distinguished output gate evaluates to 1 if and only if $a_1 a_2 \cdots a_n \in L$.

In the following, we only consider DLOGTIME-uniform $\mathsf{AC}^0(K)$ for which we write $\mathsf{uAC}^0(K)$. DLOGTIME-uniform means that there is a deterministic Turing machine which decides in time $\mathcal{O}(\log n)$ on input of two gate numbers (given in binary) and the string 1^n whether there is a wire between the two gates in the n-input circuit and also computes the type of a given gate. For more details on these definitions we refer to [36]. If the languages K and L in the above definition of $\mathsf{uAC}^0(K)$ are defined over a non-binary alphabet Σ, then one first has to fix a binary encoding of words over Σ.

The class uTC^0 is defined as uAC^0(Majority) where Majority is the problem to determine whether the input contains more 1s than 0s. The class NC^1 is the class of languages accepted by Boolean circuits of bounded fan-in and logarithmic depth. When talking about hardness for uTC^0 or NC^1 we use uAC^0-Turing reductions unless stated otherwise. As a consequence of Barrington's theorem [3], we have $\mathsf{NC}^1 = \mathsf{uAC}^0(\mathrm{WP}(A_5))$ where A_5 is the alternating group over 5 elements [36, Corollary 4.54]. Moreover, the word problem for any finite group G is in NC^1. Robinson proved that the word problem for the free group F_2 is NC^1-hard [35], i.e., $\mathsf{NC}^1 \subseteq \mathsf{uAC}^0(\mathrm{WP}(F_2))$.

3 Results

In this section we state our (and prove the easy) results on the power word problem. Outlines of the proofs of Theorems 2, 8 and 9 can be found in Sections 4 and 5, respectively.

▶ **Theorem 1.** *If G is a finitely generated nilpotent group, then* $\textsc{PowerWP}(G)$ *is in* uTC^0.

Proof. In [33], the so-called word problem with binary exponents was shown to be in uTC^0 for finitely generated nilpotent groups. We can apply the same techniques as in [33]: we compute Mal'cev normal forms of all p_i [33, Theorem 5], then use the power polynomials from [33, Lemma 2] to compute Mal'cev normal forms with binary exponents of all $p_i^{x_i}$. Finally, we compute the Mal'cev normal form of $p_1^{x_1} \cdots p_n^{x_n}$ again using [33]. ◀

▶ **Theorem 2.** *The power word problem for a finitely generated free group is* AC^0*-Turing-reducible to the word problem for the free group* F_2.

Notice that if the free group has rank one, then the power word problem is in uTC^0 because iterated addition is in uTC^0.

▶ Remark 3. If the input is of the form $(p_1, x_1, p_2, x_2, \ldots, p_n, x_n)$ where all p_i are freely reduced, then the reduction in Theorem 2 is a uTC^0-many-one reduction.

▶ Remark 4. One can consider variants of the power word problem, where the exponents are not given in binary representation but in even more compact forms. *Power circuits* as defined in [32] are such a representation that allow non-elementary compression for some integers. The proof of Theorem 2 involves iterated addition and comparison of exponents. For power circuits iterated addition is in uAC^0 (just putting the power circuits next to each other), but comparison (even for equality) is P-complete [38]. Hence, the variant of the power word problem, where exponents are encoded with power circuits is P-complete for free groups.

▶ Remark 5. The proof of Theorem 2 can be easily generalized to free products. However, in order to have a simpler presentation we only state and prove the result for free groups and postpone the free product case to a future full version.

It is easy to see that the power word problem for every finite group belongs to NC^1. The following result generalizes this fact:

▶ **Theorem 6.** *Let G be finitely generated and let $H \leq G$ have finite index. Then* $\textsc{PowerWP}(G)$ *is* NC^1*-many-one-reducible to* $\textsc{PowerWP}(H)$.

Proof sketch. W.l.o.g. we can assume that H is a finitely generated normal subgroup and R is a finite set of representatives of $Q := G/H$ with $1 \in R$. As a first step we replace in the input power word every $p_i^{x_i}$ by $h_i^{y_i} p_i^{z_i}$ where $x_i = y_i \left|Q\right| + z_i$, $0 \leq z_i < \left|Q\right|$ and h_i is a word over the generators of H with $p_i^{\left|Q\right|} =_G h_i$. Moreover, we write $p_i^{z_i}$ as a word without exponents. Using the conjugate collection process from [35, Theorem 5.2], the result can be rewritten in the form hr where h is a power word in the subgroup H and $r \in R$. ◀

As an immediate consequence of Theorem 2, Theorem 6 and the NC^1-hardness of the word problem for F_2 [35, Theorem 6.3] we obtain:

▶ **Corollary 7.** *The power word problem for every finitely generated virtually free group is* AC^0*-Turing-reducible to the word problem for the free group* F_2.

▶ **Theorem 8.** *For every finitely generated abelian group G,* $\textsc{PowerWP}(G \wr \mathbb{Z})$ *is in* uTC^0.

▶ **Theorem 9.** *Let G be either a finite non-solvable group or a finitely generated free group of rank at least two. Then* $\textsc{PowerWP}(G \wr \mathbb{Z})$ *is* coNP*-complete.*

▶ **Theorem 10.** *The power word problem for the Grigorchuk group (as defined in [15] and also known as* first Grigorchuk group*) is* uAC^0*-many-one-reducible to its word problem.*

Theorem 10 applies only if the generating set contains a neutral letter. Otherwise, the reduction is in uTC^0. It is well-know that the word problem for the Grigorchuk group is in L (see e.g. [13]). Thus, also the power word problem is in L.

Proof sketch of Theorem 10. By [5, Theorem 6.6], every element of length N in the Grigorchuk group has order at most $CN^{3/2}$ for some constant C. Since the order of every element is a power of two, we can reduce all exponents modulo the smallest power of two $\geq CN^{3/2}$ where N is the length of the longest period p_i. After that the words are short and can be written without exponents. ◀

4 Proof of Theorem 2

The proof of Theorem 2 consists of two main steps: first we do some preprocessing leading to a particularly nice instance of the power word problem. While this preprocessing is simple from a theoretical point of view, it is where the main part of the workload is performed during the execution of the algorithm. Then, in the second step, all exponents are reduced to polynomial size. After this shortening process, the power word problem can be solved by the ordinary word problem. The most difficult part is to prove correctness of the shortening process. For this, we introduce a rewriting system over an extended alphabet of words with exponents. We outline the proof in a sequence of lemmas which all follow rather easily from the previous ones and we give some small hints how to prove the lemmas.

Preprocessing. We use the notations from the paragraph on free groups in Section 2. In particular, recall that $S = \left\{ aa^{-1} \to 1 \;\middle|\; a \in \Sigma \right\}$. Fix an arbitrary order on the input alphabet Σ. This gives us the lexicographic order on Σ^*, which is denoted by $\preceq$. Let $\Omega \subseteq \mathrm{IRR}(S) \subseteq \Sigma^*$ denote the set of words w such that

- w is non-empty,
- w is cyclically reduced (i.e, w cannot be written as aua^{-1} for $a \in \Sigma$),
- w is primitive (i.e, w cannot be written as u^n for $n \geq 2$),
- w is lexicographically minimal among all cyclic permutations of w and w^{-1} (i.e., $w \preceq uv$ for all $u, v \in \Sigma^*$ with $vu = w$ or $vu = w^{-1}$).

Notice that Ω consists of Lyndon words [29, Chapter 5.1] with the stronger requirement of being freely reduced, cyclically reduced and also minimal among the conjugacy class of the inverse. The first aim is to rewrite the input power word in the form

$$w = s_0 p_1^{x_1} s_1 \cdots p_n^{x_n} s_n \qquad \text{with } p_i \in \Omega \text{ and } s_i \in \mathrm{IRR}(S). \tag{1}$$

The reason for this lies in the following crucial lemma which essentially says that, if a long factor of $p_i^{x_i}$ cancels with some $p_j^{x_j}$, then already $p_i = p_j$. Thus, only the same p_i can cancel implying that we can make the exponents of the different p_i independently smaller.

▶ **Lemma 11.** *Let $p, q \in \Omega$, $x, y \in \mathbb{Z}$ and let v be a factor of p^x and w a factor of q^y. If $vw \xRightarrow[S]{*} 1$ and $|v| = |w| \geq |p| + |q| - 1$, then $p = q$.*

Proof. Since p and q are cyclically reduced, v and w are freely reduced, i.e., $v = w^{-1}$ as words. Thus, v has two periods $|p|$ and $|q|$. Since v is long enough, by the theorem of Fine and Wilf [10] it has also a period of $\gcd(|p|, |q|)$. This means that also p and q have period $\gcd(|p|, |q|)$ (since cyclic permutations of p and q are factors of v). Assuming $\gcd(|p|, |q|) < |p|$, would mean that p is a proper power contradicting the fact that p is primitive. Hence, $|p| = |q|$. Since $|v| \geq |p| + |q| - 1 = 2|p| - 1$, p is a factor of v, which itself is a factor of q^{-y}. Thus, p is a cyclic permutation of q or of q^{-1}. By the last condition on Ω, this implies $p = q$. ◀

▶ **Lemma 12.** *The following is in* $\mathsf{uAC}^0(\mathrm{WP}(F_2))$*: given a power word v, compute a power word w of the form* (1) *such that* $v =_{F_X} w$.

The proof of this lemma is straightforward using [39, Proposition 20] in order to compute freely reduced words. We call these steps the *preprocessing steps*. Henceforth, we will assume that the inputs for the power word problem are given in the form (1).

The symbolic reduction system. We define the infinite alphabet $\Delta = \Delta' \cup \Delta''$ with $\Delta' = \Omega \times (\mathbb{Z} \setminus \{0\})$ and $\Delta'' = \mathrm{IRR}(S) \setminus \{1\}$. We write p^x for $(p, x) \in \Delta'$. A word over Δ can be read as a word over Σ in the natural way. Formally, we can define a canonical projection $\pi : \Delta^* \to \Sigma^*$ that maps a symbol $a \in \Delta$ to the corresponding word over Σ, but most of the times we will not write π explicitly.

Whenever there is the risk of confusion, we write $|v|_\Sigma$ to denote the length of $v \in \Delta^*$ read over Σ (i.e., $|v|_\Sigma = |\pi(v)|$) whereas $|v|_\Delta$ is the length over Δ. Moreover, we denote the number of occurrences of letters from Δ' in w with $|w|_{\Delta'}$. Finally, for a symbol $s \in \Delta''$ define $\lambda(s) = |s|_\Sigma$ and for $p^x \in \Delta'$ set $\lambda(p^x) = |p|_\Sigma$. For $u = a_1 \cdots a_m \in \Delta^*$ with $a_i \in \Delta$ for $1 \leq i \leq m$ we define $\lambda(u) = \sum_{i=1}^m \lambda(a_i)$. Thus, $\lambda(u)$ is the number of letters from Σ required to write down u ignoring the binary exponents.

A word w as in (1), which has been preprocessed as in the previous section, can be viewed as word over Δ with $w \in ((\Delta'' \cup \{1\})\Delta')^*(\Delta'' \cup \{1\})$, $|w|_{\Delta'} = n$ and $|w|_\Delta \leq 2n+1$ (we only have $\leq$ because some s_i might be empty).

We define the infinite string rewriting system T over Δ^* by the following rewrite rules, where $p^x, p^y, q^y \in \Delta'$, $s, t \in \Delta''$, $r \in \Delta'' \cup \{1\}$, and $d, e \in \mathbb{Z}$. Here, p^0 is identified with the empty word. Note that the strings in the rewrite rules are over the alphabet Δ, whereas the strings in the if-conditions are over the alphabet Σ.

$$p^x p^y \to p^{x+y} \tag{2}$$

$$p^x q^y \to p^{x-d} r q^{y-e} \qquad \text{if } p \neq q, p^x q^y \xrightarrow[S]{+} p^{x-d} r q^{y-e} \in \mathrm{IRR}(S) \text{ for} \tag{3}$$

$$r = p'q' \text{ with } p' <_{\mathrm{pref}} p^{\mathrm{sign}(x)} \text{ and } q' <_{\mathrm{suff}} q^{\mathrm{sign}(y)}$$

$$st \to r \qquad \text{if } st \xrightarrow[S]{+} r \in \mathrm{IRR}(S) \tag{4}$$

$$p^x s \to p^{x-d} r \qquad \text{if } p^x s \xrightarrow[S]{+} p^{x-d} r \in \mathrm{IRR}(S) \text{ for} \tag{5}$$

$$r = p's' \text{ with } p' <_{\mathrm{pref}} p^{\mathrm{sign}(x)} \text{ and } s' <_{\mathrm{suff}} s$$

$$s p^x \to r p^{x-d} \qquad \text{if } s p^x \xrightarrow[S]{+} r p^{x-d} \in \mathrm{IRR}(S) \text{ for} \tag{6}$$

$$r = s'p' \text{ with } s' <_{\mathrm{pref}} s \text{ and } p' <_{\mathrm{suff}} p^{\mathrm{sign}(x)}$$

▶ **Lemma 13.** *The following length bounds hold in the above rules:*

- *in rule* (3)*:* $0 < |r|_\Sigma \leq |p|_\Sigma + |q|_\Sigma$, $|d| \leq |q|_\Sigma$, *and* $|e| \leq |p|_\Sigma$
- *in rules* (5) *and* (6)*:* $|d| \leq |s|_\Sigma$.

The inequalities $|d| \leq |q|_\Sigma$ and $|e| \leq |p|_\Sigma$ follow from Lemma 11. The other inequalities are obvious. The next lemma is also straightforward from the definition.

▶ **Lemma 14.** *For $u \in \Delta^*$ we have $u =_{F_X} 1$ if and only if $u \xRightarrow[T]{*} 1$.*

▶ **Lemma 15.** *Let $u \in \Delta^*$. If $u \xRightarrow[T]{*} v$, then $u \xRightarrow[T]{\leq k} v$ for $k = 2\,|u|_\Delta + 4\,|u|_{\Delta'} \leq 6\,|u|_\Delta$.*

Proof sketch. The proof is based on the fact that at most $2|u|_{\Delta'} - 3$ applications of rules of the form (3) can occur. These are the only length increasing rules. All other rules either decrease the number of non-reduced two-letter factors of u (this can happen at most $|u|_\Delta - 1$ times) or decrease the length of u (this can happen at most $|u|_\Delta + 2|u|_{\Delta'} - 3$ times). ◀

Consider a word $u \in \Delta^*$ and $p \in \Omega$. Let $\Delta_p = \{p^x \mid x \in \mathbb{Z} \setminus \{0\}\}$. We can write u uniquely as $u = u_0 p^{y_1} u_1 \cdots p^{y_m} u_m$ with $u_i \in (\Delta \setminus \Delta_p)^*$. We define $\eta_p^i(u) = \sum_{j=1}^{i} y_j$ and $\eta_p(u) = \eta_p^m(u)$. By Lemma 13 we know that all rules of T change $\eta_p(\cdot)$ by at most $\lambda(u)$. We can use this observation in order to show the next lemma by induction on k.

▶ **Lemma 16.** *Let $u \xRightarrow[T]{k} v$. Then for all $v' \leq_{pref} v$ with $v' \in \Delta^*$ there is some $u' \in \Delta^*$ with $u' \leq_{pref} u$ and $|\eta_p(u') - \eta_p(v')| \leq (k+1)^2\,\lambda(u)$.*

The shortened version of a word. Take a word $u \in \Delta^*$ and $p \in \Omega$ and write u as $u = u_0 p^{y_1} u_1 \cdots p^{y_m} u_m$ with $u_i \in (\Delta \setminus \Delta_p)^*$ (we are only interested in the case that p^x appears as a letter in u for some $x \in \mathbb{Z}$). Let $\mathcal{C}$ be a finite set of finite, non-empty, non-overlapping intervals of integers, i.e., we can write $\mathcal{C} = \{\, [\ell_j, r_j] \mid 1 \leq j \leq k \,\}$ for $k = |\mathcal{C}|$ and $\ell_j \leq r_j$ for all j. We can assume that the intervals are ordered increasingly, i.e., we have $r_j < \ell_{j+1}$. We set $d_j = r_j - \ell_j + 1 > 0$. We say that u is *compatible* with $\mathcal{C}$ if $\eta_p^i(u) \notin [\ell_j, r_j]$ for any i, j. If w is compatible with $\mathcal{C}$, we define the *shortened version* $\mathcal{S}_\mathcal{C}(u)$ of u: for $i \in \{1, \ldots, m\}$ we set

$$C_i = C_i(u) = \begin{cases} \{\, j \mid 1 \leq j \leq k, \eta_p^{i-1}(u) < \ell_j \leq r_j < \eta_p^i(u) \,\} & \text{if } y_i > 0 \\ \{\, j \mid 1 \leq j \leq k, \eta_p^{i}(u) < \ell_j \leq r_j < \eta_p^{i-1}(u) \,\} & \text{if } y_i < 0, \end{cases}$$

i.e., C_i collects all intervals between $\eta_p^{i-1}(u)$ and $\eta_p^i(u)$. Then $\mathcal{S}_\mathcal{C}(u)$ is defined by

$$\mathcal{S}_\mathcal{C}(u) = u_0 p^{z_1} u_1 \cdots p^{z_m} u_m \qquad \text{where}$$

$$z_i = y_i - \operatorname{sign}(y_i) \cdot \sum_{j \in C_i} d_j = \begin{cases} y_i - \sum_{j \in C_i} d_j & \text{if } y_i > 0, \\ y_i + \sum_{j \in C_i} d_j & \text{if } y_i < 0. \end{cases}$$

A straightforward computation yields the next lemma:

▶ **Lemma 17.** *For all i we have $z_i \neq 0$ and $\operatorname{sign}(z_i) = \operatorname{sign}(y_i)$. In particular, if $u \in \mathrm{IRR}(T)$, then also $\mathcal{S}_\mathcal{C}(u) \in \mathrm{IRR}(T)$.*

Furthermore, we define $\operatorname{dist}_p(u, \mathcal{C}) = \min\{\, |\eta_p^i(u) - x| \mid 0 \leq i \leq m, x \in [\ell, r] \in \mathcal{C} \,\}$. Note that $\operatorname{dist}_p(u, \mathcal{C}) > 0$ if and only if u is compatible with $\mathcal{C}$. Moreover, if $\operatorname{dist}_p(u, \mathcal{C}) = a$, $v = v_0 p^{z_1} v_1 \cdots p^{z_m} v_m$, and $|\eta_p^i(u) - \eta_p^i(v)| \leq b$ for all $i \leq m$, then $\operatorname{dist}_p(v, \mathcal{C}) \geq a - b$.

▶ **Lemma 18.** *If $\operatorname{dist}_p(u, \mathcal{C}) > (k+1)^2\,\lambda(u)$ and $u \xRightarrow[T]{k} v$, then $\mathcal{S}_\mathcal{C}(u) \xRightarrow[T]{k} \mathcal{S}_\mathcal{C}(v)$.*

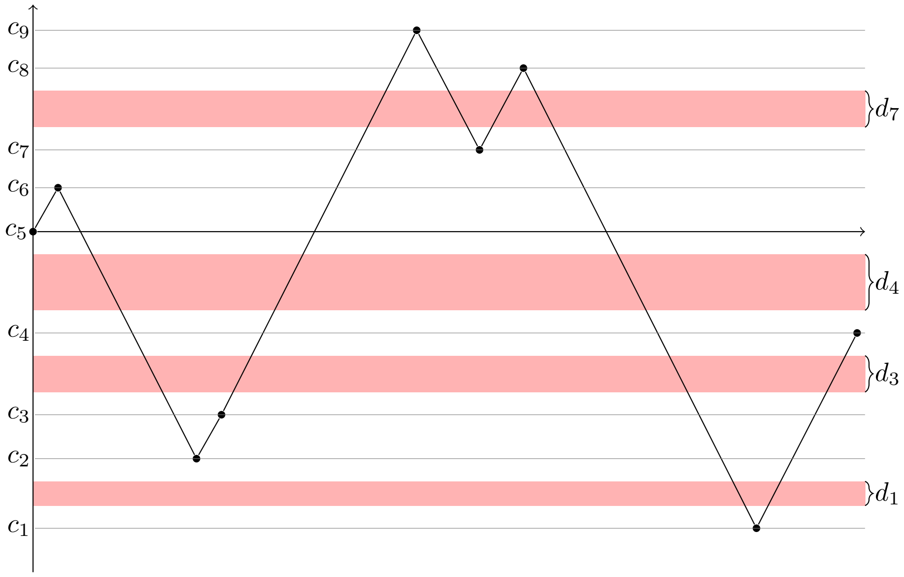

Figure 1 The red shaded parts represent the intervals from the set $\mathcal{C}_{u,p}^K$ in (7). The differences $c_3 - c_2$, $c_6 - c_5$, $c_7 - c_6$ and $c_9 - c_8$ are strictly smaller than $2K$.

Proof sketch. The first step for proving this lemma is to show that if $\operatorname{dist}_p(u, \mathcal{C}) > \lambda(u)$ and $u \underset{T}{\Longrightarrow} v$, then $S_{\mathcal{C}}(u) \underset{T}{\Longrightarrow} S_{\mathcal{C}}(v)$. To see this this, we distinguish between the rules applied: When applying one of the rules (3)–(6), we have $C_i(u) = C_i(v)$ for all i since the exponents are only changed slightly. Thus, the shortening process does the same on v as on u. When applying a rule (2), the exponents are added, which is compatible with the shortening process. Now we obtain the lemma by induction on k. In order to see that $\operatorname{dist}_p(u, \mathcal{C}) > \lambda(u)$ is satisfied in the inductive step, we use Lemma 16. ◀

We define a set of intervals which should be "cut out" from u as follows: We write $\{ c_1, \ldots, c_l \} = \{ \eta_p^i(u) \mid 0 \leq i \leq m \}$ with $c_1 < \cdots < c_l$ and we set

$$\mathcal{C}_{u,p}^K = \{ [c_j + K, c_{j+1} - K] \mid 1 \leq j \leq l-1, c_{j+1} - c_j \geq 2K \}. \tag{7}$$

Notice that $\operatorname{dist}_p(u, \mathcal{C}_{u,p}^K) = K$ (given that $\mathcal{C}_{u,p}^K \neq \emptyset$). The situation is shown in Figure 1.

▶ **Proposition 19.** *Let $p \in \Omega$, $u = u_0 p^{y_1} u_1 \cdots p^{y_m} u_m \in \Delta^*$ with $u_i \in (\Delta \setminus \Delta_p)^*$, and $K = (6\,|u|_\Delta + 1)^2\, \lambda(u) + 1$. Then $u =_{F_X} 1$ if and only if $S_{\mathcal{C}}(u) =_{F_X} 1$ for $\mathcal{C} = \mathcal{C}_{u,p}^K$.*

Proof. By Lemma 14 we have $u =_{F_X} 1$ if and only if $u \overset{*}{\underset{T}{\Longrightarrow}} 1$. Let $k = 6\,|u|_\Delta$. By Lemma 15, for all $u \overset{*}{\underset{T}{\Longrightarrow}} v$ we have $u \overset{\leq k}{\underset{T}{\Longrightarrow}} v$. By the choice of $\mathcal{C}$, we have $\operatorname{dist}_p(u, \mathcal{C}) > (k+1)^2\, \lambda(u)$. Hence, we can apply Lemma 18, which implies that $S_{\mathcal{C}}(u) \overset{*}{\underset{T}{\Longrightarrow}} S_{\mathcal{C}}(v)$ where v is a T-reduced (thus freely reduced) word for u. Clearly, if v is the empty word, then $S_{\mathcal{C}}(v)$ will be the empty word. On the other hand, if v is non-empty, then $S_{\mathcal{C}}(v)$ is non-empty and T-reduced by Lemma 17. Hence, we have $u =_{F_X} 1$ if and only if $S_{\mathcal{C}}(u) =_{F_X} 1$. ◀

▶ **Lemma 20.** *Let p, u, K, and $\mathcal{C}$ be as in Proposition 19 and $S_{\mathcal{C}}(u) = u_0 p^{z_1} u_1 \cdots p^{z_m} u_m$. Then $|z_i| \leq m \cdot (2 \cdot (6\,|u|_\Delta + 1)^2 \cdot \lambda(u) + 1)$ for all $1 \leq i \leq m$.*

Proof of Theorem 2. We start with the preprocessing as described in Lemma 12 leading to a word $w = s_0 p_1^{x_1} s_1 \cdots p_n^{x_n} s_n$ with $p_i \in \Omega$ and $s_i \in \mathrm{IRR}(S)$ as in (1). After that we apply the shortening procedure for all $p \in \{\, p_i \mid 1 \leq i \leq n \,\}$. This can be done in parallel for all p, as the outcome of the shortening only depends on the p-exponents. By Lemma 20 this leads to a word $\hat{w}$ of polynomial length. Finally, we can test whether $\hat{w} =_{F_X} 1$ using one oracle gate for $\mathrm{WP}(F_2)$ (recall that F_2 contains a copy of F_X). The computations for shortening only involve iterated addition (and comparisons of integers), which is in uTC^0 and, thus, can be solved in uAC^0 with oracle gates for $\mathrm{WP}(F_2)$. ◀

5 The power word problem in wreath products

The goal of this section is to prove Theorems 8 and 9. We first fix some notation. Let G be a finitely generated group with the finite symmetric generating set Σ. For $\mathbb{Z}$ we fix the generator a. Hence $\Sigma \cup \{a, a^{-1}\}$ is a symmetric generating set for the wreath product $G \wr \mathbb{Z}$. For a word $w = v_0 a^{e_1} v_1 \cdots a^{e_n} v_n$ with $e_i \in \{-1, 1\}$ and $v_i \in \Sigma^*$ let $\sigma(w) = e_1 + \cdots + e_n$. With $I(w)$ we denote the interval $[b, c] \subseteq \mathbb{Z}$, where b (resp., c) is the minimal (resp., maximal) integer of the form $e_1 + \cdots + e_i$ for $0 \leq i \leq n$. Note that if w represents $(f, d) \in G \wr \mathbb{Z}$, then $d = \sigma(w)$, $\mathrm{supp}(f) \subseteq I(w)$ and $0, d \in I(w)$.

Periodic words over groups. We recall a construction from [12]. With G^+ we denote the set of all tuples $(g_0, \ldots, g_{q-1})$ over G of arbitrary length $q \geq 1$. With G^ω we denote the set of all mappings $f : \mathbb{N} \to G$. Elements of G^ω can be seen as infinite sequences (or words) over the set G. We define the binary operation $\otimes$ on G^ω by pointwise multiplication: $(f \otimes g)(n) = f(n)g(n)$. The identity element is the mapping id with $\mathrm{id}(n) = 1$ for all $n \in \mathbb{N}$. For $f_1, f_2, \ldots, f_n \in G^\omega$ we write $\bigotimes_{i=1}^n f_i$ for $f_1 \otimes f_2 \otimes \cdots \otimes f_n$. If G is abelian, we write $\sum_{i=1}^n f_i$ for $\bigotimes_{i=1}^n f_i$. A function $f \in G^\omega$ is periodic with period $q \geq 1$ if $f(k) = f(k+q)$ for all $k \geq 0$. In this case, f can specified by the tuple $(f(0), \ldots, f(q-1))$. Vice versa, a tuple $u = (g_0, \ldots, g_{q-1}) \in G^+$ defines the periodic function $f_u \in G^\omega$ with $f_u(n \cdot q + r) = g_r$ for $n \geq 0$ and $0 \leq r < q$. One can view this mapping as the sequence u^ω obtained by taking infinitely many repetitions of u. Let G^ρ be the set of all periodic functions from G^ω. If f_1 is periodic with period q_1 and f_2 is periodic with period q_2, then $f_1 \otimes f_2$ is periodic with period $q_1 q_2$ (in fact, $\mathrm{lcm}(q_1, q_2)$). Hence, G^ρ forms a countable subgroup of G^ω. Note that G^ρ is not finitely generated: The subgroup generated by elements $f_i \in G^\rho$ with period q_i $(1 \leq i \leq n)$ contains only functions with period $\mathrm{lcm}(q_1, \ldots, q_n)$. For $n \geq 0$ we define the subgroup G^ρ_n of all $f \in G^\rho$ with $f(k) = 1$ for all $0 \leq k \leq n-1$. We consider the uniform membership problem for subgroups G^ρ_n, $\textsc{Membership}(G^\rho_*)$ for short:

- input: tuples $u_1, \ldots, u_n \in G^+$ (elements of G are represented by finite words over Σ) and a binary encoded number m.
- question: does $\bigotimes_{i=1}^n f_{u_i}$ belong to G^ρ_m?

The following result was shown in [12]:

▶ **Theorem 21.** *For every finitely generated abelian group G, $\textsc{Membership}(G^\rho_*)$ is in uTC^0.*

▶ **Lemma 22.** *Let $w \in (\Sigma \cup \{a, a^{-1}\})^*$ with $\sigma(w) \neq 0$, $n \geq 1$, and $I(w^n) = [b, c]$. Moreover, let $s = c - b + 1$ be the size of the interval $I(w)$ and let $(g, n \cdot \sigma(w)) \in G \wr \mathbb{Z}$ be the group element represented by w^n. Then g is periodic on the interval $[b + s, c - s]$ with period $|\sigma(w)|$.*

▶ **Example 23.** Let us consider the wreath product $\mathbb{Z} \wr \mathbb{Z}$ and let the left copy of $\mathbb{Z}$ in the wreath product be generated by b. Consider the word $w = ba^{-1}babab^3ab^3ab^5a^{-1}b$ and let $n = 8$. We have $\sigma(w) = 2$ and $I(w) = [-1, 3]$. Moreover, w represents the group element

$(f, 2)$ with $f(-1) = 1$, $f(0) = 2$, $f(1) = 3$, $f(2) = 4$, and $f(3) = 5$. Let us now consider the word w^8. The following diagram shows how to obtain the corresponding element of $\mathbb{Z} \wr \mathbb{Z}$:

-1	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17
1	2	3	4	5														
		1	2	3	4	5												
				1	2	3	4	5										
						1	2	3	4	5								
								1	2	3	4	5						
										1	2	3	4	5				
												1	2	3	4	5		
														1	2	3	4	5
1	2	4	6	9	6	9	6	9	6	9	6	9	6	9	6	8	4	5

We have $I(w^8) = [-1, 17]$ and $\sigma(w^8) = 8\sigma(w) = 16$. If $(g, 16)$ is the group element represented by w^8, then the function g is periodic on the interval $[2, 14]$ (which includes the interval $[-1 + s, 17 - s]$, where $s = |I(w)| = 5$) with period 2.

Proofs of Theorem 8 and 9. A conjunctive truth-table reduction is a Turing reduction where the output is the conjunction over the outputs of all oracle gates.

▶ **Proposition 24.** *For every finitely generated group G,* PowerWP$(G \wr \mathbb{Z})$ *is conjunctive truth-table* uTC^0*-reducible to* Membership(G_*^ρ) *and* PowerWP(G).

Proof sketch. Let $w = u_1^{x_1} u_2^{x_2} \cdots u_k^{x_k}$ be the input power word and let $(f, d) \in G \wr \mathbb{Z}$ be the element represented by w. We can check in uTC^0 whether $d = 0$. The difficult part is to check whether f is the zero-mapping. For this we compute an interval I (of exponential size) that contains the support of f. We then partition I into two sets C and $I \setminus C$. The set C has polynomial size and we can check whether f is the zero-mapping on C using polynomially many oracle calls to PowerWP(G). The complement $I \setminus C$ can be written as a union of polynomially many intervals. The crucial property of C is that on each of these intervals f can be written as a sum of periodic sequences; for this we use Lemma 22. Using oracle calls to Membership(G_*^ρ) allows us to check whether f is the zero mapping on $I \setminus C$. ◀

Since for a finitely generated abelian group G, one can solve PowerWP(G) in uTC^0, Theorem 8 is a consequence of Proposition 24 and Theorem 21.

We split the proof of Theorem 9 into three propositions: one for the upper bound and two for the lower bounds. It is straightforward to show that if the word problem for the finitely generated group G belongs to coNP, then also Membership(G_*^ρ) belongs to coNP. Since coNP is closed under conjunctive truth-table uTC^0-reducibility, Proposition 24 yields:

▶ **Proposition 25.** *Let G be a finitely generated group such that* PowerWP(G) *belongs to* coNP*. Then also* PowerWP$(G \wr \mathbb{Z})$ *belongs to* coNP.

▶ **Proposition 26.** *If G is a finite, non-solvable group,* PowerWP$(G \wr \mathbb{Z})$ *is* coNP*-hard.*

Proof sketch. Barrington [4] proved the following result: Let C be a fan-in two boolean circuit of depth d with n input gates $x_1, \ldots, x_n$. From C one can compute a sequence of triples (a so-called G-program) $P_C = (k_1, g_1, h_1)(k_2, g_2, h_2) \cdots (k_\ell, g_\ell, h_\ell) \in ([1, n] \times G \times G)^*$ of length $\ell \leq (4|G|)^d$ such that for every input valuation $v : \{x_1, \ldots, x_n\} \to \{0, 1\}$ the following two statements are equivalent:

(a) C evaluates to 0 under the input valuation v.

(b) $c_1 c_2 \cdots c_\ell = 1$ in G, where $c_i = g_i$ if $v(x_{k_i}) = 0$ and $c_i = h_i$ if $v(x_{k_i}) = 1$.

This G-program is constructed as a sequence of iterated commutators, based on the observation that $[g,h]=1$ if and only if $g=1$ or $h=1$ (given some reasonable assumptions on g and h). Every formula C in conjunctive normal form can be written as a circuit of depth $\mathcal{O}(\log|C|)$. Hence the G-program P_C has length polynomial in $|C|$. From [4] it is easy to see that on input of the formula C, the G-program P_C can be computed in logspace.

Let $P_C=(k_1,g_1,h_1)\cdots(k_\ell,g_\ell,h_\ell)$ and $x_1,\dots,x_n$ be the variables in C. We compute in logspace the n first primes $p_1,\dots,p_n$ and $M=\prod_{i=1}^n p_i$ (the latter in binary notation). Let a denote the generator of $\mathbb{Z}$ in the wreath product $G\wr\mathbb{Z}$. We now compute for every $1\le i\le\ell$ the power word $w_i=(h_i(ag_i)^{p_{k_i}-1}a)^{M/p_{k_i}}a^{-M}$ and set $w_C=w_1w_2\cdots w_\ell$. The group element of $G\wr\mathbb{Z}$ represented by w_C is of the form $(f,0)$.

We claim that $w_C=1$ in $G\wr\mathbb{Z}$ if and only if C is unsatisfiable: For a number $z\in[0,M-1]$ we define the valuation $v_z:\{x_1,\dots,x_n\}\to\{0,1\}$ by $v_z(x_i)=1$ if $z\equiv 0 \mod p_i$ and $v_z(x_i)=0$ otherwise. By the Chinese remainder theorem, for every valuation $v:\{x_1,\dots,x_n\}\to\{0,1\}$ there exists $z\in[0,M-1]$ with $v=v_z$. Based on the above statements (a) and (b), the final step of the proof checks that $f(z)=1$ if and only if C evaluates to 0 under v_z. ◀

▶ **Proposition 27.** *Let F be a finitely generated free group of rank at least two. Then* PowerWP$(F\wr\mathbb{Z})$ *is* coNP*-hard.*

The proof is almost the same as for Proposition 26. The difference is that we mimic Robinson's proof that the word problem for F_2 is NC^1-hard [35] instead of Barrington's result.

6 Further Research

We conjecture that the method of Section 4 can be generalized to right-angled Artin groups (RAAGs – also known as graph groups) and hyperbolic groups, and hence that the power word problem for a RAAG (resp., hyperbolic group) G is AC^0-Turing-reducible to the word problem for G. One may also try to prove transfer results for the power word problem with respect to group theoretical constructions, e.g., graph products, HNN extensions and amalgamated products over finite subgroups. For finitely generated linear groups, the power word problem leads to the problem of computing matrix powers with binary encoded exponents. The complexity of this problem is open; variants of this problem have been studied in [1, 11].

Another open question is what happens if we allow nested exponents. We conjecture that in the free group for any nesting depth bounded by a constant the problem is still in $\mathsf{uAC}^0(\mathrm{WP}(F_2))$. However, for unbounded nesting depth it is not clear what happens: we only know that it is in P since it is a special case of the compressed word problem; but it still could be in $\mathsf{uAC}^0(\mathrm{WP}(F_2))$ or it could be P-complete or somewhere in between.

Abstract

It is a long standing conjecture that the problem of deciding whether a quadratic word equation has a solution is in NP. It has also been conjectured that the length of a minimal solution to a quadratic equation is at most exponential in the length of the equation, with the latter conjecture implying the former. We show that both conjectures hold for some natural subclasses of quadratic equations, namely the classes of regular-reversed, k-ordered, and variable-sparse quadratic equations. We also discuss a connection of our techniques to the topic of unavoidable patterns, and the possibility of exploiting this connection to produce further similar results.

1 Introduction

A *word equation* is an equation $\alpha = \beta$ in which the two sides, α and β, are words consisting of letters from a *terminal alphabet* $\Sigma = \{\mathtt{a}, \mathtt{b}, \dots\}$ and *variables* from a set $X = \{x, y, z, \dots\}$. It has a solution if the variables may be substituted for words over Σ in such a way that the two sides become identical. For example, the equation $\mathtt{ab}x\mathtt{b}y = x\mathtt{b}yx\mathtt{b}$ has a solution where x is substituted by $\mathtt{a}$, and y is substituted by $\mathtt{ab}$. Usually such a substitution is represented by a morphism $h : (X \cup \Sigma)^* \to \Sigma^*$ which preserves the terminal symbols (i.e. $h(\mathtt{a}) = \mathtt{a}$ for all $\mathtt{a} \in \Sigma$). Situated in the intersection between computer science and algebra, word equations are an important tool for describing structural relations between words, and as such are of interest in a variety of areas, ranging from combinatorial group and monoid theory [20, 19, 7], to unification [25, 12, 14], database theory [11, 10], model checking, verification and security, where there has been much interest recently in developing so-called string solvers capable of dealing with word equations such as HAMPI [17], CVC4 [3], Stranger [28], ABC [2], Norn [1], S3P [27] and Z3str3 [4]. Of course, not all equations have solutions (consider the trivial example $\mathtt{a}x = \mathtt{b}x$, or less trivial ones such as $\mathtt{abc}x = x\mathtt{cba}$), and the problem of deciding whether a given equation has a solution – the satisfiability problem – has been at the

centre of research on word equations since their inception. It is not difficult to see that the satisfiability problem contains an inherent degree of computational complexity. In particular, there are several simple reductions from NP-complete problems such as the membership problem for pattern languages [9, 8] and linear arithmetic. On the other hand, bounding the complexity from above has proven considerably more challenging. After considerable effort, Makanin [21] famously showed that the satisfiability problem for word equations is algorithmically decidable. This result was later improved by Plandowski [23] who gave an algorithm which requires only polynomial space, and more recently this has been refined further to linear space by Jeż [13, 15] using the elegant method of recompression. Nevertheless, determining the precise complexity, and in particular whether the problem is contained in NP, remains one of the outstanding open problems in the area.

One method for obtaining upper bounds on the complexity is to consider the lengths of minimal solutions – those for which no shorter solution exists to the same equation. Since it may easily be checked in polynomial time (in the length of the substitution) whether a given substitution satisfies a given word equation: simply apply the substitution to each side and compare the resulting words, we have a clear relation between the lengths of minimal solutions and the complexity of the satisfiability problem. If the minimal solutions are guaranteed to be short enough (e.g. polynomial in the length of the equation), we have a non-deterministic polynomial time algorithm which simply guesses a solution and then checks it. In fact, Plandowski and Rytter [24] showed that minimal solutions may be compressed substantially in such a way that their compressed versions may still be checked efficiently, so a similar approach works for equations whose minimal solutions are at most exponentially long in the length of the equation. Unfortunately, the best known upper bound on the length of minimal solutions to word equations in general is double exponential. It is worth pointing out that it is not difficult to construct examples of equations for which the lengths of minimal solutions are (single) exponential in the length of the equation.

In the absence of matching upper and lower bounds on the complexity for the whole class of word equations, it makes sense to first consider subclasses. For example, equations with at most two distinct variables (which may each occur multiple times) can be solved in polynomial time (see, e.g. [6]), and thus do not exhibit the same intractability as more general classes, while another class which is generally well understood is the class of equations in which variables may only occur on one side (i.e. either $\alpha \in \Sigma^*$ or $\beta \in \Sigma^*$). In this case, the satisfiability problem is simply the (NP-complete) problem of pattern matching with variables, for which the computational complexity has been studied extensively. Aside from these examples, however, there seem to be surprisingly few classes of equations for which the satisfiability problem is known to be contained in NP, especially amongst those with corresponding hardness results.

Quadratic word equations are word equations in which each variable may occur at most twice – although the number of variables is unrestricted. There are many reasons that the quadratic equations form a particularly interesting subclass of equations. On one hand, NP-hardness remains (see [8]) but also even for the very restricted case in which the variables must occur in exactly the same order on both sides and only the terminal symbols may vary (see [5]). On the other hand, unlike the general case, there is a straightforward proof that the satisfiability problem for quadratic word equations is decidable, using so-called Nielsen transformations (see [18]). Moreover, while examples of equations with three occurrences of each variable are known for which the minimal solutions are exponentially long in the length of the equation, no such examples are known for quadratic equations. However, while these results seem to indicate that quadratic equations may not be as complex as the general case, understanding quadratic equations, and in particular determining whether the satisfiability of quadratic equations is in NP, has proven exceptionally difficult and as with the general case, remains a long-standing open problem.

Our Contribution. In the current paper, we further develop a method for showing upper bounds on the length of solutions to quadratic word equations first introduced in [5], and use it to obtain such bounds for several subclasses of quadratic equations. The method extends the existing technique of *filling the positions* (see [16, 24]), and relies on arranging the individual positions of a solution, as referenced by their origin (e.g. the third letter in the second occurrence of the variable x) into chains, which may be represented as words (chain-words). This chains-representation of solutions is discussed in detail in Section 3.

We show firstly that quadratic equations with a high concentration of terminal symbols and variables occurring only once – with few variables occurring the maximal two times – have minimal solutions at length at most $n2^{2^{O(V^4)}}$ where V is the number of variables occurring twice and n is the length of the equation. Using the previously mentioned algorithm of Plandowski and Rytter, it follows that for the class of equations for which $V < \log(n)$, which we shall refer to as *variable-sparse* quadratic equations, the satisfiability problem is in NP. Moreover, by observing that variables occurring only once do not have a dramatic impact on the length of minimal solutions (Proposition 2), we also obtain that if V is bounded by a constant, the satisfiability problem may be solved in polynomial time.

As a straightforward consequence, we are also able to show that equations which may be obtained by concatenating many "small" quadratic equations (over disjoint, constant-size sets of variables) also have short solutions, thus may be solved in non-deterministic polynomial time. Such equations may be arbitrarily disordered at a local level – we do not restrict the structure of each individual equation before concatenating – but possess a global order in which the sets of variables must occur from left to right in each side of the equation. Since these equations, which we shall call k-ordered equations, generalise the regular-ordered equations considered in [5], we also get the corresponding NP-hardness lower bound in this case. Thus, the remaining "interesting", cases must possess some global disorder among the variables.

Our main result (Theorem 21) establishes upper bounds of $n2^{3n}$ on the length of minimal solutions to a subclass of quadratic equations for which this necessary separation of the variables is maximal, namely the class of regular-reversed equations, in which the variables occur in the opposite order on the LHS as on the RHS. We also show (Proposition 14) that this bound is close to the best that we may expect using our approach. The proof of Theorem 21, although technical, revolves around two simple operations on the chains-representation of a solution. The first is a compression of certain subchains, which produces a new, shorter solution to an equation of the same length. In a sense, this kind of compression generalises the Nielsen transformations mentioned previously. The second operation, given by Lemma 22 and taking advantage of the structure induced by the carefully chosen compression, is a simple deletion of a variable from the equation (and solution) such that the property of being chain-square-free is preserved.

The final part to our contribution focusses on potential forward steps in the general case, and as such begins to explore a connection to the topic of avoidability of patterns within the field of combinatorics on words. Our main result in this direction is a characterisation of possible chain words in the case of regular equations (equations in which each variable occurs at most once on each side) which is considerably simpler than the more abstract definition given in Section 3. This leaves open a particular interesting problem to determine whether there exist "long" non-repetitive (square-free) words satisfying this characterisation, where a negative answer, for an appropriate definition of "long", would, due to results presented in Section 3, yield that the satisfiability problem for this large subclass of quadratic word equations is in NP. We also discuss, with Lemma 27 as an example, how looking at various structures other than direct repetitions might also be sufficient to obtain the same result.

The rest of the paper is organised as follows. In Section 2, we establish the basic notations and definitions we will need, along with some preliminary results. In Section 3, we shall introduce the main framework used to establish our results. This section recaps the main construction (the chains representation of solutions) and lemma (Lemma 11) originally presented in [5] which form the basis of the framework, and mentions some new additional useful results such as Lemma 12 and Proposition 14. Our main results concerning upper bounds on the length of minimal solutions to equations are presented in Sections 4 and 5. Finally, in Section 6, we present our characterisation of chain-words and discuss the connection to the topic of avoidability of patterns and the resulting possibilities for exploiting Lemma 11 in Section 3 further.

2 Preliminaries

Let Σ be an alphabet. We denote by Σ^* the set of all words over Σ. The empty word is denoted ε. A word u is a *prefix* of a word w if there exists v such that $w = uv$. Similarly, u is a *suffix* of w if there exists v such that $w = vu$, and u is a *factor* of w if there exist v, v' such that $w = vuv'$. A *square* is a word ww for some $w \in \Sigma^* \backslash \{\varepsilon\}$. The length of a word w is denoted $|w|$, and the number of occurrences of a letter $\mathtt{a}$ in a word w is denoted $|w|_{\mathtt{a}}$. The i^{th} letter of w, as counted from the left, is denoted $w[i]$. The *reversal* of a word w is the word $w^R = w[|w|]w[|w|-1]\ldots w[2]w[1]$. For two alphabets Σ_1, Σ_2, a morphism $h : {\Sigma_1}^* \to {\Sigma_2}^*$ is a mapping such that, for all $u, v \in {\Sigma_1}^*$, $h(u)h(v) = h(uv)$. Thus, a morphism is uniquely defined by its image on each letter in Σ_1. In the rest of the paper, we shall distinguish between two alphabets: an (infinite) set X of *variables*, and a *terminal alphabet* Σ. We shall generally assume that the terminal alphabet contains at least two letters, but otherwise its cardinality will not be important for our purposes. For a word $\alpha \in (X \cup \Sigma)^*$, we shall denote the set $\{x \in X \mid |\alpha|_x \geq 1\}$ by $\mathrm{var}(\alpha)$ and the set $\{\mathtt{a} \in \Sigma \mid |\alpha|_{\mathtt{a}} \geq 1\}$ by $\mathrm{alph}(\alpha)$. We shall say a morphism $h : (X \cup \Sigma)^* \to \Sigma^*$ is a *substitution* if $h(\mathtt{a}) = \mathtt{a}$ for all $\mathtt{a} \in \Sigma$.

A *word equation* is a tuple (α, β) (usually written as $\alpha = \beta$) such that $\alpha, \beta \in (X \cup \Sigma)^*$. α and β are called the left hand side (LHS) and right hand side (RHS) respectively. Solutions are substitutions $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ such that $h(\alpha) = h(\beta)$. The length of a word equation $\alpha = \beta$ is $|\alpha\beta|$. The length of a solution h to the equation is $|h(\alpha)|$. A solution is *minimal* if no shorter solution exists. The *Satisfiability Problem* is the decision problem of determining whether, for a given word equation, there exists a solution. The following result of Plandowski and Rytter establishes a relationship between the length of minimal solutions (when they exist) and the computational complexity of the satisfiability problem.

▶ **Theorem 1** ([24]). *Suppose that for a given class of word equations, there exists a polynomial P such that any equation in the class which has a solution, has one whose length is at most $2^{P(n)}$ where n is the length of the equation. Then the satisfiability problem for that class is in* NP.

A word equation $\alpha = \beta$ is *quadratic* if $|\alpha|_x + |\beta|_x \leq 2$ for every $x \in X$. It is *regular* if $|\alpha|_x \leq 1$ and $|\beta|_x \leq 1$ for all $x \in X$. It is regular-ordered if it is regular, and the variables occur in the same order in both sides of the equation (i.e. there do not exist $x, y \in X$ and $\alpha', \beta' \in (X \cup \Sigma)^*$ such that $x\alpha'y$ is a factor of α and $y\beta'x$ is a factor of β). It was shown in [5] that the satisfiability for regular-ordered word equations is NP-hard.

Finally, we remark that, when considering asymptotic bounds on the length of minimal solutions to quadratic equations, it is not necessary to consider equations in which a variable occurs only once. Hence we shall, unless otherwise stated, consider classes of equations in which the variables occur exactly twice. All of our results providing upper bounds on the length of minimal solutions (and thus containment in NP) can easily be adapted for classes permitting variables which occur only once.

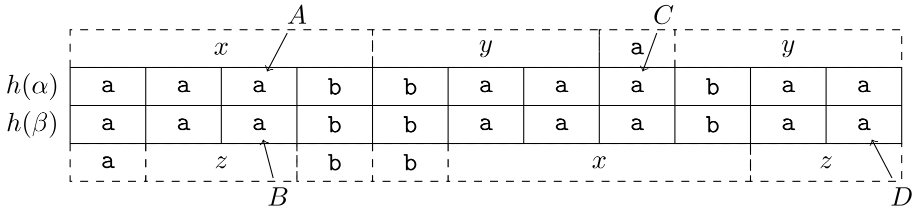
▶ **Proposition 2.** *Let $\alpha = \beta$ be a quadratic word equation and let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a minimal solution. Let X_1 be the set of variables occurring exactly once in $\alpha\beta$ and let X_2 be the set of variables occurring twice. Let $g : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to (\mathrm{var}(\alpha\beta) \cup \Sigma)^*$ be the morphism such that $g(x) = h(x)$ if $x \in X_1$ and $g(x) = x$ otherwise. Then the equation $g(\alpha) = g(\beta)$ has length less than $2|\alpha\beta|$, and has a minimal solution $h' : (X_2 \cup \Sigma)^* \to \Sigma^*$ such that $|h'(g(\alpha))| = |h(\alpha)|$.*

3 A Method for Upper Bounds

Despite Theorem 1, showing inclusion in NP often remains a challenge, particularly among those classes for which the corresponding NP-hardness lower bound exists. In the present section, we outline a framework, first presented in [5] for reasoning about the (non)-minimality of solutions which we shall rely on in the proofs of most of our results. The main idea centers around the simple principle that a solution is not minimal if we can remove some parts of it to obtain another, shorter solution. While this is in itself a trivial statement, the consequences of our approach will lead, as we shall see in Section 6, to an entirely non-trivial method of reasoning generally about the lengths of minimal solutions to quadratic equations and a surprising link to the topic of avoidability of patterns, a central theme within combinatorics on words.

Positions in a Solution. Our approach extends the method of "filling the positions", used to determine whether a word equation has a solution when the lengths of the substitutions for the variables are given explicitly (see [16, 24] for an overview). In this respect, we must first specify precisely what we mean by a position. For our reasoning, it will be convenient to be able to reference parts of the substitution/solution both purely from their location in the full image, and relative to the part of the equation – an occurrence of a variable or terminal symbol – from which they originate. Accordingly, for an equation E given by $\alpha = \beta$ and a substitution $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ such that $|h(\alpha)| = |h(\beta)|$, we define the set of *absolute positions* of h w.r.t. E as $\mathcal{AP}_E^h = \{i \mid 1 \leq i \leq |h(\alpha)|\}$, and the set of *relative positions* (or just positions) of h w.r.t. E as $\mathcal{RP}_E^h = \{(x, i, d) \mid x \in \mathrm{var}(\alpha\beta) \cup \mathrm{alph}(\alpha\beta), 1 \leq i \leq |\alpha\beta|_x, \text{ and } 1 \leq d \leq |h(x)|\}$.

Intuitively, the relative position (x, i, d) corresponds to "the d^{th} letter in the image of the i^{th} occurrence of x", where occurrences are counted from left to right in $\alpha\beta$. As such, we have exactly two relative positions corresponding to each absolute position (one for the LHS and one for the RHS). Let $f_E^h : \mathcal{RP}_E^h \to \mathcal{AP}_E^h$ be the (non-injective) function mapping a relative position to the corresponding absolute position. More formally, for a relative position $r = (x, i, d)$, let $f_E^h(r)$ be the unique integer j such that $j - d = |h(\gamma)| \mod |h(\alpha)|$ where γ is the prefix of $\alpha\beta$ up to, but not including, the i^{th} occurrence of x (i.e. the longest prefix of $\alpha\beta$ such that $|\gamma|_x < i$). We shall say that a relative position $(x, i, d) \in \mathcal{RP}_E^h$ is a *terminal position* if $x \in \Sigma$ (in which case it is guaranteed that $d = 1$), and otherwise we shall say that the position is *non-terminal* and *belongs* to the variable x.



$h(\alpha)$	a	a	a	b	b	a	a	a	b	a	a
$h(\beta)$	a	a	a	b	b	a	a	a	b	a	a

Figure 1 The solution h given by $h(x) = \texttt{aaab}$, $h(y) = \texttt{baa}$ and $h(z) = \texttt{aa}$ to the equation E given by $xy\texttt{a}y = \texttt{a}z\texttt{bb}xz$. Each individual rectangle is a position in $\mathcal{RP}_E^h$. For example, A is the position $(x, 1, 3)$, while D is the position $(z, 2, 2)$, and C is the (terminal) position $(\texttt{a}, 1, 1)$. The positions A and B are neighbours. B and D are siblings, meaning that A is the successor of D.

Neighbours and Siblings. We shall now introduce the two relations on the set of relative positions used in the method of filling the positions. Firstly, we shall say that two relative positions r_1, r_2 are *siblings* if there exist x, d, i, i' with $i \neq i'$ such that $r_1 = (x, i, d)$ and $r_2 = (x, i', d)$. Secondly, we shall say that two relative positions r_1 and r_2 are *neighbours* if $f_E^h(r_1) = f_E^h(r_2)$ and $r_1 \neq r_2$. The following remarks are immediate:

▶ Remark 3. Each relative position $r = (x, i, d)$ has exactly one neighbour. It has exactly $|\alpha\beta|_x - 1$ siblings. In particular, if $\alpha = \beta$ is quadratic, then either r is a terminal position or r has at most one sibling.

While we will not give a full description of the method of filling the positions in the present paper, it essentially consists of constructing, for a given equation E and solution h, the equivalence relation $\mathcal{R}_E^h$ obtained by the reflexive and transitive closure of the union of the neighbour and sibling relations. The following remarks are standard facts regarding the method of filling the positions and can easily be verified.

▶ Remark 4. A substitution $h : (\text{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ is a solution to the equation E given by $\alpha = \beta$ if and only if $|h(\alpha)| = |h(\beta)|$ and, for any two positions $r_1 = (x, i, d), r_2 = (x', i', d')$ such that $(r_1, r_2) \in \mathcal{R}_E^h$, we have that $h(x)[d] = h(x')[d']$.

▶ Remark 5. If $h : (\text{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ is a solution to the equation E given by $\alpha = \beta$, and there exists an equivalence class of the relation $\mathcal{R}_E^h$ which does not contain a terminal position, then the positions belonging to this class can be substituted by any word without affecting the fact that h is a solution. In particular, they can be substituted by the empty word (i.e. removed altogether), so the solution is not minimal.

The Chains Representation and Chain-words. Suppose now that we have a quadratic equation E given by $\alpha = \beta$ and a solution $h : (\text{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ to E. From now on, we shall only consider quadratic equations. Then by Remark 3, we can organise the relative positions into sequences, or *chains* using the sibling and neighbour relations as follows.

▶ **Definition 6** (Chains Representation of a Solution). *A sequence $r_1, r_2, \ldots, r_n$ of positions from $\mathcal{RP}_E^h$ is a chain-sequence of h with respect to E if*

- *$r_1 = (x_1, i_1, d_1)$ where either x_1 is a terminal symbol from Σ or $|\alpha\beta|_{x_1} = 1$,*
- *r_2 is the neighbour of r_1,*
- *$r_n = (x_n, i_n, d_n)$ where either x_n is a terminal symbol from Σ or $|\alpha\beta|_{x_n} = 1$,*
- *for all j, $2 < j \leq n$, r_j is the neighbour of the sibling of r_{j-1}.*

The set of all chain-sequences is the chains-representation *of h with respect to E. For a position r in a chain, the next position r' in the chain, if it exists, is called the* successor *of r, while r is the* predecessor *of r'. For the sake of brevity, we shall usually refer to chain-sequences simply as "chains".*

▶ Remark 7. Throughout the rest of the paper, we shall only consider solutions for which all equivalence classes of the relation $\mathcal{R}_E^h$ contain a terminal position (otherwise, we can just erase the appropriate parts to obtain a shorter solution, see Remark 5). Under this assumption, all positions $r \in \mathcal{RP}_E^h$ which are not terminal and have a sibling r' will occur (exactly once) in exactly one chain, while terminal positions and positions without a sibling will occur twice (once at the start of a chain-sequence, and once at the end). Thus the length of the solution will be at most half the sum of the lengths of all chains in the chains representation.

▶ Remark 8. For every chain $r_1, r_2, \ldots, r_n$ in the chains representation, there will also exist a dual chain $r_n, \overline{r_{n-1}}, \ldots, \overline{r_2}, r_1$ where, for $2 \leq i \leq n-1$, $\overline{r_i}$ denotes the sibling of r_i. Similarly, for every subchain $r_i, r_{i+1}, \ldots, r_j$ such that r_i and r_j are not terminal positions, there exists a dual subchain $\overline{r_j}, \overline{r_{j-1}}, \ldots, \overline{r_i}$, obtained by reversing and swapping each position for its neighbour. Each equivalence class of the relation $\mathcal{R}_E^h$ corresponds exactly to the positions contained within one chain and its dual.

▶ Remark 9. In the particular case of regular equations, the sibling of a position will always occur on the opposite side of the equation. Since the same is always true by definition for the neighbour of a position, it follows that the successor in the chains representation of a position will belong to the same side. In particular, every position (x, i, d) in the chain which belongs to a variable, with the exception of the first, will have the same value i.

▶ **Definition 10** (Chain-Words and Similarity). *Let Γ_E^h be the set $\{(x, i) \mid x \in \mathrm{var}(\alpha\beta)$ and $i \in \{1, 2\}\}$, and let $\rho : \mathcal{RP}_E^h \to \Gamma_E^h$ be the projection of $\mathcal{RP}_E^h$ onto the first two elements (so that $\rho((x, i, d)) = (x, i)$). For each chain-sequence $C = r_1, r_2, \ldots, r_n$ of h with respect to E, the chain-word induced by C is the word $w = \rho(r_2)\rho(r_3)\ldots\rho(r_{n-1})$ (over the alphabet Γ_E^h). The set of all chain-words induced by chain-sequences of h w.r.t. E is denoted $\Delta_{h,E}$. We shall say that two (sub)chains are* similar *if they induce the same chain-words.*

The following lemma is the main motivation for extending the framework of filling the positions to take into account the additional order expressed in the chains representation. It shall provide the basis for our reasoning later that long solutions to (certain) equations cannot be minimal due to the fact that their chains must contain some repetitive structure.

▶ **Lemma 11** ([5]). *Let E be a quadratic word equation given by $\alpha = \beta$ and let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a solution to E. If there exists a chain-word $w \in \Delta_{h,E}$ such that w contains a square, then h is not minimal.*

If, for a solution $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ to an equation $\alpha = \beta$, there does not exist a chain-word which contains a square, we shall say that the chains-representation is *square-free*, or that the solution h is *chain-square-free*. The simplest examples of solutions which are not chain-square-free are when two occurrences of the same variable overlap (i.e. the parts of the solution word corresponding to the occurrences of these variables intersect), leading to a square of length one in a chain-word. Generalising this slightly to squares of length two, the following lemma gives another simple example of when a solution is not chain-square-free, which is used in the proofs of our later results.

▶ **Lemma 12.** *Let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a solution to a quadratic equation E given by $\alpha = \beta$. Let $i, i', j, j' \in \{1, 2\}$ with $i \neq i'$ and $j \neq j'$, and let $x, y \in \mathrm{var}(\alpha\beta)$. If $f_E^h((x, i, 1)) \leq f_E^h((y, j, 1)) \leq f_E^h((x, i, |h(x)|)) \leq f_E^h((y, j, |h(y)|))$ and $f_E^h((x, i', 1)) \leq f_E^h((y, j', 1)) \leq f_E^h((x, i', |h(x)|)) \leq f_E^h((y, j', |h(y)|))$, then h is not chain-square-free.*

The following gives a full example of a solution to a quadratic equation along with its chains representation. The solution is not chains-square-free, and thus a shorter one exists.

▶ **Example 13.** Consider the equation E given by $xy\mathtt{a}y = \mathtt{a}z\mathtt{bb}xz$ over variables $x, y, z \in X$ and terminal symbols $\mathtt{a}, \mathtt{b} \in \Sigma$. Consider the solution $h : ((x, y, z) \cup \Sigma)^* \to \Sigma^*$ such that $h(x) = \mathtt{aaab}$, $h(y) = \mathtt{baa}$ and $h(z) = \mathtt{aa}$. Then the set of relative positions is:

$$\begin{aligned}\mathcal{RP}_E^h = \{&(x,1,1),(x,1,2),(x,1,3),(x,1,4),(x,2,1),(x,2,2),(x,2,3),(x,2,4),\\&(y,1,1),y(1,2),(y,1,3),(y,2,1),(y,2,2),(y,2,3),\\&(z,1,1),(z,1,2),(z,2,1),(z,2,2),(\mathtt{a},1,1),(\mathtt{a},2,1),(\mathtt{b},1,1),(\mathtt{b},2,1)\},\end{aligned}$$

the chains-representation of h consists of the four chains:

$$\begin{aligned}C_1 &= (\mathtt{a},1,1),(x,2,3),(z,1,2),(y,2,3),(x,2,2),(z,1,1),(y,2,2),(x,2,1),(\mathtt{a},2,1)\\C_2 &= (\mathtt{b},1,1),(x,1,4),(y,2,1),(\mathtt{b},2,1)\\C_3 &= (\mathtt{a},2,1),(x,1,1),(y,1,2),(z,2,1),(x,1,2),(y,1,3),(z,2,2),(x,1,3),(\mathtt{a},1,1)\\C_4 &= (\mathtt{b},2,1),(y,1,1),(x,2,4),(\mathtt{b},1,1)\end{aligned}$$

where C_1 and C_3 are dual, as are C_2 and C_4. The set of chain-words is given as follows, where for ease of reading, the elements $(x,1)$,$(x,2)$, $(y,1)$, $(y,2)$, $(z,1)$ and $(z,2)$ of Γ_E^h are denoted A, B, C, D, E and F respectively.

$$\Delta_{h,E} = \{BEDBEDB, AD, ACFACFA, CB\}.$$

The fact that one of the chain-words contains a square (e.g. $BEDBED$ in the first one) means that, due to Lemma 11, a shorter solution exists. In this case, we have the solution h' given by $h'(x) = \mathtt{aab}$, $h'(y) = \mathtt{ba}$ and $h'(z) = \mathtt{a}$.

Finally, we point out that this general approach of analysing the chain-words for squares can, at best, give exponential upper bounds on the length of minimal solutions to quadratic word equations, and additionally that the property of being chain-square-free, while necessary, is not sufficient for being minimal.

▶ **Proposition 14.** *Let $n \in \mathbb{N}$. Then the equation $x_n x_{n-1} \ldots x_1 \mathtt{a} = \mathtt{a} x_1 \ldots x_{n-1} x_n$ has a solution $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ which is not minimal but is chain-square-free such that $|h(x_n x_{n-1} \ldots x_1 \mathtt{a})| = 2^n$.*

4 Variable-Sparse and k-Ordered Quadratic Equations

We begin in the current section by considering quadratic equations without many repeating variables – those equations $\alpha = \beta$ for which the set $\{x \mid |\alpha\beta|_x = 2\}$ is “small”. Let the variable-sparse equations be defined as follows.

▶ **Definition 15.** *A word equation $\alpha = \beta$ is* variable-sparse *if $|\{x \mid |\alpha\beta|_x \geq 2\}| \leq \log(|\alpha\beta|)$.*

While there are practical reasons to care about variable-sparse equations – it seems reasonable to expect that equations encountered in practice may often have this form – we can also take advantage of the insights gained by considering this class to settle the complexity of another, more general class, namely the k-ordered equations, which complements, and thus motivates, the class of regular-reversed equations considered in the next section.

As the next proposition shows, the lengths of possible chains in the chains-representation of a minimal solution is bounded by a double-exponential function in number of repeating variables, and consequently so is the length of minimal solutions. The double-exponential bound is derived from the upper bound on lengths of minimal solutions to the whole class of word equations (see [22]), and thus we do not expect it to be tight. However, it is sufficient to show that in the case of variable-sparse quadratic equations, minimal solutions are at most single exponential in the length of the equation, and thus that the satisfiability problem for this class is contained in NP.

▶ **Proposition 16.** *Let $\alpha = \beta$ be a quadratic equation and let $V = |\{x \mid |\alpha\beta|_x = 2\}|$. If there exists a solution to $\alpha = \beta$, then there exists a solution $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ to $\alpha = \beta$ such that each chain in the chains representation of h w.r.t. $\alpha = \beta$ has length at most $2^{2^{O(V^4)}}$. Consequently, if h is minimal, then $|h(\alpha)| \leq |\alpha\beta|2^{2^{O(V^4)}}$. Moreover, it follows that the satisfiability problem for the class of variable-sparse quadratic equations is in NP.*

If we limit the number of variables further, bounded by a constant instead of $\log(|\alpha\beta|)$, then the bound on the length of minimal solutions becomes polynomial in the length of the equation, and we are able to infer the following.

▶ **Proposition 17.** *Let $V \in \mathbb{N}$ be a constant. Then the satisfiability problem for the class of quadratic equations with at most V variables can be solved in polynomial time.*

The k-ordered equations generalise the regular-ordered equations considered in [5], and essentially rely on the same idea of an order in which the variables must occur from left to right in both sides of the equation. However, this order is only enforced on small subsets of variables as a whole, and does not dictate the local order in which variables in a single subset may occur. For example, $x_1x_2x_3x_4x_5x_6 = x_3x_2x_1x_6x_4x_5$ is 3-ordered, but not 2-ordered.

▶ **Definition 18.** *Let $k \in \mathbb{N}$ and let $\alpha = \beta$ be a quadratic word equation. Then $\alpha = \beta$ is* k-ordered *if there exist pairwise disjoint sets of variables $X_1, X_2, \ldots, X_\ell$ with $|X_i| \leq k$ for $1 \leq i \leq \ell$, and $\alpha_i, \beta_i \in (X_i \cup \Sigma)^*$ for $1 \leq i \leq \ell$ such that $\alpha = \alpha_1\alpha_2 \ldots \alpha_\ell$ and $\beta = \beta_1\beta_2 \ldots \beta_\ell$.*

Length bounds for minimal solutions to k-ordered equations can be derived in a relatively straightforward manner from Proposition 17: after removing variables occurring only once (see Proposition 2), a basic length argument can be used to (non-deterministically) divide a k-ordered equation into linearly many individual equations over pairwise disjoint sets X_i of at most k variables X_i. Since these equations do not share any variables, solutions to the original equation can be obtained by simply combining solutions to the individual equations, which if they exist, due to Proposition 16, may be chosen to be short.

▶ **Proposition 19.** *Let $k \in \mathbb{N}$ be a constant and let $\alpha = \beta$ be a k-ordered quadratic word equation. Let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a minimal solution to $\alpha = \beta$. Then $|h(\alpha)| \leq |\alpha\beta|2^{2^{O(k^4)}}$. Thus, the satisfiability problem for k-ordered quadratic equations is in NP.*

5 Regular-Reversed Quadratic Equations

Proposition 19 settles the complexity of the satisfiability problem for a large class of quadratic equations, in which the variables occur according to some global order on both sides of the equation. In the present section, we present our main result, concerning a class of equations which are, in a sense, opposite to k-ordered equations, namely the regular-reversed equations, in which the orders in which variables occur on each side are reversed. More formally, we define regular-reversed equations as follows:

▶ **Definition 20.** *Let $\pi : (X \cup \Sigma)^* \to X^*$ be the morphism such that $\pi(x) = x$ if $x \in X$ and $\pi(x) = \varepsilon$ otherwise. A quadratic word equation $\alpha = \beta$ is* regular-reversed *if $\pi(\alpha) = \pi(\beta)^R$.*

Since the equations described in Proposition 14 are in fact regular-reversed, we cannot hope to achieve polynomial bounds on the length of minimal solutions by relying on Lemma 11; the proposition tells us that in fact, exponentially long chain-square-free solutions exist. Nevertheless, we are able to exploit Lemma 11 to obtain exponential upper bounds, which due to Theorem 1, is sufficient to show that the satisfiability problem is NP for this class.

▶ **Theorem 21.** *Let $\alpha = \beta$ be a regular-reversed equation with n distinct variables. Let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a chain-square-free solution to $\alpha = \beta$. Then $|h(\alpha)| \leq 2^{3n}|\alpha\beta|$. Consequently, the satisfiability of regular-reversed equations is in* NP*.*

The proof in full is rather technical and too long to include in the main exposition. However, in order to give a flavour of the reasoning, we include the following crucial lemma. Essentially, the lemma tells us that if a regular-reversed equation has a chain-square-free solution fulfilling certain combinatorial conditions, then we may erase a variable from both the equation and solution, to obtain a shorter equation over fewer variables and a new, shorter solution which is at least half as long as the original, but which remains chain-square-free. This reduction in the number of variables allows us to apply a straightforward induction, which, due to the linear reduction in the size of the solution in each step, yields exponential bounds on the length of chain-square-free (and hence also on minimal) solutions. The majority of the remaining effort in the proof is focused on reaching a point at which these combinatorial conditions are met. It is a straightforward observation that if the conditions are met, then the solution is not minimal, highlighting the usefulness of using chain-square-free solutions in place of minimal ones.

▶ **Lemma 22.** *Let $\alpha = \beta$ be a regular-reversed equation given by $u_0x_1u_1x_2 \dots x_nu_n = v_nx_nv_{n-1}x_{n-1} \dots v_1x_1v_0$ where $u_i, v_i \in \Sigma^*$ for $0 \leq i \leq n$, and $x_i \in X$ for $1 \leq i \leq n$. Suppose there exists a chain-square-free solution $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ such that for some $1 \leq p < q \leq n$:*

(1) *$h(u_0x_1 \dots u_{p-1}x_p) = h(v_nx_n \dots v_p)$ and $h(u_px_{p+1} \dots u_{n-1}x_nu_n) = h(x_pv_{p-1} \dots x_1v_0)$, and*

(2) *$|h(u_px_{p+1} \dots x_q)| < |h(x_p)|$ and $|h(x_qv_{q-1} \dots v_p)| \leq |h(x_p)|$, and*

(3) *$|h(u_px_{p+1} \dots x_qu_q)| + |h(v_qx_qv_{q-1} \dots v_p)| \geq |h(x_p)|$.*

Then the substitution $g : ((\mathrm{var}(\alpha\beta)\backslash\{x_p\}) \cup \Sigma)^* \to \Sigma^*$ given by $g(x) = h(x)$ for all $x \in \mathrm{var}(\alpha\beta)\backslash\{x_p\}$ is a chain-square-free solution to the equation $\alpha' = \beta'$ obtained by erasing x_p from α and β, and moreover $|g(\alpha')| \geq \frac{|h(\alpha)|}{2}$.

Proof. To see that g is a solution to $\alpha' = \beta'$, let $w = h(u_0x_1 \dots u_{p-1})$ and let $w' = h(v_{p-1} \dots x_1v_0)$. Note that $g(v_nx_n \dots v_p) = wh(x_p)$ and $g(u_px_{p+1} \dots u_{n-1}x_nu_n) = h(x_p)w'$. It follows that $g(\alpha') = wh(x_p)w' = g(\beta')$, while $h(\alpha) = wh(x_p)h(x_p)w' = h(\beta)$. It follows immediately that $|h(x_p)| \leq \frac{|h(\alpha)|}{2}$, and thus that $|g(\alpha')| = |h(\alpha)| - |h(x_p)| \geq \frac{|h(\alpha)|}{2}$. It remains to see that g is chain-square-free, for which we must understand the chains representation of g compared to that of h. In particular, we shall show (via Claims 23 and 24) that the chain(-words) of g are obtained by simply removing positions belonging to the variable x_p from the chain(-words) of h. Before we prove this statement, we observe some basic facts about the sibling and neighbour relations for each solution. Note firstly that $\mathcal{RP}^g_{\alpha'=\beta'} = \mathcal{RP}^h_{\alpha=\beta}\backslash\{(x_p, i, d) \mid i \in \{1,2\}, d \in [1..|h(x_p)|]\}$. Moreover, note that two positions $r_1, r_2 \in \mathcal{RP}^g_{\alpha'=\beta'}$ are siblings in the chains representation of g if and only if they are siblings in the chains representation of h. Finally, for each $r \in \mathcal{RP}^g_{\alpha'=\beta'}$, we have $f^g_{\alpha'=\beta'}(r) = f^h_{\alpha=\beta}(r) - \mu$ where $\mu = 0$ if $f^h_{\alpha=\beta}(r) \leq |wh(x_p)|$ and $\mu = |h(x_p)|$ otherwise. Consequently, for any position $r \in \mathcal{RP}^g_{\alpha'=\beta'}$ such that $f^h_{\alpha=\beta}(r) \leq |w|$ or $f^h_{\alpha=\beta}(r) > |h(\alpha)| - |w'|$, the neighbour of r in the chains representation of g is the same as the neighbour of r in the chains representation of h.

The following two claims describe the successor relation (and hence the chains) for g w.r.t. $\alpha' = \beta'$ in terms of the successor relation for h w.r.t. $\alpha = \beta$.

▷ Claim 23. Let r, r' be a subchain of some chain in the chains representation of h w.r.t. $\alpha = \beta$. Suppose that neither r nor r' belongs to x_p. Then r, r' is also a subchain of some chain in the chains representation of g w.r.t. $\alpha' = \beta'$.

Proof (Claim 23). Let $\overline{r} = r$ if r belongs to a terminal symbol, and let $\overline{r}$ be the sibling of r otherwise. Note that since r does not belong to x_p, the definition of $\overline{r}$ is the same for both chains-representations. Moreover, note that since no variables occur only once in the equations $\alpha = \beta$ and $\alpha' = \beta'$, the successor of r is the neighbour of $\overline{r}$ in both chains representations. If $f^h_{\alpha=\beta}(\overline{r}) \leq |w|$ or $f^h_{\alpha=\beta}(\overline{r}) > |h(\alpha)| - |w'|$, then as previously mentioned, the neighbour of $\overline{r}$, and hence successor of r, is the same in both chains representations and the claim follows. If instead $|w| < f^h_{\alpha=\beta}(\overline{r}) \leq |h(\alpha)| - |w'|$, then either $\overline{r}$ belongs to x_p, or the neighbour of $\overline{r}$ in the chains representation of h w.r.t $\alpha = \beta$ belongs to x_p. If $\overline{r}$ belongs to x_p, then r belongs to x_p which is a contradiction. Similarly, since the neighbour of $\overline{r}$ is the successor of r, namely r', if it belongs to x_p, then we again get a contradiction, so neither case is possible under the assumptions of the claim. ◁

▷ Claim 24. Let r, r', r'' be a subchain of some chain in the chains representation of h w.r.t. $\alpha = \beta$ such that r' belongs to x_p. Then neither r nor r' belongs to x_p, and moreover, r, r'' is also a subchain of some chain in the chains representation of g w.r.t. $\alpha' = \beta'$.

Proof (Claim 24). The fact that r and r'' do not belong to x_p follows immediately from the fact that h is chain-square-free along with Remark 9. As before, let $\overline{r} = r$ if r belongs to a terminal symbol and let $\overline{r}$ be the sibling of r otherwise. Again, note that since r does not belong to x_p, the definition of $\overline{r}$ is the same for both chains-representations. Let $\overline{r'}$ be the sibling of r' in the chains representation of h w.r.t $\alpha = \beta$ (recall that x_p occurs twice in $\alpha = \beta$, so the sibling exists). Then r' is the neighbour of $\overline{r}$ and r'' is the neighbour of $\overline{r'}$ in the chains representation of h w.r.t $\alpha = \beta$. We shall proceed by distinguishing two cases based on r'. Suppose firstly that $r' = (x_p, 2, d)$ for some $d \in [1..|h(x_p)|]$ (so r' belongs to the occurrence of x_p on the RHS). Then $|wh(x_p)| < f^h_{\alpha=\beta}(r') = f^h_{\alpha=\beta}(\overline{r}) \leq |h(\alpha)| - |w'|$ and $f^h_{\alpha=\beta}(\overline{r'}) + |h(x_p)| = f^h_{\alpha=\beta}(r')$. Hence $f^g_{\alpha'=\beta'}(\overline{r}) = f^h_{\alpha=\beta}(\overline{r}) - |h(x_p)|$, and

$$f^h_{\alpha=\beta}(r'') = f^h_{\alpha=\beta}(\overline{r'}) = f^h_{\alpha=\beta}(r') - |h(x_p)| = f^h_{\alpha=\beta}(\overline{r}) - |h(x_p)| \leq |h(\alpha)| - |w'| - |h(x_p)|.$$

Since $|h(\alpha)| - |w'| - |h(x_p)| = |wh(x_p)|$, this implies that $f^g_{\alpha'=\beta'}(r'') = f^h_{\alpha=\beta}(r'')$. Thus:

$$f^g_{\alpha'=\beta'}(\overline{r}) = f^h_{\alpha=\beta}(\overline{r}) - |h(x_p)| = f^h_{\alpha=\beta}(r') - |h(x_p)| = f^h_{\alpha=\beta}(\overline{r'}) = f^h_{\alpha=\beta}(r'') = f^g_{\alpha'=\beta'}(r'').$$

Symmetrically, if instead $r' = (x_p, 1, d)$ for some $d \in [1..|h(x_p)|]$ (so r' belongs to the occurrence of x_p on the LHS), then in the same manner, we can derive:

$$f^g_{\alpha'=\beta'}(\overline{r}) = f^h_{\alpha=\beta}(\overline{r}) = f^h_{\alpha=\beta}(r') = f^h_{\alpha=\beta}(\overline{r'}) - |h(x_p)| = f^h_{\alpha=\beta}(r'') - |h(x_p)| = f^g_{\alpha'=\beta'}(r'').$$

In both cases we get that $f^g_{\alpha'=\beta'}(\overline{r}) = f^g_{\alpha'=\beta'}(r'')$, so r'' and $\overline{r}$ are neighbours in the chains representation of g w.r.t $\alpha' = \beta'$ and hence r'' is the successor of r in the chains representation of g w.r.t $\alpha' = \beta'$ and the statement of the claim follows. ◁

It follows easily from Claims 23 and 24 that each chain in the chains representation of g is obtained by removing all positions belonging to x_p from some chain in the chains-representation of h. It remains to check that the act of removing the positions belonging to x_p does not introduce any squares in the resulting chain-words.

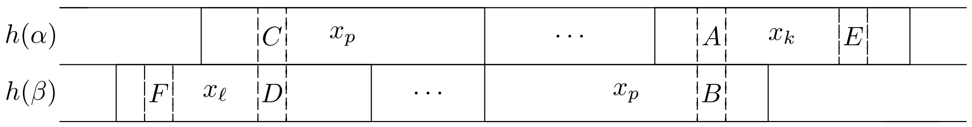


Figure 2 By Condition (1), the two occurrences of x_p are adjacent. Consequently, if (x_k, i', d_1) and (x_p, i, d_2) are neighbours, and (x_ℓ, i, d_3) and (x_p, i', d_2) are neighbours, then it cannot be the case that (x_k, i', d_4) and (x_ℓ, i, d_5) are neighbours. The case $i = 2$ is shown. The case $i = 1$ is symmetric and may be obtained by swapping the locations of x_k and x_ℓ. The positions (x_k, i', d_1), (x_p, i, d_2), (x_p, i', d_2), (x_ℓ, i, d_3), (x_k, i', d_4) and (x_ℓ, i, d_5) are marked as A, B, C, D, E and F respectively.

Suppose for contradiction that a new square is introduced. That is, there exists a subchain C in the chains representation of h for which the induced chain-word is not a square, but for which the chain-word induced by the new subchain $\hat{C}$ obtained by removing all positions belonging to x_p from C is a square. There are two ways in which this may happen. The first is that the original subchain C has the form $C', (x_p, i, d_1), C''$ where C' and C'' are subchains of length at least one and are similar (thus inducing a square in the chain-word once the central (x_p, i, d) is removed). Note that in this case there might be further positions belonging to x_p in C' and C'', but the act of removing them will not alter their similarity so we do not need to keep track of them explicitly.

By Condition (3), every position belonging to x_p is either the successor, or predecessor of a position which is either terminal or belongs to a variable x_j with $p < j \leq q$. Since the subchains C' and C'' do not contain terminal positions (this would contradict the assumption that they are similar), they must both either start with a position belonging to some x_j with $p < j \leq q$, or both end with a position to belonging to some x_j with $p < j \leq q$. It follows from Condition (2) that the neighbour of any position belonging to x_j must belong to x_p. Thus the successor and predecessor of a position belonging to x_j must also belong to x_p. However, this implies that the original subchain C occurs directly before, or after a position (x_p, i, d_2) (by Remark 9, it will have the same index i as the position (x_p, i, d_1)). However, this results in a subchain of the form $(x_p, i, d_2), C', (x_p, i, d_1), C''$ or of the form $C', (x_p, i, d_1), C'', (x_p, i, d_2)$, which in either case induces chain-word containing a square, a contradiction to the fact that h is chain-square-free.

The second possibility is that C may be divided into two further subchains C' and C'' (so $C = C', C''$), where C' and C'' are not similar, but become similar once positions belonging to x_p are removed. This implies the existence of (not necessarily consecutive) subchains $(x_k, i, d_1), (x_p, i, d_2), (x_\ell, i, d_3)$ and $(x_k, i, d_4), (x_\ell, i, d_5)$ of C (one occurring in C' and the other in C''). Clearly, since h is chain-square-free, we must have that $k \neq \ell \neq p$. Let $i' = i + 1 \mod 2$. Then (x_k, i', d_1) and (x_p, i, d_2) are neighbours, (x_p, i', d_2) and (x_ℓ, i, d_3) are neighbours and (x_k, i', d_4) and (x_ℓ, i, d_5) are neighbours. However this is only possible if the two occurrences of x_p in the solution $h(x)$ are not adjacent (see Fig. 2), or more precisely, it implies that $f^h_{\alpha=\beta}((x_p, 1, |h(x_p)|)) < f^h_{\alpha=\beta}((x_p, 2, 1)) - 1$. This clearly contradicts Condition (1). In all cases we get a contradiction, so g must be chain-square-free as claimed. ◀

6 Avoiding Squares and other Patterns

Lemma 11 invites an obvious question: do there exist long solutions for which the chain-words (which must then also be long) are square-free? This question is particularly interesting as a negative answer for the appropriate meaning of long would be sufficient to show that the satisfiability of quadratic word equations is in NP. For regular equations with two variables, the chain-words will be over an alphabet of size two, meaning we get an immediate answer: a quick exhaustive search reveals that any word over two letters of length at least 4 contains a square. Thus, for a regular equation with two variables, the chain-words of a minimal solution can have length at most 3, and thus, any minimal solution must have length at most $3n$ where n is the number of terminal symbols in the equation.

Unfortunately, a famous result of Thue [26] reveals that there exist infinitely long words over three letters which do not contain squares, meaning such a simple proof will not work for equations with more variables. This does not mean, however, that Lemma 11 is of no use in more the more general case. It is easily established that not all words may occur as chain-words of some solution to an equation (note, e.g. that the number of possible different factors of length two in a chain-word is $2n - 1$ where n is the number of variables, while in general there are n^2 such factors). The next theorem gives a characterisation of when a word w is a chain-word of some solution to a regular word equation.

▶ **Theorem 25.** *Let w be a word and let Γ be the alphabet of letters occurring in w. There exists a regular word equation E with solution h such that w is a chain-word in $\Delta_{h,E}$ if and only if, there exist letters $\$, \# \notin \Gamma$ and linear orders $<_1$, $<_2$ on the sets $\Gamma \cup \{\#\}$ and $\Gamma \cup \{\$\}$ respectively such that for every $u \in \Gamma^*$ and $A, B, C, D \in \Gamma \cup \{\$, \#\}$ with $A \neq B$ and $C \neq D$, if AuC and BuD are both factors of $\#w\$$, then either that $A <_2 B$ and $C <_1 D$ or that $B <_2 A$ and $D <_1 C$.*

▶ **Corollary 26.** *Let E be a regular word equation and let h be a solution to E. Let $w \in \Delta_{h,E}$. Let A, B, C, D be letters from w such that $A \neq B$ and $C \neq D$ Then for any word u, at least one of AuC, BuC, AuD, BuD is not a factor of w.*

While this characterisation appears not to reveal immediately whether "long" square-free chain-words exist, we can make use of it to derive further conditions which may be more useful. As an example. we show in the following lemma that chain-words avoiding squares must also avoid other types of pattern (which are not necessarily avoidable in general).

▶ **Lemma 27.** *Let E be a quadratic word equation given by $\alpha = \beta$ and let $h : (\mathrm{var}(\alpha\beta) \cup \Sigma)^* \to \Sigma^*$ be a solution to E. If there exists a chain-word $w \in \Delta_{E,h}$ which contains factor of the form $x_1x_2x_3x_4x_2x_1x_3$ such that x_3 is not a prefix of x_1 or x_2, then there exists a (possibly distinct from w) chain-word $w' \in \Delta_{E,h}$ which contains a square.*

Unlike squares, it follows from the famous Zimin algorithm [18] that all words which are "long enough" will encounter a factor of the form $x_1x_2x_3x_4x_2x_1x_3$. In other words, $x_1x_2x_3x_4x_2x_1x_3$ is an *unavoidable pattern*. Unfortunately, however, this does not guarantee the additional condition that x_3 is not a prefix of x_1 or x_2, so Lemma 27 does not immediately provide a bound on the length of chain-square-free solutions. Nevertheless, a quick exhaustive search again reveals that any word of length at least 8 over three letters contains such a factor of the form $x_1x_2x_3x_4x_2x_1x_3$ or its reversal where x_1, x_2 and x_3 are all distinct letters (and so satisfying the prefix/suffix conditions given in Lemma 27). Moreover, it is not difficult to adapt the proof of Lemma 27 to produce other "forbidden factors" which must be avoided in chain-words of chain-square-free solutions. Thus we expect it to be a promising direction to try to obtain upper bounds on the lengths of (subclasses of) quadratic word equations through the lens of unavoidable patterns: do there exist combinations of patterns which are unavoidable, at least when considered over some over-approximation of all possible chain-words which ultimately guarantee the existence of squares in the chain-words of the same solutions?

Abstract

The Weisfeiler-Leman procedure is a widely-used approach for graph isomorphism testing that works by iteratively computing an isomorphism-invariant coloring of vertex tuples. Meanwhile, a fundamental tool in structural graph theory, which is often exploited in approaches to tackle the graph isomorphism problem, is the decomposition into bi- and triconnected components.

We prove that the 2-dimensional Weisfeiler-Leman algorithm implicitly computes the decomposition of a graph into its triconnected components. Thus, the dimension of the algorithm needed to distinguish two given graphs is at most the dimension required to distinguish the corresponding decompositions into 3-connected components (assuming dimension at least 2).

Our result implies that for $k \geq 2$, the k-dimensional algorithm distinguishes k-separators, i.e., k-tuples of vertices that separate the graph, from other vertex k-tuples. As a byproduct, we also obtain insights about the connectivity of constituent graphs of association schemes.

In an application of the results, we show the new upper bound of k on the Weisfeiler-Leman dimension of graphs of treewidth at most k. Using a construction by Cai, Fürer, and Immerman, we also provide a new lower bound that is asymptotically tight up to a factor of 2.

1 Introduction

Originally introduced in [37], the Weisfeiler-Leman (WL) algorithm has become a – if not the – fundamental subroutine in the context of isomorphism testing for graphs. It is used in theoretical as well as in practical approaches to tackle the graph isomorphism problem (see e.g. [5, 19, 31, 32, 35]), among them also Babai's recent quasipolynomial-time isomorphism test [4]. For every $k \geq 1$, there is a k-dimensional version of the algorithm which colors the vertex k-tuples of the input graph and iteratively refines the coloring in an isomorphism-invariant manner.

There are various characterizations of the algorithm, which link it to other areas in theoretical computer science (see also *Further Related Work*). For example, very recent results in the context of machine learning show that the 1-dimensional version of the algorithm is as expressive as graph neural networks with respect to distinguishing graphs [34]. Following Grohe [16], an indicator to investigate the expressive power of the algorithm is the so-called *WL dimension* of a graph, defined as the minimal dimension of the WL algorithm required in order to distinguish the graph from every other non-isomorphic graph.

There is no fixed dimension of the algorithm that decides graph isomorphism in general, as was proved by Cai, Fürer, and Immerman [9]. Still, when focusing on particular graph classes, often a bounded dimension of the algorithm suffices to identify every graph in the

class. This proves that for the considered class, graph isomorphism is solvable in polynomial time, since the k-dimensional algorithm can be implemented in time $\mathcal{O}(n^{k+1}\log n)$ [27]. For example, it suffices to apply the 3-dimensional WL algorithm to identify every planar graph [29]. Also, the WL dimension of graphs of treewidth at most k is bounded by $k+2$ [18]. More generally, by a celebrated result by Grohe, for all graph classes with an excluded minor, the WL dimension is bounded [15]. Very recent work provides explicit upper bounds on the WL dimension, which are linear in the rank width [19] and in the Euler genus [17], respectively, of the graph.

Regarding combinatorial techniques, to handle graphs with complex structures, the decomposition into connected, biconnected, and triconnected components provides a fundamental tool from structural graph theory. The decomposition can be computed in linear time (see e.g. [25, 36]). Hopcroft and Tarjan used the decomposition of a graph into its triconnected components to obtain an algorithm that decides isomorphism for planar graphs in quasi-linear time [22, 23, 24], which was improved to linear time by Hopcroft and Wong [26].

Also, in [29], to prove the bound on the WL dimension for the class of planar graphs, the challenge of distinguishing two arbitrary planar graphs is reduced to the case of two arc-colored triconnected planar graphs, by exploiting the fact that the 3-dimensional WL algorithm is able to implicitly compute the decomposition of a graph into its triconnected components. Similarly, the bound on the WL dimension for graphs parameterized by their Euler genus from [17] relies on an isomorphism-invariant decomposition of the graphs into their triconnected components.

Our Contribution. We show that for $k \geq 2$, the k-dimensional WL algorithm implicitly computes the decomposition into the triconnected components of a given graph. More specifically, we prove that already the 2-dimensional WL algorithm distinguishes separating pairs, i.e., pairs of vertices that separate the given graph, from other vertex pairs. This improves on a result from [29], where an analogous statement was proved for the 3-dimensional WL algorithm. Using the decomposition techniques discussed there, we conclude that for the k-dimensional WL algorithm with $k \geq 2$, to identify a graph, it suffices to determine vertex orbits on all arc-colored 3-connected components of it. Since it is easy to see that $k = 1$ does not suffice to distinguish vertices contained in 2-separators from others, our upper bound of 2 is tight.

The expressive power of the k-dimensional algorithm corresponds to definability in the logic C^{k+1}, the extension of the $(k+1)$-variable fragment of first-order logic by counting quantifiers [9, 27]. Exploiting this correspondence, our results imply that for every $n \in \mathbb{N}$, there is a formula $\varphi_n(x_1, x_2) \in \mathsf{C}^3$ (first-order logic with counting quantifiers over three variables) such that for an n-vertex graph G, it holds that $G \models \varphi_n(v, w)$ if and only if $\{v, w\}$ is a 2-separator in G. With only three variables at our disposal, it is not possible to take the route of [29] by comparing certain numbers of walks between different pairs of vertices. Instead, the formulas obtained from our proof are essentially a disjunction over all n-vertex graphs and subformulas for two distinct graphs may look completely different, exploiting specific structural properties of the graphs. While this makes the proof rather involved, it also stresses the power of the 2-dimensional WL algorithm and equivalently, the expressive power of the logic C^3. We show that for all $n, s \in \mathbb{N}$, there is a formula $\varphi_{n,s}(x_1, x_2, x_3) \in \mathsf{C}^3$ such that for an n-vertex graph G, it holds that $G \models \varphi_{n,s}(u, v, w)$ if and only if $s = |C|$, where C is the vertex set of the connected component containing u after removing v and w from the graph G.

Our result can also be viewed in a combinatorial setting. In 1985, Brouwer and Mesner [8] proved that the vertex connectivity of a strongly regular graph equals its degree and that in fact, the only minimal disconnecting vertex sets are neighborhoods. Later, Brouwer conjectured this to be true for any constituent graph of an association scheme (i.e., any graph consisting in a single color class of the association scheme) [6]. While some progress has been made on certain special cases [13], most prominently distance-regular graphs [7], the general question is still open. Our results imply that any connected constituent graph of an association scheme is either a cycle or 3-connected. Such a statement was previously only known for symmetric association schemes [30], which are far more restricted than the general ones.

A natural use case of these results is to determine or to improve upper bounds on the WL dimension of certain graph classes. As a first application in this direction, we obtain a new upper bound of k on the WL dimension for graphs of treewidth at most k. Based on [10], we also provide a new lower bound for this graph class, thus delimiting the value of the WL dimension of graphs of treewidth bounded by k to the interval $\left[\lceil\frac{k}{2}\rceil - 3, k\right]$.

Due to space restrictions, some of the proofs and proof details have been omitted. For a full version of this paper, we refer the reader to [28].

Further Related Work. Apart from its correspondence to counting logics, the WL algorithm has further surprising links to other areas. For example, the algorithm has a close connection to Sherali-Adams relaxations of particular linear programs [3, 20] and captures the same information as certain homomorphism counts [11]. It can also be characterized via winning strategies in so-called pebble games [21], which are a particular family of Ehrenfeucht-Fraissë games.

As mentioned above, the 1-dimensional WL algorithm essentially corresponds to graph neural networks. In order to make them more powerful, the authors of [34] propose an extension of graph neural networks based on the k-dimensional WL algorithm (see also [33]).

Towards understanding the expressive power of the algorithm, in a related direction of research, it has been studied which graph properties the WL algorithm can detect, which may become particularly relevant in the graph-learning framework. In this context, Fürer [14] as well as Arvind et al. [2] obtained results concerning the ability of the algorithm to detect and count certain subgraphs.

2 Preliminaries

2.1 Graphs

A *graph* is a pair $G = \big(V(G), E(G)\big)$ of a *vertex set* $V(G)$ and an *edge set* $E(G) \subseteq \big\{\{u, v\} \mid u, v \in V(G)\big\}$. To give explicit reference to G, we also write $V(G)$ for V and $E(G)$ for E. All graphs considered in this paper are finite, simple (i.e., they contain no loops or multiple edges), and undirected. For $v, w \in V$, we also write vw as a shorthand for $\{v, w\}$. The *neighborhood* of v is denoted by $N(v)$, and the *closed neighborhood* of v is $N[v] \coloneqq N(v) \cup \{v\}$. The *degree* of v, denoted by $\deg(v)$, is the number of edges incident with v. For $X \subseteq V(G)$ we define $N(X) \coloneqq \big(\bigcup_{v \in X} N(v)\big) \setminus X$.

A *walk of length* k from v to w is a sequence of vertices $v = u_0, u_1, \dots, u_k = w$ such that $u_{i-1}u_i \in E$ for all $i \in \{1, \dots, k\}$. A *path of length* k from v to w is a walk of length k from v to w for which all occurring vertices are pairwise distinct. We refer to the *distance* between two vertices $v, w \in V(G)$ by $\operatorname{dist}(v, w)$. For a set $A \subseteq V(G)$, we denote by $G[A]$ the *induced subgraph* of G on vertex set A. Also, we denote by $G - A$ the subgraph induced by the complement of A, that is, the graph $G - A := G[V(G) \setminus A]$. A set $S \subseteq V(G)$ is a *separator of* G if $G - S$ has more connected components than G. A *k-separator* of G is a separator of G of size k. A vertex $v \in V(G)$ is a *cut vertex* if $\{v\}$ is a separator of G. The graph G is *k-connected* if it is connected and has no $(k-1)$-separator.

An *isomorphism* from G to another graph H is a bijection $\varphi\colon V(G) \to V(H)$ that respects the edge relation, that is, for all $v, w \in V(G)$, it holds that $vw \in E(G)$ if and only if $\varphi(v)\varphi(w) \in E(H)$. Two graphs G and H are *isomorphic* ($G \cong H$) if there is an isomorphism from G to H. We write $\varphi\colon G \cong H$ to denote that φ is an isomorphism from G to H.

A *vertex-colored graph* is a tuple (G, χ), where G is a graph and $\chi\colon V(G) \to \mathcal{C}$ is a mapping into some set $\mathcal{C}$ of colors. Similarly, an *arc-colored graph* is a tuple (G, χ), where G is a graph and $\chi\colon \{(v,v) \mid v \in V(G)\} \cup \{(u,v) \mid \{u,v\} \in E(G)\} \to \mathcal{C}$ is a mapping into some color set $\mathcal{C}$. Typically, $\mathcal{C}$ is chosen to be an initial segment $[n] := \{1, \dots, n\}$ of the natural numbers. Isomorphisms between vertex- and arc-colored graphs have to respect the colors of the vertices and arcs.

For details on the *treewidth* of a graph, we refer the reader to [12].

2.2 The Weisfeiler-Leman Algorithm

Let $\chi_1, \chi_2\colon V^k \to \mathcal{C}$ be colorings of the k-tuples of vertices of G, where $\mathcal{C}$ is some finite set of colors. We say χ_2 *refines* χ_1 if for all $\bar{v}, \bar{w} \in V^k$ we have $\big(\chi_2(\bar{v}) = \chi_2(\bar{w}) \;\Rightarrow\; \chi_1(\bar{v}) = \chi_1(\bar{w})\big)$. The k-dimensional WL algorithm is a procedure that, given a graph G and a coloring χ of its k-tuples of vertices, computes an isomorphism-invariant refinement of the coloring.

We describe the mechanisms of the algorithm in the following. For an integer $k > 1$ and a vertex-colored graph (G, χ), we let $\chi^0_{G,k}\colon V^k \to \mathcal{C}$ be the coloring where each k-tuple is colored with the isomorphism type of its underlying ordered colored subgraph. More formally, $\chi^0_{G,k}(v_1, \dots, v_k) = \chi^0_{G,k}(w_1, \dots, w_k)$ if and only if for all $i \in [k]$ it holds that $\chi(v_i) = \chi(w_i)$ and for all $i, j \in [k]$, it holds that $v_i = v_j \Leftrightarrow w_i = w_j$ and $v_iv_j \in E(G) \Leftrightarrow w_iw_j \in E(G)$. If G is arc-colored, the arc colors must be respected accordingly.

We then recursively define the coloring $\chi^i_{G,k}$ obtained after i rounds of the algorithm. Let $\chi^{i+1}_{G,k}(v_1, \dots, v_k) := (\chi^i_{G,k}(v_1, \dots, v_k); \mathcal{M})$, where $\mathcal{M}$ is a multiset defined as

$$\{\!\!\{ \big(\chi^i_{G,k}(\bar{v}[w/1]), \chi^i_{G,k}(\bar{v}[w/2]), \dots, \chi^i_{G,k}(\bar{v}[w/k])\big) \,\big|\, w \in V \}\!\!\}$$

where $\bar{v}[w/i] := (v_1, \dots, v_{i-1}, w, v_{i+1}, \dots, v_k)$.

For the 1-dimensional algorithm (i.e. $k = 1$), the definition is similar, but we iterate only over the neighbors of v_1, that is, the multiset $\mathcal{M}$ equals $\{\!\!\{\chi^i_{G,1}(w) \mid w \in N(v_1)\}\!\!\}$.

By definition, every coloring $\chi^{i+1}_{G,k}$ induces a refinement of the partition of the k-tuples of vertices of the graph G with coloring $\chi^i_{G,k}$. Thus, there is a minimal i such that the partition of the vertex k-tuples induced by $\chi^{i+1}_{G,k}$ is not strictly finer than the one induced by $\chi^i_{G,k}$. For this value of i, we call the coloring $\chi^i_{G,k}$ the *stable* coloring of G and denote it by $\chi_{G,k}$.

The original WL algorithm is its 2-dimensional variant [37]. Since that version is the central algorithm of this paper, we omit the index 2 and write χ_G instead of $\chi_{G,2}$.

For $k \in \mathbb{N}$, the *k-dimensional WL algorithm* takes as input a (vertex- or arc-)colored graph (G, χ) and returns the coloring $\chi_{G,k}$. The procedure can be implemented in time $O(n^{k+1} \log n)$ [27]. For two graphs G and H, we say that the k-dimensional WL algorithm *distinguishes* G and H if there is a color c such that the sets $\{\bar{v} \mid \bar{v} \in \big(V(G)\big)^k, \chi_{G,k}(\bar{v}) = c\}$ and $\{\bar{w} \mid \bar{w} \in \big(V(H)\big)^k, \chi_{H,k}(\bar{w}) = c\}$ have different cardinalities. We write $G \simeq_k H$ if the k-dimensional WL algorithm does not distinguish G and H. The algorithm *identifies* G if it distinguishes G from every non-isomorphic graph H.

Pebble Games. For further analysis, it is often cumbersome to work with the WL algorithm directly and more convenient to use the following characterization via pebble games, which is known to capture the same information. Let $k \in \mathbb{N}$. For graphs G and H on the same number of vertices and with vertex colorings χ and χ', respectively, we define the *bijective k-pebble game* $\mathrm{BP}_k(G,H)$ as follows:

- The game has two players called *Spoiler* and *Duplicator.*
- The game proceeds in rounds, each of which is associated with a pair of positions $(\bar{v},\bar{w})$ with $\bar{v} \in \big(V(G)\big)^\ell$ and $\bar{w} \in \big(V(H)\big)^\ell$, where $0 \leq \ell \leq k$.
- The initial position of the game is a pair of vertex tuples of equal length ℓ with $0 \leq \ell \leq k$. If not specified otherwise, the initial position is the pair $\big((),()\big)$ of empty tuples.
- Each round consists of the following steps. Suppose the current position of the game is $(\bar{v},\bar{w}) = ((v_1,\dots,v_\ell),(w_1,\dots,w_\ell))$. First, Spoiler chooses whether to remove a pair of pebbles or to play a new pair of pebbles. The first option is only possible if $\ell > 0$, and the latter option is only possible if $\ell < k$.

  If Spoiler wishes to remove a pair of pebbles, he picks some $i \in [\ell]$ and the game moves to position $(\bar{v} \setminus i, \bar{w} \setminus i)$ where $\bar{v} \setminus i := (v_1,\dots,v_{i-1},v_{i+1},\dots,v_\ell)$, and the tuple $(\bar{w} \setminus i)$ is defined in the analogous way. Otherwise, the following steps are performed.

  (D) Duplicator picks a bijection $f\colon V(G) \to V(H)$.

  (S) Spoiler chooses $v \in V(G)$. The new position is then $\big((v_1,\dots,v_\ell,v),(w_1,\dots, w_\ell,f(v))\big)$.

  If for the current position $\big((v_1,\dots,v_\ell),(w_1,\dots,w_\ell)\big)$, the induced ordered subgraphs of G and H are not isomorphic, Spoiler wins the play. More precisely, Spoiler wins if there is an $i \in [\ell]$ such that $\chi(v_i) \neq \chi'(w_i)$, or there are $i,j \in [\ell]$ such that $v_i = v_j \not\Leftrightarrow w_i = w_j$ or $v_iv_j \in E(G) \not\Leftrightarrow w_iw_j \in E(H)$. If there is no position of the play such that Spoiler wins, then Duplicator wins.

We say that Spoiler (and Duplicator, respectively) *wins the bijective k-pebble game* $\mathrm{BP}_k(G,H)$ if Spoiler (and Duplicator, respectively) has a winning strategy for the game.

The following theorem describes the correspondence between the Weisfeiler-Leman algorithm and the introduced pebble games.[1]

▶ **Theorem 1** (see e.g. [9]). *Let G and H be two graphs. Then $G \simeq_k H$ if and only if Duplicator wins the game* $\mathrm{BP}_{k+1}(G,H)$.

Association Schemes. Let V be a set. An *association scheme* on V is an ordered partition $(R_0,\dots,R_d)$ of V^2 such that

1. $R_0 = \{(v,v) \mid v \in V\}$, and
2. for every $i \in [d]$, there is a $j \in [d]$ such that the set $R_i^\intercal := \{(w,v) \mid (v,w) \in R_i\}$ equals R_j, and
3. for all i,j,k, there are numbers $p_{i,j}^k$ such that for all $(v,w) \in R_k$,

$$p_{i,j}^k = \big|\{x \in V \mid (v,x) \in R_i \text{ and } (w,x) \in R_j\}\big|.$$

An association scheme is *symmetric* if $R_i^\intercal = R_i$ for all $i \in [d]$. With each R_i, we associate a directed *constituent graph $G(R_i)$ of the association scheme*, defined as $G(R_i) := (V, R_i \cup R_i^\intercal)$.

[1] The pebble games in [9] are defined slightly differently. Still, a player has a winning strategy in the game described there if and only if they have one in our game and thus, Theorem 1 holds for both versions of the game.

Every association scheme induces a coloring on V^2, in which every (v, w) is colored with the relation it is contained in. This coloring is stable in the sense that it is not refined by the 2-dimensional WL algorithm (when V is interpreted as the vertex set of a complete directed graph). That is, for all $j \in [d]$ and all $(v_1, v_2), (w_1, w_2) \in R_j$, it holds that $\chi_{G(R_i)}(v_1, v_2) = \chi_{G(R_i)}(w_1, w_2)$. Conversely, every colored graph G with $\chi_G(v, v) = \chi_G(w, w)$ for all $v, w \in V(G)$ induces an association scheme in which the relations R_i are the color classes of the coloring $\chi_G = \chi_{G,2}$.

3 One Color

Our first goal is to prove that the 2-dimensional WL algorithm distinguishes vertex pairs that are separators in a graph from other pairs of vertices. We start with an analysis of the graphs in which all vertices are assigned the same color by the WL algorithm. In particular, this includes all constituent graphs of association schemes.

A main tool for the analysis are distance patterns of vertices. For a graph G and a vertex $v \in V(G)$, let $D(v) \coloneqq \{\{\mathrm{dist}(v, w) \mid w \in V(G)\}\}$. Note that for vertices $u, v \in V(G)$ it holds that $\chi_G(u, u) \neq \chi_G(v, v)$ whenever $D(u) \neq D(v)$ since the 2-dimensional WL algorithm detects distances between vertex pairs.“

▶ **Lemma 2.** *Let G be a graph and $uv \in E(G)$. Suppose that $D(u) = D(v)$. Then*

$$\begin{aligned} &\{\{\mathrm{dist}(u, w) \mid w \in V(G) \colon \mathrm{dist}(u, w) < \mathrm{dist}(v, w)\}\} \\ = &\{\{\mathrm{dist}(v, w) \mid w \in V(G) \colon \mathrm{dist}(v, w) < \mathrm{dist}(u, w)\}\}. \end{aligned}$$

Throughout the remainder of this section, if not explicitly stated otherwise, we make the following assumption.

▶ **Assumption 3.** G is a connected graph on n vertices with the following properties:

1. $\chi_G(u, u) = \chi_G(v, v)$ for all $u, v \in V(G)$, and
2. G has a 2-separator $\{w_1, w_2\}$.

In the rest of this section, we analyze the structure of G and ultimately prove that G must be a cycle. In particular, this completely characterizes constituent graphs of association schemes that are connected, but not 3-connected.

Note that Assumption 3 implies that G is regular, i.e., $\deg(u) = \deg(v)$ for all $u, v \in V(G)$.

▶ **Lemma 4.** *G is 2-connected, i.e., G does not contain any cut vertex.*

This is a consequence of Condition 1 in Assumption 3, since the 2-dimensional WL algorithm distinguishes cut vertices from other vertices (see [29, Corollary 7]). Note that the lemma implies that each of w_1 and w_2 has at least one neighbor in each of the connected components of $G - w_1w_2$.

▶ **Lemma 5.** *Let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| < \frac{n}{2}$ and let $v \in C$. Then there is no vertex $u \in N(v)$ such that $\mathrm{dist}(u, w_1) < \mathrm{dist}(v, w_1)$ and $\mathrm{dist}(u, w_2) < \mathrm{dist}(v, w_2)$.*

Proof. Suppose towards a contradiction that such a vertex $u \in N(v)$ exists. For all $w \in V(G)$, we have $|\mathrm{dist}(v, w) - \mathrm{dist}(u, w)| \leq 1$, since $uv \in E(G)$. Furthermore, it holds that $\sum_{w \in V(G)} \big(\mathrm{dist}(v, w) - \mathrm{dist}(u, w)\big) = 0$ because $D(u) = D(v)$ due to Condition 1 in Assumption 3. But $\mathrm{dist}(v, w) > \mathrm{dist}(u, w)$ for all $w \in V(G) \setminus C$, and $|V(G) \setminus C| > \frac{n}{2}$. This is a contradiction. ◀

▶ **Lemma 6.** *Let $d := \mathrm{dist}(w_1, w_2)$ and let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| \leq \frac{n-2}{2}$. Then for all $v \in C \cup \{w_1, w_2\}$ and all $i \in \{1, 2\}$, it holds that $\mathrm{dist}(v, w_i) \leq d$.*

Proof. By symmetry, it suffices to prove $\mathrm{dist}(v, w_2) \leq d$. The statement is proved by induction on $\ell := \mathrm{dist}(v, w_1)$. For $\ell = 0$, it holds that $v = w_1$ and $\mathrm{dist}(w_1, w_2) = d$. So suppose the statement holds for all $u \in C \cup \{w_1, w_2\}$ with $\mathrm{dist}(u, w_1) \leq \ell$. Obviously, the statement is true if $v = w_1$ or $v = w_2$. So pick $v \in C$ with $\mathrm{dist}(v, w_1) = \ell + 1$. Let $u \in N(v)$ such that $\mathrm{dist}(u, w_1) \leq \ell$. Then $\mathrm{dist}(v, w_2) \leq \mathrm{dist}(u, w_2) \leq d$ by Lemma 5 and the induction hypothesis. ◀

▶ **Lemma 7.** *$w_1w_2 \notin E(G)$.*

Proof. Suppose towards a contradiction that $w_1w_2 \in E(G)$. Let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| \leq \frac{n-2}{2}$. By Lemma 6, we conclude that $C \subseteq N(w_1) \cap N(w_2)$. Let $v \in C$. Since G is 2-connected, the vertex w_1 must have at least one neighbor in $V(G) \setminus C$, in addition to being adjacent to C and to w_2. Thus, $\deg(w_1) \geq |C| + 2 > |C| - 1 + |\{w_1, w_2\}| \geq \deg(v)$, which contradicts G being a regular graph. ◀

▶ **Lemma 8.** *Suppose that $N(w_1) \cap N(w_2) \neq \emptyset$. Then G is a cycle.*

Proof. By Lemma 7, it holds that $w_1w_2 \notin E(G)$. Furthermore, by the assumption of the lemma, we have $\mathrm{dist}(w_1, w_2) = 2$. Let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| \leq \frac{n-2}{2}$. Also let $C' := V(G) \setminus (C \cup \{w_1, w_2\})$. For $i, j \geq 1$ let

$$C_{i,j} := \{v \in C \mid \mathrm{dist}(v, w_1) = i \text{ and } \mathrm{dist}(v, w_2) = j\}.$$

By Lemma 6, we conclude that $C_{i,j} = \emptyset$ unless $(i, j) \in \{(1, 1), (1, 2), (2, 1), (2, 2)\}$.

Suppose there exists $v \in C_{1,2}$. We have $D(v) = D(w_1)$ and, by Lemma 4, also $N(w_1) \cap C' \neq \emptyset$. Thus, there is some vertex $u' \neq w_1$ such that $\mathrm{dist}(w_1, u') < \mathrm{dist}(v, u')$ and therefore, by Lemma 2, there is also a vertex $u \neq v$ such that $\mathrm{dist}(v, u) < \mathrm{dist}(w_1, u)$. For every such vertex u, it holds that $\mathrm{dist}(w_1, u) \leq 2$ and thus, $u \in N(v)$. Therefore, by Lemma 2, for every vertex $v' \neq w_1$ with $\mathrm{dist}(w_1, v') < \mathrm{dist}(v, v')$, it holds that $v' \in N(w_1)$. This implies that there is no $v' \in C'$ such that $\mathrm{dist}(w_1, v') = 2$ since such a vertex would satisfy $3 = \mathrm{dist}(v, v') > \mathrm{dist}(w_1, v')$.

Because w_2 is not a cut vertex (cf. Lemma 4), from every $v' \in C'$, there is a path to w_1 that does not contain w_2. However, this is only possible if there is no vertex $v' \in C'$ such that $\mathrm{dist}(w_1, v') > 1$, in other words: $C' \subseteq N(w_1)$. Since G is regular and $|N(w_1) \setminus C'| \geq 1$, it follows that $\deg(v) \geq |C'| + 1$. But $N(v) \subseteq (C \cup \{w_1\}) \setminus \{v\}$, which implies $\deg(v) \leq |C|$. The combination of both inequalities yields $|C'| + 1 \leq |C|$, which implies $n = 2 + |C| + |C'| \leq 1 + 2|C| \leq n - 1$, a contradiction. So $C_{1,2} = \emptyset$ and by symmetry, it also holds that $C_{2,1} = \emptyset$. But then $C_{2,2} = \emptyset$ by Lemma 5.

So $C = C_{1,1}$, which means that $C \subseteq N(w_1) \cap N(w_2)$. In particular, $\deg(w_1) \geq |C| + 1$ since $|N(w_1) \cap C'| \geq 1$. Since G is regular, this implies that $\deg(v) \geq |C| + 1$ for every $v \in C$, which is only possible if $N[v] = C \cup \{w_1, w_2\}$. Because $C \neq \emptyset$, this means that there is a vertex $v \in V(G)$ such that $G[N[v]]$ contains only one non-edge. Now by Condition 1 in Assumption 3, this also has to hold for w_1, and hence, since no vertex in $C \cap N(w_1)$ is adjacent to any vertex in $C' \cap N(w_1)$, it must hold that $\deg(w_1) = 2$. Therefore, by regularity, all vertices in G have degree 2 and thus, being connected, G is a cycle. ◀

▶ **Lemma 9.** *G is a cycle.*

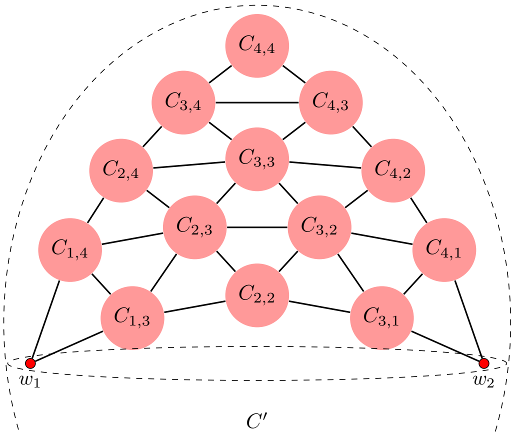

Figure 1 Visualization of the sets $C_{i,j}$ for $d = 4$ in the proof of Lemma 9. An arc between two sets indicates that there may be edges connecting vertices from the two sets.

Proof Sketch. We only present a sketch here. It suffices to prove the lemma for the case that G is a graph with a maximum edge set that satisfies Assumption 3. Indeed, if such a graph G is a cycle, then G has n edges, and the lemma trivially holds for every graph with less edges since every connected regular graph has at least n edges.

Let $d \coloneqq \text{dist}(w_1, w_2)$. By Lemmas 7 and 8, we can assume that $d \geq 3$. Let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| \leq \frac{n-2}{2}$. Also let $C' \coloneqq V(G) \setminus (C \cup \{w_1, w_2\})$. For $i, j \geq 1$ let

$$C_{i,j} \coloneqq \{v \in C \mid \text{dist}(v, w_1) = i \text{ and } \text{dist}(v, w_2) = j\}.$$

By Lemma 6, we conclude that $C_{i,j} = \emptyset$ unless $i, j \leq d$. Furthermore, by the definition of d, we have that $C_{i,j} = \emptyset$ unless $i + j \geq d$. This situation is also visualized in Figure 1.

Using similar ideas as in the proof of Lemma 8, the first step is to show that $C_{d,d} = C_{d-1,d} = C_{d,d-1} = \emptyset$. The main part of the proof is based on the following claim, which exploits the edge maximality of the graph G.

▷ Claim 10. Let $u, v \in V(G)$ such that $\text{dist}(u, v) < d$. Then there is a unique shortest path from u to v.

Indeed, if there were a pair of vertices $u, v \in V(G)$ of distance $\ell < d$ with two shortest paths, then u and v would be "on the same side" of the separator w_1w_2. Hence, since the 2-dimensional WL algorithm is capable of detecting such pairs, adding all of them to the edge set of G would result in a graph with a larger number of edges that still fulfills Assumption 3. Using similar arguments, we also obtain the following related insight.

▷ Claim 11. Let $u, v \in V(G)$ such that $\ell \coloneqq \text{dist}(u, v) < d$. Furthermore, suppose there is a walk $u = u_0, \ldots, u_{\ell+1} = v$ of length $\ell + 1$ from u to v. Then there is some $i \in [\ell]$ such that $u_{i-1}u_{i+1} \in E(G)$.

These two claims drastically restrict the structure of the graph G and allow us to prove that G is a cycle. Intuitively speaking, the claims imply that, when looking towards the connected component $G[C]$ from any of the w_i, the graph has a tree-like shape, i.e., the initial segments of paths up to length $d - 1$ starting in w_i form a tree rooted in w_i. However, this only works out if G is a cycle. More formally, for $k' \in \{d, \dots, 2d\}$, let $\mathcal{C}_{k'} := \bigcup_{i,j:i+j=k'} C_{i,j}$ and let $k \in \{d, \dots, 2d\}$ be the maximal number such that $\mathcal{C}_k \neq \emptyset$. Then $k \leq 2d-2$ since we already know that $C_{d,d} = C_{d-1,d} = C_{d,d-1} = \emptyset$.

Consider a set $C_{i,k-i}$ for some i with $k-d+1 \leq i \leq d-1$ (i.e., none of the extremal sets). Then, for all $v \in C_{i,k-i}$, it holds that $\text{dist}(v, w_1) < d$ and $\text{dist}(v, w_2) < d$, which allows us to apply Claims 10 and 11 for shortest paths from v to w_1 and w_2. With this, we show that if $C_{i,k-i} \neq \emptyset$, then there is a vertex of degree 2, which implies that G is a cycle, since it is regular. In the other case, $C_{j,k-j} = \emptyset$ for all j with $k-d+1 \leq j \leq d-1$. We then consider the extremal sets and derive a contradiction from there. ◀

Reformulating the previous lemma, we obtain the following theorem.

▶ **Theorem 12.** *Let G be a graph such that $\chi_G(u,u) = \chi_G(v,v)$ for all $u, v \in V(G)$. Then (exactly) one of the following holds:*

1. *G is not connected, or*
2. *G is 3-connected, or*
3. *G is a cycle of length $\ell \geq 4$.*

Note that the complete graphs on two and three vertices are 3-connected. The theorem also implies that a connected constituent graph of an association scheme is either 3-connected or a cycle (for other work on the connectivity of relations in association schemes, see e.g. [6, 7, 8, 13]). It thus provides a generalization of Kodalen's and Martin's result in [30], where they proved the theorem in case the graph stems from a symmetric association scheme.

4 Two Colors

Recall that our overall goal is to prove that the 2-dimensional WL algorithm assigns special colors to 2-separators in a graph. We will use Lemma 9 to prove this in case the tuples (u,u) and (v,v) of a 2-separator $\{u,v\}$ obtain the same color under the 2-dimensional WL algorithm. To treat the much more difficult case that u and v obtain distinct colors, we intend to generalize the results of the previous section to two vertex colors. Maybe somewhat surprisingly, we obtain a similar statement to Lemma 9. However, now we require the input graphs to be 2-connected (instead of only being connected). This is a necessary condition, since for example the star graphs $K_{1,n}$ for $n \geq 2$ are neither 3-connected nor cycles but still have only two vertex colors under the 2-dimensional WL algorithm.

The route to proving the statement is similar to the one described in Section 3. Still, two colors allowing for more complexity in the graph structure, the statements and lemmas become more involved and additional cases need to be considered.

▶ **Lemma 13.** *Let G be a graph and suppose there are $c_1 \neq c_2$ such that $\{\chi_G(v,v) \mid v \in V(G)\} = \{c_1, c_2\}$ for some $c_1 \neq c_2 \in \mathbb{N}$. Let $U := \{u \in V(G) \mid \chi_G(u,u) = c_1\}$ and $V := \{v \in V(G) \mid \chi_G(v,v) = c_2\}$. Also let $U_1, \dots, U_k$ be the vertex sets of the connected components of $G[U]$ and let $V_1, \dots, V_\ell$ be the vertex sets of the connected components of $G[V]$. Let G' be the graph with $V(G') = \{U_1, \dots, U_k, V_1, \dots, V_\ell\}$ and $U_iV_j \in E(G')$ if and only if there are $u \in U_i$, $v \in V_j$ such that $uv \in E(G)$.*

Then $\chi_{G'}(U_i, U_i) = \chi_{G'}(U_j, U_j)$ for all $i, j \in [k]$ and $\chi_{G'}(V_i, V_i) = \chi_{G'}(V_j, V_j)$ for all $i, j \in [\ell]$.

▶ **Theorem 14.** *Let G be a 2-connected graph with the following properties:*

1. *G has a 2-separator w_1w_2, and*
2. *for every $v \in V(G)$, there is an $i \in \{1, 2\}$ such that $\chi_G(v,v) = \chi_G(w_i, w_i)$.*

Then G is a cycle.

Proof Idea. By Lemma 9, we can assume without loss of generality that $\chi_G(w_1, w_1) \neq \chi_G(w_2, w_2)$. The statement is proved by induction on the graph size n. For $n \leq 4$, a simple case analysis among the possible graphs G yields the statement.

So let $n \geq 5$. Again, it suffices to prove the statement for the case that G is an n-vertex graph with a maximum edge set that satisfies the requirements of the theorem. Let $U := \{u \in V(G) \mid \chi_G(u, u) = \chi_G(w_1, w_1)\}$ and $V := \{v \in V(G) \mid \chi_G(v, v) = \chi_G(w_2, w_2)\}$. Let $U_1, \dots, U_k$ be the vertex sets of the connected components of $G[U]$ and let $V_1, \dots, V_\ell$ be the vertex sets of the connected components of $G[V]$. Without loss of generality, assume that $w_1 \in U_1$ and $w_2 \in V_1$. Let C be the vertex set of a connected component of $G - w_1w_2$ such that $|C| \leq \frac{n-2}{2}$. Also let $C' := V(G) \setminus (C \cup \{w_1, w_2\})$.

Consider the graph G' defined in the same way as in Lemma 13. First suppose that G' has fewer vertices than the original graph G. If the induction hypothesis is applicable to the graph G', it follows that G' is a cycle and from there, it is not difficult to prove that G also must be a cycle. However, it may happen that G' is 3-connected in which case the induction hypothesis cannot be applied. But this can only happen in very specific cases, which we then treat separately.

If $|V(G')| = |V(G)|$, then there are no edges connecting vertices of the same color with respect to the 2-dimensional WL algorithm and thus, G is bipartite. In this case, we can proceed very similarly to the proof of Lemma 9. ◀

5 Detecting Decompositions with Weisfeiler and Leman

Let S be a set of colors. We say a path $u_0, \dots, u_\ell$ *avoids* S if $\chi_G(u_i, u_i) \notin S$ for every $i \in [\ell - 1]$. Note that we impose no restriction on the colors of the endpoints of the path. It is easy to see that, given two vertices $u, v \in V(G)$, the 2-dimensional WL algorithm is aware of whether there is a path from u to v that avoids S.

▶ **Lemma 15.** *Let G be a graph and let $X := \{\chi_G(v, v) \mid v \in V(G)\}$. Furthermore, let $S \subseteq X$ and define $G[[S]] = (V, E)$, where $V = \{v \in V(G) \mid \chi_G(v, v) \in S\}$ and*

$$E = \{uv \mid \text{there is a path from } u \text{ to } v \text{ in } G \text{ that avoids } S\}.$$

Then $\chi_{G[[S]]}(u, u) = \chi_{G[[S]]}(v, v)$ for all $u, v \in V$ with $\chi_G(u, u) = \chi_G(v, v)$.

▶ **Theorem 16.** *Let G and H be 2-connected graphs and let $w_1, w_2 \in V(G)$ such that w_1w_2 forms a 2-separator in G. Also let $v_1, v_2 \in V(H)$ and suppose $\chi_G(w_1, w_2) = \chi_H(v_1, v_2)$. Then v_1v_2 forms a 2-separator in H.*

Proof. Let $S := \{\chi_G(w_1, w_1), \chi_G(w_2, w_2)\}$ and let $G' := G[[S]]$. Clearly, the graph G' is connected. We argue that G' is 2-connected. Suppose towards a contradiction that there is a separating vertex w in G'. Let C and C' be the vertex sets of two connected components of $G' - w$ and let $v \in C$ and $v' \in C'$. We show that w separates v from v' in G. Towards a contradiction, suppose there is a path P from v to v' in G that does not pass w. Then there is a corresponding path P' in G', which simply skips all inner vertices of P not contained in S. In particular, P' connects v and v', but avoids w. This contradicts w being a cut vertex in G'. Hence, G' is 2-connected.

First suppose that $|V(G')| = 2$. Let $A := \{v \in V(H) \mid \chi_H(v, v) \in S\}$. Then $|A| = 2$ and thus $A = \{v_1, v_2\}$. Moreover, $H - A$ is disconnected, since the 2-dimensional WL algorithm detects that $G - w_1w_2$ is disconnected. Hence, v_1v_2 forms a 2-separator in H.

Now assume $|V(G')| \geq 3$ and suppose there is a vertex set C of a connected component of $G - w_1w_2$ such that $V(G') \subseteq C \cup \{w_1, w_2\}$. Let C' be the vertex set of a second connected component of $G - w_1w_2$ and let $v \in C'$. Then w_1 and w_2 are the only vertices with color in S that can be reached from v via a path that avoids S. Hence, using the expressive power of the 2-dimensional WL algorithm, it is not hard to see that there must also be some $u \in V(H)$ such that v_1 and v_2 are the only vertices with color in S that can be reached from u via a path that avoids S. Since $|V(G')| \geq 3$, there is some $u' \in V(H)$ such that $v_1 \neq u' \neq v_2$ and $\chi_H(u', u') \in S$ because in order not to be distinguished, unions of color classes with color in S must have the same cardinality in both graphs. But then v_1v_2 separates u from u' in H and thus, v_1v_2 forms a 2-separator in H.

In the other case, w_1w_2 forms a 2-separator in G' and hence, G' is a cycle by Lemma 15 and Theorem 14. Note that $|V(G')| \geq 4$ and $w_1w_2 \notin E(G')$. It follows that $H[[S]]$ is also a cycle, since otherwise, the 2-dimensional WL algorithm would distinguish the graphs. Also, $|V(H[[S]])| \geq 4$ and $v_1v_2 \notin E(H[[S]])$. So v_1v_2 forms a 2-separator in $H[[S]]$ and thus, it also forms a 2-separator in H. ◀

▶ **Corollary 17.** *Suppose $k \geq 2$. Let G and H be connected graphs. Suppose $\{w_1, \dots, w_k\} \subseteq V(G)$ is a k-separator in G. Let $\{v_1, \dots, v_k\} \subseteq V(H)$ and suppose $\chi_{G,k}(w_1, \dots, w_k) = \chi_{H,k}(v_1, \dots, v_k)$. Then $\{v_1, \dots, v_k\}$ forms a k-separator in H.*

Using the corollary, we can prove a strengthened version of Theorem 13 in [29]. Following [29], we say that the k-dimensional WL algorithm *determines orbits* in a graph class $\mathcal{G}$ if for all arc-colored graphs (G, λ), (G', λ') with $G, G' \in \mathcal{G}$, arc colorings λ, λ' and for all vertices $v \in V(G)$ and $v' \in V(G')$ there exists an isomorphism from (G, λ) to (G', λ') mapping v to v' if and only if $\chi_{G,k}(v, \dots, v) = \chi_{G',k}(v', \dots, v')$.

▶ **Theorem 18.** *Let $\mathcal{G}$ be a minor-closed graph class and assume $k \geq 2$. Suppose the k-dimensional WL algorithm determines orbits on all arc-colored 3-connected graphs in $\mathcal{G}$. Then the k-dimensional WL algorithm distinguishes all non-isomorphic graphs in $\mathcal{G}$.*

Thus, since by [29], the WL dimension of the class of planar graphs is 2 or 3, the concrete value only depends on the dimension needed to determine orbits on arc-colored triconnected planar graphs.

For a graph G and $v_1, v_2, v_3 \in V(G)$ we define $s_G(v_1, v_2, v_3) := |C|$, where C is the vertex set of the connected component of $G - v_1v_2$ that contains v_3 (if $v_3 \in \{v_1, v_2\}$, then $s_G(v_1, v_2, v_3) := 0$).

▶ **Theorem 19.** *Let G and H be two 2-connected graphs. Also let $v_1, v_2, v_3 \in V(G)$ and $w_1, w_2, w_3 \in V(H)$ such that $\chi_G(v_i, v_j) = \chi_H(w_i, w_j)$ for all $i, j \in \{1, 2, 3\}$. Then $s_G(v_1, v_2, v_3) = s_H(w_1, w_2, w_3)$.*

The last theorem can also be formulated in terms of the expressive power of the 3-variable fragment C^3 of first-order logic with counting quantifiers of the form $\exists^{\geq k} x \varphi(x)$. Indeed, it implies that for all $n, s \in \mathbb{N}$, there is a formula $\varphi_{n,s}(x_1, x_2, x_3) \in \mathsf{C}^3$ such that, for every 2-connected n-vertex graph G and $v_1, v_2, v_3 \in V(G)$, it holds that $G \models \varphi_{n,s}(v_1, v_2, v_3)$ if and only if $s_G(v_1, v_2, v_3) = s$ (for details about the connection between the WL algorithm and counting logics, see e.g. [9, 27]).

6 New Bounds for Graphs of Treewidth k

As an application of the results presented so far, we investigate the WL dimension of graphs of treewidth at most k. Up to this point, the best known upper bound on the WL dimension of such graphs has been $k+2$, i.e., the $(k+2)$-dimensional WL algorithm identifies every graph of treewidth at most k [18]. In this section, we present new upper and lower bounds.

6.1 Upper Bound

The basic idea for proving a new upper bound is to provide a winning strategy for Spoiler in the corresponding bijective pebble game and it works similarly to the proof that the $(k+2)$-dimensional WL algorithm identifies every graph of treewidth at most k [18]. The main difference is a much more careful implementation of the general strategy in order to get by with the desired number of pebbles. As a major ingredient, we exploit that separators can be detected using fewer pebbles.

For a $(k+1)$-tuple $(v_1, \dots, v_k, v_{k+1})$ of vertices of a graph G, we define $s_G(v_1, \dots, v_k, v_{k+1}) := |C|$ where C is the unique connected component of $G - \{v_1, \dots, v_k\}$ with $v_{k+1} \in C$.

▶ **Corollary 20.** *Suppose $k \geq 2$. Let G, H be two graphs and let $v_1, \dots, v_{k+1} \in V(G)$ and $w_1, \dots, w_{k+1} \in V(H)$ such that $s_G(v_1, \dots, v_k, v_{k+1}) \neq s_H(w_1, \dots, w_k, w_{k+1})$. Then Spoiler wins the game $\mathrm{BP}_{k+1}(G, H)$ from the initial position $\big((v_1, \dots, v_{k+1}), (w_1, \dots, w_{k+1})\big)$.*

To build Spoiler's strategy along a given tree decomposition, we use the following characterization of treewidth. Let G be a graph of treewidth k. For a k-separator $S \subseteq V(G)$ and the vertex set C of a connected component of $G - S$, we define $G(S, C)$ to be the graph on vertex set $S \cup C$ obtained by inserting a clique between the vertices in S into $G[S \cup C]$.

▶ **Lemma 21** (Arnborg et al. [1]). *Suppose $G(S, C)$ has at least $k+2$ vertices. Then $G(S, C)$ has treewidth at most k if and only if there exists $v \in C$ such that for every connected component A of $G[C \setminus \{v\}]$, there is a k-element separator $S_A \subseteq S \cup \{v\}$ such that*

1. *no vertex in A is adjacent to the unique element from $S \setminus S_A$, and*
2. *$G\big(S_A, V(A)\big)$ has treewidth at most k.*

Suppose $G(S, C)$ has treewidth at most k. Let $D_G(S, C)$ denote the set of possible vertices $v \in C$ that satisfy Lemma 21.

▶ **Theorem 22.** *Suppose $k \geq 2$. Let G be a graph of treewidth at most k. Then the k-dimensional WL algorithm identifies G.*

Proof Idea. Given a graph G of treewidth at most k and a second non-isomorphic graph H, we show that Spoiler wins the game $\mathrm{BP}_{k+1}(G, H)$. For simplicity of notation, we view tuples $\bar{a} = (a_1, \dots, a_k)$ also as sets $\{a_1, \dots, a_k\}$. Suppose the game is at a position $(\bar{a}, \bar{b}) \in \big(V(G)\big)^k \times \big(V(H)\big)^k$ such that $G(\bar{a}, C)$ has treewidth k for every connected component C of $G - \bar{a}$. Let $m := m(\bar{a}, \bar{b})$ be the smallest number such that $G - \bar{a}$ and $H - \bar{b}$ are not isomorphic when only considering connected components of size m. We prove by induction on m that Spoiler wins the game. The case $m = 1$ is easy, since there is still one pebble left. For the case $m > 1$, Spoiler finds a connected component C_G of $G - \bar{a}$ of size m that differs from the corresponding connected component C_H (specified by Duplicator's bijection) in the graph $H - \bar{b}$. By Corollary 20, we can assume that $|C_G| = |C_H|$. Then Spoiler places a pebble on a vertex in the set $D_G(\bar{a}, C_G)$. This splits C_G into smaller connected components. Then, it can be proved that one pebble can be removed so that afterwards, we find connected components of size at most $m-1$ in which G and H differ (again using Corollary 20). ◀

6.2 Lower Bound

For the lower bound we use a construction introduced by Cai, Fürer, and Immerman [9]. For a graph G, we let $\mathrm{CFI}(G)$ be the graph obtained by applying the standard Cai, Fürer, Immerman (CFI-) construction to G, and $\mathrm{CFI}^{\times}(G)$ be the graph obtained by applying the CFI-construction with one pair of edges twisted (see [9]). We shall actually not require any further details on how the graphs $\mathrm{CFI}(G)$ and $\mathrm{CFI}^{\times}(G)$ look, since we exploit the following theorem.

▶ **Theorem 23** (Dawar and Richerby [10])**.** *Let G be a connected graph such that $\mathrm{tw}(G) \geq k+1$ and $\deg(v) \geq 2$ for all $v \in V(G)$. Then $\mathrm{CFI}(G) \simeq_k \mathrm{CFI}^{\times}(G)$.*

The strategy to obtain a good lower bound is to find graphs G where we can show a sufficiently good upper bound on the treewidth of $\mathrm{CFI}(G)$ and $\mathrm{CFI}^{\times}(G)$. For $n \geq 2$, let $G_{n,n}$ be the $n \times n$ grid.

▶ **Lemma 24.** *For $n \geq 2$, it holds that $\mathrm{tw}(\mathrm{CFI}(G_{n,n})) \leq 2n+5$ and $\mathrm{tw}(\mathrm{CFI}^{\times}(G_{n,n})) \leq 2n+5$.*

▶ **Theorem 25.** *For every $k \geq 2$, there are non-isomorphic graphs G_k and H_k of treewidth at most $2k+7$ such that $G_k \simeq_k H_k$.*

Proof. Let $G_k := \mathrm{CFI}(G_{k+1,k+1})$ and $H_k := \mathrm{CFI}^{\times}(G_{k+1,k+1})$. Then the statement follows from Theorem 23 and Lemma 24. ◀

For a graph class $\mathcal{C}$, denote by $\dim_{\mathsf{WL}}(\mathcal{C})$ the *WL dimension* of $\mathcal{C}$, i.e., the minimum $k \in \mathbb{N} \cup \{\infty\}$ such that the k-dimensional WL algorithm identifies every graph $G \in \mathcal{C}$. As a corollary from Theorems 22 and 25, we obtain the following result.

▶ **Corollary 26.** *Let $k \geq 2$. Then $\lceil \frac{k}{2} \rceil - 3 \leq \dim_{\mathsf{WL}}(\mathcal{T}_k) \leq k$, where $\mathcal{T}_k$ denotes the class of graphs of treewidth at most k.*

7 Conclusion

We have proved that for $k \geq 2$, the k-dimensional WL algorithm implicitly computes the decomposition of its input graph into its triconnected components. As a by-product, we found that every connected constituent graph of an association scheme is either a cycle or 3-connected.

We have applied this insight to improve on the upper bound on the WL dimension of graphs of bounded treewidth and have also provided a lower bound that is asymptotically only a factor of 2 away from the upper bound.

A natural use case of our results may be determining the WL dimension of certain graph classes that satisfy the requirements of Theorem 18. We conjecture that the 2-dimensional WL algorithm identifies every planar graph. Indeed, using the results of this paper, it essentially suffices to show this for triconnected planar graphs.

Abstract

We show that the domino problem is undecidable on orbit graphs of non-deterministic substitutions which satisfy a technical property. As an application, we prove that the domino problem is undecidable for the fundamental group of any closed orientable surface of genus at least 2.

1 Introduction

Initially studied by Wang [22], the domino problem is the algorithmic question of determining if a finite set of unit square tiles with colored edges –called Wang tiles– can be used to tile the plane in such a way that adjacent edges of neighbor Wang tiles have the same color. It was originally conjectured by Wang that the domino problem was decidable. However, Berger [5] and later Robinson [21] both combined their constructions of an aperiodic set of Wang tiles and a reduction from the halting problem of Turing machines to show that the domino problem was in fact undecidable.

The domino problem can be naturally extended to a much broader context. Let Γ be a labeled directed infinite graph, $\mathcal{A}$ a finite set, and $F = \{p_1, \dots, p_n\}$ a finite list of colorings p_i of vertices of finite connected subgraphs of Γ by $\mathcal{A}$. The domino problem of Γ is the language of all codings of pairs $(\mathcal{A}, F)$ as above, for which there exists a coloring of the vertices of Γ such that none of the $p_i \in F$ embed as a colored labeled subgraph. Naturally, Wang's domino problem can be reinterpreted in this setting by letting Γ be the bi-infinite square grid, $\mathcal{A}$ the set of Wang tiles, and F the list of all horizontal or vertical pairs of tiles whose colors do not match.

A particularly interesting case is when Γ is a labeled directed Cayley graph of a finitely generated group G. In this case, there is a direct correspondence between colorings of the vertices of Γ by $\mathcal{A}$ which avoid a list of forbidden colored subgraphs as described above, and subshifts of finite type (SFT), that is, closed and translation invariant subsets of $\mathcal{A}^G$ which are determined by a finite list of forbidden patterns. What is more, it can be shown that the domino problems of all such Cayley graphs of G are computationally many-one

equivalent, and thus one may speak about the domino problem of G. In the particular case when $G = \mathbb{Z}$, the domino problem is decidable: every $\mathbb{Z}$-SFT can be represented by a labeled finite graph [18], and the existence of a configuration in the SFT (i.e. a bi-infinite word) is equivalent to the existence of a cycle in the graph. The case of $\mathbb{Z}^2$ coincides with the formalism of Wang tiles, and is thus undecidable.

The domino problem on graphs other than the Cayley graphs of $\mathbb{Z}$ and $\mathbb{Z}^2$ has been studied by several authors. The undecidability for a graph which models the hyperbolic plane was settled by Kari [15], and can also be obtained from the construction of a hierarchical aperiodic tiling on the hyperbolic plane by Goodman-Strauss [12] and by Margenstern [19]. There has also been research in the case of graphs which can be obtained by self-similar substitutions [4]. For finitely generated groups, the only groups where the domino problem is known to be decidable are virtually free groups, and it is even conjectured that they are the only ones [3].

▶ **Conjecture 1.** *A finitely generated group has decidable domino problem if and only if it is virtually free.*

An interesting take on this conjecture comes from the fact that the domino problem can be expressed in MSO logic [22, 2]. The MSO logic over the Cayley graph of a finitely generated group is decidable if and only if the group is context-free [17], and a group is virtually-free if and only if it is context-free and accessible [20]. Stated differently, (using that all finitely presented groups are accessible [11]) groups that are not virtually free have an undecidable MSO logic. Proven true, the domino problem conjecture would show that the domino problem fragment is "big enough" in MSO. Recent results support the conjecture: decidability of the domino problem is a quasi-isometry invariant for finitely presented groups [10] – i.e. a geometric property of the group – and the conjecture holds true for Baumslag-Solitar groups [1], polycyclic groups [13] and groups of the form $G_1 \times G_2$ [14]. A survey on the domino problem for finitely generated groups can be found in [6, Chapter 9].

The results of Aubrun and Kari [15, 1] share a common factor: the domino problem is shown to be undecidable on two specific structures that grow exponentially with integer or rational base. But what if the structure grows with a different base? The technique employed by those authors –reduction from the immortality problem of rational piecewise affine maps– seems difficult to adapt in this case. A class of structures which can grow non-regularly is given by orbit graphs of non-deterministic substitutions (Section 3). This class of structures includes the hyperbolic plane model of [15], which can be thought of as an orbit graph of the one-letter substitution $0 \mapsto 00$. Using a technique involving the superposition of two orbit graphs of substitutions, presented in [9], we show that the domino problem is undecidable on all orbit graphs of non-deterministic substitutions that satisfy a technical property (Section 4). As an application of the previous result we show that the domino problem of the fundamental group of any closed orientable surface of genus at least 2 is undecidable (Section 5). Finally, we discuss the case of word-hyperbolic groups (Section 6) and show that if a famous conjecture of Gromov –or a weaker version– holds, then the only word-hyperbolic groups with decidable domino problem are the virtually free groups, hence confirming the conjecture for this class of groups.

2 Subshifts on graphs and the domino problem

We define a *graph* Γ to be a triple $(V_\Gamma, E_\Gamma, L_\Gamma)$ where V_Γ is an infinite countable set of vertices, $E_\Gamma \subset V_\Gamma^2$ is the set of edges, such that $|\{u \in V_\Gamma \mid (u,v) \in E_\Gamma \text{ or } (v,u) \in E_\Gamma\}| < M$ for every vertex $v \in V_\Gamma$, where M is some constant, and $L_\Gamma \colon E_\Gamma \to L$ is a labeling function which assigns to every edge a label in a finite set L. Important examples of such graphs are Cayley graphs of finitely generated groups. More precisely, given a finitely generated group G and a finite set of generators $\mathcal{S}$, its Cayley graph is given by $V_\Gamma = G$, $E_\Gamma = \{(g, gs) \mid g \in G, s \in \mathcal{S}\}$, $L_\Gamma((g, gs)) = s$. Let $\Gamma = (V_\Gamma, E_\Gamma, L_\Gamma)$ be a graph as defined above. Let S, T be two finite subsets of V_Γ. A mapping $\phi\colon S \to T$ is a *label preserving graph isomorphism* if ϕ is a bijection and

- for all $u, v \in S$, $(u, v) \in E_\Gamma$ if and only if $(\phi(u), \phi(v)) \in E_\Gamma$;
- for all $u, v \in S$, $L_\Gamma((u, v)) = L_\Gamma((\phi(u), \phi(v)))$.

Let $\mathcal{A}$ be a finite alphabet and Γ a graph. The set of mappings from V_Γ to $\mathcal{A}$, denoted $\mathcal{A}^\Gamma$, is the set of *configurations* over Γ. Endowed with the prodiscrete topology, the set $\mathcal{A}^\Gamma$ is compact and metrizable. If $S \subset V_\Gamma$ is a finite and connected set of vertices, a *pattern with support* S is a mapping $p\colon S \to \mathcal{A}$. A pattern $p\colon S \to \mathcal{A}$ *appears* in a configuration $x \in \mathcal{A}^G$ (resp. in a pattern $p'\colon S' \to \mathcal{A}$) if there exists a finite set of vertices $T \subset V_\Gamma$ (resp. $T \subset S'$) and a label preserving graph isomorphism $\phi\colon S \to T$ such that $p_u = x_{\phi(u)}$ (resp. $p_u = p'_{\phi(u)}$) for every $u \in S$. In this case, we denote $p \sqsubset x$ (resp. $p \sqsubset p'$).

A *subshift* $X_F \subset \mathcal{A}^\Gamma$ is a set of configurations that avoid some set of forbidden patterns F, i.e. $X_F := \left\{x \in \mathcal{A}^\Gamma \mid \text{ no pattern of } F \text{ appears in } x\right\}$. This notion extends the classical definition of subshift for group actions to arbitrary graphs. A *subshift of finite type* (SFT) is a subshift for which F can be chosen finite – equivalently, an SFT may also be defined by a finite set of allowed patterns. In the case where the support of all the forbidden patterns in F consist of two vertices connected by an edge, we say X_F is a *nearest neighbor subshift*.

Given a graph Γ and a finite alphabet $\mathcal{A}$, a pattern as defined above can be encoded by a finite graph, which is an induced finite subgraph of Γ, with labels on edges and letters from $\mathcal{A}$ on vertices. This is what is meant in the sequel by *coding* of a pattern.

Let Γ be a graph in the previous sense. The *domino problem for* Γ is defined as the set $\texttt{DP}(\Gamma)$ of codings of finite sets of forbidden patterns F such that $X_F \neq \emptyset$. If the set $\texttt{DP}(\Gamma)$ is recursive, we say that Γ *has decidable domino problem.*

3 Substitutions, orbits and tilings

Inspired by [9], we associate a tiling of $\mathbb{R}^2$ to the orbit of an infinite word $w \in \mathcal{A}^\mathbb{Z}$ under the action of a substitution, in which every tile codes a production rule of the substitution.

3.1 Substitution systems

We first define parent functions, which will be used to give precise descriptions of orbits of infinite words under the action of a substitution. A *parent function* $P\colon \mathbb{Z} \to \mathbb{Z}$ is an onto and non-decreasing function. In particular, such a function P satisfies that for every $i \in \mathbb{Z}$, $P(i+1) - P(i) \in \{0, 1\}$.

A *non-deterministic substitution* is a couple $(\mathcal{A}, R)$ where $\mathcal{A}$ is a finite alphabet and $R \subset \mathcal{A} \times \mathcal{A}^*$ is a finite set called the *relation*, and whose elements are called *production rules*. We say that an infinite word $\omega \in \mathcal{A}^\mathbb{Z}$ *produces* the word $\omega' \in \mathcal{A}^\mathbb{Z}$ with respect to the parent function P if for every $i \in \mathbb{Z}$, one has $(\omega_i, \omega'_{|P^{-1}(i)}) \in R$, where $\omega'_{|P^{-1}(i)}$ is the finite subword of ω' that appears on indices $\{j \in \mathbb{Z} \mid P(j) = i\}$. In this case, by abuse of notation, we denote $(\omega, \omega') \in R$. An *orbit* of a non-deterministic substitution $(\mathcal{A}, R)$ is a set $\left\{(\omega^i, P_i)\right\}_{i \in \mathbb{Z}} \in \left(\mathcal{A}^\mathbb{Z} \times \mathbb{Z}^\mathbb{Z}\right)^\mathbb{Z}$ such that for every $i \in \mathbb{Z}$, P_i is a parent function, and the word ω^i produces the word ω^{i+1} with respect to P_i. A *deterministic substitution* (or substitution for short) is a non-deterministic substitution where the relation is a function. A non-deterministic substitution $(\mathcal{A}, R)$ *has an expanding eigenvalue* if there exist $\lambda > 1$ and $v\colon \mathcal{A} \to \mathbb{R}_{>0}$ such that for every $(a, w) \in R$ if we write $w = w_1 w_2 \dots w_{|w|}$ we have,

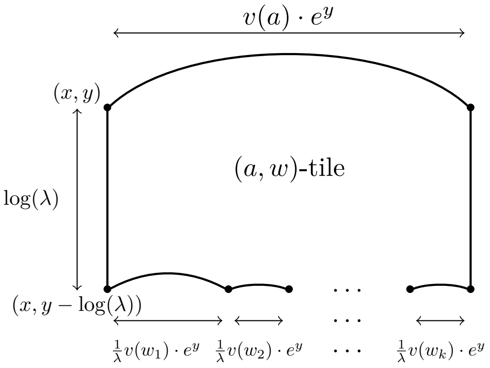
$$\lambda \cdot v(a) = \sum_{i=1}^{|w|} v(w_i).$$

▶ **Example 2.** The substitution given by the production rule $0 \mapsto 00$ has an expanding eigenvalue. This can be verified by choosing $\lambda = 2$ and $v(0) = 1$.

▶ **Example 3.** The substitution $\sigma_{\texttt{gold}}$ given by the production rules $a \mapsto aab$, $b \mapsto ba$ has an expanding eigenvalue. This can checked with $\lambda = \frac{3+\sqrt{5}}{2}$ and $v(a) = \frac{1+\sqrt{5}}{2}$, $v(b) = 1$.

3.2 Orbits as tilings of $\mathbb{R}^2$

Let $(\mathcal{A}, R)$ be a non-deterministic substitution with an expanding eigenvalue $\lambda > 1$ and $v\colon \mathcal{A} \to \mathbb{R}_{>0}$. For every production rule $(a, w) \in R$, define the (a, w)*-tile in position* $(x, y) \in \mathbb{R}^2$ as the square polygon with $|w| + 3$ edges pictured below, where $w = w_1 \dots w_k$ (horizontal edges are curved to be more visible, but are in fact just straight lines).



$v(a) \cdot e^y$
(x, y)
(a, w)-tile
$\log(\lambda)$
$(x, y - \log(\lambda))$
. . .
$\frac{1}{\lambda}v(w_1) \cdot e^y$
$\frac{1}{\lambda}v(w_2) \cdot e^y$
$\frac{1}{\lambda}v(w_k) \cdot e^y$

▶ Remark 4. The length of the top edge and the sum of lengths of bottom edges of this tile are the same. Since $(\mathcal{A}, R)$ has an expanding eigenvalue $\lambda > 1$ with v, one has

$$\sum_{j=1}^{k} \frac{1}{\lambda} v(w_i) \cdot e^y = \frac{e^y}{\lambda} \cdot \lambda \cdot v(a) = v(a) \cdot e^y,$$

so that the bottom right vertex $(x + \frac{1}{\lambda}(v(w_1) + \dots + v(w_k))\, e^y, y - \log(\lambda))$ is indeed $(x + v(a) \cdot e^y, y - \log(\lambda))$.

The $(\mathcal{A}, R)$*-tiles* is the set of all (a, w)-tiles in position (x, y) for all possible $(a, w) \in R$ and $(x, y) \in \mathbb{R}^2$. A *tiling of* $\mathbb{R}^2$ *with* $(\mathcal{A}, R)$*-tiles*, or $(\mathcal{A}, R)$-tiling for short, is a countable collection of $(\mathcal{A}, R)$-tiles that covers $\mathbb{R}^2$ and have pairwise disjoint interiors, such that tiles are edge-to-edge –the intersection of two tiles is either empty or a full edge and two vertices. In Figure 2 we illustrate a $\sigma_{\texttt{gold}}$-tiling (in blue) and a $0 \mapsto 00$-tiling (in grey).

▶ **Proposition 5.** *If a substitution* $(\mathcal{A}, R)$ *with an expanding eigenvalue admits orbits, then there exists a tiling of* $\mathbb{R}^2$ *with* $(\mathcal{A}, R)$*-tiles.*

4 Undecidability of the domino problem on orbit graphs

Let $u = (u_i)_{i\in\mathbb{Z}}$ be a bi-infinite sequence of positive integers. The *accumulation function of* u is the function $\Delta\colon \mathbb{Z} \to \mathbb{Z}$ given by

$$\Delta(i) = \begin{cases} \sum_{k=0}^{i-1} u_k & \text{if } i \geq 1 \\ 0 & \text{if } i = 0 \\ -\sum_{k=i}^{-1} u_k & \text{if } i \leq -1 \end{cases}.$$

Note that the family of discrete intervals $(I_k)_{k\in\mathbb{Z}}$ where $I_k = [\Delta(k); \Delta(k+1) - 1]$ forms a partition of $\mathbb{Z}$. If P is a parent function, and if we define the sequence u by $u_i = |P^{-1}(i)|$ for every $i \in \mathbb{Z}$, then we get that $P(j) = i$ for every $j \in [\Delta(i); \Delta(i+1) - 1]$, where Δ is the accumulation function of u.

Let $(\mathcal{A}, R)$ be a non-deterministic substitution. Denote $M = \max_{(a,w)\in R} |w|$.

▶ **Definition 6.** *The* orbit graph *associated with the orbit* $\Omega = \left\{(\omega^i, P_i)\right\}_{i\in\mathbb{Z}}$ *of* $(\mathcal{A}, R)$ *is the graph* Γ_Ω *with set of vertices* $\mathbb{Z}^2$*, edges* E_Ω *and labeling function* $L_\Omega\colon E_\Omega \to \{\texttt{next}\} \cup [0; M-1]$ *given by*

- *for every* $i, j \in \mathbb{Z}$, $((i,j),(i,j+1)) \in E_\Omega$ *and* $L_\Omega(((i,j),(i,j+1))) = \texttt{next}$*;*
- *for every* $i \in \mathbb{Z}$ *and every* $k \in [\Delta_{i+1}(j); \Delta_{i+1}(j+1) - 1]$, $((i,j),(i+1,k)) \in E_\Omega$ *and* $L_\Omega(((i,j),(i+1,k))) = k - \Delta_{i+1}(j)$*,*

where Δ_i *is the accumulation function associated with* $\left(|P_i^{-1}(j)|\right)_{j\in\mathbb{Z}}$ *for every* $i \in \mathbb{Z}$*.*

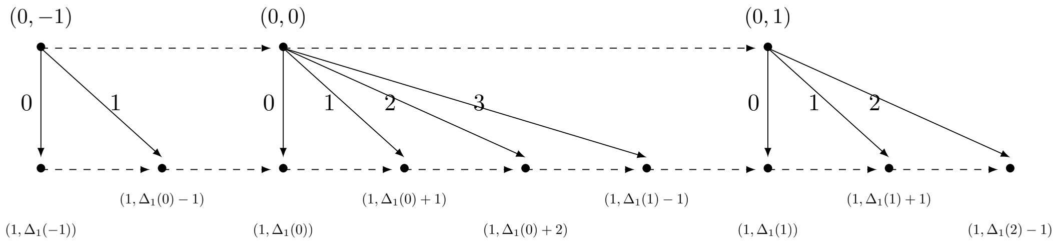


Figure 1 Part of an orbit graph. Dashed arrow are edges of the graph labeled with `next`.

In this formalism, Kari's result for the hyperbolic plane [15] is equivalent to the statement that all orbit graphs of the one-letter substitution $0 \mapsto 00$ have undecidable domino problem.

▶ **Theorem 7** (Kari [15])**.** *For all orbit graphs of the substitution* $(\{0\}, 0 \mapsto 00)$ *the domino problem is undecidable.*

The goal of this section is to show that the domino problem of any orbit graph associated to an orbit of a non-deterministic substitution $(\mathcal{A}, R)$ with an expanding eigenvalue λ is undecidable. The general idea is to show that, given any SFT over an orbit graph of $0 \mapsto 00$, it is possible to encode it in an orbit graph of $(\mathcal{A}, R)$. We do this in two steps. First (Section 4.1), we show a variation of the "Technical Lemma" of Cohen and Goodman-Strauss [9], where we prove that it is possible to encode the structure of orbit graphs of $0 \mapsto 00$ in an SFT over $(\mathcal{A}, R)$. Then (Section 4.2), we prove that in addition to the structure of its orbit graph, it is also possible to encode any SFT over orbit graphs of $0 \mapsto 00$ in an SFT over $(\mathcal{A}, R)$.

4.1 Superposition of orbits

Let us fix a non-deterministic substitution $(\mathcal{A}, R)$ with an expanding eigenvalue $\lambda > 2$ – this latter assumption ensures that letters of an alphabet $\mathcal{B}$ described below are non-degenerate, and will be suppressed later. Without loss of generality, we may choose the function $v\colon \mathcal{A} \to \mathbb{R}_{>0}$ associated to λ such that $v(a) > 4$ for each $a \in \mathcal{A}$.

Let Ω be an orbit of $(\mathcal{A}, R)$. We shall construct a finite alphabet $\mathcal{B}$ and a finite set of forbidden patterns F such that the subshift $Y \subset \mathcal{B}^{\Gamma_\Omega}$ over orbit graph Γ_Ω, defined by the set of forbidden patterns F has the following properties:

1. Y is non-empty,
2. every configuration $y \in Y$ encodes an orbit graph of the substitution $(\{0\}, 0 \mapsto 00)$.

Consider an orbit Ω of $(\mathcal{A}, R)$ and Φ an orbit of $(\{0\}, 0 \mapsto 00)$. By Proposition 5 both of these orbits can be realized as tilings of $\mathbb{R}^2$. Symbols from $\mathcal{B}$ will encode non-empty finite regions of the tiling with $(\{0\}, 0 \mapsto 00)$ that are witnessed by $(\mathcal{A}, R)$-tiles. These regions will be chosen in such a way that their union recovers the whole tiling and they are pairwise disjoint (see Figure 2).

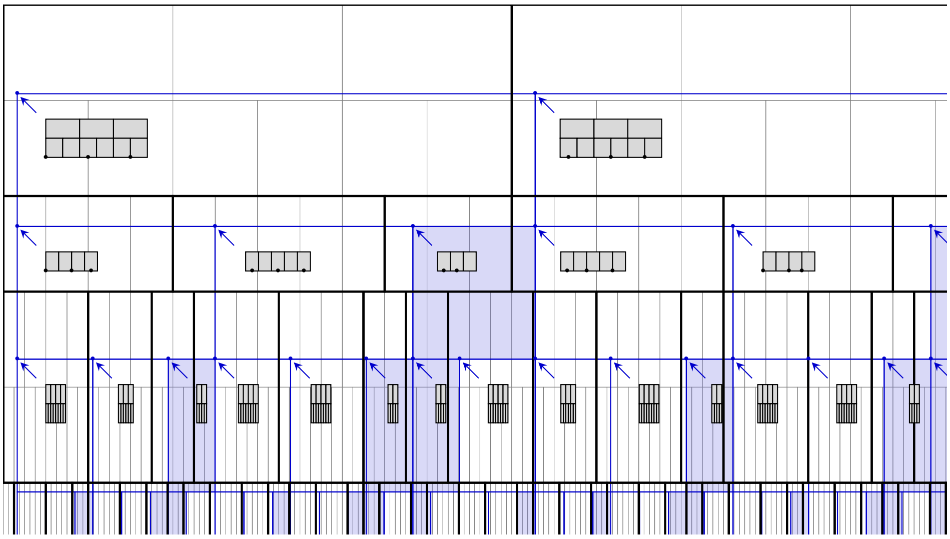

Figure 2 Γ_Φ (in black) superimposed over an orbit graph of $(\mathcal{A}, R)$ (in blue) leads to the construction of the subshift $Y \subset \mathcal{B}^{\Gamma_\Omega}$: letters of the alphabet $\mathcal{B}$ are blocks of the orbit graph Γ_Φ, such as  or  .A careful examination shows that dimensions of blocks in $\mathcal{B}$ are bounded: if (t, h) denotes the width and height of a block in $\mathcal{B}$, we get that $\min_{a \in \mathcal{A}} \lfloor \frac{v(a)}{4} \rfloor \leq t \leq \max_{a \in \mathcal{A}} \lfloor 1 + \frac{v(a)}{2} \rfloor$ and $\frac{\log(\lambda)}{\log(2)} - 1 < h \leq \frac{\log(\lambda)}{\log(2)} + 1$. Thus $\mathcal{B}$ is finite, and the assumption $\lambda > 2$ and $v(a) > 4$ ensures that blocks have non-degenerate dimensions.

The set of forbidden patterns F is the finite set of patterns that do not correspond to a valid encoding of the orbit graph of $(\{0\}, 0 \mapsto 00)$. In other words, we allow only patterns in which the finite regions of $(\{0\}, 0 \mapsto 00)$ that are encoded are consistent from one neighbor to one other. We thus obtain an SFT Y on Γ_Ω which encodes Φ and is non-empty.

▶ **Lemma 8.** *For every orbit Ω of $(\mathcal{A}, R)$ the subshift of finite type $Y \subset \mathcal{B}^{\Gamma_\Omega}$ is non-empty.*

4.2 Simulation of SFTs over of $0 \mapsto 00$ on orbit graphs of $(\mathcal{A}, R)$

Let Ω and Φ be orbits of $(\mathcal{A}, R)$ and $(\{0\}, 0 \mapsto 00)$ respectively, and Γ_Ω, Γ_Φ be orbit graphs of Ω and Φ respectively. Let Σ be a finite alphabet and F_Σ a set of nearest neighbor forbidden patterns on Γ_Φ over the alphabet Σ. We denote by X_Σ the SFT defined by forbidden patterns F_Σ. In order to encode X_Σ into Γ_Ω, we use the same method as above for Y, but enrich the patterns of $0 \mapsto 00$ with colors taken from Σ. We then construct forbidden patterns that ensure that no forbidden patterns from F_Σ appear.

More formally, we define $\mathcal{B}_\Sigma$ as the set of pairs (b, p_b) such that $b \in \mathcal{B}$ and $p_b \colon \Gamma_b \to \Sigma$ is a pattern. For a pattern p on Γ_Ω with alphabet B_Σ denote by $\pi_{\mathcal{B}}(p)$ the restriction to the first coordinate of $\mathcal{B}_\Sigma$. And denote by $q(p) \colon \Gamma_{\pi_{\mathcal{B}}(p)} \to \Sigma$ the pattern over $(\{0\}, 0 \mapsto 00)$ whose support is the graph $\Gamma_{\pi_{\mathcal{B}}(p)}$ and is obtained by pasting together the corresponding patterns p_b on the second coordinate of B_Σ.

Define $F_{\mathcal{B},\Sigma}$ as the set of all patterns p over the alphabet $\mathcal{B}_\Sigma$ which have supports which consist in three vertices $\{u, v, w\}$ in Γ_Ω such that $(u, v), (u, w)$ are edges, $L((u, v)) = \texttt{next}$ and $L((u, w)) = \ell$ for some ℓ appearing in the parent matching labels of the orbit graph Γ_Ω, and that satisfy one of the following two properties:

1. The pattern $\pi_{\mathcal{B}}(p)$ obtained by restricting p to the first coordinate of $\mathcal{B}_\Sigma$ is in F;
2. The pattern $q(p)$ obtained by pasting the patterns of p described by the second coordinate of $\mathcal{B}_\Sigma$ contains a forbidden pattern from F_Σ.

Clearly $F_{\mathcal{B},\Sigma}$ has finitely many patterns (up to label preserving graph isomorphism). For any orbit Ω of $(\mathcal{A}, R)$ we define the subshift of finite type $Y_\Sigma \subset (B_\Sigma)^{\Gamma_\Omega}$ as the set of all colorings of Γ_Ω by B_Σ where no pattern from $F_{\mathcal{B},\Sigma}$ appears.

This construction leads to the following Lemma, expressing the fact that X_Σ is indeed encoded into Y_Σ.

▶ **Lemma 9.** *Let X_Σ be the subshift on Γ_Φ with alphabet Σ defined by the nearest neighbor forbidden patterns F_Σ and let $Y_\Sigma \subset (B_\Sigma)^{\Gamma_\Omega}$ be defined as above. Then $Y_\Sigma = \emptyset$ if and only if $X_\Sigma = \emptyset$.*

▶ Remark 10. The alphabet B_Σ and the set of forbidden patterns $F_{\mathcal{B},\Sigma}$ which define Y_Σ only depend upon Σ, F_Σ and the substitution $(\mathcal{A}, R)$, and not on the choice of the orbit Ω of $(\mathcal{A}, R)$.

▶ **Theorem 11.** *The domino problem is undecidable on any orbit graph of a non-deterministic substitution with an expanding eigenvalue.*

Proof. Let us first assume that the expanding eigenvalue λ associated to $(\mathcal{A}, R)$ satisfies $\lambda > 2$. Let Σ and F_Σ be respectively an alphabet and a nearest neighbor set of forbidden patterns for an orbit graph Γ_Φ of an orbit Φ of $(\{0\}, 0 \mapsto 00)$ which define a nearest neighbor SFT X_Σ. By Lemma 9 we know that $X_\Sigma = \emptyset$ if and only if $Y_\Sigma = \emptyset$. Furthermore, we claim that the alphabet and set of forbidden patterns which define Y_Σ can be constructed effectively from Σ and F_Σ. Indeed, the subshift Y does not depend upon Σ and thus its alphabet $\mathcal{B}$ and forbidden patterns F can be hard-coded in the algorithm. It is easy to see that from $\mathcal{B}$ one can effectively construct the alphabet B_Σ and the forbidden patterns $F_{\mathcal{B},\Sigma}$ which define Y_Σ.

These two facts together show that if $\texttt{DP}(\Gamma_\Omega)$ is decidable and $\lambda > 2$, then so is $\texttt{DP}(\Gamma_\Phi)$. Using the result of Kari (Theorem 7) we have that $\texttt{DP}(\Gamma_\Phi)$ is undecidable, hence $\texttt{DP}(\Gamma_\Omega)$ is also undecidable.

For the case where $1 < \lambda \leq 2$, we consider the relation R^m defined recursively by:

- $R^1 = R$.

- R^{k+1} is the set of all pairs $(a, (c^1_1 \dots c^1_{\ell_1})(c^2_1 \dots c^2_{\ell_2}) \dots (c^1_k \dots c^1_{\ell_k}))$ in $\mathcal{A} \times \mathcal{A}^*$ for which there is a pair $(a, b_1 \dots b_k) \in R^k$ such that $(b_i, c^i_1 \dots c^i_{\ell_i}) \in R$ for each $i \in \{1, \dots, k\}$.

In other words, R^m is the set of all relations that can be obtained by starting with a symbol $a \in \mathcal{A}$ and replacing m times each letter by the right hand side of a production rule of R. Let $n \in \mathbb{N}$ such that $\lambda^n > 2$ and note that the substitution $(\mathcal{A}, R^n)$ has the expanding eigenvalue $\lambda^n > 2$. Lemma 9 then provides an encoding of the substitution $(\{0\}, 0 \mapsto 00)$ on orbit graphs of $(\mathcal{A}, R^k)$ for any $k \in \{0, \dots, n-1\}$, in the form of SFTs $Y^{n,k}_\Sigma$ such that $Y^{n,k}_\Sigma = \emptyset$ if and only if $X_\Sigma = \emptyset$. Then we are able to build an SFT Z on Γ_Ω which encodes a copy of $Y^{k,n}_\Sigma$ for each $k \in \{0, \dots, n-1\}$. One can verify that $Z = \emptyset$ if and only if $X_\Sigma = \emptyset$, leading to the same reduction as in the case $\lambda > 2$. ◀

5 The domino problem for surface groups

A fundamental result of geometry is that up to homeomorphism, closed orientable surfaces are completely classified by their genus g: any such surface is either homeomorphic to a sphere or to a finite connected sum of tori. In this section we shall classify the domino problem of their fundamental groups.

5.1 Surface groups

The *surface group of genus* g is the group defined by the following presentation:

$$G_g = \langle a_1, b_1, \dots, a_g, b_g \mid [a_1, b_1] \dots [a_g, b_g] \rangle,$$

where $[a, b] = aba^{-1}b^{-1}$ is the commutator of a and b. It is interesting to notice that $\mathbb{Z}^2 = \langle a, b \mid aba^{-1}b^{-1} \rangle$ is the surface group of genus 1, and hence by Berger's result [5] its associated domino problem is undecidable.

The domino problem for a finitely generated group is known to be a commensurability invariant [6, Corollary 9.53]. It turns out that all surface groups of genus $g \geq 2$ are commensurable [8, Proposition 6.7]. By combining these two facts, it would be enough to prove the undecidability of the domino problem for just the surface group of genus 2. In the sequel, we shall denote by G the surface group of genus 2, i.e. the group with finite presentation

$$G = \langle a, b, c, d \mid [a, b][c, d] \rangle,$$

denote by S the symmetric closure of its generating set $\{a, b, c, d\}$, and by 1_G its identity.

The Cayley graph of G associated with the presentation above is not an orbit graph of some substitution with an expanding eigenvalue, but can be seen as such just by assigning different labels to the edges. Moreover we shall see that these labels can be obtained locally, which means that we can code the relabeling inside an SFT.

5.2 Finding a substitution in the surface group of genus 2

The goal of this section is to establish a parallel between the Cayley graph of the surface group $\mathcal{C}_G := \Gamma(G, S)$ and the orbit graph of a particular substitution.

The group G has only one relation $[a, b][c, d] = 1_G$. Thus the only minimal cycles of the Cayley graph are cyclic permutations of $[a, b][c, d]$. We call them *elementary cycles*. Moreover, any edge in the Cayley graph is part of at least one elementary cycle, since all generators and their inverses appear in the relation. Let $d(g, h)$ be the smallest number of elementary cycles that must be crossed to go from g to h in $\mathcal{C}_G$. Let $B_i = \{g \in G \mid d(1_G, g) \leq i\}$ be the ball of radius i and $C_i = \{g \in G \mid d(1_G, g) = i\}$ be the sphere of radius i, so that $B_{i+1} \setminus B_i = C_{i+1}$.

Consider an element $g \in C_i$ for $i \geq 1$. There are exactly two elements $s \in S$ such that $gs \in C_i$. There can be either ($\mathtt{a}$) one or ($\mathtt{b}$) none $s \in S$ so that $gs \in C_{i-1}$. We must therefore have that there are 5 and 6 values $s \in S$ such that $gs \in C_{i+1}$ for types ($\mathtt{a}$) and ($\mathtt{b}$) respectively. More precisely, it can be verified that the sequence of elements of C_{i+1} that is obtained by following an elementary cycle from an element of type ($\mathtt{a}$) in C_i has the type sequence $\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^4$ and the sequence of types for an element of type ($\mathtt{b}$) is $\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^5\mathtt{ab}^4$.

This leads us to define the substitution $s\colon \{\mathtt{a}, \mathtt{b}\} \to \{\mathtt{a}, \mathtt{b}\}^*$ given by

$$\begin{cases} s(\mathtt{a}) = (\mathtt{ab}^5)^4\mathtt{ab}^4 \\ s(\mathtt{b}) = (\mathtt{ab}^5)^5\mathtt{ab}^4. \end{cases}$$

From now on, we fix $\Omega = \left(\omega^i, P_i\right)_{i\in\mathbb{Z}}$ an orbit of the substitution s defined above, and denote by Γ its associated orbit graph. Let us note that s admits an expanding eigenvalue ($\lambda = 17 + 12\sqrt{2}$ and $v(\mathtt{b})/v(\mathtt{a}) = \frac{1+\sqrt{2}}{2}$).

The similarities between the two graphs will allow us to perform a reduction from the domino problem on Γ (shown to be undecidable in Section 4) to the domino problem on the surface group of genus 2. In order to do this reduction, all we need is a computable map which sends sets of pattern codings over Γ into sets of pattern codings over $\mathcal{C}_G$ such that the sets defining a non-empty subshift are mapped into sets defining a non-empty subshift and vice-versa. This is not trivial because some of the edges are lost going from Γ to $\mathcal{C}_G$. In order to recover those edges, we shall construct an SFT X over G which locally recovers the lost information and use it to build the bijection needed for the reduction. Note that technically we do not need an SFT to do so, a computable bijection would be enough. However doing it with an SFT provides a locally computable mapping, which is a nice bonus.

Definition of X

To define the SFT X, we introduce a notion of directions that corresponds to following edges of the orbit graph. These directions depend on the element of the group we consider, but can nevertheless be defined by local rules. The alphabet of X contains the correspondence between generators and local directions. More formally, we first consider the general alphabet $\mathcal{A}_0$, consisting of the tuples $(c, (h_1, d_1), (h_2, d_2), \ldots, (h_8, d_8))$ such that

- $c \in \{\blacksquare, \square\}$ is the color of the cell,
- $(h_1, \ldots, h_8)$ is a permutation of $S \cup S^{-1} = \{a, a^{-1}, b, b^{-1}, c, c^{-1}, d,^{-1}\}$,
- $d_1, \ldots, d_8 \in \{\leftarrow, \rightarrow, \uparrow, \downarrow_1, \downarrow_2, \downarrow_3, \downarrow_4, \downarrow_5, \downarrow_6\}$ the directions associated to each generator.

Let $x \in \mathcal{A}_0^G$ be a configuration over $\mathcal{A}_0$. For every $g \in G$, if the first coordinate of x_g is $c = \blacksquare$ (resp. $\square$), we call x_g a black (resp. white) cell.

The alphabet $\mathcal{A}_1 \subseteq \mathcal{A}_0$ is made of three types of elements with more precise directions imposed, depending on the color c:

$$(\blacksquare, (h_1, \leftarrow), (h_2, \rightarrow), (h_3, \uparrow), (h_4, \downarrow_1), (h_5, \downarrow_2), (h_6, \downarrow_3), (h_7, \downarrow_4), (h_8, \downarrow_5))$$

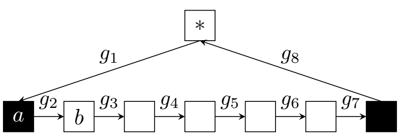
$$(\square, (h_1, \leftarrow), (h_2, \rightarrow), (h_3, \downarrow_1), (h_4, \downarrow_2), (h_5, \downarrow_3), (h_6, \downarrow_4), (h_7, \downarrow_5), (h_8, \downarrow_6))$$

Black cells have directions *left*, *right*, *up* and *down*, whereas whites ones have only *left*, *right* and *down*. Note that for black and white cells, *up*, *left* and *right* are unique. We can then define their top, left and right neighbors.

▶ **Definition 12.** *Let $x \in \mathcal{A}_1^G$ be a configuration over $\mathcal{A}_1$ and $g \in G$. We define:*

- *gh_1 the* left neighbor of *g in x, denoted by $\leftarrow_x(g)$,*
- *gh_2 is the* right neighbor of *g in x, denoted by $\rightarrow_x(g)$,*
- *if x_g is a black cell, gh_3 is the* top neighbor of *g in x, denoted by $\uparrow_x(g)$,*
- *for $i \in \{1, ..., 5\}$, gh_{3+i} (for a white cell, $i \in \{1, ..., 6\}$, gh_{2+i}) is the* i-th bottom neighbor of *g in x, denoted by $\downarrow_{i,x}(g)$.*

Using local rules, we forbid elementary cycles that do not have the colors shown on Figure 3. We also impose the orientations to be as drawn. For example, the right of $\colorbox{black}{$\textcolor{white}{a}$}$ is g_2, its top is g_1^{-1}, and the other directions of a are not constrained by this cycle. Similarly, the left of $\boxed{b}$ is g_2^{-1}, its right g_3 and other directions unconstrained. To do so, we call $\mathcal{F}_1$ the set of all elementary cycles that are not of the form of Figure 3.



🟨 **Figure 3** The two possible types of colorings of cycles. There are no color constraints on $\boxed{*}$, and the cycle $g_1 \dots g_8$ is any cyclic permutation of $[a, b][c, d]$.

We add the constraint that directions must be consistent between adjacent cells, by forbidding the finite set $\mathcal{F}_2$, which is the set of patterns on the support $\{1_G, h\}$ for $h \in G$, such that x_{1_G} and x_h are linked by mismatching directions. That is,

$$\mathcal{F}_2 = \left\{ \text{pattern } p \text{ of support}\{1_G, h\} \;\middle|\; \begin{array}{r} \leftarrow_p(1_G) = h \text{ and } \rightarrow_p(h) \neq 1_G \text{ or} \\ \rightarrow_p(1_G) = h \text{ and } \leftarrow_p(h) \neq 1_G \text{ or} \\ \uparrow_p(1_G) = h \text{ and } \forall i, \downarrow_{i,p}(h) \neq 1_G \text{ or} \\ \exists i, \downarrow_{i,p}(1_G) = h \text{ and } \uparrow_p(h) \neq 1_G \end{array} \right\}.$$

We define X as the set of all configurations over $\mathcal{A}_1$ where no forbidden patterns from $\mathcal{F}_1 \cup \mathcal{F}_2$ appear. By definition, X is an SFT.

The subshift of finite type X

We construct a configuration x in the SFT $X \subset \mathcal{A}_1^G$ as the limit of a sequence of configurations $(y_n)_{n \in \mathbb{N}}$ of another SFT $X_2 \subset (\mathcal{A}_1 \cup \{\texttt{orange}\})^G$, where

$$\texttt{orange} := \left(🟧, (a, \downarrow_1), (a^{-1}, \downarrow_2), (b, \downarrow_3), (b^{-1}, \downarrow_4), (c, \downarrow_5), (c^{-1}, \downarrow_6), (d, \downarrow_7), (d^{-1}, \downarrow_8)\right),$$

and we extend the definition of neighbors consistently. X_2 is defined by $\mathcal{F}_1 \cup \mathcal{F}_2$ the same finite set of forbidden patterns as X. Intuitively, because the letter `orange` has only bottom neighbors, an orange cell can only appear once in a configuration of X_2. Moreover, one can build bigger and bigger circles around the orange cell by simply sticking elementary cycles around, colored as on Figure 3, leading to the following lemma.

▶ **Lemma 13.** *For every i, there exists a pattern $p_i \in (\mathcal{A}_1 \cup \{\texttt{orange}\})^{B_i}$ containing no forbidden patterns of $\mathcal{F}$ and such that $(p_i)_g$ is an orange cell if and only if $g = 1_G$.*

From Lemma 13, we can build a configuration y in X_2 that contains only one orange cell at the origin. And from it, we can deduce the non-emptiness of X.

▶ **Proposition 14.** *The subshift X is non-empty.*

Proof. By compactness of $(\mathcal{A}_1 \cup \{\texttt{orange}\})^G$ and Lemma 13, there exists a configuration $y \in X_2$ which coincides with the pattern p_i on B_i for all $i \in \mathbb{N}$. In particular, the orange cell appears only at the origin. The SFT X consists of all configurations on X_2 where the orange tile does not appear. By definition of y, we can find arbitrarily large regions where 🟧 does not appear at all. We can then extract a sequence of configurations $(y_n)_{n\in\mathbb{N}}$ of X_2 such that the orange cell does not appear in $(y_n)_{|B_n}$. Any accumulation point of the sequence $(y_n)_{n\in\mathbb{N}}$ does not contain the orange cell and is thus in X. ◀

If we carefully look at configurations in X, we observe that they are all structured with infinite lines of $\rightarrow$ and $\leftarrow$. Moreover these infinite lines can be ordered with no ambiguity. This is expressed in Lemma 15: any element g of G can be reached from the identity 1_G by first going to the appropriate infinite line, and then moving to the left or right up to g. Fix some $x \in X$, and define $\rightarrow_x^{-1}(g) :=\leftarrow_x(g)$ and $\downarrow_{1,x}^{-1}(g) :=\uparrow_x(g)$.

▶ **Lemma 15.** *For any $g \in G$, there exists i, j such that $g =\rightarrow_x^j \circ \downarrow_{1,x}^i(1_G)$.*

Proof idea. The key idea here is that we can always reorder the operations by taking another way in the graph. Starting from any path from 1_G to g, we can transform it into this "normal form" by taking a longer path that uses only $\downarrow_1$ then $\rightarrow$ operations. ◀

5.2.1 A bijection between $\mathbb{Z}^2$ and the surface group

Let $x \in X$ be fixed. We define $f_x\colon \mathbb{Z}^2 \to G$ by $f_x(i,j) =\rightarrow_x^j \circ \downarrow_{1,x}^i(1_G)$ for every $i, j \in \mathbb{Z}$.

▶ **Lemma 16.** *For every $x \in X$, the function f_x is a bijection.*

Proof idea. It is enough to show that for any group element $g \in G$, there exist uniquely defined $i, j \in \mathbb{Z}$ such that $g =\rightarrow_x^j \circ \downarrow_{1,x}^i(1_G)$. The key ingredient to prove the uniqueness of this representation is to notice that any cycle in the Cayley graph of G contains as many $\uparrow$ as $\downarrow$ operations, which can be proven by induction on the size of the cycle and a careful examination of different cases. ◀

We can moreover prove that f_x also preserves locality, in the sense that neighborhoods are almost preserved, as stated in the following lemma.

▶ **Lemma 17.** *The following equivalences are true:*

1. $\begin{cases} (u,v) \in E_\Gamma \\ L_\Gamma(u,v) = \textit{next} \end{cases} \Leftrightarrow f_x(v) =\rightarrow_x(f_x(u))$
2. $\begin{cases} (u,v) \in E_\Gamma \\ L_\Gamma(u,v) = k \in \{0,\dots,M-1\} \end{cases} \Leftrightarrow f_x(v) =\rightarrow_x^k \circ \downarrow_{1,x}(f_x(u))$

   where M is the number of sons of u.

The bijection f_x itself cannot be a label preserving graph isomorphism, since we lack some edges of Γ in $\mathcal{C}_G$, but it nevertheless enjoys a useful property: if φ is a label preserving graph isomorphism for Γ, then so is $f_x \circ \varphi \circ f_x^{-1}$ for $\mathcal{C}_{G,x}$, and if φ is a label preserving graph isomorphism for $\mathcal{C}_{G,x}$, then so is $f_x^{-1} \circ \varphi \circ f_x$ for Γ, where $\mathcal{C}_{G,x}$ is a relabeling of $\mathcal{C}_g$ according to the configuration x. So roughly speaking, any local pattern is preserved by f_x or by f_x^{-1}.

▶ **Corollary 18.** *Let $\mathcal{A}$ be a finite alphabet. For any configuration $c \in \mathcal{A}^G$, $p \sqsubset c \Rightarrow f_x^{-1}(p) \sqsubset f_x^{-1}(c)$. Conversely for any $d \in \mathcal{A}^\Gamma$, $q \sqsubset d \Rightarrow f_x(q) \sqsubset f_x(d)$.*

5.3 The reduction

We now have everything in hand to prove the undecidability of the domino problem on the surface group of genus 2.

▶ **Theorem 19.** *The domino problem is undecidable on the surface group of genus 2.*

Proof. Recall that Γ is the orbit graph of an orbit of the substitution s defined on page 9. Let $\mathcal{A}$ be a finite alphabet and $Y \subseteq \mathcal{A}^{\Gamma}$ an SFT over Γ, given by a finite set of forbidden patterns $\mathcal{F}_Y$. We define Z the SFT over G with set of forbidden patterns $F_Z := f_x(F_Y)$, where f_x is defined in Lemma 16. We prove that $Z = \emptyset$ if and only if $Y = \emptyset$.

Assume $Z = \emptyset$ and consider a configuration $c \in \mathcal{A}^G$. The configuration $d := f^{-1}(c)$ is thus in $\mathcal{A}^{\Gamma}$. Since $Z = \emptyset$, necessarily c contains a forbidden pattern p from the set $\mathcal{F}_Z$. Since $p \sqsubset c$, Corollary 18 implies that $f_x^{-1}(p) \sqsubset f_x^{-1}(c) = d$. So a pattern $f_x^{-1}(p)$ from $\mathcal{F}_Y$ appears in any configuration $c \in \mathcal{A}^G$, i.e. the subshift Y is empty. Similar arguments show that if Y is empty then so is Z, and the reduction is completed. ◀

▶ **Corollary 20.** *The domino problem is undecidable for every surface group of positive genus.*

Proof. The undecidability of the domino problem is a commensurability invariant [6, Corollary 9.53], and all surface groups of genus $g \geq 2$ are commensurable [8, Proposition 6.7]. By combining these two facts with Theorem 19, we obtain the undecidability of domino problem for surface groups of any genus $g \geq 2$. As the domino problem on $\mathbb{Z}^2$ –the surface group of genus 1– is undecidable, we obtain our result. ◀

6 Remarks about word-hyperbolic groups

Surface groups of genus $g \geq 2$ are special cases of a larger class of groups called *word-hyperbolic*. They can be characterized as the finitely presented groups for which Dehn's algorithm solves the word problem. An important property of the domino problem is that groups which contain subgroups with undecidable domino problem have themselves undecidable domino problem [6, Proposition 9.3.30]. This means that every group which contains an embedded copy of a surface group has undecidable domino problem. This is of special relevance due to the following conjecture by Gromov.

▶ **Conjecture 21** (Gromov). *Every one-ended word-hyperbolic group contains an embedded copy of the surface group of genus* 2*.*

In particular, if Gromov's conjecture holds, every one-ended word-hyperbolic group would automatically have undecidable domino problem. A group can have either $0, 1, 2$ or infinitely many ends. In the case when it has 0 ends it is finite and thus its domino problem is trivially decidable, and whenever it has 2 ends it is virtually $\mathbb{Z}$ and thus it is also decidable. In the case of a finitely presented group G, a fundamental result by Dunwoody [11] shows that if G has infinitely many ends it can be expressed as the fundamental group of a finite graph of groups such that every edge is a finite group and all vertices are either finite or 1-ended. It can also be shown [16] that G is virtually free if and only if all of the vertex groups in its decomposition are finite. Therefore, if G is not virtually free, it must contain a one-ended subgroup. In the case of word-hyperbolic groups, every such group in the decomposition must also be word-hyperbolic [7]. In other words, every word-hyperbolic group which is not virtually free contains a one-ended word-hyperbolic group. This implies the following.

▶ **Proposition 22.** *If Gromov's conjecture holds then the domino problem conjecture holds for all word-hyperbolic groups.*

In fact, we could obtain the same result with an even weaker version of Gromov's conjecture. We say a group G acts *translation-like* on a metric space (X, d) if the action is free and $\sup_{x \in X} d(x, gx) < \infty$ for every $g \in G$. Clearly, if H is a subgroup of G then H acts translation like on any Cayley graph of G by multiplication. A theorem by Jeandel [14] shows that if a finitely presented group H acts translation like on a Cayley graph of a finitely generated group G, then the domino problem of H is many-one reducible to the domino problem on G, in particular, we obtain that any group on which the surface group of genus 2 acts translation-like has undecidable domino problem.

▶ **Proposition 23.** *If every* 1*-ended word-hyperbolic group admits a translation-like action of the surface group of genus* 2*, then the domino problem conjecture holds for all word-hyperbolic groups.*

P-Optimal Proof Systems for Each NP-Set but no Complete Disjoint NP-Pairs Relative to an Oracle

Titus Dose
Julius-Maximilians-Universität Würzburg, Germany

Abstract

Pudlák [17] lists several major conjectures from the field of proof complexity and asks for oracles that separate corresponding relativized conjectures. Among these conjectures are:

- DisjNP: The class of all disjoint NP-pairs has no many-one complete elements.
- SAT: NP contains no many-one complete sets that have P-optimal proof systems.
- UP: UP has no many-one complete problems.
- $\mathsf{NP} \cap \mathsf{coNP}$: $\mathrm{NP} \cap \mathrm{coNP}$ has no many-one complete problems.

As one answer to this question, we construct an oracle relative to which DisjNP, $\neg\mathsf{SAT}$, UP, and $\mathsf{NP}\cap\mathsf{coNP}$ hold, i.e., there is no relativizable proof for the implication $\mathsf{DisjNP}\wedge\mathsf{UP}\wedge\mathsf{NP}\cap\mathsf{coNP} \Rightarrow \mathsf{SAT}$. In particular, regarding the conjectures by Pudlák this extends a result by Khaniki [9]. Since Khaniki [9] constructs an oracle showing that the implication $\mathsf{SAT} \Rightarrow \mathsf{DisjNP}$ has no relativizable proof, we obtain that the conjectures DisjNP and SAT are independent in relativized worlds, i.e., none of the implications $\mathsf{DisjNP} \Rightarrow \mathsf{SAT}$ and $\mathsf{SAT} \Rightarrow \mathsf{DisjNP}$ can be proven relativizably.

1 Introduction

The main motivation for the present paper is an article by Pudlák [17] that is “motivated by the problem of finding finite versions of classical incompleteness theorems”, investigates major conjectures in the field of proof complexity, discusses their relations, and draws new connections between the conjectures. Among others, Pudlák conjectures the following assertions (note that within the present paper all reductions are polynomial-time-bounded):

- CON (resp., SAT): coNP (resp., NP) contains no many-one complete sets that have P-optimal proof systems
- $\mathsf{CON}^{\mathsf{N}}$: coNP contains no many-one complete sets that have optimal proof systems, (note that $\mathsf{CON}^{\mathsf{N}}$ is the non-uniform version of CON)
- DisjNP (resp., $\mathsf{DisjCoNP}$): The class of all disjoint NP-pairs (resp., coNP-pairs) has no many-one complete elements,
- TFNP: The class of all total polynomial search problems has no complete elements,
- $\mathsf{NP} \cap \mathsf{coNP}$ (resp., UP): $\mathrm{NP} \cap \mathrm{coNP}$ (resp., UP, the class of problems accepted by NP machines with at most one accepting path for each input) has no many-one complete elements.

The following figure contains the conjectures by Pudlák and illustrates the state of the art regarding (i) known implications and (ii) separations in terms of oracles that prove the non-existence of relativizable proofs for implications. O denotes the oracle constructed in the present paper.

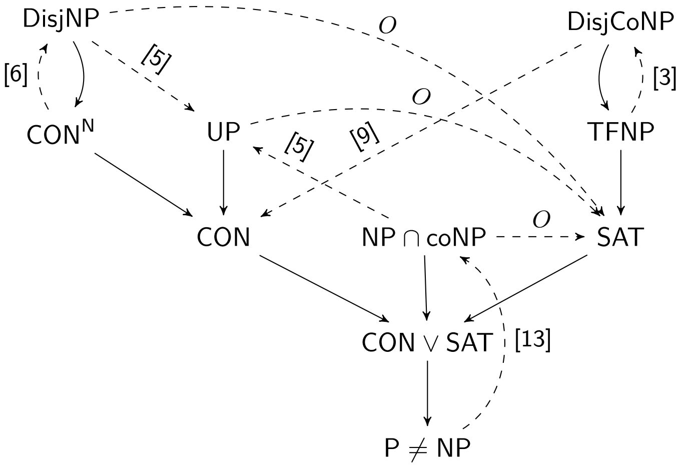

Figure 1 Solid arrows mean implications. All implications in the graphic can be proven with relativizable proofs. A dashed arrow from A to B means that there is an oracle X against the implication A ⇒ B, i.e., relative to X, it holds A ∧ ¬B. Pudlák [17] also defines the conjecture RFN$_1$ and lists it between CON ∨ SAT and P ≠ NP, i.e., CON ∨ SAT ⇒ RFN$_1$ ⇒ P ≠ NP. Khaniki [9] even shows CON ∨ SAT ⇔ RFN$_1$, which is why we omit RFN$_1$ in the figure.

The main conjectures of [17] are CON and TFNP. Let us give some background on these conjectures (for details we refer to [16]) and on the notion of disjoint pairs. The first main conjecture CON refers to the notion of proof systems introduced by Cook and Reckhow [2], who define a proof system for a set A to be a polynomial-time computable function whose range is A. The remainder of this paragraph originates from [5]. CON has an interesting connection to some finite version of an incompleteness statement. Denote by $\mathrm{Con}_T(n)$ the finite consistency of a theory T, i.e., $\mathrm{Con}_T(n)$ is the statement that T has no proofs of contradiction of length $\leq n$. Krajícek and Pudlák [12] raise the conjectures CON and CON$^\mathsf{N}$ and show that the latter is equivalent to the statement that there is no finitely axiomatized theory S which proves the finite consistency $\mathrm{Con}_T(n)$ for every finitely axiomatized theory T by a proof of polynomial length in n. In other words, ¬CON$^\mathsf{N}$ expresses that a weak version of Hilbert's program (to prove the consistency of all mathematical theories) is possible [15]. Correspondingly, ¬CON is equivalent to the existence of a theory S such that, for any fixed theory T, proofs of $\mathrm{Con}_T(n)$ in S can be constructed in polynomial time in n [12].

The conjecture TFNP was raised by Megiddo and Papadimitriou, is implied by the non-existence of disjoint coNP-pairs [1, 17], and implies that no NP-complete set has P-optimal proof systems [1, 17]. It states the non-existence of total polynomial search problems that are complete with respect to polynomial reductions.

The notion of disjoint NP-pairs, i.e., pairs (A, B) with $A \cap B = \emptyset$ and $A, B \in \mathrm{NP}$, was introduced by Grollman and Selman [7] in order to characterize promise problems. Razborov [18] connects it with the concept of propositional proof systems (pps), i.e., proof systems for the set of propositional tautologies TAUT, defining for each pps f a disjoint NP-pair, the so-called canonical pair of f, and showing that the canonical pair of an optimal pps f is complete. Hence, DisjNP ⇒ CON$^\mathsf{N}$.

In contrast to the many implications only very few oracles were known separating two of the relativized conjectures [17], which is why Pudlák asks for further oracles showing relativized conjectures to be different.

Khaniki [9] partially answers this question: besides proving two of the conjectures to be equivalent, he presents two oracles $\mathcal{V}$ and $\mathcal{W}$ showing that SAT and CON (just as TFNP and CON) are independent in relativized worlds, which means that none of the two possible implications between the two conjectures has a relativizable proof. To be more precise, relative to $\mathcal{V}$, there exist P-optimal propositional proof systems but no many-one complete disjoint coNP-pairs, where, as mentioned above, the latter implies TFNP and SAT. Relative to $\mathcal{W}$, there exist no P-optimal propositional proof systems and each total polynomial search problem has a polynomial-time solution, where the latter implies ¬SAT [10].

Dose and Glaßer [5] construct an oracle X that also separates some of the above relativized conjectures. Relative to X there exist no many-one complete disjoint NP-pairs, UP has many-one complete problems, and NP ∩ coNP has no many-one complete problems. In particular, relative to X, there do not exist P-optimal propositional proof systems. Thus, among others, X shows that the conjectures CON and UP as well as NP ∩ coNP and UP cannot be proven equivalent with relativizable proofs.

In another paper [3], the author adds one more oracle to this list proving that there is no relativizable proof for the implication TFNP ⇒ DisjCoNP.

Our Contribution

In the present paper we construct an oracle O relative to which

1. The class of all disjoint NP-pairs has no many-one complete elements.
2. NP contains no many-one complete sets that have P-optimal proof systems.
3. UP has no many-one complete problems.
4. NP ∩ coNP has no many-one complete problems.

Indeed, relative to O there even exist no disjoint NP-pairs hard for NP ∩ coNP, which implies both 1 and 4. Among others, the oracle shows that there are no relativizable proofs for the implications NP ∩ coNP ⇒ SAT and UP ⇒ SAT. Let us now focus on the properties 1 and 2 of the oracle. Regarding these, our oracle has similar properties as the aforementioned oracle $\mathcal{W}$ by Khaniki [9]: both oracles show that there is no relativizable proof for the implication CON ⇒ SAT. Relative to Khaniki's oracle $\mathcal{W}$ it even holds that each total polynomial search problem has a polynomial time solution, which implies not only ¬SAT but also that all optimal proof systems for SAT are P-optimal [10]. Regarding Pudlák's conjectures, however, our oracle O extends Khaniki's result as relative to O we have the even stronger result that there is no relativizable proof for the implication DisjNP ⇒ SAT. Since due to the oracle $\mathcal{V}$ by Khaniki [9] none of the implications DisjCoNP ⇒ DisjNP, TFNP ⇒ DisjNP, and SAT ⇒ DisjNP can be proven relativizably, our oracle shows that DisjNP is independent of each of the conjectures DisjCoNP, TFNP, and SAT in relativized worlds, i.e., none of the six possible implications has a relativizable proof.

2 Preliminaries

Major parts of this section are copied from our paper [5] coauthored by Christian Glaßer. Throughout this paper let Σ be the alphabet $\{0, 1\}$. We denote the length of a word $w \in \Sigma^*$ by $|w|$. Let $\Sigma^{\leq n} = \{w \in \Sigma^* \mid |w| \leq n\}$ and $\Sigma^{>n} = \{w \in \Sigma^* \mid |w| > n\}$. The empty word is denoted by ε and the i-th letter of a word w for $0 \leq i < |w|$ is denoted by $w(i)$, i.e., $w = w(0)w(1)\cdots w(|w| - 1)$. If v is a prefix of w, i.e., $|v| \leq |w|$ and $v(i) = w(i)$ for all $0 \leq i < |v|$, then we write $v \sqsubseteq w$. For any finite set $Y \subseteq \Sigma^*$, let $\ell(Y) \overset{df}{=} \sum_{w \in Y} |w|$.

$\mathbb{Z}$ denotes the set of integers, $\mathbb{N}$ denotes the set of natural numbers, and $\mathbb{N}^+ = \mathbb{N} - \{0\}$. The set of primes is denoted by $\mathbb{P} = \{2, 3, 5, \dots\}$ and $\mathbb{P}^{\geq 3}$ denotes the set $\mathbb{P} - \{2\}$.

We identify Σ^* with $\mathbb{N}$ via the polynomial-time computable, polynomial-time invertible bijection $w \mapsto \sum_{i<|w|}(1 + w(i))2^{|w|-1-i}$, which is a variant of the dyadic encoding. Hence, notations, relations, and operations for Σ^* are transferred to $\mathbb{N}$ and vice versa. In particular,

$|n|$ denotes the length of $n \in \mathbb{N}$. We eliminate the ambiguity of the expressions 0^i and 1^i by always interpreting them over Σ^*.

Let $\langle\cdot\rangle : \bigcup_{i\geq 0} \mathbb{N}^i \to \mathbb{N}$ be an injective, polynomial-time computable, polynomial-time invertible pairing function such that $|\langle u_1, \dots, u_n\rangle| = 2(|u_1| + \dots + |u_n| + n)$.

Given two sets A and B, $A - B$ denotes the set difference between A and B. The complement of a set A relative to the universe U is denoted by $\overline{A} = U - A$. The universe will always be apparent from the context. Furthermore, the symmetric difference is denoted by $\triangle$, i.e., $A \triangle B = (A - B) \cup (B - A)$ for arbitrary sets A and B.

The domain and range of a function t are denoted by $\mathrm{dom}(t)$ and $\mathrm{ran}(t)$, respectively.

FP, P, and NP denote standard complexity classes [14]. Define $\mathrm{co}\mathcal{C} = \{A \subseteq \Sigma^* \mid \overline{A} \in \mathcal{C}\}$ for a class $\mathcal{C}$. UP is the class of all problems accepted by nondeterministic polynomial-time Turing machines with at most one accepting path for each input. If $A, B \in \mathrm{NP}$ (resp., $A, B \in \mathrm{coNP}$) and $A \cap B = \emptyset$, then we call (A, B) a disjoint NP-pair (resp., a disjoint coNP-pair). The set of all disjoint NP-pairs (resp., coNP-pairs) is denoted by DisjNP (resp., DisjCoNP). We also consider all these complexity classes in the presence of an oracle O and denote the corresponding classes by FP^O, P^O, NP^O, and so on.

Let M be a Turing machine. $M^D(x)$ denotes the computation of M on input x with D as an oracle. For an arbitrary oracle D we let $L(M^D) = \{x \mid M^D(x) \text{ accepts}\}$. For a deterministic polynomial-time Turing transducer (i.e., a Turing machine computing a function), depending on the context, $F^D(x)$ either denotes the computation of F on input x with D as an oracle or the output of this computation.

▶ **Definition 1.** *A sequence $(M_i)_{i\in\mathbb{N}^+}$ is called* standard enumeration *of nondeterministic, polynomial-time oracle Turing machines, if it has the following properties:*

1. *All M_i are nondeterministic, polynomial-time oracle Turing machines.*
2. *For all oracles D and all inputs x the computation $M_i^D(x)$ stops within $|x|^i + i$ steps.*
3. *For every nondeterministic, polynomial-time oracle Turing machine M there exist infinitely many $i \in \mathbb{N}$ such that for all oracles D it holds that $L(M^D) = L(M_i^D)$.*
4. *There exists a nondeterministic, polynomial-time oracle Turing machine M such that for all oracles D and all inputs x it holds that $M^D(\langle i, x, 0^{|x|^i+i}\rangle)$ nondeterministically simulates the computation $M_i^D(x)$.*

Analogously we define standard enumerations of deterministic, polynomial-time oracle Turing transducers.

Throughout this paper, we fix some standard enumerations. Let $M_1, M_2, \dots$ be a standard enumeration of nondeterministic polynomial-time oracle Turing machines. Then for every oracle D, the sequence $(M_i)_{i\in\mathbb{N}^+}$ represents an enumeration of the languages in NP^D, i.e., $\mathrm{NP}^D = \{L(M_i^D) \mid i \in \mathbb{N}\}$, where as usual a computation $M_i^D(x)$ accepts if and only if it has at least one accepting path. Let $F_1, F_2, \dots$ be a standard enumeration of polynomial time oracle Turing transducers. By the properties of standard enumerations, for each oracle D the following problem is NP^D-complete (in particular it is in NP^D):

$$K^D = \{\langle 0^i, 0^t, x\rangle \mid M_i^D(x) \text{ accepts within } t \text{ steps}\}.$$

Let D be an oracle and $A, B, A', B' \subseteq \Sigma^*$ such that $A \cap B = A' \cap B' = \emptyset$. In this paper we always use the following reducibility for disjoint pairs [18]. (A', B') is polynomially many-one reducible to (A, B), denoted by $(A', B') \leq_{\mathrm{m}}^{\mathrm{pp},D} (A, B)$, if there exists $f \in \mathrm{FP}^D$ with $f(A') \subseteq A$ and $f(B') \subseteq B$. If $A' = \overline{B'}$, then we also write $A' \leq_{\mathrm{m}}^{\mathrm{p},D} (A, B)$ instead of $(A', B') \leq_{\mathrm{m}}^{\mathrm{pp},D} (A, B)$.

We say that (A, B) is $\leq_{\mathrm{m}}^{\mathrm{pp},D}$*-hard* ($\leq_{\mathrm{m}}^{\mathrm{pp},D}$*-complete*) *for* DisjNP^D if $(A', B') \leq_{\mathrm{m}}^{\mathrm{pp},D} (A, B)$ for all $(A', B') \in \mathrm{DisjNP}^D$ (and $(A, B) \in \mathrm{DisjNP}^D$). Moreover, a pair (A, B) is $\leq_{\mathrm{m}}^{\mathrm{p},D}$*-hard for* $\mathrm{NP}^D \cap \mathrm{coNP}^D$ if $A' \leq_{\mathrm{m}}^{\mathrm{p},D} (A, B)$ for every $A \in \mathrm{NP}^D \cap \mathrm{coNP}^D$.

▶ **Definition 2** ([2]). *A function $f \in \mathrm{FP}$ is called* proof system *for the set* $\mathrm{ran}(f)$*. For* $f, g \in \mathrm{FP}$ *we say that* f is simulated by g *(resp.,* f is P-simulated by g*) denoted by* $f \leq g$ *(resp.,* $f \leq^{\mathrm{p}} g$*), if there exists a function* π *(resp., a function* $\pi \in \mathrm{FP}$*) and a polynomial* p *such that* $|\pi(x)| \leq p(|x|)$ *and* $g(\pi(x)) = f(x)$ *for all* x*. A function* $g \in \mathrm{FP}$ *is* optimal *(resp.,* P-optimal*), if* $f \leq g$ *(resp.,* $f \leq^{\mathrm{p}} g$*) for all* $f \in \mathrm{FP}$ *with* $\mathrm{ran(f)} = \mathrm{ran(g)}$*. Corresponding relativized notions are obtained by using* P^O*,* FP^O*, and* $\leq^{\mathrm{p},O}$ *in the definitions above.*

The following proposition states the relativized version of a result by Köbler, Messner, and Torán [11], which they show with a relativizable proof.

▶ **Proposition 3** ([11]). *For every oracle* O*, if* A *has a* P^O*-optimal (resp., optimal) proof system and* $B \leq_{\mathrm{m}}^{\mathrm{p},O} A$*, then* B *has a* P^O*-optimal (resp., optimal) proof system.*

▶ **Corollary 4.** *For every oracle* O*, if there exists a* $\leq_{\mathrm{m}}^{\mathrm{p},O}$*-complete* $A \in \mathrm{NP}^O$ *that has a* P^O*-optimal (resp., optimal) proof system, then all sets in* NP^O *have* P^O*-optimal (resp., optimal) proof systems.*

Let us introduce some notations that are designed for the construction of oracles [5]. The support $\mathrm{supp}(t)$ of a real-valued function t is the subset of the domain that consists of all values that t does not map to 0. We say that a partial function t is injective on its support if $t(i, j) = t(i', j')$ for $(i, j), (i', j') \in \mathrm{supp}(t)$ implies $(i, j) = (i', j')$. If a partial function t is not defined at point x, then $t \cup \{x \mapsto y\}$ denotes the extension of t that at x has value y.

If A is a set, then $A(x)$ denotes the characteristic function at point x, i.e., $A(x)$ is 1 if $x \in A$, and 0 otherwise. An oracle $D \subseteq \mathbb{N}$ is identified with its characteristic sequence $D(0)D(1)\cdots$, which is an ω-word. In this way, $D(i)$ denotes both, the characteristic function at point i and the i-th letter of the characteristic sequence, which are the same. A finite word w describes an oracle that is partially defined, i.e., only defined for natural numbers $x < |w|$. We can use w instead of the set $\{i \mid w(i) = 1\}$ and write for example $A = w \cup B$, where A and B are sets. For nondeterministic oracle Turing machines M we use the following phrases: a computation $M^w(x)$ *definitely accepts*, if it contains a path that accepts and the queries on this path are $< |w|$. A computation $M^w(x)$ *definitely rejects*, if all paths reject and all queries are $< |w|$. For a nondeterministic Turing machine M we say that the computation $M^w(x)$ *is defined*, if it definitely accepts or definitely rejects. For a polynomial time oracle transducer F, the computation $F^w(x)$ *is defined*, if all queries are $< |w|$.

3 Oracle Construction

The following lemma is a slightly adapted variant of a result from [5].

▶ **Lemma 5.** *For all* $y \leq |w|$ *and all* $v \sqsupseteq w$ *it holds* $y \in K^v \Leftrightarrow y \in K^w$*.*

▶ **Theorem 6.** *There exists an oracle* O *such that the following statements hold:*

- DisjNP^O *contains no pairs that are* $\leq_{\mathrm{m}}^{\mathrm{p},O}$*-hard for* $\mathrm{NP}^O \cap \mathrm{coNP}^O$*.*
- *Each* $L \in \mathrm{NP}^O$ *has* P^O*-optimal proof systems.*
- UP^O *contains no* $\leq_{\mathrm{m}}^{\mathrm{p},O}$*-complete problems.*

Observe that the first of the three statements implies that both DisjNP^O contains no $\leq_{\mathrm{m}}^{\mathrm{pp},O}$-complete pairs and $\mathrm{NP}^O \cap \mathrm{coNP}^O$ contains no $\leq_{\mathrm{m}}^{\mathrm{p},O}$-complete problems.

Proof. Let D be a (possibly partial) oracle and p (resp., q) be in $\mathbb{P}_3$ (resp., $\mathbb{P}_1$). We define

$$\begin{aligned} A_p^D &:= \{0^{p^k} \mid k \in \mathbb{N}^+, \exists_{x\in\Sigma^{p^k}} x \in D \text{ and } x \text{ odd}\} \cup \overline{\{0^{p^k} \mid k \in \mathbb{N}^+\}} \\ B_p^D &:= \{0^{p^k} \mid k \in \mathbb{N}^+, \exists_{x\in\Sigma^{p^k}} x \in D \text{ and } x \text{ even}\} \\ C_q^D &:= \{0^{q^k} \mid k \in \mathbb{N}^+, \exists_{x\in\Sigma^{q^k}} x \in D\} \end{aligned}$$

Note that $A_p^D, B_p^D \in \mathrm{NP}^D$ and $A_p^D = \overline{B_p^D}$ if $|\Sigma^{p^k} \cap D| = 1$ for each $k \in \mathbb{N}^+$. In that case $A_p^D \in \mathrm{NP}^D \cap \mathrm{coNP}^D$. Moreover, $C_q^D \in \mathrm{UP}^D$ if and only if $|\Sigma^{q^k} \cap D| \leq 1$ for each $k \in \mathbb{N}^+$.

For the sake of simplicity, let us call a pair (M_i, M_j) an $\mathrm{NP}^D \cap \mathrm{coNP}^D$-machine if $L(M_i^D) = \overline{L(M_j^D)}$. For $i \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$ we write $c(i,x,y) := \langle 0^i, 0^{|x|^i+i}, x, y\rangle$. Thus, $|c(i,x,y)|$ is even. Note that throughout this proof we sometimes omit the oracles in the superscript, e.g., we write NP or A_p instead of NP^D or A_p^D. However, we do not do that in the "actual" proof but only when explaining ideas in a loose way in order to give the reader the intuition behind the occasionally very technical arguments.
Preview of construction. We sketch some of the very basic ideas our construction uses.

1. For all positive $i \neq j$ the construction tries to achieve that (M_i, M_j) is not an $\mathrm{NP} \cap \mathrm{coNP}$-machine. If this is not possible, then $(L(M_i), L(M_j))$ inherently is an $\mathrm{NP} \cap \mathrm{coNP}$-machine. Once we know this, we choose some odd prime p and diagonalize against all FP-functions such that $A_p = \overline{B_p}$ and A_p is not $\leq_\mathrm{m}^\mathrm{p}$-reducible to $(L(M_i), L(M_j))$.
2. For all $i \geq 1$ the construction intends to make sure that F_i is not a proof system for K. If this is not possible, then F_i inherently is a proof system for K and then we start to encode the values of F_i into the oracle. However, it is important to also allow encodings for functions that are not known to be proof systems for K yet. Regarding the P-optimal proof systems, our construction is based on ideas by Dose and Glaßer [5].
3. For all $i \geq 1$ the construction tries to ensure that M_i is not a UP-machine. If this is not possible, we know that M_i inherently is a UP machine, which enables us to diagonalize against all FP-functions so that C_q for some q that we choose is not reducible to $L(M_i)$.

▷ Claim 7. Let $w \in \Sigma^*$ be an oracle, $i \in \mathbb{N}^+$, and $x, y \in \mathbb{N}$ such that $c(i,x,y) \leq |w|$. Then the following holds.

1. $F_i^w(x)$ is defined and $F_i^w(x) < |w|$.
2. $F_i^w(x) \in K^w \Leftrightarrow F_i^w(x) \in K^v$ for all $v \sqsupseteq w$.

During the construction we maintain a growing collection of requirements that is represented by a partial function belonging to the set

$$\mathcal{T} = \Big\{ t : \mathbb{N}^+ \cup (\mathbb{N}^+)^2 \to \mathbb{Z} \mid \mathrm{dom}(t) \text{ is finite, } t \text{ is injective on its support,} \\ \blacksquare\ t(\mathbb{N}^+) \subseteq \{0\} \cup \mathbb{N}^+ \\ \blacksquare\ t(\{(i,i) \mid i \in \mathbb{N}^+\}) \subseteq \{0\} \cup \{-q \mid q \in \mathbb{P}_1\} \\ \blacksquare\ t(\{(i,j) \in (\mathbb{N}^+)^2 \mid i \neq j\}) \subseteq \{0\} \cup \{-p \mid p \in \mathbb{P}_3\} \Big\}.$$

A partial oracle w is called t-valid for $t \in \mathcal{T}$ if it satisfies the following properties.

V1 For all $i \in \mathbb{N}^+$ and all $x, y \in \mathbb{N}$, if $c(i,x,y) \in w$, then $F_i^w(x) = y \in K^w$.
(meaning: if the oracle contains the codeword $c(i,x,y)$, then $F_i^w(x)$ outputs $y \in K^w$; hence, $c(i,x,y) \in w$ is a proof for $y \in K^w$)

V2 For all distinct $i, j \in \mathbb{N}^+$, if $t(i,j) = 0$, then there exists x such that $M_i^w(x)$ and $M_j^w(x)$ definitely accept.
(meaning: for every extension of the oracle, $(L(M_i), L(M_j))$ is not a disjoint NP-pair.)

V3 For all distinct $i, j \in \mathbb{N}^+$ with $t(i,j) = -p$ for some $p \in \mathbb{P}_3$ and each $k \in \mathbb{N}^+$, it holds (i) $|\Sigma^{p^k} \cap w| \leq 1$ and (ii) if w is defined for all words of length p^k, then $|\Sigma^{p^k} \cap w| = 1$.
(meaning: if $t(i,j) = -p$, then ensure that $A_p = \overline{B_p}$ (i.e., $A_p \in \mathrm{NP} \cap \mathrm{coNP}$) relative to the final oracle.)

V4 For all $i \in \mathbb{N}^+$ with $t(i) = 0$, there exists x such that $F_i^w(x)$ is defined and $F_i^w(x) \notin K^v$ for all $v \sqsupseteq w$.
(meaning: for every extension of the oracle, F_i is not a proof system for K)

V5 For all $i \in \mathbb{N}^+$ and $x \in \mathbb{N}$ with $0 < t(i) \leq c(i, x, F_i^w(x)) < |w|$, it holds $c(i, x, F_i^w(x)) \in w$.
(meaning: if $t(i) > 0$, then from $t(i)$ on, we encode the values of F_i into the oracle.
Note that V5 is not in contradiction with e.g. V3 or V7 as $|c(\cdot,\cdot,\cdot)|$ is even.)

V6 For all $i \in \mathbb{N}^+$ with $t(i,i) = 0$, there exists x such that $M_i^w(x)$ is defined and has two accepting paths.
(meaning: for every extension of the oracle, M_i is not a UP-machine.)

V7 For all $i \in \mathbb{N}^+$ with $t(i,i) = -q \in \mathbb{P}_1$ and each $k \in \mathbb{N}^+$, it holds $|\Sigma^{q^k} \cap w| \leq 1$.
(meaning: if $t(i,i) = -q$, ensure that C_q is in UP.)

▷ Claim 8. Let $t, t' \in \mathcal{T}$ such that t' is an extension of t. For all oracles $w \in \Sigma^*$, if w is t'-valid, then w is t-valid.

▷ Claim 9. Let $t \in \mathcal{T}$ and $u, v, w \in \Sigma^*$ be oracles such that $u \sqsubseteq v \sqsubseteq w$ and both u and w are t-valid. Then v is t-valid.

Oracle construction. Let T be an enumeration of $\bigcup_{i=1}^{3} (\mathbb{N}^+)^i$ having the property that (i,j) appears earlier than (i,j,r) for all $i,j,r \in \mathbb{N}^+$. Each element of T stands for a task. We treat the tasks in the order specified by T and after treating a task we remove it and possibly other tasks from T. We start with the nowhere defined function t_0 and the t_0-valid oracle $w_0 = \varepsilon$. Then we define functions $t_1, t_2, \ldots$ in $\mathcal{T}$ such that t_{i+1} is an extension of t_i and partial oracles $w_0 \sqsubsetneq w_1 \sqsubsetneq w_2 \sqsubsetneq \ldots$ such that each w_i is t_i-valid. Finally, we choose $O = \bigcup_{i=0}^{\infty} w_i$ (note that O is totally defined since in each step we strictly extend the oracle). We describe step $s > 0$, which starts with a t_{s-1}-valid oracle w_{s-1} and extends it to a t_s-valid $w_s \sqsupsetneq w_{s-1}$ (it will be argued later that all these steps are indeed possible). Let us recall that each task is immediately deleted from T after it is treated.

- Task i: Let $t' = t_{s-1} \cup \{i \mapsto 0\}$. If there exists a t'-valid $v \sqsupsetneq w_{s-1}$, then let $t_s = t'$ and $w_s = v$. Otherwise, let $t_s = t_{s-1} \cup \{i \mapsto |w_{s-1}|\}$ and choose $w_s = w_{s-1}b$ for $b \in \{0,1\}$ such that w_s is t_s-valid.
(meaning: try to ensure that F_i is not a proof system for K. If this is impossible, require that the values of F_i are encoded into the oracle.)
- Task (i,j) with $i \neq j$: Let $t' = t_{s-1} \cup \{(i,j) \mapsto 0\}$. If there exists a t'-valid $v \sqsupsetneq w_{s-1}$, then let $t_s = t'$ as well as $w_s = v$ and delete all tasks $(i,j,\cdot)$ from T. Otherwise, let $z = |w_{s-1}|$, choose $p \in \mathbb{P}_3$ greater than $|z|$ and all p' with $p' \in \mathbb{P}^{\geq 3}$ and $-p' \in \mathrm{ran}(t_{s-1})$, let $t_s = t_{s-1} \cup \{(i,j) \mapsto -p\}$, and choose $w_s = w_{s-1}b$ for $b \in \{0,1\}$ such that w_s is t_s-valid.
(meaning: try to ensure that $(L(M_i), L(M_j))$ is not a disjoint NP-pair. If this is impossible, choose a sufficiently large prime p. It will be made sure later that A_p does not reduce to $(L(M_i), L(M_j))$.)
- Task (i,j,r) with $i \neq j$: It holds $t_{s-1}(i,j) = -p$ for a prime $p \in \mathbb{P}_3$, since otherwise, this task would have been deleted in the treatment of task (i,j). Define $t_s = t_{s-1}$ and choose a t_s-valid $w_s \sqsupsetneq w_{s-1}$ such that for some $n \in \mathbb{N}^+$ one of the following two statements holds:

  - $0^n \in A_p^v$ for all $v \sqsupseteq w_s$ and $M_i^{w_s}(F_r^{w_s}(0^n))$ definitely rejects.
  - $0^n \in B_p^v$ for all $v \sqsupseteq w_s$ and $M_j^{w_s}(F_r^{w_s}(0^n))$ definitely rejects.

  (meaning: make sure that it does not hold $A_p \leq_{\mathrm{m}}^{\mathrm{p}} (L(M_i), L(M_j))$ via F_r)
- Task (i,i): Let $t' = t_{s-1} \cup \{(i,i) \mapsto 0\}$. If there exists a t'-valid $v \sqsupsetneq w_{s-1}$, then let $t_s = t'$ as well as $w_s = v$ and delete all tasks $(i,i,\cdot)$ from T. Otherwise, let $z = |w_{s-1}|$, choose $q \in \mathbb{P}_1$ greater than $|z|$ and all p' with $p' \in \mathbb{P}^{\geq 3}$ and $-p' \in \mathrm{ran}(t_{s-1})$, let $t_s = t_{s-1} \cup \{(i,i) \mapsto -q\}$, and choose $w_s = w_{s-1}b$ for $b \in \{0,1\}$ such that w_s is t_s-valid.

  (meaning: try to ensure that M_i is not a UP-machine. If this is impossible, choose a sufficiently large prime q. It will be made sure later that C_q does not reduce to $L(M_i)$.)
- Task (i,i,r): It holds $t_{s-1}(i,j) = -q$ for a prime $q \in \mathbb{P}_1$, since otherwise, this task would have been deleted in the treatment of task (i,i). Define $t_s = t_{s-1}$ and choose a t_s-valid $w_s \sqsupsetneq w_{s-1}$ such that for some $n \in \mathbb{N}^+$ one of the following conditions holds:
  - $0^n \in C_q^v$ for all $v \sqsupseteq w_s$ and $M_i^{w_s}(F_r^{w_s}(0^n))$ definitely rejects.
  - $0^n \notin C_q^v$ for all $v \sqsupseteq w_s$ and $M_i^{w_s}(F_r^{w_s}(0^n))$ definitely accepts.

  (meaning: make sure that it does not hold $C_q \leq_{\mathrm{m}}^{\mathrm{p}} L(M_i)$ via F_r)

We now show that the construction is possible. For that purpose, we first describe how a valid oracle can be extended by one bit such that it remains valid.

▷ Claim 10. Let $s \in \mathbb{N}$ and $w \in \Sigma^*$ be a t_s-valid oracle with $w \sqsupseteq w_s$. It holds for $z = |w|$:

1. If $z = c(i,x,y)$ for $i \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$, $0 < t_s(i) \leq z$, and $F_i^w(x) = y$, then $y \in K^v$ for all $v \sqsupseteq w$.
2. There exists $b \in \{0,1\}$ such that wb is t_s-valid. In detail, the following statements hold.
   a. If $|z|$ is odd and for all $p \in \mathbb{P}$ and $k \in \mathbb{N}^+$ with $-p \in \mathrm{ran}(t_s)$ it holds $|z| \neq p^k$, then $w0$ and $w1$ are t_s-valid.
   b. If there exist $p \in \mathbb{P}_3$ and $k \in \mathbb{N}^+$ with $-p \in \mathrm{ran}(t_s)$ such that $|z| = p^k$, $z \neq 1^{p^k}$, and $w \cap \Sigma^{p^k} = \emptyset$, then $w0$ and $w1$ are t_s-valid.
   c. If there exist $p \in \mathbb{P}_3$ and $k \in \mathbb{N}^+$ with $-p \in \mathrm{ran}(t_s)$ such that $z = 1^{p^k}$ and $w \cap \Sigma^{p^k} = \emptyset$, then $w1$ is t_s-valid.
   d. If there exist $q \in \mathbb{P}_1$ and $k \in \mathbb{N}^+$ with $-q \in \mathrm{ran}(t_s)$ such that $|z| = q^k$ and $w \cap \Sigma^{q^k} = \emptyset$, then $w0$ and $w1$ are t_s-valid.
   e. If $z = c(i,x,y)$ for $i \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$, $0 < t_s(i) \leq z$, and $F_i^w(x) = y$, then $w1$ is t_s-valid and $F_i^{w1}(x) = y$.
   f. In all other cases (i.e., none of the assumptions in (a)–(e) holds) $w0$ is t_s-valid.

In order to show that the above construction is possible, assume that it is not possible and let $s > 0$ be the least number such that it fails in step s.

If step s treats a task $t \in \mathbb{N}^+ \cup (\mathbb{N}^+)^2$, then $t_{s-1}(t)$ is not defined, since the value of t is defined in the unique treatment of the task t. If $t_s(t)$ is chosen to be 0, then the construction clearly is possible. Otherwise, due to the choice of $t_s(t)$, the t_{s-1}-valid oracle w_{s-1} is even t_s-valid and Claim 10 ensures that there exists a t_s-valid $w_{s-1}b$ for some $b \in \{0,1\}$. Hence, the construction does not fail in step s, a contradiction.

For the remainder of the proof that the construction above is possible we assume that step s treats a task $(i,j,r) \in (\mathbb{N}^+)^3$. We treat the cases $i = j$ and $i \neq j$ simultaneously whenever it is possible. Recall that in the case $i = j$ we work for the diagonalization ensuring that $L(M_i)$ is not a complete UP-set and in the case $i \neq j$ we work for the diagonalization ensuring that the pair $(L(M_i), L(M_j))$ is not hard for NP $\cap$ coNP.

In any case, $t_s = t_{s-1}$ and $t_s(i,j) = -p$ for some $p \in \mathbb{P}^{\geq 3}$ (recall $p \in \mathbb{P}_1$ if $i = j$ and $p \in \mathbb{P}_3$ if $i \neq j$). Let $\gamma(x) = (x^r + r)^{i+j} + i + j$ and choose $n = p^k$ for some $k \in \mathbb{N}^+$ such that

$$2^{2n-2} > 2^{n+1} \cdot \gamma(n) \tag{1}$$

and w_{s-1} is not defined for any word of length n. Note that $\gamma(n)$ is not less than the running time of each of the computations $M_i^D(F_r^D(0^n))$ and $M_j^D(F_r^D(0^n))$ for any oracle D.

We define $u \sqsupseteq w_{s-1}$ to be the minimal t_s-valid oracle that is defined for all words of length $< n$. Such an oracle exists by Claim 10.2. Moreover, for $z \in \Sigma^n$, let $u_z \sqsupsetneq u$ be the minimal t_s-valid oracle that contains z and that is defined for all words of length $\leq \gamma(n)$. By Claim 10.2, such oracles exist and $u_z \cap \Sigma^n = \{z\}$ (in detail, the second part follows from (2b, 2c, and 2f) or (2d and 2f) depending on whether $p \in \mathbb{P}_3$ or $p \in \mathbb{P}_1$, for the first part we also need that each valid oracle can be extended by one bit without losing its validity).

▷ Claim 11. Let $z \in \Sigma^n$.

1. For each $\alpha \in u_z \cap \Sigma^{>n}$ one of the following statements holds.
   - $\alpha = 1^{p'^\kappa}$ for some $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t_s)$ and some $\kappa > 0$.
   - $\alpha = c(i', x, y)$ for some $i', x, y \in \mathbb{N}$ with $i' > 0$, $0 < t_s(i') \leq c(i', x, y)$, $F_{i'}^{u_z}(x) = y$, and $y \in K^{u_z}$.
2. For all $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t_s)$ and all $\kappa > 0$, if $n < p'^\kappa \leq \gamma(n)$, then $u_z \cap \Sigma^{p'^\kappa} = \{1^{p'^\kappa}\}$.

Proof. 1. Let $\alpha \in u_z \cap \Sigma^{>n}$. Moreover, let u' be the prefix of u_z that has length α, i.e., α is the least word that u' is not defined for. In particular, it holds $u' \cap \Sigma^{\leq n} = u_z \cap \Sigma^{\leq n}$ and thus, $z \in u'$. As $u \sqsubseteq u' \sqsubseteq u_z$ and both u and u_z are t_s-valid, Claim 9 yields that u' is also t_s-valid. Let us apply Claim 10.2 to the oracle u'. If one of the cases 2a, 2b, 2d, and 2f can be applied, then $u'0$ is t_s-valid and can be extended to a t_s-valid oracle u'' with $|u''| = |u_z|$ by Claim 10.2. As u'' and u_z agree on all words $< \alpha$ and $\alpha \in u'' - u_z$, we obtain $z \in u''$ and $u'' < u_z$. This is a contradiction to the choice of u_z (recall that u_z is the minimal t_s-valid oracle that is defined for all words of length $\leq \gamma(n)$ and contains z).

Hence, by Claim 10.2, either (i) $\alpha = 1^{p'^\kappa}$ for some $p' \in \mathbb{P}_3$ and $\kappa > 0$ with $-p' \in \mathrm{ran}(t_s)$ or (ii) $\alpha = c(i', x, y)$ for $i', x, y \in \mathbb{N}$, $i' > 0$, $0 < t_s(i') \leq \alpha$, and $F_{i'}^{u'}(x) = y$. In the latter case $F_{i'}^{u'}(x)$ is defined by Claim 7 and $y \in K^v$ for all $v \sqsupseteq u'$ by Claim 10.1, which implies $F_{i'}^{u_z}(x) = y \in K^{u_z}$.

2. As $-p' \in \mathrm{ran}(t_s)$ and u_z is t_s-valid, V3 yields that there exists $\beta \in \Sigma^{p'^\kappa} \cap u_z$. Let β be the minimal element of $\Sigma^{p'^\kappa} \cap u_z$. It suffices to show $\beta = 1^{p'^\kappa}$. For a contradiction, we assume $\beta < 1^{p'^\kappa}$. Let u' be the prefix of u_z that is defined for exactly the words of length $< p'^\kappa$. Then $u \sqsubseteq u' \sqsubseteq u_z$ and both u and u_z are t_s-valid. Then by Claim 9, the oracle u' is t_s-valid as well. By Claim 10.2 u' can be extended to a t_s-valid oracle u'' that satisfies $|u''| = |u_z|$ and $u'' \cap \Sigma^{p'^\kappa} = \{1^{p'^\kappa}\}$. The last property guarantees that $u'' < u_z$ because $\beta \in u_z - u''$ and the oracles u'' and u_z agree on all words smaller than β. As furthermore $z \in u''$, we obtain a contradiction to the choice of u_z. This finishes the proof of Claim 11. ◁

We study the case that for some odd (resp., even) $z \in \Sigma^n$ the computation $M_i^{u_z}(F_r^{u_z}(0^n))$ (resp., $M_j^{u_z}(F_r^{u_z}(0^n))$) rejects. Then it even definitely rejects since u_z is defined for all words of length $\gamma(n)$. If $i \neq j$, then $p \in \mathbb{P}_3$ and since $z \in u_z$, we have $0^n \in A_p^v$ for all $v \sqsupseteq u_z$ (resp., $0^n \in B_p^v$ for all $v \sqsupseteq u_z$ if z is even). Analogously, if $i = j$, then $p \in \mathbb{P}_1$ and as $z \in u_z$, we have $0^n \in C_p^v$ for all $v \sqsupseteq u_z$. Hence, in all these cases we can choose $w_s = u_z$ and obtain a contradiction to the assumption that step s of the construction fails.

Therefore, for the remainder of the proof that the construction is possible we assume the following: For each $z \in \Sigma^n$ odd (resp., even) the computation $M_i^{u_z}(F_r^{u_z}(0^n))$ (resp., $M_j^{u_z}(F_r^{u_z}(0^n))$) definitely accepts.

Let U_z for $z \in \Sigma^n$ odd (resp., $z \in \Sigma^n$ even) be the set of all those oracle queries of the least accepting path of $M_i^{u_z}(F_r^{u_z}(0^n))$ (resp., $M_j^{u_z}(F_r^{u_z}(0^n))$) that are of length $\geq n$. Observe

$\ell(U_z) \leq \gamma(n)$. Moreover, define $Q_0(U_z) := U_z$ and for $m \in \mathbb{N}$, define

$$Q_{m+1}(U_z) := \bigcup_{\substack{c(i',x,y) \in Q_m(U_z) \\ i',x,y \in \mathbb{N}, i'>0}} \{q \in \Sigma^{\geq n} \mid q \text{ is queried by } F_{i'}^{u_z}(x)\}.$$

Let $Q(U_z) := \bigcup_{m \in \mathbb{N}} Q_m(U_z)$. Note that all words in $Q(U_z)$ have length $\geq n$.

▷ Claim 12. Let $z \in \Sigma^n$. Then $\ell(Q(U_z)) \leq 2\ell(U_z) \leq 2\gamma(n)$ and for all $q \in Q(U_z)$, $|q| \leq \gamma(n)$.

Proof. We show that for all $m \in \mathbb{N}$, $\ell(Q_{m+1}(U_z)) \leq 1/2 \cdot \ell(Q_m(U_z))$. Then $\sum_{m=0}^{s} 1/2^m \leq 2$ for all $s \in \mathbb{N}$ implies $\ell(Q(U_z)) \leq 2 \cdot \ell(U_z)$. Moreover, from $\ell(U_z) \leq \gamma(n)$ and $\ell(Q_{m+1}(U_z)) \leq 1/2 \cdot \ell(Q_m(U_z))$ the second part of the claim follows.

Let $m \in \mathbb{N}$ and consider an arbitrary element α of $Q_m(U)$. If α is not of the form $c(i', x, y)$ for $i' \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$, then α generates no elements in $Q_{m+1}(U)$. Assume $\alpha = c(i', x, y)$ for $i' \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$. The computation $F_{i'}^{u_z}(x)$ runs for at most $|x|^{i'} + i' < |\alpha|/2$ steps, where "$<$" holds by the definition of $c(\cdot,\cdot,\cdot)$ and the properties of the pairing function $\langle\cdot\rangle$. Hence, the set of queries Q of $F_{i'}^{u_z}(x)$ satisfies $\ell(Q) < |\alpha|/2$. Consequently,

$$\begin{aligned}\ell(Q_{m+1}(U)) &\leq \sum_{\substack{c(i',x,y) \in Q_m(U_z) \\ i',x,y \in \mathbb{N}, i'>0}} \ell\big(\{q \in \Sigma^{\geq n} \mid q \text{ is queried by } F_{i'}^{u_z}(x)\}\big) \\ &\leq \sum_{\substack{c(i',x,y) \in Q_m(U_z) \\ i',x,y \in \mathbb{N}, i'>0}} |c(i',x,y)|/2 \leq \ell(Q_m(U_z))/2,\end{aligned}$$

which finishes the proof of Claim 12. ◁

For $z, z' \in \Sigma^n$ we say that $Q(U_z)$ and $Q(U_{z'})$ *conflict* if there is a word $\alpha \in Q(U_z) \cap Q(U_{z'})$ in $u_z \triangle u_{z'}$. In that case, we say $Q(U_z)$ and $Q(U_{z'})$ conflict in α. Note that whenever $Q(U_z)$ and $Q(U_{z'})$ conflict in a word α, then $\alpha \in u_z \cup u_{z'}$. The next three claims show that for all $z \in \Sigma^n$ odd and $z' \in \Sigma^n$ even, the sets $Q(U_z)$ and $Q(U_{z'})$ conflict in a word of length n. Indeed, then they conflict in z or z' as these are the only words of length n in $u_z \cup u_{z'}$.

▷ Claim 13. Let $z, z' \in \Sigma^n$ such that z is odd and z' is even. If $Q(U_z)$ and $Q(U_{z'})$ conflict, then they conflict in a word of length n.

Proof. Let α be the least word in which $Q(U_z)$ and $Q(U_{z'})$ conflict. Then $\alpha \in u_z \triangle u_{z'}$. By symmetry, it suffices to consider the case $\alpha \in u_z - u_{z'}$. For a contradiction, assume that $|\alpha| > n$. Then by Claim 11, two situations are possible.

1. Assume $\alpha = 1^{p'^\kappa}$ for $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t_s)$ and $\kappa > 0$. Then by Claim 11.2, $\alpha \in u_{z'}$, a contradiction. Hence, $\alpha \neq 1^{p'^\kappa}$ for all $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t_s)$ and $\kappa > 0$.

2. Here, $\alpha = c(i', x, y)$ for $i' \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$ with $0 < t_s(i') \leq c(i', x, y)$ and $F_{i'}^{u_z}(x) = y \in K^{u_z}$. By construction, it holds $t_s(i') = t_{s-1}(i') \leq |w_{s-1}| \leq |u| < \alpha$. Thus, $F_{i'}^{u_{z'}}(x) \neq y$, since otherwise, by the t_s-validity of $u_{z'}$ and V5, it would hold $\alpha \in u_{z'}$. Consequently, $F_{i'}^{u_{z'}}(x) \neq F_{i'}^{u_z}(x)$. Hence, there exists a query β that is asked by both $F_{i'}^{u_z}(x)$ and $F_{i'}^{u_{z'}}(x)$ and that is in $u_z \triangle u_{z'}$ (otherwise, both computations would output the same word). By definition of $Q(U_z)$ and $Q(U_{z'})$, it holds $\beta \in Q(U_z) \cap Q(U_{z'})$. Hence, $Q(U_z)$ and $Q(U_{z'})$ conflict in β and $|\beta| \leq |x|^{i'} + i' < |c(i', x, y)| = |\alpha|$, in contradiction to the assumption that α is the least word which $Q(U_z)$ and $Q(U_{z'})$ conflict in. ◁

For showing that for all odd $z \in \Sigma^n$ and all even $z' \in \Sigma^n$ the sets $Q(U_z)$ and $Q(U_{z'})$ conflict, we need one more claim. Let t' be defined such that $\mathrm{dom}(t') = \mathrm{dom}(t_s) - \{(i, j)\}$ and $t'(i', j') = t_s(i', j')$ for $(i', j') \in \mathrm{dom}(t')$. Then u and u_z for $z \in \Sigma^n$ are t'-valid by Claim 8.

▷ Claim 14. Let $t \in \{t', t_s\}$ and $z, z' \in \Sigma^n$ such that $Q(U_z)$ and $Q(U_{z'})$ do not conflict. For each t-valid oracle $v \sqsupsetneq u$ that is defined for exactly the words of length $\leq n$ and that satisfies $v(q) = u_z(q)$ for all $|v| > q \in Q(U_z)$ and $v(q) = u_{z'}(q)$ for all $|v| > q \in Q(U_z)$, there exists a t-valid oracle $v' \sqsupsetneq v$ with $|v'| = |u_z|$, $v'(q) = u_z(q)$ for all $|v'| > q \in Q(U_z)$, and $v'(q) = u_{z'}(q)$ for all $|v'| > q \in Q(U_z)$.

Proof. Let $w \sqsupseteq u$ with $|w| < |u_z|$, $w(q) = u_z(q)$ for all $|w| > q \in Q(U_z)$, and $w(q) = u_{z'}(q)$ for all $|w| > q \in Q(U_{z'})$. Moreover, let $\alpha = |w|$. It suffices to show the following:

- If $\alpha = 0^{p'^\kappa}$ for some $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t)$ and $\kappa > 0$, then there exists a t-valid $w' \sqsupsetneq w$ that is defined for the words of length p'^κ, undefined for all words of greater length, and that satisfies $w'(q) = u_z(q)$ for all $|w'| > q \in Q(U_z)$ and $w'(q) = u_{z'}(q)$ for all $|w'| > q \in Q(U_{z'})$.
  Note that in this case $|w'| \leq |u_z|$ as u_z is defined for exactly the words of length $\leq \gamma(n)$.
- If α is not of length p'^κ for all $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t)$ and all $\kappa > 0$, then there exists $b \in \{0, 1\}$ such that wb is t-valid, $wb(q) = u_z(q)$ for all $|wb| > q \in Q(U_z)$ and $wb(q) = u_{z'}(q)$ for all $|wb| > q \in Q(U_{z'})$.

We study three cases.

1. Assume $\alpha = 0^{p'^\kappa}$ for some $p' \in \mathbb{P}_3$ with $-p' \in \mathrm{ran}(t)$ and $\kappa > 0$. Then we let $w' \sqsupsetneq w$ be the minimal oracle that is defined for all words of length p'^κ and contains $1^{p'^\kappa}$, i.e., $w' = w \cup \{1^{p'^\kappa}\}$ when interpreting the oracles as sets. As $u_z \cap \Sigma^{p'^\kappa} = u_{z'} \cap \Sigma^{p'^\kappa} = \{1^{p'^\kappa}\}$ by Claim 11.2, we obtain $w'(q) = u_z(q)$ for all $|w'| > q \in Q(U_z)$ and $w'(q) = u_{z'}(q)$ for all $|w'| > q \in Q(U_{z'})$. Moreover, by Claim 10.2b and Claim 10.2c, the oracle w' is t-valid.
2. Now assume that $\alpha = c(i', x, y)$ for $i' \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$ with $0 < t(i') \leq \alpha$ such that one of the conditions $F_{i'}^{u_z}(x) = y$ and $F_{i'}^{u_{z'}}(x) = y$ holds. By Claim 10.1, then even one of the two conditions $F_{i'}^{u_z}(x) = y \in K^{u_z}$ and $F_{i'}^{u_{z'}}(x) = y \in K^{u_{z'}}$ holds. By symmetry, if suffices to argue for the case $F_{i'}^{u_z}(x) = y \in K^{u_z}$. Recall that the oracles u_z and $u_{z'}$ are t-valid. Hence, by V5 and $0 < t(i') \leq \alpha < |u_z|$, it holds $\alpha \in u_z$. We consider two cases depending on whether $F_{i'}^{w}(x)$ returns y. In any case, if $\alpha \in Q(U_z)$ (resp., $\alpha \in Q(U_{z'})$), then $F_{i'}^{w}(x) = F_{i'}^{u_z}(x)$ (resp., $F_{i'}^{w}(x) = F_{i'}^{u_{z'}}(x)$), since for all queries q of $F_{i'}^{u_z}(x)$ (resp., $F_{i'}^{u_{z'}}(x)$), it holds $q \in Q(U_z)$ (resp., $q \in Q(U_{z'})$), $|q| \leq |x|^{i'} + i' < |\alpha|$, and by assumption, $w(q) = u_z(q)$ (resp., $w(q) = u_{z'}(q)$).
   - (i) Assume $F_{i'}^{w}(x) = y$. Choose $b = 1$. As w is t-valid, $0 < t(i') \leq \alpha$, and $F_{i'}^{w}(x) = y$, Claim 10.2e yields that $w1$ is t-valid. As $\alpha \in u_z$, we have $w1(q) = u_z(q)$ for all $|w1| > q \in Q(U_z)$. It remains to show that $w1(q) = u_{z'}(q)$ for all $|w1| > q \in Q(U_{z'})$. If $\alpha \notin Q(U_{z'})$, this trivially holds. If $\alpha \in Q(U_{z'})$, then as observed above, $F_{i}^{u_{z'}}(x) = F_{i}^{w}(x) = y$. Hence, as $u_{z'}$ is t-valid and $0 < t'(i') \leq \alpha < |u_{z'}|$, it holds $\alpha \in u_{z'}$ by V5. Thus, $w1(q) = u_{z'}(q)$ for all $|w1| > q \in Q(U_{z'})$.
   - (ii) Assume $F_{i'}^{w}(x) \neq y$. Choose $b = 0$. Then Claim 10.2f states that wb is t-valid. It holds $\alpha \notin Q(U_z)$, since otherwise, as observed above, $F_{i'}^{w}(x) = F_{i'}^{u_z}(x) = y$, which would yield a contradiction. Thus, $wb(q) = u_z(q)$ for all $|wb| > q \in Q(U_z)$. It remains to show $wb(q) = u_{z'}(q)$ for all $|wb| > q \in Q(U_{z'})$. If $\alpha \notin Q(U_{z'})$, this trivially holds and otherwise, it also holds, since as observed above, we have $F_{i'}^{u_{z'}}(x) = F_{i'}^{w}(x) \neq y$, which implies $\alpha \notin u_{z'}$ (by V1, $\alpha \in u_{z'}$ would imply $F_{i'}^{u_{z'}}(x) = y$).
3. We now consider the remaining cases, i.e., we may assume: (i) α is not of length p'^κ for all $p' \in \mathbb{P}_3$ and $\kappa > 0$ with $-p' \in \mathrm{ran}(t)$ and (ii) if $\alpha = c(i', x, y)$ for some $i' \in \mathbb{N}^+$ and $x, y \in \mathbb{N}$ with $0 < t(i') \leq \alpha$, then none of the conditions $F_{i'}^{u_z}(x) = y$ and $F_{i'}^{u_{z'}}(x) = y$ holds.

In this case, it holds $\alpha \notin u_z \cup u_{z'}$ by Claim 11.1. We choose $b = 0$ and obtain that $wb(q) = u_z(q)$ for all $|wb| > q \in Q(U_z)$ and $wb(q) = u_{z'}(q)$ for all $|wb| > q \in Q(U_{z'})$. Moreover, by Claim 10.2, wb is t-valid. This shows Claim 14. ◀

▷ Claim 15. For all odd $z \in \Sigma^n$ and all even $z' \in \Sigma^n$, $Q(U_z)$ and $Q(U_{z'})$ conflict.

Proof. Let us first show that $\alpha \in Q(U_\alpha)$ for all $\alpha \in \Sigma^n$. For a contradiction, assume $\alpha \notin Q(U_\alpha)$ for some $\alpha \in \Sigma^n$. We study the cases $i = j$ and $i \neq j$ separately.

First assume $i = j$. In this case $p \in \mathbb{P}_1$. Let u' be the oracle that is defined for exactly the words of length $\leq n$ and satisfies $u' = u$ when the oracles are considered as sets. Then u' is t_s-valid by Claim 10.2d and u' and u_α agree on all words in $\Sigma^n \cap Q(U_\alpha)$ as $u_\alpha \cap \Sigma^n = \{\alpha\}$ and $\alpha \notin Q(U_\alpha)$. Thus, we can apply Claim 14 to the oracle u' for $z = z' = \alpha$. Hence, there exists a t_s-valid oracle v satisfying $|v| = |u_z|$, $v \cap \Sigma^n = \emptyset$, and $v(q) = u_\alpha(q)$ for all $q \in Q(U_\alpha)$. By the latter property and the fact that $U_\alpha \subseteq Q(U_\alpha)$ contains all queries asked by the least accepting path of $M_i^{u_\alpha}(F_r^{u_\alpha}(0^n))$, this path is also an accepting path of the computation $M_i^v(F_r^v(0^n))$. As v is defined for all words of length $\leq \gamma(n)$, the computation $M_i^v(F_r^v(0^n))$ is defined. Thus, $0^n \notin C_q^{v'}$ for all $v' \sqsupseteq v$ and $M_i^v(F_r^v(0^n))$ definitely accepts, in contradiction to the assumption that step s of the construction fails.

Now let us consider the case $i \neq j$. Here $p \in \mathbb{P}_3$. By symmetry, it suffices to consider the case that α is odd. Let α' be the minimal even element of Σ^n that is not in $Q(U_\alpha)$. Such α' exists as it holds $2^{n-1} > 4(\gamma(n)) > 2\gamma(n)$ by (1), $\ell(Q(U_\alpha)) \leq 2\gamma(n)$ by Claim 12, and hence, $\ell(Q(U_\alpha)) \leq 2\gamma(n) < 2^{n-1} = |\{\alpha'' \in \Sigma^n \mid \alpha'' \text{ even}\}|$. Now choose u' to be the oracle that is defined for exactly the words of length $\leq n$ and that satisfies $u' = u \cup \{\alpha'\}$ when the oracles are considered as sets. Then u' is t_s-valid by Claim 10.2b and Claim 10.2f. Moreover, as $\alpha, \alpha' \notin Q(U_\alpha)$, the oracles u' and u_α agree on all words in $\Sigma^n \cap Q(U_\alpha)$. Thus, we can apply Claim 14 to the oracle u' for $z = z' = \alpha$ and obtain a t_s-valid oracle v that is defined for all words of length $\leq \gamma(n)$ and satisfies both $v \cap \Sigma^n = \{\alpha'\}$ and $v(q) = u_\alpha(q)$ for all $q \in Q(U_\alpha)$. The latter property and the fact that $U_\alpha \subseteq Q(U_\alpha)$ contains all queries asked by the least accepting path of $M_i^{u_\alpha}(F_r^{u_\alpha}(0^n))$ yield that this path is also an accepting path of the computation $M_i^v(F_r^v(0^n))$. As v is defined for all words of length $\leq \gamma(n)$, the computation $M_i^v(F_r^v(0^n))$ definitely accepts. Let us study two cases depending on whether $M_j^v(F_r^v(0^n))$ definitely accepts or definitely rejects (note that this computation is defined as v is defined for all words of length $\leq \gamma(n)$):

- Assume that $M_j^v(F_r^v(0^n))$ definitely accept. Let s' be the step that treats the task (i, j). Hence, $s' < s$ since $t_s(i, j)$ is defined. By Claim 8, the oracle v is $t_{s'-1}$-valid. Now, as both $M_i^v(F_r^v(0^n))$ and $M_j^v(F_r^v(0^n))$ definitely accept, v is even t''-valid for $t'' = t_{s'-1} \cup \{(i, j) \mapsto 0\}$. But then the construction would have chosen $t_{s'} = t''$ and a suitable oracle $w_{s'}$ (e.g., $w_{s'} = v$), a contradiction.
- Assume that $M_j^v(F_r^v(0^n))$ definitely rejects. As $v \cap \Sigma^n = \{\alpha'\}$, it holds $0^n \in B_p^{v'}$ for all $v' \sqsupseteq v$. This is a contradiction to the assumption that step s of the construction fails.

Hence, from now on we may assume that $\alpha \in Q(U_\alpha)$ for all $\alpha \in \Sigma^n$. Moreover, assume there are z odd and z' even such that $Q(U_z)$ and $Q(U_{z'})$ do not conflict. Then let $u' \sqsupsetneq u$ be the minimal oracle that is defined for all words of length $\leq n$ and contains z and z', i.e., interpreting oracles as sets it holds $u' = u \cup \{z, z'\}$. Since $-p \notin \mathrm{ran}(t')$, the oracle u' is t'-valid by Claim 10.2a. If Claim 14 cannot be applied to the oracle u' for z and z', then $z \in Q(U_{z'})$ or $z' \in Q(U_z)$. Since we observed above that $z \in Q(U_z)$ and $z' \in Q(U_{z'})$ and moreover, $u_z \cap \Sigma^n = \{z\}$ and $u_{z'} \cap \Sigma^n = \{z'\}$, in this case $Q(U_z)$ and $Q(U_{z'})$ conflict. Hence, it remains to consider the case that Claim 14 can be applied to the oracle u' for z and z'.

Applying Claim 14, we obtain a t'-valid $v \sqsupseteq u'$ that is defined for all words of length $\leq \gamma(n)$ and that satisfies $v(q) = u_z(q)$ for all $q \in Q(U_z)$ and $v(q) = u_{z'}(q)$ for all $q \in Q(U_{z'})$.

Let s' be the step in which (i,j) is treated. As $t_s(i,j)$ is defined, it holds $s' < s$. Hence, t' is an extension of $t_{s'-1}$ and by Claim 8, v is $t_{s'-1}$-valid. We claim that v is t''-valid for $t'' = t_{s'-1} \cup \{(i,j) \mapsto 0\}$. Once this is proven, we obtain a contradiction as then the construction would have chosen $t_{s'} = t''$ and an appropriate $w_{s'}$ (e.g. $w_{s'} = v$). Then our assumption is wrong and for all odd $z \in \Sigma^n$ and all even $z' \in \Sigma^n$, $Q(U_z)$ and $Q(U_{z'})$ conflict.

It remains to prove that v is t''-valid for $t'' = t_{s'-1} \cup \{(i,j) \mapsto 0\}$. We study two cases.

Case 1: first we assume that $i \neq j$, i.e., it suffices to prove that $M_i^v(F_r^v(0^n))$ and $M_j^v(F_r^v(0^n))$ definitely accept. Recall that $M_i^{u_z}(F_r^{u_z}(0^n))$ and $M_j^{u_{z'}}(F_r^{u_{z'}}(0^n))$ definitely accept. Moreover, $v(q) = u_z(q)$ for all $q \in Q(U_z)$ and $v(q) = u_{z'}(q)$ for all $q \in Q(U_{z'})$ and in particular, v is defined for all words in $Q(U_z) \cup Q(U_{z'})$. This implies that the least accepting paths of $M_i^{u_z}(F_r^{u_z}(0^n))$ and $M_i^{u_z}(F_r^{u_z}(0^n))$ are also accepting paths of the computations $M_i^v(F_r^v(0^n))$ and $M_j^v(F_r^v(0^n))$.

Case 2: assume that $i = j$, i.e., we have to prove that on some input x the computation $M_i^v(x)$ has two accepting paths. As observed above, $z \in Q(U_z)$ and $z' \in Q(U_{z'})$. As $Q(U_z)$ and $Q(U_{z'})$ do not conflict, it holds $z \notin Q(U_{z'})$, which implies $Q(U_z) \neq Q(U_{z'})$. Let $\kappa \in \mathbb{N}$ be minimal such that $Q_\kappa(U_z) \neq Q_\kappa(U_{z'})$ and for a contradiction, assume $\kappa > 0$. Let $\alpha \in Q_\kappa(U_z) \triangle Q_\kappa(U_{z'})$. Without loss of generality, we assume $\alpha \in Q_\kappa(U_z) - Q_\kappa(U_{z'})$. Then there exist $i', x, y \in \mathbb{N}$ with $i' > 0$ such that $c(i', x, y) \in Q_{\kappa-1}(U_z)$ and $F_{i'}^{u_z}(x)$ asks the query α. By the choice of κ, it holds $Q_{\kappa-1}(U_{z'}) = Q_{\kappa-1}(U_z)$ and thus, $c(i', x, y) \in Q_{\kappa-1}(U_{z'})$. Consequently, all queries of $F_{i'}^{u_{z'}}(x)$ are in $Q_\kappa(U_{z'})$. However, $\alpha \notin Q_\kappa(U_{z'})$ and therefore, α cannot be asked by $F_{i'}^{u_{z'}}(x)$. This shows that there is a word $\beta \in u_z \triangle u_{z'}$ asked by both $F_{i'}^{u_z}(x)$ and $F_{i'}^{u_{z'}}(x)$ (otherwise, the two computations would ask the same queries). But then $\beta \in Q_\kappa(U_z) \cap Q_\kappa(U_{z'})$, which implies that $Q(U_z)$ and $Q(U_{z'})$ conflict, a contradiction. Hence, we obtain $\kappa = 0$ and $U_z = Q_0(U_z) \neq Q_0(U_{z'}) = U_{z'}$. Recall that U_z (resp., $U_{z'}$) is the set consisting of all oracle queries of the least accepting path P (resp., P') of the computation $M_i^{u_z}(F_r^{u_z}(0^n))$ (resp., $M_i^{u_{z'}}(F_r^{u_{z'}}(0^n))$). As $u_z(q) = v(q)$ for all $q \in Q(U_z) \supseteq U_z$ and $u_{z'}(q) = v(q)$ for all $q \in Q(U_{z'}) \supseteq U_{z'}$, the paths P and P' are accepting paths of the computation $M_i^v(F_r^v(0^n))$. Finally, P and P' are distinct paths since $U_z \neq U_{z'}$. This finishes the proof that v is t''-valid. Hence, the proof of Claim 15 is complete. ◀

The remainder of the proof that the construction is possible is based on an idea by Hartmanis and Hemachandra [8]. Consider the set

$$\begin{aligned} E &= \{\{z, z'\} \mid z, z' \in \Sigma^n, z \text{ odd} \Leftrightarrow z' \text{ even}, (z \in Q(U_{z'}) \vee z' \in Q(U_z))\} \\ &= \bigcup_{z \in \Sigma^n} \{\{z, z'\} \mid z' \in \Sigma^n, z \text{ odd} \Leftrightarrow z' \text{ even}, z' \in Q(U_z)\}. \end{aligned} \tag{2}$$

Let $z, z' \in \Sigma^n$ such that (z odd $\Leftrightarrow z'$ even). By Claim 15 and Claim 13, $Q(U_z)$ and $Q(U_{z'})$ conflict in a word of length n. Then, as observed above, they conflict in z or z', i.e., $z \in Q(U_{z'})$ or $z' \in Q(U_z)$. This shows $E = \{\{z, z'\} \mid z, z' \in \Sigma^n, z \text{ odd} \Leftrightarrow z' \text{ even}\}$ and thus, $|E| = 2^{2n-2}$. By Claim 12, for each $z \in \Sigma^n$ it holds $|Q(U_z)| \leq \ell(Q(U_z)) \leq 2\gamma(n)$. Consequently,

$$|E| \overset{(2)}{\leq} \sum_{z \in \Sigma^n} |Q(U_z)| \leq 2^n \cdot 2\gamma(n) = 2^{n+1} \cdot \gamma(n) \overset{(1)}{<} 2^{2n-2} = |E|,$$

a contradiction to the assumption that the construction fails in step s treating the task (i, j, r). This shows that the construction is possible and O is well-defined. It remains to show that DisjNP^O contains no pair $\leq_{\mathrm{m}}^{\mathrm{p},O}$-hard for $\mathrm{NP}^O \cap \mathrm{coNP}^O$, each problem in NP^O has P^O-optimal proof systems, and UP^O has no $\leq_{\mathrm{m}}^{\mathrm{p},O}$-complete problem. As the corresponding proofs are rather straightforward, we omit them. This completes the proof of Theorem 6. ◀

Abstract

We introduce the notion of a semicomputable point in $\mathbb{R}^n$, defined as a point having left-c.e. projections. We study the range of such a point, which is the set of directions on which its projections are left-c.e., and is a convex cone. We provide a thorough study of these notions, proving along the way new results on the computability of convex sets. We prove realization results, by identifying computability properties of convex cones that make them ranges of semicomputable points. We give two applications of the theory. The first one provides a better understanding of the Solovay derivatives. The second one is the investigation of left-c.e. quadratic polynomials. We show that this is, in fact, a particular case of the general theory of semicomputable points.

1 Introduction

The general goal of this paper is to improve our understanding of weak notions of computability in computable analysis. Usually these notions are more difficult to understand than plain computability, and have a rich theory. For instance we mention the notions of computably enumerable (c.e.) subsets of $\mathbb{N}$, left-c.e. reals numbers, left-c.e. real functions, c.e. closed subsets of $\mathbb{R}^n$, co-c.e. closed sets, etc.

A closed subset of $\mathbb{R}^n$ is co-c.e. if its complement is a computable union of rational balls. When a closed set can be described by a few parameters, such as a simple geometrical figure, what properties must these parameters satisfy to make it a co-c.e. closed set? The case of filled triangles has been studied in [5], but the case of disks is more challenging.

A function $f : \mathbb{R} \to \mathbb{R}$ is left-c.e. if there is a program that takes x as input and outputs better and better approximations of $f(x)$ from the left (with no assumption on the speed of convergence to $f(x)$). When a function is described by a few parameters, such as a polynomial, what properties must these parameters satisfy to make it a left-c.e. function?

The cases of co-c.e. disks and left-c.e. polynomials are surprisingly two instances of a common framework that we investigate in this paper. In both cases, the object can be identified with a point in some Euclidean space (for instance, a polynomial is a vector of coefficients) and the computability notion can be expressed as the point having uniformly left-c.e. projections in some set of directions (the directions $(1, X, X^2)$ in the case of quadratic polynomials). This observation leads us to introduce and study the notion of a *semicomputable* point in Euclidean spaces. It is an extension to several dimensions of a notion introduced in [5] in the plane. In particular we define the semicomputability range of a point as the set of directions in which it is left-c.e., and investigate the possible sets that can be obtained as ranges of semicomputable points.

The extension from the plane to higher-dimensional Euclidean spaces is not a straightforward generalization because many subtleties appear in $\mathbb{R}^3$. For instance, the range of a point is a convex cone, so it is determined by two angles in $\mathbb{R}^2$ but can have many different shapes in $\mathbb{R}^3$. Another example is that the operation of taking the conical hull of two convex cones, while simple in $\mathbb{R}^2$, is not as simple in $\mathbb{R}^3$ in terms of computability.

The main results of the paper are realizations results: given a convex cone in $\mathbb{R}^n$ with some computability property, there exists a semicomputable point in $\mathbb{R}^n$ whose range is exactly that cone:

- Theorem 4.6: every Σ^0_2 cone is the range of some semicomputable point. If its closure is not Π^0_2 then the point is *non-uniformly* left-c.e. in the directions of the cone.
- Theorem 4.8: every salient Π^0_2 convex cone is the range of some semicomputable point. Moreover, that point is *uniformly* left-c.e. in the directions of the cone.

In Section 2.4 we give results about computability of convex sets and convex cones. In Section 3 we define semicomputable points of $\mathbb{R}^n$ and develop a thorough study of this notion. In particular we define the range of a semicommputable point, which is the set of directions in which its projections are left-c.e. In Section 4 we prove the main results of the paper, in which we identify classes of convex cones that can be realized as ranges of semicomputable points. In Section 5 we use these results to study Solovay derivatives and precisely identify the possible shapes of the functions $\overline{S}(aX+b,c)$ and $\underline{S}(aX+b,c)$ when a,b,c are fixed and X varies over the computable reals. In Section 6 we investigate the left-c.e. quadratic polynomials, which can be identified with semicomputable points with a certain range.

2 Background

2.1 Computability in Euclidean spaces

We endow $\mathbb{R}^n$ with the inner product $\langle x,y\rangle=\sum_{i=1}^n x_iy_i$, where $x=(x_1,\dots,x_n)$ and $y=(y_1,\dots,y_n)$, the associated norm $\|x\|=\sqrt{\langle x,x\rangle}$ and the distance $d(x,y)=\|x-y\|$. An open set $U\subseteq\mathbb{R}^n$ is ***effectively open*** if it is the union of a computable sequence of rational open balls (centered at rational points with rational radii). Let $A\subseteq\mathbb{R}^n$ be a closed set. A is ***c.e. closed*** if A contains a dense computable sequence, or equivalently the function $x\mapsto d(x,A)=\min_{y\in A}d(x,y)$ is right-c.e. A is ***co-c.e. closed*** if the complement of A is effectively open, or equivalently the function $x\mapsto d(x,A)$ is left-c.e. A closed set is ***computably closed*** if it is both c.e. closed and co-c.e. closed. A compact set K is ***effectively compact*** if the set of finite lists of rational balls covering K is c.e. A compact set is effectively compact if and only if it is co-c.e. closed. More details on these notions can be found in [3].

A real number is ***left-c.e.*** if it is the limit of a computable increasing sequence of rational numbers. A real number x is ***right-c.e.*** if $-x$ is left-c.e. It is computable if it is both left-c.e. and right-c.e. If $D\subseteq\mathbb{R}^n$ then a function $f:D\to[-\infty,+\infty]$ is left-c.e. if there exist uniformly effective open sets $(U_q)_{q\in\mathbb{Q}}$ such that for all $q\in\mathbb{Q}$, $f^{-1}(q,+\infty)=D\cap U_q$. f is right-c.e. if $-f$ is left-c.e.

Let $f:\mathbb{R}^m\times\mathbb{R}^n$ be left-c.e.. If $K\subseteq\mathbb{R}^n$ is effectively compact then $f_{\min}:\mathbb{R}^m\to\mathbb{R}$ defined by $f_{\min}(x)=\min_{y\in K}f(x,y)$ is left-c.e. If $A\subseteq\mathbb{R}^n$ is c.e. closed then $f_{\sup}:\mathbb{R}^m\to\mathbb{R}$ defined by $f_{\sup}(x)=\sup_{y\in A}f(x,y)$ is left-c.e.

Each of these computability notions can be relativized to any oracle. We will be particularly interested in their relativization to the halting set, denoted by $\emptyset'$. For instance, a real is $\emptyset'$-left-c.e. if it is left-c.e. relative to $\emptyset'$.

2.2 Solovay derivatives

The quantitative study of Solovay reducibility was initiated in [1] and continued in [7] and [5]. We briefly recall that if a, b are real numbers such that b is left-c.e., then we define

$$\overline{S}(a,b) = \inf\{q \in \mathbb{Q} : qb - a \text{ is left-c.e.}\},$$
$$\underline{S}(a,b) = \sup\{q \in \mathbb{Q} : qb - a \text{ is right-c.e.}\}.$$

We say that a is ***Solovay reducible*** to b if $\overline{S}(a,b) < +\infty$ and $\underline{S}(a,b) > -\infty$. Intuitively, it means that a is easier to approximate than b in the following sense: if $\overline{S}(a,b) < q$ and $\underline{S}(a,b) > r$, then there exist computable sequences a_i, b_i converging to a, b such that $r \leq \frac{a-a_i}{b-b_i} \leq q$.

Some left-c.e. real numbers are ***Solovay complete***, meaning that each left-c.e. number is reducible to them, and it is proved in [1] that if b is Solovay complete, then $\overline{S}(a,b) = \underline{S}(a,b)$.

2.3 Background on convex cones

We give the minimal amount of background on convex analysis and refer the reader to [2] for more details. A ***cone*** is a set $C \subseteq \mathbb{R}^n$ that is closed under multiplication by a nonnegative scalar. A ***convex cone*** is a cone that is convex, i.e. a set that is closed under addition and multiplication by a nonnegative scalar. The ***dual*** of a set C is the closed convex cone $C^* = \{x \in \mathbb{R}^n : \forall y \in C, \langle x, y\rangle \geq 0\}$. $(C^*)^*$ is the smallest closed convex cone containing C. In particular if C is a closed convex cone then $(C^*)^* = C$.

For $x \neq 0$, let $H_x = \{z : \langle x, z\rangle \geq 0\}$ be the half-space delimited by the hyperplane orthogonal to x, in the direction of x. One has $C^* = \bigcap_{x\in C} H_x$. As a result, $d(z, C^*) \geq \sup_{x\in C} d(z, H_x)$ and we show that equality holds. Observe that $d(z, H_x) = \max(-\frac{\langle z,x\rangle}{\|x\|}, 0)$.

▶ **Lemma 2.1.** *Let C be a convex set. One has $d(z, C^*) = \sup_{x\in C} d(z, H_x)$.*

For a convex cone C, let C_1 be the intersection of C with the unit sphere. In the previous lemma, one has $d(z, C^*) = \sup_{x\in C_1} d(z, H_x)$ if C is a convex cone.

A convex cone is ***flat*** if it contains some $x \neq 0$ and its opposite $-x$. It is called ***salient*** if it is not flat. C is salient if and only if C^* is full-dimensional if and only if there exist $\epsilon > 0$ and y such that $\langle x, y\rangle > \epsilon$ for all $x \in C_1$.

If $A \subseteq \mathbb{R}^n$ is a full-dimensional convex set, then $A \subseteq \overline{\mathrm{int}(A)}$ and $\mathrm{int}(\overline{A}) \subseteq A$. In particular, among the class of full-dimensional convex sets, every closed set is regular closed and every open set is regular open.

2.4 Computability of convex sets and cones

Computability of convex sets has been investigated in [6] and [9]. Here we present new results that are used to prove the results of the paper and are of independent interest.

▶ **Proposition 2.2.** *Let $C \subseteq \mathbb{R}^n$ be a closed convex cone.*

- *C is co-c.e. closed $\iff$ C^* is c.e. closed,*
- *C is c.e. closed $\iff$ C^* is co-c.e. closed,*
- *C is computably closed $\iff$ C^* is computably closed.*

Proof. If C is c.e. closed then let $(x_i)_{i\in\mathbb{N}}$ be a dense computable sequence in C. One has $C^* = \bigcap_i H_{x_i}$ which is therefore co-c.e. closed.

If C is co-c.e. then the intersection C_1 of C with the unit sphere is effectively compact. By Lemma 2.1 one has $d(z, C^*) = \max_{x\in C} d(z, H_x) = \max_{x\in C_1} d(z, H_x)$ which is a right-c.e. function of z, so C^* is c.e. closed.

The other implications can be obtained by observing that $(C^*)^* = C$. ◀

Observe that these results relativize to any oracle. The first equivalence in the next result was proved by Ziegler [9].

▶ **Proposition 2.3.** *Let $C \subseteq \mathbb{R}^n$ be a full-dimensional closed convex set.*

- *C is co-c.e. closed $\iff$ the set of rational points outside C is c.e.,*
- *C is c.e. closed $\iff$ its interior is effectively open.*

Proof. If C is co-c.e. closed then the set of rational points outside C is obviously c.e. Conversely, assume that the set of rational points outside C is c.e. Let $C_0 \subseteq C$ be any fixed full-dimensional rational polytope. Given $z \in \mathbb{R}^n$, one can compute the convex hull of $C_0 \cup \{z\}$ and in particular enumerate its interior U_z. As U_z is dense in that convex hull, one has $z \notin C \iff U_z$ contains a rational point outside C. It gives a procedure that given z, halts exactly when $z \notin C$, showing that C is co-c.e.

If the interior of C is effectively open then one can enumerate the rational points in the interior, which are dense in C. Conversely, if C is c.e. closed then let $(x_i)_{i\in\mathbb{N}}$ be a dense computable sequence in C. A point z belongs to the interior of C iff there exist $n+1$ points in the sequence such that z belongs to the interior of their convex hull, which gives a procedure that halts exactly when $z \in \text{int}(C)$. ◀

The assumption that C is full-dimensional is needed. For the first item, if C contains no rational point then no information about C can be obtained from an enumeration of the rationals ouside C (i.e., all the rational points). For the second item, C needs to have a non-empty interior.

▶ **Lemma 2.4.** *Let $A, B \subseteq \mathbb{R}^n$ be c.e. closed convex sets.*

- *If $A \cap B$ has non-empty interior then $A \cap B$ is c.e. closed.*
- *$A \cap B$ is $\emptyset'$-co-c.e. closed. There exist $A, B \subseteq \mathbb{R}^3$ such that $A \cap B$ is not $\emptyset'$-c.e. closed.*

Proof. The interiors of A and B are effectively open and dense in A and B respectively. Their intersection is effectively open and dense in $A \cap B$, which is then c.e. closed.

In general, if A, B are c.e. closed then they are $\emptyset'$-computable and in particular $\emptyset'$-co-c.e. closed and so is their intersection.

There exists a right-c.e. convex function $f : \mathbb{R} \to \mathbb{R}$ such that $f^{-1}(0)$ is not $\emptyset'$-c.e. closed. Let $\alpha > 0$ be $\emptyset'$-right-c.e. but not $\emptyset'$-left-c.e. There exists a sequence of uniformly left-c.e. reals $\alpha_i > 0$ such that $\alpha = \inf_i \alpha_i$. Let $f_i(x) = \max(0, x - \alpha_i)$ and $f = \sum_i 2^{-i} f_i$. The functions f_i are uniformly right-c.e. so f is right-c.e., and $f^{-1}(0) = [0, \alpha]$ is not $\emptyset'$-c.e. closed because α is not $\emptyset'$-left-c.e.

Let $A = \{(x, y) : y \geq f(x)\}$ be the epigraph of f and $B = \{(x, y) : y \leq 0\}$. A and B are c.e. closed but $A \cap B = \{(x, 0) : f(x) = 0\}$ is not $\emptyset'$-c.e. closed. ◀

▶ **Proposition 2.5.** *Let $C \subseteq \mathbb{R}^n$ be a full-dimensional closed convex set.*

- *C is $\emptyset'$-co-c.e. closed $\iff$ the set of rational points outside C is $\emptyset'$-c.e. $\iff$ C is Π^0_2,*
- *C is $\emptyset'$-c.e. closed $\iff$ its interior is $\emptyset'$-effectively open $\iff$ C contains a dense Σ^0_2-set.*

Proof. Several equivalences are obtained by relativizing Proposition 2.3, we prove the others. Any set that is $\emptyset'$-co-c.e. is Π^0_2, and if C is Π^0_2 then the set of rational points ouside C is obviously $\emptyset'$-c.e.

Any $\emptyset'$-effectively open set is a Σ^0_2-set, and $\mathrm{int}(C)$ is dense in C. If C contains a dense Σ^0_2-set, then, with $\emptyset'$ as oracle, one can compute a dense sequence in that set, so C is $\emptyset'$-c.e. closed. ◀

Again the full dimension assumption is needed. For the first item, there exists a Π^0_2-singleton whose unique element is not computable relative to $\emptyset'$ (even relative to any $\emptyset^{(n)}$, $n \in \mathbb{N}$, see Proposition 1.8.62 in [8]). For the second item, if x is $\emptyset'$-computable but not computable, then $\{x\}$ is $\emptyset'$-c.e. closed convex but does not contain any non-empty Σ^0_2-set.

3 Semicomputable point

The notions of left-c.e. and right-c.e. real number can be extended to higher dimensions. A first extension to points of the plane has been introduced in [5]. We pursue this extension to $\mathbb{R}^n$ for any $n \geq 1$. Although the definition extends immediately to this more general setting, the results are more involved because higher dimensions allow richer behaviors. For instance, a convex cone in $\mathbb{R}^2$ is delimited by two directions only, while a convex cone in $\mathbb{R}^3$ is a delimited by an uncountable set of directions.

▶ **Definition 3.1.** *A point $x \in \mathbb{R}^n$ is* **semicomputable** *if there exist n linearly independent rational vectors $v_1, \dots, v_n$ such that each $\langle v_i, x\rangle$ is left-c.e., $1 \leq i \leq n$.*

▶ **Definition 3.2.** *Let $D \subseteq \mathbb{R}^n$ be a closed convex cone. We say that $x \in \mathbb{R}^n$ is D***-c.e.** *if the mapping $d \in D \mapsto \langle d, x\rangle$ is left-c.e.*

Observe that this notion really makes sense when D is full-dimensional (or full-dimensional in some computable subspace), otherwise x could be D-c.e. only because the elements of D encode information about x. For instance, if $\|x\|$ is left-c.e. and $D = \{\lambda x : \lambda \geq 0\}$ then the mapping $d \in D \mapsto \langle d, x\rangle = \|d\| \cdot \|x\|$ is left-c.e., which should not be interpreted as "x is left-c.e. in some direction".

The closedness condition on D is justified by the next observation: D can always be assumed to be closed.

▶ **Proposition 3.3.** *Let $x \in \mathbb{R}^n$ and $D \subseteq \mathbb{R}^n$ be a full-dimensional convex cone. If the mapping $d \in D \mapsto \langle d, x\rangle$ is left-c.e. then x is $\overline{D}$-c.e.*

Proof. Let $d_0 \in D$ be a rational vector in the interior of D. Let $d \in \overline{D}$ be given as oracle. The vectors $d_n = (1 - 2^{-n})d + 2^{-n}d_0$ are uniformly computable in d and belong to D. The number $\langle d, x\rangle$ is the effective limit of $\langle d_n, x\rangle$, which is left-c.e. uniformly in n and d, so $\langle d, x\rangle$ is left-c.e. uniformly in d. ◀

Being C^*-c.e. can be dually expressed in terms of C.

▶ **Proposition 3.4.** *Let $x \in \mathbb{R}^n$ and $C \subseteq \mathbb{R}^n$ be a closed convex cone.*

- *When C is co-c.e. closed, x is C^*-c.e. $\iff$ $x + C$ is co-c.e. closed,*
- *When C is c.e. closed and full-dimensional, x is C^*-c.e. $\iff$ $x - C$ is c.e. closed.*

Proof.

- If x is C^*-c.e. then the complement of $x + C$ is effectively open. Indeed, $y \notin x + C \iff y - x \notin C \iff \inf_{d \in C^*} \langle d, y - x\rangle < 0$ which is a c.e. condition as C^* is c.e. closed and $\langle d, y - x\rangle$ is right c.e. in d, y.

If $x + C$ is co-c.e. then let $K \in \mathbb{N}$ be an upper bound on $\|x\|$ and $A = (x + C) \cap \overline{B}(0, K)$. A is effectively compact, contains x and for $d \in C^*$, $\langle d, x\rangle = \min_{z\in A} \langle d, z\rangle$ which is a left-c.e. function of d.

- If x is C^*-c.e. then $\mathrm{int}(x - C)$ is effectively open. Indeed $y \in \mathrm{int}(x - C) \iff x - y \in \mathrm{int}(C) \iff \min_{d\in C_1^*} \langle d, x - y\rangle > 0$ which is a c.e. condition as C_1^* is effectively compact and $\langle d, x - y\rangle$ is left-c.e. in d, y.

  If $x - C$ is c.e. closed and $(x_i)_{i\in\mathbb{N}}$ is a dense computable sequence in $x - C$, then for $d \in C^*$ one has $\langle d, x\rangle = \sup_i \langle d, x_i\rangle$ which is left-c.e. uniformly in d. ◀

▶ **Proposition 3.5.** *Let $C \subseteq \mathbb{R}^n$ be a closed convex cone.*

- *If $x + C$ is co-c.e. closed for some $x \in \mathbb{R}^n$, then C is co-c.e. closed.*
- *If $x + C$ is c.e. closed for some $x \in \mathbb{R}^n$, then C is c.e. closed.*

Proof. Let $E \subseteq \mathbb{R}^n$ be a set such that 0 belongs to the convex hull of E. One has $C^* = \bigcup_{e\in E}(C + e)^*$. Indeed, if $y \in C^*$ then there exists $e \in E$ such that $\langle e, y\rangle \geq 0$, so $y \in (C + e)^*$. Conversely, if $y \in (C + e)^*$ and $c \in C$ then $\langle y, c\rangle = \lim_{n\to\infty} \frac{1}{n}\langle y, e + nc\rangle \geq 0$ so $y \in C^*$.

Given x, there exists a finite set E of rational points such that the convex hull of $x + E$ contains 0. As a result, $C^* = \bigcup_{e\in E}(C+x+e)^*$. If $C+x$ is co-c.e. closed then each $(C+x+e)^*$ is c.e. closed so C^* is c.e. closed, hence C is co-c.e. closed. If $C + x$ is c.e. closed then each $(C + x + e)^*$ is co-c.e. closed so C^* is co-c.e. closed, hence C is c.e. closed. ◀

It was proved in [7] and [5] that if f is computable and differentiable at c then $\underline{S}(f(c), c) = \overline{S}(f(c), c) = f'(c)$. If $x = (c, f(c))$ and $v = (1, f'(c))$ then it means that $\langle d, x\rangle$ is left-c.e. for all rational directions d such that $\langle d, v\rangle > 0$. We now investigate when this is uniform in d, i.e. when x is $\{v\}^*$-c.e.

▶ **Proposition 3.6** (Positive case)**.** *Let $f : \mathbb{R} \to \mathbb{R}$ be computable and convex or concave. If $c \in \mathbb{R}$ is left-c.e. and $x = (c, f(c))$ and $v = (1, f'_-(c))$ where $f'_-(c)$ is the left-derivative of f at c, then x is $\{v\}^*$-c.e.*

Proof. Assume that f is convex, the other case is obtained by considering $-f$. Let c_i be a computable increasing sequence converging to x. Let q, r be rational numbers such that $r < f'_-(c) < q$. Compute i such that $\frac{f(c_{i+1})-f(c_i)}{c_{i+1}-c_i} > r$. For $j \geq i$ one has $r < \frac{f(c)-f(c_j)}{c-c_j} \leq f'(c) < q$, so $rc - f(c) = \inf_{j\geq i} rc_j - f(c_j)$ and $qc - f(c) = \sup_{j\geq i} qc_j - f(c_j)$ are respectively right-c.e. and left-c.e., uniformly in r and q. ◀

▶ **Proposition 3.7** (Negative case)**.** *Let $c \in \mathbb{R}$ be left-c.e. and $f : \mathbb{R} \to \mathbb{R}$ be computable and such that $f'(c) = 0$ and $f(c)$ is not right-c.e. Let $x = (c, f(c))$ and $v = (1, f'(c)) = (1, 0)$. x is not $\{v\}^*$-c.e.*

Proof. Simply take $d = (0, -1) \in \{v\}^*$. d is computable but $\langle d, x\rangle = -f(c)$ is not left-c.e. ◀

Said differently, in that case $qc - f(c)$ is non-uniformly left-c.e. for rationals $q > 0$.

3.1 Converging sequences

We may equivalently define semicomputable points to be those points which are the limit of a computable sequence converging in some restricted region of the space, namely a salient convex cone. There is a precise relation between the cones where such sequences can live and the cones of directions in which the point is left-c.e.

The first observation is straightforward.

▶ **Proposition 3.8.** *Let $x \in \mathbb{R}^n$ and $C \subseteq \mathbb{R}^n$ be a convex cone. If there exists a computable sequence x_i converging to x in $x - C$, then x is C^*-c.e.*

Proof. If $d \in C^*$ then $\langle d, x - x_i \rangle \geq 0$ so $\langle d, x \rangle = \sup_i \langle d, x_i \rangle$ is left-c.e. uniformly in d. ◀

In general it is not an equivalence. However when C is c.e. closed, or equivalently when C^* is co-c.e. closed, the equivalence holds.

▶ **Proposition 3.9.** *Let $x \in \mathbb{R}^n$ and $C \subseteq \mathbb{R}^n$ be a salient c.e. closed convex cone. x is C^*-c.e. $\iff$ there exists a computable sequence converging to x in $x - C$.*

Proof. Assume that x is C^*-c.e. The interior of $x - C$ is an effective open set. Indeed, y belongs to that set iff $\min_{d \in C_1^*} \langle d, x - y \rangle > 0$, which is a c.e. condition as C_1^* is effectively compact. As a result, there is a computable enumeration $(y_i)_{i \in \mathbb{N}}$ of the rational vectors in that set. Define a computable sequence $(x_i)_{i \in \mathbb{N}}$ as follows: take $x_{i+1} \in \int(x - C)$ such that $y_0, \dots, y_i \prec x_{i+1}$.

As C is salient, the growing sequence x_i converges to a point in $x - C$. As it eventually exceeds each y_i, the limit must be x. ◀

3.2 Taking unions of convex cones

In $\mathbb{R}^2$, let P, Q be full-dimensional closed convex cones and R be the conical hull of $P \cup Q$. If $x \in \mathbb{R}^2$ is P-c.e. and Q-c.e., then x is R-c.e. However we will see below (Theorem 3.12) that this property fails in higher dimensions. We first show that it can be recovered under computability assumptions on P, Q.

▶ **Proposition 3.10.** *Let $P, Q \subseteq \mathbb{R}^n$ be closed convex cones, R be the conical hull of $P \cup Q$ and $x \in \mathbb{R}^n$ be P-c.e. and Q-c.e.*

- *If P and Q are c.e. closed then R is c.e. closed and x is R-c.e.,*
- *If P and Q are co-c.e. closed and R is salient, then R is co-c.e. closed and x is R-c.e.*

In the second statement, the condition that R is salient is needed otherwise the complexity of R can increase, as we now show.

▶ **Proposition 3.11.** *If $P, Q \subseteq \mathbb{R}^n$ are co-c.e. closed convex cones and R is the convex cone induced by $P \cup Q$, then R is $\emptyset'$-c.e. closed. In dimension $n \geq 3$ one can take P, Q so that R is not $\emptyset'$-co-c.e. closed.*

The proof essentially uses Lemma 2.4. Indeed, P^* and Q^* are c.e. closed and $R^* = P^* \cap Q^*$. One can embed the convex sets A, B from Lemma 2.4 in $\mathbb{R}^3$ and take their conical hulls.

We will see that the second item fails when R is not salient (Corollary 4.7). We now build a simpler example without the co-c.e. assumption about P and Q.

▶ **Theorem 3.12.** *In dimension $n \geq 3$, there exist closed convex cones $P, Q \subseteq \mathbb{R}^n$ and a point $x \in \mathbb{R}^n$ that is P-c.e. and Q-c.e. but not R-c.e., where R is the conical hull of $P \cup Q$.*

The idea of the proof is to build a, b, c such that $qc - a$ and $rc - b$ are *uniformly* left-c.e. for $q > \overline{S}(a, c)$ and $r > \overline{S}(b, c)$, but $sc - (a + b)$ is *non-uniformly* left-c.e. for $q > \overline{S}(a + b, c)$. To do this, we take $a = f(c)$ ang $b = g(c)$ where f, g satisfy the conditions of Proposition 3.6 but $f + g$ satisfies the conditions of Proposition 3.7.

3.3 Semicomputability range of a point

▶ **Definition 3.13.** *If $x \in \mathbb{R}^n$ then its* **semicomputability range***, or simply* **range***, is the set of computable $d \in \mathbb{R}^n$ such that $\langle d, x\rangle$ is left-c.e., and is denoted by* $\text{range}(x)$*.*

One of the main goals of the paper is to investigate the following problem.

▶ **Problem 1.** *What sets can be realized as* $\text{range}(x)$ *for some x?*

Let $\mathbb{R}_c$ be the field of computable real numbers. From the definition we see that $\text{range}(x)$ contains computable points from $\mathbb{R}^n_c$ only. By abuse of language, when we write $A \subseteq \text{range}(x)$ we mean $A \cap \mathbb{R}^n_c \subseteq \text{range}(x)$, and similarly, $\text{range}(x) = A$ means $\text{range}(x) = A \cap \mathbb{R}^n_c$. The interior of $\text{range}(x)$ is meant to be the interior of $\text{range}(x)$ in the subspace topology on $\mathbb{R}^n_c$.

▶ **Proposition 3.14.** *Let $x \in \mathbb{R}^n$:*

1. $\text{range}(x)$ *is a convex cone over the field* $\mathbb{R}_c$*.*
2. *If $D \subseteq \mathbb{R}^n$ is a closed polygonal convex cone with computable coordinates, then x is D-c.e. $\iff$ $D \subseteq \text{range}(x)$.*
3. *If $D \subseteq \mathbb{R}^n$ be a closed convex cone contained in the interior of* $\text{range}(x)$*, then x is D-c.e.*

Proof.

1. Straightforward.
2. x is D-c.e. $\iff$ x is d-c.e. for each extreme direction $d \in D$ $\iff$ each such direction belongs to $\text{range}(x)$.
3. There exists a rational polygonal convex cone E containing D and contained in $\text{range}(x)$. By 2., x is E-c.e. hence D-c.e. ◀

We will see that $\text{range}(x)$ is not necessarily closed (in the subspace $\mathbb{R}^n_c$), and that the third item sometimes fails when D is just contained in $\text{range}(x)$ (Theorem 4.6).

▶ **Proposition 3.15.** *Let $x \in \mathbb{R}^n$ be a semicomputable point. Let $D \subseteq \mathbb{R}^n$ be a closed convex cone such that x is D-c.e. and* $\text{range}(x) = D$*. Then D is $\emptyset'$-co-c.e. closed.*

Proof. Let M be a machine that given a rational point $d \in D$ approximates $\langle d, x\rangle$ from the left. With $\emptyset'$ as oracle, given a rational point d, one can compute x, $\langle d, x\rangle$ and $M(d)$ and eventually see whether $M(d) \neq \langle d, x\rangle$, which means that $d \notin D$. As a result, the set of rational points outside D is c.e. relative to $\emptyset'$ so D is Π^0_2 by Proposition 2.5. ◀

We will see that this is tight: every $\emptyset'$-co-c.e. closed convex cone can be obtained (Theorem 4.8).

3.4 Solovay complete coordinates

When one of the coordinates of $x \in \mathbb{R}^n$ is Solovay complete, the range of x is easily described.

▶ **Proposition 3.16.** *Let $x = (x_1, \dots, x_n) \in \mathbb{R}^n$ where x_1 is Solovay complete. Let $v = (1, S(x_2, x_1), \dots, S(x_n, x_1))$. One has $\overline{\text{range}(x)} = \{v\}^*$.*

For a closed convex cone C,

$$v \in \text{int}(C) \implies x \text{ is } C^*\text{-c.e.} \implies v \in C.$$

Proof. A computable sequence x_i converging to x must asymptotically converge along the direction v, for each rational d such that $\langle d, v\rangle > 0$, one eventually has $\langle d, x - x_i\rangle > 0$, so $\langle d, x\rangle$ is left-c.e. The set of such vectors d is dense in $\{v\}^*$.

If v belongs to the interior of C then C^* is contained in the interior of $\{v\}^* = \overline{\mathrm{range}(x)}$ so x is C^*-c.e. by Proposition 3.14 item 3. If x is C^*-c.e. then $C^* \subseteq \mathrm{range}(x) \subseteq \{v\}^*$, i.e. $v \in C$. ◀

In particular, if d is a computable vector such that $\langle d, v\rangle > 0$, then $\langle d, x\rangle$ is left-c.e.

4 Realizing convex cones

In this section we investigate the possible ranges of semicomputable points. In order to realize a given convex cone D, we build a point that is left-c.e. along each computable direction in D, and no more. To do so, we make the point *generic* in some sense. Let us briefly recall from [4] the notion of genericity that we need.

4.1 Genericity

▶ **Definition 4.1.** *Let $A \subseteq \mathbb{R}^n$. A point $x \in A$ is* **generic inside** *A if for every effective open set $U \subseteq \mathbb{R}^n$, either $x \in U$ or there exists a neighborhood B of x such that $B \cap U \cap A = \emptyset$.*

▶ **Example 4.2.**

- Taking $A = X$, being generic inside X amounts to being 1-generic,
- Every x is obviously generic inside $\{x\}$,
- In the space of real numbers with the Euclidean topology, a real number $x \in (0, 1)$ is said to be right-generic if x is generic inside $[x, 1]$,

The last example is a particular instance of the following general situation.

If τ' is a weaker topology on X then we define $S(x)$ as the intersection of the τ'-open sets containing x. Equivalently, $S(x) = \{y \in X : x \leq_{\tau'} y\}$ where $\leq_{\tau'}$ is the specialization pre-order defined by $x \leq y$ iff every τ'-neighborhood of x contains y.

Let τ be the Euclidean topology on $\mathbb{R}^n$.

▶ **Theorem 4.3** (Theorem 4.1.1 in [4]). *Let τ' a topology that is effectively weaker than τ, such that emptiness of finite intersections of basic open sets in τ and τ' is decidable. There exists a point x that is computable in $(\mathbb{R}^n, \tau')$ and generic inside $S(x)$.*

For instance, the topology τ' generated by the semi-lines $(q, +\infty)$ is effectively weaker than τ, and its specialization pre-order is the natural ordering $\leq$ on $\mathbb{R}$. Theorem 4.3 implies the existence of right-generic left-c.e. reals.

▶ **Proposition 4.4.** *Let $C \subseteq \mathbb{R}^n$ be a closed convex cone. If x is generic inside $x + C$ then* $\mathrm{range}(x) \subseteq C^*$*.*

Proof. Let $d \notin C^*$ be computable and assume that $\alpha := \langle d, x\rangle$ is left-c.e. The set $U = \{y : \langle d, y\rangle < \alpha\}$ is effectively open and $x \notin U$. As $d \notin C^*$ there exists $c \in C$ such that $\langle d, c\rangle < 0$. For $\epsilon > 0$, $\langle d, x + \epsilon c\rangle < \langle d, x\rangle = \alpha$ so $x + \epsilon c \in U \cap (x + C)$. As a result, x belongs to the closure of $U \cap (x + C)$ so x is not generic inside $x + C$. ◀

In particular, if x is C^*-c.e. and generic inside $x + C$ then $\mathrm{range}(x) = C^*$.

4.2 Realizing convex cones

Theorem 4.3 can now be applied to obtain a first class of cones realized as ranges of points.

▶ **Theorem 4.5** (C.e. closed cones). *Let $C \subseteq \mathbb{R}^n$ be a co-c.e. closed convex cone. There exists x that is C^*-c.e. and generic inside $x + C$, hence* $\mathrm{range}(x) = C^*$.

Proof. C^* is c.e. closed, llet $d_i \in C^*$ be a computable dense sequence. Consider the topology τ' generated by the basic open sets $U_{i,j} = \{x : \langle d_i, x\rangle > q_j\}$, where $(q_j)_{j\in\mathbb{N}}$ is some computable enumeration of the positive rational numbers. One easily checks that emptiness of finite intersections of basic open sets in τ, τ' is decidable, so we can apply Theorem 4.3. We obtain a point x that is computable in $(\mathbb{R}^n, \tau')$, i.e. the numbers $\langle d_i, x\rangle$ are uniformly left-c.e. hence x is C^*-c.e. and $C^* \subseteq \mathrm{range}(x)$. Moreover x is generic inside $S(x) = x + C$, hence $\mathrm{range}(x) \subseteq C^*$ by Proposition 4.4. ◀

Therefore, any c.e. closed convex cone can be realized as the range of a point. We can extend the result to other classes of closed convex cones. To do so, we need to refine the construction techniques.

▶ **Theorem 4.6** (Σ^0_2 cones). *Let $(D_k)_{k\in\mathbb{N}}$ be a growing sequence of uniformly co-c.e. closed convex cones in $\mathbb{R}^n$. There exists x such that for any co-c.e. closed convex cone K, x is K-c.e. $\iff$ K is contained in some D_k. In particular,* $\mathrm{range}(x) = \bigcup_k D_k$.

In particular, any $\emptyset'$-effectively open convex cone is the range of a point.

We can use this result to give a counter-example to Proposition 3.10 when the cone is not salient.

▶ **Corollary 4.7.** *There exists co-c.e. closed convex cones $P, Q \subseteq \mathbb{R}^3$ and a point x that is P-c.e. and Q-c.e. but not R-c.e., where R is the convex cone induced by $P \cup Q$.*

Proof. Take P, Q from Proposition 3.11. The induced cone R is $\emptyset'$-c.e. closed but not $\emptyset'$-co-c.e. closed. By Proposition 2.3, R contains a dense Σ^0_2-set R', and we can assume that R' contains P and Q (otherwise replace R' with $R' \cup P \cup Q$). By Theorem 4.6 there exists x such that $\mathrm{range}(x) = R'$, x is P-c.e. and Q-c.e. But x is not R-c.e., otherwise R would be $\emptyset'$-co-c.e. closed by Proposition 3.15. ◀

▶ **Theorem 4.8** (Π^0_2 cones). *Let $D \subseteq \mathbb{R}^n$ be a salient Π^0_2 convex cone. There exists x that is D-c.e. and such that* $\mathrm{range}(x) = D$.

4.3 Beyond linear maps

If x is C^*-c.e. and generic inside $x + C$ then we know for which computable linear maps $f : \mathbb{R}^n \to \mathbb{R}$ the number $f(x)$ is left-c.e.: exactly when $f \in C^*$ (f can be identified with the vector v such that $f(x) = \langle v, x\rangle$).

Genericity has also consequences on functions $f : \mathbb{R}^n \to \mathbb{R}$ that are not linear but totally differentiable. We recall that if f is ***totally differentiable*** at x then there exists a vector $\mathrm{grad}f(x)$ such that $f(x + h) = f(x) + \langle \mathrm{grad}f(x), h\rangle + o(h)$.

▶ **Proposition 4.9.** *Let $C \subseteq \mathbb{R}^n$ be a closed convex cone. Let $x \in \mathbb{R}^n$ be C^*-c.e. and generic inside $x + C$. Let $f : \mathbb{R}^n \to \mathbb{R}$ be computable and totally differentiable at x.*

- *If* $\mathrm{grad}f(x) \in \mathrm{int}(C^*)$ *then $f(x)$ is left-c.e.*
- *If* $\mathrm{grad}f(x) \notin C^*$ *then $f(x)$ is not left-c.e.*

Proof. Let $D^* \subseteq \mathrm{int}(C^*)$ be a computable polygonal convex salient cone containing $\mathrm{grad} f(x)$ in its interior. There exists $\delta > 0$ such that $\langle \mathrm{grad} f(x), d\rangle > \delta$ for all $d \in D_1$. As x is D^*-c.e., there exists a computable sequence $x_i \in x - D$ converging to x by Proposition 3.9. Therefore one has $f(x_i) = f(x) - \langle \mathrm{grad} f(x), (x - x_i)\rangle + o(x - x_i) < f(x) - \|x - x_i\|\, \delta + o(x - x_i) < f(x)$ for i larger than some i_0, so $f(x) = \sup_{i \geq i_0} f(x_i)$ is left-c.e.

Assume that $\mathrm{grad} f(x) \notin C^*$ and that $\alpha := f(x)$ is left-c.e. The set $U = \{y : f(y) < \alpha\}$ is effectively open. As $\mathrm{grad} f(x) \notin C^*$, there exists $c \in C$ such that $\langle \mathrm{grad} f(x), c\rangle < 0$. One has $f(x + \epsilon c) = f(x) + \epsilon\langle \mathrm{grad} f(x), c\rangle + o(\epsilon) < f(x)$ for sufficiently small ϵ, so $x + \epsilon c \in U \cap (x + C)$. Therefore $x \notin U$ and belongs to the closure of $(x + C) \cap U$, contradicting the assumption that x is generic inside $x + C$. ◀

5 Application to the Solovay derivatives

We pursue the study of the Solovay derivatives $\overline{S}(a, b)$ and $\underline{S}(a, b)$ started in [5] in the general case, i.e. without assuming that b is Solovay complete. The general goal is to find ways to calculate $\underline{S}(a, b)$ and $\overline{S}(a, b)$ for given a, b. Although formulae are available in some cases, we investigate one of the simplest situations in which no general formula exists:

▶ **Problem 2.** *If $a, b, c \in \mathbb{R}$ are fixed, what can be the shapes of the functions $\overline{S}(aX + b, c)$ and $\underline{S}(aX + b, c)$, where X varies among the computable real numbers?*

When c is Solovay complete, one has $S(x, c) := \overline{S}(x, c) = \underline{S}(x, c)$ for any d-c.e. x and

$$S(aX + b, c) = S(a, c)X + S(b, c).$$

However in general only inequalities can be derived (see [5]):

If $X \geq 0$,

$$\overline{S}(aX + b, c) \leq \overline{S}(a, c)X + \overline{S}(b, c)$$
$$\underline{S}(aX + b, c) \geq \underline{S}(a, c)X + \underline{S}(b, c).$$

If $X \leq 0$,

$$\overline{S}(aX + b, c) \leq \underline{S}(a, c)X + \overline{S}(b, c)$$
$$\underline{S}(aX + b, c)) \geq \overline{S}(a, c)X + \underline{S}(b, c).$$

It seems at first that these two functions of X should be very rigid because a, b, c are fixed, so their local shape should not depend too much on X. However, we will see that, up to some geometrical contraints, they can have a wide variety of possible shapes. Fortunately, we can use the notions and results of this paper to precisely identify the class of possible shapes of these two functions. The idea is geometrical: these functions can be read in some way from the convex cone $\mathrm{range}(x)$, where $x = (a, b, c)$. Therefore their shapes are precisely the shapes that can be obtained from arbitrary convex cones. Let $\overline{\mathbb{R}} = [-\infty, +\infty]$.

▶ **Definition 5.1.** *Let $\mathcal{F}$ be the family of pairs of functions (f, g) from $\mathbb{R}$ to $\overline{\mathbb{R}}$ such that:*

- *$f \geq g$,*
- *f is convex and g is concave (i.e., the epigraphs of f and $-g$ are convex sets),*
- *Every line segment joining the graph of f to the graph of g lies below the graph of f and above the graph of g.*

The third condition implies that $\lim_{x\to-\infty} f'(x) = \lim_{x\to+\infty} g'(x)$ and $\lim_{x\to+\infty} f'(x) = \lim_{x\to-\infty} g'(x)$. Examples of such pairs are: $f(X) = -g(X) = \sqrt{1 + X^2}$, or $f(X) = X^2$ and $g(X) = -\infty$.

The main result of this section is that $\mathcal{F}$ captures essentially the possible shapes of $(\overline{S}(aX + b, c), \underline{S}(aX + b, c))$, up to computability conditions.

▶ **Theorem 5.2.** *Let $a, b, c \in \mathbb{R}$ with c left-c.e. and non-computable. One has $(\overline{S}(aX + b, c), \underline{S}(aX + b, c)) \in \mathcal{F}$. Conversely,*

- *Any pair $(f, g) \in \mathcal{F}$ where f is $\emptyset'$-left-c.e. and g is $\emptyset'$-right-c.e. can be realized,*
- *Any pair $(f, g) \in \mathcal{F}$ where f is $\emptyset'$-right-c.e. and g is $\emptyset'$-left-c.e. can be realized,*

To prove this result we show that the pairs $(f, g) \in \mathcal{F}$ are exactly the functions that can be read on convex cones in $\mathbb{R}^3$ in the following way: given a cone C in $\mathbb{R}^3$, the intersection of C with the planes $y = \pm 1$ convex sets, and the curves delimiting them are exactly the pairs $(f, g) \in \mathcal{F}$.

Now, if $x = (a, b, c) \in \mathbb{R}^*$ then the pair $(\overline{S}(aX + b, c), \underline{S}(aX + b, c))$ is obtained in this way from the cone $C = \text{range}(x)$, so it belongs to $\mathcal{F}$. A pair $(f, g) \in \mathcal{F}$ can be realized by building a point whose range induces (f, g), which can be done by imposing computability conditions on f and g and applying the results from Section 4.

6 Left-c.e. quadratic polynomials

In this section, we briefly investigate the quadratic real polynomials $P_{a,b,c}(X) = aX^2 + bX + c$ that are left-c.e. functions of X. Our main problem is the following:

▶ **Problem 3.** *For which triples (a, b, c) is the polynomial $P_{a,b,c}$ left-c.e.?*

The key observation is that $P_{a,b,c}(X)$ is linear in (a, b, c), which allows to think of a left-c.e. polynomial as a semicomputable point $(a, b, c) \in \mathbb{R}^3$. More precisely, the ordering $(a, b, c) \preceq (a', b', c')$ defined by $P_{a,b,c} \leq P_{a',b',c'}$ is a vector space ordering. Hence its positive cone is a convex cone $C = \{(a, b, c) \in \mathbb{R}^3 : P_{a,b,c} \geq 0\} = \{(a, b, c) \in \mathbb{R}^3 : a, c \geq 0 \text{ and } b^2 \leq 4ac\}$. Its dual is $C^* = \{(a, b, c) \in \mathbb{R}^3 : a, c \geq 0 \text{ and } b^2 \leq ac\}$ and is the closure of the conical hull of the vectors $(X^2, X, 1)$, with $X \in \mathbb{R}$.

Thus $P_{a,b,c}$ is left-c.e. if and only if (a, b, c) is C^*-c.e. This reformulation allows us to think geometrically about left-c.e. polynomials, and to apply the results of this paper to these objects. Let us list a few properties of left-c.e. polynomials, some of them being derived from the analysis developed in the paper:

1. There is a symmetry between a and c and between b and $-b$. More precisely, $P_{a,b,c}$ is left-c.e. $\iff$ $P_{a,b,c}, P_{c,b,a}, P_{a,-b,c}$ and $P_{c,-b,a}$ are left-c.e. for $X \geq 1$.
2. If $P_{a,b,c}$ is left-c.e. then a, c are left-c.e. and b is d-c.e. (b is a difference of left-c.e. numbers).
3. If a is Solovay complete left-c.e. then (Proposition 3.16)
$$S(b, a)^2 < 4S(c, a) \implies P_{a,b,c} \text{ is left-c.e.} \implies S(b, a)^2 \leq 4S(c, a).$$
4. Let $P_{a,b,c}$ be left-c.e. For computable $X > 0$,
$$-\frac{1}{\sqrt{X}} \leq \underline{S}(b, aX + c) \quad \text{and} \quad \overline{S}(b, aX + c) \leq \frac{1}{\sqrt{X}}.$$
Indeed, $aX^2 + bX + c$ is left-c.e. for all computable $X \in \mathbb{R} \iff \frac{1}{\sqrt{Y}}(aY + c) \pm b$ is left-c.e. for all computable $Y > 0$ (take $Y = X^2$).
5. Let $x = (a, b, c)$ be C^*-c.e. and generic inside $x + C$ (it exists as C^* is computable, see Theorem 4.3). $P_{a,b,c}$ is left-c.e. and for computable $X > 0$,
$$-\frac{1}{\sqrt{X}} = \underline{S}(b, aX + c) \quad \text{and} \quad \overline{S}(b, aX + c) = \frac{1}{\sqrt{X}}.$$
The second equality is obtained as follows: for a rational $q < \frac{1}{\sqrt{X}}$, $(qX, -1, q) \notin C^* = \text{range}(x)$ so $q(aX + c) - b$ is not left-c.e., hence $\overline{S}(b, aX + c) = \frac{1}{\sqrt{X}}$.

Although b is Solovay reducible to $aX + c$ for each computable $X > 0$, b is not reducible to neither a nor c and $\underline{S}(b, a) = \underline{S}(b, c) = -\infty$ and $\overline{S}(b, a) = \overline{S}(b, c) = +\infty$. Indeed, for $q \in \mathbb{Q}$, both $(q, \pm 1, 0)$ and $(0, \pm 1, q)$ are outside C^*.

6. The condition that $P_{a,b,c}$ is left-c.e. cannot be reduced to a finite number of linear combination of a, b, c being left-c.e. Indeed, such a condition would express that the point (a, b, c) is D-c.e. for some polygonal convex cone D, but the convex cone C^* is not polygonal (it is determined by infinitely many directions).
7. The condition that $P_{a,b,c}$ is left-c.e. cannot be characterized by simply considering the values of $\underline{S}(b, c)$, $\overline{S}(b, c)$, $\underline{S}(a, c)$, $\overline{S}(a, c)$, $\underline{S}(b, a)$, $\overline{S}(b, a)$. Indeed, these values only reflect the intersections of range(a, b, c) with the three planes $z = 0$, $x = 0$ and $y = 0$, which do not determine completely range(a, b, c).

We do not know if it is possible to better understand Problem 3, i.e. whether it is possible to reduce this property to more fundamental properties of a, b, c. The results presented above suggest a negative answer to that question.

We mention that a similar analysis can be made of co-c.e. disks in the plane. The disk centered at (a, b) with radius c is co-c.e. if and only if the point $(a, b, c) \in \mathbb{R}^3$ is C^*-c.e., where $C = C^* = \{(x, y, z) : z \leq 0, x^2 + y^2 \leq z^2\}$. Again C^* is not polygonal so one cannot reduce the condition that the disk is co-c.e. to a finite number of conditions.

Abstract

We prove that there is a constant K such that *Tseitin* formulas for an undirected graph G requires proofs of size $2^{\mathrm{tw}(G)^{\Omega(1/d)}}$ in depth-d Frege systems for $d < \frac{K \log n}{\log \log n}$, where $\mathrm{tw}(G)$ is the treewidth of G. This extends Håstad recent lower bound for the grid graph to any graph. Furthermore, we prove tightness of our bound up to a multiplicative constant in the top exponent. Namely, we show that if a Tseitin formula for a graph G has size s, then for all large enough d, it has a depth-d Frege proof of size $2^{\mathrm{tw}(G)^{\mathcal{O}(1/d)}}\mathrm{poly}(s)$. Through this result we settle the question posed by M. Alekhnovich and A. Razborov of showing that the class of Tseitin formulas is quasi-automatizable for resolution.

1 Introduction

Propositional proof complexity is motivated by the result of Cook and Reckhow [12] saying that if there is a propositional proof system in which any unsatisfiable formula F has a short proof of unsatisfiability (of size polynomial in the size of F), then NP = coNP. In the last 30 years the complexity of proofs was investigated for several proof systems with the aim of finding concrete evidence, and eventually a proof, that for all proof systems there is a propositional formula which is not efficiently provable, i.e. requires super-polynomial proof

size. The approach followed to prove such lower bounds was essentially borrowed from circuit complexity. Lines in a proof are Boolean formulas and we can define different proof system according to the circuit complexity of such formulas. For example resolution, a well-known refutational system for CNFs, corresponds to a system where formulas are of depth 1. In circuit complexity we keep on trying to strength lower bounds to computationally more powerful class of circuits. In proof complexity we follow the analogous approach: to strength lower bounds to systems working on formulas computationally more powerful. The hope is that techniques used to prove lower bounds for classes of Boolean circuits could be lifted to work with proof systems operating with formulas in the same circuit class. At present however we are far from such ideal situation and in fact, in terms of circuit classes, lower bounds for proof systems are well below those for Boolean circuits.

The complexity of proofs in resolution is largely studied. The first lower bound for (a restriction of) resolution was given by Tseitin in [35]. To obtain his result Tseitin introduced a class of formulas (nowadays known as *Tseitin formulas*) encoding a generalisation of the principle that the sum of the degrees of all vertices in a graph is an even number. A Tseitin formula $\mathsf{T}(G, f)$ is defined for every undirected graph $G(V, E)$ and a charging function $f : V \to \{0, 1\}$. We introduce a propositional variable for every edge of G so that $\mathsf{T}(G, f)$ is a CNF representation of a linear system over the field GF(2) that for every vertex $v \in V$ states that the sum of all edges incident to v equals $f(v)$. Tseitin formulas, usually defined on graphs with good expansion properties, are among the main examples we could prove lower bounds for in different proof systems. For unrestricted resolution it was Urquhart in [36] and later Ben-Sasson and Wigderson [8] who proved exponential lower bounds for Tseitin formulas over constant-degree expander graphs. Another example of an important principle largely studied in proof complexity is the Pigeonhole principle, PHP_n. Haken [19], Beame and Pitassi [4] and Ben-Sasson Wigderson [8] proved exponential resolution lower bounds for CNF encoding of the negation of PHP_n, which were later generalized and improved in several other works [13, 30, 32, 33, 9, 24].

Bounded-depth Frege extends resolution since the formulas in the line of proofs are computable by AC^0 circuits, i.e. constant-depth circuits with unbounded fan-in gates. The importance of understanding the complexity of proofs in bounded-depth-Frege systems was due at least to two reasons: (1) for general Frege systems, where formulas have no restrictions, i.e. are of depth $\mathcal{O}(\log n)$, Buss in [10] proved that the Pigeonhole principle can be proved in polynomial size, hence obtaining an exponential separation with resolution. (2) Lower bounds for AC^0-circuits were known [21, 15] and hence we could hope for applying lower bound techniques for AC^0 to lower bounds to bounded-depth Frege. Studying the complexity of proofs in bounded-depth Frege is of the utmost importance since it is a frontier proof system, i.e. one of the strongest propositional proof systems with known significant lower bounds at the moment. Any advance is then a step towards proving lower bounds for $\mathrm{AC}^0[2]$-Frege, i.e. a bounded-depth Frege admitting also formulas with parity gates, which are unknown at the moment, though we know since a long time exponential lower bounds for $\mathrm{AC}^0[2]$ circuits [34, 31, 25]. In this work we contribute to the complexity of proofs in bounded-depth Frege proving new lower bounds for Tseitin formulas.

Ajtai in [1] was the first to prove a lower bound in bounded-depth Frege. He showed that a proof of PHP_n must have a super-polynomial size. His result was later followed by several results simplifying his technique [5] and improving the lower bound [27, 26] showing that any polynomial-size Frege proof of PHP_n must have depth $\Omega(\log \log n)$. The proof complexity of Tseitin formulas in bounded-depth Frege was first considered by Urquhart and Fu in [37], a work where they simplified and adapted the lower bound for the PHP_n to the case of Tseitin formulas over a complete graph. Ben-Sasson in [7], proved exponential lower bounds for the Tseitin formulas over constant-degree expander graphs using a new reduction from the pigeonhole principle [37]. All these lower bounds are adaptation of the technique of [27, 26], hence vanish when the depth of formulas in the proof is more than $\log\log n$. In a very recent major breakthrough [28] showed that Tseitin formulas over a 3-expander graph of n nodes requires super-polynomial bounded-depth Frege proofs at depth $\mathcal{O}(\sqrt{\log n})$. Their result was later improved to depth up to $\frac{C\log n}{\log\log n}$ by Håstad in [22] but for Tseitin formulas defined only on the 2-dimensional grid, where C is a positive constant.

Proofs of $\mathsf{T}(G, f)$ were studied in terms of the treewidth of G, $\mathrm{tw}(G)$, for resolution [2, 17] and for OBDD proof systems [18]. We use Håstad result to prove tight bounds on the complexity of proofs in bounded-depth Frege of $\mathsf{T}(G, f)$ *over any graph* G in terms of the treewidth of G. Our main result is the following theorem:

▶ **Theorem 1.** *There is a constant K such that for any graph G over n nodes and for all $d \leq K\frac{\log n}{\log\log n}$, every depth-$d$ Frege proof of $\neg\mathsf{T}(G, f)$ has size at least $2^{\mathrm{tw}(G)^{\Omega(1/d)}}$. Furthermore, for all large enough d there exist depth-d Frege proofs of $\neg\mathsf{T}(G, f)$ of size $2^{\mathrm{tw}(G)^{\mathcal{O}(1/d)}}\mathrm{poly}(|\mathsf{T}(G, f)|)$.*

A class of unsatisfiable CNFs F_n is (quasi-)automatizable in a proof systems S, if there exists a deterministic algorithm that, given F in F_n returns a proof in S in time which is (quasi-)polynomial in $|F| + |\tau_F|$, where $|\tau_F|$ is the size of shortest proof of F in S. Theorem 1, together with the results from [17, 20, 2, 3] implies that *for any graph* G, the class of Tseitin formulas is *quasi-automatizable* in all systems between treelike resolution and constant-depth Frege. This answers the problem of [2] of extending to all graphs the quasi-automazibablity of $\mathsf{T}(G, f)$ in resolution, known only for graphs with bounded cyclicity [2].

Using a result in [3, 23] we can also prove that the size of proofs of $\mathsf{T}(G, f)$ in proof systems between tree-like resolution and bounded-depth Frege are quasi-polynomially correlated, i.e. *if* $\mathsf{T}(G, f)$ *has a proof of size* S *in bounded-depth Frege, then it has a proof of size at most* $2^{\mathrm{poly}(\log(S+|\mathsf{T}(G,f)|))}$ *in treelike resolution and vice versa.* This result provides evidence to the conjecture of Urquhart that the shortest resolution proofs of $\mathsf{T}(G, f)$ are regular. Finally other consequences of Theorem 1 are: (1) It gives polynomial size Frege proofs of $\mathsf{T}(G, f)$ of depth $\log(\mathrm{tw}(G))$. (2) It improves the lower bounds of [7, 28] since expanders have treewidth $\Omega(n)$ and on such graphs our lower bound is $2^{n^{\Omega(1/d)}}$, which works for larger d than [7, 28]; (3) Induces a strict depth-hierarchy for the proof complexities of Tseitin formulas over an infinite sequence of graphs G_n.

Overview of the proof technique

In Theorem 17 we prove the lower bound from Theorem 1. The proof is based on the improvement of the Excluded Grid Theorem by Robertson and Seymour recently obtained by Chuzhoy [11]: an arbitrary graph G contains as a minor a $r \times r$ grid, where $r = \Omega\left(\mathrm{tw}(G)^{1/37}\right)$. More precisely we use the corollary of this result (see Corollary 8) stating that any graph G has a *wall* of size r as a *topological minor* (i.e. can be obtained from G by several removing of vertices, edges and *suppressions*, see Fig. 1 and Fig. 3). Our proof consists of two parts: at first, we show that if H is a topological minor of G, then any bounded-depth Frege proof of a Tseitin formula $\mathsf{T}(G, f)$ can be transformed to a proof of a $\mathsf{T}(H, f')$, with constant increase in depth and polynomial increase in size. And then we prove a lower bound on the size of depth-d Frege proof of Tseitin formulas based on walls. In this proof we use the lower bound for grid graphs proved by Håstad [22].

In Theorem 18 we prove the upper bound from Theorem 1. We consider the *compact representation* of linear functions $\mathbb{F}_2^n \to \mathbb{F}_2$ on variables $x_1, x_2, \ldots, x_n$ by propositional formulas of depth d and of size $2^{n^{\mathcal{O}(1/d)}}$. We show that for linear functions f and g if the equations $f(x) = a$ and $g(x) = b$ are given in our representation, then there is a derivation of $(h+g)(x) = a + b$ of depth d and of size $2^{n^{\mathcal{O}(1/d)}}$. We also show that if a linear equation is represented in CNF, then it is possible to infer its compact representation with depth d and size $2^{n^{\mathcal{O}(1/d)}}$. Since a Tseitin formula is an unsatisfiable system of linear equations written in CNF, hence it is possible to prove a Tseitin formula in size $2^{m^{\mathcal{O}(1/d)}}$ and depth d, where m is the number of edges in G. However we wish to have the treewidth of G instead of m. We consider a tree-partition of a graph G, the vertices of G are split into bags and there exists a tree such that bags are nodes of this tree and if two vertices of G are connected, then they are either in one bag or in adjacent bags. It is known that there is a tree partition where the size of bags are at most $\mathcal{O}(\mathrm{tw}(G)\Delta(G))$ [38]. Since the number of edges touching a given bag is $\mathcal{O}(\mathrm{tw}(G)\Delta(G)^2)$ we can use the compact representation to take care of the equations involving the parity of sum of adjacent bags with proofs growing in terms of the treewidth of G.

Organization

The paper is divided into four sections. After the Preliminary section, we have Section 3 for the lower bound (Theorem 17), Section 4 for the upper bound (Theorem 18). Proofs omitted due to space constraints may be found in [16].

2 Preliminaries

2.1 Formulas and restrictions

We consider propositional formulas over binary $\vee$ and $\wedge$, unary $\neg$ and Boolean constants $\mathbf{0}, \mathbf{1}$. We represent formulas as rooted trees such that internal vertices are labeled with connectives and leaves are labeled with propositional variables or Boolean constants. The *depth* of a formula is the maximal number of alternations of types of connectives over all the paths from the root to a leaf plus one.

We assume that disjunctions with unbounded fanin are represented via binary disjunctions. By default, we mean that $\bigvee_{i=1}^{n} x_i$ is right-associative; i.e., denotes $(\ldots(x_1 \vee x_2) \vee \ldots) \vee x_{n-1}) \vee x_n$; we also assume the same for $\bigwedge$.

We denote by $\mathsf{vars}(F)$ the set of variables of a formula F. A *partial assignment* α for a formula F is mapping from $\mathsf{vars}(F) \to \{0, 1, *\}$, where $\alpha(x) = *$ if x is unassigned. We denote by $\mathsf{dom}(\alpha) = \alpha^{-1}(\{0, 1\})$ the set of variables in F which α assigns a Boolean value.

2.2 Pudlák-Buss games

We use the game interpretation of Frege proofs introduced by Pudlák and Buss [29]. Let us define a game with two players Pavel and Sam. The game starts with initial conditions of the form $\varphi_1 = a_1, \ldots, \varphi_k = a_k$, where $\varphi_1, \varphi_2, \ldots, \varphi_k$ are propositional formulas and $a_1, a_2, \ldots, a_k \in \{0, 1\}$ such that $\bigwedge_{i=1}^{k}(\varphi_i = a_i)$ is identically false. Sam claims that he knows an assignment of variables that satisfies $\bigwedge_{i=1}^{k}(\varphi_i = a_i)$, the goal of Pavel is to convict Sam. At each his move Pavel asks Sam the value of a propositional formula and Sam gives an answer. The game stops when Pavel convicts Sam, namely Pavel finds an immediate contradiction among initial conditions and Sam's answers. An immediate contradiction with a Boolean connective $\circ$ of arity t is a set of $(t+1)$ formulas $\alpha_1, \ldots, \alpha_t$ and $\circ(\alpha_1, \ldots, \alpha_t)$ with claimed values $a_1, \ldots, a_t$ and b such that $\circ(a_1, \ldots, a_k) \neq b$. In particular, $\mathbf{0}$ with claimed value 1 is an immediate contradiction.

A strategy of Pavel is a function that maps initial conditions and the history of a game to a propositional formula (request). A winning strategy is a strategy that allows Pavel to convict Sam for any behaviour of Sam. A winning strategy of Pavel can be represented as a binary tree whose nodes are labeled with Pavel's requests and edges correspond to Sam's answers. A leaf of the tree corresponds to an immediate contradiction among initial conditions and equalities corresponding to the path from the root to this leaf.

A Pudlák-Buss game derivation of a formula ψ from formulas $\varphi_1, \varphi_2, \ldots, \varphi_s$ is a tree of a Pavel's winning strategy in a game with initial conditions $\varphi_1 = 1, \varphi_2 = 1, \ldots, \varphi_s = 1, \psi = 0$. In that follows by derivations we always mean Pudlák-Buss game derivations. We are interested in the two complexity parameters of derivations: 1) the size of a derivation S that equals the total size of formula ψ and all formulas that are used as labels of nodes; 2) the depth of a derivation d is the maximum depth of ψ and formulas that are used as labels of nodes. We use the notation $\varphi_1, \ldots, \varphi_s \vdash_d \psi$ for a derivation of ψ from $\varphi_1, \varphi_2, \ldots, \varphi_s$ of depth at most d. A derivation of φ is a derivation of φ from the empty set of formulas.

▶ **Lemma 2.** *Assume that there is a derivation $\varphi_1, \ldots, \varphi_k \vdash_{d_1} \psi_1$ of size S_1 and also there is a derivation $\varphi_1, \ldots, \varphi_k, \psi_1 \vdash_{d_2} \psi_2$ of size S_2, then there is a derivation $\varphi_1, \ldots, \varphi_k \vdash_{\max\{d_1, d_2\}} \psi_2$ of size $S_1 + S_2$.*

Proof. Let us create the new tree with the root labelled with ψ_1 such that edge form the root labelled with 0 goes to the root of the first derivation and edge labelled with 1 goes to the root of the second derivation. ◀

▶ **Lemma 3.** *1. If a formula φ has a Frege derivation of size S and depth d, then φ has a Pudlák-Buss game derivation of size $\mathcal{O}(S^2)$ and depth d. 2. If φ has a Pudlák-Buss game derivation of size S and depth d, then φ has a Frege derivation of size $\mathcal{O}(S^3)$ and depth $d + \mathcal{O}(1)$.*

▶ **Lemma 4.** *Let ψ_1 and ψ_2 be two formulas of depth at most d such that $|\mathsf{vars}(\psi_1) \cup \mathsf{vars}(\psi_2)| = k$ and ψ_1 semantically implies ψ_2. Then there exists a derivation $\psi_1 \vdash_d \psi_2$ of size at most $2^k \left(|\psi_1|^2 + |\psi_2|^2\right)$.*

A shortcut contradiction for the disjunction is a situation where Pavel asks Sam formulas $\bigvee_{i=1}^k \alpha_i$ and α_j for $j \in [k]$ and gets the answers 0 and 1 respectively. Similarly a shortcut contradiction for the conjunction is a situation where Pavel asks Sam formulas $\bigwedge_{i=1}^k \alpha_i$ and α_j for $j \in [k]$ and gets the answers 1 and 0. *An ordinary derivation* is a derivation which does not use shortcut contradictions.

▶ **Lemma 5.** *Consider a derivation of size S and of depth d that uses shortcut contradictions in leaves. Then there is an ordinary derivation of size at most S^3 and of depth d.*

Tseitin Formulas. Let $G(V, E)$ be an undirected graph and $v \in V$. We denote by $E(v)$ the set of edges in E incident with v and by $N(v)$ the set of neighbours $u \in V$ of v, i.e. the u such that $(u, v) \in E(v)$.

A vertex-charging for $G(V, E)$ is a mapping $f : V \longrightarrow \{0, 1\}$. We say that f is an odd-charging of G if $\sum_{v \in V} f(v) \equiv 1 \mod 2$. The *Tseitin formulas* defined on G using variables $x_e, e \in E$ are the formulas: $\mathsf{T}(G, f) := \bigwedge_{v \in V} \mathsf{Par}(v)$, where $\mathsf{Par}(v)$ is a CNF formula representing $\bigoplus_{e \in E(v)} x_e = f(v)$.

▶ **Lemma 6** ([36]). *$\mathsf{T}(G,f)$ is unsatisfiable if and only if there is a connected component U of G such that the restriction of f on U is odd-charging.*

In this work we will work with the tautological form of Tseitin formulas in the form of $\neg\,\mathsf{T}(G,f)$.

2.3 Grids, Walls, Minors, Topological Minors and Treewidth

We consider 4 structural operations on undirected graphs $G = (V,E)$ possibly with parallel edges, but without loops. We follow [6, 14].

- *edge removal* of $e \in E$. It produces the graph $[G\backslash e] = (V, E\backslash\{e\})$.
- *vertex removal* of $v \in V$. It produces the graph $[G\backslash v] = (V\backslash\{v\}, E\backslash E(v))$, where $E(v)$ is the set of edges in E incident with $v \in V$.
- *edge contraction* of $e = (uv) \in E$. Is the replacement of u and v with a single vertex such that edges incident to the new vertex are the edges other than e that were incident with u or v. The resulting graph $G\star e$ has one edge less than G.
- *vertex suppression* of a vertex v in G of degree 2. Let u and w be v's neighbours in G. The suppression of v is obtained by deleting v along with two edges (uv) and (wv) and adding a new edge (wu) (possibly parallel to an existing one). The resulting graph $[G\backslash_s v]$ has one vertex less than G. See Figure 1.

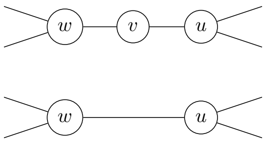

Figure 1 Suppression of v from G.

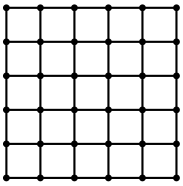

Figure 2 The grid $\mathcal{H}_{5,5}$.

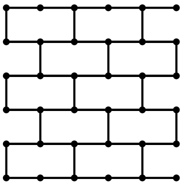

Figure 3 The wall $\mathcal{W}_5$.

A graph H is a *minor* of G if H can be obtained from G by a sequences of edge and vertex removals and edge contractions. A graph H is a *topological minor* of G if H can be obtained from G by a sequence of edge removals, vertex removals and by vertex suppressions [6, 14].

The grid $\mathcal{H}_{m,n}$ is the graph of the cellular rectangle $m \times n$; it has $(m+1)(n+1)$ vertices and $n(m+1) + m(n+1)$ edges, among them $n(m+1)$ horizontal and $m(n+1)$ vertical edges. See fig. 2.

The wall $\mathcal{W}_n$ is a subgraph of $\mathcal{H}_{n,n}$ that is obtained by the removing of several vertical edges. Vertical edges of $\mathcal{H}_{n,n}$ are in n rows and we enumerate them in every row from the left to the right. In the odd rows we remove all vertical edges with even numbers and in even rows we remove all vertical edges with odd numbers. See fig. 3.

A tree decomposition of an undirected graph $G(V,E)$ is a tree $T = (V_T, E_T)$ such that every vertex $u \in V_T$ corresponds to a set $X_u \subseteq V$ and it satisfies the following properties: 1. The union of X_u for $u \in V_T$ equals V. 2. For every edge $(a,b) \in E$ there exists $u \in V_T$ such that $a, b \in X_u$. 3. If a vertex $a \in V$ is in the sets X_u and X_v for some $u, v \in V_T$, then it is also in X_w for all w on the path between u and v in T.

The width of a tree decomposition is the maximum $|X_u|$ for $u \in V_T$ minus one. *A treewidth* of a graph G is the minimal value of the width among all tree decompositions of the graph G.

Recall the following Theorem proved in [11].

▶ **Theorem 7** ([11]). *If G has a treewidth t, then it has the grid $\mathcal{H}_{r,r}$ as a minor, where $r = \Omega(t^{1/37})$.*

The following Corollary was mentioned in [6].

▶ **Corollary 8** ([6]). *If G a has treewidth t, then it has the wall $\mathcal{W}_r$ as a topological minor, where $r = \Omega(t^{1/37})$.*

3 The Lower Bound

3.1 Topological Minors and Tseitin Formulas

Le φ be a formula and let α be a partial assignment to variables of φ. Define $\varphi[\alpha]$ to be the formula obtained from φ substituting each variable x in the domain of α, with the constant assigned to x by α. Notice that φ and $\varphi[\alpha]$ have the same size and depth.

▶ **Lemma 9.** *Let Φ_a and Φ'_a for $a \in A$ be propositional formulas of depth at most d such that $|\mathsf{vars}(\Phi_a) \cup \mathsf{vars}(\Phi'_a)| \leq k$. Assume that for all $a \in A$, Φ_a is semantically equivalent to Φ'_a. Then $\neg \bigwedge_{a\in A} \Phi'_a \vdash_{d+\mathcal{O}(1)} \neg \bigwedge_{a\in A'} \Phi_a$ of size at most $2^k \mathrm{poly}\left(\sum_{a\in A}(|\Phi_a| + |\Phi'_a|)\right)$, where $A' = \{a \in A \mid \Phi_a$ is not identically true$\}$.*

▶ **Lemma 10** ([18]). *Let $G(V, E)$ be a connected graph and $H(V', E')$ be a connected subgraph of G with $E' \neq \emptyset$ that is obtained from G by the deletion of some vertices and edges. For every unsatisfiable Tseitin formula $\mathsf{T}(G, f)$ there exists a partial assignment α to variables x_e for $e \in E \setminus E'$ such that α does not falsify any clause of $\mathsf{T}(G, f)$.*

▶ **Lemma 11.** *Let $G(V, E)$ be a connected graph and $H(V', E')$ be a connected subgraph of G. Assume that there is a derivation $\vdash_d \neg\mathsf{T}(G, f)$ of size S. Then for some f' there is a derivation $\vdash_{d+\mathcal{O}(1)} \neg\mathsf{T}(H, f')$ of size $S + \mathrm{poly}(|\mathsf{T}(G, f)|)$.*

Proof. Let T be the game tree of $\vdash_d \neg\mathsf{T}(G, f)$. Let α be given by Lemma 10 that is defined on all variables x_e for $e \in E \setminus E'$ and does not falsify any clause of $\mathsf{T}(G, f)$. $T[\alpha]$ be the tree obtained form T applying the substitution α to all the queried formulas. Size and depth do not change, hence $T[\alpha]$ defines a derivation $\vdash_d\neg\mathsf{T}(G, f)[\alpha]$ of size S. $\neg\mathsf{T}(G, f)$ has the form $\neg \bigwedge_{v\in V} \mathsf{Par}(v)$, where $\mathsf{Par}(v)$ is a parity condition of the vertex v. Hence, $\neg\mathsf{T}(G, f)[\alpha]$ is of the form $\neg \bigwedge_i \mathsf{Par}(v)[\alpha]$. If $v \notin V'$, then α assigns values to all variables from $\mathsf{Par}(v)$, since α does not falsify $\mathsf{Par}(v)$, α satisfies $\mathsf{Par}(v)$, hence $\mathsf{Par}(v)[\alpha]$ is identically true. If $v \in V'$, then $\mathsf{Par}(v)[\alpha]$ is a parity statement depending on variables x_e, where $e \in E'$ is incident to v. Hence, for $v \in V'$, $\mathsf{Par}(v)[\alpha]$ is semantically equivalent to a parity condition of a Tseitin formula $\mathsf{T}(H, \varphi')$ for some charging φ'. Let Δ be the maximal degree of G. Then every parity condition of $\mathsf{T}(H, \varphi')$ or $\mathsf{T}(G, \varphi)$ depends on at most Δ variables. Notice that since we represent parities in CNF, $|\mathsf{T}(G, f)| \geq 2^\Delta$. By Lemma 9, there is a derivation $\neg\mathsf{T}(G, f)[\alpha] \vdash_{\mathcal{O}(1)} \neg\mathsf{T}(H, f')$ of size $\mathrm{poly}(|\mathsf{T}(G, f)|)$. The claim follows using the size S, depth d derivation of $\neg\mathsf{T}(G, f)[\alpha]$ together with Lemma 2. ◀

A 1-*substitution* for a formula φ is a partial function mapping variables of φ into its literals. After applying a 1-substitution σ to φ, the depth of the new formula $\varphi[\sigma]$ can increase by one. However 1-substitutions are closed under composition: if σ_1 maps $[y \mapsto \neg z]$ and σ_2 maps $[x \mapsto \neg y]$, then $\sigma = \sigma_1 \circ \sigma_2$ is the 1-substitution $[x \mapsto z, y \mapsto \neg z]$. We use 1-substitutions to handle in $\mathsf{T}(G, f)$ the operation of *vertex suppression* on the graph G. Let $G = (V, E)$ be a graph and $v \in V$ be a node and let $\mathsf{T}(G, f)$ be a Tseitin formula on G. Let v

be a degree-2 vertex v in G with neighbours u and w. Consider the following 1-substitution σ_v and the charge function f_v for $[G\backslash_s v]$:

$$\sigma_v = \begin{cases} [x_{vw} \mapsto x_{wu}, x_{vu} \mapsto x_{wu}] & \text{if } f(v) = 0 \\ [x_{vw} \mapsto x_{wu}, x_{vu} \mapsto \neg x_{wu}] & \text{if } f(v) = 1 \end{cases} \qquad f_v(z) = \begin{cases} f(z) & \text{if } z \in V \setminus \{u, v\} \\ f(u) + f(v) & \text{if } z = u \end{cases}$$

Let $G(V,E)$ be a graph and $f : V \to \{0,1\}$ be a charging. Let A be a finite set. We say that a formula Ψ is a *pseudo Tseitin formula based on G and f with fake vertices in A*, and we write Ψ is $\mathsf{T}^*_A(G,f)$, if Ψ has the form $\bigwedge_{v\in V\cup A} \psi_v$, where

1. for all $v \in V$, ψ_v is a propositional formula depending on variables x_e for all edges e incident to v. And ψ_v is semantically equivalent to the parity condition $\mathsf{Par}(v)$ of $\mathsf{T}(G,f)$.
2. for all $v \in A$, ψ_v is a tautology.

▶ **Lemma 12.** *Let $G(V,E)$ be a connected constant-degree graph over n vertices. Let $[G\backslash_s v]$ be the graph obtained after the suppression of a degree-2 vertex v in G. If Ψ is $\mathsf{T}^*_A(G,f)$, then $\Psi[\sigma_v]$ is $\mathsf{T}^*_{A\cup\{v\}}([G\backslash_s v], f_v)$.*

Proof. Assume that v is linked to two vertices w and u in G. Let A be the set of fake vertices of Ψ so Ψ has the form $\bigwedge_{x\in V\cup A} \psi_x$, hence $\Psi[\sigma_v]$ is $\bigwedge_{x\in V\cup A} \psi_x[\sigma_v]$. For $x \in A$, $\psi(x)$ is a tautology, hence $\psi_x[\sigma_v]$ is also a tautology. By the definition of σ_v, $\psi_v[\sigma_v]$ is a tautology. It is not hard to verify that for $x \in V \setminus \{v\}$, $\psi_x[\sigma_v]$ is equivalent to parity condition of $\mathsf{T}([G\backslash_s v], f_v)$. Hence, $\Psi[\sigma_v]$ is $\mathsf{T}^*_{A\cup\{v\}}([G\backslash_s v], f_v)$ ◀

▶ **Lemma 13.** *Let $G(V,E)$ be a graph and $f : V \to \{0,1\}$ and $W = \{v_1, \ldots, v_k\}$ be degree 2 nodes in V suppressed in that order from G and $[G\backslash_s W]$ be the resulting graph. Let σ_i be the corresponding 1-substitutions and let $\sigma = \sigma_k \circ \ldots \circ \sigma_1$. There is a charging f_k of G such that if Ψ is $\mathsf{T}^*_A(G,f)$, then $\Psi[\sigma]$ is $\mathsf{T}^*_{A\cup W}([G\backslash_s W], f_k)$.*

▶ **Lemma 14.** *Let G be a connected graph on n vertices and with the maximal degree at most 3. Let H be obtained from G by several suppressions. Assume that there is a derivation of $\neg\,\mathsf{T}(G,f)$ of size S and depth d. Then for some charging f_k there is a derivation of $\neg\,\mathsf{T}(H,f_k)$ of size $\mathcal{O}(S) + \mathrm{poly}(n)$ and depth $d + \mathcal{O}(1)$.*

Proof. Assume that, in order, to get H from G we have to apply suppressions for vertices $W = \{v_1, \ldots, v_k\}$. Let σ_i be the 1-substitutions corresponding to the suppression of v_i, and let $\sigma = \sigma_k \circ \cdots \circ \sigma_1$. $\mathsf{T}(G,f)$ is $\mathsf{T}^*_\emptyset(G,f)$. Let f_k be the charging given by Lemma 13 applied to $\mathsf{T}(G,f)$ and $[G\backslash_s W] = H$. Then $\mathsf{T}(G,f)[\sigma]$ is $\mathsf{T}^*_W(H,f_k)$. We apply the 1-substitution σ to the given derivation of $\neg\,\mathsf{T}(G,f)$ and we get a derivation of $\neg\,\mathsf{T}(G,f)[\sigma]$ of size $\mathcal{O}(S)$ and depth at most $d+1$. By Lemma 9, applied on $\mathsf{T}(G,f)[\sigma]$ and $\mathsf{T}(H,f_k)$, there is a derivation $\neg\,\mathsf{T}(G,f)[\sigma] \vdash_{d+\mathcal{O}(1)} \neg\,\mathsf{T}(H,f_k)$ of size $\mathrm{poly}(n)$. Combining the two derivations together by Lemma 2 we obtain a derivation $\vdash_{d+\mathcal{O}(1)} \mathsf{T}(H,f_k)$ of size $\mathcal{O}(s) + \mathrm{poly}(n)$. ◀

3.2 From Walls To Grids

▶ **Lemma 15.** *If there exists a derivation $\vdash_d \neg\,\mathsf{T}(\mathcal{W}_n, f)$ of size S, then there exists a derivation $\vdash_{d+\mathcal{O}(1)} \neg\,\mathsf{T}(M_n, f')$ of size $\mathcal{O}(S) + \mathrm{poly}(n)$, where M_n is a connected constant-degree graph that contains $\mathcal{H}_{n,\lfloor\frac{n-1}{2}\rfloor}$ as a subgraph.*

Proof. Consider a set I of all the horizontal edges of $\mathcal{W}_n$ that belong to odd columns (on fig. 4 and 5 edges from I are red). I is a matching, i.e. no two edges from I are incident to the same vertex. If we contract all edges from I, we get the graph M_n that for odd n

coincides with $\mathcal{H}_{n,\frac{n-1}{2}}$ and for even n coincides with a graph that is obtained from $\mathcal{H}_{n,\lfloor\frac{n}{2}\rfloor}$ by the removal of several edges from the last vertical (see fig. 4 and 5). For every $e \in I$ we denote its left vertex by u_e and the right vertex by v_e. Let E_{u_e} be the set of edges of $\mathcal{W}_n$ incident to u_e except e. Let τ_e denote a CNF formula encoding $\bigoplus_{f \in E_{u_e}} x_f = f(u_e)$.

Consider a game tree T for the derivation of the Tseitin tautology $\neg\,\mathsf{T}(\mathcal{W}_n, f)$ of size S and depth d. To every formula used in this tree we apply the substitution that replaces every occurrence of x_e with τ_e. We denote the resulting tree by T'.

Notice that T' is a correct game tree of a derivation $\vdash_{d+\mathcal{O}(1)} \neg F$, where F is obtained from $\mathsf{T}(\mathcal{W}_n, f)$ by the same substitution. The depth of this derivation is increased by at most a constant since in several leaves we hang a formula of constant depth; here we also use that I is a matching and thus we do not add new occurrences of variables corresponding edges from I. The size of τ_e is $\mathcal{O}(1)$, hence any formula from the derivation is increased in at most a constant factor, thus the size of the derivation defined by the tree T' is $\mathcal{O}(S)$.

We define a function f' on vertices of M_n as follows. If a vertex w of the graph M_n is obtained by merging the vertices w', w'' of the graph $\mathcal{W}_n$, then $f'(w) = (f(w') + f(w'')) \bmod 2$. If the vertex w of $\mathcal{H}_{n,\lfloor n/2\rfloor}$ is obtained from the vertex w of $\mathcal{W}_n$, then $f'(w) = f(w)$.

Now we show how to derive $\neg\,\mathsf{T}(M_n, f')$ from $\neg F$. $\mathsf{T}(\mathcal{W}_n, f)$ is a Tseitin formula and it has the following structure: $\bigwedge_{v \in V} \psi_v$, where V is the set of vertices of $\mathcal{W}_n$ and ψ_v is a CNF formula encoding a parity condition for the vertex v. F differs from $\mathsf{T}(\mathcal{W}_n, f)$ only in conditions corresponding to vertices that are incident to an edge from I (if n is even, then there are vertices in $\mathcal{W}_n$ that are not incident to any edge from I). Notice that F has the form $\bigwedge_{v \in V} \psi'_v$ where ψ'_v is obtained by substitution from ψ_v. Let $w = u_e$ for some $e \in I$, then the formula ψ'_w is identically true. If $w = v_e$, then the condition ψ'_w is equivalent to the parity condition of the merged vertex $\{u_e, v_e\}$ in the Tseitin formula $\mathsf{T}(M_n, f')$, but ψ'_w is not written in canonical form.

Since all degrees in M_n are at most 4, then by Lemma 9 there exists a derivation $\neg F \vdash_{d+\mathcal{O}(1)} \neg\,\mathsf{T}(M_n, f')$ of size $\mathrm{poly}(n)$. The claim follows by Lemma 2. ◀

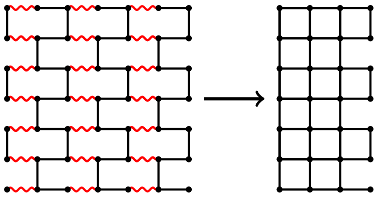

Figure 4 $\mathcal{W}_6$ is contracted to M_6.

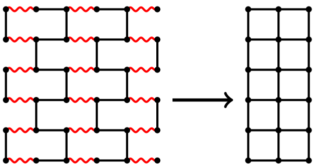

Figure 5 $\mathcal{W}_5$ is contracted to M_5.

3.3 Putting it all together

We use Håstad's Theorem from [22].

▶ **Theorem 16** ([22]). *There is a constant $K > 0$ such that for $d \leq \frac{K \log n}{\log\log n}$ any depth d derivation of $\neg\,\mathsf{T}(\mathcal{H}_{n,n}, f))$ has size at least $2^{n^{\Omega(1/d)}}$.*

▶ **Theorem 17.** *There exist constants $K > 0$ and $C > 0$ such that for every connected graph G of treewidth t and every $d \leq \frac{K \log n}{\log\log n} - C$, any depth d derivation of $\neg\,\mathsf{T}(G, f))$ has size at least $2^{t^{\Omega(1/d)}}$.*

Proof. Suppose that $\neg\,\mathsf{T}(G,f)$ have a derivation of size S and depth d. By Corollary 8 we know that G contains the wall $\mathcal{W}_r$ as a topological minor, where $r = \Omega(t^{1/37})$. Consider a sequence of operations (edge/vertex removals and suppressions) that transform G to $\mathcal{W}_r$. Assume that removals do not follow suppressions. And let G' be a subgraph of G that is obtained from G by application of all removals (hence, $\mathcal{W}_r$ can be obtained from G' by application of several suppressions).

By Lemma 11, for some f' there is a derivation of $\neg\,\mathsf{T}(G',f')$ of size $\mathrm{poly}(|\,\mathsf{T}(G,f)|) + S$ and depth $d + \mathcal{O}(1)$. Since $\mathcal{W}_r$ can be obtained from G' by application of several suppressions, G' is connected. Suppressions can not increase the degrees, hence all degrees in G' are at most 3. By Lemma 14, for some f'' there is a derivation of $\neg\,\mathsf{T}(\mathcal{W}_r, f'')$ of size $\mathrm{poly}(|\,\mathsf{T}(G,f)|) + S$ and depth $d + \mathcal{O}(1)$. By Lemma 15, for some f''' there is a derivation of $\neg\,\mathsf{T}(M_r, f''')$ of size $\mathrm{poly}(|\,\mathsf{T}(G,f)|) + \mathcal{O}(S)$ and depth $d + \mathcal{O}(1)$, where M_r is connected constant-degree graph containing $\mathcal{H}_{\lfloor (r-1)/2 \rfloor}$ as a subgraph. And finally by Lemma 11, for some f'''' there is a Frege derivation of $\mathsf{T}(\mathcal{H}_{\lfloor (r-1)/2 \rfloor}, f'''')$ of size $\mathrm{poly}(|\,\mathsf{T}(G,f)|) + \mathcal{O}(S)$ and depth $d + \mathcal{O}(1)$. Notice that S is the size of a derivation of $\neg\,\mathsf{T}(G,f)$, hence $S \geq |\,\mathsf{T}(G,f)|$. Thus, for some constants C and c there is a derivation of $\neg\,\mathsf{T}(\mathcal{H}_{\lfloor (r-1)/2 \rfloor}, f'''')$ of size S^c and depth $d + C$.

By Theorem 16, there is a constant K such that if $d + C \leq \frac{K \log n}{\log \log n}$, then $S^c \geq 2^{\lfloor (r-1)/2 \rfloor^{\Omega(1/(d+C))}}$. Hence $S \geq 2^{r^{\Omega(1/d)}}$ and, thus, $S \geq 2^{t^{\Omega(1/d)}}$. ◀

4 The Upper Bound

In this section we prove the following Theorem:

▶ **Theorem 18.** *Let $G(V,E)$ be a connected undirected graph and $\mathsf{T}(G,f)$ be an unsatisfiable Tseitin formula. Then for all large enough d the formula $\neg\,\mathsf{T}(G,f)$ has a derivation of depth d and size $2^{\mathrm{tw}(G)^{\mathcal{O}(1/d)}}\mathrm{poly}(|\,\mathsf{T}(G,f)|)$.*

In order to prove Theorem 18 we define a *compact representation* of parity by depth-d formulas, then we show that we can efficiently derive the sum of $\mathbb{F}_2$-linear equations using the compact representation of parities. And then we prove Theorem 18 using a tree-partition of the graph G.

4.1 A compact representation of parity

Let $t_1, t_2, \ldots, t_d$ be natural numbers, where d is a non-negative integer. Let $U_0, U_1, \ldots, U_d$ be partitions of a finite set F. We say that a list of partitions $U = (U_0, U_1, \ldots, U_d)$ is a $(t_1, \ldots, t_d)$*-refinement* of F if the following conditions hold:

1. U_0 consists of the only element $U_{0,1} = F$.
2. For every i, U_{i+1} is a subpartition of U_i such that every element of U_i is split into t_{i+1} parts. Hence, U_i split F into m_i parts: $U_{i,1}, U_{i,2}, \ldots, U_{i,m_i}$, where $m_i = \prod_{j=1}^{i} t_j$.
3. All elements of U_d have cardinality at most 1.

Let U be a $(t_1, \ldots, t_d)$-refinement of a set F and let $U_{i,j}$ be one of the blocks of this refinement. Then U induces on each of the blocks U_{ij} a $(t_{i+1}, \ldots, t_d)$-refinement U' which is obtained by restricting $U_i, \ldots, U_d$ to the set U_{ij}. U' is called a *sub-refinement* of U_{ij} in U.

▶ **Lemma 19.** *Let F be a set of size n and $d \geq 0$ be an integer. Let $t_1, \ldots, t_d$ be integers such that $t_1 \cdot t_2 \cdot \ldots \cdot t_d \geq n$. Then there exists a $(t_1, \ldots, t_d)$-refinement U of F.*

For $a \in \{0,1\}$ and natural number n we define a Boolean function $\mathrm{PARITY}_n^a : \{0,1\}^n \to \{0,1\}^n$ such that $\mathrm{PARITY}_n^a(x_1, \ldots, x_n) = 1$ iff $\bigoplus_{i=1}^{n} x_i = a$ for all $x_1, \ldots, x_n \in \{0,1\}$.

▶ **Lemma 20.** *Let n and d be positive integers and U be a $(t_1, t_2, \dots, t_d)$-refinement of $[n]$. Then there exists a formula representing PARITY_n^b of depth at most $3d + 1$ and of size $\prod_{i=1}^{d} 2^{t_i+1} t_i$.*

Proof. Let us prove by backward induction on i from d to 0 that for every $j \in [\prod_{k=1}^{i} t_k]$, there is a formula representing $\bigoplus_{k \in U_{i,j}} x_k$ of depth $3(d-i)$ and of size $\prod_{q=i+1}^{d} 2^{t_q+1} t_q$. If $i = d$, then $|U_{d,j}| \leq 1$, hence $\bigoplus_{k \in U_{i,j}} x_k$ is either 0 or a variable x_k and thus has size 1 and depth 0.

Assume that $i < d$. Let $\ell_1, \ell_2, \dots, \ell_{t_{i+1}}$ be such that $U_{i,j} = U_{i+1,\ell_1} \sqcup U_{i+1,\ell_2} \sqcup \dots \sqcup U_{i+1,\ell_{t_{i+1}}}$. Let for $r \in [t_{i_1}]$, β_r be a representation of $\bigoplus_{k \in U_{i+1,\ell_r}} x_k$ of size $\prod_{q=i+2}^{d} 2^{t_q+1} t_q$ and depth $3(d-i-1)$ that exists by the induction hypothesis. Consider a CNF-representation of $\beta_1 \oplus \dots \oplus \beta_{t_{i+1}}$: $\bigoplus_{k \in U_{i,j}} x_k = \bigwedge_{\substack{S \subseteq \{1,\dots,t_{i+1}\} \\ |S| \bmod 2 = 0}} \left(\bigvee_{s \in S} \neg \beta_s \vee \bigvee_{s \notin S} \beta_s \right)$. After the substitution of the representations of $\beta_1, \dots, \beta_{t_{i+1}}$ we obtain a formula of size at most $2^{t_{i+1}} t_{i+1} \cdot \prod_{q=i+2}^{d} 2^{t_q+1} t_q + 2^{t_{i+1}} t_{i+1} \leq \prod_{q=i+1}^{q} 2^{t_q+1} t_q$ and of depth $3(d-i-1) + 3 = 3(d-i)$.

Therefore we have constructed a representation of PARITY_n^1 of the needed size and depth. The representation of PARITY_n^0 could be constructed as $\neg\varphi$ where φ is the obtained representation of PARITY_n^1. ◀

We call the representation of PARITY_n^a obtained by Lemma 20 *the compact representation* of PARITY_n^a with respect to a $(t_1, \dots, t_d)$-refinement U.

Let us define for $S \subseteq [n]$ and for $a \in \{0, 1\}$, $\mathrm{PARITY}_{n,S}^a(x_1, \dots, x_n) = (\neg a) \oplus \bigoplus_{i \in S} x_i$. We define a compact representation of $\mathrm{PARITY}_{n,S}^a$ with respect to a $(t_1, \dots, t_d)$-refinement U as the result of substitutions $x_j := \mathbf{0}$ for all $j \notin S$ to the compact representation of PARITY_n^a with respect to U. We denote the compact representation of $\mathrm{PARITY}_{n,S}^a(x_1, x_2, \dots, x_n)$ w.r.t. U by $\Phi^a(S, U)$.

▶ **Lemma 21.** *Let U be a $(t_1, \dots, t_d)$-refinement of $[n]$ and U' be a sub-refinement of U_{ij} in U. Then for every $S \subseteq U_{ij}$ there exists a derivation $\Phi^a(S, U') \vdash_{3d + \mathcal{O}(1)} \Phi^a(S, U)$ of size at most $4|\Phi^a(S, U)|^3$.*

4.2 Summation of linear equations

Let $S \triangle T$ be the symmetric difference of sets S and T i.e. $S \triangle T = (S \cup T) \setminus (S \cap T)$.

▶ **Lemma 22.** *Let U be a $(t_1, \dots, t_d)$-refinement of $[n]$. Let $S_1, S_2, \dots, S_k \subseteq [n]$ and $a_1, \dots, a_k \in \{0, 1\}$. Then there exists a constant c such that:*

1. *There exists a derivation $\Phi^{a_1}(S_1, U), \Phi^{a_2}(S_2, U), \dots, \Phi^{a_k}(S_k, U) \vdash_{3d + \mathcal{O}(1)} \Phi^{a_1 \oplus \dots \oplus a_k}(S_1 \triangle \dots \triangle S_k, U)$ of size at most $c \cdot k \cdot |\Phi^1(\varnothing, U)|^6$.*
2. *If $\bigwedge_{i \in [k]} \left(\bigoplus_{j \in S_i} x_j = a_i \right)$ is unsatisfiable then there exists a derivation $\Phi^{a_1}(S_1, U), \Phi^{a_2}(S_2, U), \dots, \Phi^{a_k}(S_k, U) \vdash_{3d + \mathcal{O}(1)} \mathbf{0}$ of size at most $c \cdot k \cdot |\Phi^1(\varnothing, U)|^6$.*

4.3 Tree-partition width

Let $G(V, E)$ be an undirected graph and $S_1, \dots, S_m$ be a partition of V. $S_1, \dots, S_m$ is a tree-partition of G if there exists a tree $T([m], E_T)$ such that every edge e of G connects either two vertices from the same part S_i or connects a vertex from S_i and a vertex from S_j, where i and j are adjacent in T, i.e. $(i, j) \in E_T$. A *width* of a tree-partition $S_1, S_2, \dots, S_m$ is the size of the largest set S_i for $i \in [m]$. A *tree-partition width* of a graph G is the smallest width among all tree-partitions of G. We denote the tree-partition width of G by $\mathrm{tpw}(G)$.

If we add a new vertex in the middle of every edge (i, j) of the tree T and put the set $S_i \cup S_j$ on it, we will get a tree decomposition of G, hence $\mathrm{tw}(G) \leq 2\mathrm{tpw}(G) - 1$.

The following theorem shows an inequality in the other direction.

▶ **Theorem 23** ([38]). *If* $\mathrm{tw}(G) \geq 1$*, then* $\mathrm{tpw}(G) \leq 10\Delta(G)\mathrm{tw}(G)$*, where* $\Delta(G)$ *is the maximum degree of* G*.*

So, $\mathrm{tw}(G)$ and $\mathrm{tpw}(G)$ coincide up to a multiplicative constants for constant degree graphs.

▶ **Theorem 24.** *Let* $G(V, E)$ *be a connected graph and let a Tseitin formula* $\mathsf{T}(G, f)$ *be unsatisfiable. Then there exists a derivation* $\vdash_{3d+\mathcal{O}(1)} \mathsf{T}(G, f)$ *of size at most* $\mathrm{poly}(|\mathsf{T}(G, f)|) \cdot 2^{(\mathrm{tpw}(G)\Delta(G))^{\mathcal{O}(1/d)}}$*, where* $\Delta(G)$ *is the maximum degree of* G*.*

Proof. Let $S_1, \ldots, S_m$ be a tree-partition of G with width $\mathrm{tpw}(G)$ and let $T([m], E_T)$ be the corresponding tree. W.l.o.g. we assume that T is a rooted tree with the root m; for all $i \in [m-1]$, $p(i)$ denotes its parent and for all $i \in [m]$, $\mathrm{s}(i)$ denotes the set of direct successors of i . W.l.o.g. we assume that $p(i) > i$ for all $i \in [m-1]$.

Since $\mathsf{T}(G, f)$ is unsatisfiable and G is connected, $\bigoplus_{v \in V} f(v) = \bigoplus_{i \in [m]} \bigoplus_{v \in S_i} f(v) = 1$. We consider the sum $\bigoplus_{i \in [m]} \bigoplus_{e \in E(S_i, V \setminus S_i)} x_e$. Since each x_e occurs in the sum exactly twice, the sum (modulo 2) is 0 for all values of x_e. Then for each assignment to $\{x_e\}_{e \in E}$ there exists i_0 such that $\bigoplus_{v \in S_{i_0}} f(v) \neq \bigoplus_{e \in E(S_{i_0}, V \setminus S_{i_0})} x_e$. The first part of Pavel's strategy is to find such i_0.

Pavel will request parity of the sum of all edges between S_i and S_j for all $(i, j) \in E_T$. In order to represent these formulas in a compact way we now define m different $(t_1, \ldots, t_d)$-refinements $W^1, \ldots, W^m$; for every i, W^i is a refinement of the set $E\left(S_i, \bigcup_{j \in \mathrm{s}(i)} S_j\right)$ of all edges connecting a vertex from S_i with a vertex from $\bigcup_{j \in s(i)} S_j$. We construct appropriate refinements W^i later.

Pavel asks Sam the values of $\bigoplus_{e \in E(S_i, S_{p(i)})} x_e$ represented as $\Phi^1\left(E\left(S_i, S_{p(i)}\right), W^{p(i)}\right)$ for $i \in [m-1]$ in the increasing order until he finds i_0 such that $\bigoplus_{e \in E(S_{i_0}, V \setminus S_{i_0})} x_e \neq \bigoplus_{v \in S_{i_0}} f(v)$.

At the moment when Sam has answered the value of $\Phi^1\left(E\left(S_i, S_{p(i)}\right), W^{p(i)}\right)$ the values of $\bigoplus_{e \in E(S_i, S_j)} x_e$ for each j such that $(i, j) \in E_T$ are all determined, thus, the value of $\bigoplus_{e \in E(S_i, V \setminus S_i)} x_e$ is determined. If $\bigoplus_{e \in E(S_i, V \setminus S_i)} x_e \neq \bigoplus_{v \in S_i} f(v)$ Pavel proceeds to the next part of his strategy. Otherwise he continues to ask Sam similar questions corresponding to the vertices with larger indices.

Now we describe the strategy of Pavel in case if he finds i_0. We are going to describe this case in terms of derivation using Lemma 2 multiple times. Consider a linear system that consists of the equation $\bigoplus_{e \in E(S_{i_0}, V \setminus S_{i_0})} x_e = 1 \oplus \bigoplus_{v \in S_{i_0}} f(v)$ and all parity conditions of $\mathsf{T}(G, f)$ of the vertices from S_{i_0}. This linear system is unsatisfiable. We are going to use Lemma 22. In order to do it we need to derive the representations of these linear equations w.r.t. some refinement Q of a superset of $E(S_{i_0}, V)$.

Let for $i \in [m]$, U^i be a $(t_1, t_2, \ldots, t_d)$-refinement of the set $E(S_i)$ of all edges connecting two vertices from S_i (we construct these refinements in the end of the proof together with the refinements W^i). Let us define a $(3, t_1, \ldots, t_d)$-refinement Q as a union of $(t_1, \ldots, t_d)$-refinements $W^{i_0}, W^{p(i_0)}$ and U^{i_0} such that $Q_1 = \{E(S_{i_0}, \bigcup_{j \in \mathrm{s}(i_0)} S_j), E(S_{p(i_0)}, \bigcup_{j \in \mathrm{s}(p(i_0))} S_j), E(S_{i_0})\}$ and for every $j \in \{2, 3, \ldots, d+1\}$, Q_j is the union of $W^{i_0}_{j-1}, W^{p(i_0)}_{j-1}$ and $U^{i_0}_{j-1}$.

Let a_j be Sam's answer to the question $\bigoplus_{e \in E(S_{i_0}, S_j)} x_e$ for each j that is a neighbour of i_0 in T, hence we may assume that $\Phi^{a_j}(E(S_{i_0}, S_j), W^{i_0})$ for $j \in \mathrm{s}(i_0)$ and $\Phi^{a_{p(i_0)}}(E(S_{i_0}, E_{p(i_0)}),$

$W^{p(i_0)}$) are already derived. By Lemma 21, we derive $\Phi^{a_j}(E(S_{i_0}, S_j), Q)$ from $\Phi^{a_j}(E(S_{i_0}, S_j), W^{i_0})$ for $j \in \mathrm{s}(i_0)$ and $\Phi^{a_{p(i_0)}}(E(S_{i_0}, S_{p(i_0)}), Q)$ from $\Phi^{a_{p(i_0)}}(E(S_{i_0}, S_{p(i_0)}), W^{p(i_0)})$, where a_j are Sam's answers to the corresponding questions.

By the first part of Lemma 22 we derive $\Phi^{1\oplus\left(\bigoplus_{v\in S_{i_0}} f(v)\right)}(E(S_{i_0}, V \setminus S_{i_0}), Q)$ from the set of formulas $\{\Phi^{a_j}(E(S_{i_0}, S_j), Q) \mid (i_0, j) \in E_T\}$. We assume that the parity conditions of the vertices of G in $\mathsf{T}(G, f)$ represented as CNF are asked at the beginning of the game i.e. for each $v \in V$ we know that the CNF representation of $\bigoplus_{u:(u,v)\in E} x_e$ is true (if any clause of $\mathsf{T}(G, f)$ is false Pavel queries all subformulas of $\mathsf{T}(G, f)$ except subformulas of the clauses and gets an immediate contradiction, if any of the parity conditions is false it yields an immediate contradiction with the corresponding subset of clauses). Thus, by Lemma 4 we derive the representations of parity conditions of the vertices from S_{i_0} w.r.t. Q. Since the corresponding linear system is unsatisfiable, using the second part of Lemma 22 we get a contradiction.

▷ Claim 25. The size of the described game tree is at most $m \cdot 2^{3\Delta(G)}\Delta^2(G)\mathrm{tpw}(G)2^{\mathcal{O}\left(\sum_{i=1}^{d} t_i\right)}$.

Let us choose $t_i = (\Delta(G)\mathrm{tpw}(G))^{2/d}$ for all $i \in [d]$. Since $|S_i| \le \mathrm{tpw}(G)$, $|E(S_i)| + \left|E\left(S_i, \bigcup_{j\in \mathrm{s}(i)} S_j\right)\right| \le \Delta(G)\mathrm{tpw}(G)$. Hence, the condition $\prod_{i=1}^{d} t_i \ge \Delta(G)\mathrm{tpw}(G) \ge |E(S_i)| + \left|E\left(S_i, \bigcup_{j\in \mathrm{s}(i)} S_j\right)\right|$ holds and, thus, for all $i \in [m]$ the refinements U^i, W^i exist by Lemma 19. If we substitute choosen values in the bound from Clam 25, we get the upper bound $m \cdot 2^{\mathcal{O}\left(3\Delta(G)+d(\Delta(G)\mathrm{tpw}(G))^{2/d}\right)} = \mathrm{poly}(|\mathsf{T}(G, f)|) \cdot 2^{(\Delta(G)\mathrm{tpw}(G))^{\mathcal{O}(1/d)}}$. ◀

Now we are ready to prove Theorem 18.

Proof of Theorem 18. Theorem 24 and Theorem 23 imply that there exists a constant c and a derivation $\vdash_{3d+\mathcal{O}(1)} \neg\mathsf{T}(G, f)$ of size at most $\mathrm{poly}(|\mathsf{T}(G, f)|)2^{(10\Delta^2(G)\mathrm{tw}(G))^{c/d}}$. If $\mathrm{tw}(G) > \Delta(G)$ then we can rewrite our upper bound on the size as $\mathrm{poly}(|\mathsf{T}(G, f)|)2^{(10\mathrm{tw}(G))^{3c/d}}$. If $\mathrm{tw}(G) > 1$ then it is $\mathrm{poly}(|\mathsf{T}(G, f)|)2^{(\mathrm{tw}(G))^{\mathcal{O}(1/d)}}$. If $\mathrm{tw}(G) = 1$ then it is simply $\mathrm{poly}(|\mathsf{T}(G, f)|)$. Otherwise if $\mathrm{tw}(G) \le \Delta(G)$ we can rewrite the upper bound as $\mathrm{poly}(|\mathsf{T}(G, f)|)\cdot\ 2^{(10\Delta(G))^{3c/d}} = \mathrm{poly}(|\mathsf{T}(G, f)|)$ if $3c/d \le 1$. Thus, for $d \ge 3c$ the upper bound is $\mathrm{poly}(|\mathsf{T}(G, f)|)\cdot\ 2^{\mathrm{tw}(G)^{3c/d}}$. Therefore, for the both cases we have the needed upper bound. ◀

On the Expressivity of Linear Recursion Schemes

Pierre Clairambault

Andrzej S. Murawski
Department of Computer Science, University of Oxford, UK

Abstract

We investigate the expressive power of higher-order recursion schemes (HORS) restricted to linear types. Two formalisms are considered: multiplicative additive HORS (MAHORS), which feature both linear function types and products, and multiplicative HORS (MHORS), based on linear function types only.

For MAHORS, we establish an equi-expressivity result with a variant of tree-stack automata. Consequently, we can show that MAHORS are strictly more expressive than first-order HORS, that they are incomparable with second-order HORS, and that the associated branch languages lie at the third level of the collapsible pushdown hierarchy.

In the multiplicative case, we show that MHORS are equivalent to a special kind of pushdown automata. It follows that any MHORS can be translated to an equivalent first-order MHORS in polynomial time. Further, we show that MHORS generate regular trees and can be translated to equivalent order-0 HORS in exponential time. Consequently, MHORS turn out to have the same expressive power as 0-HORS but they can be exponentially more concise.

Our results are obtained through a combination of techniques from game semantics, the geometry of interaction and automata theory.

1 Introduction

Higher-order recursion schemes (HORS) have recently emerged as a promising technique for model-checking higher-order programs [17]. Linear higher-order recursion schemes (LHORS) were introduced in [5] to facilitate a finer analysis of HORS by mixing intuitionistic and linear types. In this paper, we investigate the expressivity of their purely linear fragment.

First, we consider *multiplicative additive* HORS (MAHORS), which in addition to the linear function types ($\multimap$) feature product types (&), and thus allow for sharing but not re-use. We show that MAHORS are equivalent to a tree-generating variant of tree-stack automata (TSA), originally introduced to capture multiple context-free languages in the word language setting [7]. The translation from MAHORS to TSA amounts to representing the game semantics of MAHORS in the spirit of abstract machines derived from Girard's Geometry of Interaction (GoI) [11, 6]. The GoI view of computation makes it possible to interpret computation as a token machine that traverses a graph strongly related to the syntactic structure of the term. Somewhat suprisingly, so far this nearly automata-theoretic

Figure 1 Typing rules for the additive linear λ-calculus.

flavour of GoI has not been exploited to establish connections with automata models, and we believe we are the first to do so explicitly. As a consequence, we can conclude that the branch languages of trees generated by MAHORS are multiple context-free and, thus, that they belong to the third level of the collapsible pushdown hierarchy [12]. In addition, we show that MAHORS are strictly more expressive than first-order HORS[1], and that they are not comparable with second-order HORS.

Secondly, we consider *multiplicative* HORS (MHORS), featuring linear function types only. In this case, our earlier MAHORS-to-TSA translation specialises to a translation into a special kind of tree-generating pushdown automata (LPDA) in which reachable configurations must be reached in a unique run. We show that MHORS and LPDA are equi-expressive and, moreover, that any MHORS can be translated to an equivalent MHORS of order 1. Further, using reachability techniques for pushdown automata, we show that LPDA are equivalent to bounded pushdown automata that forget elements stored at the bottom of the stack after the stack height exceeds a certain depth. It follows that MHORS generate regular trees, though the MHORS representation may be exponentially more succinct than order-0 HORS.

2 Linear Recursion Schemes

In this section we introduce the object of study of this paper, MAHORS and MHORS.

The main ingredient of MAHORS is the *linear λ-calculus with products* – also called the *additive linear λ-calculus*, as the product is an additive connective in the sense of Linear Logic [10]. The following definitions follow [5], restricting type formers to linear connectives (note that [5] imposes some syntactic restrictions on the shape of types and terms that we can drop here to simplify presentation, as they play no role in the technical development).

Types are formed with the ground type o and the connectives $\multimap$ and &. We define the **typed terms** directly by the typing rules of Figure 1. Typing judgments have the form $\Gamma \mid \Delta \vdash t : \varphi$, where Γ and Δ are two lists of variable declarations. Intuitively, Δ is the main context containing variables that can be used at most once (such terms are often called *affine* but we opt for the name *linear* nonetheless). In contrast, Γ comprises *duplicable* variables that may be reused at will, as witnessed by the application rule. In M(A)HORS, Γ will be used only for terminal and non-terminal symbols. Linear λ-terms are equipped with standard reduction rules; we write $\triangleright_\beta$ for β-reduction for functions and products, whose definition can be found *e.g.* in [5]. Any term t has a normal form, written $\mathrm{BT}(t)$.

Trees arise as ground-type terms typable in replicable contexts representing a ranked alphabet. Recall that in HORS, a symbol b of arity n is represented as a constant $\mathsf{b} : o \to \cdots \to o \to o$ with n arguments. Here, a ranked alphabet Σ may be represented in two distinct

[1] Type order is defined by $ord(o) = 0$ and $ord(\theta \to \theta') = \max(ord(\theta) + 1, ord(\theta'))$. The order of a HORS is the highest order of (the types of) its non-terminals.

ways: *multiplicatively*, with $\mathsf{b} : o \multimap \ldots \multimap o \multimap o$, or *additively*, with $\mathsf{b} : \&_n o \multimap o$, where $\&_n o$ stands for $o \& \cdots \& o$ (n copies)[2]. The choice does not impact how finite trees are represented: in both cases a $\triangleright_\beta$-normal $\Sigma \mid \_ \vdash t : o$ (if not $\bot$) must start with a variable from Σ with some arity n, followed by n $\triangleright_\beta$-normal sub-trees; *i.e.* it represents a tree (with certain branches possibly leading to $\bot$). The multiplicative vs additive distinction matters in the definition of schemes, though: with additive typing, resources (variables) may be shared when calculating two sub-branches of an infinite tree, which is disallowed with multiplicative typing.

Linear recursion schemes consist of a system of recursive equations, where each clause is given by a λ-term with a restricted shape. A term $\Gamma \mid \_ \vdash t : \varphi$ is called **applicative** if it is $\triangleright_\beta$-normal, and has the form $\lambda x_1^{\varphi_1} \ldots \lambda x_n^{\varphi_n}.t'$ where t' has no abstraction.

▶ **Definition 1.** *A* ***Multiplicative Additive Recursion Scheme (MAHORS)*** *is a 4-tuple $\mathcal{G} = \langle \Sigma, \mathcal{N}, \mathcal{R}, S\rangle$ where: (1) Σ is a ranked alphabet; (2) $\mathcal{N}$ is a finite set of typed* ***non-terminals****; we use upper-case letters $F, G, H, \ldots$ to range over them. We denote the type of F by $\mathcal{N}(F)$ and write $F : \mathcal{N}(F)$; (3) $S \in \mathcal{N}$ is a distinguished* ***start symbol*** *of type o; and (4) $\mathcal{R}$ is a function associating to each F in $\mathcal{N}$ an applicative term $\Sigma, \mathcal{N} \mid \_ \vdash \mathcal{R}(F) : \mathcal{N}(F)$, with Σ represented additively. A* ***MHORS*** *is defined as a MAHORS where Σ is represented multiplicatively and the typing of $\mathcal{N}$ does not involve products.*

If $\mathcal{G} = \langle \Sigma, \mathcal{N}, \mathcal{R}, S\rangle$ is a MAHORS, then for each $F \in \mathcal{N}$ and $n \in \mathbb{N}$ there is $\Sigma \mid \_ \vdash \mathsf{unf}_n(F) : \mathcal{N}(F)$ defined by $\mathsf{unf}_0(F) = \bot$ and $\mathsf{unf}_{n+1}(F) = \mathcal{R}(F)[\mathsf{unf}_n(G)/G \mid G \in \mathcal{N}]$. The family $(\mathsf{unf}_i(F))_{i\in\mathbb{N}}$ forms a chain for $\leq$ defined as usual by $\bot \leq t$, closed by congruence. As evaluation is monotone, $(\mathrm{BT}(\mathsf{unf}_i(F))_{i\in\mathbb{N}}$ also forms a chain, hence it has a lub which may be defined as the ideal completion of finite normal terms $\Sigma \mid \_ \vdash t : o$ ordered by $\leq$. We may then define $\mathrm{BT}(\mathcal{G}) = \bigsqcup_{i\in\mathbb{N}} \mathrm{BT}(\mathsf{unf}_i(S))$, the **infinite tree generated by** $\mathcal{G}$.

Our schemes comprise an explicit divergence symbol $\bot$. This is unusual, but does not affect expressivity as it could always be defined with a new non-terminal with rule $\mathcal{R}(\Omega) = \Omega$. Finally, we identify silently trees and terms $\Sigma \mid \_ \vdash t : o$.

3 Finite Memory Game Semantics and Geometry of Interaction

Game semantics is a semantic technique to give a compositional interpretation of higher-order programs [14]. By presenting higher-order computation as a *game* between two players embodying the program and its execution environment (Player for the program, Opponent for the environment), it effectively reduces higher-order computation to an exchange of tokens between terms. At first forgetting recursion, we briefly review the interpretation of the linear λ-calculus with products in *simple games*, then introduce its refined interpretation as finite-memory strategies, which will inform the translation of M(A)HORS to TSA.

3.1 Games and strategies

A **game** is a tuple $A = \langle M_A, \lambda_A, P_A\rangle$ where M_A is a set of *moves*, $\lambda_A : M_A \to \{O, P\}$ is a *polarity function* (we write $M_A^O = \lambda_A^{-1}(\{O\})$ and $M_A^P = \lambda_A^{-1}(\{P\})$), and $P_A \subseteq M_A^*$ is a non-empty prefix-closed set of *valid plays*, whose elements are O-starting and alternating: if $s = s_1 \ldots s_n \in P_A$, then $\lambda_A(s_1) = O$ and $\lambda_A(s_i) \neq \lambda_A(s_{i+1})$. We write $\epsilon \in P_A$ for the empty play and $s \sqsubseteq s'$ for the prefix ordering.

[2] [5] considers also intermediate typings, but this does not contribute extra expressivity.

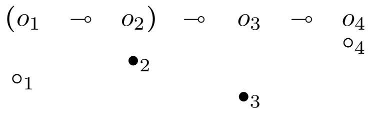

Figure 2 A play on $[\![(o \multimap o) \multimap o \multimap o]\!]$.

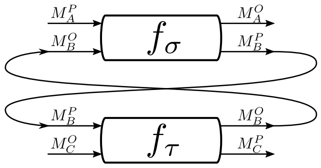

Figure 3 Composition of history-free skeletons.

Games represent *types*. Plays in a game for a type φ represent executions on φ following (for this paper) a call-by-name evaluation strategy. For instance, Figure 2 shows a play in the game for $(o \multimap o) \multimap o \multimap o$, read from top to bottom. We use indices on atom occurrences and moves for disambiguation, but the usual convention in game semantics is to signify the identity of moves simply by their position under the corresponding type component. After Opponent ($\circ$, the environment) starts computation by the initial move on the right, Player ($\bullet$, the program) responds by interrogating its function argument. Opponent, playing for this argument, calls its argument. Player terminates by calling its second argument. This play is, in fact, the maximal play of the interpretation of $\lambda f^{o \multimap o}.\, \lambda x^o.\, f\, x : (o \multimap o) \multimap o \multimap o$.

Each type φ may be interpreted as a game $[\![\varphi]\!]$. The game $[\![o]\!]$ has $M_{[\![o]\!]} = \{\circ\}$ with $\lambda(o) = O$, and $P_{[\![o]\!]} = \{\epsilon, \circ\}$. To match the type constructor $\multimap$, the **linear arrow game** $A \multimap B$ has as moves the tagged disjoint union $M_{A \multimap B} = M_A + M_B = \{1\} \times M_A \cup \{2\} \times M_B$ with polarity $\lambda_{A \multimap B}(1, a) = \overline{\lambda_A(a)}$ and $\lambda_{A \multimap B}(2, b) = \lambda_B(b)$, where $\overline{O} = P$ and $\overline{P} = O$. The plays $P_{A \multimap B}$ include all O-starting, alternating sequences $s \in M^*_{A \multimap B}$ such that the *restrictions* $s \upharpoonright A \in M^*_A$ and $s \upharpoonright B \in M^*_B$, defined in the obvious way, are in P_A and P_B respectively. Hence, $A \multimap B$ can be viewed as playing the two games A and B in parallel, with the polarity reversed in A, in such a way that any play must start in B and Player is able to switch between the components. With these definitions the reader can check that $[\![(o \multimap o) \multimap o \multimap o]\!] = ([\![o]\!] \multimap [\![o]\!]) \multimap ([\![o]\!] \multimap [\![o]\!])$ includes four moves corresponding to the four atom occurrences, and has only two maximal plays: the one in Figure 2, and $\circ_4 \bullet_3$.

The **tensor game** $A \otimes B$ has moves $M_{A \otimes B} = M_A + M_B$, polarity $\lambda_{A \otimes B}(1, a) = \lambda_A(a)$ and $\lambda_{A \otimes B}(2, b) = \lambda_B(b)$, and plays are those $s \in M^*_{A \otimes B}$ that are alternating, O-starting and such that $s \upharpoonright A \in P_A$ and $s \upharpoonright B \in P_B$. Dually to $\multimap$, it follows from the definition that here only O can change between components. The **product game** $A \,\&\, B$ has the same moves and polarity as $A \otimes B$, but only the plays where either $s \upharpoonright A$ or $s \upharpoonright B$ is empty. Hence, with their first move, Opponent fixes the component in which the rest of the game will be played.

A **strategy** σ on A, written $\sigma : A$, is $\sigma \subseteq P^{ev}_A$ (writing P^{ev}_A for the set of even-length plays) which is non-empty, closed under even-length prefix, and *deterministic*, in the sense that if $sab, sab' \in \sigma$, then $b = b'$. The interpretation of terms yields strategies; for instance

$$[\![\lambda f^{o \multimap o}.\, \lambda x^o.\, f\, x : (o \multimap o) \multimap o \multimap o]\!] = \{\epsilon,\ \circ_4 \bullet_2,\ \circ_4 \bullet_2 \circ_1 \bullet_3\}$$

is a strategy on $[\![(o \multimap o) \multimap o \multimap o]\!]$ with moves following the naming convention of Figure 2.

The interpretation of terms exploits a number of constructions on strategies. In particular, to compute the **composition** of $\sigma : A \multimap B$ and $\tau : B \multimap C$ we first let σ, τ interact by considering all sequences in $(M_A + M_B + M_C)^*$ whose restrictions to A, B and B, C are respectively in σ and τ; and then project those to $P_{A \multimap C}$ to obtain $\tau \circ \sigma : A \multimap C$. We omit the details [14]. Overall, the structure needed to interpret the linear λ-calculus with products is succinctly summarized by stating that games and strategies form a *symmetric monoidal closed category with products* [14] – to any $\_ \mid x_1 : \varphi_1, \ldots, x_n : \varphi_n \vdash t : \varphi$ this lets us associate $[\![t]\!] : \bigotimes_{1 \le i \le n} [\![\varphi_i]\!] \multimap [\![\varphi]\!]$ in such a way that this is invariant under reduction – note however that in this paper, we avoid the categorical language as much as possible.

Figure 4 The two maximal plays of contraction on $[\![o \multimap o]\!]$.

3.2 History-free and finite memory strategies

A strategy $\sigma : A$ is **history-free** if its behaviour only depends on the last move, *i.e.* there is a partial function $f : M_A^O \rightharpoonup M_A^P$ such that for all $s \in \sigma$, for all $sa \in P_A$, we have $sab \in \sigma$ iff $f(a)$ is defined and $b = f(a)$. It is key in *AJM games* [1] that, without products, terms yield history-free strategies. If $\sigma : A$ is history-free, it is characterized by the corresponding partial function $f : M_A^O \rightharpoonup M_A^P$, known as its *history-free skeleton*. For instance, the strategy $[\![\lambda f^{o \multimap o}.\, \lambda x^o.\, f\, x]\!]$ with a unique maximal play in Figure 2, has history-free skeleton $\{\circ_4 \mapsto \bullet_2,\ \circ_1 \mapsto \bullet_3\}$.

One can also directly interpret terms as history-free skeletons: this is usually referred to as *Geometry of Interaction* [11], which has close ties with game semantics [3]. In particular, composition of history-free strategies can be performed directly on skeletons. If $\sigma : A \multimap B$ and $\tau : B \multimap C$ are history-free, their history-free skeletons, which have the types

$$f_\sigma : M_A^P + M_B^O \rightharpoonup M_A^O + M_B^P \qquad\qquad f_\tau : M_B^P + M_C^O \rightharpoonup M_B^O + M_B^P,$$

may be composed via *feedback* on B, pictured in Figure 3. For any Opponent move in $A \multimap C$, we apply the corresponding function f_σ or f_τ. As long as the response is in B, we keep applying f_σ and f_τ alternately. This process may stay in B forever (a *livelock*, in which case the composition $f_{\tau\circ\sigma}$ is undefined), but otherwise we eventually get a Player move in $A \multimap C$ as required; defining a partial function $f_{\tau\circ\sigma} : M_{A\multimap C}^O \rightharpoonup M_{A\multimap C}^P$. One may visualize a token entering on the left carrying an Opponent move, then bouncing in B until it eventually exits on the right. Other constructions used in the interpretation may be presented similarly, altogether giving (for the linear λ-calculus) a presentation of evaluation through a finite automaton called a *token machine*, where a token enters through an Opponent move, and bounces through the term until it eventually exits, giving the result of computation [18].

This is our starting point to represent evaluation of M(A)HORS via an automaton. However, there is an issue: strategies for linear λ-terms *with products* are not in general history-free. For instance, Figure 4 displays the two maximal plays of a *contraction/duplication* strategy $[\![\lambda f^{o\multimap o}.\, \langle f, f\rangle : (o \multimap o) \multimap ((o \multimap o) \,\&\, (o \multimap o))]\!]$. It reacts to $\circ_1$ differently depending on the history. To account for this, one may replace partial functions $f : M_A^O \rightharpoonup M_A^P$ with $f : M_A^O \times \mathcal{M} \rightharpoonup M_A^P \times \mathcal{M}$, *i.e.* *transducers*, where $\mathcal{M}$, the *memory*, is a finite set (see the *memoryful geometry of interaction* of [13] – however, we are not aware of this being used to define finite memory strategies). We give below a definition in this spirit, adapted to ease the translation to TSA and to deal with the branching in M(A)HORS due to *terminal symbols*.

We fix a ranked alphabet Σ (the multiplicative/additive distinction plays no role here).

▶ **Definition 2.** *A* ***transducer*** $\mathcal{T}$ *on a game A, written $\mathcal{T} : A$, is $\mathcal{T} = \langle \mathcal{M}_- \uplus \mathcal{M}_+, m_0, \delta_-, \delta_+\rangle$ where $\mathcal{M}_-$ is a finite set of* ***passive memory states*** *with a distinguished* ***initial memory state*** *$m_0 \in \mathcal{M}_-$, $\mathcal{M}_+$ is a finite set of* ***active memory states****, and* ***transition functions****:*

$$\begin{array}{lcrcl} \delta_- & : & \mathcal{M}_- \times M_A^O & \to & \mathcal{M}_+ \\ \delta_+ & : & \mathcal{M}_+ & \rightharpoonup & \mathcal{M}_+ \;+\; \mathcal{M}_- \times M_A^P \;+\; \{\mathsf{b}(m_1, \ldots, m_{|\mathsf{b}|}) \mid m_i \in \mathcal{M}_+,\ \mathsf{b} \in \Sigma\}\,. \end{array}$$

$$\delta_+^{\mathcal{T}\odot\mathcal{S}}((m_\mathcal{S}^-, m_\mathcal{T}^+)) = \begin{cases} (m_\mathcal{S}^-, m') & \text{if } \delta_+^\mathcal{T}(m_\mathcal{T}^+) = m' \\ \mathsf{b}((m_\mathcal{S}^-, m_1), \dots, (m_\mathcal{S}^-, m_{|\mathsf{b}|})) & \text{if } \delta_+^\mathcal{T}(m_\mathcal{T}^+) = \mathsf{b}(m_1, \dots, m_{|\mathsf{b}|}) \\ ((m_\mathcal{S}^-, m_\mathcal{T}^-), (2, c)) & \text{if } \delta_+^\mathcal{T}(m_\mathcal{T}^+) = (m_\mathcal{T}^-, (2, c)) \\ (\delta_-^\mathcal{S}(m_\mathcal{S}^-, (2, b)), m_\mathcal{T}^-) & \text{if } \delta_+^\mathcal{T}(m_\mathcal{T}^+) = (m_\mathcal{T}^-, (1, b)) \end{cases}$$

$$\delta_+^{\mathcal{T}\odot\mathcal{S}}((m_\mathcal{S}^+, m_\mathcal{T}^-)) = \begin{cases} (m', m_\mathcal{T}^-) & \text{if } \delta_+^\mathcal{S}(m_\mathcal{S}^+) = m' \\ \mathsf{b}((m_1, m_\mathcal{T}^-), \dots, (m_{|\mathsf{b}|}, m_\mathcal{T}^-)) & \text{if } \delta_+^\mathcal{S}(m_\mathcal{S}^+) = \mathsf{b}(m_1, \dots, m_{|\mathsf{b}|}) \\ ((m_\mathcal{S}^-, m_\mathcal{T}^-), (1, a)) & \text{if } \delta_+^\mathcal{S}(m_\mathcal{S}^+) = (m_\mathcal{S}^-, (1, a)) \\ (m_\mathcal{S}^-, \delta_-^\mathcal{T}(m_-^\mathcal{T}, (1, b))) & \text{if } \delta_+^\mathcal{S}(m_\mathcal{S}^+) = (m_\mathcal{S}^-, (2, b)) \end{cases}$$

Figure 5 Positive transitions of the composition of strategic transducers.

Any transducer $\mathcal{T}$ on $[\![o]\!]$ will be called **closed**. Apart from the forced initial $\delta_-(m_0, \circ)$, it is a finite tree-generating automaton, producing a tree $\mathsf{Tree}(\mathcal{T})$. But in general transducers may play on arbitrary games. In passive states, a transducer is waiting for an Opponent move, while in active states, it is performing internal computation that may result in a terminal symbol or in a Player move and the transition to a passive state. If $\delta_+(m) = \mathsf{b}(m_1, \dots, m_{|\mathsf{b}|})$, it produces the terminal symbol b; exploring the ith child results in continuing with m_i.

Like strategies, transducers can be *composed*.

▶ **Definition 3.** *Let $\mathcal{S} = (\mathcal{M}_-^\mathcal{S} \uplus \mathcal{M}_+^\mathcal{S}, m_0^\mathcal{S}, \delta_-^\mathcal{S}, \delta_+^\mathcal{S}) : A \multimap B$ and $\mathcal{T} = (\mathcal{M}_-^\mathcal{T} \uplus \mathcal{M}_+^\mathcal{T}, m_0^\mathcal{T}, \delta_-^\mathcal{T}, \delta_+^\mathcal{T}) : B \multimap C$ be transducers. The transducer $\mathcal{T} \odot \mathcal{S}$ on game $A \multimap C$ has $\mathcal{M}_-^{\mathcal{T}\odot\mathcal{S}} = \mathcal{M}_-^\mathcal{S} \times \mathcal{M}_-^\mathcal{T}$ and $\mathcal{M}_+^{\mathcal{T}\odot\mathcal{S}} = \mathcal{M}_+^\mathcal{S} \times \mathcal{M}_-^\mathcal{T} \uplus \mathcal{M}_-^\mathcal{S} \times \mathcal{M}_+^\mathcal{T}$, with initial state $(m_0^\mathcal{S}, m_0^\mathcal{T})$. The* transition function *is defined via $\delta_-^{\mathcal{T}\odot\mathcal{S}}((m_\mathcal{S}^-, m_\mathcal{T}^-), (2, c)) = (m_\mathcal{S}^-, \delta_-^\mathcal{T}(m_\mathcal{T}^-, (2, c)))$, $\delta_-^{\mathcal{T}\odot\mathcal{S}}((m_\mathcal{S}^-, m_\mathcal{T}^-), (1, a)) = (\delta_-^\mathcal{S}(m_\mathcal{S}^-, (1, a)), m_\mathcal{T}^-)$, and positive transitions given in Figure 5.*

Besides composition, all operations on strategies used in the interpretation of the linear λ-calculus with products have a counterpart on transducers. Altogether, for any $\Sigma \mid x_1 : \varphi_1, \dots, x_n : \varphi_n \vdash t : \varphi$, this yields a transducer $\langle t \rangle : \otimes_{1 \le i \le n} [\![\varphi_i]\!] \multimap [\![\varphi]\!]$. In particular, if $\Sigma \mid \_ \vdash t : o$, this yields a *closed* transducer $\langle t \rangle : [\![o]\!]$. It is obtained directly by induction on syntax following denotational semantics, and in particular in polynomial time. We can prove:

▶ **Proposition 4.** *For any $\Sigma \mid \_ \vdash t : o$, $\mathsf{Tree}(\langle t \rangle) = \mathrm{BT}(t)$.*

The proof works by linking transducers with game semantics. The simple game semantics presented above cannot directly deal with the presence of non-terminals replicable at will and the associated branching, so we must first extend it to "tree-generating game semantics". The details, though rather direct, are too lengthy for the paper, so we instead present the connection ignoring the terminal symbols.

Ignoring branching transitions, transducers generate strategies. Writing $m^- \overset{a}{\to} m^+$ when $\delta_-(m^-, a) = m^+$, $m_1^+ \to m_2^+$ when $\delta_+(m_1^+) = m_2^+$ and $m^+ \overset{b}{\to} m^-$ when $\delta_+(m^+) = (m^-, b)$; the set $\mathrm{Traces}(\mathcal{T})$ comprises all sequences $s_1 \dots s_{2n} \in M_A^*$ such that (with $m_0, \dots, m_n \in \mathcal{M}_-$)

$$m_0 \overset{s_1}{\to} \to^* \overset{s_2}{\to} m_1 \overset{s_3}{\to} \to^* \overset{s_4}{\to} m_2 \dots m_{n-1} \overset{s_{2n-1}}{\to} \to^* \overset{s_{2n}}{\to} m_n \,.$$

We say that $\mathcal{T}$ is a **strategic transducer** if for all $s \in \mathrm{Traces}(\mathcal{T}) \cap P_A$, if $sa \in P_A$ and $sab \in \mathrm{Traces}(\mathcal{T})$, then $sab \in P_A$. Then, $\mathrm{Traces}(\mathcal{T}) \cap P_A$ is a strategy written $\mathrm{Strat}(\mathcal{T})$. We say that $\sigma : A$ has **finite memory** if $\sigma = \mathrm{Strat}(\mathcal{T})$ for a strategic transducer $\mathcal{T}$. We also recover *history-free strategies* as those for which $\mathcal{M}_-$ is a singleton. For instance, the strategy in Figure 4 is generated using $\mathcal{M}_- = \{m_0, m_1\}$ and $\mathcal{M}_+ = \mathcal{M}_- \times M^O_{[\![o \multimap o]\!]}$, $\delta_-(m, a) = (m, a)$, $\delta_+(\_, \circ_4) = (m_0, \bullet_2)$, $\delta_+(\_, \circ_6) = (m_1, \bullet_2)$, $\delta_+(m_0, \circ_1) = (m_0, \bullet_3)$ and $\delta_+(m_1, \circ_1) = (m_1, \bullet_5)$.

Proposition 4 boils down to the fact that all constructions on transducers in the interpretation preserve strategic transducers, and match operations on strategies – for instance, $\mathrm{Strat}(\mathcal{T} \odot \mathcal{S}) = \mathrm{Strat}(\mathcal{T}) \circ \mathrm{Strat}(\mathcal{S})$. This entails that for all t, $\mathrm{Strat}(\langle t \rangle) = [\![t]\!]$. But for closed transducers $\langle t \rangle$ and tree-generating game semantics, $\mathsf{Tree}(\langle t \rangle) = \mathrm{Strat}(\langle t \rangle)$. Since game semantics is invariant under reduction, $[\![t]\!] = [\![\mathrm{BT}(t)]\!] = \mathrm{BT}(t)$, and Proposition 4 follows.

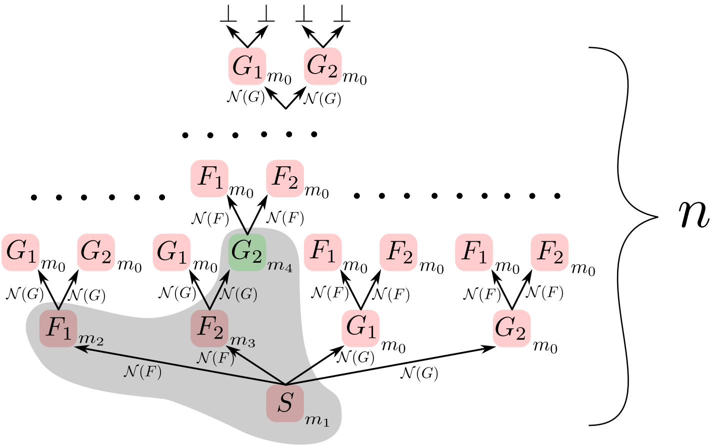

Figure 6 Illustration of a state of the n-th unfolding.

4 Game Semantics to TSA

The previous section lets us associate, to any $\Sigma \mid \_ \vdash t : o$, a finite tree-generating automaton. We extend this with recursion in two steps: first we evaluate finite unfoldings using finite automata, and then we build a single automaton with additional memory (a *Tree Stack Automaton*) whose runs amount to dynamically exploring these finite unfoldings.

4.1 Unfolding recursive calls

Let us fix a M(A)HORS $\mathcal{G} = \langle \Sigma, \mathcal{N}, \mathcal{R}, S \rangle$. By definition, for each $F \in \mathcal{N}$ we have $\Sigma, \mathcal{N} \mid \_ \vdash \mathcal{R}(F) : \mathcal{N}(F)$. Let $N \in \mathbb{N}$ be such that for all $F, G \in \mathcal{N}$, G appears at most N times in $\mathcal{R}(F)$. For all $F \in \mathcal{N}$, we choose a term $\Sigma \mid \mathcal{N}_1, \ldots, \mathcal{N}_N \vdash \mathcal{R}'(F) : \mathcal{N}(F)$ obtained by giving different names $G_1, \ldots, G_p$ ($p \leq N$) to all occurrences of $G \in \mathcal{N}$ in $\mathcal{R}(F)$. How these names are assigned does not matter. Although $\mathcal{R}'$ differs from $\mathcal{R}$, it can be equivalently used to define the finite approximations of $\mathrm{BT}(\mathcal{G})$. For each $F \in \mathcal{N}$ and $n \in \mathbb{N}$, we redefine $\Sigma \mid \_ \vdash \mathsf{unf}_n(F) : \mathcal{N}(F)$ by setting $\mathsf{unf}_0(F) = \bot$, and $\mathsf{unf}_{n+1}(F) = \mathcal{R}'(F)[\mathsf{unf}_n(G)/G_i \mid G \in \mathcal{N}_i, 1 \leq i \leq N]$. Although defined differently, this gives the same result as in Section 2.

But, unlike the original unfolding, this one can be replicated with strategic transducers. For each $F \in \mathcal{N}$, the interpretation of the previous section yields a strategic transducer:

$$\langle \mathcal{R}'(F) \rangle : \bigotimes_{1 \leq i \leq N} \bigotimes_{G \in \mathcal{N}} [\![\mathcal{N}(G)]\!] \multimap [\![\mathcal{N}(F)]\!] .$$

The unfolding above can then be replicated as follows.

▶ **Proposition 5.** *Setting $\mathcal{T}_F^0 = \bot$ with all positive transitions undefined, and $\mathcal{T}_F^{n+1} = \langle \mathcal{R}'(F) \rangle \odot (\bigotimes_{1 \leq i \leq N} \bigotimes_{G \in \mathcal{N}} \mathcal{T}_G^n) : [\![\mathcal{N}(F)]\!]$, for all $n \in \mathbb{N}$, we have $\mathsf{Tree}(\mathcal{T}_S^n) = \mathrm{BT}(\mathsf{unf}_n(S))$.*

Proof. By the substitution lemma for symmetric monoidal closed categories with products, syntactic substitution matches composition in the denotational model. It follows by induction that for all $F \in \mathcal{N}$, for all $n \in \mathbb{N}$, $\langle \mathsf{unf}_n(F) \rangle$ and $\mathcal{T}_F^n$ are transducers generating the same finite memory strategy. By Proposition 4, $\mathsf{Tree}(\mathcal{T}_S^n) = \mathsf{Tree}(\langle \mathsf{unf}_n(S) \rangle) = \mathrm{BT}(\mathsf{unf}_n(S))$. ◀

Figure 6 displays the structure of transducer compositions arriving at the finite tree automaton $\mathcal{T}_S^n$, for a M(A)HORS $\mathcal{G}$ where $\mathcal{R}(S)$ has two occurrences of F and two occurrences of G, $\mathcal{R}(F)$ has two occurrences of G, and $\mathcal{R}(G)$ has two occurrences of F. Each node stands for the matching strategic transducer (corresponding to a non-terminal), edges represent compositions. Running $\mathcal{T}_S^n$ passes control between the composed transducers, with always exactly one active after the initial transition. Figure 6 shows a possible state during a run: the grey area marks nodes that have already been explored. Outside of the grey area, the (local) transducer memory must be m_0. The green node is active, and all others passive. Following the transition function of $\langle\!\langle \mathcal{R}(G) \rangle\!\rangle$, we may next update the local memory m_4, produce a terminal and branch, or update to a passive state and send control up or down.

4.2 Tree Stack Automata

Now we give a single automaton with infinite memory whose bounded restrictions match the approximations above. It has a *stack* to deal with recursion, such that each state of the stack corresponds to a node in Figure 6. As these nodes stand for strategic transducers, they all have a finite memory. Accordingly, the automaton maintains a *store* associating, to each previously visited stack state/node, its *local memory*, accessed or updated only when visiting that node. We think of the store as a tree: the stack alphabet denotes *directions*, and stack values denote *positions* in the tree, *i.e. nodes* in (the infinite version of) Figure 6. *Pushes* and *pops* correspond to moving *up* and *down* the tree. Such an automata model is known as a *Tree Stack Automaton (TSA)* [7] – here, we introduce *tree-generating TSA*.

▶ **Definition 6.** *A tree-generating TSA $\mathcal{A}$ is a tuple $\langle \Sigma, Q, \Gamma, \mathcal{M}, \delta, q_0, \gamma_0, m_0 \rangle$ where Σ is a ranked alphabet of* terminals*, Q is a set of* states*, Γ is a finite* stack alphabet*, $\mathcal{M}$ is a finite* memory alphabet*, $q_0 \in Q$ is the* starting state*, $\gamma_0 \notin \Gamma$ is the* bottom-of-stack marker *and $m_0 \in \mathcal{M}$ is the* initial local memory*. Letting $\Gamma^\bullet = \Gamma \uplus \{\gamma_0\}$, the transition function δ has type:*

$$\delta : Q \times \mathcal{M} \times \Gamma^\bullet \rightharpoonup Q + \{\mathsf{b}(q_1, \dots, q_{|\mathsf{b}|}) \mid q_i \in Q, \mathsf{b} \in \Sigma\} + Q \times \mathcal{M} \times (\{up_\gamma \mid \gamma \in \Gamma\} + \{down\}) .$$

Informally, the transitions operate as follows. Initially, only γ_0 is on the stack. Subsequently, given state q, local memory m, and top of the stack $\gamma \in \Gamma^\bullet$:

1. if $\delta(q, m, \gamma) = q'$, the automaton changes state to q', leaving the stack and local memory unchanged;
2. if $\delta(q, m, \gamma) = \mathsf{b}(q_1, \dots, q_{|\mathsf{b}|})$, it outputs $\mathsf{b} \in \Sigma$ and branches – to explore the ith child ($1 \leq i \leq |b|$) it proceeds to state q_i leaving other components unchanged;
3. if $\delta(q, m, \gamma) = (q', m', up_{\gamma'})$, it updates the local memory to m', changes state to q' and pushes γ' onto the stack / moves up in direction γ' (if this is the first visit to that node, its local memory is set to m_0);
4. if $\delta(q, m, \gamma) = (q', m', down)$, it updates the local memory to m' and the state to q', and then pops / moves down (we adopt the convention that γ_0 cannot be popped so, if $\gamma = \gamma_0$ in this case, the automaton blocks).

Running a TSA $\mathcal{A}$ produces a possibly infinite tree $\mathsf{Tree}(\mathcal{A})$.

In the degenerate case where $\mathcal{M} = \{m_0\}$, tree-generating TSAs turn out to be precisely tree-generating deterministic pushdown automata (PDA): the local memory cannot store information, so only the stack remains. In general, however, it is not hard to see that TSAs are Turing-complete; fortunately we will only need TSAs satisfying a further condition called *restriction* [7]. A tree-generating TSA is k**-restricted** if every node can be accessed from below at most k times. It is **restricted** if it is k-restricted for some $k \in \mathbb{N}$.

We implement the evaluation of a MAHORS $\mathcal{G}$ with a restricted TSA $\mathcal{A}(\mathcal{G})$ with states

$$\mathcal{Q} = (\sum_{F \in \mathcal{N}} M^O_{\bigotimes_{1 \leq i \leq N} \bigotimes_{G \in \mathcal{N}} [\![\mathcal{N}(G)]\!] \multimap [\![\mathcal{N}(F)]\!]}) + (\sum_{F \in \mathcal{N}} \mathcal{M}_+^{\langle\!\langle \mathcal{R}'(F) \rangle\!\rangle}).$$

$$\begin{array}{rcll}
(\mathsf{Move}(F,a),(F,m),\_) & \mapsto & \mathsf{State}(F,\delta_-^F(m,a)) & \\
(\mathsf{State}(F,m),\_,\_) & \mapsto & \mathsf{State}(F,m') & \text{if } \delta_+^F(m) = m' \\
(\mathsf{State}(F,m),\_,\_) & \mapsto & \mathsf{b}(\mathsf{State}(F,m_1),\dots,\mathsf{State}(F,m_{|\mathsf{b}|})) & \text{if } \delta_+^F(m) = \mathsf{b}(m_1,\dots,m_{|\mathsf{b}|}) \\
(\mathsf{State}(F,m),\_,\_) & \mapsto & (\mathsf{Move}(G,(2,a)),(F,m'),up_{(F,i)}) & \text{if } \delta_+^F(m) = (m',(1,i,G,a)) \text{ with } a \in M^O_{\mathcal{N}(G)} \\
(\mathsf{State}(G,m),\_,(F,i)) & \mapsto & (\mathsf{Move}(F,(1,i,G,a)),(G,m'),down) & \text{if } \delta_+^G(m) = (m',(2,a)) \text{ with } a \in M^P_{\mathcal{N}(G)}
\end{array}$$

Figure 7 Transition function for the GoI TSA.

We use constructors Move and State to refer to elements from the left and right components of $\mathcal{Q}$ respectively. The *memory alphabet* is $\mathcal{M} = \sum_{F\in\mathcal{N}} \mathcal{M}_-^{\langle\mathcal{R}'(F)\rangle} / \equiv$, where $\equiv$ is the smallest equivalence relation with $(F,m_0) \equiv (G,m_0)$ for all $F,G \in \mathcal{N}$. We write m_0 for this equivalence class, providing the *initial memory state*. The *stack alphabet* is $\Gamma = N \times \mathcal{N}$ where N is the smallest integer such that all non-terminals have fewer than N occurrences in $\mathcal{R}(F)$, for all $F \in \mathcal{N}$. The start state is $q_0 = \mathsf{Move}(S,\circ)$ and the transition function is given in Figure 7.

The TSA $\mathcal{A}(\mathcal{G})$ is designed so that a run of stack size bounded by n simulates a run of $\mathcal{T}_S^n$. When in state $\mathsf{State}(F,m)$, the automaton is currently operating in a F node of $\mathcal{T}_S^n$ (as in Figure 6), performing internal computation following δ_+^F. If this internal computation produces a move, this move will be addressed either up or down the stack, depending of whether it is a Player move in $\mathcal{N}(F)$ (in which case we must move down), or an Opponent move in $\otimes_{1\le i\le N} \otimes_{G\in\mathcal{N}} [\![\mathcal{N}(G)]\!]$ (in which case we must move up, passing the control to a recursive call). If the state is $\mathsf{State}(G,m)$ and the top of the stack is (F,i), that means that we are currently running non-terminal G, which was called as the i-th occurrence of G in F. So the stack, together with the non-terminal symbol in the state, indicate the address of a node in Figure 6. When moving up or down the stack, we first change to a transient state $\mathsf{Move}(F,a)$ in which the automaton reads the input move using δ_-^F and resumes as above.

▶ **Theorem 7.** *For any MAHORS $\mathcal{G}$, there exists a restricted TSA $\mathcal{A}(\mathcal{G})$ (constructed in polynomial time) such that* $\mathsf{Tree}(\mathcal{A}(\mathcal{G})) = \mathrm{BT}(\mathcal{G})$.

Proof. For $n \ge 1$, write $\mathsf{Tree}_n(\mathcal{A}(\mathcal{G}))$ for the tree obtained from the truncated run-tree where the stack size is bounded by $n-1$ (where γ_0 has size 0). By construction, this truncated run-tree is weakly bisimilar to that of $\mathcal{T}_S^n$. In particular, $\mathsf{Tree}_n(\mathcal{A}(\mathcal{G})) = \mathsf{Tree}(\mathcal{T}_S^n) = \mathrm{BT}(\mathsf{unf}_n(S))$ by Proposition 5, so $\mathsf{Tree}(\mathcal{A}(\mathcal{G})) = \mathrm{BT}(\mathcal{G})$ by continuity.

This TSA is restricted: for any type φ, there is a bound on the length of plays in $P_{[\![\varphi]\!]}$ – in fact $M_{[\![\varphi]\!]}$ is finite, and plays in $P_{[\![\varphi]\!]}$ cannot use the same move twice. Let k be an upper bound to the maximal length of a play in $P_{\otimes_{G\in\mathcal{N}}[\![\mathcal{N}(G)]\!]}$. Then, $\mathcal{A}(\mathcal{G})$ is k-restricted. Indeed, fix a stack value $\gamma_{n+1}\gamma_n\dots\gamma_0$ with $\gamma_{n+1} = (F,i)$. Then, all transitions moving between $\gamma_{n+1}\dots\gamma_0$ and $\gamma_n\dots\gamma_0$ carry a move from $M_{\otimes_{G\in\mathcal{N}}[\![\mathcal{N}(G)]\!]}$. By construction, the sequence of such moves forms a play in $P_{\otimes_{G\in\mathcal{N}}[\![\mathcal{N}(G)]\!]}$. Hence, it is bounded by k. ◀

If the input scheme is an MHORS then each $\mathcal{R}'(F)$ is interpreted by a history-free strategy: $\mathcal{M}_-^{\langle\mathcal{R}'(F)\rangle}$ is a singleton. Consequently, $\mathcal{A}(\mathcal{G})$ has trivial memory and is in fact simply a PDA. This PDA is still k-restricted but also satisfies a stronger *linearity* property:

▶ **Lemma 8.** *Let $\mathcal{G}$ be an MHORS. Then the tree-generating PDA $\mathcal{A}(\mathcal{G})$ is **linear**, in the sense that the associated graph of reachable configurations is a tree.*

Proof. A strategic transducer on A is **reversible** if for each $a \in M_A^P$ there is at most one $m \in \mathcal{M}_+$ such that $\delta_+(m) = (\_,a)$ and for each $m \in \mathcal{M}_+$ there is at most one $(m',a) \in \mathcal{M}_- \times M_A^O$ such that $\delta_-(m',a) = m$ or at most one $m' \in \mathcal{M}_+$ such that $\delta(m') = m$, and the two possibilities are mutually exclusive. Reversible strategic transducers are closed under all operations used in the interpretation, hence if $\Sigma \mid \Delta \vdash t : A$ involves no product, $\langle t\rangle$ is *reversible* (this phenomenon is well-known in GoI [6]). This entails that $\mathcal{A}(\mathcal{G})$ is linear. ◀

5 TSA to MAHORS

In this section we show how to simulate a k-restricted TSA $\mathcal{A} = \langle \Sigma, Q, \Gamma, \mathcal{M}, \delta, q_0, \gamma_0, m_0 \rangle$ in MAHORS, i.e. we establish the converse of Theorem 7.

Let $B = |\Gamma|$ and $\Gamma = \{\gamma_1, \cdots, \gamma_B\}$. Nodes of the tree store will be represented using non-terminals $F^{u_1,\cdots,u_B;d}_{q,m,\gamma}$, where $(q,m,\gamma) \in Q \times \mathcal{M} \times \Gamma^{\bullet}$ represent the current state, node label and top of the stack respectively, d $(1 \le d \le k+1)$ is the number of times the node has already been visited from below and each u_j $(0 \le u_j \le k,\ 1 \le j \le B)$ is the number of times that the jth child has been visited from below. For brevity, we will write $\vec{u}$ instead of $u_1, \cdots, u_B$.

For $1 \le d \le k$, $F^{\vec{u};d}_{q,m,\gamma}$ has $B+1$ arguments: the first B arguments are used to simulate up_{γ_j} $(1 \le j \le B)$ and the last one corresponds to *down*. Each of the arguments is a Q-indexed tuple of continuations, so that projection can be used to select the right component to model the associated state change. When moving up the tree (up_{γ_j}), we call the jth argument passing as an argument another continuation that makes it possible to return (move down) later. Dually, when moving down the tree, we call the last argument passing as an argument a continuation that represents a further visit up. Using these ideas, one could code unrestricted TSA in an untyped setting, but we shall rely on carefully crafted types that allow, for each node, for up to k visits from below. In particular, if the automaton is moving down having visited a node k times from below, the corresponding upwards continuation for the $k+1$ visit is of type o, i.e. it is not usable for any future calls. The rules for $1 \le d \le k$ are summarised in the table below, using λ notation for brevity (for $F^{\vec{u};k+1}_{q,m,\gamma}$ we set $F^{\vec{u};k+1}_{q,m,\gamma} x_1 \cdots x_B = \bot$).

$\delta(q,m,\gamma)$	rule
q'	$F^{\vec{u};d}_{q,m,\gamma}\, x_1 \cdots x_B y = F^{\vec{u};d}_{q',m,\gamma}\, x_1 \cdots x_B y$
$\mathsf{b}(q_1, \cdots, q_{\lvert\mathsf{b}\rvert})$	$F^{\vec{u};d}_{q,m,\gamma}\, x_1 \cdots x_B y = \mathsf{b}\, \langle F^{\vec{u};d}_{q_1,m,\gamma}\, x_1 \cdots x_B y, \cdots, F^{\vec{u};d}_{q_{\lvert\mathsf{b}\rvert},m,\gamma}\, x_1 \cdots x_B y \rangle$
$(q', m', down)$	$F^{\vec{u};d}_{q,m,\gamma}\, x_1 \cdots x_B y = (\pi_{q'} y)\, \langle F^{\vec{u};d+1}_{q'',\underline{m'},\gamma}\, x_1 \cdots x_B \mid q'' \in Q \rangle$
(q', m', up_{γ_j})	$F^{\vec{u};d}_{q,m,\gamma}\, x_1 \cdots x_B y = (\pi_{q'} x_j)\, \langle \lambda z^{\overline{T_j}}. F^{\vec{u}+e_j;d}_{q'',m',\gamma}\, x_1 \cdots x_{j-1} z x_{j+1} \cdots x_B y \mid q'' \in Q \rangle$

In the *down* case, note that the q'th component of y is used to model state change and that the continuation features m' instead of m to reflect the local memory update. Note also the change from d to $d+1$, which updates the count of visits from below.

In the *up* case, the q'th component of x_j is used to model state change and the direction of the upward move (γ_j). The use of the same γ on both sides captures the same position on the stack and m' is used on the rhs to simulate the local memory update. d does *not* change, because the continuation represents revisiting the node from above (rather than from below). However, once the node is revisited from above in the future, its jth child will have been visited $u_j + 1$ times from below: hence the change to u_j (we write $\vec{u} + e_j$ for $\vec{u}$ with the jth component incremented by 1). In the *up* case, we use a λ-term inside a rule to highlight the intention more clearly, this can be avoided by using an auxiliary non-terminal.

The start symbol $S : o$ has rule $S = (F^{0,\cdots,0;1}_{q_0,m_0,\gamma_0})\, N_1 \cdots N_B \langle \bot \mid q \in Q \rangle$. The divergent terms correspond to our convention that the automaton blocks when *down* is called at the root node. N_j $(1 \le j \le B)$ stands for $\langle N_{q,j} \mid q \in Q \rangle$, where $N_{q,j}$ are auxiliary non-terminals that represent nodes visited for the first time. They are subject to the rule $N_{q,j} y = F^{0,\cdots,0;1}_{q,m_0,\gamma_j}\, N_1 \cdots N_B y$.

The scheme depends on types of the form T_i $(0 \le i \le k)$ defined by $T_k = o$ and $T_i = \overline{(\overline{T_{i+1}} \multimap o)} \multimap o$, where $\overline{T}$ stands for $\&_{q \in Q} T$, i.e. $|Q|$ copies of T. In particular, we have $F^{\vec{u};d}_{q,m,\gamma} : \overline{T_{u_1}} \multimap \cdots \multimap \overline{T_{u_B}} \multimap T_{d-1}$ and $N_{q,j} : T_0$.

▶ **Theorem 9.** *For any restricted TSA, there exists an equivalent MAHORS (constructible in exponential time).*

In conjunction with Theorem 7, this shows that MAHORS and restricted TSA are equivalent.

6 Expressivity of MAHORS

It is easy to see that any (classic) first-order recursion scheme (1-HORS) can be viewed as a MAHORS, simply by giving the terminals types of the form $o \,\&\, \cdots \,\&\, o \multimap o$. Hence, MAHORS are at least as expressive as first-order HORS. Next, informed by results from the preceding sections, we can discuss their relationship with schemes of higher orders. Because our TSA model is a tree-generating variant of the automata from [7], which capture multiple context-free languages [21], we can immediately conclude the following.

▶ **Lemma 10.** *The branch language of a tree generated by a MAHORS is multiple context-free.*

Thanks to the Lemma, we can show that MAHORS and second-order HORS are incomparable.

▶ **Example 11.** There exists a second-order HORS, which is not equivalent to any MAHORS. For example, consider the 2-HORS given by: $S = Fb$, $Ff = a(f\$)(F(Gf))$, $Gfx = f(fx)$, where $a : o \to o \to o$, $b : o \to o$ and $\$: o$ are terminals and $F : (o \to o) \to o$ and $G : (o \to o) \to o \to o$ are non-terminals. The scheme generates an infinite tree whose finite branches correspond to the language $L = \{a^n b^{2^{n-1}} \$ \,|\, n \geq 1\}$. Because it is known that L is not multiple context-free [21, Lemma 3.5], it cannot be the branch language of a MAHORS by Lemma 10.

▶ **Example 12.** We give a MAHORS that is not equivalent to any second-order HORS, exploiting the fact that the language $L = \{w\#w\#w \,|\, w \in D\}$, where D is the Dyck language ($D = \epsilon \,|\, [D]D$), is not indexed [8] (see also page 2 of [16]). The MAHORS given below (using λ-syntax for brevity) has been obtained by lifting the grammar rules for D to triples of words, encoded with the type $\mathsf{T}_3 = ((o \multimap o) \multimap (o \multimap o) \multimap (o \multimap o) \multimap o) \multimap o$. Consequently, it generates a tree whose finite branches are the words of L prefixed by a segment of b's and followed by \$. The terminal $\mathsf{b} : (o \,\&\, o) \multimap o$ represents rule choice and the other terminals $([,], \# : o \multimap o,\ \$: o)$ are used to build the word. The scheme relies on the following non-terminals: $S : o$, $D : \mathsf{T}_3$, $K : (o \multimap o) \multimap (o \multimap o) \multimap (o \multimap o)$ and $I : o \multimap o$, which are subject to the following rules:

$$\begin{aligned}&S = D(\lambda xyz.x(\#(y(\#(z\$))))), \qquad Kxyv = [(x(](yv))), \qquad Iv = v,\\ &Df = \mathsf{b}\langle fIII, D(\lambda x_1y_1z_1.D(\lambda x_2y_2z_2.f(Kx_1x_2)(Ky_1y_2)(Kz_1z_2)))\rangle\end{aligned}$$

If the scheme were equivalent to a 2-HORS, the language of its branches would be accepted by a 2-CPDA [12], i.e. it would be indexed [2]. However, indexed languages are closed under homomorphism, so L would be indexed too, because erasing b's and \$ is a homomorphism.

Lemma 10 identifies a strong restriction on branch languages of trees generated by MAHORS. Since multiple context-free languages form a subset of third-order collapsible pushdown languages [20], it is natural to ask whether every MAHORS might be equivalent to a third-order HORS. One could try to establish this, for example, by showing that, for every restricted TSA, there is an equivalent MAHORS that uses third-order types. Unfortunately, our proof of Theorem 7 uses types whose order grows linearly in the restriction parameter k. At the time of writing, we believe this necessary to capture the complexity of run-trees generated by our (infinite-)tree-generating TSA, though we are aware that similar hierarchies for (finite-)word languages and (finite-)tree languages do collapse, e.g. second-order abstract categorial grammars [19, 15]. The main difficulty that prevents us from translating TSA into MAHORS of order 3 is that there may be infinitely many (sub)runs that start from a given node, visit only nodes above it and return to the same node, and all such runs have to be captured in a single MAHORS. In contrast, for word languages, when TSA are seen as acceptors of finite words, it suffices to focus on the representation of a single run [7].

7 Multiplicative HORS (MHORS)

In this section we consider MHORS, i.e. &-free MAHORS. Recall from Lemma 8 that, for any MHORS, there exists an equivalent *linear* PDA (LPDA) $\langle \Sigma, Q, \Gamma, \delta, q_0, \gamma_0\rangle$ with transition function $\delta : Q \times \Gamma^\bullet \rightharpoonup Q + \{\mathsf{b}(q_1, \dots, q_{|\mathsf{b}|}) \mid q_i \in Q,\, \mathsf{b} \in \Sigma\} + Q \times (\{up_\gamma \mid \gamma \in \Gamma\} + \{down\})$ such that any reachable configuration must be reachable through a unique path. Next we prove the converse using first-order MHORS only. In combination with Lemma 8, this amounts to a polynomial-time translation from arbitrary MHORS to first-order MHORS.

In what follows, we view an LPDA as a pushdown system with a successor relation $\Rightarrow$, in order to exploit standard reachability techniques [4, 9]. We work with configurations of the form $(q,t) \in Q \times (\Gamma^\bullet)^*$. As we do not have the space to review all the necessary definitions, let us just recall that the techniques employ *multi-automata* over $\Gamma^\bullet$ to recognise sets of configurations. Multi-automata are finite-state machines with multiple initial states, one for each state of the analysed pushdown system. Let i_q be the initial state of a multi-automaton corresponding to $q \in Q$. Then a multi-automaton is said to recognise (q,t) if it accepts t once started from i_q (this corresponds to processing stack content top-down). In particular, we take advantage of the following facts.

- For any LPDA $\mathcal{A}$, there exists a multi-automaton $\mathcal{A}_{era}$, constructible in polynomial time, which captures erasable stack content, i.e. $\{(q,t) \in Q \times \Gamma^* \mid \exists q' \in Q.\, (q,t) \Rightarrow^* (q', \epsilon)\}$. Using terminology from [4], this corresponds to $pre^*(Q \times \{\epsilon\})$. Hence, given $\mathcal{A}$, one can calculate the relation $R_{\mathcal{A}} = \{(q,\gamma,q') \in Q \times \Gamma \times Q \mid (q,\gamma) \Rightarrow^* (q',\epsilon)\}$ in polynomial time.
- For any LPDA $\mathcal{A}$, there exists a multi-automaton $\mathcal{A}_{rea}$, constructible in polynomial time, which represents all configurations reachable from (q_0,γ_0), i.e. all $(q, t\gamma_0)$ such that $(q_0,\gamma_0) \Rightarrow^* (q, t\gamma_0)$. This corresponds to representing $post^*(\{(q_0,\gamma_0)\})$ [9].

▶ **Lemma 13.** *For any LPDA $\mathcal{A}$, there exists an equivalent MHORS (of order 1) and its construction can be carried out in polynomial time.*

Proof. The translation is similar to the PDA-to-1-HORS translation in [12] except that reachability analysis ($R_{\mathcal{A}}$) is used to identify places where variables actually get used. This is needed to produce a term that is linearly typable. ◀

Consequently, LPDA and MHORS are equivalent. We end this section by showing they generate regular trees. Our first lemma states that, if the stack of an LPDA grows sufficiently, there is a point after which elements lying below a certain level will no longer be accessible.

▶ **Lemma 14.** *Let $s \in \Gamma^*$. There exists a bound $H_s \ge 0$ such that, for any $t \in \Gamma^*$, if $(q, ts\gamma_0)$ is reachable and $|t| > H_s$ then there is no q' such that $(q,t) \Rightarrow^* (q',\epsilon)$.*

Proof. Consider $X = \{(q, s\gamma_0) \mid (q_0,\gamma_0) \Rightarrow^* (q, s\gamma_0)\}$. Observe that $0 \le |X| \le |Q|$. Because we work with an LPDA, there can be at most $|Q|$ runs from (q_0,γ_0) to X. Let H_s be the maximum stack height occurring in these runs (take 0 if $X = \varnothing$). Suppose $(q, ts\gamma_0)$ is reachable and $|t| > H_s$. If we had $(q,t) \Rightarrow^* (q',\epsilon)$ for some q' then there would be a run $(q_0,\gamma_0) \Rightarrow^* (q, ts\gamma_0) \Rightarrow^* (q', s\gamma_0)$ in which the stack height exceeds H_s (because it visits $(q, ts\gamma_0)$). This contradicts the choice of H_s. ◀

The above bound depends on s. We show that there is a uniform bound, polynomial with respect to the size of $\mathcal{A}$. First, given $s \in \Gamma^*$, the multi-automaton $\mathcal{A}_{rea}$ discussed earlier can be modified to represent $\{(q,t) \mid (q_0,\gamma_0) \Rightarrow^* (q, ts\gamma_0)\}$ simply by changing the accepting states of $\mathcal{A}_{rea}$ (to those from which an original accepting state is reachable via an $s\gamma_0$-labelled path). Let $\mathcal{A}^s_{rea}$ be the resultant automaton. Note that the size of $\mathcal{A}^s_{rea}$ is bounded by a polynomial in $|\mathcal{A}|$ that is independent of s, because the only difference between $\mathcal{A}^s_{rea}$ and $\mathcal{A}_{rea}$ is the set of accepting states, and its size bounded by $|Q|$.

Observe that $\{(q,t) \mid (q_0,\gamma_0) \Rightarrow^* (q, ts\gamma_0),\, (q,t) \Rightarrow^* (q',\epsilon) \text{ for some } q'\}$ is exactly the set of configurations that are represented by both $\mathcal{A}^s_{rea}$ and $\mathcal{A}_{era}$. Consider the product $\mathcal{A}'$ of the two multi-automata. By Lemma 14, $\mathcal{A}'$ cannot have reachable loops. Consequently, the longest word that it accepts from any initial state is bounded by the number of states of the automaton, which is polynomial in $|\mathcal{A}|$. As this reasoning is independent of s, we obtain:

▶ **Lemma 15.** *For any LPDA $\mathcal{A}$, there exists a bound H, polynomial in $|\mathcal{A}|$, such that, for any $s,t \in \Gamma^*$, if $(q, ts\gamma_0)$ is reachable and $|t| > H$ then there is no q' such that $(q,t) \Rightarrow^* (q',\epsilon)$.*

This implies that an LPDA can only use H top elements from its stack, i.e. its stack can be simulated by a finite state automaton, which is exponentially bigger. Because any 0-HORS is also an MHORS, MHORS and 0-HORS are equivalent, i.e. they generate exactly the regular trees. However, it is worth noting that MHORS may be more succinct.

▶ **Example 16.** The MHORS built from terminals $a, b : o \multimap o$, non-terminals $S : o, F_i : o \multimap o$ $(1 \le i \le n)$ with $S = F_n(bS)$, $F_0(x) = ax$ and $F_i(x) = F_{i-1}(F_{i-1}x)$ for $1 \le i \le n$ generates an infinite branch $(a^{2^n}b)^\omega$, which could only be generated by a 0-HORS of exponential size in n.

Abstract

In this article, we question the relevance of uniform random models for algorithms that use expressions as inputs. Using a general framework to describe expressions, we prove that if there is a subexpression that is absorbing for a given operator, then, after repeatedly applying the induced simplification to a uniform random expression of size n, we obtain an equivalent expression of constant expected size. This proves that uniform random expressions lack expressivity, as soon as there is an absorbing pattern. For instance, $(a+b)^\star$ is absorbing for the union for regular expressions on $\{a,b\}$, hence random regular expressions can be drastically reduced using the induced simplification.

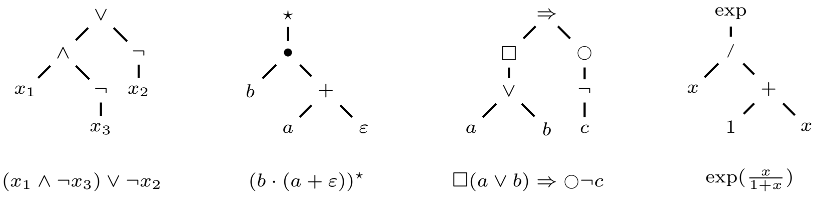
1 Introduction

Although the classical paradigm to analyze the efficiency of an algorithm is to study its worst case complexity, in many situations it is not a relevant way to describe what is observed in practice, when one actually implements and tests the algorithm. This is typically the case when worst case instances are very unlikely, and when the algorithm behaves well on most inputs. A natural way to deal with this issue is to set a probability distribution on the inputs of size n, for each n, and to study the average running time of the algorithm when the inputs are randomly chosen following the prescribed distribution.[1] The textbook example is QuickSort algorithm with a simple choice of pivot, which runs in $\mathcal{O}(n \log n)$ expected time and $\mathcal{O}(n^2)$ in the worst case. But the average case analysis raises the question of the input distribution, which is usually a difficult one. The result on QuickSort holds when the input is a permutation taken uniformly at random, but are real-life arrays uniformly shuffled? Probably not, whatever "real-life" means. For QuickSort, one can randomize the choice of the pivot to ensure the $\mathcal{O}(n \log n)$ expected running time, which is equivalent to uniformly shuffling the input. This is probably not a good idea in practice though, since we lose the property that some input can be often partially sorted: popular programming languages as Python or Java now use the recent TimSort algorithm that takes advantage of the presortedness of the input.

[1] There are other relevant theoretical alternatives, as the *smoothed analysis* of algorithms, but we will only consider average case analysis in this article.

Still, if one wants to test the efficiency of an implementation of an algorithm, or to compare two tools, and if there are not sufficiently many benchmarks available, doing the analysis on random inputs sounds reasonable. In addition, using the uniform distribution has several advantages: it ensures a lot of diversity on the generated input (as they are all equally likely) and there are several very generic methods to perform the random generation efficiently: the two main ones being the *recursive method* [20] and *Boltzmann samplers* [7]; both directly translate a combinatorial description of the inputs into a uniform random generator. And also, beyond the experiments, the theoretical average case analysis of the algorithm can be done using techniques from discrete probabilities or from analytic combinatorics.

In this article we focus on algorithms whose inputs are formulas, encoded by expressions. Informally, an expression is a tree, whose internal nodes are labelled with operators, and whose leaves are labelled with variables or constants. Such trees are very natural ways to represent formulas in many different contexts; several examples are given in Fig. 1. Observe that the equivalent reverse polish notation of the expression can be obtained by a simple tree traversal.



$(x_1 \wedge \neg x_3) \vee \neg x_2$ $(b \cdot (a+\varepsilon))^\star$ $\square(a \vee b) \Rightarrow \bigcirc\neg c$ $\exp(\frac{x}{1+x})$

Figure 1 Four expression trees and their associated formulas. From left to right: a logical formula, a regular expression, an LTL formula and a function.

We define the set of expressions by the finite sets of operators of any given degree: for regular expressions on an alphabet $\{a, b\}$, we consider that there are three kinds of leaves $\{a, b, \varepsilon\}$, one unary internal node $\{\star\}$ for the Kleene star and two binary internal nodes $\{\bullet, +\}$ for the concatenation and the union. We define the *size* of an expression as its number of nodes (including leaves). For the set of regular expressions $\mathcal{L}_R$, we have the following formal inductive description:

$$\mathcal{L}_R = a + b + \varepsilon + \overset{\star}{\underset{\mathcal{L}_R}{|}} + \overset{\bullet}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}} + \overset{+}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}}\,. \tag{1}$$

Observe that if we consider plane trees (where the children of a node are ordered, as when they are drawn on a plan), Eq. (1) is an unambiguous description of the expressions in $\mathcal{L}_R$. It is, of course, not an unambiguous description of the associated languages, since a given language admits several representations using expressions. It is clear that the other expressions of Fig. 1 also have a specification that is similar to Eq. (1). Efficient methods were developed in the field of analytic combinatorics to deal with that kind of combinatorial inductive descriptions. In a nutshell, we first associate the formal power series $L(z) := \sum_{n \geq 0} \ell_n z^n$, where ℓ_n is the number of expressions of size n. Eq. (1) translates into an equation on $L(z)$:

$$L(z) = z\phi(L(z)), \text{ with } \phi(X) = 3 + X + 2X^2. \tag{2}$$

Then we see $L(z)$ as a function from $\mathbb{C}$ to $\mathbb{C}$, which is analytic at 0, and use its functional equation Eq. (2) to derive a lot of information on ℓ_n, typically asymptotic equivalents. When considering the uniform distribution, one can easily go further and introduce formal parameters in the specification (for instance, the number of unary operators), which can also be interpreted in the analytic world, and directly obtain statistics of interest (for instance, the asymptotic equivalent of the expected number of unary operators). Combinatorial structures whose generating series satisfy an implicit functional equation $L(z) = z\phi(L(z))$ are called *simple varieties of trees* (there are some analytic conditions on ϕ, which are always satisfied in the sequel), and we refer the reader to the textbook on analytic combinatorics [9, VII.3.] for further information. For the remainder of this introduction, the reader has just to keep in mind that the technical framework used to deal with uniform random expressions is well established.

As can be expected at this point of the discussion, there are a lot of results in the literature on simple varieties of trees and on specific random expressions. They exhibit some kind of "universal" behavior: for instance, the number of such trees always grows in $\ell_n \sim \alpha\beta^n n^{-3/2}$, for some computable constants α and β [16]. Their expected height is asymptotically equivalent to $\gamma\sqrt{n}$, for some computable γ [8]. In [10], the authors proved that if a uniform random expression is compressed by identifying common subexpressions (changing the tree into a directed acyclic graph), the expected size of the result is asymptotically equivalent to $\frac{\delta n}{\sqrt{\log n}}$. It was also established [11] that computing the derivative of a random function, defined by a tree as in Fig. 1, costs $\Theta(n^{3/2})$ in expected time and space. Concerning regular expressions, the second author studied a standard construction that builds an ε-free non-deterministic automaton recognizing the same language [18]: he proved that there is an expected linear number of transitions in the resulting automaton, although it is $\Theta(n^2)$ in the worst case. This result was subsequently refined and adapted to various other similar constructions by Moreira, Reis and their co-authors (see [2] for a survey). A lot of efforts were also made for Boolean formulas, in slightly different settings: we consider the set $\mathcal{F}_k$ of the 2^{2^k} Boolean formulas on k variables. For a suitable set of logical operators, for instance $\{\vee, \wedge\}$, and for any $n \geq 1$, we consider the probability $p_n(f)$ that a random Boolean expression represents the Boolean function $f \in \mathcal{F}_k$; then we let n tend to infinity, and it can be proved that $p_n(f)$ has a limit $p(f)$, and that p is a probability distribution on $\mathcal{F}_k$. So the distribution is different, and more theoretical than what is usually used for testing implementations. But, since it relies on uniform random expressions, that kind of distributions has a lot of similarities with uniform random expressions (see [12] for a survey). While investigating this distribution on Boolean formulas, its lack of complexity was discovered: with high probability the formulas obtained are very simple [13, 14]. In fact, there is an older result in Nguyên Thê PhD's dissertation [17, Ch 4.4], where he considered and/or Boolean expressions whose leaves are either `true`, `false` or a literal; he studied the impact of inductively applying 8 different reduction rules, such as $\texttt{true} \vee \phi \rightarrow \texttt{true}$, on uniform random expressions of size n, and proved that the expected size of the simplified expression tends to a constant as n tends to infinity. This was a very negative result for uniformly chosen random Boolean expressions (with $\{\vee, \wedge\}$ operators and $\{\texttt{true}, \texttt{false}, x\}$ leaves), as most of them can be drastically simplified using simple rules.

In this article, we aim at extending Nguyên Thê's result to much more general families of expressions, proving its universality in the context of simple varieties of trees. Informally, our main result is the following:

▶ **Theorem.** *Consider a simple variety of expressions, where there is a tree pattern $\mathcal{P}$ that is an absorbing element for one of the operators $\circledast$. We consider the simplification algorithm that consists in inductively changing a $\circledast$-node by $\mathcal{P}$ whenever one of its children can be simplified into $\mathcal{P}$. Then the expected size of the simplification of a uniform random expression of size n tends to a constant as n tends to infinity.*

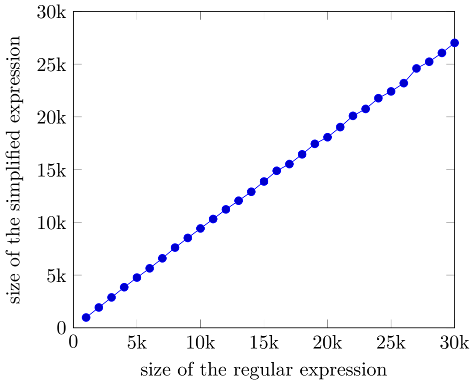


Figure 2 Experimental study of the size of a random uniform regular expression after applying the simplification rules $E + \mathcal{P} \rightsquigarrow \mathcal{P}$ and $\mathcal{P} + E \rightsquigarrow \mathcal{P}$.

As an example, the tree pattern $\mathcal{P}$ corresponding to $(a + b)^\star$ is absorbing for the union $+$ of regular expressions: for any regular expression E, one can simplify $E + \mathcal{P}$ or $\mathcal{P} + E$ into $\mathcal{P}$ without changing the described language. Hence, applying this simple simplification rule to a very large random regular expression results in an expression of constant expected size. Also, the tree pattern associated with $x_1 \vee \neg x_1$ is absorbing for $\vee$, since it evaluates to `true`: random Boolean expressions are also drastically simplified using this transformation rule. It is the same for LTL formulas, and for functions: if there is the constant 0 (or a way to produce it with a tree pattern) and the multiplication, then the same phenomenon occurs. In fact, for most natural notions of expressions, there are absorbing patterns for some operators, and uniform random expressions lack expressivity, since they can be simplified into much smaller equivalent expressions with high probability. This is a universal and negative result on uniform random expressions, which is worth knowing when designing empirical tests. Indeed, comparing two tools on uniform random expressions probably consists in simply comparing their efficiency for simplifying the input (preprocessing step). It also questions the relevance of further theoretical studies on that kind of models. The consequences are discussed in details in Section 4.

To conclude this introduction, we would like to mention that our result is not always easy to observe experimentally. We implemented uniform random samplers for regular expressions, and computed (experimentally) the expected size when using the fact that $(a + b)^\star$ is absorbing for $+$. The results are depicted on Fig. 2. It is not clear that the curve converges to some constant, as stated by our theorem. In fact, if we compute the value of the limit (we used SageMath software for the computations) we obtain a bit more than 3 624 217, a huge constant. This value can be considerably reduced if we introduce several more rewriting rules (see Section 4 for the details).

2 Definitions and settings

2.1 Combinatorial constructions and analytic combinatorics

In this article, the proofs rely on mathematical techniques developed in the framework of analytic combinatorics [9]. In this section, we recall the basic tools of this theory that will be used in the sequel (more advanced results will be introduced when needed). A *combinatorial class* is a set $\mathcal{C}$ equipped with a notion of *size* $|\cdot|$ (a mapping from $\mathcal{C}$ to $\mathbb{Z}_{\geq 0}$) such that for any $n \in \mathbb{Z}_{\geq 0}$ there are finitely many elements of $\mathcal{C}$ of size n. Let $\mathcal{C}_n = \{C \in \mathcal{C} : |C| = n\}$

and let $c_n = |\mathcal{C}_n|$ be its cardinality. The *ordinary generating series* (OGS for short) of the combinatorial class $\mathcal{C}$ is the formal power series $C(z) := \sum_{C\in\mathcal{C}} z^{|C|} = \sum_{\geq 0} c_n z^n$. Let $[z^n]C(z) := c_n$ denote the n-th coefficient of $C(z)$.

Let $\mathcal{A}$ and $\mathcal{B}$ be two combinatorial classes, and let $A(z)$ and $B(z)$ be their OGS, respectively. If $\mathcal{A}$ and $\mathcal{B}$ are disjoint, then the OGS of their union is simply $A(z) + B(z)$. Moreover, if we define the size of a pair (α, β) in $\mathcal{A} \times \mathcal{B}$ as the sum of the sizes of α and β, then $\mathcal{A} \times \mathcal{B}$ is a combinatorial class with OGS $A(z)B(z)$, as a simple computation shows. There are many other set constructions on combinatorial classes that directly translate on OGS, but we will not need them in the sequel (see [9, Part A]).

Let us take an example that will be used throughout this article, the combinatorial set $\mathcal{L}_R$ of regular expressions on the alphabet $\{a, b\}$. Its elements are plane rooted trees, whose nodes (internal and leaves) are labelled: leaves are labelled with a, b or ε, unary nodes are labelled with $\star$, and binary nodes with $\bullet$ or $+$. Rooted means that there is a root (contrary to the graph-theory notion of tree), and plane means that the order of the children matters: $\overset{+}{\underset{a\ b}{/\backslash}}$ and $\overset{+}{\underset{b\ a}{/\backslash}}$ are different elements of $\mathcal{L}_R$. Encoding trees as tuples (for instance $(\bullet, \texttt{left}, \texttt{right})$ for a tree of root $\bullet$ and left and right children `left` and `right`), we have the identity:

$$\mathcal{L}_R = \{a, b, \varepsilon\} \cup \{\star\} \times \mathcal{L}_R \cup \{\bullet, +\} \times \mathcal{L}_R \times \mathcal{L}_R, \tag{3}$$

which we rewrite as in Eq. (1) for readability: $\mathcal{L}_R = a + b + \varepsilon + \overset{\star}{\underset{\mathcal{L}_R}{|}} + \overset{\bullet}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}} + \overset{+}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}}$. From this we directly obtain the following functional equation for the associated OGS $L_R(z)$:

$$L_R(z) = 3z + zL_R(z) + 2zL_R(z)^2 = z\phi(L_R(z)), \text{ with } \phi(y) = 3 + y + 2y^2.$$

Going further, one can also encode statistics on the elements of a combinatorial class into generating series. Let ξ be a mapping from a combinatorial class $\mathcal{C}$ to $\mathbb{Z}_{\geq 0}$. We are interested in the double sequence $c_{n,k}$ that counts the number of elements $C \in \mathcal{C}_n$ such that $\xi(C) = k$. The associated bivariate generating series (BGS for short) is by definition:[2]

$$C(z, u) := \sum_{C\in\mathcal{C}} z^{|C|} u^{\xi(C)} = \sum_{n,k\geq 0} c_{n,k} z^n u^k.$$

When the statistics ξ is *additive*, which means that it is defined on pairs by $\xi((\alpha, \beta)) = \xi(\alpha) + \xi(\beta)$, then we also have a generic dictionary to translate combinatorial constructions into BGS directly (see [9, Ch III]). This is for instance the case if ξ is the number of a-leaves in a regular expression. Moreover, formal differentiation with respect to u allows us to compute the expected value of ξ for the uniform distribution: by definition, the expectation of ξ for objects of size n is $\mathbb{E}_n[\xi] = \frac{1}{|\mathcal{C}_n|} \sum_{C\in\mathcal{C}_n} \xi(C)$. But observe that

$$\frac{d}{du} C(z, u) = \frac{d}{du} \sum_{C\in\mathcal{C}} z^{|C|} u^{\xi(C)} = \sum_{n\geq 0} \left(\sum_{C\in\mathcal{C}_n} \xi(C) u^{\xi(C)-1} \right) z^n.$$

Hence, if we extract the n-th coefficient[3] in z, and set $u = 1$, we have c_n times the expectation. We thus get the following formula to compute the expectation for the uniform distribution:

$$\mathbb{E}_n[\xi] = \frac{[z^n] \frac{d}{du} C(z, u) \Big|_{u=1}}{[z^n]C(z, 1)}. \tag{4}$$

[2] Observe that $C(z, 1) = C(z)$.

[3] Recall that it is exactly what the operator $[z^n]$ does.

Higher moments are obtained similarly, by differentiating several times with respect to u.

Let us continue our example on regular expressions over a binary alphabet by studying the statistics ξ associated with the number of unary operators $\star$ in an expression. The technique consists in *marking* the $\star$-nodes (we use a circle, symbolically) and in changing the marks into the formal variable u when translating the combinatorial specification:

$$\mathcal{L}_R = a + b + \varepsilon + \underset{\mathcal{L}_R}{\overset{\circledast}{|}} + \underset{\mathcal{L}_R\ \mathcal{L}_R}{\overset{\bullet}{/\backslash}} + \underset{\mathcal{L}_R\ \mathcal{L}_R}{\overset{+}{/\backslash}} \longrightarrow L_R(z,u) = 3z + zuL_R(z,u) + 2zL_R(z,u)^2.$$

After differentiating with respect to u and setting $u = 1$ we get:

$$\frac{d}{du}L_R(z,u)\Big|_{u=1} = \frac{zL_R(z)}{1 - z - 4zL_R(z)}. \tag{5}$$

At this point, the values of interests are hidden as coefficients of formal power series, and we need to extract or estimate them. This is where we use complex analysis: when their radius of convergence at 0 is not zero, the formal power series are seen as functions from $\mathbb{C}$ to $\mathbb{C}$. Using theorems developed in the field, this proves very useful to obtain an asymptotic equivalent of the n-th coefficient. We will not state formally the theorems here, because there are some analytic conditions on the series that must be satisfied and that are a bit too long for this extended abstract (we refer to the textbook [9] for all the details). What is needed to know is the following: since we are doing combinatorics, the coefficients in our series $C(z)$ are non-negative reals. Hence, Pringsheim's theorem applies and yields that, if finite, the radius of convergence ρ of $C(z)$ is a singularity. If there are no other singularity of modulus ρ then, together with other analytic conditions, the behavior of the function $C(z)$ as $z \to \rho$ determines the asymptotic equivalent of $[z^n]C(z)$ as $n \to \infty$. For instance, the *Transfer Theorem* [9, Ch VI.3] states that, under analytic conditions, if $C(z) \sim_{z\to\rho} \lambda(1 - z/\rho)^{-\alpha}$ with $\alpha \notin \{0, -1, -2, \ldots\}$, then $[z^n]C(z) \sim \lambda\rho^{-n}n^{\alpha-1}/\Gamma(\alpha)$, where Γ is Euler's gamma-function, the generalization of factorial.

Back to our example, as a polynomial equation of degree two, Eq. (2) can be solved in $L_R(z)$. Only one of the two solutions is combinatorially meaningful (the other one has negative coefficients). The result is amenable to the Transfer Theorem, with $\rho_R = \frac{2\sqrt{6}-1}{23}$ and an exponent $-\alpha = -1/2$ near ρ_R, yielding $[z^n]L_R(z) \sim \lambda\rho_R^{-n}n^{-3/2}$, for some computable $\lambda > 0$. Similarly, we can estimate the expected number of $\star$-nodes using Eq. (4) and applying the Transfer Theorem to Eq. (5). This routine exercise yields that the expected number of $\star$-nodes is asymptotically equivalent to γn, for some computable positive constant γ.

Observe that the latter result has a direct consequence on the algorithm applying the simplification pattern $(\mathcal{T}^\star)^\star \rightsquigarrow \mathcal{T}^\star$: since it cannot remove more nodes than there are stars in the expression, the expected size after simplification is in $\Theta(n)$. In fact, we can easily be more precise using our tools, as stated in the following proposition.

▶ **Proposition 1.** *Consider the algorithm that simplifies consecutive stars in a regular expression. For the uniform distribution on $\mathcal{L}_R$, the expected size after reduction is asymptotically equivalent to κn, with $\kappa = \frac{4}{529}(126 + \sqrt{6}) \approx 0.97$.*

Hence, this simplification rule is not powerful enough to demonstrate the lack of expressivity.

2.2 Combinatorial expressions: simple varieties of trees

As announced above, our combinatorial model for expressions is the notion of simple varieties of trees [9, VII.3]. We consider expressions as a combinatorial class of $\mathcal{L}$ defined in terms of a sequence of sets of labels $\mathcal{A} = (\mathcal{A}_i)_{i\in\mathbb{Z}_{\geq 0}}$ indexed by their arity (or degree): $f \in \mathcal{A}_i$ has arity i and labels nodes with i children. For instance, the set of regular expressions over the alphabet $\{a, b\}$, can be described in this formalism using $\mathcal{A}_0 = \{\varepsilon, a, b\}$, $\mathcal{A}_1 = \{\star\}$, and $\mathcal{A}_2 = \{+, \bullet\}$, the other $\mathcal{A}_i$'s being empty for $i \geq 3$.

To avoid trivially uninteresting cases, we define combinatorial expressions as follows:

▶ **Definition 2.** *A set of* combinatorial expressions *of labels* $\mathcal{A} = (\mathcal{A}_i)_{i \in \mathbb{Z}_{\geq 0}}$ *is a combinatorial set of rooted plane trees whose nodes of arity* i *are labelled with elements of a finite set* $\mathcal{A}_i$*, under the additional conditions that* $\mathcal{A}_0 \neq \emptyset$ *and that there exists* $i \geq 2$ *such that* $\mathcal{A}_i \neq \emptyset$*. Its* characteristic series *is the formal power series* $\phi(y) = \sum_{i \geq 0} \phi_i z^i$*, where* $\phi_i = |\mathcal{A}_i|$*.*

Note that there can be infinitely many non-empty $\mathcal{A}_i$ and that a label can be in several $\mathcal{A}_i$'s: we can have the union label in $\mathcal{A}_i$ for any $i \geq 2$, to take its associativity into account.

If $\mathcal{L}$ is a set of combinatorial expressions of characteristic series $\phi(y)$, then we have the fundamental formal equation for its OGS $L(z)$:

$$L(z) = z\,\phi(L(z))\,. \tag{6}$$

In our running example, rational expressions, ϕ is a quadratic polynomial and Eq. (6) can be solved explicitly. But usually this is not the case. Fortunately, we can still work out the asymptotic equivalents directly from the functional equation Eq. (6), using implicit functions. Several conditions, gathered under the name of *Smooth inverse-function schema for trees* [9, Definition VII.3], need to be checked in order to apply this fundamental result:

▶ **Definition 3** (Smooth inverse-function schema for trees [9])**.** *A function* $L(z)$ *satisfying the functional equation* $L(z) = z\phi(L(z))$ *is said to belong to the smooth inverse-function schema if* $L(z)$ *is analytic at* $z = 0$*,* $\phi(y)$ *is analytic at* $y = 0$*,* $\phi(0) \neq 0$*, the coefficients of* ϕ *are non-negative,* ϕ *is not linear, and finally there exists a solution* τ *of the equation* $\phi(\tau) - \tau\phi'(\tau) = 0$*, with* $0 < \tau < \rho_\phi$ *where* ρ_ϕ *is the radius of convergence of* ϕ*.*

Let us check this definition when $\mathcal{L}$ is a set of combinatorial expressions of characteristic series $\phi(y)$. The fact that $\phi(y)$ is analytic at 0 means that there are not too many operators of arity i (typically, not super-exponential in i), which is indeed the case for all the examples of Fig. 1. The other conditions are satisfied by definition, except the last one. The solution τ always exists, but we have to ensure that it is smaller than the radius of convergence of ϕ. The following elementary observation is quite useful:

▶ Remark 4. If ϕ is a polynomial, i.e. only finitely many $\mathcal{A}_i$'s are non-empty, then a set of expressions of characteristic series ϕ belongs to the smooth inverse-function schema.

Consider a variation on regular expressions $\mathcal{L}'_R$, where $\mathcal{A}_0 = \{\varepsilon, a, b\}$, $\mathcal{A}_1 = \{\star\}$, $\mathcal{A}_2 = \{+, \bullet\}$, and $\mathcal{A}_i = \{+\}$ for any $i \geq 3$. Its characteristic series is $\phi(y) = 3 + y + 2y^2 + \frac{y^3}{1-y} = \frac{1}{1-y} + y^2 + 2$. Its radius of convergence is $\rho_\phi = 1$, and the positive solution of $\phi(\tau) - \tau\phi'(\tau) = 0$ is $\frac{\sqrt{5}-1}{2} \approx 0.618$. Then the characteristic series belong to the smooth inverse-function schema.

The following theorem is a key property in analytic combinatorics for the functions belonging to the smooth inverse-function schema. It is stated when $\phi(y)$ is *aperiodic*, i.e. when $\phi(y) = \psi(y^d)$ implies $d = 1$. This is not a real restriction as shown in [9, Ex. VI.17], and this implies that $L(z)$ is also aperiodic and then has a unique dominant singularity.

▶ **Theorem 5** (see [5, 9, 16])**.** *Let* $L(z)$ *that belongs to the smooth inverse-function schema with* $L(z) = z\phi(L(z))$*. Assume that* $\phi(y)$ *is aperiodic, then* $L(z)$ *has a unique dominant singularity* $\rho_L = \tau/\phi(\tau)$*. Moreover, there exist two analytic functions* $g(z)$ *and* $h(z)$ *analytic at* $z = \rho_L$*, such that, around* $z = \rho_L$ *we have:*

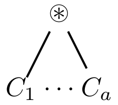
$$L(z) = g(z) - h(z)\sqrt{1 - z/\rho_L},\ \textit{with}\ h(\rho_L) \neq 0. \tag{7}$$

Moreover, we have $[z^n]L(z) \sim C_L \frac{\rho_L^{-n}}{n^{3/2}}$*, for some computable positive constant* C_L*.*

3 Main results

3.1 Simplification using an absorbing pattern: main result

Let $\mathcal{L}$ be a set of combinatorial expressions of sets of labels $(\mathcal{A}_i)_{i\geq 0}$. Let $\mathcal{P}$ be an element of $\mathcal{L}$ and let $\circledast$ be an element of $\mathcal{A}_a$ for some $a \geq 2$. If $L \in \mathcal{L}$, the *simplification of L following the absorbing pattern $\mathcal{P}$ for $\circledast$* is the element $S \in \mathcal{L}$ obtained by applying bottom-up the following rewriting rule:



$\rightsquigarrow \mathcal{P}$, whenever $C_i = \mathcal{P}$ for some $i \in \{1, \ldots, a\}$.

More formally, the simplification $s(L, \mathcal{P}, \circledast)$ of L following the absorbing pattern $\mathcal{P}$ for $\circledast$ is inductively defined by: $s(L, \mathcal{P}, \circledast) = L$ if L has size 1, $s(L, \mathcal{P}, \circledast) = \mathcal{P}$ if the root of L is $\circledast$ and at least one of its children C is such that $s(C, \mathcal{P}, \circledast) = \mathcal{P}$, and

$$s(L, \mathcal{P}, \circledast) = (\oplus, s(C_1, \mathcal{P}, \circledast), \ldots, s(C_d, \mathcal{P}, \circledast)), \text{ otherwise for } L = (\oplus, C_1, \ldots, C_d).$$

Of course, this simplification is purely syntactic, but the idea behind is that, when interpreted, the pattern $\mathcal{P}$ represents an absorbing element for the operator $\circledast$, hence the name. For instance, the pattern $\mathcal{P} = (a + b)^\star$ and operator $\circledast = +$ correspond to the fact that for languages, $\mathcal{P}$ represents $\Sigma^\star$, which is absorbing for the union $+$.

Let $\sigma_{\mathcal{P},\circledast}(L) = |s(L, \mathcal{P}, \circledast)|$ denote the size of the simplification of L, or just $\sigma(L)$ when there is no ambiguity about the $\mathcal{P}$ and the $\circledast$ considered. Our main result concerns the random variable σ when L is taken uniformly at random in $\mathcal{L}_n$.

▶ **Theorem 6.** *Let $\mathcal{L}$ be a set of combinatorial expressions whose OGS $L(z)$ belongs to the smooth inverse-function schema $L(z) = \phi(L(z))$, with ϕ aperiodic. Let $\mathcal{P} \in \mathcal{L}$ and let $\circledast$ be an operator of arity at least 2 of $\mathcal{L}$. Then the expected size of the simplification of a uniform random expression of size n in $\mathcal{L}$ following the absorbing pattern $\mathcal{P}$ for $\circledast$ tends to a constant as n tends to infinity: $\lim_{n\to\infty} \mathbb{E}_n[\sigma] = \delta$, for some positive δ. Furthermore, all moments of σ also converge: for every $i \in \mathbb{Z}_{\geq 1}$, $\lim_{n\to\infty} \mathbb{E}_n[\sigma^i] = \delta_i$ for some positive δ_i.*

Observe that it is not because the expectation converges that the moments converge too. Moreover, convergence of the moments has an implication in the analysis of algorithm, as stated in the following corollary.

▶ **Corollary 7.** *Let $\mathcal{L}$ be a set of expressions that satisfies the conditions of Theorem 6. Consider a polynomial time algorithm working on elements of $\mathcal{L}$. If we first simplify the expression before running the algorithm, then the process takes $\mathcal{O}(1)$ expected time. The simplification itself is done in linear expected time.*

Hence, the automaton construction studied in [18] is useless in the uniform random setting, since the output automaton has size polynomial in the input in the worst case. It is thus of expected constant size if we first simplify the input, according to Corollary 7.

We fix $\mathcal{L}$, ϕ, $\mathcal{P}$ and $\circledast$ for the remainder of Section 3, which is devoted to the proof of our main theorem, i.e., Theorem 6. A discussion of its consequences can be found in Section 4.

3.2 Completely reducible expression trees

An expression tree $L \in \mathcal{L}$ is *completely reducible* when $s(L, \mathcal{P}, \circledast) = \mathcal{P}$. We first study the set $\mathcal{R} \subset \mathcal{L}$ of all the completely reducible expression trees and denote by $R(z)$ its OGS.

Let $p = |\mathcal{P}|$ and let a be the arity of $\circledast$. An element of $\mathcal{R}$ is either $\mathcal{P}$ itself, or a tree of root $\circledast$ such that at least one of its subexpression is completely reducible. Hence, translating into OGS, we have the following equation for $R(z)$:

$$R(z) = z^p + z\left((L(z))^a - (L(z) - R(z))^a\right) . \tag{8}$$

We can also easily establish the following property:

▶ **Lemma 8.** *The radii of convergence of $R(z)$ and $L(z)$ are equal. Moreover, there exists $N_R \in \mathbb{Z}_{\geq 0}$ such that for every $n \geq N_R$, $[z^n]R(z) > 0$.*

We need to be more precise, as a fine grain description of $R(z)$ is an important ingredient of our proof of Theorem 6. We use an advanced analytic result established[4] by Drmota [5, Th. 1 and Prop. 3]. His theorem provides a precise estimate of the solutions of strongly connected systems of equations involving analytic functions around their (then) shared dominant singularity.

▶ **Proposition 9.** *The probability that a uniform random expression in $\mathcal{L}_n$ is completely reducible tends to a strictly positive constant γ as $n \to \infty$. Furthermore, locally around $z = \rho$, we have*

$$R(z) = g_R(z) - h_R(z)\sqrt{1 - \frac{z}{\rho}} , \tag{9}$$

where ρ is the radius of convergence of $L(z)$ and $R(z)$, and the functions $g_R(z)$ and $h_R(z)$ are analytic around $z = \rho$, and $h_R(\rho) \neq 0$.

Proof sketch. We define a complementary class $\mathcal{G} := \mathcal{L} \setminus \mathcal{R}$ of elements that do not reduce (completely) to $\mathcal{P}$. Let $G(z)$ denote its OGS. We observe that from Eq. (8) we have

$$\begin{cases} R(z) = & z^p + z\Big((G(z) + R(z))^a - G(z)^a\Big) , \\ G(z) = & \quad z\,\underline{\phi}\big(G(z) + R(z)\big) + zG(z)^a , \end{cases} \tag{10}$$

where $\underline{\phi}(x) = \phi(x) - x^a$. We demonstrate, simultaneously, that $R(z)$ and $G(z)$ verify the conclusions of the proposition by applying Drmota's multidimensional version of Theorem 5 (see [5, Thm. 1 and Prop. 3]). Thus we consider the implicit system above, in the variables z, R and G, and prove that it satisfies the conditions of Drmota's Theorem. This will then imply immediately our desired conclusions. We consider the corresponding algebraic system

$$[R, G] = \boldsymbol{F}(z, R, G), \text{ where } \boldsymbol{F}(z, R, G) = \Big[z^p + z\big((G + R)^a - G^a\big), \quad z\,\underline{\phi}\big(G + R\big) + zG^a\Big].$$

Now we need to check that all the hypotheses of Drmota's theorem are satisfied; this includes studying the Jacobian matrix of the system, which is

$$\boldsymbol{J}(z, R, G) = \begin{pmatrix} za(G + R)^{a-1} & za((G + R)^{a-1} - G^{a-1}) \\ z\underline{\phi}'(G + R) & z\underline{\phi}'(G + R) + zaG^{a-1} \end{pmatrix} .$$

Once done, we obtain Eq. (9).

From this formula and the Transfer Theorem, we conclude that $[z^n]R(z)$ satisfies an asymptotic formula similar to the one of $[z^n]L(z)$ in Theorem 5, but with a different multiplicative constant. This yields the existence of γ and thus concludes the proof. ◀

[4] It turns out that Drmota's theorem needs a little rectification, given in [1]. The theorem, among other things, gives a way to localize the dominant singularity, which was proved wrong. Fortunately, we do not need to rely on this to characterize the singularity in our case, so there is no issue for us, as we do not use the incorrect part of this result.

▶ Remark 10. If we had several reduction rules with the same pattern, rather than just one, the conclusions from Proposition 9 remain true. For instance, for regular expressions, we could add the reduction rule $\mathcal{P}^\star \rightsquigarrow \mathcal{P}$ in addition to the fact that $\mathcal{P}$ is absorbing for $+$.

For this we introduce an auxiliary series $A(x) = \sum_{i\geq 1} a_i x^i$ where a_i is the number of operations of arity i having $\mathcal{P}$ as an absorbing element. The system in the proof of Proposition 9 rewrites

$$\begin{cases} R(z) = z^p + z\Big(A(G(z)+R(z)) - A(G(z))\Big)\,, \\ G(z) = z\,\underline{\phi}\big(G(z)+R(z)\big) + zA(G(z))\,, \end{cases} \tag{11}$$

with $\underline{\phi}(x) = \phi(x) - A(x)$. The limit probability γ of Proposition 9 admits an elegant formula

$$\gamma = \frac{A'(\tau_L) - A'(\tau_L - \tau_R)}{\phi'(\tau_L) - A'(\tau_L - \tau_R)}, \text{ where } \tau_L = L(\rho) \text{ and } \tau_R = R(\rho).$$

3.3 Estimating the expectation and the moments

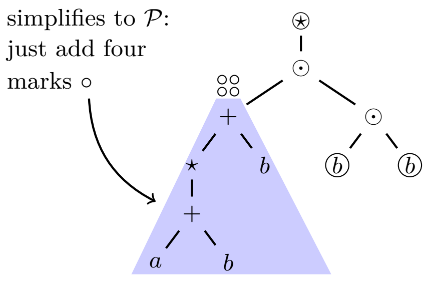
Following the method explained in Section 2.1, we use bivariate generating series to keep track of the size of the reduced expression. We therefore define $L(z,u)$ and $R(z,u)$ by (recall that $\sigma(L)$ is the size of the simplification of L):

$$L(z,u) = \sum_{L\in\mathcal{L}} z^{|L|} u^{\sigma(L)} \text{ and } R(z,u) = \sum_{R\in\mathcal{R}} z^{|R|} u^{\sigma(R)}.$$

Of course, since all elements of $\mathcal{R}$ simplify to $\mathcal{P}$, we have $R(z,u) = u^p R(z)$, with $p = |\mathcal{P}|$.

As in Section 2.1, we want to mark the expressions so that the number of marks is equal to the size of the simplified expression. For this, we put one mark on the nodes that are not simplified, and p marks on the root of a subtree that simplifies to $\mathcal{P}$, to take into account the size of $\mathcal{P}$ once reduced. We just have to reformulate the combinatorial specification and to enrich it with marks. As an example, let us consider regular expressions $\mathcal{L}_R$, with $\mathcal{P} = (a+b)^\star$ and $\circledast = +$. We mark an element $L \in \mathcal{L}_R$ the following way (we denote by $\mathcal{R}_R$ the completely reducible regular expressions):

- If $L \in \mathcal{R}_R$ then we add p marks at the root.
- If the root of L is not $+$, then we mark its children inductively (if any), and mark the root of L.
- If the root of L is $+$ and its children are all not in $\mathcal{R}_R$, then we mark its children inductively, and mark the root of L.



This expression has size 9 after simplificiation.

This way of rewriting the decomposition of $\mathcal{L}_R$ is unambiguous except for $\mathcal{P}$ which is in $\mathcal{R}_R$ and which can also be built by the standard induction, so we have to remove it once in the specification. This yields, where $\mathcal{L}_R^\circ$ and $\mathcal{R}_R^\circ$ respectively denote the marked versions of $\mathcal{L}_R$ and $\mathcal{R}_R$, and where $\mathcal{G}_R^\circ := \mathcal{L}_R^\circ \setminus \mathcal{R}_R^\circ$:

$$\mathcal{L}_R^\circ = (\mathcal{R}_R - \mathcal{P})^{\circ\circ}_{\circ\circ} + \textcircled{a} + \textcircled{b} + \textcircled{ε} + \begin{array}{c}\circledast\\ | \\ \mathcal{L}_R^\circ\end{array} + \begin{array}{c}\odot\\ /\,\backslash \\ \mathcal{L}_R^\circ\ \mathcal{L}_R^\circ\end{array} + \begin{array}{c}\oplus\\ /\,\backslash \\ \mathcal{G}_R^\circ\ \mathcal{G}_R^\circ\end{array}.$$

From this we get $L_R(z,u) = (R(z) - z^4)u^4 + 3zu + uzL_R(z,u) + zuL_R(z,u)^2 + zuG_R(z,u)^2$.

This construction generalizes easily, and we get the following lemma.

▶ **Lemma 11.** *We have the following equation for the BGS $L(z,u)$ where z counts the size of an expression and u the size of its simplification:*

$$L(z,u) = (R(z) - z^p)u^p + zu\big(\underline{\phi}(L(z,u)) + (L(z,u) - R(z,u))^a\big), \qquad (12)$$

where $\underline{\phi}(x) = \phi(x) - x^a$ and where a is the arity of $\circledast$.

At this point, we want to apply Eq. (4) to compute the expectation of σ. Hence, we differentiate with respect to u, set $u = 1$ and re-arrange the expression, obtaining

$$\frac{d}{du}L(z,u)\Big|_{u=1} = \frac{N\big(z, L(z), R(z)\big)}{D\big(z, L(z), R(z), \phi'(L(z))\big)}, \text{ where } N \text{ and } D \text{ are polynomials.} \qquad (13)$$

From this, and using an adaptation of another result of Drmota [6, Lemma 2.26] to handle quotients, we get the following lemma.

▶ **Lemma 12.** *There exist two functions $\tilde{g}(z)$ and $\tilde{h}(z)$ that are analytic at $z = \rho$, such that locally around $z = \rho$ we have the expansion $\frac{d}{du}L(z,u)\Big|_{u=1} = \tilde{g}(z) - \tilde{h}(z)\sqrt{1 - z/\rho}$.*

We can now conclude the proof of the first part of Theorem 6: using the Transfer Theorem, we obtain from Lemma 12 that, if $\tilde{h}(\rho) > 0$, then $[z^n]\frac{d}{du}L(z,u)|_{u=1} \sim \frac{\tilde{h}(\rho)}{2\sqrt{\pi}}\rho^{-n}n^{-3/2}$, so that, by Theorem 5, $\mathbb{E}_n[\sigma]$ tends to the constant $\delta = \frac{\tilde{h}(\rho)}{2C_L\sqrt{\pi}}$, since $\rho = \rho_L$. The other cases are not possible, as $\tilde{h}(\rho) < 0$ yields a negative asymptotic equivalent and $\tilde{h}(\rho) = 0$ implies that the expected size of the simplification tends to 0, but it is not possible as it is at least $p > 0$.

▶ Remark 13. Using a computer algebra software, we can deal symbolically with all the formulas obtained in the article. When applied to regular expressions, we obtain that $\delta \approx 3{,}624{,}217.39$, which is a prohibitively large number for most simulations, while the proportion of completely reducible expressions tends to $\gamma \approx 0.0016336$.

The proof for higher moments follows a similar principle as for the expectation; when we differentiate several times on u Eq. (12) from Lemma 11, we get the same factor for the highest order derivative, hence the same denominator $D(z, L(z), R(z), \phi'(L(z)))$ as in Eq. (13). As the remaining terms also fulfill a local expansion like the one in Lemma 12, we can conclude exactly as for the expectation.

4 Conclusion

We have seen in this paper that uniform random expressions have to be considered with great care when using them to analyze the efficiency of algorithms or tools. As soon as there is an absorbing pattern, everything becomes mostly trivial, even for polynomial algorithms or constructions, as stated in Corollary 7.

One could alter the specifications to try to obtain a different behavior. For instance, by weighting some of the labels (trying to get less $\star$ in random expressions). This can easily be done directly on the specification, by adding several identical operators or even positive weights on the operators. The random generation can still be done quite efficiently. However, we have not changed the framework, and if we try to specify weighted regular expressions with, for instance:

$$\mathcal{L}_R = 10 \times a + 10 \times b + \varepsilon + \overset{\star}{\underset{\mathcal{L}_R}{|}} + 20 \times \overset{\bullet}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}} + 15 \times \overset{+}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}}, \tag{14}$$

we can still apply Theorem 6, we just get a larger limit for the expected size.

Another idea is to specify expressions using combinatorial systems. For instance, we can prevent consecutive stars in regular expressions using the system:

$$\mathcal{L}_R = \mathcal{S} + \mathcal{T}; \quad \mathcal{S} = \overset{\star}{\underset{\mathcal{T}}{|}}; \quad \mathcal{T} = a + b + \varepsilon + \overset{\bullet}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}} + \overset{+}{\underset{\mathcal{L}_R\ \mathcal{L}_R}{/\backslash}}.$$

This is not covered by our main theorem, but it is work in progress to prove that the same result holds, using Drmota's tools to handle systems of equations like this one.

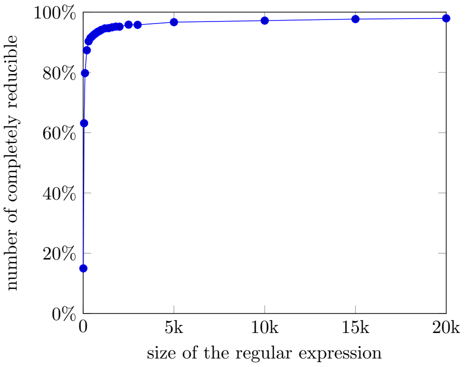


Figure 3 Experimental study of the proportion of completely reducible, for BST-like distribution, with $\mathbb{P}(\star) = \mathbb{P}(\bullet) = \mathbb{P}(+) = \frac{1}{3}$.

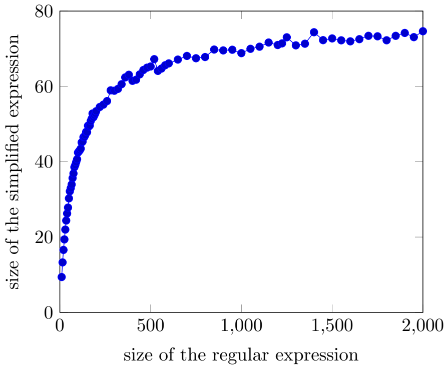

Figure 4 Experimental study of the size of a random uniform regular expression after applying a large set of simplification rules.

Yet a third idea is to completely change the distribution on the set of expressions. The other natural probability on trees is the so-called *BST-like* distribution, obtained on regular expressions as follows to generate an expression of size n: if $n = 1$ return a, b or ε; if $n = 2$ return $a^\star$, $b^\star$ or $\varepsilon^\star$; otherwise, randomly choose an operator in $\{\star, \bullet, +\}$ and if it is binary, choose the size of its left child uniformly in $\{1, \dots, n-2\}$. This distribution is not uniform, but it is often used for testing tools. See [19] for a theoretical study using this distribution on regular expressions. It is not clear if the conclusion of Theorem 6 still holds for these distributions, but we believe that they are not interesting either: on Fig. 3, we experimentally computed the ratio of expressions that can be simplified into $(a + b)^\star$, using a whole set of simplification rules, and obtained that this ratio tends to 1 as n tends to infinity: the situation is even worse than in the uniform case (see also [3, 4]).

If we apply this whole set of simplification rules to uniform random regular expressions, we get the curve depicted in Fig. 4. Apparently, the expected size of the simplified expression tends to a value around 75, which is large, but much smaller than the value 3,624,217 obtained for just using the absorbing pattern.

The real conclusion is that natural distributions on trees seem to be useless when it comes to obtaining good distributions on formulas. At this point, we have no idea on how to produce a good distribution in the general framework, sufficiently simple to have efficient random samplers and to be amenable to mathematical analysis.

Abstract

Proving super-polynomial lower bounds on the size of syntactic multilinear Algebraic Branching Programs (smABPs) computing an explicit polynomial is a challenging problem in Algebraic Complexity Theory. The order in which variables in $\{x_1, \ldots, x_n\}$ appear along any source to sink path in an smABP can be viewed as a permutation in S_n. In this article, we consider the following special classes of smABPs where the order of occurrence of variables along a source to sink path is restricted:

1. **Strict circular-interval ABPs:** For every sub-program the index set of variables occurring in it is contained in some circular interval of $\{1, \ldots, n\}$.
2. **$\mathcal{L}$-ordered ABPs:** There is a set of $\mathcal{L}$ permutations (orders) of variables such that every source to sink path in the smABP reads variables in one of these $\mathcal{L}$ orders, where $\mathcal{L} \leq 2^{n^{1/2-\epsilon}}$ for some $\epsilon > 0$.

We prove exponential (i.e., $2^{\Omega(n^\delta)}$, $\delta > 0$) lower bounds on the size of above models computing an explicit multilinear $2n$-variate polynomial in VP.

As a main ingredient in our lower bounds, we show that any polynomial that can be computed by an smABP of size S, can be written as a sum of $O(S)$ many multilinear polynomials where each summand is a product of two polynomials in at most $2n/3$ variables, computable by smABPs. As a corollary, we show that any size S syntactic multilinear ABP can be transformed into a size $S^{O(\sqrt{n})}$ depth four syntactic multilinear $\Sigma\Pi\Sigma\Pi$ circuit where the bottom Σ gates compute polynomials on at most $O(\sqrt{n})$ variables.

Finally, we compare the above models with other standard models for computing multilinear polynomials.

1 Introduction

Algebraic Complexity Theory is concerned with the classification of polynomials based on the number of arithmetic operations required to compute a polynomial from variables and constants. Arithmetic circuits are standard models for algebraic computation. One of the primary tasks in Algebraic Complexity Theory is to prove lower bounds on the size of arithmetic circuits computing an explicit polynomial. Valiant [23] conjectured that the polynomial defined by the permanent of an $n \times n$ symbolic matrix is not computable by polynomial size arithmetic circuits. This is known as Valiant's hypothesis and is one of the central questions in Algebraic Complexity Theory.

The best known size lower bound for general classes of arithmetic circuits is only super-linear in the number of variables [5]. Despite several approaches, the problem of proving lower bounds for general classes of arithmetic circuits has remained elusive. Naturally, there have been efforts to prove lower bounds for special classes of arithmetic circuits which led to the development of several lower bound techniques. Structural restrictions such as depth and fan-out, semantic restrictions such as multilinearity and homogeneity have received widespread attention in the literature.

Agrawal and Vinay [1] showed that proving exponential lower bounds for depth four circuits is sufficient to prove Valiant's hypothesis. This initiated several attempts at proving lower bounds for constant depth circuits. (See [21] for a detailed survey of these results.)

Among other restrictions, *multilinear circuits* where every gate computes a multilinear polynomial are well studied. Multilinear circuits are natural models for computing multilinear polynomials. It is sometimes more useful to consider a natural syntactic sub-class of multilinear circuits. A circuit is *syntactic multilinear* if the children of every product gate depend on disjoint sets of variables. Raz [18] obtained super-polynomial lower bounds on the size of syntactic multilinear formulas computing the determinant or permanent polynomial. This was improved to an exponential lower bound for constant-depth multilinear circuits [20, 7, 6]. However, the best known lower bound for general syntactic multilinear circuits is almost quadratic in the number of variables [2].

Algebraic Branching Programs (ABPs) are special classes of arithmetic circuits that have been studied extensively in the past. Nisan [15] obtained an exact complexity characterization of ABPs in the non-commutative setting. The problem of proving size lower bounds for the class of algebraic branching programs is widely open, even with restrictions such as homogeneity or syntactic multilinearity. When the ABP is restricted to be *homogeneous*, the best known lower bound is only quadratic in the number of variables [13]. The situation is not better in the case of syntactic multilinear ABPs, where no super-quadratic lower bound is known [2].

Models and results. In this article, we are interested in syntactic multilinear ABPs in which the order of appearance of variables along any path in the ABP is restricted. To begin with, we give a decomposition theorem for smABPs. The decomposition obtains two disjoint sets E_1 and E_2 of edges in the branching program P with source s and sink t such that the polynomial computed by P can be expressed as a sum of $\sum_{(u,v)\in E_1}[s,u]\cdot\mathsf{label}(u,v)\cdot[v,t]$ and $\sum_{(w,a)\in E_2}[s,w]\cdot\mathsf{label}(w,a)\cdot[a,t]$, where $[p,q]$ is the polynomial computed by sub-program in P with source p and sink q. Also, the sets E_1 and E_2 are chosen carefully such that the sub-programs obtained are more or less balanced in terms of the number of variables.

In the following theorem, for nodes u, v in an smABP P, we denote $[u,v]$ is the polynomial computed by sub-program in P with source u and sink v. Also, let $X_{u,v}$ denote the set of all variables that occur as labels in any path from node u to node v in P. More formally, we prove:

▶ **Theorem 1.** *Let P be an smABP of size S computing $f \in \mathbb{F}[x_1,\ldots,x_n]$. There exists edges $\{(u_1,v_1),\ldots,(u_m,v_m)\}$ and $\{(w_1,a_1),\ldots,(w_r,a_r)\}$ in P such that*

(1) *For $i \in [m]$, $n/3 \le |X_{s,u_i}| \le 2n/3$; and*

(2) *For $i \in [r]$, $|X_{s,w_i}| < n/3$ and $|X_{a_i,t}| \le 2n/3$; and*

(3) $f = \sum_{i=1}^{m}[s,u_i]\cdot\textit{label}(u_i,v_i)\cdot[v_i,t] + \sum_{i=1}^{r}[s,w_i]\cdot\textit{label}(w_i,a_i)\cdot[a_i,t]$.

Let $\Sigma\Pi^{[\sqrt{n}]}(\Sigma\Pi)^{[\sqrt{n}]}$ denote the class of depth four arithmetic circuits where the top layer of Π gates are products of at most $O(\sqrt{n})$ polynomials each being a multilinear polynomial on $O(\sqrt{n})$ variables. As an immediate corollary of the above decomposition, we obtain the following low-arity version of the depth reduction in [1, 22] for the case of smABPs:

▶ **Corollary 1.** *Let P be a syntactic multilinear ABP of size S computing a polynomial f in $\mathbb{F}[x_1, \ldots, x_n]$. Then there exists a $\Sigma\Pi^{[\sqrt{n}]}(\Sigma\Pi)^{[\sqrt{n}]}$ syntactic multilinear formula of size $2^{O(\sqrt{n}\log S)}$ computing f.*

Using the structural property of the parse trees of formulas obtained from smABPs, we prove exponential size lower bounds for two classes of smABPs with restrictions on the variable order.

(1) Strict circular-interval ABPs: A strict circular-interval ABP is an smABP in which the index set of variables in every subprogram is contained in some circular-interval in $\{1, \ldots, n\}$ (see Section 4.1 for a formal definition). Every multilinear polynomial can be computed by a strict circular-interval ABP and hence it is a universal model for computing multilinear polynomials. We obtain an exponential lower bound on the size of any strict circular-interval ABP computing the explicit multilinear polynomial defined by Raz and Yehudayoff in [19] (see Section 2 for definition of the polynomial).

▶ **Theorem 2.** *There exists an explicit multilinear polynomial g in $\mathbb{F}[x_1, \ldots, x_n]$ such that any strict circular-interval ABP computing g requires size $2^{\Omega(\sqrt{n}/\log n)}$.*

Another sub-class of smABPs that we study is the class of *bounded-order* smABPs.

(2) $\mathcal{L}$-ordered smABPs: Jansen [11] introduced *Ordered smABPs* which are branching programs with source s and sink t such that every path from s to t reads variables in a fixed order $\pi \in S_n$. Jansen [11] translated the exponential lower bound for the non-commutative model in [15] to ordered smABPs. Ordered smABPs have also been studied in the context of the polynomial identity testing problem. Further, it is shown in [12] that ordered smABPs are equivalent to Read-Once Oblivious Algebraic Branching Programs (ROABPs for short., see Section 2 for a definition). Polynomial time white-box and quasi-polynomial time black-box algorithms were obtained for identity testing of polynomials computed by ordered smABPs, (see [12, 9, 10] and the references therein).

A natural generalization of ordered smABPs is to allow multiple orders. An smABP is $\mathcal{L}$-ordered if variables can occur along any source to sink path in one of the $\mathcal{L}$ fixed orders. Since there are at most 2^n multilinear monomials in n variables, any multilinear n variate polynomial can be computed by 2^n-ordered ABPs. In this article, by exploiting a simple structural property of $\mathcal{L}$-ordered ABPs, we prove a sub-exponential lower bound for sum of $\mathcal{L}$-ordered smABPs when $\mathcal{L} = O(2^{n^{1/2-\epsilon}})$ for some $\epsilon > 0$:

▶ **Theorem 3.** *Let $\mathcal{L} \leq 2^{n^{1/2-\epsilon}}, \epsilon > 0$ and $f_1, \ldots, f_m \in \mathbb{F}[x_1, \ldots, x_n]$ be multilinear polynomials computed by $\mathcal{L}$-ordered ABPs of size $S_1, \ldots, S_m$ respectively. There exists an explicit multilinear polynomial g in $\mathbb{F}[x_1, \ldots, x_n]$ such that if $g = f_1 + \cdots + f_m$ then either $m = 2^{\Omega(n^{1/40})}$ or there is an $i \in [m]$ such that $S_i = 2^{\Omega(n^{1/40})}$.*

Further, we compare strict circular-interval ABPs and $\mathcal{L}$-ordered ABPs to other mulitlinear models of computation. We show that the construction given in [12] for the equivalence of ROABPs and 1-ordered ABPs can be generalized to $\mathcal{L}$-ordered smABPs. In particular, in Theorem 11 we prove that an $\mathcal{L}$-ordered ABP of size S can be transformed into an equivalent $\mathcal{L}$-pass smABP (see Section 2 for a definition) of size $\mathsf{poly}(S, \mathcal{L})$. Though the overall idea is simple, the construction requires a lot of book-keeping of variable orders. In the context of strict circular-interval ABPs, we compare strict circular-interval ABPs with the simplest class of smABPs: Read-Once Oblivious Algebraic Branching Programs. [15] gives exponential size lower bounds for ROABPs (ABPs on n variables with $n+1$ layers such that every edge from a node in one layer L_i to a node in the successive layer is labeled by a uni-variate polynomial in $\mathbb{F}[x_i]$). Trivially, every strict circular-interval ABP is an ROABP. In Corollary 16, we show that a generalization of strict circular-interval ABPs called *circular-interval* ABPs are more powerful than sum of ROABPs.

Related works. In an independent and simultaneous work, Kumar, Oliveira and Saptharishi [14] show an improved depth reduction (along with several other results) for syntactic multilinear circuits. In [14] (Lemma 6.1 together with Theorem 5.1), the authors show that any *multi-k-ic circuit* of size S can be transformed into an equivalent multi-k-ic $\Sigma\Pi(\Sigma\Pi)^t$ circuit of size $2^{kt} \cdot S^{O(kn/t)}$. Thus, we have $k = 1$ in the case of syntactic multilinear circuits and the circuit size bound in Lemma 6.1 of [14] matches the size bound in Corollary 1 of this paper when $t = \sqrt{n}$. However, Corollary 1 works for syntactic multilinear ABPs while the result in [14] is for the more general class of syntactic multilinear circuits.

In [16], the authors prove lower bounds for sum of $\mathcal{L}$-pass ABPs computing a multilinear polynomial in VP. The result in Theorem 3 is much stronger than the results in [16], since it allows exponentially many orders, whereas the arguments in [16] work only when $\mathcal{L} = o(n^{1/12})$.

Saptharishi and coauthors (through a personal communication) have shown that $\mathcal{L}$-ordered smABPs can be written as a sum of $\mathcal{L}$ ROABPs. While, this will help in significantly improving the lower bound given in Theorem 3, the restriction on $\mathcal{L}$ will be much smaller than $2^{n^{1/2-\epsilon}}$ as far as we are aware.

In [4], Arvind and Raja considered interval ABPs where for every node v reachable from the source, the index set of variables in the sub-program with v as the sink node must be an interval in $[1, n]$. They proved an exponential size lower bound for interval ABPs assuming the *sum-of-squares* conjecture. Although our model is more restrictive than the one in [4], our lower bound argument is unconditional.

Proofs that are omitted due to space constraints can be found int he full version [17].

2 Preliminaries

In this section, we include necessary definitions of models and notations used in this article. Let $\mathbb{F}$ be a field and $X = \{x_1, \ldots, x_n\}$ denote a finite set of variables.

An *arithmetic circuit* $\mathcal{C}$ over $\mathbb{F}$ is a directed acyclic graph with vertices of in-degree zero or two. A vertex of out-degree 0 is called an output gate. A node of in-degree zero is called an input gate and is labeled by elements from $X \cup \mathbb{F}$. Every other gate is labeled either by $+$ or $\times$. Every gate in $\mathcal{C}$ naturally computes a polynomial in $\mathbb{F}[X]$ and the polynomial computed by $\mathcal{C}$ is the polynomial computed at the output gate. When the circuit has more than one output gate, the circuit computes a set of polynomials. The *size* of $\mathcal{C}$ is the number of gates in $\mathcal{C}$ and *depth* of $\mathcal{C}$ is the length of the longest path from an input gate to the output gate in $\mathcal{C}$. An *arithmetic formula* is an arithmetic circuit where the underlying undirected graph is a tree.

A *parse tree* T of an arithmetic formula F is a sub-tree of F containing the output gate of F such that for every $+$ gate v of F that is included in T, exactly one child of v is in T and for every $\times$ gate u that is in T, both children of u are in T.

An *algebraic branching program* (ABP) P is a directed acyclic graph with one vertex s of in-degree zero (source) and one vertex t of out-degree zero (sink). The vertices of the graph are partitioned into layers $L_0, L_1, \ldots, L_\ell$ where edges are from vertices in layer L_i to those in L_{i+1} for every $0 \leq i \leq \ell - 1$. The source node s is the only vertex in layer L_0 and the sink t is the only vertex in layer L_ℓ. Every edge in e in P is labeled by an element in $X \cup \mathbb{F}$ (denoted by $\mathsf{label}(e)$). The width of P is $\max_i\{|L_i|\}$ and size is the number of nodes in P. For a path ρ the weight, $\mathsf{wt}(\rho)$ be the product of its edge labels. The polynomial computed by an ABP P is the sum of weights of all s to t paths in P. For nodes u and v in P, let $[u, v]_P$ denote the polynomial computed by the sub-program of P with u as the source node and v as the sink node. We drop the subscript from $[u, v]_P$ when P is clear from the context.

Let $X_{u,v}$ denote the set of all variables that occur as labels in any path from u to v in P.

An ABP P is said to be *syntactic multilinear* (smABP) if every variable occurs at most once in every s to t path in P, it is said to be an *oblivious* ABP if for every layer L in P, there is a variable x_{i_L} such that every edge from the layer L is labeled from $\{x_{i_L}\} \cup \mathbb{F}$. A *Read-Once Oblivious* (ROABP) is an oblivious smABP such that every variable appears as an edge label in at most one layer.

Anderson et al. [3] defined the class of $\mathcal{L}$-pass smABPs. An oblivious smABP P is $\mathcal{L}$-pass, if there are layers $i_1 < i_2 < \ldots < i_{\mathcal{L}}$ such that for every j, between layers i_j and i_{j+1} the program P is an ROABP. Let π be a permutation of $\{1, \ldots, n\}$ and P be an smABP computing an n-variate multilinear polynomial. An s to t path ρ in P is said to be *consistent* with π, if the variable labels in ρ occur as per the order given by π, i.e., if x_i and x_j occur as edge labels in ρ in that order, then $\pi(i) < \pi(j)$. For a node v of P, v is said to be consistent with π, if every s to v path is consistent with π.

An smABP P is said to be $\mathcal{L}$-*ordered*, if there are $\mathcal{L}$ permutations $\pi_1, \ldots, \pi_{\mathcal{L}}$ such that for every s to t path ρ in P, there is an $1 \le i \le \mathcal{L}$ such that ρ is consistent with π_i.

We now review the partial derivative matrix of a polynomial introduced in [18]. Let $X = Y \cup Z$ be such that $Y \cap Z = \emptyset$ and $|Y| = |Z|$. It is convenient to represent the partition $X = Y \cup Z$ as an injective function $\varphi : X \to Y \cup Z$. For a polynomial f, let f^{φ} be the polynomial obtained by substituting each variable $x_i = \varphi(x_i)$ for $1 \le i \le n$.

▶ **Definition 1** (Partial Derivative Matrix., [18]). *Let $f \in \mathbb{F}[X]$ be a multilinear polynomial. The* partial derivative matrix *of f (denoted by M_f) with respect to the partition $\varphi : X \to Y \cup Z$ is a $2^m \times 2^m$ matrix defined as follows. For multilinear monomials p and q in variables Y and Z respectively, the entry $M_f[p, q]$ is the coefficient of the monomial pq in f^{φ}.*

For a polynomial f and a partition φ, let $\mathsf{rank}_{\varphi}(f)$ denote the rank of the matrix $M_{f^{\varphi}}$ over the field $\mathbb{F}$. The following properties of $\mathsf{rank}_{\varphi}(f)$ are useful:

▶ **Lemma 4** ([18], Propositions 3.1, 3.2 and 3.3). *Let $f, g \in \mathbb{F}[Y, Z]$ be multilinear polynomials. Then, (1) $\mathsf{rank}_{\varphi}(f + g) \le \mathsf{rank}_{\varphi}(f) + \mathsf{rank}_{\varphi}(g)$; (2) If $\mathsf{var}(f) \cap \mathsf{var}(g) = \emptyset$, then $\mathsf{rank}_{\varphi}(fg) = \mathsf{rank}_{\varphi}(f) \cdot \mathsf{rank}_{\varphi}(g)$; and (3) If $f \in \mathbb{F}[Y_1, Z_1]$ for $Y_1 \subseteq Y, Z_1 \subseteq Z$, then $\mathsf{rank}_{\varphi}(f) \le 2^{\min\{|Y_1|,|Z_1|\}}$.*

Let $\mathcal{D}$ denote the uniform distribution on the set of all partitions $\varphi : X \to Y \cup Z$, where $|Y| = |Z| = |X|/2$. The following is known about the rank of ROABPs:

▶ **Lemma 5** ([16], Corollary 1). *Let f be an N-variate multilinear polynomial computed by an ROABP of size S. Then,*

$$\Pr_{\varphi \sim \mathcal{D}}[\mathsf{rank}_{\varphi}(f) \le S^{\log N} 2^{N/2 - N^{1/5}}] \ge 1 - 2^{-N^{1/5}}.$$

We need the following polynomial defined in [19] to prove lower bounds:

▶ **Definition 2** (Full rank Polynomial., [19]). *Let $n \in \mathbb{N}$ be even and $\mathcal{W} = \{w_{i,k,j}\}_{i,k,j \in [n]}$. For any two integers $i, j \in \mathbb{N}$, we define an interval $[i, j] = \{k \in \mathbb{N}, i \le k \le j\}$. Let $|[i, j]| = j - i + 1$, $X_{i,j} = \{x_p \mid p \in [i, j]\}$. Let $\mathbb{G} = \mathbb{F}(\mathcal{W})$, the rational function field. For every $[i, j]$ such that $|[i, j]|$ is even we define a polynomial $g_{i,j} \in \mathbb{G}[X]$ as $g_{i,j} = 1$ when $|[i, j]| = 0$ and if $|[i, j]| > 0$ then, $g_{i,j} \triangleq (1 + x_i x_j) g_{i+1,j-1} + \sum_k w_{i,k,j} g_{i,k} g_{k+1,j}$. where x_k, $w_{i,k,j}$ are distinct variables, $i \le k \le j$ and the summation is over $k \in [i + 1, j - 2]$ such that $|[i, k]|$ is even. Let $g \triangleq g_{1,n}$.*

It is known that for any partition $\varphi \sim \mathcal{D}$, $\mathsf{rank}_{\varphi}(g)$ is the maximum possible value:

▶ **Lemma 6** ([19], Lemma 4.3). *Let $n \in \mathbb{N}$ be even and $\mathbb{G}$ be as above. Let $g \in \mathbb{G}[X]$ be the polynomial in Definition 2. Then for any $\varphi \sim \mathcal{D}$, $\mathsf{rank}_{\varphi}(g) = 2^{n/2}$.*

3 A variable-balanced decomposition for syntactic multilinear ABPs

In this section, we give a new decomposition for smABPs. The decomposition can be seen as a variable-balanced version of the well known decomposition of arithmetic circuits given by Valiant et al. [24] for the case of smABPs. In fact, we show that a smABP can be divided into sub-programs that are almost balanced in terms of the number of variables.

▶ **Theorem 1.** *Let P be an smABP of size S computing $f \in \mathbb{F}[x_1, \ldots, x_n]$. There exists edges $\{(u_1, v_1), \ldots, (u_m, v_m)\}$ and $\{(w_1, a_1), \ldots, (w_r, a_r)\}$ in P such that*

(1) *For $i \in [m]$, $n/3 \leq |X_{s,u_i}| \leq 2n/3$; and*

(2) *For $i \in [r]$, $|X_{s,w_i}| < n/3$ and $|X_{a_i,t}| \leq 2n/3$; and*

(3) $f = \sum_{i=1}^{m} [s, u_i] \cdot \textsf{label}(u_i, v_i) \cdot [v_i, t] + \sum_{i=1}^{r} [s, w_i] \cdot \textsf{label}(w_i, a_i) \cdot [a_i, t]$.

Proof. The proof is by a careful subdivision of the program P. We assume without loss of generality that t is reachable from every node in P and that every node in P has in-degree and out-degree at most 2. Consider the following coloring procedure:

(1) Initialize by coloring t as blue. Repeat (2) until no new node is colored.

(2) Consider node u that is colored blue such that at least one of nodes v or w are uncolored, where (v, u) and (w, u) are the only edges incoming to u. For $a \in \{v, w\}$ do following :

   a. If $|X_{s,a}| > 2n/3$, then color a as blue.

   b. If $n/3 \leq |X_{s,a}| \leq 2n/3$, then color a as red.

   c. If $|X_{s,a}| < n/3$, then color a as green.

At the end of the above coloring procedure we have the following:

1. For every node u with incoming edges (v, u) and (w, u), if u is colored blue then both v and w are colored.
2. For every directed $s \rightsquigarrow t$ path ρ in P, exactly one of the following holds:
   a. ρ has exactly one edge (v, w) such that v is colored red and w is colored blue.
   b. ρ has exactly one edge (v, w) such that v is colored green and w is colored blue.
3. If a node u is colored blue, then every node v reachable from u must have color blue.

Property 1 follows from the fact that a node v is colored if and only if there is an edge (v, u) such that u is colored blue. For property 3, clearly, a node u is colored blue if and only if $|X_{s,u}| > 2n/3$, thus every node reachable from a blue node is also colored blue. For property 2, let ρ be a directed $s \rightsquigarrow t$ path and v be the first node along ρ that is colored blue. Note $|X_{s,s}| = 0$, so s cannot be colored blue. Clearly, every node that follows v in ρ is colored blue and $v \neq s$. Let u be the node that immediately precedes v in ρ, then clearly, u is either red or green. Uniqueness follows from the fact that no node that precedes u in ρ is colored blue and every node that succeeds v in ρ is colored blue, hence there cannot be another such edge.

Let $E_{rb} = \{(u, v) \in P \mid u \text{ is colored red and } v \text{ is colored blue}\}$ and $E_{gb} = \{(u, v) \in P \mid u \text{ is colored green and } v \text{ is colored blue}\}$. Let $E_{rb} = \{(u_1, v_1), \ldots, (u_m, v_m)\}$ and $E_{gb} = \{(w_1, a_1), \ldots, (w_r, a_r)\}$ where $m, r \leq 2S$. We now prove that sets E_{rb} and E_{gb} satisfy the required properties.

(1) For $i \in [m]$, since $(u_i, v_i) \in E_{rb}$, u_i is colored red. By Step 2(b) of the coloring procedure, $n/3 \leq |X_{s,u_i}| \leq 2n/3$.

(2) For $i \in [r]$, since $(w_i, a_i) \in E_{gb}$, w_i is colored green and a_i is colored blue. By Step 2(c) of the coloring procedure, $|X_{s,w_i}| < n/3$ and by Step 2(a), $|X_{s,a_i}| > 2n/3$. Since P is syntactic multilinear, $|X_{s,a_i}| + |X_{a_i,t}| \leq n$ implying $|X_{a_i,t}| \leq n/3$.

(3) By Property 2, $s \rightsquigarrow t$ paths in P are partitioned into paths that have exactly one edge in E_{rb} and paths that have exactly one edge in E_{gb}. Therefore,

$$f = \sum_{\rho: s \rightsquigarrow t} \mathsf{wt}(\rho) = \sum_{\rho: s \rightsquigarrow t,\ \rho \cap E_{rb} \neq \emptyset} \mathsf{wt}(\rho) + \sum_{\rho: s \rightsquigarrow t,\ \rho \cap E_{gb} \neq \emptyset} \mathsf{wt}(\rho)$$
$$= \sum_{i=1}^{m} [s, u_i] \cdot \mathsf{label}(u_i, v_i) \cdot [v_i, t] + \sum_{i=1}^{r} [s, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, t]. \qquad \blacktriangleleft$$

The above decomposition allows us to obtain low-depth formulas for syntactic multilinear ABPs with quasi-polynomial blow-up in size. In the following, we show that a syntactic multilinear ABP can be computed by a log-depth syntactic multilinear formula where each leaf represents a multilinear polynomial in $O(\sqrt{n})$ variables.

▶ **Lemma 7.** *Let P be a syntactic multilinear ABP of size S computing a multilinear polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$. Then, there is a syntactic multilinear formula Φ with gates of unbounded fan-in computing f of size $S^{O(\log n)}$ and depth $O(\log n)$ such that every leaf w in Φ represents a multilinear polynomial $[u, v]_{P_w}$ for some nodes u, v in P_w with $|X_{u,v}| \leq \sqrt{n}$, where P_w is a sub-program of P. Further, any parse tree of Φ has at most $3\sqrt{n}$ leaves.*

Proof. Let nodes s and t be source and sink of P. The proof constructs a formula Φ by induction on the number of variables $|X_{s,t}|$ in the program P.
Base Case : If $|X_{s,t}| \leq \sqrt{n}$, then $\phi_{s,t}$ is a leaf gate with label $[s, t]$.
Induction Step : For induction step, suppose $|X_{s,t}| > \sqrt{n}$. By Theorem 1, we have

$$f = \sum_{i=1}^{m} [s, u_i] \cdot \mathsf{label}(u_i, v_i) \cdot [v_i, t] + \sum_{i=1}^{r} [s, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, t], \qquad (1)$$

where u_i, v_i, w_i and a_i are nodes in P, with $|X_{s,t}|/3 \leq |X_{s,u_i}| \leq 2|X_{s,t}|/3$ and $|X_{s,w_i}| + |X_{a_i,t}| \leq 2|X_{s,t}|/3$. Further, $[s, u_i] \cdot \mathsf{label}(u_i, v_i)$ (resp., $[s, w_i] \cdot \mathsf{label}(w_i, a_i)$) is an smABP with at most $2|X_{s,t}|/3 + 1$ (resp., $|X_{s,t}|/3$) variables. Let

$$f = \sum_{i=1}^{m} g_i h_i + \sum_{i=1}^{r} g'_i h'_i, \qquad (2)$$

where $g_i = [s, u_i] \cdot \mathsf{label}(u_i, v_i)$, $h_i = [v_i, t]$, $g'_i = [s, w_i] \cdot \mathsf{label}(w_i, a_i)$ and $h'_i = [a_i, t]$. For any i, if $|X_{s,w_i}| + |X_{a_i,t}| < \sqrt{n}$, then we set $g'_i = [s, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, t]$ and $h'_i = 1$. By induction, suppose ϕ_i (resp. ϕ'_i) be the multilinear formula that computes g_i (resp. g'_i) and ψ_i (resp. ψ'_i) be that for h_i (resp. h'_i). Set $\Phi = \sum_{i=1}^{m} (\phi_i \times \psi_i) + \sum_{i=1}^{r} (\phi'_i \times \psi'_i)$. Let $T(n)$ denote the size of the resulting formula on n variables. Then, $T(n) \leq 2 \cdot S \cdot 2 \cdot T(2n/3) = S^{O(\log n)}$. Thus, Φ is a syntactic multilinear formula of size $S^{O(\log n)}$ and depth $O(\log n)$ computing f. By construction, every leaf represents a multilinear polynomial $[u, v]_P$ for some nodes u, v in P with $|X_{u,v}| \leq \sqrt{n}$.

It remains to prove that any parse tree of Φ has at most $3\sqrt{n}$ leaves. We begin with a description of the process for constructing parse sub-trees of Φ. By Equation (2), constructing a parse tree of Φ is equivalent to the process:

1. Choose $b \in \{0, 1\}$ (corresponds to choosing one of the summations in Equation (2)).
2. If $b = 0$ choose $i \in \{1, \ldots, m\}$, else if $b = 1$ choose $j \in \{1, \ldots, r\}$.
3. Repeat steps 1 and 2 for sub-formulas ϕ_i, ϕ'_i, ψ_i and ψ'_i (depending on choice of b).

Consider any parse tree T of Φ. It is enough to prove that every leaf in T that is not labeled by 1 is a polynomial in at least $\sqrt{n}/3$ variables. Since Φ is syntactic multilinear, it follows that any parse tree of Φ has at most $3\sqrt{n}$ leaves, as required. However, it may be noted that this may not be true always. Instead, we argue that every leaf in T can be associated with a set of at least $\sqrt{n}/3$ variables such that no other leaf in T can be associated with these variables, hence implying that the number of leaves in any parse tree T of Φ is at most $3\sqrt{n}$.

Consider a leaf v in T having less than $\sqrt{n}/3$ variables. Let u be the first sum gate on the path from v to root with $|X_u| > \sqrt{n}$. Note that such a node u exists always, excluding the cases when the smABP P is a just a product of variable disjoint ABPs. Rest of the argument is split based on whether $b = 0$ or $b = 1$ at the step for choosing v in the construction of parse tree T. For the remainder of this proof, for any gate u, let X_u denote the set of variables in the sub-formula rooted at u in Φ.

Firstly, suppose that in the construction of T, $b = 0$ at the step for choosing v. Then, either $v = [p, u_i]\cdot\mathsf{label}(u_i, v_i)$ or $v = [v_i, q]$ for some nodes p, q, u_i, v_i in P, where u_i (respectively v_i) is colored red (respectively blue) when the coloring procedure (described in the proof of Theorem 1) is performed on the sub-program with source p and sink q. If $v = [p, u_i] \cdot \mathsf{label}(u_i, v_i)$, $|X_v| \geq |X_{p,u_i}| \geq |X_u|/3 \geq \sqrt{n}/3$, a contradiction to fact that v is a leaf in T with fewer than $\sqrt{n}/3$ variables. Hence, $v = [v_i, q]$. Set $A(v) = X_u \setminus (X_{p,u_i} \cup \{\mathsf{label}(u_i, v_i)\})$. Clearly, as $|X_u| \geq \sqrt{n}$ and $|X_{p,u_i}| \leq 2|X_u|/3$, we have $|A(v)| \geq \sqrt{n}/3$.

When $b = 1$, we have the following possibilities:

Case 1 $v = [p, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, q]$. In this case, set $A(v) = X_u$. Then $|A(v)| \geq \sqrt{n}/3$.

Case 2 $v = [p, w_i] \cdot \mathsf{label}(w_i, a_i)$. In this case, set $A(v) = X_u \setminus X_{a_i,q}$. Then $|A(v)| = |X_u| - |X_{a_i,q}| \geq \sqrt{n}/3$ as $|X_{a_i,q}| \leq 2|X_u|/3$ and $|X_u| > \sqrt{n}$.

Case 3 $v = [a_i, q]$. Set $A(v) = X_u \setminus (X_{p,w_i} \cup \{\mathsf{label}(w_i, a_i)\})$. Then $|A(v)| = |X_u| - |X_{p,w_i}| \geq \sqrt{n}/3$ as $|X_{p,w_i}| \leq 2|X_u|/3$ and $|X_u| > \sqrt{n}$.

It remains to prove that, for any two distinct leaves v and v' in T such that $A(v)$ and $A(v')$ are defined, $A(v) \cap A(v') = \emptyset$. Let u and u' respectively be parents of v and v' in T.

When $u = u'$, there are four possibilities for v and v': $v = [p, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, q]$ and $v' = 1$, $v = 1$ and $v' = [p, w_i] \cdot \mathsf{label}(w_i, a_i) \cdot [a_i, q]$, $v = [p, w_i] \cdot \mathsf{label}(w_i, a_i)$ and $v' = [a_i, q]$, or $v' = [p, w_i] \cdot \mathsf{label}(w_i, a_i)$ and $v = [a_i, q]$. As $A(v)$ is defined only for non-constant leaves, the only case is when $v = [p, w_i] \cdot \mathsf{label}(w_i, a_i), v' = [a_i, q]$ or vice-versa. In either of the cases, we have $A(v) \cap A(v') = \emptyset$. Now suppose, $u \neq u'$ and $A(v) \cap A(v') \neq \emptyset$. Then, we have $X_u \cap X_{u'} \neq \emptyset$ as $A(v) \subseteq X_u$ and $A(v') \subseteq X_{u'}$. From the fact that u and u' appear in the same parse tree we can conclude that the least common ancestor of u and u' in Φ must be a $\times$ gate. Let $[p, q]$ and $[p'q']$ be the sub-programs of P that correspond to u and u' respectively. By the construction of Φ, we can conclude that either there is a path from q to p' or there is a path from q' to p in P. Either of the cases is a contradiction to the fact that P is syntactic multilinear. ◀

Now, we obtain a reduction to depth-4 formulas for syntactic multilinear ABPs. Denote by $\Sigma^{[T]}\Pi^{[d]}(\Sigma\Pi)^{[r]}$ the class $\Sigma_{i=1}^{T}\Pi_{j=1}^{O(d)}Q_{ij}$ where Q_{ij}'s are mulitlinear polynomials in $O(r)$ variables. As a corollary to Lemma 7, we have the following reduction to syntactic multilinear $\Sigma\Pi^{[\sqrt{n}]}(\Sigma\Pi)^{[\sqrt{n}]}$ formulas for smABPs.

▶ **Corollary 1.** *Let P be a syntactic multilinear ABP of size S computing a polynomial f in $\mathbb{F}[x_1, \ldots, x_n]$. Then there exists a $\Sigma\Pi^{[\sqrt{n}]}(\Sigma\Pi)^{[\sqrt{n}]}$ syntactic multilinear formula of size $2^{O(\sqrt{n}\log S)}$ computing f.*

Proof. Let P be a syntactic multilinear ABP of size S computing a multilinear polynomial f in $\mathbb{F}[x_1, \ldots, x_n]$ and Φ be the equivalent syntactic multilinear formula with the properties mentioned in Lemma 7. The leaves of any parse tree of Φ represents the multilinear polynomial $[u,v]_{P_w}$ for some nodes u,v in P_w, a sub-program of P. As Φ is a formula, every parse tree T of Φ is uniquely identified by the set of $3\sqrt{n}$ leaves in T where every leaf in Φ represents a multilinear polynomial computed by some sub-program $[u,v]_{P_w}$ for some nodes u,v in P_w, a sub-program of P. Hence, it suffices to count the number of sub-programs of P. As every sub-program $([u,v])$ in P is obtained by choosing two vertices u and v in P, there are at most $\binom{S}{2}$ sub-programs of P. The number of parse trees of Φ are $S^{O(\sqrt{n})} = 2^{O(\sqrt{n}\log S)}$. As $f = \sum_{T:\text{parse tree of }\Phi} m(T)$ where $m(T)$ is the product of multilinear polynomials corresponding to the leaves of Φ in T, there exists a $\Sigma\Pi^{[\sqrt{n}]}(\Sigma\Pi)^{[\sqrt{n}]}$ syntactic multilinear formula with gates of unbounded fan-in of size $2^{O(\sqrt{n}\log S)}$ computing f. ◀

4 Lower Bounds for special classes of smABPs

This section is devoted to lower bounds for restricted classes of smABPs. Our arguments rely on the depth reduction proved in Section 3 and the full rank polynomial given by Raz and Yehhudayoff [19] (see Defintion 2).

4.1 Lower Bounds for strict circular-interval ABPs

In this section, we prove an exponential size lower bound for a special class of smABPs that we call as strict circular-interval ABPs.

An set $I \subseteq \{1,\ldots,n\}$ is a circular π-interval if $I = \{\pi(i),\pi(i+1),\ldots,\pi(j)\}$ for some $i,j \in [n], i < j$ or $I = \{\pi(i),\pi(i+1),\ldots,\pi(n),\pi(1),\ldots,\pi(j)\}$ for some $i,j \in [n], i > j$. These intervals are called *circular intervals* as every such interval $[i,j]$ in $\{1,\ldots,n\}$ can be viewed as a chord on the circle containing n points. Two circular intervals I and J are said to be *overlapping* if the corresponding chords in the circle intersect and *non-overlapping* otherwise. We define a special class of syntactic multilinear ABPs where the set of variables involved in every sub-program is in some circular π-interval.

▶ **Definition 3** (Strict circular-interval ABP). *Let $\pi \in S_n$ be a permutation. A syntactic mulitlinear ABP P is said to be a* strict π-circular-interval ABP *if*

1. *For any pair of nodes u,v in P, the index set of $X_{u,v}$ is contained in some circular π-interval I_{uv} in $[1,n]$; and*
2. *For any u,a,v in P, the circular π-intervals I_{ua} and I_{av} are non-overlapping.*

P is said to be strict circular-interval ABP if it is a strict π-circular-interval ABP for some permutation π.

We require a few preliminaries to prove the lower bound:

1. For every permutation π in S_n, define the partition $\varphi_\pi : X \to Y \cup Z$ such that
$$\text{for all } 1 \le i \le n/2 \ \varphi(x_{\pi(i)}) = y_i \text{ and } \varphi(x_{\pi(n/2+i)}) = z_i. \tag{3}$$
2. For any π in S_n, $|\varphi_\pi(X) \cap Y| = |\varphi_\pi(X) \cap Z| = |X|/2$. For the polynomial g in Definition 2, $\mathsf{rank}_{\varphi_\pi}(g) = 2^{n/2}$ by Lemma 6.
3. For any set $X_i \subseteq X$, let $\varphi_\pi(X_i) = \{\varphi_\pi(x) \mid x \in X_i\}$. We say X_i is *monochromatic* if either $\varphi_\pi(X_i) \cap Y = \emptyset$ or $\varphi_\pi(X_i) \cap Z = \emptyset$. Observe that if X_i is monochromatic then for any polynomial $p_i \in \mathbb{F}[X_i]$, we have $\mathsf{rank}_{\varphi_\pi}(p_i) \le 1$. Further, we say set $X_i \subseteq X$ is *bi-chromatic* if $\varphi_\pi(X_i) \cap Y \neq \emptyset$ and $\varphi_\pi(X_i) \cap Z \neq \emptyset$.

In the following theorem, we show that for any strict circular-interval ABP P computing a polynomial f, there is a partition φ such that $\mathsf{rank}_\varphi(f)$ is small.

▶ **Theorem 8.** *Let P be a strict circular-interval ABP of size S computing f in $\mathbb{F}[x_1, \ldots, x_n]$. There exists a $\varphi : X \to Y \cup Z$ with $|\varphi(X) \cap Y| = |\varphi(X) \cap Z| = |X|/2$ such that $\mathsf{rank}_\varphi(f) \leq 2^{\sqrt{n} \log n \log S + \sqrt{n}}$.*

Proof. Let Φ be the syntactic multilinear formula constructed from P as given by Lemma 7. Note that any parse tree of Φ has at most $3\sqrt{n}$ leaves. The number of parse trees of Φ is at most $\binom{2^{O(\sqrt{n} \log n \log S)}}{3\sqrt{n}} \leq 2^{\epsilon \sqrt{n} \log n \log S}$. Let T be any parse tree of Φ with leaves $w_1, \ldots, w_\ell$ computing polynomials $p_1, \ldots, p_\ell$. We have $f = \sum_{T:\text{parse tree of }\Phi} m(T)$ where $m(T)$ be the product of multilinear polynomials corresponding to the leaves of Φ in T. Let $X_1, \ldots, X_\ell \subseteq X$ be such that p_i is a polynomial in $\mathbb{F}[X_i]$. For every $i \in [\ell]$, let $M_i = \{j \mid x_j \in X_i\}$ be the index set of X_i. As P is a strict circular-interval ABP, we have that sets $M_1, \ldots, M_\ell$ are circular π-intervals in $\{1, \ldots, n\}$ for some $\pi \in S_n$. Let $\varphi_\pi : X \to Y \cup Z$ be the partition function described in Equation (3). If X_i is bi-chromatic then $\mathsf{rank}_{\varphi_\pi}(p_i) \leq 2^{\sqrt{n}/2}$ as $|X_i| \leq \sqrt{n}$ by construction of formula Φ when w_i is a leaf in Φ.

A crucial observation is that for any parse tree T of Φ, at most two of $\varphi_\pi(X_1), \ldots, \varphi_\pi(X_\ell)$ are bi-chromatic. This is because the existence of bi-chromatic sets $\varphi_\pi(X_i), \varphi_\pi(X_j), \varphi_\pi(X_k)$ for some $i, j, k \in [\ell]$ implies that the circular π-intervals M_i, M_j, M_k are overlapping from the way partition φ_π is defined. As X_i, X_j, X_k are variable sets associated with leaves of the same parse tree T, we can conclude that when $\varphi_\pi(X_i), \varphi_\pi(X_j), \varphi_\pi(X_k)$ are bi-chromatic there exists nodes u, a, v in P such that circular π-intervals I_{ua} and I_{av} are overlapping, a contradiction to the fact that P is a strict circular-interval ABP.

Therefore, in any parse tree T of Φ, at most two of $\varphi_\pi(X_1), \ldots, \varphi_\pi(X_\ell)$ are bi-chromatic say $\varphi_\pi(X_i)$ and $\varphi_\pi(X_j)$. Hence $\mathsf{rank}_{\varphi_\pi}(p_i) \leq 2^{\sqrt{n}/2}$ and $\mathsf{rank}_{\varphi_\pi}(p_j) \leq 2^{\sqrt{n}/2}$. Also, $\mathsf{rank}_{\varphi_\pi}(p_k) \leq 1$ for all $k \neq i, j$. Thus, $\mathsf{rank}_{\varphi_\pi}(f) \leq 2^{\epsilon \log n \log S \sqrt{n} + \sqrt{n}}$. ◀

With the above, we can prove Theorem 2:

▶ **Theorem 2.** *There exists an explicit multilinear polynomial g in $\mathbb{F}[x_1, \ldots, x_n]$ such that any strict circular-interval ABP computing g requires size $2^{\Omega(\sqrt{n}/\log n)}$.*

Proof. Let P be a strict circular-interval ABP of size $S = 2^{o(\sqrt{n}/\log n)}$ computing g and Φ be the syntactic multilinear formula obtained from P using Lemma 7. By Theorem 8, there exists a partition $\varphi : X \to Y \cup Z$ with $|\varphi(X) \cap Y| = |\varphi(X) \cap Z| = |X|/2$ such that $\mathsf{rank}_\varphi(g) \leq 2^{\sqrt{n} + \epsilon \log n \log S \sqrt{n}} < 2^{n/2}$. However, by Lemma 6, $\mathsf{rank}_\varphi(g) = 2^{n/2}$, a contradiction. Hence, $S = 2^{\Omega(\sqrt{n}/\log n)}$. ◀

4.2 Lower bound for sum of $\mathcal{L}$-ordered ABPs

In this section, we show that by observing a simple property of the ABP to formula conversion given in Lemma 7, we can obtain lower bounds for $\mathcal{L}$-ordered ABPs for larger sub-exponential values $\mathcal{L}$. In the following lemma, we observe that in the formula obtained from an $\mathcal{L}$-ordered ABP using Lemma 7, a lot of the leaves in any parse tree are in fact 1-ordered ABPs:

▶ **Lemma 9.** *Let P be an $\mathcal{L}$-ordered ABP and F be the syntactic multilinear formula obtained from P using Lemma 7. Then, for any parse tree T of F, all but at most $O(\log \mathcal{L})$ many leaves of T are 1-ordered ABPs (ROABPs).*

Proof. Let T be any parse tree of F with leaves $w_1, \ldots, w_\ell$ and let $p_1, \ldots, p_\ell$ be the polynomials labeling $w_1, \ldots, w_\ell$. From the construction given in the proof of Lemma 7, corresponding to each leaf w_i there are nodes u_i, v_i in P such that polynomial $p_i = [u_i, v_i] \cdot \mathsf{label}(v_i, u_{i+1})$. Consider the syntactic multilinear ABP P' obtained by placing programs

$$[u_1, v_1] \cdot \mathsf{label}(v_1, u_2), [u_2, v_2] \cdot \mathsf{label}(v_2, u_3), \ldots, [u_i, v_i] \cdot \mathsf{label}(v_i, u_{i+1}), \ldots, [u_\ell, v_\ell]$$

in the above order. From the construction above, P' is a sub-program of P and hence the number of variable orders in P' is a lower bound on the number of variable orders in P. If r_i is the number of variable orders in the sub-program $[u_i, v_i]$, the total number of variable orders in the sub-program P' (and hence P) is at least $r_1 \cdot r_2 \cdots r_\ell$. Since the number of distinct orders is at most $\mathcal{L}$, we conclude that $|\{i \mid r_i \geq 2\}| \leq \log \mathcal{L}$, as required. ◀

Let $\mathcal{D}$ denote the uniform distribution on the set of all partitions $\varphi : X \to Y \cup Z$ with $|Y| = |Z|$. In the following lemma, we show that rank of a polynomial computed by an $\mathcal{L}$-ordered ABP is far from being full. Proof can be found in the full version of the article [17].

▶ **Lemma 10.** *Let P be an $\mathcal{L}$-ordered ABP of size S computing a polynomial f in $\mathbb{F}[x_1, \ldots, x_n]$. Then for $k = n^{1/20}$, $\Pr_{\varphi \sim \mathcal{D}}[\mathsf{rank}_\varphi(f) > 2^{\log n \log S \sqrt{n}} \cdot 2^{n/2 - k\sqrt{n}}] \leq S^2 \cdot 2^{-O(n^{1/20})}$.*

Now, we are ready to prove Theorem 3:

▶ **Theorem 3.** *Let $\mathcal{L} \leq 2^{n^{1/2-\epsilon}}, \epsilon > 0$ and $f_1, \ldots, f_m \in \mathbb{F}[x_1, \ldots, x_n]$ be multilinear polynomials computed by $\mathcal{L}$-ordered ABPs of size $S_1, \ldots, S_m$ respectively. There exists an explicit multilinear polynomial g in $\mathbb{F}[x_1, \ldots, x_n]$ such that if $g = f_1 + \cdots + f_m$ then either $m = 2^{\Omega(n^{1/40})}$ or there is an $i \in [m]$ such that $S_i = 2^{\Omega(n^{1/40})}$.*

Proof. Set $k = n^{1/20}$. Suppose, for every i, f_i is computed by $\mathcal{L}$-ordered ABP of size $2^{n^{1/40}}$. Then, $\mathsf{rank}_\varphi(f_i) > 2^{\sqrt{n} \log n \log(2^{n^{1/40}})} 2^{n/2 - k\sqrt{n}}$ with probability at most $2^{2n^{1/40}} 2^{-n^{1/20}}$ when $\varphi \sim \mathcal{D}$. Therefore, probability that there is a i such that $\mathsf{rank}_\varphi(f_i) > 2^{\sqrt{n} \log n \log S} 2^{n/2 - k\sqrt{n}}$ is at most $m 2^{2n^{1/40}} 2^{-n^{1/20}} < 1$ for $m < 2^{n^{1/40}}$. By union bound, there is a $\varphi \sim \mathcal{D}$ such that for every i, $\mathsf{rank}_\varphi(f_i) < 2^{\sqrt{n} \log n \log(2^{n^{1/40}})} 2^{n/2 - k\sqrt{n}} < 2^{n/2}$. But by Lemma 6, $\mathsf{rank}_\varphi(g) = 2^{n/2}$ for every partition φ, which is a contradiction. Hence, either $m = 2^{\Omega(n^{1/40})}$ or there is an $i \in [m]$ such that $S_i = 2^{\Omega(n^{1/40})}$. ◀

5 Comparison with other multilinear circuit models

In this section, we compare strict circular-interval ABPs and $\mathcal{L}$-ordered ABPs to other well known models for computing mulitlinear polynomials.

5.1 $\mathcal{L}$-ordered to $\mathcal{L}$-pass

In this section, we show that $\mathcal{L}$-ordered ABPs can be transformed into ABPs that make at most $\mathcal{L}$ passes on the input, although in different orders.

▶ **Theorem 11.** *Let P be an $\mathcal{L}$-ordered ABP of size S computing a polynomial $f \in \mathbb{F}[x_1, \ldots, x_n]$. Then there is an $\mathcal{L}$-pass ABP Q of size $\mathsf{poly}(\mathcal{L}, S)$ computing f.*

Proof. Let P be an $\mathcal{L}$-ordered ABP of size S computing a polynomial f. Let $L_0, L_1, \ldots, L_\ell$ be the layers of P where source s and sink t are the only nodes in layers L_0 and L_ℓ respectively. Let $u_{i1}, \ldots, u_{iw}$ be nodes in L_i, where $w \leq S$ is the width of P. Without loss of generality assume every node in P has in-degree and out-degree at most two, and every layer except L_0 and L_ℓ has exactly w nodes. Also, every s to t path in P respects one of the permutations $\pi_1, \pi_2, \ldots, \pi_{\mathcal{L}}$. We now construct an $\mathcal{L}$-pass ABP $\mathcal{Q}$ that reads variables in the order $(x_{\pi_1(1)}, x_{\pi_1(2)}, \ldots, x_{\pi_1(n)}), \ldots, (x_{\pi_{\mathcal{L}}(1)}, x_{\pi_{\mathcal{L}}(2)}, \ldots, x_{\pi_{\mathcal{L}}(n)})$. The source and sink of ABP $\mathcal{Q}$ are denoted by s' and t' respectively. The number of layers in $\mathcal{Q}$ will be bounded by $\mathcal{L}(\ell + 1)$ and are labeled as $L_{ir}, i \in [\mathcal{L}], r \in \{0, \ldots, \ell\}$. Intuitively, for a node u_{rj} in layer L_r in P, we have $\mathcal{L}$ copies, $u_{1rj}, u_{2rj} \ldots, u_{\mathcal{L}rj}$ in $\mathcal{Q}$, where u_{irj} is a vertex in layer L_{ir}.

Intuitively, u_{irj} would have all paths from s to u_{rj} that respect the permutation π_i, but none of the permutations π_p for $p < i$. To ensure that the resulting ABP is $\mathcal{L}$-pass, we place the layers as follows : $L_{11}, \ldots, L_{1\ell}, L_{21}, \ldots, L_{2\ell}, \ldots, L_{\mathcal{L}1}, \ldots, L_{\mathcal{L}\ell}$. We construct $\mathcal{Q}$ as follows :

(1) Base Case : In ABP P, for every edge e from source s in layer L_0 to node $u_{1j}, j \leq w$ in layer L_1 labeled by $\mathsf{label}(e) \in X \cup \mathbb{F}$, if $\mathsf{label}(e) = x_k$, then add the edge (s', u_{m1j}) with label x_k where m is the smallest value such that x_k is consistent with π_m, if $\mathsf{label}(e) = \alpha \in \mathbb{F}$, then add the edge (s', u_{m1j}) with label α.

(2) Induction Step : Consider layer $L_r, r \in \{1, \ldots, \ell\}$:

a. For every node u_{rj} in layer L_r of P, with $1 \leq j \leq w$ and every edge e of the form $e = (u_{rj}, u_{r+1,j'})$ do the following:

Case 1: $\mathsf{label}(e) = x_k \in X$. For every $1 \leq i \leq \mathcal{L}$, let m be the smallest index such that every path from s' to u_{irj} concatenated with the edge e is consistent with π_m. Note that, by the construction, $m \geq i$. Add the edge $(u_{irj}, u_{mr+1j'})$ in $\mathcal{Q}$ for every i with label x_k. For every $1 \leq i \leq \mathcal{L}$, note that the choice of m is unique.

Case 2: $\mathsf{label}(e) = \alpha \in \mathbb{F}$. For every $1 \leq i \leq \mathcal{L}$, add edge (u_{irj}, u_{ir+1j}) with label α.

b. Create the node t' in $\mathcal{Q}$, and add edges $(u_{i\ell 1}, t')$ with label 1 for every $1 \leq i \leq \mathcal{L}$.

Note that in the above construction, the resulting branching program will not be layered. It can be made layered by adding suitable new vertices and edges labeled by $1 \in \mathbb{F}$. The correctness of the construction follows from the following claim whose proof is can be found in the full version [17].

▷ Claim 12.

(1) $\mathcal{Q}$ is an $\mathcal{L}$-pass syntactic multilinear ABP and has size $\mathsf{poly}(\mathcal{L}, S)$.

(2) For $1 \leq r \leq \ell$ and node u_{rj} in layer L_r in P, $1 \leq j \leq w$, $[s, u_{rj}]_P = \sum_{i=1}^{\mathcal{L}} [s', u_{irj}]_{\mathcal{Q}}$. ◀

5.2 Circular-Interval ABP vs. Sum of ROABPs

In this section, we define *circular-interval* ABPs (a generalization of strict circular-interval ABPs) and compare them to sum of ROABPs (and sum of strict circular-interval ABPs).

▶ **Definition 4** (Circular-Interval ABP). *Let $\pi \in S_n$ be a permutation. A syntactic mulitlinear ABP P is said to a* π-circular-interval ABP *if for any node v in P, the index set of $X_{s,v}$ is contained in some circular π-interval I_{sv} in $[1, n]$. P is said to be* circular-interval ABP *if it is a π-circular-interval ABP for some permutation π in S_n.*

Let $h = (h_n)_{n \geq 0}$ be the family of multilinear polynomials defined by Dvir et al. [8].

The following properties of the polynomial h are straightforward from Theorem 3.4 of [8] and the definition of circular-interval ABPs:

▶ **Lemma 13** ([8], Theorem 3.4). *(i) Over any field $\mathbb{F}$, the mulitlinear ABP R computing h is a circular-interval ABP of polynomial size. (ii) For any partition $\Pi \sim \mathcal{D}$, $\mathsf{rank}_\Pi(h) = 2^{n/2}$.*

Now, in order to separate circular-interval ABPs from ROABPs, it suffices to construct one partition Π such that $\mathsf{rank}_\Pi(f) < 2^{n/2}$ where f is the polynomial computed by an ROABP. This is guaranteed by the following lemma, whose proof is based on the ideas in [8] and [16]:

▶ **Lemma 14.** *Let Q be an ROABP computing a multilinear polynomial $f \in \mathbb{F}[x_1, \ldots, x_N]$ and Φ_Q be the multilinear formula obtained from Q computing f. Then $\mathsf{rank}_\Pi(f) \leq |\Phi_Q| \cdot 2^{n/2 - n^{1/5000}}$ with probability at least $1 - n^{\Omega(\log n)}$ for $\Pi \sim \mathcal{D}$.*

▶ **Theorem 15.** *Let $f_1, \dots f_m$ in $\mathbb{F}[x_1, \dots, x_n]$ be multilinear polynomials computed by ROABPs of size $R_1, \dots, R_m$ respectively. There exists an explicit multilinear polynomial h in $\mathbb{F}[x_1, \dots, x_n]$ computable by circular-interval ABPs of polynomial size, such that if $h = f_1 + \cdots + f_m$ then, either $m = n^{\Omega(\log n)}$ or there is an $i \in [m]$ with $R_i = 2^{\Omega\left(n^{1/6000}/\log N\right)}$.*

As an immediate corollary to Theorem 15, we have the following:

▶ **Corollary 16.** *There is a super-polynomial separation between ROABPs and circular interval ABPs.*

Abstract

In a Nisan-Wigderson design polynomial (in short, a design polynomial), every pair of monomials share a few common variables. A useful example of such a polynomial, introduced in [34], is the following:

$$\mathsf{NW}_{d,k}(\mathbf{x}) = \sum_{h \in \mathbb{F}_d[z],\ \deg(h) \le k} \ \prod_{i=0}^{d-1} x_{i,h(i)},$$

where d is a prime, $\mathbb{F}_d$ is the finite field with d elements, and $k \ll d$. The degree of the gcd of every pair of monomials in $\mathsf{NW}_{d,k}$ is at most k. For concreteness, we fix $k = \lceil \sqrt{d} \rceil$. The family of polynomials $\mathcal{NW} := \{\mathsf{NW}_{d,k} : d \text{ is a prime}\}$ and close variants of it have been used as hard explicit polynomial families in several recent arithmetic circuit lower bound proofs. But, unlike the permanent, very little is known about the various structural and algorithmic/complexity aspects of $\mathcal{NW}$ beyond the fact that $\mathcal{NW} \in \mathsf{VNP}$. Is $\mathsf{NW}_{d,k}$ characterized by its symmetries? Is it circuit-testable, i.e., given a circuit C can we check efficiently if C computes $\mathsf{NW}_{d,k}$? What is the complexity of equivalence test for $\mathcal{NW}$, i.e., given black-box access to a $f \in \mathbb{F}[\mathbf{x}]$, can we check efficiently if there exists an invertible linear transformation A such that $f = \mathsf{NW}_{d,k}(A \cdot \mathbf{x})$? Characterization of polynomials by their symmetries plays a central role in the geometric complexity theory program. Here, we answer the first two questions and partially answer the third.

We show that $\mathsf{NW}_{d,k}$ is characterized by its group of symmetries over $\mathbb{C}$, but not over $\mathbb{R}$. We also show that $\mathsf{NW}_{d,k}$ is characterized by circuit identities which implies that $\mathsf{NW}_{d,k}$ is circuit-testable in randomized polynomial time. As another application of this characterization, we obtain the "flip theorem" for $\mathcal{NW}$.

We give an efficient equivalence test for $\mathcal{NW}$ in the case where the transformation A is a block-diagonal permutation-scaling matrix. The design of this algorithm is facilitated by an almost complete understanding of the group of symmetries of $\mathsf{NW}_{d,k}$: We show that if A is in the group of symmetries of $\mathsf{NW}_{d,k}$ then $A = D \cdot P$, where D and P are diagonal and permutation matrices respectively. This is proved by completely characterizing the Lie algebra of $\mathsf{NW}_{d,k}$, and using an interplay between the Hessian of $\mathsf{NW}_{d,k}$ and the evaluation dimension.

1 Introduction

Proving super-polynomial lower bounds for Boolean and arithmetic circuits computing explicit functions is the holy grail of circuit complexity. Over the past few decades, research on lower bounds has gradually pushed the frontier by bringing in novel methods in the arena and carefully building upon the older ones. Some of the notable achievements are – lower bounds for AC^0 circuits [2, 17, 26], monotone circuits [3, 57], $\mathsf{ACC}(p)$ circuits [58, 62] and ACC circuits [52, 63] in the Boolean case, and lower bounds for homogeneous depth three circuits [54], multilinear formulas [55, 56], homogeneous depth four circuits [23, 31, 42] and the lower bound on the depth of circuits for MaxFlow [46] in the arithmetic case. The slow progress in circuit lower bounds is explained by a few "barrier" type results, particularly by the notion of natural proofs [59] for Boolean circuits, and the notion of algebraically natural proofs [13, 21] for arithmetic circuits [1]. Most lower bound proofs, but not all [2], do fit in the natural proof framework.

It is apparent from the concept of natural proofs and its algebraic version that in order to avoid this barrier, we need to develop an approach that violates the so called *constructivity* criterion or the *largeness* criterion. Focusing on the latter criterion, it means, if an explicit function has a special property that random functions do not have, and if a lower bound proof for circuits computing this explicit function uses this special property critically, then such a proof circumvents the natural proof barrier automatically. For polynomial functions (simply polynomials), *characterization by symmetries* is such a special property[3], and the geometric complexity theory (GCT) program [51] is an approach to proving super-polynomial arithmetic circuit lower bound by crucially exploiting this property of the permanent and the determinant polynomials. From hereon, our discussion will be restricted to polynomial functions and arithmetic circuits.

The permanent family is complete for the class VNP and the determinant family is complete for the class VBP under p-projections. The class $\mathsf{VBP} \subseteq \mathsf{VP}$ consists of polynomial families that are computable by poly-size algebraic branching programs; this class has another interesting complete family, namely the iterated matrix multiplication (IMM) family. These three polynomial families have appeared in quite a few lower bound proofs [9, 15, 20, 23, 36, 42, 45, 54–56] in the arithmetic circuit literature. That permanent and determinant are characterized by their respective groups of symmetries are classical results [16, 44]. It has also been shown that IMM is characterized by its symmetries [19, 32]. There are two other polynomial families in VP, the power symmetric polynomials and the sum-product polynomials, that are known to possess this rare property (see Section 2 in [8]). However, the elementary symmetric polynomial is not characterized by its symmetries [27].

In the recent years, another polynomial, namely the Nisan-Wigderson design polynomial (in short, design polynomial), and close variants of it have been used intensely as hard explicit polynomials in several lower bound proofs for depth three, depth four and depth five circuits [10, 12, 31, 33–35, 37–42]. In some cases, the design polynomial (Definition 7) yielded lower bounds that are not known yet for the permanent, determinant and IMM (as

[1] Presently, the evidences in favor of existence of one-way functions (which implies the natural proof barrier) are much stronger than that of existence of succinct hitting-set generators (which implies the algebraically natural proof barrier). However, there are a few results in algebraic complexity that exhibit, unconditionally [11] or based on more plausible complexity theoretic assumptions [5], the limitations of some of the current techniques in proving lower bounds for certain restricted arithmetic models.

[2] like the lower bounds for monotone and ACC circuits

[3] A random polynomial is not characterized by its symmetries with high probability (see Proposition 3.4.9 in [22])

in [12,33,37,40]). It can be easily shown that the design polynomial defines a family in VNP (see Observation B.1 in [24]). But, very little is otherwise known about the various structural and algorithmic/complexity aspects of this family. Like the permanent, is it characterized by its symmetries? Is it circuit testable? What is the complexity of equivalence test for the Nisan-Wigderson design polynomial? It is reasonable to seek answers to these fundamental questions for a natural family like the design polynomials. Moreover, in the light of some recent developments in GCT [7,28,29], it may be worth studying other polynomial families (like the design polynomials and the IMM) that have some of the "nice features" of the permanent and the determinant and that may also fit in the GCT framework. We refer the reader to [1,22,50,60] for an overview of GCT. If the design polynomial family turns out to be in VP then that would be an interesting result by itself with potentially important complexity theoretic and algorithmic consequences. If a polynomial has a small depth-4 circuit, then it is a projection of a small NW design polynomial (see Observation B.2 in [24])

In this article, we answer some of the above questions on the design polynomial pertaining to its group of symmetries. Our results accord a fundamental status to this polynomial.

1.1 Our results

Some of the basic definitions and notations are given in Section 2. The design polynomial $\mathsf{NW}_{d,k}$ is defined (in Definition 7) using two parameters, d (the degree) and k (the "intersection" parameter). Our results hold for any $k \in [1, \frac{d}{4} - 5]$, but (from the lower bound point of view) it is best to think of k as d^{ϵ} for some arbitrarily chosen constant $\epsilon \in (0,1)$. The number of variables in $\mathsf{NW}_{d,k}$ is $n = d^2$. Any polynomial can be expressed as an affine projection of $\mathsf{NW}_{d,k}$, for a possibly large d (see Observation B.2 in [24]). For notational convenience, we will drop the subscripts d and k whenever they are clear from the context. Let $\mathscr{G}_f$ be the group of symmetries of a polynomial f over an underlying field $\mathbb{F}$ (see Definition 12).

▶ **Theorem 1** (Characterization by symmetries). *Let $\mathbb{F} = \mathbb{C}$ and f be a homogeneous degree-d polynomial in $n = d^2$ variables. If $\mathscr{G}_{\mathsf{NW}} \subseteq \mathscr{G}_f$ then $f = \alpha \cdot \mathsf{NW}$ for some $\alpha \in \mathbb{C}$.*

The theorem, proven in Section 3, holds over any field $\mathbb{F}$ having a d-th root of unity $\zeta \neq 1$ and $|\mathbb{F}| \neq d+1$. We also show in Section 4.3 that NW is not characterized by its symmetries over $\mathbb{R}, \mathbb{Q}$ and finite fields not containing a d-th primitive root of unity – in contrast, the permanent is characterized by its symmetries over these fields. The symmetries of NW have a nice algorithmic application: Although, it is not known if NW is computable by a poly(d) size circuit (Definition 6), the following theorem shows that checking if a given circuit computes NW can be done efficiently. In this article, whenever we mention size-s circuit, we mean size-s circuit with degree bounded by $\delta(s)$, which is an arbitrarily fixed polynomial function[4] of s. Let $\mathbf{x}$ be the set of n variables of NW. We will identify a circuit with the polynomial computed by it.

▶ **Theorem 2** (Circuit testability). *There is a randomized algorithm that takes input as black-box access to a circuit $\mathsf{C}(\mathbf{x})$ of size s over a finite field $\mathbb{F}$, where $|\mathbb{F}| \geq 4 \cdot \delta(s)$ (recall $\delta(s)$ is an upper bound on the degree of size s circuits), and determines correctly whether or not $\mathsf{C}(\mathbf{x}) = \mathsf{NW}$ with high probability, using* poly(s) *field operations.*

[4] This is the interesting scenario in algebraic complexity theory as polynomial families in VP admit circuits with degree bounded by a polynomial function of size.

A suitable version of the theorem also holds over $\mathbb{Q}, \mathbb{R}$ and $\mathbb{C}$. Such a theorem is known for the permanent with two different proofs, one using self-reducibility of the permanent [43] and the other using its symmetries [48]. We do not know if NW has a self-reducible property like the permanent, but its symmetries are powerful enough to imply the above result. The theorem is proven in Section 5 by showing that NW is characterized by circuit identities over *any* field (see Definition 18). This characterization, which uses the symmetries of NW, also implies the following result. For this result, we can assume $\delta(s) \geq d$, without any loss of generality.

▶ **Theorem 3** (Flip theorem). *Suppose* NW *is not computable by circuits of size s over a finite field $\mathbb{F}$, where $|\mathbb{F}| \geq 4 \cdot \delta(s)$ and $\delta(s)$ is an upper bound on the degree of size s circuits. Then, there exist points $\mathbf{a}_1, \ldots, \mathbf{a}_m \in \mathbb{F}^n$, where $m = \mathrm{poly}(s)$, such that for every circuit* C *over $\mathbb{F}$ of size at most s, there is an $\ell \in [m]$ satisfying $\mathsf{C}(\mathbf{a}_\ell) \neq \mathsf{NW}(\mathbf{a}_\ell)$. A set of randomly generated points $\mathbf{a}_1, \ldots, \mathbf{a}_m \in_r \mathbb{F}^n$ has this property with high probability. Moreover, black-box derandomization of polynomial identity testing for size-$(10s)$ circuits over $\mathbb{F}$ using $\mathrm{poly}(s)$ field operations implies that the above-mentioned points can be computed deterministically using $\mathrm{poly}(s)$ field operations.*

An appropriate version of the theorem also holds over $\mathbb{Q}, \mathbb{R}$ and $\mathbb{C}$. The flip theorem is known for the permanent [48, 49] [5]. Similar theorems have also been shown for the $3SAT$ problem [4, 14]. Results of this kind show that if a certain function ($3SAT$ or permanent or NW) is not computable by small circuits then there exists a short list of efficiently computable "hard instances" that fail all small circuits.
We show another algorithmic application of the knowledge of the symmetries of NW in solving a natural case of the equivalence test problem for NW, namely block-diagonal permutation-scaling equivalence test (BD-PS equivalence test, in short). An equivalence test for NW checks if a given polynomial $f \in \mathbb{F}[\mathbf{x}]$ satisfies $f = \mathsf{NW}(A \cdot \mathbf{x})$, where A is an invertible linear transformation. A BD-PS equivalence test is the special case where A is a product of a block-diagonal permutation matrix and an invertible scaling matrix. The following theorem is proved in Section 6.

▶ **Theorem 4** (BD-PS equivalence test for NW). *Let $k \in [1, \frac{d}{3}]$, $\mathbb{F}$ be a finite field such that $d \nmid (|\mathbb{F}| - 1)$ and $|\mathbb{F}| \geq 4d$. There is a randomized algorithm that takes input black-box access to a degree d polynomial $f \in \mathbb{F}[\mathbf{x}]$ and correctly decides if f is BD-PS equivalent to* NW *with high probability. If the answer is yes then it outputs a A such that $f = \mathsf{NW}(A \cdot \mathbf{x})$, where A is a product of a block-diagonal permutation matrix and an invertible scaling matrix. The running time is $\mathrm{poly}(d, \log |\mathbb{F}|)$.*

An appropriate version of the theorem holds over $\mathbb{R}$ (details given in Section F.4 of [24]). Efficient equivalence tests are known for the Permanent and IMM over $\mathbb{C}$, $\mathbb{Q}$ and finite fields [30, 32] and for the Determinant over $\mathbb{C}$ and finite fields [18, 30]. In [30], it was shown that equivalence test for the Permanent reduces to permutation-scaling (PS) equivalence test. We show in Section 6 that equivalence test for NW reduces to block-permuted equivalence test[6],i.e., we can assume without loss of generality that A is a block-permuted matrix. Theorem 4 solves the equivalence test for NW in the case where A is a block-diagonal matrix and additionally has the permutation-scaling (PS) structure. Even this case is quite nontrivial and may serve as an important ingredient for an efficient general equivalence test for NW.

[5] We have borrowed the name "flip theorem" from these work.
[6] It decides if there exists a block-permuted matrix (Definition 8) $A \in \mathrm{GL}_{d^2}(\mathbb{F})$ such that $f = \mathsf{NW}(A \cdot \mathbf{x})$

The design of the test in Theorem 4 is facilitated by a near complete understanding of the symmetries of NW as stated in the following theorem. The proof is given in Section 4.2.

▶ **Theorem 5** (Structure of $\mathscr{G}_{\mathsf{NW}}$)**.** *Let $\mathbb{F}$ be the underlying field of size greater than $\binom{d}{2}$ and* $\mathrm{char}(\mathbb{F}) \neq d$*. If $A \in \mathscr{G}_{\mathsf{NW}}$ then $A = D \cdot P$, where $D, P \in \mathscr{G}_{\mathsf{NW}}$ are diagonal and permutation matrices respectively.*

The group of symmetries of the permanent has a similar structure [44]. The above structure also plays a crucial role in showing that NW is not characterized by its symmetries over $\mathbb{R}$. The proof of the theorem involves a complete characterization of the Lie algebra of NW, and an interplay between the Hessian of NW and the evaluation dimension measure. We first prove the structural results (Theorems 1 and 5) and then show their algorithmic applications (Theorems 2, 3 and 4). The proof details are shifted to the appendix. A comparison between the Permanent and NW is summarized in a table in Section A of [24].

2 Preliminaries

Notations. The set of natural numbers is $\mathbb{N} = \{0, 1, 2 \ldots\}$ and $\mathbb{N}^{\times} = \mathbb{N}\backslash\{0\}$. For $r \in \mathbb{N}^{\times}$, $[r] = \{0, \ldots, r-1\}$. The general linear group $\mathrm{GL}_r(\mathbb{F})$ is the group of all $r \times r$ invertible matrices over $\mathbb{F}$. Throughout this article, $\mathrm{poly}(r)$ means $r^{O(1)}$ and $\exp(r)$ means 2^r. For a prime d, $\mathbb{F}_d$ is the finite field of order d whose elements are naturally identified with $[d] = \{0, 1, \ldots, d-1\}$. Let $\mathbf{x}$ be the following disjoint union of variables,

$$\mathbf{x} := \biguplus_{i \in [d]} \mathbf{x}_i, \tag{1}$$

where $\mathbf{x}_i := \{x_{i,0}, \ldots, x_{i,d-1}\}$. The total number of variables in $\mathbf{x}$ is $n = d^2$. $\mathbb{F}[\mathbf{x}]$ and $\mathbb{F}_d[z]$ denote the rings of multivariate and univariate polynomials over $\mathbb{F}$ and $\mathbb{F}_d$ in $\mathbf{x}$ and z variables respectively, and the set $\mathbb{F}_d[z]_k := \{h \in \mathbb{F}_d[z] : \deg(h) \leq k\}$. We will represent elements of $\mathbb{F}$ by lower case Greek alphabets $(\alpha, \beta, \ldots)$, elements of $\mathbb{F}_d$ by lower case Roman alphabets $(a, b, \ldots)$, multivariate polynomials over $\mathbb{F}$ by f, g and q, univariate polynomials over $\mathbb{F}_d$ by p and h, matrices over $\mathbb{F}$ by capital letters $(A, B, C, \ldots)$, and the set of variables by $\mathbf{x}, \mathbf{y}, \mathbf{z}$ and vectors over $\mathbb{F}$ by $\mathbf{a}, \mathbf{b}$. Variable sets are interpreted as column vectors when left multiplied to a matrix. For instance, in $A \cdot \mathbf{x}$, $\mathbf{x}$ is the vector $(x_{0,0}\ x_{0,1} \ldots\ x_{0,d-1}\ \ldots\ x_{d-1,0}\ x_{d-1,1} \ldots\ x_{d-1,d-1})^T$, and we say A is applied on $\mathbf{x}$.

2.1 Algebraic preliminaries

A polynomial f is homogeneous if the degree of all the monomials of f are the same. Polynomial $f \in \mathbb{F}[\mathbf{x}]$ is set-multilinear in the sets $\mathbf{x}_0, \ldots, \mathbf{x}_{d-1}$ (as defined in Equation (1)) if every monomial contains exactly one variable from each set $\mathbf{x}_i$ for $i \in [d]$.

▶ **Definition 6** (Arithmetic circuit)**.** *An arithmetic circuit C over $\mathbb{F}$ is a directed acyclic graph in which a node with in-degree zero is labelled with either a variable or an $\mathbb{F}$-element, an edge is labelled with an $\mathbb{F}$-element, and other nodes are labelled with $+$ and $\times$. Computation proceeds in a natural way: a node with in-degree zero computes its label, an edge scales a polynomial by its label, and a node labelled with $+/\times$ computes the sum/product of the polynomials computed at the end of the edges entering the node. The polynomials computed by nodes with out-degree zero are the outputs of C. The size of C is the sum of the number of nodes and edges in the graph. The* degree *of C is the maximum over the degree of the polynomials computed at all nodes of C.*

▶ **Definition 7** (Nisan-Wigderson polynomial). *Let $d > 2$ be a prime and $k \in \mathbb{N}$. The Nisan-Wigderson design polynomial is defined as in [34] (which is inspired by the Nisan-Wigderson set-systems [53]),*

$$\mathsf{NW}_{d,k}(\mathbf{x}) := \sum_{h \in \mathbb{F}_d[z]_k} \prod_{i \in \mathbb{F}_d} x_{i,h(i)}.$$

It is a degree-d homogeneous and set-multilinear polynomial in $n = d^2$ variables, having d^{k+1} monomials. We drop the subscripts d, k for notational convenience. NW satisfies the "low intersection" property, meaning any two monomials of NW have at most k variables in common. This follows because the monomials are obtained from polynomials in $\mathbb{F}_d[z]_k$.

▶ **Definition 8** (Block-permuted matrix). *A matrix $A \in \mathbb{F}^{d^2 \times d^2}$ is a block-permuted matrix with block size d if $A = B \cdot (P \otimes I_d)$, where $B \in \mathbb{F}^{d^2 \times d^2}$ is a block-diagonal matrix with block size d, $P \in \mathbb{F}^{d \times d}$ is a permutation matrix, and I_d is the $d \times d$ identity matrix.*

▶ **Definition 9** (Evaluation dimension). *Let $f \in \mathbb{F}[\mathbf{y}]$ and $\mathbf{z} \subseteq \mathbf{y}$. The evaluation dimension of f with respect to $\mathbf{z}$ is, $evalDim_{\mathbf{z}}(f) := \dim(\ \mathbb{F}\text{-}span\ \{f(\mathbf{y})|_{\mathbf{z}=\mathbf{a}} : \boldsymbol{a} \in \mathbb{F}^{|\mathbf{z}|}\}\ )$.*

▶ **Definition 10** (Hessian). *Let $f \in \mathbb{F}[\mathbf{y}]$ be a polynomial in $\mathbf{y} = \{y_1, y_2, \ldots, y_n\}$ variables. The Hessian of f is the following matrix in $(\mathbb{F}[\mathbf{y}])^{n \times n}$,*

$$H_f(\mathbf{y}) := \Big(\frac{\partial^2 f}{\partial y_i \cdot \partial y_j}\Big)_{i,j \in [n]}.$$

The following property of $H_f(\mathbf{y})$ that can be proved using chain-rule of derivatives.

▶ **Lemma 11** (Lemma 2.6 of [8]). *Let $g \in \mathbb{F}[\mathbf{y}]$ and $f = g(A \cdot \mathbf{y})$ for some $A \in \mathbb{F}^{n \times n}$. Then, $H_f(\mathbf{y}) = A^T \cdot H_g(A \cdot \mathbf{y}) \cdot A$.*

▶ **Definition 12** (Group of symmetries). *Let $f \in \mathbb{F}[\mathbf{y}]$ be an n-variate polynomial. The set $\mathscr{G}_f = \{A \in \mathrm{GL}_n(\mathbb{F}) : f(A \cdot \mathbf{y}) = f(\mathbf{y})\}$ forms a group under matrix multiplication and it is called the group of symmetries of f over $\mathbb{F}$.*

▶ **Definition 13** (Lie algebra). *Let $f \in \mathbb{F}[\mathbf{y}]$ be a polynomial in $\mathbf{y} = \{y_1, y_2, \ldots, y_n\}$ variables. The Lie algebra of f, denoted by $\mathfrak{g}_f$, is the set of matrices $B = (b_{i,j})_{i,j \in [n]} \in \mathbb{F}^{n \times n}$ satisfying the relation $\sum_{i,j \in [n]} b_{i,j} \cdot y_j \cdot \frac{\partial f}{\partial y_i} = 0$.*

It is easy to check that $\mathfrak{g}_f$ is a vector space over $\mathbb{F}$. The following property relates the Lie algebras of $f(\mathbf{y})$ and $f(A \cdot \mathbf{y})$ for $A \in \mathrm{GL}_n(\mathbb{F})$. See Proposition 58 of [30] for its proof.

▶ **Lemma 14** (Conjugacy of Lie algebras). *Let $g \in \mathbb{F}[\mathbf{y}]$ be an n-variate polynomial. If $f(\mathbf{y}) = g(A \cdot \mathbf{y})$ for $A \in \mathrm{GL}_n(\mathbb{F})$, then $\mathfrak{g}_f = A^{-1} \cdot \mathfrak{g}_g \cdot A$.*

▶ **Lemma 15.** *[30] Given black-box access to an n-variate degree d polynomial $f \in \mathbb{F}[\mathbf{x}]$, a basis of $\mathfrak{g}_f$ can be computed in randomized $poly(n, d, \rho)$ time, where ρ is the bit complexity of the coefficients of f.*

Over $\mathbb{C}$, the Lie algebra $\mathfrak{g}_f$ is related to the group of symmetries $\mathscr{G}_f$ as stated in the following definition. For $B \in \mathbb{C}^{n \times n}$, let $e^B := \sum_{i \in \mathbb{N}} \frac{B^i}{i!} \in \mathbb{C}^{n \times n}$ (the series always converges).

▶ **Definition 16** (Continuous and discrete symmetries). *Let $f \in \mathbb{C}[\mathbf{y}]$. If $A \in \mathfrak{g}_f$ then $e^{tA} \in \mathscr{G}_f$ for every $t \in \mathbb{R}$ (see [25] for a proof of this fact). Elements of the set $\{e^{tA} : A \in \mathfrak{g}_f$ and $t \in \mathbb{R}\}$ are the continuous symmetries of f. All the other symmetries in $\mathscr{G}_f$ are the discrete symmetries of f.*

▶ **Definition 17** (Characterization by symmetries). *A homogeneous degree-d polynomial $g \in \mathbb{F}[\mathbf{y}]$ is said to be characterized by its symmetries if for every degree-d homogeneous polynomial $f \in \mathbb{F}[\mathbf{y}]$, $\mathscr{G}_g \subseteq \mathscr{G}_f$ implies that $f(\mathbf{y}) = \alpha \cdot g(\mathbf{y})$ for some $\alpha \in \mathbb{F}$.*

▶ **Definition 18** (Characterization by circuit identities). *Let $g \in \mathbb{F}[\mathbf{y}]$ be an n-variate polynomial, and $\mathbf{z}, \mathbf{u}$ be two sets of constantly many variables and $|\mathbf{z}| = c$. Suppose that there exist $m = \mathrm{poly}(n)$ polynomials $q_1(\mathbf{z}, \mathbf{u}), \ldots, q_m(\mathbf{z}, \mathbf{u})$ over $\mathbb{F}$ such that for every $i \in [m]$, q_i is computable by a constant size circuit and there exist $A_{i1}, \ldots, A_{ic} \in \mathbb{F}[\mathbf{u}]^{n \times n}$ computable by $\mathrm{poly}(n)$ size circuits, and the following condition is satisfied: For $f \in \mathbb{F}[\mathbf{y}]$, $q_i(f(A_{i1} \cdot \mathbf{y}), \ldots, f(A_{ic} \cdot \mathbf{y}), \mathbf{u}) = 0$ for every $i \in [m]$ if and only if $f = \alpha \cdot g$ for some $\alpha \in \mathbb{F}$. Then, g is* characterized by circuit identities *over $\mathbb{F}$.*

The above definition is taken (after slight modifications to suit our purpose) from Definition 3.4.7 in [22] and is attributed to an article by Mulmuley [47].

3 Characterization of NW by symmetries and circuit identities

3.1 Symmetry characterization: Theorem 1

Let $\mathbb{F}$ be a field having a d-th root of unity $\zeta \neq 1$ and $|\mathbb{F}| \neq d + 1$.[7] As d is a prime, ζ is primitive, i.e., $\zeta^d = 1$ and $\zeta^t \neq 1$ for $0 < t < d$. The rows and columns of a matrix in $\mathscr{G}_{\mathsf{NW}}$ are indexed by the set $\{(i, j) : i, j \in \mathbb{F}_d\}$.

▷ Claim 19. The following matrices in $\mathbb{F}^{n \times n}$ are in $\mathscr{G}_{\mathsf{NW}}$:

1. $A_{\boldsymbol{\beta}}$, a diagonal matrix with $A_{\boldsymbol{\beta}}((i, j), (i, j)) = \beta_i \in \mathbb{F}^{\times}$ for $i, j \in [d]$, s.t. $\prod_{i \in [d]} \beta_i = 1$.
2. A_{ℓ}, a diagonal matrix with $((i, j), (i, j))$-th entry as $\zeta^{i^{\ell} \cdot j}$ for $i, j \in [d]$ and $\ell \in [d - k - 1]$.[8]
3. A_h, $h \in \mathbb{F}_d[z]_k$,such that $A_h((i, j), (i, j + h(i))) = 1$ for $i, j \in [d]$ and other entries are 0.

The proof of Claim 19 is given in Section C.1 in [24]. The matrices $A_{\boldsymbol{\beta}}$ are the continuous symmetries while A_{ℓ}, A_h are discrete symmetries of NW for all choices of $\boldsymbol{\beta}, \ell, h$. The symmetries in 2 are very different from the symmetries of the Determinant and the Permanent. The following Claim immediately implies Theorem 1. Its proof is given in Section C.2 in [24].

▷ Claim 20. Let f be a homogeneous degree-d polynomial in $\mathbb{F}[\mathbf{x}]$. If $\mathscr{G}_f$ contains $A_{\boldsymbol{\beta}}, A_{\ell}$ and A_h (for all choices of $\boldsymbol{\beta}$, ℓ and h, mentioned above) then $f = \alpha \cdot \mathsf{NW}$ for some $\alpha \in \mathbb{F}$.

3.2 Characterization by circuit identities

Here we show that NW is characterized by circuit identities (Definition 18). The lemma is crucially used to prove Theorems 2 and 3 in Section 5. Its proof is given in Section C.3 in [24].

▶ **Lemma 21.** *Polynomial* NW *is characterized by circuit identities over any field $\mathbb{F}$.*

4 Lie algebra and symmetries of NW

We first give a complete description of the Lie algebra of NW by giving an explicit $\mathbb{F}$-basis. Then, using this knowledge, we analyse the structure of the symmetries of NW and prove

[7] For a prime d, $|\mathbb{F}| = d + 1$ if and only if d is a Mersenne prime.

[8] Recall, $[d - k - 1] = \{0, 1, \ldots, d - k - 2\}$

Theorem 5. Thereafter, using Theorem 5, we show that NW is not characterized by its symmetries over fields that do not contain a d-th primitive root of unity. The rows and columns of a $n \times n$ matrix in $\mathfrak{g}_{\mathsf{NW}}$ and $\mathscr{G}_{\mathsf{NW}}$ are indexed by the set $\{(i,j) : i,j \in \mathbb{F}_d\}$, which is naturally identified with the $\mathbf{x}$-variables, where $\mathbf{x} = (x_{0,0} \dots x_{0,d-1} \, \dots \, x_{d-1,0} \dots x_{d-1,d-1})^T$.

4.1 Lie algebra of NW

It turns out that the Lie algebra of NW is a subspace of the Lie algebra of every set-multilinear polynomial. (The default partition of a set-multilinear polynomial is $\mathbf{x} = \uplus_{i\in[d]}\mathbf{x}_i$.)

▶ **Lemma 22.** *Let $\mathbb{F}$ be a field and $\mathrm{char}(\mathbb{F}) \neq d$. The dimension of $\mathfrak{g}_{\mathsf{NW}}$ over $\mathbb{F}$ is $d-1$, and the diagonal matrices $B_1, \dots, B_\ell$ (defined below) form a $\mathbb{F}$-basis of $\mathfrak{g}_{\mathsf{NW}}$. For $\ell \in \{1, \dots, d-1\}$,*

$$(B_\ell)_{(i,j),(i,j)} = \begin{cases} 1, & \text{if } i = 0, j \in [d] \\ -1, & \text{if } i = \ell, j \in [d] \\ 0, & \text{otherwise.} \end{cases}$$

The lemma is proven in Section D.1 in [24] by carefully analysing a system of linear equations obtained from the monomials of NW. It follows that every $B \in \mathfrak{g}_{\mathsf{NW}}$ is of the form $\mathrm{diag}(\alpha_0, \dots, \alpha_{d-1}) \otimes I_d$, where each $\alpha_i \in \mathbb{F}$ and $\sum_{i\in[d]} \alpha_i = 0$. The continuous symmetries of NW consist of matrices $A = \mathrm{diag}(\beta_0, \dots, \beta_{d-1}) \otimes I_d$, where each $\beta_i \in \mathbb{C}$ and $\prod_{i\in[d]} \beta_i = 1$.

4.2 Structure of $\mathscr{G}_{\mathsf{NW}}$: Theorem 5

Lemma 22 implies the following.

▷ Claim 23. Every $A \in \mathscr{G}_{\mathsf{NW}}$ is a block-permuted matrix with block size d.

The proof of the claim is given in Section D.2 in [24]. Using Claim 23, Hessian and the evaluation dimension of NW, we give a proof of Theorem 5 in Section D.3 in [24].

4.3 NW is not characterized by its symmetries over $\mathbb{R}$

Let $\mathbb{F}$ be either $\mathbb{R}, \mathbb{Q}$ or a finite field such that $d \nmid |\mathbb{F}| - 1$. Then, $\mathbb{F}$ does not contain a d-th primitive root of unity, and so the matrices A_ℓ, for $\ell \in [d-k-1]$ mentioned in Claim 19, are no longer the symmetries of NW over $\mathbb{F}$. The next lemma shows that over such $\mathbb{F}$ all the diagonal symmetries of NW are of the type $A_{\boldsymbol{\beta}}$ mentioned in Claim 19. This then implies the following theorem, which may seem somewhat surprising as we do not know all the permutation symmetries of NW. The proofs are given in Section D.4 in [24].

▶ **Lemma 24.** *If $D \in \mathscr{G}_{\mathsf{NW}}$ is a diagonal matrix over $\mathbb{F}$ then $D = diag(\beta_0, \dots, \beta_{d-1}) \otimes I_d$, where each $\beta_i \in \mathbb{F}$ and $\prod_{i\in[d]} \beta_i = 1$.*

▶ **Theorem 25.** NW *is not characterized by its symmetries over $\mathbb{F}$.*

5 Circuit testability and the flip theorem for NW

In this and the next section, we show that the knowledge of the symmetries of NW plays a crucial role in answering some of the algorithmic questions related to NW. This section is devoted to Theorems 2 and 3. The main ingredient of their proofs is Lemma 21. We present the circuit testing algorithm here and push the proof of the Flip theorem to Section E in [24].

Proof of Theorem 2. Let $\mathtt{C}$ be a given circuit of size s over $\mathbb{F}$ that computes an n-variate polynomial $f = \mathtt{C}(\mathbf{x})$. Naturally, $\deg(f) \le \delta(s)$. Algorithm 1 intends to check, in steps 2 and 3, if f satisfies the identities given in the proof of Lemma 21. If $f \neq \alpha \cdot \mathsf{NW}$ for all $\alpha \in \mathbb{F}$, then at least one of the identities is not satisfied. For the polynomials q_1, q_2 and q_3 defined in the proof of Lemma 21, observe that the degree of $q_1(f(A_i(u) \cdot \mathbf{x}), f(\mathbf{x}), u)$ is bounded by $2 \cdot \delta(s)$, whereas the degrees of $q_2(f(A_{a,r} \cdot \mathbf{x}), f(\mathbf{x}))$ and $q_3(f(A_t \cdot \mathbf{x}))$ are at most $\delta(s)$. As $|\mathbb{F}| \ge 4 \cdot \delta(s)$, by Schwartz-Zippel lemma [61, 64], step 4 returns "False" with probability at least $\frac{1}{2}$. If $f = \alpha \cdot \mathsf{NW}$ for some $\alpha \in \mathbb{F}$ then all the identities are satisfied, and step 7 ensures that $\alpha = 1$. Clearly, the algorithm uses poly(s) field operations. The success probability is boosted from $\frac{1}{2}$ to $1 - \exp(-s)$ by repeating the algorithm poly(s) times. ◀

Algorithm 1 Circuit testing for NW.

```
Input: Black-box access to a circuit $\mathtt{C}$ of size $s$ over $\mathbb{F}$.
Output: "True" if $\mathtt{C}(\mathbf{x}) = \mathsf{NW}$, else "False".
1. Pick $\mathbf{a} \in_r \mathbb{F}^n$ and $\mu \in_r \mathbb{F}$.
2. for $i \in [d], a \in \mathbb{F}_d^{\times}, r \in [k+1], t \in [d]\backslash[k+1]$ do
3.     if $(\mathtt{C}(A_i(\mu) \cdot \mathbf{a}) - \mu \cdot \mathtt{C}(\mathbf{a}) \neq 0)$ or $(\mathtt{C}(A_{a,r} \cdot \mathbf{a}) - \mathtt{C}(\mathbf{a}) \neq 0)$ or $(\mathtt{C}(A_t \cdot \mathbf{a}) \neq 0)$ then
4.         return "False".
5.     end if
6. end for
7. Let $\mathbf{b} \in \mathbb{F}^n$ be an assignment obtained by setting $x_{i0} = 1$, for $i \in [d]$, and all other
   variables to zero. If $f(\mathbf{b}) \neq 1$, return "False". Else, return "True".
```

6 Equivalence test for NW

First, we show a randomized reduction of equivalence test for NW to block-permuted equivalence test (in short, BP equivalence test) in Lemma 26. Then, we give an efficient equivalence test for NW in the special case where the linear transformation is block-diagonal and is a product of a permutation matrix and a scaling matrix (Theorem 4).

▶ **Lemma 26** (Reduction to BP equivalence test). *Let $\mathbb{F}$ be a field such that* $\mathrm{char}(\mathbb{F}) \neq d$ *and $|\mathbb{F}| \ge 2d^2$. There is a randomized algorithm that takes input as black-box access to a degree d polynomial $f \in \mathbb{F}[\mathbf{x}]$ and does the following with high probability: It outputs black-box access to a degree d polynomial $g \in \mathbb{F}[\mathbf{x}]$ such that f is equivalent to* NW *if and only if g is BP equivalent to* NW*. Moreover, the transformation for f can be recovered efficiently from the transformation for g. The running time of this reduction is* poly(d, ρ)*, where ρ is bit complexity of the coefficients of f* [9].

Proof of correctness. The efficiency of Step 1 follows from Lemma 15. The correctness of Step 2 and 3 follow from the next claim whose proof is given in Section F.1 in [24].

▷ Claim 27. With high probability, matrix D can be computed in poly(d, ρ) time. Moreover, f is equivalent to NW if and only if $f(D \cdot \mathbf{x})$ is BP equivalent to NW.

[9] We assume that univariate polynomial factorization over $\mathbb{F}$ can be done in polynomial time.

Algorithm 2 Reduction of equivalence test for NW to BP equivalence test.

```
Input: Black-box access to $f \in \mathbb{F}[\mathbf{x}]$.
Output: Black-box access to $g \in \mathbb{F}[\mathbf{x}]$.

1. Compute a basis $L_1, \ldots, L_r$ of $\mathfrak{g}_f$. If $r \neq d-1$, output "$f$ is not equivalent to NW".
2. Let $S$ be an arbitrary subset of $\mathbb{F}$ of size $d^2$. Let $L = a_1L_1 + \ldots + a_rL_r$, where $a_i \in_r S$.
   Compute $D \in \mathrm{GL}_{d^2}(\mathbb{F})$ such that $D^{-1} \cdot L \cdot D = \mathrm{diag}(\beta_1, \ldots, \beta_d) \otimes I_d$, where $\beta_j \in \mathbb{F}$. If
   no such $D$ exists then output "$f$ is not equivalent to NW."
3. Output black-box access to $f(D \cdot \mathbf{x})$.
```

6.1 BD-PS equivalence test for NW: Theorem 4

Lemma 26 implies that to solve equivalence test for NW it is sufficient to focus on BP equivalence test. Here, we solve a special case of BP equivalence test, namely BD-PS equivalence test. We prove Theorem 4 in two steps: first we reduce BD-PS equivalence test to scaling equivalence test and then solve the scaling equivalence test. The algorithm pretends that f is BD-PS equivalent to NW and computes a block-diagonal permutation matrix A and an invertible scaling matrix B. In the end, the circuit testing algorithm of NW (Algorithm 1) is used to check if $f(A^{-1} \cdot B^{-1} \cdot \mathbf{x}) = \mathsf{NW}$.

6.1.1 Reduction of BD-PS equivalence test to scaling equivalence test

Assume $f = \mathsf{NW}(B \cdot A \cdot \mathbf{x})$, where A is a block-diagonal permutation matrix and B is an invertible scaling matrix. Algorithm 3 does not explicitly use the knowledge of the entries of B. Thus, we may assume without loss of generality that $B = I_{d^2}$. Then, the task reduces to solving the BD permutation equivalence test for NW. We identify matrix A with d permutations $\sigma_0, \ldots, \sigma_{d-1}$ on $[d]$ as $A = \mathrm{diag}(M_{\sigma_0}, \ldots, M_{\sigma_{d-1}})$, where M_{σ_i} is the $d \times d$ permutation matrix corresponding to σ_i [10].

▶ **Observation 6.1.** *Suppose f is BD permutation equivalent to* NW*, i.e. $f = \mathsf{NW}(A \cdot \mathbf{x})$. Then, a monomial $\prod_{i \in \mathbb{F}_d} x_{i,h(i)}$ of* NW *gets mapped to a unique monomial $\prod_{i \in \mathbb{F}_d} x_{i,\sigma_i(h(i))}$ of f.*

Algorithm 3 starts by assuming that $\sigma_0(0) = \cdots = \sigma_k(0) = 0$ and $\sigma_0(1) = 1$. The symmetries of NW allow us to make this assumption (Claim 28). The aim is to figure out all the entries of σ_i [11]. This is done by carefully picking a bunch of polynomials from $\mathbb{F}_d[z]_k$ (which we call *nice* polynomials) and then exploiting the association between f and NW mentioned in Observation 6.1 using these polynomials. The algorithm works over every field.

Proof of correctness. The following claims argue the correctness of the algorithm. Their proofs are given in Section F.2 in [24]. In these claims, ρ is the bit complexity of the coefficients of f.

▷ Claim 28. (Canonical form of $\sigma_0, \ldots, \sigma_{d-1}$): Suppose $f \in \mathbb{F}[\mathbf{x}]$ is BD permutation equivalent to NW. Then, there exist permutations $\sigma_0, \ldots, \sigma_{d-1}$ on $[d]$ such that $\sigma_0(0) = \cdots = \sigma_k(0) = 0, \sigma_0(1) = 1$ and $A = \mathrm{diag}(M_{\sigma_0}, \ldots, M_{\sigma_{d-1}})$ satisfies $f = \mathsf{NW}(A \cdot \mathbf{x})$.

[10] For $i, r, s \in [d], M_{\sigma_i}(r, s) = 1$ if and only if $\sigma_i(r) = s$.
[11] σ_i is treated as an ordered tuple $(\sigma_i(0), \ldots, \sigma_i(d-1))$

Algorithm 3 Block-diagonal permutation equivalence test for NW.

```
Input: Black-box access to $f \in \mathbb{F}[\mathbf{x}]$.
Output: Black-box access to $g \in \mathbb{F}[\mathbf{x}]$ such that if $f$ is BD-PS equivalent to NW then $g$ is scaling equivalent to NW.

1. Assume that $\sigma_0(0) = \cdots = \sigma_k(0) = 0$ and $\sigma_0(1) = 1$ (Claim 28).
2. Construct a list of nice polynomials in $\mathbb{F}_d[z]_k$ (Definition 29) as mentioned in Claim 30.
3. Recover $(d-k)$ distinct entries of each $\sigma_0, \ldots, \sigma_{d-1}$ as mentioned in Claim 31.
4. Let $N$ be a $d \times d$ matrix, where the columns and rows are indexed by $(\sigma_0, \ldots, \sigma_{d-1})$ and
   $(0, \ldots, d-1)$ respectively and for $l, i \in [d], N(l, i) := \sigma_i(l)$. Pick $l_0, \ldots, l_k \in [d]$ such that
   in each of the rows indexed by $l_0, \ldots, l_k$ at least $k+1$ entries are known (Claim 32).
5. Use $l_0, \ldots, l_k \in [d]$ to recover all the entries of the rows of $N$ as mentioned in Claim 33.
   Compute $A = \text{diag}(M_{\sigma_0}, \ldots, M_{\sigma_{d-1}})$ and return black box access to $f(A^{-1} \cdot \mathbf{x})$
```

▶ **Definition 29.** *(List of nice polynomials in $\mathbb{F}_d[z]_k$): $\{h_0, \ldots, h_{d-k-1}\} \subseteq \mathbb{F}_d[z]_k$ is called a list of nice polynomials if the following properties are satisfied:*

1. *For distinct $r_1, r_2 \in [d-k]$, $h_{r_1}(\ell) = h_{r_2}(\ell)$ for every $\ell \in [k]$ and $h_{r_1}(\ell) \neq h_{r_2}(\ell)$ for every $\ell \in \{k, \ldots, d-1\}$.*
2. *For every $r \in [d-k], \sigma_0(h_r(0)), \ldots, \sigma_k(h_r(k))$ can be computed in poly(d, ρ) time.*

▷ Claim 30. A list of $d-k$ nice polynomials $\{h_0, \ldots, h_{d-k-1}\}$ can be computed in poly(d, ρ) time.

Using the list of nice polynomials, we recover $d-k$ distinct entries of $\sigma_0, \ldots, \sigma_{d-1}$.

▷ Claim 31. Given a list of nice polynomials $\{h_0, \ldots, h_{d-k-1}\}$, we can recover $d-k$ distinct entries in each of $\sigma_0, \ldots, \sigma_{d-1}$ in poly(d, ρ) time.

The matrix N defined in the algorithm is filled with some known entries and some unknowns. The goal is to recover all the entries of N which is accomplished by the following claims.

▷ Claim 32. Suppose $k \in [1, \frac{d}{3}]$. Then, there exist $k+1$ rows in N such that in each of these rows at least $k+1$ entries are known.

▷ Claim 33. Using $k+1$ rows of N indexed by $l_0, \ldots, l_k$ (as mentioned in Step 4), we can recover all the entries of N in poly(d, ρ) time.

6.1.2 Scaling equivalence test for NW

We present an algorithm for solving the scaling equivalence test for NW over a finite field $\mathbb{F}$, where $d \nmid |\mathbb{F}| - 1$. The same algorithm with appropriate modifications works over $\mathbb{R}$. More details on this are given in Section F.4 in [24]. Assume that f is scaling equivalent to NW.

Proof of correctness. The following claims and observations argue the correctness of the algorithm. The proofs of the claims are given in Section F.3 in [24].

▷ Claim 34. We can assume that $\alpha_{1,0} = \ldots = \alpha_{d-1,0} = 1$ without loss of generality.

The following observation can be proved easily.

▶ **Observation 6.2.** *Given a monomial m, we can recover the coefficient of m in f in* poly(d, ρ) *time.*

▷ Claim 35. In Step 4, $\alpha_{i,j}$ can be computed in poly(d, ρ) time. Further, $f = \mathsf{NW}(B \cdot \mathbf{x})$.

Algorithm 4 Scaling equivalence test for NW over finite fields.

Input: Black box access to $f \in \mathbb{F}[\mathbf{x}]$.
Output: An invertible diagonal matrix B such that $f = \mathsf{NW}(B \cdot \mathbf{x})$.

1. Let $B = \text{diag}(\alpha_{0,0}, \ldots, \alpha_{d-1,d-1})$, where $\{\alpha_{i,j} \ : \ i, j \in [d]\}$ are unknown. Set $\alpha_{1,0} = \ldots = \alpha_{d-1,0} = 1$ (Claim 34).
2. Let $S = (0, z, \ldots, (d-1)z,\ 1, z+1 \ldots, (d-1)z+1,\ \ldots\ , d-2, z+d-2 \ldots, (d-1)z+d-2,\ d-1)$ be the ordered set of $d^2 - d + 1$ polynomials in $\mathbb{F}[z]$. For every $h \in S$, query the coefficient c_h of the monomial $\prod_{i \in \mathbb{F}_d} x_{i,h(i)}$ from the black-box of f (Observation 6.2).
3. Let C be a $0/1$ matrix of size $(d^2-d+1) \times (d^2-d+1)$ whose rows and columns are indexed by S and $\mathbf{y} = (y_{0,0}, \ldots, y_{0,d-1}, y_{1,1}, \ldots, y_{1,d-1}, \ldots, y_{d-1,1}, \ldots, y_{d-1,d-1})$, respectively, such that for $h \in S$ and $y_{i,j} \in \mathbf{y}$, the $(h, y_{i,j})$-th entry of C is 1 if $h(i) = j$. (It is argued in Claim 39 in [24] that $|\det(C)|$ is a power of d). Compute the inverse of $\det(C)$ in $\mathbb{Z}_{|\mathbb{F}|-1}$ and denote it by γ. (Note that $\mathbf{y}$ does not contain the variables $\{y_{1,0}, \ldots, y_{d-1,0}\}$.)
4. Fix $\alpha_{i,j} \in \{\alpha_{0,0}, \ldots, \alpha_{d-1,d-1}\} \setminus \{\alpha_{1,0}, \ldots, \alpha_{d-1,0}\}$ arbitrarily. For every $h \in S$, compute the minor of C with respect to the row and column indexed by h and $y_{i,j}$ respectively and call it δ_h. Set $\alpha_{i,j} = \prod_{h \in S} c_h^{(\delta_h \cdot \gamma) \mod (|\mathbb{F}|-1)}$.
5. Set $B = \text{diag}(\alpha_{0,0}, \ldots, \alpha_{d-1,d-1})$. Return B. (see Claim 35)

7 Few problems

In conclusion, we state a few problems on the NW polynomial which, if resolved, would shed more light on this fundamental polynomial family.

1. Is the $\mathcal{NW} = \{\mathsf{NW}_{d,k} : d \text{ is a prime}\}$ family VNP-complete for a suitable choice of k (say, $k = d^{\epsilon}$ for a constant $\epsilon > 0$)?
2. Is there an efficient algorithm to check if $\mathsf{NW}(\mathbf{a}) = 0$ at a given point $\mathbf{a} \in \{0,1\}^n$? This problem was also posed in [6] [12].
3. Is there an efficient general equivalence test for NW? Theorem 4 may turn out to be a vital ingredient in such a test.
4. Give a complete description of the permutation symmetries of NW. Are all the permutation symmetries captured in Lemma 45 mentioned in Section D in [24]?

For the permanent polynomial, the solutions to these problems are well known.

Abstract

For every graph class $\mathcal{F}$, let $\textsc{HomInd}(\mathcal{F})$ be the problem of deciding whether two given graphs are homomorphism-indistinguishable over $\mathcal{F}$, i.e., for every graph F in $\mathcal{F}$, the number $\mathsf{hom}(F, G)$ of homomorphisms from F to G equals the corresponding number $\mathsf{hom}(F, H)$ for H. For several natural graph classes (such as paths, trees, bounded treewidth graphs), homomorphism-indistinguishability over the class has an efficient structural characterization, resulting in polynomial time solvability [6].

In particular, it is known that two non-isomorphic graphs are homomorphism-indistinguishable over the class $\mathcal{T}_k$ of graphs of treewidth k if and only if they are not distinguished by k-dimensional Weisfeiler-Leman algorithm, a central heuristic for isomorphism testing: this characterization implies a polynomial time algorithm for $\textsc{HomInd}(\mathcal{T}_k)$, for every fixed $k \in \mathbb{N}$. In this paper, we show that there is a polynomial-time-decidable class $\mathcal{F}$ of undirected graphs of *bounded* treewidth such that $\textsc{HomInd}(\mathcal{F})$ is undecidable.

Our second hardness result concerns the class $\mathcal{K}$ of complete graphs. We show that $\textsc{HomInd}(\mathcal{K})$ is co-NP-hard, and in fact, we show completeness for the class $\mathsf{C}_{=}\mathsf{P}$ (under P-time Turing reductions). On the algorithmic side, we show that $\textsc{HomInd}(\mathcal{P})$ can be solved in polynomial time for the class $\mathcal{P}$ of directed paths. We end with a brief study of two variants of the $\textsc{HomInd}(\mathcal{F})$ problem: (a) the problem of lexographic-comparison of homomorphism numbers of two graphs, and (b) the problem of computing certain distance-measures (defined via homomorphism numbers) between two graphs.

1 Introduction

A classic theorem due to Lovász [12] states that two graphs G, H are isomorphic if and only if for every graph F the number $\mathsf{hom}(F, G)$ of homomorphisms from F to G is equal to the number $\mathsf{hom}(F, H)$ of homomorphisms from F to H. Jointly with Dell, the last two authors of this paper recently proved [6] that two graphs are fractionally isomorphic, or equivalently, can be distinguished by the colour refinement algorithm (see e.g. [8]), if and only if for every tree T it holds that $\mathsf{hom}(T, G) = \mathsf{hom}(T, H)$. Another well-known fact (see e.g. [20]) is that

two graphs are co-spectral, that is, their adjacency matrices have the same sequence of eigenvalues, if and only if for every cycle C it holds that $\mathsf{hom}(C,G) = \mathsf{hom}(C,H)$. Thus counting homomorphisms from all graphs in some class gives us very interesting equivalence relations, which we call homomorphism indistinguishability: for every class $\mathcal{F}$ of graphs, two graphs G, H are *homomorphism-indistinguishable over* $\mathcal{F}$ (for short: $\mathcal{F}$*-HI*) if and only if for every $F \in \mathcal{F}$ it holds that $\mathsf{hom}(F,G) = \mathsf{hom}(F,H)$.[1] Thus two graphs are $\mathcal{G}$-HI for the class $\mathcal{G}$ of all graphs if and only if they are isomorphic. They are $\mathcal{T}$-HI for the class $\mathcal{T}$ of trees if and only if they are fractionally isomorphic, and they are $\mathcal{C}$-HI for the class $\mathcal{C}$ of cycles if and only if they are co-spectral. We have also proved in [6] that for every k, two graphs are $\mathcal{T}_k$-HI for the class $\mathcal{T}_k$ of all graphs of tree width at most k if and only if the k-dimensional Weisfeiler-Leman algorithm does not distinguish them, and we gave a characterisation of $\mathcal{P}$-HI for the class $\mathcal{P}$ of paths in terms of a natural system of linear equations. Furthermore, the first author of this paper recently proved that two directed graphs are $\mathcal{A}$-HI for the class $\mathcal{A}$ of all directed acyclic graphs if and only if they are isomorphic [3] (also see [13]).

It follows from these results that the problem of deciding whether two graphs are homomorphism-indistinguishable over some class has a quite interesting complexity theoretic behaviour. For every class $\mathcal{F}$ of graphs, let $\textsc{HomInd}(\mathcal{F})$ be the problem of deciding whether two given graphs are $\mathcal{F}$-HI. Since the graph isomorphism problem is in solvable in quasipolynomial time [2], $\textsc{HomInd}(\mathcal{G})$ is in quasipolynomial time. Furthermore, it is an immediate consequence of the characterisations above that $\textsc{HomInd}(\mathcal{T})$, $\textsc{HomInd}(\mathcal{C})$, $\textsc{HomInd}(\mathcal{P})$, and $\textsc{HomInd}(\mathcal{T}_k)$ for all $k \geq 1$ are in polynomial time. This prompts the question whether $\textsc{HomInd}(\mathcal{F})$ is in quasipolynomial time, or even in polynomial time, for every class $\mathcal{F}$ of graphs. While this seems unlikely, it is not obvious what complexities one might expect for $\textsc{HomInd}(\mathcal{F})$ as $\mathcal{F}$ ranges over all classes of graphs. We study these and related questions here.

Homomorphism counts give us embeddings of graphs into an infinite dimensional vector space: for a class $\mathcal{F}$, we can associate with every graph G a *homomorphism vector* $\mathsf{Hom}_{\mathcal{F}}(G) := \big(\mathsf{hom}(F,G) \bigm| F \in \mathcal{F}\big) \in \mathbb{R}^{\mathcal{F}}$. Then $\textsc{HomInd}(\mathcal{F})$ is simply the problem of deciding whether two graphs have the same homomorphism vector. Defining a metric or, even better, an inner product on the range vector space, we obtain a (pseudo-)metric on the class of all graphs (where two non-isomorphic graphs may have distance 0). We will also study the problem of approximately computing the distance between two graphs with respect to metrics obtained this way. Such metrics are important for machine learning tasks such as clustering and classification on graphs. In fact, homomorphism vectors are closely related to the so-called graph kernels (see, e.g. [16, 17, 21]): almost all such graph kernels are defined as the inner products of homomorphism vectors for natural graph classes. Thus our results shed some new light on the complexity of computing these kernels.

At first sight, $\textsc{HomInd}(\mathcal{F})$ looks like a problem in $\mathsf{co\text{-}NP}$: to witness that G and H are not $\mathcal{F}$-HI we just have to nondeterministically guess one $F \in \mathcal{F}$ and verify that $\mathsf{hom}(F,G) \neq \mathsf{hom}(F,H)$. But this argument is flawed for several reasons. First of all, it assumes that for given F, G we can compute $\mathsf{hom}(F,G)$ in polynomial time, which in general is not the case. Let $\#\textsc{Hom}(\mathcal{F})$ be the problem of computing $\mathsf{hom}(F,G)$, given $F \in \mathcal{F}$ and G. Then for the class $\mathcal{G}$ of all graphs, $\#\textsc{Hom}(\mathcal{G})$ is $\#\mathsf{P}$-complete. Under the complexity assumption that $\#\mathsf{W[1]} \neq \mathsf{FPT}$, it is known that $\#\textsc{Hom}(\mathcal{F})$ is in P if and only if $\mathcal{F}$ has bounded tree

[1] We note that homomorphism indistinguishability is incomparable to homomorphic equivalence; remember that two graphs G, H are *homomorphically equivalent* if there is a homomorphism from G to H and a homomorphism from H to G.

width [5]. This result extends to directed graphs and in fact all classes of relational structures of bounded arity. But even for $\mathcal{F}$ with tractable $\#\textsc{Hom}(\mathcal{F})$, the problem $\textsc{HomInd}(\mathcal{F})$ is not necessarily in co-NP, because the witness F may be very large compared to G and H.

▶ **Theorem 1.** *There is a polynomial-time-decidable class $\mathcal{F}$ of undirected graphs of bounded tree width such that $\textsc{HomInd}(\mathcal{F})$ is undecidable.*

We also prove a version of the above theorem for directed graphs (Theorem 15): the graphs in the corresponding class $\mathcal{F}$ are just directed paths padded by isolated vertices. And we cannot only prove undecidability, but also use similar arguments to obtain all kinds of complexities. So the complexity landscape for problems $\textsc{HomInd}(\mathcal{F})$, which started out in quasi-polynomial time, looks fairly complicated. But admittedly the classes $\mathcal{F}$ we can use to prove Theorem 1 are quite esoteric from a graph theoretic point of view. What about "natural" graph classes? For the class $\mathcal{K}$ of all complete graphs, the corresponding problem $\textsc{HomInd}(\mathcal{K})$ turns out to be hard.

▶ **Theorem 2.** $\textsc{HomInd}(\mathcal{K})$ *is* co-NP*-hard.*

For an upper bound, note that $\textsc{HomInd}(\mathcal{K}) \in \mathsf{P}^{\#\mathsf{P}}$, because to decide whether for two n-vertex graphs G, H it holds that $\mathsf{hom}(K, G) = \mathsf{hom}(K, H)$ for all complete graphs K, we only need to check the equality for all K of size at most n. Actually, we pinpoint the exact complexity of $\textsc{HomInd}(\mathcal{K})$ by proving it to be complete for the complexity class $\mathsf{C}_=\mathsf{P}$ (see Theorem 18). This implies that $\textsc{HomInd}(\mathcal{K})$ is not in the polynomial hierarchy PH unless PH collapses (see Corollary 22).

We also look at tractable cases of the homomorphism indistinguishability problem. In particular, we prove that $\textsc{HomInd}(\mathcal{P}_\rightarrow)$ is in P for the class $\mathcal{P}_\rightarrow$ of directed paths (see Theorem 23).

In the last section we look at variants of $\textsc{HomInd}(\mathcal{F})$. A first such variant is the problem $\textsc{HomLex}(\mathcal{F})$ of lexicographically comparing the homomorphism vectors over $\mathcal{F}$ of two input graphs. Of course the lexicographical order depends on some order of the graphs in $\mathcal{F}$; the simple classes $\mathcal{F}$ we consider (directed paths and cycles as well as complete graphs) have only one graph per size, and we can use the natural order by size. We prove that $\textsc{HomLex}(\mathcal{P}_\rightarrow)$ and $\textsc{HomLex}(\mathcal{C}_\rightarrow)$ are in polynomial time for the classes $\mathcal{P}_\rightarrow$ and $\mathcal{C}_\rightarrow$ of directed paths and cycles and that $\textsc{HomLex}(\mathcal{K})$ is #P-complete.

Finally, we study the problem of computing the distance between two graphs with respect to various metrics defined on the homomorphism vectors $\mathsf{Hom}_{\mathcal{F}}(G)$. We prove that if $\mathcal{F}$ is a polynomial time enumerable class of graphs for which $\#\textsc{Hom}(\mathcal{F})$ is in polynomial time then the distance between two graphs can be approximated up to an arbitrarily small additive error ε in polynomial time. This is not a deep result, but we believe it is quite relevant, because computing distances between graphs (even approximately) with respect to various distance measures tends to be a very hard algorithmic problem (e.g. [1, 9, 11, 14, 15]). Here we have a family of natural metrics for which it is tractable.

2 Preliminaries

Directed Graphs. A directed graph (or digraph) G consists of a finite set of vertices $V(G)$ (or V_G) and a set of edges $E(G) \subseteq V \times V$. A subgraph H of a directed graph G is a graph satisfying $V_H \subseteq V_G$ and $E_H \subseteq E_G \cap (V_H \times V_H)$. We assume familiarity with the basic terminology from graph theory, e.g., path, cycle etc., which can be found in e.g., [7]. Given two digraphs G and H, a homomorphism from G to H is an edge-preserving mapping from $V(G)$ to $V(H)$, i.e., a mapping $\varphi : V_G \to V_H$ such that its natural extension to $V_G \times V_G$ satisfies $\varphi(E_G) \subseteq E_H$.

A set X of vertices of a directed graph G is a *clique* if for all distinct $x, y \in X$, either $(x, y) \in E(G)$ or $(y, x) \in E(G)$. For every $k \geq 1$, let $c_k(G)$ be the number of cliques of size k in G. For every directed graph G and every $k \geq 1$, let $d_k(G)$ be the number of directed paths of length $k - 1$ in G. We call a directed graph P a *partial order* if it is acyclic and the edge relation is transitive. Observe that if P is a partial order then the edge relation induces a linear order on every clique. Furthermore, a subgraph Q of P is a directed path if and only if $V(Q)$ is a clique in P. Thus for every $k \geq 1$ we have $c_k(P) = d_k(P)$.

Denote $\mathsf{hom}(G, H)$ to be the number of homomorphisms from G to H. For a class $\mathcal{F}$ of graphs and a graph G, the *homomorphism vector of G over $\mathcal{F}$* is

$$\mathsf{Hom}_{\mathcal{F}}(G) := \big(\mathsf{hom}(F, G) \bigm| F \in \mathcal{F}\big).$$

Undirected Graphs. The notions of subgraph, homomorphisms and homomorphism vector have analogous standard definitions in the undirected case. Denote the edge $\{u, v\}$ of an undirected graph as uv. Let K_k denote the undirected k-clique, i.e. the graph defined by $V(G) = [k]$ and $E(G) = \binom{[k]}{2}$.

▶ **Definition 3.** *Let G, H be two undirected graphs. The product graph $G \otimes H$ is defined by*

$$V(G \otimes H) := V(G) \times V(H),$$
$$E(G \otimes H) := \big\{\{(u, v), (u', v')\} \bigm| uu' \in E(G) \text{ and } vv' \in E(H)\big\}.$$

Let G, H be two graphs, and $k \geq 1$. The following folklore lemma states that the homomorphism numbers are multiplicative for the above-mentioned product operation.

▶ **Lemma 4.** *For every graph F, $\mathsf{hom}(F, G \otimes H) = \mathsf{hom}(F, G) \cdot \mathsf{hom}(F, H)$.*

It is well-known that for every $k \in \mathbb{N}$ and every graph G, $c_k(G) = \frac{\mathsf{hom}(K_k, G)}{k!}$.

▶ **Corollary 5.** *$c_k(G \otimes H) = k! \cdot c_k(G) \cdot c_k(H)$.*

The following construction will be useful later.

▶ **Proposition 6.** *Let n, ℓ, k be fixed positive integers such that $k \leq n$ and $\ell \leq \binom{n}{k}$. In time poly(n), we can construct a graph P satisfying $c_k(P) = \ell$.*

Proof. Let

$$n_1 := \max\left\{n' \,\middle|\, n' \geq k \text{ and } \binom{n'}{k} \leq \ell\right\}, \quad i_1 := \max\left\{i \,\middle|\, i \cdot \binom{n_1}{k} \leq \ell\right\}.$$

Clearly, $k \leq n_1 \leq n$ and $1 \leq i_1$, and both can be computed in time poly(n). Moreover, the remainder

$$\ell' := \ell - i_1 \cdot \binom{n_1}{k} < \ell$$

satisfies $0 \leq \ell' < \binom{n_1}{k}$. An exhaustive application of this rule ensures the existence of numbers $1 \leq s \leq n$, $1 \leq i_1, \ldots, i_s$, and $n_s < n_{s-1} < \cdots < n_1 \leq n$ such that

$$\ell = i_1 \cdot \binom{n_1}{k} + \cdots + i_s \cdot \binom{n_s}{k}.$$

Moreover, all $i_1, \ldots, i_s$ and $n_1, \ldots, n_s$ can be computed in time poly(n). Finally, the desired graph P consists of i_1 disjoint copies of K_{n_1}, i_2 disjoint copies of K_{n_2}, and so on. Clearly, $c_k(P) = \ell$ by our construction. ◀

Cayley-Hamilton. The famous Cayley-Hamilton theorem states that the substitution of a matrix in its characteristic polynomial results in the zero matrix. Formally, let $A \in \mathbb{F}^{n \times n}$ be a square matrix over a field $\mathbb{F}$.

▶ **Theorem 7** (Cayley-Hamilton). *Let $p(\lambda) = \det(\lambda I_n - A)$ denote the characteristic polynomial of A. Then, $p(A) = 0$.*

Let $\operatorname{sum}(A)$ denote the sum of all entries of A. Recall that the trace of a matrix A, denoted by $\operatorname{tr}(A)$, is the sum of diagonal entries of A. The following lemma is standard.

▶ **Lemma 8.** *Let $A = A(G)$ be the adjacency matrix of a digraph G and $k \geq 1$. The number of walks of length k in A is equal to $\operatorname{sum}(A^k)$. Equivalently, $\operatorname{sum}(A^k) = \mathsf{hom}(P_k, G)$.*

Similarly, the number of closed walks of length k in G is equal to $\operatorname{tr}(A^k)$. Equivalently, $\operatorname{tr}(A^k) = \mathsf{hom}(C_k, G)$.

The following is a consequence of the Cayley-Hamilton theorem and is utilised in Section 6 for our tractability result regarding $\textsc{HomInd}(\mathcal{P}_{\rightarrow})$ for the class $\mathcal{P}_{\rightarrow}$ of directed paths.

▶ **Corollary 9.** *Let $A \in \mathbb{F}^{n \times n}$. There exist $a_1, \dots, a_n \in \mathbb{R}$ such that for every $\ell \geq 0$*

$$A^{n+\ell} = \sum_{i \in [n]} a_i A^{i+\ell-1}.$$

Thus

$$\operatorname{sum}(A^{n+\ell}) = \sum_{i \in [n]} a_i \cdot \operatorname{sum}(A^{i+\ell-1}) \quad \textit{and} \quad \operatorname{tr}(A^{n+\ell}) = \sum_{i \in [n]} a_i \cdot \operatorname{tr}(A^{i+\ell-1}).$$

3 Combinatorial Constructions

Theorem 10 presents our main construction, which is at the heart of both our undecidability results in Section 4 and our hardness results in Section 5. Essentially, for an arbitrary $k \geq 1$, we construct two partial orders that have the same number of directed paths on i vertices for every $i \geq 1$ except for $i = k$. Hence, these partial orders are distinguished by the directed path of length $k - 1$ but not by any other directed path.

▶ **Theorem 10.** *For every $k \geq 1$, there are partial orders P_k, Q_k of order $|P_k|, |Q_k| \leq \max\{1, 2(k-1)\}$ such that*

$$\begin{aligned} d_i(P_k) &= d_i(Q_k) && \textit{for } 1 \leq i \leq k-1, && (1)\\ d_k(P_k) &= 1, \quad d_k(Q_k) = 0, && && (2)\\ d_i(P_k) &= d_i(Q_k) = 0 && \textit{for all } i > k. && (3) \end{aligned}$$

Proof. For a directed graph G, a set $X \subseteq V(G)$, and a fresh vertex $x \notin V(G)$, let $G \triangleright_X x$ be the graph obtained from G by adding vertex x and edges from all vertices in X to x. Formally, $V(G \triangleright_X x) := V(G) \cup \{x\}$ and $E(G \triangleright_X x) := E(G) \cup \{(x', x) \mid x' \in X\}$.

Let us describe the construction of the directed graphs P_k, Q_k. Let v_i for $i \geq 1$ and w_i for $i \geq 2$ be fresh vertices. Let

$$\begin{aligned} V_1 &:= \{v_1\}, & P_1 &:= (V_1, \emptyset),\\ W_1 &:= \emptyset, & Q_1 &:= (W_1, \emptyset),\\ V_2 &:= \{v_1, v_2\}, & P_2 &:= \big(\{V_2, \{(v_1, v_2)\}\big),\\ W_2 &:= \{v_1, w_2\} & Q_2 &:= \big(W_2, \emptyset\big), \end{aligned}$$

and for $k \geq 2$, noting that $W_{k-1} \subseteq V_k$ and $V_{k-1} \subseteq W_k$, let

$$\begin{aligned} V_{k+1} &:= V_k \cup \{v_{k+1}, w_k\}, & P_{k+1} &:= (P_k \triangleright_{V_k} v_{k+1}) \triangleright_{W_{k-1}} w_k, \\ W_{k+1} &:= W_k \cup \{v_k, w_{k+1}\}, & Q_{k+1} &:= (Q_k \triangleright_{W_k} w_{k+1}) \triangleright_{V_{k-1}} v_k. \end{aligned}$$

Figure 1 illustrates the construction for $1 \leq k \leq 4$.

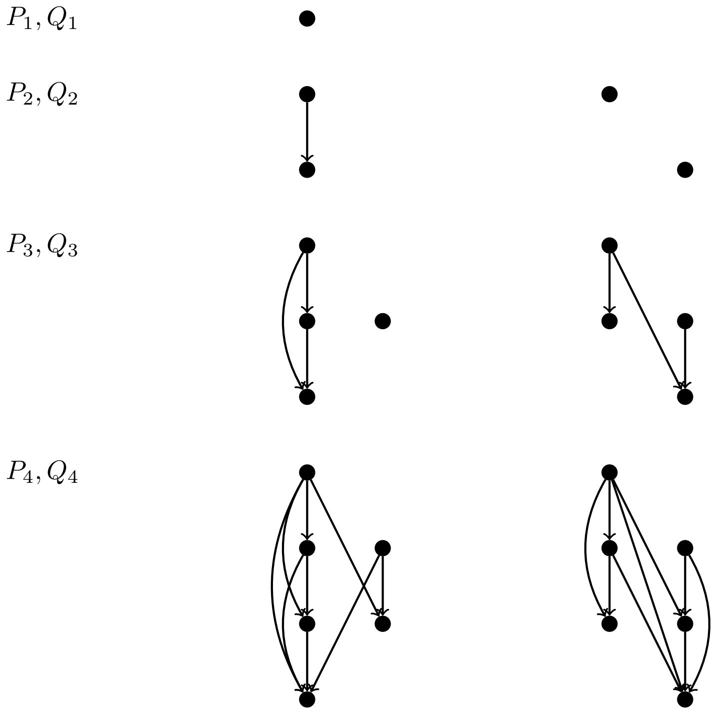

Figure 1 The graphs P_k, Q_k for $k = 1, \dots, 4$.

Note that both P_k and Q_k are directed acyclic graphs. Obviously, we have $|V_k|, |W_k| \leq \max\{1, 2(k-1)\}$ for all k. By $G[X]$, we denote the induced subgraph of a set X in a graph G. Observe that for all $\ell \geq k \geq 1$ we have $P_\ell[X] = P_k[X]$ for all $X \subseteq V_k$ and $Q_\ell[Y] = Q_k[Y]$ for all $Y \subseteq W_k$.

▷ Claim 11. For all $\ell > k \geq 1$ it holds that $P_\ell[W_k] = Q_k$ and $Q_\ell[V_k] = P_k$.

Proof. It suffices to prove the claim for $\ell = k+1$. The proof is by induction on k. For $k = 1, 2$, the assertion is immediate from Figure 1. For the inductive step, let $k \geq 2$. By the induction hypothesis, we have $P_k[W_{k-1}] = Q_{k-1}$. To construct Q_k from Q_{k-1}, we add the vertex w_k and edges from all vertices in W_{k-1} to w_k. Moreover, we add v_{k-1} and edges from all vertices in V_{k-2} to v_{k-1}. Both of these vertices and all these edges are present in P_{k+1}:

- v_{k-1} and edges from all vertices in V_{k-2} to v_{k-1} have already been added in the transition from P_{k-2} to P_{k-1};
- w_k and edges from all vertices in W_{k-1} to w_k are added in the transition from P_k to P_{k+1}.

Thus $P_{k+1}[W_k] = Q_k$. The argument that $Q_{k+1}[V_k] = P_k$ is similar. ◁

Since $V_{k+1} = V_k \cup W_k \cup \{v_{k+1}\}$ and $W_{k+1} = V_k \cup W_k \cup \{w_{k+1}\}$, a consequence of this claim is that

$$P_{k+1} \cap Q_{k+1} = P_{k+1} \setminus \{v_{k+1}\} = Q_{k+1} \setminus \{w_{k+1}\} = P_k \cup Q_k. \tag{4}$$

▷ Claim 12. The edge relations of P_k and Q_k are transitive.

Proof. This follows by induction from (4), because v_k and w_k have out-degree 0 in P_k, Q_k, respectively. ◁

Thus P_k and Q_k are partial orders.

▷ Claim 13. For all graphs G and all subsets $X \subseteq G$ we have

$$c_1\big(G \triangleright_X x\big) = c_1(G) + 1, \tag{5}$$

$$c_i\big(G \triangleright_X x\big) = c_i(G) + c_{i-1}\big(G[X]\big) \qquad \text{for } i \geq 2. \tag{6}$$

Proof. Straightforward. ◁

Thus for $k \geq 2$ and $i \geq 2$ we have

$$c_i(P_{k+1}) = c_i(P_k) + c_{i-1}(P_k) + c_{i-1}(Q_{k-1}) \tag{7}$$

and similarly

$$c_i(Q_{k+1}) = c_i(Q_k) + c_{i-1}(Q_k) + c_{i-1}(P_{k-1}). \tag{8}$$

Now we prove (1)-(3) by induction on k. We have already noted that it holds for $k = 1, 2$. For the inductive step, let $k \geq 2$ and $i \geq 1$.

Case 1: $i = 1$. We have $c_1(P_{k+1}) = |V_{k+1}| = 2k = |W_{k+1}| = c_1(Q_{k+1})$.

Case 2: $2 \leq i \leq k-1$. We have $c_i(P_k) = c_i(Q_k)$, $c_{i-1}(P_k) = c_{i-1}(Q_k)$ and $c_{i-1}(P_{k-1}) = c_{i-1}(Q_{k-1})$ by the induction hypothesis, and by (7) and (8) this implies $c_i(P_{k+1}) = c_i(P_{k+1})$.

Case 3: $i = k$. We have $c_i(P_k) = c_i(Q_k) + 1$ and $c_{i-1}(P_k) = c_{i-1}(Q_k)$ and $c_{i-1}(P_{k-1}) = c_{i-1}(Q_{k-1}) + 1$ by the induction hypothesis. Thus by (7) and (8),

$$\begin{aligned} c_i(P_{k+1}) &= c_i(P_k) + c_{i-1}(P_k) + c_{i-1}(Q_{k-1}) \\ &= c_i(Q_k) + 1 + c_{i-1}(Q_k) + c_{i-1}(P_{k-1}) - 1 = c_i(Q_{k+1}), \end{aligned}$$

which completes the proof of (1).

Case 4: $i = k+1$. We have $c_i(P_k) = c_i(Q_k) = 0$ and $c_{i-1}(P_k) = 1, c_{i-1}(Q_k) = 0$ and $c_{i-1}(P_{k-1}) = c_{i-1}(Q_{k-1}) = 0$ by the induction hypothesis. Thus by (7) and (8),

$$\begin{aligned} c_i(P_{k+1}) &= c_i(P_k) + c_{i-1}(P_k) + c_{i-1}(Q_{k-1}) = 1, \\ c_i(Q_{k+1}) &= c_i(Q_k) + c_{i-1}(Q_k) + c_{i-1}(P_{k-1}) = 0. \end{aligned}$$

This proves (2).

Case 5: $i \geq k+2$. We have $c_i(P_k) = c_i(Q_k) = c_{i-1}(P_k) = c_{i-1}(Q_k) = c_{i-1}(P_{k-1}) = c_{i-1}(Q_{k-1}) = 0$ by the induction hypothesis. Thus by (7) and (8), $c_i(P_{k+1}) = c_i(Q_{k+1}) = 0$. This proves (3).

Now assertions (1)–(3) follow, because for partial orders G we have $c_k(G) = d_k(G)$ for all $k \geq 1$. ◀

As the construction of Theorem 10 yields partial orders, for which directed path counts and clique counts are the same, we also obtain an undirected version for clique counts with Corollary 14.

▶ **Corollary 14.** *For every $k \geq 1$ there are undirected graphs G_k, H_k of order $|G_k|, |H_k| \leq \max\{1, 2(k-1)\}$ such that*

$$c_i(G_k) = c_i(H_k) \qquad \textit{for } 1 \leq i \leq k-1, \tag{9}$$

$$c_k(G_k) = 1, \quad c_k(H_k) = 0, \tag{10}$$

$$c_i(G_k) = c_i(H_k) = 0 \qquad \textit{for all } i > k. \tag{11}$$

Proof. Let G_k, H_k be the undirected graphs underlying the partial orders P_k, Q_k of Theorem 10. ◀

We also show how to generalise Theorem 10 and Corollary 14 such that number of directed paths of length $k-1$ and the number of cliques of size k in these graphs, respectively, can freely be chosen. The exact statements and their proofs can be found in the full version of the paper.

4 Undecidability Results

We proceed to derive undecidability results for HomInd($\mathcal{F}$) using the combinatorial constructions of Section 3. Before we prove our main theorem (Theorem 1), the following version for the case of directed graphs will be necessary.

▶ **Theorem 15.** *There is a polynomial time decidable class $\mathcal{F}$ of directed graphs of tree width 1 such that* HomInd($\mathcal{F}$) *is undecidable.*

Proof. Let us fix some Gödel numbering of deterministic Turing machines such that M_j denotes the machine with Gödel number j. For every pair $(j, t) \in \mathbb{N}^2$, let $F_{j,t}$ be the graph that is the disjoint union of a directed path $P^{\to}_{j+1}$ of length $(j+1)$ and an independent set of size t. Let $\mathcal{F}$ be the class of all graphs $F_{j,t}$ such that M_j halts in t steps when started on the empty input word. Clearly, $\mathcal{F}$ is decidable in polynomial time.

Observe that for every graph G and all $j, t \in \mathbb{N}$ we have

$$\mathsf{hom}(F_{j,t}, G) = \mathsf{hom}(P_{j+1}, G) \cdot |G|^t. \tag{12}$$

Let G_k, H_k be the graphs constructed in Theorem 10. It is easy to note that $\mathsf{hom}(F_{0,t}, G_1) = 1 \neq 0 = \mathsf{hom}(F_{0,t}, H_1)$ and $\mathsf{hom}(F_{j,t}, G_1) = \mathsf{hom}(F_{j,t}, H_1) = 0$ for $j \geq 1$. For $k \geq 2$, recall that $|G_k| = |H_k| = 2(k-1)$ and that $\mathsf{hom}(P^{\to}_j, G_k) = \mathsf{hom}(P^{\to}_j, H_k)$ if and only if $j \neq k$. Thus it follows from (12) that for all j, t we have

$$\mathsf{hom}(F_{j,t}, G_k) \neq \mathsf{hom}(F_{j,t}, H_k) \iff j = k-1. \tag{13}$$

This implies

$$\begin{aligned} \mathsf{Hom}_{\mathcal{F}}(G_k) \neq \mathsf{Hom}_{\mathcal{F}}(H_k) &\iff F_{(k-1),t} \in \mathcal{F} \text{ for some } t \in \mathbb{N} \\ &\iff M_{k-1} \text{ halts on the empty input word.} \end{aligned}$$

This proves that HomInd($\mathcal{F}$) is undecidable. Since every graph in $\mathcal{F}$ is a directed path with some padded isolated vertices, the treewidth of $\mathcal{F}$ is 1. Hence, proved. ◀

The above proof can be easily modified to invoke Corollary 14 instead of Theorem 10, which yields the following corollary.

▶ **Corollary 16.** *There is a polynomial time decidable class $\mathcal{F}$ of undirected graphs such that* HomInd($\mathcal{F}$) *is undecidable.*

In particular, every graph in this class of undirected graphs is a clique (padded with isolated vertices), and therefore, this class has unbounded treewidth. Our main theorem, Theorem 1, is a sharper version of the above corollary.

4.1 Proof of Theorem 1

The proof of Theorem 1 is obtained by replacing the directed graphs $F_{j,t}, G_k, H_k$ (constructed in the proof of Theorem 15) by their suitably-defined undirected versions $\widetilde{F}_{j,t}, \widetilde{G}_k, \widetilde{H}_k$. The two key requirements of this transformation are (a) the homomorphism numbers are preserved, i.e., $\mathsf{hom}(F_{j,t}, G_k) = \mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{G}_k)$ and $\mathsf{hom}(F_{j,t}, H_k) = \mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{H}_k)$, and (b) the treewidth of the transformed graphs is bounded. To satisfy these properties, we devise suitable gadgets to encode the direction of an edge: our gadgets employ homomorphically incomparable Kneser graphs in order to control the homomorphism numbers of the resulting undirected graphs. The end result of our gadget construction is the following technical lemma (note that our construction there does not exploit any special properties of the present graphs and works for arbitrary directed graphs). The proof is deferred to the full version of the paper.

Let $\mathcal{F}$ be the class of all directed graphs $F_{j,t}$ arising in the proof of Theorem 15, such that $\textsc{HomInd}(\mathcal{F})$ is undecidable.

▶ **Lemma 17.** *Given graphs $F_{j,t}, G_k, H_k$ (constructed in the proof of Theorem 15), we can construct corresponding undirected graphs $\widetilde{F}_{j,t}, \widetilde{G}_k, \widetilde{H}_k$ in polynomial time, satisfying the following properties.*

1. *For all $j, t \in \mathbb{N}$ there exists a positive integer $C_{j,t}$ such that for every $k \in \mathbb{N}$,*

$$\mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{G}_k) = C_{j,t} \cdot \mathsf{hom}(F_{j,t}, G_k),$$
$$\mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{H}_k) = C_{j,t} \cdot \mathsf{hom}(F_{j,t}, H_k).$$

2. *There exists a fixed positive integer ℓ such that for every $j, t \in \mathbb{N}$, the graph $\widetilde{F}_{j,t}$ has treewidth at most ℓ.*
3. *Let $\widetilde{\mathcal{F}}$ be the class of all undirected graphs $\widetilde{F}_{j,t}$ such that $F_{j,t} \in \mathcal{F}$. Then $\widetilde{\mathcal{F}}$ is polynomial time decidable.*

From the above lemma, we can deduce Theorem 1 as follows.

Proof of Theorem 1. The proof follows the proof of Theorem 15 closely. By Lemma 17 and Equation 13,

$$\mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{G}_k) \neq \mathsf{hom}(\widetilde{F}_{j,t}, \widetilde{H}_k) \iff j = k - 1. \tag{14}$$

This implies

$$\begin{aligned}\mathsf{Hom}_{\widetilde{\mathcal{F}}}(\widetilde{G}_k) \neq \mathsf{Hom}_{\widetilde{\mathcal{F}}}(\widetilde{H}_k) &\iff \widetilde{F}_{(k-1),t} \in \widetilde{\mathcal{F}} \text{ for some } t \in \mathbb{N}\\ &\iff F_{(k-1),t} \in \mathcal{F} \text{ for some } t \in \mathbb{N}\\ &\iff M_{k-1} \text{ halts on the empty input word.}\end{aligned}$$

This proves that $\textsc{HomInd}(\widetilde{\mathcal{F}})$ is undecidable. By Lemma 17, $\widetilde{\mathcal{F}}$ has bounded treewidth and is polynomial-time-decidable. Hence, proved. ◀

5 Hardness for Cliques

The construction of Corollary 14 allows for a simple proof of the co-NP-hardness of $\textsc{HomInd}(\mathcal{K})$.

Proof of Theorem 2. We reduce the co-NP-hard problem

$$\overline{\textsc{Clique}} = \{(F,k) \mid F \text{ graph without a } k\text{-clique}\}$$

to $\textsc{HomInd}(\mathcal{K})$. To this end, we use Corollary 14 to construct two graphs G_k and H_k in time polynomial in $k \leq n$. Then, the graphs

$$F_1 := F \otimes G_k \quad \text{and} \quad F_2 := F \otimes H_k.$$

can be constructed in time $\text{poly}(n)$. Corollary 5, together with (9)-(11), implies that

$$c_i(F_1) = c_i(F_2) \qquad \text{for } 1 \leq i \leq k-1, \tag{15}$$

$$c_k(F_1) = k! \cdot c_k(F), \quad c_k(F_2) = 0, \tag{16}$$

$$c_i(F_1) = c_i(F_2) = 0 \qquad \text{for all } i > k. \tag{17}$$

Hence, the mapping $F \mapsto (F_1, F_2)$ is the desired polynomial-time many-one reduction as $c_k(F) = 0$ if and only if $c_i(F_1) = c_i(F_2)$ for every $i \geq 1$. ◀

A more refined argument gives us a more precise classification of the complexity of $\textsc{HomInd}(\mathcal{K})$.

▶ **Theorem 18.** $\textsc{HomInd}(\mathcal{K})$ *is complete for* $\mathsf{C_{=}P}$ *under polynomial time Turing reductions.*

The complexity class $\mathsf{C_{=}P}$ was introduced in [18, 22]. Here we use the following equivalent definition from [10].

▶ **Definition 19.** *Let L be a decision problem. Then $L \in \mathsf{C_{=}P}$ if and only if there is a function f in $\#\mathrm{P}$ and a function g computable in polynomial time such that for every instance x of L*

$$x \in L \iff f(x) = g(x).$$

Before giving the proof of Theorem 18, we derive some of its consequences, which shows that $\textsc{HomInd}(\mathcal{K})$ is apparently much harder than co-NP as stated in Theorem 2, and in fact, unlikely to be in the polynomial hierarchy (PH).

It is clear that every problem in $\mathsf{C_{=}P}$ can be decided in polynomial time with an oracle to a problem in #P. The following slightly weak converse is also easy to see (cf. [4], Section 1.2).

▶ **Proposition 20.** $\mathrm{P}^{\#\mathrm{P}} \subseteq \mathrm{NP}^{\mathsf{C_{=}P}}$.

Thus Theorem 18 implies that:

▶ **Corollary 21.** $\mathrm{P}^{\#\mathrm{P}} \subseteq \mathrm{NP}^{\textsc{HomInd}(\mathcal{K})}$.

Combined with renowned Toda's Theorem [19], we conclude that $\textsc{HomInd}(\mathcal{K})$ is above the polynomial hierarchy.

▶ **Corollary 22.** $\textsc{HomInd}(\mathcal{K})$ *is not in* PH, *unless* PH *collapses.*

Now we are ready to prove Theorem 18: the proof is deferred to the full version of the paper.

6 Tractable Cases

▶ **Theorem 23.** $\textsc{HomInd}(\mathcal{F})$ *can be solved in polynomial time for the class* $\mathcal{F}$ *of directed paths.*

The proof of the theorem is deferred to the full version of the paper.

7 Related Problems

For a class of graphs $\mathcal{F}$, let $\mathcal{F}_k$ denote the class of all graphs $F \in \mathcal{F}$ of order k. For classes $\mathcal{F}$ where there is at most one graph $F \in \mathcal{F}$ of order k for every $k \geq 1$, it is only natural to consider the entries $\mathsf{hom}(F, G)$ of a homomorphism vector $\mathsf{Hom}_{\mathcal{F}}(G)$ as sorted by the order of F. Then it becomes possible to compare these vectors using the lexicographical ordering $\leq_\ell$, and for such a class $\mathcal{F}$, we let $\textsc{HomLex}(\mathcal{F})$ denote the following decision problem: given graphs G and H, decide whether $\mathsf{Hom}_{\mathcal{F}}(G) \leq_\ell \mathsf{Hom}_{\mathcal{F}}(H)$.

For the classes of directed paths and directed cycles, the proof of Theorem 23 immediately yields that the corresponding decision problems can be decided in polynomial time as, given graphs G and H with $|V(G)| = |V(H)| = n$, it suffices to consider the first $2n$ paths and n cycles, respectively.

▶ **Theorem 24.** $\textsc{HomLex}(\mathcal{F})$ *can be solved in polynomial time for the class of directed paths and the class of directed cycles.*

For the class of all complete graphs, the hardness of the $\textsc{HomLex}(\mathcal{K})$ is expected.

▶ **Theorem 25.** $\textsc{HomLex}(\mathcal{K})$ *is complete for* $\#\mathrm{P}$ *under polynomial time Turing reductions.*

The proof is deferred to the full version of the paper.

A more interesting direction is to consider the similarity of homomorphism vectors as this induces a measure of similarity on the graphs themselves (see e.g. [13], Lemma 10.22 and Lemma 10.32). It is not clear how exactly the distance of homomorphism vectors should be defined, but some natural candidates are the following:

(a) $$d^1_{\mathcal{F}}(G, H) := \sum_{\substack{k \geq 1 \\ \mathcal{F}_k \neq \emptyset}} \frac{1}{k^k |\mathcal{F}_k|} \sum_{F \in \mathcal{F}_k} |\mathsf{hom}(F, G) - \mathsf{hom}(F, H)|$$

(b) $$d^\infty_{\mathcal{F}}(G, H) := \sum_{\substack{k \geq 1 \\ \mathcal{F}_k \neq \emptyset}} \frac{1}{k^k} \max_{F \in \mathcal{F}_k} |\mathsf{hom}(F, G) - \mathsf{hom}(F, H)|$$

(c) $$d^2_{\mathcal{F}}(G, H) := \sqrt{\sum_{\substack{k \geq 1 \\ \mathcal{F}_k \neq \emptyset}} \frac{1}{k^k |\mathcal{F}_k|} \sum_{F \in \mathcal{F}_k} (\mathsf{hom}(F, G) - \mathsf{hom}(F, H))^2}$$

The scaling by k^k in the definitions is quite arbitrary and ensures that the sums converge: Let G and H be graphs with $|V(G)| \geq |V(H)|$. As the number of homomorphisms from a k-vertex graph to an n-vertex graph is at most n^k, we for example have

$$\sqrt[k]{\frac{1}{k^k |\mathcal{F}_k|} \sum_{F \in \mathcal{F}_k} |\mathsf{hom}(F, G) - \mathsf{hom}(F, H)|} \leq \sqrt[k]{\frac{|V(G)|^k}{k^k}} = \frac{|V(G)|}{k} \xrightarrow{k \to \infty} 0,$$

which implies convergence of the sum in the definition of $d^1_{\mathcal{F}}$ by the root test. Of course, one may also scale by a different factor, e.g., $k!$, and possibly even make it depend on the orders of G and H. It is not hard to see that $d^1_{\mathcal{F}}$, $d^\infty_{\mathcal{F}}$, and $d^2_{\mathcal{F}}$ are pseudometrics on graphs. For $d^2_{\mathcal{F}}$, this follows directly from the fact that it is the pseudometric induced by an inner product on homomorphism vectors proposed by Dell, Grohe, and Rattan [6].

For "simple-enough" classes of graphs, these pseudometrics can be computed up to an arbitrarily small additive error ε in polynomial time in the straightforward way: compute "enough" terms by computing the first graphs in $\mathcal{F}$ and then counting homomorphisms from them one by one. To this end, we call a class of graphs $\mathcal{F}$ polynomial-time enumerable if there is a polynomial-time algorithm that, on input 1^k, outputs all graphs in $\mathcal{F}_k$. Theorem 26 only considers $d^1_{\mathcal{F}}$ for simplicity, but the calculations can directly be adapted to $d^\infty_{\mathcal{F}}$ and $d^2_{\mathcal{F}}$. The proof is deferred to the full version of the paper.

▶ **Theorem 26.** *Let $\mathcal{F}$ be a polynomial-time enumerable class of graphs for which $\#\textsc{Hom}(\mathcal{F})$ is in polynomial time. Then, for every $\varepsilon > 0$, there is a polynomial-time algorithm $D^\varepsilon_{\mathcal{F}}$ that takes two graphs G and H as input and outputs a real number $D^\varepsilon_{\mathcal{F}}(G, H)$ such that $|d^1_{\mathcal{F}}(G, H) - D^\varepsilon_{\mathcal{F}}(G, H)| \leq \varepsilon$ holds for all G and H.*

Among the classes to which Theorem 26 applies are the class $\mathcal{C}$ of all cycles, the class $\mathcal{P}$ of all paths, and for every fixed $d \geq 1$, the class of all complete d-ary trees.

8 Conclusion

We established the rich complexity-theoretic behaviour of the problem $\textsc{HomInd}(\mathcal{F})$ for a variety of graph classes. It was already known that this problem can be solved in polynomial time for the class of paths, trees and bounded treewidth graphs. Our results are complementary: there exist polynomial-time-decidable graph classes for which this problem is undecidable, even though these graph classes satisfy strong structural restrictions (such as bounded treewidth). For the class of complete graphs and directed paths, we also provide tight upper and lower bounds for the complexity of $\textsc{HomInd}(\mathcal{F})$. Our techniques rely on combinatorial constructions of graphs with almost-identical homomorphism vectors: these constructions might be of independent interest.

Perhaps the most interesting direction of further work is the study of graph metrics induced by homomorphism vectors. These metrics induce natural measures of similarity between graphs: such measures serve as an important black-box component for the design of practical graph learning algorithms. Therefore, a better understanding of these metrics will enable a theoretical analysis of practical graph learning tools.

Abstract

We introduce the Scalable ZX-calculus (SZX-calculus for short), a formal and compact graphical language for the design and verification of quantum computations. The SZX-calculus is an extension of the ZX-calculus, a powerful framework that captures graphically the fundamental properties of quantum mechanics through its complete set of rewrite rules. The ZX-calculus is, however, a low level language, with each wire representing a single qubit. This limits its ability to handle large and elaborate quantum evolutions. We extend the ZX-calculus to registers of qubits and allow compact representation of sub-diagrams via binary matrices. We show soundness and completeness of the SZX-calculus and provide two examples of applications, for graph states and error correcting codes.

1 Introduction

The ZX-calculus is an intuitive and powerful graphical language for quantum computing, introduced by Coecke and Duncan [11]. Quantum processes can be represented by ZX-diagrams, which can be seen intuitively as a generalisation of quantum circuits. The language is also equipped with a set of rewrite rules which preserves the represented quantum evolution. Unlike quantum circuits, the ZX-calculus has been proved to be complete for various universal fragments of pure quantum mechanics [26, 23, 27, 28, 43], and also mixed states quantum mechanics [8]. Completeness means that any equality can be derived in this language: if two diagrams represent the same quantum process then they can be transformed one into the other using the rewriting rules of the language. Completeness opens avenues for various applications of the ZX-calculus in quantum information processing, including circuit optimisation [16, 30] – which out-performs all other technics for T-count reductions [34] – error correcting codes [17, 21, 9], lattice surgery [14], measurement-based quantum computing [19, 15, 32] *etc.* Automated tools for quantum reasoning, e.g. Quantomatic [35] and PyZX [33], are also based on the ZX-calculus. The ZX-calculus is also used as intermediate representation in a commercial quantum compiler [12].

The cornerstone of the ZX-calculus is that fundamental properties of quantum mechanics can be captured graphically. The language remains, however, relatively low level: each wire represents a single qubit, a feature that limits the design of larger-scale and more complex quantum procedures. We address in this paper the problem of scalability of the ZX-calculus. In [9], the authors – including one of the present paper – demonstrated that the ZX-calculus can be used in practice to design and verify quantum error correcting codes. They introduced various shortcuts to deal with the scalability of the language: mainly the use of thick wires to represent registers of qubits and matrices to represent sub-diagrams, and hence reason about families of diagrams in a compact way. However, the approach lacked a general theory and fundamental properties like soundness and completeness.

Contributions. We introduce the Scalable ZX-calculus, SZX calculus for short, to provide theoretical foundations to this approach. We extend the ZX-calculus to deal with registers of qubits by introducing some new generators and rewrite rules. We show soundness – i.e. the new generators can be used in a consistent way – as well as completeness of the SZX-calculus. A simple but key ingredient is the introduction of two generators, not present in [9], for dividing and gathering registers of qubits. A wire representing a register of $(n{+}m)$-qubits can be divided into two wires representing respectively n and m qubits. Similarly two registers can be gathered into a single larger one. We also extend the generators of the ZX-calculus so that they can act not only on a single qubit but on a register of qubits. The SZX-calculus is then constructed as a combination of the ZX-calculus and the sub-language made of the divider and the gatherer, by adding the necessary rewrite rules describing how these two sub-languages interact. We show that the SZX-calculus is universal, sound, and complete, providing an intuitive and formal language to represent quantum operations on an arbitrarily large finite number of qubits. The use of the divider and the gatherer allows one to derive inductive (graphical) proofs.

Furthermore, the SZX-calculus provides the fundamental structures – namely the (co)comutative Hopf algebras – to develop a graphical theory of binary matrices, following work on graphical linear algebra [5]. As a consequence, we introduce an additional generator parametrized by a binary matrix together with four simple rewrite rules. Note that, while matrices were also used in [9], we introduce here a more elementary generator acting on a single register (1 input/1 output) rather than two registers (2 inputs/2 outputs). We prove completeness of the SZX-calculus augmented with these matrices. The use of matrices allows a compact representation where subdiagrams can be replaced by matrices. Moreover, basic matrix arithmetic can be done graphically. It makes the SZX-calculus with matrices a powerful tool for formal and compact quantum reasoning.

In section 5, we show the SZX-calculus in action. The main application of the SZX-calculus we consider in this paper is the graph state formalism [24]. We show how graph states can be represented using SZX-diagrams and how some fundamental properties like fixpoint properties, local complementation, and pivoting can be derived in the calculus. We also consider error correcting code examples in order to show that the techniques for the design and verification of codes developed in [9] can be performed smoothly in the SZX-calculus.

Related works. Scalability is crucial in the development of the ZX-calculus and more generally for graphical languages. We review here some contributions in this domain that we briefly compare to our approach.

The !-boxes formalism [31] is a meta language for graphical languages, which has been extensively used in the development of the automated tool Quantomatic. A !-box is a region (subdiagram) of a diagram which can be discarded or duplicated. There is also a first order logic handling families of equations between concrete (i.e. !-box free) diagrams. In contrast, the scalable ZX is not a meta-language but an actual graphical language equipped with an equational theory (namely a coloured PROP). There is no obvious way to compare these two approaches (even in terms of expressive power).

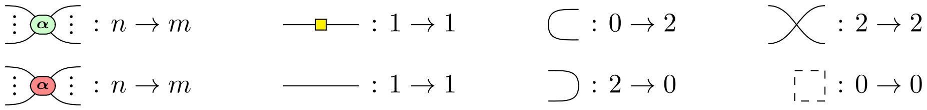
Monoidal multiplexing [10] corresponds to two categorical constructions which allow representing n diagrams in parallel. Roughly speaking, one of the two constructions would be equivalent to the use of big wires for the subclass of SZX-diagrams which are matrix, divider and gatherer-free. It is worth noticing that, to our knowledge, monoidal multiplexing has never been combined with the matrix approach, even though both were developed in the same line of research on graphical linear algebra.

Recently, Miatto [39] has independently introduced a graphical calculus involving matrices, and the equivalent of green spiders, dividers and gatherers. This graphical calculus has been developed in the context of the tensor networks, and the author mainly shows that 6 kinds of matrix products can be represented graphically. We note that the represented matrices do not coincide with the ones we are axiomatising: the matrices represented in Miatto's language correspond to $\mathbb{C}^{2^m\times 2^n}$ matrices whereas ours are in $\mathbb{F}_2^{m\times n}$, hence the equations differ. It is however worth noting that equation Fig.6 in [39] essentially corresponds to the equation governing the interaction between green spiders and the divider given in section 3.3.

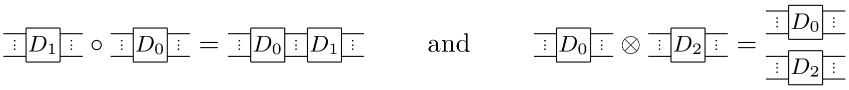
Structure of the paper. We first present the ZX-calculus in section 2, then we introduce the SZX-calculus in section 3, and an axiomatisation of binary matrices for compressing diagrams in section 4. Finally, in section 5, we use the SZX-calculus for error correcting codes and graph states. Full proofs for this paper can be found at arXiv:1905.00041 [7].

2 Background: the ZX-calculus

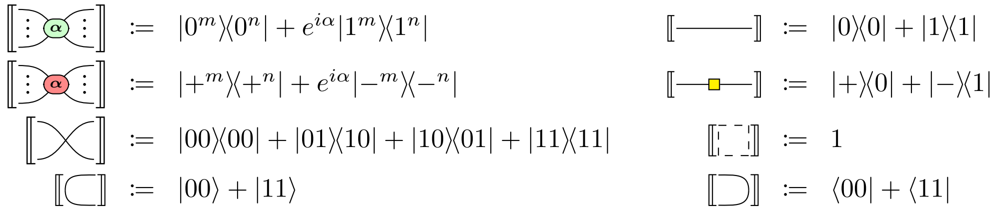
A ZX-diagram $D : k \to \ell$ with k inputs and ℓ outputs is generated by: $\forall n, m \in \mathbb{N}$, $\forall \alpha \in \mathbb{R}$,



and the two compositions: for any ZX-diagrams $D_0 : a \to b$, $D_1 : b \to c$, and $D_2 : c \to d$:



For any n, m, $ZX[n, m]$ is the set of all ZX-diagrams of type $n \to m$. The ZX-diagrams are representing quantum processes: for any ZX-diagram $D : n \to m$ its interpretation $[\![D]\!] \in \mathcal{M}_{2^m\times 2^n}(\mathbb{C})$ is inductively defined as: $[\![D_1 \circ D_0]\!] = [\![D_1]\!] \circ [\![D_0]\!]$, $[\![D_0 \otimes D_2]\!] = [\![D_0]\!] \otimes [\![D_2]\!]$, and



α
$:= \quad |0^m\rangle\langle 0^n| + e^{i\alpha}|1^m\rangle\langle 1^n|$
$:= \quad |0\rangle\langle 0| + |1\rangle\langle 1|$
α
$:= \quad |+^m\rangle\langle +^n| + e^{i\alpha}|-^m\rangle\langle -^n|$
$:= \quad |+\rangle\langle 0| + |-\rangle\langle 1|$
$:= \quad |00\rangle\langle 00| + |01\rangle\langle 10| + |10\rangle\langle 01| + |11\rangle\langle 11|$
$:= \quad 1$
$:= \quad |00\rangle + |11\rangle$
$:= \quad \langle 00| + \langle 11|$

Where $|0\rangle{:=}\binom{1}{0}$, $|1\rangle{:=}\binom{0}{1}$, $|+\rangle{:=}\frac{|0\rangle+|1\rangle}{\sqrt{2}}$, $|-\rangle{:=}\frac{|0\rangle-|1\rangle}{\sqrt{2}}$, $|a^{k+1}\rangle{:=}|a\rangle\otimes|a^k\rangle$, $|a^0\rangle{:=}1$, and $\langle a|{:=}|a\rangle^\dagger$, moreover n and m are respectively the number of inputs and outputs of the spiders.

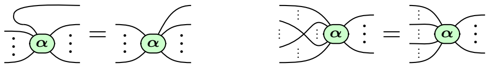
When equal to zero, the angle of the green or red spider is omitted:

ZX-diagrams are *universal* for pure qubit quantum mechanics: $\forall n, m \in \mathbb{N}$, and $\forall M \in \mathcal{M}_{2^n \times 2^m}(\mathbb{C})$, there exists a ZX-diagram $D : n \to m$ such that $[\![D]\!] = M$.

ZX-diagrams also come with a set of graphical rewrite rules, or axioms, which allows one to transform a diagram preserving its interpretation. Some of them are gathered under the *Only Topology Matters* paradigm. When using these we label the equality by top. Two diagrams that can be transformed into each other by moving around the wires are equal. This can be derived from the following rules:

The last set of rule expresses the naturality of the swap; in other words, that all the generators can be passed through wires.

The legs of the spiders of ZX-calculus can be exchanged and bent. This implies that diagrams are essentially graphs with inputs and outputs.



Finally, the rules that are not purely topological are given in Figure 1.

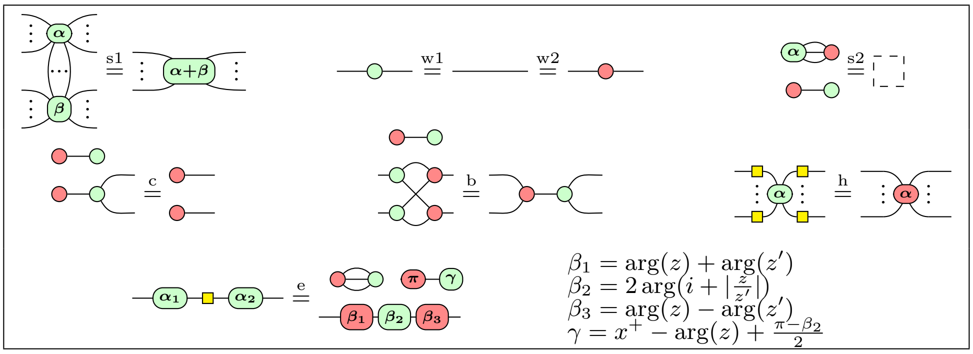


Figure 1 Axioms of the ZX-calculus, where $x^+ := \frac{\alpha_1+\alpha_2}{2}$, $x^- := x^+ - \alpha_2$, $z := -\sin(x^+) + i\cos(x^-)$, $z' := \cos(x^+) - i\sin(x^-)$ and $z' = 0 \Rightarrow \beta_2 = 0$. In the upper left rule, there must be at least one wire between the spiders annotated by α and β. The colour-swapped version of those rules also holds. A label is given to each axiom, above the equals sign, for later reference.

We write $ZX \vdash D = D'$ when D can be transformed into D' using the rules of the ZX-calculus. The rules of the ZX-calculus are sound: for any ZX-diagrams D, D', $ZX \vdash D = D' \Rightarrow [\![D]\!] = [\![D']\!]$ i.e., the rules preserve the interpretation of the language. The language is also complete: for any ZX-diagrams D, D', $[\![D]\!] = [\![D']\!] \Rightarrow ZX \vdash D = D'$ i.e., whenever two diagrams represent the same quantum evolution, we can transform one into the other using the rules of the language [43].

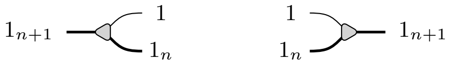
3 The scalable ZX-calculus

In the ZX-calculus, each wire represents a single qubit. Therefore, a system acting on n qubits will be represented by an n-input diagram. This quickly leads to intractable diagrams when it comes to big systems. The extension to the SZX-calculus presented here provides a more compact notation.

3.1 Divide and gather, a calculus for big wires

The input (resp. output) type of a ZX-diagram is its number of input wires, and hence number of input qubits. In the SZX-calculus, wires represent registers of qubits. A wire of type 1_n represents a register of n qubits. A type of the SZX-calculus is then a formal sum of the form $\sum_i 1_{n_i}$, the empty sum being denoted by 0. In other words, the set of types of SZX-calculus is the free monoid over $\mathbb{N}^*$, the set of positive integers. We denote it $\langle \mathbb{N}^* \rangle$. Graphically, we represent the wire of type 1_n by an bold font wires labelled by n[1], a label that is omitted when it is not ambiguous. A normal font wire always denotes a single qubit register of type 1_1. By convention the sum of m wires of type 1_n is denoted m_n with $0_n = m_0 = 0$. n_1 is simply written n. Given a type $a = \sum_i 1_{n_i}$, its size is defined as $S(a) := \sum_i n_i$.

Big wires can be divided into smaller ones and, conversely, can be gathered to form bigger ones. For any $n \in \mathbb{N}$, we introduce two new generators: the *divider* and *gatherer* of size n. They are depicted as follows:



We take the convention that the divider and the gatherer of size 0 are the identity. We define a fragment of the SZX, the wire calculus $\mathbb{W}$.

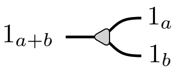
▶ **Definition 1** ($\mathbb{W}$-calculus). *The $\mathbb{W}$-calculus is defined as the graphical language generated by identity wires, the dividers, and the gatherers of any size, and satisfying the elimination rule*  *and the expansion rule* .

The roles of the dividers and gatherers in the equations are perfectly symmetric, so each time something is shown for dividers it also holds for gatherers by symmetry.

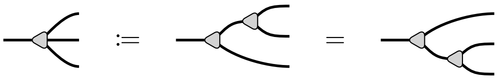
We now show a coherence theorem for scalable calculi: the rewiring theorem. It states that two diagrams of the $\mathbb{W}$-calculus with the same type are equal.

▶ **Theorem 2.** *Let $\omega \in \mathbb{W}[a,b]$ and $\omega' \in \mathbb{W}[c,d]$:* $\quad \mathbb{W} \vdash \omega = \omega' \quad \Leftrightarrow \quad a = c$ *and* $b = d$

This theorem has strong consequences. We can define generalized dividers able to divide any wire of size 1_{a+b} into a wire of size 1_a and a wire of size 1_b.



Those generalized dividers have a unique possible interpretation as diagrams of $\mathbb{W}$-calculus given by their types, and we know exactly the equations they verify: all the well typed ones. In particular, an associativity-like law holds for generalized wires allowing us to define n-ary generalized dividers.



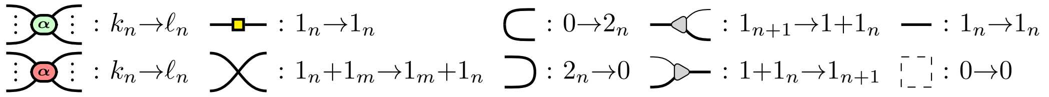
Each time we use the property that any well typed equation in $\mathbb{W}$ is true, we will label the equality by R.

[1] On a blackboard the bold font might be advantageously replaced by struck-out wires.

3.2 The SZX-diagrams

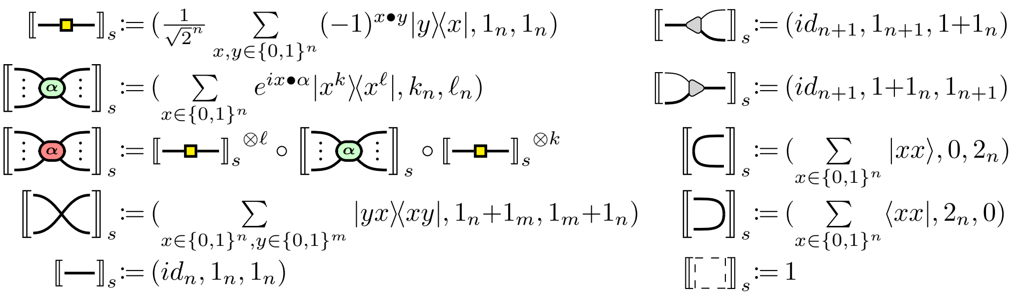
We now fuse the $\mathbb{W}$-calculus and the ZX-calculus into one language: the full SZX-calculus.

The generators of SZX-diagrams are: $\forall n, m \in \mathbb{N}^*, \forall k, \ell \in \mathbb{N}$, $\forall \alpha \in \mathbb{R}^n$,



SZX-generators can be combined using the usual sequential and spacial compositions to form SZX-diagrams. Note that for $n = m = 1$ we recover all the generators of the ZX-calculus. We denote them, as in the ZX-calculus, using thin wires e.g.  for : $1_1 \to 1_1$. Any big wire can be labelled by its size  : $1_n \to 1_n$ to avoid ambiguity. Such labels will be used mainly for scalars i.e. diagrams with no input/output. Each green or red spider is parametrised by a vector $\alpha \in \mathbb{R}^n$ of angles. With slight abuse of notation we use a single angle $\alpha_0 \in \mathbb{R}$ to denote the vector $(\alpha_0, \ldots, \alpha_0) \in \mathbb{R}^n$ when the spider has at least one leg $(k + \ell > 0)$ so that this leg can be labelled by n to avoid a potential ambiguity. Like in the ZX-calculus, the angle α_0 is omitted when $\alpha_0 = 0$.

The interpretation of ZX-diagrams is extended to SZX-diagrams as follows: for any SZX-diagram $D : a \to b$, its interpretation $\llbracket D \rrbracket_s$ is a triplet (M, a, b) where $M \in \mathcal{M}_{2^{S(b)} \times 2^{S(a)}}(\mathbb{C})$. $\llbracket D \rrbracket_s$ is inductively defined as: $\llbracket D_1 \circ D_0 \rrbracket_s = (M_1 \circ M_0, a, c)$, $\llbracket D_0 \otimes D_2 \rrbracket_s = (M_0 \otimes M_2, a + c, b + d)$ where $\llbracket D_0 \rrbracket_s = (M_0, a, b)$, $\llbracket D_1 \rrbracket_s = (M_1, b, c)$, and $\llbracket D_2 \rrbracket_s = (M_2, c, d)$. Moreover:



$:= (\frac{1}{\sqrt{2^n}} \sum_{x,y \in \{0,1\}^n} (-1)^{x \bullet y} |y\rangle\langle x|, 1_n, 1_n)$
$:= (id_{n+1}, 1_{n+1}, 1{+}1_n)$
$:= (\sum_{x \in \{0,1\}^n} e^{ix \bullet \alpha} |x^k\rangle\langle x^\ell|, k_n, \ell_n)$
$:= (id_{n+1}, 1{+}1_n, 1_{n+1})$
$:= \llbracket\ \rrbracket_s^{\otimes \ell} \circ \llbracket\ \rrbracket_s \circ \llbracket\ \rrbracket_s^{\otimes k}$
$:= (\sum_{x \in \{0,1\}^n} |xx\rangle, 0, 2_n)$
$:= (\sum_{x \in \{0,1\}^n, y \in \{0,1\}^m} |yx\rangle\langle xy|, 1_n{+}1_m, 1_m{+}1_n)$
$:= (\sum_{x \in \{0,1\}^n} \langle xx|, 2_n, 0)$
$:= (id_n, 1_n, 1_n)$
$:= 1$

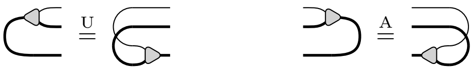
Where $\forall u, v \in \mathbb{R}^m$, $u \bullet v = \sum_{i=1}^m u_i v_i$, $M^{\otimes 0} = 1$, and $M^{\otimes k+1} = M \otimes M^{\otimes k}$.

▶ **Theorem 3** (Universality). *SZX-diagrams are universal for pure qubit quantum mechanics:* $\forall a, b \in \langle \mathbb{N}^* \rangle, \forall M \in \mathcal{M}_{2^{S(b)} \times 2^{S(a)}}(\mathbb{C})$, $\exists D : a \to b$ *such that* $\llbracket D \rrbracket_s = (M, a, b)$.

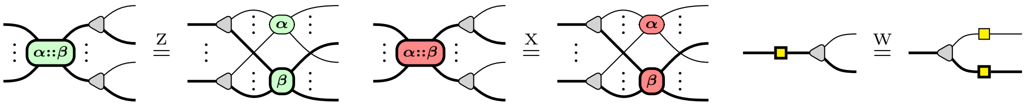
3.3 The calculus

The SZX-calculus is based on distribution rules that allow dividers and gatherers to go through the big generators. For this to work we need first to ensure that the swap behaves naturally with respect to dividers and gatherers. This is given by the following two rules:

Then the rules governing the interaction between dividers, gatherers and the so-called *cups* and *caps* are:



We put labels over the equals signs to allow subsequent reference to the rules. These rules are sufficient to fully describe possible interactions between wires of any size, gatherers and dividers. It remains to specify how dividers and gatherers interact with big generators:



Where α::β means that we append the phase $\alpha \in \mathbb{R}$ to the (generalized) phase $\beta \in \mathbb{R}^n$.

This completes the set of rules of the SZX-calculus. Note that all rules agree with the interpretation, ensuring soundness of the SZX-calculus.

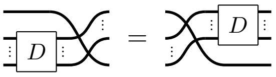
We see that any big generator s_n is in fact just n copies of the corresponding size one generator s acting in parallel. That is, a parallel composition but with a particular permutation of the inputs and outputs. Such constructions are called multiplexed diagrams in [10]. Multiplexed diagrams are shown to satisfy the same equations as size 1 diagrams. The following lemma states the same results for big generators:

▶ **Lemma 4.** *For any rule of the ZX-calculus, and any $n \in \mathbb{N}^*$, the equation obtained by replacing each generator by its big version of size n is provable in the SZX-calculus.*

We can go even further than Lemma 4. In fact, the SZX-calculus is complete:

▶ **Theorem 5.** $\forall a, b \in \langle\mathbb{N}^*\rangle, \forall D, D' \in \mathcal{SZX}[a,b],\ \llbracket D \rrbracket_s = \llbracket D' \rrbracket_s \Rightarrow SZX \vdash D = D'$.

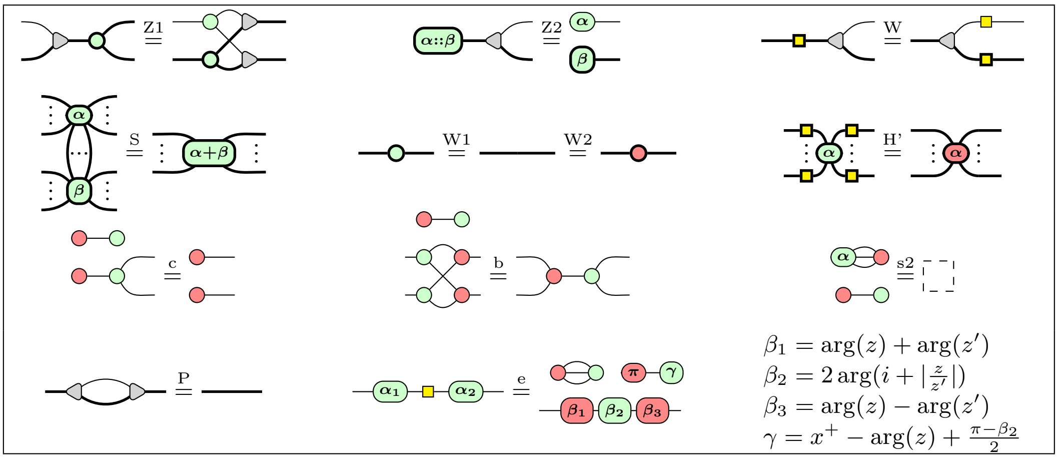
Theorem 5 has interesting graphical consequences, ensuring that the *Only Topology Matters* paradigm applies to the SZX-calculus. In particular, swaps of any size behave naturally with respect to any diagram:



This suggests a more compact presentation close to the one of the ZX-calculus, given in the next subsection.

3.4 Compact axiomatisation

Assuming that *Only Topology Matters*, the SZX-calculus enjoys a more compact axiomatisation:



Z1
α::β
Z2
α
β
W
α
S
α+β
β
W1
W2
H'
α
α
c
b
α
s2
P
α1
α2
e
π
γ
β1
β2
β3
$\beta_1 = \arg(z) + \arg(z')$
$\beta_2 = 2\arg(i + |\frac{z}{z'}|)$
$\beta_3 = \arg(z) - \arg(z')$
$\gamma = x^+ - \arg(z) + \frac{\pi - \beta_2}{2}$

Figure 2 Axioms of the SZX-calculus, where $x^+ := \frac{\alpha_1+\alpha_2}{2}$, $x^- := x^+ - \alpha_2$, $z := -\sin(x^+) + i\cos(x^-)$, $z' := \cos(x^+) - i\sin(x^-)$ and $z' = 0 \Rightarrow \beta_2 = 0$. In the spider fusion rule, there must be at least one wire between the spiders annotated by α and β. The colour-swapped versions of those rules also hold. The bold font wires stand for wires of any size $n \geq 1$.

▶ **Lemma 6.** *All the rules of the SZX-calculus can be derived from the compact axioms of Figure 2 together with the Only Topology Matters paradigm.*

4 Axiomatising binary matrices for compressing diagrams

In this section, we introduce a new generator for the SZX-calculus, parametrized by a binary matrix, allowing us to represent large graphical structures in a compact way: $\forall n, m \in \mathbb{N}^*$, $\forall A \in \mathbb{F}_2^{m\times n}$, 
$: 1_n \to 1_m$. All-ones matrices will be omitted:  := 
where $\forall i,j, J_{i,j} = 1$. The new generator is interpreted as follows:

$\forall A \in \mathbb{F}_2^{m\times n}$, ⟦ 
⟧$_s$ $= (|x\rangle \mapsto |Ax\rangle, 1_n, 1_m)$

where the matrix product Ax is in $\mathbb{F}_2$ and x is seen as a column vector i.e. $(Ax)_i = \sum_{k=1}^{n} A_{i,k}x_k \bmod 2$.

▶ Remark 7. Note that, compared to [9], the matrix is not necessarily connected to green and red spiders. It is therefore a more elementary generator.

Those matrices are required to satisfy the four axioms given in Figure 3, which are sound.

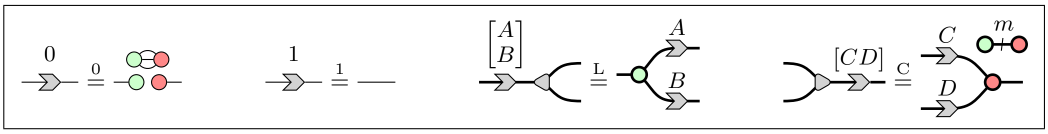


Figure 3 Axioms for matrices, where $A \in \mathbb{F}_2^{a\times n}$, $B \in \mathbb{F}_2^{b\times n}$, $C \in \mathbb{F}_2^{m\times c}$ and $D \in \mathbb{F}_2^{m\times d}$. $\begin{bmatrix}A\\B\end{bmatrix}$ and $[CD]$ are block matrices.

▶ Remark 8. The rules of the ZX-calculus define a scaled Hopf algebra between the green and red structure. This algebra is commutative and cocommutative with a trivial antipode. Thus, following the work of [44], the notion of $\{0,1\}$-matrices naturally emerges. It is worth noticing that it coincides with the matrices we are introducing in this section. Notice however that our axiomatisation of the matrices strongly relies on their interaction with the divider and the gatherer, which are not present in [44].

In the following, the SZX-calculus refers to the SZX-calculus augmented with the matrix generators and the axioms of Figure 3.

Useful equations can be derived. First, matrices are copied and erased by green nodes.

▶ **Lemma 9.** *For any $A \in \mathbb{F}_2^{m\times n}$, SZX ⊢* 
and SZX ⊢ 
We define backward matrices as follows: 
:= 
▶ **Lemma 10.** $\forall A \in \mathbb{F}_2^{m\times n}$, *SZX* ⊢ 
where A^t is the transpose of A.

As a consequence, conjugating by Hadamard ( ) reverses the orientation and transposes the matrix (up to scalars). Since conjugating by Hadamard colour-swaps the spiders and preserves the other generators of the language, one can derive from any equation a new one (up to scalars) which consists in colour-swapping the spiders, transposing the matrices and then changing their orientation. For instance Lemma 9 gives that matrices are cocopied and coerased by red nodes:

▶ **Lemma 11.** *For any $A \in \mathbb{F}_2^{m\times n}$, SZX ⊢*  *and SZX ⊢* 
Basic matrix operations like addition and multiplication (in $\mathbb{F}_2$) can be implemented graphically:

▶ **Lemma 12.** *For any $A, B \in \mathbb{F}_2^{m\times n}$, and any $C \in \mathbb{F}_2^{k\times m}$, SZX ⊢*  *and SZX ⊢*  *.*

Whereas all the previous properties about matrices are angle-free, some spiders whose angles are multiple of π can be pushed through matrices as follows:

▶ **Lemma 13.** *For any $A \in \mathbb{F}_2^{m\times n}$, any $v \in \mathbb{F}_2^n$ and any $u \in \mathbb{F}_2^m$,*

SZX ⊢  *and SZX ⊢* 
Injective matrices enjoy some specific properties:

▶ **Lemma 14.** *For any $A \in \mathbb{F}_2^{m\times n}$, the following properties are equivalent:*

(1) *A is injective.*

(3) *SZX ⊢* 
(2) *SZX ⊢* 
(4) *SZX ⊢* 
By Hadamard conjugation, we obtain some dual properties for surjective matrices:

▶ **Lemma 15.** *For any $A \in \mathbb{F}_2^{m\times n}$, the following properties are equivalent:*

(1) *A is surjective.*

(3) *SZX ⊢* 
(2) *SZX ⊢* 
(4) *SZX ⊢* 
Due to the universality of the SZX-calculus, matrices are expressible as SZX-diagrams, and the matrix generator  is actually a compact representation of a green/red bipartite graphs whose biadjacency matrix is A:

▶ **Lemma 16.** *For any $A \in \mathbb{F}_2^{m\times n}$, SZX ⊢*  *where A represents in the RHS diagram the adjacency matrix of the bipartite green/red graph, and |A| is the number of 1 in A.*

Lemma 16 and 5 imply the completeness of the SZX-calculus with matrices:

▶ **Theorem 17.** *SZX-calculus with matrices is complete.*

5 Applications

This section provides two examples of the SZX-calculus in action.

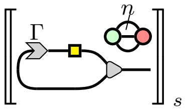
5.1 Application to graph states

Graph states [24] form a subclass of quantum states that can be represented by simple undirected graphs where each vertex represents a qubit and the edges represent intuitively the entanglement between qubits. The graph state formalism is widely used in quantum information processing, providing combinatorial characterisations of quantum properties in measurement-based quantum computing [40, 13, 6], secret sharing [37, 29, 25], error correcting codes [41, 4] etc. Graph states are also strongly related to the ZX-calculus [18] where they have been used for instance in proving the completeness of some fragments [1, 20]. A graph state is a particular kind of stabilizer state and thus can be defined as a fixpoint: given a graph G of order n, the corresponding graph state $|G\rangle$ is a the unique state (up to a global phase) such that for any vertex u, applying $X = [\![-\pi-]\!]$ on u and $Z = [\![-\pi-]\!]$ on its neighbours leaves the state unchanged. The global phase is fixed by the extra condition $\langle 0^n|G\rangle = \frac{1}{\sqrt{n}}$.

A graph state admits a simple representation as a ZX-diagram: each vertex is represented by a green spider connected to an output, and each edge is represented by a Hadamard (─□─) connecting the corresponding green dots. In the following, we provide two alternative, scalable, representations of graph states: the first is a compact matrix-based representation of bipartite graph states, the second is an inductive definition of arbitrary graph state, allowing inductive proofs. In both representations, we provide diagrammatic proofs of some key properties of the graph states.

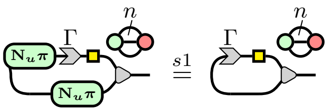
First, any bipartite graph state can be depicted with a SZX-diagram via its biadjacency matrix:

▶ **Lemma 18.** *For any bipartite graph G with biadjacency matrix $\Gamma \in \mathbb{F}_2^{m\times n}$,*

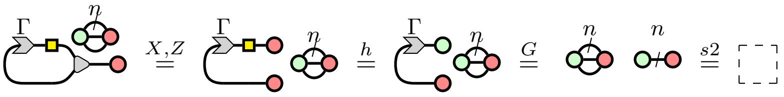


$$= (|G\rangle, 0, 1_{n+m})$$

Proof of Lemma 18. The last two components are straightforward typing, for the first one we use the characterization of $|G\rangle$ by its stabilizer [24]. $|G\rangle$ is the unique (up to a scalar) common fix point of $X_u Z_{N_u}$ for all vertices u of G. Each subset of vertices is identified with its characteristic vector, e.g. $\mathbf{N}_u\pi$ is a vector with a π at the position i if the i-th vertex is a neighbour of u, and 0 otherwise. The following proof uses the fact that $\Gamma^t u = \mathbf{N}_u$. We assume u is in the first part of the bipartite graph (the other case is similar):



It remains to take care of the scalar. We see that $\sqrt{2^{n+m}}\langle 0^{n+m}|G\rangle = 1$:

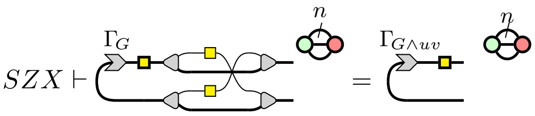


◀

A fundamental property of graph states is that graph transformations (like pivoting and local complementation) can be performed on graph states using local operations. Given a bipartite graph G, pivoting according to an edge (u, v) produces a graph denoted $G \wedge uv$ where the labels u and v are exchanged and their neighbourhood is complemented: for any $w \in \mathbf{N}_u \setminus v$ and $t \in \mathbf{N}_v \setminus u$, w and t are connected in $G \wedge uv$ iff they are not connected in G. Pivoting can be implemented on bipartite graph states by simply applying Hadamard on u

and v: $H_{u,v}|G\rangle = |G \wedge uv\rangle$ [42, 38]. This property can be derived in the SZX-calculus, and its proof, given in arXiv:1905.00041 due to space limits, provides an interesting example of the SZX-calculus in action:

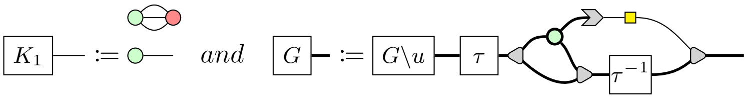
▶ **Lemma 19.** *Given a bipartite graph G and an edge (u, v),*



where Γ_G (resp. $\Gamma_{G\wedge uv}$) is the biadjacency matrix of G (resp. $G\wedge uv$) such that u corresponds to the first row (resp. column) and v to the first column (resp. row).

Now we introduce a general inductive definition of graph state boxes, which associates a SZX-diagram with any (not necessarily bipartite) graph.

▶ **Definition 20.** *Given a graph G with ordered vertices, the corresponding graph state box is defined by:*



where K_1 is the graph of order 1, u is the first vertex of G, τ is a permutation on the list of vertices of $G\backslash u$ which puts the neighbourhood of u first and then the other vertices.

▶ **Lemma 21.** $\left[\!\left[\,\boxed{G}\!-\,\right]\!\right]_s = (|G\rangle, 0, 1_n).$

We will now use the SZX-calculus to show the property known as local complementation. Given a vertex u of a graph G the local complementation of G according to u is the graph $G \star u$ which is G where all edges between neighbours of u have been complemented, that is, edges became non-edges and non-edges became edges.

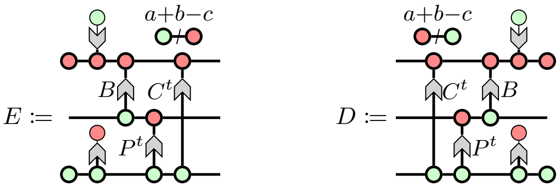
▶ **Theorem 22.** *For any graph G and vertex u, $SZX \vdash$* .

5.2 Application to error correcting codes

The original motivation for the development of a scalable ZX-calculus was the design of tripartite Coherent Parity Checking (CPC) error correcting codes [9]. We reformulate here in the SZX-calculus the definition of those codes and the proof of some elementary properties.

The idea is to spread the information of some logical qubits over a bigger number of physical qubits. In our example the code is parametrized by three matrices $B \in \mathbb{F}_2^{a\times b}$, $P \in \mathbb{F}_2^{c\times b}$ and $C \in \mathbb{F}_2^{c\times a}$. The aim is to encode b logical qubits into $a+b+c$ physical ones.

▶ **Definition 23.** *The tripartite CPC encoder $E : 1_b \to 1_a+1_b+1_c$ and decoder $D : 1_a+1_b+1_c \to 1_b$ defined by the matrices $B \in \mathbb{F}_2^{a\times b}$, $P \in \mathbb{F}_2^{c\times b}$ and $C \in \mathbb{F}_2^{c\times a}$ are:*

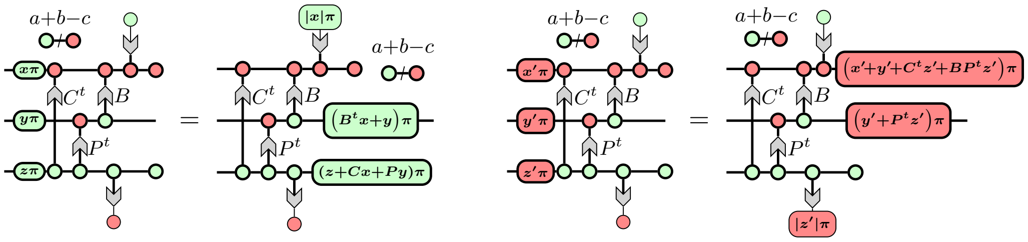


We can prove that the code is correct when there are no errors, in other words:

▶ **Lemma 24.** *The encoder is an isometry that is $SZX \vdash D \circ E = $ —.*

We now end by showing what happens when errors go through the decoder: x, y and z (resp. x', y', z') are vectors of phase flip errors (resp. bit flip errors). The implementation of the decoder involves some measurements, which according to Lemma 25, produce some syndromes ($|x| = \sum_i x_i \bmod 2$, $z{+}Cx{+}Py$, $x'{+}y'{+}C^tz'{+}BP^tz'$, and $|z'|$) which guide us to correct the middle wire. Of course the exact protocol and its efficiency depend on clever choices of B, P and C, see [9] for details.

▶ **Lemma 25.** *The following equalities hold in the SZX-calculus:*



6 Conclusion and further work

We have introduced the SZX-calculus, a formal and compact graphical language for quantum reasoning, and proved its universality, soundness, and completeness. This work is addressing two main objectives. First, to demonstrate that some of the ingredients for scalability which were sketched out in [9] – like the thick wires and the use of matrices – together with some new ingredients – like the divider and the gatherer – can be axiomatised to provide a complete scalable graphical language. Our second objective was to provide a sufficiently precise definition of the language to consider an implementation in a graphical proof assistant like Quantomatic. This last point would pave the way towards the formal verification of large scale quantum protocols and algorithms.

We aim to provide a language ready for applications and available to most of the quantum computing community. For this reason, we have deliberately avoided a categorical presentation. A fully categorical description of the scalable construction will be the subject of further work. We nevertheless provide here a sketch of how our construction can be generalised in a categorical setting. Graphical languages can be defined as props, see [3] and [44], that is symmetric strict monoidal categories whose set of objects is freely generated by one object we denote 1. In fact it is possible to define a scalable construction for any coloured prop. Given a set C of colours we can define two $\langle\langle C\rangle - \varepsilon\rangle$-coloured props $\mathbb{D}_C$ and $\mathbb{G}_C$ whose objects are formal sums of 1_{n_c} and morphisms are respectively generated by dividers and gatherers for each pair (n, c). The elimination rule is a distribution rule as in [36], which allows us to define the composed prop $\mathbb{D}_C ; \mathbb{G}_C$. The prop of wires $\mathbb{W}_C$ is then defined as this composition quotiented by the expansion rule. This last pro satisfies a rewire theorem similar to Theorem 2. Then given a C-coloured prop $\mathbf{P}$, we define the $\langle\langle C\rangle - \varepsilon\rangle$-coloured prop $\overline{\mathbf{P}}$ which has the same generators and equations as those of $\mathbf{P}$ on wires of size 1. Finally the scalable prop $\mathcal{S}\mathbf{P}$ is defined as the composition of prop $\mathbb{D}_C ; \overline{\mathbf{P}} ; \mathbb{G}_C$ quotiented by the expansion rule. The corresponding distribution rules follows the same pattern as in 3.3. Such a generalization gives scalable versions of any graphical language based on props such as the ZW–calculus [22], the ZH-calculus [2] or $\mathbb{IH}$ [5].

Abstract

Let $P = (p_1, p_2, \ldots, p_n)$ be a polygonal chain. The *stretch factor* of P is the ratio between the total length of P and the distance of its endpoints, $\sum_{i=1}^{n-1} |p_i p_{i+1}|/|p_1 p_n|$. For a parameter $c \geq 1$, we call P a *c-chain* if $|p_i p_j| + |p_j p_k| \leq c|p_i p_k|$, for every triple (i, j, k), $1 \leq i < j < k \leq n$. The stretch factor is a global property: it measures how close P is to a straight line, and it involves all the vertices of P; being a c-chain, on the other hand, is a *fingerprint*-property: it only depends on subsets of $O(1)$ vertices of the chain.

We investigate how the c-chain property influences the stretch factor in the plane: (i) we show that for every $\varepsilon > 0$, there is a noncrossing c-chain that has stretch factor $\Omega(n^{1/2-\varepsilon})$, for sufficiently large constant $c = c(\varepsilon)$; (ii) on the other hand, the stretch factor of a c-chain P is $O\left(n^{1/2}\right)$, for every constant $c \geq 1$, regardless of whether P is crossing or noncrossing; and (iii) we give a randomized algorithm that can determine, for a polygonal chain P in $\mathbb{R}^2$ with n vertices, the minimum $c \geq 1$ for which P is a c-chain in $O\left(n^{2.5} \text{ polylog } n\right)$ expected time and $O(n \log n)$ space.

Acknowledgements This work was initiated at the Fields Workshop on Discrete and Computational Geometry, held July 31–August 4, 2017, at Carleton University. The authors thank the organizers and all participants of the workshop for inspiring discussions and for providing a great research atmosphere. This problem was initially posed by Rolf Klein in 2005. We would like to thank Rolf Klein and Christian Knauer for interesting discussions on the stretch factor and related topics.

1 Introduction

Given a set S of n point sites in the plane, what is the best way to connect S into a *geometric network (graph)*? This question has motivated researchers for a long time, going back as far as the 1940s, and beyond [19,35]. Numerous possible criteria for a good geometric network

have been proposed, perhaps the most basic being the *length*. In 1955, Few [20] showed that for any set of n points in a unit square, there is a traveling salesman tour of length at most $\sqrt{2n} + 7/4$. This was improved to at most $0.984\sqrt{2n} + 11$ by Karloff [23]. Similar bounds also hold for the shortest spanning tree and the shortest rectilinear spanning tree [13, 16, 21]. Besides length, two further key factors in the quality of a geometric network are the *vertex dilation* and the *geometric dilation* [31], both of which measure how closely shortest paths in a network approximate the Euclidean distances between their endpoints.

The *dilation* (also called *stretch factor* [29] or *detour* [1]) between two points p and q in a geometric graph G is defined as the ratio between the length of a shortest path from p to q and the Euclidean distance $|pq|$. The *dilation* of the graph G is the maximum dilation over all pairs of vertices in G. A graph in which the dilation is bounded above by $t \geq 1$ is also called a *t-spanner* (or simply a *spanner* if t is a constant). A complete graph in Euclidean space is clearly a 1-spanner. Therefore, researchers focused on the dilation of graphs with certain additional constraints, for example, noncrossing (i.e., plane) graphs. In 1989, Das and Joseph [15] identified a large class of plane spanners (characterized by two simple local properties). Bose et al. [6] gave an algorithm that constructs for any set of planar sites a plane 11-spanner with bounded degree. On the other hand, Eppstein [18] analyzed a fractal construction showing that *β-skeletons*, a natural class of geometric networks, can have arbitrarily large dilation.

The study of dilation also raises algorithmic questions. Agarwal et al. [1] described randomized algorithms for computing the dilation of a given path (on n vertices) in $\mathbb{R}^2$ in $O(n \log n)$ expected time. They also presented randomized algorithms for computing the dilation of a given tree, or cycle, in $\mathbb{R}^2$ in $O(n \log^2 n)$ expected time. Previously, Narasimhan and Smid [30] showed that an $(1 + \varepsilon)$-approximation of the stretch factor of any path, cycle, or tree can be computed in $O(n \log n)$ time. Klein et al. [24] gave randomized algorithms for a path, tree, or cycle in $\mathbb{R}^2$ to count the number of vertex pairs whose dilation is below a given threshold in $O(n^{3/2+\varepsilon})$ expected time. Cheong et al. [12] showed that it is NP-hard to determine the existence of a spanning tree on a planar point set whose dilation is at most a given value. More results on plane spanners can be found in the monograph dedicated to this subject [31] or in several surveys [8, 17, 29].

We investigate a basic question about the dilation of polygonal chains. More precisely, we ask how the dilation between the endpoints of a polygonal chain (which we will call the *stretch factor*, to distinguish it from the more general notion of dilation) is influenced by *fingerprint* properties of the chain, i.e., by properties that are defined on $O(1)$-size subsets of the vertex set. Such fingerprint properties play an important role in geometry, where classic examples include the *Carathéodory property*[1] [26, Theorem 1.2.3] or the *Helly property*[2] [26, Theorem 1.3.2]. In general, determining the effect of a fingerprint property may prove elusive: given n points in the plane, consider the simple property that every 3 points determine 3 distinct distances. It is unknown [9, p. 203] whether this property implies that the total number of distinct distances grows superlinearly in n.

Furthermore, fingerprint properties appear in the general study of *local versus global properties of metric spaces* that is highly relevant to combinatorial approximation algorithms that are based on mathematical programming relaxations [5]. In the study of dilation,

[1] Given a finite set S of points in d dimensions, if every $d + 2$ points in S are in convex position, then S is in convex position.

[2] Given a finite collection of convex sets in d dimensions, if every $d + 1$ sets have nonempty intersection, then all sets have nonempty intersection.

interesting fingerprint properties have also been found. For example, a (continuous) curve C is said to have the *increasing chord property* [14, 25] if for any points a, b, c, d that appear on C in this order, we have $|ad| \geq |bc|$. The increasing chord property implies that C has (geometric) dilation at most $2\pi/3$ [33]. A weaker property is the *self-approaching property*: a (continuous) curve C is self-approaching if for any points a, b, c that appear on C in this order, we have $|ac| \geq |bc|$. Self-approaching curves have dilation at most 5.332 [22] (see also [3]), and they have found interesting applications in the field of graph drawing [4, 7, 32].

We introduce a new natural fingerprint property and see that it can constrain the stretch factor of a polygonal chain, but only in a weaker sense than one may expect; we also provide algorithmic results on this property. Before providing details, we give a few basic definitions.

Definitions. A *polygonal chain* P in the Euclidean plane is specified by a sequence of n points $(p_1, p_2, \ldots, p_n)$, called its *vertices*. The chain P consists of $n-1$ line segments between consecutive vertices. We say P is *simple* if only consecutive line segments intersect and they only intersect at their endpoints. Given a polygonal chain P in the plane with n vertices and a parameter $c \geq 1$, we call P a *c-chain* if for all $1 \leq i < j < k \leq n$, we have

$$|p_i p_j| + |p_j p_k| \leq c|p_i p_k|. \tag{1}$$

Observe that the c-chain condition is a fingerprint condition that is not really a local dilation condition – it is more a combination between the local chain substructure and the distribution of the points in the subchains.

The *stretch factor* δ_P of P is defined as the dilation between the two end points p_1 and p_n of the chain:

$$\delta_P = \frac{\sum_{i=1}^{n-1} |p_i p_{i+1}|}{|p_1 p_n|}.$$

Note that this definition is different from the more general notion of dilation (also called *stretch factor* [29]) of a graph which is the maximum dilation over all pairs of vertices. Since there is no ambiguity in this paper, we will just call δ_P the stretch factor of P.

For example, the polygonal chain $P = ((0,0), (1,0), \ldots, (n,0))$ is a 1-chain with stretch factor 1; and $Q = ((0,0), (0,1), (1,1), (1,0))$ is a $(\sqrt{2}+1)$-chain with stretch factor 3.

Without affecting the results, the floor and ceiling functions are omitted in our calculations. For a positive integer t, let $[t] = \{1, 2, \ldots, t\}$. For a point set S, let $\operatorname{conv}(S)$ denote the convex hull of S. All logarithms are in base 2, unless stated otherwise.

Our results. We deduce three upper bounds on the stretch factor of a c-chain P with n vertices (Section 2). In particular, we have (i) $\delta_P \leq c(n-1)^{\log c}$, (ii) $\delta_P \leq c(n-2)+1$, and (iii) $\delta_P = O\left(c^2\sqrt{n-1}\right)$.

From the other direction, we obtain the following lower bound (Section 3): For every $c \geq 4$, there is a family $\mathcal{P}_c = \{P^k\}_{k\in\mathbb{N}}$ of simple c-chains, so that P^k has $n = 4^k + 1$ vertices and stretch factor $(n-1)^{\frac{1+\log(c-2)-\log c}{2}}$, where the exponent converges to 1/2 as c tends to infinity. The lower bound construction does not extend to the case of $1 < c < 4$, which remains open.

Finally, we present two algorithmic results (Section 4): (i) A randomized algorithm that decides, given a polygonal chain P in $\mathbb{R}^2$ with n vertices and a threshold $c > 1$, whether P is a c-chain in $O\left(n^{2.5} \text{ polylog } n\right)$ expected time and $O(n \log n)$ space. (ii) As a corollary, there is a randomized algorithm that finds, for a polygonal chain P with n vertices, the minimum $c \geq 1$ for which P is a c-chain in $O\left(n^{2.5} \text{ polylog } n\right)$ expected time and $O(n \log n)$ space.

2 Upper Bounds

At first glance, one might expect the stretch factor of a c-chain, for $c \geq 1$, to be bounded by some function of c. For example, the stretch factor of a 1-chain is necessarily 1. We derive three upper bounds on the stretch factor of a c-chain with n vertices in terms of c and n (cf. Theorems 1–3); see Fig. 1 for a visual comparison between the bounds. For large n, the bound in Theorem 1 is the best for $1 \leq c \leq 2^{1/2}$, while the bound in Theorem 3 is the best for $c > 2^{1/2}$. In particular, the bound in Theorem 1 is tight for $c = 1$. The bound in Theorem 2 is the best for $c \geq 2$ and $n \leq 111c^2$.

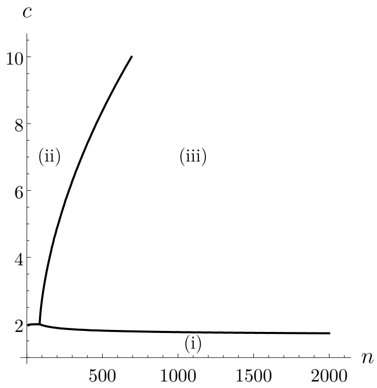

Figure 1 The values of n and c for which (i) Theorem 1, (ii) Theorem 2, and (iii) Theorem 3 give the current best upper bound.

Our first upper bound is obtained by a recursive application of the c-chain property. It holds for any positive distance function that may not even satisfy the triangle inequality.

▶ **Theorem 1.** *For a c-chain P with n vertices, we have $\delta_P \leq c(n-1)^{\log c}$.*

Proof. We prove, by induction on n, that

$$\delta_P \leq c^{\lceil \log(n-1) \rceil}, \tag{2}$$

for every c-chain P with $n \geq 2$ vertices. In the base case, $n = 2$, we have $\delta_P = 1$ and $c^{\lceil \log(2-1) \rceil} = 1$. Now let $n \geq 3$, and assume that (2) holds for every c-chain with fewer than n vertices. Let $P = (p_1, \ldots, p_n)$ be a c-chain with n vertices. Then, applying (2) to the first and second half of P, followed by the c-chain property for the first, middle, and last vertex of P, we get

$$\begin{aligned}
\sum_{i=1}^{n-1} |p_i p_{i+1}| &\leq \sum_{i=1}^{\lceil n/2 \rceil - 1} |p_i p_{i+1}| + \sum_{i=\lceil n/2 \rceil}^{n-1} |p_i p_{i+1}| \\
&\leq c^{\lceil \log(\lceil n/2 \rceil - 1) \rceil} \left(|p_1 p_{\lceil n/2 \rceil}| + |p_{\lceil n/2 \rceil} p_n| \right) \\
&\leq c^{\lceil \log(\lceil n/2 \rceil - 1) \rceil} \cdot c |p_1 p_n| \\
&\leq c^{\lceil \log(n-1) \rceil} |p_1 p_n|,
\end{aligned}$$

so (2) holds also for P. Consequently,

$$\delta_P \leq c^{\lceil \log(n-1) \rceil} \leq c^{\log(n-1)+1} = c \cdot c^{\log(n-1)} = c\,(n-1)^{\log c},$$

as required. ◀

Our second bound interprets the c-chain property geometrically and makes use of the fact that P resides in the Euclidean plane.

▶ **Theorem 2.** *For a c-chain P with n vertices, we have $\delta_P \le c(n-2)+1$.*

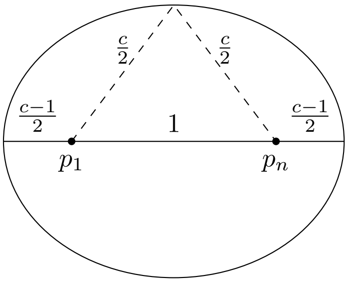

Figure 2 The entire chain P lies in an ellipse with foci p_1 and p_n.

Proof. Without loss of generality, assume that $|p_1p_n| = 1$. Since P is a c-chain, for every $1 < j < n$, we have $|p_1p_j| + |p_jp_n| \le c|p_1p_n| = c$. If we fix the points p_1 and p_n, then every p_j lies in an ellipse E with foci p_1 and p_n, for $1 < j < n$, see Figure 2. The diameter of E is its major axis, whose length is c. Since E contains all vertices of the chain P, we have $|p_1p_2|, |p_{n-1}p_n| \le \frac{c+1}{2} \le c$ and $|p_jp_{j+1}| \le c$ for all $1 < j < n-1$. Therefore the stretch factor of P is bounded above by

$$\delta_P = \frac{\sum_{j=1}^{n-1} |p_jp_{j+1}|}{|p_1p_n|} = |p_1p_2| + |p_{n-1}p_n| + \sum_{j=2}^{n-2} |p_jp_{j+1}|$$
$$\le \frac{c+1}{2} + \frac{c+1}{2} + c(n-3) = c(n-2)+1,$$

as required. ◀

Our third upper bound uses a volume argument to bound the number of long edges in P.

▶ **Theorem 3.** *Let $P = (p_1, \ldots, p_n)$ be a c-chain, for some constant $c \ge 1$, and let $L = \sum_{i=1}^{n-1} |p_ip_{i+1}|$ be its length. Then $L = O\left(c^2\sqrt{n-1}\right)|p_1p_n|$, hence $\delta_P = O\left(c^2\sqrt{n-1}\right)$.*

Proof. We may assume that p_1p_n is a horizontal segment of unit length. By the argument in the proof of Theorem 2, all points p_i ($i = 1, \ldots, n$) are contained in an ellipse E with foci p_1 and p_n, where the major axis of E has length c. Let U be the minimal axis-aligned square containing E; its side is of length c.

We set $x = 8c^2/\sqrt{n-1}$; and let L_0 and L_1 be the sum of lengths of all edges in P of length at most x and more than x, respectively. By definition, we have $L = L_0 + L_1$ and

$$L_0 \le (n-1)x = (n-1)\cdot 8c^2/\sqrt{n-1} = 8c^2\sqrt{n-1}. \tag{3}$$

We shall prove that $L_1 \le 8c^2\sqrt{n-1}$, implying $L \le 2x(n-1) = O\left(c^2\sqrt{n-1}\right)$. For this, we further classify the edges in L_1 according to their lengths: For $\ell = 0, 1, \ldots, \infty$, let

$$P_\ell = \left\{p_i : 2^\ell x < |p_ip_{i+1}| \le 2^{\ell+1}x\right\}. \tag{4}$$

Since all points lie in an ellipse of diameter c, we have $|p_ip_{i+1}| \le c$, for all $i = 0, \ldots, n-1$. Consequently, $P_\ell = \emptyset$ when $c \le 2^\ell x$, or equivalently $\log(c/x) \le \ell$.

We use a volume argument to derive an upper bound on the cardinality of P_ℓ, for $\ell = 0, 1, \dots, \lfloor \log(c/x) \rfloor$. Assume that $p_i, p_k \in P_\ell$, and w.l.o.g., $i < k$. If $k = i + 1$, then by (4), $2^\ell x < |p_i p_k|$. Otherwise,

$$2^\ell x < |p_i p_{i+1}| < |p_i p_{i+1}| + |p_{i+1} p_k| \le c|p_i p_k|, \text{ or } \frac{2^\ell x}{c} < |p_i p_k|.$$

Consequently, the disks of radius

$$R = \frac{2^\ell x}{2c} = \frac{4 \cdot 2^\ell c}{\sqrt{n-1}} \tag{5}$$

centered at the points in P_ℓ are interior-disjoint. The area of each disk is πR^2. Since $P_\ell \subset U$, these disks are contained in the R-neighborhood U_R of the square U, i.e., the Minkowski sum $R + U$. For $\ell \le \log(c/x)$, we have $2^\ell x \le c$, hence $R = \frac{2^\ell x}{2c} \le \frac{c}{2c} = \frac{1}{2} \le \frac{c}{2}$. Then we can bound the area of U_R from above as follows:

$$\text{area}(U_R) < (c + 2R)^2 \le (2c)^2 = 4c^2. \tag{6}$$

Since U_R contains $|P_\ell|$ interior-disjoint disks of radius R, we obtain

$$|P_\ell| \le \frac{\text{area}(U_R)}{\pi R^2} < \frac{4c^2}{\pi R^2} = \frac{16c^4}{\pi 2^{2\ell} x^2}. \tag{7}$$

For every segment $p_{i-1}p_i$ with length more than x, we have that $p_i \in P_\ell$, for some $\ell \in \{0, 1, \dots, \lfloor \log(c/x) \rfloor\}$. The total length of these segments is

$$\begin{aligned} L_1 &\le \sum_{\ell=0}^{\lfloor \log(c/x) \rfloor} |P_\ell| \cdot 2^{\ell+1} x < \sum_{\ell=0}^{\lfloor \log(x/c) \rfloor} \frac{16c^4}{\pi 2^{2\ell} x^2} \cdot 2^{\ell+1} x = \sum_{\ell=0}^{\lfloor \log(x/c) \rfloor} \frac{32c^4}{\pi 2^\ell x} \\ &< \frac{32c^4}{\pi x} \sum_{\ell=0}^{\infty} \frac{1}{2^\ell} = \frac{64c^4}{\pi x} = \frac{8c^2}{\pi} \cdot \sqrt{n-1}, \end{aligned}$$

as required. Together with (3), this yields $L \le 8\left(1 + c^2/\pi\right) \cdot \sqrt{n-1}$. ◀

3 Lower Bounds

We now present our lower bound construction, showing that the dependence on n for the stretch factor of a c-chain cannot be avoided.

▶ **Theorem 4.** *For every constant $c \ge 4$, there is a set $\mathcal{P}_c = \{P^k\}_{k \in \mathbb{N}}$ of simple c-chains, so that P^k has $n = 4^k + 1$ vertices and stretch factor $(n-1)^{\frac{1+\log(c-2)-\log c}{2}}$.*

By Theorem 3, the stretch factor of a c-chain in the plane is $O\left((n-1)^{1/2}\right)$ for every constant $c \ge 1$. Since

$$\lim_{c \to \infty} \frac{1 + \log(c-2) - \log c}{2} = \frac{1}{2},$$

our lower bound construction shows that the limit of the exponent cannot be improved. Indeed, for every $\varepsilon > 0$, we can set $c = \frac{2^{2\varepsilon+1}}{2^{2\varepsilon}-1}$, and then the chains above have stretch factor $(n-1)^{\frac{1+\log(c-2)-\log c}{2}} = (n-1)^{1/2-\varepsilon} = \Omega(n^{1/2-\varepsilon})$.

We first construct a family $\mathcal{P}_c = \{P^k\}_{k \in \mathbb{N}}$ of polygonal chains. Then we show, in Lemmata 5 and 6, that every chain in $\mathcal{P}_c$ is simple and indeed a c-chain. The theorem follows since the claimed stretch factor is a consequence of the construction.

Construction of $\mathcal{P}_c$. The construction here is a generalization of the iterative construction of the *Koch curve*; when $c = 6$, the result is the original Cesàro fractal (which is a variant of the Koch curve) [10]. We start with a unit line segment P^0, and for $k = 0, 1, \dots,$ we construct P^{k+1} by replacing each segment in P^k by four segments such that the middle three points achieve a stretch factor of $c_* = \frac{c-2}{2}$ (this choice will be justified in the proof of Lemma 6). Note that $c_* \geq 1$, since $c \geq 4$.

We continue with the details. Let P^0 be the unit line segment from $(0, 0)$ to $(1, 0)$; see Figure 3 (left). Given the polygonal chain P^k ($k = 0, 1, \dots$), we construct P^{k+1} by replacing each segment of P^k by four segments as follows. Consider a segment of P^k, and denote its length by ℓ. Subdivide this segment into three segments of lengths $(\frac{1}{2} - \frac{a}{c_*})\ell$, $\frac{2a}{c_*}\ell$, and $(\frac{1}{2} - \frac{a}{c_*})\ell$, respectively, where $0 < a < \frac{c_*}{2}$ is a parameter to be determined later. Replace the middle segment with the top part of an isosceles triangle of side length $a\ell$. The chains P^0, P^1, P^2, and P^4 are depicted in Figures 3 and 4.

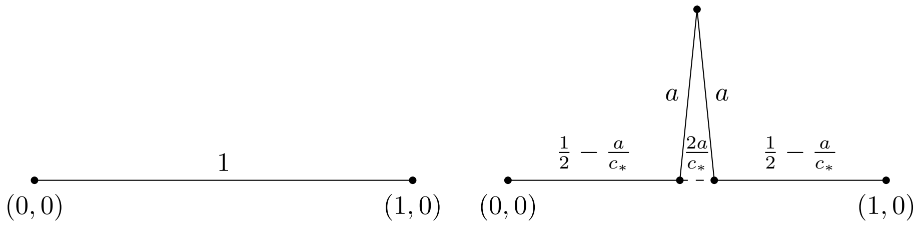

Figure 3 The chains P^0 (left) and P^1 (right).

Note that each segment of length ℓ in P^k is replaced by four segments of total length $(1 + \frac{2a(c_*-1)}{c_*})\ell$. After k iterations, the chain P^k consists of 4^k line segments of total length $\left(1 + \frac{2a(c_*-1)}{c_*}\right)^k$.

By construction, the chain P^k (for $k \geq 1$) consists of four scaled copies of P^{k-1}. For $i = 1, 2, 3, 4$, let the *ith subchain of* P^k be the subchain of P^k consisting of 4^{k-1} segments starting from the $((i-1)4^{k-1} + 1)$th segment. By construction, the ith subchain of P^k is similar to the chain P^{k-1}, for $i = 1, 2, 3, 4$.[3] The following functions allow us to refer to these subchains formally. For $i = 1, 2, 3, 4$, define a function $f_i^k : P^k \to P^k$ as the identity on the ith subchain of P^k that sends the remaining part(s) of P^k to the closest endpoint(s) along this subchain. So $f_i^k(P^k)$ is similar to P^{k-1}. Let $g_i : \mathcal{P}_c \setminus \{P^0\} \to \mathcal{P}_c$ be a piecewise defined function such that $g_i(C) = \sigma^{-1} \circ f_i^k \circ \sigma(C)$ if C is similar to P^k, where $\sigma : C \to P^k$ is a similarity transformation. Applying the function g_i on a chain P^k can be thought of as "cutting out" its ith subchain.

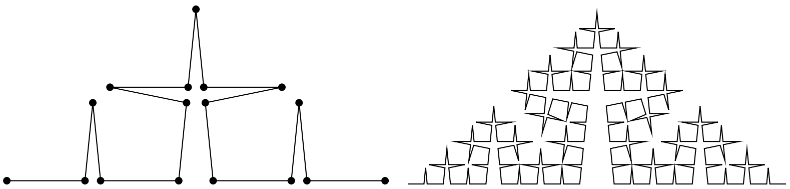

Figure 4 The chains P^2 (left) and P^4 (right).

[3] Two geometric shapes are *similar* if one can be obtained from the other by translation, rotation, and scaling; and are *congruent* if one can be obtained from the other by translation and rotation.

Clearly, the stretch factor of the chain monotonically increases with the parameter a. However, if a is too large, the chain is no longer simple. The following lemma gives a sufficient condition for the constructed chains to avoid self-crossings.

▶ **Lemma 5.** *For every constant $c \geq 4$, if $a \leq \frac{c-2}{2c}$, then every chain in $\mathcal{P}_c$ is simple.*

Proof. Let $T = \text{conv}(P^1)$. Observe that T is an isosceles triangle; see Figure 5 (left). We first show the following:

▷ Claim. If $a \leq \frac{c-2}{2c}$, then $\text{conv}(P^k) = T$ for all $k \geq 1$.

Proof. We prove the claim by induction on k. It holds for $k = 1$ by definition. For the induction step, assume that $k \geq 2$ and that the claim holds for $k-1$. Consider the chain P^k. Since it contains all the vertices of P^1, $T \subset \text{conv}(P^k)$. So we only need to show that $\text{conv}(P^k) \subset T$.

$\left(\frac{1}{2} - \frac{a}{c_*}\right)^2$

Figure 5 Left: Convex hull T of P^1 in light gray; Right: Convex hulls of $g_i(P^2)$, $i = 1, 2, 3, 4$, in dark gray, are contained in T.

By construction, $P^k \subset \bigcup_{i=1}^{4} \text{conv}(g_i(P^k))$; see Figure 5 (right). By the inductive hypothesis, $\text{conv}(g_i(P^k))$ is an isosceles triangle similar to T, for $i = 1, 2, 3, 4$. Since the bases of $\text{conv}(g_1(P^k))$ and $\text{conv}(g_4(P^k))$ are collinear with the base of T by construction, due to similarity, they are contained in T. The base of $\text{conv}(g_2(P^k))$ is contained in T. In order to show $\text{conv}(g_2(P^k)) \subset T$, by convexity, it suffices to ensure that its apex p is also in T. Note that the coordinates of the top point is $t = \left(1/2, a\sqrt{c_*^2 - 1}/c_*\right)$, so the supporting line ℓ of the left side of T is

$$y = \frac{2a\sqrt{c_*^2 - 1}}{c_*}x, \text{ and}$$

$$p = \left(\frac{1}{2} - \frac{a}{2c_*} - \frac{a^2\left(c_*^2 - 1\right)}{c_*^2}, \left(\frac{a}{2c_*} + \frac{a^2}{c_*^2}\right)\sqrt{c_*^2 - 1}\right).$$

By the condition of $a \leq \frac{c-2}{2c} = \frac{c_*}{2(c_*+1)}$ in the lemma, p lies on or below ℓ. Under the same condition, we have $\text{conv}(g_3(P^k)) \subset T$ by symmetry. Then $P^k \subset \bigcup_{i=1}^{4} \text{conv}(g_i(P^k)) \subset T$. Since T is convex, $\text{conv}(P^k) \subset T$. So $\text{conv}(P^k) = T$, as claimed. ◁

We can now finish the proof of Lemma 5 by induction. Clearly, P^0 and P^1 are simple. Assume that $k \geq 2$, and P^{k-1} is simple. Consider the chain P^k. For $i = 1, 2, 3, 4$, $g_i(P^k)$ is similar to P^{k-1}, hence simple by the inductive hypothesis. Since $P^k = \bigcup_{i=1}^{4} g_i(P^k)$, it is sufficient to show that for all $i, j \in \{1, 2, 3, 4\}$, where $i \neq j$, a segment in $g_i(P^k)$ does not intersect any segments in $g_j(P^k)$, unless they are consecutive in P^k and they intersect at a common endpoint. This follows from the above claim together with the observation that for $i \neq j$, the intersection $g_i(P^k) \cap g_j(P^k)$ is either empty or contains a single vertex which is the common endpoint of two consecutive segments in P^k. ◀

In the remainder of this section, we assume that

$$a = \frac{c-2}{2c} = \frac{c_*}{2(c_*+1)}. \tag{8}$$

Under this assumption, all segments in P^1 have the same length a. Therefore, by construction, all segments in P^k have the same length

$$a^k = \left(\frac{c_*}{2(c_*+1)}\right)^k.$$

There are 4^k segments in P^k, with 4^k+1 vertices, and its stretch factor is

$$\delta_{P^k} = 4^k \left(\frac{c_*}{2(c_*+1)}\right)^k = \left(\frac{2c_*}{c_*+1}\right)^k.$$

Consequently, $k = \log_4(n-1) = \frac{\log(n-1)}{2}$, and

$$\delta_{P^k} = \left(\frac{2c_*}{c_*+1}\right)^{\frac{\log(n-1)}{2}} = \left(\frac{2c-4}{c}\right)^{\frac{\log(n-1)}{2}} = (n-1)^{\frac{1+\log(c-2)-\log c}{2}},$$

as claimed. To finish the proof of Theorem 4, it remains to show the constructed polygonal chains are indeed c-chains.

▶ **Lemma 6.** *For every constant $c \geq 4$, $\mathcal{P}_c$ is a family of c-chains.*

We first prove a couple of facts that will be useful in the proof of Lemma 6. We defer an intuitive explanation until after the formal statement of the lemma.

▶ **Lemma 7.** *Let $k \geq 1$ and let $P^k = (p_1, p_2, \ldots, p_n)$, where $n = 4^k+1$. Then the following hold:*

(i) *There exists a sequence $(q_1, q_2, \ldots, q_m)$ of $m = 2 \cdot 4^{k-1}$ points in $\mathbb{R}^2$ such that the chain $R^k = (p_1, q_1, p_2, q_2, \ldots, p_m, q_m, p_{m+1})$ is similar to P^k.*

(ii) *For $k \geq 2$, define $g_5 : \mathcal{P}_c \setminus \{P^0, P^1\} \to \mathcal{P}_c$ by*

$$g_5(P^k) = \left(g_3 \circ g_2(P^k)\right) \cup \left(g_4 \circ g_2(P^k)\right) \cup \left(g_1 \circ g_3(P^k)\right) \cup \left(g_2 \circ g_3(P^k)\right).$$

Then $g_5(P^k)$ is similar to P^{k-1}.

Part (i) of Lemma 7 says that given P^k, we can construct a chain R^k similar to P^k by inserting one point between every two consecutive points of the left half of P^k, see Figure 6 (left). Part (ii) says that the "top" subchain of P^k that consists of the right half of $g_2(P^k)$ and the left half of $g_3(P^k)$, see Figure 6 (right), is similar to P^{k-1}.

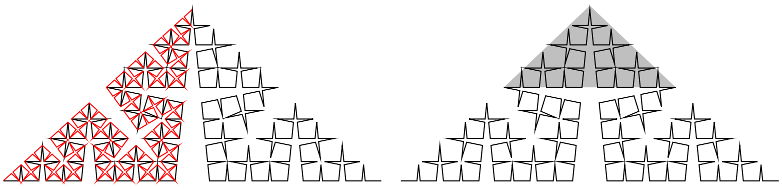

Figure 6 Left: Chain P^k with the scaled copy of itself R^k (in red); Right: Chain P^k with its subchain $g_5(P^k)$ marked by its convex hull.

Proof of Lemma 7. For (i), we review the construction of P^k, and show that R^k and P^k can be constructed in a coupled manner. In Figure 7 (left), consider $P^1 = (p_1, p_2, p_3, p_4, p_5)$. Recall that all segments in P^1 are of the same length $a = \frac{c_*}{2(c_*+1)}$. The isosceles triangles $\Delta p_1 p_2 p_3$ and $\Delta p_1 p_3 p_5$ are similar. Let $\sigma : \Delta p_1 p_3 p_5 \to \Delta p_1 p_2 p_3$ be the similarity transformation. Let $q_1 = \sigma(p_2)$ and $q_2 = \sigma(p_4)$. By construction, the chain $R^1 = (p_1, q_1, p_2, q_2, p_3)$ is similar to P^1. In particular, all of its segments have the same length. So the isosceles triangle $\Delta p_1 q_1 p_2$ is similar to $\Delta p_1 p_3 p_5$. Moreover, its base is the segment $p_1 p_2$, so $\Delta p_1 q_1 p_2$ is precisely $\mathrm{conv}(g_1(P^2))$, see Figure 7 (right).

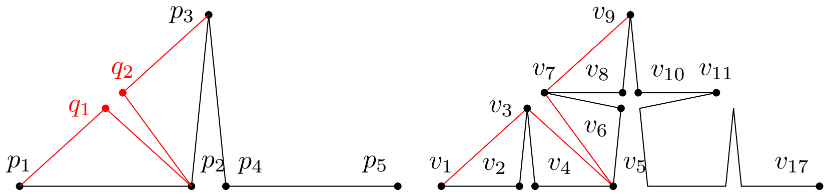

Figure 7 Left: the chains P^1 and R^1 (red); Right: the chains P^2 and R^1 (red).

Write $P^2 = (v_1, v_2, \ldots, v_{17})$, then $v_3 = q_1$ by the above argument and $v_7 = q_2$ by symmetry. Now $\Delta v_1 v_2 v_3$, $\Delta v_3 v_4 v_5$, $\Delta v_5 v_6 v_7$, and $\Delta v_7 v_8 v_9$ are four congruent isosceles triangles, all of which are similar to $\Delta v_1 v_9 v_{17}$, since the angles are the same. Repeat the above procedure on each of them to obtain $R^2 = (v_1, u_1, v_2, u_2, \ldots, v_8, u_8, v_9)$, which is similar to P^2. Continue this construction inductively to get the desired chain R^k for any $k \geq 1$.

For (ii), see Figure 7 (right). By definition, $g_5(P^2)$ is the subchain $(v_7, v_8, v_9, v_{10}, v_{11})$. Observe that the segments $v_7 v_8$ and $v_{10} v_{11}$ are collinear by symmetry. Moreover, they are parallel to $v_1 v_{17}$ since $\angle v_7 v_8 v_9 = \angle v_1 v_5 v_9$. So $g_5(P^2)$ is similar to P^1; see Figure 7 (left). Then for $k \geq 2$, $g_5(P^k)$ is the subchain of P^k starting at vertex v_7, ending at vertex v_{11}. By the construction of P^k, $g_5(P^k)$ is similar to P^{k-1}. ◀

Due to space constraints, the proof of Lemma 6 is deferred to the full version.

4 Algorithm for Recognizing c-Chains

In this section, we design a randomized Las Vegas algorithm to recognize c-chains. More precisely, given a polygonal chain $P = (p_1, \ldots, , p_n)$, and a parameter $c \geq 1$, the algorithm decides whether P is a c-chain, in $O\left(n^{2.5} \text{ polylog } n\right)$ expected time. By definition, $P = (p_1, \ldots, p_n)$ is a c-chain if $|p_i p_j| + |p_j p_k| \leq c\ |p_i p_k|$ for all $1 \leq i < j < k \leq n$; equivalently, p_j lies in the ellipse of major axis c with foci p_i and p_k. Consequently, it suffices to test, for every pair $1 \leq i < k \leq n$, whether the ellipse of major axis $c|p_i p_k|$ with foci p_i and p_k contains p_j, for all j, $i < j < k$. For this, we can apply recent results from geometric range searching.

▶ **Theorem 8.** *There is a randomized algorithm that can decide, for a polygonal chain $P = (p_1, \ldots, p_n)$ in $\mathbb{R}^2$ and a threshold $c > 1$, whether P is a c-chain in $O\left(n^{2.5} \text{ polylog } n\right)$ expected time and $O(n \log n)$ space.*

Agarwal, Matoušek and Sharir [2, Theorem 1.4] constructed, for a set S of n points in $\mathbb{R}^2$, a data structure that can answer ellipse range searching queries: it reports the number of points in S that are contained in a query ellipse. In particular, they showed that, for every $\varepsilon > 0$, there is a constant B and a data structure with $O(n)$ space, $O\left(n^{1+\varepsilon}\right)$ expected preprocessing time, and $O\left(n^{1/2}\log^B n\right)$ query time. The construction was later simplified by Matoušek and Patáková [27]. Using this data structure, we can quickly decide whether a given polygonal chain is a c-chain.

Proof of Theorem 8. Subdivide the polygonal chain $P = (p_1, \dots, p_n)$ into two subchains of equal or almost equal sizes, $P_1 = (p_1, \dots, p_{\lceil n/2\rceil})$ and $P_2 = (p_{\lceil n/2\rceil}, \dots, p_n)$; and recursively subdivide P_1 and P_2 until reaching 1-vertex chains. Denote by T the recursion tree. Then, T is a binary tree of depth $\lceil \log n\rceil$. There are at most 2^i nodes at level i; the nodes at level i correspond to edge-disjoint subchains of P, each of which has at most $n/2^i$ edges. Let W_i be the set of subchains on level i of T; and let $W = \bigcup_{i\geq 0} W_i$. We have $|W| \leq 2n$.

For each polygonal chain $Q \in W$, construct an ellipse range searching data structure $\mathrm{DS}(Q)$ described above [2] for the vertices of Q, with a suitable parameter $\varepsilon > 0$. Their overall expected preprocessing time is

$$\sum_{i=0}^{\lceil \log n\rceil} 2^i \cdot O\left(\left(\frac{n}{2^i}\right)^{1+\varepsilon}\right) = O\left(n^{1+\varepsilon}\sum_{i=0}^{\lceil \log n\rceil}\left(\frac{1}{2^i}\right)^{\varepsilon}\right) = O\left(n^{1+\varepsilon}\right),$$

their space requirement is $\sum_{i=0}^{\lceil \log n\rceil} 2^i \cdot O\left(n/2^i\right) = O(n\log n)$, and their query time at level i is $O\left(\left(n/2^i\right)^{1/2} \text{ polylog } \left(n/2^i\right)\right) = O\left(n^{1/2} \text{ polylog } n\right)$.

For each pair of indices $1 \leq i < k \leq n$, we do the following. Let $E_{i,k}$ denote the ellipse of major axis $c|p_ip_k|$ with foci p_i and p_k. The chain $(p_{i+1}, \dots, p_{k-1})$ is subdivided into $O(\log n)$ maximal subchains in W, using at most two subchains from each set W_i, $i = 0, \dots, \lceil \log n\rceil$. For each of these subchains $Q \in W$, query the data structure $\mathrm{DS}(Q)$ with the ellipse $E_{i,k}$. If all queries are positive (i.e., the count returned is $|Q|$ in *all* queries), then P is a c-chain; otherwise there exists j, $i < j < k$, such that $p_j \notin E_{i,k}$, hence $|p_ip_j| + |p_jp_k| > c|p_ip_k|$, witnessing that P is not a c-chain.

The query time over all pairs $1 \leq i < k \leq n$ is bounded above by

$$\begin{aligned}\binom{n}{2}\sum_{i=0}^{2\lceil \log n\rceil} O\left(\left(n/2^i\right)^{1/2} \text{ polylog } \left(n/2^i\right)\right) &= \binom{n}{2}\cdot O\left(n^{1/2} \text{ polylog } n\right)\\ &= O\left(n^{2.5} \text{ polylog } n\right).\end{aligned}$$

This subsumes the expected time needed for constructing the structures $\mathrm{DS}(Q)$, for all $Q \in W$. So the overall running time of the algorithm is $O\left(n^{2.5} \text{ polylog } n\right)$, as claimed. ◀

In the decision algorithm above, only the construction of the data structures $\mathrm{DS}(Q)$, $Q \in W$, uses randomization, which is independent of the value of c. The parameter c is used for defining the ellipses $E_{i,k}$, and the queries to the data structures; this part is deterministic. Hence, we can find the optimal value of c by Meggido's parametric search [28] in the second part of the algorithm.

Meggido's technique reduces an optimization problem to a corresponding decision problem at a polylogarithmic factor increase in the running time. An optimization problem is amenable to this technique if the following three conditions are met [34]: (1) the objective function is monotone in the given parameter; (2) the decision problem can be solved by evaluating bounded-degree polynomials, and (3) the decision problem admits an efficient parallel algorithm (with polylogarithmic running time using polynomial number of processors). All three conditions hold in our case: The area of each ellipse with foci in S monotonically increases with c; the data structure of [27] answers ellipse range counting queries by evaluating polynomials of bounded degree; and the $\binom{n}{2}$ queries can be performed in parallel. Alternatively, Chan's randomized optimization technique [11] is also applicable. Both techniques yield the following result.

▶ **Corollary 9.** *There is a randomized algorithm that can find, for a polygonal chain $P = (p_1, \dots, p_n)$ in $\mathbb{R}^2$, the minimum $c \geq 1$ for which P is a c-chain in $O\left(n^{2.5} \operatorname{polylog} n\right)$ expected time and $O(n \log n)$ space.*

We remark that, for $c = 1$, the test takes $O(n)$ time: it suffices to check whether points $p_3, \dots, p_n$ lie on the line spanned by p_1p_2, in that order.

5 Concluding Remarks

We end with some final observations and pointers for further research.

1. For $k \geq 1$, let $P_*^k = g_2(P^k) \cup g_3(P^k)$, see Figure 8 (right). It is easy to see that P_*^k is a c-chain with $n = 4^k/2 + 1$ vertices and has stretch factor $\sqrt{c(c-2)/8}(n-1)^{\frac{1+\log(c-2)-\log c}{2}}$. Since $\sqrt{c(c-2)/8} \geq 1$ for $c \geq 4$, this improves the result of Theorem 4 by a constant factor. Since this construction does not improve the exponent, and the analysis would be longer (requiring a case analysis without new insights), we omit the details.

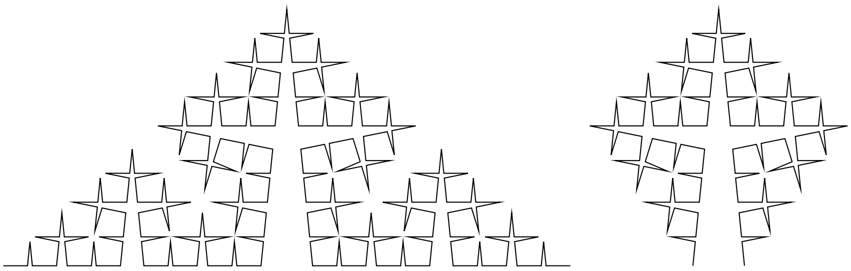

Figure 8 The chains P^4 (left) and P_*^4 (right).

2. If c is used instead of $c_* = (c-2)/2$ in the lower bound construction, then the condition $c \geq 4$ in Theorem 4 can be replaced by $c \geq 1$, and the bound can be improved from $(n-1)^{\frac{1+\log(c-2)-\log c}{2}}$ to $(n-1)^{\frac{1+\log c-\log(c+1)}{2}}$. However, we were unable to prove that the resulting P^k's, $k \in \mathbb{N}$, are c-chains, although a computer program has verified that the first few generations of them are indeed c-chains.
3. The volume argument in Theorem 3 easily generalizes to higher dimensions. If P be a c-chain in $\mathbb{R}^d$ for fixed $c \geq 1$ and $d \geq 2$, then $\delta_P = O\left(c^2(n-1)^{1-1/d}\right)$. It is interesting to find out whether extra dimension(s) allows one to achieve a larger stretch factor.
4. The upper bounds in Theorem 1–3 are valid regardless of whether the chain is crossing or not. On the other hand, the lower bound in Theorem 4 is given by noncrossing chains. A natural question is whether a sharper upper bound holds if the chains are required to be noncrossing. More specifically, can the exponent of n in the upper bound be reduced to $1/2 - \varepsilon$, where $\varepsilon > 0$ depends on c?
5. Our algorithm in Section 4 can recognize c-chains with n vertices in $O\left(n^{2.5} \operatorname{polylog} n\right)$ expected time and $O(n \log n)$ space, using ellipse range searching data structures. It is likely that the running time can be improved in the future, perhaps at the expense of increased space, when suitable time-space trade-offs for semi-algebraic range searching become available. The existence of such data structures is conjectured [2], but currently remains open.

Abstract

Spreading processes on graphs are a natural model for a wide variety of real-world phenomena, including information or behaviour spread over social networks, biological diseases spreading over contact or trade networks, and the potential flow of goods over logistical infrastructure. Often, the networks over which these processes spread are dynamic in nature, and can be modeled with graphs whose structure is subject to discrete changes over time, i.e. with *temporal graphs*. Here, we consider temporal graphs in which edges are available at specified timesteps, and study the problem of deleting edges from a given temporal graph in order to reduce the number of vertices (temporally) reachable from a given starting point. This could be used to control the spread of a disease, rumour, etc. in a temporal graph. In particular, our aim is to find a temporal subgraph in which a process starting at any single vertex can be transferred to only a limited number of other vertices using a temporally-feasible path (i.e. a path, along which the times of the edge availabilities increase). We introduce a natural deletion problem for temporal graphs and we provide positive and negative results on its computational complexity, both in the traditional and the parameterised sense (subject to various natural parameters), as well as addressing the approximability of this problem.

1 Introduction and motivation

A temporal graph is, loosely speaking, a graph that changes with time. A great variety of modern and traditional networks can be modeled as temporal graphs; social networks, wired or wireless networks which change dynamically, transportation networks, and several physical systems are only a few examples of networks that change over time [31, 38]. its vast applicability in many areas, this notion of temporal graphs has been studied from different perspectives under various names such as *time-varying* [1,24,44], *evolving* [11,15,22], *dynamic* [14, 27], and *graphs over time* [33]; for a recent attempt to integrate existing models, concepts, and results from the distributed computing perspective see the survey papers [12–14] and the references therein. Mainly motivated by the fact that, due to causality, entities and information in temporal graphs can "flow" only along sequences of edges whose time-labels are increasing, most temporal graph parameters and optimization problems that have been studied so far are based on the notion of temporal paths (see Definition 2 below) and other path-related notions, such as temporal analogues of distance, diameter, reachability, exploration, and centrality [2–4,19,21,35,37]. Recently, non-path temporal graph problems have also been addressed theoretically, including for example temporal variations of coloring [36], vertex cover [5], and maximal cliques [30,49,50].

Inspired by the foundational work of Kempe et al. [32], we adopt a simple model for such time-varying networks, in which the vertex set remains unchanged while each edge is equipped with a set of time-labels.

▶ **Definition 1** (temporal graph). *A* temporal graph *is a pair* (G, λ)*, where* $G = (V, E)$ *is an underlying (static) graph and* $\lambda : E \to 2^{\mathbb{N}}$ *is a* time-labelling *function which assigns to every edge of* G *a set of discrete-time labels.*

For every edge $e \in E$ in the underlying graph G of a temporal graph (G, λ), $\lambda(e)$ denotes the set of time slots at which e is *active* in (G, λ).

Unless stated otherwise, to simplify the presentation of our results we restrict our attention in this paper to temporal graphs in which each edge is assigned a singleton set by the time-labelling function, that is, in which each edge is active at exactly one time.

Spreading processes on networks or graphs are a topic of significant research across network science [7], and a variety of application areas [28, 29], as well as inspiring more theoretical algorithmic work [23]. Part of the motivation for this interest is the usefulness of spreading processes for modelling a variety of natural phenomena, including biological diseases spreading over contact networks, and rumours or news (both fake and real) spreading over information-passing networks. The rise of quantitative approaches in modelling these phenomena is supported by the increasing number and size of network datasets that can be used as denominator graphs on which processes can spread (e.g. human mobility and contact networks [42], agricultural trade networks [39], and social networks [34]). Typically, a vertex in one of these networks represents some entity that has a state in the process (for example, being infected with a disease, or holding a belief), and edges represent contacts over which the state can spread to other vertices.

Our work is partly motivated by the need to control contagion (be it biological or informational) that may spread over contact networks. Data specifying timed contacts that could spread an infectious disease are recorded in a variety of settings, including movements of humans via commuter patterns and airline flights [16], and fine-grained recording of livestock movements between farms in most European nations [40]. There is very strong evidence that these networks play a critical role in large and damaging epidemics, including the 2009 H1N1 influenza pandemic [10] and the 2001 British foot-and-mouth disease epidemic [28]. Because of the key importance of timing in these networks to their capacity to spread disease, methods to assess the susceptibility of temporal graphs and networks to disease incursion have recently become an active area of work within network epidemiology in general, and within livestock network epidemiology in particular [9,41,47,48].

Here, similarly to [20], we focus our attention on deleting edges from (G, λ) in order to limit the temporal connectivity of the remaining temporal subgraph. To this end, the following temporal extension of the notion of a path in a static graph is fundamental [32,35].

▶ **Definition 2** (temporal path). *A* temporal path *from u to v in a temporal graph (G, λ) is a path from u to v in G, composed of edges $e_0, e_1, \ldots, e_k$ such that each edge e_i is assigned a time $t(e_i) \in \lambda(e_i)$, where $t(e_i) < t(e_{i+1})$ for $0 \leq i < k$.*

In many applications, it may be more realistic to generalise our notion of temporal paths so that the time between arriving at and leaving any vertex must fall within some fixed range. For example, in the context of disease transmission, an upper bound on the permitted time between entering and leaving a vertex might represent the time within which an infection would be detected and eliminated (thus ensuring no further transmission). On the other hand, a lower bound might represent the time between individuals being exposed to an infection and becoming infectious themselves. We formalise this as follows:

▶ **Definition 3.** *Let (G, λ) be a temporal graph and let $\alpha \leq \beta \in \mathbb{N}$. An* (α, β)-temporal path *from u to v in (G, λ) is a path from u to v in G, composed of edges $e_0, e_1, \ldots, e_k$, such that each edge e_i, $0 \leq i < k$, is assigned a time $t(e_i)$ from its image in λ, where $\alpha \leq t(e_{i+1}) - t(e_i) \leq \beta$.*

Our contribution

We consider a natural deletion problem for temporal graphs, namely Temporal Reachability Edge Deletion (for short, TR Edge Deletion), as well as its optimisation version, and study its computational complexity, both in the traditional and the parameterised sense, subject to natural parameters. Given a temporal graph (G, λ) and two natural numbers k, h, the goal is to delete at most k edges from (G, λ) such that, for every vertex v of G, there exists a temporal path to at most $h - 1$ other vertices.

In Section 3, we show that TR Edge Deletion is NP-complete, even on very restricted classes of graphs. We give two different reductions. The first shows that, assuming the Exponential Time Hypothesis, it is unlikely that we can improve significantly on a brute-force approach when considering how the running-time depends on the input size and the number of permitted deletions. The second demonstrates that TR Edge Deletion is *para-NP-hard* (i.e. NP-hard even for constant-valued parameters) with respect to each one of the parameters h, maximum degree Δ_G, or lifetime of (G, λ) (i.e. the maximum label assigned by λ to any edge of G).

In Section 4, we turn our attention to approximation algorithms for the optimisation version of the problem, Min TR Edge Deletion, in which the goal is to find a minimum-size set of edges to delete. We begin by describing a polynomial-time algorithm to compute an h-approximation to Min TR Edge Deletion on arbitrary temporal graphs, then show how similar techniques can be applied to compute a c-approximation on inputs in which the underlying graph has cutwidth c. We conclude our consideration of approximation algorithms by showing that in general there is unlikely to be a polynomial-time algorithm to compute any constant-factor approximation, even on temporal graphs of lifetime two.

In Section 5, we consider exact FPT algorithms. Our hardness results show that the problem remains intractable when parameterised by h or Δ_G alone; here we obtain an FPT algorithm by parameterising simultaneously by h, Δ_G and the treewidth $tw(G)$ of the underlying (static) graph G. In doing so, we demonstrate a general framework in which a celebrated result by Courcelle, concerning relational structures with bounded treewidth (see Theorem 14) can be applied to solve problems in temporal graphs.

We note that all of our results can be applied, with minor modifications to the proofs, to the setting of (α, β)-temporal paths.

2 Preliminaries

Given a (static) graph G, we denote by $V(G)$ and $E(G)$ the sets of its vertices and edges, respectively. An edge between two vertices u and v of G is denoted by uv, and in this case u and v are said to be *adjacent* in G. Given a temporal graph (G, λ), where $G = (V, E)$, the maximum label assigned by λ to an edge of G, called the *lifetime* of (G, λ), is denoted by $T(G, \lambda)$, or simply by T when no confusion arises. That is, $T(G, \lambda) = \max\{t \in \lambda(e) : e \in E\}$. Throughout the paper we consider temporal graphs with *finite lifetime* T. Furthermore, we assume that the given labelling λ is arbitrary, i.e. (G, λ) is given with an explicit list of labels for every edge. Thus, the *size* of the input temporal graph (G, λ) is $O\left(|V| + T + \sum_{t=1}^{T} |E_t|\right) = O(n + mT)$: when we are considering temporal graphs in which edges are active at a single timestep, it suffices to only consider the space required to represent the single time assigned to each edge, and thus the size of the temporal graph is $O(n + m \log T)$. We say that an edge $e \in E$ *appears at time* t if $t \in \lambda(e)$, and in this case we call the pair (e, t) a *time-edge* in (G, λ). Given a subset $E' \subseteq E$, we denote by $(G, \lambda) \setminus E'$ the temporal graph (G', λ'), where $G' = (V, E \setminus E')$ and λ' is the restriction of λ to $E \setminus E'$.

We say that a vertex v is *temporally reachable* from u in (G, λ) if there exists a temporal path from u to v. Furthermore we adopt the convention that every vertex v is temporally reachable from itself. The *temporal reachability set* of a vertex u, denoted by $\text{reach}_{G,\lambda}(u)$, is the set of vertices which are temporally reachable from vertex u. The *temporal reachability* of u is the number of vertices in $\text{reach}_{G,\lambda}(u)$. Furthermore, the *maximum temporal reachability* of a temporal graph is the maximum of the temporal reachabilities of its vertices.

In this paper we mainly consider the following problem.

Temporal Reachability Edge Deletion (TR Edge Deletion)

Input: A temporal graph (G, λ), and $k, h \in \mathbb{N}$.
Output: Is there a set $E' \subseteq E(G)$, with $|E'| \leq k$, such that the maximum temporal reachability of $(G, \lambda) \setminus E'$ is at most h?

Note that the problem clearly belongs to NP as a set of edges acts as a certificate (the reachability set of any vertex in a given temporal graph can be computed in polynomial time [3, 32, 35]). It is worth noting here that the (similarly-flavored) deletion problem for finding small separators in temporal graphs was studied recently, namely the problem of removing a small number of vertices from a given temporal graph such that two fixed vertices become temporally disconnected [26, 51].

3 Computational hardness

The main results of this section demonstrate that TR Edge Deletion is NP-complete even under very strong restrictions on the input. Our first result shows that the trivial brute-force algorithm, running in time $n^{\mathcal{O}(k)}$, in which we consider all possible sets of k edges to delete, cannot be significantly improved in general.

▶ **Theorem 4.** TR Edge Deletion *is W[1]-hard when parameterised by the maximum number k of edges that can be removed, even when the input temporal graph has lifetime 2. Moreover, assuming ETH, there is no $f(k)\tau^{o(k)}$ time algorithm for* TR Edge Deletion*, where τ is the size of the input temporal graph.*

The W[1]-hardness reduction of Theorem 4 also implies that the problem TR Edge Deletion is NP-complete, even on temporal graphs with lifetime at most two. We note that, for temporal graphs of lifetime one, the problem is solvable in polynomial time: in this setting, the reachability set of each vertex is precisely its closed neighbourhood, so the problem reduces to that of deleting a set of at most k edges so that every vertex has degree at most $h-1$ which is solvable in polynomial time [43, Theorem 33.4].

We now demonstrate that TR Edge Deletion remains NP-complete on temporal graphs of lifetime two even if the underlying graph has bounded degree and the maximum permitted size of a temporal reachability set is bounded by a constant.

▶ **Theorem 5.** TR Edge Deletion *is NP-complete, even when the maximum temporal reachability h is at most 7 and the input temporal graph (G, λ) has:*

1. *maximum degree Δ_G of the underlying graph G at most 5, and*
2. *lifetime at most 2.*

Therefore TR Edge Deletion *is para-NP-hard with respect to each of the parameters h, Δ_G, and lifetime $T(G, \lambda)$.*

Proof. As we mentioned in Section 2, the problem trivially belongs to NP. Now we give a reduction from the following well-known NP-complete problem [46].

3,4-SAT

Input: A CNF formula Φ with exactly 3 variables per clause, such that each variable appears in at most 4 clauses.
Output: Does there exists a truth assignment satisfying Φ?

Let Φ be an instance of $3,4$-SAT with variables $x_1, \ldots, x_n$, and clauses $C_1, \ldots, C_m$. We may assume without loss of generality that every variable x_i appears at least once negated and at least once unnegated in Φ. Indeed, if a variable x_i appears only negated (resp. unnegated) in Φ, then we can trivially set $x_i = 0$ (resp. $x_i = 1$) and then remove from Φ all clauses where x_i appears; this process would provide an equivalent instance of 3,4-SAT of smaller size. Now we construct an instance $((G, \lambda), k, h)$ of TR Edge Deletion which is a yes-instance if and only if Φ is satisfiable.

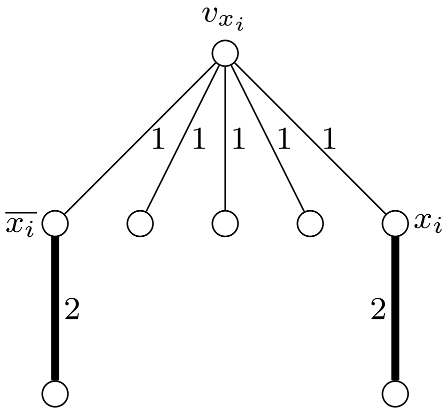

Figure 1 The gadget corresponding to variable x_i. The number beside an edge is the time step at which that edge appears. The bold edges are the ones we refer to as *literal edges*.

We construct (G, λ) as follows. For each variable x_i we introduce in G a copy of the subgraph shown in Figure 1, which we call an *x_i-gadget.* There are three special vertices in an x_i-gadget: x_i and $\overline{x_i}$, which we call *literal vertices*, and v_{x_i} which we call the *head vertex* of the x_i-gadget. All the edges incident to v_{x_i} appear in time step 1, the other two edges of x_i-gadget, which we call *literal edges*, appear in time step 2. Additionally, for every clause

C_s we introduce in G: 1) a *clause vertex* C_s that is adjacent to the three literal vertices corresponding to the literals of C_s, and 2) one more vertex adjacent only to C_s, which we call the *satellite vertex of* C_s. All the new edges incident to C_s appear in time step 1. See Figure 2 for an illustration. Finally, we set $k = n$ and $h = 7$.

First recall that, in Φ, every variable x_i appears at least once negated and at least once unnegated. Therefore, since every variable x_i appears in at most four clauses in Φ, it follows that each of the two vertices corresponding to the literals $x_i, \overline{x_i}$ is connected to at most three clause gadgets. Therefore the degree of each vertex corresponding to a literal in the constructed temporal graph (G, λ) (see Figure 2) is at most five. Moreover, it can be easily checked that the same also holds for every other vertex of (G, λ), and thus $\Delta_{G,\lambda} \leq 5$.

We continue by observing temporal reachabilities of the vertices of (G, λ). A literal vertex can temporally reach only the corresponding clause vertices, and the two neighbours in its gadget. Since every literal belongs to at most 4 clauses in Φ, the temporal reachability of the literal vertex in (G, λ) is at most 7 (including the vertex itself). The head vertex of a gadget temporally reaches only the vertices of the gadget, hence the temporal reachability of any head vertex in (G, λ) is 8. Any other vertex belonging to a gadget can temporally reach only its unique neighbour in G and so has temporal reachability 2. Every clause vertex can reach only the corresponding literal vertices, their neighbours incident to the literal edges, and its own satellite vertex. Hence the temporal reachability of every clause vertex in (G, λ) is 8. Finally, every satellite vertex reaches only its neighbour, and thus its temporal reachability is 2. Therefore in our instance of TR EDGE DELETION we only need to care about temporal reachabilities of the clause and head vertices.

Now we show that, if there is a set E of n edges such that the maximum temporal reachability of the modified graph $(G, \lambda) \setminus E$ is at most 7, then Φ is satisfiable. First, notice that since the temporal reachability of every head vertex is decreased in the modified graph and the number of gadgets is n, the set E contains exactly one edge from every gadget. Hence, as the temporal reachability of every clause vertex C_s is also decreased, set E must contain at least one literal edge that is incident to a literal neighbour of C_s. We now construct a truth assignment as follows: for every literal edge in E we set the corresponding literal to TRUE. If there are unassigned variables left we set them arbitrarily, say, to TRUE.

Since E has one edge in every gadget, every variable was assigned exactly once. Moreover, by the above discussion, every clause has a literal that is set to TRUE by the assignment. Hence the assignment is well-defined and satisfies Φ.

To show the converse, given a truth assignment $(\alpha_1, \ldots, \alpha_n)$ satisfying Φ we construct a set E of n edges such that the maximum temporal reachability of $(G, \lambda) \setminus E$ is at most 7. For every $i \in [n]$ we add to E the literal edge incident to x_i if $\alpha_i = 1$, and the literal edge incident to $\overline{x_i}$ otherwise. By the construction, E has exactly one edge from every gadget. Moreover, since the assignment satisfies Φ, for every clause C_s set E contains at least one literal edge corresponding to one of the literals of C_s. Hence, by removing E from (G, λ), we strictly decrease temporal reachability of every head and clause vertex. ◀

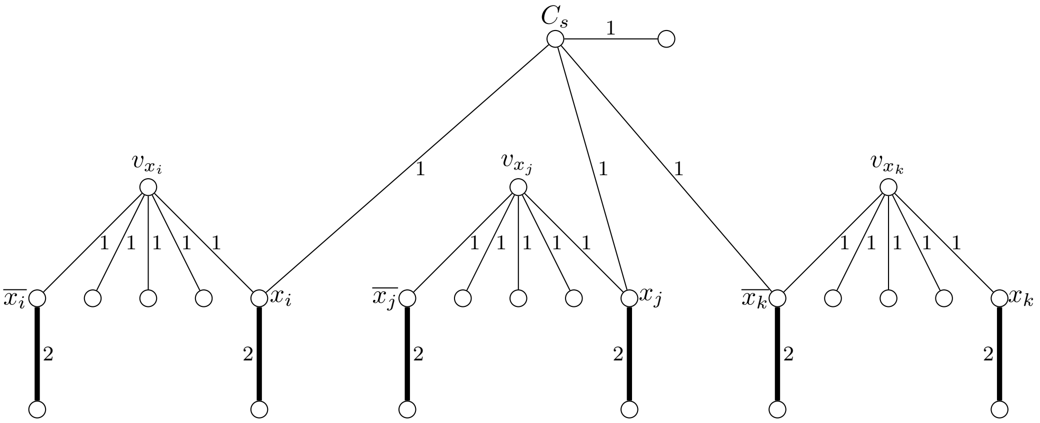

Figure 2 A subgraph of a temporal graph corresponding to an instance of 3,4-SAT.

4 Approximability

Given the strength of the hardness results proved in Section 3, it is natural to ask whether the problem admits efficient approximation algorithms for the following optimisation problem.

Minimum Temporal Reachability Edge Deletion (Min TR Edge Deletion)

Input: A temporal graph (G, λ) and $h \in \mathbb{N}$.
Output: A set X of edges of *minimum* size such that the maximum temporal reachability of $(G, \lambda) \setminus X$ is at most h?

We begin with some more notation. If (G, λ) is a temporal graph and $v \in V(G)$, we say that T is a *reachable subtree for* v if T is a subtree of G, $v \in V(T)$ and, for all $u \in V(T) \setminus \{v\}$, there is a temporal path from v to u in (T, λ'), where λ' is the restriction of λ to the edges of T. We first observe that, if a temporal graph has maximum reachability more than h, we can efficiently find a minimal reachable subtree witnessing this fact.

▶ **Lemma 6.** *Let (G, λ) be a temporal graph, and h a positive integer. There is an algorithm running in polynomial time which, on input $((G, \lambda), h)$,*

1. *if the maximum temporal reachability of (G, λ) is at most h, outputs "YES";*
2. *if the maximum temporal reachability of (G, λ) is greater than h, outputs a vertex $v \in V(G)$ and a reachable subtree T for v where T has exactly $h + 1$ vertices.*

Let h be a positive integer and $(G = (V, E), \lambda)$ be a temporal graph. We say that edge set $E' \subseteq E$ is a *valid deletion* of $(G = (V, E), \lambda)$ with respect to h if the maximum temporal reachability of $(G = (V, E), \lambda) \backslash E'$ is at most h. Where h is clear from the context, we may not refer to it explicitly. We now make a simple observation about valid deletions.

▶ **Lemma 7.** *Let (G, λ) be a temporal graph and h a positive integer. Suppose that T is a reachable subtree for some $v \in V(G)$ and that T has more than h vertices. If $E' \subseteq E(G)$ is a valid deletion with respect to h, then $|E' \cap E(T)| \geq 1$.*

Using these two observations, we now describe our first approximation algorithm.

▶ **Theorem 8.** *There exists a polynomial-time algorithm to compute an h-approximation to* Min TR Edge Deletion, *where h denotes the maximum permitted reachability.*

Proof. Let $((G,\lambda),h)$ be an input instance of Min TR Edge Deletion, and let $E_{opt} \subseteq E$ be a minimum-cardinality edge set such that $(G,\lambda) \setminus E_{\text{opt}}$ has temporal reachability at most h. It suffices to demonstrate that we can find in polynomial time a set $E' \subseteq E$ such that $(G,\lambda) \setminus E'$ has temporal reachability at most h, and $|E'| \leq h|E_{\text{opt}}|$. We claim that the following algorithm achieves this.

1. Initialise $E' := \emptyset$.
2. While (G,λ) has reachability greater than h:
   a. Find a pair (v,T) such that $v \in V(G)$, T is a reachable subtree for v and $|T| = h+1$.
   b. Add $E(T)$ to E', and update $(G,\lambda) \leftarrow (G,\lambda) \setminus E'$.
3. Return E'.

We begin by considering the running time of this algorithm. By Lemma 6 we can determine whether to execute the while loop and, if we do enter the loop, execute Step 2(a), all in polynomial time. Steps 1 and 2(b) can clearly both be carried out in linear time. Moreover, the total number of iterations of the while loop is bounded by the number of edges in G, so we see that the algorithm will terminate in polynomial time.

At every iteration, the algorithm removes exactly h edges, while the optimum deletion set E_{opt} must remove at least one of these h edges. Therefore, in total, we remove at most $h|E_{opt}|$ edges. To complete the proof, we observe that, by construction, the identified set E' is a valid deletion set. ◀

We now demonstrate that we can improve on this general approximation algorithm when the underlying graph has certain useful temporal properties, in particular when the cutwidth is bounded.

The *cutwidth* of a graph $G = (V,E)$ is the minimum integer c such that the vertices of G can be arranged in a linear order $v_1, \ldots, v_n$, called a *layout*, such that for every i with $1 \leq i < n$ the number of edges with one endpoint in $v_1, ..., v_i$ and one in $v_{i+1}, ..., v_n$ is at most c. Given a layout $v_1, v_2, \ldots, v_n$, we say that edges with one endpoint in $v_1, ..., v_i$ and one in $v_{i+1}, ..., v_n$ *span* v_i, v_{i+1}, and say that the maximum number of edges spanning a pair of consecutive vertices is the *cutwidth* of the layout. For any constant c, Thilikos et al. [45] give a linear-time algorithm to generate a layout of cutwidth at most c if one exists.

We can use a similar argument to that in Theorem 8 to give a polynomial-time algorithm to compute a c-approximation to Min TR Edge Deletion, where c is the cutwidth of the input temporal graph. In addition to Lemma 7, we will also make use of the following definition and observation:

Let $G = (V,E)$ be a graph. We say that an edge set $E_S \subseteq E$ is an *edge separator* that separates G into $G_A = (V_A, E_A)$ and $G_B = (V_B, E_B)$ if, in $G_S = (V, E \backslash E_S)$ no vertex in V_A is reachable from V_B.

▶ **Lemma 9.** *Let h be a positive integer and $(G = (V,E), \lambda)$ be a temporal graph with an edge separator E_S that separates G into $G_A = (V_A, E_A)$ and $G_B = (V_B, E_B)$. If, for the given h, E'_A and E'_B are valid deletion sets for $(G_A, \lambda|_{E_A})$, $(G_B, \lambda|_{E_B})$, respectively, then $E'_A \cup E'_B \cup E_S$ is a valid deletion set for $(G = (V,E), \lambda)$.*

We now describe a cutwidth approximation algorithm:

▶ **Theorem 10.** *There exists a polynomial-time algorithm to compute a c-approximation to* Min TR Edge Deletion *provided that a layout of cutwidth c is given.*

Proof (Sketch). Let $((G = (V,E), \lambda), h)$ be the input to Min TR Edge Deletion, and suppose that the layout $v_1, \ldots, v_n$ of V, with cutwidth c, is given. We claim that the following algorithm returns a c-approximation to Min TR Edge Deletion in polynomial time:

1. Initialise $E' := \emptyset$.
2. Initialise $i := 0$.
3. While (G, λ) has reachability greater than h:
   a. Find the maximum $j \in \{i, \dots, n\}$ such that the maximum reachability in the subgraph $(G[\{v_i, \dots, v_j\}], \lambda|_{E(G[\{v_i, \dots, v_j\}])})$ is at most h.
   b. Add all edges that span v_j, v_{j+1} to E', and and update $(G, \lambda) \leftarrow (G, \lambda) \setminus E'$.
   c. Update $i \leftarrow j + 1$
4. Return E'. ◀

For any fixed cutwidth c, using the layout generation algorithm given by Thilikos et al. [45] and the algorithm described above, we can give a cutwidth-approximation to Min TR Edge Deletion for graphs with cutwidth c.

▶ **Corollary 11.** *There exists a polynomial-time algorithm to compute a c-approximation to* Min TR Edge Deletion *whenever the cutwidth of the input graph is bounded above by c.*

Note that as paths have cutwidth one, Corollary 11 gives us an exact polynomial-time algorithm for Min TR Edge Deletion on paths.

We conclude this section by demonstrating that there is unlikely to be a polynomial-time algorithm to compute any constant factor approximation to Min TR Edge Deletion in general, even for temporal graphs of lifetime two.

▶ **Theorem 12.** *Unless $P = NP$,* Min TR Edge Deletion *cannot be approximated in polynomial time to within a factor of $(1 - o(1)) \ln \log_2 \sqrt{n}$, where n is the number of vertices in the input temporal graph, even if the input temporal graph has lifetime two.*

5 An exact FPT algorithm

In this section we show that TR Edge Deletion admits an FPT algorithm, when simultaneously parameterised by h, Δ_G, and $tw(G)$, where Δ_G is the maximum degree of G and $tw(G)$ is the treewidth of G. It is worth noting that, although the parameters h and Δ_G may at first seem to be large, parameterising only by these two parameters is not enough, as our results in the previous sections (see e.g. Theorem 5) imply that TR Edge Deletion is para-NP-hard, when simultaneously parameterised by h and Δ_G.

Our results in this section (see Theorem 16) illustrate how a celebrated theorem by Courcelle (see Theorem 14) can be applied to solve temporal graph problems, following a general framework that could potentially be applied to many other temporal problems as well: (i) we define a suitable family τ of relations (i.e. a suitable relational vocabulary) and a Monadic Second Order (MSO) formula ϕ (of length ℓ) that expresses our temporal graph problem at hand; (ii) we represent an arbitrary input temporal graph (G, λ) with an equivalent relational structure $\mathcal{A}$ (of treewidth at most t); (iii) we apply Courcelle's general theorem which solves our problem at hand in time linear to the size of the relational structure $\mathcal{A}$, whenever both ℓ and t are bounded; that is, in time $f(t, \ell) \cdot ||\mathcal{A}||$.

Here, we apply this general framework to the particular problem TR Edge Deletion (by appropriately defining τ, ϕ, and $\mathcal{A}$) such that ℓ only depends on our parameter h, while t only depends on $\mathrm{tw}(G)$ and Δ_G; this yields our FPT algorithm. Here, as it turns out, the size of $\mathcal{A}$ is quadratic on the size of the input temporal graph (G, λ). Before we present the main result of this section (see Section 5.2), we first present in Section 5.1 some necessary background on logic and on tree decompositions of graphs and relational structures. For any undefined notion in Section 5.1, we refer the reader to [25].

5.1 Preliminaries for the algorithm

Treewidth of graphs

Given any tree T, we will assume that it contains some distinguished vertex $r(T)$, which we will call the *root* of T. For any vertex $v \in V(T) \setminus \{r(T)\}$, the *parent* of v is the neighbour of v on the unique path from v to $r(T)$; the set of *children* of v is the set of all vertices $u \in V(T)$ such that v is the parent of u. The *leaves* of T are the vertices of T whose set of children is empty. We say that a vertex u is a *descendant* of the vertex v if v lies somewhere on the unique path from u to $r(T)$. In particular, a vertex is a descendant of itself, and every vertex is a descendant of the root. Additionally, for any vertex v, we will denote by T_v the subtree induced by the descendants of v.

We say that $(T, \mathcal{B})$ is a *tree decomposition* of G if T is a tree and $\mathcal{B} = \{\mathcal{B}_s : s \in V(T)\}$ is a collection of non-empty subsets of $V(G)$ (or *bags*), indexed by the nodes of T, satisfying:

(1) for all $v \in V(G)$, the set $\{s \in T : v \in \mathcal{B}_s\}$ is nonempty and induces a connected subgraph in T,

(2) for every $e = uv \in E(G)$, there exists $s \in V(T)$ such that $u, v \in \mathcal{B}_s$.

The *width* of the tree decomposition $(T, \mathcal{B})$ is defined to be $\max\{|\mathcal{B}_s| : s \in V(T)\} - 1$, and the *treewidth* of G is the minimum width over all tree decompositions of G.

Although it is NP-hard to determine the treewidth of an arbitrary graph [6], the problem of determining whether a graph has treewidth at most w (and constructing such a tree decomposition if it exists) can be solved in linear time for any constant w [8]; note that this running time depends exponentially on w.

▶ **Theorem 13** (Bodlaender [8]). *For each $w \in N$, there exists a linear-time algorithm, that tests whether a given graph $G = (V, E)$ has treewidth at most w, and if so, outputs a tree decomposition of G with treewidth at most w.*

Relational structures and monadic second order logic

A *relational vocabulary* τ is a set of relation symbols. Each relation symbol R has an *arity*, denoted $\text{arity}(R) \geq 1$. A *structure* $\mathcal{A}$ of vocabulary τ, or τ-structure, consists of a set A, called the *universe*, and an interpretation $R^{\mathcal{A}} \subseteq A^{\text{arity(R)}}$ of each relation symbol $R \in \tau$. We write $\overline{a} \in R^{\mathcal{A}}$ or $R^{\mathcal{A}}(\overline{a})$ to denote that the tuple $\overline{a} \in A^{\text{arity}(R)}$ belongs to the relation $R^{\mathcal{A}}$.

We briefly recall the syntax and semantics of first-order logic. We fix a countably infinite set of (*individual*) *variables*, for which we use small letters. *Atomic formulas of vocabulary τ* are of the form:

1. $x = y$ or
2. $R(x_1 \ldots x_r)$,

where $R \in \tau$ is r-ary and $x_1, \ldots, x_r, x, y$ are variables. *First-order formulas* of vocabulary τ are built from the atomic formulas using the Boolean connectives $\neg, \wedge, \vee$ and existential and universal quantifiers $\exists, \forall$.

The difference between first-order and second-order logic is that the latter allows quantification not only over elements of the universe of a structure, but also over subsets of the universe, and even over relations on the universe. In addition to the individual variables of first-order logic, formulas of second-order logic may also contain *relation variables*, each of which has a prescribed arity. Unary relation variables are also called *set variables.* We use capital letters to denote relation variables. To obtain second-order logic, the syntax of first-order logic is enhanced by new atomic formulas of the form $X(x_1 \ldots x_k)$, where X is k-ary relation variable. Quantification is allowed over both individual and relation variables.

A second-order formula is *monadic* if it only contains unary relation variables. Monadic second-order logic is the restriction of second-order logic to monadic formulas. The class of all monadic second-order formulas is denoted by MSO.

A *free variable* of a formula ϕ is a variable x with an occurrence in ϕ that is not in the scope of a quantifier binding x. A *sentence* is a formula without free variables. Informally, we say that a structure $\mathcal{A}$ *satisfies* a formula ϕ if there exists an assignment of the free variables under which ϕ becomes a true statement about $\mathcal{A}$. In this case we will write $\mathcal{A} \models \phi$.

Treewidth of relational structures

The definition of tree decompositions and treewidth generalizes from graphs to arbitrary relational structures in a straightforward way. A *tree decomposition* of a τ-structure $\mathcal{A}$ is a pair $(T, \mathcal{B})$, where T is a tree and $\mathcal{B}$ a family of subsets of the universe A of $\mathcal{A}$ such that:

(1) for all $a \in A$, the set $\{s \in V(T) : a \in \mathcal{B}_s\}$ is nonempty and induces a connected subgraph (i.e. subtree) in T,

(2) for every relation symbol $R \in \tau$ and every tuple $(a_1, \ldots, a_r) \in R^{\mathcal{A}}$, where $r := \text{arity}(R)$, there is a $s \in V(T)$ such that $a_1, \ldots, a_r \in \mathcal{B}_s$.

The *width* of the tree decomposition $(T, \mathcal{B})$ is the number $\max\{|\mathcal{B}_s| : s \in V(T)\} - 1$. The *treewidth* $tw(\mathcal{A})$ of $\mathcal{A}$ is the minimum width over all tree decompositions of $\mathcal{A}$.

We will make use of the version of Courcelle's celebrated theorem for relational structures of bounded treewidth, which, informally, says that the optimization problem definable by an MSO formula can be solved in FPT time with respect to the treewidth of a relational structure. The formal statement is an adaptation of an analogous theorem (see Theorem 9.21 in [18]) for the model-checking problem [17].

▶ **Theorem 14** ([18]). *Let ϕ be an MSO formula with a free set variable E, and let $\mathcal{A}$ be a relational structure on universe A, where $\text{tw}(\mathcal{A}) \leq t$. Then, given a width-$t$ tree decomposition of $\mathcal{A}$, a minimum-cardinality set $E \subseteq A$ such that $\mathcal{A}$ satisfies $\phi(E)$ can be computed in time*

$$f(t, \ell) \cdot ||\mathcal{A}||,$$

where f is a computable function, ℓ is the length of ϕ, and $||\mathcal{A}||$ is the size of $\mathcal{A}$.

5.2 The FPT algorithm

In this section we present an FPT algorithm for TR Edge Deletion when parameterised simultaneously by three parameters: h, $\text{tw}(G)$ and Δ_G. Our strategy is first, given an input temporal graph (G, λ), to construct a relational structure $\mathcal{A}_{G,\lambda}$ whose treewidth is bounded in terms of $\text{tw}(G)$ and Δ_G. Then we construct an MSO formula ϕ_h with a unique free set variable E, such that $\mathcal{A}_{G,\lambda}$ satisfies $\phi_h(E)$ for some $E \subseteq A$ if and only if the maximum reachability of $(G, \lambda) \setminus E$ is at most h. Finally, we apply Theorem 14 to find the minimum cardinality of such a set $E \subseteq A$. If the minimum cardinality is at most k, then $((G, \lambda), k, h)$ is a yes-instance of the problem, otherwise it is a no-instance.

We note that in the case we consider here in which each edge is active at a single timestep the construction below might be simplified slightly; however, in order to demonstrate the flexibility of this general framework, we choose to define a relational structure which would allow us to represent temporal graphs in which edges may be active at more than one timestep. Observe that Theorem 16 can immediately be adapted to this more general context if we replace Δ_G by the maximum temporal total degree of the input temporal graph (i.e. the maximum number of time-edges incident with any vertex).

Given a temporal graph (G, λ), we define a relational structure $\mathcal{A}_{G,\lambda}$ as follows. The ground set $A_{G,\lambda}$ consists of

- the set $V(G)$ of vertices in G,
- the set $E(G)$ of edges in G, and
- the set of all time-edges of (G, λ), i.e. the set $\Lambda(G, \lambda) = \{(e, t) \mid e \in E(G), t \in \lambda(e)\}$.

On this ground set $A_{G,\lambda}$, we define two binary relations $\mathcal{R}$ and $\mathcal{L}$ as follows:

1. $((e_1, t_1), (e_2, t_2)) \in \mathcal{R}$ if and only if the following conditions hold:
   a. $(e_1, t_1), (e_2, t_2) \in \Lambda(G, \lambda)$;
   b. e_1, e_2 share a vertex in G;
   c. $t_1 < t_2$.
2. $(e, (e, t)) \in \mathcal{L}$ if and only if $(e, t) \in \Lambda(G, \lambda)$.

First we show that the treewidth of $\mathcal{A}_{G,\lambda}$ is bounded by a function of $\mathrm{tw}(G)$ and Δ_G.

▶ **Lemma 15.** *The treewidth of $\mathcal{A}_{G,\lambda}$ is at most $(2\Delta_G + 1)(\mathrm{tw}(G) + 1) - 1$.*

Using this, we now provide the main result of this section.

▶ **Theorem 16.** TR Edge Deletion *admits an FPT algorithm with respect to the combined parameters h, $\mathrm{tw}(G)$, and Δ_G.*

6 Conclusions and open problems

In this paper we studied the problem of removing a small number of *edges* from a given *temporal graph* (i.e. a graph that changes over time) to ensure that every vertex has a temporal path to at most h other vertices. The main motivation for this problem comes from the need to limit spreading processes on dynamic graphs. Such a graph could, for example, capture potentially-infectious contacts between individuals, and removing an edge would correspond to restricting or prohibiting contact between two entities in order to limit the spread of an epidemic.

We show that our problem is W[1]-hard when parameterised by the maximum number k of edges that can be removed and, assuming the Exponential Time Hypothesis, we cannot significantly improve on the brute-force algorithm that considers all possible deletions sets of k edges. On the positive side, we prove that this problems admits a fixed-parameter tractable (FPT) algorithm with respect to the combination of three parameters: the treewidth $\mathrm{tw}(G)$ of the underlying graph G, the maximum allowed temporal reachability h, and the maximum degree Δ_G of (G, λ). Moreover, we show that the latter two parameters combined (i.e. without the treewidth $\mathrm{tw}(G)$) are not enough for deriving an FPT algorithm as the problem is para-NP-complete with respect to both of these parameters. On the other hand, it remains open whether this problem is FPT, when parameterised by treewidth $\mathrm{tw}(G)$, combined with only one of the other two parameters h and Δ_G. We also consider the approximability of this problem, and give two polynomial-time approximation algorithms. The first computes an h-approximation on an arbitrary input graph, where h denotes the maximum allowable temporal reachability, and the second computes a c-approximation on graphs of cutwidth c. We complement these positive results by showing that no constant-factor approximation algorithm exists for general input graphs unless $P = NP$. A natural open problem is whether we can improve these approximation algorithms. Our lower bound rules out a $(\log \log h)$-factor approximation, but a significant improvement on our factor h approximation may be possible.

Abstract

Marx (STOC 2010, J. ACM 2013) introduced the notion of submodular width of a conjunctive query (CQ) and showed that for any class Φ of Boolean CQs of bounded submodular width, the model-checking problem for Φ on the class of all finite structures is fixed-parameter tractable (FPT). Note that for non-Boolean queries, the size of the query result may be far too large to be computed entirely within FPT time. We investigate the free-connex variant of submodular width and generalise Marx's result to non-Boolean queries as follows: For every class Φ of CQs of bounded free-connex submodular width, within FPT-preprocessing time we can build a data structure that allows to enumerate, without repetition and with constant delay, all tuples of the query result. Our proof builds upon Marx's splitting routine to decompose the query result into a union of results; but we have to tackle the additional technical difficulty to ensure that these can be enumerated efficiently.

1 Introduction

In the past decade, starting with Durand and Grandjean [19], the fields of logic in computer science and database theory have seen a large number of contributions that deal with the efficient enumeration of query results. In this scenario, the objective is as follows: given a finite relational structure (i.e., a database) and a logical formula (i.e., a query), after a short preprocessing phase, the query results shall be generated one by one, without repetition, with guarantees on the maximum delay time between the output of two tuples. In this vein, the best that one can hope for is *constant* delay (i.e., the delay may depend on the size of the query but not on that of the input structure) and *linear* preprocessing time (i.e., time $f(\varphi)\cdot O(N)$ where N is the size of a reasonable representation of the input structure, φ is the query, and $f(\varphi)$ is a number only depending on the query but not on the input structure). Constant delay enumeration has also been adopted as a central concept in *factorised databases* that gained recent attention [37, 36].

Quite a number of query evaluation problems are known to admit constant delay algorithms preceded by linear or pseudo-linear time preprocessing. This is the case for all first-order queries, provided that they are evaluated over classes of structures of bounded degree [19, 27, 13, 30], low degree [20], bounded expansion [28], locally bounded expansion [41], and on classes that are nowhere dense [39]. Also different data models have been investigated, including tree-like data and document spanners [8, 29, 7]. Recently, also the *dynamic* setting, where a fixed query has to be evaluated repeatedly against a database that is constantly updated, has received quite some attention [31, 13, 12, 25, 14, 5, 35, 34, 6].

This paper deals with the classical, *static* setting without database updates. We focus on evaluating conjunctive queries (CQs, i.e., primitive-positive formulas) on arbitrary relational structures.[1] In the following, *FPT-preprocessing* (resp., *FPL-preprocessing*) means preprocessing that takes time $f(\varphi)\cdot N^{O(1)}$ (resp., $f(\varphi)\cdot O(N)$), and *constant delay* means delay $f(\varphi)$, where f is a computable function, φ is the query, and N is the size of the input structure.

Bagan et al. [10] showed that every free-connex acyclic CQ allows constant delay enumeration after FPL-preprocessing. More refined results in this vein are due to Bagan [9] and Brault-Baron [16]; see [40] for a survey. Bagan et al. [10] complemented their result by a conditional lower bound: assuming that Boolean matrix multiplication cannot be accomplished in time $O(n^2)$, self-join-free acyclic CQs that are *not* free-connex *cannot* be enumerated with constant delay and FPL-preprocessing. This demonstrates that even if the evaluation of *Boolean* queries is easy (as known for all acyclic CQs [42]), the enumeration of the results of non-Boolean queries might be hard (here, for acyclic CQs that are not free-connex).

Bagan et al. [10] also introduced the notion of *free-connex* (fc) treewidth (tw) of a CQ and showed that for every class Φ of CQs of bounded fc-tw, within FPT-preprocessing time, one can build a data structure that allows constant delay enumeration of the query results. This can be viewed as a generalisation, to the non-Boolean case, of the well-known result stating that the model-checking problem for classes of Boolean CQs of bounded treewidth is FPT. Note that for non-Boolean queries – even if they come from a class of bounded fc-tw – the size of the query result may be $N^{\Omega(\|\varphi\|)}$, i.e., far too large to be computed entirely within FPT-preprocessing time; and generalising the known tractability result for Boolean CQs to the non-Boolean case is far from trivial.

In a series of papers, the FPT-result for Boolean CQs has been strengthened to more and more general width-measures, namely to classes of queries of bounded generalised hypertree width (ghw) [23], bounded fractional hypertree width (fhw) [24], and bounded submodular width (subw) [33]. The result on bounded fhw has been generalised to the non-Boolean case in the context of factorised databases [37], which implies constant delay enumeration after FPT-preprocessing for CQs of bounded free-connex fractional hypertree width (fc-fhw). Related data structures that allow constant delay enumeration after FPT-preprocessing for (quantifier-free) CQs of bounded (fc-)fhw have also been provided in [18, 26].

An analogous generalisation of the result on bounded submodular width, however, is still missing. The present paper's main result closes this gap: we show that on classes of CQs of bounded fc-subw, within FPT-preprocessing time one can build a data structure that allows constant delay enumeration of the query results. And within the same FPT-preprocessing time, one can also construct a data structure that enables to test in constant time whether an input tuple belongs to the query result. Our proof uses Marx's splitting routine [33] to decompose the query result of φ on $\mathcal{A}$ into the union of results of several queries φ_i on several

[1] In this paper, structures will always be finite and relational.

structures $\mathcal{A}_i$ but we have to tackle the additional technical difficulty to ensure that the results of all the φ_i on $\mathcal{A}_i$ can be enumerated efficiently. Once having achieved this, we can conclude by using an elegant trick provided by Durand and Strozecki [21] for enumerating, without repetition, the union of query results.

As an immediate consequence of the lower bound provided by Marx [33] in the context of Boolean CQs of unbounded submodular width, one obtains that our main result is tight for certain classes of CQs, namely, recursively enumerable classes Φ of quantifier-free and self-join-free CQs: assuming the exponential time hypothesis (ETH), such a class Φ allows constant delay enumeration after FPT-preprocessing if, and only if, Φ has bounded fc-subw.

Let us mention a related recent result which, however, is incomparable to ours. Abo Khamis et al. [3] designed an algorithm for evaluating a quantifier-free CQ φ of submodular width w within time $O(N^w)\cdot(\log N)^{f(\varphi)} + O(r\cdot \log N)$; and an analogous result is also achieved for non-quantifier-free CQs of fc-subw w [2]. Here, N is the size of the input structure, r is the number of tuples in the query result, and $f(\varphi)$ is at least exponential in number of variables of φ. In particular, the algorithm does not distinguish between a preprocessing phase and an enumeration phase and does not provide a guarantee on the delay. Also, due to the factor $(\log N)^{f(\varphi)}$, where $f(\varphi)$ is not bounded in terms of w, it seems unlikely that the approach can easily be adapted to yield a method for constant delay enumeration after FPT-preprocessing for classes of CQs of bounded fc-subw.

Outline. The rest of the paper is structured as follows. Section 2 provides basic notations concerning structures, queries, and constant delay enumeration. Section 3 recalls concepts of (free-connex) decompositions of queries, provides a precise statement of our main result, and collects the necessary tools for obtaining this result. Section 4 is devoted to the detailed proof of our main result. We conclude in Section 5. Due to space restrictions, some proof details had to be deferred to the full version of the paper.

2 Preliminaries

In this section we fix notation and summarise basic definitions.

Basic notation. We write $\mathbb{N}$ and $\mathbb{R}_{\geqslant 0}$ for the set of non-negative integers and reals, respectively, and we let $\mathbb{N}_{\geqslant 1} := \mathbb{N} \setminus \{0\}$ and $[n] := \{1, \dots, n\}$ for all $n \in \mathbb{N}_{\geqslant 1}$. By 2^S we denote the power set of a set S. Whenever G denotes a graph, we write $V(G)$ and $E(G)$ for the set of nodes and the set of edges, respectively, of G. Whenever writing a to denote a k-tuple (for some arity $k \in \mathbb{N}$), we write a_i to denote the tuple's i-th component; i.e., $a = (a_1, \dots, a_k)$. For a k-tuple a and indices $i_1, \dots, i_\ell \in [k]$ we let $\pi_{i_1,\dots,i_\ell}(a) := (a_{i_1}, \dots, a_{i_\ell})$. For a set S of k-tuples we let $\pi_{i_1,\dots,i_\ell}(S) := \{\pi_{i_1,\dots,i_\ell}(a) \;:\; a \in S\}$.

If h and g are mappings with domains X and Y, respectively, we say that h and g are *joinable* if $h(z) = g(z)$ holds for all $z \in X \cap Y$. In case that h and g are joinable, we write $h \bowtie g$ to denote the mapping f with domain $X \cup Y$ where $f(x) = h(x)$ for all $x \in X$ and $f(y) = g(y)$ for all $y \in Y$. If A and B are sets of mappings with domains X and Y, respectively, then $A \bowtie B := \{h \bowtie g \;:\; h \in A,\ g \in B,$ and h and g are joinable$\}$.

We use the following further notation where A is a set of mappings with domain X and $h \in A$. For a set $I \subseteq X$, the projection $\pi_I(h)$ is the restriction $h_{|I}$ of h to I; and $\pi_I(A) := \{\pi_I(h) \;:\; h \in A\}$. For objects z, c where $z \notin X$, we write $h \cup \{(z, c)\}$ for the extension h' of h to domain $X \cup \{z\}$ with $h'(z) = c$ and $h'(x) = h(x)$ for all $x \in X$.

Signatures and structures. A *signature* is a finite set σ of relation symbols, where each $R \in \sigma$ is equipped with a fixed *arity* $\operatorname{ar}(R) \in \mathbb{N}_{\geqslant 1}$. A *$\sigma$-structure* $\mathcal{A}$ consists of a finite set A (called the *universe* or *domain* of $\mathcal{A}$) and an $\operatorname{ar}(R)$-ary relation $R^{\mathcal{A}} \subseteq A^{\operatorname{ar}(R)}$ for each $R \in \sigma$. The *size* $\|\sigma\|$ of a signature σ is $|\sigma| + \sum_{R\in\sigma} \operatorname{ar}(R)$. We write $n^{\mathcal{A}}$ to denote the cardinality $|A|$ of $\mathcal{A}$'s universe, we write $m^{\mathcal{A}}$ to denote the number of tuples in $\mathcal{A}$'s largest relation, and we write $N^{\mathcal{A}}$ or $\|\mathcal{A}\|$ to denote the size of a reasonable encoding of $\mathcal{A}$. To be specific, let $N^{\mathcal{A}} = \|\mathcal{A}\| = \|\sigma\| + n^{\mathcal{A}} + \sum_{R\in\sigma} \|R^{\mathcal{A}}\|$, where $\|R^{\mathcal{A}}\| = \operatorname{ar}(R)\cdot|R^{\mathcal{A}}|$. Whenever $\mathcal{A}$ is clear from the context, we will omit the superscript $\cdot^{\mathcal{A}}$ and write n, m, N instead of $n^{\mathcal{A}}, m^{\mathcal{A}}, N^{\mathcal{A}}$. Consider signatures σ and τ with $\sigma \subseteq \tau$. The *σ-reduct* of a τ-structure $\mathcal{B}$ is the σ-structure $\mathcal{A}$ with $A = B$ and $R^{\mathcal{A}} = R^{\mathcal{B}}$ for all $R \in \sigma$. A *τ-expansion* of a σ-structure $\mathcal{A}$ is a τ-structure $\mathcal{B}$ whose σ-reduct is $\mathcal{A}$.

Conjunctive Queries. We fix a countably infinite set $\mathbf{var}$ of *variables.* We allow queries to use arbitrary relation symbols of arbitrary arities. An *atom* α is of the form $R(v_1,\ldots,v_r)$ with $r = \operatorname{ar}(R)$ and $v_1,\ldots,v_r \in \mathbf{var}$. We write $\operatorname{vars}(\alpha)$ to denote the set of variables occurring in α. A *conjunctive query* (CQ, for short) is of the form $\exists z_1 \cdots \exists z_\ell \big(\alpha_1 \wedge \cdots \wedge \alpha_d\big)$, where $\ell \in \mathbb{N}$, $d \in \mathbb{N}_{\geqslant 1}$, α_j is an atom for every $j \in [d]$, and $z_1,\ldots,z_\ell$ are pairwise distinct elements in $\operatorname{vars}(\alpha_1) \cup \cdots \cup \operatorname{vars}(\alpha_d)$. For such a CQ φ we let $\operatorname{atoms}(\varphi) = \{\alpha_1,\ldots,\alpha_d\}$. We write $\operatorname{vars}(\varphi)$ and $\sigma(\varphi)$ for the set of variables and the set of relation symbols occurring in φ, respectively. The set of *quantified* variables of φ is $\operatorname{quant}(\varphi) := \{z_1,\ldots,z_\ell\}$, and the set of *free* variables is $\operatorname{free}(\varphi) := \operatorname{vars}(\varphi) \setminus \operatorname{quant}(\varphi)$. We sometimes write $\varphi(x_1,\ldots,x_k)$ to indicate that $x_1,\ldots,x_k$ are the free variables of φ. The *arity* of φ is the number $k := |\operatorname{free}(\varphi)|$. The query φ is called *quantifier-free* if $\operatorname{quant}(\varphi) = \emptyset$, it is called *Boolean* if its arity is 0, and it is called *self-join-free* if no relation symbol occurs more than once in φ.

The semantics are defined as usual: A *valuation* for φ on a $\sigma(\varphi)$-structure $\mathcal{A}$ is a mapping $\beta : \operatorname{vars}(\varphi) \to A$. A valuation β is a *homomorphism* from φ to a $\mathcal{A}$ if for every atom $R(v_1,\ldots,v_r) \in \operatorname{atoms}(\varphi)$ we have $\big(\beta(v_1),\ldots,\beta(v_r)\big) \in R^{\mathcal{A}}$. The *query result* $[\![\varphi]\!]^{\mathcal{A}}$ of a CQ φ on the $\sigma(\varphi)$-structure $\mathcal{A}$ is defined as the set $\{\,\pi_{\operatorname{free}(\varphi)}(\beta) : \beta$ is a homomorphism from φ to $\mathcal{A}\}$. Often, we will identify the mappings $g \in [\![\varphi]\!]^{\mathcal{A}}$ with tuples $(g(x_1),\ldots,g(x_k))$, where $x_1,\ldots,x_k$ is a fixed listing of the free variables of φ.

The size $\|\varphi\|$ of a query φ is the length of φ when viewed as a word over the alphabet $\sigma(\varphi) \cup \operatorname{vars}(\varphi) \cup \{\exists, \wedge, (\,,)\,\} \cup \{\,,\}$.

Model of computation. For the complexity analysis we assume the RAM-model with a uniform cost measure. In particular, storing and accessing elements from a structure's universe requires $O(1)$ space and time. For an r-ary relation $R^{\mathcal{A}}$ we can construct in time $O(\|R^{\mathcal{A}}\|)$ an index that allows to enumerate $R^{\mathcal{A}}$ with $O(1)$ delay and to test for a given r-tuple a whether $a \in R^{\mathcal{A}}$ in time $O(r)$. Moreover, for every $\{i_1,\ldots,i_\ell\} \subseteq [r]$ we can build a data structure where we can enumerate for every ℓ-tuple b the selection $\{a \in R^{\mathcal{A}} \ : \ \pi_{i_1,\ldots,i_\ell}(a) = b\}$ with $O(1)$ delay. Such a data structure can be constructed in time $O(\|R^{\mathcal{A}}\|)$, for instance by a linear scan over $R^{\mathcal{A}}$ where we add every tuple $a \in R^{\mathcal{A}}$ to a list $\mathcal{L}_{\pi_{i_1,\ldots,i_\ell}(a)}$. Using a constant access data structure of linear size, the list $\mathcal{L}_b$ can be accessed in time $O(\ell)$ when receiving an ℓ-tuple b.

Constant delay enumeration and testing. An *enumeration algorithm* for query evaluation consists of two phases: the preprocessing phase and the enumeration phase. In the preprocessing phase the algorithm is allowed to do arbitrary preprocessing on the query φ and the input structure $\mathcal{A}$. We denote the time required for this phase by t_p. In the subsequent enumeration phase the algorithm enumerates, without repetition, all tuples (or, mappings) in the query result $[\![\varphi]\!]^{\mathcal{A}}$, followed by the end-of-enumeration message `EOE`. The *delay* t_d is the maximum time that passes between the start of the enumeration phase and the output of the first tuple, between the output of two consecutive tuples, and between the last tuple and `EOE`.

A *testing algorithm* for query evaluation also starts with a preprocessing phase of time t_p in which a data structure is computed that allows to test for a given tuple (or, mapping) b whether it is contained in the query result $[\![\varphi]\!]^{\mathcal{A}}$. The *testing time* t_t of the algorithm is an upper bound on the time that passes between receiving b and providing the answer.

One speaks of *constant* delay (testing time) if the delay (testing time) depends on the query φ, but not on the input structure $\mathcal{A}$.

We make use of the following result from Durand and Strozecki, which allows to efficiently enumerate the union of query results, provided that each query result in the union can be enumerated and tested efficiently. Note that this is not immediate, because the union might contain many duplicates that need to be avoided during enumeration.

▶ **Theorem 2.1** ([21]). *Suppose that there is an enumeration algorithm $\mathbb{A}$ that receives a query φ and a structure $\mathcal{A}$ and enumerates $[\![\varphi]\!]^{\mathcal{A}}$ with delay $t_d(\varphi)$ after $t_p(\varphi,\mathcal{A})$ preprocessing time. Further suppose that there is a testing algorithm $\mathbb{B}$ that receives a query φ and a structure $\mathcal{A}$ and has $t_p(\varphi,\mathcal{A})$ preprocessing time and $t_t(\varphi)$ testing time. Then there is an algorithm $\mathbb{C}$ that receives ℓ queries φ_i and structures $\mathcal{A}_i$ and allows to enumerate $\bigcup_{i\in[\ell]}[\![\varphi_i]\!]^{\mathcal{A}_i}$ with $O(\sum_{i\in[\ell]} t_d(\varphi_i)+\sum_{i\in[\ell]} t_t(\varphi_i))$ delay after $O(\sum_{i\in[\ell]} t_p(\varphi_i,\mathcal{A}_i))$ preprocessing time.*

Proof (sketch). The induction start $\ell=1$ is trivial. For the induction step $\ell\to\ell+1$ start an enumeration of $\bigcup_{i\in[\ell]}[\![\varphi_i]\!]^{\mathcal{A}_i}$ and test for every tuple whether it is contained in $[\![\varphi_{\ell+1}]\!]^{\mathcal{A}_{\ell+1}}$. If the answer is no, then output the tuple. Otherwise discard the tuple and instead output the next tuple in an enumeration of $[\![\varphi_{\ell+1}]\!]^{\mathcal{A}_{\ell+1}}$. Subsequently enumerate the remaining tuples from $[\![\varphi_{\ell+1}]\!]^{\mathcal{A}_{\ell+1}}$. ◀

3 Main Result

At the end of this section, we provide a precise statement of our main result. Before we can do so, we have to recall the concept of free-connex decompositions of queries and the notion of submodular width. It will be convenient for us to use the following notation.

▶ **Definition 3.1.** *Let $\varphi=\exists z_1\cdots\exists z_\ell\,\big(\alpha_1\wedge\cdots\wedge\alpha_d\big)$ be a CQ and $S\subseteq\text{vars}(\varphi)$. We write $\varphi\langle S\rangle$ for the CQ that is equivalent to the expression*

$$\big(\,\exists y_1\cdots\exists y_r\ \alpha_1\,\big)\wedge\cdots\wedge\ \big(\,\exists y_1\cdots\exists y_r\ \alpha_d\,\big),\tag{1}$$

where $\{y_1,\ldots,y_r\}=\text{vars}(\varphi)\setminus S$.

Note that $\varphi\langle S\rangle$ is obtained from φ by discarding existential quantification and projecting every atom to S, hence $\text{free}(\varphi\langle S\rangle)=S$. However, $[\![\varphi\langle S\rangle]\!]^{\mathcal{A}}$ shall not be confused with the projection of $[\![\varphi]\!]^{\mathcal{A}}$ to S. In fact, it might be that $[\![\varphi]\!]^{\mathcal{A}}$ is empty, but $[\![\varphi\langle S\rangle]\!]^{\mathcal{A}}$ is not, as the following example illustrates:

$$\begin{aligned}\varphi &= E(x,y)\wedge E(y,z)\wedge E(x,z)\quad\text{and} &(2)\\ \varphi\langle\{x,z\}\rangle &\equiv \exists yE(x,y)\wedge\exists yE(y,z)\wedge\exists yE(x,z) &(3)\\ &\equiv E(x,z)\ . &(4)\end{aligned}$$

3.1 Constant delay enumeration using tree decompositions

We use the same notation as [22] for decompositions of queries: A *tree decomposition* (TD, for short) of a CQ φ is a tuple $TD = (T, \chi)$, for which the following two conditions are satisfied:

1. $T = (V(T), E(T))$ is a finite undirected tree.
2. χ is a mapping that associates with every node $t \in V(T)$ a set $\chi(t) \subseteq \text{vars}(\varphi)$ such that
   a. for each atom $\alpha \in \text{atoms}(\varphi)$ there exists $t \in V(T)$ such that $\text{vars}(\alpha) \subseteq \chi(t)$, and
   b. for each variable $v \in \text{vars}(\varphi)$ the set $\chi^{-1}(v) := \{t \in V(T) \ : \ v \in \chi(t)\}$ induces a connected subtree of T (this condition is called *path condition*).

To use a tree decomposition $TD = (T, \chi)$ of φ for query evaluation one considers, for each $t \in V(T)$ the query $\varphi\langle S\rangle$ for $S := \chi(t)$, evaluates this query on the input structure $\mathcal{A}$, and then combines these results for all $t \in V(T)$ along a bottom-up traversal of T. If the query is Boolean, this yields the result of φ on $\mathcal{A}$; if it is non-Boolean, $[\![\varphi]\!]^{\mathcal{A}}$ can be computed by performing additional traversals of T. This approach is efficient if the result sets $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$ are small and can be computed efficiently (later on, we will sometimes refer to the sets $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$ as *projections on bags*).

The simplest queries where this is the case are acyclic queries [11, 15]. A number of equivalent characterisations of the acyclic CQs have been provided in the literature (cf. [1, 23, 25, 17]); among them a characterisation by Gottlob et al. [23] stating that a CQ is acyclic if and only if it has a tree-decomposition where every bag is covered by an atom, i.e., for every bag $\chi(t)$ there is some atom α in φ with $\chi(t) \subseteq \text{vars}(\alpha)$. The approach described above leads to a linear time algorithm for evaluating an acyclic CQ φ that is Boolean, and if φ is non-Boolean, $[\![\varphi]\!]^{\mathcal{A}}$ is computed in time linear in $\|\mathcal{A}\| + |\,[\![\varphi]\!]^{\mathcal{A}}|$. This method is known as *Yannakakis' algorithm.* But this algorithm does not distinguish between a preprocessing phase and an enumeration phase and does not guarantee constant delay enumeration. In fact, Bagan et al. identified the following additional property that is needed to ensure constant delay enumeration.

▶ **Definition 3.2** ([10]). *A tree decomposition $TD = (T, \chi)$ of a CQ φ is* free-connex *if there is a subset $U \subseteq V(T)$ that induces a connected subtree of T and that satisfies the condition* $\text{free}(\varphi) = \bigcup_{t \in U} \chi(t)$.

Bagan et al. [10] identified the *free-connex* acyclic CQs, i.e., the CQs φ that have a free-connex tree decomposition where every bag is covered by an atom, as the fragment of the acyclic CQs whose results can be enumerated with constant delay after FPL-preprocessing:

▶ **Theorem 3.3** (Bagan et al. [10]). *There is a computable function f and an algorithm which receives a free-connex acyclic CQ φ and a $\sigma(\varphi)$-structure $\mathcal{A}$ and computes within $t_p = f(\varphi)O(\|\mathcal{A}\|)$ preprocessing time and space a data structure that allows to*
(i) *enumerate $[\![\varphi]\!]^{\mathcal{A}}$ with $f(\varphi)$ delay and*
(ii) *test for a given tuple (or, mapping) b if $b \in [\![\varphi]\!]^{\mathcal{A}}$ within $f(\varphi)$ testing time.*

The approach of using free-connex tree decompositions for constant delay enumeration can be extended from acyclic CQs to arbitrary CQs. To do this, we have to compute for every bag $\chi(t)$ in the tree decomposition the projection $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$. This reduces the task to the acyclic case, where the free-connex acyclic query contains one atom α with $\text{vars}(\alpha) = \chi(t)$ for every bag $\chi(t)$ and the corresponding relation is defined by $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$. Because the runtime in this approach is dominated by computing $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$, it is only feasible if the projections are efficiently computable for every bag. If the decomposition has bounded treewidth or bounded fractional hypertree width, then it is possible to compute $[\![\varphi\langle\chi(t)\rangle]\!]^{\mathcal{A}}$ for every bag in time $f(\varphi)\cdot\|\mathcal{A}\|^{O(1)}$ [24], which in turn implies that the result can be enumerated after FPT-preprocessing time for CQs of bounded fc-tw [10] and for CQs of bounded fc-fhw [37].

3.2 Submodular width and statement of the main result

Before providing the precise definition of the submodular width of a query, let us first consider an example. The central idea behind algorithms that rely on submodular width [33, 3, 38] is to split the input structure into several parts and use for every part a different tree decomposition of φ. This will give a significant improvement over the fractional hypertree width, which uses only one tree decomposition of φ. A typical example to illustrate this idea is the following 4-cycle query (see also [3, 38]): $\varphi_4 := E_{12}(x_1,x_2) \wedge E_{23}(x_2,x_3) \wedge E_{34}(x_3,x_4) \wedge E_{41}(x_4,x_1)$.

There are essentially two non-trivial tree decompositions $\mathit{TD}' = (T,\chi')$, $\mathit{TD}'' = (T,\chi'')$ of φ_4, which are both defined over the two-vertex tree $T = (\{t_1,t_2\},\{(t_1,t_2)\})$ by $\chi'(t_1) = \{x_1,x_2,x_3\}$, $\chi'(t_2) = \{x_1,x_3,x_4\}$ and $\chi''(t_1) = \{x_2,x_3,x_4\}$, $\chi''(t_2) = \{x_1,x_2,x_4\}$. Both tree decompositions lead to an optimal fractional hypertree decomposition of width $\mathit{fhw}(\varphi_4) = 2$. Indeed, for the worst-case instance $\mathcal{A}$ with

$$E_{12}^{\mathcal{A}} = E_{34}^{\mathcal{A}} := [\ell]\times\{a\} \ \cup\ \{b\}\times[\ell] \qquad\qquad E_{23}^{\mathcal{A}} = E_{41}^{\mathcal{A}} := [\ell]\times\{b\} \ \cup\ \{a\}\times[\ell]$$

we have $\|\mathcal{A}\| = O(\ell)$ while the projections on the bags have size $\Omega(\ell^2)$ in both decompositions:[2]

$$\begin{aligned}
[\![\varphi_4\langle\chi'(t_1)\rangle]\!]^{\mathcal{A}} &= [\![\varphi_4\langle\chi'(t_2)\rangle]\!]^{\mathcal{A}} = [\ell]\times\{a\}\times[\ell] \ \cup\ \{b\}\times[\ell]\times\{b\},\\
[\![\varphi_4\langle\chi''(t_1)\rangle]\!]^{\mathcal{A}} &= [\![\varphi_4\langle\chi''(t_2)\rangle]\!]^{\mathcal{A}} = [\ell]\times\{b\}\times[\ell] \ \cup\ \{a\}\times[\ell]\times\{a\}.
\end{aligned}$$

However, we can split $\mathcal{A}$ into $\mathcal{A}'$ and $\mathcal{A}''$ such that $[\![\varphi_4]\!]^{\mathcal{A}}$ is the disjoint union of $[\![\varphi_4]\!]^{\mathcal{A}'}$ and $[\![\varphi_4]\!]^{\mathcal{A}''}$ and the bag-sizes in the respective decompositions are small:

$$\begin{aligned}
E_{12}^{\mathcal{A}'} &= E_{34}^{\mathcal{A}'} := \{b\}\times[\ell] & E_{23}^{\mathcal{A}'} &= E_{41}^{\mathcal{A}'} := [\ell]\times\{b\}\\
E_{12}^{\mathcal{A}''} &= E_{34}^{\mathcal{A}''} := [\ell]\times\{a\} & E_{23}^{\mathcal{A}''} &= E_{41}^{\mathcal{A}''} := \{a\}\times[\ell]\\
[\![\varphi_4\langle\chi'(t_1)\rangle]\!]^{\mathcal{A}'} &= [\![\varphi_4\langle\chi'(t_2)\rangle]\!]^{\mathcal{A}'} = \{b\}\times[\ell]\times\{b\},\\
[\![\varphi_4\langle\chi''(t_1)\rangle]\!]^{\mathcal{A}''} &= [\![\varphi_4\langle\chi''(t_2)\rangle]\!]^{\mathcal{A}''} = \{a\}\times[\ell]\times\{a\}.
\end{aligned}$$

Thus, we can efficiently evaluate φ_4 on $\mathcal{A}'$ using TD' and φ_4 on $\mathcal{A}''$ using TD'' (in time $O(\ell)$ in this example) and then combine both results to obtain $\varphi_4(\mathcal{A})$. Using the strategy of Alon et al. [4], it is possible to split *every* database $\mathcal{A}$ for this particular 4-cycle query φ_4 into two instances $\mathcal{A}'$ and $\mathcal{A}''$ such that the bag sizes in TD' on $\mathcal{A}'$ as well as in TD'' on $\mathcal{A}''$ are bounded by $\|\mathcal{A}\|^{3/2}$ and can be computed in time $O(\|\mathcal{A}\|^{3/2})$ (see [3, 38] for a detailed account on this strategy). As both decompositions are free-connex, this also leads to a constant delay enumeration algorithm for φ_4 with $O(\|\mathcal{A}\|^{3/2})$ time preprocessing, which improves the $O(\|\mathcal{A}\|^2)$ preprocessing time that follows from using one decomposition.

In general, whether such a data-dependent decomposition is possible is determined by the submodular width $\mathit{subw}(\varphi)$ of the query. The notion of submodular width was introduced in [33]. To present its definition, we need the following terminology. A function $g\colon 2^{\mathrm{vars}(\varphi)} \to \mathbb{R}_{\geqslant 0}$ is

- *monotone* if $g(U) \leqslant g(V)$ for all $U \subseteq V \subseteq \mathrm{vars}(\varphi)$.

[2] recall from Section 2 our convention to identify mappings in query results with tuples; the free variables are listed canonically here, by increasing indices

- *edge-dominated* if $g(\mathrm{vars}(\alpha)) \leqslant 1$ for every atom $\alpha \in \mathrm{atoms}(\varphi)$.
- *submodular*, if $g(U) + g(V) \geqslant g(U \cap V) + g(U \cup V)$ for every $U, V \subseteq \mathrm{vars}(\varphi)$.

We denote by $\mathsf{S}(\varphi)$ the set of all monotone, edge-dominated, submodular functions $g\colon 2^{\mathrm{vars}(\varphi)} \to \mathbb{R}_{\geqslant 0}$ that satisfy $g(\emptyset) = 0$, and by $\mathsf{T}(\varphi)$ the set of all tree decompositions of φ. The *submodular width* of a conjunctive query φ is

$$subw(\varphi) \quad := \quad \sup_{g \in \mathsf{S}(\varphi)} \quad \min_{(T,\chi) \in \mathsf{T}(\varphi)} \quad \max_{t \in V(T)} \; g(\chi(t)). \tag{5}$$

In particular, if the submodular width of φ is bounded by w, then for every submodular function g there is a tree decomposition in which every bag B satisfies $g(B) \leqslant w$.

It is known that $subw(\varphi) \leqslant fhw(\varphi)$ for all queries φ [33, Proposition 3.7]. Moreover, there is a constant c and a family of queries φ such that $subw(\varphi) \leqslant c$ is bounded and $fhw(\varphi) = \Omega(\sqrt{\log \|\varphi\|})$ is unbounded [32, 33]. The main result in [33] is that the submodular width characterises the tractability of Boolean CQs in the following sense.

▶ **Theorem 3.4** ([33]).

(1) *There is a computable function f and an algorithm that receives a Boolean CQ φ, $subw(\varphi)$, and a $\sigma(\varphi)$-structure $\mathcal{A}$ and evaluates φ on $\mathcal{A}$ in time $f(\varphi)\|\mathcal{A}\|^{O(subw(\varphi))}$.*

(2) *Let Φ be a recursively enumerable class of Boolean, self-join-free CQs of unbounded submodular width. Assuming the exponential time hypothesis (ETH) there is no algorithm which, upon input of a query $\varphi \in \Phi$ and a structure $\mathcal{A}$, evaluates φ on $\mathcal{A}$ in time $\|\mathcal{A}\|^{o(subw(\varphi)^{1/4})}$.*

The *free-connex submodular width* of a conjunctive query φ is defined in a similar way as submodular width, but this time ranges over the set $\mathsf{fcT}(\varphi)$ of all free-connex tree decompositions of φ (it is easy to see that we can assume that $\mathsf{fcT}(\varphi)$ is finite).

$$fc\text{-}subw(\varphi) := \sup_{g \in \mathsf{S}(\varphi)} \quad \min_{(T,\chi) \in \mathsf{fcT}(\varphi)} \quad \max_{t \in V(T)} \; g(\chi(t)). \tag{6}$$

Note that if φ is either quantifier-free or Boolean, we have $fc\text{-}subw(\varphi) = subw(\varphi)$. In general, this is not always the case. Consider for example the following quantified version $\varphi_4' := \exists x_1 \exists x_3 \, \varphi_4$ of the quantifier-free 4-cycle query φ_4. Here we have $subw(\varphi_4') = \frac{3}{2}$, but $fc\text{-}subw(\varphi_4') = 2$: one can verify $fc\text{-}subw(\varphi_4') \geqslant 2$ by noting that every free-connex tree decomposition contains a bag $\{x_1, x_2, x_3, x_4\}$ and taking the submodular function $g(U) := \frac{1}{2}|U|$. Now we are ready to state the main theorem of this paper.

▶ **Theorem 3.5.** *For every $\delta > 0$ and $w \geqslant 1$ there is a computable function f and an algorithm which receives a CQ φ with $fc\text{-}subw(\varphi) \leqslant w$ and a $\sigma(\varphi)$-structure $\mathcal{A}$ and computes within $t_p = f(\varphi)\|\mathcal{A}\|^{(2+\delta)w}$ preprocessing time and space $f(\varphi)\|\mathcal{A}\|^{(1+\delta)w}$ a data structure that allows to*

(i) *enumerate $[\![\varphi]\!]^{\mathcal{A}}$ with $f(\varphi)$ delay and*

(ii) *test for a given tuple (or, mapping) b if $b \in [\![\varphi]\!]^{\mathcal{A}}$ within $f(\varphi)$ testing time.*

The following corollary is an immediate consequence of Theorem 3.5 and Theorem 3.4. A class Φ of CQs is said to be of *bounded free-connex submodular width* if there exists a number w such that $fc\text{-}subw(\varphi) \leqslant w$ for all $\varphi \in \Phi$. And by an *algorithm for Φ that enumerates with constant delay after FPT-preprocessing* we mean an algorithm that receives a query $\varphi \in \Phi$ and a $\sigma(\varphi)$-structure $\mathcal{A}$ and spends $f(\varphi)\|\mathcal{A}\|^{O(1)}$ preprocessing time and then enumerates $[\![\varphi]\!]^{\mathcal{A}}$ with delay $f(\varphi)$, for a computable function f.

▶ **Corollary 3.6.**

(1) *For every class Φ of CQs of bounded free-connex submodular width, there is an algorithm for Φ that enumerates with constant delay after FPT-preprocessing.*

(2) *Let Φ be a recursively enumerable class of quantifier-free self-join-free CQs and assume that the exponential time hypothesis (ETH) holds.*
Then there is an algorithm for Φ that enumerates with constant delay after FPT-preprocessing if, and only if, Φ has bounded free-connex submodular width.

4 Proof of the Main Result

To prove Theorem 3.5, we make use of Marx's splitting routine for queries of bounded submodular width. In the following, we will adapt the main definitions and concepts from [33] to our notions. While doing this, we provide the following additional technical contributions: First, we give a detailed time and space analysis of the algorithm and improve the runtime of the consistency algorithm [33, Lemma 4.5] from quadratic to linear (see Lemma 4.2). Second, we fix an oversight in [33, Lemma 4.12] by establishing strong M-consistency (unfortunately, this fix incurs a blow-up in running time). Afterwards we prove our main theorem, where the non-Boolean setting requires us to relax Marx's partition into *refinements* (Lemma 4.5) so that the subinstances are no longer disjoint.

Let φ be a quantifier-free CQ with $\text{vars}(\varphi) = \{x_1, \dots, x_k\}$, and let $\sigma := \sigma(\varphi)$. For every $S = \{x_{i_1}, \dots, x_{i_\ell}\} \subseteq \text{vars}(\varphi)$ where $i_1 < \dots < i_\ell$ we set $x_S := (x_{i_1}, \dots, x_{i_\ell})$ and let $R_S \notin \sigma$ be a fresh ℓ-ary relation symbol. For every collection $\mathfrak{s} \subseteq 2^{\text{vars}(\varphi)}$ we let

$$\sigma_{\mathfrak{s}} := \sigma \cup \{R_S \ : \ S \in \mathfrak{s}\} \quad \text{and} \tag{7}$$

$$\varphi_{\mathfrak{s}} := \varphi \wedge \textstyle\bigwedge_{S \in \mathfrak{s}} R_S(x_S). \tag{8}$$

A *refinement* of φ and a σ-structure $\mathcal{A}$ is a pair $(\mathfrak{s}, \mathcal{B})$, where $\mathfrak{s} \subseteq 2^{\text{vars}(\varphi)}$ is closed under taking subsets and $\mathcal{B}$ is a $\sigma_{\mathfrak{s}}$-expansion of $\mathcal{A}$. Note that if $(\mathfrak{s}, \mathcal{B})$ is a refinement of φ and $\mathcal{A}$, then $[\![\varphi_{\mathfrak{s}}]\!]^{\mathcal{B}} \subseteq [\![\varphi]\!]^{\mathcal{A}}$. In the following we will construct refinements that do not change the result relation, i. e., $[\![\varphi_{\mathfrak{s}}]\!]^{\mathcal{B}} = [\![\varphi]\!]^{\mathcal{A}}$. Subsequently, we will split refinements in order to partition the query result.

The following definition collects useful properties of refinements. Recall from Section 2 that for a CQ ψ and a structure $\mathcal{B}$, the query result $[\![\psi]\!]^{\mathcal{B}}$ actually is a set of mappings from $\text{free}(\psi)$ to B. For notational convenience we define $\mathbf{R}_S^{\mathcal{B}} := [\![R_S(x_S)]\!]^{\mathcal{B}}$ and use the set $\mathbf{R}_S^{\mathcal{B}}$ of mappings instead of the relation $R_S^{\mathcal{B}}$. In particular, by addressing/inserting/deleting a mapping $h \colon S \to B$ from $\mathbf{R}_S^{\mathcal{B}}$ we mean addressing/inserting/deleting the tuple $(h(x_{i_1}), \dots, h(x_{i_\ell}))$ from $R_S^{\mathcal{B}}$, where $(x_{i_1}, \dots, x_{i_\ell}) = x_S$.

▶ **Definition 4.1.** *Let φ be a quantifier-free σ-CQ, $\mathcal{A}$ a σ-structure, $(\mathfrak{s}, \mathcal{B})$ a refinement of φ and $\mathcal{A}$, and M an integer.*

1. *The refinement $(\mathfrak{s}, \mathcal{B})$ is* consistent *if*

$$\mathbf{R}_S^{\mathcal{B}} = [\![\varphi_{\mathfrak{s}}\langle S\rangle]\!]^{\mathcal{B}} \text{ for all } S \in \mathfrak{s} \text{ and} \tag{9}$$

$$\mathbf{R}_S^{\mathcal{B}} = \pi_S\big(\mathbf{R}_T^{\mathcal{B}}\big) \text{ for all } S, T \in \mathfrak{s} \text{ with } S \subset T. \tag{10}$$

2. *The refinement $(\mathfrak{s}, \mathcal{B})$ is M-*consistent *if it is consistent and*

$$S \in \mathfrak{s} \quad \Longleftrightarrow \quad \text{for all } T \subseteq S\text{: } |\,[\![\varphi_{\mathfrak{s}}\langle T\rangle]\!]^{\mathcal{B}}| \leqslant M. \tag{11}$$

3. *The refinement $(\mathfrak{s}, \mathcal{B})$ is* strongly M-consistent *if it is M-consistent and*

$$S \in \mathfrak{s},\ T \in \mathfrak{s},\ (S \cup T) \notin \mathfrak{s} \quad \Longrightarrow \quad |\,[\![\varphi_{\mathfrak{s}}\langle S \cup T\rangle]\!]^{\mathcal{B}}| > M. \tag{12}$$

The proof of the following lemma is deferred to the full version of the paper.

▶ **Lemma 4.2.** *There is an algorithm that receives a refinement $\mathcal{R} = (\mathfrak{s}, \mathcal{B})$ of φ and $\mathcal{A}$ and computes in time $O(|\mathfrak{s}| \cdot \|\mathcal{B}\|)$ a consistent refinement $(\mathfrak{s}, \mathcal{B}')$ with $R_S^{\mathcal{B}'} \subseteq R_S^{\mathcal{B}}$ for all $S \in \mathfrak{s}$ and $[\![\varphi_{\mathfrak{s}}]\!]^{\mathcal{B}'} = [\![\varphi_{\mathfrak{s}}]\!]^{\mathcal{B}}$.*

▶ **Lemma 4.3.** *Let φ be a quantifier-free CQ, let $\mathcal{A}$ be a $\sigma(\varphi)$-structure where the largest relation contains m tuples, and let $M \geqslant m$. There is an algorithm that computes in time $O(2^{|\mathrm{vars}(\varphi)|} \cdot M^2)$ and space $O(2^{|\mathrm{vars}(\varphi)|} \cdot M)$ a strongly M-consistent refinement $(\mathfrak{s}, \mathcal{B})$ that satisfies $[\![\varphi]\!]^{\mathcal{A}} = [\![\varphi_{\mathfrak{s}}]\!]^{\mathcal{B}}$.*

Algorithm 1 Computing a strongly M-consistent refinement.

```
INPUT: quantifier-free CQ $\varphi(x_1, \dots, x_k)$, $\sigma(\varphi)$-structure $\mathcal{A}$
$\mathfrak{s} \leftarrow \emptyset$ ; $\mathcal{B} \leftarrow \mathcal{A}$
repeat
    for $\ell = 1, \cdots, k$ do                                  ▷ Step 1: Ensure consition (11).
        for $S = \{x_{i_1}, \dots, x_{i_\ell}\} \subseteq \mathrm{vars}(\varphi)$ do
            if $S \notin \mathfrak{s}$ and $S \setminus \{x\} \in \mathfrak{s}$ for all $x \in S$ then
                $\mathbf{R}_S^{\mathcal{B}} \leftarrow \emptyset$
                Choose $x \in S$ arbitrary
                for $h \in \mathbf{R}_{S\setminus\{x\}}^{\mathcal{B}}$ and $c \in A$ do
                    if $h \cup \{(x,c)\} \in [\![\varphi_{\mathfrak{s}}\langle S \rangle]\!]^{\mathcal{B}}$ then $\mathbf{R}_S^{\mathcal{B}} \leftarrow \mathbf{R}_S^{\mathcal{B}} \cup \{h \cup \{(x,c)\}\}$
                if $|\mathbf{R}_S^{\mathcal{B}}| \leqslant M$ then $\mathfrak{s} \leftarrow \mathfrak{s} \cup \{S\}$

    for $S, T \in \mathfrak{s}$ such that $S \cup T \notin \mathfrak{s}$ do              ▷ Step 2: Ensure condition (12).
        for $g \in \mathbf{R}_S^{\mathcal{B}}$ and $h \in \mathbf{R}_T^{\mathcal{B}}$ do
            if $g \bowtie h \in [\![\varphi_{\mathfrak{s}}\langle S \cup T \rangle]\!]^{\mathcal{B}}$ then $\mathbf{R}_{S\cup T}^{\mathcal{B}} \leftarrow \mathbf{R}_{S\cup T}^{\mathcal{B}} \cup \{g \bowtie h\}$
            if $|\mathbf{R}_{S\cup T}^{\mathcal{B}}| > M$ then break
        if $|\mathbf{R}_{S\cup T}^{\mathcal{B}}| \leqslant M$ then $\mathfrak{s} \leftarrow \mathfrak{s} \cup \{S \cup T\}$

    $(\mathfrak{s}, \mathcal{B}) \leftarrow$ CONSISTENT$(\mathfrak{s}, \mathcal{B})$          ▷ Step 3: Apply Lemma 4.2 to ensure (9), (10).
until $\mathfrak{s}$ remains unchanged
return $(\mathfrak{s}, \mathcal{B})$
```

Proof. The pseudocode of the algorithm is shown in Algorithm 1. For computing the strongly M-consistent refinement we first compute all sets S where for all $T \subseteq S$ we have $|\,[\![\varphi_{\mathfrak{s}}\langle T \rangle]\!]^{\mathcal{B}}| \leqslant M$; as in [33], we say that such sets S are *M-small.* First note that the empty set is M-small. For nonempty sets S we know that S is only M-small if for every $x \in S$ the set $S \setminus \{x\}$ is M-small and hence already included in $\mathfrak{s}$. If this is the case, then $[\![\varphi_{\mathfrak{s}}\langle S \rangle]\!]^{\mathcal{B}}$ can be computed in time $O(M \cdot n)$ by testing for every $h \in \mathbf{R}_{S\setminus\{x\}}^{\mathcal{B}}$ (for an arbitrary $x \in S$) and every element c in the structure's universe, whether $h \cup \{(x,c)\} \in [\![\varphi_{\mathfrak{s}}\langle S \rangle]\!]^{\mathcal{B}}$. If $|[\![\varphi_{\mathfrak{s}}\langle S \rangle]\!]^{\mathcal{B}}| \leqslant M$, then we include S and $\mathbf{R}_S^{\mathcal{B}} := [\![\varphi_{\mathfrak{s}}\langle S \rangle]\!]^{\mathcal{B}}$ into our current refinement. Afterwards, we want to satisfy the condition on strong M-consistency (12) by trying all pairs of M-small sets S and T. This is the bottleneck of our algorithm and requires time $O(|\mathbf{R}_S^{\mathcal{B}}| \cdot |\mathbf{R}_T^{\mathcal{B}}|) \leqslant O(M^2)$. In the third step we apply Lemma 4.2 to enforce consistency of the current refinement. In particular, every set $S \cup T$ that was found in step 2 becomes M-small. Note that after deleting tuples to ensure consistency, new sets may become M-small. Therefore, we have to repeat steps 1–3 until no more sets became M-small. Overall, we repeat the outer loop at most 2^k times, step 1 takes time $2^{O(k)} \cdot M \cdot n$, step 2 takes time $2^{O(k)} \cdot M^2$ and step 3 takes time $2^{O(k)} \cdot M$. Since $n \leqslant M$ this leads to the required running time. ◀

The key step in the proof of Theorem 3.5 is to compute $f(\varphi)$ strongly M-consistent refinements $(\mathfrak{s}_i, \mathcal{B}_i)$ of φ and $\mathcal{A}$ such that $[\![\varphi]\!]^{\mathcal{A}} = \bigcup_i [\![\varphi_{\mathfrak{s}_i}]\!]^{\mathcal{B}_i}$. In addition to being strongly M-consistent, we want the structures $\mathcal{B}_i$ to be uniform in the sense that the degree of tuples (i. e. the number of extensions) is roughly the average degree. We make this precise in a moment, but for illustration it might be helpful to consult the example from Section 3.2 again. In every relation in $\mathcal{A}$ there is one vertex (a or b) of out-degree ℓ and there are ℓ vertices of out-degree 1. Hence the average out-degree is $2\ell/(\ell+1)$ and the vertex degrees are highly imbalanced. However, after splitting the instance in $\mathcal{A}'$ and $\mathcal{A}''$, in every relation, all vertices have either out-degree ℓ or 1 and the out-degree of every vertex matches the average out-degree of the corresponding relation. The next definition generalises this to tuples of variables. We call a refinement $(\mathfrak{s}, \mathcal{B})$ *non-trivial*, if every additional relation in the expansion $\mathcal{B}$ is non-empty. For a non-trivial consistent refinement $(\mathfrak{s}, \mathcal{B})$ and $S, T \in \mathfrak{s}$, $S \subseteq T$, we let

$$\operatorname{avgdeg}(S,T) := |\mathbf{R}_T^{\mathcal{B}}|/|\mathbf{R}_S^{\mathcal{B}}| \qquad \text{and} \tag{13}$$

$$\operatorname{maxdeg}(S,T) := \max_{g \in \mathbf{R}_S^{\mathcal{B}}} \{h \in \mathbf{R}_T^{\mathcal{B}} \ : \ \pi_S(h) = g\}. \tag{14}$$

Note that consistency ensures that these numbers are well-defined and non-zero. Furthermore, we can compute them from $(\mathfrak{s}, \mathcal{B})$ in time $O(|\mathfrak{s}|^2 \cdot \|\mathcal{B}\|)$. By definition we have $\operatorname{maxdeg}(S,T) \geqslant \operatorname{avgdeg}(S,T)$. The next definition states that maximum degree does not deviate too much from the average degree.

▶ **Definition 4.4.** *Let $(\mathfrak{s}, \mathcal{B})$ be a non-trivial consistent refinement of φ and $\mathcal{A}$, and let m be the number of tuples of largest relation of $\mathcal{A}$. The refinement $(\mathfrak{s}, \mathcal{B})$ is* ε-uniform *if for all $S, T \in \mathfrak{s}$ with $S \subseteq T$ we have* $\operatorname{maxdeg}(S,T) \leqslant m^{\varepsilon} \cdot \operatorname{avgdeg}(S,T)$.

The next lemma uses Marx's splitting routine to obtain a partition into strongly M-consistent ε-uniform refinements, for $M := m^c$.

▶ **Lemma 4.5.** *Let φ be a quantifier-free CQ, let $\mathcal{A}$ be a $\sigma(\varphi)$-structure where the largest relation contains m tuples, and let $c \geqslant 1$ and $\epsilon > 0$ be real numbers. There is a computable function f and an algorithm that computes in time $O(f(\varphi, c, \epsilon) \cdot m^{2c})$ and space $O(f(\varphi, c, \epsilon) \cdot m^c)$ a sequence of $\ell \leqslant f(\varphi, c, \epsilon)$ strongly m^c-consistent ε-uniform refinements $(\mathfrak{s}_i, \mathcal{B}_i)$ such that $[\![\varphi]\!]^{\mathcal{A}}$ is the disjoint union of the sets $[\![\varphi_{\mathfrak{s}_i}]\!]^{\mathcal{B}_i}$*

Proof (sketch). We follow the same splitting strategy as in [33], but use the improved algorithm from Lemma 4.3 to ensure strong m^c-consistency. Starting with the trivial refinement $(\emptyset, \mathcal{A})$, in each step we first apply Lemma 4.3 to ensure strong m^c-consistency. Afterwards, we check whether the current refinement $(\mathfrak{s}, \mathcal{B})$ contains sets $S, T \in \mathfrak{s}$ that contradict ϵ-uniformity, i. e., $S \subseteq T$ and $\operatorname{maxdeg}(S,T) > m^{\varepsilon} \cdot \operatorname{avgdeg}(S,T)$. If this is the case, we split the refinement $(\mathfrak{s}, \mathcal{B})$ into $(\mathfrak{s}, \mathcal{B}')$ and $(\mathfrak{s}, \mathcal{B}'')$ such that $\mathbf{R}_S^{\mathcal{B}}$ is partitioned into tuples of small degree and tuples of large degree:

$$\mathbf{R}_U^{\mathcal{B}'} = \mathbf{R}_U^{\mathcal{B}''} := \mathbf{R}_U^{\mathcal{B}} \quad \text{for all } U \in \mathfrak{s} \setminus \{S\}, \tag{15}$$

$$\mathbf{R}_S^{\mathcal{B}'} := \big\{g \in \mathbf{R}_S^{\mathcal{B}} \ : \ \big|\{h \in \mathbf{R}_T^{\mathcal{B}} \ : \ \pi_S(h) = g\}\big| \leqslant m^{\varepsilon/2} \cdot \operatorname{avgdeg}(S,T)\big\} \tag{16}$$

$$\mathbf{R}_S^{\mathcal{B}''} := \big\{g \in \mathbf{R}_S^{\mathcal{B}} \ : \ \big|\{h \in \mathbf{R}_T^{\mathcal{B}} \ : \ \pi_S(h) = g\}\big| > m^{\varepsilon/2} \cdot \operatorname{avgdeg}(S,T)\big\} \tag{17}$$

It is clear that $[\![\varphi]\!]^{\mathcal{B}}$ is the disjoint union of $[\![\varphi]\!]^{\mathcal{B}'}$ and $[\![\varphi]\!]^{\mathcal{B}''}$ and that the recursion terminates at some point with a sequence of strongly m^c-consistent ϵ-uniform refinements that partition $[\![\varphi]\!]^{\mathcal{A}}$. It is also not hard to show that the height of the recursion tree is bounded by $2^{O(|\mathrm{vars}(\varphi)|)} \cdot \frac{c}{\epsilon}$ (see [33, Lemma 4.11]). Hence, by Lemma 4.3 the procedure can be implemented in time $O(f(\varphi, c, \epsilon) \cdot m^{2c})$ and space $O(f(\varphi, c, \epsilon) \cdot m^c)$. ◀

The nice thing about ϵ-uniform and strongly m^c-consistent refinements is that they define, for small enough ϵ, a submodular function $g \in \mathsf{S}(\varphi)$, which in turn guarantees the existence of a tree decomposition with small projections on the bags. The following lemma from [33, Lemma 4.12] provides these functions. However, there is an oversight in Marx's proof and in order to fix this, we have to ensure *strong* m^c-consistency instead of only m^c-consistency as stated in [33, Lemma 4.12]. As suggested by Marx (personal communication), an alternative way to achieve strong m^c-consistency would be to enforce m^{2c}-consistency, which leads to the same runtime guarantees, but requires more space.

▶ **Lemma 4.6.** *Let $(\mathfrak{s}, \mathcal{B})$ be an ϵ-uniform strongly m^c-consistent refinement of φ and $\mathcal{A}$, and let $c \geqslant 1$ and $|\mathrm{vars}(\varphi)|^{-3} \geqslant \epsilon > 0$ be real numbers. Then $g_{\mathfrak{s},\mathcal{B}} \colon 2^{\mathrm{vars}(\varphi)} \to \mathbb{R}_{\geqslant 0}$ is a monotone, edge-dominated, submodular function that satisfies $g_{\mathfrak{s},\mathcal{B}}(\emptyset) = 0$:*

$$g_{\mathfrak{s},\mathcal{B}}(U) := \begin{cases} (1-\varepsilon^{1/3}) \cdot \log_m \left(|\mathbf{R}^{\mathcal{B}}_U|\right) + h(U) & \text{if } U \in \mathfrak{s} \\ (1-\varepsilon^{1/3}) \cdot c + h(U) & \text{if } U \notin \mathfrak{s}, \end{cases} \tag{18}$$

where $h(U) := 2\epsilon^{2/3}|U| - \epsilon|U|^2 \geqslant 0$ for all $U \subseteq \mathrm{vars}(\varphi)$.

The proof can be copied verbatim from Marx's proof of [33, Lemma 4.12] by using the notion of strong consistency instead of plain consistency and is provided in the full version of the paper. Now we are ready to prove our main theorem.

Proof of Theorem 3.5. We fix $c = (1+\delta)w$ and let ε be the minimum of $\big(1 - 1/(1+\delta)\big)^4$ and $|\mathrm{vars}(\varphi)|^{-4}$. Suppose that φ is of the form $\exists x_1 \cdots \exists x_k \, \widetilde{\varphi}$ where $\widetilde{\varphi}$ is quantifier-free. We apply Lemma 4.5 to $\widetilde{\varphi}$, $\mathcal{A}$, c, ε to obtain in time $O(f(\varphi)m^{2c})$ a sequence of $\ell \leqslant f(\varphi)$ strongly m^c-consistent ε-uniform refinements $(\mathfrak{s}_i, \mathcal{B}_i)$ such that $[\![\widetilde{\varphi}]\!]^{\mathcal{A}}$ is the disjoint union of $[\![\widetilde{\varphi}_{\mathfrak{s}_1}]\!]^{\mathcal{B}_1}$, ..., $[\![\widetilde{\varphi}_{\mathfrak{s}_\ell}]\!]^{\mathcal{B}_\ell}$. By Lemma 4.6 we have $g_{\mathfrak{s}_i,\mathcal{B}_i} \in \mathsf{S}(\widetilde{\varphi}) = \mathsf{S}(\varphi)$ for every $i \in [\ell]$. Hence, by the definition of free-connex submodular width (5), we know that there is a free-connex tree decomposition (T_i, χ_i) of φ such that $g_{\mathfrak{s}_i,\mathcal{B}_i}(\chi_i(t)) \leqslant w$ for every $t \in V(T_i)$. Note that by the choice of c , ϵ and the non-negativity of h (see Lemma 4.6) we have

$$w = c/(1+\delta) \leqslant (1-\varepsilon^{1/4}) \cdot c < (1-\varepsilon^{1/3}) \cdot c + h(U). \tag{19}$$

Hence, $g_{\mathfrak{s}_i,\mathcal{B}_i}(U) \leqslant w$ implies $U \in \mathfrak{s}$ and therefore $|\mathbf{R}^{\mathcal{B}_i}_U| = |\,[\![\varphi_{\mathfrak{s}_i}\langle U\rangle]\!]^{\mathcal{B}_i}| \leqslant m^c$ by (9) and (11). Thus, every bag of the free-connex tree-decomposition (T_i, χ_i) is small in the ith refinement. However, (T_i, χ_i) is a tree-decomposition of φ, but not necessarily of $\varphi_{\mathfrak{s}_i}$! In fact, $\varphi_{\mathfrak{s}_i}$ can be very dense, e. g., if $\mathfrak{s}_i = 2^{\mathrm{vars}(\varphi)}$. To take care of this, we thin out the refinement and only keep those atoms and relations that correspond to bags of the decomposition. In particular, for every $i \in [\ell]$ we define $\widetilde{\psi}_i := \bigwedge_{t \in V(T_i)} R_{\chi_i(t)}(x_{\chi_i(t)})$ and let $\psi_i := \exists x_1 \cdots \exists x_k \, \widetilde{\psi}_i$ be the quantified version. Note that ψ_i is a free-connex acyclic CQ. Additionally, we let $\mathcal{C}_i$ be the $\sigma(\psi_i)$-reduct of $\mathcal{B}_i$. We argue that $[\![\widetilde{\varphi}_{\mathfrak{s}_i}]\!]^{\mathcal{B}_i} \subseteq [\![\widetilde{\psi}_i]\!]^{\mathcal{C}_i} \subseteq [\![\widetilde{\varphi}]\!]^{\mathcal{A}}$. The first inclusion holds because $\widetilde{\varphi}_{\mathfrak{s}_i}$ and $\mathcal{B}_i$ refine $\widetilde{\psi}_i$ and $\mathcal{C}_i$. The second inclusion holds because every atom from $\widetilde{\varphi}$ is contained in a bag of the decomposition and is hence covered by an atom in $\widetilde{\psi}_i$ because of consistency. It therefore also follows that $\pi_F\big([\![\widetilde{\varphi}_{\mathfrak{s}_i}]\!]^{\mathcal{B}_i}\big) \subseteq \pi_F\big([\![\widetilde{\psi}_i]\!]^{\mathcal{C}_i}\big) \subseteq \pi_F\big([\![\widetilde{\varphi}]\!]^{\mathcal{A}}\big)$ for $F := \mathrm{free}(\varphi)$, and hence $[\![\varphi_{\mathfrak{s}_i}]\!]^{\mathcal{B}_i} \subseteq [\![\psi_i]\!]^{\mathcal{C}_i} \subseteq [\![\varphi]\!]^{\mathcal{A}}$. Overall, we have that $[\![\varphi]\!]^{\mathcal{A}} = \bigcup_{i \in [\ell]} [\![\psi_i]\!]^{\mathcal{C}_i}$, where the union is not necessarily disjoint, each ψ_i is free-connex acyclic, and $\|\mathcal{C}_i\| = O(|\mathrm{vars}(\varphi)|^2 m^{(1+\delta)w})$. By combining Theorem 3.3 with Theorem 2.1, the theorem follows. ◀

5 Final Remarks

In this paper, we have investigated the enumeration complexity of conjunctive queries and have shown that every class of conjunctive queries of bounded free-connex submodular width admits constant delay enumeration with FPT-preprocessing. These are by now the largest classes of CQs that allow efficient enumeration in this sense.

For quantifier-free self-join-free CQs this upper bound is matched by Marx's lower bound [33]. I. e., recursively enumerable classes of quantifier-free self-join-free CQs of unbounded free-connex submodular width do not admit constant delay enumeration after FPT-preprocessing (assuming the exponential time hypothesis ETH).

A major future task is to obtain a complete dichotomy, or at least one for all self-join-free CQs. The gray-zone for the latter are classes of CQs that have bounded submodular width, but unbounded free-connex submodular width. An intriguing example in this gray-zone is the k-star query with a quantified center, i. e., the query ψ_k of the form $\exists z \bigwedge_{i=1}^{k} R_i(z, x_i)$. Here we have $\mathit{subw}(\psi_k) = 1$ and $\mathit{fc\text{-}subw}(\psi_k) = k$. It is open whether the class $\Psi = \{\psi_k : k \in \mathbb{N}_{\geqslant 1}\}$ admits constant delay enumeration with FPT-preprocessing.

Abstract

Counting problems in general and counting graph homomorphisms in particular have numerous applications in combinatorics, computer science, statistical physics, and elsewhere. One of the most well studied problems in this area is $\#\mathsf{GraphHom}(H)$ – the problem of finding the number of homomorphisms from a given graph G to the graph H. Not only the complexity of this basic problem is known, but also of its many variants for digraphs, more general relational structures, graphs with weights, and others. In this paper we consider a modification of $\#\mathsf{GraphHom}(H)$, the $\#_p\mathsf{GraphHom}(H)$ problem, p a prime number: Given a graph G, find the number of homomorphisms from G to H modulo p. In a series of papers Faben and Jerrum, and Göbel et al. determined the complexity of $\#_2\mathsf{GraphHom}(H)$ in the case H (or, in fact, a certain graph derived from H) is square-free, that is, does not contain a 4-cycle. Also, Göbel et al. found the complexity of $\#_p\mathsf{GraphHom}(H)$ when H is a tree for an arbitrary prime p. Here we extend the above result to show that the $\#_p\mathsf{GraphHom}(H)$ problem is $\#_p$P-hard whenever the derived graph associated with H is square-free and is not a star, which completely classifies the complexity of $\#_p\mathsf{GraphHom}(H)$ for square-free graphs H.

1 Introduction

A homomorphism from a graph G to a graph H is an edge-preserving mapping from the vertex set of G to that of H. Graph homomorphisms provide a powerful framework to model a wide range of combinatorial problems in computer science, as well as a number of phenomena in combinatorics and graph theory, such as graph parameters [13, 14]. Two of the most natural problems related to graph homomorphisms is $\mathsf{GraphHom}(H)$: Given a graph G, decide whether there is a homomorphism from G to a fixed graph H, and its counting version $\#\mathsf{GraphHom}(H)$ of finding the number of such homomorphisms. Special cases of these problems include the k-Colouring and $\#k$-Colouring problems (H is a k-clique), Bipartiteness (H is an edge), counting independent sets (H is an edge with a loop at one vertex) and many others.

In general the $\mathsf{GraphHom}(H)$ and $\#\mathsf{GraphHom}(H)$ problems are NP-complete and #P-complete, respectively. However, for certain graphs H these problems are significantly easier. Hell and Nesetril [12] were the first to address this phenomenon in a systematic way. They proved that the $\mathsf{GraphHom}(H)$ problem is polynomial time solvable if and only if H has a loop or is bipartite, and $\mathsf{GraphHom}(H)$ is NP-complete otherwise. In the counting case a similar result was obtained by Dyer and Greenhill [3], in this case the $\#\mathsf{GraphHom}(H)$ problem

44th International Symposium on Mathematical Foundations of Computer Science (MFCS 2019).

is solvable in polynomial time if and only if H a complete graph with all loops present or a complete bipartite graph, otherwise the problem is #P-complete. This result was later generalized to computing partition functions for weighted graphs with nonnegative weights by Bulatov and Grohe [1], graphs with real weights by Goldberg et al. [10], and finally for complex weights by Cai et al. [2]. There have also been major attempts to find approximation algorithms for the number of homomorphisms and other related graph parameters, see, e.g. [5, 6, 11].

The modification of the $\#\mathsf{GraphHom}(H)$ problem we consider in this paper concerns finding the number of homomorphisms modulo a natural number k. The corresponding problem will be denoted by $\#_k\mathsf{GraphHom}(H)$. Although modular counting has been considered by Valiant [17] in the context of holographic algorithms, Faben and Jerrum [4] were the first who systematically considered the problem $\#_2\mathsf{GraphHom}(H)$. In particular, they posed a conjecture stating that this problem is polynomial time solvable if and only if a certain graph H^{*2} derived from H (to be defined later in this section) contains at most one vertex, and is complete in the class $\oplus\mathrm{P} = \#_2\mathrm{P}$ otherwise. Note that hardness results in this area usually show completeness in a complexity class $\#_k\mathrm{P}$ of counting the number of accepting paths in polynomial time nondeterministic Turing machines modulo k. The standard notion of reduction in this case is Turing reduction. Faben and Jerrum proved their conjecture in the case when H is a tree. This result has been extended by Göbel et al. first to the class of cactus graphs [7] and then to square-free graphs [8] (a graph is a square-free if it does not contain a 4-cycle).

In this paper we follow the lead of Göbel et al. [9] and consider the problem $\#_p\mathsf{GraphHom}(H)$ for a prime number p. We only consider loopless graphs without parallel edges. There are similarities with the $\pmod 2$ case. In particular, the derived graph constructed in [4] can also be constructed following the same principles, it is denoted H^{*p}, and it suffices to study $\#_p\mathsf{GraphHom}(H)$ for this only. On the other hand, the problem is richer, as, for example, the polynomial time solvable cases include complete bipartite graphs. Göbel et al. [9] considered the case when H is a tree. Recall that a *star* is a complete bipartite graph of the form $K_{1,n}$. Stars are the only complete bipartite graphs that are trees, and also the only complete bipartite graphs that are square-free. The main result of [9] establishes that $\#_p\mathsf{GraphHom}(H)$, H is a tree, is polynomial time solvable if and only if H^{*p} is a star. We generalize this result to arbitrary square-free graphs.

▶ **Theorem 1.** *Let H be a square-free graph and p a prime number. Then the $\#_p\mathsf{GraphHom}(H)$ problem is solvable in polynomial time if and only if the graph H^{*p} is a star, and is $\#_p$P-complete otherwise.*

We now explain the main ideas behind our result, as well as, the majority of results in this area. As it was observed by Faben and Jerrum [4], the automorphism group $\mathsf{Aut}(H)$ of graph H plays a very important role in solving the $\#_p\mathsf{GraphHom}(H)$ problem. Let φ be a homomorphism from a graph G to H. Then composing φ with an element from $\mathsf{Aut}(H)$ we again obtain a homomorphism from G to H. The set of all such homomorphisms forms the orbit of φ under the action of $\mathsf{Aut}(H)$. If $\mathsf{Aut}(H)$ contains an automorphism π of order p (that is, p is the smallest number such that π^p is the identity permutation), the cardinality of the orbit of φ is divisible by p, unless $\pi \circ \varphi = \varphi$, that is, the range of φ is the set of fixed points $\mathsf{Fix}(\pi)$ of π ($a \in V(H)$ is a fixed point of π if $\pi(a) = a$). Let H^π denote the subgraph of H induced by $\mathsf{Fix}(\pi)$. We write $H \Rightarrow_p H'$ if there is $\pi \in \mathsf{Aut}(H)$ such that H' is isomorphic to H^π. We also write $H \Rightarrow_p^* H'$ if there are graphs $H_1, \ldots, H_k$ such that H is isomorphic to H_1, H' is isomorphic to H_k, and $H_1 \Rightarrow_p H_2 \Rightarrow_p \cdots \Rightarrow_p H_k$.

▶ **Lemma 2** ([4]). *Let H be a graph and p a prime. Up to an isomorphism there is a unique smallest (in terms of the number of vertices) graph H^{*p} such that $H \Rightarrow_p^* H^{*p}$, and for any graph G it holds*

$$|\mathsf{Hom}(G,H)| \equiv |\mathsf{Hom}(G,H^{*p})| \pmod{p}.$$

Moreover, H^{*p} does not have automorphisms of order p.

The easiness part of Theorem 1 follows from the classification of the complexity of $\#\mathsf{GraphHom}(H)$ by Dyer and Greenhill [3]. Since whenever $\#\mathsf{GraphHom}(H)$ is polynomial time solvable, so is $\#_p\mathsf{GraphHom}(H)$ for any p, Lemma 2 implies that if H^{*p} is a complete graph with all loops present or a complete bipartite graph the problem $\#_p\mathsf{GraphHom}(H)$ is also solvable in polynomial time. We restrict ourselves to loopless square-free graphs, therefore, as H^{*p} is isomorphic to an induced subgraph of H, [3] only guarantees polynomial time solvability when H^{*p} is a star.

Another ingredient in our result is the $\#_p$P-hard problem we reduce to $\#_p\mathsf{GraphHom}(H)$. In most of the cited works the hard problem used to prove the hardness of $\#_2\mathsf{GraphHom}(H)$ is the problem $\#_2 IS$ of finding the parity of the number of independent sets. This problem was shown to be $\#_2$P-complete by Valiant [17]. We use a slightly different problem. For two positive real numbers λ_1, λ_2, let $\#_p BIS_{\lambda_1,\lambda_2}$ denote the following problem of counting weighted independent sets in bipartite graphs

Name: $\#_p BIS_{\lambda_1,\lambda_2}$
Input: a bipartite graph G
Output: $Z_{\lambda_1,\lambda_2}(G) = \sum_{I \in \mathcal{IS}(G)} \lambda_1^{|V_L \cap I|} \lambda_2^{|V_R \cap I|} \pmod{p}$.

It was shown by Göbel et al. in [9] that $\#_p BIS_{\lambda_1,\lambda_2}$ is $\#_p$P-complete for any λ_1, λ_2, unless one of them is equal to $0 \pmod{p}$. The main technical statement we prove here is the following

▶ **Theorem 3.** *Let H be a square-free graph such that H^{*p} is not a star. Then there are $\lambda_1, \lambda_2 \not\equiv 0 \pmod{p}$ such that $\#_p BIS_{\lambda_1,\lambda_2}$ is polynomial time reducible to the $\#_p\mathsf{GraphHom}(H)$ problem.*

We note that the requirement of being square-free is present in all results on modular counting of graph homomorphisms, explicitly or implicitely (when the graph class in question consists of square-free graphs). Clearly, this is an artifact of the techniques used in all these works, and so overcoming this requirement would be a substantial achievement.

2 Preliminaries

We use $[n]$ to denote the set $\{1,2,3,...,n\}$. Also, we usually abbreviate $A \setminus \{x\}$ to $A - x$. Let k be a positive integer, then for a function f its k-fold composition is denoted by $f^{(k)} = f \circ f \circ \cdots \circ f$.

Graphs. In this paper, *graphs* are undirected, and have no parallel edges or loops. For a graph G, the set of vertices of G is denoted by $V(G)$, and the set of edges is denoted by $E(G)$. We use uv to denote an edge of G. The set of *neighbours* of a vertex $v \in V(G)$ is denoted by $N_G(v) = \{u \in V(G) : uv \in E(G)\}$, and the degree of v is denoted by $\mathsf{deg}(v)$.

A set $I \subseteq V(G)$ is an *independent set* of G if and only if uv is an edge of G for no $u, v \in I$. The set of all independent sets of G is denoted by $\mathcal{IS}(G)$. If G is a bipartite graph, the parts of a bipartition of $V(G)$ will be denoted $V_R(G)$ and $V_L(G)$ in no particular order.

Homomorphisms. A *homomorphism* from a graph G to a graph H is a mapping φ from $V(G)$ to $V(H)$ which preserves edges, i.e. for any $uv \in E(G)$ the pair $\varphi(u)\varphi(v)$ is an edge of H. The set of all homomorphisms from G to H, is denoted by $\mathsf{Hom}(G, H)$. For a graph H the problem of counting homomorphism from a graph G to H is denoted by $\#\mathsf{GraphHom}(H)$. The problem of finding the number of homomorphisms from a given graph G to H modulo k is denoted by $\#_k\mathsf{GraphHom}(H)$:

Name: $\#_k\mathsf{GraphHom}(H)$
Input: a graph G
Output: $|\mathsf{Hom}(G, H)| \pmod{k}$.

It will be convenient to denote the vertices of the graph H by lowercase Greek letters.

A homomorphism φ from G to H is an *isomorphism* if it is bijective and for all $u, v \in V(G)$, $uv \in E(G)$ if and only if $\varphi(u)\varphi(v) \in E(H)$. An *automorphism* of G is an isomorphism from graph G to itself. The automorphism group of G is denoted by $\mathsf{Aut}(G)$. An automorphism π is an *automorphism of order k* if k is the smallest positive integer such that $\pi^{(k)}$ is the identity transformation. A *fixed point* of an automorphism π of G is a vertex $v \in V(G)$ such that $v = \pi(v)$.

Partially labelled graphs. A *partial function* from X to Y is a function $f : X' \to Y$ for a subset $X' \subseteq X$. For a graph H, a *partial H-labelled graph* $\mathcal{G}$ is a graph G (called the *underlying graph* of $\mathcal{G}$) equipped with a *pinning function* τ, which is a partial function from $V(G)$ to $V(H)$. A homomorphism from a partial H-labelled graph $\mathcal{G} = (G, \tau)$ to a graph H is a homomorphism $\sigma : G \to H$ that extends the pinning function τ, that is, for all $v \in \mathrm{dom}(\tau)$, $\sigma(v) = \tau(v)$. The set of all such homomorphisms is denoted by $\mathsf{Hom}(\mathcal{G}, H)$.

In certain situations it will be convenient to use a slightly different view on collections of homomorphisms of H-labelled graphs. A set of homomorphisms φ from a graph G to H that maps vertices $x_1, x_2, ..., x_r \in V(G)$ to the vertices $y_1, y_2, ..., y_r \in V(H)$ such that $\varphi(x_i) = y_i$ for $i \in [r]$ is denoted by $\mathsf{Hom}((G, x_1, x_2, ..., x_r), (H, y_1, y_2, ..., y_r))$.

Counting complexity classes. The class #P is defined to be the class of problems of counting the accepting paths in a polynomial time nondeterministic Turing machine. This means every problem in NP has an associated counting problem in #P, so for $A \in \mathrm{NP}$, an associated counting problem will be denoted by $\#A$. (Strictly speaking for every such problem the corresponding counting one is not uniquely defined, but in our case there will always be the "natural" one.) Classes $\#_k\mathrm{P}$, where k is a natural number are defined in a similar way, as counting the accepting paths in a polynomial time nondeterministic Turing machine modulo k. For $A \in \mathrm{NP}$ the corresponding problem in $\#_k\mathrm{P}$ is denoted by $\#_kA$.

Several kinds of reductions between counting problems have appeared in the literature. The first one, parsimonious, was introduced in the foundational papers [15, 16] by Valiant. A counting problem A is *parsimoniously reducible* to a counting problem B, denoted $A \leq B$, if there is a polynomial time algorithm that, given an instance I of A, produces an instance J of B such that the answers to I and J are the same. The other type of reduction frequently used for counting problems is Turing reduction. Counting problem A is *Turing reducible* to problem B, denoted $A \leq_T B$, if there exists a polynomial time algorithm solving A and using B as an oracle.

These two types of reductions can be applied to modular counting as well. Turing reduction does not require any modifications. For parsimonious reduction we say that a problem A from $\#_k\mathrm{P}$ is *parsimoniously reducible* to a problem B from $\#_k\mathrm{P}$ if there is a polynomial time algorithm that, given an instance I of A, produces an instance J of B such that the answers to I and J are congruent modulo k. In this paper we mostly claim Turing reducibility, although our main technical result constructs a parsimonious reduction. However, the proof of Theorem 1 involves other reductions that are not always parsimonious. Problem $\#_k A$ is said to be $\#_k$P-*complete* if it belongs to $\#_k$P and every problem from $\#_k$P is Turing reducible to $\#_k A$.

3 Outline of the proof

In this section we outline our proof strategy and formally introduce all the necessary intermediate problems and existing results. Fix a prime number p.

As it was observed in the introduction, Lemma 2 proved by Faben and Jerrum [4] combined with the classification by Dyer and Greenhill [3] proves the easiness part of Theorem 1. We therefore focus on proving the hardness part. Again, by Lemma 2 we may assume that H does not have automorphisms of order p.

For the hardness part, we use two auxiliary problems. The first one is the problem $\#_p BIS_{\lambda_1,\lambda_2}$ mentioned in the introduction. Let $\lambda_1, \lambda_2 \in \{0, \dots p-1\}$, and let $G = (V_L \cup V_R, E)$ be a bipartite graph. Define the following weighted sum over independent sets of G:

$$Z_{\lambda_1,\lambda_2}(G) = \sum_{I \in \mathcal{IS}(G)} \lambda_1^{|V_L \cap I|} \lambda_2^{|V_R \cap I|}.$$

The problem of computing function $Z_{\lambda_1,\lambda_2}(G)$ for a given bipartite graph G, prime number p and $\lambda_1, \lambda_2 \in \{0, \dots p-1\}$, is defined as follows:

Name: $\#_p BIS_{\lambda_1,\lambda_2}$
Input: a bipartite graph G
Output: $Z_{\lambda_1,\lambda_2}(G) \pmod p$.

The complexity of $\#_p BIS_{\lambda_1,\lambda_2}$ was determined by Göbel, Lagodzinski and Seidel [9].

▶ **Theorem 4.** *[9] If $\lambda_1 \equiv 0 \pmod p$ or $\lambda_2 \equiv 0 \pmod p$ then the problem $\#_p BIS_{\lambda_1,\lambda_2}$ is solvable in polynomial time, otherwise it is $\#_p$P-complete.*

The second auxiliary problem has been used in all works on $\#_p\mathsf{GraphHom}(H)$ starting from the initial paper by Faben and Jerrum [4]. It is the problem of counting homomorphisms from a given partially H-labelled graph $\mathcal{G}$ to a fixed graph H modulo prime p.

Name: $\#_p\mathsf{PartHom}(H)$
Input: a partial H-labelled graph $\mathcal{G} = (G, \tau)$
Output: $|\mathsf{Hom}(\mathcal{G}, H)| \pmod p$.

The chain of reductions we use to prove the hardness part of Theorem 1 is the following:

$$\#_p BIS_{\lambda_1,\lambda_2} \le_T \#_p\mathsf{PartHom}(H^{*p}) \le_T \#_p\mathsf{GraphHom}(H^{*p}) \le_T \#_p\mathsf{GraphHom}(H). \qquad (1)$$

The last reduction is by Lemma 2. Acually, the two last problems in the chain are polynomial time interreducible through (modular) parsimonious reduction. The second step, the reduction from $\#_p\mathsf{PartHom}(H)$ to $\#_p\mathsf{GraphHom}(H)$ was proved by Göbel, Lagodzinski and Seidel [9].

▶ **Theorem 5.** *[9] Let p be a prime number and let H be a graph that does not have any automorphism of order p. Then $\#_p\mathsf{PartHom}(H)$ can be reduced to $\#_p\mathsf{GraphHom}(H)$ through a polynomial time Turing reduction.*

Finally, the first reduction in the chain is our main contribution. We show it in three steps. Recall that we are reducing the problem of finding of the number of (weighted) independent sets in a bipartite graph to the problem of finding the number of extensions of a partial homomorphism from a given graph to H. First, in Section 4 starting from a bipartite graph G we replace its vertices and edges with gadgets, whose exact structure we do not specify at that point. We call those gadget the *vertex* and *edge* gadgets. Then we show that if the vertex and edge gadgets satisfy certain conditions, in terms of the number of homomorphisms of certain kind from the gadgets to H (Theorem 7), then $Z_{\lambda_1,\lambda_2}(G) \pmod p$ can be found in polynomial time from $|\mathsf{Hom}(\mathcal{G}, H)| \pmod p$, where $\mathcal{G}$ is the partially H-labelled graph constructed in the reduction. In the second step, Section 5, we introduce several variants of vertex and edge gadgets and show some of their properties. Finally, in Section 6 we consider several cases depending on the degree sequence of the graph H. In every case we construct vertex and edge gadgets that satisfy the conditions of Theorem 7, thus completing the reduction.

4 Hardness gadgets

Our goal in this section is to describe a general scheme of a reduction from $\#_pBIS_{\lambda_1,\lambda_2}$ to $\#_p\mathsf{PartHom}(H)$, where p is prime and H is a square-free graph.

The general idea is, given a bipartite graph $G = (V_L \cup V_R, E)$, where V_L, V_R is the bipartition of G, to construct a new partially H-labelled graph $\mathcal{G}'$, which is obtained from G by adding a copy of a *vertex* gadget $\mathcal{J}$ to every vertex of G, and replacing every edge from E with a copy of an *edge* gadget $\mathcal{K}$. The gadgets are partially H-labelled graphs and their pinning functions will define the pinning function of $\mathcal{G}'$. Since G is a bipartite graph, the vertex gadget comes in two versions, left, $\mathcal{J}_L$, and right, $\mathcal{J}_R$. Also, both vertex gadgets have a distinguished vertex, s for $\mathcal{J}_L$ and t for $\mathcal{J}_R$. The edge gadget $\mathcal{K}$ has two distinguished vertices, s and t. These distinguished vertices will be identified with the vertices of the original graph G, as shown in Fig. 1.

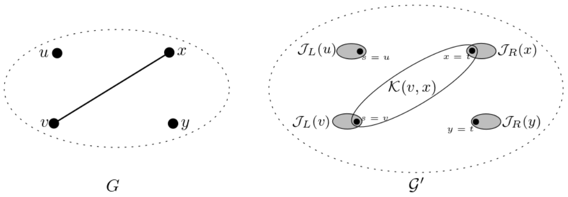

Figure 1 The structure of graph $\mathcal{G}'$. The original graph G is on the left. The resulting graph $\mathcal{G}'$ is on the right: vertex gadgets $\mathcal{J}_L, \mathcal{J}_R$ are added to every vertex, and the only edge vx of G is replaced with a copy of gadget $\mathcal{K}$.

The gadgets $\mathcal{J}_L, \mathcal{J}_R$ are associated with sets $\Delta_1, \Delta_2 \subseteq V(H)$ and vertices $\delta_1 \in \Delta_1, \delta_2 \in \Delta_2$, respectively. The pinning functions of $\mathcal{J}_L, \mathcal{J}_R$ will be defined in such a way that for any homomorphism φ of $\mathcal{J}_L$ ($\mathcal{J}_R$) to H, vertex s (respectively, t) is forced to be mapped to Δ_1 (respectively, Δ_2). For $x \in V_L$ let $\mathcal{J}_L(x)$ denote the copy of $\mathcal{J}_L$ connected to x, that is, s in $\mathcal{J}_L(x)$ is identified with x. For $y \in V_R$ the copy $\mathcal{J}_R(y)$ is defined in the same way. The vertices δ_1, δ_2 will help to encode independent sets of G. Specifically, with every independent set I of G we will associate a set of homomorphisms $\varphi : \mathcal{G}' \to H$ such that for every vertex $x \in V_L$, $x \in I$ if and only if $\varphi(x) \neq \delta_1$ (recall that x is also a vertex of $\mathcal{G}'$ identified with s in $\mathcal{J}_L(x)$); and similarly, for every $y \in V_R$, $y \in I$ if and only if $\varphi(y) \neq \delta_2$. Finally, the edge gadgets $\mathcal{K}(x, y)$ replacing every edge $xy \in E$ make sure that every homomorphism from $\mathcal{G}'$ to H is associated with an independent set.

Note that just an association of independent sets with collections of homomorphisms is not enough, the number of homomorphisms in those collections have to allow one to compute the function $Z_{\lambda_1,\lambda_2}(G)$.

Next we introduce conditions such that if for the graph H there are vertex and edge gadgets satisfying these conditions, then $\#_pBIS_{\lambda_1,\lambda_2}$ for some nonzero (modulo p) λ_1, λ_2 is reducible to $\#_p\mathsf{PartHom}(H)$.

▶ **Definition 6** (Hardness gadget). *A graph H has* hardness gadgets *if there are $\Delta_1, \Delta_2 \subseteq V(H)$, vertices $\delta_1 \in \Delta_1$ and $\delta_2 \in \Delta_2$, and three partially H-labelled graphs $\mathcal{J}_L$, $\mathcal{J}_R$, and $\mathcal{K}$ that satisfy the following properties:*

(i) $|\Delta_1| - 1 \not\equiv 0 \pmod p$, $|\Delta_2| - 1 \not\equiv 0 \pmod p$;

(ii) *for any homomorphism $\sigma : \mathcal{J}_L \to H$ ($\sigma : \mathcal{J}_R \to H$) it holds that $\sigma(s) \in \Delta_1$ (respectively, $\sigma(t) \in \Delta_2$); for any homomorphism $\sigma : \mathcal{K} \to H$ it holds that $\sigma(s) \in \Delta_1, \sigma(t) \in \Delta_2$;*

(iii) *for any $\gamma_1 \in \Delta_1, \gamma_2 \in \Delta_2$, it holds $|\mathsf{Hom}((\mathcal{J}_L, s), (H, \gamma_1))| \equiv |\mathsf{Hom}((\mathcal{J}_R, t), (H, \gamma_2))| \equiv 1 \pmod p$, and*
for any $\gamma_1 \notin \Delta_1, \gamma_2 \notin \Delta_2$, it holds $\mathsf{Hom}((\mathcal{J}_L, s), (H, \gamma_1)) = \mathsf{Hom}((\mathcal{J}_L, s), (H, \gamma_1)) = \emptyset$;

(iv) *for any $\alpha_1 \in \Delta_1 - \delta_1, \alpha_2 \in \Delta_2 - \delta_2$, it holds $\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_1, \alpha_2)) = \emptyset$;*

(v) *for any $\alpha_1 \in \Delta_1 - \delta_1$, it holds $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_1, \delta_2))| \equiv 1 \pmod p$;*

(vi) *for any $\alpha_2 \in \Delta_2 - \delta_2$, it holds $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \delta_1, \alpha_2))| \equiv 1 \pmod p$;*

(vii) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \delta_1, \delta_2))| \equiv 1 \pmod p$.

Now we are ready to state the main result of this section.

▶ **Theorem 7.** *If H has hardness gadgets, then for some $\lambda_1, \lambda_2 \not\equiv 0 \pmod p$ the problem $\#_pBIS_{\lambda_1,\lambda_2}$ is polynomial time reducible to $\#_p\mathsf{PartHom}(H)$. In particular, $\#_p\mathsf{PartHom}(H)$ is $\#_pP$-complete.*

5 Hardness gadgets and nc-walks

In this section we make the next iteration in constructing hardness gadgets and give a generic structure of such gadgets that will later be adapted to specific types of the graph H.

These gadgets make use of the square-freeness of graph H that we will apply in the following form.

▶ **Observation 8.** *Let H be a square-free graph. Then for any $\alpha, \beta \in H$, $|N_H(\alpha) \cap N_H(\beta)| \leq 1$.*

Proof. If there are two different elements γ, δ in $N_H(\alpha) \cap N_H(\beta)$, then $\alpha, \gamma, \beta, \delta$ form a 4-cycle. ◀

We call a walk in H a *non-consecutive-walk* or *nc-walk*, if it does not traverse an edge forth and then immediately back. More formally, an nc-walk is a walk $v_0, v_1, \dots, v_k$ such that for no $i \in [k-1]$ we have $v_{i-1} = v_{i+1}$.

5.1 Edge gadget

Let $W = \gamma_0\gamma_1 \cdots \gamma_k$ be an nc-walk in H of length at least one. Then the edge gadget $\mathcal{K}$ is a path $sv_1v_2 \cdots v_{k-1}t$, where each v_i is connected to another vertex u_i which is pinned to γ_i. More formally, the gadget $\mathcal{K} = (K, \tau)$ is defined as follows

$$V(K) = \{s, t\} \cup \{v_i, u_i : i \in [k-1]\},$$
$$E(K) = \{v_iv_{i+1} : i \in [k-2]\} \cup \{v_iu_i : i \in [k-1]\} \cup \{sv_1, v_{k-1}t\}.$$

The pinning function is $\tau(u_i) = \gamma_i$ for all $i \in [k-1]$.

The next two lemmas give some of the properties listed in Definition 6.

▶ **Lemma 9 (Shifting).** *Let H, $W = \gamma_0\gamma_1 \cdots \gamma_k$, and $\mathcal{K}$ be as above. Then*

(1) *For every $\theta \in N_H(\gamma_0) - \gamma_1$ and $\sigma \in \mathsf{Hom}((\mathcal{K}, s), (H, \theta))$, we have $\sigma(v_i) = \gamma_{i-1}$ for all $i \in [k-1]$.*

(2) *For every $\theta \in N_H(\gamma_k) - \gamma_{k-1}$ and $\sigma \in \mathsf{Hom}((\mathcal{K}, t), (H, \theta))$, we have $\sigma(v_i) = \gamma_{i+1}$ for all $i \in [k-1]$.*

Proof. If $k = 1$, then both cases are trivial. We prove item (1) by induction on $j \in [k-1]$, item (2) can be proved using $\gamma_k\gamma_{k-1} \cdots \gamma_0$ instead of $\gamma_0\gamma_1 \cdots \gamma_k$.

For $j = 1$, the vertex v_1 must be mapped to a common neighbour of θ and γ_1 because $\tau(u_1) = \gamma_1$. It means $\sigma(v_1) \in N_H(\theta) \cap N_H(\gamma_1) = \{\gamma_0\}$, because $\gamma_0 \in N_H(\theta) \cap N_H(\gamma_1)$ and H is a square-free graph.

Now assume that $\sigma(v_{j-1}) = \gamma_{j-2}$. Similar to the base case, $\sigma(v_j) \in N_H(\gamma_{j-2}) \cap N_H(\gamma_j)$. By the same argument, the only member of this intersection is γ_{j-1}. Thus, $\sigma(v_j) = \gamma_{j-1}$. ◀

▶ **Lemma 10 (Counting).** *Let H be a square-free graph and let $W = \gamma_0\gamma_1 \cdots \gamma_k$, $k \geq 1$ be an nc-walk in H. For any $\alpha_s \in N_H(\gamma_0) - \gamma_1$ and $\alpha_t \in N_H(\gamma_k) - \gamma_{k-1}$ the following equalities hold*

(1) $\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_s, \alpha_t)) = \emptyset$,

(2) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \alpha_t))| = 1$,

(3) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_s, \gamma_{k-1}))| = 1$,

(4) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \gamma_{k-1}))| = 1 + \sum_{i=1}^{k-1}(\mathsf{deg}(\gamma_i) - 1)$.

5.2 Vertex gadgets

In this section we construct a vertex gadget. The main role of these gadgets is to restrict the possible images of the designated vertices s and t as required in Definition 6(ii), and then do it in such a way that property (iii) in Definition 6 is also satisfied. We present vertex gadgets of two types.

For the graph H and vertices $\alpha, \beta \in V(H)$, we define gadgets $\mathcal{J}_L = (J_L, \tau_L)$ and $\mathcal{J}_R = (J_R, \tau_R)$ as follows: Graphs J_L, J_R are just edges sx and ty, respectively. The pinning functions are given by $\tau_L(x) = \alpha$, $\tau_R(y) = \beta$.

The next lemma follows straightforwardly from the definitions and guarantees that these gadgets satisfy items (iii) and (ii) of Definition 6 (note that (1) is a direct implication of (3)).

▶ **Lemma 11.** *For graph H, vertices $\alpha, \beta \in V(H)$, and $\Delta_1 = N_H(\alpha), \Delta_2 = N_H(\beta)$ the following hold*

(1) *if $\sigma \in \mathsf{Hom}(\mathcal{J}_L, H)$ then $\sigma(s) \in \Delta_1$, and if $\sigma \in \mathsf{Hom}(\mathcal{J}_R, H)$ then $\sigma(t) \in \Delta_2$,*

(2) *for any $\gamma_1 \in \Delta_1$ and $\gamma_2 \in \Delta_2$, it holds that $|\mathsf{Hom}((\mathcal{J}_L, s), (H, \gamma_1))| = |\mathsf{Hom}((\mathcal{J}_R, t), (H, \gamma_2))| = 1$,*

(3) *for any $\gamma_1' \notin \Delta_1$ and $\gamma_2' \notin \Delta_2$, it holds that $\mathsf{Hom}((\mathcal{J}_L, s), (H, \gamma_1')) = \mathsf{Hom}((\mathcal{J}_R, t), (H, \gamma_2')) = \emptyset$.*

The other type of a vertex gadget uses a cycle in H.

Let $C = \theta\gamma_1\gamma_2 \cdots \gamma_k\theta$ be a cycle in H of length at least three. Gadgets $\mathcal{J}_{CL} = (J_{CL}, \tau_{CL})$ and $\mathcal{J}_{CR} = (J_{CR}, \tau_{CR})$ are defined as follows

$$V(J_{CL}) = \{s\} \cup \{v_i, u_i : i \in [k]\} \cup \{x\},$$

$$E(J_{CL}) = \{v_iv_{i+1} : i \in [k-1]\} \cup \{v_iu_i : i \in [k]\} \cup \{sv_1, v_ks, sx\}.$$

The pinning function is given by $\tau(u_i) = \gamma_i$ for all $i \in [k]$ and $\tau(x) = \theta$.

The gadget $\mathcal{J}_{CR}$ is defined in the same way, except s is replaced with t.

▶ **Lemma 12.** *For a square-free graph H, a cycle $C = \theta\gamma_1\gamma_2\cdots\gamma_k\theta$ in H of length at least three, and $\Delta = \{\gamma_1, \gamma_k\}$ the following hold*

(1) *if $\sigma \in \mathsf{Hom}(\mathcal{J}_{CL}, H)$ or $\sigma \in \mathsf{Hom}(\mathcal{J}_{CR}, H)$, then $\sigma(s) \in \{\gamma_1, \gamma_k\}$ and $\sigma(t) \in \{\gamma_1, \gamma_k\}$, respectively;*

(2) *for any $\gamma \in \Delta$ it holds $|\mathsf{Hom}((J_{CL}, s), (H, \gamma))| = |\mathsf{Hom}((J_{CR}, t), (H, \gamma))| = 1$,*

(3) *for any $\gamma' \notin \Delta$ it holds $\mathsf{Hom}((\mathcal{J}_{CL}, s), (H, \gamma')) = \mathsf{Hom}((\mathcal{J}_{CR}, t), (H, \gamma')) = \emptyset$,*

6 The hardness of $\#_p$PartHom(H)

In this section we prove the hardness part of Theorem 1. More specifically we will apply Theorem 7 and the constructions from Section 5 to show that $\#_p BIS_{\lambda_1,\lambda_2}$ is Turing reducible to $\#_p\mathsf{PartHom}(H)$.

We consider three cases depending on the existence of vertices of certain degree in H. In each of the three cases we use slightly different variations of vertex and edge gadgets.

Case 1. The graph H has at least two vertices α and β such that $\mathsf{deg}(\alpha), \mathsf{deg}(\beta) \not\equiv 1 \pmod p$.

Let $S = \{\gamma \in V(H) : \mathsf{deg}(\gamma) \not\equiv 1 \mod p\}$; we know that S contains at least two elements. Pick $\alpha, \beta \in S$ such that the distance between them is minimal. Let $W = \alpha\gamma_1\cdots\gamma_{k-1}\gamma_k\beta$ be a shortest path between α, β. By the choice of W, $\mathsf{deg}(\gamma_i) \equiv 1 \pmod p$ for all $i \in [k]$.

We make an edge gadget $\mathcal{K} = (K, \tau)$ for this case based on this path as defined in Section 5.1. More precisely,

$$\begin{aligned} V(K) &= \{s, t\} \cup \{v_i, u_i : i \in [k]\}, \\ E(K) &= \{\{v_i, v_{i+1}\} : i \in [k-1]\} \cup \{\{v_i, u_i\} : i \in [k]\} \cup \{\{s, v_1\}, \{v_k, t\}\}. \end{aligned}$$

The labelling function is given by $\tau(u_i) = \gamma_i$ for all $i \in [k]$.

Any path is a nc-walk, so we can apply Lemma 10 to W. For the gadgets we use $\Delta_1 = N_H(\alpha), \Delta_2 = N_H(\beta)$ and $\delta_1 = \gamma_1, \delta_2 = \gamma_k$. This satisfies property (i) of hardness gadgets, because $\mathsf{deg}(\alpha), \mathsf{deg}(\beta) \not\equiv 1 \pmod p$. Then for any $\alpha_s \in \Delta_1 - \delta_1$ and $\alpha_t \in \Delta - \delta_2$ we have

(1) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_s, \alpha_t))| = 0$;

(2) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \alpha_t))| \equiv 1 \pmod p$;

(3) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_s, \gamma_k))| \equiv 1 \pmod p$

Also, for any $i \in [k]$ we have $\mathsf{deg}(\gamma_i) \equiv 1 \pmod p$, and so

$$|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \gamma_k))| = 1 + \sum_{i=1}^{k} (\mathsf{deg}(\gamma_i) - 1) = 1 + 0 \equiv 1 \pmod p.$$

Hence,

(4) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \gamma_k))| \equiv 1 \pmod p$.

Thus $\mathcal{K}$ satisfies properties (iv), (v), (vi), and (vii) of hardness gadgets.

For a vertex gadget we use the first type, that is $\mathcal{J}_L, \mathcal{J}_R$ are just edges sx and ty, respectively, see Fig. 2. By Lemma 11 these gadgets satisfy properties (ii) and (iii) of hardness gadgets.

Thus Theorem 7 yields a required reduction.

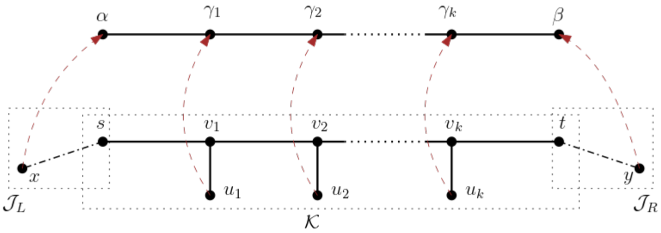

Figure 2 Vertex and edge gadgets based on the path $W = \alpha\gamma_1 \cdots \gamma_k\beta$. The vertex gadgets $\mathcal{J}_L$ and $\mathcal{J}_R$ are shown as dot-dashed boxes. The pinning function is shown by dashed lines.

Case 2. Graph H has exactly one vertex θ such that $\mathsf{deg}(\theta) \not\equiv 1 \pmod p$.

In this case we further split into two subcases. However, before we proceed with that we rule out the case of trees.

▶ **Lemma 13.** *Let H be a tree that has no automorphism of order p and is not a star. Then H has at least two vertices α and β such that $\mathsf{deg}(\alpha), \mathsf{deg}(\beta) \not\equiv 1 \pmod p$.*

Thus, we may assume that H is not a tree.

Case 2.1. The vertex θ, $\mathsf{deg}(\theta) \not\equiv 1 \pmod p$, is on a cycle C.

In this case the edge gadget is based on the cycle C. More precisely, let $C = \theta\gamma_1\gamma_2 \cdots \gamma_k\theta$ be a cycle in H of length at least 3 and such that for all $i \in [k]$ it holds that $\mathsf{deg}(v_i) \equiv 1 \pmod p$ and $\mathsf{deg}(\theta) \not\equiv 1 \pmod p$. We define gadget $\mathcal{K} = (K, \tau)$ as follows:

- $V(K) = \{s, t\} \cup \{v_i, u_i : i \in [k]\}$;
- $E(K) = \{v_iv_{i+1} : i \in [k-1]\} \cup \{v_iu_i : i \in [k]\} \cup \{sv_1, v_kt\}$;
- the labeling function is given by $\tau(u_i) = \gamma_i$ for all $i \in [k]$.

Set $\Delta_1 = \Delta_2 = N_H(\theta)$ and $\delta_1 = \gamma_1, \delta_2 = \gamma_k$. These parameters satisfy property (i) of a hardness gadget, because $\mathsf{deg}(\theta) \not\equiv 1 \pmod p$. A cycle is a nc-walk, so we can apply Lemma 10 to obtain the following

▶ **Lemma 14.** *Let H be a square-free graph and $\mathcal{K}$ an edge gadget based on the cycle $C = \theta\gamma_1\gamma_2 \cdots \gamma_k\theta$ in H. For any $\alpha_s \in \Delta_1 - \delta_1$ and $\alpha_t \in \Delta_2 - \delta_2$,*

(1) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha_s, \alpha_t))| = 0$*;*
(2) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \delta_1, \alpha_t))| \equiv 1 \pmod p$*;*
(3) $|Hom((\mathcal{K}, s, t), (H, \alpha_s, \delta_2))| \equiv 1 \pmod p$*;*
(4) $|Hom((\mathcal{K}, s, t), (H, \delta_1, \delta_2))| \equiv 1 \pmod p$*.*

Proof. The cycle C is a nc-walk. Therefore by Lemma 10 items (1), (2), and (3) hold. For item (4) note that $\mathsf{deg}(\gamma_i) \equiv 1 \pmod p$ for all $i \in [k]$, therefore

$$|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_1, \gamma_k))| = 1 + \sum_{i=1}^{k}(\mathsf{deg}(\gamma_i) - 1) = 1 + 0 \equiv 1 \pmod p. \qquad ◀$$

By Lemma 14 gadget $\mathcal{K}$ satisfies properties (iv), (v), (vi), and (vii) of hardness gadgets.

For vertex gadgets we take $\mathcal{J}_L, \mathcal{J}_R$ (which are just edges) defined in Section 5.2, with $\alpha = \beta = \theta$, see Fig 3. By Lemma 11, these gadgets satisfy properties (ii) and (iii) of hardness gadgets.

Finally, by Theorem 7 $\#_pBIS_{\lambda_1,\lambda_2}$ is Turing reducible to $\#_p\mathsf{PartHom}(H)$.

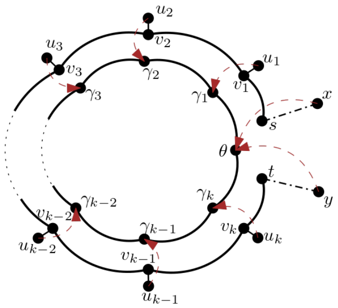

Figure 3 Hardness gadgets corresponding to a cycle $C = \theta\gamma_1 \cdots \gamma_k\theta$. The vertex gadgets $\mathcal{J}_L$ and $\mathcal{J}_R$ are shown by dot-dashed lines. The pinning function is shown by dashed lines.

Case 2.2. The vertex θ is not on any cycle.

Since H is not a tree, it contains at least one cycle; let C be such a cycle. Let $P = \gamma_0\gamma_{k+1}\gamma_{k+2}\cdots\gamma_{k+k'}\theta$ be a shortest path from a vertex γ on cycle $C = \gamma_0\gamma_1\gamma_2\cdots\gamma_k\gamma_0$ to θ. Note that $\mathsf{deg}(\gamma_i) \equiv 1 \pmod p$ for all γ_i, $i \in \{0, \dots, k+k'\}$. Edge gadget $\mathcal{K}$ in this case is based on the walk $W = \theta\gamma_{k+k'}\cdots\gamma_{k+2}\gamma_{k+1}\gamma_0\gamma_1\gamma_2\cdots\gamma_k\gamma_{k+1}\gamma_{k+2}\cdots\gamma_{k+k'}\theta$. Note that, W is an nc-walk. More precisely, the gadget $\mathcal{K} = (K, \tau)$ is defined as follows:

- $V(K) = \{s, t\} \cup \{v_i, u_i : i \in [k+2k'+2]\}$;
- $E(K) = \{v_iv_{i+1} : i \in [k+2k'+1]\} \cup \{v_iu_i : i \in [k+2k'+2]\} \cup \{sv_1, v_{k+2k'+1}t\}$;
- the pinning function is given by

$$\tau(u_i) = \begin{cases} \gamma_{k+k'+1-i} & 1 \le i \le k', \\ \gamma_{i-k'-1} & k'+1 \le i \le k+k'+1, \\ \gamma_0 & i = k+k'+2, \\ \gamma_{i-k'-2} & k+k'+3 \le i \le k+2k'+2. \end{cases}$$

Set $\delta_1 = \delta_2 = \gamma_{k+k'}$ and $\Delta_1 = \Delta_2 = N_H(\theta)$. These parameters satisfy property (i) of hardness gadgets, because $\mathsf{deg}(\theta) \not\equiv 1 \pmod p$. As W is an nc-walk, by Lemma 10 for any $\alpha \in N_H(\theta) - \gamma_{k+k'}$, we have

(1) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha, \alpha))| = 0$;

(2) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_{k+k'}, \alpha))| \equiv 1 \pmod p$;

(3) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \alpha, \gamma_{k+k'}))| \equiv 1 \pmod p$.

Also, $\mathsf{deg}(\gamma_i) \equiv 1 \pmod p$ for all $i \in [k+k'] \cup \{0\}$. Therefore

$$|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_{k+k'}, \gamma_{k+k'}))| = 1 + \sum_{i=1}^{k+k'} (\mathsf{deg}(\gamma_i) - 1) = 1 + 0 \equiv 1 \pmod p.$$

Hence,

(4) $|\mathsf{Hom}((\mathcal{K}, s, t), (H, \gamma_{k+k'}, \gamma_{k+k'}))| \equiv 1 \pmod p$.

Thus the gadget $\mathcal{K}$ satisfies properties (iv), (v), (vi), and (vii) of hardness gadgets.

Finally, for vertex gadgets we again use gadgets $\mathcal{J}_L, \mathcal{J}_R$ introduced in Section 5.2, with $\alpha = \beta = \theta$, see Fig 4. By Lemma 11, these gadgets satisfy properties (ii) and (iii) of hardness gadgets. Thus, by Theorem 7 $\#_pBIS_{\lambda_1,\lambda_2}$, $\lambda_1 = \lambda_2 = |N_H(\theta)| - 1$ is Turing reducible to $\#_p\mathsf{PartHom}(H)$.

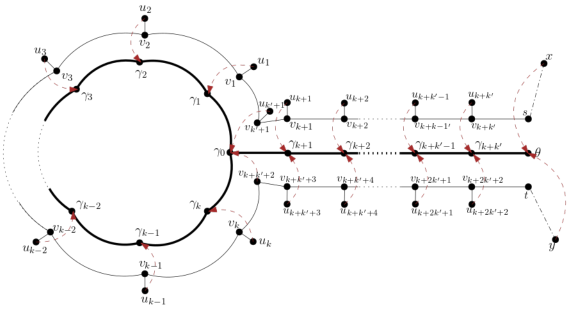

Figure 4 Gadget $\mathcal{K}$ based on the nc-walk $W = \theta\gamma_{k+k'}\cdots\gamma_{k+2}\gamma_{k+1}\gamma_0\gamma_1\gamma_2\cdots\gamma_k \gamma v_{k+1}\gamma_{k+2}\cdots\gamma_{k+k'}\theta$. The vertex gadgets $\mathcal{J}_L$ and $\mathcal{J}_R$ corresponding to θ are shown by dot-dashed lines. The pinning function is shown by dashed lines.

Case 3. For every vertex $\gamma \in V(H)$ it holds $\mathsf{deg}(\gamma) \equiv 1 \pmod{p}$.

By Lemma 13, H is not a tree, therefore it contains a cycle $C = \theta\gamma_1\gamma_2\cdots\gamma_k\theta$ such that $k \geq 3$. Set $\delta_1 = \gamma_1, \delta_2 = \gamma_k$ and $\Delta_1 = \Delta_2 = \{\gamma_1, \gamma_k\}$. These parameters satisfy property (i) of hardness gadget, because $|\Delta_1| = |\Delta_2| \not\equiv 1 \pmod{p}$. An edge gadget $\mathcal{K}$ is based on this cycle C. Since $\mathsf{deg}(\gamma) \equiv 1 \pmod{p}$ for every $\gamma \in V(H)$, as in Lemma 14 by Lemma 10 $\mathcal{K}$ satisfies properties (iv), (v), (vi), and (vii) of hardness gadgets.

For vertex gadgets we choose $\mathcal{J}_{CL}, \mathcal{J}_{CR}$ defined in Section 5.2, see Fig 5. By Lemma 12, these gadgets satisfy properties (ii) and (iii) of hardness gadgets. Therefore, by Theorem 7, $\#_pBIS_{\lambda_1,\lambda_2}$, $\lambda_1 = \lambda_2 = |\{\gamma_1, \gamma_k\}| - 1 = 1$ is Turing reducible to $\#_p\mathsf{PartHom}(H)$.

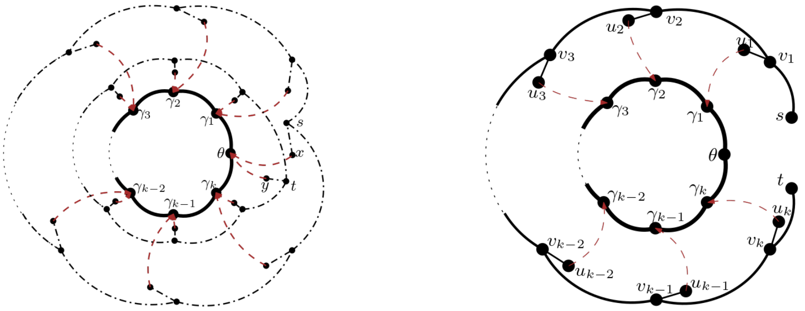

Figure 5 Hardness gadgets based on cycle $C = \theta\gamma_1\cdots\gamma_k\theta$.
On the left are the vertex gadgets $\mathcal{J}_{CL}$ and $\mathcal{J}_{CR}$ shown by dot-dashed lines. $\mathcal{J}_{CL}$ is the cycle containing vertex s, and $\mathcal{J}_{CR}$ is the cycle containing vertex t. The remaining vertices of the gadgets are not labelled. The pinning function is shown by dashed lines.
On the right, the edge gadget $\mathcal{K}$ is highlighted. Again, the pinning function is represented by dashed lines.

Note that the reduction in Case 3 can also be used to prove the result in Case 2.2, as it only depends on the existence of a cycle all of whose vertices have degrees $\equiv 1 \pmod{p}$. We, however, believe that the construction in Case 2.2 is simple, more transparent and deserves being considered.

Abstract

In this paper we study the complexity of counting Constraint Satisfaction Problems (CSPs) of the form $\#\mathrm{CSP}(\mathcal{C},-)$, in which the goal is, given a relational structure $\mathbf{A}$ from a class $\mathcal{C}$ of structures and an arbitrary structure $\mathbf{B}$, to find the number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$. Flum and Grohe showed that $\#\mathrm{CSP}(\mathcal{C},-)$ is solvable in polynomial time if $\mathcal{C}$ has bounded treewidth [FOCS'02]. Building on the work of Grohe [JACM'07] on decision CSPs, Dalmau and Jonsson then showed that, if $\mathcal{C}$ is a recursively enumerable class of relational structures of bounded arity, then assuming FPT $\neq$ #W[1], there are no other cases of $\#\mathrm{CSP}(\mathcal{C},-)$ solvable exactly in polynomial time (or even fixed-parameter time) [TCS'04].

We show that, assuming FPT $\neq$ W[1] (under randomised parametrised reductions) and for $\mathcal{C}$ satisfying certain general conditions, $\#\mathrm{CSP}(\mathcal{C},-)$ is not solvable even *approximately* for $\mathcal{C}$ of unbounded treewidth; that is, there is no fixed parameter tractable (and thus also not fully polynomial) randomised approximation scheme for $\#\mathrm{CSP}(\mathcal{C},-)$. In particular, our condition generalises the case when $\mathcal{C}$ is closed under taking minors.

1 Introduction

The Constraint Satisfaction Problem (CSP) asks to decide the existence of a homomorphism between two given relational structures (or to find the number of such homomorphisms). It has been used to model a vast variety of combinatorial problems and has attracted much attention. Since the general CSP is NP-complete (#P-complete in the counting case) and because one needs to model specific computational problems, various restricted versions of the CSP have been considered. More precisely, let $\mathcal{C}$ and $\mathcal{D}$ be two classes of relational structures. In this paper we will assume that structures from $\mathcal{C}, \mathcal{D}$ only have predicate symbols of bounded arity. The *constraint satisfaction problem* (CSP) parametrised by $\mathcal{C}$ and $\mathcal{D}$ is the following computational problem, denoted by $\mathrm{CSP}(\mathcal{C},\mathcal{D})$: given $\mathbf{A} \in \mathcal{C}$ and $\mathbf{B} \in \mathcal{D}$, is there a homomorphism from $\mathbf{A}$ to $\mathbf{B}$? CSPs in which both input structures are restricted have not received much attention (with a notable exception of matrix partitions [19, 20] and assorted graph problems on restricted classes of graphs). However, the two most

natural restrictions have been intensively studied over the last two decades. Let $-$ denote the class of all (bounded-arity) relational structures, or, equivalently, indicate that there are no restrictions on the corresponding input structure.

Problems of the form $\mathrm{CSP}(-, \{\mathbf{B}\})$, where $\mathbf{B}$ is a fixed finite relational structure, are known as *nonuniform* or *language-restricted* CSPs [33]. For instance, if $\mathbf{B} = K_3$ is the complete graph on 3 vertices then $\mathrm{CSP}(-, \{\mathbf{B}\})$ is the standard 3-Colouring problem [27]. The study of nonuniform CSPs has been initiated by Schaefer [38] who considered the case of $\mathrm{CSP}(-, \{\mathbf{B}\})$ for 2-element structures $\mathbf{B}$. The complexity of $\mathrm{CSP}(-, \{\mathbf{H}\})$, for a fixed graph $\mathbf{H}$, was studied under the name of $\mathbf{H}$-colouring by Hell and Nešetřil [32]. General nonuniform CSPs have been studied extensively since the seminal paper of Feder and Vardi [21] who in particular proposed the so-called Dichotomy Conjecture stating that every nonuniform CSP is either solvable in polynomial time or is NP-complete. The complexity of nonuniform CSPs has been resolved only recently in two independent papers by Bulatov [3] and Zhuk [39], which confirmed the dichotomy conjecture of Feder and Vardi and also its algebraic version [4].

CSPs restricted on the other side, that is, of the form $\mathrm{CSP}(\mathcal{C}, -)$, where $\mathcal{C}$ is a fixed (infinite) class of finite relational structures, are known as *structurally-restricted* CSPs. For instance, if $\mathcal{C} = \cup_{k\geq 1}\{K_k\}$ is the class of cliques of all sizes then $\mathrm{CSP}(\mathcal{C}, -)$ is the standard Clique problem [27]. In this case the complexity of CSPs is related to various "width" parameters of the associated class of graphs. For a relational structure $\mathbf{A}$ let $G(\mathbf{A})$ denote the Gaifman graph of $\mathbf{A}$, that is, the graph whose vertices are the elements of $\mathbf{A}$, and vertices v, w are connected with an edge whenever v and w occur in the same tuple of some relation of $\mathbf{A}$. Then $G(\mathcal{C})$ denotes the class of Gaifman graphs of structures from $\mathcal{C}$, and we refer to the treewidth of $G(\mathbf{A})$ as the treewidth of $\mathbf{A}$. Dalmau, Kolaitis, and Vardi showed that $\mathrm{CSP}(\mathcal{C}, -)$ is in PTIME if $\mathcal{C}$ has bounded treewidth modulo homomorphic equivalence [10]. Grohe then showed that, assuming $\mathrm{FPT} \neq \mathrm{W}[1]$, there are no other cases of (bounded arity) $\mathrm{CSP}(\mathcal{C}, -)$ solvable in polynomial time (or even fixed-parameter time, where the parameter is the size of the left-hand side structure) [29]. The case of structures with unbounded arity was extensively studied by Gottlob et al. who introduced the concept of bounded hypertree width in an attempt to characterise structurally restricted CSPs solvable in polynomial time [28]. The search for a right condition is still going on, and the most general structural property that guarantees that $\mathrm{CSP}(\mathcal{C}, -)$ is solvable in polynomial time is fractional hypertree width introduced by Grohe and Marx [30].

An important problem related to the CSP is counting: Given a CSP instance, that is, two relational structures $\mathbf{A}$ and $\mathbf{B}$, find the number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$. We again consider restricted versions of this problem. More precisely, for two classes $\mathcal{C}$ and $\mathcal{D}$ of relational structures, $\#\mathrm{CSP}(\mathcal{C}, \mathcal{D})$ denotes the following computational problem: given $\mathbf{A} \in \mathcal{C}$ and $\mathbf{B} \in \mathcal{D}$, how many homomorphisms are there from $\mathbf{A}$ to $\mathbf{B}$? This problem is referred to as a *counting* CSP. Similar to decision CSPs, problems of the form $\#\mathrm{CSP}(-, \mathcal{D})$ and $\#\mathrm{CSP}(\mathcal{C}, -)$ are the two most studied ways to restrict the counting CSP, and the research on these problems follows a similar pattern as their decision counterparts.

For a fixed finite relational structure $\mathbf{B}$, the complexity of the nonuniform problem $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ was characterised for graphs by Dyer and Greenhill [17] and for 2-element structures by Creignou and Hermann [8]. The complexity of the general nonuniform counting CSPs was resolved by Bulatov [5] and Dyer and Richerby [18]. As in the case of the decision version the complexity of nonuniform counting CSPs is determined by their algebraic properties, and every such CSP is either solvable in polynomial time or is #P-complete. These dichotomy results were later extended to the case of weighted counting CSP, for which Cai and Chen obtained a complexity classification of counting CSPs with complex weights [6].

The complexity of counting CSPs with restrictions on the left hand side structures also turns out to be related to treewidth. Flum and Grohe showed that $\#\mathrm{CSP}(\mathcal{C}, -)$ is solvable in polynomial time if $\mathcal{C}$ has bounded treewidth [22]. Dalmau and Jonsson then showed that, assuming FPT $\neq$ #W[1], there are no other cases of (bounded arity) $\#\mathrm{CSP}(\mathcal{C}, -)$ solvable exactly in polynomial time (or, again, even fixed-parameter time) [9]. Note that the result of Dalmau and Jonsson states that the class $\mathcal{C}$ itself has to be of bounded treewidth, while in Grohe's characterisation of polynomial-time solvable decision CSPs of the form $\mathrm{CSP}(\mathcal{C}, -)$ it is the class of cores of structures from $\mathcal{C}$ that has to have bounded treewidth. To the best of our knowledge there has been no research on counting problems over structures of unbounded arity except for the work of Brault-Baron et al., who showed that the (unbounded arity) structurally-restricted $\#\mathrm{CSP}(\mathcal{C}, -)$ are solvable in polynomial time for the class $\mathcal{C}$ of β-acyclic hypergraphs [2].[1]

The results we have mentioned so far concern exact counting; however, many applications of counting problems allow for approximation algorithms as well. For nonuniform CSPs the complexity landscape is much more complicated than the dichotomy results for decision CSPs or exact counting. The analogue of "easily solvable" problems in this case are those that admit a Fully Polynomial Randomised Approximation Scheme (FPRAS): a randomised algorithm that, given an instance and an error tolerance $\varepsilon \in (0, 1)$ returns in time polynomial in the size of the instance and ε^{-1} a result which is with high probability a multiplicative $(1 + \varepsilon)$-approximation of the exact solution. The parametrised version of this algorithmic model is known as a Fixed Parameter Tractable Randomised Approximation Scheme (FPTRAS). Beyond counting nonuniform CSPs, however, it was conjectured by Dyer et al. [15] that there is an infinite hierarchy of approximation complexities attainable by such problems. Only a handful of results exist for the approximation complexity of counting nonuniform CSPs. The approximation complexity of $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ for 2-element structures $\mathbf{B}$ was characterised by Dyer at al. [16], where a trichotomy theorem was proved: for every 2-element structure $\mathbf{B}$ the problem $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ either admits an FPRAS, or is interreducible with #SAT or with the problem #BIS of counting independent sets in bipartite graphs. Apart from this only partial results are known. If $\mathbf{B}$ is a connected graph and $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ does not admit an FPRAS, then Galanis, Goldberg and Jerrum [25] showed that $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ is at least as hard as #BIS. Also, if every unary relation is a part of $\mathbf{B}$ a complexity classification of $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ can be extracted from the results of Chen et al. [7],[2] see also [26].

Our Contribution

It should be clear by now that the picture painted by the short survey above misses one piece: the approximation complexity of structurally restricted CSPs. This is the main contribution of this paper.

Let $\mathcal{C}$ be a class of bounded-arity relational structures. If the treewidth of $\mathcal{C}$ modulo homomorphic equivalence is unbounded then, by Grohe's result [29], it is hard to test for the existence of a homomorphism from $\mathbf{A}$ to $\mathbf{B}$, where $\mathbf{A} \in \mathcal{C}$, for any instance $\mathbf{A}, \mathbf{B}$ of $\mathrm{CSP}(\mathcal{C}, -)$. Using standard techniques (see, e.g., the proof of [34, Proposition 3.16]), this implies, assuming that FPT $\neq$ #W[1] (under randomised parametrised reductions [14]), that

[1] Brault-Baron et al. [2] show their tractability results for so-called CSPs with default values, which in particular includes $\#\mathrm{CSP}(\mathcal{C}, -)$ as defined here.

[2] Chen et al. [7] studied the weighted version of $\#\mathrm{CSP}(-, \{\mathbf{B}\})$, and although their result does not provide a complete characterisation of the weighted problem, it allows to determine the complexity of $\#\mathrm{CSP}(-, \{\mathbf{B}\})$ as defined here.

there is not an FPTRAS for $\#\mathrm{CSP}(\mathcal{C}, -)$, let alone an FPRAS. Consequently, the tractability boundary for approximate counting of $\#\mathrm{CSP}(\mathcal{C}, -)$ lies between bounded treewidth and bounded treewidth modulo homomorphic equivalence.

As our main result, we show that for $\mathcal{C}$ such that a certain class of graphs (to be defined later) is a subset of $G(\mathcal{C})$, $\#\mathrm{CSP}(\mathcal{C}, -)$ cannot be solved even *approximately* for $\mathcal{C}$ of unbounded treewidth, assuming $\mathrm{FPT} \neq \mathrm{W}[1]$ (under randomised parametrised reductions). Before we introduce the classes of graphs we use, we review how the hardness of $\mathrm{CSP}(\mathcal{C}, -)$ or $\#\mathrm{CSP}(\mathcal{C}, -)$ is usually proved.

We follow the hardness proof of Grohe for decision CSPs [29], which was lifted to exact counting CSPs by Dalmau and Jonsson [9]. In fact Grohe's result had an important precursor [31]. The key idea is a reduction from the parametrised Clique problem to $\mathrm{CSP}(\mathcal{C}, -)$. Let $G = (V, E)$ and k be an instance of the p-Clique problem, where k is the parameter. Broadly speaking, the reduction works as follows. For a class of unbounded treewidth, the Excluded Grid Theorem of Robertson and Seymour [37] guarantees the existence of the $(k \times \binom{k}{2})$-grid (as a minor of some structure $\mathbf{A} \in \mathcal{C}$), which is used to encode the existence of a k-clique in G as a certain structure $\mathbf{B}$. The encoding usually means that G has a k-clique if and only if there is a homomorphism from $\mathbf{A}$ to $\mathbf{B}$ whose image covers a copy of the grid built in $\mathbf{B}$. For decision CSPs, the correctness of the reduction – that there are no homomorphisms from $\mathbf{A}$ to $\mathbf{B}$ not satisfying this condition – is achieved by dealing with coloured grids [31] or by dealing with structures whose cores have unbounded treewidth (with another complication caused by minor maps) [29]. For the complexity of exact counting CSPs, the correctness of the reduction [9] is achieved by employing interpolation or the inclusion-exclusion principle, a common tool in exact counting.

None of these two methods can be applied to approximate solving $\#\mathrm{CSP}(\mathcal{C}, -)$. We cannot assume that the class of cores of $\mathcal{C}$ has unbounded treewidth, because then by [29] even the decision problem cannot be solved in polynomial time, which immediately rules out the existence of an FPRAS. Interpolation techniques such as the inclusion-exclusion principle are also well known to be incompatible with approximate counting. The standard tool in approximate counting to achieve the same goal of prohibiting homomorphisms except ones from a certain restricted type, is to use gadgets to amplify the number of homomorphisms of the required type. We give a reduction from p-#Clique to $\#\mathrm{CSP}(\mathcal{C}, -)$ by using "fan-grids", formally introduced in Section 3.3. Unfortunately, due to the delicate nature of approximation preserving reductions, we cannot use minors and minor maps and have to assume that "fan-grids" themselves are present in $G(\mathcal{C})$. (In Section 5, we will briefly discuss how a weaker assumption can be used to obtain the same result.) By the Excluded Grid Theorem [37], if $\mathcal{C}$ is *closed under taking minors*, then $G(\mathcal{C})$ contains all the fan-grids (details are given in Section 3.3 and in particular in Lemma 4). Thus, the classes $\mathcal{C}$ for which we establish the hardness of $\#\mathrm{CSP}(\mathcal{C}, -)$ includes the classes $\mathcal{C}$ that are closed under taking minors.[3]

[3] We remark that the hardness for $\mathcal{C}$ closed under taking minors follows from Grohe's classification [29] of decision CSPs. Indeed, for $\mathcal{C}$ of unbounded treewidth, the Excluded Grid Theorem [37] gives grids of arbitrary sizes. Since every planar graph is a minor of some grid [11], $\mathcal{C}$ contains all planar graphs. As there exist graphs of arbitrary large treewidth that are also minimal with respect to homomorphic equivalence, Grohe's result gives W[1]-hardness of $\mathrm{CSP}(\mathcal{C}, -)$ and hence $\#\mathrm{CSP}(\mathcal{C}, -)$ cannot have an FPRAS/FPTRAS.

2 Preliminaries

$\mathbb{N}$ denotes the set of positive integers. For every $n \in \mathbb{N}$, we let $[n] = \{1, \dots, n\}$.

2.1 Relational Structures and Homomorphisms

A *relational signature* is a finite set τ of relation symbols R, each with a specified arity $\mathrm{ar}(R)$. A *relational structure* $\mathbf{A}$ over a relational signature τ (or a τ-structure, for short) is a finite universe A together with one relation $R^{\mathbf{A}} \subseteq A^{\mathrm{ar}(R)}$ for each symbol $R \in \tau$. The size $\|\mathbf{A}\|$ of a relational structure $\mathbf{A}$ is defined as

$$\|\mathbf{A}\| = |\tau| + |A| + \sum_{R\in\tau} |R^{\mathbf{A}}| \cdot \mathrm{ar}(R).$$

Let R be a binary relational symbol. We will sometimes view graphs as $\{R\}$-structures.

A *homomorphism* from a relational τ-structure $\mathbf{A}$ (with universe A) to a relational τ-structure $\mathbf{B}$ (with universe B) is a mapping $\varphi : A \to B$ such that for all $R \in \tau$ and all tuples $\mathbf{x} \in R^{\mathbf{A}}$ we have $\varphi(\mathbf{x}) \in R^{\mathbf{B}}$.

Two structures $\mathbf{A}$ and $\mathbf{B}$ are *homomorphically equivalent* if there is a homomorphism from $\mathbf{A}$ to $\mathbf{B}$ and a homomorphism from $\mathbf{B}$ to $\mathbf{A}$.

Let $\mathcal{C}$ be a class of relational structures. We say that $\mathcal{C}$ has *bounded arity* if there is a constant $r \geq 1$ such that for every τ-structure $\mathbf{A} \in \mathcal{C}$ and $R \in \tau$, we have that $\mathrm{ar}(R) \leq r$.

2.2 Treewidth and Minors

The notion of treewidth, introduced by Robertson and Seymour [36], is a well-known measure of the tree-likeness of a graph [11]. Let $G = (V(G), E(G))$ be a graph. A *tree decomposition* of G is a pair (T, β) where $T = (V(T), E(T))$ is a tree and β is a function that maps each node $t \in V(T)$ to a subset of $V(G)$ such that

1. $V(G) = \bigcup_{t\in V(T)} \beta(t)$,
2. for every $u \in V(G)$, the set $\{t \in V(T) \mid u \in \beta(t)\}$ induces a connected subgraph of T, and
3. for every edge $\{u, v\} \in E(G)$, there is a node $t \in V(T)$ with $\{u, v\} \subseteq \beta(t)$.

The *width* of the decomposition (T, β) is $\max\{|\beta(t)| \mid t \in V(T)\} - 1$. The *treewidth* $tw(G)$ of a graph G is the minimum width over all its tree decompositions.

Let $\mathbf{A}$ be a relational structure over relational signature τ. The *Gaifman graph* (also known as *primal graph*) of $\mathbf{A}$, denoted by $G(\mathbf{A})$, is the graph whose vertex set is the universe of $\mathbf{A}$ and whose edges are the pairs (u, v) for which there is a tuple $\mathbf{x}$ and a relation symbol $R \in \tau$ such that u, v appear in $\mathbf{x}$ and $\mathbf{x} \in R^{\mathbf{A}}$.

Let $\mathcal{C}$ be a class of relational structures. We say that $\mathcal{C}$ has *bounded treewidth* if there exists $w \geq 1$ such that $tw(\mathbf{A}) = tw(G(\mathbf{A})) \leq w$ for every $\mathbf{A} \in \mathcal{C}$. We say that $\mathcal{C}$ has *bounded treewidth modulo homomorphic equivalence* if there exists $w \geq 1$ such that every $\mathbf{A} \in \mathcal{C}$ is homomorphically equivalent to $\mathbf{A}'$ with $tw(\mathbf{A}') \leq w$.

A graph H is a *minor* of a graph G if H is isomorphic to a graph that can be obtained from a subgraph of G by contracting edges (for more details, see, e.g., [11]).

For $k, \ell \geq 1$, the $(k \times \ell)$-grid is the graph with the vertex set $[k] \times [\ell]$ and an edge between (i, j) and (i', j') iff $|i - i'| + |j - j'| = 1$. Treewidth and minors are intimately connected via the celebrated Excluded Grid Theorem of Robertson and Seymour.

▶ **Theorem 1** ([37]). *For every k there exists a $w(k)$ such that the $(k \times k)$-grid is a minor of every graph of treewidth at least $w(k)$.*

Let $\mathcal{C}$ be a class of relational structures. We say that $\mathcal{C}$ if *closed under taking minors* if for every $\mathbf{A} \in \mathcal{C}$ and for every minor H of $G(\mathbf{A})$, there is a structure $\mathbf{A}' \in C$ such that $G(\mathbf{A}')$ is isomorphic to H.

3 Counting CSP

3.1 Exact Counting CSP

Let $\mathcal{C}$ be a class of relational structures. We will be interested in the computational complexity of the following problem.

Name: $\#\mathrm{CSP}(\mathcal{C}, -)$
Input: Two relational structures $\mathbf{A}$ and $\mathbf{B}$ over the same signature with $\mathbf{A} \in \mathcal{C}$.
Output: The number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$.

We say that $\#\mathrm{CSP}(\mathcal{C}, -)$ is in FP, the class of function problems solvable in *polynomial time*, if there is a deterministic algorithm that solves any instance $\mathbf{A}, \mathbf{B}$ of $\#\mathrm{CSP}(\mathcal{C}, -)$ in time $(\|\mathbf{A}\| + \|\mathbf{B}\|)^{O(1)}$.

We will also consider the parametrised version of $\#\mathrm{CSP}(\mathcal{C}, -)$.

Name: p-$\#\mathrm{CSP}(\mathcal{C}, -)$
Input: Two relational structures $\mathbf{A}$ and $\mathbf{B}$ over the same signature with $\mathbf{A} \in \mathcal{C}$.
Parameter: $\|\mathbf{A}\|$.
Output: The number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$.

We say that p-$\#\mathrm{CSP}(\mathcal{C}, -)$ is in FPT, the class of problems that are *fixed-parameter tractable*, if there is a deterministic algorithm that solves any instance $\mathbf{A}, \mathbf{B}$ of p-$\#\mathrm{CSP}(\mathcal{C}, -)$ in time $f(\|\mathbf{A}\|) \cdot \|\mathbf{B}\|^{O(1)}$, where $f : \mathbb{N} \to \mathbb{N}$ is an arbitrary computable function.

The class W[1], introduced in [12], can be seen as an analogue of NP in parameterised complexity theory. Proving W[1]-hardness of a problem (under a parametrised reduction which may be randomised), is a strong indication that the problem is not solvable in fixed-parameter time as it is believed that FPT $\neq$ W[1]. For counting problems, #W[1] is the parametrised analogue of #P. Similarly to the belief that FP $\neq$ #P, it is believed that FPT $\neq$ #W[1]. We refer the reader to [24] for the definitions of W[1] and #W[1], and for more details on parameterised complexity in general.

Dalmau and Jonsson established the following result.

▶ **Theorem 2** ([9]). *Assume FPT $\neq$ #W[1] under parametrised reductions. Let $\mathcal{C}$ be a recursively enumerable class of relational structures of bounded arity. Then, the following are equivalent:*

1. $\#\mathrm{CSP}(\mathcal{C}, -)$ *is in FP.*
2. p-$\#\mathrm{CSP}(\mathcal{C}, -)$ *is in FPT.*
3. $\mathcal{C}$ *has bounded treewidth.*

The following problem is an example of a #W[1]-hard problem, as established by Flum and Grohe [23].

Name: p-#Clique
Input: A graph G and $k \in \mathbb{N}$.
Parameter: k.
Output: The number of cliques of size k in G.

Note that p-#Clique can be modelled as p-#CSP$(\mathcal{C}, -)$ if we set $\mathcal{C}$ to be the set of cliques of all possible sizes. The decision version of p-#Clique was shown to be W[1]-hard by Downey and Fellows [13].

Name: p-Clique
Input: A graph G and $k \in \mathbb{N}$.
Parameter: k.
Output: Decide if G contains a clique of size k.

3.2 Approximate Counting CSP

In view of our complete understanding of the exact complexity of #CSP$(\mathcal{C}, -)$ for $\mathcal{C}$ of bounded arity (cf. Theorem 2), we will be interested in *approximation* algorithms for #CSP$(\mathcal{C}, -)$. In particular, are there any new classes $\mathcal{C}$ of bounded arity for which the problem #CSP$(\mathcal{C}, -)$ can be solved efficiently (if only approximately)? We will provide a partial answer to this question (cf. Theorem 3): for certain general bounded-arity classes $\mathcal{C}$ (which include classes that are *closed under taking minors*), the answer is no!

The notion of efficiency for approximate counting is that of a fully polynomial randomised approximation scheme [35] and its parametrised analogue, a fixed parameter tractable randomised approximation scheme, originally introduced by Arvind and Raman [1]. We now define both concepts.

A *randomised approximation scheme* (RAS) for a function $f : \Sigma^* \to \mathbb{N}$ is a randomised algorithm that takes as input $(x, \varepsilon) \in \Sigma^* \times (0, 1)$ and produces as output an integer random variable X satisfying the condition $\Pr(|X - f(x)| \leq \varepsilon f(x)) \geq 3/4$. A RAS for a counting problem is called *fully polynomial* (FPRAS) if on input of size n it runs in time $p(n, \varepsilon^{-1})$ for some fixed polynomial p. A RAS for a parametrised counting problem is called *fixed parameter tractable* (FPTRAS) if on input of size n with parameter k it runs in time $f(k) \cdot p(n, \varepsilon^{-1})$, where p is a fixed polynomial and f is an arbitrary computable function.

To compare approximation complexity of (parametrised) counting problems two types of reductions are used. Suppose $f, g : \Sigma^* \to \mathbb{N}$. An *approximation preserving reduction* (AP-reduction) [15] from f to g is a probabilistic oracle Turing machine M that takes as input a pair $(x, \varepsilon) \in \Sigma^* \times (0, 1)$, and satisfies the following three conditions: (i) every oracle call made by M is of the form (w, δ), where $w \in \Sigma^*$ is an instance of g, and $0 < \delta < 1$ is an error bound satisfying $\delta^{-1} \leq \mathsf{poly}(|x|, \varepsilon^{-1})$; (ii) the TM M meets the specification for being a randomised approximation scheme for f whenever the oracle meets the specification for being a randomised approximation scheme for g; and (iii) the running time of M is polynomial in $|x|$ and ε^{-1}.

Similar to [34] we also use the parametrised version of AP-reductions. Again, let $f, g : \Sigma^* \to \mathbb{N}$. A *parametrised approximation preserving reduction* (parametrised AP-reduction) from f to g is a probabilistic oracle Turing machine M that takes as input a triple $(x, k, \varepsilon) \in \Sigma^* \times (0, 1)$, and satisfies the following three conditions: (i) every oracle call made by M is of the form (w, k', δ), where $w \in \Sigma^*$ is an instance of g, $k' \leq h(k)$ for some computable function h, and $0 < \delta < 1$ is an error bound satisfying $\delta^{-1} \leq \mathsf{poly}(|x|, \varepsilon^{-1})$; (ii) the TM M meets the specification for being a randomised approximation scheme for f whenever the oracle meets the specification for being a randomised approximation scheme for g; and (iii) M is fixed-parameter tractable with respect to k and polynomial in $|x|$ and ε^{-1}.

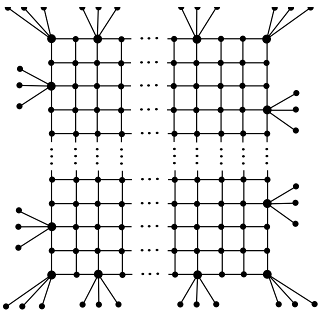

Figure 1 Fan-grid. Fan vertices are shown by larger dots.

3.3 Main Result

The following concept plays a key role in this paper. Let $k, r, \ell_1, \ell_2 \in \mathbb{N}$. The *fan-grid* $L(k, r, \ell_1, \ell_2)$ is a graph with vertex set $L_1 \cup L_2$, where $L_1 = \{(i, p) \mid i \in [k], p \in [r]\}$, $L_2 = M_1 \cup \cdots \cup M_{12}$, where $M_1, \ldots, M_{12}$ are disjoint and $|M_i| = \ell_1$ for $i \in [4]$, and $|M_i| = \ell_2$ for $i \in \{5, \ldots, 12\}$. Vertices from L_1 will be called *grid vertices*. Vertices $u_1 = (1, 1)$, $u_2 = (1, r)$, $u_3 = (k, 1)$, $u_4 = (k, r)$, $u_5 = (1, 3)$, $u_6 = (1, r - 3)$, $u_7 = (k, 3)$, $u_8 = (k, r - 3)$, $u_9 = (3, 1)$, $u_{10} = (4, r)$, $u_{11} = (k - 2, 1)$, $u_{12} = (k - 3, r)$ will be called *fan vertices*, and u_1, u_2, u_3, u_4 will be called *corner vertices*. The edges of the fan grid are as follows: $(i, p)(i', p')$ for $|i - i'| + |p - p'| = 1$, and wu_i for each $w \in M_i$ and $i \in [12]$, see Figure 1.

We call a class $\mathcal{C}$ of relational structures of bounded arity a *fan class* if either $\mathcal{C}$ has bounded treewidth or for any parameters $k, r, \ell_1, \ell_2 \in \mathbb{N}$ we have that $G(\mathcal{C})$ contains the fan-grid $L(k, r, \ell_1, \ell_2)$.

The following is our main result.

▶ **Theorem 3 (Main).** *Assume FPT $\neq$ W[1] under randomised parametrised reductions. Let $\mathcal{C}$ be a recursively enumerable class of relational structures of bounded arity. If $\mathcal{C}$ is a fan class then the following are equivalent:*

1. *$\#\text{CSP}(\mathcal{C}, -)$ is polynomial time solvable.*
2. *$\#\text{CSP}(\mathcal{C}, -)$ admits an FPRAS.*
3. *p-$\#\text{CSP}(\mathcal{C}, -)$ admits an FPTRAS.*
4. *$\mathcal{C}$ has bounded treewidth.*

Let $\mathcal{C}$ be a recursively enumerable class of relational structures of bounded arity and closed under taking minors. We claim that $\mathcal{C}$ is a fan class and thus Theorem 3 applies to such $\mathcal{C}$. For this we need Theorem 1. In particular, for any $k, r, \ell_1, \ell_2 \in \mathbb{N}$, if $\mathcal{C}$ is not of bounded treewidth then, by Theorem 1, $G(\mathcal{C})$ contains an $(s \times s)$-grid, where $s = \max(k + 2\ell_1, r + 2\ell_2)$, and thus also a $(k + 2\ell_1) \times (r + 2\ell_2)$-grid. The following simple lemma then shows that fan-grids are minors of grids (of appropriate size).

▶ **Lemma 4.** *$L(k, r, \ell_1, \ell_2)$ is a minor of $(t \times t')$-grid, where $t = k + 2\ell_1$, $t' = r + 2\ell_2$.*

4 Proof of Theorem 3

Conditions (1) and (4) in Theorem 3 are equivalent by [9]. Implications "(1) ⇒ (2) ⇒ (3)" are obvious; implication "(4) ⇒ (1)" is by the standard treewidth-based dynamic programming for exact counting. Our main contribution is to prove the "(3) ⇒ (4)" implication.

4.1 Construction

Let $G = (V, E)$ be a graph with $n = |V|$ and $m = |E|$. Let $k \in \mathbb{N}$. We construct a graph $H(G, k, W_1, W_2)$ for $W_1, W_2 > 2(n+m)$ as follows. Let $r = \binom{k}{2}$ and let ϱ be a correspondence between $[r]$ and the set of 2-element sets $\{\{i, j\} \mid i, j \in [k], i \neq j\}$. For $i \in [k]$ and $p \in [r]$, we write $i \in p$ rather than $i \in \varrho(p)$. The vertex set of $H(G, k, W_1, W_2)$ is the union of two sets $H_1 \cup H_2$, defined by

$$H_1 = \{(v, e, i, p) \mid v \in V, e \in E, \text{ and } v \in e \iff i \in p\},$$
$$H_2 = K_1 \cup \cdots \cup K_{12},$$

where $K_1, \ldots, K_{12}$ are disjoint and $|K_i| = W_1$ for $i \in [4]$, $|K_i| = W_2$ for $i \in \{5, \ldots, 12\}$.

As in fan-grids, vertices of the form $(v, e, 1, 1)$, $(v, e, 1, r)$, $(v, e, k, 1)$, (v, e, k, r), $(v, e, 1, 3)$, $(v, e, 1, r-3)$, $(v, e, k, 3)$, $(v, e, k, r-3)$, $(v, e, 3, 1)$, $(v, e, 4, r)$, $(v, e, k-2, 1)$, $(v, e, k-3, r)$ will be called *fan vertices*, and vertices of the form $(v, e, 1, 1)$, $(v, e, 1, r)$, $(v, e, k, 1)$, (v, e, k, r) will be called *corner vertices*.

The edge set of $H(G, k, W_1, W_2)$ consists of the following pairs:

- $(v, e, i, p)(v', e, i', p)$ such that $|i - i'| = 1$;
- $(v, e, i, p)(v, e', i, p')$ such that $|p - p'| = 1$;
- $u(v, e, 1, 1)$ for $u \in S_1 \subseteq K_1$ and $(v, e, 1, 1) \in H_1$, where S_1 is an arbitrary subset of K_1 whose cardinality is such that the degree of $(v, e, 1, 1)$ is exactly W_1;
  similarly, $u(v, e, 1, r)$, $u(v, e, k, 1)$, $u(v, e, k, r)$, $u(v, e, 1, 3)$, $u(v, e, 1, r-3)$, $u(v, e, k, 3)$, $u(v, e, k, r-3)$, $u(v, e, 3, 1)$, $u(v, e, 4, r)$, $u(v, e, k-2, 1)$, $u(v, e, k-3, r)$ for $u \in S_j \subseteq K_j$ (for $j = 2, \ldots, 12$ in this order) and $(v, e, 1, r)$, $(v, e, k, 1)$, (v, e, k, r), $(v, e, 1, 3)$, $(v, e, 1, r-3)$, $(v, e, k, 3)$, $(v, e, k, r-3)$, $(v, e, 3, 1)$, $(v, e, 4, r)$, $(v, e, k-2, 1)$, $(v, e, k-3, r) \in H_1$, where $S_2, \ldots, S_{12}$ are arbitrary subsets whose cardinality is such that the degree of $(v, e, 1, r), (v, e, k, 1), (v, e, k, r)$ is exactly W_1 and the degree of the remaining vertices from the list is exactly W_2.

Note that the sizes of sets $K_1, \ldots, K_{12}$ are chosen in such a way that all the corner vertices have degree W_1 and the remaining fan vertices have degree W_2.

We study homomorphisms from $L(k, r, \ell_1, \ell_2)$ to $H(G, k, W_1, W_2)$. A homomorphism $\varphi : L(k, r, \ell_1, \ell_2) \to H(G, k, W_1, W_2)$ is said to be corner-to-corner (or c-c for short) if

$$\varphi(1, 1), \varphi(1, r), \varphi(k, 1), \varphi(k, r) \in \{(v, e, 1, 1), (v, e, 1, r), (v, e, k, 1), (v, e, k, r) \mid v \in V, e \in E\}.$$

Homomorphism φ is called identity (skew identity) if $\varphi(i, p) \in \{(v, e, i, p) \mid v \in V, e \in E\}$ (respectively, $\varphi(i, p) \in \{(v, e, k-i+1, p) \mid v \in V, e \in E\}$) for all $i \in [k]$ and $p \in [r]$.

We define the *weight* of a homomorphism φ from $L(k, r, \ell_1, \ell_2)$ restricted to L_1 (the set of grid vertices) to $H(G, k, W_1, W_2)$ as the number of extensions of φ to a homomorphism from $L(k, r, \ell_1, \ell_2)$.

4.2 Weights of Homomorphisms

We start with a simple lemma.

▶ **Lemma 5.** *The weight of an identity or skew identity homomorphism is* $W_1^{4\ell_1} W_2^{8\ell_2}$.

Proof. The images of grid vertices (the set L_1) under identity and skew identity homomorphisms are fixed, while vertices from L_2 can be mapped to any neighbour of the corresponding fan vertex independently. Since the degree of a corner vertex (v, e, i, p) with $i \in \{1, k\}$ and $p \in \{1, r\}$ is W_1, and the degree of any other fan vertex is W_2, the result follows. ◀

The next lemma, which can proved using Lemma 5, is essentially [9, Lemma 3.1] adapted to our setting, which in turn builds on [29, Lemma 4.4].

▶ **Lemma 6.** *Let N be the number of k-cliques in G. Then there are $2NW_1^{4\ell_1}W_2^{8\ell_2}k!$ identity and skew identity homomorphisms.*

Next we establish an upper bound on the total weight of homomorphisms that are neither identity nor skew identity.

▶ **Lemma 7.** *Let $G = (V, E)$ has $n = |V|$ vertices and $m = |E|$ edges, let $k = 4k'$ for some k', and let $T = \log_{W_2} W_1$. If*

$$\ell_1 > \frac{8T\ell_2}{T-1},$$

then the total weight of homomorphisms that are neither identity nor skew identity is at most

$$W_1^{4\ell_1}W_2^{6\ell_2}(2n+m)^{2\ell_2} \cdot (4W_1 + 8W_2 + nmkr)^{kr}.$$

The key ideas in the proof of Lemma 7 are the following: Firstly, we show that c-c homomorphisms dominate non-c-c homomorphisms. Secondly, using crucially the special structure of fan grids and our choice of k being a multiple of four, we establish an upper bound on any c-c homomorphism that is neither identity nor skew identity. Finally, we give an upper bound on the number of all homomorphisms. These three ingredients together allows us to establish the required bound.

We now have all results required to relate the number of k-cliques in a given graph G and the number of homomorphisms from $L(k, r, \ell_1, \ell_2)$ to $H(G, K, W_1, W_2)$, for appropriately chosen values of ℓ_1, ℓ_2, W_1, W_2.

▶ **Lemma 8.** *Let $N \geq 0$ be the number of k-cliques in G, where $k = 4k'$ for some k', $n = V(G)$, $m = E(G)$, and $2n + m > 6$. Let $M = M(\ell_1, \ell_2, W_1, W_2)$ be the number of homomorphisms from $L(k, r, \ell_1, \ell_2)$, $r = \binom{k}{2}$, to $H(G, k, W_1, W_2)$. If $W_2 = (2n + m)^2$, $W_1 = W_2^2$, $\ell_2 = 8kr$, and $\ell_1 = 17\ell_2$, then we have*

$$N < \frac{M}{2W_1^{4\ell_1}W_2^{8\ell_2}k!} < N + \frac{1}{2}.$$

Finally, as Lemmas 7 and 8 are only proved for $k = 4k'$, we need to show that the problem for other values of the parameter can be reduced to k of such form. The following lemma takes care of that. Let $4p$-#Clique denote the following problem

Name: $4p$-#Clique
Input: A graph G and $k \in \mathbb{N}$.
Parameter: k.
Output: The number of cliques of size $4k$ in G.

▶ **Lemma 9.** *There is a parametrised AP-reduction from p-#Clique to $4p$-#Clique.*

In particular, Lemma 9 establishes #W[1]-hardness of the $4p$-#Clique problem.

4.3 Putting the Pieces Together

Proof of Theorem 3. As we mentioned earlier, conditions (1) and (4) are equivalent, the implications "(1) ⇒ (2) ⇒ (3)" are trivial and the implication "(4) ⇒ (1)" is known: if $\mathcal{C}$ has bounded treewidth then, by [22, Proposition 7], #CSP($\mathcal{C}, -$) belongs to FP.

The rest of the proof establishes "(3) ⇒ (4)". Assume that $\#\mathrm{CSP}(\mathcal{C},-)$ admits an FPTRAS for a fan class $\mathcal{C}$. Our goal is to show that $\mathcal{C}$ has bounded treewidth. For the sake of contradiction, assume that $\mathcal{C}$ has unbounded treewidth. We will exhibit a parametrised reduction from p-#Clique to p-$\#\mathrm{CSP}(\mathcal{C},-)$, which gives an FPTRAS for p-#Clique assuming an FPTRAS for p-$\#\mathrm{CSP}(\mathcal{C},-)$. Under the assumption that $\mathrm{FPT} \neq \mathrm{W}[1]$ (under randomised parametrised reductions [14]), the W[1]-hardness of p-Clique established in [13] implies, by [34, Corollary 3.17], the non-existence of an FPTRAS for the p-#Clique problem, a contradiction.

Let $G = (V, E)$ and k be an instance of the p-#Clique problem. By Lemma 9, we can assume that $k = 4k'$. First, we show that if G has any k-cliques at all, it can be assumed to have many k-cliques. Let $s \in \mathbb{N}$ and G_s is defined as follows. $V(G_s) = \{v_1, \ldots, v_s \mid v \in V\}$ and $v_i w_j \in E(G_s)$, for $v, w \in V$ and $i, j \in [s]$, if and only if $vw \in E$. In other words, every vertex v of G is replaced with s distinct vertices $v_1, \ldots, v_s$, and every edge vw is replaced with a complete bipartite graph $K_{s,s}$.

▷ Claim 1. If N is the number of k-cliques in G, then G_s contains $s^k N$ k-cliques.

Proof of Claim 1. As is easily seen, for any indices $i_1, \ldots, i_k \in [s]$ the vertices $v^1_{i_1}, \ldots, v^k_{i_k}$ induce a clique in G_s if and only if $v^1, \ldots, v^k$ is a clique in G. Moreover, no clique in G_s contains vertices v_i, v_j for $v \in V$ and $i, j \in [s]$. The result follows. ◁

For a given instance $G = (V, E)$, k of p-#Clique and error tolerance $\varepsilon \in (0, 1)$ using Claim 1, we first reduce it to the instance G_s, k of p-#Clique, where

$$s > \left(\frac{1 + \varepsilon/2}{\varepsilon}\right)^{\frac{1}{k}}.$$

Such a choice of s guarantees that if G_s contains any k-clique, it contains at least $\frac{1+\varepsilon/2}{\varepsilon}$ k-cliques. For simplicity we will have this assumption directly for G. We will also assume that if $n = |V|$ and $m = |E|$, then $2n + m > 6$.

Now we construct an instance $\mathbf{A}, \mathbf{B}$ of p-$\#\mathrm{CSP}(\mathcal{C},-)$ such that an $\varepsilon/2$-approximation of the number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$ yields an ε-approximation of the number of k-cliques in G. Structures $\mathbf{A}, \mathbf{B}$ will be chosen to be (essentially) $\mathbf{A} = L(k, r, \ell_1, \ell_2)$ and $\mathbf{B} = H(G, k, W_1, W_2)$, where the parameters ℓ_1, ℓ_2, W_1, W_2 are set according to Lemma 8. Let $r = \binom{k}{2}$, $\ell_1 = 17\ell_2$, and $\ell_2 = 8kr$.

Since $\mathcal{C}$ is a fan class and we assume that $\mathcal{C}$ is not of bounded treewidth, there is a structure $\mathbf{A}$ in $\mathcal{C}$ such that $L(k, r, \ell_1, \ell_2)$ is the Gaifman graph $G(\mathbf{A})$ of $\mathbf{A}$.

We enumerate the class $\mathcal{C}$ until we find such an $\mathbf{A}$. Since $L(k, r, \ell_1, \ell_2)$ does not contain triangles, we can without loss of generality assume that $\mathbf{A}$ is τ-structure where τ consists of a single binary relation symbol; i.e., $\mathbf{A}$ is a graph and hence $L(k, r, \ell_1, \ell_2)$. Let $\mathbf{B} = H(G, k, W_1, W_2)$, where $W_1 = (2n + m)^4$ and $W_2 = (2n + m)^2$. Since the parameters $n, m, \ell_1, \ell_2, W_1, W_2$ satisfy the conditions of Lemma 8, by that lemma we have

$$N < \frac{M}{2W_1^{4\ell_1} W_2^{8\ell_2} k!} < N + \frac{1}{2}, \tag{1}$$

where N is the number of k-cliques in G, which we want to approximate within ε, and M is the number of homomorphisms from $\mathbf{A}$ to $\mathbf{B}$, for which we have an FPTRAS by assumption. Let $Q = M/(2W_1^{4\ell_1} W_2^{8\ell_2} k!)$. The FPTRAS for p-$\#\mathrm{CSP}(\mathcal{C},-)$ applied with error tolerance $\varepsilon/2$ produces a number M' such that

$$(1 - \varepsilon/2)M < M' < (1 + \varepsilon/2)M. \tag{2}$$

We then return $\lfloor Q' \rfloor$, where

$$Q' = \frac{M'}{2W_1^{4\ell_1} W_2^{8\ell_2} k!}.$$

It remains to show that $(1-\varepsilon)N < Q' < (1+\varepsilon)N$. On one hand, we have

$$Q' > (1-\varepsilon/2)Q \geq (1-\varepsilon/2)N \geq (1-\varepsilon)N,$$

where the first inequality follows from (2) and the definitions of Q and Q', the second inequality follows from (1) and the definitions of Q and N, and the third inequality is trivial.

On the other hand, we have

$$Q' < (1+\varepsilon/2)Q < (1+\varepsilon/2)(N+\frac{1}{2}),$$

where again the first inequality follows from (2) and the second inequality follows from (1).

Assume first that $N = 0$. Then $Q' < \frac{1+\varepsilon/2}{2}$, and by the assumption $\varepsilon < 1$ we have $\lfloor Q' \rfloor = 0$ as required. Otherwise by the assumption on the number of k-cliques in G, $N > \frac{1+\varepsilon/2}{\varepsilon}$; therefore

$$Q' < (1+\varepsilon/2)(N+\frac{1}{2}) = (1+\varepsilon/2)N + \frac{1+\varepsilon/2}{2} < (1+\varepsilon/2)N + (\varepsilon/2)N = (1+\varepsilon)N.$$

Observe that the reduction runs in time $f(k) \cdot \mathsf{poly}(n+m, \varepsilon^{-1})$ and is a parametrised AP-reduction. Thus, the reduction gives an FPTRAS for N. Theorem 3 is proved. ◀

5 Conclusions

We do not know whether Theorem 3 holds for all classes of (bounded-arity) relational structures.

With more technicalities (but the same ideas as presented in this extended abstract), one can weaken the assumption on a fan class to obtain the same result (Theorem 3). In particular, it suffices to require that there are polynomials f_1, f_2, f_3, f_4 such that for any parameters $k, r, \ell_1, \ell_2 \in \mathbb{N}$, $G(\mathcal{C})$ contains the fan-grid $L(k', r', \ell_1', \ell_2')$, where $k' = f_1(k, r, \ell_1, \ell_2) \geq k$, $r' = f_2(k, r, \ell_1, \ell_2) \geq r$, $\ell_1' = f_3(k, r, \ell_1, \ell_2) \geq \ell_1$, $\ell_2' = f_4(k, r, \ell_1, \ell_2) \geq \ell_2$. This can be achieved by making use of Lemma 9 (as it would not be possible to test directly for cliques of all sizes) and by a modification of the construction from Section 4.1 (to accommodate for the fact that some fan-grids may not correspond to cliques due to incompatible numbers).

Abstract

Given R a binary relation between words (which we treat as a language over a product alphabet $\mathbb{A} \times \mathbb{B}$), a uniformisation of it is another relation L included in R which chooses a single word over $\mathbb{B}$, for each word over $\mathbb{A}$ whenever there exists one. It is known that **MSO**, the full class of regular languages, is strong enough to define a uniformisation for each of its relations. The quest of this work is to see which other formalisms, weaker than **MSO**, also have this property. In this paper, we solve this problem for pseudo-varieties of semigroups: we show that no nonempty pseudo-variety weaker than **MSO** can provide uniformisations for its relations.

2012 ACM Subject Classification Theory of computation → Regular languages

1 Introduction

Regular languages of finite words lie at the core of modern automata theory. The study of their properties has led to multiple fundamental discoveries. Among these discoveries was a formal introduction of the model of non-deterministic automata by Rabin and Scott [16]. Later, the results of Büchi, Elgot, and Trakhtenbrot [2, 7, 25] laid the foundations of the correspondence between automata and Monadic Second-Order (**MSO**) logic. That correspondence is now considered a golden standard, with notable extensions to other structures, like finite and infinite trees. Another breakthrough obtained over finite words was the effective characterisation of the class of star-free languages by McNaughton, Papert and Schützenberger [19, 11]. Again, this result has opened a rich area of extensions, first to infinite words [24], and later to other structures and classes of languages [23, 21, 1]. From the perspective of these results, the theory of regular languages of finite words can be seen as a test ground for novel problems and methods.

The situation is a bit different with the problem of uniformisation. This problem asks, to find an effectively definable graph of a function that is contained in a given relation R.

44th International Symposium on Mathematical Foundations of Computer Science (MFCS 2019).

Thus, it can be seen as an instance of the choice axiom: the relation $R(x, y)$ admits multiple witnesses y for each argument x and our task is to choose one of them. The origins of that problem come from descriptive set theory, with the famous theorems like that of Novikov and Kondô [9, Theorem 36.12].

The problem of uniformisation was translated to the context of automata theory by Rabin [15], directly for the most complex structures – infinite trees. In that context, the relation R is given by an **MSO**-definable language over a product alphabet $\mathbb{A} \times \mathbb{B}$, and the question of uniformisation asks to find an **MSO**-definable language that realises a function from structures over $\mathbb{A}$ to structures over $\mathbb{B}$. Therefore, the question of uniformisability can be read as the problem of effective selection of witnesses – a way of making non-determinism somehow controlled. In the course of research over that problem, it was shown that **MSO**-definable uniformisation is always possible over infinite words [20, 10, 17]; but not over infinite trees [8, 4]. In parallel, a study of *sequential uniformisation* was performed in the context of games and problems of synthesis [3].

The fact that **MSO** has[1] the uniformisation property over finite words is easy to prove and is considered folklore: it is enough to choose the lexicographically minimal witness. That is probably the reason why the case of finite words was somehow ignored in the study of uniformisation problems. It was opened by a recent paper [12], where the author asks about the possibility to uniformise for certain logics weaker than **MSO**. The results of that work are not unequivocal. On the one hand, it is shown that for multiple pairs of logics $\mathbf{L}_1 \subseteq \mathbf{L}_2 \subseteq \mathbf{MSO}$, there exists a relation R definable in $\mathbf{L}_1$ with no $\mathbf{L}_2$-definable uniformisation. On the other hand, it is shown that each relation definable in $\mathbf{FO}[\,]$ (First-Order logic with only equality and letter tests) can be effectively uniformised within First-Order logic with the order predicate. This leads to an intriguing graph of logics, one (not) uniformising another. To simplify the situation, the author formulated the above question for $\mathbf{L}_1 = \mathbf{L}_2$, *i.e.* the problem whether a given logic uniformises itself. Based on the provided results, the following conjectured:

▶ **Conjecture 1** (Conjecture 1 in [12])**.** *Let* $\mathbf{L}$ *be a fragment of* **MSO** *such that* $\mathbf{FO}^2[\,] \subseteq \mathbf{L}$ *and* $\mathbf{L}$ *satisfies some closure properties (to be specified). If* $\mathbf{L}$ *has the uniformisation property, then* $\mathbf{L}$ *is* **MSO***.*

The main result of the present paper is a positive answer to the above conjecture. The assumption that the logic $\mathbf{FO}^2[\,]$ (the two-variable fragment of First-Order logic) is contained in a given logic turned out to be unnecessary, and the relevant closure properties boil down to the standard notion of a pseudo-variety.

▶ **Theorem 2.** **MSO** *is the unique nonempty self-uniformisable pseudo-variety of semigroups.*

A class of languages corresponds to a pseudo-variety of semigroups if it is closed under Boolean combinations, left and right quotients, and pre-images under non-erasing homomorphisms. It is known that most of the classically considered logics correspond to pseudo-varieties of semigroups [18]. Since we restrict to semigroups instead of monoids (*i.e.* we require the considered homomorphisms of words to be non-erasing), this definition also captures logics with successor instead of the order. Among the notable examples of logics that do not correspond to pseudo-varieties of semigroups are the logics with modulo predicates, like $\mathbf{FO}[\leq, \mathbf{MOD}_2]$. These logics are not covered by the presented arguments. To deal with them, one would need to consider homomorphisms of words that are *length-preserving* or *length-multiplying*, see *e.g.* [14].

[1] We identify a logic with the class of languages it defines. Therefore **MSO** = **REG**, *i.e.* the class of all regular languages.

When read in terms of logics, the above result says that most of the widely considered formalisms over finite words weaker than **MSO** do not have the uniformisation property. As generally in the case of negative results, the consequences of that are more theoretical than practical: there is no hope in finding a robust formalism, that would be easier to handle than **MSO** and still retain the ability to choose unique witnesses.

The provided proof is independent from the results of [12] – instead of comparing two logics $\mathbf{L}_1 \subseteq \mathbf{L}_2$, we focus on one formalism $\mathbf{L}$ with the assumption that $\mathbf{L}$ can uniformise itself. Based on that assumption, we gradually bootstrap the expressive power of the considered formalism. It is done in a sequence of steps, showing that $\mathbf{L}$ must be able to express more and more complex properties: test the letters that appear in a given word; recognise the order in which the letters appear; *etc.* Each of these steps is based on the assumption that $\mathbf{L}$ has the uniformisation property and therefore must be sensitive to certain modifications of the input words. Thus, the proofs of the lemmas are of a similar structure.

Nevertheless, we believe that it is non-trivial and instructive to see the ways in which uniformisability guarantees the considered expressive abilities. The difficulty of these arguments lies in the fact that the assumptions about $\mathbf{L}$ speak about the algebraic properties of the semigroups recognising languages in $\mathbf{L}$, while the notion of uniformisability is a set-theoretical property of the actual languages in $\mathbf{L}$.

While the proof goes on, we have more and more tools at hand, but at the same time we need to prove stronger and stronger expressibility properties about $\mathbf{L}$. Ultimately, it turns out that $\mathbf{L}$ is able to guess evaluations with respect to arbitrary finite semigroups (*i.e.* in a sense is closed under projection) and therefore must contain all regular languages of finite words. From this perspective, the proof can be seen as a variety of concrete recipes (ranging from the least complex properties to the most complex) explaining what is the interplay between the considered expressibility property and uniformisability.

Although the results are expressed over finite words, we believe that similar arguments can be adapted to the more complex structures, like infinite words or finite trees. Therefore, finite words are used here again as a testing ground, providing new understanding that can later be transferred to richer structures.

The paper is organised as follows. Section 2 is devoted to an introduction of all relevant technical notions. Then, Sections 3.1 up to 3.7 gradually increase the expressive power of the considered class of languages $\mathbf{L}$. Finally, in Section 4 we conclude.

2 Technical background

Words and languages

We identify each natural number n with the set $\{0,\ldots,n{-}1\}$, and we denote the set of all natural numbers by ω. An *alphabet* $\mathbb{A}$ is any finite set. A function from a natural number n to an alphabet $\mathbb{A}$ is called a *(finite) word* over $\mathbb{A}$. The natural number n is the *length* of w, and we denote it by $|w|$. For each $i \in n$ the element $w(i) \in \mathbb{A}$ is called the ith *letter* of w. We write $w = w(0) \cdot w(1) \cdots w(n{-}1)$, but notice that this notation is ambiguous when the alphabet is not clear in the context: if we write $w = a \cdot b$, we do not know *a priori* if we see w as a word over $\{a, b\}$, or over any other alphabet containing $\{a, b\}$. We extend this notation: if w_1 and w_2 are two words over $\mathbb{A}$, then $w_1 \cdot w_2$, the *concatenation* of w_1 and w_2, is the word w over $\mathbb{A}$ of length $|w_1| + |w_2|$ defined by $w(i) = w_1(i)$ for $i \in |w_1|$ and $w(i) = w_2(i - |w_1|)$ for $i \geq |w_1|$.

A word of length 0 is denoted by ϵ and called the *empty word*. The set of all words over $\mathbb{A}$ is denoted by $\mathbb{A}^*$, $\mathbb{A}^n$ is the set of all words of length $n \in \omega$, and $\mathbb{A}^+$ is $\mathbb{A}^* \setminus \{\epsilon\}$, *i.e.* the set of nonempty words over $\mathbb{A}$. Note that $\emptyset^* = \{\epsilon\}$ and $\emptyset^+ = \emptyset$.

In this paper, a *language* of words over an alphabet $\mathbb{A}$ is any subset[2] of $\mathbb{A}^+$. Once again, notice that a language has to be given with its alphabet. To avoid any ambiguity like the one above, we sometimes write $\langle L, \mathbb{A}\rangle$ to emphasise the choice of the alphabet.

In order to ease the reading of the paper, we will denote by $\mathbb{A}, \mathbb{A}_0, \mathbb{A}_1 \ldots$ alphabets of letters $a, b, \ldots, x, y \ldots$ and by $\mathbb{B}, \mathbb{B}_0, \mathbb{B}_1 \ldots$ alphabets of symbols $\Box, \bullet, \triangle, \ldots$ Words over the alphabets of letters will be denoted by $u, v, w \ldots$ while words over the alphabets of symbols will be denoted by $\pi, \sigma, \tau, \ldots$

Semigroups and pseudo-varieties

In this paper, the classes of languages which we focus on correspond to *pseudo-varieties of semigroups.*

A *semigroup* is a set S provided with an associative binary operation, which we will denote by $\cdot$. We identify the semigroup $\langle S, \cdot\rangle$ with its set S. For $s \in S$ and for a natural number $n \geq 1$, s^n denotes the product $s \cdots s$, where s appears n times. An element $e \in S$ is said to be *idempotent* if $e^2 = e$.

It is considered folklore to prove that for every finite semigroup S, there exists a natural number $n \geq 1$ such that s^n is idempotent for each $s \in S$. We denote this natural number by $\sharp(S)$. When the semigroup is known from the context, we just write $\sharp$ instead of $\sharp(S)$. Notice that in the literature the symbol ω is often used instead of $\sharp$.

If S is a semigroup, then $S' \subseteq S$ is said to be a *sub-semigroup* of S if it is stable by the operation of S, that is, if for all s, t in S', $s \cdot t \in S'$. Finally, if S_1 and S_2 are two semigroups, then $S_1 \times S_2$ provided with the operation defined by $\langle s_1, s_2\rangle \cdot \langle t_1, t_2\rangle = \langle s_1 \cdot s_2, t_1 \cdot t_2\rangle$ is also a semigroup. It is called the *product* of S_1 and S_2.

Let S_1 and S_2 be two semigroups. A *homomorphism* from S_1 to S_2 is a function α from S_1 to S_2 such that for all x, y in S_1, we have $\alpha(x \cdot y) = \alpha(x) \cdot \alpha(y)$. Such a homomorphism is *surjective* (resp. *injective*, *bijective*) if so is the respective function α.

For each alphabet $\mathbb{A}$, the set $\mathbb{A}^+$ provided with the concatenation operation, is a semigroup that is known as the *free semigroup on* $\mathbb{A}$. The fact that a homomorphism $\alpha\colon \mathbb{A}^+ \to S$ must preserve the operations of the semigroups, implies that α is uniquely determined by its action on the single letters in $\mathbb{A}$.

The following variant of Ramsey's theorem is often used when working with finite semigroups.

▶ **Theorem 3** (Simon [22], see also Section II.11.1 in [13])**.** *Let $\mathbb{A}$ be an alphabet and α a homomorphism from $\mathbb{A}^+$ to some finite semigroup S. For each natural number $n \geq 2$, there exists a natural number $N(n)$ such that for each word w over $\mathbb{A}$ of length at least $N(n)$, there exists an idempotent e in S and a decomposition $w = u \cdot w_0 \cdots w_{n-1} \cdot v$, where for all $i \in n$, w_i is nonempty and $\alpha(w_i) = e$.*

Let L be a language of words over some alphabet $\mathbb{A}$ and let S be a finite semigroup. We say that S *recognises* L if there exists a homomorphism α from $\mathbb{A}^+$ to S and $T \subseteq S$ such that $L = \alpha^{-1}(T)$. In such a case we also say that the tuple $\langle S, \alpha, T\rangle$ *recognises* L.

A language of words over $\mathbb{A}$ is *regular* if it is recognised by some finite semigroup S. We denote the class of all regular languages by **REG**. As mentioned in the introduction, the class **REG** coincides with the class of languages definable in Monadic Second-Order logic (denoted **MSO**); however as logic is not directly involved in the presentation, we will rather use **REG** to emphasise the automata- and semigroup-based approach.

[2] It is more standard to define languages as subsets of $\mathbb{A}^*$ but then the natural algebraic structures are monoids, and not semigroups.

Let $\mathbf{L}$ be a class of languages and $\mathbf{S}$ a class of finite semigroups, we say that $\mathbf{L}$ *corresponds* to $\mathbf{S}$ if it is exactly the class of languages recognised by the semigroups S of $\mathbf{S}$. Notice that, under this assumption, $\mathbf{L}$ only contains regular languages.

We define now an important notion: the notion of pseudo-varieties.

▶ **Definition 4.** *Let $\mathbf{S}$ be a class of finite semigroups. We say that $\mathbf{S}$ is a* pseudo-variety *of (finite) semigroups if it has the following properties:*

- *if $S_1 \in \mathbf{S}$ and if S_2 is a sub-semigroup of S_1, then $S_2 \in \mathbf{S}$,*
- *if S_1 and S_2 are in $\mathbf{S}$, then the product semigroup $S_1 \times S_2$ is in $\mathbf{S}$,*
- *if $S_1 \in \mathbf{S}$ and if there exists a surjective homomorphism from S_1 to S_2, then $S_2 \in \mathbf{S}$.*

The following theorem is a part of the so-called Eilenberg's variety theory.

▶ **Theorem 5** (Eilenberg [6])**.** *Let $\mathbf{L}$ be a class of regular languages. Then the following propositions are equivalent:*

- *$\mathbf{L}$ corresponds to a pseudo-variety of semigroups;*
- *$\mathbf{L}$ has the following closure properties:*
  - *$\mathbf{L}$ is closed under Boolean operations: for each $\langle L_1, \mathbb{A}\rangle$ and $\langle L_2, \mathbb{A}\rangle$ in $\mathbf{L}$, $\langle L_1 \cup L_2, \mathbb{A}\rangle$ and $\langle L_1^{\mathrm{c}} := \mathbb{A}^+ \setminus L_1, \mathbb{A}\rangle$ are in $\mathbf{L}$ (and therefore also $\langle L_1 \cap L_2, \mathbb{A}\rangle$),*
  - *$\mathbf{L}$ is closed under quotients: for each $\langle L, \mathbb{A}\rangle \in \mathbf{L}$ and each word $w \in \mathbb{A}^+$, $\langle w^{-1} \cdot L, \mathbb{A}\rangle$ and $\langle L \cdot w^{-1}, \mathbb{A}\rangle$ are in $\mathbf{L}$, where $w^{-1} \cdot L = \{u \in \mathbb{A}^+ \mid w \cdot u \in L\}$, and $L \cdot w^{-1}$ is defined symmetrically,*
  - *$\mathbf{L}$ is closed under pre-images of semigroup homomorphisms: for each alphabet $\mathbb{A}$, language $\langle L, \mathbb{B}\rangle \in \mathbf{L}$, and homomorphism φ from $\mathbb{A}^+$ to $\mathbb{B}^+$, the language $\langle \varphi^{-1}(L), \mathbb{A}\rangle$ is in $\mathbf{L}$.*

All the classes of languages discussed in [12] are pseudo-varieties of semigroups. The most common are $\mathbf{MSO}$ and $\mathbf{FO}[<]$ (First-Order logic with the order). Other examples include $\mathbf{FO}^2[<]$, the fragment of $\mathbf{FO}[<]$ where only two distinct variables are allowed; and $\mathbf{FO}[\mathbf{s}]$, where instead of the order one allows the successor function $\mathbf{s}$.

Uniformisation

Let $\mathbb{A}$ and $\mathbb{B}$ be two alphabets. If $a \in \mathbb{A}$ and $\square \in \mathbb{B}$ are two letters then their pair is denoted $\binom{a}{\square} \in \mathbb{A} \times \mathbb{B}$. Let w, π be two words over $\mathbb{A}$ and $\mathbb{B}$ respectively, such that $|w| = |\pi|$. Then the pair $\langle w, \pi\rangle \in \mathbb{A}^* \times \mathbb{B}^*$ can be identified with $\binom{w}{\pi}$, the word over the product alphabet $\mathbb{A} \times \mathbb{B}$ satisfying $\binom{w}{\pi}(i) = \binom{w(i)}{\pi(i)}$ for all $i \in |w|$. This vertical notation is also extended to sets of words of fixed length, for instance, $\binom{\{a,b\}}{\square} = \{\binom{a}{\square}, \binom{b}{\square}\}$ is a set of two letters in $\mathbb{A} \times \mathbb{B}$.

Let $R \subseteq (\mathbb{A} \times \mathbb{B})^+$. Based on the previous identification, R can be seen as a binary relation between words over $\mathbb{A}$ and words over $\mathbb{B}$. The *projection* of R is the set of words $w \in \mathbb{A}^+$ such that there exists a word $\pi \in \mathbb{B}^{|w|}$ with $\binom{w}{\pi} \in R$. We denote this set by $\Pi(R)$.

A *uniformisation* of R is a relation $F \subseteq R$ such that $\Pi(F) = \Pi(R)$, and being functional, *i.e.* if $\binom{w}{\pi_1} \in F$ and $\binom{w}{\pi_2} \in F$ then $\pi_1 = \pi_2$. In that case, for each word $w \in \Pi(R)$, the unique π such that $\binom{w}{\pi} \in F$ is called the *image* of w by F.

A class $\mathbf{L}$ of languages is said to have the *uniformisation property* if each relation $R \in \mathbf{L}$ admits a uniformisation $F \in \mathbf{L}$. We also call such a class *self-uniformisable*. The fact that $\mathbf{REG}$ (*i.e.* the class of all regular languages) has the uniformisation property is considered folklore.

3 Proof of the theorem

We now begin the proof of Theorem 2. For the rest of the section, $\mathbf{L}$ denotes a class of regular languages corresponding to a nonempty pseudo-variety $\mathbf{S}$ of semigroups, and we assume that $\mathbf{L}$ has the uniformisation property. In the following subsections, we show that $\mathbf{L}$ contains certain specific languages and allows to express more and more complex properties of words. Ultimately, we show in Subsection 3.7 that $\mathbf{L}$ can validate evaluations with respect to finite semigroups, and therefore can recognise all regular languages.

3.1 Testing letters

Recall that by Theorem 5 we know that $\mathbf{L}$ is closed under Boolean operations. Also, as $\mathbf{S}$ is nonempty, we know that every *full language* $\mathbb{A}^+$ over some alphabet $\mathbb{A}$ belongs to $\mathbf{L}$: $\mathbb{A}^+ = \alpha^{-1}(S)$, for any semigroup $S \in \mathbf{S}$, and any homomorphism from $\mathbb{A}^+$ to S.

This section is devoted to a first step of the proof: we show that $\mathbf{L}$ must be able to detect which letters appear in the given word. More formally, the main result of this section is the following lemma.

▶ **Lemma 6.** *For all alphabets $\mathbb{A}_1 \subseteq \mathbb{A}_2$, the language $\langle \mathbb{A}_1^+, \mathbb{A}_2 \rangle$ is in $\mathbf{L}$.*

One can equivalently state the above lemma by saying that $\mathbf{FO}^1[] \subseteq \mathbf{L}$, or that $\mathbf{S}$ contains the pseudo-variety $\mathbf{J}_1$ of finite idempotent commutative semigroups, see [5]. However, the above statement seems to better fit the rest of the presentation.

This whole subsection is devoted to a proof of Lemma 6. To prove it, notice first that it is enough to show that the semigroup $2 = \{0, 1\}$ with the operation max belongs to $\mathbf{S}$. Indeed, given two alphabets $\mathbb{A}_1 \subseteq \mathbb{A}_2$ one can consider the homomorphism α from words over $\mathbb{A}_2$ to 2, defined by $\alpha(a) = 0$ for $a \in \mathbb{A}_1$ and $\alpha(a) = 1$ otherwise. Then, $\mathbb{A}_1^+ = \alpha^{-1}(\{0\})$, and therefore belongs to $\mathbf{L}$.

Let R be the full relation between words over $\mathbb{A} = \{x\}$ and words over $\mathbb{B} = \{\square, \triangle\}$: $R = \langle (\mathbb{A} \times \mathbb{B})^+, \mathbb{A} \times \mathbb{B} \rangle$. As discussed above, R is in $\mathbf{L}$. By the assumption, $\mathbf{L}$ must contain a uniformisation F of R that is recognised by some tuple $\langle S, \alpha, T \rangle$, with $S \in \mathbf{S}$.

Let $N = N(2)$ be the number we obtain from Theorem 3 applied for S and α in the particular case $n = 2$. Consider the word $w = x^N$, and take the unique word $\pi \in \{\square, \triangle\}^N$ such that $\binom{w}{\pi} \in F$. For convenience, for all $i \in j \in N{+}1$, we write $w_{i,j}$ (resp. $\pi_{i,j}$) for the word $w(i) \dots w(j{-}1)$ (resp. $\pi(i) \dots \pi(j{-}1)$), and $s_{i,j}$ for $\alpha(\binom{w_{i,j}}{\pi_{i,j}})$.

By the definition of N, we know that there exists an idempotent e of S, and $i \in j \in k \in N{+}1$, such that $s_{i,j} = s_{j,k} = e$. Since $j - i > 0$ and $|\mathbb{B}| \geq 2$, there exists a word $\pi' \in \mathbb{B}^{j-i}$ distinct from $\pi_{i,j}$. We define $s' = \alpha(\binom{w_{i,j}}{\pi'})$.

As e is idempotent, we know that for every $\ell \geq 1$ we have $s_{0,i} \cdot e^\ell \cdot s_{k,N} = s_{0,N} \in T$. Recall that $\sharp = \sharp(S)$ is a number such that for every $s \in S$ the element $s^\sharp$ is idempotent. Consider the particular case of the above equality for $\ell = 3 \times \sharp$, we obtain:

$$\binom{w_{0,i}}{\pi_{0,i}} \cdot \left(\binom{w_{i,j}}{\pi_{i,j}} \cdot \binom{w_{i,j}}{\pi_{i,j}} \cdot \binom{w_{i,j}}{\pi_{i,j}} \right)^\sharp \cdot \binom{w_{k,N}}{\pi_{k,N}} \in F.$$

As $\pi' \neq \pi_{i,j}$ and F is a uniformisation, we know that

$$\binom{w_{0,i}}{\pi_{0,i}} \cdot \left(\binom{w_{i,j}}{\pi_{i,j}} \cdot \binom{w_{i,j}}{\pi'} \cdot \binom{w_{i,j}}{\pi_{i,j}} \right)^\sharp \cdot \binom{w_{k,N}}{\pi_{k,N}} \notin F.$$

This implies that $e' := \left(s_{i,j} \cdot s' \cdot s_{i,j}\right)^\sharp = \left(e \cdot s' \cdot e\right)^\sharp \neq e$. Now, we set $s_0 = e$ and $s_1 = e'$. As both e and e' are idempotents, we know that $s_0 \cdot s_0 = s_0$ and $s_1 \cdot s_1 = s_1$. Moreover, because e is idempotent, it is immediate to see that $s_1 \cdot s_0 = \left(e \cdot s' \cdot e\right)^\sharp \cdot e = \left(e \cdot s' \cdot e\right)^\sharp = s_1$, and that we also have $s_0 \cdot s_1 = s_1$ symmetrically. Therefore, the subset $\{s_0, s_1\}$ of S is a sub-semigroup and it is isomorphic to $\langle 2, \max\rangle$. Because $\mathbf{S}$ is stable by taking sub-semigroups and images by surjective images, $\langle 2, \max\rangle \in \mathbf{S}$. This concludes the proof of Lemma 6.

3.2 Changing alphabets

The aim of this short section is to show that $\mathbf{L}$ is strong enough not to depend on the actual alphabet of a given language. This property is expressed by the following two lemmas.

▶ **Lemma 7.** *Let $\mathbb{A}_1 \subseteq \mathbb{A}_2$ be two alphabets and $L \subseteq \mathbb{A}_1^+$. If $\langle L, \mathbb{A}_2\rangle \in \mathbf{L}$ then $\langle L, \mathbb{A}_1\rangle \in \mathbf{L}$.*

Proof. Let $\langle S, \alpha, T\rangle$ be a tuple recognising L, with $S \in \mathbf{S}$. Let βbe the homomorphism from $\mathbb{A}_1^+$ to S defined by $\beta(a) = \alpha(a)$ for $a \in \mathbb{A}_1$. Then, by the assumption, we have $L = \beta^{-1}(T)$, and therefore $\langle L, \mathbb{A}_1\rangle \in \mathbf{L}$. ◀

▶ **Lemma 8.** *Let $\mathbb{A}_1 \subseteq \mathbb{A}_2$ be two alphabets and $L \subseteq \mathbb{A}_1^+$. If $\langle L, \mathbb{A}_1\rangle \in \mathbf{L}$ then $\langle L, \mathbb{A}_2\rangle \in \mathbf{L}$.*

Proof. Let $\langle L, \mathbb{A}_1\rangle \in \mathbf{L}$ with and $\langle S_1, \alpha_1, T_1\rangle$ a tuple recognising it, with $S_1 \in \mathbf{S}$. Assume that $\mathbb{A}_1 \subseteq \mathbb{A}_2$. We prove that $\langle L, \mathbb{A}_2\rangle$ is in $\mathbf{L}$.

We showed in the proof of Lemma 6 that the semigroup $\langle 2, \max\rangle$ is in $\mathbf{S}$. This implies that $S_1 \times 2$, with the natural product operation, is also in $\mathbf{S}$. Now, let β be the homomorphism from $\mathbb{A}_2^+$ to $S_1 \times S_2$ defined by $\beta(a) = \langle \alpha_1(a), 0\rangle$ for $a \in \mathbb{A}_1$, and $\beta(a) = \langle \alpha_1(a), 1\rangle$ for $a \in \mathbb{A}_2 \setminus \mathbb{A}_1$.

It is easy to verify that $L = \beta^{-1}(T_1 \times \{0\})$, and therefore, $\langle L, \mathbb{A}_2\rangle \in \mathbf{L}$. ◀

Lemmas 7 and 8 imply that if $L \subseteq \mathbb{A}_1^+ \cap \mathbb{A}_2^+$, then $\langle L, \mathbb{A}_1\rangle \in \mathbf{L}$ iff. $\langle L, \mathbb{A}_2\rangle \in \mathbf{L}$. Therefore, we can simply say that $L \in \mathbf{L}$, without being specific about its alphabet. Thus, from that moment on we will speak simply about languages L, instead of $\langle L, \mathbb{A}\rangle$.

Using Lemma 6, we can deduce the following result:

▶ **Corollary 9.** *Let a be any letter if an alphabet $\mathbb{A}$. By $[\exists a]_\mathbb{A}$ we denote the language of words over $\mathbb{A}$ that contain at least one occurrence of a. Then $[\exists a]_\mathbb{A} \in \mathbf{L}$.*

Moreover, by $\mathbb{A}^\oplus$ if we denote the set of all words w over $\mathbb{A}$ such that each letter of $\mathbb{A}$ appears in w, then $\mathbb{A}^\oplus$ too is in $\mathbf{L}$.

Proof. It is enough to observe that $[\exists a]_\mathbb{A} = \left((\mathbb{A} \setminus \{a\})^+\right)^\mathrm{c}$, where $^\mathrm{c}$ denotes the complement over the full language $\mathbb{A}^+$. Lemma 6 tells us that $(\mathbb{A} \setminus \{a\})^+ \in \mathbf{L}$, and, since $\mathbf{L}$ is closed under Boolean combinations, $[\exists a]_\mathbb{A} \in \mathbf{L}$.

Now, $\mathbb{A}^\oplus = \bigcap_{a \in \mathbb{A}} [\exists a]_\mathbb{A}$, and therefore $\mathbb{A}^\oplus \in \mathbf{L}$. ◀

3.3 Counting letters

Our next step towards Theorem 2 is to notice that $\mathbf{L}$ is able to test single occurrences of letters, as expressed by the following lemma:

▶ **Lemma 10.** *Let a be a letter of an alphabet $\mathbb{A}$. Then the language of words over $\mathbb{A}$ having exactly one occurrence of a is in $\mathbf{L}$. We denote this language by $[\exists^{=1} a]_\mathbb{A}$.*

Similarly as in the case of Lemma 6, the above lemma can be equivalently expressed by saying that $\mathbf{FO}^2[\,] \subseteq \mathbf{L}$ (*i.e.* the two-variable fragment of $\mathbf{FO}$ without any predicates except equality and letter tests).

To prove the above lemma, consider three distinct letters, x, y, and z, and four distinct symbols $\otimes$, $\oplus$, $\ominus$, and $\odot$. Let R^x and R^y be the relations defined as:

$$R^x = \left\{\binom{x}{\oplus}, \binom{x}{\ominus}, \binom{y}{\otimes}, \binom{z}{\odot}\right\}^{\oplus},$$
$$R^y = \left\{\binom{x}{\otimes}, \binom{y}{\oplus}, \binom{y}{\ominus}, \binom{z}{\odot}\right\}^{\oplus}.$$

We know that R^x and R^y are in $\mathbf{L}$ because of Corollary 9. Finally, we define $R = R^x \cup R^y$, which is in $\mathbf{L}$ because it is closed under unions.

Since $\mathbf{L}$ has the uniformisation property, there exists $F \in \mathbf{L}$ uniformising R. Let $\langle S, \alpha, T\rangle$, with $S \in \mathbf{S}$, be a triple recognising F.

Now, for $p, q \in \omega$, we define L^x_p and L^y_q as the following two relations:

$$L^x_p = \left\{\binom{u}{\sigma} \in \left\{\binom{x}{\otimes}, \binom{z}{\odot}\right\}^+ \mid \otimes \text{ appears exactly } p \text{ times in } \sigma\right\},$$
$$L^y_q = \left\{\binom{v}{\tau} \in \left\{\binom{y}{\otimes}, \binom{z}{\odot}\Big)\right\}^+ \mid \otimes \text{ appears exactly } q \text{ times in } \tau\right\}.$$

Notice that $\bigcup_{p\in\omega} L^x_p = \left\{\binom{x}{\otimes}, \binom{z}{\odot}\right\}^+$ and similarly $\bigcup_{q\in\omega} L^y_q = \left\{\binom{y}{\otimes}, \binom{z}{\odot}\right\}^+$.

▷ Claim 11. At least one of the two following propositions is true:

- for all $p \geq 2$ we have $\alpha(L^x_1) \cap \alpha(L^x_p) = \emptyset$,
- for all $q \geq 2$ we have $\alpha(L^y_1) \cap \alpha(L^x_q) = \emptyset$.

Proof. Assume the contrary and take:

$$p \geq 2,\ \binom{u_1}{\sigma_1} \in L^x_1, \text{ and } \binom{u_p}{\sigma_p} \in L^x_p \text{ such that } \alpha\Big(\binom{u_1}{\sigma_1}\Big) = \alpha\Big(\binom{u_p}{\sigma_p}\Big)\text{; and} \tag{1}$$
$$q \geq 2,\ \binom{v_1}{\tau_1} \in L^y_1, \text{ and } \binom{v_p}{\tau_q} \in L^y_q \text{ such that } \alpha\Big(\binom{v_1}{\tau_1}\Big) = \alpha\Big(\binom{v_q}{\tau_q}\Big). \tag{2}$$

Let w be the word $u_p \cdot v_q \cdot z$ and assume that π is the unique word over $\{\oplus, \ominus, \otimes, \odot\}$ such that $\binom{w}{\pi} \in F$. Clearly, w is in the projection of both R^x and R^y; suppose that $\binom{w}{\pi} \in R^x$ (the case $\binom{w}{\pi} \in R^y$ is symmetric). As R^x determines the symbols below the letters y and z, we know that π is of the form $\sigma \cdot \tau_q \cdot \odot$, for some word σ over $\{\oplus, \ominus, \odot\}$ of length $|u_p|$.

Consider now the new word w' over $\{x, y, z\}$ defined with $w' = u_1 \cdot v_q \cdot z$. We know that w' belongs to the projection of R^y but not to the projection of R^x, because u_1 has only one occurrence of x. Let π' be the unique word such that $\binom{w'}{\pi'} \in F$. Similarly as before, $\pi' = \sigma_1 \cdot \tau' \cdot \odot$ for some word τ' over $\{\oplus, \ominus, \odot\}$ of length $|v_q|$.

Using (1) we know that $\alpha\Big(\binom{u_1}{\sigma_1}\Big) = \alpha\Big(\binom{u_p}{\sigma_p}\Big)$, and therefore $\binom{u_p}{\sigma_p} \cdot \binom{v_q}{\tau'} \cdot \binom{z}{\odot} \in F$, whose projection onto $\mathbb{A}$ equals w, which contradicts the fact that F is a uniformisation. ◀

By the symmetry, let us assume that the first item of Claim 11 holds, *i.e.* for all $\binom{u_1}{\sigma_1} \in L^x_1$ and $\binom{u_p}{\sigma_p} \in L^x_p$ with $p \geq 2$, we have $\alpha\Big(\binom{u_1}{\sigma_1}\Big) \neq \alpha\Big(\binom{u_p}{\sigma_p}\Big)$.

▷ Claim 12. The language L^x_1 is in $\mathbf{L}$.

Proof. The language $L^x_0 = \left\{\binom{z}{\odot}\right\}^+$ is in $\mathbf{L}$. Therefore, $\bigcup_{p\geq 1} L^x_p = \left\{\binom{x}{\otimes}, \binom{z}{\odot}\right\}^+ \setminus L^x_0$ also belongs to $\mathbf{L}$. Thus, the above assumption about α-values implies the claim, because $L^x_1 = \alpha^{-1}(\alpha(L^x_1)) \cap \bigcup_{p\geq 1} L^x_p$. ◁

Now take $a \in \mathbb{A}$ as in the statement of Lemma 10. Consider a homomorphism β from $\mathbb{A}^+$ to $\{\binom{x}{\otimes}, \binom{z}{\odot}\}^+$ defined by $\beta(a) = \binom{x}{\otimes}$ and $\beta(b) = \binom{z}{\odot}$ for $b \neq a$. We have $[\exists^{=1}a]_{\mathbb{A}} = \beta^{-1}(F_1^x)$, and, because $\mathbf{L}$ is closed under pre-images under homomorphisms, $[\exists^{=1}a]_{\mathbb{A}}$ is in $\mathbf{L}$. This concludes the proof of Lemma 10.

With a similar – yet more technical – proof, one can show that for all $p \in \omega$, $\mathbf{L}$ contains $[\exists^{=p}a]_{\mathbb{A}}$, the language of words over $\mathbb{A}$ having exactly p letters a, but this point will not be involved in the following demonstrations. This results show that $\mathbf{L}$ must contain $\mathbf{FO}[\,]$, First-Order logic with only equalities between positions and letter tests. Recall that by Proposition 2 in [12], $\mathbf{FO}[\,]$ can be uniformised within $\mathbf{FO}[<]$. This explains why our proof of Theorem 2 needs to use the fact that $\mathbf{L}$ uniformises itself more than once.

▶ **Corollary 13.** *By modifying the homomorphism used in the proof of Lemma 10, we obtain that if $\mathbb{A}_1 \subseteq \mathbb{A}_2$ then the language $[\exists^{=1}\mathbb{A}_1]_{\mathbb{A}_2}$ of words over $\mathbb{A}_2$ that contain exactly one occurrence of a letter from $\mathbb{A}_1$ also belongs to $\mathbf{L}$.*

3.4 Order on letters

Our next goal is to introduce the order $<$ on the positions of letters in a given word. This is achieved gradually, with the first instance of the order expressed by the following lemma:

▶ **Lemma 14.** *Let $\mathbb{A}$ be an alphabet and $a_0, \ldots, a_{p-1}$ be $p \geq 1$ pairwise distinct letters, that do not belong to $\mathbb{A}$. Then the language $L = \mathbb{A}^* \cdot a_0 \cdot \mathbb{A}^* \cdots \mathbb{A}^* \cdot a_{p-1} \cdot \mathbb{A}^*$ is in $\mathbf{L}$.*

Proof. The proof is quite similar to the previous one. We consider two distinct letters, x and y, and $p{+}1$ distinct symbols $\square, \triangle_0, \ldots, \triangle_{p-1}$, and we define the relation $R := \mathbb{C}^{\oplus}$, where $\mathbb{C}$ is the alphabet $\{\binom{y}{\square}\} \cup \{\binom{x}{\triangle_i} \mid i \in p\}$.

We know that $R \in \mathbf{L}$ and therefore it admits a uniformisation $F \in \mathbf{L}$. Let $\langle S, \alpha, T\rangle$ be a triple recognising it, with $S \in \mathbf{S}$. Fix $\sharp = \sharp(S)$.

We define now the word $u = y^\sharp \cdot x \cdot y^\sharp \cdots y^\sharp \cdot x \cdot y^\sharp$, where x appears exactly p times. Since u is in the projection of R, it also belongs to the projection of F. Let π be the image of u by F, *i.e.* the unique word π satisfying $\binom{u}{\pi} \in F$. The word π is necessarily of the shape $\square^\sharp \cdot \triangle_{\sigma(0)} \cdot \square^\sharp \cdots \square^\sharp \cdot \triangle_{\sigma(p-1)} \cdot \square^\sharp$, where σ is a permutation of $p = \{0, \ldots, p{-}1\}$.

Let $e = \alpha(\binom{y}{\square}^\sharp) \in S$. By the definition of $\sharp(S)$, e is idempotent. Consider β the homomorphism from words over $\mathbb{A}' := \mathbb{A} \sqcup \{a_i \,|\, i \in p\}$ to S defined by $\beta(a_i) = e \cdot \alpha(\binom{x}{\triangle_{\sigma(i)}}) \cdot e$ for $i \in p$, and $\beta(a) = e$ for $a \in \mathbb{A}$.

Now, consider σ' a second permutation of p, and w the word $w_0 \cdot a_{\sigma'(0)} \cdot w_1 \cdots w_{p-1} \cdot a_{\sigma'(p-1)} \cdot w_p \in \mathbb{A}'^*$, where the w_i's are arbitrary words over $\mathbb{A}$. Because e is idempotent, we know that

$$\beta(w) = \alpha(\binom{y}{\square}^\sharp \cdot \binom{x}{\triangle_{\sigma'(\sigma(0))}} \cdot \binom{y}{\square}^\sharp \cdots \binom{y}{\square}^\sharp \cdot \binom{x}{\triangle_{\sigma'(\sigma(p-1))}} \cdot \binom{y}{\square}^\sharp).$$

Since F is a uniformisation, $\beta(w) \in T$ if and only if σ' is the identity. Therefore,

$$\beta^{-1}(T) \cap \bigcap_{i \in p} [\exists^{=1}a_i]_{\mathbb{A}'} = \mathbb{A}^* \cdot a_0 \cdot \mathbb{A}^* \cdots \mathbb{A}^* \cdot a_{p-1} \cdot \mathbb{A}^* = L.$$

Using Lemma 10, each of the languages $[\exists^{=1}\, a_i]_{\mathbb{A}'}$ is in $\mathbf{L}$. Because $\mathbf{L}$ is closed under intersections, we can conclude that L is in $\mathbf{L}$. ◀

3.5 Subsequences

Now we need to strengthen the above lemma, to be able to compare the positions of not necessarily distinct letters. This ability is expressed by the following lemma:

▶ **Lemma 15.** *Let $\mathbb{A}$ be an alphabet, and let $a_0, \ldots, a_{p-1}$ be letters of $\mathbb{A}$, with $p \geq 1$. Then the language $\mathbb{A}^* \cdot a_0 \cdot \mathbb{A}^* \cdots \mathbb{A}^* \cdot a_{p-1} \cdot \mathbb{A}^*$ is in $\mathbf{L}$. We denote this language by $[\exists a_0 {<} a_1 {<} \ldots {<} a_{p-1}]_{\mathbb{A}}$.*

Again, this lemma is equivalent to saying that $\mathcal{B}\Sigma_1[<] \subseteq \mathbf{L}$ (*i.e.* Boolean combinations of existential First-Order sentences with the order) or equivalently that the pseudo-variety of J-trivial semigroups $\mathbf{J}$ is contained in $\mathbf{S}$.

Let $\mathbb{B} := \{\triangle_0, \ldots, \triangle_{p-1}, \square\}$ be an alphabet containing $p{+}1$ pairwise distinct symbols. First, we consider the following relation:

$$R = \binom{\mathbb{A}}{\square}^* \cdot \binom{a_0}{\triangle_0} \cdot \binom{\mathbb{A}}{\square}^* \cdots \binom{\mathbb{A}}{\square}^* \cdot \binom{a_{p-1}}{\triangle_{p-1}} \cdot \binom{\mathbb{A}}{\square}^*$$

It is immediate to see that $\Pi(R)$ is exactly $[\exists a_0 {<} \ldots {<} a_{p-1}]_{\mathbb{A}}$. Consider the relations $R_1 := R \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\square}^*$ and $R_2 := \binom{\mathbb{A}}{\square}^* \cdot \binom{\bullet}{\bullet} \cdot R$, where $\bullet$ is a fresh letter (*i.e.* not in $\mathbb{A}$ nor in $\mathbb{B}$).

To conclude the proof of Lemma 15, we will use a fairly technical fact. It may be seen as an abstract generalisation of the technique used in the proof of Lemma 3 in [12].

▶ **Fact 16.** *Let R be a relation over a product alphabet $\mathbb{A} \times \mathbb{B}$, i.e. $R \subseteq \big(\mathbb{A} \times \mathbb{B}\big)^+$. Assume that $\bullet$, $\square$ are two symbols, with $\bullet \notin \mathbb{A}$. Define $R_1 := R \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\square}^*$, $R_2 := \binom{\mathbb{A}}{\square}^* \cdot \binom{\bullet}{\bullet} \cdot R$, and $P := R_1 \cup R_2$. If P is in $\mathbf{L}$ then $\Pi(R)$ is in $\mathbf{L}$.*

Proof. Let $F \in \mathbf{L}$ be a uniformisation of the above relation P, and let $\langle S, \alpha, T\rangle$ be a triple recognising F, with $S \in \mathbf{S}$.

Let β be the homomorphism from $\mathbb{A}^+$ to S defined by $\beta(a) = \alpha(\binom{a}{\square})$, for all $a \in \mathbb{A}$. Put $L := \Pi(R)$. Notice that if for all words w_1, w_2 in $\mathbb{A}^+$, the equality $\beta(w_1) = \beta(w_2)$ implies the equivalence $w_1 \in L \Leftrightarrow w_2 \in L$, then in fact L is in $\mathbf{L}$, because $\beta^{-1}\big(\beta(L)\big) = L \in \mathbf{L}$.

We show now that this implication holds for all w_1, w_2. Suppose that there exist $w_1 \in L$ and $w_2 \in L^{\mathrm{c}}$ such that $\beta(w_1) = \beta(w_2)$, in order to provide a contradiction.

Let w be the word $w_1 \cdot \bullet \cdot w_1$, over the alphabet $\mathbb{A} \sqcup \{\bullet\}$. This word w is in $\Pi(R_1) \cap \Pi(R_2)$, let π the unique word over $\mathbb{B} \cup \{\bullet, \square\}$ such that $\binom{w}{\pi} \in F$.

We suppose for instance that $\binom{w}{\pi} \in R_1$ (the case $\binom{w}{\pi} \in R_2$ is symmetric). Because $\bullet \notin \mathbb{A}$, π is necessarily of the shape $\pi_1 \cdot \bullet \cdot \square^{|w_1|}$, with $\pi_1 \in \mathbb{B}^{|w_1|}$.

Let now w' be the word $w_2 \cdot \bullet \cdot w_1$ and let π' be the unique word such that $\binom{w'}{\pi'} \in F$. Again, π' is of the shape $\square^{|w_2|} \cdot \bullet \cdot \pi_1'$, with $\pi_1' \in \mathbb{B}^{|w_1|}$. Since $\beta(w_2) = \beta(w_1)$, we know that $\alpha(\binom{w'}{\square^{|w_2|} \cdot \bullet \cdot \pi_1'}) = \alpha(\binom{w}{\square^{|w_1|} \cdot \bullet \cdot \pi_1'})$. The latter value does not belong to T because $\binom{w}{\square^{|w_1|} \cdot \bullet \cdot \pi_1'} \notin F$ – we know that F is a uniformisation and $\pi \neq \square^{|w_1|} \cdot \bullet \cdot \pi_1'$. This means that $\binom{w'}{\pi'}$ is not in F, contradicting the assumption, and concluding the proof of this fact. ◀

Now we go back to the proof of Lemma 15. The letters $\binom{a_0}{\triangle_0}, \ldots, \binom{a_{p-1}}{\triangle_{p-1}}, \binom{\bullet}{\bullet}$ are all pairwise distinct, and none of them is in the alphabet $\mathbb{A} \times \{\square\}$. Therefore, Lemma 14 tells us that R_1 and R_2 are in $\mathbf{L}$. This means that $P := R_1 \cup R_2$ is in $\mathbf{L}$, and we can conclude with Fact 16 that $[\exists a_0 {<} \ldots {<} a_{p-1}]_{\mathbb{A}} = \Pi(R)$ is in $\mathbf{L}$.

▶ **Corollary 17.** *Let $\mathbb{A}_0, \ldots, \mathbb{A}_{p-1}$ be pairwise disjoint alphabets contained in $\mathbb{A}$. Then the language $L = \mathbb{A}_0^* \cdot \mathbb{A}_1^* \ldots \mathbb{A}_{p-1}^* \setminus \{\epsilon\}$ is in L.*

Proof. It is enough to observe that $L = \bigcap_{i \in j \in p} \bigcap_{a_i \in \mathbb{A}_i} \bigcap_{a_j \in \mathbb{A}_j} [\exists a_j < a_i]_{\mathbb{A}}^{\mathrm{c}}$ (where $\mathbb{A}$ is the union of the $\mathbb{A}_i$'s). ◀

3.6 Polynomials

We will now prove a variant of Lemma 15 for *polynomials.* A *monomial* is a language of the shape $L_0 \cdot L_1 \cdots L_{p-1}$, where each L_i is either of the form $\mathbb{A}_i^*$, or a set of single-letter words over $\mathbb{A}_i$, and such that at least one of the L_i's is of the latter kind. An example of a monomial is the language

$$\{a,b\}^* \cdot \{x,y\} \cdot \{x\}^*.$$

Notice that the alphabets $\mathbb{A}_i$ are not required to be pairwise disjoint in that definition. A *polynomial* is a finite union of monomials. This section is devoted to a proof of the following lemma.

▶ **Lemma 18.** *Any polynomial is in* $\mathbf{L}$.

First notice that $\mathbf{L}$ is closed under unions and therefore it is enough to prove the lemma for monomials. Consider a monomial L over an alphabet $\mathbb{A}$, *i.e.* $L = \mathbb{A}_0^{\xi_0} \cdot \mathbb{A}_1^{\xi_1} \cdots \mathbb{A}_{p-1}^{\xi_{p-1}}$, where each ξ_i is either $*$ or 1 (because $\mathbb{A}_i^1 = \mathbb{A}_i$). Take $\mathbb{A}' := \mathbb{A} \sqcup \{\bullet\}$, $\mathbb{B} := \{\Delta_0, \ldots, \Delta_{p-1}, \bullet, \square\}$. Let $R := \binom{\mathbb{A}_0}{\Delta_0}^{\xi_0} \cdots \binom{\mathbb{A}_{p-1}}{\Delta_{p-1}}^{\xi_{p-1}}$, $R_1 := R \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\square}^*$, and $R_2 := \binom{\mathbb{A}}{\square}^* \cdot \binom{\bullet}{\bullet} \cdot R$.

Notice that

$$R_1 = \binom{\mathbb{A}_0}{\Delta_0}^* \cdots \binom{\mathbb{A}_{p-1}}{\Delta_{p-1}}^* \cdot \binom{\bullet}{\bullet}^* \cdot \binom{\mathbb{A}}{\square}^* \;\cap\; \Big[\exists^{=1}\binom{\bullet}{\bullet}\Big]_{\mathbb{A}' \times \mathbb{B}} \;\cap\; \bigcap_{i \in p} \Xi_i, \tag{3}$$

where each Ξ_i is either: $\big(\mathbb{A}' \times \mathbb{B}\big)^+$ if $\xi_i = *$; or $\big[\exists^{=1} \mathbb{A}_i \times \{\Delta_i\}\big]_{\mathbb{A}' \times \mathbb{B}}$ if $\xi_i = 1$. Now, the first ingredient on the right-hand side of (3) is as in Corollary 17 and thus belongs to $\mathbf{L}$. The other ingredients also belong to $\mathbf{L}$, see Lemma 10, and Corollary 13. Similarly we know that $R_2 \in \mathbf{L}$. Thus, Fact 16 implies that $L = \Pi(R) \in \mathbf{L}$, which concludes the proof of Lemma 18.

▶ Remark 19. The family of polynomials is closed under union and concatenation.

3.7 Semigroups

We can now conclude the proof of Theorem 2. Let L be a regular language over some alphabet $\mathbb{A}$, that is recognised by a tuple $\langle S, \alpha, T\rangle$ with a finite semigroup S that may *a priori* not belong to $\mathbf{S}$. Our aim is to prove that $L \in \mathbf{L}$.

Consider a word $\binom{w}{\sigma} \in \big(\mathbb{A} \times S\big)^+$ of length n. We say that such a word is an *evaluation* if for every $i \in n$ we have $\sigma(i) = \alpha\big(w(0) \cdots w(i)\big)$. Notice that in that case $w \in L$ if and only if $\sigma(n{-}1) \in T$. Let E be the set of words $\binom{w}{\sigma} \in \big(\mathbb{A} \times S\big)^+$ that are evaluations and $\sigma(n{-}1) \in T$.

▷ Claim 20. Using the above notions, we have $\Pi(E) = L$.

Proof. Every word $w \in \mathbb{A}^n$ with $n \geq 1$ admits a unique word $\sigma \in S^n$ such that $\binom{w}{\sigma}$ is an evaluation. In that case $\alpha(w) = \sigma(n{-}1)$. Thus, $w \in L$ iff. $\sigma(n{-}1) \in T$ iff. $\binom{w}{\sigma} \in E$. ◁

Our aim is to show that a variant of the set of evaluations E belongs to $\mathbf{L}$ and then invoke Fact 16 to project away the S coordinate of the evaluations.

Consider $a, b \in \mathbb{A}$ and $r, s \in S$ and define

$$I_{a,r} := \binom{a}{r} \cdot \binom{\mathbb{A}}{S}^*, \quad M_{a,r,b,s} := \binom{\mathbb{A}}{S}^* \cdot \binom{a}{r} \cdot \binom{b}{s} \cdot \binom{\mathbb{A}}{S}^*, \quad F_{a,r} := \binom{\mathbb{A}}{S}^* \cdot \binom{a}{r}.$$

Let W be the union of the languages: $I_{a,r}$ ranging over $a \in \mathbb{A}$, $r \in S$ such that $\alpha(a) \neq r$; $M_{a,r,b,s}$ ranging over those $a, b \in \mathbb{A}$, $r, s \in S$ such that $r \cdot \alpha(b) \neq s$; and $F_{a,r}$ ranging over $r \notin T$. Notice that W defined that way is a polynomial.

▷ Claim 21. The complement of W equals E.

Proof. Clearly $E \cap W = \emptyset$. Thus, it is enough to prove that if $\binom{w}{\sigma} \notin W$ then $\binom{w}{\sigma} \in E$. Let $n = |w| = |\sigma|$. Since $\binom{w}{\sigma} \notin W$, we know that $\sigma(n{-}1) \in T$ (see the languages $F_{a,r}$), thus it is enough to show that $\binom{w}{\sigma}$ is an evaluation. It is done inductively, for $i = 0, 1, \ldots, n{-}1$. The fact that $\sigma(0) = \alpha\big(w(0)\big)$ follows from the assumption that $\binom{w}{\sigma} \notin W$ (see the languages $I_{a,r}$).

Take $i < n{-}1$ and assume that $\sigma(i) = \alpha\big(w(0) \cdots w(i)\big)$. Observe that $\sigma(i{+}1)$ must equal $\sigma(i) \cdot \alpha\big(w(i{+}1)\big)$ (see the languages $M_{a,r,b,s}$). Thus, $\sigma(i{+}1) = \alpha\big(w(0) \cdots w(i{+}1)\big)$. ◁

Consider fresh letters • and •, and the alphabets $\mathbb{A}' := \mathbb{A} \sqcup \{\bullet\}$, $S' := S \sqcup \{\bullet, \Delta\}$. Let:

$$R_1 := W \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\Delta}^*, \qquad R_2 := \binom{\mathbb{A}}{\Delta}^* \cdot \binom{\bullet}{\bullet} \cdot W,$$
$$R_1' := R_1^{\mathrm{c}} \;\cap\; \binom{\mathbb{A}}{S}^* \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\Delta}^*, \quad R_2' := R_2^{\mathrm{c}} \;\cap\; \binom{\mathbb{A}}{\Delta}^* \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{S}^*, \quad P := R_1' \cup R_2'.$$

Notice that both R_1 and R_2 are polynomials (see Remark 19) and therefore all the five relations defined above belong to $\mathbf{L}$.

▷ Claim 22. Using the above notions, we have

$$R_1' = E \cdot \binom{\bullet}{\bullet} \cdot \binom{\mathbb{A}}{\Delta}^*, \quad R_2' = \binom{\mathbb{A}}{\Delta}^* \cdot \binom{\bullet}{\bullet} \cdot E.$$

Proof. These equalities follow directly from the definition and Claim 21. ◁

Therefore, Fact 16 applied to P guarantees that $\Pi(E) \in \mathbf{L}$. Thus, by Claim 20 we know that $L \in \mathbf{L}$. This concludes the proof of Theorem 2.

4 Conclusions

The main result of this work shows that among pseudo-varieties of semigroups, only **REG** =**MSO** is strong enough to have the uniformisation property over finite words. It seems that exactly the same techniques work also for infinite words and finite trees, however the technical details are more involved there. This means that, to be able to choose witnesses in a definable way, one needs to have access to the unrestricted quantification over these witnesses (*i.e. monadic* quantifiers).

The actual arguments used in the presented proof are rather direct: they boil down to finding an appropriate relation R that is definable in the considered formalism, such that any uniformisation of R must provide some added expressive power. However, the difficulty of that reasoning lies in the deliberate design of the relations R. From this perspective, the proof can be read as a collection of instances showing how uniformisability (or generally ability to choose witnesses) leads to an increased expressive power.

The results of this work are in a sense negative, showing that all formalisms below **MSO** do not admit uniformisation. However, still some relations can be uniformised within the limited expressive power. This leads to the following decision problem:

▶ **Problem 23.** *Given a regular language R over a product alphabet $\mathbb{A} \times \mathbb{B}$, decide if R admits an* **FO**$[<]$*-definable uniformisation.*

Note that even if R itself is not **FO**$[<]$-definable, it might be the case that there is an **FO**$[<]$-definable uniformisation of R. The status of this problem is open at the moment.

Abstract

We propose a new pumping technique for 2-dimensional vector addition systems with states (2-VASS) building on natural geometric properties of runs. We illustrate its applicability by reproving an exponential bound on the length of the shortest accepting run, and by proving a new pumping lemma for languages of 2-VASS. The technique is expected to be useful for settling questions concerning languages of 2-VASS, e.g., for establishing decidability status of the regular separability problem.

1 Introduction

Vector addition systems [8] are a widely accepted model of concurrency equivalent to Petri nets. Another equivalent model, called vector addition systems with states (VASS) [7], is an extension of finite automata with integer counters, on which the transitions can perform operations of increment or decrement (but no zero tests), with the proviso that counter values are 0 initially and must stay non-negative along a run. The number of counters d defines the *dimension* of a VASS. For brevity, we call a VASS of dimension d a d-VASS. Formally, every transition of a d-VASS V has adjoined a vector $v \in \mathbb{Z}^d$ describing the effect of executing this transition on counter values; thus a transition is a triple $(q, v, q') \in Q \times \mathbb{Z}^d \times Q$, where Q is the set of control states of V. A finite *path*, i.e., a sequence of transitions of the form $\pi = (q_0, v_1, q_1), (q_1, v_2, q_2), \ldots, (q_{n-1}, v_n, q_n)$, induces a run if the counter values stay non-negative, i.e., $v_1 + \ldots + v_i \in \mathbb{N}^d$ for every i.

In this paper we concentrate on *pumping*, i.e., techniques exploiting repetitions of states in runs. Pumping is an ubiquitous phenomenon which typically provides valuable tools in proving short run properties, or showing language inexpressibility results. It seems to be particularly relevant in case of VASS, as even the core of the seminal decision procedure for

the reachability problem in VASS by Mayr and Kosaraju [11, 9] is fundamentally based on pumping: briefly speaking, the decision procedure decomposes a VASS into a finite number of VASS, each of them admitting a property that every path can be pumped up so that it induces a run. Pumping techniques are used even more explicitly when dealing with subclasses of VASS of bounded dimension. The PSpace upper bound for the reachability problem in 2-VASS [2] relies on various un-pumping transformations of an original run, leading to a simple run of at most exponential length, in the form of a short path with adjoined short disjoint cycles. A smart surgery on those simple runs was also used to obtain a stronger upper bound (NL) in case when the transition effects are represented in unary [6]. Un-pumping is also used in [3] to provide a quadratic bound on the length of the shortest run for 1-VASS, also known as one counter automata without zero tests, and for unrestricted one counter automata. See also [1, 10] for pumping techniques in one counter automata.

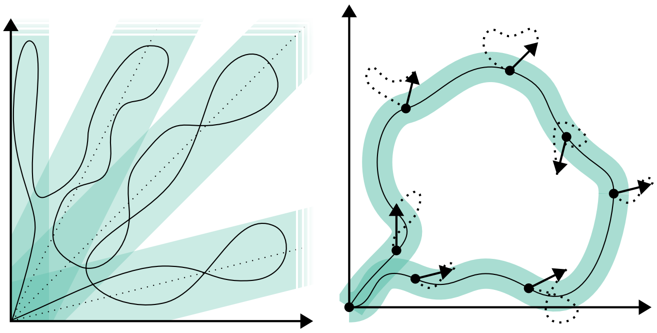

Figure 1 Thin (above) and thick run (below). Points correspond to counter values, and control states along a run are ignored.

Contribution. The above-mentioned techniques are mostly oriented towards reachable sets, and henceforth may ignore certain runs as long as the reachable set is preserved. In consequence, they are not very helpful in solving decision problems formulated in terms of the whole language accepted by a VASS, like the regular separability problem (cf. the discussion below). Our primary objective is to design a pumping infrastructure applicable to *every* run of a 2-VASS. Therefore, as our main technical contribution we perform a thorough classification of runs, in the form of a dichotomy (see the illustrations on the right): for every run π of a 2-VASS, whose initial and final values of both counters are 0,

- either π is *thin*, by which we mean that the counter values along the run stay within belts, whose direction and width are all bounded polynomially in the number of states and the largest absolute value of vectors of the 2-VASS;
- or π is *thick*, by which we mean that a number of cycles is enabled along the run, the effect vectors of these cycles span (slightly oversimplifying) the whole plane, and furthermore the lengths of cycles and the extremal factors of π are all bounded polynomially in M and exponentially in n. (For the sake of simplicity some details are omitted here; the fully precise statement of the dichotomy is Theorem 3.1 in Section 3).

The dichotomy immediately entails a pumping lemma for 2-VASS by using, essentially, the pumping scheme of 1-VASS in case of thin runs, and the cycles enabled along a run in case of thick runs (cf. Theorem 4.1). As a more subtle application of the dichotomy, we derive an alternative proof of the exponential run property (shown originally in [2]), which immediately implies PSpace-membership of the reachability problem (cf. Theorem 4.2).

Further applications. We envisage other possible applications of the dichotomy. One important case can be the regular separability problem: given two *labeled* 2-VASS V_1 and V_2, decide if there is a regular language separating languages of V_1 and V_2, i.e., including one of them and disjoint from the other. The problem is decidable in PSpace for 1-VASS [5] while the decidability status for 2-VASS is still open. A cornerstone of the decision procedure of [5] is a well-behaved over-approximation of a language of a 1-VASS V by a sequence of regular languages $(V_n)_{n\in\mathbb{N}}$, where the precision of approximation increases with increasing n. In case of 1-VASS, the language V_n is obtained by abstraction of V *modulo* n; on the other hand, as argued in [5], the very same approach necessarily fails for dimensions larger than 1. It seems that our dichotomy classification of runs of a 2-VASS prepares the ground for the right definition of abstraction V_n modulo n. Indeed, intuitively speaking, as long as the run stays within belts, 1-dimensional counting modulo n along the direction of a belt is sufficient; otherwise, a 2-dimensional abstraction modulo n can be applied as soon as a sufficient number of pumpable cycles has been identified along a run.

As our approach builds on natural geometric properties of runs, we believe that it can be generalized to dimensions larger than 2. However, one should not expect efficient length bounds from this generalization itself, as already in dimension 3 the prefix of a run preceding the first pumpable cycle has non-elementary length (the length can be as large as tower of n exponentials in the composition of n copies of the Hopcroft and Pansiot example [7]).

2 Preliminaries

2-dimensional vector addition systems with states. We use standard symbols $\mathbb{Q}, \mathbb{Z}, \mathbb{N}$ for the sets of rationals, integers, and non-negative integers, respectively. Whenever convenient we use subscripts to specify subsets, e.g., $\mathbb{Q}_{\geq 0}$ for non-negative rationals. We refer to elements of $\mathbb{Z}^2$ briefly as *vectors*. *Non-negative* vectors are elements of $\mathbb{N}^2$, and *positive* vectors are elements of $\mathbb{Z}^2_{>0}$. A vector with only non-negative coordinates and at least one positive coordinate is called *semi-positive*; it is either positive, or *vertical* of the form $(0, a)$, or *horizontal* of the form $(a, 0)$, for $a \in \mathbb{Z}_{>0}$.

A 2-dimensional *vector addition system with states* (2-VASS) V consists of a finite set of control states Q and a finite set of transitions $T \subseteq Q \times \mathbb{Z}^2 \times Q$. We refer to the vector v as the *effect* of a transition (p, v, q). A *path* in V from control state p to q is a sequence of transitions $\pi = (q_0, v_1, q_1), (q_1, v_2, q_2), \ldots, (q_{n-1}, v_n, q_n) \in T^*$ where $p = q_0$ and $q = q_n$; it is called a *cycle* whenever the starting and ending control states coincide ($q_0 = q_n$). The *effect* of a path is defined as $\mathrm{eff}(\pi) = v_1 + \ldots + v_n \in \mathbb{Z}^2$, and its *length* is n. A cycle is called non-negative, semi-positive or positive, if its effect is so.

A *configuration* of V is an element of $\mathrm{Conf} = Q \times \mathbb{N}^2$. A transition $t = (p, v, q)$ is *enabled* in a configuration $c = (p', u)$ if $p = p'$ and $u + v \in \mathbb{N}^2$. Analogously, a path π is enabled in a configuration $c = (p', u)$ if $q_0 = p'$ and $u_i = u + v_1 + \ldots + v_i \in \mathbb{N}^2$ for every i. In such case we say that π induces a *run* of the form

$$\rho = (c_0, t_1, c_1), (c_1, t_2, c_2), \ldots, (c_{n-1}, t_n, c_n) \in (\mathrm{Conf} \times T \times \mathrm{Conf})^*$$

with intermediate configurations $c_i = (q_i, u_i)$, from the *source* configuration $\mathrm{src}(\rho) = c_0$ to the *target* one $\mathrm{trg}(\rho) = c_n$. If the source configuration c_0 is clear from the context, we do not distinguish between a path enabled in c_0 and a run with source c_0, and simply say that the path *is* the run. A $(0, 0)$-*run* is a run whose source and target are $(0, 0)$-*configurations*, i.e., a configuration whose vector is $(0, 0)$.

We will sometimes relax the non-negativeness requirement on some coordinates: For $j \in \{1, 2\}$, we say that a path π is $\{j\}$-*enabled* in a configuration $c = (p', u)$ if $q_0 = p'$ and $(u + v_1 + \ldots + v_i)[j] \in \mathbb{N}$ for every i. We also say that π is $\emptyset$-*enabled* in c if just $q_0 = p'$.

The *reversal* of a 2-VASS $V = (Q, T)$, denoted $\mathrm{rev}(V)$, is a 2-VASS with the same control states and with transitions $\{(q, -v, p) \mid (p, v, q) \in T\}$. We sometimes speak of the reversal $\mathrm{rev}(\rho)$ of a run ρ of V, implicitly meaning a run in the reversal of V.

As the *norm* of $v = (v_1, v_2) \in \mathbb{Q}^2$, we take the largest of absolute values of v_1 and v_2, $\|v\| := \max\{|v_1|, |v_2|\}$. By the norm of a configuration $c = (q, v)$ we mean the norm of its vector v, and by the norm $\|V\|$ of a 2-VASS V we mean the largest among norms of effects of transitions.

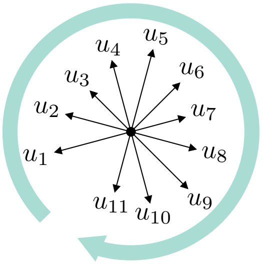

Figure 2 Above $u_1 \circlearrowright u_2 \circlearrowright \ldots \circlearrowright u_{11} \circlearrowright u_1$. Also, $u_4 \circlearrowright u_9$, but $u_4 \not\circlearrowright u_{11}$ and $u_{11} \circlearrowright u_4$. Pairs of vectors u_i, u_{i+6} are contralinear, for $i = 1, \ldots, 5$.

Sequential cones. For a vector $v \in \mathbb{Z}^2$, define the half-line induced by v as $\ell_v := \mathbb{Q}_{\geq 0} \cdot v = \{\alpha v \mid \alpha \in \mathbb{Q}_{\geq 0}\}$. We call two vectors v, w *colinear* if $\ell_v = \ell_w$, and *contralinear* if $\ell_v = \ell_{-w}$. For two vectors $u, v \in \mathbb{Z}^2 \setminus \{(0, 0)\}$, define the *angle* $\measuredangle[u, v] \subseteq \mathbb{Q}^2$ as the union of all half-lines which lie clock-wise between ℓ_u and ℓ_v, including the two half-lines themselves. In particular, $\measuredangle[v, v] = \ell_v$. Analogously we define the sets $\measuredangle[u, v)$, $\measuredangle(u, v]$ and $\measuredangle(u, v)$ which exclude one or both of the half-lines. We refer to an angle of the form $\measuredangle[v, -v]$ as *half-plane*. We write $v \circlearrowright u$ when $u \in \measuredangle(v, -v)$, i.e., u is oriented clock-wise with respect to v (see Figure 2 for an illustration). Note that $\circlearrowright$ defines a total order on pairwise non-colinear non-negative vectors.

By the *cone* of a finite set of vectors $\{v_1, \ldots, v_k\} \subseteq \mathbb{Z}^2$ we mean the set of all non-negative rational linear combinations of these vectors:

$$\textsc{Cone}(v_1, \ldots, v_k) := \{\Sigma_{j=1}^{k} a_j v_j \in \mathbb{Q}^2 \mid a_1, \ldots, a_k \in \mathbb{Q}_{\geq 0}\}.$$

We call the cone of a single vector $\textsc{Cone}(v) = \ell_v$ *trivial*, and the cone of zero vectors $\textsc{Cone}(\emptyset) = \{(0, 0)\}$ *degenerate*. Two non-zero vectors v_1 and v_2 can be in four distinct relations: (I) they are colinear, (II) they are contralinear, (III) $v_1 \circlearrowright v_2$ and hence $\textsc{Cone}(v_1, v_2) = \measuredangle[v_1, v_2]$, (IV) $v_2 \circlearrowright v_1$ and hence $\textsc{Cone}(v_1, v_2) = \measuredangle[v_2, v_1]$.

▶ **Lemma 2.1.** *Every cone either equals the whole plane $\mathbb{Q}^2$, or is included in some half-plane.*

Proof. Assume, w.l.o.g. that the vectors $v_1, \ldots, v_k$ are non-zero and include no colinear pair. Suppose there is a contralinear pair v_i, v_j among $v_1, \ldots, v_k$. If all other vectors v_h satisfy $v_i \circlearrowright v_h \circlearrowright v_j$ then $\textsc{Cone}(v_1, \ldots, v_k)$ is included in the half-plane $\measuredangle[v_i, v_j]$. Otherwise $\textsc{Cone}(v_1, \ldots, v_k)$ is the whole plane.

Now suppose there is no contralinear pair among $v_1, \ldots, v_k$. If some three v_i, v_j, v_h of them satisfy $v_i \circlearrowright v_j \circlearrowright v_h \circlearrowright v_i$ then $\textsc{Cone}(v_1, \ldots, v_k)$ includes the three angles $\measuredangle[v_i, v_j]$, $\measuredangle[v_j, v_h]$ and $\measuredangle[v_h, v_i]$, the union of which is the whole plane. Otherwise, the relation $\circlearrowright$ is transitive and hence defines a (strict) total order on $\{v_1, \ldots, v_k\}$. The minimal and maximal element v_i and v_j w.r.t. the order satisfy $v_i \circlearrowleft v_j$, and hence $\textsc{Cone}(v_1, \ldots, v_k) = \measuredangle[v_i, v_j]$ is included in the half-plane $\measuredangle[v_i, -v_i]$. ◀

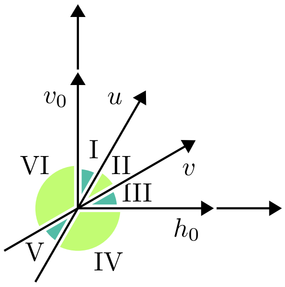
The *sequential cone* of vectors $v_1, \ldots, v_k \in \mathbb{Z}^2$ imposes additional non-negativeness conditions, namely for every i, the partial sum $a_1 v_1 + \ldots + a_i v_i$ must be non-negative (this is required later, when pumping cycles in a run whose effects are $v_1, \ldots, v_k$ in that order):

$$\textsc{SeqCone}(v_1, \ldots, v_k) := \{\Sigma_{j=1}^k a_j v_j \in \mathbb{Q}^2_{\geq 0} \mid a_1, \ldots, a_k \in \mathbb{Q}_{\geq 0}, \forall_i \ \Sigma_{j=1}^i a_j v_j \in \mathbb{Q}^2_{\geq 0}\}.$$

Note that v_1 may be assumed w.l.o.g. to be semi-positive, but other vectors v_i are not necessarily non-negative; and that every sequential cone is a subset of the non-negative orthant $\mathbb{Q}^2_{\geq 0}$. Importantly, contrarily to cones, the order of vectors $v_1, \ldots, v_k$ matters for sequential cones. In fact, sequential cones are just convenient syntactic sugar for cones of pairs of non-negative vectors:

▶ **Lemma 2.2.** *For all vectors $v_1, \ldots, v_k$, the sequential cone $\textsc{SeqCone}(v_1, \ldots, v_k)$, if not degenerate, equals $\textsc{Cone}(u, v)$, for two non-negative vectors u, v, and each of them either belongs to $\{v_1, \ldots, v_k\}$, or is horizontal, or vertical.*

Proof. We proceed by induction on k. For $k = 1$ we have $\textsc{SeqCone}(v_1) = \ell_{v_1} = \textsc{Cone}(v_1, v_1)$. Let v_0 and h_0 denote some fixed vertical and horizontal vector, respectively. For the induction step we assume $\textsc{SeqCone}(v_1, \ldots, v_{k-1}) = \textsc{Cone}(u, v)$ for non-negative vectors u, v; and compute the value of $\textsc{SeqCone}(v_1, \ldots, v_k)$, separately in each of the following distinct cases (assume w.l.o.g. $u \circlearrowleft v$):



$$\textsc{SeqCone}(v_1, \ldots, v_k) = \begin{cases} \textsc{Cone}(v_k, v) & \text{if } v_k \in \measuredangle[v_0, u) \\ \textsc{Cone}(u, v) & \text{if } v_k \in \measuredangle[u, v] \\ \textsc{Cone}(u, v_k) & \text{if } v_k \in \measuredangle(v, h_0] \\ \textsc{Cone}(u, h_0) & \text{if } v_k \in \measuredangle(h_0, -u] \\ \textsc{Cone}(v_0, h_0) & \text{if } v_k \in \measuredangle(-u, -v) \\ \textsc{Cone}(v_0, v) & \text{if } v_k \in \measuredangle[-v, v_0). \end{cases}$$

◀

3 Thin-Thick Dichotomy

The main result of this section (cf. Theorem 3.1 below) classifies $(0, 0)$-runs in a 2-VASS into *thin* and *thick* ones. Throughout this section we consider an arbitrary fixed 2-VASS $V = (Q, T)$.
Let $n = |Q|$ and $M = \|V\|$.

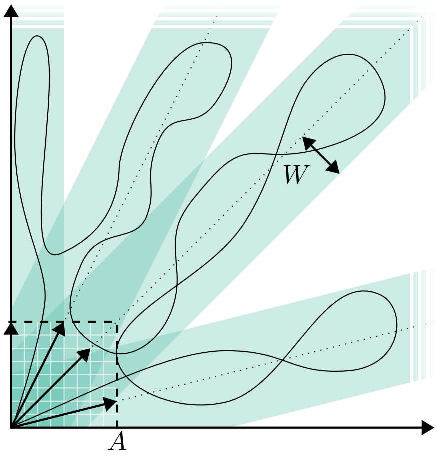


Figure 3 Thin run within belts $B_{v,W}$.

Thin runs. The *belt* of *direction* $v \in \mathbb{N}^2$ and *width* W is the set

$$\mathcal{B}_{v,W} = \{u \in \mathbb{N}^2 \mid \mathrm{dist}(u, \ell_v) \leq W\},$$

where $\mathrm{dist}(u, \ell_v)$ denotes the Euclidean distance between the point u and the half-line ℓ_v. For $A \in \mathbb{N}$, we call $\mathcal{B}_{v,W}$ an A-*belt* if $\|v\| \leq A$ and $W \leq A$. We say that a run ρ of V is A-*thin* if for every configuration c in ρ there exists an A-belt B such that $c \in Q \times B$.

Thick runs. Let $A \in \mathbb{N}$. Four cycles $\pi_1, \pi_2, \pi_3, \pi_4 \in T^*$ are A-*sequentially enabled* in a run ρ if their lengths are at most A, and the run ρ factors into $\rho = \rho_1\, \rho_2\, \rho_3\, \rho_4\, \rho_5$ so that (denote by v_1, v_2, v_3, v_4 the effects of $\pi_1, \pi_2, \pi_3, \pi_4$, respectively):

- The effect v_1 is semi-positive, the cycle π_1 is enabled in $c_1 := \mathrm{trg}(\rho_1)$, and both coordinates are bounded by A along ρ_1.
- If v_1 is positive then π_2 is $\emptyset$-enabled in $c_2 := \mathrm{trg}(\rho_2)$. Otherwise (let j be the coordinate s.t. $v_1[j] = 0$) π_2 is $\{j\}$-enabled in $c_2 := \mathrm{trg}(\rho_2)$, and jth coordinate is bounded by A along ρ_2.
- The cycle π_i is $\emptyset$-enabled in $c_i := \mathrm{trg}(\rho_i)$, for $i = 3, 4$.

We also say that the four vectors v_1, v_2, v_3, v_4 are A-sequentially enabled in ρ, quantifying the cycles existentially. A $(0,0)$-run τ is called A-*thick* if it partitions into $\tau = \rho\, \rho'$ so that

1. some vectors v_1, v_2, v_3, v_4 are A-sequentially enabled in ρ,
2. some vectors v_1', v_2', v_3', v_4' are A-sequentially enabled in $\mathrm{rev}(\rho')$,
3. $\textsc{SeqCone}(v_1, v_2, v_3, v_4) \cap \textsc{SeqCone}(v_1', v_2', v_3', v_4')$ is non-trivial.

Figure 4 illustrates the geometric ideas underlying these three conditions for A-thick runs. Concerning condition 1, a cycle π_1 depicted by a dotted line, with vertical effect v_1, can be used to increase the second (vertical) coordinate arbitrarily, which justifies the relaxed requirement that a cycle π_2 with effect v_2 is only $\{1\}$-enabled. Note that the norm of the configuration enabling π_1, as well as the first coordinate of the configuration enabling π_2, are bounded by A. Concerning condition 2, a cycle π_1' with positive effect v_1' can be used to increase both coordinates arbitrarily; therefore a cycle π_2' with effect v_2' is only required to be $\emptyset$-enabled, and no coordinate of the configuration enabling π_2' is required to be bounded by A. In the illustrated example, vectors v_3' and v_4' are not needed; formally, one can assume $v_2' = v_3' = v_4'$ and $\rho_3' = \rho_4' = \varepsilon$. Condition 3 ensures that the cycles

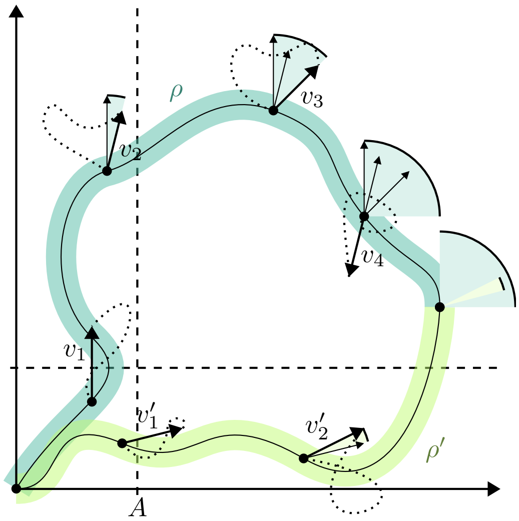

Figure 4 Thick run. Blue angles denote sequential cones $\textsc{SeqCone}(v_1, v_2)$, $\textsc{SeqCone}(v_1, v_2, v_3)$ and $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$, respectively, and green angle denotes $\textsc{SeqCone}(v'_1, v'_2)$.

$\pi_1, \ldots, \pi_4$ and $\pi'_1, \ldots, \pi'_4$ can be pumped such that the pumped versions of ρ and ρ' are still connected. In the illustrated example, observe that $\textsc{SeqCone}(v_1, v_2) \cap \textsc{SeqCone}(v'_1) = \emptyset$. Intuitively, both coordinates in the target of ρ can be increased arbitrarily using v_1 and v_2, and similarly both coordinates of the target of $\text{rev}(\rho')$ can be increased arbitrarily using v'_1, but "directions of increase" are non-crossing. Adding v_3 and v'_2 is not sufficient, as still $\textsc{SeqCone}(v_1, v_2, v_3) \cap \textsc{SeqCone}(v'_1, v'_2) = \emptyset$. When vector v_4 is adjoined, condition 3 holds as $\textsc{SeqCone}(v_1, v_2, v_3, v_4) = \mathbb{Q}^2_{\geq 0}$. Finally, the four vectors are really needed here, e.g., vector v_3 can not be omitted as $\textsc{SeqCone}(v_1, v_2, v_4) = \textsc{SeqCone}(v_1, v_2)$.

Here is the main result of this section:

▶ **Theorem 3.1** (Thin-Thick Dichotomy). *There is a polynomial p such that every $(0,0)$-run in a 2-VASS V is either $p(nM)^n$-thin or $p(nM)^n$-thick.*

For the proof of Theorem 3.1 we need the following core fact (for space reasons, the proof is only in the full version of the paper):

▶ **Lemma 3.2** (Non-negative Cycle Lemma). *There is a polynomial P such that every run ρ in V from a $(0,0)$-configuration to a target configuration of norm larger than $P(nM)^n$, contains a configuration enabling a semi-positive cycle of length at most $P(nM)$.*

Proof of Theorem 3.1. Let P be the polynomial from Lemma 3.2. The polynomial p required in Theorem 3.1 can be chosen arbitrarily as long as $p(x) \geq \sqrt{2} \cdot \big(P(x) + (x+1)^3\big) \cdot x$. for all x; note that the following inequality follows:

$$p(nM)^n \geq \sqrt{2} \cdot \big((P(nM))^n + (nM+1)^3 \big) \cdot nM. \tag{1}$$

In the sequel we deliberately confuse configurations $c = (q, v)$ with *their vectors* v: whenever convenient, we use c to denote the vector v, hoping that this does not lead to any confusion.

Let τ be a $(0,0)$-run of V which is not $p(nM)^n$-thin, i.e., τ contains therefore a configuration t which lies outside of all the $p(nM)^n$-belts. We need to demonstrate points 1–3 in the definition of thick run. To this aim we split τ into $\tau = \rho\,\rho'$ where $\mathrm{trg}(\rho) = t = \mathrm{src}(\rho')$, and are going to prove the following two claims (a) and (a'). Let $D := P(nM)^n + (nM+1)^3$. For $x, y \in \mathbb{Q}^2$, let $\mathrm{dist}(x, y)$ denote their Euclidean distance.

(a) Some vectors v_1, v_2, v_3, v_4 are $P(nM)^n$-sequentially enabled in ρ, and the sequential cone $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ with $\|u - t\| \leq D$.

(a') Some vectors v'_1, v'_2, v'_3, v'_4 are $P(nM)^n$-sequentially enabled in $\mathrm{rev}(\rho')$, and the sequential cone $\textsc{SeqCone}(v'_1, v'_2, v'_3, v'_4)$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ with $\|u - t\| \leq D$.

In simple words, instead of proving point 3, we prove that both sequential cones contain a point v which is sufficiently close to t.

▷ Claim 3.3. The conditions (a) and (a') guarantee that τ is thick.

Indeed, points 1–2 in the definition of thick run are immediate as $P(nM) \leq p(nM)$. For point 3, observe that the inequality (1) implies $p(nM)^n \geq \sqrt{2} \cdot D$, which guarantees that the circle $\{u \in \mathbb{Q}^2_{\geq 0} \mid \mathrm{dist}(u, t) \leq \sqrt{2} \cdot D\}$ does not touch any half-line ℓ_w induced by a non-negative vector w with $\|w\| \leq p(nM)^n$. In consequence, neither does the square $X := \{u \in \mathbb{Q}^2_{\geq 0} \mid \|u - t\| \leq D\}$ inscribed in the circle, and hence X lies between two consecutive half-lines ℓ_w induced by a non-negative vector w with $\|w\| \leq p(nM)^n$. Hence, as $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$ contains some point of X, by Lemma 2.2 it includes the whole X, and likewise $\textsc{SeqCone}(v'_1, v'_2, v'_3, v'_4)$. In consequence, the whole X is included in $\textsc{SeqCone}(v_1, v_2, v_3, v_4) \cap \textsc{SeqCone}(v'_1, v'_2, v'_3, v'_4)$ which entails point 3. Claim 3.3 is thus proved.

As condition (a') is fully symmetric to (a), we focus exclusively on proving condition (a), i.e., on constructing sequentially enabled vectors v_1, v_2, v_3, v_4.

Vector t lies outside of $p(nM)^n$-belts, hence outside of all the $P(nM)^n$-belts, therefore its norm $\|t\| > P(nM)^n$. Relying on Lemma 3.2, let c_1 be the first configuration in the run ρ which enables a semi-positive cycle π_1 of length bounded by $P(nM)$, and let $v_1 = \mathrm{eff}(\pi_1)$. We start with the following obvious claim (let v_0 be some vertical vector, e.g. $v_0 = (0, 1)$):

▷ Claim 3.4. $\textsc{SeqCone}(v_0)$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ such that $\|u - c_1\| \leq P(nM)^n + nM$.

Indeed, due to Lemma 3.2 we may assume $\|c_1\| \leq P(nM)^n + M$ and hence $u = (0, 0)$ does the job.

Recall that the relation $\circlearrowleft$ defines a total order on pairwise non-colinear non-negative vectors.

▷ Claim 3.5. We can assume w.l.o.g. that $v_1 \circlearrowleft t$.

Indeed, if v_1 and t were colinear then $t \in \textsc{Cone}(v_1)$ and hence condition (a) would hold.

Split ρ into the prefix ending in c_1 and the remaining suffix: $\rho = \rho_1\,\sigma$, where $\mathrm{trg}(\rho_1) = c_1 = \mathrm{src}(\sigma)$. As the next step we will identify a configuration c_2 in σ which satisfies Claim 3.6 (which will serve later as the basis of induction) and enables a cycle π_2 with effect v_2 (as stated in Claim 3.7).

▷ Claim 3.6. $\textsc{SeqCone}(v_0, v_1)$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ such that $\|u - c_2\| \leq P(nM)^n + 2nM$.

The proof of Claim 3.6 depends on whether v_1 is positive. If v_1 is so, we simply duplicate the first cycle: $c_2 := c_1$ and $\pi_2 := \pi_1$, and use Claim 3.4. Otherwise v_1 is vertical due to Claim 3.5. If $t[1] \leq W = P(nM)^n + (n+1)M$ then condition (a) holds immediately as $\textsc{SeqCone}(v_1) = \ell_{v_1}$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ with $\|u - t\| \leq P(nM)^n + (n+1)M \leq D$. Therefore suppose $t[1] > P(nM)^n + (n+1)M$, and define the sequence $d_1, \ldots, d_m$ of configurations as follows (cf. Figure 5): let $d_1 := c_1$, and let d_{i+1} be the first configuration in

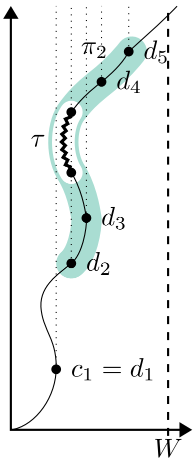

Figure 5 Proof of Claim 3.6.

σ with $d_{i+1}[1] > d_i[1]$. Recall that $d_1[1] \leq P(nM)^n + M$, and observe that $d_{i+1}[1] \leq d_i[1] + M$. Thus by the pigeonhole principle $m > n$ and hence for some $i < j \leq n+1$ the configurations d_i and d_j must have the same control state. The infix σ_{ij} of the path σ from d_i to d_j is thus a cycle, enabled in d_i, whose effect is positive on the first (horizontal) coordinate. Let $c_2 := d_i$. As $c_2[1] \leq P(nM)^n + (n+1)M$, $\textsc{SeqCone}(v_0, v_1) = \ell_{v_0}$ contains necessarily a point $u \in \mathbb{Q}^2_{\geq 0}$ such that $\|u - c_2\| \leq P(nM)^n + (n+1)M$, which proves Claim 3.6.

▷ Claim 3.7. The configuration c_2 $\{1\}$-enables a cycle π_2 of length bounded by $p(nM)^n$, such that the first coordinate of $\mathrm{eff}(\pi_2)$ is positive.

Recalling the proof of the previous claim, observe that the first (horizontal) coordinate in the infix σ_{ij} is bounded by $P(nM)^n + (n+1)M$, and think of the second (vertical) coordinate as irrelevant. Let π_2 be the path inducing σ_{ij}. For bounding the length of π_2, as long as π_2 contains a cycle α with vertical effect $(0, w)$, remove α from π_2. This process ends yielding a cycle π_2 of length at most $(P(nM)^n + (n+1)M) \cdot n$, and hence at most $p(nM)^n$ (by the inequality (1)), which is $\{1\}$-enabled in c_2, but not necessarily enabled. Let $v_2 := \mathrm{eff}(\pi_2)$.

▷ Claim 3.8. We can assume w.l.o.g. that $v_2 \circlearrowleft t$.

Indeed, if $v_1 = v_2$ then Claim 3.5 does the job; otherwise v_1 is vertical and then $t \circlearrowleft v_2$ (or t colinear with v_2) would imply $t \in \textsc{SeqCone}(v_1, v_2)$, hence condition (a) would hold again.

Split σ further into the prefix ending in c_2 and the remaining suffix: $\sigma = \rho_2\sigma'$, where $\mathrm{trg}(\rho_2) = c_2 = \mathrm{src}(\sigma')$. If σ' contains a configuration which $\emptyset$-enables a simple cycle whose effect w belongs to $\measuredangle[t, -v_2)$ then $t \in \textsc{SeqCone}(v_2, w)$ and hence condition (a) holds. We aim at achieving this objective incrementally (cf. Figure 6).

For $i \geq 2$, let c_{i+1} be the first configuration in σ' after c_i that $\emptyset$-enables a simple cycle π_{i+1} with effect $v_{i+1} \in \measuredangle(v_i, -v_i)$. As discussed above, if $v_{i+1} \in \measuredangle[t, -v_i)$ for some i then $t \in \textsc{SeqCone}(v_i, v_{i+1})$ and hence condition (a) holds. Assume therefore that the sequence $v_1, \ldots, v_m$ so defined satisfies $v_{i+1} \in \measuredangle(v_i, t)$ for all $i \geq 2$. Let $c_{m+1} := t$. As vectors $v_3, \ldots, v_m$ are pairwise different, semi-positive and, being effects of simple cycles, have norms at most nM, we know that $m \leq (nM+1)^2 + 1$.

▷ Claim 3.9. For every $i = 1, \ldots, m$, $\textsc{SeqCone}(v_0, v_i)$ contains a point $u \in \mathbb{Q}^2_{\geq 0}$ such that $\|u - c_{i+1}\| \leq P(nM)^n + (i+1)nM$.

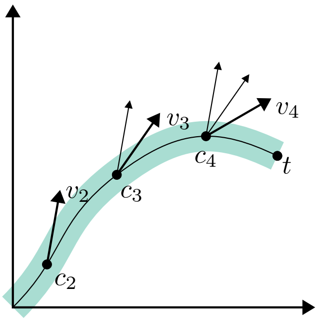

Figure 6 Incremental construction of $v_1, \ldots, v_m$.

Proof. By induction on i. The induction base is exactly Claim 3.6. For the induction step, we are going to show that $\textsc{SeqCone}(v_0, v_i)$ contains a vector u such that $\|u - c_{i+1}\| \leq P(nM)^n + (i+1)nM$. Decompose the infix of σ' which starts in c_i and ends in c_{i+1} into simple cycles, plus the remaining path $\bar{\rho}$ of length at most n. The norm of the effect $\bar{v}$ of $\bar{\rho}$ is hence bounded by nM, and we have

$$c_{i+1} \;=\; c_i + s + \bar{v},$$

where s is the sum of effects of all the simple cycles. By the definition of v_{i+1}, the effects of all the simple cycles belong to the half-plane $\measuredangle[-v_i, v_i]$, and hence there belongs s. By induction assumption there is $u' \in \textsc{SeqCone}(v_0, v_{i-1})$ such that $\|u' - c_i\| \leq P(nM)^n + inM$. As $v_{i-1} \circlearrowright v_i$, we also have $u' \in \textsc{SeqCone}(v_0, v_i)$. Consider the point

$$u \;:=\; u' + s$$

which necessarily belongs to the half-plane $\measuredangle[-v_i, v_i]$ but not necessarily to $\textsc{SeqCone}(v_0, v_i) = \measuredangle[-v_i, v_i] \cap \mathbb{Q}^2_{\geq 0}$. Ignoring this issue, by routine calculations we get

$$\|u - c_{i+1}\| \;=\; \|u' + s - c_i - s - \bar{v}\| \;\leq\; \|u' - c_i\| + \|\bar{v}\| \leq \|u' - c_i\| + nM \leq P(nM)^n + (i+1)nM$$

as required for the induction step. Finally, if $u \notin \mathbb{Q}^2_{\geq 0}$, translate u towards c_{i+1} until it enters the non-negative orthant $\mathbb{Q}^2_{\geq 0}$; clearly, the translation can only decrease the value of $\|u - c_{i+1}\|$. ◀

Applying the claim to $i = m$, and knowing that $m \leq (nM+1)^2 + 1$, we get some point $u \in \textsc{SeqCone}(v_0, v_m)$ such that $\|u - t\| \leq P(nM)^n + ((nM+1)^2+1) \cdot nM \leq P(nM)^n + (nM+1)^3$. Furthermore, relying on the assumptions that t lies outside of all $p(nM)^n$-belts and that $v_1 \circlearrowright t$ we prove, similarly as in the proof of Claim 3.3, that $v_1 \circlearrowright u$ and hence the point u belongs also to $\textsc{SeqCone}(v_1, v_m)$. This completes the proof of Theorem 3.1. ◀

4 Dichotomy in Action

This section illustrates applicability of Theorem 3.1. As before, we use symbols n and M for the number of control states, and the norm of a 2-VASS, respectively. As the first corollary we provide a pumping lemma for 2-VASS: in case of thin runs apply, essentially, pumping schemes of 1-VASS, and in case of thick runs use the cycles enabled along a run. As another application, we derive an alternative proof of the exponential run property for 2-VASS.

▶ **Theorem 4.1** (Pumping). *There is a polynomial p such that every $(0,0)$-run τ in a 2-VASS of length greater that $p(nM)^n$ factors into $\tau = \tau_0 \tau_1 \ldots \tau_k$ $(k \geq 1)$, so that for some non-empty cycles $\alpha_1, \ldots, \alpha_k$ of length at most $p(nM)^n$, the path $\tau_0 \alpha_1^i \tau_1 \alpha_2^i \ldots, \alpha_k^i \tau_k$ is a $(0,0)$-run for every $i \in \mathbb{N}$. Furthermore, the lengths of τ_0 and τ_k are also bounded by $p(nM)^n$.*

▶ **Theorem 4.2** (Exponential run). *There is a polynomial p such that for every $(0,0)$-run τ in a 2-VASS, there is a $(0,0)$-run of length bounded by $p(nM)^n$ with the same source and target as τ.*

We fix from now on a 2-VASS $V = (Q,T)$ and the polynomial p of Theorem 3.1. Let $A = p(nM)^n$. Both proofs proceed separately for thin and thick runs τ. The former (fairly standard) case is treated in the full version of the paper, so assume below τ to be A-thick. The polynomials required in Theorems 4.1 and 4.2 can be read out from the constructions.

We rely on the standard tool, cf. Prop. 2 in [4] (the norm of a system of inequalities is the largest absolute value of its coefficient, and likewise we define the norm of a solution):

▶ **Lemma 4.3.** *Let $\mathcal{U}$ be a system of d linear inequalities of norm M with k variables. Then the smallest norm of a non-negative-integer solution of $\mathcal{U}$ is in $\mathcal{O}(k \cdot M)^d$.*

Consider a split $\tau = \rho\rho'$, where $\rho = \rho_1 \rho_2 \rho_3 \rho_4 \rho_5$ and $\rho' = \rho_5' \rho_4' \rho_3' \rho_2' \rho_1'$, as well as cycles $\pi_1, \ldots, \pi_4$ and $\pi_1', \ldots, \pi_4'$ given by the definition of thick run. Let $v_1, \ldots, v_4$ and $v_1', \ldots, v_4'$ be the respective effects of $\pi_1, \ldots, \pi_4$ and $\pi_1', \ldots, \pi_4'$. For $j = 1, \ldots, 4$ let $c_j = \mathrm{trg}(\rho_j)$ and for $j = 2, \ldots, 4$ let $e_j \in \mathbb{N}^2$ be the minimal non-negative vector such that the configuration $c_j + e_j$ enables cycle π_j. We define the following system $\mathcal{U}$ of linear inequalities with 6 variables a_1, a_2, a_3, a_4, x, y (max is understood point-wise):

$$a_1 v_1 \geq e_2 \tag{2}$$

$$a_1 v_1 + a_2 v_2 \geq \max(e_2, e_3) \tag{3}$$

$$a_1 v_1 + a_2 v_2 + a_3 v_3 \geq \max(e_3, e_4) \tag{4}$$

$$a_1 v_1 + a_2 v_2 + a_3 v_3 + a_4 v_4 = (x,y) \geq e_4 \tag{5}$$

(Observe that when $v_1[j] = 0$, i.e., in case when v_1 is vertical or horizontal, $e_j = 0$ and therefore one of the two first inequalities is always satisfied, namely $a_1 v_1[j] \geq e_2[j]$.) Likewise, we have a system of inequalities $\mathcal{U}'$ with 6 variables $a_1', a_2', a_3', a_4', x', y'$. Observe that the sequential cone $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$ contains exactly (projections on (x,y) of) non-negative rational solutions of the modified system $\mathcal{U}^{(0,0)}$ obtained by replacing all the right-hand sides with $(0,0)$. Likewise we define $\mathcal{U}'^{(0,0)}$. Finally, we define the compound system $\mathcal{C}$ by enhancing the union of $\mathcal{U}$ and $\mathcal{U}'$ with two additional equalities (likewise we define the system $\mathcal{C}^{(0,0)}$)

$$(x,y) = (x',y'). \tag{6}$$

▷ Claim 4.4. $\mathcal{C}$ admits a non-negative integer solution $(a_1, a_2, a_3, a_4, x, y, a_1', a_2', a_3', a_4', x', y')$.

Proof. The system $\mathcal{C}^{(0,0)}$ admits a non-negative rational solution as the intersection of the cones $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$ and $\textsc{SeqCone}(v_1', v_2', v_3', v_4')$ is non-empty by assumption. As intersection of cones is stable under multiplications by non-negative rationals, the solution can be scaled up arbitrarily, to yield a non-negative integer one, and even a non-negative integer solution of the stronger system $\mathcal{C}$. ◀

▷ Claim 4.5. For every non-negative integer solution of $\mathcal{C}$, for the cycles defined as $\alpha_j := \pi_j^{a_j}$ and $\alpha_j' := (\pi_j')^{a_j'}$, for $j = 1, 2, 3, 4$, the following path is a $(0,0)$-run:

$$\rho_1\ \alpha_1\ \rho_2\ \alpha_2\ \rho_3\ \alpha_3\ \rho_4\ \alpha_4\ \rho_5\ \rho_5'\ \alpha_4'\ \rho_4'\ \alpha_3'\ \rho_3'\ \alpha_2'\ \rho_2'\ \alpha_1'\ \rho_1'.$$

Proof. The first two inequalities (2) enforce that the first cycle π_1 is repeated sufficiently many a_1 times so that π_2 is enabled in configuration $\mathrm{trg}(\rho_1\,\alpha_1\,\rho_2)$. Then the next two inequalities (3) enforce that π_1 and π_2 are jointly repeated sufficiently many a_1, a_2 times so that π_2 is still enabled after its last repetition (which guarantees that every of intermediate repetitions of π_2 is also enabled), and that π_3 is enabled in configuration $\mathrm{trg}(\rho_1\,\alpha_1\,\rho_2\,\alpha_2\,\rho_3)$. Likewise for (4). Finally, the inequalities (5) enforce that $\pi_1, \ldots, \pi_4$ are jointly repeated sufficiently many times so that π_4 is still enabled after its last repetition. Analogous argument, but in the reverse order, applies for the repetitions of $\pi'_4, \ldots, \pi'_1$. Finally, equalities (6) ensure that the total effect of $\alpha_1, \ldots, \alpha_4$ is precisely compensated by the total effect of $\mathrm{rev}(\alpha'_1), \ldots, \mathrm{rev}(\alpha'_4)$. ◀

Proof of Theorem 4.1. Consider a solution of $\mathcal{C}$. In particular the sum $\mathrm{eff}(\alpha_1)+\ldots+\mathrm{eff}(\alpha_j)$, as well as $\mathrm{eff}(\mathrm{rev}(\alpha'_1)) + \ldots + \mathrm{eff}(\mathrm{rev}(\alpha'_j))$, is necessarily non-negative for every $j = 1, \ldots, 4$. Therefore, as a direct corollary of Claim 4.5, for every $i \in \mathbb{N}$ the path

$$\rho_1\,\alpha_1^i\,\rho_2\,\alpha_2^i\,\rho_3\,\alpha_3^i\,\rho_4\,\alpha_4^i\,\rho_5\,\rho'_5\,(\alpha'_4)^i\,\rho'_4\,(\alpha'_3)^i\,\rho'_3\,(\alpha'_2)^i\,\rho'_2\,(\alpha'_1)^i\,\rho'_1$$

is also a $(0,0)$-run. For bounding the lengths of cycles we use Claim 4.4 and apply Lemma 4.3 to $\mathcal{C}$, to deduce that $\mathcal{C}$ admits a non-negative integer solution of norm polynomial in $A = p(nM)^n$. This, together with the bounds on lengths of cycles $\pi_1, \ldots, \pi_4$ and $\pi'_1, \ldots, \pi'_4$ in the definition of A-thick run, entails required bounds on the lengths of the pumpable cycles. Finally, the lengths of the extremal factors ρ_1 and ρ'_1 can be also bounded: if ρ_1 (resp. ρ'_1) is long enough it must admit a repetition of configuration, we add one more cycle determined by the first (resp. last) such repetition, thus increasing k from 8 to 10. ◀

For proving Theorem 4.2 we will need a slightly more elaborate pumping. By the definition of thick run, both coordinates are bounded by A along ρ_1 and ρ'_1. W.l.o.g. assume that no configuration repeats in each of the two runs, and hence their lengths are bounded by A^2.

Let $\mathcal{C}_\delta$ denote the union of of $\mathcal{U}$ and $\mathcal{U}'$ enhanced, this time, by the two equalities

$$(x, y) + (\delta_x, \delta_y) = (x', y').$$

The two additional variables δ_x, δ_y describe, intuitively, possible differences between the total effect of $\pi_1^{a_1}, \ldots, \pi_4^{a_4}$ and the total effect of $\mathrm{rev}(\pi'_1)^{a'_1}, \ldots, \mathrm{rev}(\pi'_4)^{a'_4}$. The projection of any solution of $\mathcal{C}_\delta$ on variables (δ_x, δ_y) we call below a *shift*.

▷ Claim 4.6. For some non-negative integer m bounded polynomially with respect to A, all the four vectors $(0, m)$, $(m, 0)$, $(0, -m)$ and $(-m, 0)$ are shifts.

Proof. We reason analogously as in the proof of Claim 4.4, but this time we rely on the assumption that intersection of the cones $\textsc{SeqCone}(v_1, v_2, v_3, v_4)$ and $\textsc{SeqCone}(v'_1, v'_2, v'_3, v'_4)$ is non-trivial, and hence contains, for some $v \in \mathbb{Q}^2_{>0}$ and $a \in \mathbb{Q}_{>0}$, the points v and $v + (0, a)$. By scaling we obtain an integer point $v' \in \mathbb{N}^2$ and a non-negative integer $m_1 \in \mathbb{N}$ so that v' and $v' + (0, m_1)$ both belong to the intersection of cones. Therefore the vector $(0, m_1)$ is a shift. Likewise we obtain three other non-negative integers $m_2, m_3, m_4 \in \mathbb{N}$ such that $(m_2, 0)$, $(0, -m_3)$ and $(-m_4, 0)$ are all shifts. Each of the integers $m_1, \ldots, m_4$ can be bounded polynomially in A using Lemma 4.3. As shifts are stable under multiplication by non-negative integers, it is enough to take as m the least common multiple of the four integers. ◀

Proof of Theorem 4.2. We use m from the last claim to modify all factors of τ except for ρ_1 and ρ'_1, in order to reduce their lengths to at most $n \cdot m^2$. W.l.o.g. assume m to be larger than A (take a sufficient multiplicity of m otherwise); this assumption allows us to

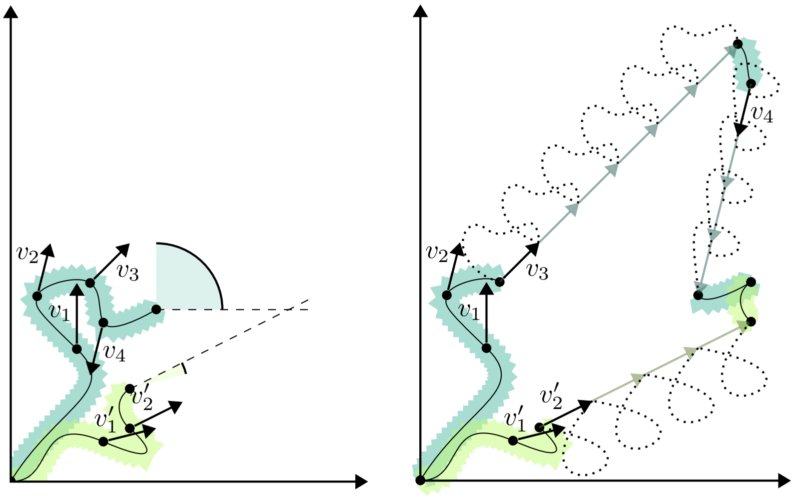

Figure 7 Contracted paths $\widetilde{\rho}, \widetilde{\rho}'$ (left) and reconstructed $(0,0)$-run $\bar{\tau} = \bar{\rho}\,\bar{\rho}'$ (right).

proceed uniformly, irrespectively whether v_1 is positive or not. Observe that any path longer than $n \cdot m^2$ must contain two configurations with the same control state whose vectors are coordinate-wise congruent modulo m. As long as this happens, we remove the infix; note that this operation changes the effect of the whole path by a multiplicity of m on every coordinate. If this operation is performed on factors ρ_2, ρ_3, ρ_4, ρ_5, ρ_5', ρ_4', ρ_3', ρ_2', the paths ρ, ρ' are transformed into contracted paths (see the left picture in Figure 7) of the form:

$$\widetilde{\rho} \;=\; \rho_1\, \widetilde{\rho}_2\, \widetilde{\rho}_3\, \widetilde{\rho}_4\, \widetilde{\rho}_5, \qquad \widetilde{\rho}' \;=\; \widetilde{\rho}_5'\, \widetilde{\rho}_4'\, \widetilde{\rho}_3'\, \widetilde{\rho}_2'\, \sigma_1,$$

each of total length at most $5\,n \cdot m^2$. Importantly, their effects $\mathrm{eff}(\widetilde{\rho})$ and $\mathrm{eff}(\widetilde{\rho}')$ are bounded polynomially in A, and their difference is (coordinate-wise) divisible by m:

$$\mathrm{eff}(\widetilde{\rho}) - \mathrm{eff}(\mathrm{rev}(\widetilde{\rho}')) \;=\; (am, bm) \qquad \text{for some integers } a, b \in \mathbb{Z} \text{ polynomial in } A.$$

Our aim is now to pump up the cycles $\pi_1, \ldots, \pi_4$ and $\mathrm{rev}(\pi_1'), \ldots, \mathrm{rev}(\pi_4')$ (see the right picture in Figure 7), to finally end up with the paths of the form

$$\bar{\rho} \;=\; \rho_1\, \pi_1^{a_1}\, \widetilde{\rho}_2\, \pi_2^{a_2}\, \widetilde{\rho}_3\, \pi_3^{a_3}\, \widetilde{\rho}_4\, \pi_4^{a_4}\, \widetilde{\rho}_5, \quad \bar{\rho}' \;=\; \widetilde{\rho}_5'\, (\pi_4')^{a_4'}\, \widetilde{\rho}_4'\, (\pi_3')^{a_3'}\, \widetilde{\rho}_3'\, (\pi_2')^{a_2'}\, \widetilde{\rho}_2'\, (\pi_1')^{a_1'}\, \rho_1', \tag{7}$$

such that $\bar{\tau} = \bar{\rho}\,\bar{\rho}'$ is a $(0,0)$-run. In other words, we aim at $\mathrm{eff}(\bar{\rho}) = \mathrm{eff}(\mathrm{rev}(\bar{\rho}'))$. We are going to use Lemma 4.3 twice. For $j = 2, \ldots, 5$ let $c_j := \mathrm{eff}(\rho_1 \widetilde{\rho}_2 \ldots \widetilde{\rho}_j) \in \mathbb{Z}^2$, and let f_j be the minimal non-negative vector such that the configuration $c_{j-1} + f_j$ enables $\widetilde{\rho}_j$. For $j = 2, \ldots, 4$ let $e_j \in \mathbb{N}^2$ be the minimal non-negative vector such that the configuration $c_j + e_j$ enables π_j. Finally, let e_5 be the minimal non-negative vector such that $c_5 + e_5 \geq (0,0)$. Analogously to the system $\mathcal{U}$ (2)–(5), we define the system $\widetilde{\mathcal{U}}$ of linear inequalities:

$$\begin{aligned} a_1 m v_1 &\;\geq\; \max(e_2, f_2) \\ a_1 m v_1 + a_2 m v_2 &\;\geq\; \max(e_2, e_3, f_3) \\ a_1 m v_1 + a_2 m v_2 + a_3 m v_3 &\;\geq\; \max(e_3, e_4, f_4) \\ a_1 m v_1 + a_2 m v_2 + a_3 m v_3 + a_4 m v_4 &\;\geq\; \max(e_4, e_5, f_5) \end{aligned}$$

In words, $\widetilde{\mathcal{U}}$ requires that every prefix of $\bar{\rho}$ is enabled in the source $(0,0)$-configuration, and that the number of repetitions of every cycle π_i is divisible by m. Clearly $\widetilde{\mathcal{U}}$ has a non-negative integer solution, as v_1 is either positive, or vertical or horizontal in which case

v_2 is positive on the relevant coordinate. Likewise we define a system of inequalities $\widetilde{\mathcal{U}}'$ that requires that every prefix of $\mathrm{rev}(\bar{\rho}')$ is enabled in the target $(0,0)$-configuration. Consider some fixed solutions of $\widetilde{\mathcal{U}}$ and $\widetilde{\mathcal{U}}'$ bounded, by the virtue of Lemma 4.3, polynomially in A. We have thus two fixed runs $\bar{\rho}$ and $\mathrm{rev}(\bar{\rho}')$ of the form (7), with source vector $(0,0)$; the number of repetitions of each cycles is divisible by m, and the difference of their effects is (coordinate-wise) divisible by m:

$$\mathrm{eff}(\bar{\rho}) - \mathrm{eff}(\mathrm{rev}(\bar{\rho}')) \;=\; (am, bm) \qquad \text{for some integers } a, b \in \mathbb{Z} \text{ polynomial in } A.$$

As shifts are closed under addition, by Claim 4.6 we know that (am, bm) is a shift. Substituting (am, bm) for (δ_x, δ_y) in the system $\mathcal{C}_\delta$ yields a system which admits, again by Lemma 4.3, a solution bounded polynomially in A. We use such a solution to increase the numbers of repetitions of respective cycles $a_1, \ldots, a_4$ and $a'_4, \ldots, a'_1$ in $\bar{\rho}$ and $\bar{\rho}'$, respectively. This turns the path $\bar{\tau} = \bar{\rho}\,\bar{\rho}'$ into a $(0,0)$-run of length bounded polynomially in A. ◀

Abstract

Many variations of synchronization of finite automata have been studied in the previous decades. Here, we suggest studying the question if synchronizing words exist that belong to some fixed constraint language, given by some partial finite automaton called constraint automaton. We show that this synchronization problem becomes PSPACE-complete even for some constraint automata with two states and a ternary alphabet. In addition, we characterize constraint automata with arbitrarily many states for which the constrained synchronization problem is polynomial-time solvable. We classify the complexity of the constrained synchronization problem for constraint automata with two states and two or three letters completely and lift those results to larger classes of finite automata.

1 Introduction

Synchronization is an important concept for many applied areas: parallel and distributed programming, system and protocol testing, information coding, robotics, etc. At least some aspects of synchronization are captured by the notion of a synchronizing automaton; for

44th International Symposium on Mathematical Foundations of Computer Science (MFCS 2019).

instance, synchronizing automata adequately model situations in which one has to direct a certain system to a particular state without a priori knowledge of its current state. We only refer to some survey papers [24, 28], as well as to Chapter 13 in [17], that also report on some of these applications. An automaton is called synchronizing if there exists a word that brings it to a known state independently of the starting state. This concept is quite natural and has been investigated intensively in the last six decades. It is related to the arguably most famous open combinatorial question in automata theory, formulated by Černý in [8]. The Černý conjecture states that every n-state synchronizing automaton can be synchronized by a word of length smaller or equal $(n-1)^2$. Although this bound was proven for several classes of finite-state automata, the general case is still widely open. The currently best upper bound on this length is cubic, and only very little progress has been made, basically improving on the multiplicative constant factor in front of the cubic term, see [25, 27].

Due to the importance of this notion of synchronizing words, quite a large number of generalizations and modifications have been considered in the literature. We only mention four of these in the following. Instead of synchronizing the whole set of states, one could be interested in synchronizing only a subset of states. This and related questions were first considered by Rystsov in [23]. Instead of considering deterministic finite automata (DFAs), one could alternatively study the notion of synchronizability for nondeterministic finite automata [12, 21]. The notion of synchronizability naturally transfers to partially defined transition functions where a synchronizing automata avoiding undefined transitions is called *carefully synchronizing*, see [9, 20, 21]. To capture more adaptive variants of synchronizing words, synchronizing strategies have been introduced in [19]. Recall that the question of synchronizability (without length bounds) is solvable in polynomial time for complete DFAs [28]. However, in all of the mentioned generalizations, this synchronizability question becomes even PSPACE-complete. This general tendency can also be observed in the generalization that we introduce in this paper, which we call *regular constraints*. These constraints are defined by some (fixed) finite automaton describing a regular language R, and the question is, given some DFA A, if A has some synchronizing word from R. This notion explicitly appeared in [13] as an auxiliary tool: it was shown that the synchronization problem of every automaton $A = (\Sigma, Q, \delta)$ whose letters σ have ranks at most r, i.e., $|\delta(Q, \sigma)| \leq r$, is equivalent to the synchronization of an r-state automaton A' under some regular constraints.

The main research question that we look into is to understand for which regular constraints the question of synchronizability is solvable in polynomial time (as it is for $R = \Sigma^*$), or for which it is hard. Furthermore, it would be interesting to see complexity classes different from P and PSPACE to show up (depending on R). In our paper, we give a complete description of the complexity status for constraints that can be described by partial 2-state deterministic automata on alphabets with at most three letters. In this case, indeed, we only observe P and PSPACE situations. However, we also find 3-state automata (on binary input alphabets) that exhibit an NP-complete synchronization problem when considered as constraints. We describe several ways how to generalize our results to larger constraint automata. Moreover, we identify several classes of constraint automata that imply feasible synchronization problems. We motivate our study of synchronization under regular constraints by the following example.

A motivating result. In the theory of synchronizing automata, one normally allows the directing instruction to be an arbitrary word over the input language of the corresponding automaton. In reality, however, available commands might be subject to certain restrictions; for instance, it is quite natural to assume that a directing instruction should always start and end with a specific command that first switches the automaton to a “directive” mode and then returns the automaton to its usual mode. In its simplest form, the switching between "normal mode" and "directive" (synchronization) mode can be modeled as ab^*a. This scenario produces an NP-complete synchronization problem. In order to state our first result formally, we make use of some (standard) notions defined in Section 2.

▶ **Proposition 1.** *The following problem is NP-complete: Given a deterministic finite complete automaton A with $L(A) \subseteq \{a, b\}^*$, is there a synchronizing word $w \in ab^*a$ for A?*

Notice that this contrasts with the complexity of the synchronizability question for complete DFAs, which can be solved in quadratic time; see, e.g., [24, 28]. Also, it contrasts the complexity of synchronizability for partial DFAs, which is PSPACE-complete; see [21].

The constraint automaton describing ab^*a has three states. As we will see below, only P- and PSPACE-results can be observed for two-state constraint automata over binary and ternary input alphabets. Hence, in a sense, Proposition 1 is a minimal example of a complexity status inbetween P and PSPACE. A proof sketch of Proposition 1 is given below.

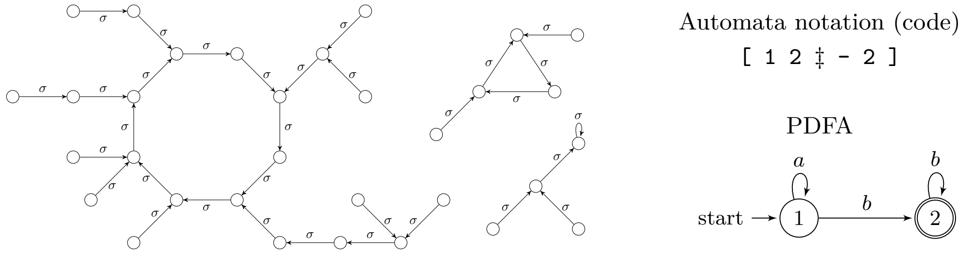
Rystsov [23] considered a problem that he called Global Inclusion Problem for Non-initial Automata. As we will see below, this problem (together with a variation) will be the key problem in our reductions. Looking at the proof of [23, Theorem 2.1], we can observe the following refined result. We consider the next problem that we call $\mathcal{P}_\Sigma$ for brevity. Given a complete DFA A with state set Q and input alphabet Σ, with $a \in \Sigma$, as well as a designated state subset S, is there some word $w \in \{a\}(\Sigma \setminus \{a\})^*$ such that w drives A into S, irrespectively of where A starts processing w? Trivially, $\mathcal{P}_\Sigma$ is in P if $|\Sigma| = 1$.

▶ **Theorem 2.** *$\mathcal{P}_\Sigma$ is NP-hard if $|\Sigma| = 2$, and PSPACE-hard if $|\Sigma| > 2$.*

In particular, the case distinction between binary input alphabets and larger input alphabets (concerning hardness results) comes from the fact that the reduction of Rystsov uses DFA-Intersection Nonemptiness, the non-emptiness of intersection problem for deterministic finite automata on the alphabet $\Sigma \setminus \{a\}$, using Theorem 6.1 in [26] (more details in [11, 18]). In Rystsov's reduction, the state set of the automaton A consists of a part $Q_\cap$, which just copies the n automata A_i (over alphabet $\Sigma \setminus \{a\}$) of a DFA-Intersection Nonemptiness instance, together with n new states $t_i \in Q_\rightarrow$ that move on input a into the initial state s_i of A_i. Likewise, from any state q_i of A_i, letter a leads to s_i. All transitions not yet defined are self-loops. Set S collects all final states of all A_i. Hence, a word $w \in (\Sigma \setminus \{a\})^*$ is accepted by all of the A_i iff aw drives A into S, starting out from any state. The promised proof sketch follows. Modify A to obtain an automaton A' such that A' has a synchronizing word awa, with $w \in (\Sigma \setminus \{a\})^*$ iff aw drives A into S as follows: add a new state s where all letters loop; for all $q \in S$, replace the a-transitions leading from q into s_i by a-transitions leading into s. For more details (membership in NP for $\Sigma = \{a, b\}$ is non-trivial), see Theorem 19.

2 Preliminaries and Definitions

Throughout the paper, we consider deterministic finite automata (DFAs). Recall that a DFA A is a tuple $A = (\Sigma, Q, \delta, q_0, F)$, where the alphabet Σ is a finite set of input symbols, Q is the finite state set, with start state $q_0 \in Q$, and final state set $F \subseteq Q$. The transition function $\delta : Q \times \Sigma \to Q$ extends to words from Σ^* in the usual way. The function δ can be further extended to sets of states in the following way. For every set $S \subseteq Q$ with $S \neq \emptyset$ and $w \in \Sigma^*$, we set $\delta(S, w) := \{\, \delta(q, w) \mid q \in S \,\}$. We sometimes refer to the function δ as a relation and we identify a transition $\delta(q, \sigma) = q'$ with the tuple (q, σ, q'). We call A *complete* if δ is defined for every $(q, a) \in Q \times \Sigma$; if δ is undefined for some (q, a),



```

```

(a) Unary automaton A_σ consisting of 3 sun-structures.

(b) Automata notation and PDFA using its standard interpretation.

Figure 1 Illustration of sun-structures and of the notation of PDFAs.

the automaton A is called *partial*. If $|\Sigma| = 1$, we call A a *unary* automaton. The set $L(A) = \{\, w \in \Sigma^* \mid \delta(q_0, w) \in F \,\}$ denotes the language accepted by A. A semi-automaton is a finite automaton without a specified start state and with no specified set of final states. Notice that $(\Sigma, \binom{Q}{\leq k}, \delta)$ can be viewed as a semi-automaton for each $k \leq |Q|$, when $\binom{Q}{\leq k}$ is the set formed by all subsets of Q of cardinality at most k. The properties of being *deterministic*, *partial*, and *complete* of semi-automata are defined as for DFA. When the context is clear, we call both deterministic finite automata and semi-automata simply *automata*. We call a deterministic complete semi-automaton a DCSA and a partial deterministic finite automaton a PDFA for short. If we want to add an explicit initial state r and an explicit set of final states S to a DCSA A or change them in a DFA A, we use the notation $A_{r,S}$.

An automaton A is called *synchronizing* if there exists a word $w \in \Sigma^*$ with $|\delta(Q, w)| = 1$. In this case, we call w a *synchronizing word* for A. For a word w, we call a state in $\delta(Q, w)$ an *active* state. We call a state $q \in Q$ with $\delta(Q, w) = \{q\}$ for some $w \in \Sigma^*$ a *synchronizing state*. A state from which some final state is reachable is called *co-accessible*. For a set $S \subseteq Q$, we say S is *reachable* from Q or Q is synchronizable to S if there exists a word $w \in \Sigma^*$ such that $\delta(Q, w) = S$. An automaton A is called *returning*, if for every state $q \in Q$, there exists a word $w \in \Sigma^*$ such that $\delta(q, w) = q_0$, where q_0 is the start state of A.

▶ **Fact 1.** *[28] For any DCSA, we can decide if it is synchronizing in polynomial time $O(|\Sigma||Q|^2)$. Additionally, if we want to compute a synchronizing word w, then we need time $O(|Q|^3 + |Q|^2|\Sigma|)$ and the length of w will be $O(|Q|^3)$.*

The following obvious remark will be used frequently without further mentioning.

▶ **Lemma 3.** *Let $A = (\Sigma, Q, \delta)$ be a DCSA and $w \in \Sigma^*$ be a synchronizing word for A. Then for every $u, v \in \Sigma^*$, the word uwv is also synchronizing for A.*

For an automaton A over the alphabet Σ, we denote with $A_{\Sigma'}$ for every $\Sigma' \subset \Sigma$ the restriction of A to the alphabet Σ'. Automaton $A_{\Sigma'}$ is obtained from A by deleting all transitions with labels in $\Sigma \setminus \Sigma'$. We will identify $A_{\{\sigma\}}$ with A_σ for every $\sigma \in \Sigma$. For a complete deterministic automaton A_σ, each connected component of A_σ consists of exactly one cycle and some tails leading into the cycle (see Figure 1a). A cycle is a sequence of states $q_1, q_2, \ldots, q_k$, for $k \in \mathbb{N}$ such that $\delta(q_i, \sigma) = q_{i+1}$ and $\delta(q_k, \sigma) = q_1$. In particular, a cycle may consist of one single state only. The tails are only leading into the cycle since A is deterministic. We call components of this form *sun-structures* as illustrated in Figure 1a.

We call two automata A and A' isomorphic if one automaton can be obtained from the other one by renaming states and alphabet-symbols. Notice that the number of non-isomorphic automata can be quite huge even for small number of states and alphabet sizes;

see [3, 10, 14]. In order to address the presented automata in a compact way, we introduce a short notation motivated by [1, 2, 22], where we assume some order is given on the alphabet and on the state set. Each automaton is denoted by a tuple of size $|Q| \cdot |\Sigma|$ where for each state the mapping of this state with each alphabet symbol is listed. The states themselves are separated by ‡-signs. For example, the first entry of the tuple denotes the transition of the first state under the first symbol (and "-" for an undefined transition), while the second entry denotes the transition of the first state by the second symbol, and so on. We will always assume the first state in the ordering of the states to be the start state of the automaton. See Figure 1b for an example. Final states are not part of this coding.
For a fixed PDFA $\mathcal{B} = (\Sigma, P, \mu, p_0, F)$, we define the *constrained synchronization problem*:

▶ **Definition 4.** $L(\mathcal{B})$-CONSTR-SYNC
Input*: DCSA* $A = (\Sigma, Q, \delta)$*.*
Question*: Is there a synchronizing word* w *for* A *with* $w \in L(\mathcal{B})$*?*

The automaton $\mathcal{B}$ will be called the *constraint automaton*. If an automaton A is a yes-instance of $L(\mathcal{B})$-CONSTR-SYNC we call A *synchronizing with respect to* $\mathcal{B}$. Occasionally, we do not specify $\mathcal{B}$ and rather talk about L-CONSTR-SYNC. We are going to inspect the complexity of this problem for different (small) constraint automata. We assume the reader to have some basic knowledge in computational complexity theory and formal language theory, as contained, e.g., in [15]. For instance, we make use of regular expressions to describe languages. We also identify singleton sets with its elements. We also make use of complexity classes like P, NP, or PSPACE. At one point, we also mention the parameterized complexity class XP. With $\leq_m^{\log}$ we denote a logspace many-one reduction. If for two problems L_1, L_2 it holds that $L_1 \leq_m^{\log} L_2$ and $L_2 \leq_m^{\log} L_1$, then we write $L_1 \equiv_m^{\log} L_2$.

For establishing some of our results, we need the following computational problems taken from [6], which are PSPACE-complete problems for at least binary alphabets, also see [23, 24].

▶ **Definition 5.** SYNC-FROM-SUBSET
Input*: DCSA* $A = (\Sigma, Q, \delta)$ *and* $S \subseteq Q$*.*
Question*: Is there a word* w *with* $|\delta(S, w)| = 1$*?*

▶ **Definition 6.** SYNC-INTO-SUBSET
Input*: DCSA* $A = (\Sigma, Q, \delta)$ *and* $S \subseteq Q$*.*
Question*: Is there a word* w *with* $\delta(Q, w) \subseteq S$*?*

▶ Remark 7. The terminology is not homogeneous in the literature. For instance, SYNC-INTO-SUBSET has different names in [6] and in [23].

3 Placing Constrained Problems Within Complexity Classes

In this section we present several criteria for L which lead to the membership of L-CONSTR-SYNC in different complexity classes, starting by studying unary languages.

▶ **Lemma 8.** *Let* $A = (\{\sigma\}, Q, \delta)$ *be a unary synchronizing DCSA. For all* $i \geq |Q| - 1$*, we have* $\delta(Q, \sigma^i) = \delta(Q, \sigma^{i+1})$*. A shortest word* w *synchronizing* $S \subseteq Q$ *obeys* $|w| \leq |Q| - 1$*.*

▶ **Corollary 9.** *If* $L(\mathcal{B}) \subseteq \{\sigma\}^*$ *for a PDFA* $\mathcal{B}$*, then* $L(\mathcal{B})$-CONSTR-SYNC $\in$ *P.*

▶ **Theorem 10.** *If* L *is regular, then* L-CONSTR-SYNC *is contained in PSPACE.*

We continue with 1-state constraint automata and unions of constraint languages.

▶ **Lemma 11.** *Let $\mathcal{B} = (\Sigma, P, \mu, p_0, F)$ be a PDFA. If $L(\mathcal{B}) = L(\mathcal{B}_{\Sigma\setminus\{\sigma\}})$ for some $\sigma \in \Sigma$, then $L(\mathcal{B})$-*Constr-Sync *$\equiv_m^{\log} L(\mathcal{B}_{\Sigma\setminus\{\sigma\}})$-*Constr-Sync*.*

▶ **Corollary 12.** *$L(\mathcal{B})$-*Constr-Sync *$\in$ P for every one-state constraint automaton $\mathcal{B}$.*

▶ **Lemma 13.** *If L is a finite union of languages $L_1, L_2, \ldots, L_n$ such that for each $1 \leq i \leq n$ the problem L_i-*Constr-Sync *$\in$ P, then L-*Constr-Sync *$\in$ P.*

▶ **Theorem 14.** *Let $L \subseteq \Sigma^*$. If $\{ v \in \Sigma^* \mid \exists u, w \in \Sigma^* : uvw \in L \} = \Sigma^*$, L-*Constr-Sync *$\in$ P.*

Proof. Let $A = (\Sigma, Q, \delta)$ be a DCSA. To decide if A has a synchronizing word from L, simply test if A is synchronizing at all, cf. Fact 1. Assume $v \in \Sigma^*$ is a synchronizing word for A. By assumption, $uvw \in L$ for some $u, w \in \Sigma^*$. Moreover, uvw also synchronizes A. ◀

With the same type of reasoning, one can show:

▶ **Theorem 15.** *Let $L \subseteq L' \subseteq \Sigma^*$. If $L' \subseteq \{ v \in \Sigma^* \mid \exists u, w \in \Sigma^* : uvw \in L \}$, then L-*Constr-Sync *$\equiv_m^{\log} L'$-*Constr-Sync*.*

In [28], the unconstrained synchronization problem can be decided in polynomial time by verifying that every pair of states can be synchronized. In essence, we generalize this algorithm here for returning constraint automata.

▶ **Lemma 16.** *Let $A = (\Sigma, Q, \delta)$ be a DCSA. If the constraint automaton $\mathcal{B} = (\Sigma, P, \mu, p_0, F)$ is returning, then A is synchronizing with respect to $\mathcal{B}$ if and only if for all $q, q' \in Q$ we find $w \in \Sigma^*$ with $\mu(p_0, w) = p_0$ such that $\delta(q, w) = \delta(q', w)$.*

Proof sketch. If $u \in L(\mathcal{B})$ is a synchronizing word for A, u collapses any pair of states, but this is also true for $w = uv$ with $\mu(p_0, w) = p_0$ that must exist as $\mathcal{B}$ is returning. Repeatedly using this idea to prolong collapsing words, the somewhat more involved argument for proving the converse implication can be adapted from the unconstrained setting. ◀

As we just have to check pairs of states we can devise a polynomial-time algorithm to decide $L(\mathcal{B})$-Constr-Sync of a returning automaton $\mathcal{B}$.

▶ **Theorem 17.** *If $\mathcal{B} = (\Sigma, P, \mu, p_0, F)$ is returning, then $L(\mathcal{B})$-*Constr-Sync *$\in$ P.*

Proof. Let $A = (\Sigma, Q, \delta)$ be an DCSA with $n = |Q|$. Let $m = |P|$. From A, we construct the DCSA $A^{\leq 2} = (\Sigma, \binom{Q}{\leq 2}, \delta')$. Then, for each two-element set $\{q_1, q_2\} \in \binom{Q}{\leq 2}$, define $A' = A^{\leq 2}_{\{q_1,q_2\},Q}$, identifying Q with all 1-element state sets. We check for each two-element set $\{q_1, q_2\} \in \binom{Q}{\leq 2}$ if $L(A') \cap L(\mathcal{B}_{p_0,\{p_0\}}) \neq \emptyset$. By Lemma 16, the DCSA A is synchronizing with respect to $\mathcal{B}$ if and only if each intersection is non-empty. Each of the $\binom{n}{2}$ intersections can be checked by using the product-automaton construction in time $\mathcal{O}\left((n + \binom{n}{2})m\right)$. ◀

Our considerations can be turned into a polynomial-time algorithm for computing a synchronizing word for A with respect to $\mathcal{B}$, which implies the following result.

▶ **Corollary 18.** *If the constraint automaton $\mathcal{B}$ is returning, a shortest synchronizing word with respect to $\mathcal{B}$ is polynomially bounded in the size of the input automaton.*

▶ **Theorem 19.** *Let $\mathcal{B} = (\Sigma, P, \mu, p_0, F)$ be a PDFA. Then, $L(\mathcal{B})$-*Constr-Sync *$\in$ NP if there is a $\sigma \in \Sigma$ such that for all states $p \in P$, if $L(\mathcal{B}_{p,\{p\}})$ is infinite, then $L(\mathcal{B}_{p,\{p\}}) \subseteq \{\sigma\}^*$.*

Proof. By assumption, the letters in $\Sigma \setminus \{\sigma\}$ do not appear in any pumpable substring. Hence, their number in a word in $L(\mathcal{B})$ is bounded by $|P| = m$. Therefore, any word $w \in L(\mathcal{B})$ can be partitioned into at most $2m-1$ substrings $w = u_1 v_1 \dots u_{m-1} v_{m-1} u_m$ with $u_i \in \{\sigma\}^*$ and $v_i \in (\Sigma \setminus \{\sigma\})^*$ for all $i \leq m$. Note that $|v_i| \leq m-1$, for all $i < m$. Let $A = (\Sigma, Q, \delta)$ be a yes-instance of $L(\mathcal{B})$-Constr-Sync with $|Q| = n$. Let k be the number of sun-structures in A_σ. Let $w \in L(\mathcal{B})$ be a synchronizing word for A partitioned as mentioned above.

▷ Claim 1. If for some $i \leq m$, $|u_i| > (mn)^k + n$, then we can replace u_i by some $u_i' \in \{\sigma\}^*$ with $|u_i'| \leq (mn)^k + n$, yielding a word $w' \in L(\mathcal{B})$ that synchronizes A.

We will now show that we can decide whether A is synchronizing with respect to $\mathcal{B}$ in polynomial time using nondeterminism despite the fact that an actual synchronizing word might be exponentially large. This problem is circumvented by some preprocessing based on modulo arithmetics. This allows us to guess a binary representation $\mathrm{bin}(u_i)$ of $|u_i|$ instead of u_i itself. Hence, we guess $w_{\mathrm{bin}} = \mathrm{bin}(u_1)v_1 \dots \mathrm{bin}(u_{m-1})v_{m-1}\,\mathrm{bin}(u_m)$. Since all u_i are single exponential in size, the length of w_{bin} is polynomially bounded in the size of A.

▷ Claim 2. For each $q \in Q$, one can compute in polynomial time numbers $\ell(q), \tau(q) \leq n$ such that, given some number x in binary, based on $\ell(q), \tau(q)$, one can compute in polynomial time a number $y \leq n$ such that $\delta(q, a^x) = \delta(q, a^y)$.

As $\mathcal{B}$ is even fixed, we can do a similar preprocessing also for $\mathcal{B}$ in polynomial time.

The NP-machine guesses w_{bin} part-by-part, keeping track of the set S of active states of A and of the current state p of $\mathcal{B}$. Initially, $S = Q$ and $p = p_0$. When guessing the number $x_i = |u_i|$ in binary, by Claim 1 we guess $\log(|u_i|) \leq \log((mn)^k + n) \in O(n \log n)$ many bits. By Claim 2, we can update $S := \delta(S, \sigma^{x_i})$ and $p := \mu(p, \sigma^{x_i})$ in polynomial time. After guessing v_i, we can simply update $S := \delta(S, v_i)$ and $p := \mu(p, v_i)$ by simulating this input, as $|v_i| \leq m = |P|$, which is a constant in our setting. Finally, check if $|S| = 1$ and if $p \in F$. ◀

Observe that our NP-algorithm was guessing at most $b(n,k) \in O((k+1)\log(nm))$ many bits with $b(n,k) \leq m^2 \log(|\Sigma|) + (m-1)(k+1)(\log(m) + \log(n))$. As m and $|\Sigma|$ are constants and as $n, k < n$ depend on A, we can determinize this algorithm by testing $b(n,k)$ many bits.

▶ **Corollary 20.** *Under the assumptions of Theorem 19, $L(\mathcal{B})$-Constr-Sync is in XP with parameter k counting the number of sun-structures in A_σ for an input DCSA A.*

When $k = 1$, we face a one-cluster automaton, see [4].

After these more general thoughts, we focus on two-state constraint automata $\mathcal{B}$, giving a complete picture of the complexity of $L(\mathcal{B})$-Constr-Sync over alphabets Σ with $|\Sigma| \leq 3$.

4 Constraint Automata with Two States and Two or Three Letters

There are already very many 2-state PDFA. We explain why we need to consider only one automaton for each automaton code listed in Tables 1 and 2. Here, we consider 1 as the start state and $\{2\}$ as the set of final states and call this the *standard interpretation* of a code.

▶ **Lemma 21.** *Let $\mathcal{B} = (\Sigma, P, \mu)$ be some partial deterministic semi-automaton with two states, i.e., $P = \{1, 2\}$. Then, for each $p_0 \in P$ and each $F \subseteq P$, either $L(\mathcal{B}_{p_0,F})$-Constr-Sync $\in$ P, or $L(\mathcal{B}_{p_0,F})$-Constr-Sync $\equiv_m^{\log}$ $L(\mathcal{B}')$-Constr-Sync for a PDFA $\mathcal{B}' = (\Sigma, P', \mu', 1, \{2\})$.*

Hence, we only need to specify $\mathcal{B} = (\Sigma, \{1, 2\}, \mu)$ in the following. Let $\Sigma_{ij} := \{\, a \in \Sigma \mid \mu(i, a) = j \,\}$ for $1 \leq i, j \leq 2$. As $\mathcal{B}$ is deterministic, $\Sigma_{i1} \cap \Sigma_{i2} = \emptyset$. Consider easy cases first.

Table 1 List of all PDFAs with two states and a binary alphabet, with $\Sigma_{1,2} = \{a, b\}$ or $\Sigma_{1,2} = \{b\}$.

Automaton code	Why in P?	Automaton code	Why in P?
`[ * 2 ‡ 1 * ]`	$a \in \Sigma_{2,1}$ Propos. 22, (2)	`[ 2 2 ‡ 2 - ]`	Theorem 24
`[ * 2 ‡ * 1 ]`	$b \in \Sigma_{2,1}$ Propos. 22, (2)	`[ 2 2 ‡ - 2 ]`	Isomorphic to `[ 2 2 ‡ 2 - ]`
`[ * 2 ‡ 2 2 ]`	$\Sigma_{1,1} \cup \Sigma_{1,2} = \Sigma_{2,2}$ Propos. 22, (3)	`[ {2,-} 2 ‡ - - ]`	$\Sigma_{1,1} \cup \Sigma_{2,2} = \emptyset$ Propos. 22, (4)
`[ 1 2 ‡ {-,2} - ]`	Theorem 24	`[ - 2 ‡ 2 - ]`	Theorem 24
`[ 1 2 ‡ - 2 ]`	Theorem 24	`[ - 2 ‡ - 2 ]`	$\Sigma_{1,1} \cup \Sigma_{1,2} = \Sigma_{2,2}$ Propos. 22, (3)

▶ **Proposition 22.** *If one of the following conditions hold, then $L(\mathcal{B}_{1,\{2\}})$-*Constr-Sync *$\in$ P: (1) $\Sigma_{1,2} = \emptyset$, (2) $\Sigma_{2,1} \neq \emptyset$, (3) $\Sigma_{1,1} \cup \Sigma_{1,2} \subseteq \Sigma_{2,2}$, or (4) $\Sigma_{1,1} \cup \Sigma_{2,2} = \emptyset$.*

Proof. (1) If $\Sigma_{1,2} = \emptyset$ means $L(\mathcal{B}_{1,\{2\}}) = \emptyset$. (2) If $\Sigma_{2,1} \neq \emptyset$, then $\mathcal{B}$ is returning (Theorem 17). (3) Lemma 11 and Theorem 14 cover this case. (4) Now, $L(\mathcal{B}_{1,\{2\}})$ is finite. ◀

For $\mathcal{B} = (\Sigma, \{1, 2\}, \mu)$ and $x \in \Sigma_{1,2}$, let $\mathcal{B}^x$ denote the variation with transition function μ^x defined by $\mu^x = \mu \cap (\{\, (p, y, p) \mid p \in \{1, 2\}, y \in \Sigma \,\} \cup \{(1, x, 2)\})$. Then Lemma 13 implies:

▶ **Lemma 23.** *If $L(\mathcal{B}^x_{1,\{2\}})$-*Constr-Sync *$\in$ P for each $x \in \Sigma_{1,2}$ and if $\Sigma_{2,1} = \emptyset$, then $L(\mathcal{B}_{1,\{2\}})$-*Constr-Sync *$\in$ P.*

Lemma 23 gives some final arguments why we only study the standard interpretation.

For 2-state constraint automata with alphabet $\Sigma = \{a, b\}$, in order to avoid isomorphic automata and by Proposition 22, we can assume that either (1) $a \in \Sigma_{1,1}$ and $b \in \Sigma_{1,2}$ and $|\Sigma_{2,2}| \leq 1$ or (2) $a \in \Sigma_{1,2}$ but $b \notin \Sigma_{1,1}$ and $|\Sigma_{2,2}| > 0$. See Table 1.

The constrained synchronization problem for constraint automata with a binary alphabet is not easy in general, as we have seen already in Proposition 1 for 3-state constraint PDFA.

▶ **Theorem 24.** *For any two-state binary PDFA $\mathcal{B}$, $L(\mathcal{B})$-*Constr-Sync *$\in$ P.*

Proof. By Table 1, we only need to show the claim for $\mathcal{B}_1$ = `[ 1 2 ‡ 2 - ]`, $\mathcal{B}_2$ = `[ 1 2 ‡ - 2 ]`, $\mathcal{B}_3$ = `[ 1 2 ‡ - - ]`, $\mathcal{B}_4$ = `[ - 2 ‡ 2 - ]`, and $\mathcal{B}_5$ = `[ 2 2 ‡ 2 - ]`. Let $A = (\Sigma, Q, \delta)$ be a DCSA with $n := |Q| - 1$. Consider the first PDFA $\mathcal{B}_1$ with $L(\mathcal{B}_1) = a^*ba^*$. Let $a^\ell ba^m$ be some synchronizing word for A, then by Lemma 8, applied to A_a, we have $\delta(Q, a^\ell) = \delta(Q, a^j)$ for some $j \leq n$, and moreover, by a similar argument, we find $k \leq n$ with $\delta(\delta(Q, a^j b), a^m) = \delta(\delta(Q, a^j b), a^k)$. So, the word $a^j ba^k$ is synchronizing and according to Lemma 3 the word $a^n ba^n$ is also synchronizing. In order to decide synchronizability with respect to $\mathcal{B}_1$, we simply have to check this last word. With the same argument, for $\mathcal{B}_2$ we only have to test the word $a^n b^n$, for $\mathcal{B}_3$ the word $a^n b$, and for $\mathcal{B}_4$ the word ba^n. As $\mathcal{B}_5$ accepts the union of $L(\mathcal{B}_4)$ and a unary regular language, the claim follows with Corollary 9 and Lemma 13. ◀

Next, we give a full classification on the complexity of the constrained synchronization problem for constraint automata with two states and a ternary alphabet. As can be verified by a case-by-case analysis, the only automaton with a constrained synchronization problem in P not covered by the generalization results in Section 3 is `[ 1 2 - ‡ - - 2 ]`.

▶ **Theorem 25.** *Let $\mathcal{B}$ = `[ 1 2 - ‡ - - 2 ]`. Then $L(\mathcal{B})$-*Constr-Sync *is in P.*

Proof. The language accepted by the constraint automaton $\mathcal{B}$ = `[ 1 2 - ‡ - - 2 ]` is a^*bc^*. Let $A = (\Sigma, Q, \delta)$ be a DCSA, $n = |Q|$. By arguments along the lines of the proof of Theorem 24, one can show that there is a synchronizing word for A with respect to $\mathcal{B}$ if and only if $a^n bc^n$ synchronizes A. This condition is easy to check. ◀

Table 2 Constraint automata (2 states, 3 letters) causing PSPACE-hard synchronization.

Case	Automaton code	Language
1	[2 - - ‡ - 2 2]	$a(b+c)^*$
	[2 2 2 ‡ 2 2 -]	$(a+b+c)(a+b)^*$
	[2 2 - ‡ 2 - 2]	$(a+b)(a+c)^*$
2	[1 1 2 ‡ - - -]	$(a+b)^*c$
	[1 1 2 ‡ 2 - -]	$(a+b)^*ca^*$
	[1 1 2 ‡ 2 2 -]	$(a+b)^*c(a+b)^*$
	[1 1 2 ‡ - - 2]	$(a+b)^*cc^*$
3	[1 2 - ‡ 2 - 2]	$a^*b(a+c)^*$
	[1 2 2 ‡ 2 2 -]	$a^*(b+c)(a+b)^*$
4	[1 2 - ‡ - 2 2]	$a^*b(b+c)^*$
	[1 1 2 ‡ - 2 2]	$(a+b)^*c(b+c)^*$
	[1 2 2 ‡ - 2 2]	$a^*(b+c)(b+c)^*$

The leftover two-state automata over a ternary alphabet are listed in Table 2. For all of them, the corresponding constrained synchronization problem is PSPACE-complete (see Theorem 26). We want to point out that there is no constraint automaton with two states and a ternary alphabet for which the $L(\mathcal{B})$-Constr-Sync is not either PSPACE-complete or contained in P, as we covered all possible automata of this kind.

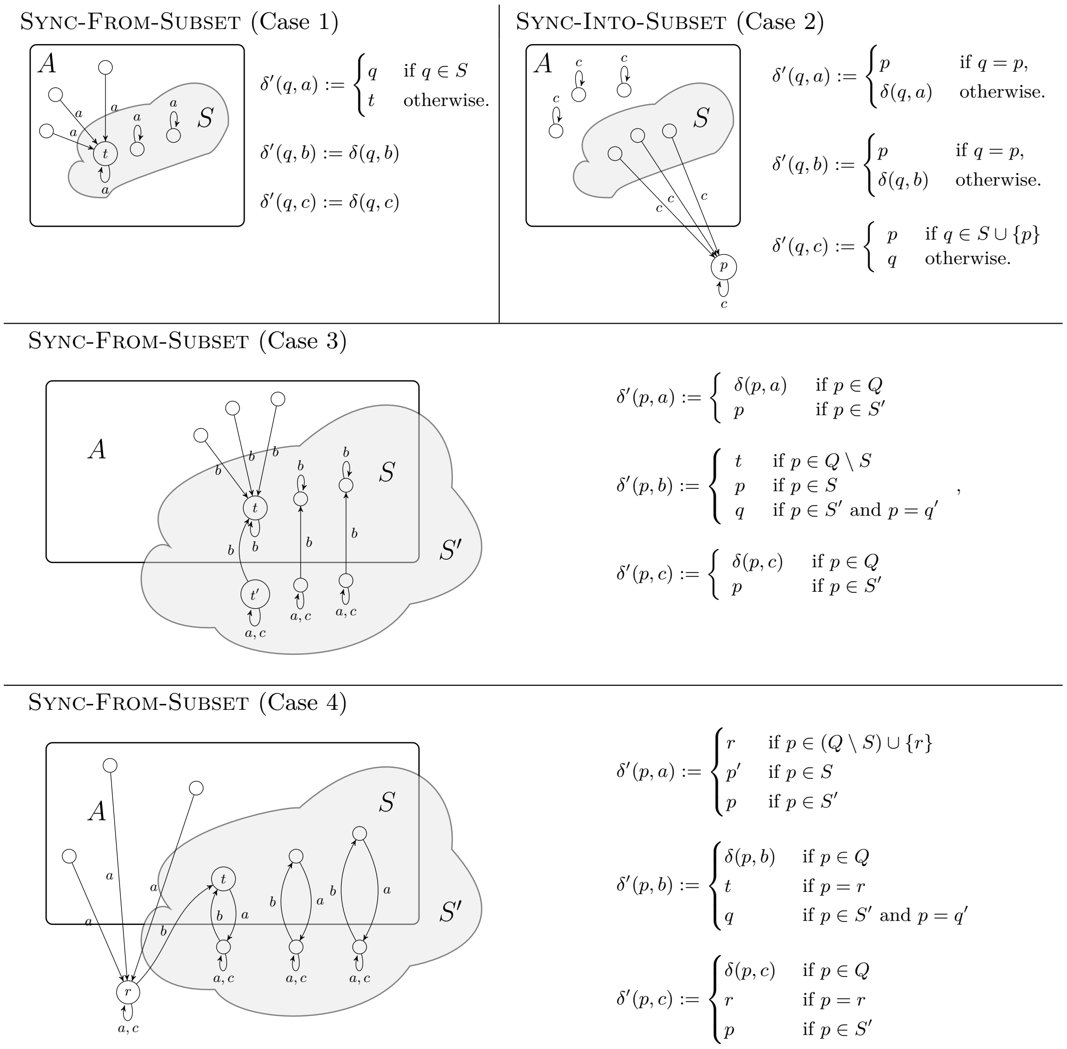
▶ **Theorem 26.** *For each constraint automaton $\mathcal{B}$ in Table 2 the problem $L(\mathcal{B})$-*Constr-Sync *is PSPACE-hard.*

Proof. We prove each case separately by giving an explicit reduction for one of the automata, the statement for the other automata of that case follows by the same argument. Our reductions are illustrated in Figure 2. Each reduction is starting out from (A, S), with $A = (\Sigma, Q, \delta)$ being a DCSA and $S \subseteq Q$. Depending on the considered case, (A, S) is either an instance of Sync-From-Subset (or of Sync-Into-Subset, resp.). We construct from A a DCSA $A' = (\Sigma', Q', \delta')$, with $\Sigma' = \Sigma \cup \{\sigma\}$ for an appropriately chosen letter $\sigma \notin \Sigma$, such that there exists $w \in \Sigma^*$ with $|\delta(S, w)| = 1$ (or $\delta(Q, w) \subseteq S$, resp.) if and only if A' is synchronizing with respect to $\mathcal{B}$. This construction is described and illustrated in Figure 2.

Case 1: Consider the first automaton $\mathcal{B} =$ [2 - - ‡ - 2 2]. Then, $L(\mathcal{B}) = a(b+c)^*$. We reduce from the PSPACE-complete problem Sync-From-Subset for the binary alphabet $\Sigma = \{b, c\}$. Since the constraint automaton forces us to read an a as the first letter, we start synchronizing A' with $\delta'(Q, a) = S$. After the first a, we are allowed to read any letter from Σ. Hence, if $|\delta(S, w)| = 1$ by a word $w \in \Sigma^*$, then $aw \in L(\mathcal{B})$ synchronizes A'. Conversely, if there exists a word v that synchronizes A' with respect to $\mathcal{B}$, then v must be of the form $v = au$ with $u \in \{b, c\}^*$. By the definition of δ', $|\delta(S, u)| = 1$.

The PSPACE-hardness of constrained synchronization with respect to the PDFA [2 2 2 ‡ 2 2 -] with the language $(a + b + c)(a + b)^*$ follows with the same reduction with the letters a and c interchanged. The same idea applies to [2 2 - ‡ 2 - 2].

Case 2: The language accepted by $\mathcal{B} =$ [1 1 2 ‡ - - -] is $L(\mathcal{B}) = (a+b)^*c$. We reduce from Sync-Into-Subset. Note that by construction if A' is synchronizing, p must be the unique synchronization state. The state p can only be reached by a transition with the letter c, but the constraint automaton only allows us to read one single c as the last letter of the synchronizing word. Hence, if there exists a synchronizing word w for A' with respect to $\mathcal{B}$, it is of the form uc with $u \in \{a, b\}^*$. Since $\delta'(Q, w) = p$, $\delta'(Q, u) \subseteq \{\, q \in Q \mid \delta'(q, c) = p \,\}$; by definition of δ', this equals the set $S \cup \{p\}$. Hence, u synchronizes the automaton A into a subset of S. Conversely, if w is a word that synchronizes A to a subset of S, by the construction of δ', the word wc synchronizes A' to $\{p\}$ and since $w \in \{a, b\}^*$, $wc \in L(\mathcal{B})$.



Sync-From-Subset (Case 1)

$$\delta'(q,a) := \begin{cases} q & \text{if } q \in S \\ t & \text{otherwise.} \end{cases}$$

$$\delta'(q,b) := \delta(q,b)$$

$$\delta'(q,c) := \delta(q,c)$$

Sync-Into-Subset (Case 2)

$$\delta'(q,a) := \begin{cases} p & \text{if } q = p, \\ \delta(q,a) & \text{otherwise.} \end{cases}$$

$$\delta'(q,b) := \begin{cases} p & \text{if } q = p, \\ \delta(q,b) & \text{otherwise.} \end{cases}$$

$$\delta'(q,c) := \begin{cases} p & \text{if } q \in S \cup \{p\} \\ q & \text{otherwise.} \end{cases}$$

Sync-From-Subset (Case 3)

$$\delta'(p,a) := \begin{cases} \delta(p,a) & \text{if } p \in Q \\ p & \text{if } p \in S' \end{cases}$$

$$\delta'(p,b) := \begin{cases} t & \text{if } p \in Q \setminus S \\ p & \text{if } p \in S \\ q & \text{if } p \in S' \text{ and } p = q' \end{cases},$$

$$\delta'(p,c) := \begin{cases} \delta(p,c) & \text{if } p \in Q \\ p & \text{if } p \in S' \end{cases}$$

Sync-From-Subset (Case 4)

$$\delta'(p,a) := \begin{cases} r & \text{if } p \in (Q \setminus S) \cup \{r\} \\ p' & \text{if } p \in S \\ p & \text{if } p \in S' \end{cases}$$

$$\delta'(p,b) := \begin{cases} \delta(p,b) & \text{if } p \in Q \\ t & \text{if } p = r \\ q & \text{if } p \in S' \text{ and } p = q' \end{cases}$$

$$\delta'(p,c) := \begin{cases} \delta(p,c) & \text{if } p \in Q \\ r & \text{if } p = r \\ p & \text{if } p \in S' \end{cases}$$

Figure 2 Schematic illustration of our reductions. Transitions inherited from A are not shown.

We can only reach the synchronizing state by reading the letter c and for each automaton of this case we are only allowed to read one single letter c. Therefore, allowing additional letters a and b in the synchronizing word after reading the letter c does not change the synchronizability of A' and hence the same construction works for the constraint automata `[ 1 1 2 ‡ 2 - - ]` and `[ 1 1 2 ‡ 2 2 - ]`. The same holds if we allow only additional letters c (and no a or b) after the first c. In A', c only leads in the synchronization state from states in S and is the identity on other states. Therefore, $\delta(q, cc) = \delta(q, c)$ for any state q and the construction of Case 2 also works for the constraint automaton `[ 1 1 2 ‡ - - 2 ]`.

Case 3: The language accepted by $\mathcal{B}$ = `[ 1 2 - ‡ 2 - 2 ]` is $L(\mathcal{B}) = a^*b(a+c)^*$. We reduce from Sync-From-Subset for $\Sigma = \{a, c\}$ similar to the one in Case 1, but we have to ensure that the whole set S is active after reading the letter b, since a preceding a might already merge some states in S. The idea is to add for each state $q \in S$ a new state q' for which we stay in q' with the letters a, c and go to q with the letter b. Therefore, we ensure that $\delta(Q, a^i b) = S$ for every integer i. Since, starting from the whole state set,

A' is precisely in the state set S after the first and only b letter, the rest of the argument follows as in Case 1. For the constraint automaton [1 2 2 ‡ 2 2 -], accepting the language $a^*(b+c)(a+b)^*$, the same idea applies.

Case 4: The language accepted by $\mathcal{B} =$ [1 2 - ‡ - 2 2] is $L(\mathcal{B}) = a^*b(b+c)^*$. Here, we do not have a special letter which appears exactly once in a word from $L(\mathcal{B})$. We will use the optional a letters in order to jump into S, since a word from $L(\mathcal{B})$ that does not contain any a must synchronize the whole state set and therefore also the subset S. We reduce from the problem Sync-From-Subset for the alphabet $\Sigma = \{b, c\}$. We decompose the state set Q with the letter a in S and $Q \setminus S$. The states in S are stored in an annotated copy S' of S. The other states are gathered up in a new state r. With the first b, we restore the set S as the set of active states. The remainder of a synchronizing word then synchronizes S.

If the set S in A is synchronizable to a single state by a word $u \in \{b,c\}^*$, then the word $abu \in L(\mathcal{B})$ synchronizes A' since $\delta'(Q', ab) = S$. For the other direction, assume A' is synchronizing with respect to $\mathcal{B}$ by a word w. Then w is of the form ubv with $u \in a^*$, $v \in \{b,c\}^*$. If $u \neq \epsilon$, then $\delta(Q', ub) = S$ and v synchronizes S to a single state. If $u = \epsilon$, then $S \subseteq \delta'(Q', b) \subseteq Q$ since we never synchronized any states into r and we leave all states in the set $S' \cup \{r\}$ with b and are not able to reach them again. In particular $\delta'(S', b) = S$. Therefore, bv synchronizes S to a single state without ever leaving Q. The same idea can be applied to the constraing automata [1 1 2 ‡ - 2 2] and [1 2 2 ‡ - 2 2]. ◀

5 Generalizations to Lift Results

In this section, we aim for more general results, either by lifting existing cases by homomorphic images, or by identifying common patterns. For a map $\varphi : \Sigma \to \Gamma^*$ we identify it with its natural homomorphism extension $\varphi : \Sigma^* \to \Gamma^*$ without further mentioning.

▶ **Theorem 27.** *Let $L \subseteq \Gamma^*$ and $\varphi : \Sigma^* \to \Gamma^*$ be an homomorphism such that $\varphi(\varphi^{-1}(L)) = L$. Then L-Constr-Sync $\leq_m^{\log}$ $\varphi^{-1}(L)$-Constr-Sync.*

A typical application of the preceding theorem is to lift hardness results from smaller to bigger alphabets; e.g., knowing PSPACE-hardness for the constraint language $a(b+c)^*$ lifts to PSPACE-hardness for the constraint language $a(b+c+d)^*$ via $\varphi : a \mapsto a, b \mapsto b, c \mapsto c, d \mapsto c$.

▶ Remark 28. It is impossible to further generalize the previous result from homomorphisms to mappings induced by deterministic gsm. Such a machine allows to map $(a+b)(a+b)^*$ to $a(b+c)^*$, but the constraint $(a+b)(a+b)^*$ yields a synchronization problem in P.

▶ **Theorem 29.** *Let $L \subseteq \Sigma^*$. Let $\varphi : \Sigma \to \Gamma^*$ be an homomorphism such that $\varphi(\Sigma)$ is a prefix code. Let $c \in \Gamma$ with $\{c\}\Gamma^* \cap \varphi(\Sigma) = \emptyset$. Let $k := \max\{\, \ell \geq 0 \mid \exists u, v \in \Gamma^* : uc^\ell v \in \varphi(\Sigma) \,\}$. Then L-Constr-Sync $\leq_m^{\log}$ $\{c^{k+1}\}\varphi(L)$-Constr-Sync.*

In the special case where c does not occur in $\varphi(\Sigma)$ at all, it is sufficient to choose $k = 0$, i.e., to consider the language $\{c\}\varphi(L)$ as constraint language. With Theorem 29, we can transfer hardness results with constraint language L over arbitrary alphabets to hardness results with constraint languages over a binary alphabet.

▶ Remark 30. With the construction presented in Corollary 1 (see pp. 220-221) in [5] we can lift our hardness results for constrained synchronization with constraint automata with two states and a ternary alphabet to constrained synchronization problems with 6 states and a binary alphabet. More generally we can reduce the alphabet size of a constraint automata from $k = |\Sigma|$ to 2 by enlarging the size of its state set from $n = |Q|$ to $k \cdot n$ without affecting the hardness of the associated constrained synchronization problem.

Up to this point, we did not make use of the fact that constraint languages considered in this paper are given by finite automata. This changes from here onward.

It is hardness-preserving to plug sub-automata of some kind in front of an automata with a hard constrained synchronization problem. A partial automaton A is called *carefully synchronizing* if there exists a synchronizing word w for A such that the transition function of A is defined for w on every state of A.

▶ **Theorem 31.** *Let $\mathcal{B} = (\Sigma^{\mathcal{B}}, P^{\mathcal{B}}, \mu^{\mathcal{B}}, p_0^{\mathcal{B}}, F)$ and $\mathcal{C} = (\Sigma^{\mathcal{C}}, P^{\mathcal{C}}, \mu^{\mathcal{C}}, p_0^{\mathcal{C}}, \emptyset)$ be PDFAs with $P^{\mathcal{B}} \cap P^{\mathcal{C}} = \emptyset$. For $p_x \in P^{\mathcal{C}}$ let $\nu \subseteq \{p_x\} \times (\Sigma^{\mathcal{B}} \cup \Sigma^{\mathcal{C}}) \times \{p_0^{\mathcal{B}}\}$ define the automaton $\mathcal{B}' = (\Sigma^{\mathcal{B}} \cup \Sigma^{\mathcal{C}}, P^{\mathcal{B}} \cup P^{\mathcal{C}}, \mu^{\mathcal{B}} \cup \mu^{\mathcal{C}} \cup \nu, p_0^{\mathcal{C}}, F)$. If the following three conditions are satisfied:*

1. *automaton $\mathcal{B}'$ is deterministic,*
2. *automaton $\mathcal{C}' = (\Sigma^{\mathcal{B}} \cup \Sigma^{\mathcal{C}}, P^{\mathcal{C}} \cup \{p_0^{\mathcal{B}}\}, \mu^{\mathcal{C}} \cup \nu \cup \{p_0^{\mathcal{B}}\} \times (\Sigma^{\mathcal{B}} \cup \Sigma^{\mathcal{C}}) \times \{p_0^{\mathcal{B}}\})$ is carefully synchronizing, and*
3. *there exists a synchronizing word $v = v_1 \dots v_n$ for $\mathcal{C}'$ such that $v_1 \dots v_{n-1} \in L(\mathcal{C}_{p_x})$, where $\mathcal{C}_{p_x}$ results from $\mathcal{C}$ by adding p_x to the set of final states,*

then $L(\mathcal{B})$-Constr-Sync $\leq L(\mathcal{B}')$-Constr-Sync.

Proof. Note that the start state of $\mathcal{B}'$ is the start state of $\mathcal{C}$, but the final states of $\mathcal{B}'$ are the ones from $\mathcal{B}$. Let $A = (\Sigma^{\mathcal{B}}, Q, \delta)$ be a DCSA. We extend A to a DCSA $A' = (\Sigma^{\mathcal{B}} \cup \Sigma^{\mathcal{C}}, Q', \delta')$ in the following way. For every state $q \in Q$ we add a copy of $\mathcal{C}$ to A', where a self-loop is added for every yet undefined transition in A'. The $\mathcal{C}$-copy is connected to q with the transitions in ν where the target $p_0^{\mathcal{B}}$ is replaced by q. Since the automaton $\mathcal{B}'$ is deterministic by condition (1), the $\mathcal{C}$-copies, which are added to A, are also deterministic and so is A'.

It remains to show that A is synchronizing with respect to $\mathcal{B}$ if and only if A' is synchronizing with respect to $\mathcal{B}'$. For the only if direction, assume $w \in L(\mathcal{B})$ is a synchronizing word for A. Considering A', condition (2) states that there exists a word v that, applied to all states of a copy of $\mathcal{C}$, leads every state of this copy through the exit state p_x into the original states of A. Further, condition (3) specifies that the last state leaves through p_x with the last letter of v and that this last state is the image of the start state. Hence v is the label of a path from $p_0^{\mathcal{C}}$ to $p_0^{\mathcal{B}}$ in $\mathcal{B}'$ and $vw \in L(\mathcal{B}')$. Starting in all states of A', the active states in each $\mathcal{C}$-copy act synchronously. Hence, $\delta'(Q', v) = Q$. Note that no state of a $\mathcal{C}$-copy is reachable by a state of Q. Since A' acts like A on Q, $|\delta'(Q, w)| = 1$ and vw is a synchronizing word for A' with respect to $\mathcal{B}'$. For the other direction, we refer to the long version of this paper. ◀

As an illustration, we apply Theorem 31 to a family of languages.

▶ **Corollary 32.** *Let the language-family $\mathcal{L}$ consists of languages $L_i := (b^*a)^i$ with $i \geq 2$. The constrained synchronization problem for all languages in $\mathcal{L}$ is NP-complete.*

6 Conclusions and Prospects

We have commenced a study of synchronization under regular constraints. The complexity landscape of 2-state constraint automata with at most ternary input alphabets is completely understood. In particular, binary alphabets yield polynomial-time solvable synchronization problems, while ternary alphabets split the constrained synchronization problems into polynomial-time solvable and PSPACE-complete cases. As already seen in the introduction, this picture changes with 3-state automata, giving an NP-complete scenario with binary alphabets. Our general results also imply PSPACE-complete synchronization problems for binary constraint automata with at least six states. In the following theorem, we present a three state constraint automaton with a binary alphabet for which the associated constrained synchronization problem is PSPACE-complete, also because of Theorem 10.

▶ **Theorem 33.** *Let* $\mathcal{B} = $ `[ - 2 ‡ 3 3 ‡ 2 - ]` *be a three state PDFA over the alphabet* $\{0, 1\}$ *with start state* 1 *and final state* 3*. The problem* $L(\mathcal{B})$-Constr-Sync *is PSPACE-hard.*

Hence, binary 3-state constraint automata offer easy synchronization problems as well as problems complete for NP and for PSPACE. However, we have no complete complexity picture here, giving a natural research question. Motivated by a remark of Rystsov [23] in a related setting, one could also ask if there are regular language constraints that define synchronization problems that are complete for other levels of the polynomial-time hierarchy. We presented several criteria for a regular language L such that L-Constr-Sync $\in P$ as well as generalization-results to transfer the obtained hardness results for fixed L to larger classes of constraint languages, but a full classification of the complexity of L-Constr-Sync for regular constraint languages L is still an open research problem.

A Constant-Time Colored Choice Dictionary with Almost Robust Iteration

Torben Hagerup
Institut für Informatik, Universität Augsburg, 86135 Augsburg, Germany
hagerup@informatik.uni-augsburg.de

Abstract

A (colored) choice dictionary is a data structure that is initialized with positive integers n and c and subsequently maintains a sequence of n elements of $\{0,\ldots,c-1\}$, called colors, under operations to inspect and to update the color in a given position and to return the position of an occurrence of a given color. Choice dictionaries are fundamental in space-efficient computing. Some applications call for the additional operation of dynamic iteration, i.e., enumeration of the positions containing a given color while the sequence of colors may change. An iteration is robust if it enumerates every position that contains the relevant color throughout the iteration but never enumerates a position more than once or when it does not contain the color in question. We describe the first choice dictionary that executes every operation in constant amortized time and almost robust iteration in constant amortized time per element enumerated. The iteration is robust, except that it may enumerate some elements a second time. The data structure occupies $n\log_2 c+O((\log n)^2)$ bits. The time and space bounds assume that $c=O((\log n)^{1/2}(\log\log n)^{-3/2})$.

1 Introduction

Following similar earlier definitions [3, 5] and concurrently with that of [2], the (colored) choice dictionary was introduced by Hagerup and Kammer [10]. It appears to be fundamental in space-efficient computing and has already been shown to have a number of applications [2, 5, 10, 11, 12]. Its precise definition is as follows:

▶ **Definition 1.1.** *A (colored) choice dictionary is a data structure that can be initialized with integers $n, c \in \mathbb{N}=\{1,2,\ldots\}$ and subsequently maintains a sequence $(e_1,\ldots,e_n)$ of n integers drawn from $\{0,\ldots,c-1\}$, initially $(0,\ldots,0)$, under the following operations:*

color(i) $(i\in\{1,\ldots,n\})$: *Returns e_i.*
setcolor(j,i) $(j\in\{0,\ldots,c-1\}$ *and* $i\in\{1,\ldots,n\})$: *Replaces e_i by j.*
choice(j) $(j\in\{0,\ldots,c-1\})$: *With $S_j=\{i\in\{1,\ldots,n\}: e_i=j\}$, returns an (arbitrary) element of S_j if $S_j\neq\emptyset$, and 0 if $S_j=\emptyset$.*

We call the elements of $\{0,\ldots,c-1\}$ *colors*. The choice dictionary is similar to an array of colors that supports reading (*color*) and writing (*setcolor*), but with a crucial additional operation (*choice*) to locate an occurrence of a given color. Our terminology will sometimes pretend that the elements of $\{1,\ldots,n\}$ have colors. For $j=0,\ldots,c-1$, we define $S_j=\{i\in\{1,\ldots,n\}: e_i=j\}$ as above and call S_j a *color class*.

In some applications of choice dictionaries, notably to the computation of a breadth-first search or BFS forest of a given graph [9, 10], it is essential for a choice dictionary to support the additional operation of iteration over a given color class (while other computation takes place in an interleaved fashion). The BFS algorithms of [9, 10], for instance, repeatedly

iterate over the *gray* vertices, those with a given distance d from a start vertex, in order to identify the vertices at distance $d+1$. This is not straightforward because the algorithms – in order to save colors – also color the vertices at distance $d+1$ gray. In other words, the set of gray vertices changes while it is being iterated over. Hagerup and Kammer [10] coined the phrase *robust iteration* to describe the ideal that one would like to have in such a situation. An iteration over a dynamic set S is robust if every element that belongs to S throughout the iteration is certain to be enumerated by the iteration, while no element is enumerated more than once or at a time when it does not belong to S. Elements that belong to S during part but not all of the iteration may or may not be enumerated. We say that an iteration works in constant time if there are constant-time operations to initialize for a new iteration, to test whether more elements remain to be enumerated, and – if so – to enumerate the next element.

By the information-theoretic lower bound, a choice dictionary with parameters n and c must occupy at least $\lceil n \log c \rceil$ bits ("log" always denotes the binary logarithm function $\log_2$). Kammer and Sajenko [13] recently described a choice dictionary that occupies $n \log c + O(\log n)$ bits and executes every operation including iteration in constant time, but is severely restricted:

- The number c of colors must be a power of 2.
- Moreover, c must be a constant.
- The iteration is *static*: While an iteration is underway, no changes to colors are allowed.

We present a new choice dictionary that also executes every operation including iteration in constant time and alleviates the drawbacks listed above. The number of colors is not restricted to be a power of 2, it is not required to be a constant – but we do impose the condition $c = O((\log n)^{1/2}(\log \log n)^{-3/2})$ – and the iteration is dynamic and almost robust. By "almost robust" we mean that the definition of robust iteration is satisfied, except that some elements may be enumerated a second time (the BFS algorithms discussed above can tolerate this). Compared to the choice dictionary of [13], the new data structure has a few drawbacks of its own:

- It is more complicated.
- The operation times are amortized, not worst-case.
- The number of bits needed is $n \log c + O((\log n)^2)$, not $n \log c + O(\log n)$.

The third drawback should be seen in light of the fact that even if only the operations *color* and *setcolor* (i.e., those of an array) are to be supported in constant time, every known data structure that does not restrict c to be a power of 2 requires $n \log c + \Omega((\log n)^2)$ bits. As for the condition $c = O((\log n)^{1/2}(\log \log n)^{-3/2})$, it may be noted that the performance of comparable choice dictionaries [7, 10] also degrades sharply if the number of colors exceeds similar thresholds.

The main novelty of our work lies in the almost robust iteration. Allowing amortization changes the ground rules of iteration and was crucial to obtaining the results described here. It becomes feasible to begin a dynamic iteration over a color class S_j by an "internal" static iteration that can serve, among other things, to determine $|S_j|$. Enumerating the elements that belong to S_j at that time, i.e., at the start of the iteration, would satisfy the conditions of robustness, but the elements that are enumerated must be handed to a caller one by one, and there is no space to store them temporarily (cf. the BFS algorithms discussed above). Once S_j is allowed to change while it is being iterated over, it becomes difficult to keep track of which elements have already been enumerated and therefore to prevent elements from being enumerated repeatedly and perhaps an unbounded number of times (i.e., the iteration might not terminate). Enumerating the elements of S_j in sorted order would take care of this problem, but constant time per element is not enough to sort. Our iteration sorts a small part of S_j initially. If the changes to S_j during the iteration are relatively few, the partial sorting is sufficient to guarantee robustness. If there are many changes to S_j, on the other hand, these can "pay for" a complete sorting of what remains of S_j. An element is enumerated at most once before and at most once after the complete sorting.

The only previous choice dictionary with robust iteration was devised by Hagerup and Kammer [10], but for worse time and/or space bounds (e.g., constant time together with $n \log c + O(n/(\log n)^t)$ bits for constant c and arbitrary fixed $t \in \mathbb{N}$). It should be noted that in contrast with the robust iteration of [10], if the iteration described here is terminated early, its time bound is the same as if it had run to completion, i.e., incomplete iteration is not supported efficiently.

2 Preliminaries

Our model of computation is the standard word RAM [1, 6] with a word length of $w \in \mathbb{N}$ bits, where we assume that w is large enough to allow all memory words in use to be addressed. As part of ensuring this, we assume that $w \geq \log n$. The word RAM has constant-time operations for addition, subtraction and multiplication modulo 2^w, division with truncation ($(x, y) \mapsto \lfloor x/y \rfloor$ for $y > 0$), left shift modulo 2^w ($(x, y) \mapsto (x \ll y) \bmod 2^w$, where $x \ll y = x \cdot 2^y$), right shift ($(x, y) \mapsto x \gg y = \lfloor x/2^y \rfloor$), and bitwise Boolean operations (AND, OR and XOR (exclusive or)). The machine is also assumed to be able to compute $\lfloor \log x \rfloor$ in constant time for every given $x \in \{1, \ldots, 2^w - 1\}$.

Like all comparable data structures, the new choice dictionary depends on standard low-level word-RAM routines, some of which are conveniently collected in the following lemma.

▶ **Lemma 2.1** ([10], Lemma 3.2). *Let m and f be given integers with $1 \leq m, f < 2^w$ and suppose that a sequence $A = (a_1, \ldots, a_m)$ with $a_i \in \{0, \ldots, 2^f - 1\}$ for $i = 1, \ldots, m$ is given in the form of the (mf)-bit binary representation of the integer $\sum_{i=0}^{m-1} 2^{if} a_{i+1}$. Then the following holds:*

(a) *Let $I_0 = \{i \in \{1, \ldots, m\} : a_i = 0\}$. Then, in $O(1 + mf/w)$ time, we can test whether $I_0 = \emptyset$ and, if not, compute* $\min I_0$.

(b) *If an additional integer $k \in \{0, \ldots, 2^f - 1\}$ is given, then $O(1 + mf/w)$ time suffices to compute the integer $\sum_{i=0}^{m-1} 2^{if} b_{i+1}$, where $b_i = 1$ if $k \geq a_i$ and $b_i = 0$ otherwise for $i = 1, \ldots, m$.*

(c) *If $m < 2^f$ and an additional integer $k \in \{0, \ldots, 2^f - 1\}$ is given, then $\mathit{rank}(k, A) = |\{i \in \{1, \ldots, m\} : k \geq a_i\}|$ can be computed in $O(1 + mf/w)$ time.*

3 Informal Overview

This section tries to convey the basic intuition behind the new data structure. The necessary nitty-gritty details and calculations will be presented in the subsequent sections.

It is known from the work of Dodis, Pătraşcu and Thorup [4] that a sequence of n color values drawn from $\{0, \ldots, c - 1\}$ can be stored in a data structure that occupies $n \log c + O((\log n)^2)$ bits and supports the operations *color* and *setcolor* in constant time. Let us call this structure a *c-ary array*. Our task can be viewed as that of adding efficient *choice* and almost robust iteration to a c-ary array.

Suppose that, in addition to being represented in a c-ary array, the elements of each color class S_j, where $j \in \{0, \ldots, c-1\}$, are organized in a doubly-linked list L_j. Then executing *choice*(j) is trivial – return an arbitrary element of L_j – and with a little care we can also carry out a robust iteration over S_j via a traversal of L_j during which elements that drop out of S_j splice themselves out of L_j and elements that enter S_j are inserted at the beginning of L_j, where they will not be enumerated – they may be "trying to sneak in again" after having already been enumerated in the past.

The problem with the scheme outlined above is, of course, that the doubly-linked lists $L_0, \ldots, L_{c-1}$ would need far too much space – $\Theta(n \log n)$ bits – for two pointers for each of the n elements. In order to alleviate this problem, we divide the n elements into equal-sized groups and represent each group via a data structure called a *container.* Provided that groups are not too large, iteration within a container can be handled efficiently with techniques based on Lemma 2.1. If every container holds at least one element of a color class S_j, we can therefore iterate over S_j by iterating over all containers and enumerating the elements of S_j in each. Thus at this point the problem can be viewed as represented by the containers that are *j-free*, i.e., do not contain any occurrences of j. The list L_j that we would now like to have for each $j \in \{0, \ldots, c-1\}$ chains together those containers that are not j-free. In contrast with what was the case before, a container can belong to many lists, for which reason it may need up to $2c$ pointers rather than just two pointers.

Even though we have reduced the need for pointers from two per element to $2c$ per container, the basic problem remains that we have already used up practically all the available space and cannot afford to store even a single pointer per container. If some color is missing entirely from a container, however, $\log c$ bits per element is a tad more than what is strictly necessary to record the contents of the container. Using a more efficient encoding, we can compress the information stored in the container slightly to leave room for a couple of pointers – provided that containers are sufficiently large. The same is true if a color is not missing completely, but has very few occurrences, as we can then store the sequence of these "exceptional" occurrences explicitly while using the efficient encoding for the other elements in the container. If several colors are missing or rare in a container, we can pack the container even more tightly. As a result, the container has room for a couple of pointers for each such color, which in turn means that we can treat the colors somewhat independently.

Let $j \in \{0, \ldots, c-1\}$ and let us call a container H *j-sparse* if the number of occurrences of j in H is bounded by some suitably chosen r, and *j-abundant* otherwise. For a moment, let us make the unrealistic assumption that all j-sparse containers are to the left of (have smaller indices than) all j-abundant containers. Then we can keep in L_j those containers that are j-sparse (and therefore have room for the necessary pointers) but not j-free (since a main goal is to skip the j-free containers). To iterate over S_j, iterate both over L_j and over the j-abundant containers. The latter is easy because the j-abundant containers, by assumption, are consecutively numbered.

Even though the unrealistic assumption is unrealistic, we can still keep track of the number μ_j of j-sparse containers and imagine that the leftmost μ_j containers (say that these form the *left part*) "normally" are j-sparse. There may be containers that go against the norm, j-abundant containers in the left part – call these *j-masters* – and j-sparse containers in the right part, *j-slaves.* It is easy to see that the number of j-masters equals the number of j-slaves, and the *in-place chain technique* of Katoh and Goto [14] suggests to maintain a perfect matching between the j-masters and the j-slaves. This helps us to solve two problems: (1) A j-master, by virtue of not being in the right part, needs to belong to L_j in order to be iterated over, but has no room for pointers. (2) Because it is in the right part, a j-slave is iterated over, but may be j-free, in which case it cannot "pay for" its share of the iteration. To solve problem (1), we relocate some of the data of the master to the slave, which has room to spare. As for problem (2), even though the slave cannot "pay", its master can.

We cannot keep track of the number of occurrences of a color j in a container once that number exceeds r, and therefore replace the notions j-sparse and j-abundant by algorithmically more tractable j*-weak* and j*-strong*. A j-weak container is certain to be j-sparse, but a j-strong container may be j-sparse or j-abundant. If the number of occurrences of j in a j-weak container H grows beyond r, H is converted to being j-strong. A conversion of H back to j-weak, however, takes place only if and when H is later discovered to have fewer than r occurrences of j, and this in turn happens essentially only in connection with an iteration over H. The iteration can "pay" a constant for each element that is enumerated, and the operations that changed the colors of the other elements formerly of color j can "pay" a constant for each of these. In an amortized setting, therefore, a conversion between j-weak and j-strong can be allowed to have a cost of $O(r)$, and r is chosen accordingly. A budget of $O(r)$ also covers the conversion of a j-strong container, for the purpose of iteration over the container, from the very compact usual representation to one that supports efficient iteration.

A final problem is represented by containers that migrate from the left to the right side (as a consequence of a decrease in μ_j). Such a container might be iterated over on the left side, because it belongs to L_j, and later again as a container on the right side. In order to prevent elements from being enumerated repeatedly, the iteration is designed to enumerate elements roughly in sorted order. In more detail, first the number $|L_j|$ of containers in L_j is determined, and then the containers in L_j that belong to a "buffer zone" of width $|L_j|^2$ at the right end of the left part are sorted, which can happen in $O(|L_j|+1)$ time, and placed last in L_j. If the buffer zone is consumed entirely, i.e., migrates completely to the right part before it starts to take part in the iteration, this is evidence of so many color changes during the iteration that we can afford to sort the remaining containers in L_j. After that point in time, an element is enumerated at most once, but it may also have been enumerated once before the sorting. If some part of the buffer zone remains in the left part throughout the iteration over the part of L_j on its left, on the other hand, the order of iteration over the containers on its left is immaterial, and the iteration is robust.

4 The Data Representation

This section describes the organization of data in the choice dictionary after it has been initialized with parameters $n, c \geq 2$ with $c = O((\log n)^{1/2}(\log\log n)^{-3/2})$. We first describe a slightly bigger data structure that uses $n \log c + O(c(\log n)^2)$ bits.

For a positive integer $s = \Theta(c \log n)$, we divide the sequence $(e_1, \ldots, e_n)$ of n color values to be maintained into $N = \lfloor n/s \rfloor$ subsequences of exactly s consecutive color values each, with at most $s-1$ color values left over. The left-over color values can be handled separately in $O(s \log s) = O((\log n)^2)$ bits, essentially by keeping a doubly-linked list for each color of the positions in which the color occurs. We omit the easy details and assume in the following that n is a multiple of s. For $\ell = 1, \ldots, N$, the ℓth subsequence is stored in a data structure H_ℓ called a *container* (as anticipated in the previous section). Each container partitions the set $\{0, \ldots, c-1\}$ of colors into a set of *weak* colors and the complementary set of *strong* colors. If a color $j \in \{0, \ldots, c-1\}$ is weak in a container H, we call H j*-weak*; otherwise H is j*-strong* (again, these terms as well as notation introduced below were used already in Section 3). For $j = 0, \ldots, c-1$, we keep a global count $\mu_j \in \{0, \ldots, N\}$ of the number of j-weak containers. For $\ell \in \{1, \ldots, N\}$ and $j \in \{0, \ldots, c-1\}$, we say that H_ℓ is *j-left* if $\ell \le \mu_j$ and *j-right* if $\ell > \mu_j$. Finally, we call H_ℓ *j-free* if the sequence of color values stored in H_ℓ does not contain any occurrence of j.

Let $\ell \in \{1, \ldots, N\}$ and suppose that $(a_0, \ldots, a_{s-1})$ is the subsequence of color values stored in H_ℓ – thus $a_i = e_{(\ell-1)s+i+1}$ for $i = 0, \ldots, s-1$. If H_ℓ is j-weak, where $j \in \{0, \ldots, c-1\}$, we require the number $|\{i \in \{0, \ldots, s-1\} : a_i = j\}|$ of occurrences of j in H_ℓ to be bounded by a positive integer r with $r = \Theta(\log n/(c \log\log n))$.

If H_ℓ is j-strong and j-right for all $j \in \{0, \ldots, c-1\}$, H_ℓ is *atomic*, by which we mean that its representation, which we will call $D_{\overline{W}}$, consists of the single integer $x = \sum_{i=0}^{s-1} a_i c^i$. Provided that we keep a table of the powers $c^0, c^1, \ldots, c^{s-1}$, we can then inspect and update individual values in $(a_0, \ldots, a_{s-1})$ with a constant number of arithmetic operations. E.g., $a_i = \lfloor x/c^i \rfloor \bmod c$ for $i = 0, \ldots, s-1$. This does not necessarily translate into constant time, as we may not be able to operate on integers as large as c^s in constant time. To remedy this, we obtain s as $s_0 s_1$, where s_0 and s_1 are positive integers with $s_0 = \Theta(\log n/\log c)$ and $s_1 = \Theta(c \log c)$, and actually represent x through s_1 digits – called *big digits* – to base $C = c^{s_0} = n^{O(1)}$. We can operate on big digits in constant time, and it is easy to see that we can still inspect and update individual color values by operating only on the appropriate big digit. Now we need only the powers $c^0, \ldots, c^{s_0-1}$. For reasons that will become clear shortly, we store in fact a table of all powers bounded by C of the form i^k, where $i \in \{2, \ldots, c\}$ and $k \in \mathbb{N}$. The number of bits required for the table is easily seen to be $O(c(\log n)^2)$.

In all other cases, namely if H_ℓ is j-weak or j-left for at least one $j \in \{0, \ldots, c-1\}$, H_ℓ is *composite*, namely represented through a collection of four substructures: D_{C}, which stores information concerning the roles played by the various colors in H_ℓ; D_W and $D_{\overline{W}}$, which specify the distribution of weak and strong colors in H_ℓ, respectively; and D_{P}, which links H_ℓ to other containers. The details are as follows:

- First, for various subsets M of $\{0, \ldots, c-1\}$ we store $\mathit{rank}_M(j) = |\{i \in M : i \le j\}|$ for $j = 0, \ldots, c-1$ and $\mathit{select}_M(k) = \min\{j \in \mathbb{N} \cup \{0\} : \mathit{rank}_M(j) = k\}$ for $k = 1, \ldots, |M|$. Thus we store a table of rank_M, which numbers the elements of M consecutively, and a table of select_M, which realizes the inverse mapping. In detail, let W, $\overline{W}$, R and $\overline{R}$ be the sets of colors j for which H_ℓ is j-weak, j-strong, j-right and j-left, respectively, Then we store tables of *rank* and *select* for all of the sets W, $\overline{W}$, R and $\overline{R}$ as well as for all unions and intersections of two of these (we actually need only a few of the tables). D_{C} is the collection of these tables, which occupy $O(c \log c)$ bits and can be computed from W and R in $O(c)$ time.
- Second, D_W stores the set $\{(i, a_i) \mid i \in \{0, \ldots, s-1\}$ and $a_i \in W\}$ and, more abstractly, maintains a subset A of $\{0, \ldots, s-1\} \times \{0, \ldots, c-1\}$ and supports the following operations in constant time:
  - Given a pair $(i, j) \in A$, delete it from A.
  - Given a pair $(i, j) \in \{0, \ldots, s-1\} \times \{0, \ldots, c-1\}$, insert it in A, provided that before the operation no pair in A has first component i and fewer than r pairs in A have second component j.
  - Given $i \in \{0, \ldots, s-1\}$, return the pair of the form (i, j) in A or an indication that A contains no such pair.
  - Given $(i, j) \in \{0, \ldots, s-1\} \times \{0, \ldots, c-1\}$, return the pair of the form (i', j) in A with $i' \ge i$ for which i' is minimal or an indication that A contains no such pair.
  - Given $j \in \{0, \ldots, c-1\}$, return the number of pairs of the form (i, j) in A.

  D_W can be thought of as an embellished associative array for the weak colors. What makes its realization easy is the fact that the number of pairs in A at all times is bounded by cr, while every component of a pair is an integer of f bits, where $f = O(\log s) = O(\log\log n)$. We can simply store $|A|$, an integer of $O(\log(cr)) = O(\log\log n)$ bits, and two arrays A_1 and A_2 of cr f-bit entries each such that the first $|A|$ entries in A_1 contain the first components of the pairs in A in sorted order and the first $|A|$ entries in A_2 contain their second components in the corresponding order, i.e., so that the two components of each pair have the same index in A_1 and A_2. Each of A_1 and A_2 is stored as a single integer of $crf = O(\log n)$ bits, and without loss of generality (choose s_0 and hence s sufficiently large) we will assume that D_{C} and D_W fit together in a single big digit.

To delete a pair (i, j) from A, we can form the bitwise XOR of A_1 with an integer that contains the integer i in each of $|A|$ f-bit fields and can be obtained in constant time with a multiplication, and subsequently use the algorithm of Lemma 2.1(a) to discover the position in A_1 and A_2 of the pair (i, j) (or an indication that (i, j) does not occur in A). After subtracting 1 from the variable that stores $|A|$, we can easily carry out the remainder of the operation, namely prizing out a field from A_1 and A_2 and closing the gap, in constant time with a combination of bitwise Boolean operations, applications of bit masks and shifts.

When inserting a pair (i, j) in A, rather than an exact match of i in A_1, we want to find the correct place in which to insert i while keeping A_1 sorted. We therefore use part (c) instead of part (a) of Lemma 2.1, but can otherwise proceed similarly as in the case of a deletion. The remaining operations listed above can be implemented to work in constant time in similar ways and are left to the interested reader (the last operation can also be handled by maintaining an additional array of counts).

- Third, the distribution of strong colors in H_ℓ is recorded in $D_{\overline{W}}$ in one of several formats, chosen in dependence of $|\overline{W}|$ and c: If $|\overline{W}| = 0$, there are no strong colors in H_ℓ, and $D_{\overline{W}}$ is a dummy data structure (denoted by $\emptyset$, say) that takes up no space. If $|\overline{W}| = 1$ and $c = 2$, we also take $D_{\overline{W}} = \emptyset$, since the necessary information can be gleaned from D_W – an element whose color is stored in H_ℓ has the strong color precisely if it does not have the weak color. If $1 \le |\overline{W}| \le c - 2$, $D_{\overline{W}}$ stores the sequence $(a'_0, \ldots, a'_{s-1})$, where $a'_i = 0$ if $a_i \in W$ and $a'_i = \mathit{rank}_{\overline{W}}(a_i)$ if $a_i \in \overline{W}$, for $i = 0, \ldots, s - 1$, essentially in the form of the integer $y = \sum_{i=0}^{s-1} a'_i(|\overline{W}|+1)^i$. In other words, every weak color is encoded via a zero, the strong colors are encoded via the integers $1, \ldots, |\overline{W}|$, and the sequence of codes is represented similarly as for atomic containers. Finally, if $|\overline{W}| \ge \max\{c-1, 2\}$, we redefine a'_i as $\mathit{rank}_{\overline{W}}(a_i) - 1$ for $a_i \in \overline{W}$ and store $y = \sum_{i=0}^{s-1} a'_i|\overline{W}|^i$. Thus for $|\overline{W}| = c - 1 \ge 2$ we give up on distinguishing between the weak color and one strong color.

Informally, the idea behind D_W and $D_{\overline{W}}$ is that weak colors have only few occurrences, which can be stored in little space by listing them explicitly (in D_W), while this allows the strong colors to be represented more economically via smaller codes (in $D_{\overline{W}}$). Having two distinct conventions for y is a necessary complication: We must be able to store H_ℓ in less space even if only a single color is weak, which precludes the use of the first convention (i.e., reserving a code value for weak colors) when $|\overline{W}| \ge c - 1$. On the other hand, the second convention (not distinguishing between weak colors and the smallest strong color j_0) cannot be used when $|W| = c - |\overline{W}|$ is large, since it requires us to find the occurrences of j_0 by testing all occurrences of a zero in $(a'_0, \ldots, a'_{s-1})$ and filtering out those that correspond to weak colors – we cannot allow too many "false positives". Moreover, the case $|\overline{W}| = c - 1$ must be handled separately in $D_{\overline{W}}$ for $c = 2$ (namely not at all), because $|\overline{W}| = 1$ cannot be used as the basis of a positional system.

As was the case for x, if $1 \le |\overline{W}| \le c - 2$ or $|\overline{W}| \ge \max\{c-1, 2\}$ it is necessary to express y through a sequence of big digits but, unless $|\overline{W}| = c$, the task is now hampered by rounding issues. Assume that $|\overline{W}| \le c - 1$. The s *small digits* to base $|\overline{W}| + h$, where $h = 1$

if $1 \le |\overline{W}| \le c-2$ and $h = 0$ if $|\overline{W}| = c-1 \ge 2$, are to be distributed over a number of big digits to base $C = c^{s_0}$. A single big digit can accommodate $\lfloor (s_0 \ln c)/\ln(|\overline{W}|+h)\rfloor$ small digits. Now $\ln(|\overline{W}|+h) = \ln(c-|W|+h) = \ln c+\ln(1-(|W|-h)/c) \le \ln c-(|W|-h)/c \le \ln c - |W|/(2c)$ and

$$\frac{s_0 \ln c}{\ln(|\overline{W}|+h)} \ge \frac{s_0 \ln c}{\ln c - |W|/(2c)} = \frac{s_0}{1-|W|/(2c\ln c)} \ge s_0(1+|W|/(2c\ln c)).$$

Since $|W| \ge 1$ and $s_0/(c\ln c) = \Omega(\ln n/(c(\ln c)^2)) = \omega(1)$, we may conclude that a big digit can accommodate $s_0(1+\Omega(|W|/(c\ln c)))$ small digits (even taking the $\lfloor\cdots\rfloor$ operation into account). Moreover, since

$$\frac{s}{s_0(1+\Omega(|W|/(c\ln c)))} = \frac{s_1}{1+\Omega(|W|/(c\ln c))} = s_1(1-\Omega(|W|/(c\ln c)))$$

and $s_1 = \Theta(c\ln c)$, by choosing s_1 and hence s sufficiently large we can ensure that the total number of big digits necessary to accommodate all s small digits is at most $s_1 - 2K|W|$ for an arbitrary constant $K \in \mathbb{N}$ of our choice (but independent of s).

- Fourth and finally, D_{P} is an array that maps each color $j \in \{0,\ldots,c-1\}$ for which H_ℓ is j-weak or j-left to a *block* of three pointers, each of which points to a container or has the value *null* (points to nothing). By choosing s_0 and therefore s sufficiently large, we can assume that a block fits in a big digit. Two of the pointers stored for a color j are used to organize certain j-left containers in a doubly-linked list L_j, namely those that are j-strong or not j-free (informally, those that might contain occurrences of j). The third pointer, called a *matching pointer*, is used (has a value different from *null*) only if H_ℓ is j-left and j-strong – then H_ℓ is called a *j-master* – or H_ℓ is j-right and j-weak – then H_ℓ is called a *j-slave*. As essentially noted before, the number of j-masters always equals the number of j-slaves, and the matching pointers form a perfect matching between the j-masters and the j-slaves, with each matching pointer of a master pointing to its corresponding slave, and vice versa.

In order to reduce the space needed for tables of powers of integers to $O((\log n)^2)$ bits, we replace the set $\{c, c-1,\ldots,2\}$ of possible bases used to represent the integer y of $D_{\overline{W}}$ by the smaller set $\{c, c-1, c-2, c-4, c-8,\ldots\}$: The base $c-i$, where $i \in \{1,\ldots,c-2\}$, is replaced by $c-2^{\lfloor \log i\rfloor}$. Then y takes up more space, but the inequality $2^{\lfloor \log(|W|-h)\rfloor} \ge |W|/2$ for $0 \le h \le \min\{|W|-1, 1\}$ shows that it is still the case that y can be represented in $s_1 - 2K|W|$ big digits, where W is the set of weak colors of the container under consideration. Now we need powers of only $O(\log c)$ integers, at most one of which is smaller than $\sqrt{c}$, so the number of bits needed comes to $O(\log c \cdot s_0 \log C) = O((\log n)^2)$. This ends the description of the structure of a composite container H_ℓ.

The use of masters and slaves is an element of the in-place chain technique of Katoh and Goto [14]. Another element requires us to distinguish between *conceptual containers* (intended until this point) and *physical containers*. The number of big digits needed to store a composite container H_ℓ was bounded above by $1 + (s_1 - 2K|W|) + |W \cup \overline{R}|$, where W and $\overline{R}$ are the sets of colors j for which H_ℓ is j-weak and j-left, respectively. This number varies from one (conceptual) container to another, which is precisely the problem – we cannot store the containers in little space so as to allow constant-time access to a given container. This problem is solved by a transfer of data between containers. For each $j \in \{0,\ldots,c-1\}$ and each pair (H, H') of containers such that H and H' are a j-master and its j-slave, respectively, K big digits are relocated from H to H'. A container chooses the at most Kc big digits to relocate as a master to be among at least $s_1 - 1 - c = \omega(c)$ big digits reserved for $D_{\overline{W}}$ and not to overlap with the at most Kc digits received as a slave – if s_1 and hence s are chosen sufficiently large, this is always possible. The first condition means that no "bookkeeping information" is moved to a place where it might be difficult to find (most obviously, the pointer to a slave should not be relocated to the slave), and the second condition ensures that a master can always access one of its relocated big digits in constant time – it must follow a pointer chain of length 1 only.

With the transfer of data described above, the number of big digits needed by a composite container H_ℓ changes to

$$\begin{aligned} &1 + (s_1 - 2K|W|) + |W \cup \overline{R}| - K|\overline{W} \cap \overline{R}| + K|W \cap R| \\ &\le 1 + s_1 - K(|W| + |\overline{W} \cap \overline{R}|) + |W \cup \overline{R}| \\ &= s_1 + 1 - (K-1)|W \cup \overline{R}| \end{aligned}$$

where, again, W, $\overline{W}$, R and $\overline{R}$ are those of H_ℓ. Because H_ℓ is composite, $|W \cup \overline{R}| \ge 1$, so that the quantity above is at most $s_1 - (K-2)$. After the transfer of data, therefore, every conceptual container H can be stored in a physical container of exactly s_1 big digits, and if H is composite, it additionally offers $K-2$ big digits of freely usable *extra space*.

The $P = Ns_1$ big digits of the N physical containers are maintained in an instance of the ingenious data structure of Dodis et al. [4] embodied in the lemma below. The number of bits needed is $P \log C + O((\log P)^2) = Ns_1 s_0 \log c + O((\log(Ns_1))^2) = n \log c + O((\log n)^2)$.

▶ **Lemma 4.1** ([4], Theorem 1). *There is a data structure that, given arbitrary positive integers P and C with $C = P^{O(1)}$, can be initialized in $O(\log P)$ time and subsequently maintains an array of P elements drawn from $\{0, \dots, C-1\}$ in $P \log C + O((\log P)^2)$ bits such that individual array elements can be read and written in constant time.*

When nothing else is stated, in the following "container" means "conceptual container". A subtle point is that an atomic container must be prevented from "posing as" a composite container – there is no space for an atomic/composite bit, and every bit combination is in use for an atomic container. If an atomic container H "claims" to be j-left for some $j \in \{0, \dots, c-1\}$, such a j can be found in constant time with D_{C}, and the claim can be falsified in constant time by inspection of μ_j. Otherwise, if H "claims" to be j-weak for some $j \in \{0, \dots, c-1\}$ and hence a j-slave, the claim can be falsified in constant time by the lack of a reverse pointer to H in its purported j-master. Thus we can always test in constant time whether a given container is atomic or composite.

In addition to the "per-container" data detailed above, we store globally, for each color, a *choice buffer* and an *iteration buffer*, maintained in a special *loose representation* that is wasteful of space, but allows efficient operations corresponding to *choice* and robust iteration. Each buffer is *derived* from a container H_ℓ whose index ℓ is remembered. If the data structure $D_{\overline{W}}$ of H_ℓ stores the sequence $(a'_0, \dots, a'_{s-1})$ of codes, the loose representation of H_ℓ consists of the integer $\sum_{i=0}^{s-1} 2^{if} a'_i$, where $f = \lceil \log c \rceil$. The derivation of a choice or iteration buffer can be carried out in $O(\log s_0)$ time per big integer and $O(s_1 \log s_0) = O(c \log c \log \log n) = O(r)$ time altogether with the algorithm of Lemma 4.2 below, which is a word-parallel version (i.e., essentially independent computations take place simultaneously in different regions of a word) of a simple divide-and-conquer procedure.

▶ **Lemma 4.2** ([7], Lemma 3.3 with $p = 1$). *Given positive integers c, d, f and s with $c, d \ge 2$ and $f \ge \lceil \log_2 \max\{c, d\} \rceil$ and an integer of the form $\sum_{j=0}^{s-1} a_j c^j$, where $0 \le a_j < \min\{c, d\}$ for $j = 0, \dots, s-1$, the integer $\sum_{j=0}^{s-1} a_j d^j$ can be computed in $O(\lceil sf/w \rceil (\log s + (\log(2 + sf/w))^2))$ time.*

Because each code a_i' is readily available in an f-bit field in the loose representation, we can use the algorithm of Lemma 2.1(a), applied to a buffer for a color j and derived from a container H, to carry out a *sweep* of H that reports all elements stored in H whose color is j when they are hit by the sweep. This takes $O(1 + sf/w) = O(c \log c)$ time plus time proportional to the number of occurrences reported plus, possibly, $O(r)$ time to skip occurrences of weak colors with the same code as j, and clearly satisfies the conditions for a robust iteration over H. We generally suspend the sweep as soon as we have found one occurrence of j and resume the sweep later to find the next occurrence, for which reason we also store with each buffer how far the current sweep over the buffer has progressed. In the case of a choice buffer, the sweep is resumed one position earlier so that it reports the same element as last time unless the color of that element has changed. The space needed is $O(sf) = O(c \log c \log n)$ bits per buffer and $O(c^2 \log c \log n) = O((\log n)^2)$ bits for all $2c$ buffers.

When a buffer for a color j derived from a container H is replaced by a different buffer, j is made weak in H if this is possible, i.e., if j occurs at most r times in H. The procedure for doing this is described in the following section.

Initially all containers are 0-strong and j-weak for $j = 1, \ldots, c-1$, and there are no masters or slaves.

5 Conversion Between Weak and Strong Colors

If the number of occurrences of a color j in a container H_ℓ is bounded by r, H_ℓ may be changed from j-weak to j-strong, or vice versa. This section describes the details.

Assume first that H_ℓ is composite both before and after the change. Let the sets W, R, etc., and the substructures D_{C}, D_W, etc., be those of H_ℓ. First, W changes in the obvious way by gaining or losing an element, and D_{C} is recomputed accordingly from skratch in $O(c)$ time. Second, up to r pairs are inserted in or removed from D_W, which can happen in $O(r)$ time.

Consider now the necessary update of $D_{\overline{W}}$. Recall that in the nontrivial cases, $D_{\overline{W}}$ is represented by an integer y composed of s small digits to base $|\overline{W}|$ or $|\overline{W}| + 1$ distributed over a number of big digits. Using the algorithm of Lemma 4.2, we first convert y to the loose representation, which takes $O(r)$ time as before. Informally, we must either create a gap among the code values of the existing strong colors to make room for a new strong color or, conversely, prize out the code value of a color that stops being strong and subsequently close the gap that it leaves. Both of these can be done in $O(r)$ time with the algorithm of Lemma 2.1(b). We omit the details. For $c \geq 3$, these vary a little depending on whether or not $|\overline{W}|$ switches between $c-2$ and $c-1$, i.e., depending on whether or not the interpretation of y switches between the first and the second convention. After the creation of a gap for the code value of a new strong color, the $r+1$ occurrences of that code are “planted” one by one in $O(r)$ time. Similarly, the occurrences of the code of a color that becomes weak are replaced by the code of weak colors (i.e., zero) before the code value of the formerly strong color is prized out. When these changes have taken place, the algorithm of Lemma 4.2 is applied again to convert the loose representation back to the usual representation of $D_{\overline{W}}$ as an integer y. Altogether, the update of $D_{\overline{W}}$ can happen in $O(r)$ time.

The final task is to repair the matching between j-masters and j-slaves. In the special case in which H_ℓ switches not only between j-weak and j-strong, but simultaneously between j-left and j-right (this happens if μ_j switches between ℓ and $\ell - 1$), H_ℓ is neither a j-master nor a j-slave neither before nor after the switch, and nothing needs to be done. Otherwise let $H \neq H_\ell$ be the container that switches as above between j-left and j-right because of the change in μ_j. There are two main cases: (1) If H_ℓ switches from j-weak to j-strong and therefore μ_j decreases by 1 and H switches from j-left to j-right, H_ℓ either becomes a j-master (it is j-left) or stops being a j-slave (it is j-right), and H either stops being a j-master (it is j-strong) or becomes a j-slave (it is j-weak). In all combinations there is a master without a slave and a slave without a master, and they are matched. (2) If H_ℓ switches from j-strong to j-weak and H switches from j-right to j-left, the situation is completely analogous: H_ℓ either becomes a j-slave (it is j-right) or stops being a j-master (it is j-left), and H either stops being a j-slave (it is j-weak) or becomes a j-master (it is j-strong). Again, there is a slave without a master and a master without a slave, and they are matched. In each case the matching pointers are adjusted and the data relocated from masters to slaves is moved appropriately. In addition, the substructure D_{C} of H must be updated. All of this can be done in $O((s \log c)/w) = O(r)$ time.

If H_ℓ is atomic either before or after the conversion, the algorithmic steps are very similar, except that the bookkeeping information for H_ℓ is only implicit when H_ℓ is atomic. A similar situation obtains when H_ℓ has $D_{\overline{W}} = \emptyset$ either before or after the conversion. In all cases, the total time needed for the complete conversion is $O(r)$.

6 The Operations

This section describes how to execute the operations *color*, *setcolor* and *choice* and how to carry out an almost robust iteration.

color

In order to execute a call *color*(i), we identify the container H that stores the ith color value. The substructures D_W, $D_{\overline{W}}$ and D_{C} mentioned in the following are those of H. Accessing D_W, we can determine whether the color j to be returned is weak in H and, if so, j itself. If j is strong and $|\overline{W}| \geq 2$, we can access $D_{\overline{W}}$ to learn the code of j in H, from which j itself can be recovered using D_{C}. If j is strong and $|\overline{W}| = 1$, j is the unique element of $\overline{W}$. Once j is known, it is returned. The execution of *color* takes constant time.

setcolor

Suppose that a call of *setcolor* changes the color of some $i \in \{1, \ldots, n\}$ from j to j'. If j' is weak in the relevant container H and the operation causes the number of occurrences of j' in H to exceed r, H is first converted from j'-weak to j'-strong, as described in the previous section. The rest of the operation is straightforward. If j is weak in H, the pair (i, j) is removed from the substructure D_W of H, and if j' is weak in H, (i, j') is inserted in D_W. Similarly, if j' is strong in H and $|\overline{W}| \geq 2$, the code of j' in H is obtained from the substructure D_{C} of H, after which it is easy to carry out the appropriate update of the sequence $(a'_0, \ldots, a'_{s-1})$ stored in the substructure $D_{\overline{W}}$. A call of *setcolor* needs $O(r)$ time if it carries out a conversion of a container and constant time if not.

choice

The execution of a call *choice*(j) continues the sweep over the choice buffer for the color j, if any, until an occurrence of j is found or the sweep is complete. In the former case the position found is returned. In the latter case, as far as possible, a container H is selected that either belongs to L_j or is j-right – if there is no such container, there are no occurrences of j, and 0 is returned. If H is j-weak, we distinguish between two cases: If H belongs to L_j, it is not j-free, and an occurrence of j in H can be found in constant time and returned. If H is j-right and therefore a j-slave, it is replaced by its corresponding j-master. Now H is strong, a new choice buffer for the color j is derived from H, and the procedure is restarted recursively.

Almost Robust Iteration

Consider an iteration over a given color class S_j. In preparation for the iteration, we step through the list L_j to determine $|L_j|$. Then, using $O(\log n)$ bits of additional space, we split L_j into two lists L_j' and L_j'', with L_j' consisting of precisely those containers H_ℓ in L_j for which $\ell \leq \mu_j - |L_j|^2$. The time needed to do this is $O(|L_j| + 1)$. Since the indices ℓ of the containers in L_j'' are distinct integers in the range $\{\mu_j - |L_j|^2 + 1, \ldots, \mu_j\}$ of size $|L_j|^2$, we can sort the containers in L_j'' by their indices with 2-pass radix sorting in $O(|L_j| + 1)$ time. If K is chosen sufficiently large, the $O(|L_j| \log n)$ bits of additional space needed for this can be supplied by the extra space, discussed shortly before Lemma 4.1, of the containers H_ℓ with $\mu_j - |L_j|^2 < \ell \leq \mu_j$. At this point L_j is updated to be the concatenation of L_j' with the sorted L_j''.

Now the iteration proper can begin. We move a *token* through L_j, always robustly enumerating the elements of S_j in the *current container* H, the container that holds the token. If H is j-strong, this is done by deriving the iteration buffer for j from H and sweeping it, as described in Section 4. If H is j-weak, it is done similarly, by always remembering the last occurrence enumerated and using the fourth operation listed for D_W to enumerate the next occurrence. We will speak of a sweep also in this case. If a container H drops out of L_j because it becomes j-free while it holds the token, the token is first passed on to the successor of H in L_j, if any.

If a container H is j-strong or not j-free and H is to be inserted in L_j because it becomes j-left, then H is inserted at the end of L_j, i.e., so that it will still be swept. If a container is to be inserted in L_j because it stops being j-free, however, it is inserted at the beginning of L_j, i.e., so that it will not be swept.

Suppose that the iteration starts with $\mu_j = \widehat{\mu_j}$. If μ_j decreases all the way to $\widehat{\mu_j} - |L_j|^2$ (i.e., to the "border" between L_j' and L_j'') before all containers in L_j' have been fully swept, the enumeration is suspended and the containers in L_j whose sweep has not yet begun are sorted. Although it is not strictly necessary, this can happen "in-place" with Bubblesort in $O(|L_j|^2)$ time. Then the enumeration is resumed. When the iteration reaches the end of L_j, it proceeds to sweep the containers $H_{\overline{\mu_j}+1}, \ldots, H_N$ in that order, where $\overline{\mu_j}$ is the value of μ_j when the iteration over L_j finishes.

7 Analysis of Correctness and Execution Times

The correctness of the implementation of *color*, *setcolor* and *choice* is easy to see or has already been argued. Consider therefore an iteration over a color class S_j. Every element i that belongs to S_j throughout the iteration is stored in a container H that belongs to L_j or is j-right at the beginning of the iteration, and it is stored in H throughout any sweep over H. During the iteration H can drop out of L_j only by becoming j-right, and if H stops being j-right it is inserted at the end of L_j, where it will still be swept. Thus i is enumerated.

Let t_0 be the point in time when the iteration over L_j' ends or when what remains of L_j is sorted, whatever happens first. Until t_0 only containers in L_j' are iterated over, and any containers that enter L_j during this period are inserted at the beginning of L_j, where they will not be iterated over. Thus no element is enumerated more than once before t_0. After t_0 the enumeration happens strictly in increasing order, so again no element is enumerated more than once. Thus an element is enumerated at most once before t_0 and at most once after t_0. It is easy to see that no element is ever enumerated when it does not belong to S_j. It follows that the iteration is almost robust, as claimed.

The basic idea of the amortized timing analysis is simple: Disregarding iteration, all operations that involve only weak colors take constant time. Consider a point in time at which a container H is converted from j-weak to j-strong for some color j. At that time H contains more than r elements of color j. Because of this, before a conversion of H from j-weak to j-strong can happen again, a buffer for the color j must be derived from H, and the data structure must operate on each of the more than r elements of color j in H by enumerating the element, returning it (*choice*) or changing its color. We can "charge" all of the following to these more than r operations: The derivation of up to two buffers for color j from H, the sweep over the buffers, exclusive of the time spent reporting occurrences of j found there, and a possible conversion of H from j-strong to j-weak and back.

A problematic issue with the argument in the previous paragraph is that operations on elements in a buffer are called upon to pay for the derivation of the buffer, which happened earlier. For every color j other than 0 there is no problem here, since more than r operations – which can pay for the cost – must change the colors of elements in H to j before j can become strong in H for the first time. This argument does not apply to the color 0 because all elements have color 0 initially. However, using the structure D_W of H, a suitably represented first buffer for the color 0 can be derived from H in a time that is at most proportional to a constant plus the number of color changes executed on H since the initialization, so these operations can be charged with the cost.

Certain costs of an iteration are not covered by the analysis above (and, indeed, an iteration may temporarily "go into dept", which is why we cannot support incomplete iteration efficiently). First, there is the cost associated with sorting. The first sorting of part of L_j happens in $O(|L_j|+1)$ time, which is acceptable because every container that does not drop out of L_j before it receives the iteration token eventually contributes at least one occurrence of j to be enumerated or – if it turns out to be j-free – is converted from j-strong to j-weak, the cost of which was considered above. The second sorting of part of L_j is carried out, in $O(|L_j|^2)$ time, only after at least $|L_j|^2$ operations on elements of color j have been executed during the iteration, and the cost of the sorting can be charged to these operations. Second, there is the cost associated with sweeping j-slaves and j-weak former j-slaves that turn out to be j-free (so that the cost of the sweep cannot be charged to the occurrences found). This cost, however, can be charged to the sweeping of the corresponding masters or to the color changes that created or destroyed the matching links to these masters.

Theorem 4 of [8] furnishes a variant of the data structure of Lemma 4.1 that initializes all array elements to zero and can itself be initialized in constant time. Storing the global book-keeping information such as $\mu_0, \ldots, \mu_{c-1}$ in another instance of this data structure and interpreting the all-zero initial values appropriately allows the choice dictionary developed here to be initialized in constant time. We omit the details.

▶ **Theorem 7.1.** *There is a choice dictionary that, for arbitrary given positive integers n and c with $c = O((\log n)^{1/2}(\log\log n)^{-3/2})$, can be initialized with parameters n and c in constant time and subsequently occupies $n\log_2 c + O((\log n)^2)$ bits and executes color, setcolor and choice in constant amortized time and complete almost robust iteration (an element may be enumerated a second time) in constant amortized time per element enumerated.*

Abstract

We present an algorithm for a fault tolerant Depth First Search (DFS) Tree in an undirected graph. This algorithm is drastically simpler than the current state-of-the-art algorithms for this problem, uses optimal space and optimal preprocessing time, and still achieves better time complexity. This algorithm also leads to a better time complexity for maintaining a DFS tree in a fully dynamic environment.

1 Introduction

Depth First Search (DFS) is a widely popular graph traversal method. The traversal routine, formalized by Tarjan [44] in 1972, has played a crucial role in various graph problems including reachability, bi-connectivity, topological sorting, and strongly connected components.

Given an undirected graph $G = (V, E)$ with $n = |V|$ vertices and $m = |E|$ edges, DFS traversal on the graph takes $\mathcal{O}(m + n)$ time and results in a DFS tree of G.

Most of the graphs in real-world applications keep changing with time. Vertices and edges keep entering and leaving the graph at various time steps. This dynamic aspect has motivated researchers to design algorithms that can update the solution of the corresponding problem efficiently after each such change in the graph. There are two models used for solving these graph problems, namely, fault tolerant algorithms and dynamic graph algorithms.

The *fault tolerant* version of any problem $\mathcal{P}$ on a graph G is to construct a compact data structure, using which, for any given set of failed edges or vertices F, one can efficiently report the solution of $\mathcal{P}$ on $G \setminus F$. Many elegant fault tolerant algorithms have been designed for problems including connectivity [13, 21, 25], shortest paths [10, 11, 16, 20, 28], and spanners [12, 15].

The *dynamic* version of any problem $\mathcal{P}$ on G is modeled as follows. For any online sequence of updates (insertion or deletion of an edge/vertex), one has to report the solution of $\mathcal{P}$ efficiently after every update. Note that, unlike the fault tolerant version, the updates are persistent in dynamic version, i.e., after each update, the solution has to be reported taking into account all the updates made so far. Algorithms which handle both insertion and deletion of vertices/edges are called *fully dynamic* graph algorithms, whereas the algorithms that handle either insertions or deletions are called *partially dynamic* graph algorithms, more specifically *incremental* or *decremental* graph algorithms, respectively. The prominent results for dynamic graph problems include connectivity [22, 30, 32], reachability [39, 41], shortest path [19, 29, 40], matching [6, 9, 43], spanner [8, 26, 38], min cut [45], Even-Shiloach tree [23], minimum spanning tree [31, 35], and graph sparsifiers [1].

1.1 Previous Results on Fault Tolerant and Dynamic DFS

Franciosa *et al.* [24] presented an incremental algorithm for maintaining a DFS tree in a directed acyclic graph (DAG) which takes overall $\mathcal{O}(mn)$ time for any sequence of m edge insertions. For undirected graphs, Baswana and Khan [7] presented an incremental algorithm for a DFS tree which takes overall $\mathcal{O}\left(n^2\right)$ time for any sequence of edge insertions. Baswana and Choudhary [4] designed a randomized decremental algorithm for a DFS tree in a DAG with overall expected $\mathcal{O}(mn \log n)$ time for any sequence of edge deletions.

None of the partially dynamic algorithms stated above achieves an $o(m)$ bound over the worst-case complexity of a single update. Moreover, there were no fully dynamic or fault tolerant algorithms for DFS in undirected graphs until recently. In 2016, the first fault tolerant algorithm was presented that takes $\mathcal{O}\left(nk \log^4 n\right)$ time to report a DFS tree for any set of k failed vertices or edges [3]. The time complexity was further improved by Chen *et al.* [17] to $\mathcal{O}\left(nk \log^2 n\right)$. Both [3, 17] require a data structure occupying $\mathcal{O}\left(m \log^2 n\right)$ bits. Nakamura and Sadakane [34] reduced the space occupied by the data structure to $\mathcal{O}(m \log n)$ bits which is indeed optimal [1]. Using the standard technique of periodic rebuilding, the fault tolerant algorithms presented in [3, 17, 34] were also extended to $o(m)$ fully dynamic DFS algorithms (refer to Table 1 for comparison).

Recently, Chen *et al.* [18] designed an $\mathcal{O}(n)$ time incremental algorithm for DFS tree in undirected graphs, which is optimal if it is required to output the DFS tree after each update. For the hardness results for the dynamic *ordered* DFS problem, the reader may refer to the work of Reif [36, 37] and Miltersen *et al.* [33].

1.2 Familiarizing with the Fault Tolerant DFS Problem

For an undirected graph, DFS traversal results in a spanning tree rooted at the vertex from where the DFS begins. The depth first nature of the traversal ensures the following property:

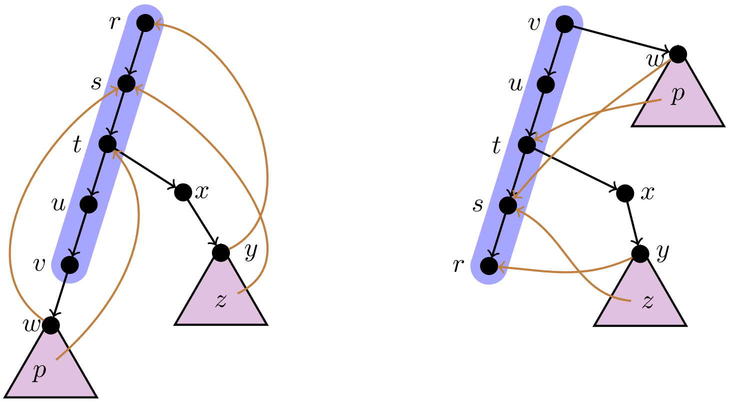
▶ **Property 1.** *(DFS Property) For each vertex $v \in V$, every neighbour of v in the graph appears either as an ancestor of v or as a descendant of v in any DFS tree.*

The DFS property implies that a non-tree edge is never a *cross edge* - an edge whose endpoints do not share an ancestor-descendant relationship. It is due to this reason that each non-tree edge is called a back edge. We now define ancestor-descendant paths.

▶ **Definition 2.** *(Ancestor-descendant Path) A path in a DFS tree is called an ancestor-descendant path if its endpoints have an ancestor-descendant relationship in the tree.*

In order to familiarize with the problem of fault tolerant DFS tree, we discuss another related, but simpler problem, namely, rerooting of a DFS tree defined as follows.

[1] Precisely, their data structure occupies $(m + o(m)) \log n$ bits by using a wavelet tree.



(a) a DFS tree rooted at r.

(b) reversing $path(r, v)$ results in transforming many back edges to cross edges.

Figure 1 Non-triviality of rerooting problem.

▶ **Problem 3.** *Preprocess an undirected graph $G = (V, E)$ to build a compact data structure so that given any vertex $v \in V$, we can report the DFS tree rooted at v efficiently.*

Let T be an initial DFS tree, rooted at a vertex, say r (see Figure 1(a)). We use $T(q)$ to represent the subtree of T rooted at the vertex q. Also, let $path(a, b)$ denote the path from vertex a to b in T. For computing a DFS tree rooted at any vertex v, the first natural idea is to just reverse the direction of the path from r to v in T. However, this may result in transforming many back edges to cross edges and hence a violation of the DFS property (see Figure 1(b)). To fix this problem, we may need to reroot various subtrees hanging from the reversed path. Along these lines, [3] presented an algorithm that takes $\mathcal{O}\left(n \log^3 n\right)$ time to compute a DFS tree rooted at any vertex.

In order to see how rerooting a DFS tree is related to the problem of fault tolerant DFS tree, consider the failure of vertex u in Figure 1(a). The subtree $T(v)$ is connected to the remaining tree through many back edges, and the back edge (p, t) is incident closest to u on the $path(r, u)$. If we reroot the subtree $T(v)$ at vertex p and hang it from the remaining tree through the edge (p, t), the resulting tree will indeed be a valid DFS tree of $G \backslash \{u\}$.

The fault tolerant DFS tree problem becomes more complex in the presence of multiple faults. However, the distribution of faults plays an important role as follows. If the failing vertices do not have any ancestor-descendant relationship in the DFS tree, they can be handled *independently*. For example, the simultaneous failure of vertices u and x in the DFS tree shown in Figure 1(a) requires rerooting the respective subtrees $T(v)$ and $T(y)$ at vertices p and z respectively. So, even for arbitrarily large number of faults, if no two of them appear on the same root to leaf path, we have to just reroot the corresponding disjoint subtrees of T to report the DFS tree avoiding those failures. However, if two or more faults indeed appear on a single root to leaf path, the problem becomes more complex. For this case, [3] presents an algorithm which is quite different from their rerooting algorithm.

1.3 Overview of the Previous Results

We now begin with an overview of the existing algorithms for fault tolerant DFS tree. For any set of k failures, the algorithm presented in [3] first partitions the original DFS tree into a pool of connected components. This pool consists of k paths (specifically, *ancestor-descendant paths*) and potentially a large number of subtrees. The algorithm treats each of these components as a *super vertex* and uses them to grow the DFS tree T^* that avoids all the failures. At a high level, the algorithm can be visualized as a traversal on these super vertices. Each traversal extracts a path from the super vertex, attaches it to T^*, and places the remaining portion of the super vertex back into the pool. In order to pursue DFS traversal further in an efficient manner, the algorithm needs to compute *minimal* adjacency lists for the vertices of the traversed path (referred to as *reduced adjacency lists*). The algorithm makes use of the following crucial property of DFS traversal.

▶ **Property 4.** *(Components Property [3]) Consider any DFS Traversal on any undirected graph $G = (V, E)$. When the traversal reaches a vertex $v \in V$, let the set of connected components induced by the unvisited vertices be C. If from any component $c \in C$, there exists two edges - e to vertex v and e' to any of the visited vertices (including v), then for building a valid DFS tree, it is sufficient to consider only the edge e during the rest of DFS traversal, that is, e' can be ignored.*

In order to use the above property to populate the reduced adjacency list, the algorithm needs a data structure to answer the following queries repeatedly.

- $Query(w, x, y)$: among all the edges from w that are incident on the $path(x, y)$ in T, return an edge that is incident nearest to x on the $path(x, y)$.
- $Query(T(w), x, y)$: among all the edges from $T(w)$ that are incident on the $path(x, y)$ in T, return an edge that is incident nearest to x on the $path(x, y)$.

It is quite obvious from the description given above that these queries are quite non-trivial, and so a sophisticated data structure is designed in [3] to answer these queries efficiently. In addition to the complex data structure, the complete difference in the processing of a path and a subtree obfuscates the algorithm and its analysis.

The subsequent results [17, 34] keep the algorithm unchanged and replace the data structure used in [3] with alternate data structures. Chen *et al.* [17] model the two queries mentioned above as Orthogonal Range Successor/Predecessor(ORS/ORP) queries and this improves the query processing time. Nakamura and Sadakane [34] compressed the data structure used in [17] using Wavelet Trees [27] to achieve optimal space. Despite these improvements, the core of the fault tolerant algorithm remains intricate and the data structure still remains complex. Recently, in an empirical study [5], it was found that this algorithm, for incremental updates, performs even worse than the static DFS algorithm for certain classes of graphs. This naturally raises the question whethere there exists a simpler algorithm for this fundamental problem.

In addition to being complex, all these algorithms fail to exploit the distribution of the faults to achieve efficiency. The running time of these algorithm is $\mathcal{O}(nk\ polylog(n))$ time irrespective of how the k faults are distributed in the DFS tree. In the extreme case, when no two faults share the ancestor-descendant relaitonship, there is a simple $\mathcal{O}(n\ polylog(n))$ time algorithm as described in Section 1.2. This raises the question whether it is possible to have a fault tolerant DFS algorithm whose time complexity depends upon the maximum number of faults lying on any ancestor-descendant path instead of the total number of faults.

1.4 Our Contribution

We take a much simpler approach as compared to the previous algorithms. We first present a new and simple rerooting algorithm based on the following ideas. After building an initial DFS tree, say T, we decompose T into a disjoint collection $\mathcal{P}$ of ancestor-descendant paths. Similar to [3], each of these paths are treated like *super vertices.* At a high level, the algorithm can still be viewed as a traversal on these super vertices. However, as the reader may also verify, the algorithm turns out to be lighter and quite different at the core. Interestingly, the original DFS tree alone acts as a powerful data structure to be used for rerooting or for the computation of another valid DFS tree in the presence of faults. The algorithm crucially exploits an implicit hierarchy among the ancestor-descendant paths in $\mathcal{P}$. This hierarchy along with the DFS property of T enables us to use much simpler queries. In particular, each query will ask only for an edge from a vertex to one of its ancestor paths in the hierarchy. The hierarchy allows us to represent T as another tree structure, called *shallow tree*. In a nutshell, our algorithm can be viewed as an efficient DFS traversal guided by this shallow tree.

This rerooting algorithm extends to the fault tolerant algorithm with very little and obvious modifications. While preserving simplicity, the fault tolerant algorithm turns out to be faster than all the previous algorithms. Moreover, our algorithm is the first to implicitly incorporate the distribution of faults to gain efficiency. We summarize our result in the following theorem.

▶ **Theorem 5.** *An undirected graph G can be preprocessed in $\mathcal{O}(m+n)$ time to build a DFS tree, say T, and a data structure of $\mathcal{O}(m+n)$ words*[2] *such that for any set F of k failed vertices or edges, a DFS tree of $G \setminus F$ can be reported in $\mathcal{O}(n(k'+\log n)\log n)$ time, where $k' \leq k$ is the maximum number of faults on any root-leaf path in the tree T.*

We now present the highlights of our algorithm.
Drastically simpler algorithm: Our algorithm is drastically simpler and more intuitive than the previous algorithm. We feel confident to defend that it can be taught even in an undergraduate course on algorithms. The pseudo-codes in Algorithm 1 and Algorithm 2 are concise and very close to the corresponding implementations.

Faster time complexity: Our algorithm takes $\mathcal{O}(n(k'+\log n)\log n)$ time, where k' is the maximum number of failures on any ancestor-descendant path of the DFS tree when k edges/vertices fail. In the worst-case k' can be as large as k. However, k' can be $o(k)$ as well. In the latter case, our result improves all the existing results significantly. Moreover, even in the case $k'=k$, our time complexity is superior to the previous best by a log factor.

Optimal preprocessing time: Our preprocessing relies upon DFS traversal only, taking $\mathcal{O}(m+n)$ time. Given a graph, in order to report the initial DFS tree, one anyway has to run a static DFS. Hence, our preprocessing time is optimal.

Optimal space and elementary data structure: In contrast to the heavy data structure used by [3, 17], our algorithm makes use of very elementary data structures which are compact as well. Each vertex keeps an array storing edges incident on it from ancestors sorted according to their levels. This data structure uses just $m+n$ words and still achieves $\mathcal{O}\left(n(k'+\log n)\log^2 n\right)$ time to report a DFS tree upon failure of any k vertices or edges. By using fractional cascading [14], we get rid of one log factor while still keeping space requirement to be $\mathcal{O}(m+n)$ words.

Faster Fully Dynamic Algorithm: Using Theorem 5 and periodic rebuilding technique used in [3], we also get the fastest algorithm for fully dynamic DFS.

▶ **Theorem 6.** *Given an undirected graph, one can maintain a DFS tree for any online sequence of insertions and deletions of vertices/edges in $\mathcal{O}\left(\sqrt{mn\log n}\right)$ worst-case time per update.*

[2] One word stores $\lceil \log m \rceil$ bits.

Table 1 Comparison of the existing and the new results. Note that k is the total number of faults, whereas k' is the maximum number of faults lying on any root-to-leaf path of the DFS tree.

	[3]	[17]	[34]	**New**
Space (in bits)	$\mathcal{O}(m\log^2 n)$	$\mathcal{O}(m\log^2 n)$	$\mathcal{O}(m\log n)$	$\mathcal{O}(m\log n)$
Preprocessing	$\mathcal{O}(m\log n)$	$\mathcal{O}(m\log n)$	$\mathcal{O}\left(m\sqrt{\log n}\right)$	$\mathcal{O}\left(m+n\right)$
Fault tolerant	$\mathcal{O}(nk\log^4 n)$	$\mathcal{O}(nk\log^2 n)$	$\mathcal{O}(nk\frac{\log^3 n}{\log\log n})$	$\mathcal{O}\left(n(k'+\log n)\log n\right)$
Dynamic DFS	$\mathcal{O}(\sqrt{mn}\log^{2.5} n)$	$\mathcal{O}(\sqrt{mn}\log^{1.5} n)$	$\mathcal{O}(\sqrt{mn}\frac{\log^{1.75} n}{\sqrt{\log\log n}})$	$\mathcal{O}(\sqrt{mn\log n})$

The new fully dynamic algorithm can be used to solve the dynamic subgraph problems discussed in [3] and improves upon their time complexity as well. Due to space constraint, we do not discuss these problems here. These can be accessed in the full version of the paper.

Table 1 offers a comparison of our results with all the previous results.

1.5 Organisation of the Paper

Section 2 introduces the notations and some well-known techniques/properties used throughout the paper. Section 3 defines the *shallow tree* representation, a concise structure which encapsulates the hierarchy of paths in the initial DFS tree. Section 4 is the core of our work. Here, we describe how a DFS tree can be rerooted efficiently. Section 5 describes how with some minor modifications to the data structure, rerooting procedure extends to a fault tolerant algorithm. We present the fully dynamic algorithm in Section 6.

2 Preliminaries

2.1 Notations

Following notations will be used throughout this paper.

- T: Any DFS tree of the original graph G.
- $dfn\,(x)$: The depth first number, i.e., the discovery time of the vertex x during the DFS traversal.
- $v\,(i)$: the vertex $x \in V$ such that $dfn(x) = i$.
- $dist\,(x, y)$: distance between the vertices x and y in the DFS tree T.

For the sake of ease of explanation, we shall assume that the graph remains connected at all times. This assumption is without loss of generality because of the following standard way of transforming the original graph right in the beginning - Introduce a dummy vertex r and connect it to all vertices of the graph. Henceforth, we maintain a DFS tree rooted at r for this augmented graph. It is easy to observe that the augmented graph remains connected throughout and the DFS tree rooted at r will be such that the subtrees rooted at the children of r constitute a DFS forest of the original graph.

2.2 Heavy-Light Decomposition

Sleator and Tarjan, in their seminal result on dynamic trees [42] introduced a technique of partitioning any rooted tree called Heavy-light decomposition. Given any rooted tree, this technique splits it into a set of vertex-disjoint ancestor-descendant paths. It marks all the tree edges either dashed or solid - a tree edge is marked solid iff the subtree of the child vertex is heaviest (in terms of number of vertices) among the subtrees of all its siblings and dashed otherwise. A maximal sequence of vertices connected through solid edges constitutes the required ancestor-descendant path. This decomposition can be carried out using DFS traversal in $\mathcal{O}(n)$ time.

2.3 Fractional Cascading

Given n sorted arrays and a value x, suppose we need to find the predecessor/successor of x in each of them. A naive way is to make a binary search on each array. Chazelle and Guibas [14] introduced a novel tool called fractional cascading using which this problem can be solved more efficiently. Also, Chen *et al.*[18] used this tool for arriving at an $\mathcal{O}(n)$ algorithm for incremental updates. We adapt a customized version of their method.

▶ **Lemma 7.** *Fractional cascading: Given n sorted arrays $\{A_i\}_{i\in[n]}$ each with $l_i = |A_i|$ elements and total $\sum_i^n l_i = m$ elements. There exists a data structure of $\mathcal{O}(m+n)$ words, which can be built in $\mathcal{O}(m+n)$ time, such that for any given x, i, and k satisfying $i, k \in [n]$ and $i + k \leq n$, we can search for x (or its predecessor/successor) in all arrays $A_i, \ldots, A_{i+k}$ using the data structure in $\mathcal{O}(k + \log m)$ time.*

3 Shallow Tree Representation

We now introduce the shallow tree representation for DFS tree T that plays a key role in our algorithm. Using heavy-light decomposition, T is broken down into a set of vertex-disjoint ancestor-descendant paths. Let's denote this set with $\mathcal{P}$. Observe that these paths are connected through dashed edges in T. These dashed edges introduce a hierarchy among paths in $\mathcal{P}$ and the shallow tree defined below captures this hierarchy.

▶ **Definition 8.** *Given a DFS tree T of an undirected graph G, let $\mathcal{P}$ be the set of paths obtained through heavy-light decomposition of T. Let H be the set of edges marked dashed during the decomposition. For tree T, its shallow tree S is a rooted tree formed by collapsing each element of $\mathcal{P}$ into a single node (super vertex). Note that, for each edge $(y, z) \in H$ with $y = parent(z)$, the node in S that contains y is the parent of the node containing z.*

Figure 2 demonstrates how a DFS tree is decomposed to form a set of ancestor-descendant paths $\mathcal{P}$ which is subsequently used to form the shallow tree S.

To avoid ambiguity, we address the vertices in the shallow tree as "nodes" and the vertices in the DFS tree as "vertices". $node(x)$ denotes the shallow tree node corresponding to the path in $\mathcal{P}$ containing vertex x.

The construction of S described above ensures the following simple but crucial properties.

- As a result of heavy-light decomposition of a tree T with n vertices, there can be at most $\log n$ dashed edges on any root to leaf path in T. Recall that each edge in S corresponds to a dashed edge. Thus, the depth of any node in tree S can't be larger than $\log n$. It is because of this small depth that we choose the name *shallow tree* for S.
- From the DFS property, neighbours of any vertex $v \in V$ in the graph are either ancestors or descendants of v in T. Consider any such neighbour u. Let p_1 be the path in $\mathcal{P}$ containing v and p_2 be the path in $\mathcal{P}$ containing u. u and v may also lie in the same path in $\mathcal{P}$. From the construction of S, the nodes corresponding to p_1 and p_2 will share an ancestor-descendant relation in S. So we can state the following lemma.

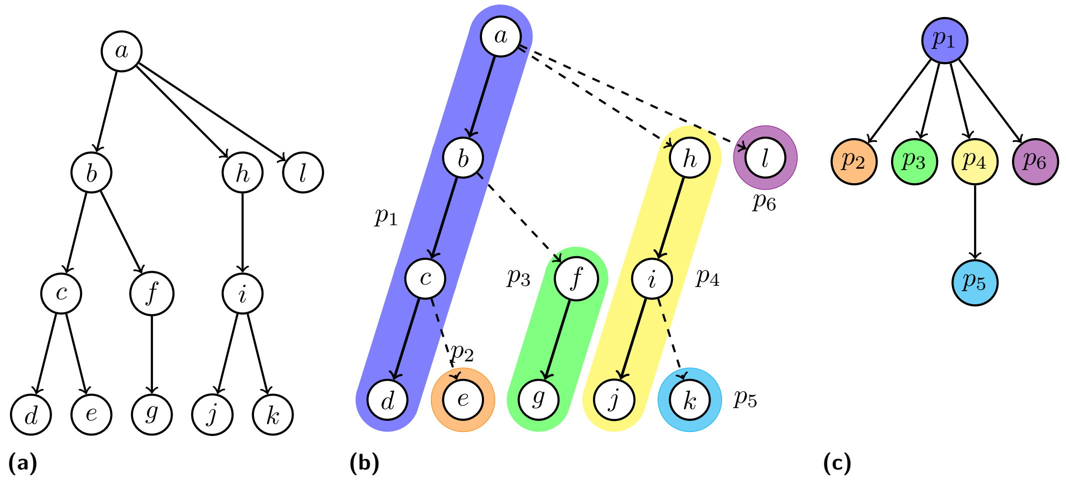


Figure 2 (a) A DFS tree T. (b) Heavy light decomposition of T and the resulting paths in $\mathcal{P}$. (c) The corresponding shallow tree.

▶ **Lemma 9.** *For a DFS tree T of an undirected graph $G = (V, E)$ with shallow tree S, any vertex $v \in V$ which lies in node $\mu \in S$ can have edges only to vertices lying in the nodes which are ancestors or descendants of μ in S.*

We require that the vertices of each solid path have consecutive dfn. This enables us to represent each path $p \in \mathcal{P}$ in a compact manner using just the smallest and largest dfn of vertices on p. For each path p, we store this pair as *PathEndPoints* at the corresponding node of the shallow tree S. Assigning consecutive dfn to each solid path can be accomplished easily - we carry out another DFS on T where for each vertex, the next vertex to be visited is its child hanging through a solid edge. Thus, the processing of T to make the shallow tree S requires only DFS on T and takes $\mathcal{O}(n)$ time.

4 Rerooting DFS Tree T

Given a DFS tree T for a graph $G = (V, E)$ and a vertex $r' \in V$, the objective is to compute a DFS tree T^* rooted at r' for the same graph G. First we compute the shallow tree representation S of T. We now describe the rerooting procedure.

4.1 Reroot Procedure

The tree T^* is empty in the beginning and is grown gradually starting from r'. To build this tree efficiently, we use the following two ideas. The first idea is to re-use the paths from $\mathcal{P}$. Observe that while rerooting, if we use the original adjacency list for scanning the neighbours, we need $\mathcal{O}(m + n)$ time. So the second idea is to populate for each vertex only a subset of its adjacency list which is small and yet sufficient to compute a DFS tree (this idea was used by [3] in the fault tolerant DFS problem). These lists we refer as *reduced adjacency lists*. We take a lazy and frugal approach to populate them.

The intuition sketched above is materialized by carrying out a DFS traversal *guided* by the shallow tree S. Note that a node of the shallow tree corresponds to a path in $\mathcal{P}$. To compute T^*, our algorithm performs a sequence of steps. Each step begins with entering a node of S through some vertex present on the path stored at the node and leaving it after traversing the path along one direction. The first node to be visited is $node(r')$. We now provide complete details of the computation involved in each step. Consider any node $\nu \in S$. Let $path(y,z)$ be the path corresponding to ν. When the DFS traversal enters ν through a vertex, say x, the following 3 simple operations are carried out.

1. *Move towards the farther end of the path.*
   We determine the vertex from $\{y,z\}$ farther from x. Let this vertex be y. DFS traversal proceeds from x to y and $path(x,y)$ is attached to the tree T^*. Next, we update the $PathEndpoints\,(\nu)$ such that it stores the endpoints of the untraversed part of $path(y,z)$. This choice of direction ensures that at least half of the path is traversed (referred to as path halving technique, also used in [2, 3]).
2. *Populate the reduced adjacency list of the path just traversed.*
   For vertices on $path(x,y)$, we populate the reduced adjacency list $\mathcal{L}$ using ancestors and descendants of ν in the shallow tree S. This will be explained below in Section 4.1.1.
3. *Continue traversal.*
   Using the reduced adjacency list $\mathcal{L}$ of the traversed path computed in step 2 above, we continue the DFS traversal along the unvisited neighbours of the vertices in the order from y to x (opposite to the direction of traversal, due to the recursive nature of DFS).

Algorithm 1 presents the complete pseudocode of the rerooting procedure based on the above 3 steps. All vertices are marked *unvisited* initially and the reduced adjacency list $\mathcal{L}$ is empty. Invoking Reroot(r') produces the DFS tree rooted at r'.

Algorithm 1 Recursive procedure to reroot the DFS Tree T.

```
Function Reroot (x)
    $(y,z) \leftarrow PathEndpoints\,(node\,(x))$ ;
    if $dist(x,z) > dist(x,y)$ then Swap $(y,z)$;      /* compute $dist$ using $dfns$ */
    Attach $path\,(x,y)$ to $T^*$;
    if $x \neq z$ then
        $w \leftarrow$ Neighbour of $x$ on $path(y,z)$ nearest to $z$ ;
        $PathEndpoints\,(node\,(x)) \leftarrow (w,z)$ ;               /* untraversed path */
    end
    $\mathcal{L} \leftarrow ReducedAL\,(\mathcal{L},(x,y))$ ;      /* Update $\mathcal{L}$ for vertices on $path(x,y)$ */
    for $i = dfn(y)$ to $dfn(x)$ do  $status(v(i)) \leftarrow visited$ ;
    for $i = dfn(y)$ to $dfn(x)$ do
        foreach $vertex\ u \in \mathcal{L}(v(i))$ do
            if  $status(u) = unvisited$ then  {add $(v\,(i)\,,u)$ to $T^*$; Reroot$(u)$} ;
        end
    end
```

4.1.1 Populating Reduced Adjacency Lists

Here we define a query $Q\,(u,(p_s,p_e))$, where $u,p_s,p_e \in V$ satisfy the following constraints:

- p_s and p_e are the endpoints of an ancestor-descendant path in T.
- u is a descendant of the highest vertex on $path\,(p_s,p_e)$, but does not lie on the path.

This query finds an edge from the vertex u that is incident to $path(p_s,p_e)$ closest to p_e. It returns *null* if no such edge exists, otherwise it returns the endpoint other than u.

Consider any node $\nu \in S$, and let $path(y,z)$ be its corresponding path in $\mathcal{P}$. When the DFS traversal enters ν through x and proceeds towards y, we populate the reduced adjacency lists of vertices on $path(x,y)$ using Lemma 9 as follows.

- *Processing Ancestors of vertices on path(x, y).*
  For each $u \in path(x, y)$ and for each ancestor μ of ν, we add $Q\left(u, PathEndpoints\left(\mu\right)\right)$ to $\mathcal{L}\left(u\right)$.
- *Processing Descendants of vertices on path(x, y).*
  Using the shallow tree S, one can list all the vertices that are descendants of vertices on $path(x, y)$ in T. From all these vertices, we query for an edge to $path(x, y)$ which is incident closest to y. For any descendant u, if the query $Q\left(u, (x, y)\right)$ returns a non-*null* value, say w, then we add u to $\mathcal{L}\left(w\right)$.

▶ Remark 10. In Algorithm 1, after visiting x, if we moved towards the leaf node, then the untraversed part of ν has to be treated as an ancestor path while populating the reduced adjacency lists of $path\left(x, y\right)$, and as a descendant path, otherwise.

Algorithm 2 Populating reduced adjacency lists of vertices on $path(x, y)$.

```
Function ReducedAL ($\mathcal{L}, (x, y)$)
    $\mu \leftarrow$ parent (node ($x$));
    while $\mu \neq NULL$ do                                   /* edges to ancestor paths */
        for $i = dfn(y)$ to $dfn(x)$ do
            $\mathcal{L}(v(i)) \leftarrow \mathcal{L}(v(i)) \cup \{Q(v(i), PathEndPoints(\mu))\}$;
        end
        $\mu \leftarrow parent(\mu)$ ;
    end
    if $dfn(x) < dfn(y)$ then $z \leftarrow x$ else $z \leftarrow y$;   /* $z$ is ancestor among two */
    $\mathcal{C} \leftarrow \mathrm{Desc}_T(z) \setminus \{v(dfn(x)), \ldots, v(dfn(y))\}$;
    foreach $u \in \mathcal{C}$ do                             /* each descendant of $path(x, y)$ */
        $w \leftarrow Q(u, (x, y))$ ;                           /* ensure $w$ is closest to $y$ */
        if $w \neq NULL$ then $\mathcal{L}(w) \leftarrow \mathcal{L}(w) \cup \{u\}$ ;
    end
    return $\mathcal{L}$
```

In Algorithm 2, we used query $Q\left(u, (p_s, p_e)\right)$ as a black box. This query can be answered very easily as follows. The constraints of $Q\left(u, (p_s, p_e)\right)$ imply that the returned edge is always an edge from u to an ancestor of u. For answering this query, we use a data structure $\mathcal{D}$ which stores the following information for each vertex u.

▶ **Definition 11.** *$\mathcal{D}\left(u\right)$ is an array that stores each ancestor of u in T to which u is a neighbour and it stores them in the increasing order of distance from the root of T.*

This data structure enables us to answer query $Q\left(u, (p_s, p_e)\right)$ using a binary search on array $\mathcal{D}\left(u\right)$ and it takes $\mathcal{O}\left(\log n\right)$ time only. Interestingly, the data structure $\mathcal{D}$ can be preprocessed very easily in $\mathcal{O}\left(m + n\right)$ time as follows. We visit vertices in the increasing order of their depth first numbers. Note that for each vertex v, the neighbours of v which have dfn larger than that of v are its descendants. For each such descendant u, we append v to $\mathcal{D}(u)$. Iterating in increasing order of dfn ensures that all arrays in $\mathcal{D}$ are sorted as needed.

▶ **Theorem 12.** *Given a DFS Tree T of an undirected graph G, it takes $\mathcal{O}\left(m + n\right)$ time to build a data structure consisting of exactly $(m + n)$ words which can answer the query $Q\left(u, (p_s, p_e)\right)$ in $\mathcal{O}\left(\log n\right)$ time.*

4.2 Time Complexity Analysis

During preprocessing, we construct the shallow tree S for the DFS tree T and build $\mathcal{D}$. This processing as shown earlier can be completed in $\mathcal{O}(m+n)$ time. The time complexity of the Reroot procedure is bounded by the time required to populate the reduced adjacency lists $\mathcal{L}$. This in turn, is bounded by the number of calls to query Q. To analyse the number of calls made from any vertex w, let ν be the node in the shallow tree S, containing w. In general, if the bound on height of S is d, ReducedAL makes worst-case d queries from w to ancestors of ν. Also when an ancestor of ν in S, say μ, is visited during Reroot procedure, ReducedAL makes a query from w to μ. The path halving technique (line 3 in Algorithm 1) ensures that any node in S (or a path in $\mathcal{P}$) is visited at most $\log n$ times. This implies that any such ancestor μ may be visited at most $\log n$ times. Thus, we can have worst-case $d(\log n+1)$ queries from w to its ancestor paths throughout the Reroot procedure. Summing over all the vertices, there can be at most $nd(\log n+1)$ calls to query Q. Therefore, populating the reduced adjacency lists $\mathcal{L}$ takes overall $\mathcal{O}\left(nd\log^2 n\right)$ time. From Section 3, we know $d \leq \log n$. Thus, using Theorem 12, we can state the following lemma.

▶ **Lemma 13.** *Given a DFS Tree T of an undirected graph G, it takes $\mathcal{O}(m+n)$ time to build a data structure of $(m+n)$ words using which we can compute a DFS Tree of G rooted at any given vertex in $\mathcal{O}\left(n\log^3 n\right)$ time.*

4.2.1 Getting rid of a log factor

Consider the moment when the Reroot procedure enters a $path(y,z)$ through the vertex x and reaches the endpoint y. In Algorithm 2, for each descendant w of $path(x,y)$, we perform query $Q(w,(x,y))$ separately. Instead, using Fractional Cascading, we can perform all these queries together in an efficient manner. Among x and y, let x be the vertex closer to the root of T. As described earlier, all the vertices of $path(x,y)$ have consecutive dfn, and so do the vertices of subtree $T(x)$. Let $last(x)$ be the vertex in $T(x)$ with the largest dfn. Since vertices on $path(x,y)$ have already been visited, we need to query for edges only from vertices with dfn between $dfn(y)+1$ and $dfn(last(x))$. Finding edges to $path(x,y)$ from these vertices can be done with a single query to the fractionally cascaded $\mathcal{D}$ (Lemma 7). It takes $\mathcal{O}(\log m + dfn(last(x)) - dfn(y))$ time to execute this query. We charge the $\log m$ part of the query time to the vertices on $path(x,y)$ and the $dfn(last(x)) - dfn(y)$ is distributed among the descendant vertices. Thus, each descendant vertex incurs a constant charge.

Note that, queries to the ancestors of $path(x,y)$ are answered using the original $\mathcal{D}$ itself. Therefore, in a shallow tree of height d, each vertex $v \in V$ incurs following charges during Reroot procedure - $\mathcal{O}(d\log n)$ when v acts as a descendant in the queries made while visiting ancestors of v, and $\mathcal{O}(d\log n+\log m)$ while visiting v itself. Overall the charge on any vertex is $\mathcal{O}(d\log n)$ and, therefore, the time complexity of Reroot procedure reduces to $\mathcal{O}(nd\log n)$. So we can state the following lemma.

▶ **Lemma 14.** *Given an undirected graph G, the DFS tree T and corresponding shallow tree of height d, it takes $\mathcal{O}(m+n)$ time to build a data structure occupying $\mathcal{O}(m+n)$ words using which the Reroot algorithm executes in $\mathcal{O}(nd\log n)$ time.*

4.3 Correctness of Reroot Procedure

As is evident from the pseudocode of Algorithm 1, besides populating the reduced adjacency lists, Reroot imitates a usual DFS traversal. So in order to show that Reroot computes a valid DFS tree, we need to prove the following. Each edge e that is not added to reduced adjacency list is indeed redundant and will appear as a back edge in the resulting DFS tree. We can show this as follows.

During Reroot procedure, consider the moment when we attach some path, say $path(x, y)$ to T^*. Lemma 9 implies that all the neighbours of vertices on the $path(x, y)$ will lie either in ancestors or in descendants of $path(x, y)$ in the shallow tree. For each descendant vertex v of $path(x, y)$, we add an edge from v incident on $path(x, y)$ closest to y (lines 12,13 of Algorithm 2). For each ancestor path of $path(x, y)$, say μ, we add an edge from each vertex of $path(x, y)$ to μ (line 5 of Algorithm 2). These ensure that at the moment $path\,(x, y)$ is visited and attached to T^*, from each connected component in the graph induced by unvisited vertices, the edge incident on $path(x, y)$ closest to vertex y is added to $\mathcal{L}$ (if exists). Using Components Property, it follows that all those edges incident on $path(x, y)$, that are not added to $\mathcal{L}$, will appear as back edges in the resulting DFS tree. Hence, the traversal performed using the reduced adjacency lists indeed results in a valid DFS tree.

5 Extension to Fault Tolerant DFS Tree

Given an undirected graph G, we build a DFS tree of G, say T, the corresponding shallow tree S, and the fractionally cascaded D. Let F be the set of failures (edges/vertices) in G, with $|F| = k$. Here, we describe how with some elementary modifications to the shallow tree of T, procedure Reroot can be utilized to report a DFS tree of $G \setminus F$. For the given set F, we update the set $\mathcal{P}$ and the shallow tree S as follows.

1. Each vertex maintains a state: *active* or *failed*. For a failed vertex $x \in F$, we toggle x's state to *failed*. Let $p \in \mathcal{P}$ be the path containing x. We remove x from p. The resulting smaller paths are added to $\mathcal{P}$ and p is removed from $\mathcal{P}$.
2. For each failed edge $e = (u, v)$, we mark the corresponding entries in the adjacency lists of u and v as *failed*. Here, we do not make any changes to fractionally cascaded $\mathcal{D}$. If failed edge e is a tree-edge and was marked *solid* during heavy-light decomposition, $\mathcal{P}$ is updated as follows. Path $p \in \mathcal{P}$ containing e is split into two smaller paths. These smaller paths are added to $\mathcal{P}$ and p is removed from $\mathcal{P}$.
3. After updating $\mathcal{P}$, shallow tree S is updated as follows. For any path $p \in \mathcal{P}$, let the vertex in p closest to root of T be x. The parent of node corresponding to p in S will be the node containing the nearest active ancestor of x.

Given the set F, we can update $\mathcal{P}$ and S in $\mathcal{O}\,(n)$ time as follows - Make a DFS traversal through T while ensuring vertices are visited in increasing order of their dfn. Update $\mathcal{P}$ and S as discussed above. For each failure, the number of nodes in S increases by at most one. After k updates, S can have at most k new nodes and may not be shallow anymore. However, the depth of a node ν in S doesn't increase due to any failure which does not lie on the path from ν to root of S. Thus, if the maximum number of failures on any root-leaf path in T is k', the height of the shallow tree will be at most $k' + \log n$.

To ensure that no *deleted* vertices/edges are traversed during Reroot procedure, we make the following modifications. Since no changes are made to fractionally cascaded $\mathcal{D}$, the result of some query $Q\,(v, (p_s, p_e))$ may be an endpoint of a *failed* edge. In such a case, we iterate in $\mathcal{D}\,(v)$ starting from the *failed* edge towards p_s until we find an edge present in $G \setminus F$. However, if we cross p_s in doing so, it implies that there is no edge between vertex v and $path\,(p_s, p_e)$, we stop and return *null*. During the procedure Reroot, we spend overall $\mathcal{O}\,(k)$ time in such iterations. Also note that each node of the updated S corresponds to a path consisting of active vertices only. So $Q\,(v, (p_s, p_e))$ never returns a failed vertex. It follows from the changes in the query and the shallow tree described above that Reroot procedure reports a valid DFS tree of $G \setminus F$. Using Lemma 14, we can conclude the following theorem.

▶ **Theorem 15.** *An undirected graph G can be preprocessed in $\mathcal{O}(m+n)$ time to build a DFS tree, say T, and a data structure of $\mathcal{O}(m+n)$ words such that for any set F of k failed vertices or edges, a DFS tree of $G \setminus F$ can be reported in $\mathcal{O}(n(k'+\log n)\log n)$ time, where $k' \leq k$ is the maximum number of faults on any root-leaf path in the tree T.*

6 Fully Dynamic DFS

We first describe how the fault tolerant DFS algorithm can handle incremental updates. Following that, we use the *overlapped periodic rebuilding technique* to arrive at a fully dynamic DFS algorithm. The ideas utilized in both of these steps were used by Baswana *et al.* [3].

Let U be the set of updates in any undirected graph G. For the edge insertions, we directly add them to the reduced adjacency lists of the endpoints of the edges. To handle insertion of a vertex, we add the new vertices in V and treat their edges as edge insertions. Observe that these modifications are sufficient to handle incremental updates. The size of the reduced adjacency lists after $|U|$ updates is at most $n(|U|+\log n)(\log n+1)$ (from Section 4.2). So the worst-case time complexity of our algorithm is $\mathcal{O}(n(|U|+\log n)\log n)$.

We can use the Reroot procedure to report a DFS tree after every update. But as $|U|$ increases, the algorithm slows down. Therefore, we need to rebuild the data structures (denoted collectively using $\mathcal{A}$) periodically to maintain the efficiency. We rebuild them after, let's say, every c updates. It takes $\mathcal{O}(m+n)$ time to rebuild the data structures. The cost of rebuilding is amortized among the c updates. This results in an amortized runtime fully dynamic algorithm.

To get a worst-case bound, the rebuilding is done in an overlapped fashion as follows. The original data structures $\mathcal{A}_0$ are used till first $2c$ updates. At the end of kc updates (for $k \geq 1$), we start building $\mathcal{A}_k$, the data structures for the graph after incorporating the first kc updates. The computation of building $\mathcal{A}_k$ is distributed evenly over the next c updates to the graph (from $(kc+1)$ to $(k+1)c$ updates). However, during these updates we use $\mathcal{A}_{k-1}$ to report the updated DFS Tree. This ensures $|U|$ is never larger than $2c$. After $(k+1)c$ updates, we have $\mathcal{A}_k$ ready for use and we can discard $\mathcal{A}_{k-1}$. This helps us manage our data structures in $\mathcal{O}(m+n)$ space. For this overlapped periodic rebuilding framework, the following lemma from [3] provides the worst-case bound on the update time we can derive.

▶ **Lemma 16.** *(Overlapped Periodic Rebuilding: Lemma 6.1 in [3]) Let $\mathcal{D}$ be a data structure that can be used to report the solution of a graph problem after a set of U updates on an input graph G. If $\mathcal{D}$ can be built in $\mathcal{O}(f)$ time and the solution for graph $G+U$ can be reported in $\mathcal{O}(h+|U|\cdot g)$time, then $\mathcal{D}$ can be used to report the solution after every update in worst-case $\mathcal{O}\left(\sqrt{fg}+h\right)$ update time, given that $f/g \leq n$.*

Substituting $f=m$, $g=n\log n$ and $h=n\log^2 n$, we obtain, $\mathcal{O}\left(\sqrt{fg}+h\right)=\mathcal{O}\left(\sqrt{mn}\log n\right)$. Hence we conclude with the following theorem.

▶ **Theorem 17.** *An undirected graph can be preprocessed in $\mathcal{O}(m+n)$ time to build a data structure occupying $\mathcal{O}(m+n)$ words, using which one can maintain a DFS tree for any online sequence of insertions and deletions of vertices/edges in $\mathcal{O}\left(\sqrt{mn}\log n\right)$ worst-case time per update.*

Abstract

We show that the edit distance between two run-length encoded strings of compressed lengths m and n respectively, can be computed in $\mathcal{O}(mn \log(mn))$ time. This improves the previous record by a factor of $\mathcal{O}(n/\log(mn))$. The running time of our algorithm is within subpolynomial factors of being optimal, subject to the standard SETH-hardness assumption. This effectively closes a line of algorithmic research first started in 1993.

1 Introduction

The edit distance is one of the most common distance measures between strings. For two strings of length M and N respectively, the edit distance counts the minimum number of single character insertions, deletions and substitutions needed to transform one string into the other. The first record of an $\mathcal{O}(MN)$ algorithm to compute the edit distance is from 1968 [14] although it was rediscovered independently a number of times subsequently. Masek and Paterson improved the running time to $\mathcal{O}(MN/\log N)$, for $N \geq M$, in 1980 and this is the fastest known algorithm to date [12]. Much more recently it has been shown that no $\mathcal{O}(MN^{1-\epsilon})$ time edit distance algorithm can exist, subject to the strong exponential time hypothesis (SETH) [4, 5]. As a result, it is likely that little further progress can be made in terms of improving its worst case complexity.

In this paper we focus on the problem of computing the edit distance between two compressed strings. The run-length encoding (RLE) of a string compresses consecutive identical symbols into a run, denoted σ^i if the symbol σ is repeated i times. For example `aaabbbbaaa` would be compressed to $\mathtt{a}^3\mathtt{b}^4\mathtt{a}^3$. This form of compression is commonly used for image compression but also has wider applications including, for example, in image processing [9, 15] and succinct data structures [11].

In 1993 Bunke and Csirik proposed the first algorithm for computing the edit distance between RLE strings. For two strings of RLE-compressed lengths m and n respectively, their algorithm runs in $\mathcal{O}(mn)$ time in the special case where all the runs are of the same length [6]. However the running time falls back to the naive complexity of $\mathcal{O}(MN)$ time in the worst case where M and N are the uncompressed lengths of the two strings. This worst case complexity was subsequently improved to $\mathcal{O}(Nm + Mn)$ [3, 7] and then $\mathcal{O}(\min\{Nm, Mn\})$ time in 2007 [10]. Finally in 2013 the fastest solution prior to this current work was given running in $\mathcal{O}(mn^2)$ time, where $n \geq m$ [8]. This was the also the first algorithm for the RLE edit distance problem whose running time did not depend on the uncompressed lengths of the input strings.

For uncompressed strings, the longest common subsequence (LCS) problem has long been considered a close relative of the edit distance problem. This is partly due to the similarity of their dynamic programming solutions and partly because LCS is a special case of edit distance when general costs are allowed for the different mismatch and substitution operations. Moreover, the two problems have the same quadratic time upper bounds and SETH-hardness lower bounds [5]. Somewhat surprisingly, however, the history of algorithms for LCS and edit distance have *not* mirrored each other when the problems are considered on RLE strings. In particular, an $\mathcal{O}(mn\log(mn))$ time algorithm for computing the LCS on RLE strings was given in 1999 [2] which is considerably faster than has been possible up to this point for the edit distance problem. Some work has also been carried out since that date to improve the log factor in the running time complexity for the LCS problem [1, 13].

In this paper we speed up the running time for the edit distance problem on RLE strings by a factor of $\mathcal{O}(n/\log(mn))$, matching the fastest LCS algorithm to within a logarithmic factor and making it within subpolynomial factors of being optimal, assuming SETH holds. As a result, our new algorithm shows that the LCS and edit distance problems are indeed of essentially the same complexity even when the input strings are run-length encoded. This effectively closes a line of algorithmic research first started in 1993.

▶ **Theorem 1.** *Given two RLE strings of compressed length n and m respectively, there exists an algorithm to compute their edit distance which runs in $\mathcal{O}(mn\log(mn))$ time.*

2 Previous Work and Preliminaries

The classic dynamic programming solution for computing the edit distance between uncompressed strings X and Y of uncompressed lengths M and N respectively, computes the distance between all prefixes $X[1, \ldots, i]$ and $Y[1, \ldots, j]$. The key recurrence which enables us to do this efficiently is given by:

$$\mathsf{ED}(i, j) = \min(\mathsf{ED}(i-1, j-1) + \delta(X_i \neq Y_j), \mathsf{ED}(i-1, j) + 1, \mathsf{ED}(i, j-1) + 1).$$

From this the classic $\mathcal{O}(MN)$ time solution follows directly.

The previous approaches for the edit distance problem on RLE strings take this recurrence and the implied dynamic programming table as their starting point. The basic idea was introduced by Bunke and Csirk [6] whose algorithm works by dividing the dynamic programming table into "blocks", where each block is defined by a run in the original strings.

For each block the central task is to compute its bottom row and rightmost column given the bottom row of the block above and the rightmost column of the block to the left. For simplicity of terminology, we will refer to the rightmost column of the block to the left and the bottom row of the block above collectively as the *input border* of a block and the bottom row and rightmost column of a block as its *output border*. Figure 1 illustrates an example.

In [3,7] it was shown that the work needed to derive the values of all the output borders of blocks is at most linear in their length. When computing the edit distance between strings X and Y, the length of each row in the dynamic programming table is the uncompressed length of string Y and the length of each column is the uncompressed length of X. If there are m runs in string X and n runs in Y then the total time complexity for computing the edit distance using their approach is therefore $\mathcal{O}(Nm + Mn)$.

The work closest to ours is the $\mathcal{O}(mn^2)$ algorithm of Chen and Chao [8]. They observe that the borders of the blocks in the dynamic programming table are piecewise linear with gradient ±1 or 0. The borders can be therefore concisely represented by specifying their starting values as well as the positions and types of the points of changing gradient called the *turning points*. They prove that for a given block the number of turning points in an output border is at most a constant greater than in its input border. Consequently, a simple calculation shows that the total number of turning points is $\mathcal{O}(mn^2)$ (for $m \leq n$). Chen and Chao arrive at their final complexity by designing a procedure that computes the representation of the output border of a block, given the representation of its input border, in time proportional to the number of turning points. We now summarise their approach using our own notation.

There are two distinct types of blocks in the dynamic programming table. A match block corresponds to a rectangle where the corresponding symbols in the two strings match. A mismatch block corresponds to a rectangle where the corresponding symbols mismatch. Figure 1 shows both match and mismatch blocks. Borrowing notation from [8] we say that element (i, j) of the dynamic programming table ED is in *diagonal* $j - i$. Let (i_d, j_d) be the intersection of the input border with diagonal $j - i$.

▶ **Lemma 2** ([8, Lemma 1]). *For a match block,* $\mathsf{ED}(i, j) = \mathsf{ED}(i_d, j_d)$.

Lemma 2 indicates that for a match block we can simply copy the values from the corresponding position in the input border to derive the values of the output border. The main challenge is therefore how to handle mismatch blocks.

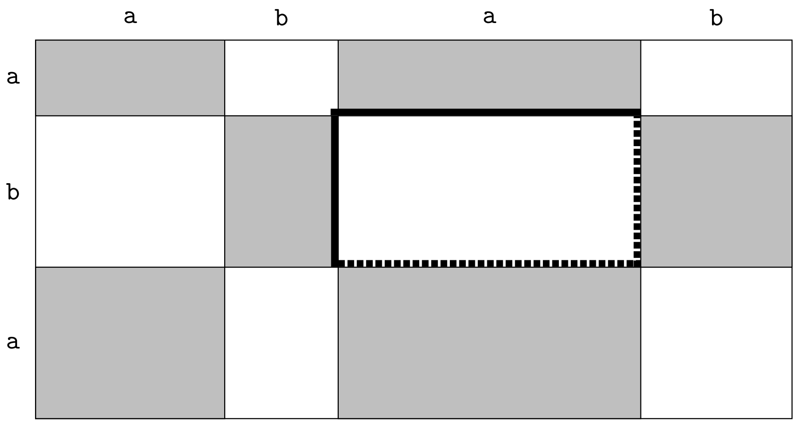

Figure 1 Match blocks are in grey. The thick line is for an input border and the dotted line an output border. The input border is contained entirely inside the neighbouring match blocks.

For mismatch blocks Chen and Chao's algorithm, in a similar manner to previous RLE edit distance algorithms, splits the problem into two parts corresponding to shortest paths that pass through the leftmost column or the top row [3, 6–8]. Consider a mismatch block of height h and width w corresponding to runs a^{h-1} and b^{w-1} such that $h \leq w$ (the other case can be processed similarly by swapping the left and the top part of the input border). $\mathrm{LEFT}[1, h]$ and $\mathrm{TOP}[1, w]$ denotes the values of the left and the top part of the input border, numbered in a bottom-to-top and a left-to-right direction, respectively. For an array $S[1, n]$ and a parameter $h \in \mathbb{Z}^+$, let $S^{(h)}[i] = \min\{S[j] \mid i - h + 1 \leq j \leq i, 1 \leq j \leq n\}$. Chen and Chao separately compute all the output border values that are derived from a value in the left part of the input border, denoted $\mathrm{OUT}_{\mathrm{LEFT}}[1, w + h - 1]$, and similarly compute all the output border values that are derived from a value in the top part of the input border, denoted $\mathrm{OUT}_{\mathrm{TOP}}[1, w + h - 1]$, as follows.

$$\mathrm{OUT}_{\mathrm{LEFT}}[i] \quad = \quad \begin{cases} \mathrm{LEFT}^{(h)}[i] + i - 1 & \text{for } i \in [1, h]; \\ \mathrm{LEFT}^{(h)}[h] + i - 1 & \text{for } i \in [h, w]; \\ \mathrm{LEFT}^{(h)}[i - w + h] + w - 1 & \text{for } i \in [w, w + h - 1]; \end{cases} \tag{1}$$

$$\mathrm{OUT}_{\mathrm{TOP}}[i] \quad = \quad \begin{cases} \mathrm{TOP}^{(h)}[i] + h - 1 & \text{for } i \in [1, w]; \\ \mathrm{TOP}^{(h)}[i] + w + h - 1 - i & \text{for } i \in [w, w + h - 1]. \end{cases} \tag{2}$$

We start with reformulating the algorithmic framework of Chen and Chao using the following notation.

▶ **Definition 3.** *Let $S[1, n]$ be a 1-indexed array of length n.*

- *For a parameter $h \in \mathbb{Z}^+$, SWM(S, h) (Sliding Window Minima) returns the array $S^{(h)}$ of length $n + h - 1$.*
- *split(S, m) returns the two subarrays $S[1, m]$, and $S[m + 1, n]$.*
- *$S \pm \overrightarrow{1}$ returns S with the gradient decreased/increased by one, or formally $S'[i] = S[i] \pm i$.*
- *For an integer constant c, $S + c$ returns S with every value increased by c.*
- *initialise(ℓ) returns an array of length ℓ initially filled with zeroes.*
- *join(S_1, S_2) simply concatenates two arrays.*

Now, equations (1) and (2) can be rephrased as Algorithms 1 and 2, respectively. The final step of the algorithm is to compute the output border as the minimum of $\mathrm{OUT}_{\mathrm{TOP}}[i]$ and $\mathrm{OUT}_{\mathrm{LEFT}}[i]$ for each index i. This is performed in linear time per block by Chen and Chao [8]. In Section 3 we will design a new implementation of both algorithms and a subtle amortised argument for this final step. The latter is based on the fundamental property of the values in an output border summarised by Lemma 4.

▶ **Lemma 4** ([8, Lemma 7]). *If there exists an i such that $\mathrm{OUT}_{\mathrm{TOP}}[i] \leq \mathrm{OUT}_{\mathrm{LEFT}}[i]$, then $\mathrm{OUT}_{\mathrm{TOP}}[j] \leq \mathrm{OUT}_{\mathrm{LEFT}}[j]$ for all $j \geq i$.*

Algorithm 1 Compute the shortest path passing through the left border.

```
$S \leftarrow \mathsf{SWM}_h(\mathrm{LEFT}[1, h], h)$;
$S^\ell, S^r \leftarrow \mathsf{split}(S, h)$;
$S_1 \leftarrow S^\ell + \overrightarrow{1} - 1$;
$S_2 \leftarrow \mathsf{initialise}(w - h) + \overrightarrow{1} + S[h] + h - 1$;

$\mathrm{OUT}_{\mathrm{TOP}} \leftarrow \mathsf{join}(S_1,S_2)$;
```

Before we go on to explain how we speed up the task of deriving the borders of blocks, it is worth exploring for a moment why we cannot simply apply, perhaps with some small modifications, the known $\mathcal{O}(mn\log(mn))$ time solution for LCS on RLE strings [2]. The key obstacle comes from the different nature of optimal paths in the dynamic programming table of the LCS and edit distance problems.

For the LCS problem on RLE strings Apostolico et al. [2] introduced two important concepts. The first is *forced paths* and the second *corner paths*. They say that a path beginning at the upper-left corner of a match block is *forced* if it traverses the block by strictly diagonal moves and, whenever the right (respectively, lower) side of an intermediate match block is reached, proceeds to the next match block by a straight horizontal (respectively, vertical) line through the mismatch blocks in between. A *corner* path is one that enters match blocks in the top left corner and exits only through the bottom right corner. They show that there is always a longest common subsequence between two strings corresponding to the concatenation of subpaths of corner and forced paths. This fact greatly reduces the number of different paths that have to be considered and hence the complexity of solving the overall LCS problem. However for the edit distance problem this property of forced paths no longer holds. Figures 2 and 3 show an example of this key difference between optimal paths under edit distance and LCS. In Figure 2 we can see that there is no optimal vertical (or horizontal) path through the mismatch block. By contrast, there is indeed an optimal vertical path for the LCS problem as illustrated by Figure 3.

In order to speed up edit distance computation on RLE strings we introduce a new data structure for input borders and output borders. This will allow us to derive the values of output borders from their respective input borders in amortised logarithmic time per border, rather than the previous linear time. The rest of the paper is devoted to this task.

3 Efficient Manipulation of Piecewise-Linear Functions

In this section, we describe the data structure we will use to represent input borders and output borders in the dynamic programming table. We will then show how the operations from Definition 3 can be implemented efficiently using this data structure.

Recall that *a piecewise linear function* is a real-valued function F whose domain $\mathrm{dom}(F)$ is a closed interval that can be represented as a union of closed intervals $\mathrm{dom}(F) = \bigcup_{j=1}^{k} I_j$ such that F restricted to I_j is an affine function ($g_j x + h_j$ for some coefficients g_j and h_j). The input and output borders as defined in Section 2 are by definition piecewise linear.

In this section, we impose a few further restrictions:

- For each integer $x \in \mathrm{dom}(F)$, the value $F(x)$ is also an integer.
- The gradient g_j of each $F|_{I_j}$ is -1, 0, or 1.
- The endpoints of $\mathrm{dom}(F)$ are integers or half-integers.

The graph of a piecewise linear function F is a simple polygonal curve, and thus it can be interpreted as a sequence of *turning points* connected by straight-line *segments*. Due to the restrictions imposed on F, each turning point has integer or half-integer coordinates. We represent such a function F as a sequence of segments stored in an annotated balanced binary search tree, where each segment explicitly keeps the coordinates of its endpoints.[2]

We first provide a simple implementation of curves supporting a few basic operations, and then we gradually augment it to handle more complicated operations. We conclude with an amortised running time analysis.

3.1 Basic Operations

Our first implementation just stores the corresponding segment for each node v:

(x_ℓ, y_ℓ): The coordinates of the left endpoint of the segment corresponding to v.
(x_r, y_r): The coordinates of the right endpoint of the segment corresponding to v.

Nevertheless, we are already able to implement some operations useful in Algorithms 1 and 2.

Create. The create operation produces a function F whose graph consists of just one segment S with given endpoints (x_ℓ, y_ℓ) and (x_r, y_r). This enables us to implement the whole of line 4 of Algorithm 1 in worst-case constant time.

Join. The join operation takes two functions, F_L and F_R with domains $\mathrm{dom}(F_L) = [x_L, x_M]$ and $\mathrm{dom}(F_R) = [x_M, x_R]$, respectively, and with a common endpoint $F_L(x_M) = F_R(x_M)$. It returns a function F with $\mathrm{dom}(F) = [x_L, x_R]$ such that $F_L = F|_{[x_L,x_M]}$ and $F_R = F|_{[x_M,x_R]}$. To implement this operation, we first join the two balanced binary search trees. If the rightmost segment of F_L has the same gradient as the leftmost segment of F_R, we also join these segments. The resulting tree represents F. The worst-case running time is logarithmic.

Split. The split operation takes a function F with $\mathrm{dom}(F) = [x_L, x_R]$ and a value $x_M \in \mathrm{dom}(F)$. It returns two functions $F_L = F|_{[x_L,x_M]}$ and $F_R = F|_{[x_M,x_R]}$. To implement it, we first descend the binary search tree to find a segment S with $x_M \in \mathrm{dom}(S)$. If x_M lies in the interior of $\mathrm{dom}(S)$, we split this segment into two. Next, we split the binary search tree to separate the segments to the left of x_M from the segments to the right of x_M. The resulting two trees represent F_L and F_R, respectively. The worst-case running time is logarithmic.

[2] Note that the coordinates of each internal turning point are stored with both incident segments.

Combine. The combine operation takes two functions F_1 and F_2 over the same domain $\mathrm{dom}(F_1) = \mathrm{dom}(F_2) = [x_L, x_R]$ and returns their pointwise minimum: a function F with $\mathrm{dom}(F) = [x_L, x_R]$ such that $F(x) = \min(F_1(x), F_2(x))$ for $x \in \mathrm{dom}(F)$. We assume that there exists $x_M \in [x_L, x_R]$ such that $F_1(x) > F_2(x)$ if $x < x_M$ and $F_1(x) \le F_2(x)$ if $x \ge x_M$.

If $F_1(x_L) \le F_2(x_L)$, then $x_M = x_L$. Hence, we return $F = F_1$ and discard F_2. Similarly, if $F_1(x_R) > F_2(x_R)$, then $x_M = x_R$. Hence, we return $F = F_2$ and discard F_1.

Otherwise, we are guaranteed that $F_1(x_M) = F_2(x_M)$. Our first task is to find x_M. For this, we locate segments S_1 of F_1 and S_2 of F_2 such that $x_M \in \mathrm{dom}(S_1) \cap \mathrm{dom}(S_2)$.

We observe that S_1 corresponds to the leftmost node v in the BST of F_1 such that $v.y_r = F_1(v.x_r) \le F_2(v.x_r)$. Hence, we perform a left-to-right in-order traversal of the BST to find S_1. For each visited node v, we evaluate $F_2(v.x_r)$ by descending the BST of F_2 to find a segment whose domain contains $v.x_r$. Symmetrically, S_2 corresponds to the rightmost node v in the BST of F_2 such that $F_1(v.x_\ell) > F_2(v.x_\ell) = v.y_\ell$, so we find S_2 by performing a right-to-left in-order traversal of the BST.

Next, we note that $(x_M, F_1(x_M)) = (x_M, F_2(x_M))$ is the leftmost common point of S_1 and S_2. Hence, we can now compute x_M easily (the restrictions on F_1 and F_2 guarantee that it is an integer or a half-integer). Finally, we split both F_1 and F_2 at x_M, discard $F_1|_{[x_L,x_M]}$ and $F_2|_{[x_M,x_R]}$, join $F_2|_{[x_L,x_M]}$ with $F_1|_{[x_M,x_R]}$, and return the resulting function as F.

As far as the running time is concerned, the cost is logarithmic for each discarded segment. We can now also implement the final combine step that produces our representation of the output border from the outputs of Algorithms 1 and 2 by finding the minimum at each index.

3.2 Shifts

Next, we extend our data structure to implement the shift operation which moves the whole function by a given vector. It is useful in Algorithms 1 and 2 for altering S^ℓ and S^r.

Formally, given a function F with $\mathrm{dom}(F) = [x_L, x_R]$ and a vector (Δ_x, Δ_y), we transform F into F' such that $F'(x) = F(x - \Delta_x) + \Delta_y$ for each $x \in \mathrm{dom}(F') = [x_L + \Delta_x, x_R + \Delta_x]$.

This update is performed using a technique known as *lazy propagation*. We augment each node v with the following extra field:

(δ_x, δ_y): A deferred shift to be propagated within the subtree of v.

This change is then lazily propagated as further operations are executed. Here, we rely on a key structural property of BST operations:

▶ **Observation 5.** *The execution of every BST operation can be extended (at the cost of an extra multiplicative constant in the running time) with a sequence of node* activations *and* deactivations *such that:*

- *a node v is accessed only when it is active and has no active descendant,*
- *when v is active, then all its ancestors are active,*
- *no node is active at the beginning and the end of the execution.*

The idea behind lazy propagation is that the deferred updates stored at a node v are propagated when v is activated. This way, every active node has no delayed updates pending. Hence, from the perspective of any other operation, the effect is the same as if we have meticulously modified every node for each update.

The shift propagation is very simple: when a node v receives a request for a shift by (Δ_x, Δ_y), then we just add (Δ_x, Δ_y) to the delayed shift $(v.\delta_x, v.\delta_y)$ stored at v. Upon activation of v, we propagate $(v.\delta_x, v.\delta_y)$ to the children of v, add $(v.\delta_x, v.\delta_y)$ to both (x_ℓ, y_ℓ)

and (x_r, y_r), and reset $(v.\delta_x, v.\delta_y) := (0, 0)$. To implement the *shift* operation, we just send a request for a shift by (Δ_x, Δ_y) to the root node r.

The worst-case running time of a shift is constant, and the extra cost of propagation does not increase the asymptotic running time of the remaining operations.

3.3 Gradient Changes

The gradient change operation takes a function F and a coefficient Δ_g, and it transforms F into F' such that $F'(x) = F(x) + \Delta_g \cdot x$ for each $x \in \operatorname{dom}(F') = \operatorname{dom}(F)$. This operation is needed in both Algorithms 1 and 2 to transform S^r and S^ℓ, respectively.

We first note that the constraints imposed on the gradients of functions F and F' yield that $\Delta_g = -1$, F is non-decreasing, and F' is non-increasing, or $\Delta_g = 1$, F is non-increasing, and F' is non-decreasing. However, these limitations only become relevant in Section 3.4.

To implement gradient change, we just add another field to each node v:

δ_g: A deferred gradient change to be propagated within the subtree of v.

We now have two types of lazily propagated updates: shift and gradient change. These two operations do *not* commute, so we need to decide how to interpret the two kinds of deferred updates stored at a node v. We shall assume that the gradient change by δ_g is to be performed *before* the shift by (δ_x, δ_y).

Thus, while shift propagation is implemented as in Section 3.2, adding Δ_g to $v.\delta_g$ is insufficient when a node v receives a request to change gradient by Δ_g: we also need to add $\Delta_g \cdot \delta_x$ to δ_y. This approach is correct since a shift by (Δ_x, Δ_y) followed by a gradient change by Δ_g is equivalent to a gradient change by Δ_g followed by a shift by $(\Delta_x, \Delta_y + \Delta_g \cdot \Delta_x)$.

Upon activation of v, we first apply the deferred gradient change: we propagate it to the children of v, increase $v.y_\ell$ by $v.\delta_g \cdot v.x_\ell$ and $v.y_r$ by $v.\delta_g \cdot v.x_r$, and reset $v.\delta_g = 0$. Then, we handle the deferred shift as in Section 3.2.

Finally, we note that to implement the *gradient change* operation, we just send a request for a gradient change by Δ_g to the root node r. The worst-case running time is constant.

3.4 Sliding Window Minima

We can finally show how to implement the SWM operation efficiently on our data structure. This is the most involved of the operations we will need. The SWM operation given a function F with $\operatorname{dom}(F) = [x_L, x_R]$ and a *window width* t, returns a function F' with $\operatorname{dom}(F') = [x_L, x_R + t]$ such that $F'(x) = \min\{F(x') : x' \in [x - t, x] \cap \operatorname{dom}(F)\}$.

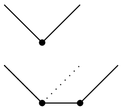
Combinatorial Properties

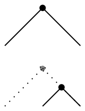
We begin by observing that the SWM operation is composable.

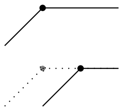
► **Observation 6.** *Every function F and positive window widths t, t' satisfy $\mathsf{SWM}(\mathsf{SWM}(F, t), t') = \mathsf{SWM}(F, t + t')$.*

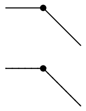
Hence, instead of applying $\mathsf{SWM}(\cdot, t)$ for an integer width t, we may equivalently apply the $\mathsf{SWM}(\cdot, 1)$ operation t times. The key property of width 1 is that the changes to the transformed function are very local. The structure of these modifications can be described in terms of *types* of turning points. We classify internal turning points by the gradients (**I**ncreasing, **F**lat, or **D**ecreasing) of the incident segments; see Table 1, where we also analyse how a function changes in the vicinity of each turning point subject to $\mathsf{SWM}(\cdot, 1)$.

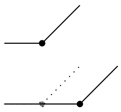
Table 1 Types of internal turning points and their behaviour subject to the SWM operation.

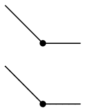
Type DI	Type ID	Type IF	Type FD	Type FI	Type DF
					












- A point of type FD or DF remains intact.
- A point of type FI or IF is shifted by $(1, 0)$.
- A point of type ID is shifted by $(0.5, -0.5)$.
- A point of type DI transformed into a point of type DF and a point of type FI, and the latter is shifted by $(1, 0)$.

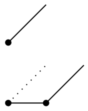
Note that the behaviour of DI points is unlike that of other types. However, this discrepancy disappears if we replace every DI point with two coinciding points of types DF and FI, respectively, with an artificial length-0 segment in between. Hence, whenever a new internal turning point is created (which happens only within the join operation), if the turning point would be of type DI, we pre-emptively replace it by two coinciding points of type DF and FI, respectively. Note that the resulting length-0 segment never changes its gradient since gradient change is allowed only on a monotone function. However, when an incident segment is modified, we may need to remove the length-0 segment. This process cannot cascade, though, causing another length zero segment to be removed.

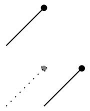
Next, we analyse in Table 2 how the $\mathsf{SWM}(F, 1)$ operation affects the endpoints of the graph of F. In most cases, the left endpoint stays intact and the right endpoint is shifted by $(0, 1)$. The only exceptions are endpoints of type -I and D-, which exhibit similar behaviour to the internal turning points of type DI. Moreover, this discrepancy also disappears if we introduce artificial flat segments of length 0. Hence, we replace a point of type -I with two points of type -F and FI, respectively, and a point of type D- with two points of type DF and F-, respectively. However, this time the replacement is *not* pre-emptive: we perform it as the first step in the implementation of the SWM operation. This is possible because there are just two endpoints, while the number of internal turning points of type DI could be large. Our gain, on the other hand, is that we avoid length-0 segments changing their gradients.

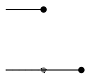
With the artificial length-0 segments in place, it is now true that the effect of the SWM operation on each turning point can be described as a shift depending only on the type of the point. As a result of these shifts, some segments may disappear as their length reaches 0; in this case, we say that a segment *collapses*. Only segments of three kinds may collapse:

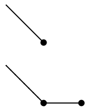
- a segment between a point of type ID and point of type DF;
- a segment between a point of type IF and point of type FD;
- a segment between a point of type FI and point of type ID;

Table 2 Types of endpoints and their behaviour subject to the SWM operation.

Type -I	Type -F	Type -D	Type I-	Type F-	Type D-
					








When a segment collapses, it is removed and the two incident turning points are merged.[3] Each segment of the three affected kinds has the *collapse time*, defined as the smallest t for which $\mathsf{SWM}(\cdot, t)$ makes it collapse (assuming no interaction from incident segments) equal to the Manhattan distance between its endpoints. Note that due to the restrictions on the piecewise linear functions considered in this section, the collapse time is always an integer.

Implementation

To implement the SWM operation, we augment each node v with the following fields:

$\mathbf{type}_\ell, \mathbf{type}_r$: The types of the turning points joined by the segment corresponding to v.
$\boldsymbol{\delta_t}$: The amount of a deferred SWM to be propagated within the subtree of v.
$\boldsymbol{t}_{\mathbf{min}}$: The minimum collapse time among the segments in the subtree of v.

Note that the type of each internal turning point is stored twice. Hence, whenever a node type changes, this fact needs to be reflected at both incident segments (and we need to reach the corresponding nodes by descending the BST; shortcuts would violate Observation 5).

The field $v.t_{\min}$ is of a kind we have not encountered yet: its value depends on the corresponding values for the children of v and on other fields at v. It is brought up to date whenever v is deactivated (so that it can be accessed only when v is inactive). We shall assume that its value already reflects the deferred updates stored at v. The procedure of recomputing $v.t_{\min}$ is simple: we determine the collapse time of the segment represented by v (which is infinite or equal to $|v.x_r - v.x_\ell| + |v.y_r - v.y_\ell|$ depending on the types of the incident turning points), and take the minimum of this value and $u.t_{\min}$ for every child u of v. Since v has no deferred changes when it is deactivated, the resulting minimum is $v.t_{\min}$.

Propagation. The main structural modification to the lazy propagation procedures is that we maintain an additional invariant that no deferred changes are stored on the leftmost and on the rightmost path of the BSTs representing every function F. To maintain this invariant, immediately after lazily updating of the whole F (sending a request to the root node r), we descend to the leftmost and to the rightmost segment F; this increases the cost of shift and gradient change to logarithmic. Note that the split operation must anyway visit the nodes representing the new boundary segments (to update the types of new endpoints). Moreover, if a path from the root to a given node v contains no deferred updates, then this is still true after any rebalancing of the BST (as only active nodes get rotated).

Concerning the lazy SWM propagation, we explicitly forbid requesting for SWM with window width exceeding $r.t_{\min}$, because collapsed segments need to be removed before we proceed further. Also, the window widths (and hence the values δ_t) are always non-negative.

We have three kinds of deferred updates now: SWM, gradient change, and shift. We fix the semantics of the fields δ_t, δ_g, and (δ_x, δ_y) so that an SWM of width δ_t is performed first, a gradient change by δ_g second, and a shift by (δ_x, δ_y) last. The requests for a shift and for a gradient change are still implemented as in Section 3.3; note that these updates do not affect the collapse times (the three segment kinds with finite collapse times cannot appear in monotone functions). On the other hand, the request for an SWM with a window width Δ_t requires more care. We clearly need to increase δ_t by Δ_t and decrease $t_{\min}$ by the same amount. The aforementioned steps suffice if $\delta_g = 0$. Otherwise, we note that the turning

[3] Two adjacent segments may collapse simultaneously. In that special case, three subsequent points, of type FI, ID, and DF, respectively, need to be deleted.

points in the subtree of v are all of types DF and FD or all of types IF and FI. (Observe that there are no deferred changes in the proper ancestors of v and that v is not on the leftmost or rightmost path in this case.) We can easily distinguish the two cases by analysing the endpoints of the segment corresponding to v. Moreover, the SWM operation is void in the first of these cases, and in the second one it reduces to a shift by $(\Delta_t, 0)$. Hence, we shall implement it this way rather than by modifying $v.\delta_t$.

The propagation itself is relatively easy: upon activation of a node v, we first propagate the SWM operation to the children of v, update the endpoints of the segment corresponding to v (according to Tables 1 and 2, with the shift multiplied by δ_t), and finally reset $\delta_t = 0$. Then, we propagate the gradient change and the shift. This is implemented as in Section 3.3 except that the gradient change now affects not only the coordinates but also the types of the segment's endpoints.

SWM Procedure. To implement the SWM procedure itself, we first check the endpoint types and perform appropriate substitutions for endpoints of type -I and D-. Next, we would like to lazily apply the SWM operation with window width t to the root r. However, this could result in negative collapse time $r.t_{\min}$, so instead we perform SWM gradually based on Observation 6. If $r.t_{\min} < t$, we make a request for SWM with window width just $r.t_{\min}$, leaving the remaining quantity $t - r.t_{\min}$ for later on. This already results in $r.t_{\min} = 0$, which indicates that there is a collapsed segment. We descend the tree to find such a collapsed segment (activating nodes on the way there and deactivating them on the way back), and take care of this segment appropriately (this may affect neighbouring segments as well). We repeat the process as long as $r.t_{\min} = 0$. Once this value is positive again, we are ready to proceed with further application of SWM.

As far as the running time is concerned, the cost of SWM consists of a logarithmic term for visiting the endpoints and further logarithmic terms for each collapsed segment.

3.5 Complexity Analysis

We complete this section by showing that the aforementioned operations run in *amortised* logarithmic time.

▶ **Lemma 7.** *A sequence of k operations on piecewise linear functions takes $\mathcal{O}(k \log k)$ time.*

Proof. Our potential is $\log k$ multiplied by the total number of turning points in all the stored functions. First, we observe that this potential grows by $\mathcal{O}(\log k)$: each operation creates a constant number of new turning points. In particular, the total number of turning points is $\mathcal{O}(k)$, so manipulating BSTs takes $\mathcal{O}(\log k)$ time. Next, we note that the worst-case running time of most operations is $\mathcal{O}(\log k)$, with extra $\mathcal{O}(\log k)$ time needed for each discarded or collapsed segment. However, every such segment decreases the potential by $\log k$. ◀

4 An $\mathcal{O}(mn \log(mn))$ time RLE Edit Distance Algorithm

As in the previous algorithm by Chen and Chao [8], we go through the dynamic programming table block by block. For every block, we transform the representation of its input border to the representation of its output border. As mentioned earlier, borders are piecewise linear with gradient ±1 or 0 so they can be maintained in the structure described in Section 3. We will assume that the left and the top part of the input border of every block are stored in separate structures. We start by generating the structures corresponding to the left and the top border of the whole dynamic programming table. These left and top borders are each a single decreasing and increasing sequence, respectively. As a result, we can generate the data structure for the parts corresponding to all blocks trivially in $\mathcal{O}(m+n)$ time using $m+n$ create operations. Now, we have to describe how to obtain the structure corresponding to the right and the bottom part of the output border of the current block given the structures corresponding to the left and the top part of its input border. We stress that any structure will be created and then used once as an input to a further operation, which is crucial for the amortisation argument within Lemma 7.

Recall that the semantics of split and join operating on arrays in Section 2 and of split and join operating on piecewise linear functions in Section 3 is slightly different: split now creates two functions that both contain the value of the original function at x_M; symmetrically, join takes two functions defined on $[x_L, x_M]$ and $[x_M, x_R]$ that share the same value at x_M. This is, however, not an issue because the cases in both (1) and (2) overlap at the boundaries.

For a match block, the value stored in an element (i, j) of the output border is a copy of the value stored in the corresponding element (i_d, j_d) of the input border. Recalling that (i_d, j_d) is the intersection of the input border with diagonal $j - i$, this can be readily implemented with a constant number of split and join operations.

For a mismatch block, we need to apply Algorithms 1 and 2, merge the returned solutions by taking the minimum at every position, and finally create separate structures corresponding to the right and the bottom part of the output border with a single split operation. Note that while we have already observed that both input border and output border are piecewise linear with gradient ±1 or 0, we need to make sure that the same is true for every function obtained inside Algorithms 1 and 2, and for $\mathrm{OUT}_{\mathrm{TOP}}$ and $\mathrm{OUT}_{\mathrm{LEFT}}$ in particular.

▶ **Lemma 8.** *Every function obtained in Algorithms 1 and 2 is piecewise linear with gradient* ± 1 *or* 0.

Proof. Consider Algorithm 1. It is easy to verify that S and hence also S^ℓ and S^r are indeed piecewise linear with gradient ±1 or 0. Additionally, $S^\ell[i]$ is equal to the minimum in $\mathrm{LEFT}[1, i]$ and so S^ℓ is non-increasing. Consequently, S_1, S_2, and S_3 are all piecewise linear with gradient ±1 or 0. We only need to verify that the same holds for their concatenation. This is true because each of these three parts corresponds to a case considered in (1), and these cases overlap at the boundaries.

Next, consider Algorithm 2. Similarly as above, it is easy to verify that S and so also S^ℓ and S^r are piecewise linear with gradient ±1 or 0. Furthermore, $S^r[i]$ is equal to the minimum in $\mathrm{TOP}[w-h+i+1, w]$ and so S^r is non-decreasing. Thus, S_1 and S_2 are piecewise linear with gradient ±1 or 0 and the same holds for their concatenation because the cases in (2) overlap at the boundaries. ◀

We now explain in detail how to implement Algorithm 1. We start with computing S^ℓ and S^r by first calling $\mathsf{SWM}(\mathrm{LEFT}, h-1)$ and then using split. Next, S_1 is obtained by applying gradient change and shift to S^ℓ, S_2 is obtained by calling create, and S_3 is obtained by applying shift to S^r. Finally, $\mathrm{OUT}_{\mathrm{LEFT}}$ is created with two calls to join.

Algorithm 2 is implemented by calling $\mathsf{SWM}(\mathrm{TOP}, w-1)$ and then using split. Next, S_1 is obtained by applying shift to S^ℓ, while S_2 is obtained by applying gradient change and shift to S^r. Finally, $\mathrm{OUT}_{\mathrm{TOP}}$ is created by a single call to join.

Having obtained a representation of $\mathrm{OUT}_{\mathrm{LEFT}}$ and $\mathrm{OUT}_{\mathrm{TOP}}$, we call combine to obtain a representation of the output border. Such a call is valid due to Lemma 4. The overall number of operations on structures is $\mathcal{O}(mn)$, making the final time complexity $\mathcal{O}(mn\log(mn))$ by Lemma 7.

Abstract

We consider the problem of compactly representing the Depth First Search (DFS) tree of a given undirected or directed graph having n vertices and m edges while supporting various DFS related queries efficiently in the RAM with logarithmic word size. We study this problem in two well-known models: *indexing* and *encoding* models. While most of these queries can be supported easily in constant time using $O(n \lg n)$ bits[1] of extra space, our goal here is, more specifically, to beat this trivial $O(n \lg n)$ bit space bound, yet not compromise too much on the running time of these queries. In the *indexing* model, the space bound of our solution involves the quantity m, hence, we obtain different bounds for sparse and dense graphs respectively. In the *encoding* model, we first give a space lower bound, followed by an almost optimal data structure with extremely fast query time. Central to our algorithm is a partitioning of the DFS tree into connected subtrees, and a compact way to store these connections. Finally, we also apply these techniques to compactly index the shortest path structure, biconnectivity structures among others.

1 Introduction

Depth First Search (DFS) is a very well-known method for visiting the vertices and edges of a directed or undirected graph. DFS differs from other ways of traversing the graph such as Breadth First Search (BFS) by the following DFS protocol: Whenever two or more vertices were discovered by the search method and have unexplored incident (out)edges, an (out)edge incident on the most recently discovered such vertex is explored first. This DFS traversal produces a rooted spanning tree (forest), called DFS tree (forest) along with assigning an index to every vertex v i.e., the time vertex v is discovered for the first time during DFS. We call it depth-first-index (DFI(v)). Let $G = (V, E)$ be a graph on $n = |V|$ vertices and $m = |E|$ edges where $V = \{v_1, v_2, \cdots, v_n\}$. It takes $O(m + n)$ time to perform a DFS traversal of G and to generate its DFS tree (forest) with DFIs of all the vertices. The DFS rule confers a number of structural properties on the resulting graph traversal that cause DFS to have a large number of applications. These properties are captured in the DFS tree (forest), and can be used crucially to design efficient algorithms for many basic and fundamental algorithmic graph problems, namely, biconnectivity [22], 2-edge connectivity [23], strongly connected components [22], topological sorting [22], dominators [24], *st*-numbering [13] and planarity testing [17] among many others.

[1] We use lg to denote logarithm to the base 2.

There are two versions of DFS studied in the literature. In the lexicographically smallest DFS or lex-DFS problem, when DFS looks for an unvisited vertex to visit in an adjacency list, it picks the "first" unvisited vertex where the "first" is with respect to the appearance order in the adjacency list. The resulting DFS tree will be unique. In contrast to lex-DFS, an algorithm that outputs some DFS numbering of a given graph, treats an adjacency list as a set, ignoring the order of appearance of vertices in it, and outputs a vertex ordering Q such that there exists some adjacency ordering R such that Q is the DFS numbering with respect to R. We say that such a DFS algorithm performs general-DFS. In this work, we focus only on lex-DFS, thus, given a source vertex, the DFS tree is always unique. Given the lex-DFS tree, the non-tree edges of a given directed graph can be classified into four categories as follows. An edge directed from a vertex to its ancestor in the tree is called a back edge. Similarly, an edge directed from a vertex to its descendant in the tree is called a forward edge. Further, an edge directed from right to left in the DFS tree is called a cross edge. The remaining edges directed from left to right in the tree are called anti-cross edges. In the undirected graphs, there are no cross edges. Note that, we can store the complete DFS tree explicitly using $O(n \lg n)$ bits by storing pointers between nodes. In what follows, we formally define the problem which we call the DFS-Indexing problem.

DFS-Indexing problem
Input: A directed or undirected graph $G = (V, E)$ where $|V| = n$, $|E| = m$, and a source vertex v_s, preprocess G and answer the following queries with respect to the DFS tree T rooted at v_s:

1. Given any pair of vertices v_i and v_j,
   a. Who is visited first in the DFS traversal of G?
   b. Is v_i an ancestor of v_j in T?
2. Given v_i,
   a. Return the parent of v_i in T.
   b. Return the number of children (if any) of v_i in T.
   c. Enumerate all the children (if any) of v_i in T.
   d. Return the DFI of v_i.
3. Enumerate the order in which vertices of G are visited in the DFS.
4. Given $1 \leq i \leq n$, return the vertex with DFI i.

We study the DFS-Indexing problem in two well-known models: the *indexing* and *encoding* models [21]. In the indexing model, we wish to build an index *ind* after preprocessing the input graph G such that queries can be answered using both *ind* and G whereas in the encoding model, we seek to build a data structure *encod* after preprocessing the input graph G such that queries have to be answered using *encod* only. Typically the parameters of interest are (i) query time, (ii) space consumed (in bits) by *ind* and *encod* resp. and (iii) the preprocessing time and space. We address all these issues in our paper for the DFS-Indexing problem, assuming our computational model is a Random-Access-Machine with constant time operations on $O(\lg n)$-bit words. In both models, it is not hard to see that using $O(n \lg n)$ bits, we can answer all the queries of the DFS-Indexing problem in the optimal $O(1)$ time except the query of 3 which takes $O(n)$ time. Our main objective here is to beat this trivial $O(n \lg n)$ bit space bound without compromising too much on the query time.

The motivation for studying this question mainly stems from the rise of the "big data" phenomenon and its implications. To illustrate, the rate at which we store data is increasing even faster than the speed and capacity of computing hardware. Thus, if we want to use the stored data efficiently, we need to represent it in sophisticated ways. Many applications dealing with huge data structures can benefit from keeping them in compressed form. Compression has many advantages: it can allow a representation to fit in main memory rather than swapping out to disk, and it improves cache performance since it allows more data to fit into the cache. However, such a data structure is only handy if it allows the application to perform fast queries to the data, and this is the direction we want to explore for the DFS tree. More specifically, we are interested in representing the DFS tree of a given graph compactly while supporting all the queries mentioned above efficiently.

1.1 Representation of the Input Graph

We assume that the input graphs $G = (V, E)$ are represented using the *adjacency array* format, i.e., G is given by an array of length $|V|$ where the i-th entry stores a pointer to an array that stores all the neighbors of the i-th vertex. For the directed graphs, we assume that the input representation has both in/out adjacency array for all the vertices i.e., for directed graphs, every vertex v has access to two arrays, one array is for all the in-neighbors of v and the other array is for all the out-neighbors of v. This form of input graph representation has now become somewhat standard and was recently used in plenty of other works [2, 6, 7, 8, 9, 10]. Throughout this paper, we call a graph sparse when $m = O(n)$, and dense otherwise (i.e., $m = \omega(n)$).

1.2 Our Main Results and Organization of the Paper

We start by mentioning some preliminary results that will be used throughout the paper in Section 2. Section 3 contains the description of our main index for solving the DFS-Indexing problem in the indexing model. Our main results here can be summarized as follows,

▶ **Theorem 1.** *In the indexing model, given any sparse (dense resp.) undirected or directed graph G, there exists an $O(m + n)$ time and $O(n \lg n)$ bits preprocessing algorithm which outputs a data structure of size $O(n)$ ($O(n \lg(m/n))$ resp.) bits, using which the queries 1(a), 1(b), 2(d) and 4 can be reported in $O(\lg n)$ time, 2(a) and 2(b) in $O(1)$ time, 2(c) in time proportional to the number of solutions, and finally 3 can be solved in $O(n)$ time resp. for the* DFS-Indexing *problem.*

We want to emphasize that obtaining better results for sparse graphs is not only interesting from theoretical perspective but also from practical point of view as these graphs do appear very frequently in most of the realistic network scenario in real world applications, e.g., Road networks and the Internet.

In Section 4, we provide the detailed proof of our index in the encoding model. This contains a space lower bound for any index for the DFS-Indexing problem, followed by an index whose size asymptotically matches the lower bound and has efficient query time. We summarize our main results below.

▶ **Theorem 2.** *In the encoding model, the size of any data structure for the* DFS-Indexing *problem must be $\Omega(n \lg n)$ bits. On the other hand, given any (un)directed graph, there exists an $O(m + n)$ time and $O(n \lg n)$ bits preprocessing scheme that outputs an index of size $(1 + \epsilon)n \lg n + 2n + o(n)$ bits (for any constant $\epsilon > 0$), using which the queries 1(a), 1(b), 2(a), 2(b), 2(d) can be reported in $O(1)$ time, 2(c) in time proportional to the number of solutions, 3 in $O(n/\epsilon)$ time, and finally 4 in $O(1/\epsilon)$ time resp. for the* DFS-Indexing *problem in this setting.*

Building on all these aforementioned results, we also show a host of applications of our techniques in designing indices for other fundamental graph problems. We provide the details about these results in the full version of our paper. Finally, we conclude in Section 5 with some open problems and possible future directions to explore further.

Remark. At this point we want to emphasize that our results are more general, i.e., they can be extended to store any arbitrary labeled tree (arising from some underlying graph) along with the mechanism for fast querying. This method is very useful as many graph algorithms (like shortest path, minimum spanning tree, biconnectivity etc) induce a tree structure which is used subsequently during the execution of the algorithm. Hence, we can use our technique to store and query those trees compactly as well as efficiently. Thus, we also believe that our algorithm may find many other potential interesting applications. However, we chose to provide all the details in terms of DFS as DFS is very widely popular graph traversal technique and is used as the backbone for multiple fundamental algorithms, yet there is no explicit indexing scheme for storing DFS tree compactly. In the full version of our paper, we show how one can extend these techniques to design indexing schemes for a variety of other classical and fundamental graph problems.

1.3 Related Works

There already exists a large body of work concerning compactly representing various specific classes of graphs, for example planar, constant genus graphs etc [1, 5, 16, 18, 20, 21, 25]. All of these works are able to store an n-vertex unlabeled planar graph in $O(n)$ bits, and some of them even allow for $O(1)$-time neighbor queries. Generally what is meant by unlabeled is that the algorithm is free to choose an ordering on the vertices (integer labels from 1 to n). Our setting here is slightly different as we work with graphs whose vertices are labeled, and matches closely with [3]. Also we want to support more complex queries whereas the previous works only focused on adjacency queries mostly. Even though DFS being such a widely known method, and having many applications, to the best of our knowledge, we are not aware of any previous work focusing on compactly representing the DFS tree with efficient query support.

2 Preliminaries

Rank-Select. We make use of the following theorem:

▶ **Theorem 3** ([11]). *We can store a bitstring B of length n with additional $o(n)$ bits such that rank and select operations (defined below) can be supported in $O(1)$ time. Such a structure can also be constructed from the given bitstring in $O(n)$ time and space.*

For any $a \in \{0, 1\}$, the rank and select operations are defined as follows :

- $rank_a(B, i)$ = the number of occurrences of a in $B[1, i]$, for $1 \leq i \leq n$;
- $select_a(B, i)$ = the position in B of the i-th occurrence of a, for $1 \leq i \leq n$.

When the bitvector B is sparse, the space overhead of $o(n)$ bits can be avoided by using the following theorem, which will also be used later in our paper.

▶ **Theorem 4** ([21]). *We can store a bitstring B of length n with m 1s using $m \lg(n/m) + O(m)$ bits such that $select_1(B, 1)$ can be supported in $O(1)$ time, $select_0(B, 1)$ in $O(\lg m)$ time, and both the rank queries ($rank_1(B, i)$ and $rank_0(B, i)$) can be supported in $O(min(\lg m, \lg n/m))$ time. Such a structure can also be constructed from B in $O(n)$ time and space.*

Permutation. We also use the following theorem:

▶ **Theorem 5** ([19]). *A permutation π of length n can be represented using $(1+\epsilon)n \lg n$ bits so that $\pi(i)$ is answered in $O(1)$ time and π^{-1} in time $O(1/\epsilon)$ for any constant $\epsilon > 0$. Such a representation can be constructed using $O(n)$ time and space.*

Succinct Tree Representation. We need following result from [15].

▶ **Theorem 6** ([15]). *There exists a data structure to succinctly encode an ordered tree with n nodes using $2n + o(n)$ bits such that, given a node v, (a) child(v,i): i-th child of v, (b) degree(v): number of children of v, (c) depth(v): depth of v, (d) $select_{pre}(v)$: position of v in preorder, (e) $LA(v, i)$: ancestor of v at level i can be supported in $O(1)$ time among many others. Such a structure can also be constructed in $O(n)$ time and space.*

3 Algorithms in the Indexing Model

In this section, we provide the main algorithmic ideas needed for the solution of the DFS-Indexing problem in the indexing model. We start by describing the preprocessing procedure which is followed by the query algorithms.

3.1 Preprocessing Step

We first describe our algorithms for undirected graphs, and later mention the modifications required for the case of directed graphs. The preprocessing step of the algorithm is divided into two parts. In the first part, we perform a DFS of the input graph G along with storing some necessary data structures. In the second step, we perform a partition of the DFS tree of G using the well-known "tree covering technique" of the succinct data structures world [14], and also store some auxiliary data structures. Later, in the final step of our algorithm, we show how to use these data structures to answer the required queries. In what follows, we describe each step in detail.

Step 1: Creating Parent-Child Array using Unary Degree Sequence Array. The main idea of this step is to perform a DFS traversal of G and store in a *compact way* the parent-child relationship of the DFS tree T. The way we achieve this is by using three bitvectors of length $O(m + n)$ bits. Recall that, our input graphs $G = (V, E)$ are represented using the standard adjacency array. Central to our preprocessing algorithm is an encoding of the degrees of the vertices in unary. As usual, let $V = \{v_1, v_2, \cdots, v_n\}$ be the vertex set of G. The unary degree sequence encoding D of the undirected graph G has n 1s to represent the n vertices and each 1 is followed by a number of 0s equal to its degree. Moreover, if d is the degree of vertex v_i, then d 0s following the i-th 1 in the D array corresponds to d neighbors of v_i (or equivalently the edges from v_i to the d neighbors of v_i) in the same order as in the adjacency array of v_i. Clearly D uses $n + 2m$ bits and can be obtained from the neighbors of each vertex in $O(m + n)$ time. Now using *rank/select* queries of Theorem 3 in Section 2, the j-th outgoing edge of vertex v_i can be identified with the position $p = select_1(D, i) + j$ of D $(1 \leq j \leq degree(v_i)$ where $degree(v_i)$ denotes the degree of the vertex v_i). From a position p, we can obtain an endpoint of the corresponding edge by $i = rank_1(D, p)$, and the other endpoint is the j-th neighbor of v_i where $j = p - select_1(D, i)$.

We also use two bitvectors E, P of the same length where every bit is initialized to 0, and the bits in E, P are in one-to-one correspondence with bits in D. The bitvector E will be used to mark the tree edges of the DFS tree T, and the bitvector P to mark the unique parent of every vertex in T. The marking is carried out while performing a DFS of G in the preprocessing step. I.e., if (v_i, v_j) is an edge in the DFS tree where v_i is the parent of v_j, and suppose k is the index of the edge (v_i, v_j) in D, then the corresponding location in E is marked as 1 during DFS. At the same time, we scan the adjacency array of v_j to find the position of v_i (as G is undirected, there will be two entries for each edge in the adjacency array), and suppose t is the index of the edge (v_j, v_i) in D, then the corresponding location in P is marked as 1 during DFS. Thus, assuming G is a connected graph, once DFS finishes traversing G, the number of ones in E is exactly the number of tree edges (which is $n-1$) and the number of ones in P will be $n-1$ as root does not have any parent.

The parent of v_i in T is computed in $O(1)$ time as follows. Let v_r be the root of T. Then if $i > r$ (resp. $i < r$), the marked bit representing the parent of v_i is the $(i-1)$-st (resp. i-th) 1 in P. Let $p = select_1(P, i-1)$ (resp. $p = select_1(P, i)$) and $j = p - select_1(D, i)$. Then the parent of v_i is the j-th neighbor of v_i.

We use another bitvector D_T of length $2n$, which encodes the degree of each vertex in T by unary sequences. Then the degree of vertex v_i in T is $select_1(D_T, i+1) - select_1(D_T, i) - 1$, and j-th child of v_i in T is p-th neighbor of v_i in G where $p = select_1(E, select_1(D_T, i-1) + j) - select_1(D, i)$. These are computed in constant time.

Note that, the classical linear time implementation of DFS [12] uses a stack (which could grow to $O(n \lg n)$ bits) and a color array (of size $O(n)$ bits). Thus, the procedure takes $O(m+n)$ time and $O(n \lg n)$ bits overall. First, we argue that using the same linear time, we can also create bitvectors D, E and P and fill up them correctly. It's easy to see that creating D as well as initializing E and P to all zero takes $O(m+n)$ time. All it remains is to show, how one can fill up E and P while performing DFS. For this purpose, we build the data structures to support the constant time *rank/select* query (of Theorem 3) on D (and on E, P as well, the reason will be clear in the query step) and use the result of the select query to mark the tree edges on E (as they are in one-to-one correspondence). To illustrate, suppose, while traversing from v_i, DFS discovers the edge (v_i, v_j) as a tree edge in T where v_i is the parent of v_j, and suppose v_j is the c-th neighbor in v_i's adjacency array, then we find the index of the c-th zero after i-th one in D (using select query), and the corresponding index is marked as 1 in the E array. This takes $O(1)$ time for each tree edge marking. After this, we mark the index in P as 1 corresponding to the edge (v_j, v_i) to denote that v_i is the parent of v_j. Thus, marking parent takes $O(degree(v_j))$ time for the vertex v_j. Note that, all of this happens along with the classical stack-based DFS implementation. Thus overall it takes $O(m+n)$ time, and space required to store all these arrays is $O(m+n)$ bits. We refer to the bitvector D as the unary degree sequence array, E as the child array, and P the parent array. These three arrays are stored and used for the query step of our algorithm. Thus, we obtain the following lemma.

▶ **Lemma 7.** *Given an undirected graph G, there exists an $O(m+n)$ time and $O(n \lg n)$ bits preprocessing algorithm to construct the unary degree sequence array, parent and child arrays for G, each of which takes $O(m+n)$ bits of space.*

Step 2: Decomposing the DFS tree by the Tree Covering Technique. The main idea of this step is to perform a decomposition of the DFS tree, and along with storing some crucial informations which will be very useful for navigating the tree during the query step of our algorithm. For this purpose, we use the well-known tree covering technique in the context of succinct representation of rooted ordered trees. The high level idea is to decompose the tree into subtrees called *minitrees*, and further decompose the minitrees into yet smaller subtrees called *microtrees*. The microtrees are small enough to be stored in a compact table. The root

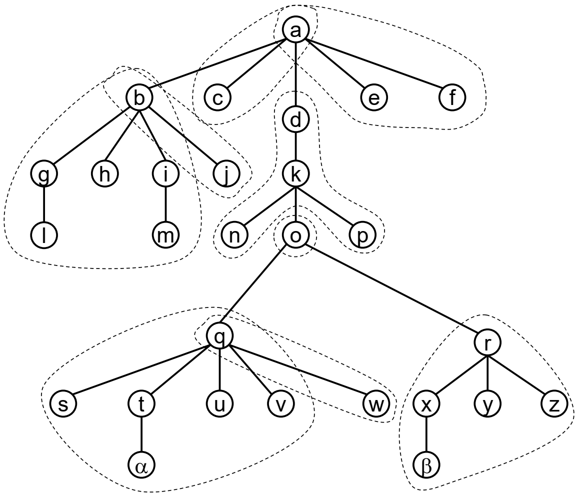

Figure 1 An example of Tree Covering technique with $L = 5$. Each closed region formed by the dotted lines represents a minitree. Here each minitree has at most one "child" minitree (other than the minitrees that share its root).

of a minitree can be shared by several other minitrees. To represent the tree, we only have to represent the connections and links between the subtrees. One such tree decomposition method was given by Farzan and Munro [14] where each minitree has at most one node, other than the root of the minitree, that is connected to the root of another minitree. This guarantees that in each minitree, there exists at most one non-root node which is connected to (the root of) another minitree. We use this decomposition in our algorithms, and the main result of Farzan et al. [14] is summarized in the following theorem:

▶ **Theorem 8** ([14]). *For any parameter $L \geq 1$, a rooted ordered tree with n nodes can be decomposed into $\Theta(n/L)$ minitrees of size at most $2L$ which are pairwise disjoint aside from the minitree roots. Furthermore, aside from edges stemming from the minitree root, there is at most one edge leaving a node of a minitree to its child in another minitree. The decomposition can be performed in linear time using linear words of space.*

See Figure 1 for an illustration. For the purpose of our algorithms, we apply Theorem 8 with $L = \lg n$ on the DFS tree T of G. For this parameter L, since the number of minitrees is only $O(n/\lg n)$, we can represent the structure of the minitrees within the original tree (i.e., how the minitrees are connected with each other) using $O(n)$ bits by simply storing both way pointers (so that we can traverse easily) between the roots of the minitrees. We refer to this as the *skeleton* S of the DFS tree T. See Figure 2 for a demonstration of Figure 1's skeleton. The decomposition algorithm of [14] also ensures that each minitree has at most one "child" minitree (other than the minitrees that share its root) in this structure. We use this property crucially later.

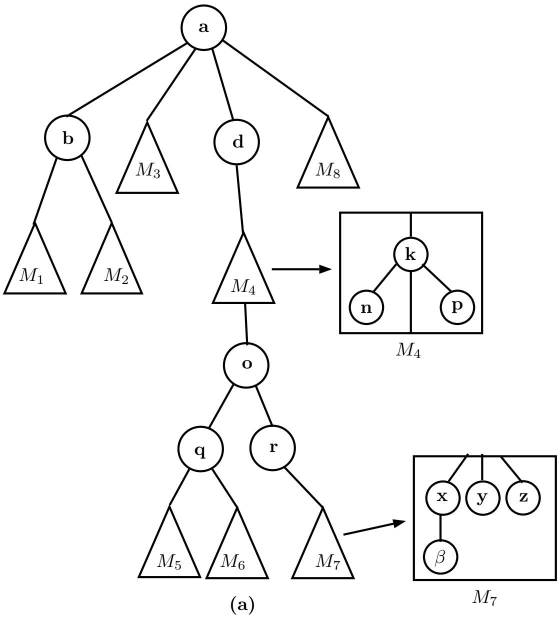

Figure 2 (a) A rough sketch of the skeleton of the tree decomposition shown in Figure 1. In this diagram, the triangles represent the minitrees along with the roots of the minitrees are marked inside the circle. For example, the minitrees M_1 and M_2 share the same root b. Also the node o is a minitree on its own. Strictly speaking, the skeleton will not have the traingles, rather it just contains the pointers between the roots of the minitrees (i.e., circles in this diagram). But we put this diagram for better visual description of the compact representation of the previous diagram.

In what follows, we explain how we compactly represent the minitree structure, and we refer to this compact representation obtained using this tree covering (TC) approach as the TC representation of the DFS tree. Towards this, first observe that every minitree root has unique first child and last child inside the minitree. In some cases, both are the same (see the minitree rooted at node d of Figure 1), and in some cases, both are absent (see the minitree rooted at node o of Figure 1). Thus, if we specify these two quantities, we can uniquely identify the root of the minitree (along with the exact portion of the nodes which are children of the root of this minitree and also belong to the same minitree as the first and last child of the root) even though the root is shared between multiple minitrees. We use this idea crucially in the design of the TC representation of the DFS tree.

We mark in a bitvector R of size n all the nodes which are the last child of a minitree root inside a minitree. Note that, there are $O(n/\lg n)$ such nodes which are marked as 1 in R. In the case of a minitree root not having any children, we mark the minitree root itself as 1 in R. We also build the data structure to support $O(1)$ time *rank/select* queries on R using Theorem 3. Next, we create an array C where each of the $O(n/\lg n)$ entries are $O(\lg n)$ bits long, thus overall it takes $O(n)$ bits. Basically, each entry of C stores some informations regarding the minitree for which the last child of the minitree root is marked 1 in R. More specifically, For a typical node, say v_i, which is the last child of some minitree, we have $R[i] = 1$, and $C[j]$ (where $j = rank_1(R, i)$) comprises of the following six informations (some of which could be empty), (i) label of the minitree root, say v_r, for which v_i is the last child inside the minitree, (ii) location of the first child, say v_j, of v_r inside the minitree in the adjacency array of v_r, (iii) DFI of v_j, (iv) the edge (v_c, v_d) (if any) that goes out of the minitree, (v) the size of the subtree rooted at v_c in the DFS tree, (vi) depth of v_r in the

DFS tree. The tree decomposition method ensures that a minitree has at most one edge (v_c, v_d), where v_c is a non-root node of minitree and v_d is a root of a different minitree, that goes out of the minitree. We also mark in a bitvector Z of size n bits all such vertices like v_c (also note, there could be $O(n/\lg n)$ such vertices). We mark in a bitvector L all the vertices which are the rightmost leaves of every minitree. Note that these vertices (there are, again, $O(n/\lg n)$ of them) have the highest DFI inside the minitree. In another bitvector A, we mark all the roots of the minitrees as 1, and build rank/select structure on top of A. Correspondingly, the F array will store the DFI of the roots so that we can retrieve them in constant time. More specifically, for a minitree root v_r, $A[r] = 1$ and $F[j]$ ($j = rank_1(A, r)$) will store the DFI of v_r. Next we build the $O(1)$ time level ancestor data sturcture, say LA, on the $O(n/\lg n)$ minitree roots (i.e., on the skeleton structure) using [4]. Thus, here, LA takes $O(n)$ bits and $O(n)$ time. As a root of the minitree is shared between multiple minitrees, from each node v_i of the skeleton S (where v_i is a root of a minitree), we store pointers to all the minitrees (in C array) which has v_i as their root. Overall these pointers also consume $O(n)$ bits. This completes the description of the TC representation. Note that, the creation of the skeleton and the TC representation for T can be done in $O(n)$ time using $O(n \lg n)$ bits (using Theorem 8) after the DFS (which takes $O(m + n)$ time and $O(n \lg n)$ bits). Hence, we obtain the following,

▶ **Lemma 9.** *Given an undirected graph G, there exists an $O(m + n)$ time and $O(n \lg n)$ bits preprocessing algorithm to construct the skeleton S and the TC representation of the DFS tree T of G, each of which occupies $O(n)$ bits.*

First observe that, the outputs of the previous step are the unary degree sequence array (D), parent array (E), child array (P), the D_T array, TC representation of T (this includes R, C, Z, A, F and L) along with the skeleton S with pointers to C, and finally the LA structure on S. The arrays D, E, and P take $O(m + n)$ bits, and the others take $O(n)$ bits. Now we show how to efficiently solve the DFS-Indexing problem using these structures.

Query Algorithms. Given v_i, to answer 2(a) in $O(1)$ time, we do the following. If v_i is the root of the DFS tree, we return null. Otherwise, we can compute the answer by using only $select_1$ queries on P and D, as described previously.

To answer 2(b) in $O(1)$ time, we use $select_1$ queries on the bitvector D_T.

To answer 2(c), we first compute the number of children of v_i in T using the query 2(b). Then j-th child is obtained in constant time as described above.

Note that, the queries 2(a), 2(b) and 2(c) can be answered using only D, E, P and D_T arrays. Before explaining the algorithms for the rest of the queries, we first prove the following very crucial lemma.

▶ **Lemma 10.** *Given any query node v_i which is not a root of a minitree, we can reconstruct the minitree M containing v_i in time proportional to the size of M along with the DFIs of all the nodes inside M. In the same amount of time, we can also retrieve the root node of M.*

Proof. First note that if a node v belongs to the minitree M, its children in T also belong to M, except for the following two cases. The first case is that v is the root v_r of M and the second case is that v is v_c of M. In the first case, as we have stored the location (in the adjacency array) of the first child, say v_j, of v_r inside M in the C array, we can enumerate all the children of v_r in M in constant time for each until we hit the rightmost child of v_r in M, which is stored in R. In the second case, we can also enumerate all the children of v_c

in T in constant time for each and discard v_d. For other vertices in M, we can enumerate children using constant time for each output. Note also that going to the parent can be performed in constant time.

The algorithm to achieve the claim can be broken down into three steps. In the first step, given v_i, we launch a DFS starting from v_i, and continue till we retrieve the rightmost leaf, say v_j, of the minitree M. In second step, we follow the path in T (by going to v_j's parent, then its parent and so on) till we reach the rightmost child, say v_k, of the root, say v_r, inside M by using the query algorithm to find the parent repeatedly. In the third and final step, we use the C array, by using v_k, to extract all the informations needed to reconstruct the full minitree by performing another round of DFS. We provide the details below.

To perform the first step, we only need to use the parent and child related queries, whose execution we already showed previously. Note that, as we have stored the information (in Z array) regarding the only edge that goes out of the minitree, we never incorrectly go out of M. Also we can verify if we have reached the unique node v_j which is the rightmost leaf of M from the L array. Once we reach v_j, it's easy to see that v_k has to be an ancestor of v_j (note that v_k and v_j could be same in some cases). Thus, we can reach v_k from v_j by repeatedly using the parent query algorithm, and this completes the second step. Finally, once we reach v_k, we use the informations in $C[j]$ (where $j = rank_1(R, k)$) to retrieve the root v_r of M and other informations. Then we carry out a DFS from v_r by first going to the first child of v_r inside M (retrieved from C), then its first child and so on till we fully reconstruct M. This step also requires repeated invoking of parent and child query only.

In order to retrieve the DFIs of the nodes inside M, observe that, if M doesn't have any child minitree (i.e., no edge is going out of M), then while doing the final DFS from v_r, we can easily compute the DFIs of all the nodes inside M. Otherwise, assume the edge (v_c, v_d) goes out of M where v_c belongs to M, then the DFI of next node inside M can be calculated by adding the size of the subtree rooted at v_c in T (which is stored in C) to the DFI of v_c. It is clear that all of these procedures can be performed in the time proportional to the size of M, which is $O(\lg n)$ here. This completes the description of the proof. ◀

As a corollary of the previous lemma, it is easy to see that the query of 2(d) can be reported in $O(\lg n)$ time for any node v_i which is not a root of the minitree. Otherwise, it can be done in $O(1)$ time by reporting the value stored in $F[j]$ where $j = rank_1(A, i)$.

To answer 1(a), first we invoke query algorithm of 2(d) for both v_i and v_j to retrieve their DFIs respectively, and then answer accordingly. Thus, this also takes $O(\lg n)$ time.

Answering 1(b) involves a few cases. In the first case, if both of them belong to the same minitree then we can figure out the answer by reconstructing the complete minitree. Secondly, suppose v_i and v_j are roots of the two separate minitrees, and their depths in T are x and y respectively (depth can be obtained from C array). Then using these values in LA data structure, we can figure out the required answer. Finally, if both of these nodes belong to two separate minitrees but are not the roots of the minitrees, then first we retrieve the roots of those minitrees using Lemma 10, then follow almost the same procedure as before to figure out the answer. Note that, in this case, it is enough to reconstruct the path from v_c (of the minitree located near to the root) to the root of that minitree (for the case when one of the minitree root is an ancestor of the other minitree root) to figure out the answer of the query. Thus, overall, it takes $O(\lg n)$ time.

To return the query for 3, we do a standard DFS traversal on the skeleton S and each time we visit a new node v_i in S, we follow the pointer from v_i in S to the part of the C array where the informations regarding the minitree rooted at v_i is stored. Note that, v_i might be shared between multiple minitrees, hence, we always start following these pointers from left to right. More specifically, if v_i is the root of p minitrees, we have p pointers emanating from v_i, and going to p different locations of C array. As these pointers are stored from left to right order, which is the same order in DFS of all the minitrees that share the root v_i. Thus we follow the first pointer, and reach the specific portion of C, use Lemma 10 to generate the complete minitree along with the DFIs of the nodes. Then if this minitree has any child minitree, we go on to explore that and so on (by following the (v_c, v_d) edge stored in that minitree). Once we finish all the descendant minitree of the first minitree rooted at v_i, we come back and start exploring the second minitree (by following the second pointer from v_i) and so on. Thus, we need to store these intermediate pointers, in stack, to know how much progress has been made in every node's (in skeleton) list. This procedure is continued until all the nodes of S are exhausted. It is clear that this procedure takes $O(n)$ time as there are $O(n/\lg n)$ nodes in S and for each node, we spend $O(\lg n)$ time. Also, we need $O(n)$ bits (as there could be $O(n/\lg n)$ pointers) of intermediate space for the execution of the DFS.

To answer 4, first note that, in any minitree M, if there is no egde going out (i.e., no (v_c, v_d) type edge), then the DFIs inside M are consecutive, i.e., in general, first child of root inside M has the smallest DFI and the rightmost leaf in M has the maximum DFI, and the numbers are consecutive. Otherwise, DFIs are consecutive from the root of M to the DFI of v_c, then there is a jump of DFI by the size of the subtree rooted at v_c in the DFS tree, then it's consecutive DFI again until the rightmost leaf (which has the largest DFI inside M) of M. Thus, the range of DFIs of the vertices inside any arbitrary minitree M can be broken into at most two disjoint consecutive intervals. We store these (at most $O(n/\lg n)$) intervals in an interval tree along with augmenting it with the last child of M inside M. Now, given i, we first find the interval where i belongs to from the tree and simultaneously retrieve the last child, say v_a, of the corresponding minitree, all using $O(\lg n)$ time. Then, we use the information from R and C array corresponding to v_a to invoke Lemma 10, and retrieve the desired vertex with DFI i using $O(\lg n)$ overall time. This completes the description of the query algorithms for undirected graphs.

We can handle directed graphs similarly except a few changes in the data structures. Recall that, for directed graphs, every vertex v_i has access to its in-neighbors array as well as out-neighbors array, and additionally we create two unary degree sequence arrays (each of size $O(m+n)$ bits), D_1 for the out-neighbors and D_2 for the in-neighbors. We also have two separate arrays, say E_1 (having one-to-one map with D_1), for marking child of every node and E_2 (having one-to-one map with D_2) where parents are marked. It is easy to see that almost in a similar fashion as in the undirected case, we can correctly mark, for any node v_i, the children of v_i in E_1 array and parent of v_i in E_2 array using both the D_1 and D_2 arrays while performing DFS of G. The second preprocessing step doesn't require any changes for the directed graphs. Now reporting queries also can be suitably modified to make use of these changes without affecting the asymptotic running time of the query algorithms. Basically the only change that takes place is as follows, whenever we need to find the parent of a node, now we need to use the in-neighbor array whereas finding children can be handled by consulting out-neighbor array along with the mapping with their respective unary degree sequence array. We omit the details. Thus, we obtain the following,

▶ **Theorem 11.** *Given any undirected or directed graph G, there exists an $O(m+n)$ time and $O(n \lg n)$ bits preprocessing algorithm which outputs a data structure of size $O(m+n)$ bits, using which the queries 1(a), 1(b), 2(d) and 4 can be reported in $O(\lg n)$ time, 2(a) and 2(b) in $O(1)$ time, 2(c) can be answered in time proportional to the number of solutions, and finally 3 can be solved in $O(n)$ time respectively for the* DFS-Indexing *problem.*

Note that, if the given input graph is sparse (i.e., $m = O(n)$), then both unary degree sequence array (D), and parent and child arrays (E, P) take $O(n)$ bits, and every other data structure anyway takes $O(n)$ in total, thus, we obtain the result mentioned in Theorem 1 for the case of sparse graphs. When the input graph is dense (i.e., $m = \omega(n)$), we compress the D, E, P arrays using Theorem 4. Note that we use only $select_1$ queries on compressed arrays and thus query time complexity on the arrays is still constant. Hence, we obtain the result of Theorem 1 for the dense graph case. It is worth mentioning that except the case for very dense graphs, our space bound *always* beats the space bound of the naive algorithm for every edge density in the full spectrum, albeit with super-constant query time. Thus, when the graph is sufficiently dense, it is better to use the standard solution which uses $O(n \lg n)$ bits with constant query time. This completes the description of our algorithms in the indexing model, and hence, the proof of Theorem 1.

4 Algorithms in the Encoding Model

Recall that in the encoding model, we seek to build a data structure *encod* after preprocessing the input graph G such that queries have to be answered using *encod* only, *without* accessing G. To this end, we first provide a lower bound for the space needed for *encod* to answer queries of the DFS-Indexing problem.

4.1 Space lower-bound

Observe that, in order to correctly answer the queries, the data structure *encod* must contain the information regarding the topology of the DFS tree T of the graph G along with the labels of the vertices of T as, unlike the indexing model, we don't have the access to G during the query time. It's easy to see that we need $\Omega(n \lg n)$ bits to store the vertex labels mappings. In what follows, we give a proof for the space needed to store the topology of the DFS tree by counting the number of such trees in any arbitrary graph G.

▶ **Lemma 12.** *For a graph with n vertices and m edges, the size of data structures for storing the topology of the DFS trees is $\Omega\left(n \lg \frac{m}{n}\right)$ bits.*

Proof. Let us consider the following graph G with n vertices and m edges ($m < n^2/2$). It has a vertex r, $k = m/n$ vertices $u_1, \ldots, u_k$, and $n-k-1$ vertices $v_1, \ldots, v_{n-k-1}$. The vertex r is connected to all u_i, and each v_j is also connected to all u_i. To construct a spanning tree of G, we choose one edge among all k edges connected to each v_j. Then the number of different spanning trees of G is at least k^{n-k-1}, and for all different spanning trees the set of DFI's are different. Therefore the size of data structure must be at least $\lg k^{n-k-1}$ bits, which is $\Omega\left(n \lg \frac{m}{n}\right)$. ◀

Thus, the space lower bound for *encod* is $\Omega(max\{n \lg \frac{m}{n}, n \lg n\})$ bits, which is $\Omega(n \lg n)$ bits as mentioned in Theorem 2. In what follows, we complement the above claim by providing a simple indexing structure which asymptotically matches this lower bound.

4.2 Upper-bound

Preprocessing Step. Our index for the DFS-Indexing problem consists of two components which we prepare during the preprocessing step. In the first component, we store, for every vertex v_i, DFI(v_i) as permutation using the structure of Theorem 5 of Section 2. Secondly, we encode the DFS tree succinctly using the structure of Theorem 6 of Section 2.

Query Algorithm. We answer the queries using the two above mentioned structures as follows. To answer 2(d), we just use $\pi(i)$. Similarly, 4 can be answered by invoking $\pi^{-1}(i)$. We report v_i (resp. v_j) as the answer for query 1(a) if $\pi(i) < \pi(j)$ (resp. $\pi(i) > \pi(j)$). We enumerate the vertex ordering as traversed in the DFS order by invoking $\pi^{-1}(1)$, then $\pi^{-1}(2)$, and so on till $\pi^{-1}(n)$. We answer 1(b) in affirmative by checking if $LA(v_j, depth(v_i))$ matches with v_i, otherwise no. To answer 2(a), we return $LA(v_i, depth(v_i) - 1)$. We return the answer of 2(b) by using the query $degree(v_i)$. Finally, we enumerate the children of a node v_i as requested in query 2(c) by using the query $child(v_i, 1)$ till $child(v_i, degree(v_i))$. Hence we obtain the results mentioned in Theorem 2.

5 Conclusion

In this paper, we provided procedures for compactly storing the DFS tree for any graph with efficiently supporting various queries in the indexing and encoding models, and showed how to extend these techniques to design indexing schemes for other fundamental and basic graph problems. With some work, our algorithm can be extended for indexing BFS tree (and other graph search tree also) as well while supporting similar types of queries. Also, as mentioned previously, our results are more general, and can be used in other situations as well.

This work opens up many possible future directions to explore. Can we further improve the query time while keeping the space bound same in the indexing model? Can we prove a space lower bound in the indexing model? Can we design compact data structures for indexing problems like maximum flow? Finally, we conclude by remarking that using [2, 9], we can improve the preprocessing space of our algorithms to $O(n)$ bits (from $O(n \lg n)$ bits) with marginal increment in the preprocessing time.

Abstract

We study the dynamical behavior of D-dimensional ($D \geq 1$) additive cellular automata where the alphabet is any finite abelian group. This class of discrete time dynamical systems is a generalization of the systems extensively studied by many authors among which one may list [36, 43, 44, 40, 12, 11]. Our main contribution is the proof that topologically transitive additive cellular automata are ergodic. This result represents a solid bridge between the world of measure theory and that of topology theory and greatly extends previous results obtained in [12, 43] for linear CA over $\mathbb{Z}_m$ i.e. additive CA in which the alphabet is the cyclic group $\mathbb{Z}_m$ and the local rules are linear combinations with coefficients in $\mathbb{Z}_m$. In our scenario, the alphabet is any finite abelian group and the global rule is any additive map. This class of CA strictly contains the class of linear CA over $\mathbb{Z}_m^n$, i.e., with the local rule defined by $n \times n$ matrices with elements in $\mathbb{Z}_m$ which, in turn, strictly contains the class of linear CA over $\mathbb{Z}_m$. In order to further emphasize that finite abelian groups are more expressive than $\mathbb{Z}_m$ we prove that, contrary to what happens in $\mathbb{Z}_m$, there exist additive CA over suitable finite abelian groups which are roots (with arbitrarily large indices) of the shift map.

As a consequence of our results, we have that, for additive CA, ergodic mixing, weak ergodic mixing, ergodicity, topological mixing, weak topological mixing, topological total transitivity and topological transitivity are all equivalent properties. As a corollary, we have that invertible transitive additive CA are isomorphic to Bernoulli shifts. Finally, we provide a first characterization of strong transitivity for additive CA which we suspect it might be true also for the general case.

1 Introduction

Cellular automata (CA) are widely known formal models for studying and simulating complex systems [9]. They are used in many disciplines ranging from physics to biology, stepping through sociology and, of course, computer science (for recent results and an up-to date bibliography on CA, see [25, 28, 17, 16, 3], while for other models of natural computing see for instance [21, 19, 26, 18]). Their extensive use is due to the huge variety of dynamical behaviors. In computer science, applications can be found in many different contexts such as cryptography, pseudo-random number generation, image processing, data compression, *etc.*

More formally, a CA can be defined as an infinite set of finite automata arranged on the regular lattice $\mathbb{Z}^D$, where $D \in \mathbb{N}$ is the *dimension* of the CA. Each finite automaton has a *state* which is chosen from a finite set G, called the *set of states* or the *alphabet*. All finite automata update synchronously according to a *local rule* which takes into account the current state of the automaton and the states of a *neighborhood* $\mathcal{N}$ of neighboring automata. The local rule f induces a *global map* $F \colon G^{\mathbb{Z}^D} \to G^{\mathbb{Z}^D}$ which describes the overall evolution of the CA at each time tick.

Despite of their apparent simplicity, CA may exhibit extremely complex dynamical behaviors. Indeed, in most cases the problem of deciding if a given CA has a certain dynamical property or not is undecidable [5, 30, 37] and some Rice-like theorems have been proved [34, 39]. The complex dynamics of CA has been described through a great number of properties (see Section 2 for definitions) involving both the measure theoretical and the topological point of views. Figure 1 illustrates the relations between those that are studied in this paper.

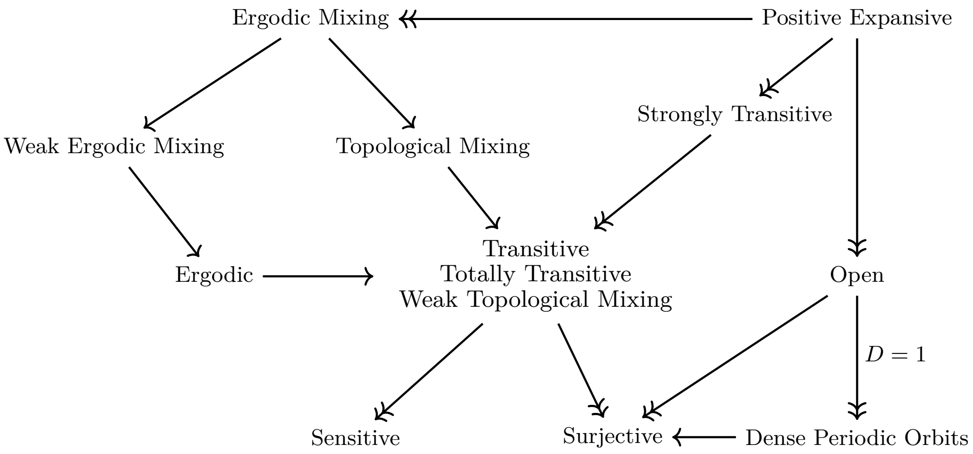

Figure 1 Known relations between dynamical properties of CA. An arrow with single tip indicates that the converse relation is unknown, an arrow with double tip means that the converse relation is false. Labels on arrows indicate that implications have been proved only for specific dimensions. Note that there are no expansive CA in dimension $D > 1$.

Imposing some additional constraints to the global update map allows a complete and efficient description of the dynamical behavior. These properties can take the form of a conservation law [33, 29, 32, 6, 49] or superposition principles induced by an algebraic structure imposed on the alphabet [36, 43, 44, 40, 12, 11] (in both cases the literature is really huge, only a small excerpt is cited here).

Similarly, in this paper, it is required that the alphabet G of the CA is a finite abelian group and its global update map is additive, i.e., an endomorphism of $G^{\mathbb{Z}^D}$. This is a pretty broad requirement which characterizes a class of CA generalizing those with linear local rule defined by $n \times n$ matrices (see the previous citations for the case $n = 1$ and [40, 8] for a generic n). Indeed, the local rule of an additive CA over a group $\langle G, + \rangle$ can be written as

$$f(x_1, \ldots, x_r) = \sum_{i=1}^{r} f_i(x_i)$$

where the functions f_i are endomorphisms of G and $\{x_1, \ldots, x_r\}$ is the neighborhood $\mathcal{N}$.

The fundamental theorem of finite abelian groups states that every finite abelian group is isomorphic to $\bigoplus_{i=1}^{h} \mathbb{Z}_{k_i}$ where the numbers $k_1, \ldots, k_h$ are powers of (not necessarily distinct) primes and $\oplus$ is the direct sum operation. Hence, the global rule F of an additive CA over G splits into the direct sum of a suitable number h' of additive CA over subgroups $G_1, \ldots, G_{h'}$ with $h' \leq h$ and such that $\gcd(|G_i|, |G_j|) = 1$ for each pair of distinct $i, j \in \{1, \ldots, h'\}$. Each of them can be studied separately and then the analysis of the dynamical behavior of F can be carried out by combining together the results obtained for each component.

In order to make things clearer, consider the following example. If F is an additive CA over $G \cong \mathbb{Z}_4 \times \mathbb{Z}_8 \times \mathbb{Z}_3 \times \mathbb{Z}_3 \times \mathbb{Z}_{25}$ then F splits into the direct sum of 3 additive CA over $\mathbb{Z}_4 \times \mathbb{Z}_8$, $\mathbb{Z}_3 \times \mathbb{Z}_3$ and $\mathbb{Z}_{25}$, respectively. Therefore, F will be topologically transitive iff each component is topologically transitive while F will be sensitive to initial conditions iff at least one component is sensitive to initial conditions (see Section 2.1 for the precise definitions of these properties).

The above considerations lead us to three distinct scenarios:

- $\boldsymbol{G \cong \mathbb{Z}_{p^k}}$. Then, G is cyclic and we can define each f_i simply assigning the value of f_i applied to the unique generator of G. Moreover, every pair f_i, f_j commutes, i.e. $f_i \circ f_j = f_j \circ f_i$, and this makes it possible a detailed analysis of the global behavior of F. For additive cellular automata over $\mathbb{Z}_{p^k}$ almost all dynamical properties are well understood and characterized [43].
- $\boldsymbol{G \cong \mathbb{Z}_{p^k}^n}$. In this case, G is not cyclic anymore and has n generators. We can define each f_i assigning the value of f_i for each generator of G. This gives rise to the class of linear CA over $\mathbb{Z}_{p^k}^n$ that have been studied in [20, 40, 8]. Now, f_i and f_j do not commute in general and this makes the analysis of the dynamical behavior much harder. As pointed out in [20], we also recall that linear CA over $\mathbb{Z}_{p^k}^n$ allow the investigation of some classes of non-uniform CA over $\mathbb{Z}_{p^k}$ (for these latter see [22, 10, 24, 23]).
- $\boldsymbol{G \cong \bigoplus_{i=1}^{n} \mathbb{Z}_{p^{k_i}}}$. In this case ($\mathbb{Z}_4 \times \mathbb{Z}_8$ in the example), G is again not cyclic and F turns out to be a subsystem (in the sense of topological dynamics) of a suitable linear CA. In this last case the analysis of the dynamical behavior of F is even more complex than in the previous case. We do not even know easy checkable characterizations of basic properties like surjectivity or injectivity.

Even if the superposition principle still allows us to prove deep and interesting results on the asymptotic behavior of additive CA over finite abelian groups, their dynamics is definitely more interesting and expressive than that of linear CA over $\mathbb{Z}_m$ and exhibits much more complex features. As a first example, consider the set A of graphs with n nodes represented by their adjacency matrices. A can be equipped with a binary operation "+" that makes it a finite (or finitely generated) abelian group G (isomorphic to the group of all $n \times n$ matrices over $\mathbb{Z}_2$ with the "+" operation). The group operation can be defined in many different ways,

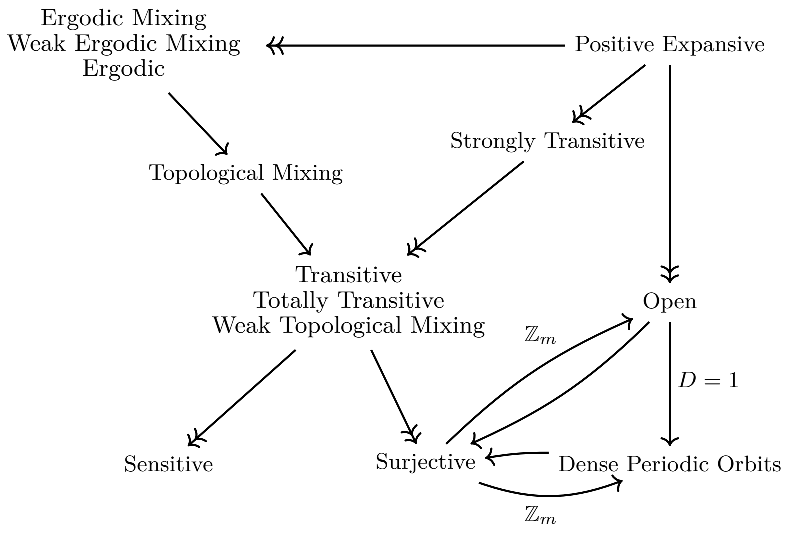

Figure 2 Known relations among dynamical properties of additive CA before the present paper. An arrow with single tip indicates that the converse relation is unknown, an arrow with double tip means that the converse relation is false. Labels on arrows indicate that implications have been proved only for specific alphabets or dimensions. Note that there are no expansive CA in dimension $D > 1$.

e.g. sum of matrices or, for undirected graphs, product of (symmetric) matrices. The local rule of the CA can be any map preserving the group structure. It is easy to verify that the dynamics of this kind of automata cannot be simulated by any linear CA over $\mathbb{Z}_m$.

This richness in terms of expressive power is further stressed by Theorem 9 which shows how the group structure of $\mathbb{Z}_{p^k}$ constraints the dynamics. However, there exist additive one-dimensional CA over suitable abelian groups that are arbitrarily "small" roots of the shift map, as illustrated in Example 10. This means that the group structure helps out in constructing CA which are able of transmitting the information (encoded in the initial configuration) at arbitrary slow speed. In particular, this allows the construction of ergodic maps with arbitrary low Lyapunov exponents. Theorem 8 tells that the same cannot be done by one-dimensional CA over alphabets of prime cardinality.

Figure 2 illustrates the known relations among dynamical properties of linear CA before the present paper. Figure 3 illustrates the impact of the results of the present paper. As a matter of fact, the overall picture have been greatly simplified and the dynamics much better understood.

The paper is structured as follows. Section 2 introduces all the necessary background and formal definitions. Section 3 states the main contributions of the paper and the next one provides all the proofs. In the last section we draw our conclusions and provide some perspectives.

2 Background

We begin by reviewing some general notions and introducing notations we will use throughout the paper.

Let $\mathbb{Z}$ and $\mathbb{N}$ be the set of integers and natural numbers, respectively. For any $v \in \mathbb{Z}^D$ we denote $||v|| = ||(v_1, \ldots, v_D)|| = \max\{|v_1|, \ldots, |v_D|\}$.

Figure 3 Relations among dynamical properties of additive CA taking into account the results of the present paper. An arrow with single tip indicates that the converse relation is unknown, an arrow with double tip means that the converse relation is false. Labels on arrows indicate that implications have been proved only for specific dimensions. Note that there are no expansive CA in dimension $D > 1$.

Let G be a finite alphabet. A **configuration** over G is a map from $\mathbb{Z}^D$ to G. For any configuration $c \in G^{\mathbb{Z}^D}$ and any vector $v \in \mathbb{Z}^D$, $c(v)$ is the value of c in position v. The configuration space $G^{\mathbb{Z}^D}$ is equipped with the distance d defined as follows

$$\forall c, c' \in G^{\mathbb{Z}^D}, \quad d(c, c') = \begin{cases} 0, & \text{if} \quad c = c', \\ 2^{-\min\{||\boldsymbol{v}|| \,:\, c(v) \neq c'(v)\}}, & \text{otherwise} \end{cases} .$$

In this way, the set $G^{\mathbb{Z}^D}$ equipped with the topology induced by d turns out to be a compact, perfect, and totally disconnected topological space (i.e., a Cantor space). In the sequel, the configuration space $G^{\mathbb{Z}^D}$ will be sometimes denoted by X.

A **pattern** P is a function from $\{-\ell, \ldots, \ell\}^D$ to G, for some $\ell \in \mathbb{N}$. For any $\ell \in \mathbb{N}$, denote by $\mathcal{P}_\ell$ the set of all patterns with domain $\{-\ell, \ldots, \ell\}^D$. For any $P \in \mathcal{P}_\ell$, the **cylinder** individuated by the pattern P is the set $[P] = \{c \in G^{\mathbb{Z}^D} | \forall v \in \{-\ell, \ldots, \ell\}^D, c(v) = P(v)\}$. Cylinders are clopen sets and the set $\{[P] : \ell \in \mathbb{N}, P \in \mathcal{P}_\ell\}$ of all cylinders is a basis for the topology induced by d.

For some fixed integer $s \geq 1$, let f (named, s-sized *local rule*) and $\mathcal{N}$ (s-sized *neighborhood frame*) be any map from G^s to G and an ordered set of distinct vectors $u_1, \ldots, u_s$, respectively. A ***D*-dimensional CA** over G is a pair $(G^{\mathbb{Z}^D}, F)$, where $F \colon G^{\mathbb{Z}^D} \to G^{\mathbb{Z}^D}$ is the function (named, *global transition map*) defined on the basis of f and $\mathcal{N}$ as follows

$$\forall c \in G^{\mathbb{Z}^D}, \forall v \in \mathbb{Z}^D, \quad F(c)(v) = f\left(c(v + u_1), \ldots, c(v + u_s)\right) \quad . \tag{1}$$

Recall that F is a uniformly continuous map w.r.t. the metric d and any function $F : G^{\mathbb{Z}^D} \to G^{\mathbb{Z}^D}$ is the global transition map of a D-dimensional CA iff it is uniformly continuous and shift-commuting (Hedlund's theorem from [35]), i.e., $F \circ \sigma^u = \sigma^u \circ F$ for any $u \in \mathbb{Z}^D$, where $\sigma^u : G^{\mathbb{Z}^D} \to G^{\mathbb{Z}^D}$ is the D-dimensional **shift map** defined by $\forall c \in G^{\mathbb{Z}^D}, \forall v \in \mathbb{Z}^D, \sigma^u(c)(v) = c(v + u)$. From now on, for the sake of simplicity, we identify a CA with its global map. Moreover, we will denote σ^1 simply by σ.

In the sequel, the alphabet G will be an **abelian group**, with group operation $+$, neutral element 0, and inverse operation $-$. In this way, both the configuration space $G^{\mathbb{Z}^D}$ and the set $\mathcal{P}_\ell$ turn out to be abelian groups, too, where the group operation of $G^{\mathbb{Z}^D}$ and $\mathcal{P}_\ell$ is the component-wise extension of $+$ to $G^{\mathbb{Z}^D}$ and $\mathcal{P}_\ell$. With an abuse of notation, we denote by the same symbols $+$, 0, and $-$ the group operation, the neutral element, and the inverse operation, respectively, both of $\mathbb{Z}^D$, G, $G^{\mathbb{Z}^D}$, and $\mathcal{P}_\ell$. Observe that $+$ and $-$ are continuous functions in the topology induced by cylinders. Hence, $G^{\mathbb{Z}^D}$ is a compact topological group.

A configuration $c \in G^{\mathbb{Z}^D}$ is said to be finite if the number of positions $v \in \mathbb{Z}^D$ with $c(v) \neq 0$ is finite. A CA $(G^{\mathbb{Z}^D}, F)$ over G is **additive** if

$$\forall c, c' \in G^{\mathbb{Z}^D}, \quad F(c+c') = F(c) + F(c') \ .$$

In other words, additive D-dimensional CA over G are endomorphisms of $G^{\mathbb{Z}^D}$.

The **sum of two additive CA** F_1 and F_2 over G is naturally defined as the map on $G^{\mathbb{Z}^D}$ denoted by $F_1 + F_2$ and such that

$$\forall c \in G^{\mathbb{Z}^D}, \quad (F_1 + F_2)(c) = F_1(c) + F_2(c) \ .$$

2.1 Topological and measure theoretic properties

We now recall the definition of some topological and measure theoretical properties for general systems.

A **discrete time dynamical system (DTDS)** is a pair $(\mathcal{X}, \mathcal{F})$, where $\mathcal{X}$ is any set equipped with a distance d and $\mathcal{F}$ is a transformation on $\mathcal{X}$ which is continuous with respect to d. Clearly, CA are DTDS. A DTDS $(\mathcal{X}, \mathcal{F})$ is **surjective**, resp., **open**, if $\mathcal{F}$ is surjective, resp., open. Open CA are surjective (for a proof see [25], for instance). Moreover, any open one-dimensional CA F is characterized by the following property: there exists a natural $k > 0$ such that for every configuration $c \in G^{\mathbb{Z}^D}$ it holds that $|F^{-1}(c)| = k$. Two DTDS $(\mathcal{X}, \mathcal{F})$ and $(\mathcal{X}', \mathcal{F}')$ are isomorphic if there exists an homeomorphism $\varphi : \mathcal{X} \to \mathcal{X}'$ such that $\varphi \circ \mathcal{F} = \mathcal{F}' \circ \varphi$.

A DTDS $(\mathcal{X}, \mathcal{F})$ is **topologically transitive** (or, simply, transitive) if for all nonempty open subsets U and V of $\mathcal{X}$ there exists a natural number t such that $\mathcal{F}^t(U) \cap V \neq \emptyset$, while it is said to be **topologically mixing** if for all nonempty open subsets U and V of $\mathcal{X}$ there exists a natural number t_0 such that the previous intersection condition holds for every $t \geq t_0$. Intuitively, a topologically transitive system $(\mathcal{X}, \mathcal{F})$ has elements of $\mathcal{X}$ which eventually move under iteration of $\mathcal{F}$ from one arbitrarily small neighbourhood to any other. As a consequence, the dynamical system cannot be decomposed into two disjoint open sets which are invariant under the map $\mathcal{F}$. Clearly, topological mixing is a stronger condition than transitivity. Further, $(\mathcal{X}, \mathcal{F})$ is **topologically weakly mixing** if the DTDS $(\mathcal{X} \times \mathcal{X}, \mathcal{F} \times \mathcal{F})$ is topologically transitive, while it is **totally transitive** if $(\mathcal{X}, \mathcal{F}^t)$ is topologically transitive for all $t \in \mathbb{N}$. We now recall another condition stronger than transitivity. A DTDS is **strongly transitive** if for any nonempty open subset U of $\mathcal{X}$ it holds that $\bigcup_{t=1}^{\infty} \mathcal{F}^t(U) = \mathcal{X}$.

A DTDS $(\mathcal{X}, \mathcal{F})$ is **sensitive to initial conditions** if there exists $\epsilon > 0$ such that for any $\delta > 0$ and $x \in \mathcal{X}$, there are an element $y \neq x$ with $d(y, x) < \delta$ and a natural number t such that $d(\mathcal{F}^t(y), \mathcal{F}^t(x)) > \epsilon$. Roughly speaking, $(\mathcal{X}, \mathcal{F})$ is sensitive to initial conditions, or simply sensitive, if there exist elements arbitrarily close to x which eventually separate from x by at least ϵ under iteration of $\mathcal{F}$. If a DTDS is sensitive, then, for all practical purposes, the dynamics eventually defy numerical approximation. Small errors in computation which are introduced by round-off may become magnified upon iteration. The results of numerical computation of an orbit, no matter how accurate, may be completely different from the real orbit. In [13] it has been proven that, for CA, topological transitivity implies sensitivity. Thus, for CA, the notion of topological transitivity becomes central to chaos theory. A DTDS $(\mathcal{X}, \mathcal{F})$ is said to be **positively expansive** if there exists $\epsilon > 0$ such that for any pair of elements $x, y \in \mathcal{X}$ with $x \neq y$ there exists a natural number t such that $d(\mathcal{F}^t(y), \mathcal{F}^t(x)) > \epsilon$. If $\mathcal{X}$ has infinite cardinality then expansivity is a stronger condition than sensitivity (see [31] for a study concerning expansivity and sensitivity in CA). While there are no positively expansive D-dimensional CA when $D \geq 2$, in dimension 1, expansivity implies both mixing, strong transitivity, and openness [41].

An element $x \in \mathcal{X}$ is a periodic point for a DTDS $(\mathcal{X}, \mathcal{F})$ if $\mathcal{F}^t(x) = x$ for some integer $t > 0$. A DTDS $(\mathcal{X}, \mathcal{F})$ has **dense periodic orbits** (DPO) if the set of its periodic points is dense in $\mathcal{X}$. The popular book by Devaney [27] isolates three components as being the essential features of chaos for DTDS: topological transitivity, sensitivity to initial conditions and denseness of periodic orbits (see [27, Def. 8.5]).

Let $(\mathcal{X}, \mathcal{M}, \mu)$ be a probability space and let $(\mathcal{X}, \mathcal{F})$ be a DTDS where $\mathcal{F}$ is a measurable map which preserves μ, i.e., $\mu(E) = \mu(\mathcal{F}^{-1}(E))$ for every $E \in \mathcal{M}$. The DTDS $(\mathcal{X}, \mathcal{F})$, or, the map $\mathcal{F}$, is **ergodic** with respect to μ if for every $E \in \mathcal{M}$

$$\left(E = \mathcal{F}^{-1}(E)\right) \Rightarrow (\mu(E) = 0 \text{ or } \mu(E) = 1) .$$

It is well known that $\mathcal{F}$ is ergodic iff for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} \mu(\mathcal{F}^{-i}(A) \cap B) = \mu(A)\mu(B)$$

The DTDS $(\mathcal{X}, \mathcal{F})$ is **(ergodic) mixing**, if for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{n\to\infty} \mu(\mathcal{F}^{-n}(A) \cap B) = \mu(A)\mu(B) \quad ,$$

while it is **(ergodic) weak mixing**, if for any pair of sets $A, B \in \mathcal{M}$ it holds that

$$\lim_{n\to\infty} \frac{1}{n} \sum_{i=0}^{n-1} |\mu(\mathcal{F}^{-i}(A) \cap B) - \mu(A)\mu(B)| = 0$$

In order to apply ergodic theory to CA, we need to define the collection $\mathcal{M}$ of measurable subsets of $G^{\mathbb{Z}^D}$ and a probability measure $\mu : \mathcal{M} \to [0, 1]$. We will use the normalized *Haar* measure μ_H defined over the σ-algebra generated by the cylinders which is, to our knowledge, one of the most widely used probabilistic setting in CA theory. The measure μ_H is defined as the product measure induced by the uniform probability distribution over G. In this way, for any $\ell \in \mathbb{N}$ and any pattern $P \in \mathcal{P}_\ell$, it holds that $\mu_H([P]) = \frac{1}{|G|^{(2\ell+1)^D}}$. Since in the rest of this paper we will only use the Haar measure, then we will write μ instead of μ_H.

3 Statement of the main results

In this section, we state the main results of this paper. They allow us to simplify the relationships between the dynamical and measure theoretic properties of additive CA, as depicted in Figure 3.

The following is the main result of the paper. It builds a bridge between two pretty different ways of approaching the study of the dynamics of CA: measure-theoretic and topological. The arguments used in the proofs are closely crafted on the additivity property of the global rule and on the group structure of the alphabet, however, the overall impression is that this tight link between topology and measure theory shall be true in a much more general setting.

▶ **Theorem 1.** *Let F be an additive D-dimensional CA over a finite abelian group. If F is topologically transitive then F is ergodic.*

Theorem 2 provides a new facet of the ergodicity property. This time ergodicity is related to set theoretic properties like surjectivity and aperiodicity of finite configurations.

▶ **Theorem 2.** *Any additive D-dimensional CA F over a finite abelian group is ergodic if and only if F is surjective and no finite configuration except 0 is a periodic point for F.*

The following corollary collects all the known properties which are related to ergodicity in the context of additive CA over finite abelian groups.

▶ **Corollary 3.** *Let F be an additive D-dimensional CA over a finite abelian group. The following properties are equivalent*

1. *ergodic mixing;*
2. *weak ergodic mixing;*
3. *ergodicity;*
4. *topological mixing;*
5. *total transitivity;*
6. *weak topological mixing;*
7. *topological transitivity;*
8. *F is surjective and no finite configuration except 0 is a periodic point of F.*

▶ **Corollary 4.** *Let F be an additive D-dimensional CA over a finite abelian group. If F is invertible and transitive then F is isomorphic to a Bernoulli shift.*

Surjectivity has strong implications on the dynamics of general CA, the following proposition and its corollary prove that in the context of additive CA, those implications are even stronger.

▶ **Proposition 5.** *Let F be an additive D-dimensional CA over a finite abelian group. If F is surjective then it is open.*

▶ **Corollary 6.** *Surjectivity and openness are equivalent properties for additive D-dimensional CA over a finite abelian group. Furthermore, they are equivalent to DPO in dimension $D = 1$.*

The following theorem provides a first characterization of strong transitivity for additive CA over finite abelian groups. Roughly speaking, the theorem states that this property is conserved under translations and iterations. We wonder whether the same holds for general CA.

▶ **Theorem 7.** *Let F be and additive D-dimensional CA over a finite abelian group. The following conditions are equivalent:*

1. *F is strongly transitive;*
2. *for every $v \in \mathbb{Z}^D$, the CA $\sigma^v \circ F$ is strongly transitive;*
3. *for every $n \in \mathbb{N}$, the CA F^n is strongly transitive;*

In the context of 1-dimensional CA, the following result characterizes the *roots* of powers of the shift map. Recall that a CA F is a root of another CA F' if there exists an integer $n > 0$ such that $F^n = F'$.

▶ **Theorem 8.** *[35, Thm. 18.1] Let F be a 1-dimensional CA over an alphabet G of prime cardinality. If $F^n = \sigma^m$ for some naturals n, m with $n \geq 1$, then $n|m$.*

In the case of linear CA over an alphabet of cardinality which is a power of a prime, the following weaker form of Theorem 8 can be proved.

▶ **Theorem 9.** *Let $G = \mathbb{Z}_{p^k}$ with p prime and let F be a 1-dimensional CA over G defined by the neighborhood $\mathcal{N} = \{-r, \ldots, r\}$ and the local rule $f : \mathbb{Z}_{p^k}^{2r+1} \to \mathbb{Z}_{p^k}$ expressed by the linear combination with coefficients $a_{-r}, \ldots, a_r \in \mathbb{Z}_{p^k}$. If $F^n = \sigma^m$ for some naturals $n \geq 1$ and $m \geq 1$, then $m \geq n$.*

The following example shows that Theorem 9 is no longer true for additive CA over finite abelian groups.

▶ **Example 10.** Let F be the 1-dimensional CA over $\mathbb{Z}_m^n$ defined by the neighbourhood $\mathcal{N} = \{0, 1\}$ and the local rule $f : (\mathbb{Z}_m^n)^2 \to \mathbb{Z}_m^n$ such that

$$\forall (x_0, x_1) \in (\mathbb{Z}_m^n)^2, \quad f(x_0, x_1) = M_0 x_0 + M_1 x_1 \ ,$$

where

$$M_0 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 \\ 0 & 0 & 0 & \cdots & 0 \end{bmatrix} \quad \text{and} \quad M_1 = \begin{bmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 \\ 1 & 0 & 0 & \cdots & 0 \end{bmatrix} .$$

It is easy to check that $F^n = \sigma$ contradicting the statement of Theorem 9.

Example 10 has also other important consequences. On the one hand, it provides examples of CA that are arbitrarily "small" roots of the shift map. On the other hand, it provides the basic building blocks for systems which are ergodic but have both arbitrarily low Lyapunov exponents and arbitrarily low topological entropies.

4 Proofs of the main results

4.1 Useful known results

Before going into the proofs of our main results let us recall some known facts which helped in shaping the situation depicted in Figure 2.

▶ **Theorem 11.** *[50, Thm. 1.28, pag. 50] Mixing, weak mixing and ergodicity are equivalent properties for endomorphisms of compact groups.*

▶ **Theorem 12.** *[4, Thm. 1] An ergodic automorphism of a compact metric abelian group is a Bernoulli shift.*

▶ **Proposition 13.** *[15, Prop. 6.7, pag. 32] Ergodic (resp., weak ergodic) mixing implies topological (resp., weak) mixing for endomorphisms of compact groups and measures with full support.*

The following will be fundamental for proving our main result.

▶ **Theorem 14.** *[48, Thm. 1] Let F be any endomorphism of a compact abelian group with normalized Haar measure. Then, F is ergodic if and only if F is surjective and $F^n - I$ is surjective for all $n \in \mathbb{N}$ (I is the identity map).*

4.2 Proofs of our results

In order to make the proof of the main result more readable, we cut it into several lemmata.

▶ **Lemma 15.** *Let F be an additive D-dimensional CA over a finite abelian group G. For all $n \geq 1$, it holds that*

$$F^n - I = (F - I) \circ (I + F + \cdots + F^{n-1}) = (I + F + \cdots + F^{n-1}) \circ (F - I) \tag{2}$$

Proof. It is an immediate consequence of the fact that the composition operation on the set of additive CA is distributive over the sum operation (defined on the same set). ◀

▶ **Lemma 16.** *Let F be an additive CA over a finite abelian group G. Let $\ell \in \mathbb{N}$ and $w \in \mathcal{P}_l$ such that $(F - I)(X) \cap [w] = \emptyset$. Then, it holds that*

$$\forall n \geq 1, \quad (F^n - I)(X) \cap [w] = \emptyset \ .$$

Proof. For every natural $n \geq 1$, by Lemma 15, we get

$$(F^n - I)(X) = (F - I)\left((I + F + \cdots + F^{n-1})(X)\right) \subseteq (F - I)(X) \ .$$

Since $(F - I)(X) \cap [w] = \emptyset$, it follows that $(F^n - I)(X) \cap [w] = \emptyset$. ◀

▶ **Lemma 17.** *Let F be an additive D-dimensional CA over a finite abelian group G. If there exist $\ell \in \mathbb{N}$ and $w \in \mathcal{P}_l$ such that*

$$\forall n \geq 1, \quad (F^n - I)(X) \cap [w] = \emptyset \ ,$$

then F is not topologically transitive.

Proof. For the sake of argument, assume that F is topologically transitive. Choose arbitrarily two patterns $w_1, w_2 \in \mathcal{P}_l$ such that $w_2 - w_1 = w$. By transitivity, there exist a configuration $c \in [w_1]$ and a natural $n \geq 1$ such that $F^n(c) \in [w_2]$. Thus, $F^n(c) - c \in [w]$, or, equivalently, $(F^n - I)(c) \in [w]$, which is a contradiction. ◀

At present all the necessary pieces have been built to go through the proof of Theorem 1.

Proof of Theorem 1. For the sake of argument, assume that F is transitive but not ergodic. Since transitive CA are surjective, then, by Theorem 14, there exists $n \geq 1$ such that $F^n - I$ is not surjective. Let $H = F^n$. Since $H - I$ is not surjective and $(H - I)(X)$ is closed, there exist a natural $\ell \in \mathbb{N}$ and a pattern $w \in \mathcal{P}_\ell$ such that $(H - I)(X) \cap [w] = \emptyset$. So, by Lemma 16, it follows that

$$\forall m \geq 1, \quad (H^m - I)(X) \cap [w] = \emptyset \ .$$

Therefore, by Lemma 17, H is not topologically transitive. Since topologically transitive CA are totally transitive (see [46], where the proof involving 1-dimensional CA can be extended to any dimension D), we conclude that neither is F, which is a contradiction. ◀

Proof of Theorem 2. By Theorem 14, F is ergodic if and only if it is surjective and for every natural $m \geq 1$ the CA $I - F^m$ is surjective. Fix an arbitrary natural $m \geq 1$ and define $H^{(m)} = I - F^m$. The Garden-of-Eden Theorem for CA [45, 47] guarantees that $H^{(m)}$ is surjective if and only if it is injective on finite configurations, i.e., $H^{(m)}(c) \neq H^{(m)}(c')$ for every pair of distinct finite configurations $c, c' \in G^{\mathbb{Z}^D}$. Set $d = c - c' \in G^{\mathbb{Z}^D}$. Clearly d is a finite configuration. Furthermore, by additivity, it holds that $H^{(m)}(c) \neq H^{(m)}(c')$ if and only if $H^{(m)}(d) \neq 0$. By definition of $H^{(m)}$, the condition $H^{(m)}(d) \neq 0$ is true for every $m \geq 1$ if and only if $F^m(d) \neq d$, i.e., d is not a periodic point of F. ◀

Proof of Proposition 5. We are going to prove that F is open at the configuration $0 \in G^{\mathbb{Z}^D}$, i.e., equivalently, for every $\ell \in \mathbb{N}$, the set $F([0])$ is open, where $0 \in \mathcal{P}_\ell$. Since F is an endomorphism of the topological group $G^{\mathbb{Z}^D}$, we conclude that F is open.

To proceed, consider any arbitrary $\ell \in \mathbb{N}$. Clearly, it holds that $G^{\mathbb{Z}^D} = \bigcup_{w \in \mathcal{P}_\ell}[w]$ and, since F is surjective, we get $G^{\mathbb{Z}^D} = \bigcup_{w \in \mathcal{P}_\ell} F([w])$. Thus, there exists $w' \in \mathcal{P}_\ell$ such that $F([w'])$ has non-empty interior. Let $c \in [w']$ be the configuration such that $c(v) = 0 \in G$ for every position $v \in \mathbb{Z}^D$ with $||v|| > \ell$. One gets $F([w']) = F([0] + c) = F([0]) + F(c)$ (where $[0] + c$ and $F([0]) + F(c)$ denote suitable cosets of $[0]$ and $F([0])$, respectively). Therefore, $F([0])$ must have non-empty interior, too. Since $F([0])$ is a subgroup of the topological group $G^{\mathbb{Z}^D}$, it follows that $F([0])$ is open. ◀

Proof of Corollary 6. It is well-known that any open D-dimensional CA is surjective. By Proposition 5, surjective additive D-dimensional CA over a finite abelian group are open. It is easy to see that DPO implies surjectivity in any dimension. While, by Proposition 5 and the fact that open 1-dimensional CA have DPO [7, Thm. 4.4], it follows that surjective additive 1-dimensional CA have DPO. ◀

Proof of Corollary 4. By Theorem 1, F is ergodic. The thesis follows from Theorem 12. ◀

▶ **Lemma 18.** *An additive CA F over a finite abelian group G is strongly transitive if and only if the following condition holds: for any natural $\ell \in \mathbb{N}$ and any pattern $P \in \mathcal{P}_\ell$ there exists $t \in \mathbb{N}$ such that $0 \in F^t([P])$.*

Proof. The "only if" part trivially follows from the definition of strong transitivity. Let us prove the "if" part. Assume that F is an additive CA over a finite abelian group G and satisfying the condition in the statement. Consider an arbitrary natural $\ell \in \mathbb{N}$. For every $P \in \mathcal{P}_\ell$ let $n_{P,\ell}$ be the smallest natural t such that $0 \in F^t([P])$. Define $n_\ell = \max\{n_{P,\ell} : P \in \mathcal{P}_\ell\}$. Since $F(0) = 0$ it holds that

$$\forall P \in \mathcal{P}_\ell, \quad 0 \in F^{n_\ell}([P]) \tag{3}$$

We now show that for any configuration $e \in G^{\mathbb{Z}^D}$, any natural ℓ, and any pattern $P \in \mathcal{P}_\ell$ there exists $t' = n_\ell$ such that $e \in F^{t'}([P])$, that is, F is strongly transitive. Choose arbitrarily a configuration $e \in G^{\mathbb{Z}^D}$, a natural ℓ, and pattern $P \in \mathcal{P}_\ell$. Let c be any configuration belonging to $F^{-n_\ell}(e)$. If $c \in [P]$ we are done. Otherwise, by (3), there exists $c' \in G^{\mathbb{Z}^D}$ such that $c + c' \in [P]$ and $F^{n_\ell}(c') = 0$. Thus, we get

$$F^{n_\ell}(c + c') = F^{n_\ell}(c) + F^{n_\ell}(c') = F^{n_\ell}(c) + 0 = F^{n_\ell}(c) = e \ ,$$

and this concludes the proof. ◀

Proof of Theorem 7. It is an immediate consequence of Lemma 18 and the fact that for every $v \in \mathbb{Z}^D$ and every $n \in \mathbb{N}$ both $\sigma^v(0) = 0$ and $F^n(0) = 0$ hold. ◀

Proof of Theorem 9. The CA F can be represented by the Laurent polynomial $\mathbb{p}(x, x^{-1}) = \sum_{i=-r}^{r} a_i x^i \in \mathbb{Z}_{p^k}[x, x^{-1}]$, while σ^1 can be represented by the Laurent polynomial x. Assume that $F^n = \sigma^m$ for some naturals n, m with $n \geq 1$ and $m \geq 1$. It is easy to verify that $F^n = \sigma^m$ if and only if $\left(\mathbb{p}(x, x^{-1})\right)^n = x^m$. We consider two cases. 1) If $p | a_i$ for each $i \in \mathcal{N}$ with $i \neq 0$ then, by [14, Lemma 5], putting $h = p^{k-1} \in \mathbb{N}$ we have that $\left(\mathbb{p}(x, x^{-1})\right)^h$ is a constant (i.e., it does not contain the formal variable x). Hence, for every $s \in \mathbb{N}$ it holds that $\left(\mathbb{p}(x, x^{-1})\right)^{sh} \neq x^{mh}$ and this contradicts that $F^n = \sigma^m$. 2) Otherwise, there exists $i \neq 0$ such that $\gcd(a_i, p) = 1$ (since $F^n = \sigma^m$ then F must be injective and so for every other coefficient a_j with $i \neq j$ we have $\gcd(a_j, p) = p$). First of all, we prove that there always exist n' and m' with $m' \geq n'$ such that $F^{n'} = \sigma^{m'}$. Indeed, by [14, Lemma 5], for $h = p^{k-1} \in \mathbb{N}$ we get $\left(\mathbb{p}(x, x^{-1})\right)^h = a_i^h x^{ih}$. Therefore, for $t = \varphi(p^k)$ (where φ is the Euler's totient function) we get $\left(\mathbb{p}(x, x^{-1})\right)^{n'} = x^{m'}$, i.e., $F^{n'} = \sigma^{m'}$, with $n' = ht$ and $m' = iht$. To conclude, assume by contradiction that $F^n = \sigma^m$ with $m < n$. Then, we get $F^{n'n} = \sigma^{m'n}$ and $F^{n'n} = \sigma^{n'm}$. So, it follows that $m'n = n'm$, but this is not possible since $m'n \geq n'n > n'm$. Thus, it holds that $m \geq n$ and this concludes the proof. ◀

5 Conclusions and perspectives

Comparing Figure 2 and 3, one can immediately appreciate the impact of the results in the paper. All single arrow tips (i.e. the known relations for which the opposite implication was unknown) disappeared and several properties coalesced in the group of transitivity, total transitivity and weak topological mixing. However, what is more important is that many measure theoretical and topological properties coincide. These facts legitimate the following

▶ **Conjecture 1.** *Transitive CA are ergodic with respect to Bernoulli measures.*

Solving the previous conjecture will probably clarify also the status of the properties of ergodic mixing, weakly ergodic mixing and topological mixing, much like it happened for the case of endomorphisms of compact abelian groups in this paper. Investigating, the following well-known conjecture due to Blanchard and Tisseur (see [2, Conjecture 1] and [1] for more details) will definitively complete the overall picture.

▶ **Conjecture 2.** *All surjective CA have a dense set of periodic orbits.*

Another interesting research direction consists in establishing the decidability of the dynamical properties. In the framework of general CA, recent results from Ville Lukkarila have shown that both topological mixing and transitivity are undecidable properties [42]. Undecidability of sensitivity, surjectivity (for dimensions larger than 1) and openness (for dimensions larger than 1) were already known for years [38, 30]. It is therefore natural to conjecture that the remaining ones are also undecidable.

▶ **Conjecture 3.** *Ergodicity, weak ergodic mixing, ergodic mixing and strong transitivity are undecidable for CA.*

We want to remark that we intentionally left out the expansivity property from Conjecture 3, since it is so peculiar that we believe it might be decidable.

Finally, it would be very interesting to extend Theorem 7 to all CA, and not only to additive CA. In some way, this would turn strong transitivity into the "strongest" translation invariant property, since it is well-known that expansivity is not translations invariant and that there are no expansive CA for dimensions greater than one.

Abstract

We study two formalisms that allow to compare transducers over words under origin semantics: rational and regular resynchronizers, and show that the former are captured by the latter. We then consider some instances of the following synthesis problem: given transducers T_1, T_2, construct a rational (resp. regular) resynchronizer R, if it exists, such that T_1 is contained in $R(T_2)$ under the origin semantics. We show that synthesis of rational resynchronizers is decidable for functional, and even finite-valued, one-way transducers, and undecidable for relational one-way transducers. In the two-way setting, synthesis of regular resynchronizers is shown to be decidable for unambiguous two-way transducers. For larger classes of two-way transducers, the decidability status is open.

1 Introduction

The notion of word transformation is pervasive in computer science, as computers typically process streams of data and transform them between different formats. The most basic form of word transformation is realized using finite memory. Such a model is called finite-state transducer and was studied from the early beginnings of automata theory. Differently from automata, the expressiveness of transducers is significantly affected by the presence of non-determinism (even when the associated transformation is a function), and by the capability of processing the input in both directions (one-way vs two-way transducers). Another difference is that many problems, notably, equivalence and containment, become undecidable when moving from automata to transducers [11, 14].

An alternative semantics for transducers, called *origin semantics*, was introduced in [4] in order to obtain canonical two-way word transducers. In the origin semantics, the output is tagged with positions of the input, called origins, that describe where each output element was produced. According to this semantics, two transducers may be non-equivalent even when they compute the same relation in the classical semantics. From a computational viewpoint, the origin semantics has the advantage that it allows to recover the decidability of equivalence and containment of non-deterministic (and even two-way) transducers [6].

It can be argued that comparing two transducers in the origin semantics is rather restrictive, because it requires that the same output is generated at precisely the same place. A natural approach to allow some 'distortion' of the origin information when comparing two transducers was proposed in [10]. *Rational* resynchronizers allow to compare *one-way* transducers (hence, the name 'rational') under origin distortions that are generated with finite control. A rational resynchronizer is simply a one-way transducer that processes an interleaved input-output string, producing another interleaved interleaved input-output string with the same input and output projection. For two-way transducers (or equivalently, streaming string transducers [1]) a different formalism is required to capture origin distortion, since the representation of the origin information through interleaved input-output pairs does not work anymore. To this purpose, *regular resynchronizers* were introduced in [6] as a logic-based transformation of origin graphs, in the spirit of Courcelle's monadic second-order logic definable graph transductions [8]. In [6] it was shown that containment of two-way transducers up to a (bounded) regular resynchronizer is decidable.

In this paper we first show that bounded regular resynchronizers capture the rational ones. This result is rather technical, because rational resynchronizers work on explicit origin graphs, encoded as input-output pairs, which is not the case for regular resynchronizers. Then we consider the following problem: given two transducers T_1, T_2, we ask whether some rational, or bounded regular, resynchronizer R exists such that T_1 is origin-contained in T_2 up to R. So here, the resynchronizer R is not part of the input, and we want to synthesize such a resynchronizer, if one exists.

Our main contributions can be summarized as follows:

1. synthesis of rational resynchronizers for functional (or even finite-valued) one-way transducers is decidable,
2. synthesis of rational resynchronizers for unrestricted one-way transducers is undecidable,
3. synthesis of bounded regular resynchronizers for unambiguous two-way transducers is decidable.

Somewhat surprisingly, for both decidable cases above the existence of a resynchronizer turns out to be equivalent to the classical inclusion of the two transducers.

Full proofs of the results presented in this paper can be found in the extended version `https://arxiv.org/abs/1906.08688`.

2 Preliminaries

One-way transducers

One of the simplest transducer model is the one-way non-deterministic finite-state transducer (hereafter, simply one-way transducer), capturing the class of so-called *rational relations*. This is basically an automaton in which every transition consumes one letter from the input and appends a word of any length to the output.

Formally, a *one-way transducer* is a tuple $T = (\Sigma, \Gamma, Q, I, E, F, L)$, where Σ, Γ are finite input and output alphabets, Q is a finite set of states, $I, F \subseteq Q$ are subsets of initial and final states, $E \subseteq Q \times \Sigma \times Q$ is a finite set of transition rules, and $L : E \uplus F \to 2^{\Gamma^*}$ is a function specifying a regular language of partial outputs for each transition rule and each final state. The relation defined by T contains pairs (u, v) of input and output words, where $u = a_1 \dots a_n$ and $v = v_1 \dots v_n \, v_{n+1}$, for which there is a run $q_0 \xrightarrow{a_1 \mid v_1} q_1 \xrightarrow{a_2 \mid v_2} \dots q_n \xrightarrow{\mid v_{n+1}}$ such that $q_0 \in I$, $q_n \in F$, $(q_{i-1}, a_i, q_i) \in E$, $v_i \in L(q_{i-1}, a_i, q_i)$, and $v_{n+1} \in L(q_n)$. The transducer is called *functional* if it associates at most one output with each input, namely, if it realizes a partial function. For example, Figure 1 shows two one-way transducers with input alphabet

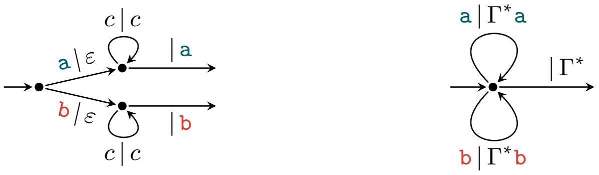

Figure 1 Examples of functional and relational one-way transducers.

$\Sigma = \{a, b\}$ and output alphabet $\Gamma \supseteq \Sigma$. The first transducer is functional, and realizes the cyclic rotation $f : cu \mapsto uc$, for any letter $c \in \{a, b\}$ and any word $u \in \{a, b\}^*$. The second transducer is not functional, and associates with an input $u \in \Sigma^*$ any possible word $v \in \Gamma^*$ as output such that u is a sub-sequence of v.

Two-way transducers

Allowing the input head to move in any direction, to the left or to the right, gives a more powerful model of transducer, which captures e.g. the relation $\{(u, u^n) : u \in \Sigma^*, n \in \mathbb{N}\}$. To define two-way transducers, we adopt the convention that, for any given input $u \in \Sigma^*$, $u(0) = \vdash$ and $u(|u| + 1) = \dashv$, where $\vdash, \dashv \notin \Sigma$ are special markers used as delimiters of the input. In this way, a transducer can detect when an endpoint of the input has been reached.

A *two-way transducer* is a tuple $T = (\Sigma, \Gamma, Q, I, E, F, L)$, whose components are defined just like those of a one-way transducer, except that the state set Q is partitioned into two subsets, $Q_\prec$ and $Q_\succ$, the set I of initial states is contained in $Q_\succ$, and the set E of transition rules is contained in $(Q \times \Sigma \times Q) \uplus (Q_\prec \times \{\vdash\} \times Q_\succ) \uplus (Q_\succ \times \{\dashv\} \times Q_\prec)$. The partitioning of the set of states is useful for specifying which letter is read from each state: states from $Q_\prec$ read the letter to the left, whereas states from $Q_\succ$ read the letter to the right. Given an input $u \in \Sigma^*$, a configuration of a two-way transducer is a pair (q, i), with $q \in Q$ and $i \in \{1, \ldots, |u| + 1\}$. Based on the types of source and target states in a transition rule, we can distinguish four types of transitions between configurations (the output v is always assumed to range over the language $L(q, a, q')$):

- $(q, i) \xrightarrow{a \mid v} (q', i + 1)$ if $(q, a, q') \in E$, $q, q' \in Q_\succ$, and $a = u(i)$,
- $(q, i) \xrightarrow{a \mid v} (q', i)$ if $(q, a, q') \in E$, $q \in Q_\succ$, $q' \in Q_\prec$, and $a = u(i)$,
- $(q, i) \xrightarrow{a \mid v} (q', i - 1)$ if $(q, a, q') \in E$, $q, q' \in Q_\prec$, and $a = u(i - 1)$,
- $(q, i) \xrightarrow{a \mid v} (q', i)$ if $(q, a, q') \in E$, $q \in Q_\prec$, $q' \in Q_\succ$, and $a = u(i - 1)$.

Note that, when reading a marker $\vdash$ or $\dashv$, the transducer is obliged to make a U-turn, either left-to-right or right-to-left. The notions of successful run, realized relation, and functional transducer are naturally generalized from the one-way to the two-way variant, (we refer to [6] for more details).

In [5], a slight extension of two-way transducers, called two-way transducers *with common guess*, was proposed. Before processing its input, such a transducer can non-deterministically guess some arbitrary annotation of the input over a fixed alphabet. Once an annotation is guessed, it remains the same during the computation. Transitions may then depend on the input letter and the guessed annotation at the current position. For example, this extension allows to define relations of the form $\{(u, vv) \mid u \in \Sigma^*, v \in \Gamma^*, |u| = |v|\}$. Note that the extension with common guess does not increase the expressiveness of one-way transducers, since these are naturally closed under input projections. Likewise, common guess does not affect the expressive power of functional two-way transducers, since one can guess a canonical annotation at runtime.

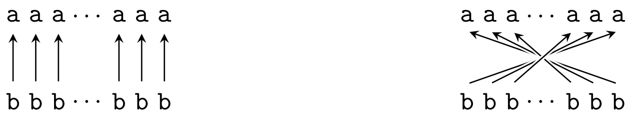

Figure 2 Input-output pairs annotated with origin information.

Classical vs origin semantics

In the previous definitions, we associated a classical semantics to transducers (one-way or two-way), which gives rise to relations or functions between input words over Σ and output words over Γ. In [4] an alternative semantics for transducers, called *origin semantics*, was introduced with the goal of getting canonical transducers for any given word function. Roughly speaking, in the origin semantics, every position of the output word is annotated with the position of the input where that particular output element was produced. This yields a bipartite graph, called *origin graph*, with two linearly ordered sets of nodes, representing respectively the input and the output elements, and edges directed from output nodes to input nodes, representing the so-called *origins*. Figure 2 depicts an input-output pair (a^n, b^n) annotated with two different origins: in the first graph, a position i in the output has its origin at the same position i in the input, while in the second graph it has origin at position $n - i$.

Formally, the origin semantics of a transducer is a relation $S_o \subseteq \Sigma^* \times (\Gamma \times \mathbb{N})^*$ consisting of pairs (u, ν), where $u = a_1 \dots a_n \in \Sigma^*$ is a possible input and $\nu = \nu_1 \dots \nu_{m+1} \in (\Gamma \times \mathbb{N})^*$ is the corresponding output tagged with input positions, as induced by a successful run of the form $(q_0, i_0) \xrightarrow{a_1 \mid \nu_1} (q_1, i_1) \xrightarrow{a_2 \mid \nu_2} \dots (q_m, i_m) \xrightarrow{\mid \nu_{m+1}}$, with each $\nu_j \in (\Gamma \times \{i_j\})^*$. We identify a pair (u, ν) with the origin graph obtained by arranging the input elements and the output elements along two lines (we omit the successor relation in the graph notation), and adding edges from every output element (a, i) to the i-th element of the input. Given an origin graph $G = (u, \nu)$, we denote by $\mathsf{in}(G)$, $\mathsf{out}(G)$, and $\mathsf{orig}(G)$ respectively the input word u, the output word obtained by projecting ν onto the finite alphabet Γ, and the sequence of input positions (origins) obtained by projecting ν onto $\mathbb{N}$.

For one-way transducers, there is a simpler presentation of origin graphs in the form of interleaved words. Assuming that the alphabets Σ and Γ are disjoint, we interleave the input and output word by appending after each input symbol the output word produced by reading that symbol. For example, if $\Sigma = \{a\}$ and $\Gamma = \{b\}$, then a word of the form $abb \dots abb$ represents an origin graph (a^n, ν), where $|\nu| = 2n$ and $\nu(2i - 1) = \nu(2i) = (b, i)$, for all $i = 1, \dots, n$. Words over $\Sigma \uplus \Gamma$ are called *synchronized words*. Just as every synchronized word represents an origin graph, a regular language over $\Sigma \uplus \Gamma$ represents a rational relation with origins, or equally the origin semantics of a one-way transducer.

In general, when comparing transducers, we can refer to one of the two possible semantics. Clearly, two transducers that are equivalent in the origin semantics are also equivalent in the classical semantics, but the converse is not true.

3 Resynchronizations

The central concept of this paper is that of resynchronization, which is a transformation of origin graphs that preserves the underlying input and output words. The concept was originally introduced in [10], and mostly studied in the setting of rational relations. Here we use the concept in the more general setting of relations definable by two-way transducers.

Formally, a *resynchronization* is any relation $R \subseteq (\Sigma^* \times (\Gamma \times \mathbb{N})^*)^2$ that contains only pairs (G, G') of origin graphs such that $\mathsf{in}(G) = \mathsf{in}(G')$ and $\mathsf{out}(G) = \mathsf{out}(G')$, namely, with the same projections onto the input and output alphabets.[1] A resynchronization R can be used to modify the origin information of a relation, while preserving the underlying input-output pairs. Formally, for every relation $S_o \subseteq \Sigma^* \times (\Gamma \times \mathbb{N})^*$ with origins, we define the *resynchronized relation* $R(S_o) = \{G' \in S_o \mid (G, G') \in R,\ G \in S_o\}$. Note that if the origin information is removed from both $R(S_o)$ and S_o, then $R(S_o) \subseteq S_o$. Moreover, $R(S_o) = S_o$ when R is the *universal resynchronization*, that is, when R contains all pairs (G, G'), with $G, G' \in \Sigma^* \times (\Gamma \times \mathbb{N})^*$, $\mathsf{in}(G) = \mathsf{in}(G')$, and $\mathsf{out}(G) = \mathsf{out}(G')$.

Definability of resynchronized relations

An important property that we need to guarantee in order to enable some effective reasoning on resynchronizations is the definability of the resynchronized relations. More precisely, given a class $\mathcal{C}$ of transducers, we say that a resynchronization R *preserves definability in* $\mathcal{C}$ if for every transducer $T \in \mathcal{C}$, the relation $R(T)$ is realized by some transducer $T' \in \mathcal{C}$, that can be effectively constructed from R and T. The class $\mathcal{C}$ will usually be the class of one-way transducers or the class of two-way transducers, and this will be clear from the context.

Below, we recall the definitions of two important classes of resynchronizations, called rational [10] and regular resynchronizers [6], that preserve definability by one-way transducers and by two-way transducers, respectively. We will then compare the expressive power of these two formalisms, showing that rational resynchronizers are strictly less expressive than regular resynchronizers.

Rational resynchronizers

A natural definition of resynchronizers for one-way transducers is obtained from rational relations over the disjoint union $\Sigma \uplus \Gamma$ of the input and output alphabets. Any such relation consists of pairs of synchronized words (w, w'), and thus represents a transformation of origin graphs. In addition, if the induced synchronized words w and w' have the same projections over the input and output alphabets, then the relation represents a resynchronization. We also recall that rational relations are captured by one-way transducers, so, by analogy, we call *rational resynchronizer* any one-way transducer over $\Sigma \uplus \Gamma$ that preserves the input and output projections.

It is routine to see that rational resynchronizers preserve definability of relations by one-way transducers. It is also worth noting that every rational resynchronizer is a length-preserving transducer. By a classical result of Elgot and Mezei [9] every rational resynchronizer can be assumed to be a *letter-to-letter* one-way transducer, namely, a transducer with transitions of the form $q \xrightarrow{a \mid b} q'$, with $a, b \in \Sigma \uplus \Gamma$.

▶ **Example 1.** Consider the functional one-way transducers T_1, T_2 in Figure 3. The domain of both transducers is $(aa)^*$. An origin graph of T_1 is a one-to-one mapping from the output to the input (each a produces one b). On the other hand, in an origin graph of T_2, every a at input position $2i+1$ is the origin of two b's at output positions $2i+1, 2i+2$. The transducer R depicted to the right of the figure transforms synchronized words while preserving their input and output projections. It is then a rational resynchronizer. In particular, R transforms origin graphs of T_1 to origin graphs of T_2.

[1] In [10], resynchronizers were further restricted to contain at least the pairs of identical origin graphs. Here we prefer to avoid this additional restriction and reason with a more general class of resynchronizations.

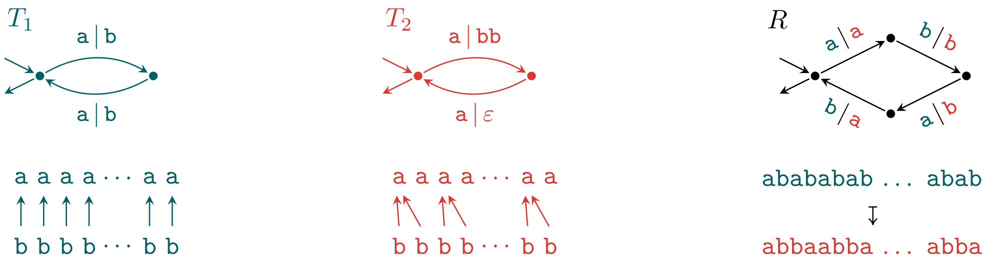

Figure 3 Two functional 1NFT T_1, T_2, their origin graphs, and a rational resynchronizer R.

Regular resynchronizers

While languages of synchronized words are a faithful representation of rational relations, this notation does not capture regular relations, so relations realized by two-way transducers. An alternative formalism for resynchronizations of relations defined by two-way transducers was proposed in [6] under the name of MSO resynchronizer (here we call it simply "resynchronizer"). The formalism describes pairs (G, G') of origin graphs by means of two relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$ $(\gamma, \gamma' \in \Gamma)$ in the spirit of MSO graph transductions. More precisely:

- move_γ describes how the origin y of an output position x labeled by γ is redirected to a new origin z (for short, we call y and z the *source* and *target* origins of x). Formally, move_γ is a relation contained in $\Sigma^* \times \mathbb{N} \times \mathbb{N}$ that induces resynchronization pairs (G, G') such that, for all output positions x, if $\mathsf{out}(G)(x) = \gamma$, $\mathsf{orig}(G)(x) = y$, and $\mathsf{orig}(G')(x) = z$, then $(\mathsf{in}(G), y, z) \in \mathsf{move}_\gamma$.
- $\mathsf{next}_{\gamma,\gamma'}$ constrains the target origins z and z' of any two consecutive output positions x and $x+1$ that are labelled by γ and γ', respectively. Formally, $\mathsf{next}_{\gamma,\gamma'}$ is a relation contained in $\Sigma^* \times \mathbb{N} \times \mathbb{N}$ that induces resynchronization pairs (G, G') such that, for all output positions x and $x+1$, if $\mathsf{out}(G)(x) = \gamma$, $\mathsf{out}(G)(x+1) = \gamma'$, $\mathsf{orig}(G')(x) = z$, and $\mathsf{orig}(G')(x+1) = z'$, then $(\mathsf{in}(G), z, z') \in \mathsf{next}_{\gamma,\gamma'}$.

A *resynchronizer* is a tuple $\big((\mathsf{move}_\gamma)_{\gamma\in\Gamma}, (\mathsf{next}_{\gamma,\gamma'})_{\gamma,\gamma'\in\Gamma}\big)$, and defines the resynchronization R with pairs (G, G') induced by the relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$, where $\gamma, \gamma' \in \Gamma$.

In order to obtain a well-behaved class of resynchronizations, that in particular preserves definability by two-way transducers, we need to enforce some restrictions. First, we require that the relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$ are described by regular languages (or equally, definable in monadic second-order logic). By this we mean that we encode the input positions y, z, z' with suitable annotations over the binary alphabet $\mathbb{B} = \{0, 1\}$, so that we can identify the relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$ with some *regular* languages over the expanded alphabet $\Sigma \times \mathbb{B}^2$. We call *regular resynchronizer* a resynchronizer where the relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$ are given by regular languages. In addition, we also require that regular resynchronizers are k*-bounded*, for some $k \in \mathbb{N}$, in the sense that for every input u, every output letter γ, and every target origin z, there are at most k positions y such that $(u, y, z) \in \mathsf{move}_\gamma$.

▶ **Example 2.** Consider the resynchronization R of Figure 4, containing the pairs (G, G'), where G (resp. G') is the origin graph that maps every output position to the first (resp. last) input position. R is "one-way", in the sense that it contains only origin graphs that are admissible outcomes of runs of one-way transducers. However, R is not definable by any rational resynchronizer, since, in terms of synchronized words, it should map $a\,v\,u$ to $a\,u\,v$, for every $a \in \Sigma$, $u \in \Sigma^*$, and $v \in \Gamma^*$, which is clearly not a rational relation. The resynchronization R can however be defined by a 1-bounded regular resynchronizer, e.g. $\big((\mathsf{move}_\gamma)_{\gamma\in\Gamma}, (\mathsf{next}_{\gamma,\gamma'})_{\gamma,\gamma'\in\Gamma}\big)$, with $\mathsf{move}_\gamma = \{(u, y, z) \mid u \in \Sigma^*, y = 1, z = |u|\}$ and

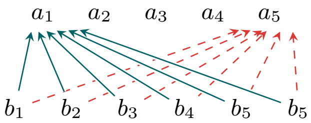

Figure 4 A 1-bounded, regular resynchronization that is not rational.

$\mathsf{next}_{\gamma,\gamma'} = \Sigma^* \times \mathbb{N} \times \mathbb{N}$.

One can observe that, in the previous example, next is not restricting the resynchronization further. For other examples that use next in a non-trivial way see for instance [6, Example 13].

The notion of resynchronizer can be slightly enhanced in order to allow some additional amount of non-determinism in the way origin graphs are transformed (this enhanced notion is indeed the one proposed in [6]). The principle is very similar to the idea of enhancing two-way transducers with common guess. More precisely, we allow additional monadic parameters that annotate the input and the output, thus obtaining words over expanded alphabets of the form $\Sigma \times \Sigma'$ and $\Gamma \times \Gamma'$. A resynchronizer *with parameters* is thus a tuple $\big(\mathsf{ipar}, \mathsf{opar}, (\mathsf{move}_\gamma)_\gamma, (\mathsf{next}_{\gamma,\gamma'})_{\gamma,\gamma'}\big)$, where $\mathsf{ipar} \subseteq (\Sigma \times \Sigma')^*$ describes the possible annotations of the input, $\mathsf{opar} \subseteq (\Gamma \times \Gamma')^*$ describes the possible annotations of the output, and, for every $\gamma, \gamma' \in \Gamma \times \Gamma'$, $\mathsf{move}_\gamma \subseteq (\Sigma \times \Sigma' \times \mathbb{B}^2)^*$ describes a transformation from source to target origins of γ-labelled output positions, and $\mathsf{next}_{\gamma,\gamma'} \subseteq (\Sigma \times \Sigma' \times \mathbb{B}^2)$ constraints the target origins of consecutive output positions labelled by γ and γ'. The resynchronization pairs (G, G') in this case are induced by $\big((\mathsf{move}_\gamma)_{\gamma \in \Gamma \times \Gamma'}, (\mathsf{next}_{\gamma,\gamma'})_{\gamma,\gamma' \in \Gamma \times \Gamma'}\big)$ and are obtained by projecting the input and output over the original alphabets Σ and Γ, under the assumption that the annotations satisfy ipar and opar. A resynchronizer with parameters is called *regular* if all its relations are regular. A regular resynchronizer is called *bounded* if is k-bounded for some k.

In [6] it was shown that, given a bounded regular resynchronizer R with parameters and a two-way transducer T with common guess, one can construct a two-way transducer T' with common guess such that $T' =_o R(T)$. The notation $T' =_o R(T)$ is used to represent the fact that T' and $R(T)$ define the same relation in the origin semantics.

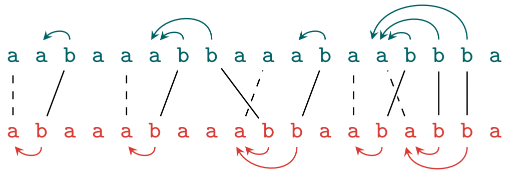
Unless otherwise stated, hereafter we assume that two-way transducers are enhanced with common guess, and regular resynchronizers are enhanced with parameters.

Rational vs regular resynchronizers

Our first result shows that bounded, regular resynchronizers are more expressive than rational resynchronizers. Consider for instance Example 1: it can be captured by the regular resynchronizer with opar annotating even/odd positions. The resynchronizer shifts the origins of the even positions of the output by one to the left and keeps the origins of the odd positions unchanged. So here move_γ can be described by a regular language. On the other hand, Example 2 shows that there are bounded, regular resynchronizers that cannot be captured by rational resynchronizers.

▶ **Theorem 3.** *For every rational resynchronizer, there is an equivalent* 1*-bounded regular resynchronizer.*

The proof of the above result is rather technical and can be found in the extended version. Here we only provide a rough idea. Consider a rational resynchronizer R, that is, a one-way transducer that transforms synchronized words while preserving the input and output projections. For example, Figure 5 represents a possible pair of synchronized words,



a a b a a a b b a a a b a a b b b a
a b a a a b a a a b b a a b a b b a

Figure 5 A 1-bounded, regular resynchronization that is not rational.

denoted w and w', shown in blue and in red, respectively, such that $(w, w') \in R$. We assume that $\Sigma = \{a\}$ and $\Gamma = \{b\}$.

From the given rational resynchronizer R we construct an equivalent 1-bounded, regular resynchronizer R'. The natural approach is to encode a successful run ρ of R over a synchronized word w. By measuring the differences between the partial inputs and the partial outputs that are consumed and produced along the run ρ, we obtain a partial bijection on the input letters that represents a mapping from source origins to target origins. This mapping determines the relation move_γ of R', and in fact depends on a suitable additional annotation γ of the underlying output position. The additional annotation is needed in order to distinguish output elements with the same origin in the source, but with different origins in the target.

For example, by referring again to the figure above, consider the first occurrence of b in w. Its origin in w is given by the closest input letter to the left (follow the blue arrow). To find the origin in w', one finds the same occurrence of b in w' (solid line), then moves to the closest input letter to the left (red arrow), and finally maps the latter input position in w' back to w (dashed line). The resulting position determines the new origin (w.r.t. w') of the considered output element.

The remaining components ipar, opar, and $\mathsf{next}_{\gamma,\gamma'}$ of R' are used to guarantee the correctness of the various annotations (notably, the correctness of the encoding of the run ρ and that of the output annotations).

4 Synthesis of Resynchronizers

Recall that containment between transducers depends on the adopted semantics. More precisely, according to the classical semantics, T_1 is contained in T_2 (denoted $T_1 \subseteq T_2$) if all input-output pairs realized by T_1 are also realized by T_2; according to the origin semantics, T_1 is contained in T_2 (denoted $T_1 \subseteq_o T_2$) if all origin graphs realized by T_1 are also realized by T_2. In this section, we study the following variant of the containment problem:

Resynchronizer synthesis problem.
Input: two transducers T_1, T_2.
Question: does there exist some resynchronization R such that $T_1 \subseteq_o R(T_2)$.

In fact, the above problem comes in several variants, depending on the model of transducers considered (one-way or two-way) and the class of admissible resynchronizations R (rational or bounded regular). Moreover, for the positive instances of the above problem, we usually ask to compute a witnessing resynchronization R from the given T_1 and T_2 (this is the reason for calling the problem a *synthesis problem*).

Clearly, the synthesis problem for unrestricted resynchronizers is equivalent to a classical containment, that is, $T_1 \subseteq T_2$ if and only if $T_1 \subseteq_o R(T_2)$ for some resynchronizer R. Therefore, the synthesis problem for unrestricted resynchronizers is undecidable. Thus we will consider the synthesis problem of rational (resp. bounded regular) resynchronizers for one-way (resp. two-way) transducers.

We also recall that rational resynchronizers preserve definability of relations by one-way transducers [10], while bounded regular resynchronizers (which, by Theorem 3, are strictly more expressive than rational resynchronizers) preserve definability by two-way transducers [6]. For the sake of presentation, we shall first consider the synthesis of rational resynchronizers in the functional one-way setting, that is, for instances given by functional one-way transducers. We show that in this setting the problem collapses again to the classical containment problem, which is however decidable now, that is: $T_1 \subseteq T_2$ if and only if $T_1 \subseteq_o R(T_2)$ for some rational resynchronizer R. The decidability result can be slightly extended to some non-functional transducers. More precisely, we will show that synthesis of rational resynchronizers for finite-valued one-way transducers is still decidable. When moving to the relational case, however, the problem becomes undecidable.

The decidability status in the one-way setting could be also contrasted with the two-way setting. In this respect, we observe that, in the functional case, the synthesis problem does not collapse anymore to classical containment, as there are functional two-way transducers T_1, T_2 such that $T_1 \subseteq T_2$, but for which no bounded regular resynchronizer R satisfies $T_1 \subseteq_o R(T_2)$ (an example can be found at the beginning of Section 4.3). We are able to prove decidability of synthesis of bounded, regular resynchronizers for unambiguous two-way transducers. The decidability status, however, remains open in the functional two-way case, as well as in the unrestricted (non-functional) two-way case.

4.1 Resynchronizing functional, one-way transducers

Recall that it can be decided in PSpace whether a transducer (be it one-way or two-way) is functional [2], and that the classical containment problem for functional (one-way/two-way) transducers is also in PSpace [3]. The following result shows that, for functional one-way transducers, classical containment and rational resynchronizer synthesis are inter-reducible.

▶ **Theorem 4.** *Let T_1, T_2 be two functional one-way transducers. The following conditions are equivalent, and decidable:*

1. $T_1 \subseteq T_2$,
2. $T_1 \subseteq_o R(T_2)$ *for some resynchronization R,*
3. $T_1 =_o R(T_2)$ *for some rational resynchronizer R.*

Proof sketch. The implications from 2. to 1. and 3. to 2. are trivial. The implication from 1. to 3. is proved by constructing a rational resynchronizer R as a product of T_1, T_2: at each step, R consumes a symbol $a \in \Sigma$ and a word $v_1 \in \Gamma^*$ from a transition of T_1 and produces the same symbol a and possibly a different word $v_2 \in \Gamma^*$ from a corresponding transition of T_2. The fact that R preserves the outputs relies on functionality of T_1 and T_2. ◀

A natural question arises: can a characterization similar to Theorem 4 be obtained for transducers that compute arbitrary relations, rather than just functions? The example below provides a negative answer to this question. Later in Section 4.2, we will see that synthesis of rational resynchronizers for unrestricted one-way transducers is an undecidable problem.

▶ **Example 5.** Consider a one-way transducer T_1 that checks that the input is from $(aa)^*$ and produces a single output letter b for each consumed input letter a, and another transducer T_2 that works in two phases: during the first phase, it produces two b's for each consumed a, and during the second phase consumes the remaining part of the input without producing any output. We have $T_1 \subseteq T_2$, but $T_1 \nsubseteq_o T_2$. The only resynchronization R that satisfies $T_1 \subseteq_o R(T_2)$ must map synchronized words from $(ab)^*$ to $(abb)^*(a)^*$, while preserving the number of a's and b's. Such a transformation cannot be defined by any rational resynchronizer, nor by a bounded regular resynchronizer.

There is however an intermediate case, between the functional and the full relational case, for which a generalization of Theorem 4 is possible. This is the case of *finite-valued* one-way transducers, that is, transducers that realize finite unions of partial functions. The generalization exploits a result from [10], stated just below, that concerns synthesis of bounded-delay resynchronizers. Formally, given two origin graphs G and G' with the same input and output projections, and given an input position y, we denote by $\mathsf{delay}_{G,G'}(y)$ the difference between the largest $x \in \mathsf{dom}(\mathsf{out}(G))$ such that $\mathsf{orig}(G)(x) = y$ and the largest $x' \in \mathsf{dom}(\mathsf{out}(G'))$ such that $\mathsf{orig}(G')(x') = y$. Given $d \in \mathbb{N}$, we define the *d-delay resynchronizer* as the resynchronization that contains all pairs (G, G') with the same input and output projections and such that $\mathsf{delay}_{G,G'}(y) \in [-d, +d]$ for all input positions y. It is easy to see that the d-delay resynchronizer is a special case of a rational resynchronizer.

▶ **Theorem 6** (Theorem 13 in [10]). *Let T_1, T_2 be one-way transducers, where T_2 is k-ambiguous.*[2] *One can compute a d-delay resynchronizer R_d, for some $d \in \mathbb{N}$, such that $T_1 \subseteq T_2$ implies $T_1 \subseteq_o R_d(T_2)$.*

As a corollary we can generalize Theorem 4 to k-valued one-way transducers, with the only difference that the witnessing rational resynchronizer now satisfies $T_1 \subseteq_o R(T_2)$ rather than $T_1 =_o R(T_2)$. We also recall that classical containment remains decidable for k-valued one-way transducers, thanks to the fact that these can be effectively transformed to finite unions of functional transducers [15]:

▶ **Corollary 7.** *Let T_1, T_2 be k-valued one-way transducers. The following conditions are equivalent, and decidable:*

1. $T_1 \subseteq T_2$,
2. $T_1 \subseteq_o R(T_2)$ *for some resynchronization R,*
3. $T_1 \subseteq_o R(T_2)$ *for some rational resynchronizer R.*

Proof. We prove the only interesting implication from 1. to 3. Suppose that T_1, T_2 are k-valued one-way transducers such that $T_1 \subseteq T_2$. Using the decomposition theorem from [15], we can construct a k-ambiguous one-way transducer T_2' that is classically equivalent to T_2 and such that $T_2' \subseteq_o T_2$. Since $T_1 \subseteq T_2'$, by Theorem 6 we can compute a d-delay (in particular, rational) resynchronizer R_d such that $T_1 \subseteq_o R_d(T_2')$. Finally, since $T_2' \subseteq_o T_2$, $T_1 \subseteq_o R_d(T_2')$, and $R_d(T_2') \subseteq_o R_d(T_2)$, we get $T_1 \subseteq_o R_d(T_2)$. ◀

4.2 Resynchronizing arbitrary one-way transducers

In the previous section we saw how to synthesize a rational resynchronizer for functional, or even finite-valued, one-way transducers. One may ask if finite-valuedness is necessary. We already know that classical containment $T_1 \subseteq T_2$ is undecidable [11, 12] for arbitrary one-way transducers, whereas origin-containment $T_1 \subseteq_o T_2$ is decidable [6]. Synthesis of a rational resynchronizer R such that $T_1 \subseteq_o R(T_2)$ is a question that lies between the two questions above. We show in this section that in the case of *real-time* transducers with unary output alphabet, the latter question is equivalent to language-boundedness of one-counter automata, a problem that we define below.

A transducer is said to be *real-time* if it produces bounded outputs for each consumed input symbol. A *one-counter automaton* (OCA) is a non-deterministic pushdown automaton

[2] A transducer is k-ambiguous if each input admits at most k successful runs.

with a single stack symbol, besides the bottom stack symbol. In the definition of the language-boundedness problem, we assume that the OCA recognizes a universal language; this assumption is used in the reduction to the synthesis problem.

Language-boundedness of OCA.
Input: An OCA A over alphabet Ω that recognizes the *universal* language $L(A) = \Omega^*$.
Question: Does there exist some bound k such that every word over Ω can be accepted by A with a run where the counter never exceeds k?

Our reductions between language-boundedness of OCA and synthesis of rational resynchronizers rely on the following result from [10], that implies that bounded-delay resynchronizers are enough for synthesizing resynchronizers of real-time transducers:

▶ **Theorem 8** (Theorem 11 in [10]). *Let T_1, T_2 be real-time, one-way transducers and R a rational resynchronizer such that $T_1 \subseteq_o R(T_2)$. One can compute a d-delay resynchronizer R_d such that $T_1 \subseteq_o R_d(T_2)$.*

▶ **Proposition 9.** *Synthesis of rational resynchronizers for real-time one-way transducers with unary output alphabet and language-boundedness of OCA are inter-reducible problems. Moreover, in the reductions, one can assume that the left hand-side transducer is functional.*

Proof sketch. Given some real-time transducers T_1, T_2, one constructs an OCA A that, when the input encodes a successful run of T_1, guesses and simulates an equivalent successful run of T_2. The OCA A keeps track in its counter, how ahead or behind is the partial output produced by the encoded run of T_1 compared to the partial output produced by the simulated run T_2, and accepts with an empty counter. Moreover, A accepts all inputs that do not encode successful runs of T_1: as soon as an error is detected, the counter is reset and frozen. Thus, badly-formed encodings do not affect language-boundedness. Then, using Theorem 8, one shows that A is language-bounded if and only if $T_1 \subseteq_o R(T_2)$ for some rational (and w.l.o.g. bounded-delay) resynchronizer R.

In the opposite reduction, one has to construct some real-time transducers T_1, T_2 from a given OCA A. Both transducers receive inputs over the same alphabet as A. T_1 is a simple functional transducer that outputs one symbol for each consumed input symbol. T_2, instead, guesses and simulates a run of A, and ouputs two symbols when the counter of the OCA increases, and no symbol when it decreases. As before, one argues using Theorem 8 that A is language-bounded if and only if $T_1 \subseteq_o R(T_2)$ for some rational resynchronizer R. ◀

The status of the problem of language-boundedness of OCA was open, to the best of our knowledge. Piotr Hofman communicated to us the following unpublished result, which can be obtained by a reduction from the undecidable boundedness problem for Minsky machines (the proof is in the extended version of this paper):

▶ **Theorem 10** ([13]). *The language-boundedness problem for OCA is undecidable.*

▶ **Corollary 11.** *Synthesis of rational resynchronizers for (real-time) one-way transducers is undecidable, and this holds even when the left hand-side transducer is functional.*

4.3 Resynchronizing unambiguous, two-way transducers

We now focus on the resynchronizer synthesis problem for two-way transducers. Here the appropriate class of resynchronizations is that of regular resynchronizers, since, differently from rational resynchronizer, they can handle origin graphs induced by two-way transducers.

The situation is more delicate, as the synthesis problem does not reduce anymore to classical containment. As an example, consider the transducer T_1 that consumes an input of the form a^* from left to right, while copying the letters to the output, and a two-way transducer T_2 that realizes the same function but while consuming the input in reverse. We have that $T_1 \subseteq T_2$, but there is no resynchronizer R that satisfies $T_1 \subseteq_o R(T_2)$ and that is bounded and regular at the same time. As we will see, extending Theorem 4 to two-way transducers is possible if we move beyond the class of regular resynchronizers and consider bounded resynchronizers defined by Parikh automata. The existence of bounded regular resynchronizers between functional two-way transducers can thus be seen as a strengthening of the classical containment relation. Unfortunately, we are only able to solve the synthesis problem of bounded regular resynchronizers for *unambiguous* two-way transducers, so the problem remains open for functional two-way transducers.

First we introduce resynchronizers definable by Parikh automata. Formally, a *Parikh automaton* is a finite automaton $A = (\Sigma, Q, I, E, F, Z, S)$ equipped with a function $Z : E \to \mathbb{Z}^k$ that associates vectors of integers to transitions and a semi-linear set $S \subseteq \mathbb{Z}^k$. A successful run of A is a run starting in I, ending in F and such as the sum of the weights of its transitions belongs to S. We say that A is *unambiguous* if the underlying finite automaton is. In this case, we can associate with each input u the vector $A(u) \in \mathbb{Z}^k$ associated with the unique accepting run of the underlying automaton of A on u, if this exists, otherwise $A(u)$ is undefined. By taking products, one can easily prove that unambiguous Parikh automata are closed under pointwise sum and difference, that is, given A_1 and A_2, there are A_+ and A_- such that $A_+(u) = A_1(u) + A_2(u)$ and $A_-(u) = A_1(u) - A_2(u)$ for all possible inputs u. Hereafter, we will only consider languages recognized by *unambiguous* Parikh automata with the trivial semilinear set $S = \{0^k\}$.

By a slight abuse of terminology, we call *Parikh resynchronizer* any resynchronizer with parameters whose relations move_γ and $\mathsf{next}_{\gamma,\gamma'}$ are recognizable by unambiguous Parikh automata, and ipar and opar are regular. We naturally inherit from regular resynchronizers the notion of boundedness. Moreover, we introduce another technical notion, that will be helpful later. Given a resynchronizer R, we define its *target set* as the set of all pairs (u, z) where u is an input, z is a position in it, and $(w, y, z) \in \mathsf{move}_\gamma$ for some annotation w of u with input parameters, some input position y, and some output type γ. Similarly, we define the *target set* of a two-way transducer T as the set of all pairs (u, z), where $u = \mathsf{in}(G)$ and $z \in \mathsf{orig}(G)(x)$ for some $x \in \mathsf{dom}(\mathsf{out}(G))$ and some origin graph G realized by T.

▶ **Theorem 12.** *Let T_1, T_2 be two unambiguous two-way transducers. The following conditions are equivalent:*

1. *$T_1 \subseteq T_2$,*
2. *$T_1 \subseteq_o R(T_2)$ for some resynchronization R,*
3. *$T_1 =_o R(T_2)$ for some 1-bounded Parikh resynchronizer R whose target set coincides with that of T_1 and where, each relation $\mathsf{next}_{\gamma,\gamma'}$ is regular if move_γ and $\mathsf{move}_{\gamma'}$ are regular.*

Proof sketch. We focus on the implication from 1. to 3., as the other implications are trivial. Similarly to the one-way case, to synthesize a resynchronizer, we need to annotate the input with the (unique) successful runs of T_1 and T_2 (if these runs exist). Since T_1, T_2 are two-way, the natural way of doing it is to use *crossing sequences*. Thanks to the encoding of runs by means of crossing sequence, we can describe any output position x with a pair (y, i), where y is the origin of x (according to T_1 or T_2) i is the number of output positions before x with the same origin y. Note that i is bounded, as the transducers here are unambiguous, and hence every input position is visited at most a bounded number of times.

Given $T = T_1$ or $T = T_2$ and an index i, one can construct a unambiguous Parikh automaton $A_{T,i}$ that, when receiving as input a word u with a marked position y, produces the unique position x that is encoded by the pair (y, i), according to the transducer T. It follows that, for every output element correctly annotated with $\gamma = (a, i, j)$, the relation move_γ can be defined as $\{(y, z) \mid A_{T_2,i}(y) - A_{T_1,j}(z) = 0\}$, which is a unambiguous Parikh language. This almost completes the definition of the Parikh resynchronizer R. The remaining components of R consists of suitable relations $\mathsf{next}_{\gamma,\gamma'}$ that check correctness of the annotations. In particular, the relations $\mathsf{next}_{\gamma,\gamma'}$ are obtained by pairing a regular property with properties defined in terms of the prior relations move_γ and $\mathsf{move}_{\gamma'}$, and hence $\mathsf{next}_{\gamma,\gamma'}$ is regular whenever move_γ and $\mathsf{move}_{\gamma'}$ are. ◀

We now explain how to exploit the above characterization to decide bounded regular resynchronizer synthesis problem. We provide the following characterization, whose proof follows from the previous theorem:

▶ **Theorem 13.** *Let T_1, T_2 be two unambiguous two-way transducers such that $T_1 \subseteq T_2$, and let $\hat{R}$ be the bounded Parikh resynchronizer obtained from Theorem 12. The following conditions are equivalent:*

1. *$\hat{R}$ is a regular resynchronizer,*
2. *$T_1 \subseteq_o R(T_2)$ for some bounded regular resynchronizer R,*
3. *$T_1 \subseteq_o R(T_2)$ for some 1-bounded regular resynchronizer R,*
4. *$T_1 =_o R(T_2)$ for some 1-bounded regular resynchronizer R with the same target set as T_1.*

Theorems 12 and 13 together provide a characterization of those pairs of unambiguous two-way transducers T_1, T_2 for which there is a bounded regular resynchronizer R such that $T_1 \subseteq_o R(T_2)$. The effectiveness of this characterization stems from the decidability of regularity of languages recognized by unambiguous Parikh automata [7]. This result requires unambiguity and uses Presburger arithmetics to determine for each (simple) loop a threshold such that iterating the loop more than the threshold always satisfies the Parikh constraint. The language of the Parikh automaton is regular if and only if every (simple) loop has such a threshold. We thus conclude:

▶ **Corollary 14.** *Given two unambiguous two-way transducers T_1, T_2, one can decide whether there is a regular resynchronizer R such that $T_1 \subseteq_o R(T_2)$.*

5 Conclusions

We studied two notions of resynchronization for transducers with origin, called rational resynchronizer and regular resynchronizer. Rational resynchronizers are suited for transforming origin graphs of one-way transducers, while regular resynchronizers can be applied also to origin graphs of two-way transducers. We showed that the former are strictly included in the latter, even when restricting the origin graphs to be one-way. We then studied the following variant of containment problem for transducers: given two transducers T_1, T_2, decide whether $T_1 \subseteq_o R(T_2)$ for some (rational or regular) resynchronizer R. That is, if all origin graphs of T_1 can be seen as some origin graph of T_2 transformed according to R, then compute such a resynchronizer R. This problem can be seen as a synthesis problem of resynchronizers. It is shown that the synthesis problem is decidable when T_1, T_2 are finite-valued one-way transducers and the resynchronizer is constrained to be rational, as well as when T_1, T_2 are unambiguous two-way transducers and the resynchronizer is allowed to be regular (and bounded). In the one-way setting, the problem turns out to be undecidable already for unrestricted (non-functional) transducers and rational resynchronizers. In the two-way setting, the decidability status remains open already when the transducers are not unambiguous (be them functional or not). Concerning this last point, however, we recall that the synthesis problem becomes undecidable as soon as we consider regular resynchronizers that are unbounded, as in this case the problem is at least as hard as classical containment.

Abstract

We consider notions of freeness and ambiguity for the acceptance probability of Moore-Crutchfield Measure Once Quantum Finite Automata (MO-QFA). We study the distribution of acceptance probabilities of such MO-QFA, which is partly motivated by similar freeness problems for matrix semigroups and other computational models. We show that determining if the acceptance probabilities of all possible input words are unique is undecidable for 32 state MO-QFA, even when all unitary matrices and the projection matrix are rational and the initial configuration is defined over real algebraic numbers. We utilize properties of the skew field of quaternions, free rotation groups, representations of tuples of rationals as a linear sum of radicals and a reduction of the mixed modification Post's correspondence problem.

1 Introduction

Measure-Once Quantum Finite Automata (MO-QFA) were introduced in [24] as a natural quantum variant of probabilistic finite automata. The model is defined formally in Section 3, but briefly a MO-QFA over an alphabet Σ is defined by a three tuple $\mathcal{Q} = (P, \{X_a | a \in \Sigma\}, u)$ where P is a projection matrix, X_a is a complex unitary matrix for each alphabet letter $a \in \Sigma$ and u is a unit length vector with respect to the Euclidean (ℓ^2) norm. Given an input word $w = w_1 \cdots w_k \in \Sigma^*$, then the acceptance probability $f_\mathcal{Q} : \Sigma^* \to \mathbb{R}$ of w under $\mathcal{Q}$ is given by

$$f_\mathcal{Q}(w) = ||PX_{w_k} \cdots X_{w_1} u||^2 .$$

The related model of Probabilistic Finite Automata (PFA) with n states over an alphabet Σ is defined as $\mathcal{P} = (\mathbf{x}, \{M_a | a \in \Sigma\}, \mathbf{y})$ where $\mathbf{y} \in \mathbb{R}^n$ is the initial probability distribution (unit length under ℓ^1 norm); $\mathbf{x} \in \{0,1\}^n$ is the final state vector and each $M_a \in \mathbb{R}^{n \times n}$ is a stochastic matrix. For a word $w = w_1 w_2 \cdots w_k \in \Sigma^*$, we define the acceptance probability $f_\mathcal{P} : \Sigma^* \to \mathbb{R}$ of $\mathcal{P}$ as:

$$f_\mathcal{P}(w) = \mathbf{x}^T M_{w_k} M_{w_{k-1}} \cdots M_{w_1} \mathbf{y}.$$

For any $\lambda \in [0,1]$ and automaton $\mathcal{A}$ (either PFA or QFA) over alphabet Σ, we define a cut-point language to be: $L_{\geq\lambda}(\mathcal{A}) = \{w \in \Sigma^* | f_\mathcal{A}(w) \geq \lambda\}$, and a strict cut-point language $L_{>\lambda}(\mathcal{A})$ by replacing $\geq$ with $>$. The (strict) emptiness problem for a cut-point language is to determine if $L_{\geq\lambda}(A) = \emptyset$ (resp. $L_{>\lambda}(A) = \emptyset$).

The MO-QFA model is very restricted due to unitarity constraints and can recognize only group languages (those regular languages whose syntactic monoid is a group [10]). Whereas the emptiness question for a strict cut-point stochastic languages is undecidable, it surprisingly becomes decidable for MO-QFA [9]. The decidability is established via the compactness of the group generated by unitary matrices: a compact algebraic group has a finite polynomial basis, and the decision procedure is then based on Tarski's quantifier elimination theorem [9].

Another surprising undecidability result was already manifested in [9]: The emptiness problem for non-strict (allowing equality) cut-point languages is undecidable. The sizes of the automata exhibiting undecidability were subsequently improved in [17]. As the aforementioned examples illuminate, the border between decidability and undecidability may be crossed with a minor modification to the model or premises.

Underlying each linear automata model are matrices, which represent the dynamics of the computational model as input symbols are read. For deterministic/nondeterministic finite automata, the underlying matrices are binary matrices; for weighted automata, the matrices are integer; for probabilistic automata the matrices are stochastic (the set of columns of each matrix should be a probability distribution); and for quantum finite automata, the matrices are unitary (the set of columns of each matrix should be orthonormal).

Reachability problems for matrix semigroups have attracted a great deal of attention over the past few years. Typically in such problems we are given a finite set of generating matrices $\mathcal{G}$ forming a semigroup $\mathcal{S} = \langle \mathcal{G} \rangle$ and we ask some question about $\mathcal{S}$. As an example, it was shown even back in 1970 by M. Paterson that the mortality problem for integer matrix semigroups is undecidable in dimension three [25]. In this problem, $\mathcal{G} \subseteq \mathbb{Z}^{3\times 3}$ and we ask whether the zero matrix belongs to $\mathcal{S} = \langle \mathcal{G} \rangle$. It was later shown that the similar identity problem (does the identity matrix belong to the semigroup generated by a given set of generating matrices) is also undecidable for four-dimensional integral matrices [5].

A related problem is the freeness problem for integer matrices – given a set $\mathcal{G} \subseteq \mathbb{F}^{n\times n}$, where $\mathbb{F}$ is a semiring, determine if $\mathcal{G}$ is a code for the semigroup generated by $\mathcal{G}$ (i.e., if every element of $\langle \mathcal{G} \rangle$ has a unique factorization over elements of $\mathcal{G}$). It was proven by Klarner et al. that the freeness problem is undecidable over $\mathbb{N}^{3\times 3}$ in [20] and this result was improved by Cassaigne et al. to hold even for *upper-triangular* matrices over $\mathbb{N}^{3\times 3}$ in [11].

There are many open problems related to freeness in 2×2 matrices; see [12, 13, 14] for good surveys. The freeness problem over $\mathbb{H}^{2\times 2}$ is undecidable [4], where $\mathbb{H}$ is the skew-field of quaternions (in fact the result even holds when all entries of the quaternions are rationals). The freeness problem for two upper-triangular 2×2 rational matrices remains open, despite many partial results being known [13].

The freeness problem for matrix semigroups defined by a *bounded language* was recently studied. Given a finite set of matrices $\{M_1, \ldots, M_k\} \subseteq \mathbb{Q}^{n\times n}$, we define a bounded language of matrices to be of the form: $\{M_1^{j_1} \cdots M_k^{j_k} | j_i \geq 0 \text{ where } 1 \leq i \leq k\}$.

The freeness problem for such a bounded language of matrices asks if there exists a choice of these variables such that $j_1, \ldots, j_k, j'_1, \ldots, j'_k \geq 0$, where at least one $j_i \neq j'_i$ such that $M_1^{j_1} \cdots M_k^{j_k} = M_1^{j'_1} \cdots M_k^{j'_k}$ in which case the bounded language of matrices is not free. This problem was shown to be decidable when $n = 2$, but undecidable in general [13].

In a similar vein, we may study the vector freeness and ambiguity problems, where we are given a finite set of matrices $\mathcal{G} \subseteq \mathbb{F}^{n\times n}$ and a vector $u \in \mathbb{F}^n$. The *ambiguity problem* is to determine whether there exists two matrices $M_1, M_2 \in \mathcal{S} = \langle \mathcal{G} \rangle$ with $M_1 \neq M_2$ such that $M_1 u = M_2 u$ and the *freeness problem* is to determine the uniqueness of factorizations of $\{Mu | M \in \mathcal{S}\}$ i.e., does $M_{i_1} \cdots M_{i_k} u = M_{j_1} \cdots M_{j_{k'}} u$, where each $M_t \in \mathcal{G}$, imply that

$k = k'$ and $M_{i_r} = M_{j_r}$ for $1 \leq r \leq k$? It should be noted that these (related but distinct) problems are more difficult to solve than freeness for matrix semigroups, since by multiplying matrix M_1 and M_2 with u, some information may be lost. The motivation for such a problem is that many linear dynamic systems/computational models are defined in this way. The freeness question now asks whether starting from some initial point, we have two separate computational paths which coincide at some later point, or else whether every configuration starting from u is unique. Such vector ambiguity and freeness questions were studied in [3] and the problems were shown to be undecidable when $\mathcal{S} \subseteq \mathbb{Z}^{4\times4}$, or when $\mathcal{S} \subseteq \mathbb{Q}^{3\times3}$. The NP-completeness of the vector ambiguity and freeness problems for $\mathrm{SL}(2,\mathbb{Z})$ was recently shown in [21] (where $\mathrm{SL}(2,\mathbb{Z})$ is the special linear group of 2×2 matrices).

Whilst vector reachability questions are interesting from the point of view of dynamical systems, many computational models have the notion of a projection being taken at the end, in order to determine whether a computation path is successful or not. This usually takes the form of defining a partition of configurations into accepting or nonaccepting states. This leads to the notion of *scalar reachability* (also known as half-space reachability [15]), which may be defined in terms of *two* vectors, u and v, where we now study the set of scalars $\{u^T Mv | M \in \mathcal{S}\}$. The *scalar ambiguity* question then asks whether or not this set of scalars is unique i.e., does there exist two matrices $M_1, M_2 \in \mathcal{S}$ with $M_1 \neq M_2$ such that $u^T M_1 v = u^T M_2 v$? The difficulty with extending the undecidability result for vector reachability is that all information about each matrix M needs to be stored within a single scalar value $u^T Mv$ in a unique way.

In [1], the freeness problem (defined formally in Section 3.1) for 4-state weighted and 6-state probabilistic automata was shown to be undecidable together with results concerning the related ambiguity problem. The undecidability result was shown to hold even when the input words come from a bounded language, thus the matrices appear in some fixed order, and are taken to an arbitrary power. The problem can also be stated in terms of *formal power series*: given a formal power series r, determine if r has two equal coefficients. This problem was studied in [22] and Theorem 3.4 of [18]. As mentioned above, several reachability problems for PFA (such as emptiness of cut-point languages) are known to be *undecidable* [26], even in a fixed dimension [8, 17]. The reachability problem for PFA defined on a bounded language (i.e., where input words are from a bounded language which is given as part of the input) was shown to be undecidable in [2]. We may note that the scalar freeness and ambiguity problems are a similar concept to the *threshold isolation problem* which asks whether a given cutpoint may be approached arbitrarily closely and which is known to be undecidable [6, 8].

It is therefore natural to ask whether the *freeness and ambiguity problems* are undecidable for MO-QFA. This problem appears more difficult to prove than for weighted/probabilistic automata, since the acceptance probability of a MO-QFA $\mathcal{Q}$ has the form $f_{\mathcal{Q}}(w) = ||PX^R u||^2$ and it is thus difficult to encode sufficient information about the matrix X within $f_{\mathcal{Q}}(w)$ to guarantee uniqueness of matrices from $\mathcal{G}$. We show that freeness and ambiguity are undecidable for 32 (resp. 33) state MO-QFA by using an encoding of the mixed modification Post's Correspondence Problem and a result related to linear independence of rationals of a basis of squarefree radicals as well as techniques from linear algebra and properties of quaternions.

2 Notation

Let $\Sigma = \{x_1, x_2, \dots, x_k\}$ be a finite set of *letters* called an *alphabet*. A word w is a finite sequence of letters from Σ, the set of all words over Σ is denoted Σ^* and the set of nonempty words is denoted Σ^+. The *empty word* is denoted by ε. We use $|u|$ to denote the length of a word u and thus $|\varepsilon| = 0$. For two words $u = u_1u_2 \cdots u_i$ and $v = v_1v_2 \cdots v_j$, where $u, v \in \Sigma^*$, the concatenation of u and v is denoted by $u \cdot v$ (or by uv for brevity) such that $u \cdot v = u_1u_2 \cdots u_iv_1v_2 \cdots v_j$. Word $u^R = u_i \cdots u_2u_1$ denotes the mirror image or reverse of word u. A subset L of Σ^* is called a *language*. A language $L \subseteq \Sigma^*$ is called a *bounded language* if and only if there exist words $w_1, w_2, \dots, w_m \in A^+$ such that $L \subseteq w_1^*w_2^* \cdots w_m^*$. Given an alphabet Σ as above, we denote by Σ^{-1} the set $\{x_1^{-1}, \dots, x_k^{-1}\}$, where each x_i^{-1} is a new letter with the property that $x_ix_i^{-1} = x_i^{-1}x_i = \varepsilon$ are the only identities of the group $\langle \Sigma \cup \Sigma^{-1} \rangle$. A word $w = w_1w_2 \cdots w_i \in (\Sigma \cup \Sigma^{-1})^*$ is called *reduced* if there does not exist $1 \le j < i$ such that $w_{j+1} = w_j^{-1}$; i.e., no two consecutive letters are inverse.

Given any two rings R_1 and R_2 we use the notation $R_1 \hookrightarrow R_2$ to denote a *monomorphism* i.e., an injective homomorphism between R_1 and R_2. Given a finite set $\mathcal{G}$, we use the notation $\langle \mathcal{G} \rangle$ (resp. $\langle \mathcal{G} \rangle_{\text{gp}}$) to denote the *semigroup* (resp. group) generated by $\mathcal{G}$.

Semirings and quaternions

We denote by $\mathbb{N}$ the natural numbers, $\mathbb{Z}$ the integers, $\mathbb{Q}$ the rationals, $\mathbb{C}$ the complex numbers and $\mathbb{H}$ the quaternions. We denote by $\mathbb{C}(\mathbb{Q})$ the complex numbers with rational parts, by $\mathbb{H}(\mathbb{Q})$ the quaternions with rational parts and by $\mathbb{A}_{\mathbb{R}}$ the real algebraic numbers.

Given any semiring $\mathbb{F}$ we denote by $\mathbb{F}^{i \times j}$ the set of $i \times j$ matrices over $\mathbb{F}$. We denote by e_i the i'th basis vector of some dimension (which will be clear from the context).

In a similar style to complex numbers, a rational quaternion $\vartheta \in \mathbb{H}(\mathbb{Q})$ can be written $\vartheta = a+b\mathbf{i}+c\mathbf{j}+d\mathbf{k}$ where $a, b, c, d \in \mathbb{Q}$. To ease notation let us define the vector: $\mu = (1, \mathbf{i}, \mathbf{j}, \mathbf{k})$ and it is now clear that $\vartheta = (a, b, c, d) \cdot \mu$ where $\cdot$ denotes the inner or "dot" product.

Quaternion addition is simply the componentwise addition of elements. It is well known that quaternion multiplication is not commutative (hence they form a skew field). Multiplication is completely defined by the equations $\mathbf{i}^2 = \mathbf{j}^2 = \mathbf{k}^2 = -1$, $\mathbf{ij} = \mathbf{k} = -\mathbf{ji}$, $\mathbf{jk} = \mathbf{i} = -\mathbf{kj}$ and $\mathbf{ki} = \mathbf{j} = -\mathbf{ki}$. Thus for two quaternions $\vartheta_1 = (a_1, b_1, c_1, d_1)\mu$ and $\vartheta_2 = (a_2, b_2, c_2, d_2)\mu$, we can define their product as $\vartheta_1\vartheta_2 = (a_1a_2 - b_1b_2 - c_1c_2 - d_1d_2) + (a_1b_2 + b_1a_2 + c_1d_2 - d_1c_2)\mathbf{i} + (a_1c_2 - b_1d_2 + c_1a_2 + d_1b_2)\mathbf{j} + (a_1d_2 + b_1c_2 - c_1b_2 + d_1a_2)\mathbf{k}$.

In a similar way to complex numbers, we define the conjugate of $\vartheta = (a, b, c, d) \cdot \mu$ by $\overline{\vartheta} = (a, -b, -c, -d) \cdot \mu$. We can now define a norm on the quaternions by $||\vartheta|| = \sqrt{\vartheta\overline{\vartheta}} = \sqrt{a^2 + b^2 + c^2 + d^2}$. Any non zero quaternion has a multiplicative (and obviously an additive) inverse [23]. The other properties of being a skew field can be easily checked.

A *unit* quaternion (norm 1) corresponds to a rotation in three dimensional space [23].

Linear Algebra

Given $A = (a_{ij}) \in \mathbb{F}^{m \times m}$ and $B \in \mathbb{F}^{n \times n}$, we define the direct sum $A \oplus B$ and Kronecker product $A \otimes B$ of A and B by:

$$A \oplus B = \left[\begin{array}{c|c} A & \mathbf{0}_{m,n} \\ \hline \mathbf{0}_{n,m} & B \end{array}\right], \quad A \otimes B = \begin{bmatrix} a_{11}B & a_{12}B & \cdots & a_{1m}B \\ a_{21}B & a_{22}B & \cdots & a_{2m}B \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1}B & a_{m2}B & \cdots & a_{mm}B \end{bmatrix},$$

where $\mathbf{0}_{i,j}$ denotes the zero matrix of dimension $i \times j$. Note that neither $\oplus$ nor $\otimes$ are commutative in general. Given a finite set of matrices $\mathcal{G} = \{G_1, G_2, \ldots, G_m\} \subseteq \mathbb{F}^{n\times n}$, $\langle \mathcal{G} \rangle$ is the semigroup generated by $\mathcal{G}$. We will use the following notations:

$$\bigoplus_{j=1}^{m} G_j = G_1 \oplus G_2 \oplus \cdots \oplus G_m, \qquad \bigotimes_{j=1}^{m} G_j = G_1 \otimes G_2 \otimes \cdots \otimes G_m.$$

Given a single matrix $G \in \mathbb{F}^{n\times n}$, we inductively define $G^{\otimes k} = G \otimes G^{\otimes (k-1)} \in \mathbb{F}^{n^k \times n^k}$ with $G^{\otimes 1} = G$ as the k-fold Kronecker power of G. Similarly, $G^{\oplus k} = G \oplus G^{\oplus (k-1)} \in \mathbb{F}^{n^k \times n^k}$ with $G^{\oplus 1} = G$. The following properties of $\oplus$ and $\otimes$ are well known; see [19] for proofs.

▶ **Lemma 1.** *Let $A, B, C, D \in \mathbb{F}^{n\times n}$. We note that:*

- *$(A \otimes B) \otimes C = A \otimes (B \otimes C)$ and $(A \oplus B) \oplus C = A \oplus (B \oplus C)$, thus $A \otimes B \otimes C$ and $A \oplus B \oplus C$ are unambiguous.*
- *Mixed product properties: $(A \otimes B)(C \otimes D) = (AC) \otimes (BD)$ and $(A \oplus B)(C \oplus D) = (AC) \oplus (BD)$.*
- *If A and B are unitary matrices, then so are $A \oplus B$ and $A \otimes B$.*

Given two vectors $u \in \mathbb{F}^{n_1}$ and $v \in \mathbb{F}^{n_2}$, we define $u \oplus v \in \mathbb{F}^{n_1+n_2}$ as $u \oplus v = (u_1, \ldots, u_{n_1}, v_1, \ldots, v_{n_2})$.

3 Quantum Finite Automata and Undecidability

▶ **Definition 2.** *A measure-once n-state quantum automaton (MO-QFA) over a k-letter alphabet Σ is a triplet $(P, \{X_a \mid a \in \Sigma\}, u)$, where $P \in \mathbb{C}^{n\times n}$ is a projection, each $X_a \in \mathbb{C}^{n\times n}$ is a unitary matrix (where rows form an orthonormal set), and $u \in \mathbb{C}^n$ is a unit-length vector.*

A morphism $\Sigma^* \to \langle X_a \rangle$ is defined as $w = a_{i_1} \ldots a_{i_t} \mapsto X_w \overset{def}{=} X_{i_1} \ldots X_{i_t}$ and the acceptance probability *of a MO-QFA $\mathcal{Q}$ is defined as $f_{\mathcal{Q}}(w) = ||PX_{w^R}u||^2$. We use the reverse of the word w, denoted w^R, so that w_1 is applied first, then w_2 etc.*

3.1 Ambiguity and Freeness for QFA

Consider a finite set of unitary matrices $\mathcal{G} = \{X_1, X_2, \ldots, X_k\} \subset \mathbb{C}^{n\times n}$, a projection matrix $P \in \mathbb{Z}^{n\times n}$ and a unit column vector $u \in \mathbb{C}^n$. Let $\mathcal{Q} = (P, \mathcal{G}, u)$ be a QFA and define $\Lambda(\mathcal{Q})$ be the set of scalars such that $\Lambda(\mathcal{Q}) = \{||PXu||^2 ; X \in \langle \mathcal{G} \rangle\}$. If for $\lambda \in \Lambda(\mathcal{Q})$ there exists a unique matrix $X \in \langle \mathcal{G} \rangle$ such that $\lambda = ||PXu||^2$, then we say that λ is *unambiguous* with respect to $\mathcal{Q}$. We call $\Lambda(\mathcal{Q})$ unambiguous if every $\lambda \in \Lambda(\mathcal{Q})$ is unambiguous.

An acceptance probability $\lambda \in \Lambda(\mathcal{Q})$ is called *free* with respect to $\mathcal{Q}$ if

$$\lambda = ||PX_{i_1}X_{i_2}\cdots X_{i_m}u||^2 = \left|\left|PX_{j_1}X_{j_2}\cdots X_{j_{m'}}u\right|\right|^2,$$

where each $X_{i_k}, X_{j_{k'}} \in \mathcal{G}$ for $1 \leq k \leq m$ and $1 \leq k' \leq m'$ implies that $m = m'$ and each $i_k = j_k$ for $1 \leq k \leq m$. We call $\Lambda(\mathcal{Q})$ free if every $\lambda \in \Lambda(\mathcal{Q})$ is free.

▶ **Problem 3** (QFA Scalar Ambiguity). *Given a Quantum Finite Automaton $\mathcal{Q}$, is $\Lambda(\mathcal{Q})$ unambiguous?*

▶ **Problem 4** (QFA Scalar Freeness [1]). *Given a Quantum Finite Automaton $\mathcal{Q}$, is $\Lambda(\mathcal{Q})$ free?*

[1] We may also call this the *injectivity problem* for QFA; does there exist two distinct words $w_1, w_2 \in \Sigma^*$ such that $f_{\mathcal{Q}}(w_1) = f_{\mathcal{Q}}(w_2)$?

▶ **Example 5.** Let $A = \begin{pmatrix} \frac{3}{5} & \frac{4}{5} \\ -\frac{4}{5} & \frac{3}{5} \end{pmatrix}$, $P = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$ and $u = (1,0)^T$. We thus see that $\mathcal{Q} = (P, \{A\}, u)$ is a unary 2-state QFA. Note that A represents rotations of the Euclidean plane of angle $\arccos(3/5)$, and thus we see that $f_{\mathcal{Q}}(a^k) = ||PA^k u||^2$ is dense in $[0,1]$ for $k \in \mathbb{N}$. Since the angle of rotation of A is an irrational multiple of π, then every acceptance probability of $\mathcal{Q}$ is unique, and thus $\mathcal{Q}$ is both free and unambiguous.

We show that freeness and ambiguity are undecidable for MO-QFA in Section 5. The reduction is from the Mixed Modification Post's Correspondence Problem, now defined.

▶ **Problem 6** (Mixed Modification PCP (MMPCP)). *Given set of letters $\Sigma = \{s_1, \ldots, s_{|\Sigma|}\}$, binary alphabet Σ_2, and pair of homomorphisms $h, g : \Sigma^* \to \Sigma_2^*$, the MMPCP asks to decide whether there exists a word $w = x_1 \cdots x_k \in \Sigma^+, x_i \in \Sigma$ such that*

$$h_1(x_1)h_2(x_2)\cdots h_k(x_k) = g_1(x_1)g_2(x_2)\cdots g_k(x_k),$$

where $h_i, g_i \in \{h, g\}$, and there exists at least one j such that $h_j \neq g_j$.

▶ **Theorem 7.** *[11] - The Mixed Modification PCP is undecidable for $|\Sigma| \geq 9$.*

▶ **Definition 8.** *We call an instance of the (MM)PCP a* Claus instance *if the minimal solution words are of the form $w = s_1 x_2 x_3 \cdots x_{k-1} s_{|\Sigma|}$, where $x_2, \ldots, x_{k-1} \in \Sigma - \{s_1, s_{|\Sigma|}\}$, i.e., the minimal solution words must start with letter s_1, end with letter $s_{|\Sigma|}$, and all other letters are not equal to s_1 or $s_{|\Sigma|}$.*

In fact most proofs of the undecidability of (MM)PCP have this property [16]. Claus instances can be useful for decreasing the resources required for showing certain undecidability results, and we use this property later.

▶ **Theorem 9.** *[16] - Mixed Modification PCP is undecidable for Claus instances, when $|\Sigma| \geq 9$.*[2]

4 A mapping from arbitrary words to rational unitary matrices

Let $\Sigma_n = \{x_1, x_2, \ldots, x_n\}$ be an n-letter alphabet for some $n > 0$. We begin by deriving a monomorphism $\gamma : \Sigma_n^* \hookrightarrow \mathbb{Q}^{4\times 4}$ such that $\gamma(w)$ is a unitary matrix for any $w \in \Sigma_n^*$. The mapping γ will be a composition of several monomorphisms.

Given alphabet $\Sigma_n = \{x_1, x_2, \ldots, x_n\}$, we now show that there exists a monomorphism $\gamma : \Sigma_n^* \hookrightarrow \mathbb{Q}^{4\times 4}$ where $\gamma(w)$ is unitary for all $w \in \Sigma_n^*$.

We first describe a monomorphism γ_1 from an arbitrary sized alphabet to a binary alphabet. We then show monomorphism γ_2 from a binary alphabet to unit quaternions, and conclude by injectively mapping such quaternions to unitary matrices.

γ_1: Let $\Sigma_2 = \{a, b\}$ be a binary alphabet. We define $\gamma_1 : \Sigma_n^* \hookrightarrow \Sigma_2^*$ by $\gamma_1(x_k) = a^k b$ for $1 \leq k \leq n$. It is immediate that γ_1 is injective.

γ_2: Define mapping $\gamma_2 : \Sigma_2^* \hookrightarrow \mathbb{H}(\mathbb{Q})$ by $\gamma_2(a) = \left(\frac{3}{5}, \frac{4}{5}, 0, 0\right) \cdot \mu$ and $\gamma_2(b) = \left(\frac{3}{5}, 0, \frac{4}{5}, 0\right) \cdot \mu$. It is known that γ_2 is an injective homomorphism [4] since such quaternions represent rotations about perpendicular axes by a rational angle (not equal to $0, \pm\frac{1}{2}, \pm 1$), thus $\gamma_2 : \Sigma_2^* \hookrightarrow \mathbb{H}(\mathbb{Q})$ and $\gamma_2(w_1) = \gamma_2(w_2)$ for $w_1, w_2 \in \Sigma_2^*$ implies that $w_1 = w_2$ [27].

[2] The result in [16] states undecidability for $|\Sigma| \geq 7$ since they fix the first/last letters of a potential solution.

γ_3: Define $\gamma_3 : \mathbb{H}(\mathbb{Q}) \hookrightarrow \mathbb{Q}^{4\times 4}$ by:

$$\gamma_3((r,x,y,z)\cdot\mu) = \begin{pmatrix} r & x & y & z \\ -x & r & z & -y \\ -y & -z & r & x \\ -z & y & -x & r \end{pmatrix}. \tag{1}$$

It is well known that γ_3 is a monomorphism in this case. Injectivity is clear, and using the rules of quaternion multiplication shows that γ_3 is a homomorphism.

We finally define $\gamma = \gamma_3 \circ \gamma_2 \circ \gamma_1$ and thus by the above reasoning $\gamma : \Sigma_n^* \hookrightarrow \mathbb{Q}^{4\times 4}$ is an injective homomorphism. Note that the matrix $\gamma(w)$ for a word $w \in \Sigma_n^*$ contains quite a lot of redundancy, and in fact can be uniquely described by just four elements (the top row) as is shown by the matrix in Eqn. (1). Of course, these four elements simply correspond to the four elements of the quaternion used in the construction of γ. Note also that $\gamma(w)$ is a unitary matrix since γ_2 generates a *unit quaternion* (of norm 1) in each case.

Using γ, we can now find matrices $A, B \in \mathbb{Q}^{4\times 4}$, such that $\gamma(w) \in \langle\{A,B\}\rangle_{\mathrm{gp}}$ for all $w \in \Sigma^*$; i.e., the value of $\gamma(w)$ lies within the semigroup generated by $\{A, B\}$. This will prove useful later since we may reason about the structure of this freely presented semigroup.

▶ **Definition 10.** *Given $\Sigma_2 = \{a, b\}$, then let:*

$$A = \gamma_3(\gamma_2(a)) = \begin{pmatrix} \frac{3}{5} & \frac{4}{5} & 0 & 0 \\ -\frac{4}{5} & \frac{3}{5} & 0 & 0 \\ 0 & 0 & \frac{3}{5} & \frac{4}{5} \\ 0 & 0 & -\frac{4}{5} & \frac{3}{5} \end{pmatrix}, \; B = \gamma_3(\gamma_2(b)) = \begin{pmatrix} \frac{3}{5} & 0 & \frac{4}{5} & 0 \\ 0 & \frac{3}{5} & 0 & -\frac{4}{5} \\ -\frac{4}{5} & 0 & \frac{3}{5} & 0 \\ 0 & \frac{4}{5} & 0 & \frac{3}{5} \end{pmatrix},$$

and define $\Gamma' = \langle\{A,B\}\rangle \subset \mathbb{Q}^{4\times 4}$, which is a free semigroup (freely generated by $\{A, B\}$). All elements in the range of γ thus belong to Γ'. We define $\Gamma \subset \Gamma'$ by $\Gamma = \{\gamma(w) | w \in \Sigma_n^*\}$.

5 Freeness and ambiguity for QFA with radicals

In order to prove that the ambiguity and freeness problems are undecidable for QFA defined over rationals (with real algebraic initial vector), we require the following (folklore) theorem. This will essentially allow us to uniquely represent a tuple of rationals as a linear sum of radicals. For completeness, we will show a simple proof of this theorem using the theory of field extensions.

▶ **Theorem 11** ([7]). *The (finite) set*

$$\mathcal{S} = \{\sqrt{m_1}, \ldots, \sqrt{m_n} : \; m_i \textit{ are coprime square-free numbers}\}$$

is linearly independent over $\mathbb{Q}$.

Proof. Define $E_k = \mathbb{Q}(\sqrt{m_1}, \ldots, \sqrt{m_k})$, so $E_0 = \mathbb{Q}$ and $E_1 = \mathbb{Q}(\sqrt{m_1})$. Clearly $[E_0 : \mathbb{Q}] = 1 = 2^0$, and $[E_1 : \mathbb{Q}] = 2^1$. As each element $\sqrt{m_i}$ satisfies a quadratic equation over $\mathbb{Q}$, the field extension degree $[E_n : \mathbb{Q}]$ is at most 2^n. The theorem is proven if we can show that $[E_n : \mathbb{Q}] = 2^n$.

Assume the induction hypothesis true for values less than k. We will prove it true for $k + 1$, as well, i.e., $[E_{k+1} : E_k] = 2$. For this aim, we must demonstrate that $\sqrt{m_{k+1}} \notin E_k$, so let us assume the contrary, that

$$\sqrt{m_{k+1}} \in E_k = E_{k-1}(\sqrt{m_k}),$$

hence $\sqrt{m_{k+1}} = a + b\sqrt{m_k}$, where $a, b \in E_{k-1}$ Then

$$m_{k+1} = a^2 + m_k b^2 + 2ab\sqrt{m_k}.$$

If $ab \neq 0$, then $\sqrt{m_k} \in E_{k-1}$, which implies that $[E_k : E_{k-1}] = 1$, a contradiction.

If $a = 0$, then $\sqrt{m_{k+1}} = b\sqrt{m_k}$, and hence $\sqrt{m_k}\sqrt{m_{k+1}} = bm_k \in E_{k-1}$. By the induction hypothesis we then have

$$[\mathbb{Q}(\sqrt{m_1}, \dots, \sqrt{m_{k-1}}, \sqrt{m_k m_{k+1}}) : \mathbb{Q}] = 2^k,$$

but since the last extending element belongs to E_{k-1}, the extension degree cannot be more than 2^{k-1}, a contradiction. Here we actually need the assumption that the numbers are coprime, since otherwise $m_k m_{k+1}$ would not necessarily be squarefree.

If $b = 0$, then $\sqrt{m_{k+1}} \in \mathbb{E}_{k-1}$, and as above, the induction hypothesis gives

$$[\mathbb{Q}(\sqrt{m_1}, \dots, \sqrt{m_{k-1}}, \sqrt{m_{k+1}}) : \mathbb{Q}] = 2^k,$$

but as the last extending element belongs to E_{k-1}, the extension degree cannot be more than 2^{k-1}, a contradiction. ◀

For example, given $p_1, p_2, q_1, q_2 \in \mathbb{Q}$, then the equality $p_1\sqrt{2} + q_1\sqrt{3} = p_2\sqrt{2} + q_2\sqrt{3}$ is true iff $p_1 = p_2$ and $q_1 = q_2$.

The following technical lemma concerns the free group $\mathcal{S}$ generated by $\mathcal{G} = \{\gamma_2(a), \gamma_2(b)\}$ and will crucially allow us to characterise elements of $\mathcal{S}$ which differ only in the signs of one or more of their imaginary components. To define this lemma we require a nonstandard inversion function defined on elements of $\mathcal{S} = \langle \mathcal{G} \rangle_{gr}$. Since $\mathcal{S}$ is free, any reduced (i.e., not containing consecutive inverses) $q_w \in \mathcal{S}$ can be uniquely written in the form

$$q_w = \gamma_2(a)^{k_0}\gamma_2(b)^{k_1}\gamma_2(a)^{k_2} \cdots \gamma_2(a)^{k_{n-2}}\gamma_2(b)^{k_{n-1}}\gamma_2(a)^{k_n},$$

where $k_0, k_n \in \mathbb{Z}$ and $k_1, \dots, k_{n-1} \in \mathbb{Z} - \{0\}$, i.e., an alternating product of either positive or negative powers of $\gamma_2(a)$ and $\gamma_2(b)$ which may start and end with either element. We define the following three functions:

i) $\lambda_a(q_w) = \gamma_2(a)^{-k_0}\gamma_2(b)^{k_1}\gamma_2(a)^{-k_2} \cdots \gamma_2(a)^{-k_{n-2}}\gamma_2(b)^{k_{n-1}}\gamma_2(a)^{-k_n}$;

ii) $\lambda_b(q_w) = \gamma_2(a)^{k_0}\gamma_2(b)^{-k_1}\gamma_2(a)^{k_2} \cdots \gamma_2(a)^{k_{n-2}}\gamma_2(b)^{-k_{n-1}}\gamma_2(a)^{k_n}$;

iii) $\lambda_{a,b}(q_w) = \gamma_2(a)^{-k_0}\gamma_2(b)^{-k_1}\gamma_2(a)^{-k_2} \cdots \gamma_2(a)^{-k_{n-2}}\gamma_2(b)^{-k_{n-1}}\gamma_2(a)^{-k_n}$.

These three functions thus invert all $\gamma_2(a)$ elements in a product for λ_a, all $\gamma_2(b)$ elements in a product for λ_b and both $\gamma_2(a)$ and $\gamma_2(b)$ elements in a product for $\lambda_{a,b}$. As an example, if $q_w = \gamma_2(a)^3\gamma_2(b)^2\gamma_2(a)^{-4}\gamma_2(b)$, then $\lambda_a(q_w) = \gamma_2(a)^{-3}\gamma_2(b)^2\gamma_2(a)^4\gamma_2(b)$, $\lambda_b(q_w) = \gamma_2(a)^3\gamma_2(b)^{-2}\gamma_2(a)^{-4}\gamma_2(b)^{-1}$ and $\lambda_{a,b}(q_w) = \gamma_2(a)^{-3}\gamma_2(b)^{-2}\gamma_2(a)^4\gamma_2(b)^{-1}$. Bizzare as such a definition may appear, it allows us to exactly characterize those elements of $\mathcal{S}$ which differ only in the sign of one or more of their imaginary components, as we now show.

▶ **Lemma 12.** *Given a quaternion $q_w = \gamma_2(w) = (r, x, y, z) \cdot \mu \in \langle \gamma_2(a), \gamma_2(b) \rangle_{gr}$ with $w = w_1 w_2 \cdots w_{|w|}$, each $w_i \in (\Sigma_2 \cup \Sigma_2^{-1})$ and $\Sigma_2 = \{a, b\}$, then:*

i) $q_{w^R} = \gamma_2(w^R) = (r, x, y, -z) \cdot \mu$;

ii) $\lambda_a(q_w) = (r, -x, y, -z) \cdot \mu$;

iii) $\lambda_b(q_w) = (r, x, -y, -z) \cdot \mu$;

iv) $\lambda_{a,b}(q_w) = (r, -x, -y, z) \cdot \mu$.

Proof. We proceed via induction. For the base case, when $w = \varepsilon$, then $q_w = (1,0,0,0) \cdot \mu$ and $q_{w^R} = \lambda_a(q_w) = \lambda_b(q_w) = \lambda_{a,b}(q_w) = (1,0,0,0) \cdot \mu$ and so the properties (trivially) hold. For the induction hypothesis, assume $i) - iv)$ are true for q_w. We handle each property individually.

i) By assumption, $q_{w^R} = (r, x, y, -z) \cdot \mu$. Since $\gamma_2(a) = \left(\frac{3}{5}, \frac{4}{5}, 0, 0\right) \cdot \mu$ and $\gamma_2(b) = \left(\frac{3}{5}, 0, \frac{4}{5}, 0\right) \cdot \mu$, by the rules of quaternion multiplication, we see that:

$$\begin{aligned}
\gamma_2(a) \cdot q_w &= \frac{1}{5}(3r - 4x, 3x + 4r, 3y - 4z, 3z + 4y) \cdot \mu, \\
q_{w^R} \cdot \gamma_2(a) &= \frac{1}{5}(3r - 4x, 3x + 4r, 3y - 4z, -3z - 4y) \cdot \mu
\end{aligned}$$

Note that the fourth component is negated as expected. In a similar way, we also see that:

$$\begin{aligned}
\gamma_2(b) \cdot q_w &= \frac{1}{5}(3r - 4y, 3x + 4z, 3y + 4r, 3z - 4x) \cdot \mu, \\
q_{w^R} \cdot \gamma_2(b) &= \frac{1}{5}(3r - 4y, 3x + 4z, 3y + 4r, -3z + 4x) \cdot \mu
\end{aligned}$$

with negated fourth element. Since $\gamma_2(a^{-1}) = \left(\frac{3}{5}, -\frac{4}{5}, 0, 0\right) \cdot \mu$ and $\gamma_2(b^{-1}) = \left(\frac{3}{5}, 0, -\frac{4}{5}, 0\right) \cdot \mu$, then the property of the fourth element being negated is also clearly true for $\gamma_2(c^{-1}) \cdot q_w$ and $q_{w^R} \cdot \gamma_2(c^{-1})$ for $c \in \{a, b\}$. The other properties are similar, we give a brief proof of each.

ii) By the induction hypothesis, $\lambda_a(q_w) = (r, -x, y, -z) \cdot \mu$ and thus:

$$\begin{aligned}
q_w \cdot \gamma_2(a) &= \frac{1}{5}(3r - 4x, 3x + 4r, 3y + 4z, 3z - 4y) \cdot \mu, \\
\lambda_a(q_w) \cdot \gamma_2(a)^{-1} &= \frac{1}{5}(3r - 4x, -3x - 4r, 3y + 4z, -3z + 4y) \cdot \mu,
\end{aligned}$$

with the second and fourth components negated as required. Also,

$$\begin{aligned}
q_w \cdot \gamma_2(a)^{-1} &= \frac{1}{5}(3r + 4x, 3x - 4r, 3y - 4z, 3z + 4y) \cdot \mu, \\
\lambda_a(q_w) \cdot \gamma_2(a) &= \frac{1}{5}(3r + 4x, -3x + 4r, 3y - 4z, -3z - 4y) \cdot \mu,
\end{aligned}$$

as expected. Right multiplication of q_w and $\lambda_a(q_w)$ by either $\gamma_2(b)$ or $\gamma_2(b)^{-1}$ retains the given structure, as is not difficult to calculate.

iii) By the induction hypothesis, $\lambda_b(q_w) = (r, x, -y, -z) \cdot \mu$ and thus:

$$\begin{aligned}
q_w \cdot \gamma_2(b) &= \frac{1}{5}(3r - 4y, 3x - 4z, 3y + 4r, 3z + 4x) \cdot \mu, \\
\lambda_b(q_w) \cdot \gamma_2(b)^{-1} &= \frac{1}{5}(3r - 4y, 3x - 4z, -3y - 4r, -3z - 4x) \cdot \mu,
\end{aligned}$$

with the third and fourth components negated as required. Also,

$$\begin{aligned}
q_w \cdot \gamma_2(b)^{-1} &= \frac{1}{5}(3r + 4y, 3x + 4z, 3y - 4r, 3z - 4x) \cdot \mu, \\
\lambda_b(q_w) \cdot \gamma_2(b) &= \frac{1}{5}(3r + 4y, 3x + 4z, -3y + 4r, -3z + 4x) \cdot \mu,
\end{aligned}$$

as expected. Right multiplication of q_w and $\lambda_b(q_w)$ by either $\gamma_2(a)$ or $\gamma_2(a)^{-1}$ retains the given structure, as is not difficult to calculate.

iv) By the induction hypothesis, $\lambda_{a,b}(q_w) = (r, -x, -y, z) \cdot \mu$ and thus:

$$\begin{aligned}
\lambda_{a,b}(q_w) \cdot \gamma_2(a) &= \frac{1}{5}(3r + 4x, -3x + 4r, -3y + 4z, 3z + 4y) \cdot \mu, \\
\lambda_{a,b}(q_w) \cdot \gamma_2(b) &= \frac{1}{5}(3r + 4y, -3x - 4z, -3y + 4r, 3z - 4x) \cdot \mu, \\
\lambda_{a,b}(q_w) \cdot \gamma_2(a)^{-1} &= \frac{1}{5}(3r - 4x, -3x - 4r, -3y - 4z, 3z - 4y) \cdot \mu, \\
\lambda_{a,b}(q_w) \cdot \gamma_2(b)^{-1} &= \frac{1}{5}(3r - 4y, -3x + 4z, -3y - 4r, 3z + 4x) \cdot \mu,
\end{aligned}$$

with the second and third components of each product negated with relation to $q_w \cdot \gamma_2(a)^{-1}$, $q_w \cdot \gamma_2(b)^{-1}$, $q_w \cdot \gamma_2(a)$ and $q_w \cdot \gamma_2(b)$ (resp.) as required. ◀

The following lemma allows us to represent a quaternion (and its corresponding rotation matrix) by using only absolute values and will be crucial later.

▶ **Lemma 13.** *Given a word $w \in \Sigma_k^*$, then $\gamma_2(\gamma_1(w)) = (r, x, y, z) \cdot \mu$ is uniquely determined by $(|r|, |x|, |y|, |z|)$. All matrices $\gamma(w) \in \Gamma$ are similarly uniquely determined by*

$$(|\gamma(w)_{1,1}|, |\gamma(w)_{1,2}|, |\gamma(w)_{1,3}|, |\gamma(w)_{1,4}|),$$

i.e., by the absolute values of each element of the top row of the matrix.

Proof. Another way to state this Lemma is that if we have $u = u_1 u_2 \cdots u_t$ and $v = v_1 v_2 \cdots v_{t'}$ with each $u_i, v_i \in \Sigma_k^*$, such that $\gamma_2(\gamma_1(u)) = (a_1, b_1, c_1, d_1) \cdot \mu$, $\gamma_2(\gamma_1(v)) = (a_2, b_2, c_2, d_2) \cdot \mu$ and $(|a_1|, |b_1|, |c_1|, |d_1|) = (|a_2|, |b_2|, |c_2|, |d_2|)$, then $t = t'$ and $u_i = v_i$ for all $1 \leq i \leq t$. A similar property holds for the top row of the unitary matrices when applying γ_3 to these elements. We shall now prove this.

By definition, $\gamma_2 : \Sigma_2^* \hookrightarrow \mathbb{H}(\mathbb{Q})$ maps to a free monoid $\mathcal{S}$ of $\mathbb{H}(\mathbb{Q})$ generated by $\mathcal{G} = \{\gamma_2(a), \gamma_2(b)\}$ with $\gamma_2(a) = \left(\frac{3}{5}, \frac{4}{5}, 0, 0\right) \cdot \mu$ and $\gamma_2(b) = \left(\frac{3}{5}, 0, \frac{4}{5}, 0\right) \cdot \mu$. As shown in Section 4, $\gamma_2 \circ \gamma_1 : \Sigma_n^* \hookrightarrow \mathbb{H}(\mathbb{Q})$; i.e., $\gamma_2 \circ \gamma_1$ is an injective homomorphism. Let $\Gamma' = \{\gamma_2(\gamma_1(w')) | w' \in \Sigma_n^*\} \subseteq \mathbb{H}(\mathbb{Q})$. Clearly then, Γ' is freely generated by $\{\gamma_2(\gamma_1(w')) | w' \in \Sigma_n\}$ by the injectivity of $\gamma_2 \circ \gamma_1$.

Let $q_w = \gamma_2(\gamma_1(w)) = (r, x, y, z) \cdot \mu \in \Gamma' \subseteq \mathcal{S}$ and define $Q_w = \{(\pm r, \pm x, \pm y, \pm z) \cdot \mu\}$, thus $|Q_w| = 16$. We will now show that for all $q' \in Q_w - \{q_w\}$ then $q' \notin \Gamma'$ which proves the lemma.

Since (unit) quaternion inversion simply involves negating all imaginary components, then using the identities of Lemma 12, we can derive that $q_w^{-1} = (r, -x, -y, -z)$, $\lambda_a(q_w)^{-1} = (r, x, -y, z)$ and $\lambda_b(q_w)^{-1} = (r, -x, y, z)$ which we summarize in the following table.

q_w	$(r, x, y, z)\mu$	q_w^{-1}	$(r, -x, -y, -z)\mu$
$\lambda_a(q_w)$	$(r, -x, y, -z)\mu$	$\lambda_a(q_w)^{-1}$	$(r, x, -y, z)\mu$
$\lambda_b(q_w)$	$(r, x, -y, -z)\mu$	$\lambda_b(q_w)^{-1}$	$(r, -x, y, z)\mu$
$\lambda_{a,b}(q_w)$	$(r, -x, -y, z)\mu$	q_{w^R}	$(r, x, y, -z)\mu$

We might also notice other identites, such as $q_{w^R} = \lambda_{a,b}(q_w)^{-1}$ which is clear from the definition of $\lambda_{a,b}$. Note that this table covers 8 elements of Q_w.

Note q_w belongs (by definition) to $\Gamma' = (\gamma_2(a)^+ \gamma_2(b))^+ = \{\gamma_2(\gamma_1(w')) | w' \in \Sigma_n\} \subseteq \mathcal{S}$. Since $\langle \gamma_2(a), \gamma_2(b) \rangle_{gr}$ generates a free group, this means that no reduced element of $\mathcal{S}$ is equal to a product with a nontrivial[3] factor $\gamma_2(a)^{-1}$ or $\gamma_2(b)^{-1}$. Each element in the above

[3] Reduced meaning the element contains no consecutive inverse elements and nontrivial meaning we ignoring any such element adjacent to its multiplicative inverse.

table contains at least one nonreducible factor $\gamma_2(a)^{-1}$ or $\gamma_2(b)^{-1}$, excluding q_w and q_{w^R}. Note however that q_{w^R} trivially does not belong to $\Gamma' = (\gamma_2(a)^+\gamma_2(b))^+$ since it necessarily begins with nonreducible factor $\gamma_2(b)$.

Finally, to cover the remaining 8 elements of Q_w, we consider the *free group* $\mathcal{S}_{\rm gr} = \langle\{\gamma_2(a), \gamma_2(b)\}|\emptyset\rangle_{gr}$. For any $q'_w \in \mathcal{S}_{\rm gr}$ then $-q'_w \notin \mathcal{S}_{\rm gr}$ since $\mathcal{S}_{\rm gr}$ is free. This holds since if $-q'_w \in \mathcal{S}$, then $-1 \in \mathcal{S}$ (because $(q'_w)^{-1} \in \mathcal{S}$), which gives a nontrivial identity $-1^2 = 1$ in $\mathcal{S}_{\rm gr}$ (a contradiction).

This covers all sixteen possible elements of Q_w and shows that q_w is the only member of Q_w belonging to Γ'. By the definition of $\gamma_3 : \mathbb{H}(\mathbb{Q}) \hookrightarrow \mathbb{Q}^{4\times4}$, then also all matrices $\gamma(w) \in \Gamma$ are uniquely determined by $(|\gamma(w)_{1,1}|, |\gamma(w)_{1,2}|, |\gamma(w)_{1,3}|, |\gamma(w)_{1,4}|)$ as required. ◀

▶ **Theorem 14.** *The freeness problem for measure-once quantum finite automata is undecidable for* 32 *states over an alphabet of size* 17*.*

Proof. We will encode an instance (h, g) of the mixed modification Post's Correspondence Problem into a finite set of matrices so that if there exists a solution to the instance then there exists some scalar which is nonfree, otherwise every scalar is free.

Let $\Sigma = \{x_1, x_2, \ldots, x_{n-2}\}$ and $\Delta = \{x_{n-1}, x_n\}$ be distinct alphabets and $h, g : \Sigma^* \to \Delta^*$ be an instance of the mixed modification PCP and let $\Sigma_n = \Sigma \cup \Delta$. The naming convention will become apparent below, but intuitively we will be applying γ, from Section 4 to both the input and output alphabets.

Recall that we showed the injectivity of γ in Section 4, and thus have a monomorphism $\gamma : \Sigma_n^* \hookrightarrow \mathbb{Q}^{4\times4}$. We define a function $\varphi : \Sigma_n^* \times \Sigma_n^* \hookrightarrow \mathbb{Q}^{32\times32}$ by

$$\varphi(w_1, w_2) = \bigoplus_{j=1}^{4} \gamma(w_1) \oplus \bigoplus_{j=1}^{4} \gamma(w_2).$$

We may note that $\varphi(w_1, w_2)$ remains a unitary matrix since $\gamma(w_i)$ is unitary and the direct sum of unitary matrices is unitary. Define $\mathcal{G} = \{\varphi(x_i, h(x_i)), \varphi(x_i, g(x_i))|x_i \in \Sigma\} \subset \mathbb{Q}^{32\times32}$.

Let p_i denote the i'th prime number and define $u_i = \sqrt[4]{p_i} \cdot e_i \in {\mathbb{A}_\mathbb{R}}^4$, $v_i = \sqrt[4]{p_{4+i}} \cdot e_i \in {\mathbb{A}_\mathbb{R}}^4$ for $1 \leq i \leq 4$ (${\mathbb{A}_\mathbb{R}}^4$ denotes a 4-tuple of elements from $\mathbb{A}_\mathbb{R}$) and $u' = \bigoplus_{j=1}^4 u_j \oplus \bigoplus_{j=1}^4 v_j \in {\mathbb{A}_\mathbb{R}}^{32}$. Now, we normalise this vector so that $u = \frac{u'}{\sqrt{\sum_{i=1}^8 \sqrt{p_i}}} \in {\mathbb{A}_\mathbb{R}}^{32}$, with u a unit vector. Note that each element of u is a real algebraic number. Let $P_1 = 1 \oplus \mathbf{0}_3$ where $\mathbf{0}_3$ is the 3×3 zero matrix, thus P_1 has a 1 in the upper left element and zero elsewhere. Then define $P = P_1^{\oplus 8} \in \mathbb{Q}^{32\times32}$. Note that $P^2 = P$ and P is a projection matrix.

We are now ready to define our QFA $\mathcal{Q}$ by the triple $\mathcal{Q} = (P, \mathcal{G}, u)$ and prove the claim of the theorem.

Let $X = X_{i_1} \cdots X_{i_p} = \varphi(x_{i_1}, f_{i_1}(x_{i_1})) \cdots \varphi(x_{i_p}, f_{i_p}(x_{i_p}))$, with $f_{i_k} \in \{g, h\}$ for $1 \leq k \leq p$ be one factorization of a matrix $X \in \mathcal{G}$. Define $x = x_{i_1} \cdots x_{i_p}$ and $f(x) = f_{i_1}(x_{i_1}) \cdots f_{i_p}(x_{i_p})$. Then we see that:

$$
\begin{aligned}
||PXu||^2 &= \left\| \frac{\bigoplus_{j=1}^4 (P_1\gamma(x)u_j) \oplus \bigoplus_{j=1}^4 (P_1\gamma(f(x))v_j)}{\sqrt{\sum_{i=1}^8 \sqrt{p_i}}} \right\|^2 && (2)\\
&= \left\| \frac{\bigoplus_{j=1}^4 (P_1\gamma(x)\sqrt[4]{p_j}\cdot e_j) \oplus \bigoplus_{j=1}^4 (P_1\gamma(f(x))\sqrt[4]{p_{4+j}}\cdot e_j)}{\sqrt{\sum_{i=1}^8 \sqrt{p_i}}} \right\|^2 && (3)\\
&= \left(\sqrt{\frac{\sum_{j=1}^4 (\gamma(x)_{1,j}\sqrt[4]{p_j})^2 + \sum_{j=1}^4 (\gamma(f(x))_{1,j}\sqrt[4]{p_{4+j}})^2}{\sqrt{\sum_{i=1}^8 \sqrt{p_i}}}} \right)^2 && (4)\\
&= \frac{\sum_{j=1}^4 \gamma(x)_{1,j}^2\sqrt{p_j} + \sum_{j=1}^4 \gamma(f(x))_{1,j}^2\sqrt{p_{4+j}}}{\sqrt{\sum_{i=1}^8 \sqrt{p_i}}}. && (5)
\end{aligned}
$$

Assume that matrix X has two distinct factorizations $X = X_{i_1}\cdots X_{i_p} = X_{j_1}\cdots X_{j_q} \in \mathcal{G}^+$ and $p \neq q$ or $X_{i_k} \neq X_{j_k}$ for some $1 \leq k \leq p$, such that

$$||PXu||^2 = \left|\left|PX_{i_1}\cdots X_{i_p}u\right|\right|^2 = \left|\left|PX_{j_1}\cdots X_{j_q}u\right|\right|^2,$$

and thus $\Lambda(\mathcal{Q})$ is not free. Let $X = X_{j_1}\cdots X_{j_q} = \varphi(x_{j_1}, f'_{j_1}(x_{j_1}))\cdots\varphi(x_{j_q}, f'_{j_q}(x_{j_q}))$, with $f'_{j_k} \in \{g,h\}$ for $1 \leq k \leq q$ and define $x' = x_{j_1}\cdots x_{j_q}$ and $f'(x') = f'_{j_1}(x_{j_1})\cdots f'_{j_q}(x_{j_p})$ with each $f'_{j_k} \in \{g,h\}$. Note that in Eqn. (5) the denominator is constant and thus when determining equality $\left|\left|PX_{i_1}\cdots X_{i_p}u\right|\right|^2 = \left|\left|PX_{j_1}\cdots X_{j_q}u\right|\right|^2$ we may ignore it. By Lemma 13, each $\gamma(w)$ is uniquely determined by the absolute value of the top four elements of the matrix (e.g. $|\gamma(w)_{1,j}|$ for $1 \leq j \leq 4$). Since each p_j is squarefree, for $1 \leq j \leq 8$, then by Theorem 11, the following equation is satisfied if and only if $|\gamma(x)| = |\gamma(x')|$ and $|\gamma(f(x))| = |\gamma(f'(x'))|$:

$$
\begin{aligned}
&\sum_{j=1}^4 \gamma(x)_{1,j}^2\sqrt{p_j} + \sum_{j=1}^4 \gamma(f(x))_{1,j}^2\sqrt{p_{4+j}}\\
= \;&\sum_{j=1}^4 \gamma(x')_{1,j}^2\sqrt{p_j} + \sum_{j=1}^4 \gamma(f'(x'))_{1,j}^2\sqrt{p_{4+j}}.
\end{aligned}
$$

Finally, note that $\gamma(x) = \gamma(x')$ if and only if $x = x'$. As before, let $x = x_{i_1}\cdots x_{i_p}$, then $\gamma(f(x)) = f_{i_1}(x_{i_1})\cdots f_{i_p}(x_{i_p}) = f_{j_1}(x_{i_1})\cdots f_{j_p}(x_{i_p}) = \gamma(f'(x'))$ with some $f_{i_k} \neq f_{j_k}$ for $1 \leq k \leq p$ if and only if the instance of the MMPCP has a solution.

If the MMPCP is undecidable for Claus instances with an alphabet of size n' (see Theorem 9), then the undecidability of the current theorem holds for $|\mathcal{G}| \geq 2n'$. We now prove that the result holds for $|\mathcal{G}| \geq 2n' - 1$. Let $\Sigma = \{x_1, \ldots, x_{n'}\}$. Since h, g is a Claus instance, any solution word w is of the form $w = x_1 w' x_{n'}$, with $w' \in (\Sigma - \{x_1, x_{n'}\})^*$. By symmetry, we may assume that $h_1 = h$ and by the proof in [16], $g_i = g$ and $h_i = h$ for all $1 \leq i \leq t$. Clearly then, one of $h(x_{n'})$ and $g(x_{n'})$ is a proper suffix of the other (assume that $g(x_{n'})$ is a suffix of $h(x_{n'})$; the opposite case is similar). Now, redefine $u' = \gamma(x_{n'}, g(x_{n'}))u$, remove the matrix corresponding to $g(x_{n'})$ from $\mathcal{G}$ and redefine the matrix corresponding to $h(x_{n'})$ by $h'(x_{n'}) = \gamma(x_{n'}, h(x_{n'})g(x_{n'})^{-1})$. Since $g(x_{n'})$ is a proper suffix of $h(x_{n'})$, then $h(x'_n)g(x'_n)^{-1}$ is the prefix of $h(x_{n'})$ after removing the common suffix with $g(x_{n'})$. This means that an ambiguous scalar only exists if there exists a solution to the instance of MMPCP and we had reduced the alphabet size by 1. MMPCP is undecidable for instances of size 9 (Theorem 9), thus the undecidability holds for MO-QFA with 32 states and an alphabet size of 17. ◀

▶ **Corollary 15.** *The ambiguity problem for measure-once quantum finite automata is undecidable for* 33 *states over an alphabet of size* 17*.*

Proof. The corollary follows from the proof of Theorem 14. We notice that if there exists a solution to the encoded instance of the MMPCP, then some matrix X has two distinct factorizations over $\mathcal{G}$ and therefore there exists two distinct matrix products giving the same scalar. Our technique in this corollary is to make these two factorizations produce distinct matrices X_1 and X_2, such that they still lead to the same scalar. This is simple to accomplish by redefining the projection matrix P as $P' = P \oplus 0$, redefining the initial vector u as $u' = u \oplus 0$ and for each matrix $M \in \mathcal{G} - \{\varphi(x_1, h(x_1))\}$, we redefine M as $M' = M \oplus 1$ and let $\varphi(x_1, h(x_1))$ be redefined as $\varphi(x_1, h(x_1)) \oplus -1$. In this case, any matrix product containing $\varphi(x_1, h(x_1)) \oplus -1$ will have -1 in the bottom right element, otherwise the bottom right element is 1. Since we encode a Claus instance of MMPCP, one factorization has -1 in this case, and the other has 1, and thus we always have distinct matrices. If no solution exists, then each matrix leads to a unique scalar anyway.

Note that we increased the number of states of the MO-QFA by 1 and also note that the acceptance probability is unaffected by the above modifications since the projection matrix was increased by a zero row/column. ◀

6 Conclusion

An interesting question is whether Theorem 14 can be shown to hold when the initial vector is rational, rather than real algebraic. We can prove this result if a certain open problem related to rational packing functions holds (does there exist a polynomial which maps n-tuples of rationals to a single rational injectively). Such a function is well known for integer values (the Cantor polynomial), but not for rational n-tuples. This seems a difficult problem to approach however, and thus we leave the following open problem.

▶ **Open Problem 16.** *Can undecidability of the ambiguity and freeness problems for MO-QFA be shown when the initial vector, projection matrix and all unitary matrices are over rationals?*

We also note that in [1] the ambiguity and freeness problems for weighted finite automata and probabilistic finite automata were shown to be undecidable even when the input words were restricted to come from a given *letter monotonic language*, which is a restriction of bounded languages of the form $x_1^* x_2^* \cdots x_k^*$ where each x_i is a single letter of the input alphabet. The undecidability result of [1] used an encoding of Hilbert's tenth problem, which seems difficult to encode into unitary matrices and thus we pose the following open problem.

▶ **Open Problem 17.** *Can the undecidability of the ambiguity and freeness problems for MO-QFA be shown when the input word is necessarily from a given letter monotonic language?*

Abstract

Given a regular expression R and a string Q, the regular expression parsing problem is to determine if Q matches R and if so, determine how it matches, e.g., by a mapping of the characters of Q to the characters in R. Regular expression parsing makes finding matches of a regular expression even more useful by allowing us to directly extract subpatterns of the match, e.g., for extracting IP-addresses from internet traffic analysis or extracting subparts of genomes from genetic data bases. We present a new general techniques for efficiently converting a large class of algorithms that determine if a string Q matches regular expression R into algorithms that can construct a corresponding mapping. As a consequence, we obtain the first efficient linear space solutions for regular expression parsing.

1 Introduction

A regular expression specifies a set of strings formed by characters combined with concatenation, union (`|`), and Kleene star (`*`) operators. For instance, `(a|(ba))*)` describes the set of strings of `a`s and `b`s, where every `b` is followed by an `a`. Regular expressions are a fundamental concept in formal language theory and a basic tool in computer science for specifying search patterns. Regular expression search appears in diverse areas such as internet traffic analysis [14, 27, 17], data mining [11], data bases [19, 21], computational biology [23], and human computer interaction [16].

Given a regular expression R and a string Q, the *regular expression parsing problem* [15, 8, 10, 24, 25, 18] is to determine if Q matches a string in the set of strings described by R and if so, determine how it matches by computing the corresponding sequence of positions of characters in R, i.e., the mapping of each character in Q to a character in R corresponding to the match. For instance, if $R =$ `(a|(ba))*)` and $Q =$ `aaba`, then Q matches R and $1, 1, 2, 3$ is a corresponding parse specifying that $Q[1]$ and $Q[2]$ match the first `a` in R, $Q[3]$ match the `b` in R, and $Q[4]$ match the last `a` in R[1]. Regular expression parsing makes finding matches of a regular expression even more useful by allowing us to directly extract subpatterns of the match, e.g., for extracting IP-addresses from internet traffic analysis or extracting subparts of genomes from genetic data bases.

[1] Another typical definition of parsing is to compute a parse tree (or a variant thereof) of the derivation of Q on R. Our definition simplifies our presentation and it is straightforward to derive a parse tree from our parses.

To state the existing bounds, let n and m be the length of the string and the regular expression, respectively. As a starting point consider the simpler *regular expression matching problem*, that is, to determine if Q matches a string in the set of strings described by R (without necessarily providing a mapping from characters in Q to characters in R). A classic textbook algorithm to matching, due to Thompson [26], constructs and simulates a non-deterministic finite automaton (NFA) in $O(nm)$ time and $O(m)$ space. An immediate approach to solve the parsing problem is to combine Thompson's algorithm with backtracking. To do so, we store all state-sets produced during the NFA simulation and then process these in reverse order to recover an accepting path in the NFA matching Q. From the path we then immediately obtain the corresponding parse of Q since each transition labeled by a character uniquely corresponds to a character in R. This algorithm uses $O(nm)$ time and space. Hence, we achieve the same time bound as matching but increase the space by an $\Omega(n)$ factor. We can improve the time by polylogarithmic factors using faster algorithms for matching [22, 3, 4, 6, 7], but by a recent conditional lower bound [2] we cannot hope to achieve $\Omega((nm)^{1-\varepsilon})$ time assuming the strong exponential time hypothesis. Other direct approaches to regular expression parsing [15, 8, 10, 24, 25, 18] similarly achieve $\Theta(nm)$ time and space (ignoring polylogarithmic factors), leaving a substantial gap between linear space for matching and $\Theta(nm)$ space for parsing. The goal of this paper is to address this gap.

1.1 Results

We present a new technique to efficiently extend the classic state-set transition algorithms for matching to also solve parsing in the same time complexity while only using linear space. Specifically, we obtain the following main result based on Thompson's algorithm:

▶ **Theorem 1.** *Given a regular expression of length m and a string of length n, we can solve the regular expression parsing problem in $O(nm)$ time and $O(n+m)$ space.*

This is the first bound to significantly improve upon the combination of $\Theta(nm)$ time and space. The result holds on a comparison-based, pointer machine model of computation. Our techniques are sufficiently general to also handle the more recent faster state-set transition algorithms [22, 4, 3] and we also obtain a similar space improvement for these.

1.2 Techniques

Our overall approach is similar in spirit to the classic divide and conquer algorithm by Hirschberg [13] for computing a longest common subsequence of two strings in linear space. Let A be the *Thompson NFA* (TNFA) for R built according to Thompson's rules [26] (see also Figure 1) with m states, and let Q be the string of length n.

We first decompose A using standard techniques into a pair of nested subTNFAs called the *inner subTNFA* and the *outer subTNFA*. Each have roughly at most $2/3$ of the states of A and overlap in at most 2 boundary states. We then show how to carefully simulate A to decompose Q into substrings corresponding to subparts of an accepting path in each of the subTNFAs. The key challenge here is to efficiently handle cyclic dependencies between the subTNFAs. From this we construct a sequence of subproblems for each of the substrings corresponding to the inner subTNFAs and a single subproblem for the outer subTNFA. We recursively solve these to construct a complete accepting path in A. This strategy leads to an $O(nm)$ time and $O(n \log m + m)$ space solution. We show how to tune and organize the recursion to avoid storing intermediate substrings leading to the linear space solution in Theorem 1. Finally, we show how to extend our solution to obtain linear space parsing solutions for other state-set transition algorithms.

2 Preliminaries

Strings. A string Q of length $n = |Q|$ is a sequence $Q[1] \dots Q[n]$ of n characters drawn from an alphabet Σ. The string $Q[i] \dots Q[j]$ denoted $Q[i, j]$ is called a substring of Q. The substrings $Q[1, i]$ and $Q[j, n]$ are the ith prefix and the jth suffix of Q, respectively. The string ϵ is the unique empty string of length zero.

Regular Expressions. First we briefly review the classical concepts used in the paper. For more details see, e.g., Aho et al. [1]. We consider the set of non-empty regular expressions over an alphabet Σ, defined recursively as follows. If $\alpha \in \Sigma \cup \{\epsilon\}$ then α is a regular expression, and if S and T are regular expressions then so is the *concatenation*, $(S) \cdot (T)$, the *union*, $(S)|(T)$, and the *star*, $(S)^*$. The *language* $L(R)$ generated by R is defined as follows. If $\alpha \in \Sigma \cup \{\epsilon\}$, then $L(\alpha)$ is the set containing the single string α. If S and T are regular expressions, then $L(S \cdot T) = L(S) \cdot L(T)$, that is, any string formed by the concatenation of a string in $L(S)$ with a string in $L(T)$, $L(S)|L(T) = L(S) \cup L(T)$, and $L(S^*) = \bigcup_{i \geq 0} L(S)^i$, where $L(S)^0 = \{\epsilon\}$ and $L(S)^i = L(S)^{i-1} \cdot L(S)$, for $i > 0$. The *parse tree* $\mathcal{T}^P(R)$ of R (not to be confused with the parse of Q wrt. to R) is the rooted, binary tree representing the hierarchical structure of R. The leaves of $\mathcal{T}^P(R)$ are labeled by a character from Σ or ϵ and internal nodes are labeled by either $\cdot$, $|$, or $*$.

Finite Automata. A *finite automaton* is a tuple $A = (V, E, \Sigma, \theta, \phi)$, where V is a set of nodes called *states*, E is a set of directed edges between states called *transitions* either labeled ϵ (called ϵ-transitions) or labeled by a character from Σ (called character-transitions), $\theta \in V$ is a *start state*, and $\phi \in V$ is an *accepting state*[2]. In short, A is an edge-labeled directed graph with a special start and accepting node. A is a *deterministic finite automaton* (DFA) if A does not contain any ϵ-transitions, and all outgoing transitions of any state have different labels. Otherwise, A is a *non-deterministic automaton* (NFA). When we deal with multiple automatons, we use a subscript $_A$ to indicate information associated with automaton A, e.g., θ_A is the start state of automaton A.

Given a string Q and a path P in A we say that Q and P *match* if the concatenation of the labels on the transitions in P is Q. Given a state s in A we define the *state-set transition* $\delta_A(s, Q)$ to be the set of states reachable from s through paths matching Q. For a set of states S we define $\delta_A(S, Q) = \bigcup_{s \in S} \delta_A(s, Q)$. We say that A *accepts* the string Q if $\phi_A \in \delta_A(\theta_A, Q)$. Otherwise A *rejects* q. For an accepting path P in A, we define the *parse* of P for A to be the sequence of character transitions in A on P. Given a string Q accepted by A, a parse of Q is a parse for A of any accepting path matching Q.

We can use a sequence of state-set transitions to test acceptance of a string Q of length n by computing a sequence of state-sets $S_0, \dots, S_n$, given by $S_0 = \delta_A(\theta_A, \epsilon)$ and $S_i = \delta_A(S_{i-1}, Q[i])$, $i = 1, \dots, n$. We have that $\phi_A \in S_n$ iff A accepts Q. We can extend the algorithm to also compute the parse of Q for A by processing the state-sets in reverse order to recover an accepting path and output the character transitions. Note that for matching we only need to store the latest two state-sets at any point to compute the final state-set S_n, whereas for parsing we store the full sequence of state-sets.

Thompson NFA. Given a regular expression R, we can construct an NFA accepting precisely the strings in $L(R)$ by several classic methods [20, 12, 26]. In particular, Thompson [26] gave the simple well-known construction shown in Figure 1. We will call an NFA constructed

[2] Sometimes NFAs are allowed a *set* of accepting states, but this is not necessary for our purposes.

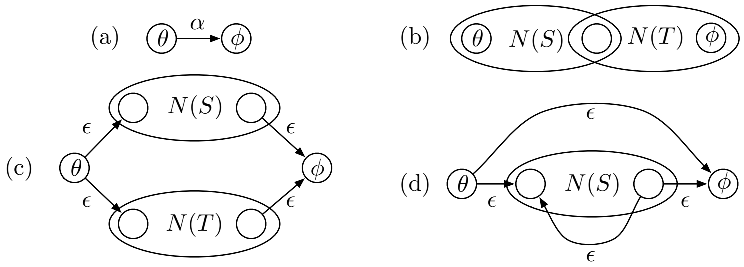

Figure 1 Thompson's recursive NFA construction. The regular expression $\alpha \in \Sigma \cup \{\epsilon\}$ corresponds to NFA (a). If S and T are regular expressions then $N(ST)$, $N(S|T)$, and $N(S^*)$ correspond to NFAs (b), (c), and (d), respectively. In each of these figures, the leftmost state θ and rightmost state ϕ are the start and the accept nodes, respectively. For the top recursive calls, these are the start and accept states of the overall automaton. In the recursions indicated, e.g., for $N(ST)$ in (b), we take the start state of the subautomaton $N(S)$ and identify with the state immediately to the left of $N(S)$ in (b). Similarly the accept state of $N(S)$ is identified with the state immediately to the right of $N(S)$ in (b).

with these rules a *Thompson NFA* (TNFA). A TNFA $N(R)$ for R has at most $2m$ states, at most $4m$ transitions, and can be computed in $O(m)$ time. Note that each character in R corresponds to a unique character transition in $N(R)$ and hence a parse of a string Q for $N(R)$ directly corresponds to a parse of Q for R. The parse tree of a TNFA $N(R)$ is the parse tree of R. With a breadth-first search of A we can compute a state-set transition for a single character in $O(m)$ time. By our above discussion, it follows that we can solve regular expression matching in $O(nm)$ time and $O(m)$ space, and regular expression parsing in $O(nm)$ time and $O(nm)$ space.

TNFA Decomposition. We need the following decomposition result for TFNAs (see Figure 2). Similar decompositions are used in [22, 3]. Given a TNFA A with $m > 2$ states, we decompose A into an *inner subTNFA* A_I and an *outer subTNFA* A_O. The inner subTNFA consists of a pair of *boundary states* θ_{A_I} and ϕ_{A_I} and all states and transitions that are reachable from θ_{A_I} without going through ϕ_{A_I}. Furthermore, if there is a path of ϵ-transitions from ϕ_{A_I} to θ_{A_I} in A_O, we add an ϵ-transition from ϕ_{A_I} to θ_{A_I} in A_I (following the rules from Thompson's construction). The outer subTNFA is obtained by removing all states and transitions of A_I except θ_{A_I} and ϕ_{A_I}. Between θ_{A_I} and ϕ_{A_I} we add a special transition labeled $\beta_{A_I} \notin \Sigma$ and if A_I accepts the empty string we also add an ϵ-transition (corresponding to the regular expression $(\beta_{A_I} \mid \epsilon)$). The decomposition has the following properties. Similar results are proved in [22, 3] (see also full version [5] for a the proof).

▶ **Lemma 2.** *Let A be any TNFA with $m > 2$ states. In $O(m)$ time we can decompose A into inner and outer subTNFAs A_O and A_I such that*

(i) *A_O and A_I have at most $\frac{2}{3}m + 8$ states each, and*

(ii) *any path from A_O to A_I crosses θ_{A_I} and any path from A_I to A_O crosses ϕ_{A_I}.*

3 String Decompositions

Let A be a TNFA decomposed into subTNFAs A_O and A_I and Q be a string accepted by A. We show how to efficiently decompose Q into substrings corresponding to subpaths matched in each subTNFA. The algorithm will be a key component in our recursive algorithm in the next section.

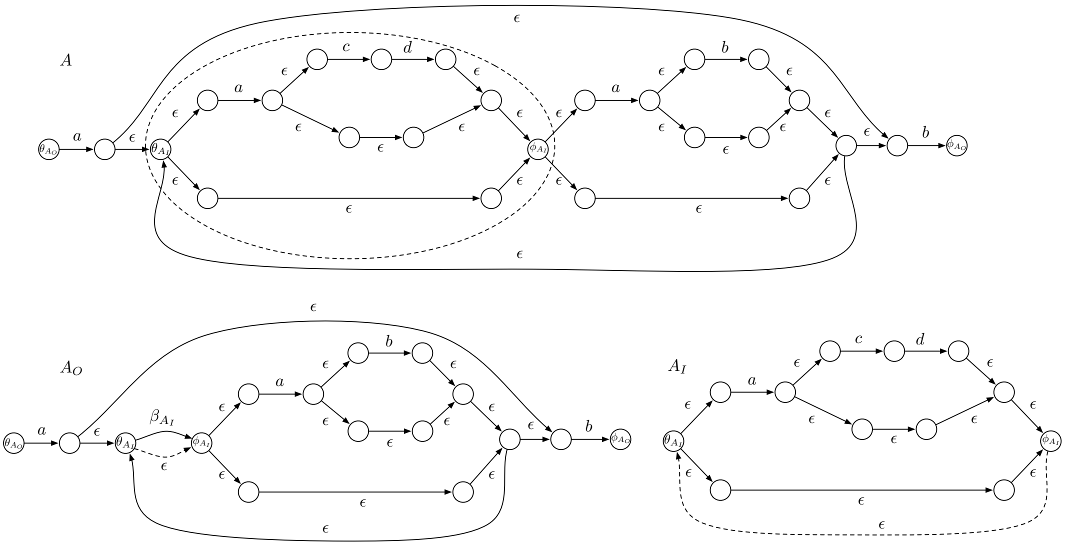

Figure 2 Decomposition of TNFA A into subTNFAs A_O and A_I. The dotted ϵ-transition in A_O exists since A_I accepts the empty string, and the dotted ϵ-transition in A_I exists since there is a path of ϵ-transitions from ϕ_{A_I} to θ_{A_I}.

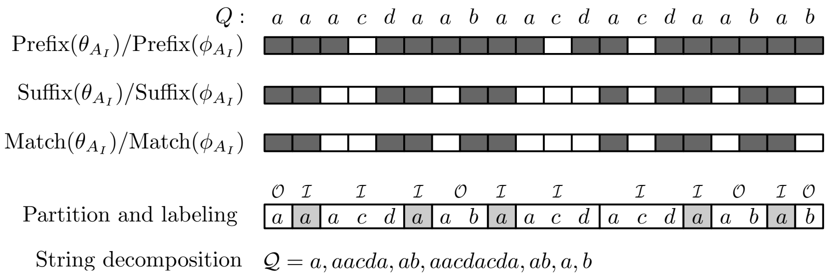
Given an accepting path P in A, we define the *path decomposition* of P wrt. A_I to be the partition of P into a sequence of subpaths $\mathcal{P} = \overline{p}_1, p_1, \overline{p}_2, p_2, \ldots, \overline{p}_\ell, p_\ell, \overline{p}_{\ell+1}$, where the *outer subpaths*, $\overline{p}_1, \ldots, \overline{p}_{\ell+1}$, are subpaths in A_O and the *inner subpaths*, $p_1, \ldots, p_\ell$ are the subpaths in A_I. The *string decomposition* induced by $\mathcal{P}$ is the sequence of substrings $\mathcal{Q} = \overline{q}_1, q_1, \overline{q}_2, q_2, \ldots, \overline{q}_\ell, q_\ell, \overline{q}_{\ell+1}$ formed by concatenating the labels of the corresponding subpath in A. A sequence of substrings is a substring decomposition wrt. to A_I if there exists an accepting path that induces it. Our goal is to compute a string decomposition in $O(nm)$ time and $O(n + m)$ space, where n is the length of Q and m is the number of states in A.

An immediate idea would be to process Q from left to right using state-set transitions and "collapse" the state set to a boundary state b of A_I whenever the state set contains b and there is a path from b to ϕ_A matching the rest of Q. Since A_O and A_I only interact at the boundary states, this effectively corresponds to alternating the simulation of A between A_O and A_I. However, because of potential cyclic dependencies from paths of ϵ-transition from ϕ_{A_I} to θ_{A_I} in A_O and θ_{A_I} to ϕ_{A_I} in A_I we cannot immediately determine which subTNFA we should proceed in and hence we cannot correctly compute the string decomposition. For instance, consider the string $Q = aaacdaabaacdacdaabab$ from Figure 3. After processing the first two characters (aa) both θ_{A_I} and ϕ_{A_I} are in the state set, and there is a path from both these states to ϕ_A matching the rest of Q. The same is true after processing the first six characters ($aaacda$). In the first case the substring consisting of the next three characters (acd) only matches a path in A_I, whereas in the second case the substring consisting of the next two characters (ab) only matches a path in A_O. A technical contribution in our algorithm in the next section is to efficiently overcome these issues by a two-step approach that first decomposes the string into substrings and labels the substrings greedily to find a correct string decomposition.



Q : a a a c d a a b a a c d a c d a a b a b
Prefix(θ_{A_I})/Prefix(ϕ_{A_I})
Suffix(θ_{A_I})/Suffix(ϕ_{A_I})
Match(θ_{A_I})/Match(ϕ_{A_I})
Partition and labeling
$\mathcal{O}$ $\mathcal{I}$ $\mathcal{I}$ $\mathcal{I}$ $\mathcal{O}$ $\mathcal{I}$ $\mathcal{I}$ $\mathcal{I}$ $\mathcal{I}$ $\mathcal{O}$ $\mathcal{I}$ $\mathcal{O}$
a a a c d a a b a a c d a c d a a b a b
String decomposition
$Q = a, aacda, ab, aacdacda, ab, a, b$

Figure 3 The string decomposition of the string $Q = aaacdaabaacdacdaabab$ wrt. A_I in Figure 2 and the corresponding suffix/prefix match sets. The dark grey blocks in the prefix, suffix and match sets are the positions contained in the sets. The blocks in the partition of the string are labeled $\mathcal{O}$ and $\mathcal{I}$ for outer and inner, respectively. The grey blocks in the partition are the substrings that can be parsed by both the inner and outer automaton. According to our procedure these blocks are labeled *inner*.

3.1 Computing String Decompositions

We need the following new definitions. Let i be a position in Q and let s be a state in A. We say that (i, s) is a *valid pair* if there is a path from θ_A to s matching $Q[1, i]$ and from s to ϕ_A matching $Q[i + 1, n]$. For any set of states X in A, we say that (i, X) is a valid pair if each pair (i, x), $x \in X$, is a valid pair. An accepting path P in A *intersects* a valid pair (i, X) if some state $x \in X$ is on the path, the subpath of P from θ_A to x matches $Q[1, i]$, and the subpath of P from x to ϕ_A matches $Q[i + 1, n]$.

Our algorithm consist of the following steps. In step 1, we process Q from left to right and right to left to compute and store the *match sets*, consisting of all valid pairs for the boundary states θ_{A_I} and ϕ_{A_I}. We then use the match sets in step 2 to process Q from left to right to build a sequence of valid pairs for the boundary states that all intersect a single accepting path P in A matching Q, and that has the property that all positions where the accepting path P contains θ_{A_I} or ϕ_{A_I} correspond to a valid pair in the sequence. Finally, in step 3 we construct the string decomposition using a greedy labeling of the sequence of valid pairs. See Figure 3 for an example of the computation in each step.

Step 1: Computing Match Sets

First, compute the *match sets* given by

$$\text{Match}(\theta_{A_I}) = \{i \mid (i, \theta_{A_I}) \text{ is a valid pair}\}$$
$$\text{Match}(\phi_{A_I}) = \{i \mid (i, \phi_{A_I}) \text{ is a valid pair}\}$$

Thus, Match(θ_{A_I}) and Match(ϕ_{A_I}) are the positions in Q that correspond to a valid pair for the boundary states θ_{A_I} and ϕ_{A_I}, respectively. To compute these, we first compute the *prefix match sets*, Prefix(s), and *suffix match sets*, Suffix(s), for $s \in \{\theta_{A_I}, \phi_{A_I}\}$. A position i is in Prefix(s) if there is a path from θ_A to s accepting the prefix $Q[1, i]$, and in Suffix(s) if there is a path from s to ϕ_A accepting the suffix $Q[i + 1, n]$. To compute the prefix match sets we perform state-set transitions on Q and A and whenever the current state-set contains either θ_{A_I} or ϕ_{A_I} we add the corresponding position to Prefix(s). We compute the suffix match sets in the same way, but now we perform the state-set transitions on Q from right to left and A with the direction of all transitions reversed. Each step of the state-set transition takes $O(m)$ time and hence we use $O(nm)$ time in total.

Finally, we compute the match sets Match(s), for $s \in \{\theta_{A_I}, \phi_{A_I}\}$, by taking the intersection of Prefix(s) and Suffix(s). In total we use $O(mn)$ time and $O(n+m)$ space to compute and store the match sets.

Step 2: Computing Valid Pairs

We now compute a sequence of valid pairs

$$V = (i_1, X_1), (i_2, X_2), \ldots, (i_k, X_k)$$

such that $0 \leq i_1 < \cdots < i_k \leq n$ and $X_j \subseteq \{\theta_{A_I}, \phi_{A_I}\}$ and with the property that the states of all pairs intersect a single accepting path P in A and at all places where P is equal to either θ_{A_I} or ϕ_{A_I} correspond to a valid pair in V.

To compute the sequence we run a slightly modified state-set transition algorithm: For $i = 0, 1, \ldots, n$ we set $S_i = \delta_A(S_{i-1}, Q[i])$ (for $i = 0$ set $S_0 := \delta_A(\theta_A, \epsilon)$) and compute the set

$$X := \{x \mid x \in \{\theta_{A_I}, \phi_{A_I}\} \text{ and } i \in \text{Match}(x)\} \cap S_i \ .$$

Thus X is the set of boundary states in S_i that corresponds to a valid pair computed in Step 1. If $X \neq \emptyset$ we add (i, X) to the sequence V and set $S_i := X$.

We argue that this produces a sequence V of valid pairs with the required properties. First note that by definition of X we inductively produce state-set $S_0, \ldots, S_n$ such that S_i contains the set of states reachable from θ_A that match $Q[1, i]$ and the paths used to reach S_i intersect the states of the valid pairs produced up to this point. Furthermore, we include all positions in V where S_i contains θ_{A_I} or ϕ_{A_I}. It follows that V satisfies the properties.

Each of modified state-set transition uses $O(m)$ time and hence we use $O(nm)$ time in total. The sequence V uses $O(n)$ space. In addition to this we store the match sets and a constant number of active state-sets using $O(n+m)$ space.

Step 3: Computing the String Decomposition

We now convert the sequence $V = (i_1, X_1), (i_2, X_2), \ldots, (i_k, X_k)$ into a string decomposition. First, we construct the partition $q_0, \ldots, q_{k+1}$ of Q such that $q_0 = Q[1, i_1]$, $q_j = Q[i_j + 1, i_{j+1}]$, and $q_{k+1} = Q[i_k + 1, n]$. Note that q_0 and q_{k+1} may be the empty string. Next, we convert this partition into a string decomposition by first labeling each substring as inner or outer and then greedily merging these substrings to obtain an alternating sequence forming a string decomposition. We discuss these steps in detail below.

Labeling. We label the substrings as follows. First label q_0 and q_{k+1} with outer. For the rest of the substrings, if $X_i = \{\theta_{A_I}\}$ and $X_{i+1} = \{\phi_{A_I}\}$ then label q_i with inner, and if $X_i = \{\phi_{A_I}\}$ and $X_{i+1} = \{\theta_{A_I}\}$ then label q_i with outer. If either X_i or X_{i+1} contain more than one boundary state then we use state-set transitions in A_I and A_O to determine if A_I accepts q_i or if there is a path in A_O from ϕ_{A_I} to θ_{A_I} that matches q_i. If a substring is accepted by A_I then it can be an inner substring and if there is a path in A_O from ϕ_{A_I} to θ_{A_I} that matches q_i then it can be an outer substring. If a substring can only be either an inner or an outer substring then it is labeled with inner or outer, respectively. Let q_i be a substring that can be both an inner or an outer substring. We divide this into two cases. If there is an ϵ-path from ϕ_{A_I} to θ_{A_I} then label all such q_i with inner. Otherwise label all such q_i with outer. See also Algorithm 1.

Algorithm 1 Labeling.

```
Input: A sequence $V$ of valid pairs $(i_1, X_1), \dots (i_k, V_k)$ and the corresponding
       partition $q_0, \dots, q_{k+1}$ of $Q$.
Output: A labeling of the partition
The (possible empty) substrings $q_0$ and $q_{k+1}$ are labeled outer.
for $i = 1$ to $k$ do
    if $X_i = \{\theta_{A_I}\}$ and $X_{i+1} = \{\phi_{A_I}\}$ then                        /* Case 1 */
        label $q_i$ inner.
    else if $X_i = \{\phi_{A_I}\}$ and $X_{i+1} = \{\theta_{A_I}\}$ then                   /* Case 2 */
        label $q_i$ outer.
    else if $X_i$ or $X_{i+1}$ contains more than one boundary node then /* Case 3 */
        Use standard state-set transitions in $A_I$ and $A_O$ to determine if $A_I$ accepts $q_i$
         or if there is a path in $A_O$ from $\phi_{A_I}$ to $\theta_{A_I}$ that matches $q_i$.
        if $q_i$ is only accepted by $A_I$ then                              /* Subcase 3a */
            label $q_i$ inner
        else if $q_i$ is only accepted by $A_O$ then                         /* Subcase 3b */
            label $q_i$ with outer
        else /* $q_i$ is accepted by both $A_I$ and $A_O$                                 */
            There are two cases.
            if there is an $\epsilon$-path from $\phi_{A_I}$ to $\theta_{A_I}$ then               /* Subcase 3c */
                label $q_i$ inner.
            else label $q_i$ outer.                                       /* Subcase 3d */
        end
    end
end
```

For correctness first note that q_0 and q_{k+1} are always (possibly empty) outer substrings. The cases where both $|X_i| = |X_{i+1}|$ (case 1 and 2) are correct by the correctness of the sequence of valid pairs V. Due to cyclic dependencies we may have that X_i and X_{i+1} contain more than one boundary state. This can happen if there is an ϵ-path from θ_{A_I} to ϕ_{A_I} and/or there is an ϵ-path from ϕ_{A_I} to θ_{A_I}. If a substring only is accepted by one of A_I (case 3a) or A_O (case 3b) then it follows from the correctness of V that the labeling is correct. It remains to argue that the labeling in the case where q_i is accepted by both A_I and A_O is correct. To see why the labeling in this case is consistent with a string decomposition of the accepting path consider case 3c. Here, it is safe to label q_i with inner, since if we are in ϕ_{A_I} after having read q_{i-1} we can just follow the ϵ-path from ϕ_{A_I} to θ_{A_I} and then start reading q_i from here.The argument for case 3d is similar.

Except for the state-set transitions in case 3 all cases takes constant time. The total time of all the state-set transitions is $O(nm)$. The space of V and the partition together with the labeling uses $O(n)$ space.

String decomposition. Now every substring has a label that is either inner or outer. We then merge adjacent substrings that have the same label. This produces an alternating sequence of inner and outer substrings, which is the final string decomposition. Such an alternating subsequence must always exist since each pair in V intersects an accepting path.

In summary, we have the following result.

▶ **Lemma 3.** *Given string Q of length n, and TNFA A with m states decomposed into A_O and A_I, we can compute a string decomposition wrt. A_I in $O(nm)$ time and $O(n+m)$ space.*

4 Computing Accepting Paths

Let Q be a string of length n accepted by a TNFA A with m states. In this section we show how to compute an accepting path for Q in A in $O(nm)$ time and $O(n+m)$ space. Since an accepting path may have length $\Omega(nm)$ (there may be $\Omega(m)$ ϵ-transitions between each character transition) we cannot afford to explicitly compute the path in our later $o(nm)$ time algorithms. Instead, our algorithm will compute *compressed paths* of size $O(n)$ obtained by deleting all ϵ-transitions from a path. Note that the compressed path stores precisely the information needed to solve the parsing problem.

To compute the compressed path we define a recursive algorithm $\text{Path}(A, Q)$ that takes a TNFA A and a string Q and returns a compressed accepting path in A matching Q as follows. If $n < \gamma_n$ or $m < \gamma_m$, for constants $\gamma_n, \gamma_m > 0$ that we will fix later, we simply run the naive algorithm that stores all state-sets during state-set simulation from left-to-right in Q. Since one of n or m is constant this uses $O(nm) = O(n+m)$ time and space. Otherwise, we proceed according to the following steps.

Step 1: Decompose. We compute a decomposition of A into inner and outer subTNFAs A_I and A_O and compute a corresponding string decomposition $\mathcal{Q} = \overline{q}_1, q_1, \overline{q}_2, q_2, \overline{q}_\ell, q_\ell, \overline{q}_{\ell+1}$ for Q.

Step 2: Recurse. We build a single substring corresponding to all the subpaths in A_O and ℓ substrings for A_I (one for each subpath in A_I) and recursively compute the compressed paths. To do so, construct $\overline{q} = \overline{q}_1 \cdot \beta_{A_I} \cdot \overline{q}_2 \cdot \beta_{A_I} \cdots \beta_{A_I} \cdot \overline{q}_{\ell+1}$. Recall, that β_{A_I} is the label of the special transition we added between θ_{A_I} and ϕ_{A_I}in A_O. Then, recursively compute the compressed paths

$$\begin{aligned} \overline{p} &= \text{Path}(A_O, \overline{q}) \\ p_i &= \text{Path}(A_I, q_i) \qquad 1 \leq i \leq \ell \end{aligned}$$

Step 3: Combine. Finally, extract the subpaths $\overline{p}_1, \overline{p}_2, \ldots, \overline{p}_{\ell+1}$ from $\overline{p}$ corresponding to the substrings $\overline{q}_1, \overline{q}_2, \ldots, \overline{q}_{\ell+1}$ and return the combined compressed path

$$P = \overline{p}_0 \cdot p_1 \cdot \overline{p}_1 \cdot p_2 \cdot \overline{p}_2 \cdots p_\ell \cdot \overline{p}_{\ell+1}$$

Inductively, it directly follows that the returned compressed path is a compressed accepting path for Q in A.

4.1 Analysis

We now show that the total time $T(n,m)$ of the algorithm is $O(nm)$. If $n < \gamma_n$ or $m < \gamma_m$, we run the backtracking algorithm using $O(nm) = O(n+m)$ time and space. If $n \geq \gamma_n$ and $m \geq \gamma_m$, we implement the recursive step of the algorithm using $O(nm)$ time. Let n_i be the length of the inner string q_i in the string decomposition and let $n_0 = \sum_{i=1}^{\ell+1} |\overline{q}_i|$. Thus, $n = \sum_{i=1}^{\ell+1} n_i$ and $|\overline{q}| = n_0 + \ell$. In step 2, the recursive call to compute $\overline{p}$ takes $O(T(n_0{+}\ell, \frac{2}{3}m{+}8))$ time and the recursive calls to compute $p_1, \ldots, p_\ell$ take $\sum_{i=1}^{\ell} T(n_i, \frac{2}{3}m{+}8)$

time. The remaining steps of the algorithm all take $O(nm)$ time. Hence, we have the following recurrence for $T(n, m)$.

$$T(n,m) = \begin{cases} \sum_{i=1}^{\ell} T(n_i, \frac{2}{3}m + 8) + T(n_0 + \ell, \frac{2}{3}m + 8) + O(mn) & m \geq \gamma_m \text{ and } n \geq \gamma_n \\ O(m+n) & m < \gamma_m \text{ or } n < \gamma_n \end{cases}$$

It follows that $T(n, m) = O(nm)$ for $\gamma_n = 2$ and $\gamma_m = 25$ (see full version [5] for a detailed proof).

Next, we consider the space complexity. First, note that the total space for storing R and Q is $O(n + m)$. To analyse the space during the recursive calls of the algorithm, consider the recursion tree $\mathcal{T}_{\text{rec}}$ for $\text{Path}(A, Q)$. For a node v in $\mathcal{T}_{\text{rec}}$, we define Q_v of length n_v to be the string and A_v with m_v states to be the TNFA at v. Consider a path $v_1, \ldots, v_j$ of nodes in $\mathcal{T}_{\text{rec}}$ from the root to leaf v_j corresponding to a sequence of nested recursive calls of the algorithm. If we naively store the subTNFAs, the string decompositions, and the compressed paths, we use $O(n_{v_i} + m_{v_i})$ space at each node v_i, $1 \leq i \leq j$. By Lemma 2(i) the sum of the sizes of the subTNFAs on a path forms a geometrically decreasing sequence and hence the total space for the subTNFAs is $\sum_{i=1}^{j} m_{v_i} = O(m)$. However, since each string (and hence compressed path) at each node v_i, $1 \leq i \leq j$, may have length $\Omega(n)$ we may need $\Omega(n \log m)$ space in total for these. We show how to improve this to $O(n + m)$ space in the next section.

4.2 Squeezing into Linear Space

We now show how to improve the space to $O(n + m)$. To do so we show how to carefully implement the recursion to only store the strings for a selected subset of the nodes along any root to leaf path in $\mathcal{T}_{\text{rec}}$ that in total take no more than $O(n)$ space.

First, consider a node v in $\mathcal{T}_{\text{rec}}$ and the corresponding string Q_v and TNFA A_v. Define χ_v^Q to be the function that maps each character position in Q_v (ignoring β_{A_I} transitions) to the unique corresponding character in Q and χ_v^A to be the function that maps each character transition (non-ϵ transition) in A_v to the unique character transition in A. Note that these are well-defined by the construction of subproblems in the algorithm. At a node v, we represent χ_v^Q by storing for each character in Q_v a pointer to the corresponding character in Q. Similarly, we represent χ_v^A by storing for each character transition in A_v a pointer to the corresponding character transition in A. This uses $O(n_v + m_v)$ additional space. It is straightforward to compute these mappings during the algorithm directly from the string and TNFA decomposition in the same time. With the mappings we can now output transitions on the compressed path as pairs of position in Q and transitions in A immediately as they are computed in a leaf of $\mathcal{T}_{\text{rec}}$. Thus, when we have traversed a full subtree at a node we can free the space for that node since we do not have to wait to return to the root to combine the pieces of the subpath with other subpaths.

We combine the mappings with an ordering of the recursion according to a *heavy-path decomposition* of $\mathcal{T}_{\text{rec}}$. Let v be an internal node in $\mathcal{T}_{\text{rec}}$. The *string length* of v is n_v. We define the *heavy child* of v to be a child of v of maximum string length among the children of v. The remaining children are *light children* of v. We have the following key property of light children (see full version [5] for a proof).

▶ **Lemma 4.** *For any node v with light child u in $\mathcal{T}_{rec}$, we have that $n_u \leq \frac{3}{4}n_v + O(1)$.*

We order the recursive calls at each node v as follows. First, we recursively visit all the light children of v and upon completing each recursive call, we free the space for that node. Note that the mappings allow us to do this. We then construct the subproblem for the heavy child of v, free the space for v, and continue the recursion at the heavy child.

To analyse the space of the modified algorithm, consider a path a path $v_1, \ldots, v_j$ of nodes in $\mathcal{T}_{\text{rec}}$ from the root to a leaf v_j. We now have that only nodes v_i, $1 \leq i < j$ will explicitly store a string if v_{i+1} is a light child of v_i. By Lemma 4 the sum of these lengths form a geometrically decreasing sequence and hence the total space is now $O(n)$. In summary, we have shown the following result.

▶ **Theorem 5.** *Given a TNFA with m states and a string of length n, we can compute a compressed accepting path for Q in A in $O(nm)$ time and $O(n + m)$ space.*

Note that the algorithm works in a comparison-based, pointer model of computation. By our discussion this immediately implies the main result of Theorem 1.

5 Speeding up the Algorithm

We now show how to adapt the algorithm to use the faster state-set simulation algorithms such as Myers' algorithm [22] and later variants [4, 3] that improve the $O(m)$ bound for a single state-set transition. These results and ours all work on a unit-cost word RAM model of computation with w-bit words and a standard instruction set including addition, bitwise boolean operations, shifts, and multiplication. We can store a pointer to any position in the input and hence $w \geq \log(n + m)$. For simplicity, we will show how to adapt the tabulation-based algorithm of Bille and Farach-Colton [4].

5.1 Fast Matching

Let A be a TNFA with m states and let Q be a string of length n. Assume first that the alphabet is constant. We briefly describe the main features of the algorithm by Bille and Farach-Colton [4] that solves the matching problem in $O(nm/\log n + n + m)$ time and $O(n^{\varepsilon} + m)$ space, for any constant $\varepsilon > 0$. In the next section we show how to adapt the algorithm to compute an accepting path.

Given a parameter $t < w$, we will construct a global table of size $2^{ct} < 2^{w}$, for a constant c, to speed up the state-set transition. We decompose A into a tree MS of $O(\lceil m/t \rceil)$ micro TNFAs, each with at most t states. For each $M \in MS$, each child C is represented by its start and accepting state and a pseudo-transition connecting these. By similar arguments as in Lemma 2 we can always construct such a decomposition.

We represent each micro TNFA $M \in MS$ uniquely by its parse tree using $O(t)$ bits. Since M has at most t states, we can represent the state-set for M, called the *local state-set* and denoted S_M, using t bits. Hence, we can make a universal table of size $2^{O(t)}$ that for every possible micro TNFA M of size $\leq t$, local state-set S_M, and character $\alpha \in \Sigma \cup \{\epsilon\}$ computes the state-set transition $\delta_M(S_M, \alpha)$ in constant time.

We use the tabulation to efficiently implement a global state-set transition on A as follows. We represent the state-set for A as the union of the local state-sets in MS. Note that parents and children in MS share some local states, and these states will be copied in the local state-sets.

To implement a state-set transition on A for a character α, we first traverse all transitions labeled α in each micro TNFA from the current state-set. We then follow paths of ϵ transition in two depth-first left-to-right traversal of MS. At each micro TNFA M, we compute all states reachable via ϵ-transitions and propagate the shared states among parents and children in MS. Since any cycle free path in a TNFA contains at most one *back transition* (see [22, Lemma 1]) it follows that two such traversals suffices to to correctly compute all states in A reachable via ϵ-transitions.

With the universal table, we process each micro TNFA in constant time, leading to an algorithm using $O(|MS|/t + n + m) = O(nm/t + n + m)$ time and $O(2^t + m)$ space. Setting $t = \varepsilon \log n$ produces the stated result. Note that each state-set uses $O(\lceil m/t \rceil)$ space. To handle general alphabets, we store dictionaries for each micro TNFA with bit masks corresponding to characters appearing in the TNFA and combine these with an additional masking step in state-set transition. The leads a general solution with the same time and space bounds as above.[3]

5.2 Fast Parsing

We now show how to modify our algorithm from Section 4 to take advantage of the fast state-set transition algorithm. Let $t < w$ be the desired speed up as above. We have the following two cases.

If $n \geq t$ and $m \geq t$ we implement the recursive step of the algorithm but replace all state-set transitions, that is when we compute the match sets and valid pairs, by the fast state-set transition algorithm. To compute the suffix match sets we need to compute fast state-set transitions on A with the direction of all transitions reversed. To do so, we make a new universal table of size $2^{O(t)}$ for the micro TNFAs with the direction of transitions reversed. We traverse the tree of micro TNFAs with two depth traversals as before except that we now traverse children in right to left order to correctly compute all reachable states. It follows that this uses $O(nm/t)$ time.

Otherwise ($n < t$ or $m < t$), we use backtracking to compute the accepting path as follows. First, we process Q from left-to-right using fast state-set transitions to compute the sets $S_0, \ldots, S_n$ of states reachable via paths from θ_A for each prefix of Q. We store each of these state-sets. This uses $O(nm/t + n + m) = O(n + m)$ time and space. Then, we process Q from right-to-left to recover a compressed accepting path in A. Starting from ϕ_A we repeatedly do a fast state-set transition A with the direction of transition reversed, compute the intersection of the resulting state-set with the corresponding state-set from the first step, and update the state-set to a state in the intersection. We can compute the intersection of state-sets and the update in $O(m/t)$ time using standard bit wise operations. We do the state-set transitions on the TNFA with directions of transitions reversed as above. In total, this uses $O(nm/t + n + m) = O(n + m)$ time.

In summary, we have the following recurrence for the time $T(n, m)$.

$$T(n,m) = \begin{cases} \sum_{i=0}^{\ell} T(n_i, \frac{2}{3}m + 8) + T(n_0 + \ell, \frac{2}{3}m + 8) + O\left(\frac{nm}{t}\right) & n \geq t \text{ and } m \geq t \\ O\left(n + m\right) & m < t \text{ or } n < t \end{cases}$$

Similar to Section 4.1 it follows that $T(n, m) = O(nm/t + n + m)$, for $25 \leq t < w$. The space is linear as before. Plugging in $t = \epsilon \log n$ and including the preprocessing time and space for the universal tables we obtain the following logarithmic improvement of Theorem 1.

► **Theorem 6.** *Given a regular expression of length m, a string of length n, we can solve the regular expression parsing problem in $O(nm/\log n + n + m)$ time and $O(n + m)$ space.*

[3] Note that the time bound in the original paper has an additional $m \log m$ term [4]. Using atomic heaps [9] to represent dictionaries for micro TNFAs this term is straightforward to improve to $O(m)$. See also Bille and Thorup [6, Appendix A].

Abstract

Recently, M. Kompatscher proved that for each finite supernilpotent algebra $\mathbf{A}$ in a congruence modular variety, there is a polynomial time algorithm to solve polynomial equations over this algebra. Let μ be the maximal arity of the fundamental operations of $\mathbf{A}$, and let

$$d := |A|^{\log_2 \mu + \log_2 |A| + 1}.$$

Applying a method that G. Károlyi and C. Szabó had used to solve equations over finite nilpotent rings, we show that for $\mathbf{A}$, there is $c \in \mathbb{N}$ such that a solution of every system of s equations in n variables can be found by testing at most cn^{sd} (instead of all $|A|^n$ possible) assignments to the variables. This also yields new information on some circuit satisfiability problems.

Acknowledgements The author thanks G. Horváth and M. Kompatscher for dicussions on solving equations over nilpotent algebras. Several of these discussions took place during a workshop organized by P. Aglianò at the University of Siena in June 2018. The author also thanks A. Földvári, C. Szabó, M. Kompatscher, and S. Kreinecker for their comments on preliminary versions of the manuscript, and the anonymous referees for several useful suggestions.

1 Introduction

We study systems of polynomial equations over a finite algebraic structure $\mathbf{A}$. Such a system is given by equations of the form $p(x_1, \dots, x_n) \approx q(x_1, \dots, x_n)$, where p, q are polynomial terms of $\mathbf{A}$; a polynomial term of $\mathbf{A}$ is a term of the algebra $\mathbf{A}^*$ which is obtained by expanding $\mathbf{A}$ with one nullary function symbol for each $a \in A$. A *solution* to a system $p_i(x_1, \dots, x_n) \approx q_i(x_1, \dots, x_n)$ $(i = 1, \dots, s)$ is an element $\boldsymbol{a} = (a_1, \dots, a_n) \in A^n$ such that $p_i^{\mathbf{A}}(\boldsymbol{a}) = q_i^{\mathbf{A}}(\boldsymbol{a})$ for all $i \in \{1, \dots, s\}$. The problem to decide whether such a solution exists has been called PolSysSat($\mathbf{A}$), and PolSat($\mathbf{A}$) if the system consists of one single equation, and the terms of the input are encoded as strings over $\{x_1, \dots, x_n\} \cup A \cup F$, where F is the set of function symbols of $\mathbf{A}$. A survey of results on the computational complexity of this problem is given, e.g., in [13, 17]. In algebras such as groups, rings or Boolean algebras, one can reduce an equation $p(\boldsymbol{x}) \approx q(\boldsymbol{x})$ to an equation of the form $f(\boldsymbol{x}) \approx y$, where $y \in A$. A system of equations of this form then has the form $f_i(\boldsymbol{x}) \approx y_i$ $(i = 1, \dots, s)$. For $n \in \mathbb{N}$, let $\mathrm{Pol}_n(\mathbf{A})$ denote the n-ary polynomial functions on $\mathbf{A}$ [19, Definition 4.4]. For a finite

nilpotent ring or group $\mathbf{A}$, [10, 12] establish the existence of a natural number $d_{\mathbf{A}}$ such that for every $f \in \mathrm{Pol}_n(\mathbf{A})$ and for every $\boldsymbol{a} \in A^n$, there exists $\boldsymbol{b}$ such that $f^{\mathbf{A}}(\boldsymbol{a}) = f^{\mathbf{A}}(\boldsymbol{b})$ and $\boldsymbol{b}$ has at most $d_{\mathbf{A}}$ components that are different from 0. Hence the equation $f(\boldsymbol{x}) \approx y$ has a solution if and only if it has a solution with at most $d_{\mathbf{A}}$ nonzero entries. Thus for the algebra $\mathbf{A}$, testing only vectors with at most $d_{\mathbf{A}}$ nonzero entries is an algorithm, which, given an equation $f(\boldsymbol{x}) \approx y$ of length n, takes at most $c(\boldsymbol{A}) \cdot n^{d_{\mathbf{A}}+1}$ many steps to find whether this equation is solvable: there are at most $\sum_{i=0}^{d_{\mathbf{A}}} \binom{n}{i}(|A|-1)^i \leq c_1(\mathbf{A}) \cdot n^{d_{\mathbf{A}}}$ many evaluations to be done, each of them taking at most $c_2(\mathbf{A}) \cdot n$ many steps. The number $d_{\mathbf{A}}$ in [12] is obtained from Ramsey's Theorem and therefore rather large. In [17], it is proved that for every finite supernilpotent algebra in a congruence modular variety, such a number $d_{\mathbf{A}}$ exists, again using Ramsey's Theorem. For rings, lower values of $d_{\mathbf{A}}$ have been obtained in [15] (cf. [14]). In [7, 8], A. Földvári provides polynomial time algorithms for solving equations over finite nilpotent groups and rings relying on the structure theory of these algebras. In this paper, we extend the method developed in [15] from finite nilpotent rings to arbitrary finite supernilpotent algebras in congruence modular varieties. For such algebras, we compute $d_{\mathbf{A}}$ as $|A|^{\log_2 \mu + \log_2 |A| + 1}$, where μ is the maximal arity of the fundamental operations of $\mathbf{A}$ (Theorem 10). The technique that allows to generalize Károlyi's and Szabó's method is the coordinatization of nilpotent algebras of prime power order by elementary abelian groups from [1, Theorem 4.2]. The method can be generalized to systems of equations: we show for a given finite supernilpotent algebra $\mathbf{A}$ in a congruence modular variety, and a given $s \in \mathbb{N}_0$, there is a polynomial time algorithm to test whether a system of at most s polynomial equations over $\mathbf{A}$ has a solution. If s is not fixed in advance, then [18, Corollary 3.13] implies that if $\mathbf{A}$ is not abelian, PolSysSat($\mathbf{A}$) is NP-complete.

Let us finally explain to which class of algebras our results applies: A finite algebra $\mathbf{A}$ from a congruence modular variety with finitely many fundamental operations is supernilpotent if and only if it is a direct product of nilpotent algebras of prime power order; modulo notational differences explained, e.g., in [1, Lemma 2.4], this result has been proved in [16, Theorem 3.14]. Such an algebra is therefore always nilpotent, has a Mal'cev term (cf. [9, Theorem 6.2], [16, Theorem 2.7]), and hence generates a congruence permutable variety. For a more detailed introduction to supernilpotency and, for $k \in \mathbb{N}$, to k-supernilpotency, we refer to [2, 3, 1].

2 A theorem of Károlyi and Szabó

In this section, we state a special case of [15, Theorem 3.1]. Since their result is much more general than needed for our purpose, we also include a self-contained proof, which is a reduction Károlyi's and Szabó's proof to the case of elementary abelian groups.

For $n \in \mathbb{N} = \{1, 2, 3, \ldots\}$, we denote the set $\{1, 2, \ldots, n\}$ by $\underline{n}$. Let A be a set with an element $0 \in A$, and let $J \subseteq \underline{n}$. For $\boldsymbol{a} \in A^n$, $\boldsymbol{a}^{(J)}$ is defined by $\boldsymbol{a}^{(J)} \in A^n$, $\boldsymbol{a}^{(J)}(j) = \boldsymbol{a}(j)$ for $j \in J$ and $\boldsymbol{a}^{(J)}(j) = 0$ for $j \in \underline{n} \setminus J$. Suppose that 1 is an element of A. Then by $\boldsymbol{1}$, we denote the vector $(1, 1, \ldots, 1)$ in A^n, and for $J \subseteq \underline{n}$, $\boldsymbol{1}^{(J)}$ is the vector $(v_1, \ldots, v_n)$ with $v_j = 1$ if $j \in J$ and $v_j = 0$ if $j \notin J$. For any sets C, D, we write $C \subset D$ for ($C \subseteq D$ and $C \neq D$).

We first need the following variation of [5, Theorem 1] and [15, Theorem 3.2], which is proved using several arguments from the proof of [4, Theorem 3.1] and from [5].

▶ **Lemma 1.** *Let F be a finite field, let $k, m, n \in \mathbb{N}$, let $q := |F|$, let $p_1, \ldots, p_m \in F[x_1, \ldots, x_n]$ be polynomials such that for each $i \in \underline{m}$, each monomial of p_i contains at most k variables. Then there exists $J \subseteq \underline{n}$ such that $|J| \leq km(q-1)$ and $p_i(\boldsymbol{1}^{(J)}) = p_i(\boldsymbol{1})$ for all $i \in \underline{m}$.*

Proof. We proceed by induction on n. If $n \le km(q-1)$, then we take $J := \underline{n}$. For the induction step, we assume that $n > km(q-1)$.

We first produce a set $J_1 \subset \underline{n}$ such that $p_i(\boldsymbol{1}^{(J_1)}) = p_i(\boldsymbol{1})$ for all $i \in \underline{m}$. Seeking a contradiction, we suppose that no such J_1 exists. Following an idea from the proof of [4, Theorem 3.1], we consider the polynomials

$$\begin{array}{lcl} q_1(x_1,\dots,x_n) & := & \prod_{i=1}^{m}(1-(p_i(\boldsymbol{x})-p_i(\boldsymbol{1}))^{q-1}), \\ q_2(x_1,\dots,x_n) & := & x_1x_2\cdots x_n - q_1(x_1,\dots,x_n). \end{array}$$

We first show that for all $\boldsymbol{a} \in \{0,1\}^n$, $q_2(\boldsymbol{a}) = 0$. To this end, we first consider the case $\boldsymbol{a} = \boldsymbol{1}$. Then $q_2(\boldsymbol{a}) = 1 - \prod_{i=1}^{m} 1 = 0$. If $\boldsymbol{a} \in \{0,1\}^n \setminus \{\boldsymbol{1}\}$, then by the assumptions, there is $i \in \underline{m}$ such that $p_i(\boldsymbol{a}) \neq p_i(\boldsymbol{1})$. Then $1 - (p_i(\boldsymbol{a}) - p_i(\boldsymbol{1}))^{q-1} = 0$. Therefore $q_2(\boldsymbol{a}) = 0$. Hence the polynomial q_2 vanishes at $\{0,1\}^n$. By the Combinatorial Nullstellensatz [4, Theorem 1.1] applied to $g_j(x_j) := x_j^2 - x_j$, q_2 then lies in the ideal V of $F[x_1,\dots,x_n]$ generated by $G = \{x_j^2 - x_j \mid j \in \underline{n}\}$. Hence $x_1x_2\cdots x_n - q_1(x_1,\dots,x_n) \in V$. Since the leading monomials of the polynomials in G are coprime, G is a Gröbner basis of V (with respect to $x_1 > x_2 > \cdots > x_n$, lexicographic order, cf. [6, p.337]). Therefore, reducing $q_1(x_1,\dots,x_n)$ modulo G, we must obtain $x_1x_2\cdots x_n$ as the remainder (as defined, e.g., in [6, p.334]). Because of the form of all polynomials in G (all variables of g_j occur in the leading term of g_j), none of the reduction steps increases the number of variables in any monomial. Therefore, $q_1(x_1,\dots,x_n)$ must contain a monomial that contains all n variables. Computing the expansion of q_1 by multiplying out all products from its definition, we see that each monomial in q_1 contains at most $km(q-1)$ variables. Hence $n \le km(q-1)$, which contradicts the assumption $n > km(q-1)$. This contradiction shows that there is a set $J_1 \subset \underline{n}$ such that $p_i(\boldsymbol{1}^{(J_1)}) = p_i(\boldsymbol{1})$ for all $i \in \underline{m}$. Now we let $n' := |J_1|$, and we assume that $J_1 = \{j_1,\dots,j_{n'}\}$ with $j_1 < \cdots < j_{n'}$. For $i \in \underline{m}$, we define $p_i' \in F[y_1,\dots,y_{n'}]$ by

$$p_i'(x_{j_1},\dots,x_{j_{n'}}) = p_i(\boldsymbol{x}^{(J_1)}).$$

By the induction hypothesis, there exists $J_2 \subseteq \underline{n'}$ with $|J_2| \le km(q-1)$ such that $p_i'(\boldsymbol{1}^{(J_2)}) = p_i'(\boldsymbol{1})$ for all $i \in \underline{m}$. Now we define $J := \{j_t \mid t \in J_2\}$. We have $J \subseteq J_1$, and therefore $\boldsymbol{1}^{(J)} = (\boldsymbol{1}^{(J)})^{(J_1)}$. Then $p_i(\boldsymbol{1}^{(J)}) = p_i((\boldsymbol{1}^{(J)})^{(J_1)}) = p_i'(\boldsymbol{1}^{(J)}(j_1),\dots,\boldsymbol{1}^{(J)}(j_{n'})) = p_i'(\boldsymbol{1}^{(J_2)}) = p_i'(\boldsymbol{1}) = p_i(\boldsymbol{1}^{(J_1)}) = p_i(\boldsymbol{1})$, which completes the induction step. ◀

We will need the following special case of [15, Theorem 3.1]. For a set U, let $\mathcal{P}_{\le k}(U)$ denote the set $\{I \subseteq U : |I| \le k\}$ of subsets of U with at most k elements.

▶ **Theorem 2** (cf. [15, Theorem 3.1]). *Let $n \in \mathbb{N}$, let $k \in \mathbb{N}_0$, let p be a prime, and let $m \in \mathbb{N}$. Let $\varphi : \mathcal{P}_{\le k}(\underline{n}) \to \mathbb{Z}_p^m$. Then there is $U \subseteq \underline{n}$ with $|U| \le km(p-1)$ such that*

$$\sum_{J \in \mathcal{P}_{\le k}(\underline{n})} \varphi(J) = \sum_{J \in \mathcal{P}_{\le k}(U)} \varphi(J).$$

Proof. We denote the vector $\varphi(J)$ by $((\varphi(J))_1,\dots,(\varphi(J))_m)$, and we define m polynomial functions $f_1,\dots,f_m \in \mathbb{Z}_p[x_1,\dots,x_n]$ by

$$f_i(x_1,\dots x_n) := \sum_{J \in \mathcal{P}_{\le k}(\underline{n})} \big((\varphi(J))_i \cdot \prod_{j \in J} x_j\big).$$

for $i \in \underline{m}$. By Lemma 1, there is a subset U of $\underline{n}$ with $|U| \le km(p-1)$ such that for all $i \in \underline{m}$, we have $f_i(\boldsymbol{1}) = f_i(\boldsymbol{1}^{(U)})$. Hence $\sum_{J \in \mathcal{P}_{\le k}(\underline{n})} (\varphi(J))_i = f_i(\boldsymbol{1}) = f_i(\boldsymbol{1}^{(U)}) = \sum_{J \in \mathcal{P}_{\le k}(\underline{n}), J \subseteq U} (\varphi(J))_i = \sum_{J \in \mathcal{P}_{\le k}(U)} (\varphi(J))_i$. ◀

3 Absorbing components

Let A be a set, let 0_A be an element of A, let $\mathbf{B} = (B, +, -, 0)$ be an abelian group, let $n \in \mathbb{N}$, let $f : A^n \to B$, and let $I \subseteq \underline{n}$. By $\operatorname{Dep}(f)$ we denote the set $\{i \in \underline{n} \mid f \text{ depends on its } i\text{th argument}\}$. We say that f is *absorbing in its j th argument* if for all $\boldsymbol{a} = (\boldsymbol{a}(1), \dots, \boldsymbol{a}(n)) \in A^n$ with $\boldsymbol{a}(j) = 0_A$ we have $f(\boldsymbol{a}) = 0$. In the sequel, we will denote 0_A simply by 0. We say that f is *absorbing in I* if $\operatorname{Dep}(f) \subseteq I$ and for every $i \in I$, f is absorbing in its i th argument.

▶ **Lemma 3.** *Let A be a set, let 0 be an element of A, let $\mathbf{B} = (B, +, -, 0)$ be an abelian group, let $n \in \mathbb{N}$, and let $f : A^n \to B$. Then there is exactly one sequence $(f_I)_{I \subseteq \underline{n}}$ of functions from A^n to B such that for each $I \subseteq \underline{n}$, f_I is absorbing in I and $f = \sum_{I \subseteq \underline{n}} f_I$. Furthermore, each function f_I lies in the subgroup $\mathbf{F}$ of $\mathbf{B}^{A^n}$ that is generated by the functions $\boldsymbol{x} \mapsto f(\boldsymbol{x}^{(I)})$, where $I \subseteq \underline{n}$.*

Proof. We first prove the existence of such a sequence. To this end, we define f_I by recursion on $|I|$. We define $f_\varnothing(\boldsymbol{a}) := f(0, \dots, 0)$ and for $I \neq \varnothing$, we let

$$f_I(\boldsymbol{a}) := f(\boldsymbol{a}^{(I)}) - \sum_{J \subset I} f_J(\boldsymbol{a}).$$

By induction on $|I|$, we see that $\operatorname{Dep}(f_I) \subseteq I$ and that f_I lies in the subgroup $\mathbf{F}$. We will now show that each f_I is absorbing in I, and we again proceed by induction on $|I|$. Let $i \in I$, and let $\boldsymbol{a} \in A^n$ be such that $\boldsymbol{a}(i) = 0$. We have to show $f_I(\boldsymbol{a}) = 0$. We compute $f_I(\boldsymbol{a}) = f(\boldsymbol{a}^{(I)}) - \sum_{J \subset I} f_J(\boldsymbol{a})$. By the induction hypothesis, we have $f_J(\boldsymbol{a}) = 0$ for those J with $i \in J$. Hence $f(\boldsymbol{a}^{(I)}) - \sum_{J \subset I} f_J(\boldsymbol{a}) = f(\boldsymbol{a}^{(I)}) - \sum_{J \subseteq I \setminus \{i\}} f_J(\boldsymbol{a})$, and because of $\boldsymbol{a}^{(I)} = \boldsymbol{a}^{(I \setminus \{i\})}$, this is equal to $f(\boldsymbol{a}^{(I \setminus \{i\})}) - \sum_{J \subseteq I \setminus \{i\}} f_J(\boldsymbol{a}) = f(\boldsymbol{a}^{(I \setminus \{i\})}) - \sum_{J \subset I \setminus \{i\}} f_J(\boldsymbol{a}) - f_{I \setminus \{i\}}(\boldsymbol{a})$. By the definition of $f_{I \setminus \{i\}}$, the last expression is equal to $f_{I \setminus \{i\}}(\boldsymbol{a}) - f_{I \setminus \{i\}}(\boldsymbol{a}) = 0$. This completes the induction proof; hence each f_I is absorbing in I. In order to show $f = \sum_{I \subseteq \underline{n}} f_I$, we choose $\boldsymbol{a} \in A^n$ and compute $\sum_{I \subseteq \underline{n}} f_I(\boldsymbol{a}) = f_{\underline{n}}(\boldsymbol{a}) + \sum_{I \subset \underline{n}} f_I(\boldsymbol{a}) = f(\boldsymbol{a}^{(\underline{n})}) - \sum_{J \subset \underline{n}} f_J(\boldsymbol{a}) + \sum_{I \subset \underline{n}} f_I(\boldsymbol{a}) = f(\boldsymbol{a})$. This completes the proof of the existence of such a sequence.

For the uniqueness, assume that $f = \sum_{I \subseteq \underline{n}} f_I = \sum_{I \subseteq \underline{n}} g_I$ and that for all I, f_I and g_I are absorbing in I. We show by induction on $|I|$ that $f_I = g_I$. Let $I := \varnothing$. First we notice that $f(0, \dots, 0) = \sum_{J \subseteq \underline{n}} f_J(0, \dots, 0) = \sum_{J \subseteq \underline{n}} g_J(0, \dots, 0)$. Since f_J and g_J are absorbing, the summands with $J \neq \varnothing$ are 0, and thus $f_\varnothing(0, \dots, 0) = \sum_{J \subseteq \underline{n}} f_J(0, \dots, 0) = f(0, \dots, 0) = \sum_{J \subseteq \underline{n}} g_J(0, \dots, 0) = g_\varnothing(0, \dots, 0)$. Since both $f_\varnothing$ and $g_\varnothing$ are constant functions, they are equal. For the induction step, we assume $|I| \geq 1$. Let $\boldsymbol{a} \in A^n$. Then $\sum_{J \subseteq \underline{n}} f_J(\boldsymbol{a}^{(I)}) = \sum_{J \subseteq \underline{n}} g_J(\boldsymbol{a}^{(I)})$. Only the summands with $J \subseteq I$ can be nonzero, and therefore $\sum_{J \subseteq I} f_J(\boldsymbol{a}^{(I)}) = \sum_{J \subseteq I} g_J(\boldsymbol{a}^{(I)})$. By the induction hypothesis, $f_J = g_J$ for $J \subset I$. Therefore, $f_I(\boldsymbol{a}^{(I)}) = g_I(\boldsymbol{a}^{(I)})$. Since f_I and g_I depend only on the arguments at positions in I, we obtain $f_I(\boldsymbol{a}) = f_I(\boldsymbol{a}^{(I)}) = g_I(\boldsymbol{a}^{(I)}) = g_I(\boldsymbol{a})$. Thus $f_I = g_I$. ◀

Actually, the component f_I can be computed by $f_I(\boldsymbol{a}) = \sum_{J \subseteq I} (-1)^{|I|+|J|} f(\boldsymbol{a}^{(J)})$.

▶ **Definition 4.** *Let A be a set, let 0 be an element of A, let $\mathbf{B} = (B, +, -, 0)$ be an abelian group, let $n \in \mathbb{N}$, let $f : A^n \to B$, and let $J \subseteq \underline{n}$. Then we call the sequence $(f_I)_{I \subseteq \underline{n}}$ such that for each $I \subseteq \underline{n}$, f_I is absorbing in I, and $f = \sum_{I \subseteq \underline{n}} f_I$ the* absorbing decomposition *of f, and f_J the J-*absorbing component *of f. We define the* absorbing degree *of f by $\operatorname{adeg}(f) := \max\left(\{-1\} \cup \{|J| : J \subseteq \underline{n} \text{ and } f_J \neq 0\}\right)$.*

▶ **Theorem 5.** *Let A be a set, let 0 be an element of A, let p be a prime, let $k \in \mathbb{N}_0$, let $n \in \mathbb{N}$, and let $f_1, \dots, f_m : A^n \to \mathbb{Z}_p$. We assume that each f_i is of absorbing degree at most k. Let $\boldsymbol{a} \in A^n$. Then there is U with $|U| \le km(p-1)$ such that for all $i \in \underline{m}$, we have $f_i(\boldsymbol{a}) = f_i(\boldsymbol{a}^{(U)})$.*

Proof. We define a function $\varphi : \mathcal{P}_{\le k}(\underline{n}) \to \mathbb{Z}_p^m$ by $\varphi(J) := ((f_1)_J(\boldsymbol{a}), \dots, (f_m)_J(\boldsymbol{a}))$, where for $i \in \underline{m}$, $\big((f_i)_J\big)_{J \subseteq \underline{n}}$ is the absorbing decomposition of f_i. Then Theorem 2 yields a subset U of $\underline{n}$ with $|U| \le km(p-1)$ such that $\sum_{J \in \mathcal{P}_{\le k}(\underline{n})} \varphi(J) = \sum_{J \in \mathcal{P}_{\le k}(U)} \varphi(J)$. Since $(f_i)_J = 0$ for all J with $|J| > k$, we have $\sum_{J \in \mathcal{P}_{\le k}(\underline{n})} \varphi(J) = \sum_{J \in \mathcal{P}_{\le k}(\underline{n})} ((f_1)_J(\boldsymbol{a}), \dots, (f_m)_J(\boldsymbol{a})) = \sum_{J \subseteq \underline{n}} ((f_1)_J(\boldsymbol{a}), \dots, (f_m)_J(\boldsymbol{a})) = (f_1(\boldsymbol{a}), \dots, f_m(\boldsymbol{a}))$ and

$$\begin{aligned}\sum_{J \in \mathcal{P}_{\le k}(U)} \varphi(J) &= \sum_{J \in \mathcal{P}_{\le k}(U)} ((f_1)_J(\boldsymbol{a}), \dots, (f_m)_J(\boldsymbol{a})) \\ &= \sum_{J \subseteq U} ((f_1)_J(\boldsymbol{a}), \dots, (f_m)_J(\boldsymbol{a})) = \sum_{J \subseteq U} ((f_1)_J(\boldsymbol{a}^{(U)}), \dots, (f_m)_J(\boldsymbol{a}^{(U)})) \\ &= \sum_{J \subseteq \underline{n}} ((f_1)_J(\boldsymbol{a}^{(U)}), \dots, (f_m)_J(\boldsymbol{a}^{(U)})) = (f_1(\boldsymbol{a}^{(U)}), \dots, f_m(\boldsymbol{a}^{(U)})).\end{aligned}$$

◀

4 Polynomial mappings

In this section, we develop a property of polynomial mappings of finite supernilpotent algebras in congruence modular varieties. We call an algebra $\mathbf{A} = (A, +, -, 0, (f_i)_{i \in S})$ an *expanded group* if its reduct $\mathbf{A}^+ = (A, +, -, 0)$ is a group, an *expanded abelian group* if $\mathbf{A}^+$ is an abelian group, and an *expanded elementary abelian group* if $\mathbf{A}^+$ is elementary abelian, meaning that $\mathbf{A}^+$ is abelian and all its nonzero elements have the same prime order.

▶ **Lemma 6.** *Let $k, n \in \mathbb{N}$, let $\mathbf{A}$ be a k-supernilpotent expanded abelian group, and let $f \in \mathrm{Pol}_n(\mathbf{A})$. Then f is of absorbing degree at most k.*

Proof. Let $J \subseteq \underline{n}$ with $|J| > k$, and let f_J be the J-absorbing component of f. Let $m := |J|$ and let $J = \{i_1, \dots, i_m\}$. Using Lemma 3, we obtain that the function $g : A^m \to A$ defined by $g(a_{i_1}, \dots, a_{i_m}) := f_J(\mathbf{a})$ for $\mathbf{a} \in A^n$ is an absorbing function in $\mathrm{Pol}_m(\mathbf{A})$. Hence [1, Lemma 2.3] and the remark immediately preceding that Lemma yield that g is the zero function. Thus $f_J = 0$. Hence the absorbing degree of f is at most k. ◀

We first consider polynomial mappings of supernilpotent expanded elementary abelian groups of prime power order.

▶ **Theorem 7.** *Let $k, n, s, \alpha \in \mathbb{N}$, let $p \in \mathbb{P}$, and let $\mathbf{A}$ be a k-supernilpotent expanded elementary abelian group of order p^α. Let $F = (f_1, \dots, f_s) \in \mathrm{Pol}_n(\mathbf{A})^s$, and let $\boldsymbol{a} \in A^n$. Then there is $U \subseteq \underline{n}$ with $|U| \le ks\alpha(p-1)$ such that $F(\boldsymbol{a}) = F(\boldsymbol{a}^{(U)})$.*

Proof. We let π be a group isomorphism from $(A, +, -, 0)$ to $\mathbb{Z}_p^\alpha$, and for $a \in A$, we denote $\pi(a)$ by $(\pi_1(a), \dots, \pi_\alpha(a))$. For each $r \in \underline{s}$ and each $\beta \in \underline{\alpha}$, let $f_{r,\beta} : A^n \to \mathbb{Z}_p$ be defined by $f_{r,\beta}(\boldsymbol{a}) = \pi_\beta(f_r(\boldsymbol{a}))$; hence $f_{r,\beta}(\boldsymbol{a})$ is the βth component of $f_r(\boldsymbol{a})$. Since $f_r \in \mathrm{Pol}_n(\mathbf{A})$ and $\mathbf{A}$ is k-supernilpotent, Lemma 6 implies that each of these $f_{r,\beta}$ is of absorbing degree at most k. Setting $m := s\alpha$, Theorem 5 yields U with $|U| \le ks\alpha(p-1)$ such that $f_{r,\beta}(\boldsymbol{a}) = f_{r,\beta}(\boldsymbol{a}^{(U)})$ for all $r \in \underline{s}$ and $\beta \in \underline{\alpha}$. Then clearly $F(\boldsymbol{a}) = F(\boldsymbol{a}^{(U)})$. ◀

We apply this result to polynomial mappings of *direct products* of finite supernilpotent expanded elementary abelian groups. For a vector $\boldsymbol{a} \in A^n$, we call the number of its nonzero entries the *weight* of $\mathbf{a}$; formally, $\mathrm{wt}(\boldsymbol{a}) := |\{j \in \underline{n} : \boldsymbol{a}(j) \neq 0\}|$.

▶ **Theorem 8.** *Let $n, s, t, k_1, \dots, k_t \in \mathbb{N}$. For each $i \in \underline{t}$, let $\mathbf{B}_i$ a k_i-supernilpotent expanded elementary abelian group with $|\mathbf{B}_i| = p_i^{\alpha_i}$, where p_i is a prime and $\alpha_i \in \mathbb{N}$. Let $\mathbf{A} := \prod_{i=1}^{t} \mathbf{B}_i$, let $F \in \mathrm{Pol}_n(\mathbf{A})^s$, and let $\boldsymbol{a} \in A^n$. Then there is $\boldsymbol{y} \in A^n$ with $\mathrm{wt}(\boldsymbol{y}) \leq \sum_{i=1}^{t} k_i s \alpha_i (p_i - 1)$ such that $F(\boldsymbol{a}) = F(\boldsymbol{y})$.*

Proof. For $i \in \underline{t}$, let ν_i be the ith projection kernel. Applying Theorem 7 to $\mathbf{A}/\nu_i$, which is isomorphic to $\mathbf{B}_i$, and $\boldsymbol{b} := \boldsymbol{a}/\nu_i$, we obtain $U_i \subseteq \underline{n}$ with $|U_i| \leq k_i s \alpha_i (p_i - 1)$ such that $F^{\mathbf{A}/\nu_i}(\boldsymbol{b}^{(U_i)}) = F^{\mathbf{A}/\nu_i}(\boldsymbol{b})$. Lifting $\boldsymbol{b}^{(U_i)}$ to A, we obtain $(x_{i,1}, \dots, x_{i,n}) \in A^n$ such that $(x_{i,1}, \dots, x_{i,n})/\nu_i = \boldsymbol{b}^{(U_i)}$ and $x_{i,j} = 0$ for $j \in \underline{n} \setminus U_i$. Now for every $j \in \underline{n}$, we define $y_j \in A$ by the equations

$$y_j \equiv_{\nu_i} x_{i,j} \text{ for all } i \in \underline{t}.$$

For each $i \in \underline{t}$, we have $F(y_1, \dots, y_n)/\nu_i = F^{\mathbf{A}/\nu_i}(x_{i,1}/\nu_i, \dots, x_{i,n}/\nu_i) = F^{\mathbf{A}/\nu_i}(\boldsymbol{b}^{(U_i)}) = F^{\mathbf{A}/\nu_i}(\boldsymbol{b}) = F^{\mathbf{A}/\nu_i}(\boldsymbol{a}/\nu_i) = F(\boldsymbol{a})/\nu_i$. Hence $F(\boldsymbol{y}) = F(\boldsymbol{a})$. For $j \in \underline{n} \setminus (U_1 \cup \dots \cup U_t)$, and for all $i \in \underline{t}$, we have $x_{i,j} = 0$, and therefore $y_j = 0$. Hence the number of nonzero entries in $\boldsymbol{y}$ is at most $\sum_{i=1}^{t} |U_i| \leq \sum_{i=1}^{t} k_i s \alpha_i (p_i - 1)$. ◀

Now we consider *arbitrary* finite supernilpotent algebras in congruence modular varieties. In these algebras, we can introduce group operations preserving nilpotency using [1].

▶ **Lemma 9.** *Let $\mu \in \mathbb{N}$, let $\mathbf{A} = (A, (f_i)_{i \in S})$ be a finite supernilpotent algebra in a congruence modular variety all of whose fundamental operations have arity at most μ, and let $z \in A$. Let $t \in \mathbb{N}_0$, let $p_1, \dots, p_t$ be different primes, and let $\alpha_1, \dots, \alpha_t \in \mathbb{N}$ such that $|\mathbf{A}| = \prod_{i=1}^{t} p_i^{\alpha_i}$. For $i \in \underline{t}$, let $k_i := (\mu(p_i^{\alpha_i} - 1))^{\alpha_i - 1}$. Then there are operations $+$ (binary), $-$ (unary), 0 (nullary) on A such that $\mathbf{A}' = (A, +, -, 0, (f_i)_{i \in S})$ is isomorphic to a direct product $\prod_{i=1}^{t} \mathbf{B}'_i$, where each $\mathbf{B}'_i$ is a k_i-supernilpotent expanded elementary abelian group, and $0^{\mathbf{A}'} = z$.*

Proof. Since the result is true for $|A| = 1$, we henceforth assume $|A| \geq 2$. By [16], $\mathbf{A}$ is isomorphic to a direct product $\prod_{i=1}^{t} \mathbf{B}_i$ of nilpotent algebras of prime power order. We let $(\pi_1(a), \dots, \pi_t(a))$ denote the image of a of the underlying isomorphism. As a finite supernilpotent algebra in a congruence modular variety, $\mathbf{A}$ is nilpotent (cf. [1, Lemma 2.4]) and therefore has a Mal'cev term [9, Theorem 6.2]. We use [1, Theorem 4.2] to expand each $\mathbf{B}_i$ with operations $+_i$ and $-_i$ such that the expansion $\mathbf{B}'_i$ is a nilpotent expanded elementary abelian group with zero element $\pi_i(z)$. By [1, Theorem 1.2], $\mathbf{B}'_i$ is k_i-supernilpotent. ◀

We note that the supernilpotency degree of $\mathbf{A}'$ may be strictly larger than the supernilpotency degree of $\mathbf{A}$.

Combining these results, we obtain the following result on polynomial mappings on arbitrary finite supernilpotent algebras in congruence modular varieties.

▶ **Theorem 10.** *Let $\mu \in \mathbb{N}$, let $\mathbf{A}$ be a finite supernilpotent algebra in a congruence modular variety all of whose fundamental operations have arity at most μ. Let $p_1, \dots, p_t$ be distinct primes, and let $\alpha_1, \dots, \alpha_t \in \mathbb{N}$ such that $|\mathbf{A}| = \prod_{i=1}^{t} p_i^{\alpha_i}$. Let $F \in \mathrm{Pol}_n(\mathbf{A})^s$ be a polynomial map from A^n to A^s, and let $z \in A$. Then for every $\boldsymbol{a} \in A^n$ there is $\boldsymbol{y} \in A^n$ such that $F(\boldsymbol{y}) = F(\boldsymbol{a})$ and $|\{j \in \underline{n} : \boldsymbol{y}(j) \neq z\}| \leq s \sum_{i=1}^{t} (\mu(p_i^{\alpha_i} - 1))^{\alpha_i - 1} \alpha_i (p_i - 1) \leq s\mu^{-1} |A|^{\log_2 \mu + \log_2 |A|} \log_2 |A| \leq s|A|^{\log_2 \mu + \log_2 |A| + 1}$.*

Proof. Let $\mathbf{A}' = \prod_{i=1}^t \mathbf{B}'_i$ with $|\mathbf{B}'_i| = p_i^{\alpha_i}$ be the expansion of $\mathbf{A}$ produced by Lemma 9. Clearly, F is a also a polynomial map of $\mathbf{A}'$. Let $k_i = (\mu(p_i^{\alpha_i} - 1))^{\alpha_i - 1}$. Then Theorem 8 yields $\boldsymbol{y} \in A^n$ such that $|\{j \in \underline{n} : \boldsymbol{y}(j) \neq z\}| \leq \sum_{i=1}^t k_i s \alpha_i (p_i - 1)$. Using the obvious estimate $\alpha_i \leq \log_2 |A|$, we obtain

$$\begin{aligned}
&\sum_{i=1}^t k_i s \alpha_i (p_i - 1) = s \sum_{i=1}^t (\mu(p_i^{\alpha_i} - 1))^{\alpha_i - 1} \log_2 |A| (p_i - 1) \\
&\leq s \log_2 |A| \sum_{i=1}^t \mu^{\alpha_i - 1} (p_i^{\alpha_i})^{\alpha_i - 1} p_i^{\alpha_i} \leq s \log_2 |A| \sum_{i=1}^t \mu^{\log_2 |A| - 1} (p_i^{\alpha_i})^{\alpha_i} \\
&\leq s \mu^{\log_2 |A| - 1} \log_2 |A| \sum_{i=1}^t (p_i^{\alpha_i})^{\log_2 |A|} \leq s \mu^{\log_2 |A| - 1} \log_2 |A| (\sum_{i=1}^t p_i^{\alpha_i})^{\log_2 |A|} \\
&\leq s \mu^{\log_2 |A| - 1} \log_2 |A| (\prod_{i=1}^t p_i^{\alpha_i})^{\log_2 |A|} \leq s \mu^{\log_2 |A| - 1} \log_2 |A| \, |A|^{\log_2 |A|} \\
&\qquad\qquad\qquad = s \mu^{-1} |A|^{\log_2 \mu + \log_2 |A|} \log_2 |A| \leq s |A|^{\log_2 \mu + \log_2 |A| + 1}.
\end{aligned}$$

◀

5 Systems of equations

We will now explain how these results give a polynomial time algorithm for solving systems of a fixed number of equations over the finite supernilpotent algebra $\mathbf{A}$. The size m of a system of polynomial equations is measured as the length of the polynomial terms used to represent the system. For measuring the "running time" of our algorithm, we count the number of $\mathbf{A}$-operations: each such $\mathbf{A}$-operation, may, for example, be done by looking up one value in the operation tables defining $\mathbf{A}$.

▶ **Theorem 11.** *Let $\mathbf{A}$ be a finite supernilpotent algebra in a congruence modular variety all of whose fundamental operations are of arity at most μ, and let $s \in \mathbb{N}$. We consider the following algorithmic problem s-*PolSysSat*$(\mathbf{A})$:*

Given: *$2s$ polynomial terms $f_1, g_1, \ldots, f_s, g_s$ over $\mathbf{A}$.*
Asked: *Does the system $f_1 \approx g_1, \ldots, f_s \approx g_s$ have a solution in $\mathbf{A}$?*

Let m be the length of the input of this system, and let

$$e := s|A|^{\log_2 \mu + \log_2 |A| + 1} + 1.$$

*Then we can decide s-*PolSysSat*$(\mathbf{A})$ using at most $O(m^{e-1})$ evaluations of all terms occuring in the system. Therefore, we have an algorithm that determines whether a system of s polynomial equations over $\mathbf{A}$ has a solution using $O(m^e)$ many $\mathbf{A}$-operations.*

Proof. Let n be the number of different variables that occur in the given system. We may assume that these variables are $x_1, \ldots, x_n$, and that our system is $\bigwedge_{i=1}^s f_i(x_1, \ldots, x_n) \approx g_i(x_1, \ldots, x_n)$. We choose an element $z \in A$, and we will show: if this system has a solution in A^n, then it has a solution in

$$C := \{\boldsymbol{y} \in A^n : |\{j \in \underline{n} : \boldsymbol{y}(j) \neq z\}| \leq e - 1\}.$$

For proving this claim, we first observe that $\mathbf{A}$ is a finite nilpotent algebra in a congruence modular variety, and it therefore has a Mal'cev term d. We consider the polynomial map

$H = (h_1, \dots, h_s)$, where $h_i(\boldsymbol{x}) := d(f_i(\boldsymbol{x}), g_i(\boldsymbol{x}), z)$ for $i \in \underline{s}$ and $\boldsymbol{x} \in A^n$. Since $\boldsymbol{a}$ is a solution of the system, $H(\boldsymbol{a}) = (z, z, \dots, z)$. By Theorem 10, there is $\boldsymbol{y} \in C$ such that $H(\boldsymbol{y}) = H(\boldsymbol{a})$. Then for every $i \in \underline{s}$, we have $d(f_i(\boldsymbol{y}), g_i(\boldsymbol{y}), z) = z$. By [9, Corollary 7.4], the function $x \mapsto d(x, g_i(\boldsymbol{y}), z)$ is injective. Since $d(f_i(\boldsymbol{y}), g_i(\boldsymbol{y}), z) = z = d(g_i(\boldsymbol{y}), g_i(\boldsymbol{y}), z)$, this injectivity implies that $f_i(\boldsymbol{y}) = g_i(\boldsymbol{y})$. Hence $\boldsymbol{y}$ is a solution that lies in C.

The algorithm for solving the system now simply evaluates the system at all places in C; if a solution is found, the answer is "yes". If we find no solution inside C , we answer "no", and by the argument above, we know that in this case, the system has no solution inside $\mathbf{A}^n$ at all.

We now estimate the complexity of this procedure: There is a $c \in \mathbb{N}$ such that for all $n \in \mathbb{N}$, $|C| \le cn^{e-1}$, hence we have to do $O(n^{e-1})$ evaluations of all the terms f_i, g_i in the system. Such an evaluation can be done using at most $O(m)$ many $\mathbf{A}$-operations. Since the length of the input m is at least the number of variables n occuring in it, this solves s-PolSysSat($\mathbf{A}$) using at most $O(m^e)$ many $\mathbf{A}$-operations. ◀

We remark that the exponent e involves neither the nilpotency nor the supernilpotency degree of the algebra $\mathbf{A}$; this is a result of the fact that Theorem 1.2 from [1] bounds the supernilpotency degree of $\mathbf{A}$ in terms of only μ, $|A|$, and the height of the congruence lattice of $\mathbf{A}$, which is bounded from above by $\log_2 |A|$. In the same vein, we can now also bound the exponent in the complexity bound for the *identity checking* or *polynomial equivalence* problem for supernilpotent algebras (cf. [2, Theorem 2.2]). For every algebra $\mathbf{A}$ satisfying the assumptions of Theorem 11, there is $c \in \mathbb{N}$ such that for any two n-ary polynomial terms $s(x_1, \dots, x_n)$ and $t(x_1, \dots, x_n)$, we can check whether $\mathbf{A} \models s \approx t$ using at most cn^d evaluations of both s and t, where $d := (\mu(|A| - 1))^{\log_2 |A| - 1}$ comes from Corollary 1.3 of [1].

6 Circuit satisfiability

With every finite algebra $\mathbf{A}$, [13] associates a number of computational problems that involve circuits whose gates are taken from the fundamental operations of $\mathbf{A}$. One of these problems is SCsat($\mathbf{A}$). It takes as an input $2s$ circuits $f_1, g_1, \dots, f_s, g_s$ over $\mathbf{A}$ with n input variables, and asks whether there is an $\boldsymbol{a} \in A^n$ such that the evaluations at $\boldsymbol{a}$ satisfy $f_i(\boldsymbol{a}) = g_i(\boldsymbol{a})$ for all $i \in \underline{s}$. For finite algebras of finite type (i.e., with finitely many fundamental operations) in congruence modular varieties, [18, Corollary 3.13] implies that SCsat($\mathbf{A}$) is in P when $\mathbf{A}$ is abelian, and NP-complete otherwise. However, if we restrict the number s of circuits, we obtain a different problem, which we call s-SCsat($\mathbf{A}$) in the sequel. Obviously, 1-SCsat($\mathbf{A}$) is the circuit satisfiability problem called Csat($\mathbf{A}$) in [13]. The method used to prove Theorem 11 immediately yields:

▶ **Theorem 12.** *Let $\mathbf{A}$ be a finite supernilpotent algebra of finite type in a congruence modular variety, and let $s \in \mathbb{N}$. Then s-SCsat($\mathbf{A}$) is in* P.

Hence a supernilpotent, but not abelian algebra $\mathbf{A}$ has s-SCsat($\mathbf{A}$) in P, whereas SCsat is NP-complete. In the converse direction, Theorem 9.1 from [13] has the following corollary.

▶ **Corollary 13.** *Let $\mathbf{A}$ be a finite algebra of finite type from a congruence modular variety. If $\mathbf{A}$ has no homomorphic image $\mathbf{A}'$ such that* 2-SCsat($\mathbf{A}'$) *is* NP-*complete, then $\mathbf{A}$ is nilpotent.*

Proof. Suppose that $\mathbf{A}$ has a homomorphic image $\mathbf{A}'$ for which Csat($\mathbf{A}'$) is NP-complete. Then also 2-SCsat($\mathbf{A}'$) is NP-complete because an algorithm solving 2-SCsat can be used to solve an instance $(\exists \boldsymbol{a})(f(\boldsymbol{a}) = g(\boldsymbol{a}))$ of Csat($\mathbf{A}'$) by solving 2-SCsat on the input

$(\exists \boldsymbol{a})(f(\boldsymbol{a}) = g(\boldsymbol{a})\ \&\ f(\boldsymbol{a}) = g(\boldsymbol{a}))$. Thus the assumptions imply that for no homomorphic image $\mathbf{A}'$ of $\mathbf{A}$, the problem CSat($\mathbf{A}'$) is NP-complete. Now by [13, Theorem 9.1], $\mathbf{A}$ is isomorphic to $\mathbf{N} \times \mathbf{D}$, where $\mathbf{N}$ is nilpotent and $\mathbf{D}$ is a subdirect product of 2-element algebras each of which is polynomially equivalent to a two element lattice. If $|\mathbf{D}| > 1$, then there is a homomorphic image $\mathbf{A}_2$ of $\mathbf{A}$ such that $\mathbf{A}_2$ is polynomially equivalent to a two element lattice. By [11], 2-SCSat($\mathbf{A}_2$) is NP-complete, contradicting the assumptions. Hence $|\mathbf{D}| = 1$, and therefore $\mathbf{A}$ is nilpotent. ◀

Abstract

This paper investigates induced Steiner subgraphs as a variant of the classical Steiner trees, so as to compactly represent the (exponentially many) Steiner trees sharing the same underlying induced subgraph. We prove that the enumeration of all (inclusion-minimal) induced Steiner subgraphs is harder than the well-known Hypergraph Transversal enumeration problem if the number of terminals is not fixed. When the number of terminals is fixed, we propose a polynomial delay algorithm for listing all induced Steiner subgraphs of minimum size. We also propose a polynomial delay algorithm for listing the set of minimal induced Steiner subgraphs when the number of terminals is 3.

1 Introduction

Paths and cycles are the basic components for connecting nodes in undirected graphs. It is natural to ask, for a given subset of nodes, how to connect them in a component of minimal cost, where the cost is, e.g., the total sum of the weights on the edges or the number of nodes.

Classical instances of this problem follow two main patterns [7]. Some are *edge*-centric components in (usually) weighted graphs, such as shortest paths/cycles, spanning trees, Steiner trees, k-edge-connected components. Others are *node*-centric components in unweighted graphs, such as induced paths, chordless cycles (holes), k-node-connected components.

The above is not actually a dichotomy of edge- vs. node-centric components as, for example, node-weighted Steiner trees lay at the cross of the two. Nevertheless, it seems that most of the literature has been devoted to edge-centric components.

For instance, in the rich research area on Steiner trees, the online compendium in [12] reports over 60 variations of the Steiner tree problem, but just a couple are node-centric (survivable network design problem [3] and node weighted generalized Steiner tree [11]). The interest in the Steiner tree problem and its variants is well rooted in real world applications. Some examples can be seen in the 11th DIMACS challenge [8], which aimed at identifying a benchmark for algorithms and data generators, with emphasis on network optimization, computer-aided design, phylogenetic tree reconstruction and other applications. It is also of great interest in implementation challenges of the parameterized community, *e.g.*, [16], thus we believe it is worth investigating its natural extensions in node-centric scenarios.

Induced Steiner subgraphs. Special node-centric components have been introduced by Telle and Villanger [17] as a generalization of the induced paths.[1] In this paper, we study these components, hereafter renamed *induced Steiner subgraphs* as they seem to us a natural extension to the scenario of Steiner trees. Given an undirected graph $G = (V(G), E(G))$ and a subset $W \subseteq V(G)$ of $t = |W|$ nodes, called *terminals*, we want a set of nodes, minimal under inclusion, that connects all nodes in W.

▶ **Definition 1** (Induced Steiner Subgraph). *Given $W \subseteq V(G)$, an Induced Steiner Subgraph of G is a set of nodes $S \subseteq V(G) \setminus W$ such that the induced subgraph $G[S \cup W]$ is connected. We say that S is a (inclusion wise)* Minimal *Induced Steiner Subgraph (*MISS*) if there is no $S' \subset S$ such that $G[S' \cup W]$ is connected. The nodes in S are called Steiner points.*[2]

An example of a MISS is given in Figure 1, where we illustrate also its connection with the classical notion of Steiner tree. Similarly to how Steiner trees generalize paths between two nodes, it can be noted that MISS's generalize induced paths, which correspond to MISS's for $|W| = 2$. On the other extreme, for $W = V(G)$, Steiner trees correspond to spanning trees of the graph, while there would be a single empty MISS corresponding to the whole graph.

Definition 1 makes sense in domains where nodes are preferred to edges in components, for example in network design [11] and graph database query optimization [2, 14]. In these cases, rather than a minimal set of edges that ensures connection (i.e. a tree), a minimal set of connected nodes and their induced subgraph (i.e. a MISS) are sought for. Note that the notion of induced Steiner subgraph can be easily extended to graphs with weights on the nodes, and MISS's correspond to solutions of minimal cost (otherwise their cost could be reduced by removing nodes). Our approach focuses on unweighted graphs, where Steiner trees also have many applications [12].

Results. In this paper we consider the problem of *output-sensitive* enumeration of MISS's, which corresponds to bounding the cost to a polynomial of the input and output size.

- In Section 3 we show that the problem is harder than the well-known TRANS-ENUM problem [10] for an arbitrary number of terminals. To classify its output-sensitive

[1] In [17], these are called MINIMAL T-CONNECTING SETS and are motivated by the study of the 2-DISJOINT CONNECTED SUBGRAPHS problem which is the following: given a connected graph $G = (V, E)$ and two disjoint subsets of terminal vertices $Z_1, Z_2 \subseteq V$, decide whether there exists a partition A_1, A_2 of $V(G)$, with $Z_1 \subseteq A_1$, $Z_2 \subseteq A_2$ and $G[A_1], G[A_2]$ both connected.

[2] We abuse the terminology a bit and refer by S also to the induced subgraph $G[S \cup W]$, as we enumerate all feasible S's while keeping the same set W. This simplifies notation in the rest of the paper.

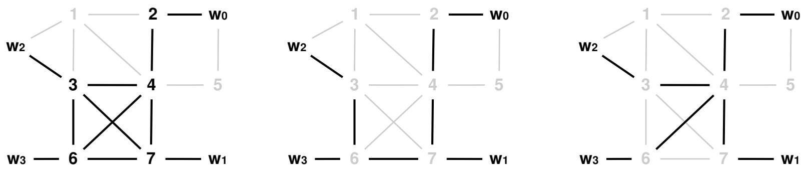

Figure 1 A MISS (left) and two Steiner trees corresponding to the same MISS (center and right).

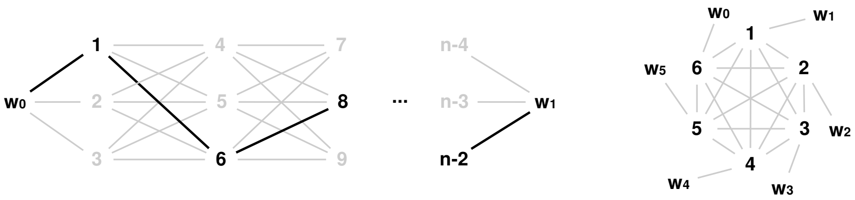

Figure 2 Left: A graph with $\Omega(3^{n/3})$ minimum Steiner trees and MISS's. Right: A graph with 1 MISS and n^{n-2} minimum Steiner trees (by Cayley's formula).

enumeration complexity, we consider the problem when the number of terminals $t = |W|$ is fixed. Concerning this, we show that the EXTENSION PROBLEM (see Section 3.2) is NP-complete already for $t \geq 2$, meaning that the sub-problems of any backtracking algorithm [10] should be carefully designed to avoid incurring instances of NP-complete problems.

- In this scenario, we propose a polynomial delay algorithm in Section 4 when the number of terminals is $t = 3$. (Note that the delay is the time required to list the "next" solution.) This is the first non-trivial case, as for $t = 1$ the problem is not defined, and for $t = 2$ it is the well-known problem of listing induced paths.
- Furthermore, we investigate in Section 2 the relationships of MISS's and Steiner trees, proving properties which allow us to use the algorithm of Dourado et al. [9] as a subroutine in order to list just the MISS's of *minimum* size with output-sensitive guarantees, for a bounded number t of terminals.

Discussion. Given a MISS S for W, we observe that each spanning tree in the induced subgraph $G[S \cup W]$ is a Steiner tree for W. Also the vice versa holds, so this could be useful for the packing edge-disjoint Steiner tree problem, which received attention in recent years [1, 4, 13] and consists of finding a largest possible set of Steiner trees that do not share edges or nodes.

If we look for an *individual* min-size Steiner subgraph for W (i.e., with the least number of nodes), it can be obtained as the subgraph induced by the Steiner points of a min-size Steiner tree for W. A different situation occurs instead if we look for *all* min-size induced Steiner subgraphs for W. A number of deep results for Steiner trees could be employed: for example, [9] proposes an algorithm for listing them with linear delay, assuming that the number $t = |W|$ of terminals is $O(1)$; [15] introduces a general enumeration framework for matroids with certain properties, which can be applied to generalized Steiner trees, containing as special cases minimal Steiner trees and minimal Steiner forests. Unfortunately, this approach gives rise over and over to the same min-size Steiner subgraph in our case, as there can be exponentially many Steiner trees for the same set of Steiner points (Fig. 2(left)).

Here comes an interesting feature of a MISS, as it is a compact representation of many Steiner trees. Observing that a min-size Steiner subgraph for W is a MISS for W of minimum size, we can thus list the MISS's for W twice: the first time to discover the minimum size, and the second time to single out the MISS's of that size (i.e. min-size induced Steiner subgraphs).

This approach can be dramatically more efficient than listing min-size Steiner trees to catch min-size induced Steiner subgraphs (see Fig. 2 (right)). On the other hand, the results in this paper (see Section 2.2) show the latter to be a viable approach if W has bounded size.

As for weighted graphs, we observe that the min-edge-weight Steiner tree problem reduces to min-node-weight Steiner subgraph problem.[3] Once we can list MISS's efficiently, we can also find min-node-weight induced Steiner subgraphs and thus min-edge-weight Steiner trees.

In summary, finding MISS's subsumes finding min-node-weight, min-edge-weight, and min-size Steiner trees, and becomes a sort of "universal" problem for this family of connectivity problems on graphs that compactly represent these trees. This motivates the problem of *listing* MISS's efficiently, which is central to this paper.

Previous results on MISS enumeration were already obtained in [17] from an *input-sensitive* point of view:[4] the authors proved that the number of MISS's for t terminals, in any graph of n nodes, is at most $\binom{n-t}{t-2} \cdot 3^{\frac{n-t}{3}}$, and propose an *input-sensitive* algorithm running in $O^*(\binom{n-t}{t-2} \cdot 3^{\frac{n-t}{3}})$ total time, where the O^* notation ignores factors polynomial in n. Here we consider the opposite direction, i.e., output-sensitive enumeration.

Preliminaries. We refer to [7] for our graph terminology. Let $G = (V(G), E(G))$ be an undirected graph, where $V(G)$ is its node set and $E(G)$ its edge set. $N(v)$ is the set of neighbors of a node v. When G is clear from the context we will refer to node and edge sets simply as V and E. For a set of nodes $A \subseteq V(G)$, let $E[A] \subseteq E(G)$ be the set of edges whose endpoints are both in A, and denote by $G[A] = (A, E[A])$ the graph thus obtained, also called the subgraph *induced* by A. A subgraph is a forest if it is acyclic, and a tree if it is a connected forest. A node $v \in I$ is a *leaf* if v has degree 1 in $G[I]$. Removing a leaf from a tree yields a tree. Regarding the Steiner Tree/Subgraph problem, we will refer to the set of terminal nodes as W, and to its size $|W|$ as t. We recall that an induced Steiner subgraph is a set of nodes S such that $G[S \cup W]$ is connected, and is minimal if inclusion-minimal. For a MISS S, we call *junctions* the nodes in $S \cup W$ which, in $G[S \cup W]$, have either degree ≥ 3, or are terminals with degree ≥ 2.

The notions for induced Steiner subgraphs and MISS given in Definition 1 can be applied to any subset of the terminals in W: for example, S is a MISS for $X \subseteq W$ if $G[S \cup X]$ is connected and so on. Without loss of generality, we can assume that no two terminals in W are connected by an edge: otherwise we can contract that edge into a single node and eliminate the resulting duplicated edges, preserving a one-to-one correspondence between solutions of the old graph and the new. In the following, given a set of nodes S, let $W(S)$ be the set of terminals in W that have neighbors in S. Note that S is an induced Steiner subgraph for $X = W(S)$ as long as $G[S \cup W(S)]$ is connected. Let us make the following observation before continuing.

▶ **Fact 1.** *Let S be a* MISS *for a set W of terminals. Then, $G[S \cup W]$ is not 2-connected. Moreover, $G[S \cup W]$ cannot contain a leaf vertex $v \in S$.*

Proof. Because no two terminals are adjacent, if $G[S \cup W]$ is 2-connected, then $|S| \geq 2$. By definition of 2-connectedness, for any vertex $v \in S$, we have that $G[(S \setminus \{v\}) \cup W]$ is connected, contradicting the minimality of S.

If $G[S \cup W]$ contains a leaf vertex $v \in S$, then $G[(S \setminus \{v\}) \cup W]$ is still connected as no path can contain v as an internal vertex, contradicting the minimality of S. ◀

[3] It suffices to replace each each edge $\{x, y\}$ with weight w by two edges $\{x, z\}$ and $\{z, y\}$ where z is a new node of weight w and x and y have weight zero [11]

[4] In exact exponential-time algorithms, a input-sensitive cost measures the running time in the input length.

2 Properties of Steiner Subgraphs and Listing Minimum Steiner Subgraphs

We are interested in this section in the enumeration of MISS's of minimum size, and refer to them as *minimum* MISS*'s*. In this section we prove some useful properties of MISS's in general, and some special properties of minimum MISS's, to outline the relationship between minimum Steiner trees and MISS's (Section 2.1) and to get an output-sensitive algorithm for minimum MISS's (Section 2.2).

2.1 Relationship with minimum Steiner trees

We first prove that, for a given set W of terminals, one minimum MISS corresponds to many Steiner trees (Lemma 2). We then prove an upper bound (in terms of t) for the number of junctions and the degree of the nodes involved in a MISS. We highlight here that both upper bounds hold for any MISS, minimum or not. Aside of telling that MISS's have strong topological properties, these bounds allow us to obtain the converse of Lemma 2, that is how to turn MISS's into Steiner trees (Lemma 5).

One-to-many correspondence to minimum Steiner trees. A minimum Steiner tree T for the set W of terminals is clearly a spanning tree of the subgraph $G[M \cup W]$ induced by the set $M = V(T) \setminus W$ of nodes plus the terminals, and thus M is a minimum MISS for W. On the other hand, consider any minimum MISS M for W: each spanning tree T of $G[M \cup W]$ is actually a minimum Steiner tree for W. For example, the two trees in Figure 1 correspond to the same MISS.

▶ **Lemma 2.** *Given a set W of terminals and a minimum* MISS *M for W, any spanning tree T of the induced subgraph $G[M \cup W]$ is a minimum Steiner tree for W.*

Proof. All the terminals in W are connected through T by definition of spanning tree, so T is a Steiner tree, not necessarily of minimum size (and the terminals are not necessarily all in its leaves). Suppose by contradiction that there exists another Steiner tree T' of size smaller than T (where T' can use nodes or edges outside $G[M \cup W]$). Then the subgraph $G[M' \cup W]$ induced by the set $M = V(T') \setminus W$ of nodes of T' would be a MISS with fewer nodes than $G[M \cup W]$, contradicting the fact that the latter is a minimum MISS. ◀

Upper bound on the number of junctions. Consider a MISS S (not necessarily minimum), and recall that a *junction* is either a node of S with degree at least 3 in the induced subgraph $G[S \cup W]$, or a terminal in W with degree at least 2 in $G[S \cup W]$. Although S is minimal, it can contain arbitrarily long induced paths independently of the number t of terminals. Still, we can bound the number of junctions in terms of t.

▶ **Lemma 3.** *Given a set W of terminals, any* MISS *S contains at most $3t$ junctions.*

Proof. By induction on the number of terminals. Recalling that $t = |W|$, if $t \leq 3$ then the claim is trivially true (see also Fact 2). Assume then that $t \geq 4$.

Consider the induced subgraph $G[S \cup W]$ ignoring the rest of G. In order to prove our claim, we replace each junction terminal v' with a new node v, and link v' and v together with an edge, so that v' becomes a leaf terminal and v is a junction. Now, as no junction can have degree 2, we replace each induced path $x_1, x_2, \ldots, x_\ell$ by an edge $\{x_1, x_\ell\}$ when x_1 and x_ℓ have degree $\neq 2$.

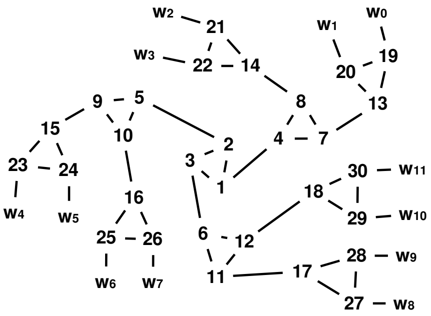

Figure 3 A MISS with 12 terminals and 30 junctions. Suitably enlarging the structure sets the junctions/terminals ratio arbitrarily close to 3.

Let G' be the resulting graph. Note that G' and $G[S \cup W]$ have the same number of terminals and junctions by construction. As a result, it suffices to prove our claim using G'. Note also that each node v in G' has degree 1 if and only if it is a terminal, and at least 3 otherwise. If G' is a tree, then the claim holds as the number of internal nodes of degree 3 in a tree is upper bounded by the number of leaves.

Let us assume that G' is not a tree. By Fact 1 we know that $G[S \cup W]$ is not 2-connected and by construction G' is also not 2-connected. Let T be the tree of bi-connected components of G' (called blocks). Because all non-terminal nodes in G' are junctions, each leaf block C of T is an edge $\{v, w\}$ with v a junction node and w a terminal because all the terminal nodes are non-adjacent and a leaf block has at most one non-terminal node. Let C be a block all of whose neighbors, except possibly 1, are leaf blocks. Such a block always exists, e.g., we could take a non-leaf block of maximum depth after rooting the tree arbitrarily. If except C, all the other blocks are leaf blocks (meaning that T is a star), then we are done because C is 2-connected, meaning any node removal does not disconnect it, meaning in turn any node must be connected to a leaf-terminal in order for it not to be redundant, so C contains at most t nodes. Otherwise, T is not a star and then for all possible choices for C let us take the one with biggest size. Let $w_1, \ldots, w_p$ be the terminals adjacent to junction nodes in C. Clearly, by the choice of C, $p \geq 2$ because either C has size ≥ 3, and at least two of the junction nodes are adjacent to terminals, or C has size 2 and at least one of the junction nodes is adjacent to two terminals. Let v be the junction node of C belonging to another block that is not a leaf block (v exists by the choice of C). Notice that C has size at most $p+1$ because except possibly v, all the junction nodes in C are adjacent to at least one terminal. Let $G'' = G' \setminus (\{w_1, \ldots, w_p\} \cup (C \setminus \{v\}))$ and consider v as a terminal in G''. It is not hard to check that G'' is a MISS for $(W \setminus \{w_1, \ldots, w_p\}) \cup \{v\}$. By induction G'' has at most $3(t-p+1)$ junctions because G'' has $t-p+1$ terminals. And then G has at most $3(t-p+1)+(p+1)$ junctions, which is bounded by $3t$. ◀

Furthermore, Figure 3 shows Lemma 3 to be tight (up to constant additive factors).

Upper bound on the node degree. Although any MISS S can be arbitrarily large independently of the number t of terminals, we prove that any node cannot have degree larger than t in $G[S \cup W]$.

▶ **Lemma 4.** *Given a set W of terminals and any* MISS *S for W and any node $v \in S \cup W$, $|N(v) \cap (S \cup W)| \leq t$.*

Proof. Let G' be the induced subgraph $G[S \cup W]$. Let us start with the case $v \in S$. For each $w \in W$, consider one shortest path between v and w in G', and let S' be the set of nodes containing all the nodes on these t shortest paths, excluding the nodes in W. Note that $S' \subseteq S$ by definition. As they are all shortest paths (hence induced paths with no shortcut edges), v can only be adjacent to the next node in each such path, and no other: thus $|N(v) \cap (S' \cup W)| \leq t$. Since all terminals are connected to each other using these paths, clearly S' is a Steiner induced subgraph. Since S is minimal, the only option is $S' = S$. The case $v \in W$ follows along the same lines. ◀

Removing edges to get a minimum Steiner trees. Consider any MISS S and select a subset of edges in the induced subgraph $G[S \cup W]$ to obtain a Steiner tree T. Lemma 3 and 4 imply the result that any T can be obtained from S by removing at most $3t^2$ edges from $G[S \cup W]$. Note that the number of edges in $G[S \cup W]$ could be much larger, but most of them are incident to degree-2 nodes of $G[S \cup W]$, and should be taken to form T (otherwise some terminals in W would be disconnected from the others). This property holds for the special case of minimum MISS, and hence minimum Steiner tree, immediately giving the following result.

▶ **Lemma 5.** *Given a set W of terminals and any* MISS *S for W, every Steiner tree T contained in $G[S \cup W]$ can be obtained by removing at most $3t^2$ edges.*

2.2 Listing minimum Steiner subgraphs

The properties of Steiner subgraphs seen so far allow us to design an algorithm for listing minimum Steiner subgraphs, parameterized in t. Consider a minimum MISS M, and the subgraph $G_M = G[M \cup W]$. By Lemma 2 each spanning tree of G_M is a minimum Steiner tree. By Lemma 5, G_M is turned into a spanning tree by removing α edges, for some $\alpha \leq 3t^2$. A closer look gives a suggestion on how to do that: even if the number of nodes and edges in G_M can be much larger than $3t^2$, there are at most $3t$ junctions by Lemma 3, with degree greater than 2; the rest of the (possibly many) nodes have all degree 2, and thus their incident edges must be taken to keep G_M connected. Hence, the α edges are incident to these junctions, each of degree at most t in G_M by Lemma 4, thus giving at most $3t^2$ edges to select from. As there are at most 2^{3t^2} possible choices for the α edges, there are $O(2^{3t^2})$ minimum Steiner trees yielding the same minimum Steiner subgraph M.

We exploit this observation by using [9] to list minimum Steiner trees of G with $O(n^2m + n^{t-2})$ preprocessing time and space, and $O(n)$ delay. To avoid duplications, as the same minimum MISS M can be obtained $O(2^{3t^2})$ times with distinct minimum Steiner trees, we simply define a “canonical spanning tree” T^* of M as an arbitrary spanning tree obtained from G_M with some deterministic procedure: when the algorithm in [9] yields T, we output its corresponding minimum MISS only if $T = T^*$, and discard it otherwise (note that this computation takes an additional $O(m)$ time per solution).

▶ **Theorem 6.** *Minimum Steiner subgraphs of G for a terminal set W can be listed with $O(n^2m + n^{t-2})$ preprocessing time and space, in $O(m \cdot 2^{3t^2})$ time per solution.*

3 Negative Results on Minimal Steiner Subgraphs

As for the classical Steiner tree problem, finding just one MISS is easy, but finding the smallest MISS, i.e., the one having minimum number of nodes, is NP-hard: as we saw in Section 2 any spanning tree of a MISS with k nodes is a Steiner tree with exactly $k - 1$ edges. This means that there is a one-to-many correspondence between MISS and Steiner trees of smallest size, and that finding a smallest MISS solves the unweighted Steiner tree problem.

Concerning listing MISS's, in Section 3.1 we show that this problem is actually harder than listing minimal hypergraph transversals. In particular, this result implies that an output-polynomial algorithm for MISS's enumeration would imply an output-polynomial algorithm for minimal hypergraph transversals, which is a long-standing open problem (see the survey [10] for more information on the problem).

In Section 3.2 we investigate the reason behind the difficulty of listing MISS's, showing that classical techniques for listing algorithms which make use of the so-called *extension problem* are difficult to apply, as the extension problem for MISS's is actually NP-complete. In particular, we prove that deciding whether a partial MISS can be completed into a MISS is NP-complete. Surprisingly, our reduction shows that this result holds even if the number of terminals, i.e. t, is bounded. This means that a general output-polynomial algorithm for MISS's enumeration which works for any number of terminals and which is polynomial both in the size of the graph and the number of terminals should rely on different techniques.

3.1 Listing reduction from Hypergraph Transversal Enumeration

We show that the problem of listing MISS's is at least as hard as a well-known problem, known as HYPERGRAPH TRANSVERSAL ENUMERATION (in short TRANS-ENUM). The latter problem deals with a hypergraph $\mathcal{H} = (X, H)$, where $H \subseteq 2^X$ is the set of hyperedges. A transversal for $\mathcal{H}$ is a hitting set $S \subseteq X$ for the hyperedges in H, namely, $S \cap e \neq \emptyset$ for each hyperedge $e \in H$. A transversal S is (inclusion-wise) minimal if no other $S' \subset S$ is a transversal. The TRANS-ENUM problem asks to list all the minimal transversals for $\mathcal{H}$, and the existence of an output-polynomial algorithm for it is a long-standing open question in the area of enumeration algorithms. Indeed, the latter would provide also the solutions for many enumeration problems arising in several diverse areas such as data-mining, integer programming, biology, databases, game theory, learning theory, and so on (see [10]).

In the following we show how to transform an instance of TRANS-ENUM, i.e. an hypergraph $\mathcal{H}$, to an instance of MISS's enumeration, i.e. a graph $G = (V, E)$ and a set $W \subseteq V$ of terminals, so for each minimal transversal of $\mathcal{H}$ there is a MISS for W in G, and vice versa.

▶ **Lemma 7.** *There is a one-to-one reduction from* TRANS-ENUM *to* MISS*'s enumeration (even in split graphs).*

Proof. We refer to the bipartite formulation of TRANS-ENUM, that is we consider the bipartite graph B whose vertices are partitioned into X and H, and whose edges represent the membership of each vertex of X in the hyperedges of H in which it is involved, and we look at the minimal subsets of X hitting all the vertices of H. We transform B into an instance of MISS's enumeration, i.e. a graph G and a set W, in the following way: choose G as a copy of B, add to G edges between all pairs of vertices of X, i.e., forming a clique, and choose as W the vertices in H. G is by construction a split graph. A minimal hitting set $S \subseteq X$ hits all the vertices in H and is such that there is no $S' \subset S$ doing the same. As $G[S \cup W]$ is connected, while $G[S' \cup W]$ is not, S corresponds to a MISS. Conversely, consider a MISS S in G. Thus $G[S \cup W]$ is connected and each $S' \subset S$ is such that $G[S' \cup W]$ is not. This means that for each vertex in W, i.e., a vertex in H, one of its neighbor is in S, i.e., an element hitting the vertex. Moreover, as S is a clique, each subset S' is still connected, meaning that $G[S' \cup W]$ disconnects some terminal in W, that is S' does not hit some vertex in W. Hence, S corresponds to a minimal hitting set. ◀

3.2 Hardness of the extension problem for miss's

Providing an output-polynomial algorithm for MISS's seems to be a challenging problem, even for a small number of terminals. As the Extension problem is a core block of many classical output-sensitive algorithms such as those based on *binary partition* or *backtracking*, we argue whether we can follow this path: roughly speaking, this is the problem of deciding whether a partial solution, e.g., a subset of nodes, can be completed into a final solution. In this section we show the hardness of the Extension problem for MISS's.

▶ **Problem 1** (Extension problem for MISS's). *Given a graph G, a terminal set W, and $P \subseteq V(G) \setminus W$, is there a minimal induced Steiner subgraph (*MISS*) S such that $P \subseteq S$?*

Note that, if $P = \emptyset$, the answer is trivially always yes, as we can find a MISS by simply setting $S = V(G) \setminus W$, and removing nodes from it until it is possible to do so without disconnecting W. For $t = 1$ the problem is not well defined (or could be considered trivially true if and only if $P = \emptyset$). One may think that the hardness would be influenced by the size of W, or that of P, however, this is not the case.

For $t = 2$ and $|P| = 1$, the smallest non-trivial sizes, the problem is already hard: let $W = \{w_0, w_1\}$ and $P = \{p\}$; as MISS's for $t = 2$ are induced paths, we obtain the problem of finding an induced path between w_0 and w_1 passing through p. Finding such an induced path has been proved to be NP-complete in [6]. This immediately yields the following result.

▶ **Theorem 8.** *The extension problem for* MISS*'s is NP-complete, even for two terminals.*

The difficulty of the extension problem excludes the possibility of applying some well known general techniques, motivating the interest in this combinatorial structure and in ad-hoc techniques for its enumeration.

4 Listing Minimal Steiner Subgraphs with Three Terminals

The problem of listing MISS's seems to be a challenging one as we have shown that the extension problem, which is a core block of many output-sensitive listing algorithms based on the backtracking and binary partition techniques, is NP-complete for MISS's already when the number of terminals is 2 (see Section 3.2). Indeed, in the case of $t = 2$, if the partial solution is just an arbitrary node which is not a terminal, deciding whether there is an induced path involving that node is NP-complete [6]. However, the problem can be solved with polynomial delay [18]: since we are listing induced paths from a source to a target, this limitation can be overcome by suitably defining the partial solution; in this case, a partial solution always includes a terminal, i.e. the source. The same strategy, i.e. forcing each partial solution to include a terminal, clearly does not apply when $t > 2$, as extending that solution will lead again to the hard problem of deciding whether there is an induced path involving that terminal. We show in this section that a workaround is still possible for the special case $t = 3$.

We will characterize some special instances of the extension problem, extending what we will call a *partial Steiner subgraph* (PSS for short), showing that we can indeed find a solution in polynomial time, and that it is possible to obtain a complete binary partition algorithm by just relying on these restricted instances.

To characterize a partial Steiner subgraph, let us define a removable node:

▶ **Definition 9.** *Let S be a Steiner subgraph for $W(S)$, the set of terminals in W that have neighbors in S. Then $v \in S$ is a* removable node *for S if $G[S \cup W(S) \setminus \{v\}]$ is connected.*

Note that if $v \in S$ is a removable node then $W(S) = W(S \setminus \{v\})$ (i.e., $S \setminus \{v\}$ is still a Steiner subgraph for $W(S)$).

As an example, consider Figure 1 (left), with $W = \{w_0, w_1, w_2, w_3\}$: $S = \{2, 3, 4, 6, 7\}$ has no removable node, as $W(S) = W$ and each removal of a node of S would disconnect at least one of the terminals from the others. On the other hand, $S' = \{3, 4, 6, 7\}$ has 4 as removable node, since $W(S) = \{w_1, w_2, w_3\}$.

We can now define a PSS:

▶ **Definition 10** (Partial Steiner Subgraph). *$S \neq \emptyset$ is a partial Steiner subgraph (PSS) if*

- *$W(S) \neq \emptyset$,*
- *S is a Steiner subgraph for $W(S)$,*
- *there is* at most *1 removable node in S.*

Note that a MISS is also a partial Steiner subgraph, as it has no removable nodes. We can now detail the listing procedure in Algorithm 1:

Algorithm 1 List all MISS's of G with $t = 3$.

```
Input  : A graph $G = (V(G), E(G))$ and a terminal set $W \subseteq V(G)$ with $t = |W| = 3$
Output : All MISS's of $G$ and $W$
Call 3-ENUM$(G, W, \emptyset)$
Function 3-ENUM$(G, W, S)$
    if $W(S) = W$ then
        output $S$    // $S \neq \emptyset$
    else
        $X \leftarrow \emptyset$
        foreach $v \in V(G) \setminus (S \cup W) : S \cup \{v\}$ is a PSS do
            if $\exists S' \supseteq (S \cup \{v\}) : S'$ is a MISS in $G$ then
                3-ENUM$(G \setminus X, W, S \cup \{v\})$
            $X \leftarrow X \cup \{v\}$
```

In essence, every recursive node of Algorithm 1 considers a partial Steiner subgraph S: at each step, it identifies all nodes v for which $S \cup \{v\}$ is also a partial Steiner subgraph, and check whether it is possible to eventually extend it into a solution, if so, it recurs adding v to S; afterwards, v is removed from the graph in subsequent recursive calls to avoid duplication (this is modeled by the set X).

To prove that the algorithm is correct, we will use the following fact and lemma.

▶ **Fact 2.** *Let S be a MISS for W with $t = |W| = 3$. Then $G[S \cup W]$ is either (1) a subdivision of the claw, (2) a triangle with 3 pending paths or (3) an induced path.*

Proof. Assume that $G[S \cup W]$ is neither an induced path nor a subdivision of the claw and let P be an induced path in $G[S \cup W]$ from two terminals w_a and w_b. Let P' be the shortest path in $G[S \cup W]$ from w_c to P, and let v be the penultimate vertex of P' not in P. Because $G[P \cup P' \cup W]$ is connected, we can conclude that $S = P \cup P'$, and no vertex of P', but v, is adjacent to a vertex in P. If v is adjacent to two non-adjacent vertices x and x' of P', then any vertex in P between x and x' can be removed without disconnecting the rest, contradicting the minimality of S. Therefore, S is as stated. ◀

▶ **Lemma 11.** *Given a graph G and a set of terminals $W \subseteq V(G)$ with $t = |W| = 3$, let S be a* PSS *and S' a* MISS *such that $S \subset S'$. Then there exists $v \in S' \setminus S$ such that $S \cup \{v\}$ is a* PSS.

Proof. Since $S \cup W(S)$ and $S' \cup W$ are connected subgraphs, and recalling from the preliminaries that no two terminals are adjacent, there must exist at least a node $x \in S' \setminus S$ such that $S \cup \{x\} \cup W(S)$ is connected. Let P be the set of all such nodes, and let us consider the possible cases. To complete the proof, we need to show that for some node $v \in P$ we have that $S \cup \{v\}$ has at most one removable node, meaning it meets all conditions of a PSS. We separately prove 3 comprehensive cases:

- **S has no removable node**. Then it must be that $W(S) = 2$ and S is exactly an induced path between two terminals w_a and w_b.[5] Consider a shortest path from the third terminal w_c to $S \cup \{w_a, w_b\}$ in $G[S' \cup W]$, and let v be the last vertex of the path not belonging to $S \cup \{w_a, w_b\}$. It clearly belongs to P. Consider now $S \cup \{v\}$: either v is connected to w_c, so $S \cup \{v\}$ is a MISS, i.e., $S' = S \cup \{v\}$, or v is removable and $S' \neq S \cup \{v\}$. If v is removable in $S \cup \{v\}$ and makes another vertex x removable in $S \cup \{v\}$, then x is in a path between two non-adjacent neighbors of v in $S \cup \{w_a, w_b\}$. But then $S' \setminus \{x\}$ would be a Steiner subgraph of W, a contradiction. Thus $S \cup \{v\}$ is a PSS.
- $|\mathbf{P}| = \mathbf{1}$. Then all other nodes of S' may reach S only via the single node $v \in P$. This means that if any node of $S \cup \{v\}$ other than v is removable, i.e., does not disconnect v from the rest of S and $W(S)$, then it is also removable in S', contradicting the minimality of S'. Thus the only possible removable node in $S \cup \{v\}$ is v and $S \cup \{v\}$ is a PSS.
- $|\mathbf{P}| \geq \mathbf{2}$ **and S has a removable node** b. We first note that $|W(S)| = 1$. Indeed, if $|W(S)| = 2$, then in any case of Fact 2, a connected subset S connecting two terminals cannot be extended into a connected subset with more than one vertex from $S' \setminus S$. Therefore, we can conclude that S is a path from a vertex b to a terminal w, with b the removable node of S. Because $|W(S)| = 1$ and $b \in S'$, then again by Fact 2 b should have a neighbor v not adjacent to any vertex in $S \setminus \{b\}$. Therefore, $S \cup \{v\}$ is a path included in S', and is then a PSS. ◀

Furthermore, let us prove that the extension problem for PSSs is solvable in polynomial time when $t = 3$.

▶ **Lemma 12.** *Given a graph G, terminal set $W \subseteq V(G)$ with $t = |W| = 3$ and a* PSS *S, the question "is there a* MISS *S' of G such that $S \subseteq S'$?" can be answered in $O(mn)$ time.*

Proof. Let us consider the three possible cases based on $W(S)$:

- $|\mathbf{W(S)}| = \mathbf{1}$. Let $W(S) = \{w_a\}$; as $S \neq \emptyset$, S consists of a path from w_a to the only removable node b of S. Let R be the set of nodes not in S or W that are neighbors of either w_a or some node in $S \setminus \{b\}$, i.e., $R = \{v \in V(G) \setminus (S \cup W) : N(v) \cap (W(S) \cup S \setminus \{b\}) \neq \emptyset\}$. Note that connecting terminals via nodes of R makes b redundant, as such nodes can reach w_a without using b; thus we must connect at least one terminal to w_a without using nodes of R, i.e., we may use at most one node of R. Consider $G \setminus R$: note that b is the only node in $S \cup \{w_a\}$ with neighbors outside the solution. How many terminals distinct from w_a are in the same connected component of $G \setminus R$ as b? If *zero*, we can answer **no**, as we will need to connect the remaining two terminals via R, making b redundant (thus the result not minimal). If *two*, we can answer **yes**, as the three terminals are in the same connected component, and any MISS of $G \setminus R$ will fully contain S. Finally, if *one*,

[5] If $W(S) = 1$, S is an induced path from a terminal, and the node opposite to it is always removable.

let us call it w_b and let C_1 be the connected component of $G \setminus R$ containing w_a, b and w_b, and C_2 the one containing the final terminal w_c; recall that we may use one node $c \in R$, and this node must connect S to C_2. We try all possible choices for c, noting that c cannot make any node of S removable other than b (otherwise it would remain removable in S'), and when testing c we must remove all its neighbors in $C_1 \setminus S \cup W$ from the graph (otherwise we may use them to bypass b, making b redundant). If any such suitable c exists, we get a MISS S' by taking any induced path from c to w_c in C_2 and any induced path from b to w_b in $C_1 \setminus (N(c) \setminus (S \cup W))$, and adding them to S, and thus we can answer **yes**. Otherwise, there is no other possibility of minimally connecting w_b and w_c to w_a without making b or some other node redundant, so we answer **no**.

- $|\mathbf{W(S)}| = \mathbf{2}$. Let $W(S) = \{w_a, w_b\}$. If there is a removable node b in S, define as before $R = \{v \in V(G) \setminus (S \cup W) : N(v) \cap (W(S) \cup S \setminus \{b\}) \neq \emptyset\}$. In this case, we may not use any node of R to connect the remaining terminal w_c, as this would allow us to bypass b, making it redundant. Thus if w_c is in the same connected component as b in $G \setminus R$, we can answer **yes**, as any induced path between b and w_c in this graph yields a MISS when added to S. Otherwise, there is no connection without using some node of R and making b redundant, so we can answer **no**. Otherwise, if there is no removable node in S, define $R' = \{v \in V(G) \setminus (S \cup W) : N(v) \cap (W(S) \cup S) \neq \emptyset\}$: clearly any MISS extending S must contain at least one (actually, exactly one) node from R', and for any $v \in R'$, v is removable in $S \cup \{v\}$, so we can test all possible nodes in R' as above, since $S \cup \{v\}$ has a removable node (trivially accounting for the special cases where v directly connects to the third terminal resulting directly in a MISS, or where v makes some other node in S removable and thus cannot be added to S).
- $|\mathbf{W(S)}| = \mathbf{3}$. Then either S is a MISS and the answer is **yes**, or it has removable nodes and the answer is **no**.

As for the time complexity, removing a set of nodes and computing the connected components of a graph can be done in $O(m)$ time. The cost is dominated by cases $|\mathbf{W(S)}| = \mathbf{1}$ and $|\mathbf{W(S)}| = \mathbf{2}$, where we need to perform such a test for each node in R or R', respectively. As these sets have size $O(n)$ we can answer the question in $O(mn)$ time. ◀

We can finally claim correctness and complexity of the algorithm:

▶ **Theorem 13.** *Given G and a set of terminals $W \subseteq V(G)$ with $t = |W| = 3$, Algorithm 1 lists all MISS's of G for W in $O(mn^3)$ time per solution.*

Proof. Firstly, the initial call with $S = \emptyset$ clearly does not trigger the output in Line 4 as $W(S) = \emptyset$. On all other recursive calls, S is a PSS such that there exist some MISS S' including S (due to Line 8 in the parent call). Whenever $W(S) = W$, it follows that $S' = S$ because S' is minimal and cannot contain other (redundant) nodes. So the algorithm only outputs MISS's.

Furthermore, let S^* be an arbitrary MISS, we show that it is found: let X be any recursion node of Algorithm 1 such that no node of S^* has been removed from G, and the current S, called here S_X, is fully contained in S^* (X exists as both conditions are met in the beginning, when no node has been removed from G and $S = \emptyset$). Let x be the first node of $S^* \setminus S_X$ considered on Line 7 such that $S_X \cup \{x\}$ is a PSS (x exists by Lemma 11): when x is considered, clearly no node of S^* has yet been removed from G; furthermore, the condition in Line 8 is true by the existence of S^*, so a child recursive call is generated with $S_Y = S_X \cup \{x\}$ and G still fully containing S^*. By induction, the algorithm will, in some path of the recursion tree, at each step add one more node of S^* without removing any from G, until eventually S^* is found.

Finally, duplication is impossible by the binary partition argument, as all solutions generated from a recursive call on Line 9 will contain v, and all subsequent recursive calls will remove v from G (see Line 10), thus will find different solutions.

As for the cost per solution, since all leaves of the recursion tree output solutions, it is bound by the cost of the recursion nodes of a root-to-leaf path in the recursion tree, which are $O(n)$ as each node adds a node to S when recurring. In each node, we must identify all v such that $S \cup \{v\}$ is a PSS: some trivial case analysis (using Fact 2) can reveal that this is true only when v is a neighbor only of the removable node of S, or when S has no removable node and v has at most two neighbors in S, adjacent to each other, thus this takes $O(|N(v)|)$, for a total of $O(\sum_{v \in V(G)} |N(v)|) = O(m)$ time. Furthermore, the test in Line 8 takes $O(mn)$ time by Lemma 12 and is performed $O(n)$ times, for a total cost per recursion node of (mn^2). The cost per solution of Algorithm 1 is thus $O(mn^3)$. ◀

5 Conclusions

We considered minimal Steiner induced subgraphs, a natural variant of Steiner trees, shifting our focus on a node-centric view. We studied these combinatorial objects providing an output-sensitive algorithm for minimum MISS's. On the other hand, getting all MISS's with an output-sensitive algorithm seems to be more challenging for unbounded number of terminals, as we have shown that this problem is actually harder than listing all the minimal hypergraph transversals. Moreover, the fact that the extension problem is actually NP-complete, even with bounded number of terminals, makes us thinking that an *ad hoc* strategy should be thought for different sizes of W. For $t = 2$, the problem can be solved by known listing algorithm for induced paths. In this paper we have provided an output-sensitive algorithm for the case $t = 3$.

As a final remark, we observe that for many problems, like, for instance, listing maximum size and maximal independent sets [5], listing minimum/maximum solutions is harder than listing minimal/maximal solutions. In contrast, in the case of MISS's with a bounded number of terminals, listing minimum size MISS's seems to be easier than getting all MISS's, as we could efficiently solve the former case for $t = O(1)$, while the latter only for $t \leq 3$.

Abstract

In this paper, we present enumeration algorithms to list all preferred extensions of an argumentation framework. This task is equivalent to enumerating all maximal semikernels of a directed graph. For directed graphs on n vertices, all preferred extensions can be enumerated in $O^*(3^{n/3})$ time and there are directed graphs with $\Omega(3^{n/3})$ preferred extensions. We give faster enumeration algorithms for directed graphs with at most $0.8004 \cdot n$ vertices occurring in 2-cycles. In particular, for oriented graphs (digraphs with no 2-cycles) one of our algorithms runs in time $O(1.2321^n)$, and we show that there are oriented graphs with $\Omega(3^{n/6}) > \Omega(1.2009^n)$ preferred extensions.

A combination of three algorithms leads to the fastest enumeration times for various proportions of the number of vertices in 2-cycles. The most innovative one is a new 2-stage sampling algorithm, combined with a new parameterized enumeration algorithm, analyzed with a combination of the recent monotone local search technique (STOC 2016) and an extension thereof (ICALP 2017).

1 Introduction

In Dung's theory of abstract argumentation [15], an *argumentation framework* (AF) is a digraph $G = (V, E)$, where each vertex represents an argument, and an arc $(u, v) \in E$ denotes that argument u *attacks* argument v. There are various semantics that express what properties a set of arguments should have for a rational agent to stand by that set of arguments. One of the most central semantics is the *preferred semantics* that was already proposed by Dung in his foundational paper [15]. Let $S \subseteq V$ be a subset of vertices (also called *extension*) of a digraph $G = (V, E)$. The set S is *conflict-free* if no arc has both endpoints in S. A vertex $v \in V$ is *acceptable* with respect to S if for each arc $(u, v) \in E$ there is an arc $(w, u) \in E$ with $w \in S$. In other words, for each argument u that attacks v, there is an argument w in S that attacks u. We say in this case that w *defends* v against u. The set S is *admissible* if it is conflict-free and each argument in S is acceptable with respect to S. The set S is *preferred* if it is an inclusion-wise maximal admissible set.

While we will use the language of abstract argumentation, we remark that such vertex sets have also been studied in graph theory. Neumann-Lara [27] (see also [21]) defined the notion of *semikernels*. Maximal *semikernels* are equal to the preferred extensions in the directed graph where all arcs are reversed. The related notion of *kernels* [32] has the same correspondence with stable extensions in abstract argumentation, and was introduced as an abstract solution concept in cooperative game theory, but has been extensively studied in the theory of directed graphs. In particular, various issues around the enumeration of kernels and semikernels have been considered in previous work [2, 5, 20, 29].

Motivation. A central problem in abstract argumentation is the enumeration of extensions prescribed by a given semantics. The enumeration of preferred extensions is of particular interest, firstly for its own sake, but also in the study of other semantics as it forms the basis of several other semantics refining this set. A number of existing algorithms and implementations enumerate all preferred extensions of a digraph (see, e.g., [6, 7, 9, 10, 11, 12, 14, 25, 28, 30, 31]). The enumeration of preferred extensions is also a part of the biennial International Competition on Computational Models of Argumentation (ICCMA). Computational problems where the enumeration of extensions are used involve answering the questions: is a given argument in some / all preferred extensions and what is the number of preferred extensions containing a given argument / in total. Upper bounds on the number of extensions under various semantics have also been proposed as fundamental characteristics to compare various semantics in abstract argumentation [3, 16].

We study the enumeration of preferred extensions in digraphs with no, or relatively few, 2-cycles (i.e., bidirectional arcs). Our aim is to determine how much the presence of 2-cycles affects the number of preferred extensions of an AF. Mutually attacking arguments play a special role in abstract argumentation [24], but this conflict is often resolved rather easily if the strength of the two attacks can be evaluated [4], or the user's preference between the two arguments can be elicited [26, 1]. These methods of resolving conflicts motivate the study of problems, and in particular enumeration problems, for AFs with no or few 2-cycles.

Our results. Define the *resolution order* of a digraph $G = (V, E)$, denoted $r(G)$, as the number of vertices that belong to a 2-cycle in G. We study enumeration algorithms and combinatorial upper bounds on the number of preferred extensions in *oriented graphs* (digraphs without 2-cycles) and digraphs that have small resolution order.

Our main result is an algorithm that, for any $\varepsilon > 0$, enumerates all preferred extensions of a digraph G on n vertices in time

$$O^*\left(\left(\min\left(\varphi^{2r}\cdot\varphi^{1-r},\ \left(\left(1+2^{\frac{1}{4}}-\frac{1}{\sqrt{2}}\right)^{r}\cdot\left(2-\frac{1}{\sqrt{2}}\right)^{1-r}\right)^{1+\varepsilon},\ 3^{1/3}\right)\right)^{n}\right)$$

$$\le O^*\left(\left(\min\left(1.5180^{r}\cdot 1.2321^{1-r},\ 1.4822^{r}\cdot 1.2929^{1-r},\ 1.4423\right)\right)^{n}\right),$$

where $r = r(G)/n$, and $\varphi \approx 1.2321$ is the positive root of $1 - x^{-1} - x^{-8}$. The O^* notation hides factors that are polynomial in the input size. See Figure 1, which plots the base α of the running time expressed as $O^*(\alpha^n)$ for r varying from 0 to 1. For $r = 1$, this is best possible and follows from the work in [16, 26]. At the other end of the spectrum, i.e., for oriented graphs where $r = 0$, the upper bound is $O^*(\varphi^n) \le O(1.2321^n)$ and is obtained via a carefully constructed branching algorithm and running time analysis. We also give a lower bound on the largest number of preferred extensions an oriented graph on n vertices may have of $\Omega(3^{n/6}) \ge \Omega(1.2009^n)$. A construction, which we call the *Oriented Translation*, reducing an arbitrary digraph $G = (V, E)$ to an oriented graph with $|V| + r(G)$ vertices,

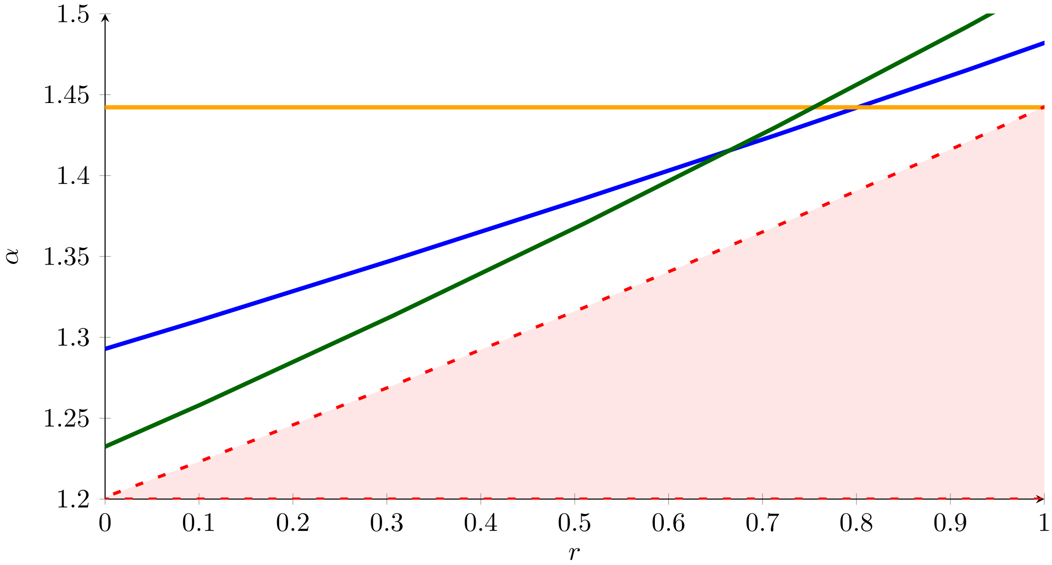

Figure 1 The graph depicts the base of the exponential running times $O^*(\alpha^n)$ of the three enumeration algorithms, according to $r = r(G)/n$. When $r < 0.6684$, our branching algorithm for oriented graphs together with the Oriented Translation (dark green) gives the fastest algorithm. For $r > 0.8005$, the algorithm based on previous work [16, 26] (orange) is fastest. In the middle range, the combination of the 2-phase monotone local search with the parameterized enumeration algorithm (blue) is fastest. Our lower bound on the largest number of preferred extensions is drawn with a dashed red line.

such that there is a bijection between their preferred extensions, allows us to generalize these upper and lower bounds to $O^*\left(\varphi^{2\cdot r(G)} \cdot \varphi^{n-r(G)}\right) \leq O(1.5180^{r(G)} \cdot 1.2321^{n-r(G)})$ and $\Omega(3^{r(G)/3} \cdot 3^{(n-r(G))/6}) \geq \Omega(1.4422^{r(G)} \cdot 1.2009^{n-r(G)})$, respectively.

Our main technical contribution is the third algorithm. It relies on a parameterized enumeration algorithm and extensions of the recent monotone local search framework [17]. The parameterized enumeration algorithm has as input a digraph $G = (V, E)$, a set of arguments S, and a non-negative integer k, and it enumerates all maximal admissible extensions $T \subseteq S$ of G within distance k of S. Its running time can be upper bounded by $O^*(2^{k/2+r(G[S])/4})$. This is optimal, since there are instances for which the solution consists of $\Omega(2^{k/2+r(G[S])/4})$ preferred extensions at distance at most k from S. Furthermore, under the Strong Exponential Time Hypothesis, the corresponding decision problem has no $O^*(2^{(1-\varepsilon)(k/2+r(G[S])/4)})$ time solution for any $\varepsilon > 0$. We use this parameterized enumeration algorithm in a new 2-phase monotone local search procedure, where we separately sample vertices from B, the set of vertices in at least one 2-cycle, and $V \setminus B$ and then apply the parameterized enumeration algorithm. The running time analysis is a new combination of the results in [17] for the first sampling phase and [23] for the second sampling phase, combined with the parameterized subroutine. From a technical point of view, this is the most innovative part of this paper. (From a conceptual point of view, the most innovative contribution is probably the synergy between modern enumeration algorithmics and the theory of abstract argumentation.) This results in an algorithm enumerating all preferred extensions of a given digraph G in time $O^*\left(\left(1+2^{1/4}-2^{-1/2}\right)^{(1+\varepsilon)\cdot r(G)} \cdot \left(2-2^{-1/2}\right)^{(1+\varepsilon)\cdot(n-r(G))}\right)$.

Interpretation of results. Figure 1 indicates we have narrowed the gap between best known lower and upper bounds for a wide range of r and improved algorithms and combinatorial upper bounds whenever $r \leq 0.8004$. The result for $r = 0$ shows that for oriented graphs, our new algorithm allows to handle instances with 75% more arguments, compared with the previous best $O(3^{n/3})$ upper bound. (We have that $\log_{1.2321}(3^{1/3}) \approx 1.7545$.)

Outline. Sections 3 and 4 describe our monotone local search algorithm. Section 5 describes our branching algorithm for oriented graphs.

First we introduce the parameterized enumeration problem that will form the subroutine of our Monotone Local Search.

Maximal Admissible Subset Enumeration (MASE)

Input:	Graph G, set $S \subseteq V(G)$, integer k
Parameter:	k
Output:	Enumerate all maximal admissible sets $T \subseteq S$ such that $\lvert S \setminus T\rvert \leq k$.

There is a subtlety here with how we define maximal. We say T is a maximal admissible subset of S if there does not exist an admissible set U such that $T \subsetneq U \subseteq S$. Notably T is not necessarily a preferred extension (though T is if $S = V(G)$).

In Section 3, we present an algorithm for MASE, parameterized by k and $r(G[S])$, the resolution order of the subgraph of G induced by S.

▶ **Theorem 1.** *For an instance $I = (G, S, k)$ of MASE, let $\mu(I) := \frac{k}{2} + \frac{r(G[S])}{4}$. Then MASE can be solved in $O^*(2^{\mu(I)})$ time. Furthermore, there are at most $2^{\mu(I)}$ maximal admissible subsets of S within distance k of S. Hence, there are at most $2^{\mu(I)}$ preferred extensions that are subsets of S with size $\geq |S| - k$.*

Our algorithm is a standard parameterized branching algorithm. Compared to the enumeration of independent sets, the primary additional tool we have is a powerful simplification rule, **(Undefendable)**, for vertices with in-degree 0.

In Section 4, we extend our parameterized algorithm into a general enumeration algorithm through a novel 2-phase application of Monotone Local Search. Since 2-cycles increase the run time of our MASE subroutine, we modify Monotone Local Search to sample separately between a set of "bad vertices" (ones contained in a 2-cycle) and "good vertices" (ones not contained in any 2-cycle). This presents a speed up compared to a more direct application of the Monotone Local Search framework. We believe this may be useful for other problems.

Separately, Section 5 presents a branching algorithm for oriented graphs. Again, **(Undefendable)** plays a critical role. By carefully setting up the state we also have a simplification rule for vertices with out-degree 0. We tailor our branching rules to take full advantage of these two simplification rules. This is combined with a lot of careful case analysis and ad-hoc methods (including a graph classification theorem for Case 4).

Each of our algorithms also provide a corresponding combinatorial upper bound on the number of preferred extensions. The various enumeration algorithms and bounds are collected in Section 6. To extend the results from Section 5 to general graphs we require the following result which we call the *Oriented Translation.*

▶ **Theorem 2.** *There is a linear time algorithm that transforms any AF G into an oriented AF G' with $|V(G')| = |V(G)| + r(G) + 3$ such that there is a bijection between the preferred extensions of G and the preferred extensions of G' that can be applied in linear time.*

The basic idea of the construction is carefully converting 2-cycles into 4-cycles by duplicating vertices contained in at least one 2-cycle. The construction can be found in the full version.

In the full version we include all omitted proofs (including, in particular, the case analysis of our branching algorithms) and a few extra results:

We apply Theorem 2 to derive complexity results on oriented graphs by extending constructions for directed graphs. We show that:

- Unless P=NP, no algorithm enumerates the admissible or preferred extensions of an AF in output-polynomial time, even when the AF is an oriented graph.
- Assuming the Strong Exponential Time Hypothesis, our algorithm for the decision variant of MASE is optimal.
- The enumeration bound in Theorem 1 is tight (i.e: there exist instances with $2^{\mu(I)}$ maximal admissible subsets within distance k).

We also briefly justify the choice of the measure μ we use for our MASE algorithm by comparing it against similar measures.

Notation. An *oriented graph* is a digraph with no 2-cycles.

We will use the notation $N(v)$ to denote the set of vertices adjacent to v and $N[v]$ to denote $N(v) \cup \{v\}$.

We will assume throughout that AFs have no self loops. In the full version we present the Loopless Translation which, with a (small) constant overhead, transforms any AF into a loopless AF with the same lattice of admissible extensions (under inclusion).

2 Background on Analysis of Branching Algorithms

All results here can be found in standard textbooks. We mostly follow Fomin & Kratsch [19].

To analyze our branching algorithms we use Measure & Conquer [18]. A *measure* is a function assigning a non-negative number to each instance I.

We define the following standard terminology (e.g: see [19, 13]).

▶ **Definition 3** (Branching Vector and Number [19]). *Let μ be a measure. Let b be a branching rule that for any input instance, say I, branches into r instances with measures $\mu(I) - t_1, \mu(I) - t_2, \ldots, \mu(I) - t_r$ such that for all i, $t_i > 0$. Then we call $\mathbf{b} = (t_1, t_2, \ldots, t_r)$ the* branching vector *of branching rule b.*

Let α be the unique positive real root of $x^n - x^{n-t_1} - x^{n-t_2} - \ldots - x^{n-t_r}$.

We call α the branching number *of the branching vector $\mathbf{b}$.*

The following lemma from [22] forms the basis for the analysis of our branching algorithms.

▶ **Lemma 4** (Combine Analysis Lemma [22]). *Let A be an algorithm for a problem which for each instance, say I, either directly solves the instance in $O^*(\alpha_0^{\mu(I)})$ time or after polynomial time, applies one of r branching rules b_i, the i-th of which has branching number α_i. Then A has running time $O^*(\alpha^{\mu(I)})$ where $\alpha = \max_{0 \le i \le r}(\alpha_i)$.*

The following lemma forms the basis of our enumeration bounds. The search tree of a branching algorithm is the tree formed by the recursive calls, with the leaves being cases that can be solved directly. In all our applications the number of leaves is an upper bound on the number of objects being enumerated.

▶ **Lemma 5** (Combine Analysis Lemma for Enumeration). *Let A be an algorithm for a problem which for each instance, say I, either directly solves the instance with a branching algorithm that generates at most $\alpha_0^{\mu(I)}$ leaves or applies one of r branching rules b_i, the i-th of which has branching number α_i. Then the search tree for applying A to I has at most $\alpha^{\mu(I)}$ leaves where $\alpha = \max_i(\alpha_i)$.*

3 Parameterized Enumeration Problems

Our algorithm for MASE follows a standard template for parameterized branching algorithms (see Section 2 for notation). We will consider the measure $\mu(I) = \frac{k}{2} + \frac{b}{4}$ where k is the number of vertices we are allowed to remove and $b := r(G[S])$ is the resolution order of $G[S]$. We will design a branching algorithm with run time $O^*(2^{\mu(I)})$ which recurses into subinstances and collates their results to obtain the maximal admissible subsets of S.

However, there is a technical difficulty in the collation step arising from the fact that a maximal admissible subset of $S' \subsetneq S$ may not be a maximal admissible subset of S. This gives rise to the following subproblem:

Maximal Subset Collation

Input:	Graph G, c pairs (S_i, C_i) where for each i, $S_i \subseteq V(G)$ and C_i is a set containing only maximal admissible subsets of S_i
Output:	A set containing all maximal elements of $\bigcup_{i=1}^{c} C_i$

The main result we need is:

▶ **Lemma 6.** *Maximal Subset Collation can be solved in* $O(c\sum_{i=1}^{c}|C_i| \cdot \mathrm{poly}(|V|))$ *time.*

An algorithm for Maximal Subset Collation can be found in the full version. It is a consequence of Lemma 7.

3.1 An $O^*(2^{\mu(I)})$ algorithm for Maximal Admissible Subset Enumeration

The overall structure of our algorithm is described in Algorithm 1.

The following table lists the branching rules in application order with the first row being the base case. The second column describes the instances each rule is applicable to. After applying simplification rules, our branching algorithm will always apply the first rule that is applicable to the input instance.

Case	Requirement to apply	Running Time
Base	S is conflict-free.	Solves in $O^*(1)$ time, returns ≤ 1 set.
1	$G[S]$ is oriented with maximum total degree ≤ 2.	Branching vector $(1,1)$, branching number 2.
2	There is a 2-cycle in $G[S]$.	Branching vector $(1,1)$, branching number 2.
3	$G[S]$ has maximum total degree ≥ 4.	Branching vector $(2, \frac{1}{2})$, branching number ≈ 1.91.
4	$G[S]$ contains a vertex with total degree 3.	Branching vector $(1, \frac{3}{2})$, branching number ≈ 1.76.

We note that these requirements are exhaustive, hence there will always be at least one applicable rule in any instance.

The base case follows trivially from the following more general result:

▶ **Lemma 7.** *Suppose $S \subseteq V(G)$ induces a DAG in G. Then S has exactly one maximal admissible subset and it can be found in polynomial time.*

The main tool for this is the following Simplification Rule which we will use repeatedly:

▶ **Simplification Rule 1 (Undefendable).** *Let $u \in S$ be a vertex such that there exists a vertex $a \in V(G)$, a attacks u and no vertex in S attacks a. Then there is no admissible subset of S that contains u so we can safely set $S \leftarrow S \setminus \{u\}$.*

Algorithm 1 Structure of MASE branching algorithm.

```
Ensure: Returns all maximal admissible subsets $T \subseteq S$ such that $|S \setminus T| \leq k$
  function MASE($S, k$)
    if $k < 0$ then
      return $\emptyset$
    while (Undefendable) applies do
      Apply (Undefendable)
    if Base Case applies then
      Solve the instance directly through the base case subroutine.
    else
      Let $b_i$ be the first branching rule that applies.
      Let $(S_1, k_1) \ldots (S_r, k_r)$ be the subinstances obtained from applying $b_i$.
      Let $C_i = \text{MASE}(S_i, k_i)$, for all $1 \leq i \leq r$.
      return Maximal_Subset_Collation($(S_1, C_1), \ldots, (S_r, C_r)$)
```

Lemma 7 follows from applying **(Undefendable)** to S until it is no longer applicable. Then S is acceptable with respect to S (all vertices in V attacking S are also attacked by S) and conflict-free (else **(Undefendable)** would be applicable to any vertex attacked by a maximal vertex in $G[S]$). Hence, by definition, S is admissible. It is the unique maximal admissible subset as **(Undefendable)** only removes vertices in no admissible subsets of S.

The above results are essentially all well known (see [14, 8] for earlier applications of **(Undefendable)**). The full version contains the above argument in more detail.

Proofs of the branching cases can be found in the full version. A few short remarks:

Case 1 follows from noting $G[S]$ must be a family of cycles.

Cases 2 and 3 follow from picking a specific vertex v then applying a 2-way branch, in one branch enumerating all maximal admissible subsets that include v, in the other branch enumerating all that do not include v. In case 2 we pick the vertex in the 2-cycle with higher total degree. In case 3 we pick any vertex with total degree at least 4.

Case 4 is probably the most instructive. It best showcases the power of **(Undefendable)**. First we show a vertex v exists with in-degree 1, out-degree 2. Then a 2-way branch is applied to the vertex attacking v, using **(Undefendable)** to improve the branch where the vertex is excluded and v is left with in-degree 0.

3.2 Running Time Analysis

The base case is solvable in polynomial time. Each of our branching rules has branching number ≤ 2. Hence, if we ignore the calls to Maximal Subset Collation, by the Combine Analysis Lemma our algorithm has running time $O^*(2^{\mu(I)})$.

Maximal Subset Collation is applied to each admissible subset encountered by the MASE algorithm (i.e: each leaf in the search tree) at most d times, where d is the maximum depth of the search tree. By Lemma 6 each application incurs a $O(\text{poly}(|V|))$ cost ($c \leq 2$ for our branching rules). Hence the overall cost incurred by the Maximal Subset Collation step is

$$O(A \cdot d \cdot \text{poly}(|V|))$$

where A is the total number of admissible subsets encountered by the MASE algorithm (equivalently, the number of leaves in the search tree). By the Combine Analysis Lemma for Enumeration, A is $O(2^{\mu(I)})$. The maximum depth d is $O(\mu(I))$ which we may take to be $O(|V|)$. Hence Maximal Subset Collation incurs an overhead cost of $O^*(2^{\mu(I)})$.

As noted, our algorithm also satisfies the requirements for applying the Combine Analysis Lemma for Enumeration. We summarize all the above results in the following theorem.

▶ **Theorem 8.** *Let $\mu(I) = \frac{k}{2} + \frac{b}{4}$, where b is the resolution order of $G[S]$. Then MASE can be solved in $O^*(2^{\mu(I)})$ time. Furthermore, there are at most $2^{\mu(I)}$ maximal admissible subsets of S within distance k of S. Hence, there are at most $2^{\mu(I)}$ preferred extensions that are subsets of S with size $\geq |S| - k$.*

4 Monotone Local Search

In this section, we apply Monotone Local Search to our $O^*(2^{\mu(I)})$ algorithm for Maximal Admissible Subset Enumeration. A basic exposition of Monotone Local Search will be provided here, see [17] for additional background. We adopt the notation of [17].

The framework normally applies to extension problems. However we can just as easily apply it to removal problems (formally by focusing on the complement of each set, we can turn any removal problem into an extension problem). Hence, we will freely use the framework with removal problems instead.

For our application, the instance I is the graph G and the family we are looking to enumerate, $\mathcal{F}_I$, is the set of all preferred extensions of G. We will apply Monotone Local Search using MASE as our subroutine.

For a MASE instance $I' = (G, X, k)$, let $\mathcal{F}^k_{I,X}$ denote the set of all maximal admissible sets $T \subseteq X$ such that $|X \setminus T| \leq k$. Hence $\mathcal{F}^k_{I,X}$ contains all preferred extensions that are subsets of X within distance k, but may also contain admissible extensions that are not preferred extensions.

Because of this, our Monotone Local Search will enumerate F_I, however, it may also enumerate some non-maximal admissible extensions. Our result, Theorem 10, will account for this, however, for simplicity we will just speak of enumerating F_I throughout this section.

A naive application of the Monotone Local Search framework with our $O^*\left(2^{\frac{k}{2}+\frac{b}{4}}\right)$ algorithm for enumerating $\mathcal{F}^k_{I,X}$ yields an $O^*\left(2^{\frac{b}{4}}\left(2 - \frac{1}{\sqrt{2}}\right)^{n+o(n)}\right) \approx O^*(1.1893^b \cdot 1.2929^n)$ time algorithm that enumerates all preferred extensions of G. To improve this we need a basic understanding of how Monotone Local Search works.

4.1 Basic Overview of Monotone Local Search

We need the following definition from [17] (slightly modified to account for our preference for removal problems):

▶ **Definition 9** ([17]). *Let U be a universe of size n and let $0 \leq p \leq q \leq n$. A family $C \subseteq \binom{U}{q}$ is an (n, p, q)-set-containing-family if for every set $S \in \binom{U}{p}$, there exists a $Y \in C$ such that $S \subseteq Y$.*

For any fixed s, a value $t \geq s$ will somehow be chosen. Then, a (n, s, t)-set-containing-family C_s is constructed. For each set in C_s, its subsets from $\mathcal{F}_I$ obtained by removing at most $t - s$ elements are then enumerated using an enumeration subroutine. This enumerates all elements of $\mathcal{F}_I$ with size s. Supposing the subroutine has run time $O^*(\alpha^k)$ (where k is the parameter), this step of Monotone Local Search has run time $O^*(|C_s| \cdot \alpha^{t-s})$.

Repeating this for all s, Monotone Local Search has running time $O^*(\max_{1\leq s\leq n} |C_s| \cdot \alpha^{t-s})$. With the right choices of t and C_s, [17] shows the running time $O^*((2 - \frac{1}{\alpha})^{n+o(n)})$.

Algorithm 2 Structure of Improved Monotone Local Search algorithm.

```
Ensure: Returns a set containing all preferred extensions of $G$ (and possibly some non-preferred extensions)
  function ImprovedMLS($G$)
      Let $\mathcal{F}_I = \emptyset$.
      for $b = 1$ to $|B|$ do
          Let $b' = \text{determine\_b}'(b)$.
          Let $C_b$ be a $(|B|, b, b')$-set-containing-family.
          for $d = 1$ to $|D|$ do
              Let $d' = \text{determine\_d}'(d)$.
              Let $C_d$ be a $(|D|, d, d')$-set-containing-family.
              for all pairs $(S, T)$ with $S \in C_b, T \in C_d$ do
                  Let $\mathcal{F}_I = \mathcal{F}_I \cup \text{MASE}(S \cup T, (b' - b) + (d' - d))$.
      return $\mathcal{F}_I$
```

4.2 Improving our Monotone Local Search

We start with some notation. For any digraph $G = (V, E)$, let B be the set of vertices in V in at least one 2-cycle and let $D := V \setminus B$. The key idea is we will sample vertices from B and D separately. The overall structure is described in Algorithm 2. Except for the separate sampling, it is identical to a standard application of Monotone Local Search.

First, we argue correctness, i.e: that every preferred extension is enumerated at least once. Fix a preferred extension, say U, and suppose U contains b vertices in B and d vertices in D. Then, by the definition of set-containing-families, there exists a $S \in C_b$ such that $U \cap B \subseteq S$ and a $T \in C_d$ such that $U \setminus B \subseteq T$. Now we note that $S \subseteq B, T \subseteq V \setminus B$ to get:

$$|(S \sqcup T) \setminus U| = |S \setminus (U \cap B)| + |T \setminus (U \setminus B)| = (b' - b) + (d' - d)$$

Hence U is enumerated in the call to $\text{MASE}(S \cup T, (b' - b) + (d' - d))$ as required.

Now we argue the runtime. For a fixed b, d the calls to MASE have total run time $O^*(|C_b| \cdot |C_d| \cdot 2^{\frac{(b'-b)+(d'-d)}{2} + \frac{b'}{4}})$ for some choice of b', d'. Our overall running time is

$$O^*\left(\max_{0 \le b \le |B|} \max_{0 \le d \le |D|} |C_b| \cdot |C_d| \cdot 2^{\frac{(b'-b)+(d'-d)}{2} + \frac{b'}{4}} \right)$$

We can split this into two terms to get a complexity of $O^*\left(\max_{0 \le d \le |D|} |C_d| \cdot 2^{\frac{(d'-d)}{2}} \right)$ multiplied by $O^*\left(\max_{0 \le b \le |B|} |C_b| \cdot 2^{\frac{(b'-b)}{2} + \frac{b'}{4}} \right)$.

We will now analyze the running time with the right choices of b' and d'.

The first of these two terms can be analyzed using the analysis in [17]. This term is the complexity one attains for Monotone Local Search with a $O^*(2^{\frac{k}{2}})$ subroutine. Hence the analysis in [17] gives a complexity of $O^*((2 - \frac{1}{\sqrt{2}})^{|D|+o(|D|)})$.

We need the extended analysis presented in [23] to analyze the second term. This term is the complexity one attains for Monotone Local Search with a $O^*(2^{\frac{k}{2} + \frac{n-|X|}{4}})$ subroutine (where k is the parameter, $n = |U|$ the size of the underlying set and X is the set we are extending). Hence the analysis in [23] gives a complexity of $O^*((1 + 2^{\frac{1}{4}} - \frac{1}{\sqrt{2}})^{|B|+o(|B|)})$.

The papers we have cited also give a corresponding combinatorial upper bound on the number of preferred extensions. We summarize the above results as follows.

▶ **Theorem 10.** *Let $G = (V, E)$ be a digraph. Let r be the proportion of vertices in V that are in at least one 2-cycle.*

Then there exists a $O^*(((1+2^{\frac{1}{4}}-\frac{1}{\sqrt{2}})^r(2-\frac{1}{\sqrt{2}})^{1-r})^{|V|+o(|V|)}) \approx O^*((1.4822^r 1.2929^{1-r})^{|V|})$ time algorithm that enumerates all preferred extensions of G; however it may also enumerate some non-maximal admissible extensions. Furthermore, there are at most $O^*(((1+2^{\frac{1}{4}}-\frac{1}{\sqrt{2}})^r(2-\frac{1}{\sqrt{2}})^{1-r})^{|V|}) \approx O^*((1.4822^r 1.2929^{1-r})^{|V|})$ preferred extensions in G.

5 Improved Enumeration Algorithm for Oriented Graphs

Finally, we outline a branching algorithm with a finer analysis for oriented graphs. As with MASE, we will follow a standard template for branching algorithms. A summary of the necessary concepts can be found in Section 2. Our algorithm creates a search tree with at most φ^n leaves where $\varphi \approx 1.2321$ is the branching number for branching vector $(8, 1)$.

In Section 6 we will use the Oriented Translation (Theorem 2) to obtain a general enumeration algorithm parameterized by the number of vertices in at least one 2-cycle.

5.1 Overview

The overall structure of our algorithm is described in Algorithm 3.

The state of the algorithm consists of the subset Und $\subseteq V(G)$ and a queue of vertices Def (Und for undecided and Def for deferred). Und is the set of vertices we have yet to make a decision on whether we should include them. Def is a queue of vertices which have no outgoing arcs to Und. These vertices will be handled in the base case. While branching we can essentially assume the vertices in Def do not exist.

We maintain the following invariants. We outline why they are invariant, it is straightforward to verify that each case of our branching algorithm maintains these invariants.

1. Und and Def are disjoint. This holds as vertices are only ever deleted from or moved between Und and Def, never copied.
2. $G[\text{Def}]$ is a DAG where each vertex $v \in$ Def only attacks vertices that were added to Def before v. This is crucial for the base case since a DAG has 1 maximal admissible subset. This holds as only vertices with out-degree 0 in $G[\text{Und}]$ are ever moved to Def.
3. There is no attack from any vertex in Def to any vertex in Und. This holds for the same reason as Invariant 2.

Our measure is $\mu = |\text{Und}|$. For any instance, our algorithm creates a search tree with at most φ^μ leaves. Hence, calling OrientedEnumeration$(V(G), [])$ will return all preferred extensions of G by traversing a search tree with at most $\varphi^{|V(G)|}$ leaves.

5.2 Extra Notation

We will say a vertex has degree $(a, -)$ if it has in-degree a, a vertex has degree $(-, b)$ if it has out-degree b and a vertex has degree (a, b) if it has in-degree a and out-degree b.

5.3 Simplification Rules

Both of these are applicable in polynomial time and decrease $\mu = |\text{Und}|$.

▶ **Simplification Rule 2** (Out-degree 0)**.** *Let v be a vertex in $G[\text{Und}]$ with out-degree 0. Move v from* Und *to the end of the queue* Def*.*

Algorithm 3 Structure of Oriented maximal admissible enumeration algorithm.

```
Require: $\mathrm{Und} \cap \mathrm{Def} = \emptyset$.
Require: $G[\mathrm{Def}]$ is a DAG where each $v \in \mathrm{Def}$ only attacks vertices added to Def before $v$.
Require: There is no attack from any vertex in Def to any vertex in Und.
Ensure: Returns all maximal admissible subsets of $\mathrm{Und} \cup \mathrm{Def}$.
  function OrientedEnumeration(Und, Def)
    while Any simplification rule applies do
      Apply said simplification rule
    if Base Case applies then
      Solve the instance directly through the base case subroutine.
    else
      Let $b_i$ be the first branching rule that applies.
      Let $(U_1, D_1) \dots (U_r, D_r)$ be the subinstances obtained from applying $b_i$.
      Let $C_i = \mathrm{OrientedEnumeration}(U_i, D_i)$, for all $1 \le i \le r$.
      return Maximal_Subset_Collation($(U_1 \cup D_1, C_1), \dots, (U_r \cup D_r, C_r)$)
```

▶ **Simplification Rule 3** (In-degree 0). *Let v be any vertex in $G[\mathrm{Und}]$ with in-degree 0. Then by Invariant 3, v has in-degree 0 in $G[\mathrm{Und} \cup \mathrm{Def}]$. Applying Simplification Rule* ***(Undefendable)*** *we can set $\mathrm{Und} \leftarrow \mathrm{Und} \setminus N(v)$. After that, v has out-degree 0 in $G[\mathrm{Und}]$ and hence we move v from Und to Def.*

Our new instance $I' = (\mathrm{Und}', \mathrm{Def}')$ has:

- $\mathrm{Und}' = \mathrm{Und} \setminus N[v]$.
- $\mathrm{Def}' = \mathrm{Def} \cup \{v\}$.

Due to these rules, henceforth we may assume each vertex in $G[\mathrm{Und}]$ has in-degree ≥ 1, out-degree ≥ 1 and (total) degree ≥ 2.

5.4 Branching Rules

Our algorithm will apply the first rule applicable to the instance:

Case	Requirement to apply	Worst case branching number
Base	$\mathrm{Und} = \emptyset$.	Solves in $O^*(1)$, returns 1 set.
1	$\exists v \in G[\mathrm{Und}]$ with total degree ≥ 7.	Branching vector $(8,1)$, branching number $\varphi \approx 1.2321$.
2	$\exists v \in G[\mathrm{Und}]$ with degree $(1,-)$.	Branching vector $(4,3)$, branching number ≈ 1.221.
3	$\exists v \in G[\mathrm{Und}]$ with in-degree $\neq$ out-degree.	Branching vector $(6,5,5)$, branching number ≈ 1.2298.
4	$G[\mathrm{Und}]$ has a weakly connected component where every vertex has degree $(2,2)$.	Branching vector $(6,5,5)$, branching number ≈ 1.2298.
5	$G[\mathrm{Und}]$ has a weakly connected component where every vertex has degree $(3,3)$.	Branching vector $(7,7,7,7)$, branching number ≈ 1.219.
6	There is a weakly connected component in $G[\mathrm{Und}]$ where every vertex has in-degree $=$ out-degree.	Branching vector $(7,5,5)$, branching number ≈ 1.218.

We note the base case and cases 3 and 6 cover all possible inputs. Hence there will always be at least one applicable rule.

Our primary strategy is to pick a specific vertex v and do a 2-way branch, separately enumerating the maximal admissible subsets that include v and the ones that exclude v.

- In the branch where we include v we must exclude v's neighbors. Hence we create a new instance $I' = (\text{Und}', \text{Def})$ where $\text{Und}' = \text{Und} \setminus N(v)$.
  Now v is isolated in $G[\text{Und}']$ so by Simplification Rule 2 we may move v from Und' to Def'. Hence in our new instance we finally have:
  - $\text{Und}' = \text{Und} \setminus N[v]$.
  - $\text{Def}' = \text{Def} \cup \{v\}$.

  and hence $\mu(I') = \mu(I) - |N[v]| = \mu(I) - \deg(v) - 1$.
  As a technical note, not every subset enumerated in this branch contains v, however, every maximal admissible subset that contains v will be enumerated in this branch.
- In the branch where we exclude v our new instance $I' = (\text{Und}', \text{Def}')$ is:
  - $\text{Und}' = \text{Und} \setminus \{v\}$.
  - $\text{Def}' = \text{Def}$.

  and hence $\mu(I') = \mu(I) - 1$.

Hence our branching vector is $(\deg(v) + 1, 1)$. However, often our choice of v allows us to immediately apply our simplification rules to improve the branch where v is excluded.

Full proofs of each case can be found in the full version. A few short remarks:

In the base case, by Invariant 2, $G[\text{Und} \cup \text{Def}]$ is a DAG. The base case then follows trivially from Lemma 7.

Case 2 is a good example of the strategy of picking a specific v to apply a 2-way branch on. We will pick a v that allows us to apply our simplification rules in the branch where v is excluded. However, the choice of v will depend on some case analysis on degrees of vertices.

Case 3 is similar to Case 2, a specific v is chosen on which we apply a 2-way branch.

Case 4 is done through a graph classification theorem. We classify the family of oriented graphs where each vertex has in-degree 2, out-degree 2 and both in-neighbors adjacent (if there is a vertex with independent in-neighbors then we instead apply a 3-way branch on that vertex and its in-neighbors).

Case 5 is just a 4-way branch on any vertex v and its 3 in-neighbors.

For Case 6, we first show there is a vertex with degree $(3, 3)$ attacking a vertex with degree $(2, 2)$, say b. Then we apply a 3-way branch on b and its 2 in-neighbors.

5.5 Summary of results

In our base case we enumerate 1 extension in polynomial time.

Otherwise, we apply a branching rule with branching number $\leq \varphi$.

As in MASE, the Maximal Subset Collation subroutine does not incur additional overhead as the search tree's depth is bounded by $|V(G)|$ (see Subsection 3.2 for the argument which we can apply verbatim).

Applying the Combine Analysis Lemma and Combine Analysis Lemma for Enumeration we obtain:

► **Theorem 11.** *Let $G = (V, E)$ be an oriented graph. Then there is an algorithm that enumerates all preferred extensions of G with running time $O^*(\varphi^{|V|})$ where φ is the unique positive root of $1 - x^{-1} - x^{-8} = 0$, $\varphi \approx 1.23205 < 1.2321$.*

Furthermore, G has at most $\varphi^{|V|}$ preferred extensions.

6 Bounds on number of preferred extensions

In this section, we collect our results bounding the number of preferred extensions.

6.1 Bounds on general directed graphs

A tight upper bound is $O(3^{\frac{|V|}{3}})$ [16]. This bound is easily attainable since preferred extensions coincide with maximal independent sets(MIS) in graphs where every edge is in a 2-cycle.

We can also enumerate them in $O^*(3^{\frac{|V|}{3}})$. We note each MIS has a single maximal admissible subset. We then take a branching algorithm for MIS[22], allowing us to apply the Maximal Subset Collation subroutine to remove the non preferred extensions without additional overhead. Hence, all preferred extensions can be enumerated in $O^*(3^{\frac{|V|}{3}})$.

6.2 Parameterizing by Resolution Order

We will give bounds based on r, the proportion of vertices that are in at least one 2-cycle.

6.2.1 Lower Bound

An undirected 3-cycle has 3 preferred extensions. Hence, applying the Oriented Translation to it, we obtain an oriented structure with 6 vertices and 3 preferred extensions.

Our construction for lower bounding will be to include as many undirected 3-cycles as possible and then include as many oriented translations of 3-cycles as possible. We can include $\frac{r|V|}{3}$ undirected 3-cycles and $\frac{(1-r)|V|}{6}$ oriented translations, obtaining an AF with $\Omega((3^{\frac{r}{3}}3^{\frac{1-r}{6}})^{|V|}) \approx ((1.44^r 1.2^{1-r})^{|V|})$ preferred extensions.

6.2.2 Upper Bound

There are 3 different upper bounds that are all optimal in a different range. See also Figure 1.

- $(\varphi^{2r}\varphi^{1-r})^{|V|} \approx O((1.5180^r 1.2321^{1-r})^{|V|})$ where φ is the unique positive root of $1-x^{-1}-x^{-8}$. This bound is obtained from using the Oriented Translation along with Theorem 11. This is best for r up to around 0.6684.
- $O^*(((1+2^{\frac{1}{4}}-\frac{1}{\sqrt{2}})^r(2-\frac{1}{\sqrt{2}})^{1-r})^{|V|}) \approx O^*((1.4822^r 1.2929^{1-r})^{|V|})$, the bound from our 2-phase Monotone Local Search. This is best for a small range where $0.6685 \leq r \leq 0.8004$.
- $3^{\frac{|V|}{3}}$. This is best for $r \geq 0.8005$.

7 Conclusion

We again note that the concept of an admissible (resp. preferred) extension has also been studied as a *semikernel*[27] (resp. maximal *semikernel*) in graph theory. Hence our result may be interpreted as a combinatorial upper bound on the number of maximal *semikernels*, parameterized by the proportion of vertices in at least one 2-cycle.

Abstract

Cost register automata (CRA) are machines reading an input word while computing values using write-only registers: values from registers are combined using the two operations, as well as the constants, of a semiring. Particularly interesting is the subclass of copyless CRAs where the content of a register cannot be used twice for updating the registers. Originally deterministic, non-deterministic variant of CRA may also be defined: the semantics is then obtained by combining the values of all accepting runs with the additive operation of the semiring (as for weighted automata). We show that finitely-ambiguous copyless non-deterministic CRAs (i.e. the ones that admit a bounded number of accepting runs on every input word) can be effectively transformed into an equivalent copyless (deterministic) CRA, without requiring any specific property on the semiring. As a corollary, this also shows that regular look-ahead can effectively be removed from copyless CRAs.

1 Introduction

Quantitative languages extend "classical" languages by associating with each word a weight or a cost from an algebraic structure. Such algebraic structures could be monoids, semirings, fields or any other convenient structures. Quantitative languages have been successfully applied to various domains such as natural language processing [15] or modelisation of stochastic systems [17, 16]. The seminal work on quantitative languages from Schützenberger [18] introduces the model of weighted automata, that associates with each word a weight from a semiring. The weight of a run is the *product* of its transition weights whereas the weights of the multiple runs on a single word (due to non-determinism) are combined by *sum*. Classical word languages are then the particular case of weighted languages over the Boolean semiring. There have been a long line of research that studied properties of weighted automata [10]. As for finite-state automata, two-way [6] and alternating [12, 7] automata have been considered, as well as extensions to infinite words [8].

Recently, Alur et al. [3] introduced another automata model for defining mappings from words to some algebraic structures (in particular semirings), named Cost Register Automata (CRA). These are deterministic machines equipped with a finite collection of registers storing values: while reading the input word, each transition reads an input letter and updates the registers by combining the current contents of registers and values from the considered

algebraic structure. A distinguished subclass of CRAs is the one of *copyless* CRAs: intuitively, for such a machine, the content of a register cannot be used twice for updating the registers. Properties regarding expressiveness of this class have been studied in [14, 13]. The decision problem of equivalence of copyless CRA on the tropical semiring is proved undecidable in [1]. Some other works have also considered the register minimisation problem (computing the smallest number of registers to define a particular function) for copyless CRAs [5, 9].

Following [14], we consider both deterministic and non-deterministic copyless CRAs on semirings (to distinguish them, we call NCRA the class of non-deterministic CRAs). Non-determinism is resolved, as in weighted automata, by the sum operation of the semiring: the value associated with some input word is computed as the sum of the values computed by each accepting run on this input. We investigate a limited form of non-determinism, k-ambiguity: a non-deterministic CRA is said to be k-ambiguous if it has at most k accepting runs per input. In the context of weighted automata, k-ambiguous weighted automata are strictly more powerful than deterministic weighted automata, yet less powerful than weighted automata, leading to an appealing class of weighted languages with good decision properties (the equivalence problem becomes decidable for k-ambiguous weighted automata over the $(\max, +)$-semiring [11]). Surprisingly, in the context of CRAs, our main result is:

▶ **Theorem 1.** *Every finitely-ambiguous copyless* NCRA *can be effectively transformed into an equivalent copyless (deterministic)* CRA*.*

Moreover, the example developed in [14, Theorem 2] allows one to build a linearly-ambiguous copyless NCRA that cannot be recognised with a finitely-ambiguous copyless NCRA, showing that our result cannot be improved regarding ambiguity. An alternative way to resolve non-determinism is to consider a regular look-ahead. When reading a word from left to right, the look-ahead provides some (regular) information about the unread suffix of the word that allows to determine the unique transition to be applied at each step. In this case, the machine is said to be deterministic with look-ahead. In [3], this class is introduced and named CRA-RLA. It is proved there that for copyless CRA-RLA, the look-ahead can be removed preserving the copyless property provided that the considered algebraic structure is extended with unary mappings (using the so-called *streaming string-to-tree transducers* [2] as an intermediate step). In [14], Mazowiecki and Riveros proved that copyless CRA, unlike weighted automata, are not closed under reverse but claimed that “Like for unambiguous copyless CRAs, we do not know if extending copyless CRAs with regular look-ahead results in a more expressive model”. However, they defined the subclass of bounded-alternation copyless CRAs which are closed under reverse and for which deterministic look-aheads do not increase expressiveness.

A look-ahead can be given as a complete co-deterministic automaton B and transitions of the CRA A are then parameterised by some state of B. It is folklore that one can compute the product of A and B to obtain a machine equivalent to A which is look-ahead free, now non-deterministic, but still unambiguous. This construction still applies when A is a copyless CRA and the product yields an unambiguous copyless CRA. Therefore, by Theorem 1, we close the open problem stated in [14]:

▶ **Theorem 2.** *Every copyless CRA with look-ahead can be effectively transformed into an equivalent copyless CRA.*

The article is structured as follows: in Section 2, we define CRAs as well as several subclasses (copyless CRAs, $\diamond$-less CRAs, and bounded-copy CRAs). They are defined by means of flow graphs representing the flow of registers during runs in an abstract way. The proof of Theorem 1 is given as a cascade of three transformations leading from one subclass to another one, that are described successively in Sections 3, 4 and 5.

2 Cost register automata

Terms and substitutions. Fix a semiring $\mathbb{S} = (S, +, \times, 0, 1)$ and a finite set of variables $\mathcal{X}$ disjoint from S. We denote by $\mathrm{Term}(\mathcal{X})$ the set of *terms* generated by the grammar:

$t ::= s \mid x \mid t + t \mid t \times t$

where $s \in S$ and $x \in \mathcal{X}$. For a term $t \in \mathrm{Term}(\mathcal{X})$, we denote by $\mathrm{Var}(t)$ its set of variables. We call t a *ground term* if $\mathrm{Var}(t) = \emptyset$, and then define $[\![t]\!] \in S$ to be the evaluation of t with respect to $\mathbb{S}$. We call a term $t \in \mathrm{Term}(\mathcal{X})$ *copyless* if every variable appears at most once in t. In the following, we will represent terms as binary trees, where leaves are labelled by variables or constants, and internal nodes are labelled by operations of the semiring.

▶ **Example 3.** On the semiring $(\mathbb{N}, +, \times, 0, 1)$, examples of terms are $3x + 1$ (we often make implicit the product operator) or $y + 2zx + 3$, making use of the associativity of both operators to drop useless parentheses. On the semiring $(\mathbb{Z} \cup \{\infty\}, \min, +, \infty, 0)$, the same terms are written $\min(3 + x, 1)$ and $\min(y, 2 + z + x, 3)$. Other examples of terms on the non-commutative semiring $(\mathfrak{P}(\{a, b\}^*), \cup, \cdot, \emptyset, \{\varepsilon\})$ of languages over alphabet $\{a, b\}$ are $\{a\}x\{\varepsilon, aab\} \cup y \cup \{b\}$. All these terms are copyless.

A *substitution* is a mapping $\sigma : \mathcal{X} \to \mathrm{Term}(\mathcal{X})$. We denote the set of all substitutions over $\mathcal{X}$ by $\mathrm{Subs}(\mathcal{X})$. If t is a term, we let $[x \mapsto t]$ be the substitution defined by $[x \mapsto t](x) = t$ and $[x \mapsto t](y) = y$ for all variables $y \neq x$. A *ground substitution* σ is a substitution where the term $\sigma(x)$ is ground for every $x \in \mathcal{X}$. Substitutions are extended canonically to a term morphism, and may thus be composed: $\sigma_1 \circ \sigma_2(x) = \sigma_1(\sigma_2(x))$.

A *valuation* is defined as a substitution of the form $\nu \colon \mathcal{X} \to S$. We denote the set of all valuations over $\mathcal{X}$ by $\mathrm{Val}(\mathcal{X})$. Clearly, any valuation ν composed with a substitution σ defines a ground substitution. We say that two terms t_1 and t_2 are equivalent (denoted by $t_1 \equiv t_2$) if $[\![\nu(t_1)]\!] = [\![\nu(t_2)]\!]$ for every valuation $\nu \in \mathrm{Val}(\mathcal{X})$. Similarly, we say that two substitutions σ_1 and σ_2 are equivalent (denoted by $\sigma_1 \equiv \sigma_2$) if $\sigma_1(x) \equiv \sigma_2(x)$ for every $x \in \mathcal{X}$.

Non-deterministic cost register automata. A non-deterministic CRA (NCRA) over the semiring $\mathbb{S}$ is a tuple $\mathcal{A} = (Q, \Sigma, \mathcal{X}, \Delta, I, \nu_{ini}, F, \varphi)$, where Q is a finite set of states, Σ is the input alphabet, $\mathcal{X}$ a finite set of registers, $\Delta \subseteq Q \times \Sigma \times \mathrm{Subs}(\mathcal{X}) \times Q$ is the finite transition relation with updates of the registers, $I \subseteq Q$ is the set of initial states, $\nu_{ini} \colon I \to \mathrm{Val}(\mathcal{X})$ defines an initial valuation of the registers for each initial state, F is the set of final states and $\varphi \colon F \to \mathrm{Term}(\mathcal{X})$ the final output function. Transition (q, a, σ, q') is denoted by $q \xrightarrow{a|\sigma} q'$.

A configuration of $\mathcal{A}$ is a tuple (q, ν) where $q \in Q$ and $\nu \in \mathrm{Val}(\mathcal{X})$ represents the current values in the registers of $\mathcal{A}$. Given a word $w = a_1 \cdots a_n \in \Sigma^*$, a *run* ρ of $\mathcal{A}$ over w is a sequence of configurations linked by transitions $(q_0, \nu_0) \xrightarrow{a_1|\sigma_1} (q_1, \nu_1) \xrightarrow{a_2|\sigma_2} \cdots \xrightarrow{a_n|\sigma_n} (q_n, \nu_n)$ such that $q_0 \in I$, $\nu_0 = \nu_{ini}(q_0)$, for $1 \leq i \leq n$, $q_{i-1} \xrightarrow{a_i|\sigma_i} q_i$ is a transition and $\nu_i(x) = [\![\nu_{i-1} \circ \sigma_i(x)]\!]$ for each $x \in \mathcal{X}$. A run is accepting if it ends in a final state $q_n \in F$. The output of an accepting run $\rho = (q_0, \nu_0) \xrightarrow{a_1|\sigma_1} \cdots \xrightarrow{a_n|\sigma_n} (q_n, \nu_n)$, denoted by $[\![\rho]\!]$, is the value $[\![\nu_n(\varphi(q_n))]\!]$. The output of $\mathcal{A}$ over w is defined as $[\![\mathcal{A}]\!](w) = 0$ if there is no accepting run of $\mathcal{A}$ over w, and $[\![\mathcal{A}]\!](w) = \sum_\rho [\![\rho]\!]$ over all accepting runs ρ over w otherwise. Two NCRAs are said *equivalent* if they compute the same output on every input word.

For some positive k, a NCRA $\mathcal{A}$ is *k-ambiguous* if there are at most k accepting runs over each word w. $\mathcal{A}$ is *finitely-ambiguous* if it is k-ambiguous for some k, and *unambiguous* if it is 1-ambiguous. A NCRA is said to be *deterministic*, and denoted by CRA, if I is a singleton and for all $q \in Q$, $a \in \Sigma$, there exists at most one state $q' \in Q$ and one register update $\sigma \in \mathrm{Subs}(\mathcal{X})$ such that $q \xrightarrow{a|\sigma} q' \in \Delta$.

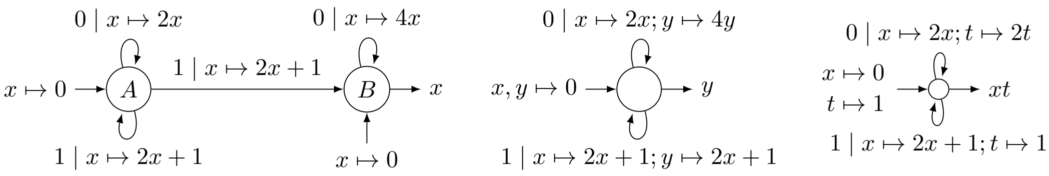

Figure 1 Three equivalent automata: an unambiguous copyless NCRA $\mathcal{A}_n$ (on the left), a $\diamond$-less CRA $\mathcal{A}_d$ (in the middle), a copyless CRA $\mathcal{A}_c$ (on the right).

▶ **Example 4.** Consider the copyless NCRA $\mathcal{A}_n$ depicted on the left of Figure 1 over the alphabet $\{0,1\}$ and the semiring $(\mathbb{N}, +, \times, 0, 1)$. It has a single register x, so that we hereby denote configurations by pairs $(q, \nu(x))$. Every word $w \in \{0,1\}^*$ has two runs, only one being accepting: thus $\mathcal{A}_n$ is unambiguous. For instance, on the word $w = 10100$, the two runs are

$$(A,0) \xrightarrow{1|x\mapsto 2x+1} (A,1) \xrightarrow{0|x\mapsto 2x} (A,2) \xrightarrow{1|x\mapsto 2x+1} (A,5) \xrightarrow{0|x\mapsto 2x} (A,10) \xrightarrow{0|x\mapsto 2x} (A,20)$$
$$(A,0) \xrightarrow{1|x\mapsto 2x+1} (A,1) \xrightarrow{0|x\mapsto 2x} (A,2) \xrightarrow{1|x\mapsto 2x+1} (B,5) \xrightarrow{0|x\mapsto 4x} (B,20) \xrightarrow{0|x\mapsto 4x} (B,80)$$

Therefore, A is a state computing the integer value of the word as binary representation with less significant bits first. To accept, we must jump into the unique final state B while reading the last 1 (or start directly in B if the word contains only 0s), then multiplying by 4 for each remaining 0: it is as if each 0 of the last block of 0s is considered to be duplicated by the CRA. The same function can also be recognised by a deterministic CRA, using two registers x and y, depicted in the middle of Figure 1. Instead of using non-determinism to guess the last 1 of the word, $\mathcal{A}_d$ always computes both the multiplications by 2 and 4 in separate registers x and y when reading 0. On each letter 1 though, the content of register y is reset to the same content as register x: operationally, this means that the content of register x must be duplicated when reading 1.

Flow of registers. A crucial notion in NCRAs is their ability to copy, or not, contents of registers into several registers. A NCRA is therefore called *copyless* if no register updates σ of Δ or terms of φ copy some register (see [3]). A more graphical definition of copyless can be achieved by gathering the *flows* of registers in a notion of *flow graphs*, that we define now, inspired by a close notion of dependency graph introduced in [4]:

▶ **Definition 5.** *A* flow graph *over the set of variables $\mathcal{X}$ is a (finite) directed acyclic (multi)graph (V, E) where $V = (\mathcal{X} \times \{0, 1, \dots, \ell_{max}\}) \uplus \{\Omega\}$ (with $\ell_{max} \geq 0$) is a finite set of vertices (x, ℓ) where ℓ is called the* layer *of the vertex (with ℓ_{max} being the maximal layer of the flow graph), and $E \colon V^2 \to \mathbb{N}$ being a multiset of edges satisfying:*

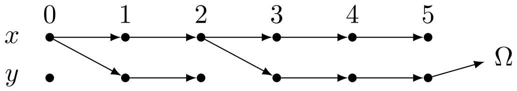
1. *E is consistent with the layers: $E((x_1,\ell_1),(x_2,\ell_2)) \neq 0 \implies \ell_2 = \ell_1 + 1$, and*
2. *Ω has no outgoing edges and all its ingoing edges come from the maximal layer: $E((x,\ell),\Omega) \neq 0 \implies \ell = \ell_{max}$.*

Each run $\rho = q_0 \xrightarrow{a_1|\sigma_1} q_1 \xrightarrow{a_2|\sigma_2} \cdots \xrightarrow{a_k|\sigma_k} q_k$ of a NCRA $\mathcal{A}$ is associated with the flow graph $G_{\mathcal{A}}(\rho) = (V, E)$ defined by: $V = \mathcal{X} \times \{0, \dots, k\} \cup \{\Omega\}$; for $\ell \in \{1, \dots, k\}$, and $x, y \in \mathcal{X}$, $E((x, \ell-1), (y, \ell))$ is the number of occurrences of the variable x in $\sigma_\ell(y)$; $E((x,k),\Omega)$ is the number of occurrences of x in $\varphi(q_k)$, and 0 if $q_k \notin F$.

Copyless restriction of NCRAs can be recovered directly on the flow graphs generated by their runs. For this reason, we say that a vertex of a flow graph is a *copy vertex* if it is the source of at least two edges. We use those to define two other related properties of the flow graphs that will be used in the following.

▶ **Definition 6.** *A flow graph (V, E) is* diamondless *(shorten as* $\diamond$-less *in the following) if there is at most one path linking every pair of vertices. It is called* k-copy *if every vertex can reach at most k copy vertices. We say that it is* copyless *if it is 0-copy.*

▶ **Example 7.** Consider once again the word 10100, and the unique run of the CRA $\mathcal{A}_d$ of Figure 1. Here is a pictural representation of the associated flow graph:



One can observe on this picture that $\mathcal{A}_d$ is not copyless, since register x is copied when reading letter 1. However, there are no diamonds (neither in this particular run, nor in any possible run), which means that $\mathcal{A}_d$ is $\diamond$-less.

By extension, a NCRA is said to be copyless (resp. $\diamond$-less or k-copy) if the flow graphs of all possible accepting runs of the NCRA are copyless (resp. $\diamond$-less or k-copy). It is said to be bounded-copy if it is k-copy for a certain value k. This alternative definition of copyless NCRA is equivalent to one of [3], whenever CRAs are supposed to be trimmed (i.e. all states are reachable from the initial ones and can reach a final state). Note that in the flow graphs of a $\diamond$-less CRAs, the multiset E is indeed a set (all pairs evaluate to 0 or 1). However, this does not imply that the CRA is copyless since a register can appear in the updates of two different registers. The $\diamond$-less property simply ensures that every register will flow at most once in the final output, in every possible execution: there may exist copies, but when it is the case, we are sure that at most one copy will resist up to the end; however, this exact copy can not be known yet as it might depend on the input word.

Contribution. Our main result is Theorem 1 stated already in the introduction. As the class of copyless CRA is obviously included into the class of finitely-ambiguous copyless NCRA, this result implies that these two classes define the same family of functions.

▶ **Example 8.** Our running example can indeed be recognised by the copyless CRA $\mathcal{A}_c$ on the right of Figure 1 which keeps in a register x the binary value of the input, and keeps in another register t the powers of 2 corresponding to the current longest suffix of letter 0. We multiply x by t in the final output function, and reset t when reading a letter 1.

Our construction is split into a cascade of transformations detailed in the next sections:

$$\begin{array}{c}\text{finitely-ambiguous}\\ \text{copyless NCRA}\end{array} \xrightarrow{\text{Prop. 9}} \begin{array}{c}\diamond\text{-less}\\ \text{CRA}\end{array} \xrightarrow{\text{Prop. 11}} \begin{array}{c}\text{bounded-copy}\\ \text{CRA}\end{array} \xrightarrow{\text{Prop. 19}} \begin{array}{c}\text{copyless}\\ \text{CRA}\end{array}$$

The first step in the construction is given in Section 3: a determinisation procedure of the finitely-ambiguous copyless CRA allows us to build a (deterministic) CRA, that may not be copyless, thus trading non-determinism for copies. This new CRA will indeed be $\diamond$-less. The second step is to reduce the number of copies in order to build an equivalent CRA that is bounded-copy: this is not trivial since the $\diamond$-less property does not forbid that unboundedly many copies can be performed. The idea is to delay copies until a moment where we know that enough copies have become useless. This more difficult step is the main contribution of this article and presented in Section 4. Finally, it remains to show in Section 5 how to remove all copies of the bounded-copy CRA, by replicating the registers as many times as needed.

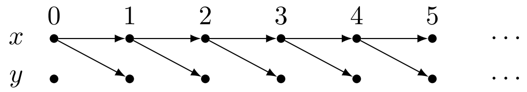
3 From finitely-ambiguous CRAs to diamondless CRAs

As a first step in our construction, we start by transforming every k-ambiguous NCRA into a $\diamond$-less CRA: this is a determinisation step where we maintain replicas of the registers, indexed by the states and a number in $\{1, \dots, k\}$ to distinguish the k possible runs.

▶ **Proposition 9.** *For every finitely-ambiguous copyless* NCRA*, we can compute an equivalent* $\diamond$*-less* CRA.

▶ **Example 10.** Starting from the unambiguous copyless NCRA $\mathcal{A}_n$ of Figure 1, we obtain a $\diamond$-less CRA $\mathcal{A}'$ isomorphic to the CRA $\mathcal{A}_d$: the single state represents the set $\{A, B\}$ of states of $\mathcal{A}$, while registers (x, A) and (x, B) of $\mathcal{A}'$ are the registers x and y on the picture.

The next step aims to limit the number of copies of the $\diamond$-less CRA. Indeed, $\diamond$-less CRAs are not necessarily copyless, and may even copy certain registers an unbounded number of times (in arbitrarily long runs). This is the case for the $\diamond$-less CRA $\mathcal{A}_d$ of Figure 1: for instance, the flow graph associated with the run over the word $11111\cdots$ is of the form



and has thus an unbounded number of copies of register x, that are all reachable from vertex $(x, 0)$; thus, $\mathcal{A}_d$ is not bounded-copy.

4 From diamondless CRAs to bounded-copy CRAs

In this section, we prove the most difficult step of the overall construction:

▶ **Proposition 11.** *For every* $\diamond$*-less* CRA*, we can construct an equivalent bounded-copy* CRA.

As seen in the example of the previous section, this result is not straightforward as $\diamond$-less CRAs may have an unbounded number of copies. Our approach somehow extends the one developed for streaming string transducers in [4]. However, the proof is simpler in the case of transducers where only a single operation exists (the product of a monoid). This allows one to represent in an alternative way the valuation of a register as a product of constants and other registers: instead of storing in registers the value of these products, it is going to be abstracted, storing in fresh registers the constant values separating two consecutive registers in products. In the setting of semirings, with two operations, it is much more intricate to do so, since the content of a register has to be viewed now as a term involving both operations. Hence, it is less clear a priori what could be the constants separating two "consecutive" registers of this term. We start by clarifying this, introducing special terms we call *shapes*, associated with *coefficients* that are these separating constants. Similar kind of shapes are used in [14, Theorem 3] to remove unambiguous non-determinism from bounded-alternation NCRAs, i.e. NCRAs that can only alternate a bounded number of times between sums and products in the register updates. The treatment of shapes is more complex in our case since we have no such limitation on alternations.

Shapes and coefficients. The *shape* of a term t over the set of variables $\mathcal{X}$ is a term with no constants, but with additional variables, obtained as follows. First, all constants are removed from the term to obtain a term $\tilde{t}$ where all leaves are labelled with variables of $\mathcal{X}$: for instance, if $t = (3x_1(5+2)+4) \times (2x_2) + 3$, then $\tilde{t} = x_1 \times x_2$. Doing so, we lose much information on the term, that we then recover by decorating every subterm t' of $\tilde{t}$ with some fresh coefficients α, β, γ, replacing the root of t' by $\alpha t'\beta + \gamma$: α, β represent respectively the left and the right multiplicative coefficient, and γ the additive coefficient. The *shape* of t is the term obtained by decorating each subterm of $\tilde{t}$. It is associated with a valuation χ mapping each coefficient of the shape to its value. On the example, the shape obtained is $\alpha_3[(\alpha_1 x_1 \beta_1 + \gamma_1) \times (\alpha_2 x_2 \beta_2 + \gamma_2)]\beta_3 + \gamma_3$, and the valuation of its coefficients is defined by $\chi(\alpha_1) = 3$, $\chi(\beta_1) = 7$, $\chi(\gamma_1) = 4$, $\chi(\alpha_2) = 2$, $\chi(\beta_2) = \chi(\alpha_3) = \chi(\beta_3) = 1$, $\chi(\gamma_2) = 0$, $\chi(\gamma_3) = 3$.[1] For the special case of a constant term t (without any variables), the shape is reduced to a special coefficient ω.

Shapes are canonical way to store terms. In particular, note that there is only a finite number of shapes of *copyless* terms over $\mathcal{X}$, denoted by Shape($\mathcal{X}$), though there are infinitely many possible coefficient valuations associated with these shapes. This will allow us to store the shapes in states of the bounded-copy CRA, while keeping in registers the valuations of coefficients (that could not fit in a CRA with a finite number of states).

Given a shape τ and an associated coefficient valuation χ, we denote by $\chi(\tau)$ the term obtained by replacing each coefficient of τ by its value: thus, $\chi(\tau)$ is a term over variables $\mathcal{X}$.

▶ **Proposition 12.** *There is a linear-time algorithm that, given a term t, builds a shape τ of t and a coefficient valuation χ, such that t and $\chi(\tau)$ are equivalent terms.*

Unfolding of a CRA. In the rest of the section, we let $\mathcal{A} = (Q, \Sigma, \mathcal{X}, \Delta, I = \{q_{ini}\}, \nu_{ini}, F, \varphi)$ be a $\diamond$-less CRA. We construct another CRA $\mathcal{A}_\infty = (Q', \Sigma, \mathcal{X}', \Delta', I = \{q'_{ini}\}, \nu'_{ini}, F', \varphi')$ equivalent to $\mathcal{A}$, by unfolding: states contain shapes, and registers store the valuations of all corresponding coefficients. At first, $\mathcal{A}_\infty$ will thus have an infinite number of states: we explain afterwards how to reduce it to a finite number.

States of $\mathcal{A}_\infty$ are pairs (q, s), where q is a state of $\mathcal{A}$ and s maps each pair $(x, \ell) \in \mathcal{X} \times \{1, \ldots, \ell_{max}\}$, where $\ell_{max} \in \mathbb{N}$ depends on the state of $\mathcal{A}_\infty$, to a term of Shape($\mathcal{X} \times \{\ell - 1\}$), and each pair $(x, 0)$ to a shape of the form ω: s records the register updates applied so far, keeping only the shapes in memory. We call s the *shape substitution* of the state. Moreover, we enforce all coefficients appearing in all the shapes of s to be different. Notice that such a state (q, s) is associated uniquely with a flow graph $G = (\mathcal{X} \times \{0, \ldots, \ell_{max}\} \uplus \{\Omega\}, E)$ where E is the set[2] defined by $((x, \ell - 1), (y, \ell)) \in E$ iff $(x, \ell - 1)$ appears in $s(y, \ell)$, and $((x, \ell_{max}), \Omega) \in E$ iff $x \in \varphi(q)$. In the following, we use the notions of layers originating from flow graphs directly on s. All vertices of the flow graph that cannot reach a vertex of the maximal layer are useless : their value will not be used in the output of the CRA. Hence, we clean up s by mapping them to constant coefficients ω. In the following, we always consider that shape substitutions s are cleaned up this way.

Registers of $\mathcal{A}_\infty$ are all the possible coefficients appearing in its states (notice that there is an infinite number of them). However, at each point of the execution of $\mathcal{A}_\infty$, only coefficients that appear in the shape substitution of the current state are initialised, other registers being useless at this point. We may call *coefficients* the registers of $\mathcal{A}_\infty$ to emphasise their role.

The initial state is $q'_{ini} = (q_{ini}, s_{ini})$ with s_{ini} mapping $(x, 0)$ to a distinct coefficient ω_x for all x ($\ell_{max} = 0$ for this state); hence, only coefficients ω_x appear in these shapes of q'_{ini} and their value is given by $\nu'_{ini}(q'_{ini})(\omega_x) = \nu_{ini}(q_{ini})(x)$. All other registers can be set to 0 (their value will never be used in the following).

[1] Notice that the use of separate left and right multiplicative is only necessary in non-commutative semirings: in commutative ones, we could merge both of them in a single α coefficient.

[2] E turns out to be not some arbitrary multiset, as we start from a $\diamond$-less CRA $\mathcal{A}$

...

Figure 2 An infinite CRA equivalent to the $\diamond$-less CRA $\mathcal{A}_d$.

Final states of F' are all pairs (q, s) with $q \in F$, and the associated final output φ' is the term using only coefficients obtained by applying the shape substitution as many times as the number of layers from the maximal layer, in order to remove all variables (x, ℓ): $\varphi'(q, s) = \big[x \mapsto s^{\ell_{max}+1}(x, \ell_{max}) \quad \forall x \in \mathcal{X}\big]\,\big(\varphi(q)\big)$ where s^h is the composition of s with itself h times, and ℓ_{max} is the maximal layer of the flow graph associated with s.

We finally describe the transitions of $\mathcal{A}_\infty$. For all states $(q, s) \in Q'$ and transitions $q \xrightarrow{a|\sigma} q'$ in Δ, we add a transition $(q, s) \xrightarrow{a|\sigma'} (q', s')$ in Δ', where s' is the extension of s with an additional layer. If the maximal layer of s is ℓ_{max}, then the maximal layer of s' is $\ell_{max} + 1$. For the additional maximal layer $\ell_{max} + 1$, for all $x \in \mathcal{X}$, the term $\sigma(x)$ associated with the update of the register x in $\mathcal{A}$ can be decomposed, by Prop. 12, into a shape τ and a valuation χ of its fresh coefficients: we have $\chi(\tau) \equiv \sigma(x)$. Then, we let $s'(x, \ell_{max} + 1)$ be the shape τ in which every variable y is replaced by (y, ℓ_{max}). Corresponding (fresh) coefficients κ of τ are set to their value in χ: $\sigma'(\kappa) = \chi(\kappa)$. Layers $0, 1, \ldots, \ell_{max}$ are kept intact, except that vertices that can no longer reach layer $\ell_{max} + 1$ are mapped to a constant shape ω. More precisely, for all $\ell \in \{0, 1, \ldots, \ell_{max}\}$ and $x \in \mathcal{X}$, if (x, ℓ) can reach layer $\ell_{max} + 1$ (in the so-extended flow graph) then $s'(x, \ell) = s(x, \ell)$ and the corresponding coefficients κ remain the same by the update $\sigma'(\kappa) = \kappa$. Otherwise $s'(x, \ell)$ is mapped to a constant shape ω and $\sigma'(\omega) = 0$: coefficients of $s(x, \ell)$ are freed, e.g. by resetting them to 0 by σ'.

▶ **Example 13.** We illustrate this construction on the $\diamond$-less CRA $\mathcal{A}_d$ of Figure 1. A portion of the infinite CRA is shown in Figure 2. We depict in each state the associated flow graph (without the output vertices) as well as the shapes that are different than the corresponding shapes in the predecessor state. In the updates, we only show the values different from 0. Notice the dotted edge in the state reached after having read word 11: this edge disappears from the flow graph since the vertex $(y, 1)$ can no longer reach the maximal layer.

The infinite CRA $\mathcal{A}_\infty$ satisfies the following invariant: each run ρ of $\mathcal{A}$, ending in state q, is bijectively mapped to a run ρ' of $\mathcal{A}_\infty$ that ends in a state (q, s) associated with a flow graph isomorphic to $G_{\mathcal{A}}(\rho)$. Moreover,

▶ **Invariant 14.** *For all words w, if (q, ν) is the (unique) configuration reached by $\mathcal{A}$ over word w, the configuration $((q', s), \nu')$ reached by $\mathcal{A}'$ reading w satisfies: $q = q'$ and for every $x \in \mathcal{X}$, $\nu(x) = [\![\nu' \circ s^{\ell_{max}+1}(x, \ell_{max})]\!]$ where $\ell_{max} + 1$ is the number of layers in s.*

Figure 3 Finite CRA obtained by merging copyless layers of the CRA in Figure 2.

In particular, both CRAs are equivalent by construction since

$$
\begin{aligned}
[\![\mathcal{A}]\!](w) &= [\![\nu(\varphi(q))]\!] \\
&= [\![\left[x \mapsto \nu' \circ s^{\ell_{max}+1}(x, \ell_{max})\ \forall x \in \mathcal{X}\right](\varphi(q))]\!] = [\![\nu'(\varphi'(q,s))]\!] = [\![\mathcal{A}']\!](w)
\end{aligned}
$$

The goal is now to make $\mathcal{A}_\infty$ finite by contracting the flow graph associated with its states. The main operation is the merging of a layer with the previous one; this merge will require some copies of registers. Starting from the finite $\diamond$-less (but not necessarily bounded-copy) CRA $\mathcal{A}$, the merge operation will turn $\mathcal{A}_\infty$ into a finite CRA, that is moreover bounded-copy.

Merge of two consecutive layers. Let s be the shape substitution in a state of $\mathcal{A}_\infty$ with maximal layer ℓ_{max} and let L be some layer. We now explain how to merge the layers $L-1$ and L of s, leading to a new shape substitution s' with one layer less. This will require an update σ' of the coefficients appearing in the corresponding shapes. s' and σ' are defined as follows for all layers $\ell \in \{0, 1, \ldots, \ell_{max}\}$:

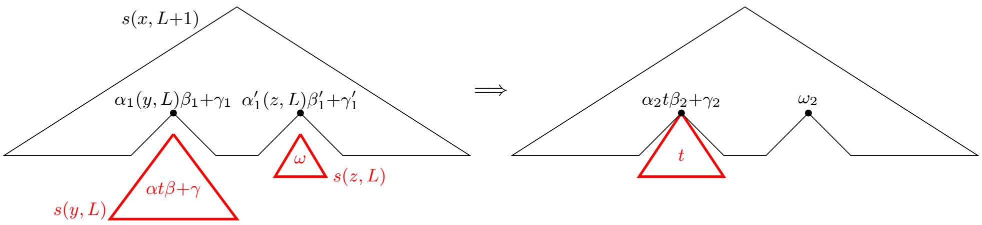
1. if $\ell < L-1$, nothing is changed: for all $x \in \mathcal{X}$, $s'(x,\ell) = s(x,\ell)$ and all the corresponding coefficients κ are left unchanged, i.e. $\sigma'(\kappa) = \kappa$;
2. if $\ell \geq L$, we simply shift down all the layers by one: for all $x \in \mathcal{X}$, $s'(x,\ell) = s(x,\ell+1)$ and the corresponding coefficients κ are left unchanged too;
3. if $\ell = L-1$, we must incorporate the shapes in-between layers $L-1$ and L into layer $L-1$:
   - if $s(x,L)$ is a constant shape ω, then we simply shift it as before: $s'(x,L-1) = \omega$ and coefficient ω is left unchanged by σ';
   - otherwise, consider the term $t = s^2(x,L)$ obtained by replacing all variables y appearing in the shape $s(x,L)$ by the shape $s(y,L-1)$. Unfortunately, t may not be a shape anymore, but Proposition 12 allows us to recover a new shape τ from t with new coefficients whose values are given by χ. We thus have to store $s'(x,L-1) = \tau$ in the state of $\mathcal{A}_\infty$ and update the coefficients accordingly, so that $\sigma'(s'(x,L-1)) = \chi(\tau) \equiv t$.

The most promising merge to perform in the infinite CRA $\mathcal{A}_\infty$ in a state (q,s) is the merge of a *copyless* layer L (such that the substitution $[x \mapsto s(x,L)]$ is copyless) with layer $L-1$.

▶ **Example 15.** Consider the infinite CRA $\mathcal{A}_\infty$ built in Figure 2. Three of its depicted states contain copyless layers: notice in particular that, in the state above right, it becomes possible to merge the first two layers after removing the useless (dotted) edge in the flow graph. After these merges, we obtain the finite copyless (and thus bounded-copy) CRA of Figure 3.

The definition of the new transition function (and coefficient updates) given above is correct, but not precise enough to prove afterwards that we obtain a bounded-copy CRA. Therefore, we need to describe an operational method to build s' and σ' with as few copies of coefficients as possible. There are two difficulties.

First, when glueing together $s(x, L+1)$ with all the shapes $s(y, L)$ (with (y, L) appearing in $s(x, L+1)$), we need to gather the coefficients at the glueing interface. There are two cases:



$s(x,L{+}1)$
$\alpha_1(y,L)\beta_1{+}\gamma_1$
$\alpha_1'(z,L)\beta_1'{+}\gamma_1'$
ω
$s(z,L)$
$\alpha t\beta{+}\gamma$
$s(y,L)$
$\Longrightarrow$
$\alpha_2 t\beta_2{+}\gamma_2$
ω_2
t

Consider first the case where $s(y, L)$ is a (non-constant) shape of the form $\alpha t\beta + \gamma$ with t a term. Let $\alpha_1(y, L)\beta_1 + \gamma_1$ be the subterm of $s(x, L+1)$ where (y, L) appears. The glueing should replace this subterm by $\alpha_1(\alpha t\beta + \gamma)\beta_1 + \gamma_1 \equiv \alpha_1\alpha t\beta\beta_1 + \alpha_1\gamma\beta_1 + \gamma_1$. This is obtained by replacing it by a shape $\alpha_2 t\beta_2 + \gamma_2$ with α_2, β_2 and γ_2 fresh coefficients that we set via $\sigma'(\alpha_2) = \alpha_1\alpha$, $\sigma'(\beta_2) = \beta\beta_1$ and $\sigma'(\gamma_2) = \alpha_1\gamma\beta_1 + \gamma_1$. Coefficients of t are preserved by the update σ'. Notice that σ' uses twice the content of coefficients α_1 and β_1.

The other case is the one where $s(y, L)$ is a constant shape ω. Then, we replace in $s(x, L+1)$ the subterm $\alpha_1'(y, L)\beta_1' + \gamma_1'$ by a fresh constant coefficient ω_2, set via $\sigma'(\omega_2) = \alpha_1'\omega\beta_1' + \gamma_1'$.

After glueing, in case where certain shapes we glued were constant shapes ω, a final step is required. Either the term does not contain variables of $\mathcal{X}$ anymore (all variables have been replaced by constant shapes ω), and we then replace the whole term t by a constant shape ω with $\sigma'(\omega) = t$. Or, there are still variables of $\mathcal{X}$, in which case we need to remove all ω-leaves. They are removed one by one, thus modifying the term and the update of coefficients. If there is a subterm of the form $\alpha_1(\omega_2 \odot \omega_3)\beta_1 + \gamma_1$ with two ω-leaves (and $\odot \in \{+, \times\}$), we replace this subterm by a fresh constant coefficient ω_4 set via $\sigma'(\omega_4) = \alpha_1(\omega_2 \odot \omega_3)\beta_1 + \gamma_1$. Once removed all those terms, there might remain isolated ω-leaves: consider thus a subterm with a single ω-leaf, e.g. of the form $\alpha_1\big((\alpha_2 t\beta_2 + \gamma_2) \odot \omega_3\big)\beta_1 + \gamma_1$ with t a shape without any ω. Notice that we can rewrite this term as:

$$\alpha_1\big((\alpha_2 t\beta_2 + \gamma_2) \odot \omega_3\big)\beta_1 + \gamma_1 \equiv \begin{cases} \alpha_1\alpha_2 t\beta_2\beta_1 + \alpha_1(\gamma_2 + \omega_3)\beta_1 + \gamma_1 & \text{if } \odot = + \\ \alpha_1\alpha_2 t\beta_2\omega_3\beta_1 + \alpha_1\gamma_2\omega_3\beta_1 + \gamma_1 & \text{if } \odot = \times \end{cases}$$

Then, this subterm is replaced by a shape $\alpha_4 t\beta_4 + \gamma_4$ with the coefficient updates:

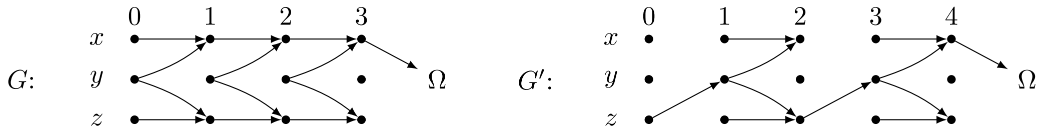
$$\sigma'(\alpha_4) = \alpha_1\alpha_2 \qquad \sigma'(\beta_4) = \begin{cases} \beta_2\beta_1 & \text{if } \odot = + \\ \beta_2\omega_3\beta_1 & \text{if } \odot = \times \end{cases} \qquad \sigma'(\gamma_4) = \alpha_1(\gamma_2 \odot \omega_3)\beta_1 + \gamma_1$$

Notice the copy of ω_3 in the case $\odot = \times$, and the copies of α_1 and β_1 in both cases.

During a whole merge step, we can show that the only coefficients to be copied are the ones of layer $L+1$ and of the constant shapes ω of layer L, and these are copied at most twice.

Primarily-copyless layer. The merge of copyless layers with their predecessor may not be sufficient to obtain a finite CRA, as shown in the following more involved example.

▶ **Example 16.** Consider the $\diamond$-less CRA $\mathcal{A}_3$ over the semiring $(\mathfrak{P}(\{a, b\}), \cup, \cdot, \emptyset, \{\varepsilon\})$ and alphabet $\{a, b\}$, with one state q and three registers x, y, z, that outputs $\varphi(q) = x$ and with transitions $q \xrightarrow{a|\sigma_a} q$ and $q \xrightarrow{a|\sigma_b} q$ using updates $\sigma_a = [x \mapsto xy, y \mapsto a, z \mapsto zya]$ and $\sigma_b = [x \mapsto \varepsilon, y \mapsto zb, z \mapsto \varepsilon]$. Here are the flow graphs G and G' obtained after reading the input words aaa and $baba$ respectively:



The flow graph G' illustrates that $\mathcal{A}_3$ is not bounded-copy, since the flow graphs on input words $(ba)^n$ require a chain of n copies. In G though, no layer is copyless, and thus no merging based on copyless layers can be performed. Notice that the value of register z is not used in the output, but it would be so if the word aaa is extended with b: thus, we cannot simply remove register z to recover some copyless layers. Here, the idea is rather to notice that the second time we see register y being copied (in-between layers 1 and 2), we learn the fact that indeed the previous content of register y is not copied many times (because of the $\diamond$-less hypothesis): if we do not consider this copy anymore, layer 2 becomes copyless and can thus safely be merged with layer 1. It will cost copies, but not too much, as we will see later.

Hence, removing copyless layers is not a sufficient criterion to obtain a *finite* (bounded-copy) CRA from $\mathcal{A}_\infty$. To define the correct criterion, we distinguish some special vertices in a flow graph. A *source* is a vertex (x, ℓ) without predecessors (in the state of $\mathcal{A}_\infty$, this means that $s(x, \ell) = \omega$). The sources of a vertex are all its ancestors that are sources: in the previous flow graph G of Example 16, sources of $(x, 2)$ are $(x, 0)$, $(y, 0)$ and $(y, 1)$. A source is *primary* if it is a source, with lowest layer, of a vertex in the maximal layer: $(x, 0)$, $(y, 0)$, $(z, 0)$ and $(y, 3)$ are all the primary sources of G (note that $(y, 3)$ is source with lowest layer of $(y, 3)$ itself), while $(y, 1)$ and $(y, 2)$ are not. A vertex is *primary* if it is a descendant of a primary source. All other vertices are called *secondary*: in G, $(y, 1)$ and $(y, 2)$ are all the secondary vertices. In particular, all vertices of the maximal layer are primary. On the minimal layer, all vertices that can reach the maximal layer are primary sources. Notice that whenever the flow graph is extended, some primary sources may turn secondary, and new primary sources may appear, but only on the maximal layer; also, vertices may not reach the maximal layer anymore in which case they are removed. A layer L is *primarily-copyless* when only secondary vertices of layer $L - 1$ are possibly copied, i.e. all primary vertices $(x, L - 1)$ are linked to a single vertex of layer L. In G, only layers 2 and 3 are primarily-copyless.

Obviously, we do not build the infinite CRA $\mathcal{A}_\infty$, but instead build a finite CRA $\mathcal{A}'$ step by step by extending it along transitions and directly merging each primarily-copyless layers with the previous one, as much as possible. The idea is that merging such primarily-copyless layers will cost some copies of coefficients, but not too many, yielding the fact that $\mathcal{A}'$ is a bounded-copy CRA with a finite number of states equivalent to the $\diamond$-less CRA $\mathcal{A}$. These properties are proved in the rest of the section, and imply Proposition 11.

$\mathcal{A}'$ is equivalent to $\mathcal{A}$. By Invariant 14, the infinite CRA (without merge of primarily-copyless layers) is equivalent to $\mathcal{A}$. Then, we prove that it remains true when we perform the merge of two consecutive layers. It is a consequence of the following invariant:

▶ **Invariant 17.** *Let s be a shape substitution with $\ell_{max} + 1$ layers, and let s' and σ' be the shape substitution and update obtained by merging layers L and $L - 1$ from s. Then* $\sigma' \circ s'^{\ell_{max}}(x, \ell_{max} - 1) \equiv s^{\ell_{max}+1}(x, \ell_{max})$.

$\mathcal{A}'$ is finite. Given a state $(q, s) \in Q'$, using Lemma 18 (below), s has less than $|\mathcal{X}|^4$ vertices. The substitution is exactly defined by the shapes $s(x, \ell)$ for every vertices (x, ℓ). In each of these shapes, each register in $\mathcal{X}$ appears at most once and there are $|\mathcal{X}|^{\mathcal{O}(|\mathcal{X}|)}$ possible of such shapes. Thus, $|Q'| \leq |Q| \cdot |\mathcal{X}|^{\mathcal{O}(|\mathcal{X}|^5)}$ and $\mathcal{A}'$ is finite.

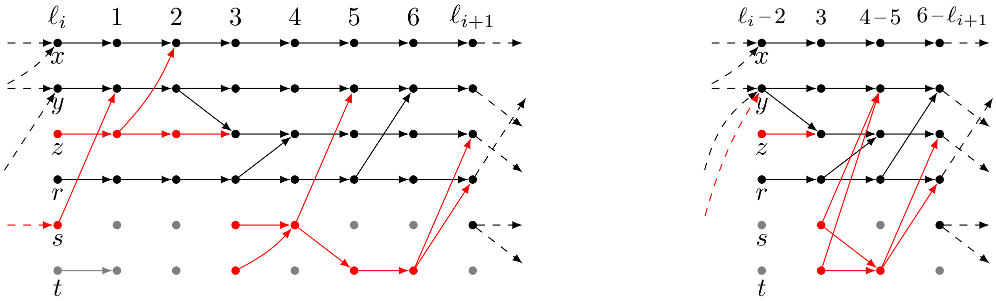


Figure 4 Merging of primarily copyless layers with the previous one.

▶ **Lemma 18.** *For all states (q, s) in $\mathcal{A}'$, the flow graph associated with s has less than $|\mathcal{X}|^2$ primary sources, $|\mathcal{X}|^3$ layers, and $|\mathcal{X}|^4$ vertices.*

Proof. Recall that there are $|\mathcal{X}|$ vertices per layer. In the flow graph, each vertex of the maximal layer defines exactly one minimal layer for its ancestors. All primary sources are on those layers and there are at most $|\mathcal{X}|$ such layers. Each layer contains at most $|\mathcal{X}|$ vertices, thus there are at most $|\mathcal{X}|^2$ primary sources in the flow graph. Also, this implies that the bound on the number of vertices is a direct consequence of the bound on the number of layers. We note $\ell_1, \ldots, \ell_k$ the layers where primary sources are, with $k \leq |\mathcal{X}|$ and $0 = \ell_1 < \ell_2 < \cdots < \ell_k$ (the first layer contains only primary sources). For $1 \leq i < k$, we now bound the number of layers separating ℓ_i from ℓ_{i+1}.

Recall that a copy vertex is a vertex with at least two out-going edges. A *primary copy vertex* is a copy vertex that is primary. A *bad layer* is a layer that is not primarily-copyless layer. Bad layers are exactly layers that remain after the removal of all primarily-copyless layers. Note that by definition, a bad layer contains at least one primary copy vertex. Also, as every primary vertex only reaches primary vertices and as the flow graph is $\diamond$-less, a primary copy vertex reaches primary vertices of the next layer that pairwise cannot flow in the same vertex while they all flow in the maximal layer.

Figure 4 depicts vertices of a flow graph between two layers ℓ_i and ℓ_{i+1} before removing primarily copyless layers on the left and after on the right. Primary vertices are represented in black, secondary vertices are represented in red, and vertices that cannot reach the last layer are represented in gray. Vertices (r, ℓ_i) and (s, ℓ_{i+1}) are primary sources. Between ℓ_i and ℓ_{i+1}, there are 3 primary copy vertices: $(y, 2)$, $(r, 3)$ and $(r, 5)$. Layers ℓ_i, 1 and 2 are merged, as well as layers 4 and 5, and also layers 6 and ℓ_{i+1}.

As the flow graph is $\diamond$-less, every primary vertex (x, ℓ_i) flows at most once in every primary vertex of layer ℓ_{i+1}. We note $n_{x,i}$ the number of vertices of layer ℓ_{i+1} reachable from (x, ℓ_i), we have that $n_{x,i} \leq |\mathcal{X}|$. Then, (x, ℓ_i) reaches at most $n_{x,i} - 1$ copy vertices between layers ℓ_i (included) and ℓ_{i+1} (excluded), all of which are primary. Since this holds for all primary vertices of layer ℓ_i, there are at most $|\mathcal{X}| \left(|\mathcal{X}| - 1\right)$ primary copy vertices between layers ℓ_i and ℓ_{i+1}. This directly implies the same bound for the number of (bad) layers. The argument still holds for (bad) layers between ℓ_k and the maximal layer ℓ_{max} of the flow graph. As a consequence, there are at most $|\mathcal{X}|^2 \left(|\mathcal{X}| - 1\right) \leq |\mathcal{X}|^3$ layers in s. ◀

$\mathcal{A}'$ is bounded-copy. We need some additional intuition on how secondary vertices flow. Consider a secondary vertex v that flows into vertices of the last layer, that are primary. Along the path from v to the last layer, there are secondary vertices, followed by primary vertices. The first primary vertex encountered is called a *target* of v: in the flow graph G of

Example 16, targets of $(y, 1)$ are $(x, 2)$ and $(z, 2)$. Notice that every target is a descendant of some primary source, by definition of primary vertices. A primary vertex is its own target. *Primary sources* of a vertex are all the sources of its targets, that are primary: again in the example G, primary sources of $(y, 2)$ are $(x, 0)$, $(y, 0)$ and $(z, 0)$.

We define a measure on the coefficients of all the shapes in a state of $\mathcal{A}'$ that bounds the number of times it can copy into other coefficients in the future. The measure of a coefficient κ appearing in the shape of a vertex $v = (x, \ell)$ of the shape substitution is defined as the tuple $\|\kappa\| = (\ell, p, c, \ell_\pi, g)$ where p is the number of primary sources in s restricted to the previous layers $\{0, \dots, \ell - 1\}$; $c = 1$ if the coefficient κ is an ω-coefficient, and $c = 0$ otherwise; ℓ_π is the maximal layer of a primary source of vertex v; g is the number of targets of vertex v. We can show that along the update of every transition of $\mathcal{A}'$, if a coefficient κ is used to update the value of another coefficient κ' then $\|\kappa\| \geq \|\kappa'\|$ (where tuples are ordered lexicographically). Moreover, if κ is used in at least two coefficients, then $\|\kappa\| > \|\kappa'\|$. We can bound the length of all decreasing sequences of tuples by $2|\mathcal{X}|^9$. When a coefficient is copied, it flows into at most $2|\mathcal{X}|$ coefficients. Thus, $\mathcal{A}'$ is $(2|\mathcal{X}|)^{2|\mathcal{X}|^9}$-copy.

5 From bounded-copy CRAs to copyless CRAs

The final step of our construction is to remove all copies from a bounded-copy CRA. This is achieved in a purely greedy manner: it suffices to have enough replicas of each register from the beginning, and then split the replicas evenly when the bounded-copy CRA performs copies.

▶ **Proposition 19.** *For every k-copy* CRA*, we can construct an equivalent copyless* CRA*.*

▶ Remark 20. Note that our definition of bounded-copy differs from the one of [4]. There, flow graphs are first trimmed with respect to the output vertex, and k-copy means that there are at most k copy vertices in the whole trimmed flow graph. In this sense, 0-copy implies $\diamond$-less in our setting. Therefore, removing copies is the core of their transformation from functional copyless (non-deterministic) streaming string transducers into copyless deterministic ones.

This ends the proof of Theorem 1. Actually, this last step in the proof extends easily to show that bounded-copy finitely-ambiguous CRAs can be effectively transformed into equivalent finitely-ambiguous CRAs. Applying then Theorem 1, we obtain

▶ **Corollary 21.** *Every bounded-copy finitely-ambiguous* NCRA *can be effectively transformed into an equivalent copyless* CRA*.*

6 Conclusion

We have shown a construction removing the finite-ambiguity of a copyless NCRA, with an application to the removal of regular look-aheads in copyless CRA-RLAs in arbitrary semirings. It can be shown that the result does no longer hold for linear-ambiguous copyless NCRAs using the example of [14, Theorem 2], therefore finite-ambiguity seems the weakest condition for which our result holds. Moreover, existing techniques of regular look-ahead removal for streaming string-to-tree transducers [3] cannot be used directly, as the addition of unary mappings update strictly increases the expressive power of copyless CRAs. Going back to the example of Figure 1, notice that the application of our construction from the finitely-ambiguous NCRA $\mathcal{A}_n$ yields a copyless CRA that is bigger than the alternative solution $\mathcal{A}_c$: it has more states, and more registers. As future works, we thus plan to study minimisation of copyless CRAs in the general setting of semirings. Our results work even for non-commutative semirings. However it heavily relies on the distributivity property of semirings, in order to normalise the terms into shapes. The transformation from a ◇-less CRA to a bounded-copy CRA also relies on the capability to multiply two registers (coefficients) together: this is thus unclear how to extend our approach to the so-called *additive* copyless CRAs where products in register updates must happen between a register and a constant.

Abstract

By fundamental results of Schützenberger, McNaughton and Papert from the 1970s, the classes of first-order definable and aperiodic languages coincide. Here, we extend this equivalence to a quantitative setting. For this, weighted automata form a general and widely studied model. We define a suitable notion of a weighted first-order logic. Then we show that this weighted first-order logic and aperiodic polynomially ambiguous weighted automata have the same expressive power. Moreover, we obtain such equivalence results for suitable weighted sublogics and finitely ambiguous or unambiguous aperiodic weighted automata. Our results hold for general weight structures, including all semirings, average computations of costs, bounded lattices, and others.

1 Introduction

Fundamental results of Schützenberger, McNaughton and Papert established that aperiodic, star-free and first-order definable languages, respectively, coincide [40, 32]. In this paper, we develop such an equivalence in a quantitative setting, i.e., for suitable notions of aperiodic weighted automata and weighted first-order logic.

Already Schützenberger [39] investigated weighted automata and characterized their behaviors as rational formal power series. Weighted automata can be viewed as classical finite automata in which the transitions are equipped with weights. These weights could model, e.g., the cost, reward or probability of executing a transition. The wide flexibility of this automaton model soon led to a wealth of extensions and applications, cf. [38, 28, 2, 36, 15]. Whereas traditionally weights are taken from a semiring, recently, motivated by practical examples, also average and discounted computations of weights were considered, cf. [8, 7].

In the boolean setting, the seminal Büchi-Elgot-Trakhtenbrot theorem [6, 21, 41] established the expressive equivalence of finite automata and monadic second-order logic (MSO). A weighted monadic second-order logic with the same expressive power as weighted automata was developed in [12, 13]. This led to various extensions to weighted automata and weighted logics on trees [19], infinite words [18], timed words [34], pictures [22], graphs [10], nested words [11], and data words [1], but also for more complicated weight structures including

average and discounted calculations [16] or multi-weights [17]. Recently, in [23], weighted MSO logic was revisited with a more structured syntax, called core-wMSO, and shown to be expressively equivalent to weighted automata, while permitting a uniform approach to semirings and these more complicated weight structures.

Here, we consider the first-order fragment wFO of this weighted logic. It extends the full classical boolean first-order logic quantitatively by adding weight constants and if-then-else applications, followed by a first-order (universal) product and then further if-then-else applications, finite sums, or first-order (existential) sums. We will show that its expressive power leads to aperiodic weighted automata which, moreover, are polynomially ambiguous. Natural subsets of connectives will correspond to unambiguous or finitely ambiguous aperiodic weighted automata. These various levels of ambiguity are well-known from classical automata theory [24, 42, 26, 25].

Following the approach of [23], we take an *arbitrary* set R of weights. A path in a weighted automaton over R then has the sequence of weights of its transitions as its value. The *abstract semantics* of the weighted automaton is defined as the function mapping each non-empty word to the multiset of weight sequences of the successful paths executing the given word. Correspondingly, we will define the abstract semantics of wFO sentences also as functions mapping non-empty words to multisets of sequences of weights. Our main result will be the following.

▶ **Theorem 1.** *Let Σ be an alphabet and* R *a set of weights. Then the following classes of weighted automata and weighted first-order logics are expressively equivalent:*

1. *Aperiodic polynomially ambiguous weighted automata (*wA*) and* wFO *sentences,*
2. *Aperiodic finitely ambiguous* wA *and* wFO *sentences without first-order sums,*
3. *Aperiodic unambiguous* wA *and* wFO *sentences without binary or first-order sums.*

Note that these characterizations hold without any restrictions on the weights. The above result applies not only to the abstract semantics. As immediate consequence, we obtain corresponding expressive equivalence results for classical weighted automata over arbitrary (even non-commutative) semirings, or with average or discounted calculations of weights, or bounded lattices as in multi-valued logics. All our constructions are effective. In fact, given a wFO sentence and deterministic aperiodic automata for its boolean subformulas, we can construct an equivalent aperiodic weighted automaton of exponential size. We give typical examples for our constructions. The class of arbitrary aperiodic weighted automata and its subclasses of polynomially resp. finitely ambiguous or unambiguous weighted automata form a proper hierarchy for each of the following semirings: natural numbers $\mathbb{N}_{+,\times}$, the max-plus-semiring $\mathbb{N}_{\max,+}$ and the min-plus semiring $\mathbb{N}_{\min,+}$ [14].

It should be noticed that standard constructions used to establish equivalence between automata and MSO logic cannot be applied. Indeed, starting from an automaton $\mathcal{A}$, one usually constructs an *existential* MSO sentence where the existential set quantifications are used to guess an accepting run and the easy first-order kernel is used to check that this guess indeed defines an accepting run. Here, we cannot use quantifications $\exists X$ over set variables X, or their weighted equivalent $\sum_X$. Instead, we take advantage of the fine structure of possible paths of polynomially ambiguous automata, namely the fact that it must be unambiguous on strongly connected components (SCC-unambiguous), as employed for different goals already in [24, 42]. We first give a new construction of a wFO sentence without sums starting from an aperiodic and unambiguous automaton. Then, we extend the construction to polynomially ambiguous aperiodic automata using first-order sums $\sum_x$ to guess positions where the run switches between the unambiguous SCCs. For part 2 of Theorem 1, we also prove that for each *aperiodic* finitely ambiguous weighted automaton we can construct finitely many *aperiodic* unambiguous weighted automata whose disjoint union has the same semantics.

Again, for the implication from weighted formulas to weighted automata, we cannot simply use standard constructions which crucially rely on the fact that functions defined by weighted automata are closed under morphic images. This was used to handle first-oder sums $\sum_x$ and second-order sums $\sum_X$, but also in the more involved proof for the first-order product $\prod_x$ applied to finitely valued weighted automata. But it is well-known that aperiodic languages are not closed under morphic images. Handling the first-order product $\prod_x$ requires a completely new and highly non-trivial proof preserving aperiodicity properties.

Detailed proofs and additional examples are given in the full version [14].

Related work. In [27], polynomially ambiguous, finitely ambiguous and unambiguous weighted automata (without assuming aperiodicity) over commutative semirings were shown to be expressively equivalent to suitable fragments of weighted monadic second order logic. This was further extended in [33] to cover polynomial degrees and weighted tree automata.

A hierarchy of these classes of weighted automata (again without assuming aperiodicity) over the max-plus semiring was described in [26]. As a consequence of pumping lemmas for weighted automata, a similar hierarchy was obtained in [30] for the min-plus semiring.

We note that in [13, 20], an equivalence result for full weighted first-order logic was given, but only for very particular classes of semirings or strong bimonoids as weight structures.

A characterization of the full weighted first-order logic with transitive closure by weighted pebble automata was obtained in [5]. An equivalence result for fragments of weighted first-order logic, weighted LTL and weighted counter-free automata over the max-plus semiring with discounting was given in [29].

2 Preliminaries

A non-deterministic automaton is a tuple $\mathcal{A} = (Q, \Sigma, \Delta)$ where Q is a finite set of states, Σ is a finite alphabet, and $\Delta \subseteq Q \times \Sigma \times Q$ is the set of transitions. The automaton $\mathcal{A}$ is complete if $\Delta(q, a) \neq \emptyset$ for all $q \in Q$ and $a \in \Sigma$. A run ρ of $\mathcal{A}$ is a nonempty sequence of transitions $\delta_1 = (p_1, a_1, q_1)$, $\delta_2 = (p_2, a_2, q_2)$, …, $\delta_n = (p_n, a_n, q_n)$ such that $q_i = p_{i+1}$ for all $1 \leq i < n$. We say that ρ is a run from state p_1 to state q_n and that ρ reads, or has label, the word $a_1 a_2 \cdots a_n \in \Sigma^+$. We denote by $\mathcal{L}(\mathcal{A}_{p,q}) \subseteq \Sigma^*$ the set of labels of runs of $\mathcal{A}$ from p to q. When $p = q$, we include the empty word ε in $\mathcal{L}(\mathcal{A}_{p,q})$ and say that ε labels the empty run from p to p.

An automaton with accepting conditions is a tuple $\mathcal{A} = (Q, \Sigma, \Delta, I, F)$ where (Q, Σ, Δ) is a non-deterministic automaton, $I, F \subseteq Q$ are the sets of initial and final states respectively. The language defined by the automaton is $\mathcal{L}(\mathcal{A}) = \mathcal{L}(\mathcal{A}_{I,F}) = \bigcup_{p \in I, q \in F} \mathcal{L}(\mathcal{A}_{p,q})$. Subsequently, we also consider automata with several accepting sets $F, G, \ldots$ so that the same automaton may define several languages $\mathcal{L}(\mathcal{A}_{I,F})$, $\mathcal{L}(\mathcal{A}_{I,G})$, …An automaton $\mathcal{A} = (Q, \Sigma, \Delta, I, F)$ is *deterministic* if $I = \{\iota\}$ is a singleton and the set Δ of transitions is a partial function: for all $(p, a) \in Q \times \Sigma$ there is at most one state $q \in Q$ such that $(p, a, q) \in \Delta$.

Next, we consider degrees of ambiguity of automata. A run in an automaton is *successful*, if it leads from an initial to a final state. The automaton $\mathcal{A}$ is called *polynomially ambiguous* if there is a polynomial p such that for each $w \in \Sigma^+$ the number of successful paths in $\mathcal{A}$ for w is at most $p(|w|)$. Then, $\mathcal{A}$ is *finitely ambiguous* if p can be taken to be a constant. Further, for an integer $k \geq 1$, $\mathcal{A}$ is k-ambiguous if $p = k$, and *unambiguous* means 1-ambiguous. Notice that k-ambiguous implies $(k+1)$-ambiguous. An automaton $\mathcal{A}$ is at most *exponentially ambiguous*.

A non-deterministic automaton $\mathcal{A} = (Q, \Sigma, \Delta)$ is *aperiodic* if there exists an integer $m \geq 1$, called aperiodicity index, such that for all states $p, q \in Q$ and all words $u \in \Sigma^+$, we have $u^m \in \mathcal{L}(\mathcal{A}_{p,q})$ iff $u^{m+1} \in \mathcal{L}(\mathcal{A}_{p,q})$. In other words, the non-deterministic automaton $\mathcal{A}$ is aperiodic iff its transition monoid $\mathsf{Tr}(\mathcal{A})$ is aperiodic. It is well-known that aperiodic languages coincide with first-order definable languages, cf. [40, 32, 9].

The syntax of first-order logic is given in Section 4 (FO). The semantics is defined by structural induction on the formula and requires an interpretation of the free variables. Let $\mathcal{V} = \{y_1, \dots, y_n\}$ be a finite set of first-order variables. Given a nonempty word $u \in \Sigma^+$, we let $\mathsf{pos}(u) = \{1, \dots, |u|\}$ be the set of positions of u. A valuation or interpretation is a map $\sigma \colon \mathcal{V} \to \mathsf{pos}(u)$ assigning positions of u to variables in $\mathcal{V}$. For a first-order formula φ having free variables contained in $\mathcal{V}$, we write $u, \sigma \models \varphi$ when the word u satisfies φ under the interpretation defined by σ. When φ is a *sentence*, the valuation σ is not needed and we simply write $u \models \varphi$.

We extend the classical semantics by defining when the empty word ε satisfies a sentence. We have $\varepsilon \models \top$ and if $\forall x \psi$ is a sentence then $\varepsilon \models \forall x \psi$. The semantics $\varepsilon \models \varphi$ is extended to all sentences φ since they are boolean combinations of the basic cases above. Notice that if φ has free variables then $\varepsilon \models \varphi$ is not defined. When φ is a sentence we denote by $\mathcal{L}(\varphi) \subseteq \Sigma^*$ the set of words satisfying φ. Notice that $\mathcal{L}(\forall x \bot) = \{\varepsilon\}$ where $\bot = \neg\top$.

▶ **Theorem 2** ([40, 32, 9]). *Let $\mathcal{A}$ be an aperiodic non-deterministic automaton. For all states p, q of $\mathcal{A}$ we can construct a first-order sentence $\varphi_{p,q}$ such that $\mathcal{L}(\mathcal{A}_{p,q}) = \mathcal{L}(\varphi_{p,q})$.*

For the converse of Theorem 2, we need a stronger statement to deal with formulas having free variables. As usual, we encode a pair (u, σ) where $u \in \Sigma^+$ is a nonempty word and $\sigma \colon \mathcal{V} \to \mathsf{pos}(u)$ is a valuation by a word $\overline{u}$ over the extended alphabet $\Sigma_{\mathcal{V}} = \Sigma \times \{0,1\}^{\mathcal{V}}$. A word $\overline{u}$ over $\Sigma_{\mathcal{V}}$ is a *valid* encoding if for each variable $y \in \mathcal{V}$, its projection on the y-component belongs to 0^*10^*. Throughout the paper, we identify a valid word $\overline{u}$ with its encoded pair (u, σ).

▶ **Theorem 3** ([40, 32, 9]). *For each FO-formula φ having free variables contained in $\mathcal{V}$, we can build a deterministic, complete and aperiodic automaton $\mathcal{A}_{\varphi,\mathcal{V}} = (Q, \Sigma_{\mathcal{V}}, \Delta, \iota, F, G)$ over the extended alphabet $\Sigma_{\mathcal{V}}$ such that for all words $\overline{u} \in \Sigma_{\mathcal{V}}^+$ we have:*

- *$\Delta(\iota, \overline{u}) \in F$ iff $\overline{u}$ is a valid encoding of a pair (u, σ) with $(u, \sigma) \models \varphi$,*
- *$\Delta(\iota, \overline{u}) \in G$ iff $\overline{u}$ is a valid encoding of a pair (u, σ) with $(u, \sigma) \models \neg\varphi$,*
- *$\Delta(\iota, \overline{u}) \notin F \cup G$ otherwise, i.e., iff $\overline{u}$ is not a valid encoding of a pair (u, σ).*

Given $u \in \Sigma^+$ and integers k, ℓ, we denote by $u[k, \ell]$ the factor of u between positions k and ℓ. By convention $u[k, \ell] = \varepsilon$ is the empty word when $\ell < k$ or $\ell = 0$ or $k > |u|$.

We will apply the equivalence of Theorem 2 to prefixes, infixes or suffixes of words. Towards this, we use the classical *relativization* of sentences. Let φ be a first-order sentence and let $x, y \in \mathcal{V}$ be first-order variables. We define below the relativizations $\varphi^{<x}$, $\varphi^{(x,y)}$ and $\varphi^{>y}$ so that for all words $u \in \Sigma^+$, and all positions $i, j \in \mathsf{pos}(u) = \{1, \dots, |u|\}$ we have

$$\begin{array}{rcr} u, x \mapsto i \models \varphi^{<x} & \text{iff} & u[1, i-1] \models \varphi \\ u, x \mapsto i, y \mapsto j \models \varphi^{(x,y)} & \text{iff} & u[i+1, j-1] \models \varphi \\ u, x \mapsto j \models \varphi^{>x} & \text{iff} & u[j+1, |u|] \models \varphi \end{array}$$

Notice that, when $i = 1$ or $j \leq i + 1$ or $j = |u|$, the relativization is on the empty word, this is why we had to define when $\varepsilon \models \psi$ for sentences ψ. The relativization is defined by

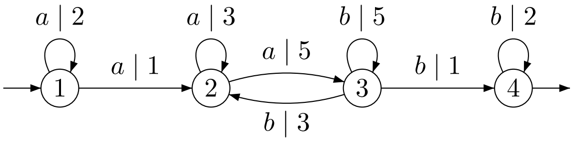

Figure 1 A weighted automaton, which is both aperiodic and polynomially ambiguous.

structural induction on the formulas as follows:

$$\begin{array}{lll} \top^{<x} = \top & (P_a(z))^{<x} = P_a(z) & (y \leq z)^{<x} = (y \leq z) \\ (\neg\psi)^{<x} = \neg(\psi^{<x}) & (\psi_1 \wedge \psi_2)^{<x} = \psi_1^{<x} \wedge \psi_2^{<x} & (\forall z \psi)^{<x} = \forall z (z < x \implies \psi^{<x}) \end{array}$$

The relativizations $\varphi^{(x,y)}$ and $\varphi^{>x}$ are defined similarly. Notice that when φ is a sentence, i.e., a boolean combination of formulas of the form $\top$ or $\forall z \psi$, then the above equivalences hold even when $i = 1$ for $\varphi^{<x}$, or when $i = |u|$ for $\varphi^{>x}$, or when $j \leq i + 1$ for $\varphi^{(x,y)}$.

3 Weighted Automata

Given a set X, we let $\mathbb{N}\langle X \rangle$ be the collection of all finite multisets over X, i.e., all functions $f \colon X \to \mathbb{N}$ such that $f(x) \neq 0$ only for finitely many $x \in X$. The union $f \uplus g$ of two multisets $f, g \in \mathbb{N}\langle X \rangle$ is defined by pointwise addition of functions: $(f \uplus g)(x) = f(x) + g(x)$ for $x \in X$.

For a set R of weights, an R-weighted automaton over Σ is a tuple $\mathcal{A} = (Q, \Sigma, \Delta, \mathsf{wt})$ where (Q, Σ, Δ) is a non-deterministic automaton and $\mathsf{wt} \colon \Delta \to \mathsf{R}$ assigns a weight to every transition. The weight sequence of a run $\rho = \delta_1\delta_2 \cdots \delta_n$ is $\mathsf{wt}(\rho) = \mathsf{wt}(\delta_1)\mathsf{wt}(\delta_2) \cdots \mathsf{wt}(\delta_n) \in \mathsf{R}^+$. The *abstract semantics* of $\mathcal{A}$ from state p to state q is the map $\{\!|\mathcal{A}_{p,q}|\!\} \colon \Sigma^+ \to \mathbb{N}\langle \mathsf{R}^+ \rangle$ which assigns to a word $u \in \Sigma^+$ the multiset of weight sequences of runs from p to q with label u:

$$\{\!|\mathcal{A}_{p,q}|\!\}(u) = \{\!\{\mathsf{wt}(\rho) \mid \rho \text{ is a run from } p \text{ to } q \text{ with label } u\}\!\} \, .$$

Notice that $\{\!|\mathcal{A}_{p,q}|\!\}(u) = \emptyset$ is the empty multiset when there are no runs of $\mathcal{A}$ from p to q with label u, i.e., when $u \notin \mathcal{L}(\mathcal{A}_{p,q})$. When we consider a weighted automaton $\mathcal{A} = (Q, \Sigma, \Delta, \mathsf{wt}, I, F)$ with initial and final sets of states, for all $u \in \Sigma^+$ the semantics $\{\!|\mathcal{A}|\!\}$ is defined as the multiset union: $\{\!|\mathcal{A}|\!\}(u) = \biguplus_{p \in I, q \in F} \{\!|\mathcal{A}_{p,q}|\!\}(u)$. Hence, $\{\!|\mathcal{A}|\!\}$ assigns to every word $u \in \Sigma^+$ the multiset of all weight sequences of accepting runs of $\mathcal{A}$ reading u. The support of $\mathcal{A}$ is the set of words $u \in \Sigma^+$ such that $\{\!|\mathcal{A}|\!\}(u) \neq \emptyset$, i.e., $\mathsf{supp}(\mathcal{A}) = \mathcal{L}(\mathcal{A})$.

For instance, consider the weighted automaton $\mathcal{A}$ of Figure 1. We have $\mathsf{supp}(\mathcal{A}) = a^+a(a+b)^*b^+$. Consider $w = a^m(ba)^nb^p$ with $m > 1$ and $p > 0$. We have $w \in \mathsf{supp}(\mathcal{A})$ and $\{\!|\mathcal{A}|\!\}(w) = \{\!\{2^{k-1} \cdot 1 \cdot 3^{m-k-1} \cdot 5 \cdot (3 \cdot 5)^n \cdot 5^{\ell-1} \cdot 1 \cdot 2^{p-\ell} \mid 1 \leq k < m \text{ and } 1 \leq \ell \leq p\}\!\}$.

A concrete semantics over semirings, or valuation monoids, or valuation structures can be obtained from the abstract semantics defined above by applying the suitable aggregation operator $\mathsf{aggr} \colon \mathbb{N}\langle \mathsf{R}^+ \rangle \to S$ as explained in [23], see also [14]. For the natural semiring $(\mathbb{N}, +, \times, 0, 1)$, the sum-product aggregation operator $\mathsf{aggr}_{\mathsf{sp}}(f)$ gives the sum over all sequences $s_1s_2 \cdots s_k$ in the multiset f of the products $s_1 \times s_2 \times \cdots \times s_k$ in $\mathbb{N}$. We continue the example with the automaton $\mathcal{A}$ of Figure 1 and the word $w = a^m(ba)^nb^p$ with $m > 1$ and $p > 0$. The concrete semantics is given by

$$[\![\mathcal{A}]\!](w) = \mathsf{aggr}_{\mathsf{sp}}(\{\!|\mathcal{A}|\!\}(w)) = \sum_{1 \leq k < m} \sum_{1 \leq \ell \leq p} 2^{k-1+p-\ell} 3^{m-k-1+n} 5^{n+\ell} \, .$$

In further examples, we also use the max-plus semiring $\mathbb{N}_{\max,+} = (\mathbb{N} \cup \{-\infty\}, \max, +, -\infty, 0)$ and the min-plus semiring $\mathbb{N}_{\min,+} = (\mathbb{N} \cup \{\infty\}, \min, +, \infty, 0)$.

Now, we investigate finitely ambiguous weighted automata. It was shown in [26] that over the max-plus semiring $\mathbb{N}_{\max,+}$ they are expressively equivalent to finite disjoint unions of unambiguous weighted automata. Moreover, it was proved in [37] that a K-valued rational transducer can be decomposed into K unambiguous transducers. In particular this implies that a K-ambiguous weighted automaton can be decomposed into K unambiguous weighted automata. We can prove that the same holds for aperiodic weighted automata [14].

▶ **Theorem 4.** *Let $K \geq 1$. Given an aperiodic K-ambiguous weighted automaton $\mathcal{A}$, we can construct aperiodic unambiguous weighted automata $\mathcal{B}_1, \dots, \mathcal{B}_K$ such that $\{\!|\mathcal{A}|\!\} = \{\!|\mathcal{B}_1 \uplus \cdots \uplus \mathcal{B}_K|\!\} = \{\!|\mathcal{B}_1|\!\} \uplus \cdots \uplus \{\!|\mathcal{B}_K|\!\}$.*

Our proof is based on lexicographic ordering of runs. The proof of [37] uses lexicographic coverings. It would be interesting to see whether this proof also preserves aperiodicity and to compare the complexity of the constructions.

4 Weighted First-Order Logic

In this section, we define the syntax and semantics of our weighted first-order logic. In [12, 13], weighted MSO used the classical syntax of MSO logic; only the semantics over a semiring was changed to use sums for disjunction and existential quantifications, and products for conjunctions and universal quantifications. The possibility to express boolean properties in wMSO was obtained via so-called unambiguous formulae. To improve readability, a more structured syntax was later used [3, 16, 27], separating a boolean MSO layer with classical boolean semantics from the higher level of weighted formulas using *products* ($\prod_X$, $\prod_x$ corresponding to $\forall X$, $\forall x$) and sums ($\sum_X$, $\sum_x$ corresponding to $\exists X$, $\exists x$) with quantitative semantics. As shown in [12, 13], in general, to retain equivalence with weighted automata, wMSO has to be restricted. Products $\prod_X$ over set variables are disallowed, and first-order products $\prod_x$ must be restricted to finitely valued series where the pre-image of each value is recognizable. This basically means that first-order products cannot be nested or applied after first-order or second-order sums $\sum_x$ or $\sum_X$. This motivated the equivalent and even more structured syntax of core-wMSO introduced in [23].

As in Section 3, we consider a set R of weights. The syntax of wFO is obtained from core-wMSO by removing set variables, set quantifications and set sums. In addition to the classical boolean first-order logic (FO), it has two weighted layers. Step formulas defined in (step-wFO) consist of constants and if-then-else applications, where the conditions are formulated in boolean first-order logic. Finally, wFO builds on this by performing products of step formulas and then applying if-then-else, finite sums, or existential sums.

$$\varphi ::= \top \mid P_a(x) \mid x \leq y \mid \neg\varphi \mid \varphi \wedge \varphi \mid \forall x \varphi \tag{FO}$$

$$\Psi ::= r \mid \varphi \,?\, \Psi : \Psi \tag{step-wFO}$$

$$\Phi ::= \mathbf{0} \mid \textstyle\prod_x \Psi \mid \varphi \,?\, \Phi : \Phi \mid \Phi + \Phi \mid \textstyle\sum_x \Phi \tag{wFO}$$

with $a \in \Sigma$, $r \in \mathsf{R}$ and x, y first-order variables.

The semantics of step-wFO formulas is defined inductively. As above, let $u \in \Sigma^+$ be a nonempty word and $\sigma \colon \mathcal{V} \to \mathsf{pos}(u) = \{1, \dots, |u|\}$ be a valuation. For step-wFO formulas whose free variables are contained in $\mathcal{V}$, we define the $\mathcal{V}$-semantics as

$$[\![r]\!]_{\mathcal{V}}(u,\sigma) = r \qquad [\![\varphi \,?\, \Psi_1 : \Psi_2]\!]_{\mathcal{V}}(u,\sigma) = \begin{cases} [\![\Psi_1]\!]_{\mathcal{V}}(u,\sigma) & \text{if } u,\sigma \models \varphi \\ [\![\Psi_2]\!]_{\mathcal{V}}(u,\sigma) & \text{otherwise.} \end{cases}$$

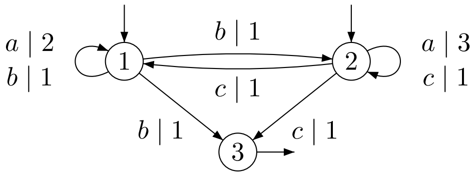

Figure 2 A weighted automaton, which is both aperiodic and unambiguous.

Notice that the semantics of a step-wFO formula is always a single weight from R.

For wFO formulas Φ whose free variables are contained in $\mathcal{V}$, we define the $\mathcal{V}$-semantics $\{\!|\Phi|\!\}_{\mathcal{V}}\colon \Sigma_{\mathcal{V}}^{+} \to \mathbb{N}\langle \mathsf{R}^{+}\rangle$. First, we let $\{\!|\Phi|\!\}_{\mathcal{V}}(\overline{u}) = \emptyset$ be the empty multiset when $\overline{u} \in \Sigma_{\mathcal{V}}^{+}$ is not a valid encoding of a pair (u,σ). Assume now that $\overline{u} = (u,\sigma)$ is a valid encoding of a nonempty word $u \in \Sigma^{+}$ and a valuation $\sigma\colon \mathcal{V} \to \mathsf{pos}(u)$. The semantics of wFO formulas is also defined inductively: $\{\!|\mathbf{0}|\!\}_{\mathcal{V}}(u,\sigma) = \emptyset$ is the empty multiset, and

$$\{\!|\textstyle\prod_x \Psi|\!\}_{\mathcal{V}}(u,\sigma) = \{\!\{r_1 r_2 \cdots r_{|u|}\}\!\} \text{ where } r_i = [\![\Psi]\!]_{\mathcal{V}\cup\{x\}}(u,\sigma[x\mapsto i]) \text{ for } 1 \le i \le |u|$$

$$\{\!|\varphi \mathbin{?} \Phi_1 : \Phi_2|\!\}_{\mathcal{V}}(u,\sigma) = \begin{cases} \{\!|\Phi_1|\!\}_{\mathcal{V}}(u,\sigma) & \text{if } u,\sigma \models \varphi \\ \{\!|\Phi_2|\!\}_{\mathcal{V}}(u,\sigma) & \text{otherwise} \end{cases}$$

$$\{\!|\Phi_1 + \Phi_2|\!\}_{\mathcal{V}}(u,\sigma) = \{\!|\Phi_1|\!\}_{\mathcal{V}}(u,\sigma) \uplus \{\!|\Phi_2|\!\}_{\mathcal{V}}(u,\sigma)$$

$$\{\!|\textstyle\sum_x \Phi|\!\}_{\mathcal{V}}(u,\sigma) = \biguplus_{i\in\mathsf{pos}(u)} \{\!|\Phi|\!\}_{\mathcal{V}\cup\{x\}}(u,\sigma[x\mapsto i])\,.$$

The semantics of the product (first line), is a singleton multiset which consists of a weight sequence whose length is $|u|$. We deduce that all weight sequences in a multiset $\{\!|\Phi|\!\}_{\mathcal{V}}(u,\sigma)$ have the same length and $\{\!|\Phi|\!\}_{\mathcal{V}}(u,\sigma) \in \mathbb{N}\langle \mathsf{R}^{|u|}\rangle$. We simply write $[\![\Psi]\!]$ and $\{\!|\Phi|\!\}$ when the set $\mathcal{V}$ of variables is clear from the context.

As explained in Section 3, applying an aggregation function allows to recover the semantics $[\![\Phi]\!]$ over semirings such as $\mathbb{N}_{+,\times}$, $\mathbb{N}_{\max,+}$, etc. For instance, consider the function $f\colon \{a,b\}^{+} \to \mathbb{N}$ which assign to a word $w \in \{a,b\}^{+}$ the length of the maximal a-block, i.e., $f(w) = n$ if a^n is a factor of w but a^{n+1} is not. Over $\mathbb{N}_{\max,+}$, we have $f = [\![\Phi]\!]$ where

$$\Phi = \textstyle\sum_{y,z} (\forall u\,(y \le u \le z) \to P_a(u)) \mathbin{?} (\prod_x (y \le x \le z) \mathbin{?} 1 : 0) : (\prod_x 0)\,.$$

We refer to [13] for further examples of quantitative specifications in weighted logic.

5 From Weighted Automata to Weighted FO

We say that a non-deterministic automaton $\mathcal{A} = (Q,\Sigma,\Delta)$ is *unambiguous from state p to state q* if for all words $u \in \Sigma^{+}$, there is at most one run of $\mathcal{A}$ from p to q with label u.

▶ **Theorem 5.** *Let $\mathcal{A}$ be an aperiodic weighted automaton which is unambiguous from p to q. We can construct a* wFO *sentence $\Phi_{p,q} = \varphi_{p,q} \mathbin{?} \prod_x \Psi_{p,q} : \mathbf{0}$ where $\varphi_{p,q}$ is a first-order sentence and $\Psi_{p,q}(x)$ is a* step-wFO *formula with a single free variable x such that $\{\!|\mathcal{A}_{p,q}|\!\} = \{\!|\Phi_{p,q}|\!\}$.*

Before proving Theorem 5, we start with an example. The automaton $\mathcal{A}$ of Figure 2 is unambiguous and it accepts the language $\mathcal{L}(\mathcal{A}) = (a^*b + a^*c)^{+} = (a+b+c)^*(b+c)$. We define a wFO sentence $\Phi_{1,3} = \varphi_{1,3} \mathbin{?} \prod_x \Psi_{1,3}(x) : \mathbf{0}$ as follows. The FO sentence $\varphi_{1,3}$ checks that $\mathcal{A}$ has a run from state 1 to state 3 on the input word w, i.e., that $w \in a^*b(a^*b + a^*c)^*$:

$$\varphi_{1,3} = \exists y\,(P_b(y) \wedge \forall z\,(z < y \implies P_a(z))) \wedge \exists y\,(\neg P_a(y) \wedge \forall z\,(z \le y))$$

When this is the case, the step-wFO formula $\Psi_{1,3}(x)$ computes the weight of the transition taken at a position x in the input word:

$$\Psi_{1,3}(x) = (P_b(x) \vee P_c(x))\,?\,1 : \exists y\,(x < y \wedge P_b(y) \wedge \forall z\,(x < z < y \implies P_a(z)))\,?\,2 : 3\,.$$

Notice that the same formula $\Psi = \Psi_{2,3} = \Psi_{1,3}$ also allows to compute the sequence of weights for the accepting runs starting in state 2. Therefore, $\mathcal{A}$ is equivalent to the wFO sentence

$$\Phi = \exists y\,(\neg P_a(y) \wedge \forall z\,(z \leq y))\,?\,\prod_x \Psi(x) : \mathbf{0}\,.$$

Proof of Theorem 5. Let $\mathcal{A} = (Q, \Sigma, \Delta, \mathsf{wt})$ be the aperiodic weighted automaton. By Theorem 2, for every pair of states $r, s \in Q$ there is a first-order sentence $\varphi_{r,s}$ such that $\mathcal{L}(\mathcal{A}_{r,s}) = \mathcal{L}(\varphi_{r,s})$. This gives in particular the first-order sentence $\varphi_{p,q}$ which is used in $\Phi_{p,q}$.

▷ Claim 6. We can construct a step-wFO formula $\Psi_{p,q}(x)$ such that for each word $u \in \mathcal{L}(\mathcal{A}_{p,q})$ and each position $1 \leq i \leq |u|$ in the word u, we have $[\![\Psi_{p,q}]\!](u, x \mapsto i) = \mathsf{wt}(\delta)$ where δ is the ith transition of the unique run ρ of $\mathcal{A}$ from p to q with label u.

Before proving this claim, let us show how we can deduce the statement of Theorem 5. Clearly, if a word $u \in \Sigma^+$ is not in $\mathcal{L}(\mathcal{A}_{p,q})$ then we have $\{\!|\mathcal{A}_{p,q}|\!\}(u) = \emptyset = \{\!|\Phi_{p,q}|\!\}(u)$. Consider now a word $u = a_1 a_2 \cdots a_n \in \mathcal{L}(\mathcal{A}_{p,q})$ and the unique run $\rho = \delta_1 \delta_2 \cdots \delta_n$ of $\mathcal{A}$ from p to q with label u. We have $\{\!|\mathcal{A}_{p,q}|\!\}(u) = \{\{\mathsf{wt}(\delta_1)\mathsf{wt}(\delta_2) \cdots \mathsf{wt}(\delta_n)\}\} = \{\!|\prod_x \Psi_{p,q}|\!\}(u)$ where the second equality follows from Claim 6. We deduce that $\{\!|\mathcal{A}_{p,q}|\!\} = \{\!|\Phi_{p,q}|\!\}$.

We turn now to the proof of Claim 6. Let $\delta = (r, a, s) \in \Delta$ be a transition of $\mathcal{A}$. We define the FO-formula with one free variable $\varphi_\delta(x) = \varphi_{p,r}^{<x} \wedge P_a(x) \wedge \varphi_{s,q}^{>x}$.

▷ Claim 7. For each word $u \in \Sigma^+$ and position $1 \leq i \leq |u|$, we have $u, x \mapsto i \models \varphi_\delta$ iff $u \in \mathcal{L}(\mathcal{A}_{p,q})$ and δ is the ith transition of the unique run of $\mathcal{A}$ from p to q with label u.

Indeed, assume that $u, x \mapsto i \models \varphi_\delta$. Then, $u[1, i-1] \models \varphi_{p,r}$ and there is a run ρ' of $\mathcal{A}$ from p to r with label $u[1, i-1]$. Notice that if $i = 1$ then $p = r$ and ρ' is the empty run. Similarly, from $u[i+1, |u|] \models \varphi_{s,q}$ we deduce that there is a run ρ'' of $\mathcal{A}$ from s to q with label $u[i+1, |u|]$. Finally, $u, x \mapsto i \models P_a(x)$ means that the ith letter of u is a. We deduce that $\rho = \rho'\delta\rho''$ is a run of $\mathcal{A}$ from p to q with label u, hence $u \in \mathcal{L}(\mathcal{A}_{p,q})$. Moreover, ρ is the unique such run since $\mathcal{A}$ is unambiguous from p to q. Now, δ is the ith transition of ρ, which concludes one direction. Conversely, assume that $u \in \mathcal{L}(\mathcal{A}_{p,q})$ and δ is the ith transition of the unique run of $\mathcal{A}$ from p to q with label u. Then, $u[1, i-1] \models \varphi_{p,r}$, $u[i+1, |u|] \models \varphi_{s,q}$, and the ith letter of u is a. Therefore, $u, x \mapsto i \models \varphi_\delta$. This concludes the proof of Claim 7.

Now, choose an arbitrary enumeration $\delta^1, \delta^2, \ldots, \delta^k$ of the transitions in Δ and define the step-wFO formula with one free variable

$$\Psi_{p,q}(x) = \varphi_{\delta^1}(x)\,?\,\mathsf{wt}(\delta^1) : \varphi_{\delta^2}(x)\,?\,\mathsf{wt}(\delta^2) : \;\cdots\; \varphi_{\delta^k}(x)\,?\,\mathsf{wt}(\delta^k) : \mathsf{wt}(\delta^k)\,.$$

We show that this formula satisfies the property of Claim 6. Consider a word $u \in \mathcal{L}(\mathcal{A}_{p,q})$ and a position $1 \leq i \leq |u|$. Let δ be the ith transition of the unique run of $\mathcal{A}$ from p to q with label u. By Claim 7, we have $u, x \mapsto i \models \varphi_{\delta^j}$ iff $\delta^j = \delta$. Therefore, $[\![\Psi_{p,q}]\!](u, x \mapsto i) = \mathsf{wt}(\delta)$, which concludes the proof of Claim 6. ◀

▶ **Corollary 8.**

1. *Let $\mathcal{A}$ be an aperiodic and unambiguous weighted automaton. We can construct a* wFO *sentence Φ which does not use any $\sum_x$ operator or $+$ operator, and such that $\{\!|\mathcal{A}|\!\} = \{\!|\Phi|\!\}$.*
2. *Let $\mathcal{A}$ be an aperiodic and finitely ambiguous weighted automaton. We can construct a* wFO *sentence Φ which does not use any $\sum_x$ operator, and such that $\{\!|\mathcal{A}|\!\} = \{\!|\Phi|\!\}$.*

Let $\mathcal{A} = (Q, \Sigma, \Delta)$ be a non-deterministic automaton. Two states $p, q \in Q$ *are in the same strongly connected component* (SCC), denoted $p \approx q$, if $p = q$ or there exist a run of $\mathcal{A}$ from p to q and also a run of $\mathcal{A}$ from q to p. Note that $\approx$ is an equivalence relation on Q. We denote by $[p]$ the strongly connected component of p, i.e., the equivalence class of p under $\approx$.

The automaton $\mathcal{A}$ is *SCC-unambiguous* if it is unambiguous on each strongly connected component, i.e., $\mathcal{A}$ is unambiguous from p to q for all p, q such that $p \approx q$. A trimmed (all states are reachable and co-reachable) and unambiguous automaton is SCC-unambiguous.

For instance, the automaton $\mathcal{A}$ of Figure 1 has three strongly connected components: $\{1\}$, $\{2, 3\}$ and $\{4\}$. It is not unambiguous from 1 to 4, but it is SCC-unambiguous.

▶ **Proposition 9** ([35, 24] and [42] Thm 4.1)**.** *Let $\mathcal{A} = (Q, \Sigma, \Delta, I, F)$ be a trimmed non-deterministic automaton. Then $\mathcal{A}$ is polynomially ambiguous iff $\mathcal{A}$ is SCC-unambiguous.*

▶ **Theorem 10.** *Let $\mathcal{A}$ be an aperiodic weighted automaton which is SCC-unambiguous. For each pair of states p and q, we can construct a* wFO *sentence $\Phi_{p,q}$ such that $\{\!|\mathcal{A}_{p,q}|\!\} = \{\!|\Phi_{p,q}|\!\}$. Moreover, we can construct a* wFO *sentence Φ such that $\{\!|\mathcal{A}|\!\} = \{\!|\Phi|\!\}$.*

First, we give for the weighted automaton $\mathcal{A}$ of Figure 1 the equivalent wFO formula $\Phi_{1,4} = \sum_{y_1}\sum_{y_2}\varphi(y_1, y_2) \,?\, \prod_x \Psi(x, y_1, y_2) : \mathbf{0}$ where φ and Ψ are defined below. When reading a word $w \in \mathsf{supp}(\mathcal{A})$, the automaton makes two non-deterministic choices corresponding to the positions y_1 and y_2 at which the transitions *switching* between the strongly connected components are taken, i.e., transition from state 1 to state 2 is taken at position y_1, and transition from 3 to 4 is taken at position y_2. Since the automaton is SCC-unambiguous, given the input word and these two positions, the run is uniquely determined. Formula $\varphi(y_1, y_2)$ states that it is possible to take the switching transitions at positions y_1 and y_2:

$$\varphi(y_1, y_2) = y_1 < y_2 \wedge \forall z\,(z \le y_1 \to P_a(z)) \wedge P_a(y_1 + 1) \wedge \forall z\,(y_2 \le z \to P_b(z))\,.$$

When this is the case, the step-wFO formula $\Psi(x, y_1, y_2)$ computes the weight of the transition taken at a position x in the input word:

$$\Psi(x, y_1, y_2) = (x < y_1 \vee y_2 < x) \,?\, 2 : (x = y_1 \vee x = y_2) \,?\, 1 : P_a(x + 1) \,?\, 3 : 5\,.$$

With these definitions, we obtain $\{\!|\mathcal{A}|\!\} = \{\!|\Phi_{1,4}|\!\}$. The proof of Theorem 10 is in [14]. Intuitively, a run from p to q reading a word $w \in \Sigma^+$ uses a sequence of transitions switching between connected components of $\mathcal{A}$. The positions where these switches are taken can be described by a sequence of $\sum_y$-operators. Since there are only finitely many sequences of switching transitions, they can be described by a finite sum of wFO sentences.

6 From Weighted FO to Weighted Automata

Let $\mathcal{A} = (Q, \Sigma, \Delta)$ and $\mathcal{A}' = (Q', \Sigma, \Delta')$ be two non-deterministic automata over Σ. Assuming that $Q \cap Q' = \emptyset$, we define their disjoint union as $\mathcal{A} \uplus \mathcal{A}' = (Q \uplus Q', \Sigma, \Delta \uplus \Delta')$ and their product as $\mathcal{A} \times \mathcal{A}' = (Q \times Q', \Sigma, \Delta'')$ where $\Delta'' = \{((p, p'), a, (q, q')) \mid (p, a, p') \in \Delta \wedge (p', a, q') \in \Delta'\}$.

▶ **Lemma 11.** *The following holds.*

1. *If $\mathcal{A}$ and $\mathcal{A}'$ are aperiodic, then $\mathcal{A} \uplus \mathcal{A}'$ and $\mathcal{A} \times \mathcal{A}'$ are also aperiodic.*
2. *If $\mathcal{A}$ and $\mathcal{A}'$ are SCC-unambiguous, then $\mathcal{A} \uplus \mathcal{A}'$ and $\mathcal{A} \times \mathcal{A}'$ are also SCC-unambiguous.*

Now let φ be an FO-formula with free variables contained in the finite set $\mathcal{V}$, and let $\mathcal{A}_{\varphi,\mathcal{V}} = (Q, \Sigma_{\mathcal{V}}, \Delta, \iota, F, G)$ be the deterministic, complete, trim and aperiodic automaton given by Theorem 3. For $i = 1, 2$, let $\mathcal{A}_i = (Q_i, \Sigma_{\mathcal{V}}, \Delta_i, \mathsf{wt}_i, I_i, F_i)$ be two weighted automata over $\Sigma_{\mathcal{V}}$ with $Q_1 \cap Q_2 = \emptyset$. Define the weighted automaton $\mathcal{A}' = (Q', \Sigma_{\mathcal{V}}, \Delta', \mathsf{wt}', I', F')$ by

- $Q' = Q \times Q_1 \uplus Q \times Q_2$, $I' = \{\iota\} \times I_1 \uplus \{\iota\} \times I_2$, $F' = F \times F_1 \uplus G \times F_2$,
- $\Delta' = \{\big((p,p'),a,(q,q')\big) \mid (p,a,q) \in \Delta$ and $(p',a,q') \in \Delta_1 \cup \Delta_2\}$, and $\mathsf{wt}'\big((p,p'),a,(q,q')\big) = \mathsf{wt}_i(p',a,q')$ if $(p',a,q') \in \Delta_i$ for $i = 1,2$.

▶ **Lemma 12.** *For each $\overline{u} \in \Sigma_{\mathcal{V}}^+$, we have*

$$\{\!|\mathcal{A}'|\!\}(\overline{u}) = \begin{cases} \{\!|\mathcal{A}_1|\!\}(\overline{u}), & \text{if } \overline{u} \text{ is valid and } \overline{u} \models \varphi, \\ \{\!|\mathcal{A}_2|\!\}(\overline{u}), & \text{if } \overline{u} \text{ is valid and } \overline{u} \not\models \varphi, \\ \emptyset, & \text{if } \overline{u} \text{ is not valid.} \end{cases}$$

Moreover, if $\mathcal{A}_1$ and $\mathcal{A}_2$ are aperiodic (resp. unambiguous, SCC-unambiguous) then so is $\mathcal{A}'$.

Let $\mathcal{V}$ be a finite set of first-order variables and let $\mathcal{V}' = \mathcal{V} \cup \{y\}$ where $y \notin \mathcal{V}$. Given a word $\overline{w} \in \Sigma_{\mathcal{V}}^+$ and a position $i \in \mathsf{pos}(w)$, we denote by $(\overline{w}, y \mapsto i)$ the word over $\Sigma_{\mathcal{V}'}$ whose projection on $\Sigma_{\mathcal{V}}$ is $\overline{w}$ and projection on the y-component is $0^{i-1}10^{|w|-i}$, i.e., has a unique 1 on position i. Given a function $A\colon \Sigma_{\mathcal{V}'}^+ \to \mathbb{N}\langle X\rangle$, we define the function $\sum_y A\colon \Sigma_{\mathcal{V}}^+ \to \mathbb{N}\langle X\rangle$ for $\overline{w} \in \Sigma_{\mathcal{V}}^+$ by $(\sum_y A)(\overline{w}) = \biguplus_{i \in \mathsf{pos}(w)} A(\overline{w}, y \mapsto i)$.

▶ **Lemma 13.** *Let $\mathcal{A}$ be a weighted automaton over $\Sigma_{\mathcal{V}'}$. We can construct a weighted automaton $\mathcal{A}'$ over $\Sigma_{\mathcal{V}}$ such that $\{\!|\mathcal{A}'|\!\} = \sum_y \{\!|\mathcal{A}|\!\}$. Moreover, if $\mathcal{A}$ is aperiodic then $\mathcal{A}'$ is also aperiodic, and if $\mathcal{A}$ is SCC-unambiguous then $\mathcal{A}'$ is also SCC-unambiguous.*

We turn now to one of our main results: given a $\mathsf{step\text{-}wFO}$ formula Ψ, we can construct a weighted automaton for $\prod_x \Psi$ which is both aperiodic and unambiguous.

When weights are uninterpreted, a weighted automaton $\mathcal{A} = (Q, \Sigma, \Delta, \mathsf{wt}, I, F)$ is a letter-to-letter transducer from its input alphabet Σ to the output alphabet R. If in addition the input automaton is unambiguous, then we have a functional transducer. In the following, we will construct such functional transducers using the boolean output alphabet $\mathbb{B} = \{0,1\}$.

▶ **Lemma 14.** *Let $\mathcal{V} = \{y_1, \ldots, y_m\}$. Given an* FO *formula φ with free variables contained in $\mathcal{V}' = \mathcal{V} \cup \{x\}$, we can construct a transducer $\mathcal{B}_{\varphi,\mathcal{V}}$ from $\Sigma_{\mathcal{V}}$ to $\mathbb{B}$ which is aperiodic and unambiguous and such that for all words $\overline{w} \in \Sigma_{\mathcal{V}}^+$*

1. *there is a (unique) accepting run of $\mathcal{B}_{\varphi,\mathcal{V}}$ on the input word $\overline{w}$ iff it is a valid encoding of a pair (w, σ) where $w \in \Sigma^+$ and $\sigma\colon \mathcal{V} \to \mathsf{pos}(w)$ is a valuation,*
2. *and in this case, for all $1 \le i \le |w|$, the ith bit of the output is 1 iff $w, \sigma[x \mapsto i] \models \varphi$.*

Proof (sketch). Notice that $\Sigma_{\mathcal{V}'} = \Sigma_{\mathcal{V}} \times \mathbb{B}$ so letters in $\Sigma_{\mathcal{V}'}$ are of the form $(\overline{a}, 0)$ or $(\overline{a}, 1)$ where $\overline{a} \in \Sigma_{\mathcal{V}}$. Abusing the notations, when $\overline{v} \in \Sigma_{\mathcal{V}}^*$, we write $(\overline{v}, 0)$ to denote the word over $\Sigma_{\mathcal{V}'}$ whose projection on $\Sigma_{\mathcal{V}}$ is $\overline{v}$ and projection on the x-component consists of 0's only.

Consider the deterministic, complete and aperiodic automaton $\mathcal{A}_{\varphi,\mathcal{V}'} = (Q, \Sigma_{\mathcal{V}'}, \Delta, \iota, F, G)$ associated with φ by Theorem 3. We also denote by Δ the extension of the transition function to subsets of Q. So we see the deterministic and complete transition relation both as a total function $\Delta\colon Q \times \Sigma_{\mathcal{V}'} \to Q$ and $\Delta\colon 2^Q \times \Sigma_{\mathcal{V}'} \to 2^Q$.

We construct now the transducer $\mathcal{B}_{\varphi,\mathcal{V}} = (Q', \Sigma_{\mathcal{V}}, \Delta', \mathsf{wt}, I', F')$. The set of states is $Q' = Q \times 2^Q \times 2^Q \times \mathbb{B}$. The unique initial state is $\iota' = (\iota, \emptyset, \emptyset, 0)$. The set of final states is $F' = (Q \times 2^F \times 2^G \times \mathbb{B}) \setminus \{\iota'\}$. Then, we define the following transitions:

- $\delta = ((p,X,Y,b), \overline{a}, (p',X',Y',1)) \in \Delta'$ is a transition with weight $\mathsf{wt}(\delta) = 1$ if $p' = \Delta(p, (\overline{a}, 0))$, $X' = \Delta(X, (\overline{a}, 0)) \cup \{\Delta(p, (\overline{a}, 1))\}$ and $Y' = \Delta(Y, (\overline{a}, 0))$,
- $\delta = ((p,X,Y,b), \overline{a}, (p',X',Y',0)) \in \Delta'$ is a transition with weight $\mathsf{wt}(\delta) = 0$ if $p' = \Delta(p, (\overline{a}, 0))$, $X' = \Delta(X, (\overline{a}, 0))$ and $Y' = \Delta(Y, (\overline{a}, 0)) \cup \{\Delta(p, (\overline{a}, 1))\}$.

Notice that, whenever we read a new input letter $\overline{a} \in \Sigma_{\mathcal{V}}$, there is a non-deterministic choice. In the first case above, we guess that formula φ will hold on the input word when the valuation is extended by assigning x to the current position, whereas in the second case we guess that φ will not hold. The guess corresponds to the output of the transition, as required by the second condition of Lemma 14. Now, we have to check that the guess is correct. For this, the first component of $\mathcal{B}_{\varphi,\mathcal{V}}$ computes the state $p = \Delta(\iota, (\overline{u}, 0))$ reached by $\mathcal{A}_{\varphi,\mathcal{V}'}$ after reading $(\overline{u}, 0)$ where $\overline{u} \in \Sigma_{\mathcal{V}}^*$ is the current prefix of the input word. When reading the current letter $\overline{a} \in \Sigma_{\mathcal{V}}$, the transducer adds the state $\Delta(p, (\overline{a}, 1)) = \Delta(\iota, (\overline{u}, 0)(\overline{a}, 1))$ either to the "positive" X-component or to the "negative" Y-component of its state, depending on its guess as explained above. Then, the transducer continues reading the suffix $\overline{v} \in \Sigma_{\mathcal{V}}^*$ of the input word. It updates the X (resp. Y)-component so that it contains the state $q = \Delta(\iota, (\overline{u}, 0)(\overline{a}, 1)(\overline{v}, 0))$ at the end of the run. Now, the acceptance condition allows us to check that the guess was correct.

1. If $\overline{w} = \overline{uav}$ is not a valid encoding of a pair (w, σ) with $w \in \Sigma^+$ and $\sigma \colon \mathcal{V} \to \mathsf{pos}(w)$ then $q \notin F \cup G$ and the run of the transducer is not accepting. Otherwise, let $i \in \mathsf{pos}(w)$ be the position where the guess was made.
2. If the guess was positive then q belongs to the X-component and the accepting condition implies $q \in F$, which means by definition of $\mathcal{A}_{\varphi,\mathcal{V}'}$ that $w, \sigma[x \mapsto i] \models \varphi$.
3. If the guess was negative then q belongs to the Y-component and the accepting condition implies $q \in G$, which means by definition of $\mathcal{A}_{\varphi,\mathcal{V}'}$ that $w, \sigma[x \mapsto i] \not\models \varphi$. ◀

▶ **Theorem 15.** *Let $\mathcal{V} = \{y_1, \ldots, y_m\}$. Given a* step-wFO *formula Ψ with free variables contained in $\mathcal{V}' = \mathcal{V} \cup \{x\}$, we can construct a weighted automaton $\mathcal{A}_{\Psi,\mathcal{V}}$ over $\Sigma_{\mathcal{V}}$ which is aperiodic, unambiguous and equivalent to $\prod_x \Psi$, i.e., $\{\!|\mathcal{A}_{\Psi,\mathcal{V}}|\!\}(\overline{w}) = \{\!|\prod_x \Psi|\!\}_{\mathcal{V}}(\overline{w})$ for all words $\overline{w} \in \Sigma_{\mathcal{V}}^+$.*

Proof. In case $\Psi = r$ is an atomic step-wFO formula, we replace it with the equivalent $\top \,?\, r : r$ step-wFO formula. Let $\varphi_1, \ldots, \varphi_k$ be the FO formulas occurring in Ψ. By the above remark, we have $k \geq 1$. Consider the aperiodic and unambiguous transducers $\mathcal{B}_1, \ldots, \mathcal{B}_k$ given by Lemma 14. For $1 \leq i \leq k$, we let $\mathcal{B}_i = (Q_i, \Sigma_{\mathcal{V}}, \Delta_i, \mathsf{wt}_i, I_i, F_i)$. The weighted automaton $\mathcal{A}_{\Psi,\mathcal{V}} = (Q, \Sigma_{\mathcal{V}}, \Delta, \mathsf{wt}, I, F)$ is essentially a cartesian product of the transducers $\mathcal{B}_i$. More precisely, we let $Q = \prod_{i=1}^k Q_i$, $I = \prod_{i=1}^k I_i$, $F = \prod_{i=1}^k F_i$, and

$$\Delta = \{((p_1, \ldots, p_k), \overline{a}, (q_1, \ldots, q_k)) \mid (p_i, \overline{a}, q_i) \in \Delta_i \text{ for all } 1 \leq i \leq k\}\,.$$

Since the transducers $\mathcal{B}_i$ are all aperiodic and unambiguous, we deduce by Lemma 11 that $\mathcal{A}_{\Psi,\mathcal{V}}$ is also aperiodic and unambiguous. It remains to define the weight function wt.

Given a bit vector $\overline{b} = (b_1, \ldots, b_k) \in \mathbb{B}^k$ of size k, we define $\Psi(\overline{b})$ as the weight from R resulting from the step-wFO formula Ψ when the FO conditions $\varphi_1, \ldots, \varphi_k$ evaluate to $\overline{b}$. Formally, the definition is by structural induction on the step-wFO formula:

$$r(\overline{b}) = r \qquad\qquad (\varphi_i \,?\, \Psi_1 : \Psi_2)(\overline{b}) = \begin{cases} \Psi_1(\overline{b}) & \text{if } b_i = 1 \\ \Psi_2(\overline{b}) & \text{if } b_i = 0\,. \end{cases}$$

Consider a transition $\delta = ((p_1, \ldots, p_k), \overline{a}, (q_1, \ldots, q_k)) \in \Delta$ and let $\delta_i = (p_i, \overline{a}, q_i)$ for $1 \leq i \leq k$. Let $\overline{b} = (b_1, \ldots, b_k) \in \mathbb{B}^k$ where $b_i = \mathsf{wt}(\delta_i) \in \mathbb{B}$ for all $1 \leq i \leq k$. We define $\mathsf{wt}(\delta) = \Psi(\overline{b})$.

Let $\overline{w} \in \Sigma_{\mathcal{V}}^+$. If $\overline{w}$ is not a valid encoding of a pair (w, σ) then $\{\!|\prod_x \Psi|\!\}_{\mathcal{V}}(\overline{w}) = \emptyset$ by definition. Moreover, $\{\!|\mathcal{A}_{\Psi,\mathcal{V}}|\!\}(\overline{w}) = \emptyset$ since by Lemma 14, $\overline{w}$ is not in the support of $\mathcal{B}_1$. We assume below that $\overline{w}$ is a valid encoding of a pair (w, σ) where $w \in \Sigma^+$ and $\sigma \colon \mathcal{V} \to \mathsf{pos}(w)$ is a valuation. Then, each transducer $\mathcal{B}_i$ admits a unique accepting run ρ_i reading the input word $\overline{w}$. These result in the unique accepting run ρ of $\mathcal{A}_{\Psi,\mathcal{V}}$ reading $\overline{w}$. The projections of ρ on $\mathcal{B}_1, \ldots, \mathcal{B}_k$ are $\rho_1, \ldots, \rho_k$. Let $j \in \mathsf{pos}(w) = \{1, \ldots, |w|\}$ be a position in $\overline{w}$ and let δ^j be the j-th transition of ρ. For $1 \leq i \leq k$, we denote by δ_i^j the projection of δ^j on $\mathcal{B}_i$ and we let $b_i^j = \mathsf{wt}(\delta_i^j)$. By Lemma 14, we get $b_i^j = 1$ iff $w, \sigma[x \mapsto j] \models \varphi_i$. Finally, let $\overline{b}^j = (b_1^j, \ldots, b_k^j)$. From the above, we deduce that $[\![\Psi]\!]_{\mathcal{V}\cup\{x\}}(w, \sigma[x \mapsto j]) = \Psi(\overline{b}^j) = \mathsf{wt}(\delta^j)$. Putting things together, we have $\{\!|\mathcal{A}_{\Psi,\mathcal{V}}|\!\}(w, \sigma) = \{\{\mathsf{wt}(\rho)\}\} = \{\{\mathsf{wt}(\delta^1) \cdots \mathsf{wt}(\delta^{|w|}\}\} = \{\!|\prod_x \Psi|\!\}_{\mathcal{V}}(w, \sigma)$. ◀

▶ **Theorem 16.** *Let Φ be a* wFO *sentence. We can construct an aperiodic SCC-unambiguous weighted automaton $\mathcal{A}$ such that $\{\!|\mathcal{A}|\!\} = \{\!|\Phi|\!\}$. Moreover, if Φ does not contain the sum operations $+$ and $\sum_x$, then $\mathcal{A}$ can be chosen to be unambiguous. If Φ does not contain the sum operation $\sum_x$, we can construct $\mathcal{A}$ as a finite union of unambiguous weighted automata.*

Proof. We proceed by structural induction on Φ. For $\Phi = \mathbf{0}$ this is trivial. For $\Phi = \prod_x \Psi$ with a step-wFO formula Ψ, we obtain an aperiodic unambiguous weighted automaton $\mathcal{A}$ by Theorem 15. For formulas $\varphi\,?\,\Phi_1 : \Phi_2$, $\Phi_1 + \Phi_2$ and $\sum_x \Phi$, we apply Lemmas 12, 11, 13. ◀

In the proof of Theorem 16, we may obtain the final statement also as a consequence of the preceding one by the following observations which could be of independent interest. Let φ be an FO-formula and Φ_1, Φ_2 two wFO formulas, with free variables contained in $\mathcal{V}$. Then,

$$\{\!|\varphi\,?\,\Phi_1 : \Phi_2|\!\}_{\mathcal{V}} = \{\!|\varphi\,?\,\Phi_1 : \mathbf{0} + \neg\varphi\,?\,\Phi_2 : \mathbf{0}|\!\}_{\mathcal{V}} \,,$$
$$\{\!|\varphi\,?\,\Phi_1 + \Phi_2 : \mathbf{0}|\!\}_{\mathcal{V}} = \{\!|\varphi\,?\,\Phi_1 : \mathbf{0} + \varphi\,?\,\Phi_2 : \mathbf{0}|\!\}_{\mathcal{V}} \,.$$

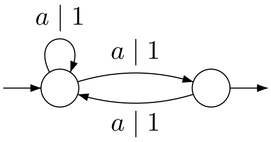
Hence, given a wFO sentence Φ not containing the sum operation $\sum_x$, we can rewrite Φ as a sum of $\mathbf{0}$, $\prod_x \Psi$ and if-then-else sentences of the form $\varphi\,?\,\Phi' : \mathbf{0}$ where Φ' does not contain the sum operations $+$ or $\sum_x$.

Proof of Thm 1. Immediate by Theorem 10, Theorem 4, Corollary 8 and Theorem 16. ◀

7 Concluding remarks

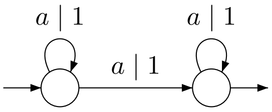
We introduced a model of aperiodic weighted automata and showed that a suitable concept of weighted first order logic and two natural sublogics have the same expressive power as polynomially ambiguous, finitely ambiguous, resp. unambigous aperiodic weighted automata. For the three semirings $\mathbb{N}_{+,\times}$, $\mathbb{N}_{\max,+}$ and $\mathbb{N}_{\min,+}$ the hierarchies of these automata classes and thereby of the corresponding logics are strict. Some separating examples are given below. Proofs and other separating examples can be found in [14].

▶ **Example 17.** Let $\Sigma = \{a\}$ and consider the automaton $\mathcal{A}$ below over the semiring $\mathbb{N}_{+,\times}$ of natural numbers. Note that the weighted automaton computes the sequence $(F_n)_{n\geq 0}$ of Fibonacci numbers $0, 1, 1, 2, 3, 5, \cdots$. More precisely, for any $n \in \mathbb{N}$, we have $[\![\mathcal{A}]\!](a^n) = F_n$.



Clearly, $\mathcal{A}$ is exponentially ambiguous and aperiodic with index 2. But $[\![\mathcal{A}]\!]$ cannot be realized by an aperiodic polynomially ambiguous weighted automaton. In [31], it was shown that the Fibonacci numbers cannot be computed by copyless cost-register automata. ⌟

▶ **Example 18.** Consider the automaton $\mathcal{A}$ below over $\Sigma = \{a\}$ and the semiring $\mathbb{N}_{+,\times}$. Clearly, $[\![\mathcal{A}]\!](a^n) = n$ for each $n > 0$, and $\mathcal{A}$ is aperiodic and polynomially (even linearly) ambiguous. But $\mathcal{A}$ is not equivalent to any finitely ambiguous weighted automaton.



◀

▶ **Example 19.** Let $\Sigma = \{a\}$ and consider the function $f \colon \Sigma^* \to \mathbb{N}$ defined by $f(a^n) = 2^n + 1$. We have $f = [\![\mathcal{A}]\!]$ for some aperiodic and 2-ambiguous weighted automaton: one self-loop computes 2^n and another self-loop computes 1. But f cannot be realized by an unambiguous weighted automaton over $\mathbb{N}_{+,\times}$.

Our main theorem generalizes to the weighted setting a classical result of automata theory. A challenging open problem is to obtain similar results for suitable weighted linear temporal logics. Another interesting problem is to characterize wFO with unrestricted weighted products, possibly using *aperiodic* restrictions of the pebble weighted automata studied in [4, 27, 5].

Decidability problems for wFO or equivalently for weighted aperiodic automata are also open and very interesting. For instance, given a wMSO sentence, is there an equivalent wFO sentence? Decidability may indeed depend on the specific semiring.

1 Introduction

In this paper we consider the problem of building the minimal deterministic finite-state automaton generating a given regular language. This is a classical issue that arises in many different areas of computer science such as verification, regular expression searching and natural language processing, to name a few.

There exists a number of methods, such as Hopcroft's [10] and Moore's algorithms [14], that receive as input a deterministic finite-state automaton (DFA for short) generating a language and build the minimal DFA for that language. In general, these methods rely on computing a partition of the set of states of the input DFA which is then used as the set of states of the minimal DFA.

On the other hand, Brzozowski [4] proposed the *double-reversal method* for building the minimal DFA for the language generated by an input non-deterministic automaton (NFA for short). This algorithm alternates a reverse operation and a determinization operation twice,

relying on the fact that, for any given NFA $\mathcal{N}$, if the reverse automaton of $\mathcal{N}$ is deterministic then the determinization operation yields the minimal DFA for the language of $\mathcal{N}$. This method has been recently generalized by Brzozowski and Tamm [5]. They showed the following *necessary and sufficient condition*: the determinization operation yields the minimal DFA for the language of $\mathcal{N}$ if and only if the reverse automaton of $\mathcal{N}$ is *atomic*.

It is well-known that all these approaches to the DFA minimization problem aim to compute Nerode's equivalence relation for the considered language. However, the double-reversal method and its later generalization appear to be quite isolated from other methods such as Hopcroft's and Moore's algorithms. This has led to different attempts to better explain Brzozowski's method [3] and its connection with other minimization algorithms [1, 7, 16]. We use a framework of automata constructions based on equivalence classes over *words* to give new insights on the relation between these algorithms.

In this paper we consider equivalence relations over words on an alphabet Σ that induce finite partitions over Σ^*. Furthermore, we require that these partitions are well-behaved with respect to concatenation, namely, *congruences*. Given a regular language L and an equivalence relation satisfying these conditions, we use well-known automata constructions that yield automata generating the language L [6, 13]. In this work, we consider two types of equivalence relations over words verifying the required conditions.

First, we define a *language-based equivalence*, relative to a regular language, that behaves well with respect to *right* concatenation, also known as the right Nerode's equivalence relation for the language. When applying the automata construction to the right Nerode's equivalence, we obtain the minimal DFA for the given language [6, 13]. In addition, we define an *automata-based equivalence*, relative to an NFA. When applying the automata construction to the automata-based equivalence we obtain a determinized version of the input NFA.

On the other hand, we also obtain counterpart automata constructions for relations that are well-behaved with respect to *left* concatenation. In this case, language-based and automata-based equivalences yield, respectively, the minimal co-deterministic automaton and a co-deterministic NFA for the language.

The relation between the automata constructions resulting from the language-based and the automata-based congruences, together with the the duality between right and left congruences, allows us to relate determinization and minimization operations. As a result, we formulate a sufficient and necessary condition that guarantees that determinizing an automaton yields the minimal DFA. This formulation evidences the relation between the double-reversal and the state partition refinement minimization methods.

We start by giving a simple proof of Brzozowski's double-reversal method [4], to later address the generalization of Brzozowski and Tamm [5]. Furthermore, we relate the iterations of Moore's partition refinement algorithm, which works on the states of the input DFA, to the iterations of the greatest fixpoint algorithm that builds the right Nerode's partition on words. We conclude by relating the automata constructions introduced by Brzozowski and Tamm [5], named the *átomaton* and *the partial átomaton*, to the automata constructions described in this work.

Structure of the paper. After preliminaries in Section 2, we introduce in Section 3 the automata constructions based on congruences on words and establish the duality between these constructions when using right and left congruences. Then, in Section 4, we define language-based and automata-based congruences and analyze the relations between the resulting automata constructions. In Section 5, we study a collection of well-known constructions for the minimal DFA. Finally, we give further details on related work in Section 6. For space reasons, missing proofs are deferred to the extended version of this paper [9].

2 Preliminaries

Languages. Let Σ be a finite nonempty *alphabet* of symbols. Given a word $w \in \Sigma^*$, w^R denotes the *reverse* of w. Given a language $L \subseteq \Sigma^*$, $L^R \stackrel{\text{def}}{=} \{w^R \mid w \in L\}$ denotes the *reverse language* of L. We denote by L^c the *complement* of the language L. The *left (resp. right) quotient* of L by a word u is defined as the language $u^{-1}L \stackrel{\text{def}}{=} \{x \in \Sigma^* \mid ux \in L\}$ (resp. $Lu^{-1} \stackrel{\text{def}}{=} \{x \in \Sigma^* \mid xu \in L\}$).

Automata. A *(nondeterministic) finite-state automaton* (NFA for short), or simply *automaton*, is a 5-tuple $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, where Q is a finite set of *states*, Σ is an alphabet, $I \subseteq Q$ are the *initial* states, $F \subseteq Q$ are the *final* states, and $\delta : Q \times \Sigma \to \wp(Q)$ is the *transition* function. We denote the *extended transition function* from Σ to Σ^* by $\hat{\delta}$. Given $S, T \subseteq Q$, $W^{\mathcal{N}}_{S,T} \stackrel{\text{def}}{=} \{w \in \Sigma^* \mid \exists q \in S, q' \in T : q' \in \hat{\delta}(q, w)\}$. In particular, when $S = \{q\}$ and $T = F$, we define *the right language* of state q as $W^{\mathcal{N}}_{q,F}$. Likewise, when $S = I$ and $T = \{q\}$, we define the *left language* of state q as $W^{\mathcal{N}}_{I,q}$. We define $\mathrm{post}^{\mathcal{N}}_w(S) \stackrel{\text{def}}{=} \{q \in Q \mid w \in W^{\mathcal{N}}_{S,q}\}$ and $\mathrm{pre}^{\mathcal{N}}_w(S) \stackrel{\text{def}}{=} \{q \in Q \mid w \in W^{\mathcal{N}}_{q,S}\}$. In general, we omit the automaton $\mathcal{N}$ from the superscript when it is clear from the context. We say that a state q is *unreachable* iff $W^{\mathcal{N}}_{I,q} = \emptyset$ and we say that q is *empty* iff $W^{\mathcal{N}}_{q,F} = \emptyset$. Finally, note that $\mathcal{L}(\mathcal{N}) = \bigcup_{q \in I} W^{\mathcal{N}}_{q,F} = \bigcup_{q \in F} W^{\mathcal{N}}_{I,q} = W^{\mathcal{N}}_{I,F}$.

Given an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, the *reverse NFA* for $\mathcal{N}$, denoted by $\mathcal{N}^R$, is defined as $\mathcal{N}^R = (Q, \Sigma, \delta_r, F, I)$ where $q \in \delta_r(q', a)$ iff $q' \in \delta(q, a)$. Clearly, $\mathcal{L}(\mathcal{N})^R = \mathcal{L}(\mathcal{N}^R)$.

A *deterministic finite-state automaton* (DFA for short) is an NFA such that, $I = \{q_0\}$, and, for every state $q \in Q$ and every symbol $a \in \Sigma$, there exists exactly one $q' \in Q$ such that $\delta(q, a) = q'$. According to this definition, DFAs are always *complete*, i.e., they define a transition for each state and input symbol. In general, we denote NFAs by $\mathcal{N}$, using $\mathcal{D}$ for DFAs when the distinction is important. A *co-deterministic finite-state automata* (co-DFA for short) is an NFA $\mathcal{N}$ such that $\mathcal{N}^R$ is deterministic. In this case, co-DFAs are always *co-complete*, i.e., for each target state q' and each input symbol, there exists a source state q such that $\delta(q, a) = q'$. Recall that, given an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, the well-known *subset construction* builds a DFA $\mathcal{D} = (\wp(Q), \Sigma, \delta_d, \{I\}, F_d)$ where $F_d = \{S \in \wp(Q) \mid S \cap F \neq \emptyset\}$ and $\delta_d(S, a) = \{q' \mid \exists q \in S, q' \in \delta(q, a)\}$ for every $a \in \Sigma$, that accepts the same language as $\mathcal{N}$ [11]. Given an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$, we denote by $\mathcal{N}^D$ the DFA that results from applying the subset construction to $\mathcal{N}$ where only subsets (including the empty subset) that are reachable from the initial subset of $\mathcal{N}^D$ are used. Then, $\mathcal{N}^D$ possibly contains empty states but no state is unreachable. A DFA for the language $\mathcal{L}(\mathcal{N})$ is *minimal*, denoted by $\mathcal{N}^{DM}$, if it has no unreachable states and no two states have the same right language. The minimal DFA for a regular language is unique modulo isomorphism.

Equivalence Relations and Partitions. Recall that an *equivalence relation* on a set X is a binary relation $\sim$ that is reflexive, symmetric and transitive. Every equivalence relation $\sim$ on X induces a *partition* $P_\sim$ of X, i.e., a family $P_\sim = \{B_i\}_{i \in \mathcal{I}} \subseteq \wp(X)$ of subsets of X, with $\mathcal{I} \subseteq \mathbb{N}$, such that:

(i) $B_i \neq \emptyset$ for all $i \in \mathcal{I}$;
(ii) $B_i \cap B_j = \emptyset$, for all $i, j \in \mathcal{I}$ with $i \neq j$; and
(iii) $X = \bigcup_{i \in \mathcal{I}} B_i$.

We say that a partition is *finite* when $\mathcal{I}$ is finite. Each B_i is called a *block* of the partition. Given $u \in X$, then $P_\sim(u)$ denotes the unique block that contains u and corresponds to the *equivalence class* u w.r.t. $\sim$, $P_\sim(u) \stackrel{\text{def}}{=} \{v \in X \mid u \sim v\}$. This definition can be extended in a natural way to a set $S \subseteq X$ as $P_\sim(S) \stackrel{\text{def}}{=} \bigcup_{u \in S} P_\sim(u)$. We say that the partition $P_\sim$

represents precisely S iff $P_{\sim}(S) = S$. An equivalence relation $\sim$ is *of finite index* iff $\sim$ defines a finite number of equivalence classes, i.e., the induced partition $P_{\sim}$ is finite. In the following, we will always consider equivalence relations of finite index, i.e., finite partitions.

Finally, denote $Part(X)$ the set of partitions of X. We use the standard refinement ordering $\preceq$ between partitions: let $P_1, P_2 \in Part(X)$, then $P_1 \preceq P_2$ iff for every $B \in P_1$ there exists $B' \in P_2$ such that $B \subseteq B'$. Then, we say that P_1 is *finer than* P_2 (or equivalently, P_2 is *coarser than* P_1). Given $P_1, P_2 \in Part(X)$, define the *coarsest common refinement*, denoted by $P_1 \curlywedge P_2$, as the coarsest partition $P \in Part(X)$ that is finer than both P_1 and P_2. Likewise, define the *finest common coarsening*, denoted by $P_1 \curlyvee P_2$, as the finest partition P that is coarser than both P_1 and P_2. Recall that $(Part(X), \preceq, \curlyvee, \curlywedge)$ is a complete lattice where the top (coarsest) element is $\{X\}$ and the bottom (finest) element is $\{\{x\} \mid x \in X\}$.

3 Automata Constructions from Congruences

We will consider equivalence relations on Σ^* (and their corresponding partitions) with good properties w.r.t. concatenation. An equivalence relation $\sim$ is a *right (resp. left) congruence* iff for all $u, v \in \Sigma^*$, we have that $u \sim v \Rightarrow ua \sim va$, for all $a \in \Sigma$ (resp. $u \sim v \Rightarrow au \sim av$). We will denote right congruences (resp. left congruences) by $\sim^r$ (resp. $\sim^\ell$). The following lemma gives a characterization of right and left congruences.

▶ **Lemma 1.** *The following properties hold:*

1. *$\sim^r$ is a right congruence iff $P_{\sim^r}(v)u \subseteq P_{\sim^r}(vu)$, for all $u, v \in \Sigma^*$.*
2. *$\sim^\ell$ is a left congruence iff $uP_{\sim^\ell}(v) \subseteq P_{\sim^\ell}(uv)$, for all $u, v \in \Sigma^*$.*

Given a right congruence $\sim^r$ and a regular language $L \subseteq \Sigma^*$ such that $P_{\sim^r}$ represents precisely L, i.e., $P_{\sim^r}(L) = L$, the following automata construction recognizes exactly the language L [13].

▶ **Definition 2** (Automata construction $\mathsf{H}^r(\sim^r, L)$)**.** *Let $\sim^r$ be a right congruence and let $P_{\sim^r}$ be the partition induced by $\sim^r$. Let $L \subseteq \Sigma^*$ be a language. Define the automaton $\mathsf{H}^r(\sim^r, L) = (Q, \Sigma, \delta, I, F)$ where $Q = \{P_{\sim^r}(u) \mid u \in \Sigma^*\}$, $I = \{P_{\sim^r}(\varepsilon)\}$, $F = \{P_{\sim^r}(u) \mid u \in L\}$, and $\delta(P_{\sim^r}(u), a) = P_{\sim^r}(v)$ iff $P_{\sim^r}(u)a \subseteq P_{\sim^r}(v)$, for all $u, v \in \Sigma^*$ and $a \in \Sigma$.*

▶ Remark 3. Note that $\mathsf{H}^r(\sim^r, L)$ is *finite* since we assume $\sim^r$ is of finite index. Note also that $\mathsf{H}^r(\sim^r, L)$ is a complete *deterministic* finite-state automaton since, for each $u \in \Sigma^*$ and $a \in \Sigma$, there exists *exactly one* block $P_{\sim^r}(v)$ such that $P_{\sim^r}(u)a \subseteq P_{\sim^r}(v)$, which is $P_{\sim^r}(ua)$. Finally, observe that $\mathsf{H}^r(\sim^r, L)$ possibly contains empty states but no state is unreachable.

▶ **Lemma 4.** *Let $\sim^r$ be a right congruence and let $L \subseteq \Sigma^*$ be a language such that $P_{\sim^r}(L) = L$. Then $\mathcal{L}(\mathsf{H}^r(\sim^r, L)) = L$.*

Due to the left-right duality between $\sim^\ell$ and $\sim^r$, we can give a similar automata construction such that, given a left congruence $\sim^\ell$ and a language $L \subseteq \Sigma^*$ with $P_{\sim^\ell}(L) = L$, recognizes exactly the language L.

▶ **Definition 5** (Automata construction $\mathsf{H}^\ell(\sim^\ell, L)$)**.** *Let $\sim^\ell$ be a left congruence and let $P_{\sim^\ell}$ be the partition induced by $\sim^\ell$. Let $L \subseteq \Sigma^*$ be a language. Define the automaton $\mathsf{H}^\ell(\sim^\ell, L) = (Q, \Sigma, \delta, I, F)$ where $Q = \{P_{\sim^\ell}(u) \mid u \in \Sigma^*\}$, $I = \{P_{\sim^\ell}(u) \mid u \in L\}$, $F = \{P_{\sim^\ell}(\varepsilon)\}$, and $P_{\sim^\ell}(v) \in \delta(P_{\sim^\ell}(u), a)$ iff $aP_{\sim^\ell}(v) \subseteq P_{\sim^\ell}(u)$, for all $u, v \in \Sigma^*$ and $a \in \Sigma$.*

▶ Remark 6. In this case, $\mathsf{H}^\ell(\sim^\ell, L)$ is a co-complete *co-deterministic* finite-state automaton since, for each $v \in \Sigma^*$ and $a \in \Sigma$, there exists *exactly one* block $P_{\sim^\ell}(u)$ such that $aP_{\sim^\ell}(v) \subseteq P_{\sim^\ell}(u)$, which is $P_{\sim^\ell}(av)$. Finally, observe that $\mathsf{H}^\ell(\sim^\ell, L)$ possibly contains unreachable states but no state is empty.

▶ **Lemma 7.** *Let $\sim^\ell$ be a left congruence and let $L \subseteq \Sigma^*$ be a language such that $P_{\sim^\ell}(L) = L$. Then $\mathcal{L}(\mathsf{H}^\ell(\sim^\ell, L)) = L$.*

Lemma 8 shows that H^ℓ and H^r inherit the left-right duality between $\sim^\ell$ and $\sim^r$.

▶ **Lemma 8.** *Let $\sim^r$ and $\sim^\ell$ be a right and left congruence respectively, and let $L \subseteq \Sigma^*$ be a language. If the following property holds*

$$u \sim^r v \Leftrightarrow u^R \sim^\ell v^R \tag{1}$$

then $\mathsf{H}^r(\sim^r, L)$ is isomorphic to $\left(\mathsf{H}^\ell(\sim^\ell, L^R)\right)^R$.

4 Language-based Congruences and their Approximation using NFAs

Given a language $L \subseteq \Sigma^*$, we recall the following equivalence relations on Σ^*, which are often denoted as *Nerode's equivalence relations* (e.g., see [13]).

▶ **Definition 9** (Language-based Equivalences). *Let $u, v \in \Sigma^*$ and let $L \subseteq \Sigma^*$ be a language. Define:*

$$u \sim^r_L v \Leftrightarrow u^{-1}L = v^{-1}L \qquad \text{Right-}\textit{language-based Equivalence} \tag{2}$$

$$u \sim^\ell_L v \Leftrightarrow Lu^{-1} = Lv^{-1} \qquad \text{Left-}\textit{language-based Equivalence} \tag{3}$$

Note that the right and left language-based equivalences defined above are, respectively, right and left *congruences*. Furthermore, when L is a regular language, $\sim^r_L$ and $\sim^\ell_L$ are of *finite index* [6, 13]. Since we are interested in congruences of finite index (or equivalently, finite partitions), we will always assume that L is a regular language over Σ.

The following result states that, given a language L, the right Nerode's equivalence induces the coarsest partition of Σ^* which is a right congruence and precisely represents L.

▶ **Lemma 10** (de Luca and Varricchio [8]). *Let $L \subseteq \Sigma^*$ be a regular language. Then,*

$$P_{\sim^r_L} = \bigvee\{P_{\sim^r} \mid \sim^r \textit{ is a right congruence and } P_{\sim^r}(L) = L\} \ .$$

In a similar way, one can prove that the same property holds for the left Nerode's equivalence. Therefore, as we shall see, applying the construction H to these equivalences yields minimal automata. However, computing them becomes unpractical since languages are possibly infinite, even if they are regular. Thus, we will consider congruences based on the states of the NFA-representation of the language which induce finer partitions of Σ^* than Nerode's equivalences. In this sense, we say that the automata-based equivalences *approximate* Nerode's equivalences.

▶ **Definition 11** (Automata-based Equivalences). *Let $u, v \in \Sigma^*$ and let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an NFA. Define:*

$$u \sim^r_{\mathcal{N}} v \Leftrightarrow \mathrm{post}^{\mathcal{N}}_u(I) = \mathrm{post}^{\mathcal{N}}_v(I) \qquad \text{Right-}\textit{automata-based Equivalence} \tag{4}$$

$$u \sim^\ell_{\mathcal{N}} v \Leftrightarrow \mathrm{pre}^{\mathcal{N}}_u(F) = \mathrm{pre}^{\mathcal{N}}_v(F) \qquad \text{Left-}\textit{automata-based Equivalence} \tag{5}$$

Note that the right and left automata-based equivalences defined above are, respectively, right and left *congruences*. Furthermore, they are of *finite index* since each equivalence class is represented by a subset of states of $\mathcal{N}$.

The following result gives a sufficient and necessary condition for the language-based (Definition 9) and the automata-based equivalences (Definition 11) to coincide.

▶ **Lemma 12.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an automaton with $L = \mathcal{L}(\mathcal{N})$. Then,*

$$\sim^r_L = \sim^r_{\mathcal{N}} \quad \textit{iff} \quad \forall u, v \in \Sigma^*,\ W^{\mathcal{N}}_{\mathrm{post}^{\mathcal{N}}_u(I),F} = W^{\mathcal{N}}_{\mathrm{post}^{\mathcal{N}}_v(I),F} \Leftrightarrow \mathrm{post}^{\mathcal{N}}_u(I) = \mathrm{post}^{\mathcal{N}}_v(I) \ . \tag{6}$$

4.1 Automata Constructions

In what follows, we will use Min and Det to denote the construction H when applied, respectively, to the language-based congruences induced by a regular language and the automata-based congruences induced by an NFA.

▶ **Definition 13.** *Let $\mathcal{N}$ be an NFA generating the language $L = \mathcal{L}(\mathcal{N})$. Define:*

$$\mathsf{Min}^r(L) \stackrel{\text{def}}{=} \mathsf{H}^r(\sim^r_L, L) \qquad \mathsf{Det}^r(\mathcal{N}) \stackrel{\text{def}}{=} \mathsf{H}^r(\sim^r_{\mathcal{N}}, L)$$
$$\mathsf{Min}^\ell(L) \stackrel{\text{def}}{=} \mathsf{H}^\ell(\sim^\ell_L, L) \qquad \mathsf{Det}^\ell(\mathcal{N}) \stackrel{\text{def}}{=} \mathsf{H}^\ell(\sim^\ell_{\mathcal{N}}, L) \ .$$

Given an NFA $\mathcal{N}$ generating the language $L = \mathcal{L}(\mathcal{N})$, all constructions in the above definition yield automata generating L. However, while the constructions using the right congruences result in DFAs, the constructions relying on left congruences result in co-DFAs. Furthermore, since the pairs of relations (2)-(3) and (4)-(5), from Definition 9 and 11 respectively, are dual, i.e., they satisfy the hypothesis of Lemma 8, it follows that $\mathsf{Min}^\ell(L)$ is isomorphic to $(\mathsf{Min}^r(L^R))^R$ and $\mathsf{Det}^\ell(\mathcal{N})$ is isomorphic to $(\mathsf{Det}^r(\mathcal{N}^R))^R$.

On the other hand, since Min^r relies on the language-based congruences, the resulting DFA is minimal, which is not guaranteed to occur with Det^r. This easily follows from the fact that the states of the automata constructions are the equivalence classes of the given congruences and there is no right congruence (representing L precisely) that is coarser than the right Nerode's equivalence (see Lemma 10).

Finally, since every co-deterministic automaton satisfies the right-hand side of Equation (6), it follows that determinizing (Det^r) a co-deterministic automaton ($\mathsf{Det}^\ell(\mathcal{N})$) results in the minimal DFA ($\mathsf{Min}^r(\mathcal{L}(\mathcal{N}))$), as already proved by Sakarovitch [15, Proposition 3.13].

We formalize all these notions in Theorem 14. Finally, Figure 1 summarizes all these well-known connections between the automata constructions given in Definition 13.

▶ **Theorem 14.** *Let $\mathcal{N}$ be an NFA generating language $L = \mathcal{L}(\mathcal{N})$. Then the following properties hold:*

(a) $\mathcal{L}(\mathsf{Min}^r(L)) = \mathcal{L}(\mathsf{Min}^\ell(L)) = L = \mathcal{L}(\mathsf{Det}^r(\mathcal{N})) = \mathcal{L}(\mathsf{Det}^\ell(\mathcal{N}))$.

(b) $\mathsf{Min}^r(L)$ *is isomorphic to the minimal deterministic automaton for L.*

(c) $\mathsf{Det}^r(\mathcal{N})$ *is isomorphic to $\mathcal{N}^D$.*

(d) $\mathsf{Min}^\ell(L)$ *is isomorphic to* $(\mathsf{Min}^r(L^R))^R$.

(e) $\mathsf{Det}^\ell(\mathcal{N})$ *is isomorphic to* $(\mathsf{Det}^r(\mathcal{N}^R))^R$.

(f) $\mathsf{Det}^r(\mathsf{Det}^\ell(\mathcal{N}))$ *is isomorphic to* $\mathsf{Min}^r(L)$.

5 A Congruence-based Perspective on Known Algorithms

We can find in the literature several well-known independent techniques for the construction of minimal DFAs. Some of these techniques are based on refining a state partition of an input DFA, such as Moore's algorithm [14], while others directly manipulate an input NFA, such as the double-reversal method [4]. Now, we establish a connection between these algorithms through Theorem 16, which gives a necessary and sufficient condition on an NFA so that determinizing it yields the minimal DFA.

▶ **Lemma 15.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an NFA with $L = \mathcal{L}(\mathcal{N})$ and $\sim^r_L = \sim^r_{\mathcal{N}}$. Then $\forall q \in Q,\ P_{\sim^r_L}(W^{\mathcal{N}}_{I,q}) = W^{\mathcal{N}}_{I,q}$.*

$$\begin{tikzcd}
\mathcal{N} \arrow[r, "\mathsf{Det}^\ell"] \arrow[rr, bend left, "\mathsf{Min}^r"] \arrow[d, leftrightarrow, "R"'] & \mathsf{Det}^\ell(\mathcal{N}) \arrow[r, "\mathsf{Det}^r"] \arrow[d, leftrightarrow, "R"'] & \mathsf{Det}^r(\mathsf{Det}^\ell(\mathcal{N})) \arrow[d, leftrightarrow, "R"'] \\
\mathcal{N}^R \arrow[r, "\mathsf{Det}^r"] \arrow[rr, bend right, "\mathsf{Min}^\ell"'] & \mathsf{Det}^r(\mathcal{N}^R) \arrow[r, "\mathsf{Det}^\ell"] & \mathsf{Det}^\ell(\mathsf{Det}^r(\mathcal{N}^R))
\end{tikzcd}$$

The upper part of the diagram follows from Theorem 14 (f). Both squares of the diagram follow from Theorem 14 (e), which states that $\mathsf{Det}^\ell(\mathcal{N})$ is isomorphic to $(\mathsf{Det}^r(\mathcal{N}^R))^R$. Finally, the bottom curved arc follows from Theorem 14 (d). Incidentally, the diagram shows a new relation which follows from the left-right dualities between $\sim^\ell_L$ and $\sim^r_L$, and $\sim^\ell_\mathcal{N}$ and $\sim^r_\mathcal{N}$: $\mathsf{Min}^\ell(\mathcal{L}(\mathcal{N}^R))$ is isomorphic to $\mathsf{Det}^\ell(\mathsf{Det}^r(\mathcal{N}^R))$.

Figure 1 Relations between the constructions $\mathsf{Det}^\ell, \mathsf{Det}^r, \mathsf{Min}^\ell$ and Min^r. Note that constructions Min^r and Min^ℓ are applied to the language generated by the automaton in the origin of the labeled arrow, while constructions Det^r and Det^ℓ are applied directly to the automaton.

Proof.

$$\begin{aligned}
P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = \quad & [\text{By definition of } P_{\sim^r_L}] \\
\{w \in \Sigma^* \mid \exists u \in W^\mathcal{N}_{I,q},\ w^{-1}L = u^{-1}L\} = \quad & [\text{Since } \sim^r_L = \sim^r_\mathcal{N}] \\
\{w \in \Sigma^* \mid \exists u \in W^\mathcal{N}_{I,q},\ \mathrm{post}^\mathcal{N}_w(I) = \mathrm{post}^\mathcal{N}_u(I)\} \subseteq \quad & [u \in W^\mathcal{N}_{I,q} \iff q \in \mathrm{post}^\mathcal{N}_u(I)] \\
\{w \in \Sigma^* \mid q \in \mathrm{post}^\mathcal{N}_w(I)\} = \quad & [\text{By definition of } W^\mathcal{N}_{I,q}] \\
W^\mathcal{N}_{I,q} \quad . &
\end{aligned}$$

By reflexivity of $\sim^r_L$, we conclude that $P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = W^\mathcal{N}_{I,q}$. ◀

▶ **Theorem 16.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an NFA with $L = \mathcal{L}(\mathcal{N})$. Then $\mathsf{Det}^r(\mathcal{N})$ is the minimal DFA for L iff $\forall q \in Q,\ P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = W^\mathcal{N}_{I,q}$.*

Proof. Assume $\mathsf{Det}^r(\mathcal{N})$ is minimal. Then $P_{\sim^r_\mathcal{N}}(u) = P_{\sim^r_L}(u)$ for all $u \in \Sigma^*$, i.e. $\sim^r_L = \sim^r_\mathcal{N}$. It follows from Lemma 15 that $P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = W^\mathcal{N}_{I,q}$.

Now, assume that $P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = W^\mathcal{N}_{I,q}$, for each $q \in Q$. Then, for every $u \in \Sigma^*$,

$$P_{\sim^r_\mathcal{N}}(u) = \bigcap_{q \in \mathrm{post}^\mathcal{N}_u(I)} W^\mathcal{N}_{I,q} \cap \bigcap_{q \notin \mathrm{post}^\mathcal{N}_u(I)} (W^\mathcal{N}_{I,q})^c = \bigcap_{q \in \mathrm{post}^\mathcal{N}_u(I)} P_{\sim^r_L}(W^\mathcal{N}_{I,q}) \cap \bigcap_{q \notin \mathrm{post}^\mathcal{N}_u(I)} (P_{\sim^r_L}(W^\mathcal{N}_{I,q}))^c$$

where the first equality follows by rewriting $P_{\sim^r_\mathcal{N}}(u) = \{v \in \Sigma^* \mid \mathrm{post}^\mathcal{N}_u(I) = \mathrm{post}^\mathcal{N}_v(I)\}$ with universal quantifiers, hence intersections, and the last equality follows from the initial assumption $P_{\sim^r_L}(W^\mathcal{N}_{I,q}) = W^\mathcal{N}_{I,q}$.

It follows that $P_{\sim^r_\mathcal{N}}(u)$ is a *union* of blocks of $P_{\sim^r_L}$. Recall that $\sim^r_L$ induces the coarsest right congruence such that $P_{\sim^r_L}(L) = L$ (Lemma 10). Since $\sim^r_\mathcal{N}$ is a right congruence satisfying $P_{\sim^r_\mathcal{N}}(L) = L$ then $P_{\sim^r_\mathcal{N}} \preccurlyeq P_{\sim^r_L}$. Therefore, $P_{\sim^r_\mathcal{N}}(u)$ necessarily corresponds to one single block of $P_{\sim^r_L}$, namely, $P_{\sim^r_L}(u)$. Since $P_{\sim^r_\mathcal{N}}(u) = P_{\sim^r_L}(u)$ for each $u \in \Sigma^*$, we conclude that $\mathsf{Det}^r(\mathcal{N}) = \mathsf{Min}^r(L)$. ◀

5.1 Double-reversal Method

In this section we give a simple proof of the well-known double-reversal minimization algorithm of Brzozowski [4] using Theorem 16. Note that, since $\mathsf{Det}^r(\mathcal{N})$ is isomorphic to $\mathcal{N}^D$ by Theorem 14 (c), the following result coincides with that of Brzozowski.

▶ **Theorem 17** ([4])**.** *Let $\mathcal{N}$ be an NFA. Then $\mathsf{Det}^r((\mathsf{Det}^r(\mathcal{N}^R))^R)$ is isomorphic to the minimal DFA for $\mathcal{L}(\mathcal{N})$.*

Proof. Let $L = \mathcal{L}(\mathcal{N})$. By definition, $\mathcal{N}' = (\mathsf{Det}^r(\mathcal{N}^R))^R$ is a co-DFA and, therefore, satisfies the condition on the right-hand side of Equation (6). It follows from Lemma 12 that $\sim^r_L = \sim^r_{\mathcal{N}'}$ which, by Lemma 15 and Theorem 16, implies that $\mathsf{Det}^r(\mathcal{N}')$ is minimal. ◀

Note that Theorem 17 can be inferred from Figure 1 by following the path starting at $\mathcal{N}$, labeled with $R - \mathsf{Det}^r - R - \mathsf{Det}^r$ and ending in $\mathsf{Min}^r(\mathcal{L}(\mathcal{N}))$.

5.2 Generalization of the Double-reversal Method

Brzozowski and Tamm [5] generalized the double-reversal algorithm by defining a necessary and sufficient condition on an NFA which guarantees that the determinized automaton is minimal. They introduced the notion of *atomic* NFA and showed that $\mathcal{N}^D$ is minimal iff $\mathcal{N}^R$ is atomic. We shall show that this result is equivalent to Theorem 16 due to the left-right duality between the language-based equivalences (Lemma 8).

▶ **Definition 18** (Atom [5])**.** *Let L be a regular language L. Let $\{K_i \mid 0 \leq i \leq n-1\}$ be the set of left quotients of L. An* atom *is any non-empty intersection of the form $\widetilde{K_0} \cap \widetilde{K_1} \cap \ldots \cap \widetilde{K_{n-1}}$, where each $\widetilde{K_i}$ is either K_i or K_i^c.*

This notion of atom coincides with that of equivalence class for the left language-based congruence $\sim^\ell_L$. This was first noticed by Iván [12].

▶ **Lemma 19.** *Let L be a regular language. Then for every $u \in \Sigma^*$,*

$$P_{\sim^\ell_L}(u) = \bigcap_{\substack{u \in w^{-1}L \\ w \in \Sigma^*}} w^{-1}L \;\cap \bigcap_{\substack{u \notin w^{-1}L \\ w \in \Sigma^*}} (w^{-1}L)^c \ .$$

▶ **Definition 20** (Atomic NFA [5])**.** *An NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ is* atomic *iff for every state $q \in Q$, the right language $W^{\mathcal{N}}_{q,F}$ is a union of atoms of $\mathcal{L}(\mathcal{N})$.*

It follows from Lemma 19 that the set of atoms of a language L corresponds to the partition $P_{\sim^\ell_L}$. Therefore, a set $S \subseteq \Sigma^*$ is a union of atoms iff $P_{\sim^\ell_L}(S) = S$. This property, together with Definition 20, shows that an NFA $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ with $L = \mathcal{L}(\mathcal{N})$ is *atomic* iff

$$\forall q \in Q,\; P_{\sim^\ell_L}(W^{\mathcal{N}}_{q,F}) = W^{\mathcal{N}}_{q,F} \ . \tag{7}$$

We are now in condition to give an alternative proof of the generalization of Brzozowski and Tamm [5] relying on Theorem 16.

▶ **Lemma 21.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an NFA with $L = \mathcal{L}(\mathcal{N})$. Then $\mathcal{N}^R$ is atomic iff $\mathsf{Det}^r(\mathcal{N})$ is the minimal DFA for L.*

Proof. Let $\mathcal{N}^R = (Q, \Sigma, \delta_r, F, I)$ and $L^R = \mathcal{L}(\mathcal{N}^R)$. Then,

$$\begin{aligned}
\forall q \in Q,\; P_{\sim^\ell_{L^R}}(W^{\mathcal{N}^R}_{q,I}) = W^{\mathcal{N}^R}_{q,I} &\iff && [\text{By } A = B \Leftrightarrow A^R = B^R] \\
\forall q \in Q,\; \left(P_{\sim^\ell_{L^R}}(W^{\mathcal{N}^R}_{q,I})\right)^R = \left(W^{\mathcal{N}^R}_{q,I}\right)^R &\iff && [\text{By } u \sim^\ell_L v \Leftrightarrow u^R \sim^r_{L^R} v^R] \\
\forall q \in Q,\; P_{\sim^r_L}\left(\left(W^{\mathcal{N}^R}_{q,I}\right)^R\right) = \left(W^{\mathcal{N}^R}_{q,I}\right)^R &\iff && [\text{By } \left(W^{\mathcal{N}^R}_{q,I}\right)^R = W^{\mathcal{N}}_{I,q}] \\
\forall q \in Q,\; P_{\sim^r_L}(W^{\mathcal{N}}_{I,q}) = W^{\mathcal{N}}_{I,q} \ . &&&
\end{aligned}$$

It follows from Theorem 16 that $\mathsf{Det}^r(\mathcal{N})$ is minimal. ◀

We conclude this section by collecting all the conditions described so far that guarantee that determinizing an automaton yields the minimal DFA.

▶ **Corollary 22.** *Let $\mathcal{N} = (Q, \Sigma, \delta, I, F)$ be an NFA with $L = \mathcal{L}(\mathcal{N})$. The following are equivalent:*

(a) $\mathsf{Det}^r(\mathcal{N})$ *is minimal.*

(b) $\sim^r_{\mathcal{N}} = \sim^r_L$.

(c) $\forall u, v \in \Sigma^*,\ W^{\mathcal{N}}_{\mathrm{post}^{\mathcal{N}}_u(I),F} = W^{\mathcal{N}}_{\mathrm{post}^{\mathcal{N}}_v(I),F} \Leftrightarrow \mathrm{post}^{\mathcal{N}}_u(I) = \mathrm{post}^{\mathcal{N}}_v(I)$.

(d) $\forall q \in Q,\ P_{\sim^r_L}(W^{\mathcal{N}}_{I,q}) = W^{\mathcal{N}}_{I,q}$.

(e) $\mathcal{N}^R$ *is atomic.*

5.3 Moore's Algorithm

Given a DFA $\mathcal{D}$, Moore [14] builds the minimal DFA for the language $L = \mathcal{L}(\mathcal{D})$ by removing unreachable states from $\mathcal{D}$ and then performing a stepwise refinement of an initial partition of the set of reachable states of $\mathcal{D}$. Since we are interested in the refinement step, in what follows we assume that all DFAs have no unreachable states. In this section, we will describe Moore's state-partition $\mathcal{Q}^{\mathcal{D}}$ and the right-language-based partition $P_{\sim^r_L}$ as greatest fixpoint computations and show that there exists an isomorphism between the two at each step of the fixpoint computation. In fact, this isomorphism shows that Moore's DFA M satisfies $P_{\sim^r_L}(W^M_{I,q}) = W^M_{I,q}$ for every state q. Thus, by Theorem 16, M is isomorphic to $\mathsf{Min}^r(\mathcal{L}(\mathcal{D}))$.

First, we give Moore's algorithm which computes the state-partition that is later used to define Moore's DFA.

Moore's Algorithm Algorithm for constructing Moore's partition.

```
Data: DFA $\mathcal{D} = \langle Q, \Sigma, \delta, I, F \rangle$ with $L = \mathcal{L}(\mathcal{D})$.
Result: $\mathcal{Q}^{\mathcal{D}} \in Part(Q)$.
$\mathcal{Q}^{\mathcal{D}} := \{F, F^c\}$, $\mathcal{Q}' := \varnothing$;
while $\mathcal{Q}^{\mathcal{D}} \neq \mathcal{Q}'$ do
    $\mathcal{Q}' := \mathcal{Q}^{\mathcal{D}}$;
    forall $a \in \Sigma$ do
        $\mathcal{Q}_a := \curlywedge_{p \in \mathcal{Q}^{\mathcal{D}}} \{\mathrm{pre}^{\mathcal{D}}_a(p), (\mathrm{pre}^{\mathcal{D}}_a(p))^c\}$;
    $\mathcal{Q}^{\mathcal{D}} := \mathcal{Q}^{\mathcal{D}} \curlywedge \curlywedge_{a \in \Sigma} \mathcal{Q}_a$;
return $\mathcal{Q}^{\mathcal{D}}$;
```

▶ **Definition 23** (Moore's DFA)**.** *Let $\mathcal{D} = (Q, \Sigma, \delta, I, F)$ be a DFA, and let $\mathcal{Q}^{\mathcal{D}}$ be the partition of Q built by using Moore's algorithm.* Moore's DFA *for $\mathcal{L}(\mathcal{D})$ is $M = (Q^M, \Sigma, \delta^M, I^M, F^M)$ where $Q^M = \mathcal{Q}^{\mathcal{D}}$, $I^M = \{\mathcal{Q}^{\mathcal{D}}(q) \mid q \in I\}$, $F^M = \{\mathcal{Q}^{\mathcal{D}}(q) \mid q \in F\}$ and, for each $S, S' \in Q^M$ and $a \in \Sigma$, we have that $\delta^M(S, a) = S'$ iff $\exists q \in S, q' \in S'$ with $\delta(q, a) = q'$.*

Next, we describe Moore's state-partition $\mathcal{Q}^{\mathcal{D}}$ and the right-language-based partition $P_{\sim^r_L}$ as greatest fixpoint computations and show that there exists an isomorphism between the two at each step of the fixpoint computation.

▶ **Definition 24** (Moore's state-partition)**.** *Let $\mathcal{D} = (Q, \Sigma, \delta, I, F)$ be a DFA. Define* Moore's state-partition w.r.t. *$\mathcal{D}$, denoted by $\mathcal{Q}^{\mathcal{D}}$, as follows.*

$$\mathcal{Q}^{\mathcal{D}} \stackrel{\mathrm{def}}{=} \mathrm{gfp}(\lambda X. \curlywedge_{a \in \Sigma, S \in X} \{\mathrm{pre}_a(S), (\mathrm{pre}_a(S))^c\} \curlywedge \{F, F^c\}) \ .$$

On the other hand, by Theorem 14 (b), each state of the minimal DFA for L corresponds to an equivalence class of $\sim^r_L$. These equivalence classes can be defined in terms of non-empty intersections of complemented or uncomplemented right quotients of L.

▶ **Lemma 25.** *Let L be a regular language. Then, for every $u \in \Sigma^*$,*

$$P_{\sim^r_L}(u) = \bigcap_{\substack{u \in Lw^{-1} \\ w \in \Sigma^*}} Lw^{-1} \cap \bigcap_{\substack{u \notin Lw^{-1} \\ w \in \Sigma^*}} (Lw^{-1})^c \ .$$

It follows from Lemma 25 that $P_{\sim^r_L} = \curlywedge_{w \in \Sigma^*} \{Lw^{-1}, (Lw^{-1})^c\}$, for every regular language L . Thus, $P_{\sim^r_L}$ can also be obtained as a greatest fixpoint computation as follows.

▶ **Lemma 26.** *Let L be a regular language. Then*

$$P_{\sim^r_L} = \mathrm{gfp}(\lambda X. \bigcurlywedge_{a \in \Sigma, B \in X} \{Ba^{-1}, (Ba^{-1})^c\} \curlywedge \{L, L^c\}) \ . \tag{8}$$

The following result shows that, given a DFA $\mathcal{D}$ with $L = \mathcal{L}(\mathcal{D})$, there exists a partition isomorphism between $\mathcal{Q}^{\mathcal{D}}$ and $P_{\sim^r_L}$ at each step of the fixpoint computations given in Definition 24 and Lemma 26 respectively.

▶ **Theorem 27.** *Let $\mathcal{D} = (Q, \Sigma, \delta, I, F)$ be a DFA with $L = \mathcal{L}(\mathcal{D})$ and let $\varphi : \wp(Q) \to \wp(\Sigma^*)$ be a function defined by $\varphi(S) \overset{\text{def}}{=} W^{\mathcal{D}}_{I,S}$. Let $\mathcal{Q}^{\mathcal{D}(n)}$ and $P^{(n)}_{\sim^r_L}$ be the n-th step of the fixpoint computation of $\mathcal{Q}^{\mathcal{D}}$ (Definition 24) and $P_{\sim^r_L}$ (Lemma 26), respectively. Then, φ is an isomorphism between $\mathcal{Q}^{\mathcal{D}(n)}$ and $P^{(n)}_{\sim^r_L}$ for each $n \geq 0$.*

Proof. In order to show that φ is a partition isomorphism, it suffices to prove that φ is a bijective mapping between the partitions. We first show that $\varphi(\mathcal{Q}^{\mathcal{D}(n)}) = P^{(n)}_{\sim^r_L}$, for every $n \geq 0$. Thus, the mapping φ is surjective. Secondly, we show that φ is an injective mapping from $\mathcal{Q}^{\mathcal{D}(n)}$ to $P^{(n)}_{\sim^r_L}$. Therefore, we conclude that φ is a bijection.

To show that $\varphi(\mathcal{Q}^{\mathcal{D}(n)}) = P^{(n)}_{\sim^r_L}$, for each $n \geq 0$, we proceed by induction.

- *Base case:* By definition, $\mathcal{Q}^{\mathcal{D}(0)} = \{F, F^c\}$ and $P^{(0)}_{\sim^r_L} = \{L, L^c\}$. Since $\mathcal{D}$ is deterministic (and complete), it follows that $\varphi(F) = W^{\mathcal{D}}_{I,F} = L$ and $\varphi(F^c) = W^{\mathcal{D}}_{I,F^c} = L^c$.
- *Inductive step:* Before proceeding with the inductive step, we show that the following equations hold for each $a, b \in \Sigma$ and $S, S_i, S_j \in \mathcal{Q}^{\mathcal{D}(n)}$ with $n \geq 0$:

$$\varphi(\mathrm{pre}_a(S)^c) = ((W^{\mathcal{D}}_{I,S})a^{-1})^c \tag{9}$$

$$\varphi(\mathrm{pre}_a(S_i) \cap \mathrm{pre}_b(S_j)) = (W^{\mathcal{D}}_{I,S_i})a^{-1} \cap (W^{\mathcal{D}}_{I,S_j})b^{-1} \ . \tag{10}$$

For each $S \in \mathcal{Q}^{\mathcal{D}(n)}$ and $a \in \Sigma$ we have that:

$$\begin{aligned}
\varphi(\mathrm{pre}_a(S)^c) = {} & \quad [\text{By definition of } \varphi] \\
W^{\mathcal{D}}_{I,\mathrm{pre}_a(S)^c} = {} & \quad [I = \{q_0\} \text{ and def. of } W^{\mathcal{D}}_{I,\mathrm{pre}_a(S)^c}] \\
\{w \in \Sigma^* \mid \exists q \in \mathrm{pre}_a(S)^c,\ q = \hat{\delta}(q_0, w)\} = {} & \quad [\mathcal{D} \text{ is deterministic and complete}] \\
\{w \in \Sigma^* \mid \exists q \in \mathrm{pre}_a(S),\ q = \hat{\delta}(q_0, w)\}^c = {} & \quad [\text{By definition of } \mathrm{pre}_a(S)] \\
\{w \in \Sigma^* \mid \exists q \in S,\ q = \hat{\delta}(q_0, wa)\}^c = {} & \quad [\text{By definition of } (W^{\mathcal{D}}_{I,S})a^{-1}] \\
((W^{\mathcal{D}}_{I,S})a^{-1})^c \ . &
\end{aligned}$$

Therefore Equation (9) holds at each step of the fixpoint computation. Consider now Equation (10). Let $S_i, S_j \in \mathcal{Q}^{\mathcal{D}(n)}$. Then,

$$
\begin{aligned}
\varphi(\mathrm{pre}_a(S_i) \cap \mathrm{pre}_b(S_j)) = \quad & [\text{By Def. } \varphi] \\
W^{\mathcal{D}}_{I,(\mathrm{pre}_a(S_i)\cap\mathrm{pre}_b(S_j))} = \quad & [I = \{q_0\} \text{ and def. } W_{I,S}] \\
\{w \in \Sigma^* \mid \exists q \in \mathrm{pre}_a(S_i) \cap \mathrm{pre}_b(S_j), q = \hat{\delta}(q_0, w)\} = \quad & [\text{By Def. of } \cap] \\
\{w \in \Sigma^* \mid \exists q \in \mathrm{pre}_a(S_i),\ q \in \mathrm{pre}_b(S_j), q = \hat{\delta}(q_0, w)\} = \quad & [\mathcal{D} \text{ is deterministic}] \\
W^{\mathcal{D}}_{I,\mathrm{pre}_a(S_i)} \cap W^{\mathcal{D}}_{I,\mathrm{pre}_b(S_j)} = \quad & [\text{By Def. of } (W^{\mathcal{D}}_{I,S})a^{-1}] \\
(W^{\mathcal{D}}_{I,S_i})a^{-1} \cap (W_{I,S_j})b^{-1} \quad . &
\end{aligned}
$$

Therefore Equation (10) holds at each step of the fixpoint computation.
Let us assume that $\varphi\left(\mathcal{Q}^{\mathcal{D}(n)}\right) = P^{(n)}_{\sim^r_L}$ for every $n \leq k$ with $k > 0$. Then,

$$
\begin{aligned}
\varphi\big(\mathcal{Q}^{\mathcal{D}(k+1)}\big) = & \ [\text{By Def. 24 with } X = \mathcal{Q}^{\mathcal{D}(k)}] \\
\varphi\Big(\bigcurlywedge_{a\in\Sigma, S\in X} \{\mathrm{pre}_a(S), \mathrm{pre}_a(S)^c\} \curlywedge \{F, F^c\}\Big) = & \ [\text{By Eqs. (9), (10) and def. of } \bigcurlywedge] \\
\bigcurlywedge_{\substack{a\in\Sigma \\ \varphi(S)\in\varphi(X)}} \{(W^{\mathcal{D}}_{I,S})a^{-1}, ((W^{\mathcal{D}}_{I,S})a^{-1})^c\} \curlywedge \{L, L^c\} = & \ [\text{By induction hypothesis, } \varphi(X) = P^{(k)}_{\sim^r_L}] \\
\bigcurlywedge_{a\in\Sigma, B\in X'} \{Ba^{-1}, (Ba^{-1})^c\} \curlywedge \{L, L^c\} = & \ [\text{By Lemma 26 with } X' = P^{(k)}_{\sim^r_L}] \\
P^{(k+1)}_{\sim^r_L} \quad . &
\end{aligned}
$$

Finally, since $\mathcal{D}$ is a DFA then, for each $S_i, S_j \in \mathcal{Q}^{\mathcal{D}(n)} (n \geq 0)$ with $S_i \neq S_j$ we have that $W^{\mathcal{D}}_{I,S_i} \neq W^{\mathcal{D}}_{I,S_j}$, i.e., $\varphi(S_i) \neq \varphi(S_j)$. Therefore, φ is an injective mapping. ◀

▶ **Corollary 28.** *Let $\mathcal{D}$ be a DFA with $L = \mathcal{L}(\mathcal{D})$. Let $\mathcal{Q}^{\mathcal{D}(n)}$ and $P^{(n)}_{\sim^r_L}$ be the n-th step of the fixpoint computation of $\mathcal{Q}^{\mathcal{D}}$ and $P_{\sim^r_L}$ respectively. Then, for each $n \geq 0$,*

$$P^{(n)}_{\sim^r_L}(W^{\mathcal{D}}_{I,S}) = W^{\mathcal{D}}_{I,S} \ \ , \textit{ for each } S \in \mathcal{Q}^{\mathcal{D}(n)} \ \ .$$

It follows that Moore's DFA M, whose set of states corresponds to the state-partition at the end of the execution of Moore's algorithm, satisfies that $\forall q \in Q^M$, $P_{\sim^r_L}(W^M_{I,q}) = W^M_{I,q}$ with $L = \mathcal{L}(M)$. By Theorem 16, we have that $\mathsf{Det}^r(M)(= M$, since M is a DFA) is minimal.

▶ **Theorem 29.** *Let $\mathcal{D}$ be a DFA and M be Moore's DFA for $\mathcal{L}(\mathcal{D})$ as in Definition 23. Then, M is isomorphic to $\mathsf{Min}^r(\mathcal{L}(\mathcal{D}))$.*

Finally, recall that Hopcroft [10] defined a DFA minimization algorithm which offers better performance than Moore's. The ideas used by Hopcroft can be adapted to our framework to devise a new algorithm for computing $P_{\sim^r_L}$. However, by doing so, we could not derive a better explanation than the one provided by Berstel et al. [2].

6 Related Work and Conclusions

Brzozowski and Tamm [5] showed that every regular language defines a unique NFA, which they call *átomaton*. The átomaton is built upon the minimal DFA $\mathcal{N}^{DM}$ for the language, defining its states as non-empty intersections of complemented or uncomplemented right languages of $\mathcal{N}^{DM}$, i.e., the atoms of the language. They also observed that the atoms correspond to intersections of complemented or uncomplemented left quotients of the language. Then they proved that the átomaton is isomorphic to the reverse automaton of the minimal deterministic DFA for the reverse language.

Intuitively, the construction of the átomaton based on the right languages of the minimal DFA corresponds to $\mathsf{Det}^{\ell}(\mathcal{N}^{DM})$, while its construction based on left quotients of the language corresponds to $\mathsf{Min}^{\ell}(\mathcal{L}(\mathcal{N}))$.

▶ **Corollary 30.** *Let $\mathcal{N}^{DM}$ be the minimal DFA for a regular language L. Then,*
(a) $\mathsf{Det}^{\ell}(\mathcal{N}^{DM})$ *is isomorphic to the átomaton of L.*
(b) $\mathsf{Min}^{\ell}(L)$ *is isomorphic to the átomaton of L.*

In the same paper, they also defined the notion of *partial átomaton* which is built upon an NFA $\mathcal{N}$. Each state of the partial atomaton is a non-empty intersection of complemented or uncomplemented right languages of $\mathcal{N}$, i.e., union of atoms of the language. Intuitively, the construction of the partial átomaton corresponds to $\mathsf{Det}^{\ell}(\mathcal{N})$.

▶ **Corollary 31.** *Let $\mathcal{N}$ be an NFA. Then,* $\mathsf{Det}^{\ell}(\mathcal{N})$ *is isomorphic to the partial átomaton of $\mathcal{N}$.*

Finally, they also presented a number of results [5, Theorem 3] related to the átomaton $\mathcal{A}$ of a minimal DFA $\mathcal{D}$ with $L = \mathcal{L}(\mathcal{D})$:

1. $\mathcal{A}$ is isomorphic to $\mathcal{D}^{RDR}$.
2. $\mathcal{A}^{R}$ is the minimal DFA for L^{R}
3. $\mathcal{A}^{D}$ is the minimal DFA for L.
4. $\mathcal{A}$ is isomorphic to $\mathcal{N}^{RDMR}$ for every NFA $\mathcal{N}$ accepting L.

All these relations can be inferred from Figure 2 which connects all the automata constructions described in this paper together with the constructions introduced by Brzozowski and Tamm. For instance, property 1 corresponds to the path starting at $\mathcal{N}^{DM}$ (the minimal DFA for $\mathcal{L}(\mathcal{N})$), labeled with $R - \mathsf{Det}^{r} - R$, and ending in the átomaton of $\mathcal{L}(\mathcal{N})$. On the other hand, property 4 corresponds to the path starting at $\mathcal{N}$, labeled with $R - \mathsf{Min}^{r} - R$ and ending in the átomaton of $\mathcal{L}(\mathcal{N})$. Finally, the path starting at $\mathcal{N}$, labeled with $R - \mathsf{Det}^{r} - R$ and ending in the partial átomaton of $\mathcal{N}$ shows that the later is isomorphic to $\mathcal{N}^{RDR}$.

In conclusion, we establish a connection between well-known independent minimization methods through Theorem 16. Given a DFA, the left languages of its states form a partition on words, P, and thus, each left language is identified by a state. Intuitively, Moore's algorithm merges states to enforce the condition of Theorem 16, which results in merging blocks of P that belong to the same Nerode's equivalence class. Note that Hopcroft's partition refinement method [10] achieves the same goal at the end of its execution though, stepwise, the partition computed may differ from Moore's. On the other hand, any co-deterministic NFA satisfies the right-hand side of Equation (6) hence, by Lemma 15, satisfies the condition of Theorem 16. Therefore, the double-reversal method, which essentially determinizes a co-determinized NFA, yields the minimal DFA. Finally, the left-right duality (Lemma 8) of the language-based equivalences shows that the condition of Theorem 16 is equivalent to that of Brzozowski and Tamm [5].

Some of these connections have already been studied in order to offer a better understanding of Brzozowski's double-reversal method [1, 3, 7, 16]. In particular, Adámek et al. [1] and Bonchi et al. [3] offer an alternative view of minimization and determinization methods in a uniform way from a category-theoretical perspective. In contrast, our work revisits these well-known minimization techniques relying on simple language-theoretical notions.

Abstract

Can we efficiently compute optimal solutions to instances of a hard problem from optimal solutions to neighboring (i.e., locally modified) instances? For example, can we efficiently compute an optimal coloring for a graph from optimal colorings for all one-edge-deleted subgraphs? Studying such questions not only gives detailed insight into the structure of the problem itself, but also into the complexity of related problems; most notably graph theory's core notion of critical graphs (e.g., graphs whose chromatic number decreases under deletion of an arbitrary edge) and the complexity-theoretic notion of minimality problems (also called criticality problems, e.g., recognizing graphs that become 3-colorable when an arbitrary edge is deleted).

We focus on two prototypical graph problems, Colorability and Vertex Cover. For example, we show that it is NP-hard to compute an optimal coloring for a graph from optimal colorings for *all* its one-vertex-deleted subgraphs, and that this remains true even when optimal solutions for *all* one-edge-deleted subgraphs are given. In contrast, computing an optimal coloring from all (or even just two) one-edge-added supergraphs is in P. We observe that Vertex Cover exhibits a remarkably different behavior, demonstrating the power of our model to delineate problems from each other more precisely on a structural level.

Moreover, we provide a number of new complexity results for minimality and criticality problems. For example, we prove that Minimal-3-UnColorability is complete for DP (differences of NP sets), which was previously known only for the more amenable case of deleting vertices rather than edges. For Vertex Cover, we show that recognizing β-vertex-critical graphs is complete for Θ_2^{p} (parallel access to NP), obtaining the first completeness result for a criticality problem for this class.

1 Introduction and Related Work

In Subsection 1.1, we introduce and motivate our new model, which we then compare and contrast to related notions in Subsection 1.2. Finally, we present in Subsection 1.3 an overview of our most interesting results and place them into the context of the wider literature.

1.1 Our Model

In view of the almost complete absence of progress in the question of P versus NP, it is natural to wonder just how far and in what way these sets may differ. For example, how much additional information enables us to design an algorithm that solves an otherwise NP-hard problem in polynomial time? We are specifically interested in the case where this additional information takes the form of optimal solutions to neighboring (i.e., locally modified) instances. This models situations such as that of a newcomer who may ask experienced peers for advice on how to solve a difficult problem, for instance finding an optimal work route. Similar circumstances arise when new servers join a computer network. Formally, we consider the following oracle model: An algorithm may, on any given input, repeatedly select an arbitrary instance neighboring the given one and query the oracle for an optimal solution to it. Occasionally, it will be interesting to limit the number of queries that we grant the algorithm. In general, we do not impose such a restriction, however.

What precisely constitutes a local modification and thus a neighbor depends on the specific problem, of course. We examine the prototypical graph problems Colorability and Vertex Cover, considering the following four local modifications, which are arguably the most natural choices: deleting an edge, adding an edge, deleting a vertex (including adjacent edges), and adding a vertex (including an arbitrary, possibly empty, set of edges from the added vertex to the existing ones). For example, we ask whether there is a polynomial-time algorithm that computes a minimum vertex cover for an input graph G if it has access to minimum vertex covers for all one-edge-deleted subgraphs of G. We will show that questions of this sort are closely connected to and yet clearly distinct from research in other areas, in particular the study of critical graphs, minimality problems, self-reducibility, and reoptimization.

1.2 Related Concepts

Criticality. The notion of criticality was introduced into the field of graph theory by Dirac [7] in 1952 in the context of Colorability with respect to vertex deletion. Thirty years later, Wessel [19] generalized the concept to arbitrary graph properties and modification operations. Nevertheless, Colorability has remained a central focus of the extensive research on critical graphs. Indeed, a graph G is called *critical* without any further specification if it is χ-critical under edge deletion, that is, if its chromatic number $\chi(G)$ (the number of colors used in an optimal coloring of G) changes when an arbitrary edge is deleted. Besides Colorability, one other problem has received a comparable amount of attention and thorough analysis in three different manifestations: Independent Set, Vertex Cover, and Clique. The corresponding notions are α-criticality, β-criticality, and ω-criticality, where α is the *independence number* (size of a maximum independent set), β is the *vertex cover number* (size of a minimum vertex cover), and ω is the *clique number* (size of a maximum clique). Note that these graph numbers are all monotone – either nondecreasing or nonincreasing – with respect to each of the local modifications examined in this paper.

Minimality. Another strongly related notion is that of minimality problems. An instance is called *minimal* with respect to a property if only the instance itself but none of its neighbors has this property; that is, it inevitably loses the property under the considered local modification. The corresponding minimality problem is to decide whether an instance is minimal in the described sense. For example, a graph G is minimally 3-uncolorable (with respect to edge deletion) if it is not 3-colorable, yet all its one-edge-deleted neighbors are. The minimality problem MINIMAL-3-UNCOLORABILITY is the set of all minimally 3-uncolorable graphs. Note that a graph is critical exactly if it is minimally k-uncolorable for some k.

While minimality problems tend to be in DP (i.e., differences of two NP sets, the second level of the Boolean hierarchy), DP-hardness is so difficult to prove for them that only a few have been shown to be DP-complete so far; see for instance Papadimitriou and Wolfe [14]. Note that the notion of minimality is not restricted to graph problems. Indeed, minimally unsatisfiable formulas figure prominently in many of our proofs.

Auto-Reducibility. Our model provides a refinement of the notion of functional auto-reducibility; see Faliszewski and Ogihara [8]. An algorithm solves a function problem $R \subseteq \Sigma_1^* \times \Sigma_2^*$ if on input $x \in \Sigma_1^*$ it outputs some $y \in \Sigma_2^*$ with $(x, y) \in R$. The problem R is *auto-reducible* if there is a polynomial-time algorithm with unrestricted access to an oracle that provides solutions to all instances except x itself. The task of finding an optimal solution to a given instance is a special kind of function problem. Defining all instances to be neighbors (local modifications) of each other lets the two concepts coincide.

Self-Reducibility. Self-reducibility is auto-reducibility with the additional restriction that the algorithm may query the oracle only on instances that are smaller in a certain way. There are a multitude of definitions of self-reducibility that differ in what exactly is considered to be "smaller," the two seminal ones stemming from Schnorr [15] and from Meyer and Paterson [13]. For Schnorr, an instance is smaller than another one if its encoding input string is strictly shorter. While his definition does allow for functional problems (i.e., more than mere decision problems, in particular the problem of finding an optimal solution), it is too restrictive for self-reducibility to encompass our model since not all neighboring graphs have shorter strings under natural encodings.

Meyer and Paterson are less rigid and allow instead any partial order having short downward chains to determine which instances are considered smaller than the given one.[1] The partial orders induced by deleting vertices, by deleting edges, and by adding edges all have short downward chains. The definition by Meyer and Paterson is thus sufficient for our model to become part of functional self-reducibility for all local modifications considered in this paper but one, namely, the case of adding a vertex, which is too generous a modification to display any particularly interesting behavior.

As an example, consider the graph decision problem COLORABILITY $= \{(G, k) \mid \chi(G) \leq k\}$, which is self-reducible by the following observation. Any graph G with at least two vertices that is not a clique is k-colorable exactly if at least one of the polynomially many graphs that result from merging two non-adjacent vertices in G is k-colorable. This works for the optimization variant of the problem as well. Any optimal coloring of G assigns at

[1] Formally, a partial order is said to *have short downward chains* if the following condition is satisfied: There is a polynomial p such that every chain decreasing with respect to the considered partial order and starting with some string x is shorter than $p(|x|)$ and such that all strings preceding x in that order are bounded in length by $p(|x|)$.

least two vertices the same color, except in the trivial case of G being a clique. An optimal coloring for the graph that has two such vertices merged then yields an optimal coloring for G. This contrasts well with the findings for Colorability's behavior under our new model discussed below.

Reoptimization. Reoptimization examines optimization problems under a model that is tightly connected to ours. The notion of reoptimization was coined by Schäffter [16] and first applied by Archetti et al. [1]. The reoptimization model sets the following task for an optimization problem:

> *Given an instance, an optimal solution to it, and a local modification of this instance, compute an optimal solution to the modified instance.*

The proximity to our model becomes clearer after a change of perspective. We reformulate the reoptimization task by reversing the roles of the given and the modified instance.

> *Given an instance, a local modification of it, and an optimal solution to the modified instance, compute an optimal solution to the original instance.*

Note that this perspective switch flips the definition of local modification; for example, edge deletion turns into edge addition. Aside from this, the task now reads almost identical to that demanded in our model. The sole but crucial difference is that in reoptimization, the neighboring instance and the optimal solution to it are given as part of the input, whereas in our model, the algorithm may select any number of neighboring instances and query the oracle for optimal solutions to them. Even if we limit the number of queries to just one, our model is still more generous since the algorithm is choosing (instead of being given) the neighboring instance to which the oracle will supply an optimal solution. Thus, hardness in our model always implies hardness for reoptimization, but not vice versa. In fact, all problems examined under the reoptimization model so far remain NP-hard. Only for some of them could an improvement of the approximation ratio be achieved after extensive studies, the first discovered examples being TSP under edge-weight changes [4] and addition or deletion of vertices [2]. This stands in stark contrast to the results for our model, as outlined in the next section.

1.3 Results

We shed a new light on two of the most prominent and well-examined graph problems, Colorability and Vertex Cover. Our results come in two different types.

The first type concerns the hardness of the two problems in our model for the most common local modifications; Table 1 summarizes the main results of this type. In addition, Corollaries 2 and 14 show that Satisfiability and Vertex Cover remain NP-hard for any number of queries if the local modification is the deletion of a clause or a triangle, respectively. The results for the vertex-addition columns are trivial since we can just query an optimal solution for the graph with an added isolated vertex; see Theorem 16 in Appendix A [3]. The hardness results for the one-query case all follow from the same simple Theorem 17, variations of which appear in the study of self-reducibility and many other fields; see Appendix B [3]. The findings of Theorems 10, 12, and 19 in Appendix F [3] clearly delineate our model from that in reoptimization, where the NP-hard problems examined in the literature remain NP-hard despite the significant amount of advice in form of the provided optimal solution; see Böckenhauer et al. [5].

Table 1 An overview of our results regarding the hardness of Colorability and Vertex Cover in our model for the most common definitions of a local modification. The v stands for a vertex and the e stands for an edge. The question mark indicates an interesting open problem. The results in the vertex-addition columns are trivial; see Theorem 16 in Appendix A [3]. The NP-hardness results for the 1-query case all follow from rather simple Turing reductions; see Theorem 17 in Appendix B [3].

No. of Queries	Colorability				Vertex Cover			
	Add v	Delete v	Add e	Delete e	Add v	Delete v	Add e	Delete e
1	P	NP-hard	NP-hard	NP-hard	P	NP-hard	NP-hard	NP-hard
2 or more	P [Thm. 16]	NP-hard [Thm. 4]	P [Thm. 10]	NP-hard [Thm. 6]	P [Thm. 16]	P [Thm. 12]	P [Thm. 19]	?

The results of the second type locate criticality problems in relation to the complexity classes DP and Θ_2^{p}. The class Θ_2^{p} was introduced by Wagner [17] and represents the languages that can be decided in polynomial time by an algorithm that has access to an NP oracle under the restriction that all queries are submitted at the same time. The definitions of the classes immediately yield the inclusions $\mathrm{NP} \cup \mathrm{coNP} \subseteq \mathrm{DP} \subseteq \Theta_2^{\mathrm{p}}$.

Papadimitriou and Wolfe [14] have shown that Minimal-UnSat (the set of unsatisfiable formulas that become satisfiable when an arbitrary clause is deleted) is DP-complete. Cai and Meyer [6] built upon this to prove DP-completeness of VertexMinimal-k-UnColorability (the set of graphs that are not k-colorable but become k-colorable when an arbitrary vertex is deleted), for all $k \geq 3$. With Theorems 7 and 8, we were able to extend this result to classes that are analogously defined for the much smaller local modification of edge deletion, which is considered the default setting; namely, we prove DP-completeness of Minimal-k-UnColorability, for all $k \geq 3$.

In Theorem 9, we show that recognizing criticality and vertex-criticality are in Θ_2^{p} and DP-hard. As Joret [12] points out, a construction by Papadimitriou and Wolfe [14] proves the DP-hardness of recognizing β-critical graphs. This problem also lies in Θ_2^{p}, but no finer classification has been achieved so far. In Theorem 15, we show that this problem is in fact Θ_2^{p}-hard, yielding the first known Θ_2^{p}-completeness result for a criticality problem.

2 Preprocessing 3-Sat

Our main technique for proving the nontrivial hardness results in our model is the following: We build in polynomial-time computable solutions for each locally modified problem instance. That way, the solutions to the locally modified problem instances do not give away any information about the instance to be solved. A similar approach is taken in some proofs of DP-completeness for minimality problems. Indeed, we can occasionally combine the proof of DP-hardness with that of the NP-hardness of computing an optimal solution from optimal solutions to locally modified instances. Denote by 3-CNF the set of nonempty CNF-formulas with exactly three distinct literals per clause.[2] We begin by showing in Theorem 1 that there is a reduction from 3-Sat (the set of satisfiable 3-CNF-formulas) to 3-Sat that builds in polynomial-time computable solutions for all one-clause-deleted subformulas of the resulting 3-CNF-formula. At first glance, this very surprising result may seem dangerously close to

[2] This set is often denoted E3-CNF in the literature.

proving P = NP; Corollary 2 will make explicit where the hardness remains. We will then use the reduction of Theorem 1 as a preprocessing step in reductions from 3-Sat to other problems.

▶ **Theorem 1.** *There is a polynomial-time many-one reduction f from* 3-Sat *to* 3-Sat *and a polynomial-time computable function s such that, for every* 3-CNF*-formula Φ and for every clause C in $f(\Phi)$, $s(f(\Phi) - C)$ is a satisfying assignment for $f(\Phi) - C$.*

Proof. Papadimitriou and Wolfe [14, Lemma 1] give a reduction from 3-UnSat to Minimal-UnSat (the set of CNF-formulas that are unsatisfiable but that become satisfiable with the removal of an arbitrary clause). In Appendix C [3], we show how to enhance this reduction such that it has all properties of our theorem. First, we carefully prove that there is a function s that together with the original reduction satisfies all properties of our theorem, except that we may output a formula that is not in 3-CNF. In order to rectify this, we show that the standard reduction from Sat to Sat that decreases the number of literals per clause to at most three maintains all the required properties. The same is then shown for the standard reduction that transforms CNF-formulas with at most three literals per clause into 3-CNF-formulas that have exactly three distinct literals per clause. Combining these three reductions, we can therefore satisfy all requirements of our theorem. ◀

▶ **Corollary 2.** *Computing a satisfying assignment for a* 3-CNF*-formula whose one-clause-deleted subformulas all have a satisfying assignment from these assignments is* NP*-hard.*

Proof. Given a 3-CNF-formula Φ, compute $f(\Phi)$, where f is the reduction from Theorem 1. Now compute $s(f(\Phi) - C)$ for every clause C in $f(\Phi)$ and compute a satisfying assignment for $f(\Phi)$ from these solutions. Use this assignment to determine whether Φ is satisfiable. ◀

3 Colorability

As mentioned in the previous section, the constructions of some DP-completeness results for minimality problems can be adapted to obtain NP-hardness for computing optimal solutions from optimal solutions to locally modified instances. There are remarkably few complexity results for minimality problems; fortunately, however, VertexMinimal-3-UnColorability (the graphs that are not 3-colorable but that are 3-colorable after deleting any vertex)[3] is DP-complete by reduction from Minimal-3-UnSat [6]. We will show how to extract from said reduction a proof of the fact that computing an optimal coloring for a graph from optimal colorings for its one-vertex-deleted subgraphs is NP-hard (Theorem 4). However, the standard notion of criticality is χ-criticality under edge deletion, and the construction by Cai and Meyer [6] does unfortunately not yield the analogous result for deleting edges. This was to be expected, since working with edge deletion is much harder. Surprisingly, however, a targeted modification of the constructed graph allows us to establish, through a far more elaborate case distinction, that computing an optimal coloring for a graph from optimal colorings for its one-edge-deleted subgraphs is NP-hard (Theorem 6) as well as that the related minimality problem Minimal-3-UnColorability is DP-complete (Theorem 7).

[3] It should be noted that VertexMinimal-3-UnColorability is denoted by Minimal-3-UnColorability by Cai and Meyer [6] despite the fact that minimality problems usually refer to the case of edge deletion.

▶ **Lemma 3.** *There is a polynomial-time many-one reduction g from* 3-Sat *to* 3-Colorability *and a polynomial-time computable function* opt *such that, for every* 3-CNF*-formula* Φ *and for every vertex v in $g(\Phi)$,* $\text{opt}(g(\Phi) - v)$ *is an optimal coloring for $g(\Phi) - v$.*

Proof. Given a 3-CNF-formula Φ, let $g(\Phi) = h(f(\Phi))$, where f is the reduction from Theorem 1 and h is the reduction from Minimal-3-UnSat to VertexMinimal-3-UnColorability by Cai and Meyer [6]. Since h also reduces 3-Sat to 3-Colorability [6, Lemma 2.2], so does g. A careful inspection of the reduction g reveals that there is a polynomial-time computable function opt such that, for every vertex v in $g(\Phi)$, $\text{opt}(g(\Phi) - v)$ is a 3-coloring of $g(\Phi) - v$. We can also verify that $g(\Phi) - v$ does not have a 2-coloring, hence $\text{opt}(g(\Phi) - v)$ is an optimal coloring. We do not dive into the details as this lemma immediately follows from the proof of the analogous result for edge deletion (Lemma 5), as explained in Appendix D [3]. ◀

▶ **Theorem 4.** *Computing an optimal coloring for a graph from optimal colorings for its one-vertex-deleted subgraphs is* NP*-hard.*

Proof. Given a 3-CNF-formula Φ, compute $g(\Phi)$, where g is the reduction from Lemma 3, compute $\text{opt}(g(\Phi) - v)$ for every vertex v in $g(\Phi)$, and from these optimal solutions compute one for $g(\Phi)$. This determines whether $g(\Phi)$ is 3-colorable and thus whether Φ is satisfiable. ◀

▶ **Lemma 5.** *There is a polynomial-time many-one reduction g from* 3-Sat *to* 3-Colorability *and a polynomial-time computable function* opt *such that, for every* 3-CNF*-formula* Φ *and for every edge e in $g(\Phi)$,* $\text{opt}(g(\Phi) - e)$ *is an optimal coloring of $g(\Phi) - e$.*

Proof. Given a 3-CNF-formula Φ, let $g(\Phi) = h(f(\Phi)) - e$, where f is the reduction from Theorem 1, h is the reduction to VertexMinimal-3-UnColorability by Cai and Meyer [6], and e is the edge $\{v_c, v_s\}$, with v_c being the unique vertex adjacent to all variable-setting vertices and v_s being the only remaining neighbor vertex of v_c. We prove in detail that g has all the desired properties in Appendix D [3]. See Figure 1 in Appendix D [3] for an example of the construction. ◀

▶ **Theorem 6.** *Computing an optimal coloring for a graph from optimal colorings for its one-edge-deleted subgraphs is* NP*-hard.*

Proof. The same argument as for Theorem 4 can be applied here. ◀

▶ **Theorem 7.** Minimal-3-UnColorability *is* DP*-complete.*

Proof. Membership in DP is immediate, since given a graph $G = (V, E)$, determining whether $G - e$ is 3-colorable for every $e \in E$ is in NP and so is determining whether G is 3-colorable. As for DP-hardness, the argument from the proof of Lemma 5 shows that mapping Φ to $h(\Phi) - \{v_c, v_s\}$, where h is the reduction from Minimal-3-UnSat to VertexMinimal-3-UnColorability by Cai and Meyer [6], gives a reduction from Minimal-3-UnSat to Minimal-3-UnColorability (and to VertexMinimal-3-UnColorability as well). Recall that Minimal-3-UnSat is DP-hard [14]. ◀

Cai and Meyer [6] show DP-completeness for VertexMinimal-k-UnColorability, for all $k \geq 3$. We now prove that the analogous result for deletion of edges holds as well.

▶ **Theorem 8.** Minimal-k-UnColorability *is* DP*-complete, for every $k \geq 3$.*

Proof. Membership in DP is again immediate. To show hardness for $k \geq 4$, we reduce Minimal-3-UnColorability to Minimal-k-UnColorability. We use the construction for deleting vertices [6, Theorem 3.1] and map graph G to $G + K_{k-3}$.[4] Note that $\chi(K_{k-3}) = k-3$ and $\chi(H + H') = \chi(H) + \chi(H')$ for any two graphs H and H'. First suppose $G + K_{k-3}$ is in Minimal-k-UnColorability. Then $G + K_{k-3}$ is not k-colorable, and so G is not 3-colorable. Let e be an edge in G. Then $(G - e) + K_{k-3} = (G + K_{k-3}) - e$ is k-colorable, and thus $G - e$ is 3-colorable. It follows that G is in Minimal-3-UnColorability.

Now suppose G is in Minimal-3-UnColorability. Then $G + K_{k-3}$ is not k-colorable. Let e be an edge in $G + K_{k-3}$. If e is an edge in G, then $G - e$ is 3-colorable and so $(G + K_{k-3}) - e = (G - e) + K_{k-3}$ is k-colorable. If e is an edge in K_{k-3}, then $K_{k-3} - e$ is $(k-4)$-colorable and G is 4-colorable (let $\hat{e}$ be any edge in G, take a 3-coloring of $G - \hat{e}$, and change the color of one of the vertices incident to $\hat{e}$ to the remaining color), so $(G + K_{k-3}) - e = G + (K_{k-3} - e)$ is k-colorable. Finally, if $e = \{v, w\}$ for a vertex v in G and a vertex w in K_{k-3}, let $\hat{e}$ be an edge in G incident to v, take a 3-coloring of $G - \hat{e}$, take a disjoint $(k-3)$-coloring of K_{k-3}, and change the color of v to the color of w. As a result, for all edges e in $G + K_{k-3}$, $(G + K_{k-3}) - e$ is k-colorable. It follows that $G + K_{k-3}$ is in Minimal-k-UnColorability. ◀

The construction above does not prove the analogues of Lemmas 3 and 5: Note that G is 3-colorable if and only if $(G + K_{k-3}) - v$ and $(G + K_{k-3}) - e$ are both $(k-1)$-colorable for every vertex v in K_{k-3} and for every edge e in K_{k-3}, and so we can certainly determine whether a graph is 3-colorable from the optimal solutions to the one-vertex-deleted subgraphs and one-edge-deleted subgraphs of $G + K_{k-3}$ in polynomial time. Turning to criticality and vertex-criticality, we can bound their complexity as follows.

▶ **Theorem 9.** *The two problems of determining whether a graph is critical and whether it is vertex-critical are both in* Θ_2^{p} *and* DP*-hard.*

Proof. For the Θ_2^{p}-membership of the two problems, we observe that the relevant chromatic numbers of a graph $G = (V, E)$ and its neighbors can be computed by querying the NP oracle Colorability $= \{(G, k) \mid \chi(G) \leq k\}$ for every (G, k), $(G - e, k)$, and $(G - v, k)$ for every $e \in E$, $v \in V$, and $k \leq \|V(G)\|$ in parallel.

For the DP-hardness of the two problems, we prove that $h(\Phi) - \{v_{\mathrm{c}}, v_{\mathrm{s}}\}$ is a reduction from Minimal-3-UnSat to both of them. We have already seen that it reduces Minimal-3-UnSat to Minimal-3-UnColorability. Hence, for every $\Phi \in$ Minimal-3-UnSat, the graph $h(\Phi) - \{v_{\mathrm{c}}, v_{\mathrm{s}}\}$ is in Minimal-3-UnColorability $\subseteq$ VertexMinimal-3-UnColorability and thus both critical and vertex-critical. For the converse it suffices to note that, for every $\Phi \in$ CNF with clauses of size at most 3, $h(\Phi) - \{v_{\mathrm{c}}, v_{\mathrm{s}}\}$ is 4-colorable and thus in Minimal-3-UnColorability (in VertexMinimal-3-UnColorability, respectively) if and only if it is critical (vertex-critical, respectively). ◀

The exact complexity of these problems remains open, however. In particular, it is unknown whether they are Θ_2^{p}-hard. This contrasts with the case of Vertex Cover, for which we prove in Theorem 15 that recognizing β-vertex-criticality is indeed Θ_2^{p}-complete.

Before that, however, we return to our model and consider Colorability under the local modification of adding an edge. If we allow only one query, the problem stays NP-hard via a simple Turing reduction: Iteratively adding edges to the given instance eventually leads to

[4] For two graphs G_1 and G_2, the *graph join* $G_1 + G_2$ is the disjoint union $G_1 \cup G_2$ plus a *join edge* added from every vertex of G_1 to every vertex of G_2; see, e.g., Harary's textbook on graph theory [10, p. 21].

a clique as a trivial instance, see Theorem 17 in Appendix B [3]. Note that the restriction to one query is crucial for this reduction to work; without it, the branching may lead to an exponential blowup in the number of instances that need to be considered. The following theorem shows that this breakdown of the hardness proof is inevitable unless P = NP since the problem becomes in fact polynomial-time solvable if just one more oracle call is granted.

▶ **Theorem 10.** *There is a polynomial-time algorithm that computes an optimal coloring for a graph from optimal colorings of all its one-edge-added supergraphs; in fact, two optimal colorings, one for each of two specific one-edge-added supergraphs, suffice.*

For the proof of this theorem, we naturally extend the notion of universal vertices as follows.

▶ **Definition 11.** *An edge $\{u, v\} \in E$ of a graph $G = (V, E)$ is called* universal *if, for every vertex $x \in V - \{u, v\}$, we have $\{x, u\} \in E$ or $\{x, v\} \in E$. A graph is called* universal-edged *if all its edges are universal.*

Additionally, we denote, for any given graph $G = (V, E)$ and any vertex $x \in V$, the *open neighborhood* of x in G by $N(x) \coloneqq \{y \mid \{x, y\} \in E\}$ and the *closed neighborhood* of x in G by $N[x] \coloneqq N(x) \cup \{x\}$. We are now ready to give the proof of Theorem 10.

Proof of Theorem 10. We show that COLORER (Algorithm 1), which uses the oracle of our model and SUBCOL (Algorithm 2) as subroutines, has the desired properties.

Algorithm 1 COLORER.

Input: An undirected graph $G = (V, E)$.
Output: An optimal coloring for G.
Description: Optimizes universal-edged graphs with two queries to ORACLE, which provides optimal solutions to one-edge-added supergraphs; other graphs are optimized via SUBCOL.

```
 1: for every edge $\{u, v\} \in E$ do
 2:     for every vertex $x \in V - \{u, v\}$ do
 3:         if $\{u, x\} \notin E \wedge \{v, x\} \notin E$ then
 4:             $f_1 \leftarrow$ ORACLE($G \cup \{u, x\}$)
 5:             $f_2 \leftarrow$ ORACLE($G \cup \{v, x\}$)
 6:             if $f_1$ uses fewer colors on $G$ than $f_2$ then
 7:                 return $f_1$
 8:             else
 9:                 return $f_2$
10: $k \leftarrow 1$
11: while SUBCOL($G, k$) = NO do
12:     $k \leftarrow k + 1$
13: return SUBCOL($G, k$)
```

We begin by proving that COLORER is correct. Assume first that the input graph $G = (V, E)$ is not universal-edged. Then COLORER can find an edge $\{u, v\} \in E$ with a non-neighboring vertex $x \in V$ and query the oracle on $G \cup \{u, x\}$ and $G \cup \{v, x\}$ for optimal colorings f_1 and f_2. We argue that at least one of them is also optimal for G. Let f be any optimal coloring of G. Since u and v are connected by an edge, we have $f(u) \neq f(v)$ and hence $f(x) \neq f(u)$ or $f(x) \neq f(v)$; see Figure 2in Appendix E [3]. Thus, f is also an optimal coloring of $G \cup \{x, u\}$ or $G \cup \{x, v\}$, and so we have $\chi(G) = \chi(G \cup \{x, u\})$ or $\chi(G) = \chi(G \cup \{x, v\})$. Therefore, f_1 or f_2 is an optimal coloring for G as well and returned on line 7 or 9, respectively.

Algorithm 2 SUBCOL.

Input: An undirected, universal-edged graph $G = (V, E)$ and a positive integer k.
Output: A k-coloring f for G if there is one; NO if there is none.
Description: Works by recursion on k, with $k = 1$ and $k = 2$ serving as the base cases.

```
 1: if $G$ has no edge then
 2:     return the constant 1-coloring with $f(x) = 1$ for all $x \in V$.
 3: else if $k = 1$ then
 4:     return NO.
 5: if $G$ has bipartition $\{A, B\}$ then
 6:     return the 2-coloring $f(x) = \begin{cases} 1 & \text{for } x \in A \text{ and} \\ 2 & \text{for } x \in B. \end{cases}$
 7: else if k=2 then
 8:     return NO.
 9: Choose an arbitrary edge $\{\ell, r\} \in E$.
10: $L \leftarrow N(\ell) - N[r]$;   $R \leftarrow N(r) - N[\ell]$;   $M \leftarrow N(\ell) \cap N(r)$
11: $g \leftarrow \textsc{Subcol}(G[M], k - 2)$
12: if $g =$ NO then
13:     return NO
14: return the $k$-coloring $f(x) = \begin{cases} g(x) & \text{for } x \in M, \\ k - 1 & \text{for } x \in L \cup \{r\}, \text{ and} \\ k & \text{for } x \in R \cup \{\ell\}. \end{cases}$
```

The while loop can be entered only if the graph G is universal-edged. This allows us to compute an optimal solution to G with no queries at all by using SUBCOL (Algorithm 2). We will show that SUBCOL is a polynomial-time algorithm that computes, for any universal-edged graph G and any positive integer k, a k-coloring of G if there is one, and outputs NO otherwise. The while loop of COLORER thus searches the smallest integer k such that G has a k-coloring, that is, $k = \chi(G)$. Hence, an optimal coloring of G is returned on line 13. Due to $k = \chi(G) \leq \|V\|$, COLORER has polynomial time complexity.

It remains to prove the correctness and polynomial time complexity of SUBCOL. This can be done by bounding its recursion depth and verifying the correctness for each of the six return statements; this is hardest for the last two. The proof relies on the properties of the partition $M \cup L \cup R \cup \{\ell\} \cup \{r\}$ as illustrated in Figure 3 in Appendix E [3]; see Appendix E [3] for all details. ◀

In this section, we have proven that MINIMAL-k-UNCOLORABILITY is complete for DP for every $k \geq 3$ and demonstrated that Colorability remains NP-hard in our model for deletion of vertices or edges, whereas it becomes polynomial-time solvable when the local modification is the addition of an edge. In the next section, we turn our attention to Vertex Cover.

4 Vertex Cover

This section will show that the behavior of Vertex Cover in our model is distinctly different from the one that we demonstrated for Colorability in the previous section. In particular, Theorem 12 proves that computing an optimal vertex cover from optimal solutions of one-vertex-deleted subgraphs can be done in polynomial time, which is impossible for optimal colorings according to Theorem 4 unless P = NP.

First, we note that the NP-hardness proof for our most restricted case with only one query still works (i.e., Theorem 17 in Appendix B [3] is applicable): Deleting vertices, adding edges, or deleting edges repeatedly will always lead to the null graph, an edgeless graph, or a clique through polynomially many instances. As we have seen for Colorability in the previous section, hardness proofs of this type may fail due to exponential branching as soon as multiple queries are allowed. We can show that, unless P = NP, this is necessarily the case for edge addition and vertex deletion since two granted queries suffice to obtain a polynomial-time algorithm.

▶ **Theorem 12.** *There is a polynomial-time algorithm that computes an optimal vertex cover for a graph from two optimal vertex covers for some one-vertex-deleted subgraphs.*

Proof. Observe what can happen when a vertex v is removed from a graph G with an optimal vertex cover of size k. If v is part of any optimal vertex cover of G, then the size of an optimal vertex cover for $G-v$ is $k-1$. Given any graph G, pick any two adjacent vertices v_1 and v_2. Since there is an edge between them, one of them is always part of an optimal vertex cover, thus either $G-v_1$ or $G-v_2$ or both will have an optimal vertex cover of size $k-1$. Two queries to the oracle return optimal vertex covers for $G-v_1$ and $G-v_2$. The algorithm chooses the smaller of these two covers (or any, if they are the same size) and adds the corresponding v_i. The resulting vertex cover has size k and is thus optimal for G. ◀

Theorem 19 in Appendix F [3] proves that the analogous result for adding an edge holds as well.

At this point, we would like to prove either an analogue to Theorem 6, showing that computing an optimal vertex cover is NP-hard even if we get access to a solution for every one-edge-deleted subgraph, or an analogue to Theorem 19 in Appendix F [3], showing that the problem is in P if we have access to a solution for more than one one-edge-deleted subgraph. We were unable to prove either, however. The latter is easy to do for many restricted graph classes (e.g., graphs with bridges), yet we suspect that the problem is NP-hard in general. We will detail a few reasons for the apparent difficulty of proving this statement after the following theorem and corollary, which look at deleting a triangle as the local modification.

▶ **Theorem 13.** *There is a reduction g from* 3-SAT *to* VERTEXCOVER *such that, for every* 3-CNF*-formula Φ and for every triangle T in $g(\Phi)$, there is a polynomial-time computable optimal vertex cover of $g(\Phi)-T$.*

The proof of Theorem 13 relies on the standard reduction from 3-SAT to VERTEXCOVER; see [9], where clauses correspond to triangles; see Appendix G [3] for the details. Applying the same argument as in the proof of Theorem 4 yields the following corollary.

▶ **Corollary 14.** *Computing an optimal vertex cover for a graph from optimal vertex covers for the one-triangle-deleted subgraphs is* NP*-hard.*

What can we say about optimal vertex covers for one-edge-deleted graphs? Papadimitriou and Wolfe show [14, Theorem 4] that there is a reduction g from MINIMAL-3-UNSAT to MINIMAL-k-NOVERTEXCOVER (called CRITICAL-VERTEXCOVER in [14]; asking, given a graph G and an integer k, whether G does not have a vertex cover of size k but all one-edge-deleted subgraphs do). The reduction builds in a polynomial-time computable vertex cover of size k for every one-edge-deleted subgraph. And so g is a reduction from 3-SAT to VERTEXCOVER such that there exists a polynomial-time computable function opt such that for every 3-CNF-formula Φ and $g(\Phi)=(G,k)$, it holds, for every edge e in G, that

$\text{opt}(G-e)$ is a vertex cover of size k. Unfortunately, it may happen that an optimal vertex cover of $G-e$ has size $k-1$; namely, if e is an edge connecting two triangles, an edge between two variable-setting vertices, or any edge of the clause triangles. The function opt does thus not give us an optimal vertex cover, thwarting the proof attempt. This shows that we cannot always get results for our model from the constructions for criticality problems.

The following would be one approach to design a polynomial-time algorithm that computes an optimal vertex cover from optimal vertex covers for all one-edge-deleted subgraphs: It is clear that deleting an edge does not increase the size of an optimal vertex cover and decreases it by at most one. If, for any two neighbor graphs, the provided vertex covers differ in size, then we can take the smaller one, restore the deleted edge, and add any one of the two incident vertices to the vertex cover; this gives us the desired optimal vertex cover. If the optimal vertex cover size decreases for all deletions of a single edge, we can do the same with any of them. Thus, it is sufficient to design a polynomial-time algorithm that solves the problem on graphs whose one-edge-deleted subgraphs all have optimal vertex covers of the same size as an optimal vertex cover of the original graph. One might suspect that only very few and simple graphs can be of this kind. However, we obtain infinitely many such graphs by the removal of any edge from different cliques, as already mentioned in the introduction. In fact, there is a far larger class of graphs with this property and no apparent communality to be exploited for the efficient construction of an optimal vertex cover.

We now turn to our complexity results of β-(vertex-)criticality. The reduction from MINIMAL-3-UNSAT to MINIMAL-k-NOVERTEXCOVER by Papadimitriou and Wolfe [14] establishes the DP-hardness of deciding whether a graph is β-critical. However, it seems unlikely that β-criticality is in DP. The obvious upper bound is Θ_2^{p}, since a polynomial number of queries to a VERTEXCOVER oracle, namely (G,k) and $(G-e,k)$ for all edges e in G and all $k \leq \|V(G)\|$, in parallel allows us to determine $\beta(G)$ and $\beta(G-e)$ for all edges e in polynomial time, and thus allows us to determine whether G is β-critical. While we have not succeeded in proving a matching lower bound, or even any lower bound beyond DP-hardness, we do get this lower bound for β-vertex-criticality, thereby obtaining the first Θ_2^{p}-completeness result for a criticality problem.

▶ **Theorem 15.** *Determining whether a graph is β-vertex-critical is Θ_2^{p}-complete.*

Proof. Membership follows with the same argument as above, this time querying the oracle VERTEXCOVER in parallel for all (G,k) and $(G-v,k)$ for all vertices v in G and all $k \leq \|V(G)\|$. To show that this problem is Θ_2^{p}-hard, we use a similar reduction as the one by Hemaspaandra et al. [11, Lemma 4.12] to prove that it is Θ_2^{p}-hard to determine whether a given vertex is a member of a minimum vertex cover. We reduce from the Θ_2^{p}-complete problem $\text{VC}_= = \{(G,H) \mid \beta(G) = \beta(H)\}$ [18]. Let $n = \max(\|V(G)\|, \|V(H)\|)$, let G' consist of $n+1-\|V(G)\|$ isolated vertices, let H' consist of $n+1-\|V(H)\|$ isolated vertices, and let $F = (G \cup G') + (H \cup H')$. Note that $\beta(F) = (n+1) + \min(\beta(G), \beta(H))$. If $\beta(G) = \beta(H)$, then $\beta(F) = (n+1) + \beta(G) = (n+1) + \beta(H)$ and for every vertex v in F, $\beta(F-v) = n + \beta(G)$. Thus, F is critical. If $\beta(G) \neq \beta(H)$, assume without loss of generality that $\beta(G) < \beta(H)$. Then $\beta(F) = n+1+\beta(G)$. Let v be a vertex in G'. Then $\beta(F-v) = \min(n+1+\beta(G), n+\beta(H)) = n+1+\beta(G)$, and therefore F is not critical. ◀

5 Conclusion and Future Research

We defined a natural model that provides new insights into the structural properties of NP-hard problems. Specifically, we revealed interesting differences in the behavior of Colorability and Vertex Cover under different types of local modifications. While Colorability remains

NP-hard when the local modification is the deletion of either a vertex or an edge, there is an algorithm that finds an optimal coloring by querying the oracle on at most two edge-added supergraphs. Vertex Cover, in contrast, becomes easy in our model for both deleting vertices and adding edges, as soon as two queries are granted. The question of what happens for the local modification of deleting an edge remains as an intriguing open problem that defies any simple approach, as briefly outlined above. Moreover, examples of problems where one can prove a jump from membership in P to NP-hardness at a given number of queries greater than 2 might be especially instructive.

With its close connections to many distinct research areas, most notably the study of self-reducibility and critical graphs, our model can serve as a tool for new discoveries. In particular, we were able to exploit the tight relations to criticality in the proof that recognizing β-vertex-critical graphs is Θ_2^{P}-hard, yielding the first completeness result for Θ_2^{P} in the field.

Abstract

In this paper, we study the problem of deciding if there is a transformation between two given minimum Steiner trees of an unweighted graph such that each transformation step respects a prescribed reconfiguration rule and results in another minimum Steiner tree of the graph. We consider two reconfiguration rules, both of which exchange a single vertex at a time, and generalize the known reconfiguration problem for shortest paths in an unweighted graph. This generalization implies that our problems under both reconfiguration rules are PSPACE-complete for bipartite graphs. We thus study the problems with respect to graph classes, and give some boundaries between the polynomial-time solvable and PSPACE-complete cases.

1 Introduction

Recently, *combinatorial reconfiguration* [7] has been extensively studied in the field of theoretical computer science. In combinatorial reconfiguration, we are given two feasible solutions of a combinatorial search problem, and are asked to determine whether we can transform one into the other by repeatedly applying a specified reconfiguration rule so that all intermediate results are also feasible. Such problems are called *reconfiguration problems* and have been studied intensively for several combinatorial search problems. (See, e.g., surveys [6, 11].) For example, the SHORTEST PATH RECONFIGURATION problem (SPR, for short) is defined as follows [1, 2, 8, 13]: We are given two shortest paths between two vertices s and t in an unweighted graph, and are asked to determine whether or not we can transform one into the other by exchanging a single vertex in a shortest path at a time so that all intermediate results remain shortest paths between s and t. The problem is known to be

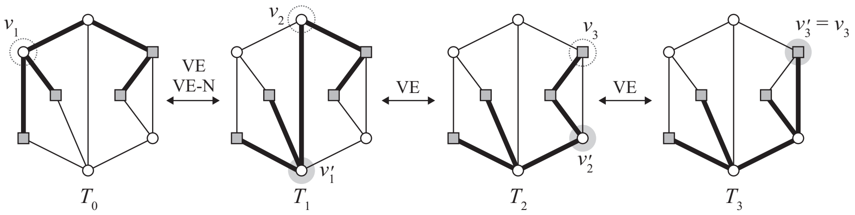

Figure 1 A sequence of minimum Steiner trees, where the terminals are depicted by gray squares, non-terminals by white circles, the edges in Steiner trees by thick lines.

PSPACE-complete [1, 13], and solvable in polynomial time for several graph classes [1, 2, 13]. Interestingly, the polynomial-time solvable cases include planar graphs [2], although many reconfiguration problems remain PSPACE-complete for planar graphs.

In this paper, we introduce and study reconfiguration problems for minimum Steiner trees in a graph, as generalizations of SPR.

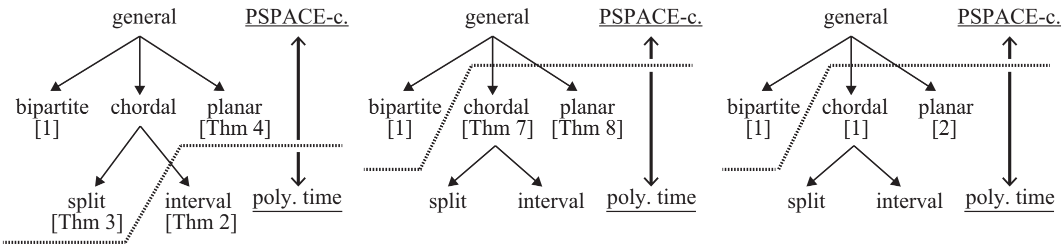
1.1 Our problems

For an unweighted graph G and a vertex subset $S \subseteq V(G)$, called a *terminal set*, a *Steiner tree* of G for S is a subtree of G which contains all vertices in S. A Steiner tree of G for S is *minimum* if it has the minimum number of edges among all Steiner trees of G for S. For example, Figure 1 illustrates four minimum Steiner trees of the same graph G for the same terminal set S. Note that minimum Steiner trees can be seen as a generalization of shortest paths, because any shortest path in G between two vertices s and t forms a minimum Steiner tree of G for $S = \{s, t\}$. We use the terms *node* for Steiner trees and *vertex* for input graphs.

In this paper, we introduce following two reconfiguration rules, which define slightly different adjacency relations on minimum Steiner trees of a graph G for a terminal set S. Both rules exchange a single node v in a minimum Steiner tree T for a single vertex in G (possibly v itself) so that it results in another minimum Steiner tree T' of G for S. (Formal definitions will be given in Section 2.)

- **Vertex Exchange** (VE, for short):
  We say that two minimum Steiner trees T and T' of G for S are *adjacent under* VE if there exist two vertices $v \in V(T)$ and $v' \in V(T')$ such that their removal results in the common subgraph of T and T'. For example, any two consecutive minimum Steiner trees in Figure 1 are adjacent under VE. It should be noted that v and v' can be the same vertex; in such a case, only edges incident to $v = v'$ may be changed between T and T'. (See T_2 and T_3 in Figure 1 as an example.)
- **Vertex Exchange without changing Neighbors** (VE-N, for short):
  We say that two minimum Steiner trees T and T' of G for S are *adjacent under* VE-N if there exist two vertices $v \in V(T)$ and $v' \in V(T')$ such that (a) their removal results in the common subgraph of T and T', and (b) the neighborhood of v in T is equal to that of v' in T'. In Figure 1, only two Steiner trees T_0 and T_1 are adjacent under VE-N. It can hold also under this rule that $v = v'$, but then $T = T'$ holds.

We now define our problems. Given two minimum Steiner trees T_0 and T_r of a graph G for a terminal set S, *the* Minimum Steiner Tree Reconfiguration *problem* (MSTR, for short) *under* VE (resp., VE-N) asks to determine whether or not we can transform one into the other via adjacent minimum Steiner trees under VE (resp., VE-N). For example, when we



(a) MSTR under VE (b) MSTR under VE-N (c) SPR (MSTR with $|S| = 2$)

Figure 2 Our results for MSTR and some known results for SPR, where each arrow between graph classes represents their inclusion relationship: $A \to B$ represents that the graph class B is properly included in the graph class A.

are given two minimum Steiner trees T_0 and T_3 in Figure 1, the answer is yes under VE as illustrated in the figure; while it is a no-instance under VE-N. We note that if $|S| = 2$, then any minimum Steiner tree for S forms a shortest path between the two terminals, and both the rules VE and VE-N are equivalent to the reconfiguration rule of SPR. Therefore, MSTR under both rules VE and VE-N are generalizations of SPR.

1.2 Known and related work

There are several reconfiguration problems for subtrees in an unweighted graph [1, 2, 4, 8, 10, 12, 13]. However, to the best of our knowledge, there is no direct relationship between our problems and these known problems, except for the following two reconfiguration problems.

It is known that SPR is PSPACE-complete even for bipartite graphs [1], and for bounded bandwidth (and hence bounded pathwidth) graphs [13]. Since MSTR under VE and VE-N are generalizations of SPR, they are also PSPACE-complete for bipartite graphs and for bounded bandwidth graphs. As positive results, there are polynomial-time algorithms to solve SPR for planar graphs [2], for chordal graphs [1], and for claw-free graphs [1]. (Figure 2(c) shows a part of these results.)

There is another reconfiguration problem for Steiner trees [10], but it is not a generalization of SPR; its reconfiguration rule is exchanging edges (not vertices). As we have seen in the example of Figure 1, the existence of a transformation often changes according to the choice of reconfiguration rules. However, we will show in Section 3 that some known results for this edge-variant [10] can be converted to our MSTR under VE.

1.3 Our contribution

In this paper, we study the computational complexity of MSTR under VE and VE-N with respect to graph classes. (Figure 2 shows all our results for MSTR.)

We first show that MSTR under VE is solvable in polynomial time for interval graphs, while is PSPACE-complete even for split graphs and for planar graphs. Recall that SPR is solvable in polynomial time for planar graphs and for chordal graphs (and hence split graphs). We next show that MSTR under VE-N is solvable in polynomial time for chordal graphs and for planar graphs; these results generalize the known results for SPR [1, 2].

Notice that there are interesting contrasts between the reconfiguration rules VE and VE-N when we focus on planar graphs, chordal graphs, and split graphs: MSTR is PSPACE-complete under VE, while is solvable in polynomial time under VE-N.

We omit proofs for the claims marked with (∗) from this extended abstract.

2 Preliminaries

In this paper, we consider only simple and unweighted graphs. For a graph G, we denote by $V(G)$ and $E(G)$ the vertex set and the edge set of G, respectively. For a graph G and its vertex subset $S \subseteq V(G)$, we denote by $G[S]$ the subgraph of G induced by S. For a vertex $v \in V(G)$, let $N_G(v)$ be the set of all neighbors of v in G, that is, $N_G(v) = \{w \in V(G) \mid vw \in E(G)\}$.

We now formally define our reconfiguration rules. Let T and T' be two minimum Steiner trees of a graph G for a terminal set S. Then, T and T' are *adjacent under* VE if there exist two vertices $v \in V(T)$ and $v' \in V(T')$ such that

- $T[V(T) \setminus \{v\}] = T'[V(T') \setminus \{v'\}]$.

Recall that v and v' can be the same vertex; in such a case, only edges incident to $v = v'$ may be changed between T and T'. On the other hand, T and T' are *adjacent under* VE-N if there exist two vertices $v \in V(T)$ and $v' \in V(T')$ such that

- $T[V(T) \setminus \{v\}] = T'[V(T') \setminus \{v'\}]$; and
- $N_T(v) = N_{T'}(v')$.

Note that the first condition for VE-N is the same as the condition for VE. It can hold also under VE-N that $v = v'$, but then $T = T'$ holds.

For two minimum Steiner trees T and T', a *reconfiguration sequence* between T and T' under VE (resp., VE-N) is a sequence $\langle T = T_0, T_1, \ldots, T_\ell = T' \rangle$ of minimum Steiner trees such that T_i and T_{i+1} are adjacent under VE (resp., VE-N) for each $i \in \{0, 1, \ldots, \ell - 1\}$. We write $T \overset{\mathsf{VE}}{\leftrightsquigarrow} T'$ (resp., $T \overset{\mathsf{VE\text{-}N}}{\leftrightsquigarrow} T'$) if there exists a reconfiguration sequence between T and T' under VE (resp., VE-N). Then, we formally define the Minimum Steiner Tree Reconfiguration problem (MSTR, for short) under VE (resp., VE-N) as follows:

MSTR under VE (resp., VE-N)
Input: A graph G, a terminal set $S \subseteq V(G)$, and two minimum Steiner trees T_0 and T_r of G for S.
Task: Determine whether $T_0 \overset{\mathsf{VE}}{\leftrightsquigarrow} T_\mathrm{r}$ (resp., $T_0 \overset{\mathsf{VE\text{-}N}}{\leftrightsquigarrow} T_\mathrm{r}$) or not.

We denote by a 4-tuple $(G, S, T_0, T_\mathrm{r})$ an instance of the problems. Throughout the paper, we assume without loss of generality that $|V(T_0)| = |V(T_\mathrm{r})|$ holds; otherwise it is clearly a no-instance.

3 Minimum Steiner Tree Reconfiguration under VE

In this section, we show that MSTR under VE is solvable in polynomial time for interval graphs, while it is PSPACE-complete for split graphs and for planar graphs. To this end, we use the concept of "Steiner sets" and their reconfiguration, which was introduced by [10].

3.1 Steiner sets and their reconfiguration

For a graph G and a terminal set S, a *Steiner set* of G for S is a vertex subset $F \subseteq V(G)$ such that $S \subseteq F$ and $G[F]$ is connected. Notice that if a subtree T of G is a Steiner tree for S, then $V(T)$ is a Steiner set of G for S. Conversely, if F is a Steiner set of G for S, then any spanning tree of $G[F]$ is a Steiner tree for S. A Steiner set F of G for S is *minimum* if the cardinality of F is minimum among all Steiner sets of G for S.

For two Steiner sets F and F' of G for S, a sequence $\langle F = F_0, F_1, \ldots, F_\ell = F' \rangle$ of Steiner sets of G for S is called a *Steiner set sequence* between F and F' if $|F_i \setminus F_{i+1}| = |F_{i+1} \setminus F_i| = 1$ holds for each $i \in \{0, 1, \ldots, \ell - 1\}$. Note that all Steiner sets in the sequence have the same cardinality. The following lemma shows that, in some sense, we do not need to care the tree structure property (but need to care only a connectivity) when we want to check the existence of a reconfiguration sequence under VE.

▶ **Lemma 1** (∗). *Let T and T' be Steiner trees of a graph G for a terminal set S. Then, $T \overset{\mathsf{VE}}{\leftrightsquigarrow} T'$ holds if and only if there exists a Steiner set sequence between two Steiner sets $V(T)$ and $V(T')$ of G for S.*

The concept of Steiner sets was introduced for the reconfiguration of Steiner trees via edge exchanges [10]. Lemma 1 allows us to convert two known results for this edge-exchange variant [10] to our MSTR under VE.

We first consider interval graphs. A graph G with $V(G) = \{v_1, v_2, \dots, v_n\}$ is an *interval graph* if there exists a set $\mathcal{I}$ of (closed) intervals $I_1, I_2, \dots, I_n$ such that $v_i v_j \in E(G)$ if and only if $I_i \cap I_j \neq \emptyset$ for each $i, j \in \{1, 2, \dots, n\}$. For a given graph G, it can be determined in linear time whether G is an interval graph or not [9].

▶ **Theorem 2.** *Let $(G, S, T_0, T_\mathrm{r})$ be a given instance of* MSTR *under* VE *such that G is an interval graph. Then, $T_0 \overset{\mathsf{VE}}{\leftrightsquigarrow} T_\mathrm{r}$ holds.*

Proof. It is known that if a given graph is an interval graph, then there always exists a Steiner set sequence between any pair of Steiner sets of the same cardinality [10]. Thus, the theorem follows from Lemma 1. ◀

We then consider split graphs. A graph is a *split graph* if its vertex set can be partitioned into a clique and an independent set. The following theorem can be obtained by a polynomial-time reduction which is similar to that for Theorem 3 of [10].

▶ **Theorem 3** (∗). MSTR *under* VE *is PSPACE-complete for split graphs.*

3.2 PSPACE-completeness for planar graphs

In this subsection, we consider planar graphs, and give the following theorem.

▶ **Theorem 4.** MSTR *under* VE *is PSPACE-complete for planar graphs.*

We note that MSTR under VE is in PSPACE. Therefore, in the remainder of this subsection, we will prove that the problem is PSPACE-hard for planar graphs. To this end, we construct a polynomial-time reduction from the Minimum Vertex Cover Reconfiguration problem.

Recall that a *vertex cover* C of a graph G is a vertex subset of G which contains at least one of the two endpoints of every edge in G. A vertex cover C of G is *minimum* if the cardinality of C is minimum among all vertex covers of G. Given a graph G and two minimum vertex covers C_0 and C_r of G, the Minimum Vertex Cover Reconfiguration problem (MVCR, for short) asks to determine whether or not there exists a sequence $\langle C_0, C_1, \dots, C_\ell = C_\mathrm{r} \rangle$ of minimum vertex covers of G such that $|C_i \setminus C_{i+1}| = |C_{i+1} \setminus C_i| = 1$ holds for any $i \in \{0, 1, \dots, \ell - 1\}$; we call such a sequence a *vertex cover sequence* between C_0 and C_r. We denote by a triple (G, C_0, C_r) an instance of MVCR. This problem is known to be PSPACE-complete for planar graphs [5].[1]

[1] Precisely, Hearn and Demaine [5] showed the PSPACE-completeness for the reconfiguration of maximum independent sets. However, it immediately yields the PSPACE-completeness of MVCR.

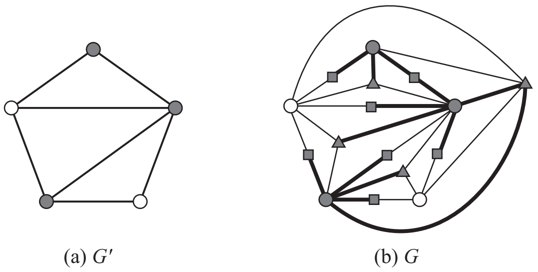


Figure 3 (a) An input graph G' of MVCR with a minimum vertex cover C', where the vertices in C' are depicted by gray vertices, and (b) its corresponding planar graph G of MSTR together with the minimum Steiner tree corresponding to C', where face-terminals are depicted by triangles, edge-terminals by squares, and the minimum Steiner tree by thick lines.

Reduction

Let (G', C'_0, C'_r) be a given instance of MVCR such that G' is a planar graph. We fix a planar embedding of G' arbitrarily, and denote by $F(G')$ the set of all faces (including the outer face) of G'. We construct the corresponding instance (G, S, T_0, T_r) of MSTR under VE, as follows. (See Figure 3 as an example.)

We first construct the corresponding graph G from G'. For each face $f \in F(G')$, we add a new vertex w_f, and join w_f and all vertices on the boundary of f by adding new edges. Then, we subdivide each original edge $e = uv \in E(G')$ by adding a new vertex w_e. Let G be the resulting graph. Then, G is a planar graph.

We then define the corresponding terminal set S as the set of all newly added vertices, that is, $S = \{w_f \mid f \in F(G')\} \cup \{w_e \mid e \in E(G')\}$; each w_f is called a *face-terminal*, while each w_e is called an *edge-terminal*.

We finally define the corresponding minimum Steiner trees T_0 and T_r. We will prove later in Lemma 5 that both $C'_0 \cup S$ and $C'_r \cup S$ form minimum Steiner sets of G for S. Then, we choose arbitrary spanning trees of $G[C'_0 \cup S]$ and $G[C'_r \cup S]$ as T_0 and T_r, respectively.

This completes the construction of (G, S, T_0, T_r). The construction can be done in polynomial time.

Correctness

We start with showing that both $C'_0 \cup S$ and $C'_r \cup S$ form minimum Steiner sets of G for S, and hence T_0 and T_r are indeed minimum Steiner trees of G for S.

▶ **Lemma 5** ($*$). *Let C' be a vertex subset of $V(G')$. Then, C' is a minimum vertex cover of G' if and only if $C' \cup S$ is a minimum Steiner set of G for S.*

The following lemma completes the proof of Theorem 4.

▶ **Lemma 6.** *(G', C'_0, C'_r) is a* yes*-instance of* MVCR *if and only if (G, S, T_0, T_r) is a* yes*-instance of* MSTR.

Proof. By Lemma 1, it suffices to show that there exists a vertex cover sequence on G' between C'_0 and C'_r if and only if there exists a Steiner set sequence on G between $V(T_0)$ and $V(T_r)$.

First, suppose that there exists a Steiner set sequence $\langle V(T_0) = F_0, F_1, \ldots, F_\ell = V(T_r)\rangle$ between $V(T_0)$ and $V(T_r)$. Then, Lemma 5 implies that the sequence $\langle C'_0 = F_0 \setminus S, F_1 \setminus S, \ldots, F_\ell \setminus S = C'_r\rangle$ is a vertex cover sequence on G' between C'_0 and C'_r.

Second, suppose that there exists a vertex cover sequence $\langle C'_0, C'_1, \ldots, C'_{\ell'} = C'_{\mathrm{r}} \rangle$ between C'_0 and C'_{r}. Then, Lemma 5 implies that the sequence $\langle V(T_0) = C'_0 \cup S, C'_1 \cup S, \ldots, C'_{\ell'} \cup S = V(T_{\mathrm{r}}) \rangle$ is a Steiner set sequence on G between $V(T_0)$ and $V(T_{\mathrm{r}})$. ◀

4 Minimum Steiner Tree Reconfiguration under VE-N

In this section, we show that MSTR under VE-N is solvable in polynomial time for chordal graphs and for planar graphs.

We first consider chordal graphs. A graph is *chordal* if G has no induced cycle of length at least four [3]. We use a well-known characterization of chordal graphs, called perfect elimination orderings [3], and give the following theorem.

▶ **Theorem 7** (∗). MSTR *under* VE-N *is solvable in polynomial time for chordal graphs.*

We then consider planar graphs. Recall that MSTR under VE is PSPACE-complete for planar graphs (as shown in Theorem 4). In contrast, we give the following theorem.

▶ **Theorem 8.** MSTR *under* VE-N *is solvable in polynomial time for planar graphs.*

As a proof of the Theorem 8, we construct a polynomial-time algorithm to solve MSTR under VE-N for planar graphs. Roughly speaking, our idea is to decompose a given instance of MSTR under VE-N into several SPR instances for planar graphs. Then, we can solve each SPR instance by using the polynomial-time algorithm for SPR on planar graphs [2]. Finally, we combine the answers to SPR instances, and output the answer to the original MSTR instance under VE-N. To this ends, we introduce the concept of Steiner tree embeddings and their reconfiguration, which gives a necessary condition for the existence of a reconfiguration sequence under VE-N.

4.1 Steiner tree embeddings and their reconfiguration

We first introduce the concept of Steiner tree embeddings. Let T be a Steiner tree of a graph G for a terminal set S. An injection $\varphi \colon V(T) \to V(G)$ is called a T*-embedding* into G if the following two conditions hold:

- $\varphi(x)\varphi(y) \in E(G)$ if $xy \in E(T)$; and
- $\varphi(s) = s$ holds for each $s \in S \subseteq V(T)$.

Thus, a T-embedding φ *defines* a Steiner tree T_φ of G for S. Observe that no two distinct T-embeddings define the same Steiner tree. A Steiner tree T' is said to be T*-embeddable* if there exists a T-embedding φ which defines T'. Note that T itself is T-embeddable. We now give the following lemma.

▶ **Lemma 9** (∗). *Let T_a and T_b be any two minimum Steiner trees of a graph G for a terminal set S. If $T_a \overset{\textsf{VE-N}}{\rightsquigarrow} T_b$, then T_b is T_a-embeddable.*

By taking a contrapositive of Lemma 9, we can conclude that a given instance $(G, S, T_0, T_{\mathrm{r}})$ is a no-instance if T_{r} is not T_0-embeddable; this can be checked in polynomial time. Thus, in the remainder of this section, we assume without loss of generality that T_{r} is T_0-embeddable.

We then introduce the reconfiguration of Steiner tree embeddings. Let T be a Steiner tree of a graph G for a terminal set S. We say that two T-embeddings φ and φ' are *adjacent* if exactly one node in T is mapped into different vertices between φ and φ', that is, $|\{x \in V(T) \mid \varphi(x) \neq \varphi'(x)\}| = 1$ holds. For two T-embeddings φ and φ', an *embedding sequence* between φ and φ' is a sequence $\langle \varphi = \varphi_0, \varphi_1, \ldots, \varphi_\ell = \varphi' \rangle$ of T-embeddings such that φ_i and φ_{i+1} are adjacent for each $i \in \{0, 1, \ldots, \ell - 1\}$. We write $\varphi \overset{\textsf{emb}}{\rightsquigarrow} \varphi'$ if there exists an embedding sequence between φ and φ'. Then, we have the following lemma.

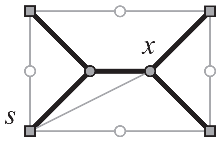

Figure 4 The subtree T depicted by thick lines is a minimum Steiner tree. However, the subpath on T between s and x is not a shortest path in the underlying graph.

▶ **Lemma 10** (∗). *Suppose that T_a and T_b are any two minimum Steiner trees of a graph G for a terminal set S such that T_b is T_a-embeddable. Let φ_a and φ_b be T_a-embeddings which define T_a and T_b, respectively. Then, $T_a \overset{\text{VE-N}}{\leftrightsquigarrow} T_b$ if and only if $\varphi_a \overset{\text{emb}}{\leftrightsquigarrow} \varphi_b$.*

By Lemmas 9 and 10, MSTR under VE-N can be rephrased to the following problem: Given a graph G, a terminal set S, a minimum Steiner tree T (actually T_0), and two T-embeddings φ_0 and φ_{r} into G, we are asked to determine whether or not there exists an embedding sequence between φ_0 and φ_{r}. Therefore, we also denote by $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ an instance of MSTR under VE-N.

4.2 Layers for Steiner trees

We here introduce one more important concept, called layers, which was originally introduced by Bonsma [1] for SPR. We generalize the concept to Steiner trees.

Let T be a minimum Steiner tree of a graph G for a terminal set S. For each $x \in V(T)$, let $L_T(x) = \{\varphi(x) \in V(G) \mid \varphi \text{ is a } T\text{-embedding into } G\}$; we call $L_T(x)$ the *layer* of x. Notice that $L_T(s) = \{s\}$ holds for each $s \in S$. We write $L_T(V') = \bigcup_{x \in V'} L_T(x)$ for any node subset $V' \subseteq V(T)$. Then, we have the following property, which says that the layers are disjoint.

▶ **Lemma 11** (∗). *Let T be any minimum Steiner tree of a graph G for a terminal set S. Then, $L_T(x) \cap L_T(y) = \emptyset$ holds for any two distinct nodes $x, y \in V(T)$.*

We call a node $x \in V(T)$ a *branching node* of T if $|N_T(x)| \geq 3$. Let $B(T)$ be the set of all branching nodes of T. Then, we show that a layer of each node in $B(T)$ contains at most two vertices if a given graph is planar.

▶ **Lemma 12** (∗). *Let T be any minimum Steiner tree of a graph G for a terminal set S. If G is planar, then $|L_T(x)| \leq 2$ holds for every branching node $x \in B(T)$.*

We now explain how to compute the layers for a Steiner tree. In SPR [1], we can easily find the layers for a shortest path by computing the distances from the two terminals to each vertex in the underlying graph. This is because the subpath between each node and each terminal is always a shortest path in the underlying graph. On the other hand, this property does not always hold if $|S| \geq 3$, and hence it is difficult to find the layers simply by computing the distances. (For example, see Figure 4.)

Our idea is to compute the "refined" layers for a Steiner tree, instead of computing the layers completely. Let $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ be a given instance of MSTR under VE-N. Then, for all nodes $x \in V(T)$, it suffices to find vertex subsets $L'_T(x)$ such that

(a) $L'_T(x) \subseteq L_T(x)$; and

(b) $\varphi(x) \in L'_T(x)$ holds for any T-embedding φ satisfying $\varphi_0 \overset{\text{emb}}{\leftrightsquigarrow} \varphi$ or $\varphi_{\mathrm{r}} \overset{\text{emb}}{\leftrightsquigarrow} \varphi$.

To avoid a confusion, we call such a vertex subset $L'_T(x)$ the *refined-layer* of x, while call the (original) layer $L_T(x)$ the *complete-layer* of x. We know that the vertices in $L_T(x) \setminus L'_T(x)$

are useless when we want to check if $\varphi_0 \overset{\mathsf{emb}}{\leftrightsquigarrow} \varphi_{\mathrm{r}}$ or not. The following lemma says that the refined-layers can be found in polynomial time.

▶ **Lemma 13** (∗). *Let* $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ *be a given instance of* MSTR *under* VE-N *such that* G *is a planar graph. Then, there exists a polynomial-time algorithm to compute the refined-layers for all nodes in* T*.*

Given an instance $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ of MSTR under VE-N, we can compute refined-layers in polynomial time by Lemma 13. Since the vertices in $L_T(x) \setminus L'_T(x)$, $x \in V(T)$, are useless, we can remove such useless vertices from G. In this way, we can assume without loss of generality that each vertex in G belongs to exactly one (complete-)layer, and we indeed know the layer $L_T(x)$ for each node $x \in V(T)$.

4.3 Decomposition of an MSTR instance into SPR instances

Suppose that $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ is an instance of MSTR under VE-N, and that we have the layer $L_T(x)$ for each node $x \in V(T)$. We say that two nodes $x, y \in B(T) \cup S$ are *close* if the unique path on T between x and y contains no vertex in $(B(T) \cup S) \setminus \{x, y\}$. To avoid the duplication of $\{x, y\}$ and $\{y, x\}$, we choose one of the ordered pairs (x, y) and (y, x) arbitrarily for each pair of close nodes, and define the set $C(T)$ of all ordered pairs (x, y) of close nodes x, y in $B(T) \cup S$; we call each pair in $C(T)$ a *close pair.*

For each close pair (x, y) in $C(T)$, we now construct the corresponding instance SPR(x, y) $= (G', S', T', \varphi'_0, \varphi'_{\mathrm{r}})$ such that $|S'| = 2$, as follows. Let P be the unique path on T between x and y. Note that by the definition of close pairs, P is a shortest path on G between x and y. Consider the subgraph of G induced by the vertices in $L_T(V(P))$. We add two new vertices s_x and t_y to the subgraph so that s_x is joined to all vertices in $L_T(x)$ and t_y is joined to all vertices in $L_T(y)$; note that each of s_x and t_y is indeed adjacent to one or two vertices. Let G' be the resulting graph, and let $S' = \{s_x, t_y\}$. We then define T' as the path on G' between s_x and t_y obtained by adding s_x and t_y to P. Note that T' is a shortest path on G' between s_x and t_y. We finally define φ'_0 as a T'-embedding into G' such that $\varphi'_0(s_x) = s_x$, $\varphi'_0(t_y) = t_y$, and $\varphi'_0(x) = \varphi_0(x)$ for each $x \in V(P)$. Similarly, we define φ'_{r} as a T'-embedding into G' such that $\varphi'_{\mathrm{r}}(s_x) = s_x$, $\varphi'_{\mathrm{r}}(t_y) = t_y$, and $\varphi'_{\mathrm{r}}(x) = \varphi_{\mathrm{r}}(x)$ for each $x \in V(P)$. This completes the construction of SPR(x, y). The corresponding instance SPR(x, y) can be obtained in polynomial time, and satisfies the following property.

▶ **Lemma 14** (∗). *If* G *is planar, then* G' *is also planar.*

By Lemma 14 we can solve the instance SPR(x, y) for each close pair $(x, y) \in C(T)$ by the polynomial-time algorithm for SPR on planar graphs [2]. We can immediately conclude that the given instance $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$ of MSTR under VE-N is a no-instance if there exists at least one instance SPR(x, y) whose answer is no. However, even if the answers are yes to all instances SPR(x, y), $(x, y) \in C(T)$, it is not always possible to extend their embedding sequences to a whole embedding sequence between φ_0 and φ_{r} for the original instance $(G, S, T, \varphi_0, \varphi_{\mathrm{r}})$. To check this, we introduce further notion.

Consider an embedding sequence $\mathcal{R} = \langle \varphi = \varphi_0, \varphi_1, \ldots, \varphi_\ell = \varphi' \rangle$ between two T-embeddings φ and φ'. For each node $x \in V(T)$, we say that $\mathcal{R}$ is *x-touching* if the assignment of x is changed by $\mathcal{R}$ at least once; otherwise it is *x-untouching.* Note that if $\varphi(x) \neq \varphi'(x)$ for a node $x \in V(T)$, then any embedding sequence between φ and φ' must be x-touching. On the other hand, if $|L_T(x)| = 1$, then any embedding sequence must be x-untouching. For each close pair $(x, y) \in C(T)$ and its corresponding instance SPR$(x, y) =$ $(G', S', T', \varphi'_0, \varphi'_{\mathrm{r}})$, we define the set $\mathsf{Touch}(x, y) \subseteq \{(\mathsf{u}, \mathsf{u}), (\mathsf{u}, \mathsf{t}), (\mathsf{t}, \mathsf{u}), (\mathsf{t}, \mathsf{t})\}$, as follows:

- $(\mathsf{u},\mathsf{u}) \in \mathsf{Touch}(x,y)$ if and only if there exists an embedding sequence between φ'_0 and φ'_{r} which is x-untouching and y-untouching;
- $(\mathsf{u},\mathsf{t}) \in \mathsf{Touch}(x,y)$ if and only if there exists an embedding sequence between φ'_0 and φ'_{r} which is x-untouching and y-touching;
- $(\mathsf{t},\mathsf{u}) \in \mathsf{Touch}(x,y)$ if and only if there exists an embedding sequence between φ'_0 and φ'_{r} which is x-touching and y-untouching; and
- $(\mathsf{t},\mathsf{t}) \in \mathsf{Touch}(x,y)$ if and only if there exists an embedding sequence between φ'_0 and φ'_{r} which is x-touching and y-touching.

Note that $\mathsf{Touch}(x,y) = \emptyset$ if there is no embedding sequence between φ'_0 and φ'_{r}. Then, we have the following lemma.

▶ **Lemma 15** (∗). *For each close pair $(x,y) \in C(T)$, $\mathsf{Touch}(x,y)$ can be computed in polynomial time.*

We finally solve the given instance $(G,S,T,\varphi_0,\varphi_{\mathrm{r}})$ of MSTR under VE-N. Assume that $\mathrm{SPR}(x,y)$ are yes-instances for all close pairs $(x,y) \in C(T)$, and hence $\mathsf{Touch}(x,y) \neq \emptyset$; otherwise $(G,S,T,\varphi_0,\varphi_{\mathrm{r}})$ is a no-instance. Consider an assignment $\alpha : B(T) \cup S \to \{\mathsf{u},\mathsf{t}\}$. Then, we say that α is *synchronizing* if $(\alpha(x),\alpha(y)) \in \mathsf{Touch}(x,y)$ holds for every close pair $(x,y) \in C(T)$. The following lemma completes the proof of Theorem 8.

▶ **Lemma 16** (∗). *Suppose that $(G,S,T,\varphi_0,\varphi_{\mathrm{r}})$ is an instance of* MSTR *under* VE-N *such that G is a planar graph. Then, it is a* yes*-instance if and only if there exists a synchronizing assignment α. Furthermore, the existence of a synchronizing assignment can be checked in polynomial time.*

5 Conclusion

In this paper, we have introduced the Minimum Steiner Tree Reconfiguration (MSTR) problems under two reconfiguration rules VE and VE-N. As summarized in Figure 2, we have studied the polynomial-time solvability of the problems with respect to graph classes, and shown several interesting contrasts. In particular, when we focus on planar graphs, chordal graphs, and split graphs, MSTR is PSPACE-complete under VE, while is solvable in polynomial time under VE-N. It would give us a deeper understanding of the problems if there is a graph class such that MSTR is solvable in polynomial time under VE but is intractable under VE-N.

Abstract

We study the PERFECT MATCHING RECONFIGURATION problem: Given two perfect matchings of a graph, is there a sequence of flip operations that transforms one into the other? Here, a flip operation exchanges the edges in an alternating cycle of length four. We are interested in the complexity of this decision problem from the viewpoint of graph classes. We first prove that the problem is PSPACE-complete even for split graphs and for bipartite graphs of bounded bandwidth with maximum degree five. We then investigate polynomial-time solvable cases. Specifically, we prove that the problem is solvable in polynomial time for strongly orderable graphs (that include interval graphs and strongly chordal graphs), for outerplanar graphs, and for cographs (also known as P_4-free graphs). Furthermore, for each yes-instance from these graph classes, we show that a linear number of flip operations is sufficient and we can exhibit a corresponding sequence of flip operations in polynomial time.

1 Introduction

Given an instance of some combinatorial search problem and two of its feasible solutions, a *reconfiguration problem* asks whether one solution can be transformed into the other in a step-by-step fashion, such that each intermediate solution is also feasible. Reconfiguration problems capture dynamic situations, where some solution is in place and we would like to move to a desired alternative solution without becoming infeasible. A systematic study of the complexity of reconfiguration problems was initiated in [21]. Recently the topic has gained a lot of attention in the context of constraint satisfaction problems and graph problems, such as the independent set problem, the matching problem, and the dominating set problem. Reconfiguration problems naturally arise for operational research problems but also are closely related to uniform sampling (using Markov chains) or enumeration of solutions of a problem. For an overview of recent results on reconfiguration problems, the reader is referred to the surveys of van den Heuvel [17] and Nishimura [27].

In order to define valid step-by-step transformations, an adjacency relation on the set of feasible solutions is needed. Depending on the problem, there may be different natural choices of adjacency relations. For instance, we may assume that two matchings of a graph are adjacent if one can be obtained from the other by exchanging precisely one edge, i.e., there exist $e \in M$ and $f \in M'$ such that $M \setminus \{e\} = M' \setminus \{f\}$. The corresponding modification of a matching is usually referred to as *token jumping* (TJ). Here, the *tokens* are placed on the edges of a matching and a token may be "moved" from an edge of the matching to another edge so that we obtain another matching. There is another similar adjacency relation, where two matchings are adjacent if one can be obtained from the other by moving a token to some incident edge. This adjacency relation is called *token sliding* (TS). Ito et al. [21] gave a polynomial-time algorithm that decides if there is a transformation between two given matchings under the TJ and TS operations.

1.1 The perfect matching reconfiguration problem

Recall that a matching of a graph is *perfect* if it covers each vertex. We study the complexity of deciding if there is a step-by-step transformation between two given perfect matchings of a graph. However, according to the adjacency relations given by the TS and TJ operations, there is no transformation between any two distinct perfect matchings of a graph. Since the symmetric difference of any two perfect matchings of a graph consists of even-length disjoint cycles, it is natural to consider a different adjacency relation for perfect matchings. We say that two perfect matchings of a graph differ by a *flip* (or *swap*) if their symmetric difference induces a cycle of length four. We consider two perfect matchings to be *adjacent* if they differ by a flip. Intuitively, for two adjacent perfect matchings M and M', we think of a flip as an operation that exchanges edges in $M \setminus M'$ for edges in $M' \setminus M$.

An example of a transformation between two perfect matchings of a graph is given in Figure 1. We formalize the task of deciding the existence of a transformation between two given perfect matchings as follows.

Perfect Matching Reconfiguration
Input: Graph G, perfect matchings M_s and M_t of G.
Question: Is there a sequence of flips that transforms M_s into M_t?

We take the flip operation on a cycle of length four as the adjacency relation in this paper, because a flip is in some sense a minimal modification of a perfect matching. Note that if we do not restrict the length of a cycle in the definition of a flip, then for any two perfect

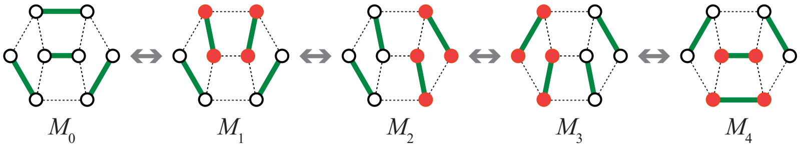

Figure 1 A transformation between perfect matchings M_0 and M_4 under the flip operation. For each i, $1 \leq i \leq 4$, the matching M_i can be obtained from M_{i-1} by applying the flip operation to the cycle induced by the four painted (red) vertices in M_i.

matchings M_s and M_t of a graph, there always exists a sequence of flip operations that transforms M_s into M_t, since we can perform a flip on each (disjoint) cycle in the symmetric difference of M_s and M_t. As a compromise, we may extend our problem definition to flips on cycles of fixed constant length ℓ, where $\ell \geq 4$ and ℓ is even. We refer to the corresponding flip operation as the ℓ-flip operation, and the corresponding reconfiguration problem as PERFECT MATCHING ℓ-FLIP RECONFIGURATION. It should be noted that the ℓ-flip operation must be applied to a cycle of length *exactly* ℓ, and hence there is no guarantee of the existence of a transformation.

1.2 Related work

Transformation of matchings has been considered under several types of flip operations for generating random matchings. Under the TS and TJ operations, numerous algorithms and hardness results are available for finding transformations between matchings, more generally, between independent sets. Furthermore, similar types of flip operations are well known for stable matchings and some geometric matching problems related to finding transformations between triangulations. More directly, a restriction of PERFECT MATCHING (4-FLIP) RECONFIGURATION to grid graphs has been considered before in the setting of domino tilings. In this restricted setting, Saldanha et al. [28] gave a criterion for the existence of a transformation between two tilings (which correspond to perfect matchings of a grid graph) and a formula for their distance of a transformation.

Sampling random perfect matchings

The problem of sampling or enumerating perfect matchings in a graph received considerable attention (see, e.g., [31]). Determining the connectivity and the diameter of the solution space formed by perfect matchings under the flip operation provide some information on the ergodicity or the mixing time of the underlying Markov chain. Indeed, the connectivity of the chain ensures the irreducibility (and usually the ergodicity) of the underlying Markov chain. Additionally, the diameter of the solution space provides a lower bound on the mixing time of the chain.

The use of flips for sampling random perfect matchings was first started in [8] where it is seen as a generalization of transpositions for permutations. Their work was later improved and generalized in [13] and [12]. The focus of these last two articles is to investigate the problem of sampling random perfect matchings using a Markov Chain called the switch chain. Starting from an arbitrary perfect matching, the chain proceeds by applying at each step a random 4-flip operation (called switch in these papers). The aim of these papers is to characterize classes of graphs for which simulating this chain for a polynomial number of steps is enough to generate a perfect matching close to uniformly distributed. Some of their results can be reformulated in the reconfiguration terminology. In [13], it is proved that the largest hereditary class of bipartite graphs for which the solution space formed by perfect matchings under the 4-flip operation is connected is the class of chordal bipartite graphs. This result is generalized in [12] where they characterize the hereditary class of general (non-bipartite) graphs for which the solution space is connected. They call this class Switchable. Note that it is not clear whether graphs in this class can be recognized in polynomial time. The question of the complexity of Perfect Matching (4-Flip) Reconfiguration is also mentioned in [12].

Reconfiguration of matchings and independent sets

Recall that matchings of a graph correspond to independent sets of its line graph. Although reconfiguration of independent sets received a considerable attention in the last decade (e.g., [5, 6, 7, 16, 22, 23, 33]), all the known results for reconfiguration of independent sets are based on the TJ or TS operations as adjacency relations. Thus, none of these results carry over to the Perfect Matching Reconfiguration problem.

A related problem can be found in a more general setting: The problem of determining, enumerating, or randomly generating graphs with a fixed degree sequence has received a considerable attention since the fifties (see, e.g., [30, 15, 32]). Given two graphs with a fixed degree sequence, one might want to know if it is possible to transform the one into the other via a sequence of 4-flip operations and if yes, how many steps are needed for such a transformation; note that the host graph (i.e., the graph G in our problem) is a clique in this setting. Hakimi [15] proved that such a transformation always exists. Will [32] proved that the problem of finding a shortest transformation is NP-complete, and Bereg and Ito [2] provide a $\frac{3}{2}$-approximation algorithm for this problem.

Stable matchings

Suppose we are given a bipartite graph and for each vertex a linear preference order of its neighbors. A matching M is not stable if there is an edge vw not in M such that v prefers w and w prefers v to their respective partners in M. The well-known algorithm by Gale and Shapley yields a stable matching in polynomial time [14]. It is known that any two stable matchings cover the same vertices, so the stable matchings are perfect matchings of some subgraph. Furthermore, they form a distributive lattice under *rotations* on preference-oriented cycles, see for example [14]. Essentially, the symmetric difference of two stable matchings consists of disjoint cycles (of several lengths) and we may exchange edges on these cycles to obtain another stable matching. If we drop the preferences, then the question is simply if we can find a transformation between two perfect matchings by exchanging edges on cycles in the symmetric difference. Clearly the answer is always yes, for example by processing the cycles in the symmetric difference one by one. We consider a similar setting, but restrict the length of the cycles.

Diagonal-flips of triangulations

A diagonal-flip of a triangulation in geometry is similar to our 4-flip operation in the sense that we switch between two states of a quadrilateral. In the context of triangulations, a diagonal-flip operation switches the diagonal of a quadrilateral. Transformations between triangulations of point sets and polygons have been studied mostly in the plane. It is known that the solution space formed by triangulations of point sets and polygons in the plane is connected and has diameter $O(n^2)$, where n is the number of points [20, 24]. Recently, NP-completeness has been proved for deciding the distance in the solution space between triangulations of a point set in the plane [25] and triangulations of a simple polygon [1].

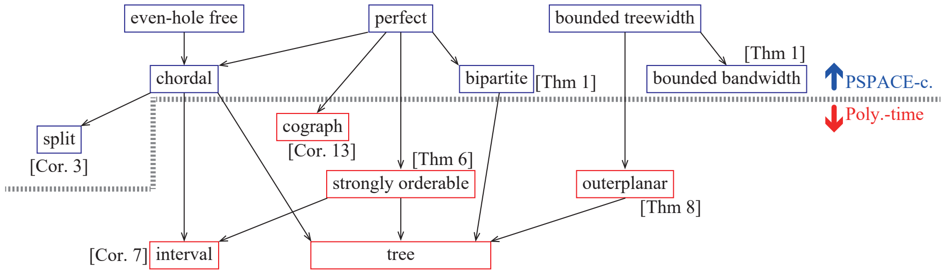

Figure 2 Our results, where each arrow represents the inclusion relationship between graph classes: $A \rightarrow B$ represents that the graph class B is properly included in the graph class A.

Houle et al. [18] have considered triangulations of point sets in the plane that admit a perfect matching. They show that any two such triangulations are connected under the diagonal-flip operation. For this purpose they consider the graph of non-crossing perfect matchings, where two matchings are adjacent if they differ by a single non-crossing cycle (of arbitrary length). They show that the graph of non-crossing perfect matchings is connected and conclude from this that any two triangulations that admit a perfect matching must be connected. In contrast to their setting, we remove all geometric requirements, but restrict the length of the cycles allowed for our flip operation.

1.3 Our results

In this paper, we study the complexity of Perfect Matching Reconfiguration from the viewpoint of graph classes. Figure 2 summarizes our results.

Recall that reconfiguration of matchings under the TS and TJ operations can be solved in polynomial time for any graph [21]. In contrast, we prove that Perfect Matching Reconfiguration is PSPACE-complete, even for split graphs, and for bipartite graphs of bounded bandwidth and of maximum degree five. We note that our hardness result for bipartite graphs gives contrast to chordal bipartite graphs for which there always exists a transformation between any two perfect matchings [13]. In addition, we extend our hardness result to a more general setting, namely the reconfiguration of k-factor subgraphs under the ℓ-flip operation for any fixed $k \geq 1$ and any fixed even integer $\ell \geq 4$.

We then investigate polynomial-time solvable cases. We prove that Perfect Matching Reconfiguration admits a polynomial-time algorithm on strongly orderable graphs (these include interval graphs and strongly chordal graphs), outerplanar graphs, and cographs (also known as P_4-free graphs). More specifically, we give the following results:

- For strongly orderable graphs, a transformation between two perfect matchings always exists; hence the answer is always yes. Furthermore, there is a transformation of linear length (i.e., a linear number of flip operations) between any two perfect matchings and such a transformation can be found in polynomial time.
- Perfect Matching Reconfiguration on outerplanar graphs can be solved in linear time, and we can find a transformation of linear length for a yes-instance in linear time. (Note that there are no-instances, e.g., long cycles).
- Perfect Matching Reconfiguration on cographs can be solved in polynomial time, and we can find a transformation of linear length for a yes-instance in polynomial time. (Again, there are no-instances).

Due to the page limitation, we omit proofs of the claims marked with (∗).

1.4 Notation

For standard definitions and notations on graphs, we refer the reader to [9]. Let $G = (V, E)$ be a simple graph. We sometimes denote by $V(G)$ and $E(G)$ the vertex set and edge set of G, respectively. A *matching* $M \subseteq E$ of G is a set of edges that share no endpoint. A vertex v is *covered* by a matching M if v is incident to an edge in M. For a vertex set $V' \subseteq V$, we denote by $G[V']$ the subgraph of G induced by V'. For a vertex set $W \subseteq V$, let $G - W := G[V \setminus W]$. For a vertex $v \in V$, we denote by $N(v)$ the *neighborhood* of v, that is, $N(v) := \{w \in V \mid vw \in E\}$.

Two perfect matchings M and M' of G are *adjacent* if their symmetric difference $M \triangle M'$ induces a cycle of length four. A sequence $M_0, M_1, \ldots, M_q$ of perfect matchings in G is called a *reconfiguration sequence between M and M'* if $M_0 = M$, $M_q = M'$, and M_{i-1} and M_i are adjacent for each i, $1 \leq i \leq q$. Given two perfect matchings M_{s} and M_{t} of a graph G, Perfect Matching Reconfiguration is to determine whether there exists a reconfiguration sequence between M_{s} and M_{t}. We denote by a triple $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ an instance of the problem.

2 PSPACE-completeness

In this section, we prove that perfect matching reconfiguration is PSPACE-complete. Interestingly, the problem remains intractable even for bipartite graphs, even though matchings in bipartite graphs satisfy several nice properties.

▶ **Theorem 1.** Perfect matching reconfiguration *is* PSPACE-*complete for bipartite graphs whose maximum degree is five and whose bandwidth is bounded by a fixed constant.*

Proof. Observe that the problem can be solved in (most conveniently, nondeterministic [29]) polynomial space, and hence it is in PSPACE. As a proof of Theorem 1, we thus prove that the problem is PSPACE-hard for such graphs, by giving a polynomial-time reduction from the Nondeterministic Constraint Logic problem (NCL for short) [16].

Definition of nondeterministic constraint logic

An NCL “machine” is an undirected graph together with an assignment of weights from $\{1, 2\}$ to each edge of the graph. An *(NCL) configuration* of this machine is an orientation (direction) of the edges such that the sum of weights of in-coming arcs at each vertex is at least two. Figure 3(a) illustrates a configuration of an NCL machine, where each weight-2 edge is depicted by a (blue) thick line and each weight-1 edge by a (red) thin line. Then, two NCL configurations are *adjacent* if they differ in a single edge direction. Given an NCL machine and its two configurations, it is known to be PSPACE-complete to determine whether there exists a sequence of adjacent NCL configurations which transforms one into the other [16].

An NCL machine is called an and/or *constraint graph* if it consists of only two types of vertices, called “NCL and vertices” and “NCL or vertices” defined as follows: A vertex of degree three is called an *NCL* and *vertex* if its three incident edges have weights 1, 1, and 2. (See Figure 3(b).) An NCL and vertex u behaves as a logical and, in the following sense: the weight-2 edge can be directed outward for u only if both two weight-1 edges are directed inward for u. Note that, however, the weight-2 edge is not necessarily directed outward even when both weight-1 edges are directed inward. A vertex of degree three is called an *NCL* or *vertex* if its three incident edges have weights 2, 2, and 2. (See Figure 3(c).) An NCL

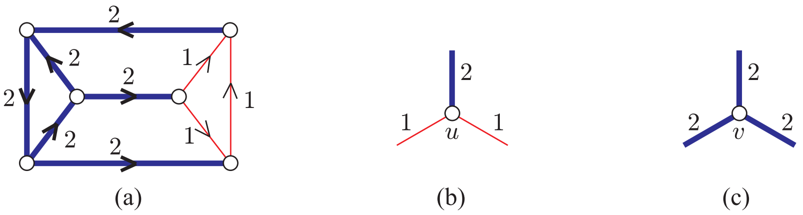

Figure 3 (a) A configuration of an NCL machine, (b) an NCL AND vertex u, and (c) an NCL OR vertex v.

OR vertex v behaves as a logical OR: one of the three edges can be directed outward for v if and only if at least one of the other two edges is directed inward for v. It should be noted that, although it is natural to think of NCL AND/OR vertices as having inputs and outputs, there is nothing enforcing this interpretation; especially for NCL OR vertices, the choice of input and output is entirely arbitrary because an NCL OR vertex is symmetric. For example, the NCL machine in Figure 3(a) is an AND/OR constraint graph. From now on, we call an AND/OR constraint graph simply an *NCL machine*, and call an edge in an NCL machine an *NCL edge*. NCL remains PSPACE-complete even if an input NCL machine is planar, bounded bandwidth, and of maximum degree three [34].

Gadgets and reduction

Suppose that we are given an instance of NCL, that is, an NCL machine and two configurations of the machine. We will replace each of the NCL edges and NCL AND/OR vertices with its corresponding gadget; if an NCL edge e is incident to an NCL vertex v, then we connect the corresponding gadgets for e and v by a pair of vertices, called *connectors* (*between* v *and* e) or (v, e)-*connectors*, as illustrated in Figure 4(a) and (b). Thus, each edge gadget has two pairs of connectors, and each AND/OR gadget has three pairs of connectors. Our gadgets are all edge-disjoint, and share only connectors.

Figure 5 shows our three types of gadgets which correspond to NCL edges and NCL AND/OR vertices. As illustrated in Figure 4, we replace each of the NCL edges and NCL AND/OR vertices with its corresponding gadget; let G be the resulting graph. Notice that each of our three gadgets is of maximum degree three, and connectors in the edge gadget are of degree two; thus, G is of maximum degree five. In addition, each of our three gadgets is a bipartite graph such that two connectors in the same pair belong to different sides of the bipartition; therefore, G is bipartite. Furthermore, since NCL remains PSPACE-complete even if an input NCL machine is bounded bandwidth [34], the resulting graph G is also bounded bandwidth and of maximum degree five; notice that, since each gadget consists of only a constant number of edges, the bandwidth of G is also bounded.

We next construct two perfect matchings of G which correspond to two given NCL configurations C_s and C_t of the NCL machine. In our reduction, we construct the correspondence between orientations of an NCL machine and perfect matchings of the corresponding graph, as follows: We regard that the orientation of an NCL edge $e = vw$ is inward direction for v if the two (v, e)-connectors are both covered by (edges in) the AND/OR gadget for v. On the other hand, we regard that the orientation of $e = vw$ is outward direction for w if the two (w, e)-connectors are both covered by the edge gadget for e. To achieve this correspondence, our gadgets are constructed so that both two (v, e)-connectors are always covered by exactly one of the gadgets for v and e. Note that there are (in general, exponentially) many perfect matchings which correspond to the same NCL configuration. However, by the construction of

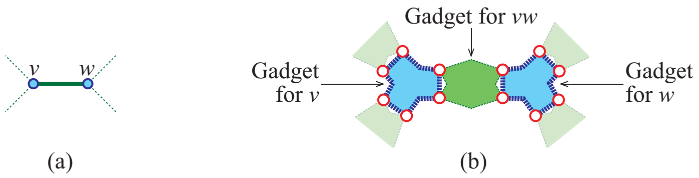

Figure 4 (a) An NCL edge vw, and (b) its corresponding gadgets, where the connectors are depicted by (red) circles.

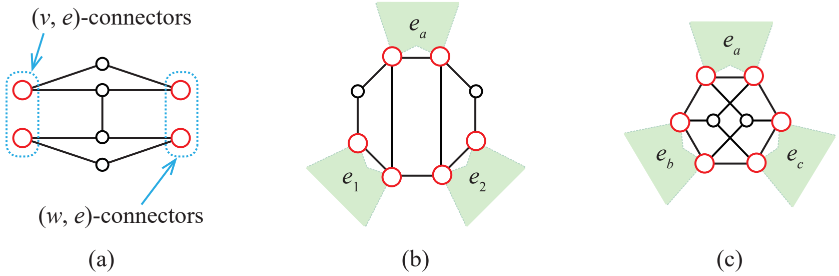

Figure 5 Illustrations of (a) an edge gadget for an NCL edge $e = vw$, (b) an AND gadget, and (c) an OR gadget. In the AND/OR gadget, the three light green parts represent the edge gadgets corresponding to the edges incident to the NCL vertex; e_1 and e_2 in the AND gadget correspond to weight-1 edges.

the three gadgets, no two distinct NCL configurations correspond to the same perfect matching of G. We arbitrarily choose two perfect matchings M_{s} and M_{t} of G which correspond to C_{s} and C_{t}, respectively.

This completes the construction of our corresponding instance of PERFECT MATCHING RECONFIGURATION. The construction can be done in polynomial time. Furthermore, the following lemma gives the correctness of our reduction.

▶ **Lemma 2** (∗). *There exists a desired sequence of NCL configurations between C_{s} and C_{t} if and only if there exists a reconfiguration sequence between M_{s} and M_{t}.*

This completes the proof of Theorem 1. ◀

Remarks

We conclude this section by giving some remarks that can be obtained from Theorem 1. We first prove that the problem remains intractable even for split graphs. A graph is *split* if its vertex set can be partitioned into a clique and an independent set.

▶ **Corollary 3.** PERFECT MATCHING RECONFIGURATION *is* PSPACE*-complete for split graphs.*

Proof. By Theorem 1 the problem remains PSPACE-complete for bipartite graphs. Consider the graph obtained by adding new edges so that one side of the bipartition forms a clique. The resulting graph is a split graph. We claim that these new edges can never be part of any perfect matching of the graph. Indeed, since the original graph was bipartite, there must be the same number of vertices on each side of the bipartition. In a perfect matching of the split graph, all the vertices from the independent set must be matched with vertices from the clique, and no vertex from the clique remains to be matched together. Thus, the claim holds, and hence the corollary follows. ◀

We finally extend Theorem 1 into two directions: regular spanning subgraphs and flip operations on alternating cycles of a fixed length. Let k be a positive integer. A spanning subgraph H of a graph G is a *k-factor* if all the vertices in H have degree exactly k. Thus, a 1-factor of G is a perfect matching of G. Based on the proof of Theorem 1, we can obtain the following theorem.

▶ **Theorem 4** ($*$). *Let $k \geq 1$ be a fixed integer, and let $\ell \geq 4$ be a fixed even integer. Given two k-factors H_{s} and H_{t} of a graph G, it is* PSPACE*-complete to decide if there is a sequence of ℓ-flip operations transforming H_{s} into H_{t}.*

3 Polynomial-time algorithms

In this section, we investigate the polynomial-time solvability of PERFECT MATCHING RECONFIGURATION from the viewpoint of graph classes. We first give the following lemma, which holds for any graph.

▶ **Lemma 5.** *It suffices to solve* PERFECT MATCHING RECONFIGURATION *for* 2*-connected graphs having at least four vertices.*

Proof. Let $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ be a given instance of PERFECT MATCHING RECONFIGURATION. If G is not connected, then we can simply consider each connected component separately.

Since the input graph $G = (V, E)$ has a perfect matching, it has an even number of vertices. If $|V| = 2$, then it must hold that $M_{\mathrm{s}} = M_{\mathrm{t}} = E$, and hence the instance is trivially a yes-instance. Therefore, it suffices to solve the problem for $|V| \geq 4$.

Suppose that G is not 2-connected and has a cut vertex $v \in V$, that is, $G - \{v\}$ consists of more than one connected component. Since $|V|$ is even, there exists a vertex subset $X \subseteq V \setminus \{v\}$ such that $|X|$ is odd and $G[X]$ forms a connected component of $G - \{v\}$. Then, any perfect matching in G contains an edge connecting v and X. This shows that we can consider two subgraphs $G_1 := G[X \cup \{v\}]$ and $G_2 := G - (X \cup \{v\})$, separately. That is, we output "yes" if $(G_i, M_{\mathrm{s}} \cap E_i, M_{\mathrm{t}} \cap E_i)$ is a yes-instance for every $i \in \{1, 2\}$, where E_i is the edge set of G_i, and output "no" otherwise. Thus, the lemma follows. ◀

3.1 Strongly orderable graphs

Interval graphs form easy instances for many NP-hard problems, and the situation is no different here. In fact, we prove that any instance on an interval graph is a yes-instance. Our argument also yields a linear-time algorithm to compute a reconfiguration sequence of a linear number of flip operations between any two perfect matchings.

For the sake of generality, we consider a wider class of graphs, called strongly orderable graphs. A graph $G = (V, E)$ is *strongly orderable* if there is a *strong ordering* on its vertices, defined as follows: an order $(v_1, v_2, \ldots, v_n)$ of V such that for every i, j, k, ℓ with $i < j$ and $k < \ell$, if all of $v_i v_k, v_i v_\ell$ and $v_j v_k$ are edges, then $v_j v_\ell$ is an edge. Note that the class of strongly orderable graphs is hereditary: every induced subgraph of a strongly orderable graph is strongly orderable.

Our proof strategy for the following theorem is to show that every perfect matching N of a strongly orderable graph G can be transformed into some particular perfect matching M of G, called the canonical perfect matching; then, any two perfect matchings N and N' of G admit a reconfiguration sequence between them via M. The *canonical perfect matching* of a graph G with respect to an order $\mathcal{O} = (v_1, v_2, \ldots, v_n)$ is a perfect matching of G (if any) greedily obtained by selecting, among the available edges, the one with endpoints of smallest indices. Note that any strongly orderable graph that admits a perfect matching, also admits a canonical perfect matching with respect to a corresponding order on the vertices (see, e.g., [10]). We give the following theorem in this subsection.

▶ **Theorem 6** (∗). *Let G be a strongly orderable graph. Then, there is a reconfiguration sequence of linear length between any two perfect matchings of G. Furthermore, such a reconfiguration sequence can be found in linear time if we are given a strong ordering on the vertices of G as a part of the input.*

The natural question regarding Theorem 6 is whether a strong ordering can be computed efficiently. In general, Dragan [11] proved that strongly orderable graphs $G = (V, E)$ can be recognized in $O(|V| \cdot (|V| + |E|))$ time, and if so we can obtain its strong ordering in the same running time. However, when restricted to interval graphs, we can obtain a strong ordering in linear time [19]. We thus have the following corollary.

▶ **Corollary 7.** *Let G be an interval graph. Then, there is a reconfiguration sequence of linear length between any two perfect matchings of G. Furthermore, such a reconfiguration sequence can be found in linear time.*

3.2 Outerplanar graphs

In this subsection, we consider outerplanar graphs. Note that there are no-instances for outerplanar graphs, e.g., induced cycles of even length more than four. Nonetheless, we give the following theorem.

▶ **Theorem 8.** Perfect Matching Reconfiguration *can be solved in linear time for outerplanar graphs. Moreover, for a* yes*-instance, a reconfiguration sequence of linear length can be output in linear time.*

We give such an algorithm as a proof of Theorem 8. Suppose we are given a simple outerplanar graph $G = (V, E)$, and two perfect matchings M_s and M_t in G. By Lemma 5 we assume without loss of generality that G is 2-connected and $|V| \geq 4$. Then, G has a planar embedding such that the outer face boundary is a simple cycle and all the vertices of G are on the outer face boundary. Suppose that the vertices $v_1, v_2, \ldots, v_n$ appear in this order along the cycle. For notational convenience, we denote $v_{n+1} = v_1$, $v_{n+2} = v_2$, and $v_0 = v_n$. We first give the following assumption without loss of generality.

▶ **Lemma 9.** Perfect Matching Reconfiguration *for outerplanar graphs can be reduced to the case when $v_i v_j \notin E$ holds for any pair of indices $i, j \in \{1, 2, \ldots, n\}$ such that $|i - j|$ is even. In particular, $v_i v_{i+2} \notin E$ holds for any $i \in \{1, 2, \ldots, n\}$.*

Proof. Suppose that there exists a pair of indices $i, j \in \{1, 2, \ldots, n\}$ such that $|i - j|$ is even and $v_i v_j \in E$. Then, the edge $v_i v_j$ cannot be contained in any perfect matching of G, because $G[\{v_{i+1}, v_{i+2}, \ldots, v_{j-1}\}]$ forms a connected component in $G - \{v_i, v_j\}$ even though it contains an odd number of vertices. Therefore, we can remove $v_i v_j$ from G. ◀

We now show the following lemma for an outerplanar graph $G = (V, E)$.

▶ **Lemma 10** (∗). *If $v_i v_{i+2} \notin E$ for any $i \in \{1, 2, \ldots, n\}$, then there exists an index $k \in \{1, 2, \ldots, n\}$ such that both v_k and v_{k+1} are of degree two.*

Let $k \in \{1, 2, \ldots, n\}$ be an index such that both v_k and v_{k+1} are of degree two, and let $e_i := v_i v_{i+1}$ for each $i \in \{k - 1, k, k + 1\}$. Note that if a perfect matching of G does not contain $e_k = v_k v_{k+1}$, then it has to contain both $e_{k-1} = v_{k-1} v_k$ and $e_{k+1} = v_{k+1} v_{k+2}$. We consider the following two cases separately.

Case 1: We first consider the case with $v_{k-1}v_{k+2} \notin E$. In this case, we can see that e_k is not contained in any cycles of length four, and hence e_k is never touched by any flip operation. Thus, we consider one of the following three sub-cases.

- If $e_k \in M_{\mathrm{s}} \triangle M_{\mathrm{t}}$, then we can immediately conclude that $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ is a no-instance.
- If $e_k \in M_{\mathrm{s}} \cap M_{\mathrm{t}}$, then we solve the smaller instance $(G - \{v_k, v_{k+1}\}, M_{\mathrm{s}} \setminus \{e_k\}, M_{\mathrm{t}} \setminus \{e_k\})$.
- If $e_k \notin M_{\mathrm{s}} \cup M_{\mathrm{t}}$, then we solve the smaller instance $(G - \{v_{k-1}, v_k, v_{k+1}, v_{k+2}\}, M_{\mathrm{s}} \setminus \{e_{k-1}, e_{k+1}\}, M_{\mathrm{t}} \setminus \{e_{k-1}, e_{k+1}\})$.

Case 2: We next consider the case with $v_{k-1}v_{k+2} \in E$. Then, $G[\{v_{k-1}, v_k, v_{k+1}, v_{k+2}\}]$ forms a cycle of length four. For each $i \in \{\mathrm{s}, \mathrm{t}\}$, we define

$$M'_i := \begin{cases} M_i \setminus \{e_k\} & \text{if } e_k \in M_i, \\ (M_i \setminus \{e_{k-1}, e_{k+1}\}) \cup \{v_{k-1}v_{k+2}\} & \text{otherwise.} \end{cases}$$

Let $G' = G - \{v_k, v_{k+1}\}$, and we solve the smaller instance $(G', M'_{\mathrm{s}}, M'_{\mathrm{t}})$.

In either case, we can reduce the original instance $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ to a smaller instance, which implies that our algorithm runs in polynomial time. Indeed, we can implement the above arguments so that the algorithm runs in linear time. (The details are omitted.) The correctness of Case 1 is obvious, while the correctness of Case 2 is guaranteed as follows.

▶ **Lemma 11** (∗). *$(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ is a* yes*-instance if and only if $(G', M'_{\mathrm{s}}, M'_{\mathrm{t}})$ is a* yes*-instance.*

This completes the proof of Theorem 8. ◀

3.3 Cographs

We consider cographs in this subsection. Cographs, also known as P_4-free graphs, are graphs without a path on four vertices as an induced subgraph. As examples concerning reconfiguration on this class of graphs, it is known that the problems INDEPENDENT SET RECONFIGURATION and STEINER TREE RECONFIGURATION can be solved in polynomial time for cographs [3, 4, 26], while they are PSPACE-complete for general graphs [21, 26]. We will show that the situation is similar for PERFECT MATCHING RECONFIGURATION.

To describe our algorithm for cographs, we generalize our problem to non-perfect matchings. In the generalized problem, we regard that two matchings are *adjacent* if their symmetric difference is either a cycle of length four, or a path on three vertices. Note that any two adjacent matchings have the same size. Then, the generalized problem is defined as follows:

GENERAL MATCHING RECONFIGURATION
Input: Graph G, two matchings M_{s} and M_{t} of G.
Question: Is there a sequence of adjacent matchings that transforms M_{s} into M_{t}?

An instance of the generalized problem is also denoted by a triple $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$, and a sequence of adjacent matchings is also called a *reconfiguration sequence*. $(G, M_{\mathrm{s}}, M_{\mathrm{t}})$ is clearly a no-instance if $|M_{\mathrm{s}}| \neq |M_{\mathrm{t}}|$, and hence we assume that $|M_{\mathrm{s}}| = |M_{\mathrm{t}}|$ holds.

Our main result of this subsection is the following theorem.

▶ **Theorem 12** (∗). GENERAL MATCHING RECONFIGURATION *can be solved in polynomial time for cographs. Moreover, for a* yes*-instance, a reconfiguration sequence of linear length can be output in polynomial time.*

We note that when two input matchings are perfect, every connected component in their symmetric difference is a cycle. Therefore, even in the generalized problem, two adjacent perfect matchings differ by a flip operation on a cycle of length four. We thus obtain the following result as a corollary of Theorem 12.

▶ **Corollary 13.** Perfect Matching Reconfiguration *can be solved in polynomial time for cographs. Moreover, for a* yes*-instance, a reconfiguration sequence of linear length can be output in polynomial time.*

As a proof of Theorem 12, we give such an algorithm in this subsection. We will use the recursive characterization of cographs. For two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, their *disjoint union* $G_1 \cup G_2$ is the graph such that $V(G_1 \cup G_2) = V_1 \cup V_2$ and $E(G_1 \cup G_2) = E_1 \cup E_2$, while their *complete join* $G_1 \vee G_2$ is the graph such that $V(G_1 \vee G_2) = V_1 \cup V_2$ and $E(G_1 \vee G_2) = E_1 \cup E_2 \cup \{vw \mid v \in V_1, w \in V_2\}$. Then, a *cograph* can be recursively defined, as follows:

- a graph consisting of a single vertex is a cograph;
- if G_1 and G_2 are cographs, then their disjoint union $G_1 \cup G_2$ is a cograph; and
- if G_1 and G_2 are cographs, then their complete join $G_1 \vee G_2$ is a cograph.

Let $(G, M_\mathrm{s}, M_\mathrm{t})$ be a given instance of General Matching Reconfiguration such that $G = (V, E)$ is a cograph. By Lemma 5 we assume without loss of generality that G is connected and $|V| \geq 4$, and hence $G = G_1 \vee G_2$ for two cographs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$. Assume that $|V_1| \geq |V_2|$, and let $k := |M_\mathrm{s}| = |M_\mathrm{t}|$. We first give a sufficient condition for which there exists a reconfiguration sequence between M_s and M_t.

▶ **Lemma 14** (∗)**.** *There is a reconfiguration sequence between M_s and M_t if G has a matching M of size k such that at least one of the following two conditions holds:*
(C1) *$M \cap E_2 \neq \emptyset$; and*
(C2) *at least one vertex of G_2 is not covered by M.*
Furthermore, a reconfiguration sequence of linear length can be output in polynomial time.

We claim that this sufficient condition can be checked in polynomial time. The existence of a matching satisfying the condition **(C1)** can be checked as follows: For each edge $vw \in E_2$, we check if the graph $G - \{v, w\}$ has a matching of size $k - 1$, or not. This can be done in polynomial time since a maximum matching in a graph can be computed in polynomial time. Similarly, the condition **(C2)** can be checked in polynomial time, as follows: For each vertex $v \in V_2$, we check if the graph $G - \{v\}$ has a matching of size k, or not.

We then consider the case where the sufficient condition of Lemma 14 does not hold. Recall that $G = G_1 \vee G_2$ and $|V_1| \geq |V_2|$.

▶ **Lemma 15** (∗)**.** *Suppose that G does not have a matching of size k satisfying the conditions* **(C1)** *or* **(C2)** *of Lemma 14. Then, the following two claims hold.*

- *$(G, M_\mathrm{s}, M_\mathrm{t})$ is a* yes*-instance if and only if $(G_1, M_\mathrm{s} \cap E_1, M_\mathrm{t} \cap E_1)$ is a* yes*-instance.*
- *For a* yes*-instance $(G, M_\mathrm{s}, M_\mathrm{t})$, a reconfiguration sequence between M_s and M_t of linear length can be output in polynomial time.*

The above arguments can be implemented so that the algorithm runs in polynomial time, since we reduce the original instance $(G, M_\mathrm{s}, M_\mathrm{t})$ to a smaller instance $(G_1, M_\mathrm{s} \cap E_1, M_\mathrm{t} \cap E_1)$.

This completes the proof of Theorem 12. ◀

4 Conclusion

We introduced the Perfect Matching Reconfiguration problem and analyzed its complexity from the viewpoint of graph classes. We showed that this problem is PSPACE-complete on split graphs and bipartite graphs of bounded bandwidth and maximum degree five.

Furthermore, we gave polynomial-time algorithms for strongly orderable graphs, outerplanar graphs, and cographs. Each of the algorithms outputs a reconfiguration sequence of linear length in polynomial time.

A natural open question is on which graph classes a *shortest* reconfiguration sequence can be found in polynomial time. Furthermore, it would be interesting to investigate if the flip operation can be used in order to sample perfect matchings uniformly.

Abstract

The spectra of signed matrices have played a fundamental role in social sciences, graph theory, and control theory. In this work, we investigate the computational problems of *finding* symmetric signings of matrices with natural spectral properties. Our results are the following:

1. We characterize matrices that have an invertible signing: a symmetric matrix has an invertible symmetric signing *if and only if* the support graph of the matrix contains a perfect 2-matching. Further, we present an efficient algorithm to search for an invertible symmetric signing.
2. We use the above-mentioned characterization to give an algorithm to find a minimum increase in the support of a given symmetric matrix so that it has an invertible symmetric signing.
3. We show NP-completeness of the following problems: verifying whether a given matrix has a symmetric signing that is singular or has bounded eigenvalues. However, we also illustrate that the complexity could differ substantially for input matrices that are adjacency matrices of graphs.

We use combinatorial techniques in addition to classic results from matching theory.

1 Introduction

The spectra of several graph-related matrices such as the adjacency and the Laplacian matrices have become fundamental objects of study in computer science. In this work, we undertake a systematic and comprehensive investigation of the spectrum and the invertibility of *symmetric signings* of matrices. We study natural spectral properties of symmetric signed

matrices and address the computational problems of finding and verifying the existence of symmetric signings with these spectral properties.

For a real-valued symmetric $n \times n$ matrix M and a $\{\pm 1\}$-valued $n \times n$ matrix s – which we refer to as a *signing* – we define the *signed matrix* $M(s)$ to be the matrix obtained by taking entry-wise products of M and s. Signed adjacency matrices (respectively, Laplacians) correspond to signed matrices $M(s)$ where M is the adjacency matrix (respectively, Laplacian) of a graph. We say that s is a *symmetric* signing if s is a symmetric matrix and an *off-diagonal* signing if all the diagonal entries of s are $+1$. In this work we consider the following computational problems:

BoundedEvalueSigning: Given a real symmetric matrix M and a real number λ, verify if there exists an off-diagonal symmetric signing s such that the largest eigenvalue $\lambda_{\max}(M(s))$ is at most λ.

IncludeSigning: Given a real symmetric matrix M and a real number λ, verify if there exists an off-diagonal symmetric signing s such that $M(s)$ has λ as an eigenvalue.

AvoidSigning: Given a real symmetric matrix M and a real number λ, verify if there exists a symmetric signing s such that $M(s)$ does not have λ as an eigenvalue.

It suffices to focus on instances where λ is 0. Indeed, solving an instance of one of the above problems on input (M, λ) corresponds exactly to solving the same problem on input $(M - \lambda I, 0)$. Hence, we focus our attention on the corresponding specialized problems:

NsdSigning: Given a real symmetric matrix M, verify if there exists a symmetric signing s such that $M(s)$ is negative semi-definite.

SingularSigning: Given a real symmetric matrix M, verify if there exists an off-diagonal symmetric signing s such that $M(s)$ is singular.

InvertibleSigning: Given a real symmetric matrix M, verify if there exists a symmetric signing s such that $M(s)$ is invertible (that is, non-singular).

1.1 Motivations

Spectra of Signed Matrices and Expanders. Let G be a connected d-regular graph on n vertices and let $d = \lambda_0 > \lambda_1 \geq \cdots \geq \lambda_{n-1}$ be the eigenvalues of its adjacency matrix. Then G is a Ramanujan expander if $\max_{|\lambda_i|<d} |\lambda_i| \leq 2\sqrt{d-1}$. Efficient construction of Ramanujan expanders of arbitrary degrees remains an important open problem.[1] A combinatorial approach to this problem, initiated by Friedman [9], is to obtain larger Ramanujan graphs from smaller ones while preserving the degree. A 2-*lift* H of G is obtained as follows: Introduce two copies of each vertex u of G, say u_1 and u_2, as the vertices of H and for each edge $\{u, v\}$ in G, introduce either $\{u_1, v_2\}, \{u_2, v_1\}$ or $\{u_1, v_1\}, \{u_2, v_2\}$ as edges of H. There is a bijection between 2-lifts and symmetric signed adjacency matrices of G. Furthermore, the eigenvalues of the adjacency matrix of a 2-lift H are given by the union of the eigenvalues of the adjacency matrix of the base graph G (also called the “old” eigenvalues) and the signed adjacency matrix of G that corresponds to the 2-lift. (the “new” eigenvalues).

Marcus, Spielman, and Srivastava [16] showed that every d-regular bipartite graph has a 2-lift whose new eigenvalues are bounded in absolute value by $2\sqrt{d-1}$. However, this result [16] is not constructive and their work raises the question of whether there is an efficient

[1] While efficient construction of bipartite Ramanujan *multi-graphs* of all degrees is known [5], it still remains open to efficiently construct bipartite Ramanujan *simple* graphs of all degrees.

algorithm to find a symmetric signing that minimizes the largest eigenvalue. This motivates investigating BoundedEvalueSigning which is the decision variant of the computational problem. More precisely, it motivates investigating BoundedEvalueSigning when the input matrix is an adjacency matrix.

It is also natural to investigate the complexity of several related problems. As we will see in the next section, BoundedEvalueSigning is NP-hard for arbitrary symmetric matrices. The reduction which shows BoundedEvalueSigning is NP-hard suggests a close relationship with AvoidSigning which is also NP-hard. Hoping to make progress on BoundedEvalueSigning for adjacency matrices, we investigate AvoidSigning for adjacency matrices. IncludeSigning arises naturally as the complement of AvoidSigning.

Solvability Index of a Signed Matrix. The notion of *balance* of a symmetric signed matrix has been studied extensively in social sciences [14, 11, 13, 17]. A signed adjacency matrix is *balanced* if there is a partition of the vertex set such that all edges within each part are positive, and all edges in between two parts are negative (one of the parts could be empty). A number of works [3, 10, 18, 17, 19, 20] have explored the problem of minimally modifying signed graphs (or signed adjacency matrices) to convert it into a balanced graph.

In this work, we introduce a related problem regarding symmetric signed matrices: Given a symmetric matrix M, what is the smallest number of non-diagonal zero entries of M whose replacement by non-zeroes gives a symmetric matrix M' that has an invertible symmetric signing? We define this quantity to be the *solvability index*[2]. Knowing this number might be helpful in studying systems of linear equations in signed matrices that might be ill-defined, and thus do not have a (unique) solution and in minimally modifying such matrices so that the resulting linear system becomes (uniquely) solvable. We use classic graph-theoretic techniques to show that solvability index is indeed computable efficiently.

1.2 Our Results

Intriguingly, the complexity of BoundedEvalueSigning has not been studied in the literature even though it is widely believed to be a difficult problem in the graph sparsification community. We shed light on this problem by showing that it is NP-complete.

▶ **Theorem 1.** NsdSigning *and* SingularSigning *are NP-complete.*

Theorem 1 also implies that BoundedEvalueSigning and AvoidSigning are NP-complete. In contrast to SingularSigning, we show that InvertibleSigning admits an efficient algorithm. In fact, we show a stronger result: there exists an algorithm to efficiently solve the search variant of InvertibleSigning, which we denote by SearchInvertibleSigning (here the goal is to *find* an invertible signing if it exists).

▶ **Theorem 2.** *There exists a polynomial-time algorithm to solve* SearchInvertibleSigning*.*

Theorem 2 also implies that the search variant of IncludeSigning is solvable efficiently. Our proof of Theorem 2 leads to a structural characterization for the existence of invertible signings through the existence of *perfect* 2*-matchings* in the support graph of the matrix.

[2] Our definition of *solvability index* is similar to the notion of *frustration index* [12, 1]. The *frustration index* of a matrix M is the minimum number of non-zero off-diagonal entries of M whose deletion results in a *balanced signed graph*. Computing the frustration index of a signed graph is NP-hard [15].

We believe that this structural characterization could be of independent interest and hence, discuss it in detail in Section 1.2.1.

The hard instances generated by our proof of Theorem 1 are real symmetric matrices with non-zero diagonal entries and hence, it does not resolve the computational complexity of the problem of finding a signing of a given *graph-related* matrix (for example, the adjacency matrix) that minimizes its largest eigenvalue. Our next result provides some evidence that one might be able to design efficient algorithms to solve the NP-complete problems appearing in Theorem 1 for graph-related matrices. In particular, we show that SINGULARSIGNING and its search variant admit efficient algorithms when the input matrix corresponds to the adjacency matrix of a *bipartite* graph.

▶ **Theorem 3.** *There exists a polynomial-time algorithm to verify if the adjacency matrix A_G of a given bipartite graph G has a symmetric signing s such that $A_G(s)$ is singular; and if so, find such a signing.*

Finally, we define the *solvability index* of a real symmetric matrix M to be the smallest number of non-diagonal zero entries that need to be converted to non-zeroes so that the resulting symmetric matrix has an invertible symmetric signing. We emphasize that the support-increase operation that we consider preserves symmetry, that is, if we replace the zero entry $A[i,j]$ by α, then the zero entry $A[j,i]$ is also replaced by α. We give an efficient algorithm to find the solvability index of a given symmetric matrix M.

▶ **Theorem 4.** *There exists a polynomial-time algorithm to find the solvability index of a given real symmetric matrix.*

1.2.1 Structural Characterization for Invertible Signings

Theorem 2, in particular, implies that INVERTIBLESIGNING is solvable efficiently. In fact, our proof-technique gives an efficient characterization for the existence of an invertible signing. This characterization also leads to an alternative algorithm to solve INVERTIBLESIGNING. We believe that this characterization might be of independent interest and hence describe it here.

The *support graph* of a real symmetric $n \times n$ matrix M is an undirected graph G where the vertex set of G is $[n] := \{1, \ldots, n\}$, and the edge set of G is $\big\{\{u,v\} \mid M[u,v] \neq 0\big\}$. We note that G could have self-loops depending on the diagonal entries of M. A *perfect 2-matching* in a graph G with edge set E is an assignment $x : E \to \{0,1,2\}$ of values to the edges such that $\sum_{e \in \delta(v)} x_e = 2$ holds for every vertex v in G (where $\delta(v)$ denotes the set of edges incident to v). Equivalently, a perfect 2-matching in a graph G is a vertex-disjoint union of edges and cycles (cycles could be loop edges) in G such that each vertex is incident to at least one edge. We show the following characterization:

▶ **Theorem 5.** *Let M be a symmetric $n \times n$ matrix and let G be the support graph of M. The following are equivalent:*

(i) *There exists a symmetric signing s such that the signed matrix $M(s)$ is invertible.*

(ii) *The support graph G contains a perfect 2-matching.*

▶ Remark 1. The structural characterization of Theorem 5 leads to a polynomial-time algorithm to solve INVERTIBLESIGNING – it suffices to verify if the support graph of the input matrix contains a perfect 2-matching which can be done in polynomial-time.

▶ Remark 2. We present a constructive proof of Theorem 5 via a generalization (see Theorem 8 in Section 2). Our proof of Theorem 5 is constructive but we are aware of a non-constructive proof using Combinatorial Nullstellensatz. This alternative non-constructive proof is available online in an earlier arXiv version of this [4].

1.3 Related Work

Skew Symmetric Matrix of Indeterminates. A square skew-symmetric matrix of indeterminates with zeroes on the diagonal is known as the *Tutte matrix* of its support graph. A well-known result by Tutte shows that the determinant polynomial of the Tutte matrix is non-zero if and only if the corresponding support graph has a perfect matching. Our result in Theorem 5 can be interpreted as a variant of Tutte's result to square *symmetric* matrices of indeterminates with zeros on the diagonal.

Cunningham and Geelen [6] extended Tutte's work along a different direction by giving a characterization of invertible submatrices of the Tutte matrix using *path-matchings*. Given a graph G with vertex set V and vertex subsets $R, L \subseteq V$, a (R, L)-*path-matching* in G is a collection of vertex-disjoint paths from R to L and edges in $G[V \setminus (R \cup L)]$. A *perfect* (R, L)-path-matching is a (R, L)-path-matching in which every vertex in G is incident to some edges of the vertex-disjoint paths. They showed that the determinant polynomial of a square submatrix of the Tutte matrix of G with column set R and row set L is non-zero if and only if there exists a perfect (R, L)-path-matching in G. The notion of *cycle-covers* that we introduce in Section 2 and our result in Theorem 8 can be interpreted as variants of Cunningham and Geelen's result to square *symmetric* matrices of indeterminates with zeros on the diagonal.

Our results in Theorems 5 and 8 go further than Cunningham and Geelen's result by not only giving similar characterizations for the determinant to be a non-zero polynomial but also by giving polynomial-time algorithms to find a point in $\{\pm 1\}^E$ at which the polynomial is non-zero.

Minimum Rank Problems. A line of work seemingly related to ours is the minimum rank problem (e.g., see [8, 7]): given a graph G, the goal is to compute the minimum rank of the weighted adjacency matrix of a graph obtained by giving non-zero real-valued weights to the edges of G. We emphasize that the allowed weights in the minimum rank problem are arbitrary and are not simply signs of the given adjacency matrix as in the case of our work. A signed variant of the minimum rank problem has also been addressed in the literature: given a sign pattern matrix S, the goal is to compute the minimum rank of a matrix with real-valued entries whose sign pattern is identical to S. Once again, we emphasize the distinction between the signed variant of the minimum rank problem and the problems studied in our work: in the signed variant of the minimum rank problem, the sign pattern is the input and the goal is to find a matrix with real-valued entries matching the input sign pattern and achieving minimum rank. In contrast, the problems studied in our work have real-valued entries as inputs and the goal is to find a symmetric sign pattern of the entries to achieve the specified spectral properties.

A year after posting our work on arXiv [4], Akbari, Ghafari, Kazemian, and Nahvi [2] also posted an article addressing InvertibleSigning[3]. They show the same characterization as Theorem 5 with a proof identical to the non-constructive proof appearing in the early arXiv version of our work [4]. We emphasize that in addition to showing the structural characterization in Theorem 5, this work resolves the search problem in Theorem 2, and

[3] Our arXiv post dated Nov, 2016: `https://arxiv.org/abs/1611.03624`; the post by Akbari, Ghafari, Kazemian, and Nahvi dated Aug, 2017: `https://arxiv.org/abs/1708.07118`.

moreover shows a much more general structural characterization in Theorem 8 with a constructive proof.

1.4 Organization

In Section 1.5, we review definitions and notations. In Section 2, we describe an efficient algorithm to find an invertible signing (Theorem 2). Due to space constraints, we refer the reader to the full version of the paper for all missing proofs [4].

1.5 Preliminaries

Unless otherwise specified, all matrices are symmetric and take values over the reals. Since all of our results are for symmetric signings, we will just use the term *signing* to refer to a symmetric signing in the rest of this work. We denote the entry-wise product of two $n \times n$ matrices M and s as $M(s)$ (even when s is not necessarily a signing).

Let S_n be the set of permutations of n elements, M be a real symmetric $n \times n$ matrix, and s be a symmetric $n \times n$ signing. Then, the *permutation expansion* of the determinant of a signed matrix $M(s)$ is given by

$$\det M(s) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \cdot \prod_{i=1}^{n} M(s)[i, \sigma(i)].$$

A permutation σ in S_n has a unique cycle decomposition and hence corresponds to a vertex-disjoint union of directed cycles on n vertices. Removing the orientation gives an undirected graph which is a vertex disjoint union of cycles, self-loops, and matching edges.

2 Finding Invertible Signings

In this section, we focus on invertible signings and the proof of Theorem 2. We prove a much more general statement in comparison to the one given in Theorem 5, which we believe could be of independent interest. We start by introducing the background needed to state the general version.

Symmetric signings of asymmetric sub-matrices. Let M be a symmetric $n \times n$ matrix. For $X, Y \subseteq [n]$ being a subset of row and column indices of the same cardinality, let $M[X, Y]$ denote the submatrix of M obtained by picking the rows in X and the columns in Y. We note that $M[X, Y]$ is a square matrix, but it may *not* be symmetric even though M is symmetric. We are interested in finding a symmetric $n \times n$ signing s so that the square submatrix $M(s)[X, Y]$ is invertible. We emphasize that for a symmetric signing s, the (possibly asymmetric) matrix $M(s)[X, Y]$ is symmetric on $X \cap Y$, that is, the $[i, j]$'th and the $[j, i]$'th entries of the matrix $M(s)[X, Y]$ are the same for every $i, j \in X \cap Y$.

Perfect 2-matchings in subgraphs. Let G be a simple undirected graph, possibly containing self-loops. Let X, Y be vertex subsets of G. We consider the subgraph $G[X \cup Y]$ induced by $X \cup Y$. An (X, Y)-*cycle-cover* is a collection of edges of the subgraph $G[X \cup Y]$ that induce a vertex-disjoint union of paths and cycles (cycles could be loop edges) in $G[X \cup Y]$ such that (1) every cycle is a subgraph of $G[X \cap Y]$, (2) every vertex of $X \cup Y$ is incident to at least one edge, and (3) every path either has one end-vertex in $X \setminus Y$, the other end-vertex in $Y \setminus X$, and all intermediate vertices in $X \cap Y$, or has both end-vertices in $X \cap Y$ with only one edge (see Figure 1 for an example). We note that (X,X)-cycle-covers correspond to perfect 2-matchings in $G[X]$ and hence, (V,V)-cycle-covers correspond to perfect 2-matchings in G. It follows that in (X,X)-cycle-covers all paths are only a single edge in G. Furthermore, the existence of an (X,Y)-cycle-cover is possible only if $|X|=|Y|$. The following lemma states that the existence of an (X,Y)-cycle-cover in a given graph can be verified efficiently.

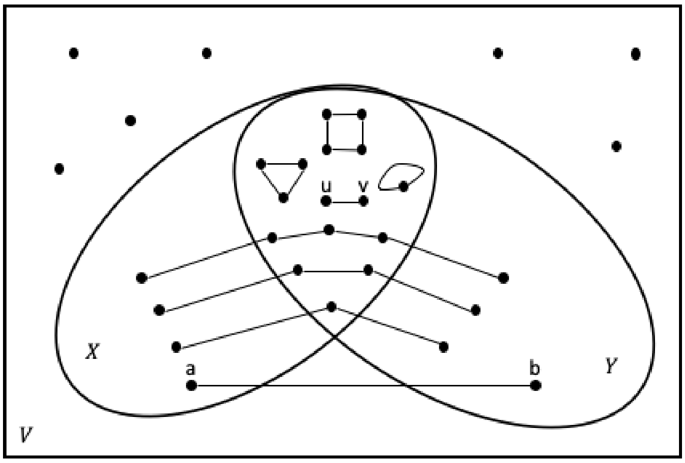

Figure 1 An (X,Y)-cycle-cover F. Furthermore, by our definitions below, the edge $\{a,b\}$ is in Paths(F) while the edge $\{u,v\}$ is in Matchings(F).

▶ **Lemma 6.** *There exists a polynomial-time algorithm that decides if there is an (X,Y)-cycle-cover in a given graph G for given vertex subsets X,Y of G.*

The key observation to prove Lemma 6 is that finding an (X,Y)-cycle-cover can be reduced to finding a perfect matching in an auxiliary bipartite graph.

Let $M \in \mathbb{R}^{n\times n}$ be a symmetric matrix, $X,Y \subseteq [n]$ with $|X|=|Y|$ and s be a symmetric $n\times n$ matrix. Recall that we are interested in finding a symmetric $n\times n$ signing s so that the square submatrix $M(s)[X,Y]$ is invertible. We derive a convenient expression for $\det(M(s)[X,Y])$ that is based on (X,Y)-cycle-covers. For an (X,Y)-cycle-cover F, let Cycles(F), Paths(F), and Matchings(F) denote the set of cycles in F, paths in F with end-vertices in $X\setminus Y$ and $Y\setminus X$, and paths in F that are contained in $G[X\cap Y]$, respectively. Moreover, let Loops(F) and NTCs(F) denote the set of self-loops and non-trivial-cycles in F. We emphasize that Cycles(F) = Loops(F) ∪ NTCs(F). We also note that Cycles(F), Paths(F), and Matchings(F) are all vertex-disjoint from one another and if $X=Y$ then Paths$(F)=\emptyset$. We define

$$\begin{aligned} M(s)_{\mathrm{Cycles}(F)} &:= \prod_{C\in\mathrm{Cycles}(F)}\ \prod_{\{u,v\}\in C} M(s)[u,v], \\ M(s)_{\mathrm{Paths}(F)} &:= \prod_{P\in\mathrm{Paths}(F)}\ \prod_{\{u,v\}\in P} M(s)[u,v], \text{ and} \\ M(s)_{\mathrm{Matchings}(F)} &:= \prod_{\{u,v\}\in\mathrm{Matchings}(F)} M(s)[u,v]^2. \end{aligned}$$

With this notation, we have the following claim that the determinant of $M(s)[X,Y]$ is a $\{\pm1\}$-linear combination of terms corresponding to (X,Y)-cycle-covers in G.

▶ **Lemma 7** ($(\boldsymbol{X},\boldsymbol{Y})$-cycle-cover expansion)**.** *Let $M \in \mathbb{R}^{n\times n}$ be a symmetric $n \times n$ matrix, $X, Y \subseteq [n]$ with $|X| = |Y|$, and s be a symmetric $n \times n$ matrix. Let G be the support graph of M and $\mathcal{F}$ be the set of all (X,Y)-cycle-covers in G. Then, there exists $\lambda_F \in \{\pm 1\}$ for all $F \in \mathcal{F}$ such that*

$$\det(M(s)[X,Y]) = \sum_{F\in\mathcal{F}} \lambda_F \cdot 2^{|NTCs(F)|} \cdot M(s)_{Cycles(F)} \cdot M(s)_{Paths(F)} \cdot M(s)_{Matchings(F)}.$$

Moreover, if there are $F_1, F_2 \in \mathcal{F}$ such that $Cycles(F_1) = Cycles(F_2)$ and $Paths(F_1) = Paths(F_2)$ then $\lambda_{F_1} = \lambda_{F_2}$.

Proof. For simplicity, we denote $M' = M[X,Y]$. Let $k := |X|$ and let S_k denote the set of permutations on k elements. Then, by the permutation expansion of the determinant, we have

$$\det(M'(s)) = \sum_{\sigma\in S_k} \mathrm{sgn}(\sigma) \cdot \prod_{i=1}^{k} s[i,\sigma(i)] \cdot M'[i,\sigma(i)].$$

We recall that $\mathrm{sgn}(\sigma) \in \{\pm 1\}$. Moreover, if $\sigma_1, \sigma_2 \in S_k$ such that σ_1 and σ_2 have the same cycle structure then $\mathrm{sgn}(\sigma_1) = \mathrm{sgn}(\sigma_2)$. Now, we note that there is a one-to-one correspondence between S_k and bijections from X to Y. So, we may view $\sigma \in S_k$ as a bijection $\sigma' : X \to Y$. Now, consider the graph $H_{\sigma'}$ on vertex set $X \cup Y$ and edge set $F_{\sigma'} := \{\{u,v\} \mid \sigma'(u) = v\}$. Since σ' is a bijection, it follows that $F_{\sigma'}$ is an (X,Y)-cycle-cover in the complete graph on vertex set $X \cup Y$. Moreover, since each non-trivial-cycle in an (X,Y)-cycle-cover can take one of two orientations in any corresponding permutation, there are $2^{|\mathrm{NTCs}(F)|}$ distinct permutations which map to each (X,Y)-cycle-cover F. Hence,

$$\begin{aligned}\prod_{i=1}^{n} s[i,\sigma(i)] \cdot M'[i,\sigma(i)] &= \prod_{u\in X} s[u,\sigma(u)] \cdot M[u,\sigma'(u)] \\ &= M(s)_{\mathrm{Cycles}(F_{\sigma'})} \cdot M(s)_{\mathrm{Paths}(F_{\sigma'})} \cdot M(s)_{\mathrm{Matchings}(F_{\sigma'})}.\end{aligned}$$

The above-term is non-zero only if $F_{\sigma'}$ is an (X,Y)-cycle-cover in the support graph of G. Furthermore, if $F_1, F_2 \in \mathcal{F}$ such that $\mathrm{Cycles}(F_1) = \mathrm{Cycles}(F_2)$ and $\mathrm{Paths}(F_1) = \mathrm{Paths}(F_2)$ then $\lambda_{F_1} = \lambda_{F_2}$ since the corresponding permutations would have the same cycle structure. ◀

To prove Theorems 5 and 2, we show the following theorem which gives a generalized structural characterization: it characterizes the existence of invertible symmetric signings for (potentially asymmetric) submatrices of symmetric matrices.

▶ **Theorem 8.** *Let M be a real symmetric $n \times n$ matrix with support graph G and $X, Y \subseteq [n]$ with $|X| = |Y|$. The following are equivalent:*

(i) *There exists an (X,Y)-cycle-cover in G.*

(ii) *There exists a symmetric signing s such that $M(s)[X,Y]$ is invertible.*

Moreover, there exists a polynomial-time algorithm that takes a real symmetric $n \times n$ matrix M and $X, Y \subseteq [n]$ as input and verifies if there exists a symmetric signing s such that $M(s)[X,Y]$ is invertible and if so, find such a signing.

Notation. Let M be a real symmetric $n \times n$ matrix with support graph G. Let A and B be vertex subsets of G. We define $E[A,B]$ to be the set of edges with one end-vertex in A and the other end-vertex in B. We use $E[A]$ to denote $E[A,A]$. Let e be an edge in G corresponding to the non-zero entry $M[u,v]$ $(= M[v,u])$. We define $M^{\overline{e}}$ as the matrix obtained by setting $M[u, v]$ and $M[v, u]$ to 0. For a signing s and row and column indices $u, v \in [n]$, we can obtain another signing s' such that $s'[u, v] := -s[u, v]$, $s'[v, u] := -s[v, u]$ and $s'[i, j] := s[i, j]$ for every entry $(i, j) \in [n] \times [n] \setminus \{(u, v), (v, u)\}$. We call this operation as s' *obtained from* s *by flipping on* $\{u, v\}$.

Proof of Theorem 8. We first present a constructive proof of the characterization. We will then use the proof to design the algorithm.

Lemma 7 immediately shows that (ii) implies (i): If we have a symmetric signing s such that $M(s)[X, Y]$ is invertible, then at least one of the terms in the (X, Y)-cycle-cover expansion of $\det(M(s)[X, Y])$ is non-zero. Hence, there exists an (X, Y)-cycle-cover in G.

We show that (i) implies (ii). Suppose not. Among the counterexamples, consider the ones with $|X|$ minimum and among these, pick a matrix M with minimum number of non-zero entries. Without loss of generality, let M be an $n \times n$ matrix with support graph G and let $X, Y \subseteq [n]$ with $|X| = |Y|$. Since we chose a counterexample, we have that

(A) there exists an (X, Y)-cycle-cover in G, but

(B) there is no symmetric signing s such that $M(s)[X, Y]$ is invertible.

We will arrive at a contradiction by showing that a signing s satisfying (ii) exists. We begin with the following claim about the counterexample.

▷ Claim 9. $E[X \setminus Y, Y] = \emptyset$ and $E[Y \setminus X, X] = \emptyset$.

Proof. Suppose there exists an edge $e \in E[X \setminus Y, Y]$. Let $e := \{u, v\}$ with $u \in X \setminus Y$ and $v \in Y$. Then there exists $\alpha \in \{\pm 1\}$ such that the determinant of $M(s)[X, Y]$ can be expressed as a linear function of $s[u, v]$:

$$\det(M(s)[X, Y]) = \alpha \cdot s[u, v] \cdot M[u, v] \cdot \det(M(s)[X - u, Y - v]) + \det(M^{\overline{e}}(s)[X, Y]). \quad (1)$$

Case 1: Suppose there exists an (X, Y)-cycle-cover F containing e. We observe that $F - e$ is an $(X - u, Y - v)$-cycle-cover in G. Since we have a smallest counterexample, it follows that there exists a symmetric signing s such that $\det(M(s)[X - u, Y - v]) \neq 0$. Since $\det(M(s)[X, Y])$ is a linear function of $s[u, v]$, it follows that $\det(M(s)[X, Y]) \neq 0$ or $\det(M(s')[X, Y]) \neq 0$ where s' is a signing obtained from s by flipping on $\{u, v\}$. Hence, we have a contradiction to assumption B about the counterexample.

Case 2: Suppose that every (X, Y)-cycle-cover in G does not contain e. Then there is no $(X - u, Y - v)$-cycle-cover in G. Since (ii) implies (i), it follows that $\det(M(s)[X - u, Y - v]) = 0$ for every symmetric signing s. Let F be an (X, Y)-cycle-cover in G (as promised to exist by A). Then F is an (X, Y)-cycle-cover in $G - e$. Since we have a smallest counterexample, it follows that there exists a symmetric signing s such that $\det(M^{\overline{e}}(s)[X, Y]) \neq 0$. By (1), we observe that $\det(M(s)[X, Y]) \neq 0$. Thus, the symmetric signing s is a contradiction to assumption B about the counterexample.

Hence, $E[X \setminus Y, Y] = \emptyset$. Similarly $E[Y \setminus X, X] = \emptyset$. ◁

Now, if $X \setminus Y \neq \emptyset$ and there is no edge $e \in E[X \setminus Y, Y]$, then there is no (X, Y)-cycle-cover in G, a contradiction to assumption A about the counterexample. Hence, $X \setminus Y = \emptyset$. Similarly, $Y \setminus X = \emptyset$. Thus, we have $X = Y$ in the counterexample. We next show that the counterexample cannot have any self-loop edges.

▷ Claim 10. There are no self-loop edges in $E[X]$.

Proof. Suppose there exists a self-loop edge in $E[X]$. Let $e = \{u, u\}$ for some $u \in X$. Then, we again have that $\det(M(s)[X, Y])$ is a linear function of $s[u, u]$:

$$\det(M(s)[X, X]) = s[u, u] \cdot M[u, u] \cdot \det(M(s)[X - u, X - u]) + \det(M^{\overline{e}}(s)[X, X]). \quad (2)$$

We arrive at a contradiction by proceeding similar to the proof of the previous claim. We avoid restating the proof in the interests of brevity. ◁

By Claim 10, the counterexample has no self-loop edges in $E[X]$. Our next claim strengthens this further by showing that the counterexample has no (X, Y)-cycle-cover with cycle edges.

▷ Claim 11. Every (X, X)-cycle-cover in G has no cycles.

Proof. Suppose there exists an (X, X)-cycle-cover F in G with a cycle C induced by F. Let $e = \{u, v\}$ be an edge in the cycle. By Claim 10, we know that $u \neq v$. We observe that $\det(M(s)[X, X])$ is a quadratic function of $s[u, v]$, i.e., there exists $\alpha \in \{\pm 1\}$ such that the determinant of $M(s)[X, X]$ can be expressed as

$$\begin{aligned}\det(M(s)[X, X]) = &-s[u, v]^2 \cdot M[u, v]^2 \cdot \det(M(s)[X - \{u, v\}, X - \{u, v\}]) \\ &+ 2\alpha \cdot s[u, v] \cdot M[u, v] \cdot \det(M^{\overline{e}}(s)[X - u, X - v]) \\ &+ \det(M^{\overline{e}}(s)[X, X]).\end{aligned} \quad (3)$$

Furthermore, $F - e$ is an $(X - u, X - v)$-cycle-cover in G. Since we have a smallest counterexample, it follows that there exists a symmetric signing s such that $\det(M^{\overline{e}}(s)[X - u, X - v]) \neq 0$. We now define the quadratic function

$$\begin{aligned}f(x) := &-x^2 \cdot M[u, v]^2 \cdot \det(M(s)[X - \{u, v\}, X - \{u, v\}]) \\ &+ 2\alpha x \cdot M[u, v] \cdot \det(M^{\overline{e}}(s)[X - u, X - v]) + \det(M^{\overline{e}}(s)[X, X]),\end{aligned}$$

and consider the roots of the quadratic equation $f(x) = 0$. Since $\det(M^{\overline{e}}(s)[X-u, X-v]) \neq 0$, the sum of the roots of this quadratic equation is non-zero. Since the real roots of a quadratic function are symmetric about the extreme point of the parabola defined by the function (i.e., symmetric about $\arg\min f(x)$), there exists $x \in \{\pm 1\}$ that is *not* a root of $f(x)$. Hence, either $\det(M(s)[X, Y]) \neq 0$ or $\det(M(s')[X, Y]) \neq 0$ where s' is a signing obtained from s by flipping on $\{u, v\}$. Thus, either s or s' contradict assumption B about the counterexample. ◁

By Claims 9 and 10, the counterexample has $X = Y$ with no loop edges in $E[X]$. Furthermore, by Claim 11, every (X, X)-cycle-cover in G has no cycles. By definition of (X, X)-cycle-covers, it follows that each (X, X)-cycle-cover in G corresponds to a perfect matching in $G[X]$. Let N be an (X, X)-cycle-cover in G.

▷ Claim 12. N is the unique (X, X)-cycle-cover in G.

Proof. Let e be an arbitrary edge in N. Suppose there exists an (X, X)-cycle-cover N' in $G - e$. Then, Claims 10 and 11 imply that N' is also a perfect matching in $G[X]$. We consider $N'' := N \cup N'$. Since N and N' are perfect matchings in $G[X]$, the set of edges N'' induces a vertex-disjoint union of edges and cycles of even length in $G[X]$. Hence, N'' is an (X, X)-cycle-cover in G. Furthermore, since $e \in N \setminus N'$, it follows that N'' contains at least one cycle. This contradicts Claim 11. Thus, every edge $e \in N$ belongs to every (X, X)-cycle-cover in G. Consequently, N is the unique (X, X)-cycle-cover in G. ◁

Since N is the unique (X, X)-cycle-cover in G, by Lemma 7, we have that

$$\det(M(s)[X, X]) = (-1)^{|N|} \prod_{\{u,v\} \in N} M(s)[u, v]^2$$

which is non-zero for every signing s. Thus, there exists a symmetric signing s such that $\det(M(s)[X, X]) \neq 0$, a contradiction to assumption B about the counterexample. This completes the proof of the characterization. We note that the above proof of the characterization is constructive and immediately leads to the algorithm FindSigning(M, X, Y) in Algorithm 1.

Algorithm 1 The algorithm FindSigning(M, X, Y).

```
FindSigning($M, X, Y$):
Input: $M \in \mathbb{R}^{n \times n}$ with support graph $G$, and $X, Y \subseteq [n]$ satisfying $|X| = |Y|$.
Output: A symmetric signing $s \in \{\pm 1\}^{n \times n}$ such that $M(s)[X, Y]$ is invertible if
        such a signing exists.
  1. If $|X| = |Y| \leq 1$, then brute-force search for a symmetric signing $s$ for
     which $\det(M(s))[X, Y] \neq 0$:
       1.1. If such a signing exists, return $s$.
       1.2. Else return “No Invertible Signing”.
  2. If there exists no $(X, Y)$-cycle-cover then return “No Invertible Signing”.
  3. If $E[X \setminus Y, Y] \cup E[Y \setminus X, X] \neq \emptyset$:
       3.1. Pick $e := \{u, v\} \in E[X \setminus Y, Y]$ such that $u \in X \setminus Y$ and $v \in Y$.
       3.2. If there is no $(X - u, Y - v)$-cycle-cover in $G$:
              3.2.1 $s \leftarrow$ FindSigning($M^{\overline{e}}, X, Y$).
       3.3. Else: (when there is an $(X - u, Y - v)$-cycle-cover in $G$)
              3.3.1 $s \leftarrow$ FindSigning($M, X - u, Y - v$).
       3.4. If $M(s)[X, Y]$ is invertible then return $s$.
       3.5. Else return $s'$ obtained from $s$ by flipping on $\{u, v\}$.
  4. Else: (when sets $X$ and $Y$ are identical)
       4.1. If there exists an $(X, Y)$-cycle-cover in $G$ with a cycle edge $\{u, v\}$:
              4.1.1. $s \leftarrow$ FindSigning($M, X - u, Y - v$).
              4.1.2. If $M(s)[X, Y]$ is invertible then return $s$.
              4.1.3. Else return $s'$ obtained from $s$ by flipping on $\{u, v\}$.
       4.2. Else: (when all $(X, Y)$-cycle-covers are perfect matchings in $G[X]$)
              4.2.1 Return $\mathbf{1}$ (the all-positive signing).
```

We now describe an efficient implementation of the non-trivial steps in FindSigning. In Step 1, the algorithm performs a brute-force search. We note that the search needs to be conducted only for the entries $s[u, v]$ where $u, v \in X \cup Y$ since $\det(M(s)[X, Y])$ is independent of the remaining entries of the signing s. Since $|X \cup Y| \leq 2$, the search can be conducted in constant time by picking an arbitrary sign for the remaining entries.

Lemma 6 implies that Steps 2 and 3.2 can be implemented to run in polynomial time. We recall that any cycle edge in an (X, X)-cycle-cover must be a cycle edge in some perfect 2-matching in $G[X]$. Claim 13 shows that Step 4.1 can be implemented to run in polynomial time. Finally, the recursive algorithm terminates in polynomial time since each recursive call reduces either $|X \cup Y|$ or the number of non-zero entries in M. ◀

▷ Claim 13. There is a polynomial-time algorithm that given a graph, finds an edge that belongs to a cycle in some perfect 2-matching of the graph or decides that no such edge exists.

Algorithm 2 The algorithm FindCycleEdge(G).

```
FindCycleEdge($G$):
Input: A graph $G$ with vertex set $V$.
Output: An edge $e$ that is a cycle edge in some perfect 2-matching in $G$ if one exists.
  1. If there exists no perfect 2-matching in $G$ then return "No edge".
  2. Let $F$ be a perfect 2-matching in $G$.
  3. If $F$ contains a cycle $C$ then return any edge in $C$.
  4. For $e \in F$:
       4.1. Let $N_e$ be a perfect 2-matching in $G - e$ if one exists.
       4.2. If $N_e$ exists and has a cycle $C$ then return any edge in $C$.
  5. If Step 4 finds $N_e$ for some $e \in F$, then return $e$.
  6. Else return "No edge".
```

Proof. To prove the claim we consider the algorithm FindCycleEdge(G) in Algorithm 2. If at any point we find a perfect 2-matching with a cycle then we return an edge from it. Hence, it only remains to show the correctness of Steps 5 and 6. Let F be a perfect 2-matching with no cycle edge. Suppose there exists a perfect 2-matching N_e for some edge e with no cycle edge. Then N_e and F are both perfect matchings in G. It follows that $N_e \cup F$ will be a perfect 2-matching where e is in a cycle and hence Step 5 is correct to return e. Now suppose that for all e there is no perfect 2-matching N_e. It follows that G has one unique perfect 2-matching F that is a perfect matching and hence Step 6 correctly returns that no cycle edge exists.

Using the algorithm from Lemma 6 we can perform Steps 1, 2, and 4.1 in polynomial time. Thus, FindCycleEdge(G) runs in polynomial time. ◁

Efficient Analysis of Unambiguous Automata Using Matrix Semigroup Techniques

Stefan Kiefer
University of Oxford, UK

Cas Widdershoven
University of Oxford, UK

Abstract

We introduce a novel technique to analyse unambiguous Büchi automata quantitatively, and apply this to the model checking problem. It is based on linear-algebra arguments that originate from the analysis of matrix semigroups with constant spectral radius. This method can replace a combinatorial procedure that dominates the computational complexity of the existing procedure by Baier et al. We analyse the complexity in detail, showing that, in terms of the set Q of states of the automaton, the new algorithm runs in time $O(|Q|^4)$, improving on an efficient implementation of the combinatorial algorithm by a factor of $|Q|$.

1 Introduction

Given a finite automaton $\mathcal{A}$, what is the proportion of words accepted by it? This question is natural but imprecise: there are infinitely many words and the proportion of accepted words may depend on the word length. One may consider the sequence $d_0, d_1, \ldots$ where d_i is the proportion of length-i words accepted by $\mathcal{A}$, i.e., $d_i = \frac{|L(\mathcal{A}) \cap \Sigma^i|}{|\Sigma|^i}$. The sequence does not necessarily converge, but one may study, e.g., possible limits and accumulation points [5].

Alternatively, one can specify a probability distribution on words, e.g., with a Markov chain, and ask for the probability that a word is accepted by $\mathcal{A}$. For instance, if $\Sigma = \{a, b\}$, one may generate a random word, letter by letter, by outputting a, b with probability $1/3$ each, and ending the word with probability $1/3$. For an NFA $\mathcal{A}$, determining whether the probability of generating an accepted word is 1 is equivalent to universality (is $L(\mathcal{A}) = \Sigma^*$?), a PSPACE-complete problem. However, if $\mathcal{A}$ is unambiguous, i.e., every accepted word has exactly one accepting path, then one can compute the probability of generating an accepted word in polynomial time by solving a linear system of equations. Unambiguousness allows us to express the probability of a union as the sum of probabilities:

▶ **Example 1.** Consider the unambiguous automaton $\mathcal{A}$ in Figure 1 (left). If we generate a random word over $\{a, b\}$ according to the process described above, we have the following linear system for the vector $\vec{z}$ where $\vec{z}_q$ is, for each $q \in \{q_0, q_1, q_2, q_3\}$, the probability that the word is accepted when q is taken as initial state:

$$\begin{aligned} \vec{z}_{q_0} &= \tfrac{1}{3}\vec{z}_{q_1} + \tfrac{1}{3} & \qquad \vec{z}_{q_1} &= \tfrac{1}{3}\vec{z}_{q_0} + \tfrac{1}{3}(\vec{z}_{q_1} + \vec{z}_{q_3}) \\ \vec{z}_{q_2} &= \tfrac{1}{3}\vec{z}_{q_3} + \tfrac{1}{3}(\vec{z}_{q_0} + \vec{z}_{q_2}) & \qquad \vec{z}_{q_3} &= \tfrac{1}{3}\vec{z}_{q_2} \end{aligned}$$

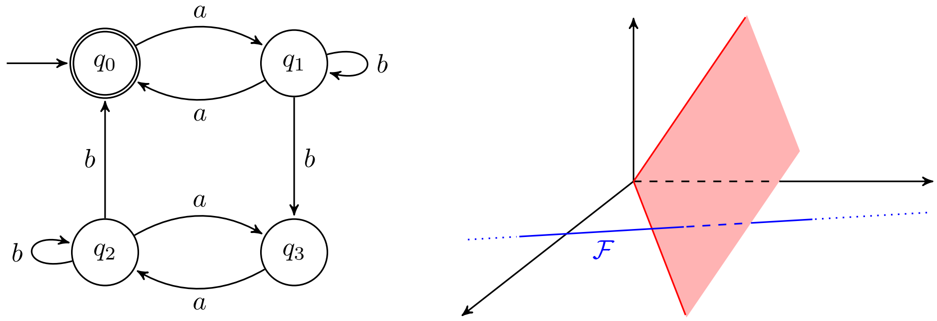

Figure 1 Left: unambiguous automaton $\mathcal{A}$. Right: visualisation of the affine space $\mathcal{F}$ (blue) and the vector space spanned by (pseudo-)cuts (red); these spaces are orthogonal.

The constant term in the equation for $\vec{z}_{q_0}$ reflects the fact that q_0 is accepting. The (other) coefficients $\frac{1}{3}$ correspond to the production of either a or b. The linear system has a unique solution.

One may view an NFA $\mathcal{A}$ as a Büchi automaton, so that its language $L(\mathcal{A}) \subseteq \Sigma^\omega$ is the set of those infinite words that have an accepting run in $\mathcal{A}$, i.e., a run that visits accepting states infinitely often. There is a natural notion of an infinite random word over Σ: in each step sample a letter from Σ uniformly at random, e.g., if $\Sigma = \{a, b\}$ then choose a and b with probability $1/2$ each. Perhaps more significantly, model checking Markov chains against Büchi automata, i.e., computing the probability that the random word generated by the Markov chain is accepted by the automaton, is a key problem in the verification of probabilistic systems. Unfortunately, like the aforementioned problem on finite words, it is also PSPACE-complete [8]. However, if the Büchi automaton is unambiguous, i.e., every accepted (infinite) word has exactly one accepting path, then one can compute the probability of generating an accepted word in polynomial time [2], both in the given Büchi automaton and in a given (discrete-time, finite-state) Markov chain. Since LTL specifications can be converted to unambiguous Büchi automata with a single-exponential blow-up, this leads to an LTL model-checking algorithm with single-exponential runtime, which is optimal. The polynomial-time algorithm from [2] for unambiguous Büchi automata is more involved than in the finite-word case.

▶ **Example 2.** In the following we view the automaton $\mathcal{A}$ from Figure 1 as an (unambiguous) Büchi automaton. If we generate a random word over $\{a, b\}$ according to the process described above, then the vector $\vec{z}$ where for each $q \in \{q_0, q_1, q_2, q_3\}$, $\vec{z}_q$ is the probability that the word is accepted when q is taken as initial state, is a solution to the following linear system:

$$\begin{aligned} \vec{z}_{q_0} &= \tfrac{1}{2}\vec{z}_{q_1} & \qquad \vec{z}_{q_1} &= \tfrac{1}{2}\vec{z}_{q_0} + \tfrac{1}{2}(\vec{z}_{q_1} + \vec{z}_{q_3}) \\ \vec{z}_{q_2} &= \tfrac{1}{2}\vec{z}_{q_3} + \tfrac{1}{2}(\vec{z}_{q_0} + \vec{z}_{q_2}) & \qquad \vec{z}_{q_3} &= \tfrac{1}{2}\vec{z}_{q_2} \end{aligned}$$

However, this linear system has multiple solutions: indeed, any scalar multiple $(1, 2, 2, 1)^\top$ is a solution.

In order to make such a linear system uniquely solvable, one needs to add further equations, and finding these further equations is where the real challenge lies. Assuming that the state space Q of $\mathcal{A}$ is strongly connected and the Markov chain generates letters uniformly at random as described above, a single additional equation $\vec{\mu}^\top \vec{z} = 1$ suffices (this can be shown with Perron-Frobenius theory: the eigenspace for the dominant eigenvalue of a nonnegative irreducible matrix is one-dimensional). We call such a vector $\vec{\mu} \in \mathbb{R}^Q$ a *normaliser*. The aim of this paper is to use a novel, linear-algebra based technique to compute normalisers more efficiently.

The suggestion in [2] was to take as normaliser the characteristic vector $[c] \in \{0,1\}^Q$ of a so-called *cut* $c \subseteq Q$. To define this, let us write $\delta(q, w)$ for the set of states reachable from a state $q \in Q$ via the word $w \in \Sigma^*$. A *cut* is a set of states of the form $c = \delta(q, w)$ such that $\delta(q, wx) \neq \emptyset$ holds for all $x \in \Sigma^*$. If a cut does not exist or if $\mathcal{A}$ does not have accepting states, then we have $\vec{z} = \vec{0}$.

▶ **Example 3.** In the automaton $\mathcal{A}$ from Figure 1, we have a cut $c = \delta(q_0, aba) = \{q_0, q_2\}$. Hence its characteristic vector $\vec{\mu} = (1, 0, 1, 0)^\top$ is a normaliser, allowing us to add the equation $\vec{\mu}^\top \vec{z} = \vec{z}_{q_0} + \vec{z}_{q_2} = 1$. Now the system is uniquely solvable: $\vec{z} = \frac{1}{3}(1, 2, 2, 1)^\top$. The equation $\vec{z}_{q_0} + \vec{z}_{q_2} = 1$ is valid by an ergodicity argument: intuitively, given a finite word that leads to q_0 *and* q_2, a random infinite continuation will almost surely enable an accepting run. For instance, $\vec{z}_{q_0} = \frac{1}{3}$ is the probability that a random infinite word over $\{a, b\}$ has an odd number of as before the first b. (This holds despite the fact that the word $abbb\ldots$ is not accepted from q_0.)

In Proposition 14 we show that an efficient implementation of the algorithm from [2] for computing a cut runs in time $O(|Q|^5)$. Our goal is to find a normaliser $\vec{\mu}$ more efficiently.

The general idea is to move from a combinatorial problem, namely computing a set $c \subseteq Q$, to a continuous problem, namely computing a vector $\vec{\mu} \in \mathbb{R}^Q$. To illustrate this, note that since we can choose as $\vec{\mu}$ the characteristic vector of an arbitrary cut, we may also choose a convex combination of such vectors, leading to a normaliser $\vec{\mu}$ with entries other than 0 or 1.

The technical key ideas of this paper draw on the observation that for unambiguous automata with cuts, the transition matrices generate a semigroup of matrices whose spectral radii are all 1. (The spectral radius of a matrix is the largest absolute value of its eigenvalues.) This observation enables us to adopt techniques that have recently been devised by Protasov and Voynov [16] for the analysis of matrix semigroups with constant spectral radius. To the best of the authors' knowledge, such semigroups have not previously been connected to unambiguous automata. This transfer is the main contribution of this paper.

To sketch the gist of this technique, for any $a \in \Sigma$ write $M(a) \in \{0,1\}^{Q \times Q}$ for the transition matrix of the unambiguous automaton $\mathcal{A}$, define the average matrix $\overline{M} = \frac{1}{|\Sigma|}\sum_{a \in \Sigma} M(a)$, and let $\vec{y} = \overline{M}\vec{y} \in \mathbb{R}^Q$ be an eigenvector with eigenvalue 1 (the matrix $\overline{M}$ has such an eigenvector if $\mathcal{A}$ has a cut). Since the matrix semigroup, $\mathcal{S} \subseteq \{0,1\}^{Q \times Q}$, generated by the transition matrices $M(a)$ has constant spectral radius, it follows from [16] that one can efficiently compute an affine space $\mathcal{F} \subseteq \mathbb{R}^Q$ with $\vec{y} \in \mathcal{F}$ and $\vec{0} \notin \mathcal{F}$ such that for any $\vec{v} \in \mathcal{F}$ and any $M \in \mathcal{S}$ we have $M\vec{v} \in \mathcal{F}$. Using the fact that $\delta(q, wx)$ is a cut (for all $x \in \Sigma^*$) whenever $\delta(q, w)$ is a cut, one can show that all characteristic vectors of cuts have the same scalar product with all $\vec{v} \in \mathcal{F}$, i.e., all characteristic vectors of cuts are in the vector space orthogonal to $\mathcal{F}$. Indeed, we choose as normaliser $\vec{\mu}$ a vector that is orthogonal to $\mathcal{F}$. This linear-algebra computation can be carried out in time $O(|Q|^3)$. In the visualisation on the right of Figure 1, the characteristic vectors of cuts lie in the plane shaded in red, which is orthogonal to straight line $\mathcal{F}$ (blue).

▶ **Example 4.** In the automaton $\mathcal{A}$ from Figure 1, the vector $\vec{y} = (1, 2, 2, 1)^\top$ satisfies $\overline{M}\vec{y} = \vec{y}$ where $\overline{M} = \frac{1}{2}(M(a) + M(b))$. The affine space $\mathcal{F} := \{\vec{y} + s(1, -1, -1, 1)^\top \mid s \in \mathbb{R}\}$ has the mentioned closure properties, i.e., $M(a)\mathcal{F} \subseteq \mathcal{F}$ and $M(b)\mathcal{F} \subseteq \mathcal{F}$. Note that the vector $\vec{\mu}$ from Example 3 is indeed orthogonal to $\mathcal{F}$, i.e., $\vec{\mu}^\top(1, -1, -1, 1)^\top = 0$.

However, to ensure that $\vec{\mu}$ is a valid normaliser, we need to restrict it further. To this end, we compute, for some state $q \in Q$, the set $Co(q) \subseteq Q$ of *co-reachable* states, i.e., states $r \in Q$ such that $\delta(q, w) \supseteq \{q, r\}$ holds for some $w \in \Sigma^*$. This requires a combinatorial algorithm, which is similar to a straightforward algorithm that would verify the unambiguousness of $\mathcal{A}$. Its runtime is quadratic in the number of transitions of $\mathcal{A}$, i.e., $O(|Q|^4)$ in the worst case. Then we restrict $\vec{\mu}$ such that $\vec{\mu}_q = 1$ and μ is non-zero only in entries that correspond to $Co(q)$. In the visualisation on the right of Figure 1, restricting some components of $\vec{\mu}$ to be 0 corresponds to the vectors in the shaded (red) plane that lie on the plane described by $q' = 0$ for all $q' \in Q \setminus Co(q)$.

▶ **Example 5.** We have $Co(q_0) = \{q_0, q_2\}$. So we restrict $\vec{\mu}$ to be of the form $(1, 0, x, 0)^\top$. Together with the equation $\vec{\mu}^\top (1, -1, -1, 1)^\top = 0$ this implies $\vec{\mu} = (1, 0, 1, 0)^\top$. The point is that, although this is the same vector computed via a cut in Example 3, the linear-algebra based computation of $\vec{\mu}$ is more efficient.

In the rest of the paper we analyse the general case of model checking a given Markov chain against a given unambiguous Büchi automaton. The efficiency gain we aim for with our technique can only be with respect to the automaton, not the Markov chain; nevertheless, we analyse in detail the runtime in terms of the numbers of states and transitions in both the automaton and the Markov chain. The main results are developed in Section 3. In Section 3.1 we describe the general approach from [2, 3]. In Section 3.2 we analyse the runtime of an efficient implementation of the algorithm from [2, 3] for computing a cut. Our main contribution lies in Section 3.3, where we develop a new approach for computing a normaliser, based on the mentioned spectral properties of the transition matrices in unambiguous automata. We close in Section 4 with a discussion. The full version of this paper [12] contains an appendix with proofs.

2 Preliminaries

We assume the reader to be familiar with basic notions of finite automata over infinite words and Markov chains, see, e.g., [9, 13]. In the following we provide a brief summary of our notation and a few facts related to linear algebra.

Finite automata. A *Büchi automaton* is a tuple $\mathcal{A} = (Q, \Sigma, \delta, Q_0, F)$ where Q is the finite set of states, $Q_0 \subseteq Q$ is the set of initial states, Σ is the finite alphabet, $\delta : Q \times \Sigma \to 2^Q$ is the transition function, and $F \subseteq Q$ is the set of accepting states. We extend the transition function to $\delta : Q \times \Sigma^* \to 2^Q$ and to $\delta : 2^Q \times \Sigma^* \to 2^Q$ in the standard way. For $q \in Q$ we write $\mathcal{A}_q$ for the automaton obtained from $\mathcal{A}$ by making q the only initial state.

Given states $q, r \in Q$ and a finite word $w = a_0 a_1 \cdots a_{n-1} \in \Sigma^*$, a *run* for w from q to r is a sequence $q_0 q_1 \cdots q_n \in Q^{n+1}$ with $q_0 = q$, $q_n = r$ and $q_{i+1} \in \delta(q_i, a_i)$ for $i \in \{0, \ldots, n-1\}$. A *run* in $\mathcal{A}$ for an infinite word $w = a_0 a_1 a_2 \cdots \in \Sigma^\omega$ is an infinite sequence $\rho = q_0 q_1 \cdots \in Q^\omega$ such that $q_0 \in Q_0$ and $q_{i+1} \in \delta(q_i, a_i)$ for all $i \in \mathbb{N}$. Run ρ is called *accepting* if $\inf(\rho) \cap F \neq \emptyset$ where $\inf(\rho) \subseteq Q$ is the set of states that occur infinitely often in ρ. The *language* $\mathcal{L}(\mathcal{A})$ of accepted words consists of all infinite words $w \in \Sigma^\omega$ that have at least one accepting run. $\mathcal{A}$ is called *unambiguous* if each word $w \in \Sigma^\omega$ has at most one accepting run. We use the acronym UBA for unambiguous Büchi automaton.

We define $|\delta| := |\{(q, r) \mid \exists\, a \in \Sigma : r \in \delta(q, a)\}|$, i.e., $|\delta| \leq |Q|^2$ is the number of transitions in $\mathcal{A}$ when allowing for multiple labels per transition. In [12, Appendix A] we give an example that shows that the number of transitions can be quadratic in $|Q|$, even for UBAs with a strongly connected state space. We assume $|Q| \le |\delta|$, as states without outgoing transitions can be removed. In this paper, Σ may be a large set (of states in a Markov chain), so it is imperative to allow for multiple labels per transition. We use a lookup table to check in constant time whether $r \in \delta(q, a)$ holds for given r, q, a.

A *diamond* is given by two states $q, r \in Q$ and a finite word w such that there exist at least two distinct runs for w from q to r. One can remove diamonds (see [12, Appendix B.1]):

▶ **Lemma 6.** *Given a UBA, one can compute in time $O(|\delta|^2|\Sigma|)$ a UBA of at most the same size, with the same language and without diamonds.*

For the rest of the paper, we assume that UBAs do not have diamonds.

Vectors and matrices. We consider vectors and square matrices indexed by a finite set S. We write (column) vectors $\vec{v} \in \mathbb{R}^S$ with arrows on top, and $\vec{v}^\top$ for the transpose (a row vector) of $\vec{v}$. The zero vector and the all-ones vector are denoted by $\vec{0}$ and $\vec{1}$, respectively. For a set $T \subseteq S$ we write $[T] \in \{0,1\}^S$ for the characteristic vector of T, i.e., $[T]_s = 1$ if $s \in T$ and $[T]_s = 0$ otherwise. A matrix $M \in [0,1]^{S \times S}$ is called *stochastic* if $M\vec{1} = \vec{1}$, i.e., if every row of M sums to one. For a set $U \subseteq S$ we write $\vec{v}_U \in \mathbb{R}^U$ for the restriction of $\vec{v}$ to U. Similarly, for $T, U \subseteq S$ we write $M_{T,U}$ for the submatrix of M obtained by deleting the rows not indexed by T and the columns not indexed by U. The (directed) *graph* of a nonnegative matrix $M \in \mathbb{R}^{S \times S}$ has vertices $s \in S$ and edges (s,t) if $M_{s,t} > 0$. We may implicitly associate M with its graph and speak about graph-theoretic concepts such as reachability and strongly connected components (SCCs) in M.

Markov chains. A (finite-state discrete-time) *Markov chain* is a pair $\mathcal{M} = (S, M)$ where S is the finite set of states, and $M \in [0,1]^{S \times S}$ is a stochastic matrix that specifies transition probabilities. An *initial distribution* is a function $\iota : S \to [0,1]$ satisfying $\sum_{s \in S} \iota(s) = 1$. Such a distribution induces a probability measure $\Pr_\iota^{\mathcal{M}}$ on the measurable subsets of S^ω in the standard way, see for instance [1, chapter 10.1, page 758]. If ι is concentrated on a single state s, we may write $\Pr_s^{\mathcal{M}}$ for $\Pr_\iota^{\mathcal{M}}$. We write E for the set of edges in the graph of M. Note that $|S| \le |E| \le |S|^2$, as M is stochastic.

Solving linear systems. Let $\kappa \in [2,3]$ be such that one can multiply two $n \times n$-matrices in time $O(n^\kappa)$ (in other literature, κ is often denoted by ω). We assume that arithmetic operations cost constant time. One can choose $\kappa = 2.4$, see [14] for a recent result. One can check whether an $n \times n$ matrix is invertible in time $O(n^\kappa)$ [6]. Finally, one can solve a linear system with n equations using the Moore-Penrose pseudo-inverse [11] in time $O(n^\kappa)$ [15].

Spectral theory. The *spectral radius* of a matrix $M \in \mathbb{R}^{S \times S}$, denoted $\rho(M)$, is the largest absolute value of the eigenvalues of M. By the Perron-Frobenius theorem [4, Theorems 2.1.1, 2.1.4], if M is nonnegative then the spectral radius $\rho(M)$ is an eigenvalue of M and there is a nonnegative eigenvector $\vec{x}$ with $M\vec{x} = \rho(M)\vec{x}$. Such a vector $\vec{x}$ is called *dominant*. Further, if M is nonnegative and strongly connected then $\vec{x}$ is strictly positive in all components and the eigenspace associated with $\rho(M)$ is one-dimensional.

3 Algorithms

Given a Markov chain $\mathcal{M}$, an initial distribution ι, and a Büchi automaton $\mathcal{A}$ whose alphabet is the state space of $\mathcal{M}$, the *probabilistic model-checking problem* is to compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$.

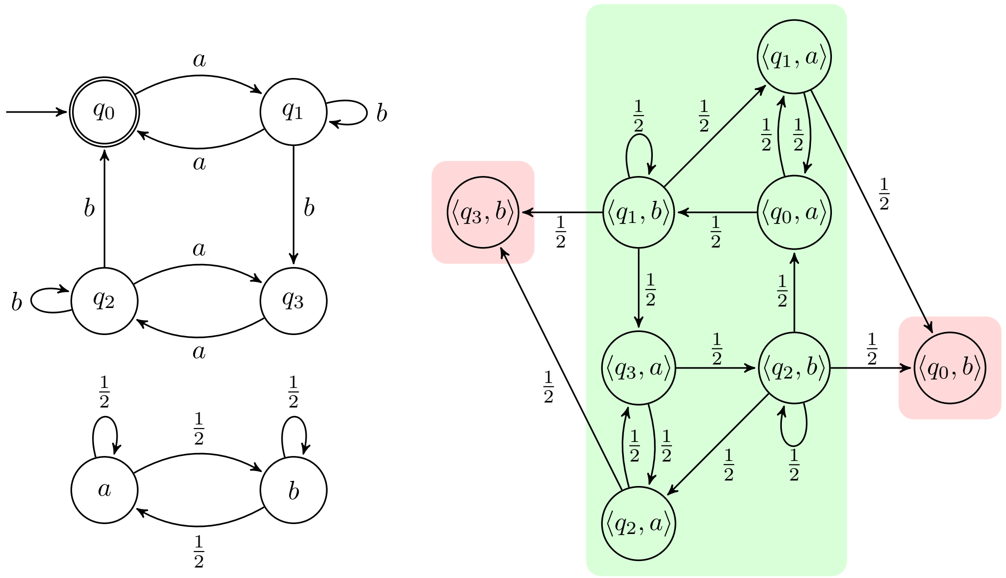

Figure 2 The UBA from Figure 1 and the Markov chain $\mathcal{M}$ on the left, and their product, B, on the right. The (single) accepting recurrent SCC is shaded green, and the two other SCCs are shaded red.

This problem is PSPACE-complete [8, 7], but solvable in polynomial time if $\mathcal{A}$ is deterministic. For UBAs a polynomial-time algorithm was described in [2, 3]. In this paper we obtain a faster algorithm (recall that E is the set of transitions in the Markov chain):

▶ **Theorem 7.** *Given a Markov chain $\mathcal{M} = (S, M)$, an initial distribution ι, and a UBA $\mathcal{A} = (Q, S, \delta, Q_0, F)$, one can compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$ in time $O(|Q|^\kappa |S|^\kappa + |Q|^3|E| + |\delta|^2|E|)$.*

Before we prove this theorem in Section 3.3, we describe the algorithm from [2, 3] and analyse the runtime of an efficient implementation.

3.1 The Basic Linear System

Let $\mathcal{M} = (S, M)$ be a Markov chain, ι an initial distribution. Let $B \in \mathbb{R}^{(Q\times S)\times(Q\times S)}$ be the following matrix:

$$B_{\langle q,s\rangle,\langle q',s'\rangle} = \begin{cases} M_{s,s'} & \text{if } q' \in \delta(q,s) \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

Define $\vec{z} \in \mathbb{R}^{Q\times S}$ by $\vec{z}_{\langle q,s\rangle} = \Pr_s^{\mathcal{M}}(\mathcal{L}(\mathcal{A}_q))$. Then $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A})) = \sum_{q\in Q_0}\sum_{s\in S}\iota(s)\vec{z}_{\langle q,s\rangle}$. Lemma 4 in [3] implies that $\vec{z} = B\vec{z}$.

▶ **Example 8.** Consider the UBA $\mathcal{A}$ from Figure 1 and the two-state Markov chain $\mathcal{M}$ shown on the left of Figure 2. The weighted graph on the right of Figure 2 represents the matrix B, obtained from $\mathcal{A}$ and $\mathcal{M}$ according to Equation (1). It is natural to think of B as a product of $\mathcal{A}$ and $\mathcal{M}$. Notice that B is not stochastic: the sum of the entries in each row (equivalently, the total outgoing transition weight of a graph node) is not always one.

Although $\vec{z}$ is a solution the system of equations $\vec{\zeta} = B\vec{\zeta}$, this system does not uniquely identify $\vec{z}$. Indeed, any scalar multiple of $\vec{z}$ is a solution for these equations. To uniquely identify $\vec{z}$ by a system of linear equations, we need to analyse the SCCs of B.

All SCCs D satisfy $\rho(D) \leq 1$, see [3, Proposition 7]. An SCC D of B is called *recurrent* if $\rho(B_{D,D}) = 1$. It is called *accepting* if there is $\langle q, s\rangle \in D$ with $q \in F$.

▶ **Example 9.** The matrix B from Figure 2 has three SCCs, namely the two singleton sets $\{\langle q_0, b\rangle\}$ and $\{\langle q_3, b\rangle\}$, and $D = \{\langle q_0, a\rangle, \langle q_1, a\rangle, \langle q_1, b\rangle, \langle q_2, a\rangle, \langle q_2, b\rangle, \langle q_3, a\rangle\}$. Only D is recurrent; indeed, $\vec{y} = (\vec{y}_{\langle q_0,a\rangle}, \vec{y}_{\langle q_1,a\rangle}, \vec{y}_{\langle q_1,b\rangle}, \vec{y}_{\langle q_2,a\rangle}, \vec{y}_{\langle q_2,b\rangle}, \vec{y}_{\langle q_3,a\rangle})^\top = (2, 1, 3, 1, 3, 2)^\top$ is a dominant eigenvector with $B_{D,D}\vec{y} = \vec{y}$. Since q_0 is accepting, D is accepting recurrent.

Denote the set of accepting recurrent SCCs by $\mathcal{D}_+$ and the set of non-accepting recurrent SCCs by $\mathcal{D}_0$. By [3, Lemma 8], for $D \in \mathcal{D}_+$ we have $\vec{z}_d > 0$ for all $d \in D$, and for $D \in \mathcal{D}_0$ we have $\vec{z}_D = \vec{0}$. Hence, for $D \in \mathcal{D}_+$, there exists a *D-normaliser*, i.e., a vector $\vec{\mu} \in \mathbb{R}^D$ such that $\vec{\mu}^\top \vec{z}_D = 1$. This gives us a system of linear equations that identifies $\vec{z}$ uniquely [3]:

▶ **Lemma 10** (Lemma 12 in [3]). *Let $\mathcal{D}_+$ be the set of accepting recurrent SCCs, and $\mathcal{D}_0$ the set of non-accepting recurrent SCCs. For each $D \in \mathcal{D}_+$ let $\vec{\mu}(D)$ be a D-normaliser. Then $\vec{z}$ is the unique solution of the following linear system:*

$$\begin{aligned} & & \vec{\zeta} &= B\vec{\zeta} \\ &\textit{for all } D \in \mathcal{D}_+: & \vec{\mu}(D)^\top \vec{\zeta}_D &= 1 \\ &\textit{for all } D \in \mathcal{D}_0: & \vec{\zeta}_D &= \vec{0} \end{aligned} \tag{2}$$

Uniqueness follows from the fact that the system $\vec{\zeta} = B\vec{\zeta}$ describes the eigenspace of the dominant eigenvalue (here, 1) of a nonnegative strongly connected matrix (here, B), and such eigenspaces are one-dimensional. This leads to the following result:

▶ **Proposition 11.** *Suppose N is the runtime of an algorithm to calculate a normaliser for each accepting recurrent SCC. Then one can compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$ in time $O(|Q|^\kappa |S|^\kappa) + N$.*

Proof. Lemma 10 implies correctness of the following procedure to calculate $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$:

1. Set up the matrix B from Equation (1).
2. Compute the SCCs of B.
3. For each SCC C, check whether C is recurrent.
4. For each accepting recurrent SCC D, compute its D-normaliser $\vec{\mu}(D)$.
5. Compute $\vec{z}$ by solving the linear system (2) in Lemma 10.
6. Compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A})) = \sum_{s\in S} \sum_{q\in Q_0} \iota(s)\vec{z}_{q,s}$.

One can set up B in time $O(|Q|^2|S|^2)$. Using Tarjan's algorithm one can compute the SCCs of B in time linear in the vertices and edges of B, hence in $O(|Q|^2|S|^2)$ [17]. One can find those SCCs D which are recurrent in time $O(|Q|^\kappa|S|^\kappa)$ by checking if $I - B_{D,D}$ is invertible. The linear system (2) has $O(|Q||S|)$ equations, and thus can be solved in time $O(|Q|^\kappa|S|^\kappa)$. Hence the total runtime is $O(|Q|^\kappa|S|^\kappa) + N$. ◀

In Section 3.2 we describe the combinatorial, *cut* based, approach from [2, 3] to calculating D-normalisers and analyse its complexity. In Section 3.3 we describe a novel linear-algebra based approach, which is faster in terms of the automaton.

3.2 Calculating D-Normalisers Using Cuts

For the remainder of the paper, let D be an accepting recurrent SCC. A *fibre over $s \in S$* is a subset of D of the form $\alpha \times \{s\}$ for some $\alpha \subseteq Q$. Given a fibre $f = \alpha \times \{s\}$ and a state $s' \in S$, if $M_{s,s'} > 0$ we define the fibre $f \triangleright s'$ as follows:

$$f \triangleright s' := \{\langle q, s'\rangle \mid q \in \delta(\alpha, s)\} \cap D.$$

If $M_{s,s'} = 0$, then $f \triangleright s'$ is undefined, and for $w \in S^*$ we define $f \triangleright w = f$ if $w = \varepsilon$ and $f \triangleright ws' = (f \triangleright w) \triangleright s'$. If $f = \{d\}$ for some $d \in D$ we may write $d \triangleright s'$ for $f \triangleright s'$.

We call a fibre c a *cut* if $c = d \triangleright v$ for some $v \in S^*$ and $d \in D$, and $c \triangleright w \neq \emptyset$ for all $w \in S^*$ whenever $c \triangleright w$ is defined. Note that if c is a cut then so is $c \triangleright w$ whenever it is defined. Given a cut $c \subseteq D$ we call its characteristic vector $[c] \in \{0,1\}^D$ a *cut vector.* In the example in Figure 2, it is easy to see that $\{\langle q_1, b\rangle\} = \langle q_0, a\rangle \triangleright b$ is a cut.

▶ **Lemma 12** (Lemma 10 in [3]). *There exists a cut. Any cut vector $\vec{\mu}$ is a normaliser, i.e., $\vec{\mu}^\top \vec{z}_D = 1$.*

Loosely speaking, $\vec{\mu}^\top \vec{z}_D \leq 1$ follows from unambiguousness, and $\vec{\mu}^\top \vec{z}_D \not< 1$ follows from an ergodicity argument (intuitively, all states in the cut are almost surely visited infinitely often). The following lemma is the basis for the cut computation algorithm in [2, 3]:

▶ **Lemma 13** (Lemma 17 in [3]). *Let $D \subseteq Q \times S$ be a recurrent SCC. Let $d \in D$. Suppose $w \in S^*$ is such that $d \triangleright w \ni d$ is not a cut. Then there are $v \in S^*$ and $e \neq d$ with $d \triangleright v \supseteq \{d, e\}$ and $e \triangleright w \neq \emptyset$. For any such e, $d \triangleright w \cap e \triangleright w = \emptyset$. Hence $d \triangleright vw \supseteq \{d, e\} \triangleright w \supsetneq d \triangleright w$.*

This suggests a way of generating an increasing sequence of fibres, culminating in a cut. We prove the following proposition:

▶ **Proposition 14.** *Let $D \subseteq Q \times S$ be a recurrent SCC. Denote by T the set of edges in $B_{D,D}$. One can compute a cut in time $O(|Q|^2|\delta||D| + |\delta||T|)$.*

Define, for some $d = \langle q, s\rangle \in D$, its *co-reachability* set $Co(d) \subseteq D$: it consists of those $e \in D$ such that there exists a word w with $\{d, e\} \subseteq d \triangleright w$. Note that $Co(d)$ is a fibre over s. In the example of Figure 2 we have that $Co(\langle q_0, a\rangle) = \{\langle q_0, a\rangle, \langle q_2, a\rangle\}$, with $\{\langle q_0, a\rangle, \langle q_2, a\rangle\} \in \langle q_0, a\rangle \triangleright ba$. The following lemma (proof in [12, Appendix B.2]) gives a bound on the time to compute $Co(d)$:

▶ **Lemma 15.** *One can compute $Co(d)$ in time $O(|Q||D| + |\delta||T|)$. Moreover, one can compute in time $O(|Q|^2|D| + |\delta||T|)$ a list $(CoPath(d)(e))_{e \in Co(d)}$ such that $CoPath(d)(e) \in S^*$ and $\{d, e\} \subseteq d \triangleright CoPath(d)(e)$ and $|CoPath(d)(e)| \leq |Q||D|$.*

The lemma is used in the proof of Proposition 14:

Proof sketch of Proposition 14. Starting from a singleton fibre $\{d\}$, where $d = \langle q, s\rangle \in D$ is chosen arbitrarily, we keep looking for words $v \in S^*$ that have the properties described in Lemma 13 to generate larger fibres $d \triangleright w$:

```
1. $w := \varepsilon$ (the empty word)
2. while $\exists\, v \in S^*$ and $\exists\, e \neq d$ such that $d \triangleright v \supseteq \{d, e\}$ and $e \triangleright w \neq \emptyset$ :
       $w := vw$
3. return $d \triangleright w$.
```

By [2, Lemma 18] the algorithm returns a cut. In every loop iteration the fibre $d \triangleright w$ increases, so the loop terminates after at most $|Q|$ iterations. For efficiency we calculate $Co(d)$ and $CoPath(d)$ using Lemma 15, and we use dynamic programming to maintain the set, *Survives*, of those $e \in D$ for which $e \triangleright w \neq \emptyset$ holds. Whenever a prefix v is added to w, we update *Survives* by processing v backwards. This leads to the following algorithm:

```
1. Calculate $Co(d)$ and $CoPath(d)$ using Lemma 15
2. $w := \varepsilon$; $Survives := (Q \times \{s\}) \cap D$
```

```
3. while $\exists\, e \in \mathit{Co}(d) \setminus \{d\}$ such that $e \in \mathit{Survives}$:
       $v_0 = s$; $v_1 \dots v_n := \mathit{CoPath}(d)(e)$
       for $i = n, n-1, \dots, 1$:
           $\mathit{Survives} := \{\langle p, v_{i-1}\rangle \in D \mid (\delta(p, v_{i-1}) \times \{v_i\}) \cap \mathit{Survives} \neq \emptyset\}$
       $w := v_1 \dots v_n w$
4. return $d \triangleright w$
```

The runtime analysis is in [12, Appendix B.2]. ◀

▶ **Example 16.** Letting $d = \langle q_0, a\rangle$ and $e = \langle q_2, a\rangle$ we have $\mathit{Co}(d) = \{d, e\}$ with $\mathit{CoPath}(d)(d) = \varepsilon$ and $\mathit{CoPath}(d)(e) = baa$. Initially we have $\mathit{Survives} = Q \times \{a\}$. In the first iteration the algorithm can only pick e. The inner loop updates *Survives* first to $\{q_0, q_1, q_2, q_3\} \times \{a\}$ (i.e., to itself), then to $\{q_1, q_2\} \times \{b\}$, and finally to $\{q_0, q_3\} \times \{a\}$. Now $(\mathit{Co}(d) \setminus d) \cap \mathit{Survives}$ is empty and the loop terminates. The algorithm returns the cut $d \triangleright baa = \{d, e\}$.

Applying Proposition 14 to the general procedure (Proposition 11) leads to the following result on the combinatorial approach:

▶ **Theorem 17.** *Given a Markov chain $\mathcal{M} = (S, M)$, an initial distribution ι, and a UBA $\mathcal{A} = (Q, S, \delta, Q_0, F)$, one can compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$ in time $O(|Q|^\kappa |S|^\kappa + |Q|^3|\delta||S| + |\delta|^2|E|)$.*

3.3 Calculating D-Normalisers Using Linear Algebra

Recall that D is an accepting recurrent SCC. For $t \in S$ define the matrix $\Delta(t) \in \{0,1\}^{D \times D}$ as follows:

$$\Delta(t)_{\langle q,s\rangle,\langle q',s'\rangle} := \begin{cases} 1 & \text{if } s' = t,\ M_{s,t} > 0, \text{ and } q' \in \delta(q,s) \\ 0 & \text{otherwise} \end{cases}$$

Note that the graph of $\Delta(t)$ contains exactly the edges of the graph of $B_{D,D}$ that end in vertices in $Q \times \{t\}$. If $M_{s,t} > 0$ holds for all pairs (s,t), then the matrices $(\Delta(t))_{t \in S}$ generate a semigroup of matrices, all of which have spectral radius 1. Such semigroups were recently studied by Protasov and Voynov [16]. Specifically, Theorem 5 in [16] shows that there exists an affine subspace $\mathcal{F}$ of $\mathbb{R}^D$ which excludes $\vec{0}$ and is invariant under multiplication by matrices from the semigroup. Moreover, they provide a way to compute this affine subspace efficiently. One can show that cut vectors are orthogonal to $\mathcal{F}$. The key idea of our contribution is to generalise cut vectors to *pseudo-cuts*, which are vectors $\vec{\mu} \in \mathbb{R}^D$ that are orthogonal to $\mathcal{F}$. We will show (in Lemma 20 below) how to derive a D-normaliser based on a pseudo-cut that is non-zero only in components that are in a co-reachability set $\mathit{Co}(d)$ (from Lemma 15).

If $M_{s,t} = 0$ holds for some s, t (which will often be the case in model checking), then $\Delta(s)\Delta(t)$ is the zero matrix, which has spectral radius 0, not 1. Therefore, the results of [16] are not directly applicable and we have to move away from matrix semigroups. In the following we re-develop and generalise parts of the theory of [16] so that the paper is self-contained and products of $\Delta(s)\Delta(t)$ with $M_{s,t} = 0$ are not considered.

Let $w = s_1 s_2 \dots s_n \in S^*$. Define $\Delta(w) = \Delta(s_1)\Delta(s_2)\cdots\Delta(s_n)$. We say w is *enabled* if $M_{s_i, s_{i+1}} > 0$ holds for all $i \in \{1, \dots, n-1\}$. If $f \subseteq D$ is a fibre over s such that sw is enabled, we have $[f \triangleright w]^\top = [f]^\top \Delta(w)$. We overload the term *fibre over s* to describe any vector $\vec{\mu} \in \mathbb{R}^D$ such that $\vec{\mu}_{\langle q,s'\rangle} = 0$ whenever $s' \neq s$. We define *pseudo-cuts over s* to be fibres $\vec{\mu}$ over s such that $\vec{\mu}^\top \Delta(w) \vec{z} = \vec{\mu}^\top \vec{z}$ holds for all $w \in S^*$ such that sw is enabled. Let $c \subseteq Q \times \{s\}$ be a cut with sw enabled. Then $c \triangleright w$ is a cut, and $[c]^\top \Delta(w) \vec{z} = 1 = [c]^\top \vec{z}$ holds by Lemma 12. It follows that cut vectors are pseudo-cuts.

▶ **Example 18.** Since $c = \{\langle q_0, a\rangle, \langle q_2, a\rangle\}$ from Example 16 is a cut, $[c]$ is a pseudo-cut over a. Pseudo-cuts do not need to be combinations of cut vectors: although the fibre $f = \{\langle q_0, a\rangle, \langle q_1, a\rangle\}$ is not a cut, $[f]$ is a pseudo-cut over a.

Fix some $d = \langle q, s\rangle \in D$. Recall that $Co(d)$ consists of those $e \in D$ such that there exists a word w with $\{d, e\} \subseteq d \triangleright w$. We define *$Co(d)$-pseudo-cuts* to be pseudo-cuts $\vec{\mu}$ over s such that $\vec{\mu}_d \neq 0$ and $\vec{\mu}_e = 0$ holds for all $e \notin Co(d)$.

▶ **Example 19.** Any cut vector is a $Co(d)$-pseudo-cut for some $d \in D$, by definition, and so are scalar multiples of cut vectors. The vector $[f]$ in Example 18, however, is not a $Co(d)$-pseudo-cut, since $\langle q_1, a\rangle \notin Co(\langle q_0, a\rangle)$ and $\langle q_0, a\rangle \notin Co(\langle q_1, a\rangle)$.

From a $Co(d)$-pseudo-cut we can easily derive a D-normaliser:

▶ **Lemma 20.** *Let $\vec{\mu} \in \mathbb{R}^D$ be a $Co(d)$-pseudo-cut. Then $\frac{1}{\vec{\mu}_d}\vec{\mu}$ is a D-normaliser.*

Proof. Let w be an enabled word in M such that $d \triangleright w$ is a cut containing d. Such a word exists (see the proof sketch of Proposition 14). Since $([d]^\top \Delta(w))^\top = [d \triangleright w]$ is a D-normaliser (by Lemma 12), it suffices to prove that $\frac{1}{\vec{\mu}_d}\vec{\mu}^\top \vec{z} = [d]^\top \Delta(w)\vec{z}$.

We can write $\vec{\mu}$ as $\sum_{d' \in Co(d)} \vec{\mu}_{d'}[d']$, so $\vec{\mu}^\top \Delta(w) = \sum_{d' \in Co(d)} \vec{\mu}_{d'}[d']^\top \Delta(w)$. For any $d' \in Co(d) \setminus \{d\}$, let w' be such that $\{d, d'\} \subseteq d \triangleright w'$. Now we see that $d' \in d \triangleright ww'$, and since $d \triangleright w$ is a cut so are $d \triangleright ww'$ and $d \triangleright ww'w$. Thus,

$$[d]^\top \Delta(w)\vec{z} \;=\; [d]^\top \Delta(ww'w)\vec{z} \;\geq\; [d]^\top \Delta(w)\vec{z} + [d']^\top \Delta(w)\vec{z},$$

which implies $[d']^\top \Delta(w)\vec{z} = 0$ for every $d' \in Co(d) \setminus \{d\}$. This means that

$$\vec{\mu}^\top \Delta(w)\vec{z} = \sum_{d' \in Co(d)} \vec{\mu}_{d'}[d']^\top \Delta(w)\vec{z} = \vec{\mu}_d[d]^\top \Delta(w)\vec{z}.$$

Since $\vec{\mu}$ is a pseudo-cut, this implies that $\frac{1}{\vec{\mu}_d}\vec{\mu}^\top \vec{z} = \frac{1}{\vec{\mu}_d}\vec{\mu}^\top \Delta(w)\vec{z} = [d]^\top \Delta(w)\vec{z}$. ◀

By Lemma 20, to find a D-normaliser it suffices to find a $Co(d)$-pseudo-cut. Fix a dominant eigenvector $\vec{y}$ of $B_{D,D}$ so that $\vec{y}$ is strictly positive in all components. One can compute such $\vec{y}$ in time $O(|D|^\kappa)$. By [2, Lemma 8] the vector $\vec{z}_D$ is also a dominant eigenvector of $B_{D,D}$, hence $\vec{y}$ and $\vec{z}_D$ (the latter of which is yet unknown) are scalar multiples. In order to compute a $Co(d)$-pseudo-cut, we compute a basis for the space spanned by $\Delta(w)\vec{y}$ for all enabled words w. We use a technique similar to the one employed by Tzeng in [18] for checking equivalence of probabilistic automata. To make this more efficient, we compute separate basis vectors for each $s \in S$. Define $\Delta'(t) \in \{0,1\}^{D \times D}$ as $\Delta'(t)_{\langle q_1, s_1\rangle, \langle q_2, s_2\rangle} = 1$ if $q_1 = q_2$ and $s_1 = s_2 = t$ and 0 otherwise. Note that $\Delta(s)\Delta'(s) = \Delta(s)$ holds for all $s \in S$.

▶ **Lemma 21.** *Suppose $\vec{y} = B_{D,D}\vec{y}$ is given. Denote by $V(s) \subseteq \mathbb{R}^D$ the vector space spanned by the vectors $\Delta'(s)\Delta(w)\vec{y}$ for $w \in S^*$ and $s \in S$. Let $Q_{D,t} = (Q \times \{t\}) \cap D$ and let $E(t) = \{(s, t) \mid M_{s,t} > 0\}$ be the set of edges in M that end in t. One can compute a basis $R(s)$ of $V(s)$ for all $s \in S$ in time $O(|Q|^2 \sum_{t \in S} |Q_{D,t}||E(t)|)$, where for each $\vec{r} \in R(s)$ we have $\vec{r} = \Delta'(s)\Delta(w)\vec{y}$ for some enabled word sw.*

Proof sketch. Fix an arbitrary total order $<_S$ on S. We define a total order $\ll_S$ on S^* as the "shortlex" order but with words read from right to left. That is, the empty word ε is the smallest element, and for $v, w \in S^*$ and $s, t \in S$, we have $vs \ll_S wt$ if (1) $|vs| < |wt|$ or (2) $|vs| = |wt|$ and $s <_S t$ or (3) $|vs| = |wt|$ and $s = t$ and $v \ll_S w$.

We use a technique similar to the one by Tzeng in [18]. At every step in the algorithm, *worklist* is a set of pairs $(sw, \Delta'(s)\Delta(w)\vec{y})$. We write $\min_{\ll_S}(\textit{worklist})$ to denote the pair in *worklist* where sw is minimal with respect to $\ll_S$.

```
1. for each $s \in S$, let $R(s) := \{\Delta'(s)\vec{y}\}$ and $R(s)_\perp := \{\Delta'(s)\vec{y}\}$
2. $worklist := \{(st, \Delta'(s)\Delta(t)\vec{y}) \mid M_{s,t} > 0\}$
3. while $worklist \neq \emptyset$:
       $(tw, \vec{u}) := \min_{\ll_S}(worklist)$; $worklist := worklist \setminus \{(tw, \vec{u})\}$
       Using the Gram-Schmidt process[1], let $\vec{u}_\perp$ be the orthogonalisation of $\vec{u}$ against $R_\perp(t)$
       if $\vec{u}_\perp \neq \vec{0}$, i.e., if $\vec{u}$ is linearly independent of $R_\perp(t)$:
           $R(t) := R(t) \cup \{\vec{u}\}$ and $R_\perp(t) := R_\perp(t) \cup \{\vec{u}_\perp\}$
           $worklist := worklist \cup \{(stw, \Delta'(s)\Delta(t)\vec{u}) \mid M_{s,t} > 0\}$
4. return $R(s)$ for all $s \in S$
```

At any point and for all $s \in S$, the sets $R(s)$ and $R(s)_\perp$ span the same vector space, and this space is a subspace of $V(s)$. The sets $R(s)$ and $R(s)_\perp$ consist of linearly independent fibres over s, and these fibres are possibly nonzero only in the $Q_{D,s}$-components. Hence $|\bigcup_{s \in S} R(s)| \leq |D|$ and thus there are at most $|D|$ iterations of the while loop that increase *worklist*. At every iteration where $\vec{u}$ is dependent on $R(t)_\perp$ the set *worklist* decreases by one, and therefore the algorithm terminates. In [12, Appendix B.3] we prove that in the end we have that $R(s)$ spans $V(s)$, and we analyse the runtime. ◀

▶ **Example 22.** Let us return to our running example. We see that the vector $\vec{y} = (\vec{y}_{\langle q_0,a\rangle}, \vec{y}_{\langle q_1,a\rangle}, \vec{y}_{\langle q_1,b\rangle}, \vec{y}_{\langle q_2,a\rangle}, \vec{y}_{\langle q_2,b\rangle}, \vec{y}_{\langle q_3,a\rangle})^\top = (2,1,3,1,3,2)^\top$ is a dominant eigenvector of $B_{D,D}$. Fix the order $a <_S b$. Step 1 initialises $R(a)$ to $\{\Delta'(a)\vec{y}\}$ and $R(b)$ to $\{\Delta'(b)\vec{y}\}$, where $\Delta'(a)\vec{y} = (2,1,0,1,0,2)^\top$ and $\Delta'(b)\vec{y} = (0,0,3,0,3,0)^\top$. Step 2 computes $\Delta'(a)\Delta(a)\vec{y} = (1,2,0,2,0,1)^\top$, which is linearly independent of $\Delta'(a)\vec{y}$. However, $\Delta'(b)\Delta(a)\vec{y} = (0,0,3,0,3,0)^\top = \Delta'(b)\vec{y}$. Also, $\Delta'(a)\Delta(b)\vec{y} = (3,0,0,0,0,3)^\top = 2\Delta'(a)\vec{y} - \Delta'(a)\Delta(a)\vec{y}$ and $\Delta'(b)\Delta(b)\vec{y} = (0,0,3,0,3,0)^\top = \Delta'(b)\vec{y}$. One can check that $\Delta'(a)\Delta(aa)\vec{y} = \Delta'(a)\vec{y}$ and $\Delta'(b)\Delta(aa)\vec{y} = \Delta'(b)\vec{y}$. Hence the algorithm returns $R(a) = \{(2,1,0,1,0,2)^\top, (1,2,0,2,0,1)^\top\}$ and $R(b) = \{(0,0,3,0,3,0)^\top\}$.

Fix $d = \langle q, s\rangle \in D$ for the rest of the paper. The following lemma characterises $Co(d)$-pseudo-cuts in a way that is efficiently computable:

▶ **Lemma 23.** *A vector $\vec{\mu} \in \mathbb{R}^D$ with $\vec{\mu}_d = 1$ and $\vec{\mu}_e = 0$ for all $e \notin Co(d)$ is a $Co(d)$-pseudo-cut if and only if $\vec{\mu}^\top \vec{r} = \vec{\mu}^\top \vec{y}$ holds for all $\vec{r} \in R(s)$.*

For an intuition of the proof, consider the affine space, $\mathcal{F} \subseteq \mathbb{R}^D$, affinely spanned by those $\Delta'(s)\Delta(w)\vec{y}$ for which sw is enabled. This affine space was alluded to in the beginning of this subsection and is visualised as a blue straight line on the right of Figure 1. The shaded plane in this figure is the vector space of pseudo-cuts over s. This space is orthogonal to $\mathcal{F}$. The following lemma says that $\mathcal{F}$ is affinely spanned by the points in $R(s)$. This strengthens the property of $R(s)$ in Lemma 21 where $R(s)$ was defined to span a *vector* space.

▶ **Lemma 24.** *Let $w \in S^*$ be such that sw is enabled. By the definition of $R(s)$ there are $\gamma_{\vec{r}} \in \mathbb{R}^D$ for each $\vec{r} \in R(s)$ such that $\Delta'(s)\Delta(w)\vec{y} = \sum_{\vec{r} \in R(s)} \gamma_{\vec{r}}\vec{r}$. We have $\sum_{\vec{r} \in R(s)} \gamma_{\vec{r}} = 1$.*

Proof. Let c be a cut containing d. Since $R(s)$ is a basis, for any $\vec{r} = \Delta'(s)\Delta(w_{\vec{r}})\vec{y} \in R(s)$ the word $sw_{\vec{r}}$ is enabled. Therefore, $c \triangleright w_{\vec{r}}$ is a cut and by Lemma 12 we have $[c \triangleright w_{\vec{r}}]^\top \vec{y} = [c]^\top \vec{y}$.

[1] For good numerical stability, one should use the so-called Modified Gram-Schmidt process [10, Chapter 19].

Hence $[c]^\top \vec{r} = [c]^\top \Delta'(s)\Delta(w_{\vec{r}})\vec{y} = [c]^\top \Delta(w_{\vec{r}})\vec{y} = [c \triangleright w_{\vec{r}}]^\top \vec{y} = [c]^\top \vec{y}$. Moreover, we have:

$$\begin{aligned}
[c]^\top \vec{y} &= [c]^\top \Delta(w)\vec{y} && \text{since } sw \text{ is enabled and by Lemma 12}\\
&= [c]^\top \Delta'(s)\Delta(w)\vec{y} && \text{since } [c] \text{ is a fibre over } s\\
&= [c]^\top \sum_{\vec{r}\in R(s)} \gamma_{\vec{r}}\vec{r} && \text{by the definition of } \gamma_{\vec{r}}\\
&= [c]^\top \vec{y} \sum_{\vec{r}\in R(s)} \gamma_{\vec{r}} && \text{as argued above.}
\end{aligned}$$

Therefore, $\sum_{\vec{r}\in R(s)} \gamma_{\vec{r}} = 1$. ◀

Now we can prove Lemma 23:

Proof of Lemma 23. For the “if” direction, let w be such that sw is enabled, and it suffices to show that $\vec{\mu}^\top \Delta(w)\vec{y} = \vec{\mu}^\top \vec{y}$. By Lemma 24 there are $\gamma_{\vec{r}}$ such that $\Delta'(s)\Delta(w)\vec{y} = \sum_{\vec{r}\in R(s)} \gamma_{\vec{r}}\vec{r}$ and $\sum_{\vec{r}\in R(s)} \gamma_{\vec{r}} = 1$. We have:

$$\vec{\mu}^\top \Delta(w)\vec{y} \;=\; \vec{\mu}^\top \Delta'(s)\Delta(w)\vec{y} \;=\; \sum_{\vec{r}\in R(s)} \gamma_{\vec{r}}\vec{\mu}^\top \vec{r} \;=\; \sum_{\vec{r}\in R(s)} \gamma_{\vec{r}}\vec{\mu}^\top \vec{y} \;=\; \vec{\mu}^\top \vec{y}\,,$$

where the last equality is from Lemma 24.

For the “only if” direction, suppose $\vec{\mu}$ is a $Co(d)$-pseudo-cut. Let $\vec{r} = \Delta'(s)\Delta(w_{\vec{r}})\vec{y} \in R(s)$. Then $sw_{\vec{r}}$ is enabled and $\vec{\mu}^\top \vec{r} = \vec{\mu}^\top \Delta'(s)\Delta(w_{\vec{r}})\vec{y} = \vec{\mu}^\top \Delta(w_{\vec{r}})\vec{y} = \vec{\mu}^\top \vec{y}$. ◀

▶ **Example 25.** In Example 16 we derived that $\vec{y} = (2,1,3,1,3,2)^\top$ and $R(a) = \{(2,1,0,1,0,2)^\top, (1,2,0,2,0,1)^\top\}$. The cut vector $\vec{\mu} = (1,0,0,1,0,0)^\top$ from Example 18 satisfies $\vec{\mu}^\top \vec{r} = 3 = \vec{\mu}^\top \vec{y}$ for both $\vec{r} \in R(a)$.

Using Lemmas 15, 21 and 23 we obtain:

▶ **Proposition 26.** *Let $D \subseteq Q \times S$ be a recurrent SCC. Denote by T_D the set of edges of $B_{D,D}$. For $t \in S$, let $E(t)$ denote the set of edges of M that end in t, and let $Q_{D,t} = (Q \times \{t\}) \cap D$. Let $d = \langle q, s\rangle \in D$. One can compute a $Co(d)$-pseudo-cut in time $O(|D|^\kappa + |Q||D| + |\delta||T_D| + |Q|^2 \sum_{t\in S} |Q_{D,t}||E(t)|)$.*

Now our main result follows, which we restate here:

▶ **Theorem 7.** *Given a Markov chain $\mathcal{M} = (S, M)$, an initial distribution ι, and a UBA $\mathcal{A} = (Q, S, \delta, Q_0, F)$, one can compute $\Pr_\iota^{\mathcal{M}}(\mathcal{L}(\mathcal{A}))$ in time $O(|Q|^\kappa |S|^\kappa + |Q|^3|E| + |\delta|^2|E|)$.*

4 Discussion

We have analysed two algorithms for computing normalisers: the cut-based one by Baier et al. [2, 3], and a new one, which draws from techniques by Protasov and Voynov [16] for the analysis of matrix semigroups. The first approach is purely combinatorial, and in terms of the automaton, an efficient implementation runs in time $O(|Q|^3|\delta| + |\delta|^2) = O(|Q|^3|\delta|)$ (Proposition 14).

The second approach combines a linear-algebra component to compute $R(s)$ with a combinatorial algorithm to compute the co-reachability set $Co(d)$. In terms of the automaton, the linear-algebra component runs in time $O(|Q|^3)$ (Lemma 21), while the combinatorial part runs in time $O(|\delta|^2)$, leading to an overall runtime of $O(|Q|^3 + |\delta|^2)$. Note that for all $r \in [1, 2]$, if $|\delta| = \Theta(|Q|^r)$ then the second approach is faster by at least a factor of $|Q|$.

Although it is not the main focus of this paper, we have analysed also the model-checking problem, where a non-trivial Markov chain is part of the input. The purely combinatorial algorithm runs in time $O(|Q|^\kappa|S|^\kappa + |Q|^3|\delta||S| + |\delta|^2|E|)$, and the linear-algebra based algorithm in time $O(|Q|^\kappa|S|^\kappa + |Q|^3|E| + |\delta|^2|E|)$. There are cases in which the latter is asymptotically worse, but not if $\kappa = 3$ (i.e., solving linear systems in a normal way such as Gaussian elimination) or if $|E|$ is $O(|S|)$.

It is perhaps unsurprising that a factor of $|\delta|^2$ from the computation of $Co(d)$ occurs in the runtime, as it also occurs when one merely verifies the unambiguousness of the automaton, by searching the product of the automaton with itself. Can the factor $|\delta|^2$ (which may be quartic in $|Q|$) be avoided?

Abstract

We consider the following variant of the Mortality Problem: given $k \times k$ matrices $A_1, A_2, \dots, A_t$, does there exist nonnegative integers $m_1, m_2, \dots, m_t$ such that the product $A_1^{m_1} A_2^{m_2} \cdots A_t^{m_t}$ is equal to the zero matrix? It is known that this problem is decidable when $t \leq 2$ for matrices over algebraic numbers but becomes undecidable for sufficiently large t and k even for integral matrices.

In this paper, we prove the first decidability results for $t > 2$. We show as one of our central results that for $t = 3$ this problem in any dimension is Turing equivalent to the well-known Skolem problem for linear recurrence sequences. Our proof relies on the Primary Decomposition Theorem for matrices that was not used to show decidability results in matrix semigroups before. As a corollary we obtain that the above problem is decidable for $t = 3$ and $k \leq 3$ for matrices over algebraic numbers and for $t = 3$ and $k = 4$ for matrices over real algebraic numbers. Another consequence is that the set of triples (m_1, m_2, m_3) for which the equation $A_1^{m_1} A_2^{m_2} A_3^{m_3}$ equals the zero matrix is equal to a finite union of direct products of semilinear sets.

For $t = 4$ we show that the solution set can be non-semilinear, and thus it seems unlikely that there is a direct connection to the Skolem problem. However we prove that the problem is still decidable for upper-triangular 2×2 rational matrices by employing powerful tools from transcendence theory such as Baker's theorem and S-unit equations.

1 Introduction

A large number of naturally defined matrix problems are still unanswered, despite the long history of matrix theory. Some of these questions have recently drawn renewed interest in the context of the analysis of digital processes, verification problems, and links with several fundamental questions in mathematics [11, 7, 37, 39, 38, 35, 17, 14, 15, 36, 5, 41, 27].

One of these challenging problems is the *Mortality Problem* of whether the zero matrix belongs to a finitely generated matrix semigroup. It plays a central role in many questions from control theory and software verification [44, 10, 8, 36, 2]. The mortality problem has been known to be undecidable for matrices in $\mathbb{Z}^{3\times 3}$ since 1970 [40] and the current undecidability bounds for the $M(d, k \times k)$ problem (i.e. the mortality problem for semigroups generated by d matrices of size $k \times k$) are $M(6, 3 \times 3)$, $M(4, 5 \times 5)$, $M(3, 9 \times 9)$ and $M(2, 15 \times 15)$, see [13]. It is also known that the problem is NP-hard for 2×2 integer matrices [4] and is decidable for 2×2 integer matrices with determinant $0, \pm 1$ [34]. In the case of finite matrix semigroups of any dimension the mortality problem is known to be PSPACE-complete [26].

In this paper, we study a very natural variant of the mortality problem when matrices must appear in a fixed order (i.e. under bounded language constraint): *Given $k \times k$ matrices $A_1, A_2, \ldots, A_t$ over a ring $\mathcal{F}$, do there exist $m_1, m_2, \ldots, m_t \in \mathbb{N}$ such that $A_1^{m_1} A_2^{m_2} \ldots A_t^{m_t} = \mathbf{O}_{k,k}$, where $\mathbf{O}_{k,k}$ is $k \times k$ zero matrix?*

In general (i.e. replacing $\mathbf{O}_{k,k}$ by other matrices) this problem is known as the solvability of multiplicative matrix equations and has been studied for many decades. In its simplest form, when $k = 1$, the problem was studied by Harrison in 1969 [21] as a reformulation of the "accessibility problem" for linear sequential machines. The case $t = 1$ was solved in polynomial time in a celebrated paper by Kannan and Lipton in 1980 [25]. The case $t = 2$, i.e. $A^x B^y = C$ where A, B and C are commuting matrices was solved by Cai, Lipton and Zalcstein in 1994 [12]. Later, in 1996, the solvability of matrix equations over commuting matrices was solved in polynomial time in [1] and in 2010 it was shown in [3] that $A^x B^y = C$ is decidable for non-commuting matrices of any dimension with algebraic coefficients by a reduction to the commutative case from [1]. However, it was also shown in [3] that the solvability of multiplicative matrix equations for sufficiently large natural numbers t and k is in general undecidable by an encoding of *Hilbert's tenth problem* and in particular for the mortality problem with bounded language constraint. In 2015 it was also shown that the undecidability result holds for such equations with unitriangluar matrices [31] and also in the case of specific equations with nonnegative matrices [23].

The decidability of matrix equations for non-commuting matrices is only known as corollaries of either recent decidability results for solving membership problem in 2×2 matrix semigroups [41, 42] or in the case of quite restricted classes of matrices, e.g. matrices from the Heisenberg group [27, 28] or row-monomial matrices over commutative semigroups [30]. In the other direction, progress has been made for matrix-exponential equations, but again in the case of commuting matrices [36].

In this paper, we prove the first decidability results for the above problem when $t = 3$ and $t = 4$. We will call these problems the ABC-Z and ABCD-Z problems, respectively. More precisely, we will show that the ABC-Z problem in any dimension is Turing equivalent to the Skolem problem (also known as Skolem-Pisot problem) which asks whether a given linear recurrence sequence ever reaches zero. Our proof relies on the Primary Decomposition Theorem for matrices (Theorem 2) that was not used to show decidability results in matrix semigroups before. As a corollary, we obtain that the ABC-Z problem is decidable for 2×2 and 3×3 matrices over algebraic numbers and also for 4×4 matrices over real algebraic numbers. Another consequence of the above equivalence is that the set of triples (m, n, ℓ) that satisfy the equation $A^m B^n C^\ell = \mathbf{O}_{k\times k}$ can be expressed as a finite union of direct products of semilinear sets.

In contrast to the ABC-Z problem, we show that the solution set of the ABCD-Z problem can be non-semilinear. This indicates that the ABCD-Z problem is unlikely to be related to the Skolem problem. However we will show that the ABCD-Z problem is decidable for upper-triangular 2×2 rational matrices. The proof of this result relies on powerful tools from transcendence theory such as Baker's theorem for linear forms in logarithms, S-unit equations from algebraic number theory and the Frobenius rank inequality from matrix analysis. More precisely, we will reduce the ABCD-Z equation for upper-triangular 2×2 rational matrices to an equation of the form $ax + by + cz = 0$, where x, y, z are S-units, and then use an upper bound on the solutions of this equation (as in Theorem 5). On the other hand, if we try to generalize this result to arbitrary 2×2 rational matrices or to upper-triangular matrices of higher dimension, then we end up with an equation that contain a sum of four or more S-units, and for such equations no effective upper bounds on their solutions are known. So, these generalizations seems to lie beyond the reach of current mathematical knowledge.

2 Preliminaries

We denote by $\mathbb{N}$, $\mathbb{Z}$, $\mathbb{Q}$ and $\mathbb{C}$ the sets of natural, integer, rational and complex numbers, respectively. Further, we denote by $\mathbf{A}$ the set of algebraic numbers and by $\mathbf{A}_\mathbb{R}$ the set of real algebraic numbers.

For a prime number p we define a valuation $v_p(x)$ for nonzero $x \in \mathbb{Q}$ as follows: if $x = p^k \frac{m}{n}$, where $m, n \in \mathbb{Z}$ and p does not divide m or n, then $v_p(x) = v_p(p^k \frac{m}{n}) = k$.

Throughout this paper $\mathcal{F}$ will denote either the ring of integers $\mathbb{Z}$ or one of the fields $\mathbb{Q}$, $\mathbf{A}$, $\mathbf{A}_\mathbb{R}$ or $\mathbb{C}$. We will use the notation $\mathcal{F}^{n\times m}$ for the set of $n \times m$ matrices over $\mathcal{F}$.

We denote by $\mathbf{e}_i$ the i'th standard basis vector of some dimension (which will be clear from the context). Let $\mathbf{O}_{n,m}$ be the zero matrix of size $n \times m$, $\mathbf{I}_n$ be the identity matrix of size $n \times n$, and $\mathbf{0}_n$ be the zero column vector of length n. Given a finite set of matrices $\mathcal{G} \subseteq \mathcal{F}^{n\times n}$, we denote by $\langle \mathcal{G} \rangle$ the multiplicative semigroup generated by $\mathcal{G}$.

If $A \in \mathcal{F}^{m\times m}$ and $B \in \mathcal{F}^{n\times n}$, then we define their direct sum as $A \oplus B = \left[\begin{array}{c|c} A & \mathbf{O}_{m,n} \\ \hline \mathbf{O}_{n,m} & B \end{array}\right]$. Let $C \in \mathcal{F}^{k\times k}$ be a square matrix. We write $\det(C)$ for the determinant of C. We call C singular if $\det(C) = 0$, otherwise it is said to be invertible (or non-singular). Matrices A and B from $\mathcal{F}^{k\times k}$ are called *similar* if there exists an invertible $k \times k$ matrix S (perhaps over a larger field containing $\mathcal{F}$) such that $A = SBS^{-1}$. In this case, S is said to be a similarity matrix transforming A to B.

We will also require the following inequality regarding ranks of matrices, known as the *Frobenius rank inequality*, see [24] for further details.

▶ **Theorem 1** (Frobenius Rank Inequality). *Let $A, B, C \in \mathcal{F}^{k\times k}$. Then*

$$\mathit{Rk}(AB) + \mathit{Rk}(BC) \leq \mathit{Rk}(ABC) + \mathit{Rk}(B)$$

In the proof of our first main result about the ABC-Z problem we will make use of the primary decomposition theorem for matrices.

▶ **Theorem 2** (Primary Decomposition Theorem [22]). *Let A be a matrix from $\mathcal{F}^{n\times n}$, where $\mathcal{F}$ is a field. Let $m_A(x)$ be the minimal polynomial for A such that*

$$m_A(x) = p_1(x)^{r_1} \cdots p_k(x)^{r_k},$$

where the $p_i(x)$ are distinct irreducible monic polynomials over $\mathcal{F}$ and the r_i are positive integers. Let W_i be the null space of $p_i(A)^{r_i}$ and let S_i be a basis for W_i. Then

(1) *$S_1 \cup \cdots \cup S_k$ is a basis for $\mathcal{F}^n$ and $\mathcal{F}^n = W_1 \oplus \cdots \oplus W_k$,*

(2) *each W_i is invariant under A, that is, $A\mathbf{x} \in W_i$ for any $\mathbf{x} \in W_i$,*

(3) *let S be a matrix whose columns are equal to the basis vectors from $S_1 \cup \cdots \cup S_k$; then*

$$S^{-1}AS = A_1 \oplus \cdots \oplus A_k,$$

where each A_i is a matrix over $\mathcal{F}$ of the size $|S_i| \times |S_i|$, and the minimal polynomial of A_i is equal to $p_i(x)^{r_i}$.

The next two propositions are well-known facts.

▶ **Proposition 3.** *If $p(x)$ is a polynomial over a field $\mathcal{F}$, where $\mathcal{F}$ is either $\mathbb{Q}$, $\mathbf{A}$ or $\mathbf{A}_{\mathbb{R}}$, then the primary decomposition of $p(x)$ can be algorithmically computed.*

▶ **Proposition 4.** *Let $A \in \mathcal{F}^{n\times n}$ and $m_A(x)$ be the minimal polynomial of A. Then A is invertible if and only if $m_A(x)$ has nonzero free coefficient, i.e., $m_A(x)$ is not divisible by x.*

Our proof of the decidability of ABCD-Z problem for 2×2 upper-triangular rational matrices relies on the following result which is proved using Baker's theorem on linear forms in logarithms (see Corollary 4 in [16] and also [18]).

▶ **Theorem 5.** *Let $S = \{p_1, \dots, p_s\}$ be a finite collection of prime numbers and let a, b, c be relatively prime nonzero integers, that is, $\gcd(a, b, c) = 1$.*

If x, y, z are relatively prime nonzero integers composed of primes from S that satisfy the equation $ax + by + cz = 0$, then

$$\max\{|x|, |y|, |z|\} < \exp(s^{Cs} P^{4/3} \log A)$$

for some constant C, where $P = \max\{p_1, \dots, p_s\}$ and $A = \max\{|a|, |b|, |c|, 3\}$.

▶ Remark. Rational numbers whose numerator and denominator are divisible only by the primes from S are called *S-units*.

3 Linear recurrence sequences and semilinear sets

There is a long history in computer science and mathematics of studying sequences of numbers defined by some recurrence relation, where the next value in the sequence depends upon some "finite memory" of previous values in the sequence. Possibly the simplest, and certainly the most well known of these, is the *Fibonacci sequence*, which may be defined by the recurrence $F(n) = F(n-1) + F(n-2)$ with $F(0) = F(1) = 1$ being given as the *initial conditions* of the sequence. We may generalise the Fibonacci sequence to define a *linear recurrence sequence*, which find application in many areas of mathematics and other sciences and for which many questions remain open. Let $\mathcal{F}$ be a ring; a sequence $(u_n)_{n=0}^{\infty}$ is called a *linear recurrence sequence* (1-LRS) if it satisfies a relation of the form:

$$u_n = a_{k-1}u_{n-1} + \cdots + a_1 u_{n-k+1} + a_0 u_{n-k},$$

for any $n \geq k$, where each $a_0, a_1, \dots, a_{k-1} \in \mathcal{F}$ are fixed coefficients[1]. Such a sequence $(u_n)_{n=0}^{\infty}$ is said to be of depth k if it satisfies no shorter linear recurrence relation (for any

[1] In the literature, such a sequence is ordinarily called an LRS; we use the nomenclature 1-LRS since we will study a multidimensional variant of this concept. Also, 1-LRS are usually considered over integers, but in the present paper we will consider such sequences over algebraic numbers.

$k' < k$). We call the initial k values of the sequence $u_0, u_1, \dots, u_{k-1}$ the initial conditions of the 1-LRS. Given the initial conditions and coefficients of a 1-LRS, every element is uniquely determined.

The *zero set* of a 1-LRS is defined as follows: $\mathcal{Z}(u_n) = \{j \in \mathbb{N} \mid u_j = 0\}$.

There are various questions that one may ask regarding $\mathcal{Z}(u_n)$. One notable example relates to the famous "Skolem's problem" which is stated in the following way:

▶ **Problem 6** (Skolem's Problem)**.** *Given the coefficients and initial conditions of a depth k 1-LRS $(u_n)_{n=0}^{\infty}$, determine if $\mathcal{Z}(u_n)$ is the empty set.*

Skolem's problem has a long and rich history, see [19] for a good survey. We note here that the problem remains open despite properties of zero sets having been studied even since 1934 [43]. It is known that the Skolem problem is at least NP-hard [9] and that it is decidable for depth 3 over $\mathbf{A}$ and for depth 4 over $\mathbf{A}_{\mathbb{R}}$, see [44] and [33][2]. Other interesting questions are related to the structure of $\mathcal{Z}(u_n)$. We remind the reader the definition of semilinear sets.

▶ **Definition 7** (Semilinear set)**.** *A set $S \subseteq \mathbb{N}$ is called* semilinear *if it is the union of a finite set and finitely many arithmetic progressions.*

A seminal result regarding 1-LRSs is that there zero sets are semilinear.

▶ **Theorem 8** (Skolem, Mahler, Lech [32, 43, 29] and [19, 20])**.** *The zero set of a 1-LRS over $\mathbb{C}$ (or more generally over any field of characteristic 0) is semilinear.*

In particular, if $(u_n)_{n=0}^{\infty}$ is a 1-LRS whose coefficients and initial conditions are algebraic numbers, then one can algorithmically find a number $L \in \mathbb{N}$ such that for every $i = 0, \dots, L-1$, if we let $u_m^i = u_{i+mL}$, then

(1) *the sequence $(u_m^i)_{m=0}^{\infty}$ is a 1-LRS of the same depth as $(u_n)_{n=0}^{\infty}$, and*

(2) *either $\mathcal{Z}(u_m^i) = \mathbb{N}$ or $\mathcal{Z}(u_m^i)$ is finite.*

Note that in the above theorem we can decide whether $\mathcal{Z}(u_m^i)$ is finite or $\mathcal{Z}(u_m^i) = \mathbb{N}$ because $\mathcal{Z}(u_m^i) = \mathbb{N}$ if and only if $u_0^i = \cdots = u_{k-1}^i = 0$, where k is the depth of $(u_m^i)_{m=0}^{\infty}$.

We will also consider a stronger version of the Skolem problem.

▶ **Problem 9** (Strong Skolem's Problem)**.** *Given the coefficients and initial conditions of a 1-LRS $(u_n)_{n=0}^{\infty}$ over $\mathbf{A}$, find a description of the set $\mathcal{Z}(u_n)$. That is, find a finite set F such that $\mathcal{Z}(u_n) = F$ if $\mathcal{Z}(u_n)$ is finite or, if $\mathcal{Z}(u_n)$ is infinite, find a finite set F, a constant $L \in \mathbb{N}$ and numbers $i_1, \dots, i_t \in \{0, \dots, L-1\}$ such that*

$$\mathcal{Z}(u_n) = F \cup \{i_1 + mL : m \in \mathbb{N}\} \cup \dots \cup \{i_t + mL : m \in \mathbb{N}\}.$$

Using the Skolem-Mahler-Lech theorem we can prove an equivalence between the strong version of the Skolem problem and the standard version[3].

▶ **Theorem 10.** *Skolem's problem of depth k over $\mathbf{A}$ is Turing equivalent to the strong Skolem's problem of the same depth.*

Proof. Obviously, Skolem's problem is reducible to the strong Skolem's problem. We now show a reduction in the other direction.

Let $(u_n)_{n=0}^{\infty}$ be a depth-k 1-LRS over $\mathbf{A}$. By Theorem 8, we can algorithmically find a number L such that, for every $i = 0, \dots, L-1$, the sequence $u_m^i = u_{i+mL}$ is a 1-LRS of

[2] A proof of decidability for depth 5 was claimed in [19], although there is possibly a gap in the proof [37].

[3] This result was announced in [44] without a proof, probably with a similar construction in mind.

depth k which is either everywhere zero, that is, $\mathcal{Z}(u^i_m) = \mathbb{N}$ or $\mathcal{Z}(u^i_m)$ is finite. Recall that we can decide whether $\mathcal{Z}(u^i_m)$ is equal to $\mathbb{N}$ by considering the first k terms of $(u^i_m)_{m=0}^\infty$.

By definition, we have $\mathcal{Z}(u_n) = \bigcup_{i=0}^{L-1} \{i+L\mathcal{Z}(u^i_m)\}$. So, if $\mathcal{Z}(u^i_m) = \mathbb{N}$, then $\{i+L\mathcal{Z}(u^i_m)\} = \{i + mL : m \in \mathbb{N}\}$, and if $\mathcal{Z}(u^i_m)$ is finite, then so is $\{i + L\cdot\mathcal{Z}(u^i_m)\}$.

To finish the proof we need to show how to compute $\mathcal{Z}(u^i_m)$, and hence $\{i + L\cdot\mathcal{Z}(u^i_m)\}$, when it is finite. For this we will use an oracle for the Skolem problem. Let m' be the smallest number such that $\mathcal{Z}(u^i_{m+m'})$ is empty. Such m' exists because $\mathcal{Z}(u^i_m)$ is finite. Furthermore, $(u_{m+m'})_{m=0}^\infty$ is a 1-LRS of depth k for any m'. So, we ask the oracle for the Skolem problem to decide whether $\mathcal{Z}(u^i_{m+m'}) = \emptyset$ for each $m' \in \mathbb{N}$ starting from 0 until we find one for which $\mathcal{Z}(u^i_{m+m'})$ is empty. Note that we do not have any bound on m' because we do not even know the size of $\mathcal{Z}(u^i_m)$. All we know is that $\mathcal{Z}(u^i_m)$ is finite, and hence the above algorithm will eventually terminate. Since $\mathcal{Z}(u^i_m)$ is a subset of $\{0, \dots, m'\}$, then we can compute it by checking whether $u^i_m = 0$ for $m = 0, \dots, m'$. ◀

Linear recurrence sequences can also be represented using matrices [19]:

▶ **Lemma 11.** *Let $\mathcal{F}$ be a ring; for a sequence $(u_n)_{n=0}^\infty$ over $\mathcal{F}$ the following are equivalent:*

(1) *$(u_n)_{n=0}^\infty$ is a 1-LRS of depth k.*

(2) *There are vectors $\mathbf{u}, \mathbf{v} \in \mathcal{F}^k$ and a matrix $M \in \mathcal{F}^{k\times k}$ such that $u_n = \mathbf{u}^T M^n \mathbf{v}$ for $n \in \mathbb{N}$.*

Moreover, for any matrix $M \in \mathcal{F}^{k\times k}$, the sequence $u_n = (M^n)_{[1,k]}$ is a 1-LRS of depth at most k. On the other hand, if $(u_n)_{n=0}^\infty$ is a 1-LRS of depth k, then there is a matrix $M \in \mathcal{F}^{(k+1)\times(k+1)}$ such that $u_n = (M^n)_{[1,k+1]}$ for all $n \in \mathbb{N}$.

Lemma 11 motivates the following definition of n-dimensional Linear Recurrence Sequences (n-LRSs) which as we show later are related to the mortality problem for bounded languages.

▶ **Definition 12** (n-LRS)**.** *A multidimensional sequence $u_{m_1,m_2,\dots,m_n}$ is called an n-LRS of depth k over $\mathcal{F}$ if there exist two vectors $\mathbf{u}, \mathbf{v} \in \mathcal{F}^k$ and matrices $M_1, M_2, \dots, M_n \in \mathcal{F}^{k\times k}$ such that*

$$u_{m_1,m_2,\dots,m_n} = \mathbf{u}^T M_1^{m_1} M_2^{m_2} \cdots M_n^{m_n} \mathbf{v}.$$

4 The mortality problem for bounded languages

We remind the reader the definition of the mortality problem for bounded languages.

▶ **Problem 13** (Mortality for bounded languages)**.** *Given $k \times k$ matrices $A_1, \dots, A_t$ over a ring $\mathcal{F}$, do there exist $m_1, m_2, \dots, m_t \in \mathbb{N}$ such that*

$$A_1^{m_1} A_2^{m_2} \dots A_t^{m_t} = \mathbf{O}_{k,k}.$$

Recall that for $t = 3$ and $t = 4$ this problem is called the ABC-Z and ABCD-Z problem, respectively. Our first main result is that the ABC-Z problem is computationally equivalent to the Skolem problem for 1-LRS. Our reduction holds in any dimension and over the same number field which means that any new decidability results for the Skolem problem will automatically extend the decidability of ABC-Z equations and can immediately lead to new decidability results for equations in dimensions 2, 3 and 4. For the proof we will need the following technical lemma.

▶ **Lemma 14.** *Let $\mathcal{F}$ be a field, and suppose $A, B, C \in \mathcal{F}^{k\times k}$ are matrices of the form*

$$A = \left[\begin{array}{c|c} A_{s,s} & \mathbf{O}_{s,k-s} \\ \hline \mathbf{O}_{k-s,s} & \mathbf{O}_{k-s,k-s} \end{array}\right], \; B = \left[\begin{array}{c|c} B_{s,t} & X_{s,k-t} \\ \hline Y_{k-s,t} & Z_{k-s,k-t} \end{array}\right], \; C = \left[\begin{array}{c|c} C_{t,t} & \mathbf{O}_{t,k-t} \\ \hline \mathbf{O}_{k-t,t} & \mathbf{O}_{k-t,k-t} \end{array}\right]$$

for some $s, t \le k$, where $A_{s,s}$, $B_{s,t}$, $X_{s,k-t}$, $Y_{k-s,t}$, $Z_{k-s,k-t}$ and $C_{t,t}$ are matrices over $\mathcal{F}$ whose dimensions are indicated by their subscripts (in particular, $A = A_{s,s} \oplus \mathbf{O}_{k-s,k-s}$ and $C = C_{t,t} \oplus \mathbf{O}_{k-t,k-t}$). If $A_{s,s}$ and $C_{t,t}$ are invertible matrices, then the equation $ABC = \mathbf{O}_{k,k}$ is equivalent to $B_{s,t} = \mathbf{O}_{s,t}$.

Proof. It is not hard to check that

$$AB = \left[\begin{array}{c|c} A_{s,s} & \mathbf{O}_{s,k-s} \\ \hline \mathbf{O}_{k-s,s} & \mathbf{O}_{k-s,k-s} \end{array}\right] \cdot \left[\begin{array}{c|c} B_{s,t} & X_{s,k-t} \\ \hline Y_{k-s,t} & Z_{k-s,k-t} \end{array}\right] = \left[\begin{array}{c|c} A_{s,s}B_{s,t} & A_{s,s}X_{s,k-t} \\ \hline \mathbf{O}_{k-s,t} & \mathbf{O}_{k-s,k-t} \end{array}\right],$$

and hence

$$(AB)C = \left[\begin{array}{c|c} A_{s,s}B_{s,t} & A_{s,s}X_{s,k-t} \\ \hline \mathbf{O}_{k-s,t} & \mathbf{O}_{k-s,k-t} \end{array}\right] \cdot \left[\begin{array}{c|c} C_{t,t} & \mathbf{O}_{t,k-t} \\ \hline \mathbf{O}_{k-t,t} & \mathbf{O}_{k-t,k-t} \end{array}\right] = \left[\begin{array}{c|c} A_{s,s}B_{s,t}C_{t,t} & \mathbf{O}_{s,k-t} \\ \hline \mathbf{O}_{k-s,t} & \mathbf{O}_{k-s,k-t} \end{array}\right].$$

So, if $B_{s,t} = \mathbf{O}_{s,t}$, then $ABC = \mathbf{O}_{k,k}$. Conversely, if $ABC = \mathbf{O}_{k,k}$, then $A_{s,s}B_{s,t}C_{t,t} = \mathbf{O}_{s,t}$. Using the fact that $A_{s,s}$ and $C_{t,t}$ are invertible matrices, we can multiply the equation $A_{s,s}B_{s,t}C_{t,t} = \mathbf{O}_{s,t}$ by $A_{s,s}^{-1}$ on the left and by $C_{t,t}^{-1}$ on the right to obtain that $B_{s,t} = \mathbf{O}_{s,t}$. ◀

▶ **Theorem 15.** *Let $\mathcal{F}$ be the ring of integers $\mathbb{Z}$ or one of the fields $\mathbb{Q}$, $\mathbf{A}$ or $\mathbf{A}_{\mathbb{R}}$. Then the ABC-Z problem for matrices from $\mathcal{F}^{k\times k}$ is Turing equivalent to the Skolem problem of depth k over $\mathcal{F}$.*

Proof. First, we show reduction from the ABC-Z problem to the Skolem problem.

Clearly, the ABC-Z problem over $\mathbb{Z}$ is equivalent to the ABC-Z problem over $\mathbb{Q}$ (by multiplying the matrices A, B, C by a suitable integer number). It is also not hard to see that the Skolem problem for 1-LRS over $\mathbb{Q}$ is equivalent to the Skolem problem over $\mathbb{Z}$ for 1-LRS of the same depth. Indeed, by Lemma 11 we can express any 1-LRS $(u_n)_{n=0}^{\infty}$ over $\mathbb{Q}$ as $u_n = \mathbf{u}^T M^n \mathbf{v}$ for some rational vectors $\mathbf{u}$ and $\mathbf{v}$ and a rational matrix M. If we multiply $\mathbf{u}$, $\mathbf{v}$ and M by a suitable natural number t, then $(t^{n+2}u_n)_{n=0}^{\infty}$ will be an integer 1-LRS, which has the same zero set as $(u_n)_{n=0}^{\infty}$. Hence, without loss of generality, we will assume that $\mathcal{F}$ is one of the fields $\mathbb{Q}$, $\mathbf{A}$ or $\mathbf{A}_{\mathbb{R}}$.

Consider an instance of the ABC-Z problem: $A^m B^n C^\ell = \mathbf{O}_{k,k}$, where $A, B, C \in \mathcal{F}^{k,k}$. Let $\chi_A(x)$ be the characteristic polynomial of A. By Proposition 3, we can find a primary decomposition $\chi_A(x) = p_1(x)^{m_1} \cdots p_t(x)^{m_t}$, where $p_1(x), \dots, p_t(x)$ are distinct irreducible monic polynomials. From this decomposition we can find the minimal polynomial $m_A(x)$ of A because $m_A(x)$ is a factor of $\chi_A(x)$, and we can check all divisors of $\chi_A(x)$ to find $m_A(x)$.

Let $m_A(x) = p_1(x)^{r_1} \cdots p_u(x)^{r_u}$, where $p_1(x), \dots, p_u(x)$ are distinct irreducible monic polynomials. Now we apply the Primary Decomposition Theorem (Theorem 2) to A. Let S_i be a basis for the null space of $p_i(A)^{r_i}$, which can be found, e.g., using Gaussian elimination. Let S be a matrix whose columns are the vectors of the basis $S_1 \cup \cdots \cup S_u$. Then

$$S^{-1}AS = A_1 \oplus \cdots \oplus A_u,$$

where the minimal polynomial of A_i is $p_i(A)^{r_i}$ for $i = 1, \dots, u$. Similarly, we can compute a primary decomposition $m_C(x) = q_1(x)^{s_1} \cdots q_v(x)^{s_v}$ of the minimal polynomial for C, where $q_1(x), \dots, q_v(x)$ are distinct irreducible monic polynomials, and a matrix T such that

$$T^{-1}CT = C_1 \oplus \cdots \oplus C_v,$$

where the minimal polynomial of C_i is $q_i(C)^{s_i}$ for $i = 1, \dots, v$.

Note that if $p(x)$ is an irreducible monic polynomial, then either $p(x) = x$ or x does not divide $p(x)$. So, among the polynomials $p_1(x), \dots, p_u(x)$ in the primary decomposition of $m_A(x)$ at most one is equal to x, and the same holds for the polynomials $q_1(x), \dots, q_v(x)$ in the primary decomposition of $m_C(x)$.

Suppose, for example, that $p_u(x) = x$. In this case $m_A(x) = p_1(x)^{r_1} \cdots p_{u-1}(x)^{r_{u-1}} x^{r_u}$, and $S^{-1}AS = A_1 \oplus \cdots \oplus A_{u-1} \oplus A_u$, where the minimal polynomial of A_u is x^{r_u}, and hence A_u is a nilpotent matrix of index r_u. Recall that, for $i = 1, \dots, u-1$, the polynomial $p_i(x)$ is not divisible by x, and so is $p_i(x)^{r_i}$, which is the minimal polynomial for A_i. Hence, by Proposition 4, A_i is invertible. Let $A_{\text{inv}} = A_1 \oplus \cdots \oplus A_{u-1}$ and $A_{\text{nil}} = A_u$. Then we obtain

$$S^{-1}AS = A_{\text{inv}} \oplus A_{\text{nil}}, \tag{1}$$

where A_{inv} is invertible, and A_{nil} is nilpotent. If $p_i(x) = x$ for some $i < u$, then we need in addition to permute some rows and columns of matrix S to obtain one that gives us Equation (1) above. If none of the $p_i(x)$ is equal to x, then we assume that A_{nil} is the empty matrix of size 0×0.

The same reasoning can be applied to matrix C, that is, we can compute an invertible matrix C_{inv}, a nilpotent (or empty) matrix C_{nil}, and an invertible matrix T such that

$$T^{-1}CT = C_{\text{inv}} \oplus C_{\text{nil}}.$$

Note that the indices of the nilpotent matrices A_{nil} and C_{nil} are at most k, and hence A^k_{nil} and C^k_{nil} are zero (or empty) matrices.

Our goal is to find all triples $(m, n, \ell) \in \mathbb{N}^3$ for which $A^m B^n C^\ell = \mathbf{O}_{k,k}$. In order to do this we will consider four cases: (1) $m \geq k$ and $\ell \geq k$, (2) $m < k$ and $\ell < k$, (3) $m \geq k$ and $\ell < k$, and (4) $m < k$ and $\ell \geq k$.

Before dealing with each of these cases, we note that the equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$ is equivalent to

$$\begin{aligned} &S(A^m_{\text{inv}} \oplus A^m_{\text{nil}})S^{-1}B^nT(C^\ell_{\text{inv}} \oplus C^\ell_{\text{nil}})T^{-1} = \mathbf{O}_{k,k} \quad \text{or to} \\ &\ (A^m_{\text{inv}} \oplus A^m_{\text{nil}})S^{-1}B^nT(C^\ell_{\text{inv}} \oplus C^\ell_{\text{nil}}) = \mathbf{O}_{k,k} \end{aligned}$$

because S and T are invertible matrices.

Now suppose A_{inv} has size $s \times s$, and C_{inv} has size $t \times t$ for some $s, t \leq k$.

Case 1: $m \geq k$ and $\ell \geq k$. Since $m, \ell \geq k$, we have $A^m_{\text{nil}} = \mathbf{O}_{k-s,k-s}$ and $C^\ell_{\text{nil}} = \mathbf{O}_{k-t,k-t}$, and hence the equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$ is equivalent to

$$(A^m_{\text{inv}} \oplus \mathbf{O}_{k-s,k-s})S^{-1}B^nT(C^\ell_{\text{inv}} \oplus \mathbf{O}_{k-t,k-t}) = \mathbf{O}_{k,k}. \tag{2}$$

Suppose the matrix $S^{-1}B^nT$ has a form $S^{-1}B^nT = \left[\begin{array}{c|c} B_{s,t} & X_{s,k-t} \\ \hline Y_{k-s,t} & Z_{k-s,k-t} \end{array}\right]$. Since A^m_{inv} and C^ℓ_{inv} are invertible matrices, Lemma 14 implies that Equation (2) is equivalent to $B_{s,t} = \mathbf{O}_{s,t}$. Therefore, we obtain the following equivalence: $A^m B^n C^\ell = \mathbf{O}_{k,k}$ if and only if

$$s^{i,j}_n = (\mathbf{e}_i^\top S^{-1})B^n(T\mathbf{e}_j) = 0 \quad \text{for all } i = 1, \dots, s \text{ and } j = 1, \dots, t. \tag{3}$$

By Lemma 11, the sequence $(s^{i,j}_n)^\infty_{n=0}$ is a 1-LRS of order k over $\mathcal{F}$. As in the proof of Theorem 10, we can use an oracle for the Skolem problem for 1-LRS of depth k over $\mathcal{F}$ to compute the descriptions of the semilinear sets $\mathcal{Z}(s^{i,j}_n)$. Hence we can compute a description of the intersection $Z_1 = \bigcap\limits_{\substack{i=1,\dots,s \\ j=1,\dots,t}} \mathcal{Z}(s^{i,j}_n)$, which is also a semilinear set. An important observation is that the set Z_1 does not depend on m and ℓ.

Below is a brief description of the remaining cases. The detailed proof of Cases 2, 3 and 4 can be found in the full version [6].

Case 2: $m < k$ and $\ell < k$. Fix some $m < k$ and $\ell < k$. For this particular choice of m and ℓ, we can compute a description of the semilinear set $Z_2(m, \ell)$ which is equal to all values of n for which $A^m B^n C^\ell = \mathbf{O}_{k,k}$ holds for fixed $m, \ell < k$.

Case 3: $m \geq k$ and $\ell < k$ and **Case 4: $m < k$ and $\ell \geq k$.** To solve these cases we will combine ideas from Cases 1 and 2. Namely, we can compute the descriptions of the semilinear sets $Z_3(\ell)$ and $Z_4(m)$ such that

- $Z_3(\ell) \;= \{\, n \;:\; A^m B^n C^\ell = \mathbf{O}_{k,k} \;\text{ for all } m \geq k\,\}$.
- $Z_4(m) = \{\, n \;:\; A^m B^n C^\ell = \mathbf{O}_{k,k} \;\text{ for all } \ell \geq k\,\}$.

Combining all the above cases together, we conclude that the set of all triples $(m, n, \ell) \in \mathbb{N}^3$ that satisfy the equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$ is equal to the following union

$$\begin{aligned}\{(m,n,\ell) : n \in Z_1 \text{ and } m, \ell \geq k\} \bigcup \bigcup_{m,\ell<k} \{(m,n,\ell) : n \in Z_2(m,\ell)\} \bigcup \\ \bigcup_{\ell<k} \{(m,n,\ell) : n \in Z_3(\ell) \text{ and } m \geq k\} \bigcup \bigcup_{m<k} \{(m,n,\ell) : n \in Z_4(m) \text{ and } \ell \geq k\}.\end{aligned} \tag{4}$$

Having a description for the above set, we can decide whether is it empty or not, that is, whether there exist $m, n, \ell \in \mathbb{N}$ such that $A^m B^n C^\ell = \mathbf{O}_{k,k}$.

We now show the reduction in the other direction. Let $(u_n)_{n=0}^\infty$ be a 1-LRS that satisfies a relation

$$u_n = a_{k-1}u_{n-1} + \cdots + a_1 u_{n-k+1} + a_0 u_{n-k},$$

where $a_0 \neq 0$. Let A, B and C be the following matrices of size $k \times k$:

$$A = \begin{pmatrix} u_{k-1} & \cdots & u_1 & u_0 \\ 0 & \cdots & 0 & 0 \\ 0 & \cdots & 0 & 0 \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & 0 & 0 \end{pmatrix}, \; B = \begin{pmatrix} a_{k-1} & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ a_2 & 0 & \cdots & 1 & 0 \\ a_1 & 0 & \cdots & 0 & 1 \\ a_0 & 0 & \cdots & 0 & 0 \end{pmatrix}, \; C = \begin{pmatrix} 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cdots & 0 & 1 \end{pmatrix}.$$

A straightforward computation shows that the product $A^m B^n C^\ell$ is equal to a matrix where all entries equal zero except for the entry in the upper-right corner which is equal to $u_{k-1}^{m-1} u_n$. So, if we assume that $u_{k-1} \neq 0$, then we have the following implications: (1) if $A^m B^n C^\ell = \mathbf{O}_{k,k}$ for some $m, n, \ell \in \mathbb{N}$ with $m, \ell \geq 1$, then $u_n = 0$; and (2) if $u_n = 0$, then the equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$ holds for any $m, \ell \geq 1$.

The assumption that $u_{k-1} \neq 0$ is not a serious restriction because we can shift the original sequence by at most k positions to ensure that $u_{k-1} \neq 0$. In other words, instead of $(u_n)_{n=0}^\infty$ we can consider a sequence $(u_{n+t})_{n=0}^\infty$ for some $t > 0$. It is easy to check that a 1-LRS of depth k is identically zero if and only if it contains k consecutive zeros. Hence if $(u_n)_{n=0}^\infty$ is not identically zero, then we can find $t < k$ such that the sequence $(u_{n+t})_{n=0}^\infty$ satisfies the condition that $u_{k-1+t} \neq 0$. ◀

▶ **Corollary 16.** *The set of triples (m, n, ℓ) that satisfy an equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$ is equal to a finite union of direct products of semilinear sets.*

Proof. The corollary follows from Equation (4) above that describes all triples (m, n, ℓ) that satisfy the equation $A^m B^n C^\ell = \mathbf{O}_{k,k}$. By construction and the Skolem-Mahler-Lech theorem, the sets Z_1, $Z_2(m, \ell)$, $Z_3(\ell)$ and $Z_4(m)$ are semilinear. In Equation (4) we take direct product of these sets either with singleton sets or with sets of the form $\mathbb{N}_k = \{n \in \mathbb{N} : n \geq k\}$, which are also semilinear sets, and then take a finite union of such products. In other words, Equation (4) can be rewritten as follows

$$\mathbb{N}_k \times Z_1 \times \mathbb{N}_k \bigcup \bigcup_{m,\ell<k} \{m\} \times Z_2(m,\ell) \times \{\ell\} \bigcup \bigcup_{\ell<k} \mathbb{N}_k \times Z_3(\ell) \times \{\ell\} \bigcup \bigcup_{m<k} \{m\} \times Z_4(m) \times \mathbb{N}_k.$$

The main corollary of Theorem 15 is the following result. ◀

▶ **Corollary 17.** *The ABC-Z problem is decidable for* 3×3 *matrices over algebraic numbers and for* 4×4 *matrices over real algebraic numbers.*

Proof. By Theorem 15, the ABC-Z problem for 3×3 matrices over $\mathbf{A}$ is equivalent to the Skolem problem of depth 3 over $\mathbf{A}$, and the ABC-Z problem 4×4 matrices over $\mathbf{A}_{\mathbb{R}}$ is equivalent to the Skolem problem of depth 4 over $\mathbf{A}_{\mathbb{R}}$. Now the corollary follows from the fact that the Skolem problem is decidable for linear recurrence sequences of depth 3 over $\mathbf{A}$ and of depth 4 over $\mathbf{A}_{\mathbb{R}}$ [44, 33]. ◀

5 The ABCD-Z problem in dimension two

Recall that the ABCD-Z problem in dimension two asks whether there exist natural numbers $k, m, n, \ell \in \mathbb{N}$ such that

$$A^k B^m C^n D^\ell = \mathbf{O}_{2,2}. \tag{5}$$

In this section we will show that this problem is decidable for 2×2 upper-triangular matrices with rational coefficients. In the proof we will use the following simple lemmas which show how to diagonalise and compute powers of an upper-triangular 2×2 matrix.

▶ **Lemma 18.** *Given an upper triangular matrix* $\begin{pmatrix} a & b \\ 0 & c \end{pmatrix}$ *such that* $a \neq c$ *then:*

$$\begin{pmatrix} a & b \\ 0 & c \end{pmatrix} = \begin{pmatrix} 1 & -\frac{b}{a-c} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} a & 0 \\ 0 & c \end{pmatrix} \begin{pmatrix} 1 & \frac{b}{a-c} \\ 0 & 1 \end{pmatrix}$$

▶ **Lemma 19.** *For any matrices of the form* $\begin{pmatrix} a & b \\ 0 & c \end{pmatrix}$ *and* $\begin{pmatrix} a & b \\ 0 & a \end{pmatrix}$, *such that* $a \neq c$, *and any* $k \in \mathbb{N}$ *we have* $\begin{pmatrix} a & b \\ 0 & c \end{pmatrix}^k = \begin{pmatrix} a^k & b\dfrac{a^k - c^k}{a - c} \\ 0 & c^k \end{pmatrix}$ *and* $\begin{pmatrix} a & b \\ 0 & a \end{pmatrix}^k = \begin{pmatrix} a^k & kba^{k-1} \\ 0 & a^k \end{pmatrix}$.

▶ **Theorem 20.** *The ABCD-Z problem is decidable for* 2×2 *upper-triangular matrices over rational numbers.*

Proof. First, note that if one of the matrices A, B, C or D is nilpotent, then Equation (5) obviously has a solution. So from now on we assume that none of A, B, C or D is nilpotent. Furthermore, if A or D is invertible, then the ABCD-Z problem reduces to the ABC-Z problem for rational matrices of dimension two that is decidable by Theorem 15. So, without loss of generality, we will assume that both A and D are singular matrices.

Now suppose we are given an instance of the ABCD-Z problem which satisfies the above-mentioned requirements. We will show that if Equation (5) has a solution, then it has a solution with $k = \ell = 1$. Indeed, assume Equation (5) has a solution, and let (k, m, n, ℓ) be a solution of minimal length, where the length of a solution is the sum $k + m + n + \ell$. Using

Theorem 15 we can exclude the case when $k = 0$ or $\ell = 0$ since in this case our problem is just an instance of the ABC-Z for 2×2 matrices. So we will assume that in the above solution $k, \ell \geq 1$.

By the Frobenius rank inequality (Theorem 1), we have that:

$$\mathsf{Rk}(A^k B^m C^n D^{\ell-1}) + \mathsf{Rk}(A^{k-1} B^m C^n D^{\ell}) \leq \mathsf{Rk}(A^{k-1} B^m C^n D^{\ell-1}).$$

This follows since $\mathsf{Rk}(A^k B^m C^n D^{\ell}) = \mathsf{Rk}(\mathbf{O}_{2,2}) = 0$. In the above inequality, notice that neither $A^k B^m C^n D^{\ell-1}$ nor $A^{k-1} B^m C^n D^{\ell}$ is the zero matrix by the assumption that the solution has minimal length. Hence the ranks of the matrices on the left hand side are at least 1. Therefore, $\mathsf{Rk}(A^{k-1} B^m C^n D^{\ell-1}) = 2$. Since we assumed that A and D are singular, it is necessary that $k = \ell = 1$. Also notice that if $\mathsf{Rk}(B) = 1$ or $\mathsf{Rk}(C) = 1$, then we must have $m = 0$ or $n = 0$, respectively. Again these cases can be excluded by Theorem 15.

Thus, using the Frobenius rank inequality and the assumption that the solution is of minimal length, we reduced the ABCD-Z problem to an equation of the form:

$$AB^m C^n D = \mathbf{O}_{2,2},$$

where $\mathsf{Rk}(A) = \mathsf{Rk}(D) = 1$ and $\mathsf{Rk}(B) = \mathsf{Rk}(C) = 2$.

We assumed that A and D have rank one but are not nilpotent. This means that they have one zero and one nonzero element on the diagonal, in particular, they satisfy the condition of Lemma 18. Hence we can find invertible rational matrices S_A and S_D such that

$$A = S_A^{-1} \begin{pmatrix} a & 0 \\ 0 & 0 \end{pmatrix} S_A \quad \text{and} \quad D = S_D^{-1} \begin{pmatrix} d & 0 \\ 0 & 0 \end{pmatrix} S_D,$$

where a, d are nonzero rational numbers. Applying Lemma 14 with matrix $S_A B^m C^n S_D^{-1}$ in place of B, we conclude that $AB^m C^n D = \mathbf{O}_{2,2}$ holds if and only if the $(1,1)$-entry of $S_A B^m C^n S_D^{-1}$ equals zero. In other words, the equation $AB^m C^n D = \mathbf{O}_{2,2}$ is equivalent to $s_{m,n} = \mathbf{u}^\top B^m C^n \mathbf{v} = 0$, where $\mathbf{u}^\top = \mathbf{e}_1^\top S_A$ and $\mathbf{v} = S_D^{-1} \mathbf{e}_1$ are vectors with rational coefficients.

We will consider three cases: (1) both B and C have distinct eigenvalues, (2) both B and C have a single eigenvalue of multiplicity 2 and (3) one matrix has distinct eigenvalues and the other has a single eigenvalue of multiplicity 2.

Case (1): B and C have distinct eigenvalues, that is, $B = \begin{pmatrix} b_1 & b_3 \\ 0 & b_2 \end{pmatrix}$ and $C = \begin{pmatrix} c_1 & c_3 \\ 0 & c_2 \end{pmatrix}$, where $b_1 \neq b_2$ and $c_1 \neq c_2$. By Lemma 19 we have

$$B^m = \begin{pmatrix} b_1^m & b_3 \dfrac{b_1^m - b_2^m}{b_1 - b_2} \\ 0 & b_2^m \end{pmatrix} \quad \text{and} \quad C^n = \begin{pmatrix} c_1^n & c_3 \dfrac{c_1^n - c_2^n}{c_1 - c_2} \\ 0 & c_2^n \end{pmatrix}$$

Multiplying these matrices we obtain: $B^m C^n =$

$$= \begin{pmatrix} b_1^m & b_3 \dfrac{b_1^m - b_2^m}{b_1 - b_2} \\ 0 & b_2^m \end{pmatrix} \begin{pmatrix} c_1^n & c_3 \dfrac{c_1^n - c_2^n}{c_1 - c_2} \\ 0 & c_2^n \end{pmatrix} = \begin{pmatrix} b_1^m c_1^n & b_3 \dfrac{b_1^m c_2^n - b_2^m c_2^n}{b_1 - b_2} + c_3 \dfrac{b_1^m c_1^n - b_1^m c_2^n}{c_1 - c_2} \\ 0 & b_2^m c_2^n \end{pmatrix}$$

From this formula one can see that the entries of $B^m C^n$ are linear combinations of $b_1^m c_1^n$, $b_1^m c_2^n$ and $b_2^m c_2^n$ with rational coefficients. Notice that the term $b_2^m c_1^n$ does not appear in the entries of $B^m C^n$. Since $\mathbf{u}$ and $\mathbf{v}$ are rational vectors we conclude that

$$s_{m,n} = \mathbf{u}^\top B^m C^n \mathbf{v} = \alpha b_1^m c_1^n + \beta b_1^m c_2^n + \gamma b_2^m c_2^n,$$

where $\alpha, \beta, \gamma \in \mathbb{Q}$. Multiplying the equation $s_{m,n} = \alpha b_1^m c_1^n + \beta b_1^m c_2^n + \gamma b_2^m c_2^n = 0$ by the product of denominators of α, β, γ and b_1, b_2, c_1, c_2 we can rewrite it in the following form

$$as^m r^n + bs^m t^n + cq^m t^n = 0$$

where a, b, c, q, r, s, t are integers and a, b, c are relatively prime. Recall that we want to find out if there exist $m, n \in \mathbb{N}$ that satisfy the above exponential Diophantine equation. If one of the coefficients a, b, c is zero, then this problem is easy to solve. For instance, if $b = 0$ then the above equation is equivalent to $as^m r^n = -cq^m t^n$. This equality holds if and only if $as^m r^n$ and $-cq^m t^n$ have the same sign and $v_p(as^m r^n) = v_p(-cq^m t^n)$ for every prime divisor p of a, c, s, r, q or t. Each of these conditions can be expressed as a linear Diophantine equation. For instance, the sign of $as^m r^n$ or $-cq^m t^n$ depends on the parity of m and n. So, the requirement that $as^m r^n$ and $-cq^m t^n$ have the same sign can be written as a linear congruence equation in m and n modulo 2, which in turn can be expressed as a linear Diophantine equation. Since a system of linear Diophantine equations can be effectively solved, we can find out whether there exist m and n that satisfy $as^m r^n = -cq^m t^n$.

Now suppose that a, b, c are relatively prime nonzero integers. Let T be all primes that appear in s, r, q or t. Theorem 5 gives an upper bound on nonzero relatively prime integers x, y, z that are composed of the primes from T and satisfy the equation $ax + by + cz = 0$. Therefore, we can algorithmically compute the following set

$$\mathcal{U} = \{(x, y, z) \ : \ ax + by + cz = 0, \ x, y, z \neq 0 \text{ and } \gcd(x, y, z) = 1\}.$$

Next for each triple $(x, y, z) \in \mathcal{U}$ we want to find out if there exist $m, n \in \mathbb{N}$ such that

$$(s^m r^n, s^m t^n, q^m t^n) = (xg, yg, zg) \tag{6}$$

for some $g \in \mathbb{N}$ that is composed of the primes from T. It is not hard to see that Equation (6) holds if and only if for every $p \in T$

$$v_p(s^m r^n) - v_p(x) = v_p(s^m t^n) - v_p(y) = v_p(q^m t^n) - v_p(z)$$

and $s^m r^n, s^m t^n, q^m t^n$ have the same signs as x, y, z, respectively. Since these conditions can be expressed as a system of linear Diophantine equations, we can algorithmically find if there are $m, n \in \mathbb{N}$ that satisfy Equation (6). If such m and n exist for at least one triple $(x, y, z) \in \mathcal{U}$, then the original equation $s_{m,n} = 0$ has a solution. Otherwise, the equation $s_{m,n} = 0$ does not have a solution.

To finish the proof we also need to consider the following cases:

Case (2): both B and C have a single eigenvalue of multiplicity 2.

Case (3): one matrix has distinct eigenvalues and the other has a single eigenvalue of multiplicity 2.

Case (2) is the easiest one in the sense that in this case we can reduce the ABCD-Z problem to a single linear Diophantine equation without using Baker's theorem. In Case (3) we will reduce the ABCD-Z problem to a linear-exponential Diophantine equation of the form $c\frac{s^m}{t^m} = a + bn$, where $a, b, c, s, t \in \mathbb{Z}$, $t > 0$ and $\gcd(s, t) = 1$, which is not hard solve. Again, this case does not require the use of Baker's theorem. All the necessary details for the proof of Cases (2) and (3) are given in the full version [6]. ◀

▶ Remark. It is interesting to note that in Cases (1) and (2) the solutions (m, n) of the equation $s_{m,n} = 0$ are described by linear Diophantine equations, and only in Case (3) we have a linear-exponential equation. This agrees with an example from Proposition 23, in which matrix A has a single eigenvalue 1 of multiplicity 2 and matrix B has distinct eigenvalues 1 and 2.

▶ Remark. In the above argument we used Theorem 5 to obtain a bound on the solutions of the equation $as^m r^n + bs^m t^n + cq^m t^n = 0$, which is a special type of an S-unit equation. This leaves open an interesting question of whether any S-unit equation can be encoded into the ABCD-Z problem.

The obvious question is how hard would it be to solve n-LRSs, or in general multiplicative matrix equations, in low dimensions. In fact we can show that the Skolem problem for n-LRSs of depth 2 is NP-hard. It is not direct but an easy corollary following the hardness proof of the mortality problem for 2 × 2 matrices [4].

▶ **Theorem 21** ([4]). *The mortality problem for integer matrices of dimension two is NP-hard.*

▶ **Corollary 22.** *Determining if the zero set of an n-LRS of depth 2 is empty is NP-hard.*

Proof. The main idea of the proof is to reuse the NP-hardness result for the mortality problem in 2 × 2 integral matrices from [4] by replacing the simulation of alternatives in subset sum problem defined by a state structure (which is guaranteed by specific order of unique cancellations) by the equation structure in which avoiding alternatives corresponds to the elements in the equation with zero power. See the formal construction in the full version [6]. ◀

Another interesting observation is that the zero set of a 2-LRS is not necessarily semilinear, in contrast to the situation for 1-LRSs, which indicates that the Skolem problem for 2-LRSs is likely to be significantly harder than the Skolem problem for 1-LRSs even for sequences of small depth.

▶ **Proposition 23.** *There exists a 2-LRS of depth 2 for which the zero set is not semilinear.*

Proof. Let $u = (0,1)^T, v = (1,-1)^T$, $A = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$ and $B = \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}$. Define

$$s_{n,m} = u^T A^n B^m v = (0,1) \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}^n \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix}^m \begin{pmatrix} 1 \\ -1 \end{pmatrix} = n - 2^m.$$

Then $s_{n,m} = 0$ if and only if $n = 2^m$. Clearly, the zero set is not semilinear. ◀
