LIPICs – Leibniz International Proceedings in Informatics

LIPICs is a series of high-quality conference proceedings across all fields in informatics. LIPICs volumes are published according to the principle of Open Access, i.e., they are available online and free of charge.

Editorial Board

- Luca Aceto (*Chair*, Gran Sasso Science Institute and Reykjavik University)
- Christel Baier (TU Dresden)
- Mikolaj Bojanczyk (University of Warsaw)
- Roberto Di Cosmo (INRIA and University Paris Diderot)
- Javier Esparza (TU München)
- Meena Mahajan (Institute of Mathematical Sciences)
- Dieter van Melkebeek (University of Wisconsin-Madison)
- Anca Muscholl (University Bordeaux)
- Luke Ong (University of Oxford)

■ Contents

Preface	
<i>Michael A. Bender, Ola Svensson, and Grzegorz Herman</i>	0:xi
Constant-Factor FPT Approximation for Capacitated k -Median	
<i>Marek Adamczyk, Jarosław Byrka, Jan Marcinkowski, Syed M. Meesum, and Michał Włodarczyk</i>	1:1–1:14
Fragile Complexity of Comparison-Based Algorithms	
<i>Peyman Afshani, Rolf Fagerberg, David Hammer, Riko Jacob, Irina Kostitsyna, Ulrich Meyer, Manuel Penschuck, and Nodari Sitchinava</i>	2:1–2:19
Universal Reconfiguration of Facet-Connected Modular Robots by Pivots: The $O(1)$ Musketeers	
<i>Hugo A. Akitaya, Esther M. Arkin, Mirela Damian, Erik D. Demaine, Vida Dujmović, Robin Flatland, Matias Korman, Belen Palop, Irene Parada, André van Renssen, and Vera Sacristán</i>	3:1–3:14
Constructing Light Spanners Deterministically in Near-Linear Time	
<i>Stephen Alstrup, Søren Dahlgaard, Arnold Filtser, Morten Stöckel, and Christian Wulff-Nilsen</i>	4:1–4:15
Repetition Detection in a Dynamic String	
<i>Amihood Amir, Itai Boneh, Panagiotis Charalampopoulos, and Eitan Konradovsky</i>	5:1–5:18
Longest Common Substring Made Fully Dynamic	
<i>Amihood Amir, Panagiotis Charalampopoulos, Solon P. Pissis, and Jakub Radoszewski</i>	6:1–6:17
Bilu-Linial Stability, Certified Algorithms and the Independent Set Problem	
<i>Haris Angelidakis, Pranjal Awasthi, Avrim Blum, Vaggos Chatziafratis, and Chen Dan</i>	7:1–7:16
On the Complexity of Anchored Rectangle Packing	
<i>Antonios Antoniadis, Felix Biermeier, Andrés Cristi, Christoph Damerius, Ruben Hoeksma, Dominik Kaaser, Peter Kling, and Lukas Nölke</i>	8:1–8:14
Quantum Walk Sampling by Growing Seed Sets	
<i>Simon Apers</i>	9:1–9:12
PUFFINN: Parameterless and Universally Fast Finding of Nearest Neighbors	
<i>Martin Aumüller, Tobias Christiani, Rasmus Pagh, and Michael Vesterli</i>	10:1–10:16
Online Multistage Subset Maximization Problems	
<i>Evrpidis Bampis, Bruno Escoffier, Kevin Schewior, and Alexandre Teiller</i>	11:1–11:14
A Constant Approximation for Colorful k -Center	
<i>Sayan Bandyapadhyay, Tanmay Inamdar, Shreyas Pai, and Kasturi Varadarajan</i> ..	12:1–12:14
Parametrized Complexity of Expansion Height	
<i>Ulrich Bauer, Abhishek Rathod, and Jonathan Spreer</i>	13:1–13:15

UnLimited TRAnsfers for Multi-Modal Route Planning: An Efficient Solution <i>Moritz Baum, Valentin Buchhold, Jonas Sauer, Dorothea Wagner, and Tobias Zündorf</i>	14:1–14:16
Streaming and Massively Parallel Algorithms for Edge Coloring <i>Soheil Behnezhad, Mahsa Derakhshan, MohammadTaghi Hajiaghayi, Marina Knittel, and Hamed Saleh</i>	15:1–15:14
Quantum Algorithms for Classical Probability Distributions <i>Aleksandrs Belovs</i>	16:1–16:11
More Applications of the d -Neighbor Equivalence: Connectivity and Acyclicity Constraints <i>Benjamin Bergougnoux and Mamadou Moustapha Kanté</i>	17:1–17:14
Online Bin Covering with Limited Migration <i>Sebastian Berndt, Leah Epstein, Klaus Jansen, Asaf Levin, Marten Maack, and Lars Rohwedder</i>	18:1–18:14
Computing k -Modal Embeddings of Planar Digraphs <i>Juan José Besa, Giordano Da Lozzo, and Michael T. Goodrich</i>	19:1–19:16
Cost Sharing over Combinatorial Domains: Complement-Free Cost Functions and Beyond <i>Georgios Birmpas, Evangelos Markakis, and Guido Schäfer</i>	20:1–20:17
Efficiently Generating Geometric Inhomogeneous and Hyperbolic Random Graphs <i>Thomas Bläsius, Tobias Friedrich, Maximilian Katzmann, Ulrich Meyer, Manuel Penschuck, and Christopher Weyand</i>	21:1–21:14
Randomized Incremental Construction of Delaunay Triangulations of Nice Point Sets <i>Jean-Daniel Boissonnat, Olivier Devillers, Kunal Dutta, and Marc Glisse</i>	22:1–22:13
Fine-Grained Complexity of k -OPT in Bounded-Degree Graphs for Solving TSP <i>Édouard Bonnet, Yoichi Iwata, Bart M. P. Jansen, and Łukasz Kowalik</i>	23:1–23:14
Linear Transformations Between Colorings in Chordal Graphs <i>Nicolas Bousquet and Valentin Bartier</i>	24:1–24:15
Patching Colors with Tensors <i>Cornelius Brand</i>	25:1–25:16
On Geometric Set Cover for Orthants <i>Karl Bringmann, Sándor Kisfaludi-Bak, Michał Pilipczuk, and Erik Jan van Leeuwen</i>	26:1–26:18
Simpler and Better Algorithms for Minimum-Norm Load Balancing <i>Deeparnab Chakrabarty and Chaitanya Swamy</i>	27:1–27:12
On Computing Centroids According to the p -Norms of Hamming Distance Vectors <i>Jiehua Chen, Danny Hermelin, and Manuel Sorge</i>	28:1–28:16
Non-Cooperative Rational Interactive Proofs <i>Jing Chen, Samuel McCauley, and Shikha Singh</i>	29:1–29:16

Stronger ILPs for the Graph Genus Problem <i>Markus Chimani and Tilo Wiedera</i>	30:1–30:15
Complexity of C_k -Coloring in Hereditary Classes of Graphs <i>Maria Chudnovsky, Shenwei Huang, Paweł Rzażewski, Sophie Spirkl, and Mingxian Zhong</i>	31:1–31:15
Consistent Digital Curved Rays and Pseudoline Arrangements <i>Jinhee Chun, Kenya Kikuchi, and Takeshi Tokuyama</i>	32:1–32:16
Efficient Approximation Schemes for Uniform-Cost Clustering Problems in Planar Graphs <i>Vincent Cohen-Addad, Marcin Pilipczuk, and Michał Pilipczuk</i>	33:1–33:14
Improved Bounds for the Excluded-Minor Approximation of Treedepth <i>Wojciech Czerwiński, Wojciech Nadara, and Marcin Pilipczuk</i>	34:1–34:13
Building a Nest by an Automaton <i>Jurek Czyzowicz, Dariusz Dereniowski, and Andrzej Pelc</i>	35:1–35:14
Robustness of Randomized Rumour Spreading <i>Rami Daknama, Konstantinos Panagiotou, and Simon Reisser</i>	36:1–36:15
Structural Rounding: Approximation Algorithms for Graphs Near an Algorithmically Tractable Class <i>Erik D. Demaine, Timothy D. Goodrich, Kyle Kloster, Brian Lavallee, Quanquan C. Liu, Blair D. Sullivan, Ali Vakilian, and Andrew van der Poel</i>	37:1–37:15
Dense Peelable Random Uniform Hypergraphs <i>Martin Dietzfelbinger and Stefan Walzer</i>	38:1–38:16
Efficient Gauss Elimination for Near-Quadratic Matrices with One Short Random Block per Row, with Applications <i>Martin Dietzfelbinger and Stefan Walzer</i>	39:1–39:18
Greedy Strategy Works for k -Center Clustering with Outliers and Coreset Construction <i>Hu Ding, Haikuo Yu, and Zixiu Wang</i>	40:1–40:16
Bidirectional Text Compression in External Memory <i>Patrick Dinklage, Jonas Ellert, Johannes Fischer, Dominik Köppl, and Manuel Penschuck</i>	41:1–41:16
Bisection of Bounded Treewidth Graphs by Convolutions <i>Eduard Eiben, Daniel Lokshantov, and Amer E. Mouawad</i>	42:1–42:11
Oracle-Based Primal-Dual Algorithms for Packing and Covering Semidefinite Programs <i>Khaled Elbassioni and Kazuhisa Makino</i>	43:1–43:15
Online Disjoint Set Cover Without Prior Knowledge <i>Yuval Emek, Adam Goldbraikh, and Erez Kantor</i>	44:1–44:16
Bayesian Generalized Network Design <i>Yuval Emek, Shay Kutten, Ron Lavi, and Yangguang Shi</i>	45:1–45:16

Obviously Strategyproof Mechanisms for Machine Scheduling <i>Diodato Ferraioli, Adrian Meier, Paolo Penna, and Carmine Ventre</i>	46:1–46:15
Going Far From Degeneracy <i>Fedor V. Fomin, Petr A. Golovach, Daniel Lokshantov, Fahad Panolan, Saket Saurabh, and Meirav Zehavi</i>	47:1–47:14
Group Activity Selection with Few Agent Types <i>Robert Ganian, Sebastian Ordyniak, and C. S. Rahul</i>	48:1–48:16
Optimal Sorting with Persistent Comparison Errors <i>Barbara Geissmann, Stefano Leucci, Chih-Hung Liu, and Paolo Penna</i>	49:1–49:14
Dynamic Dominators and Low-High Orders in DAGs <i>Loukas Georgiadis, Konstantinos Giannis, Giuseppe F. Italiano, Aikaterini Karanasiou, and Luigi Laura</i>	50:1–50:18
On the Hardness and Inapproximability of Recognizing Wheeler Graphs <i>Daniel Gibney and Sharma V. Thankachan</i>	51:1–51:16
Evaluation of a Flow-Based Hypergraph Bipartitioning Algorithm <i>Lars Gottesbüren, Michael Hamann, and Dorothea Wagner</i>	52:1–52:17
Parameterized Approximation Schemes for Independent Set of Rectangles and Geometric Knapsack <i>Fabrizio Grandoni, Stefan Kratsch, and Andreas Wiese</i>	53:1–53:16
Packing Cars into Narrow Roads: PTASs for Limited Supply Highway <i>Fabrizio Grandoni and Andreas Wiese</i>	54:1–54:14
Engineering Negative Cycle Canceling for Wind Farm Cabling <i>Sascha Gritzbach, Torsten Ueckerdt, Dorothea Wagner, Franziska Wegner, and Matthias Wolf</i>	55:1–55:16
Towards Improving Christofides Algorithm for Half-Integer TSP <i>Arash Haddadan and Alantha Newman</i>	56:1–56:12
Counting to Ten with Two Fingers: Compressed Counting with Spiking Neurons <i>Yael Hitron and Merav Parter</i>	57:1–57:17
Triconnected Planar Graphs of Maximum Degree Five are Subhamiltonian <i>Michael Hoffmann and Boris Klemz</i>	58:1–58:14
Parallel Weighted Random Sampling <i>Lorenz Hübschle-Schneider and Peter Sanders</i>	59:1–59:24
External Memory Priority Queues with Decrease-Key and Applications to Graph Algorithms <i>John Iacono, Riko Jacob, and Konstantinos Tsakalidis</i>	60:1–60:14
Shortest Reconfiguration of Perfect Matchings via Alternating Cycles <i>Takehiro Ito, Naonori Kakimura, Naoyuki Kamiyama, Yusuke Kobayashi, and Yoshio Okamoto</i>	61:1–61:15
Closing the Gap for Pseudo-Polynomial Strip Packing <i>Klaus Jansen and Malin Rau</i>	62:1–62:14

Odd-Cycle Separation for Maximum Cut and Binary Quadratic Optimization <i>Michael Jünger and Sven Mallach</i>	63:1–63:13
Triangles and Girth in Disk Graphs and Transmission Graphs <i>Haim Kaplan, Katharina Klost, Wolfgang Mulzer, Liam Roditty, Paul Seiferth, and Micha Sharir</i>	64:1–64:14
Reliable Hubs for Partially-Dynamic All-Pairs Shortest Paths in Directed Graphs <i>Adam Karczmarz and Jakub Łącki</i>	65:1–65:15
Min-Cost Flow in Unit-Capacity Planar Graphs <i>Adam Karczmarz and Piotr Sankowski</i>	66:1–66:17
Global Curve Simplification <i>Mees van de Kerkhof, Irina Kostitsyna, Maarten Löffler, Majid Mirzanezhad, and Carola Wenk</i>	67:1–67:14
Trace Reconstruction: Generalized and Parameterized <i>Akshay Krishnamurthy, Arya Mazumdar, Andrew McGregor, and Soumyabrata Pal</i>	68:1–68:25
Generalized Assignment via Submodular Optimization with Reserved Capacity <i>Ariel Kulik, Kanthi Sarpatwar, Baruch Schieber, and Hadas Shachnai</i>	69:1–69:15
Resilient Dictionaries for Randomly Unreliable Memory <i>Stefano Leucci, Chih-Hung Liu, and Simon Meierhans</i>	70:1–70:16
Hermitian Laplacians and a Cheeger Inequality for the Max-2-Lin Problem <i>Huan Li, He Sun, and Luca Zanetti</i>	71:1–71:14
Packing Directed Circuits Quarter-Integrally <i>Tomáš Masařík, Irene Muzi, Marcin Pilipczuk, Paweł Rzażewski, and Manuel Sorge</i>	72:1–72:13
Equal-Subset-Sum Faster Than the Meet-in-the-Middle <i>Marcin Mucha, Jesper Nederlof, Jakub Pawlewicz, and Karol Węgrzycki</i>	73:1–73:16
Hardness of Bichromatic Closest Pair with Jaccard Similarity <i>Rasmus Pagh, Nina Mesing Stausholm, and Mikkel Thorup</i>	74:1–74:13
Compact Oblivious Routing <i>Harald Räcke and Stefan Schmid</i>	75:1–75:14
Geometric Crossing-Minimization – A Scalable Randomized Approach <i>Marcel Radermacher and Ignaz Rutter</i>	76:1–76:16
An Approximate Kernel for Connected Feedback Vertex Set <i>M. S. Ramanujan</i>	77:1–77:14
Multicommodity Multicast, Wireless and Fast <i>R. Ravi and Oleksandr Rudenko</i>	78:1–78:20
Recognizing Planar Laman Graphs <i>Jonathan Rollin, Lena Schlipf, and André Schulz</i>	79:1–79:12
Simultaneous Representation of Proper and Unit Interval Graphs <i>Ignaz Rutter, Darren Strash, Peter Stumpf, and Michael Vollmer</i>	80:1–80:15
Correlation Clustering with Same-Cluster Queries Bounded by Optimal Cost <i>Barna Saha and Sanjay Subramanian</i>	81:1–81:17

0:x **Contents**

Graph Balancing with Orientation Costs <i>Roy Schwartz and Ran Yeheskel</i>	82:1–82:15
FPT-Algorithms for Computing Gromov-Hausdorff and Interleaving Distances Between Trees <i>Elena Farahbakhsh Touli and Yusu Wang</i>	83:1–83:14

■ Preface

This volume contains the extended abstracts selected for presentation at ESA 2019, the 27th European Symposium on Algorithms, held in Munich/Garching, Germany, on 9–11 September 2019, as part of ALGO 2019. The scope of ESA includes original, high-quality, theoretical and applied research on algorithms and data structures. Since 2002, it has had two tracks: the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions dealing with real-world applications, engineering, and experimental analysis of algorithms. Information on past symposia, including locations and proceedings, is maintained at <http://esa-symposium.org>.

In response to the call for papers for ESA 2019, 329 papers were submitted, 276 for Track A and 53 for Track B (these are the counts after the removal of papers with invalid format and after withdrawals). Paper selection was based on originality, technical quality, exposition quality, and relevance. Each paper received at least three reviews. The program committees selected 83 papers for inclusion in the program, 70 from track A and 13 from track B, yielding an acceptance rate of about 25%.

The European Association for Theoretical Computer Science (EATCS) sponsored a best paper award and a best student paper award. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission. The best student paper award for track A was given to Cornelius Brand for the paper “Patching Colors with Tensors”. The best paper award for track A was given to Peyman Afshani, Rolf Fagerberg, David Hammer, Riko Jacob, Irina Kostitsyna, Ulrich Meyer, Manuel Penschuck and Nodari Sitchinava for the paper “Fragile Complexity of Comparison-Based Algorithms”. The best paper award for track B was given to Thomas Bläsius, Tobias Friedrich, Maximilian Katzmann, Ulrich Meyer, Manuel Penschuck and Christopher Weyand for the paper “Efficiently Generating Geometric Inhomogeneous and Hyperbolic Random Graphs”. No best student paper award has been given this year.

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the program committees for their hard work, and all the external reviewers who assisted the program committees in the evaluation process. Special thanks go to the local organizing committee, who helped us with the organization of the conference.

■ Program Committees

Track A (Design and Analysis) Program Committee

- Aditya Bhaskara, University of Utah
- Sayan Bhattacharya, University of Warwick
- Sebastian Brandt, ETHZ
- Raphaël Clifford, University of Bristol
- Éric Colin de Verdière, CNRS and Université Paris-Est
- Moran Feldman, The Open University of Israel
- Jugal Garg, University of Illinois at Urbana-Champaign
- Sariel Har-Peled, University of Illinois at Urbana-Champaign
- Pinar Heggernes, University of Bergen
- Stacey Jeffery, CWI
- Sagar Kale, EPFL
- Matya Katz, Ben-Gurion University
- Tsvi Kopelowitz, Bar-Ilan University
- Bundit Laekhanukit, Shanghai University of Finance and Economics
- Silvio Lattanzi, Google
- Pasin Manurangsi, UC Berkeley
- Claire Mathieu, CNRS, Paris
- Nicole Megow, University of Bremen
- Shay Moran, Princeton University
- Rad Niazadeh, Stanford University
- Ely Porat, Bar-Ilan University
- Eva Rotenberg, Technical University of Denmark
- Aviad Rubinfeld, Stanford University
- Barna Saha, University of Massachusetts Amherst
- Pascal Schweitzer, TU Kaiserslautern
- David Shmoys, Cornell University
- Sahil Singla, Princeton University
- Cliff Stein, Columbia University
- Ola Svensson, EPFL, (PC Chair)
- Aravindan Vijayaraghavan, Northwestern University
- Magnus Wahlström, Royal Holloway, University of London
- Justin Ward, Queen Mary University of London
- Standa Živný, University of Oxford

Track B (Engineering and Applications) Program Committee

- Dan Alistarh, Institute of Science and Technology Austria (IST Austria)
- Michael A. Bender, Stony Brook University, (PC Chair)
- Anne Benoit, Ecole Normale Supérieure de Lyon
- Jon Berry, Sandia National Laboratories
- Timo Bingmann, Karlsruhe Institute of Technology
- Kevin Buchin, TU Eindhoven
- Matteo Ceccarello, IT University of Copenhagen and BARC
- Martín Farach-Colton, Rutgers University
- Rati Gelashvili, NeuralMagic
- Seth Gilbert, National University of Singapore
- Piyush Kumar, Florida State University
- Rob Johnson, VMware Research
- Irina Kostitsyna, TU Eindhoven
- Jing Li, New Jersey Institute of Technology
- Samuel McCauley, Bar Ilan University
- John Owens, UC Davis
- Prashant Pandey, Carnegie Mellon University
- Tao B. Schardl, MIT
- Julian Shun, MIT
- Francesco Silvestri, University of Padova
- Sebastian Wild, University of Waterloo
- Maxwell Young, Mississippi State University

Abstract

Capacitated k -median is one of the few outstanding optimization problems for which the existence of a polynomial time constant factor approximation algorithm remains an open problem. In a series of recent papers algorithms producing solutions violating either the number of facilities or the capacity by a multiplicative factor were obtained. However, to produce solutions without violations appears to be hard and potentially requires different algorithmic techniques. Notably, if parameterized by the number of facilities k , the problem is also $W[2]$ hard, making the existence of an exact FPT algorithm unlikely. In this work we provide an FPT-time constant factor approximation algorithm preserving both cardinality and capacity of the facilities. The algorithm runs in time $2^{\mathcal{O}(k \log k)} n^{\mathcal{O}(1)}$ and achieves an approximation ratio of $7 + \varepsilon$.

1 Introduction

For many years approximation algorithms and FPT algorithms were developed in parallel. Recently the two paradigms are being combined and provide intriguing discoveries in the intersection of the two worlds. It is particularly interesting in the case of problems for which we fail to make progress on improving the approximation ratios in polynomial time. An excellent example of such a combination is the FPT approximation algorithm for the k -CUT problem by Gupta et al. [17].

In this work we focus on the CAPACITATED k -MEDIAN problem, whose approximability attracted attention of many researchers. Unlike in the case of the k -CUT problem, it is still not clear what approximation is possible for CAPACITATED k -MEDIAN in polynomial time. As shall be discussed in more detail in the following section, the best true approximation known is $\mathcal{O}(\log k)$ based on tree embedding of the underlying metric. The other algorithms either violate the bound on the number of facilities or the capacity constraints.

Our main result is a $(7 + \epsilon)$ -approximation algorithm for the CAPACITATED k -MEDIAN problem running in $\text{FPT}(k)$ time, that exploits techniques from both – approximation and FPT – realms. The algorithm builds on the idea of clustering the clients into $\ell = \mathcal{O}(k \cdot (\log n)/\epsilon)$ locations, which is similar to the approach from the $\mathcal{O}(\log k)$ -approximation algorithm, where one creates $\mathcal{O}(k)$ clusters. This is followed by guessing the distribution of the k facilities inside these ℓ clusters. Having such a structure revealed, we simplify the instance further by rounding particular distances and reduce the problem to linear programming over a totally unimodular matrix.

1.1 Problems overview and previous work

In the CAPACITATED k -MEDIAN problem (CKM), we are given a set F of facilities, each facility f with a capacity $u_f \in \mathbb{Z}_{\geq 0}$, a set C of clients, a metric d over $F \cup C$ and an upper bound k on the number of facilities we can open. A solution to the CKM problem is a set $S \subseteq F$ of at most k open facilities and a connection assignment $\phi : C \rightarrow S$ of clients to open facilities such that $|\phi^{-1}(f)| \leq u_f$ for every facility $f \in S$. The goal of the problem is to find a solution that minimizes the connection cost $\sum_{c \in C} d(c, \phi(c))$. In the case when all the facilities can serve at most u clients, for some integer u , we obtain the UNIFORM CKM problem.

Uncapacitated k -median. The standard k -median problem, where there is no restriction on the number of clients served by a facility, can be approximated up to a constant factor [9, 2]. The current best is the $(2.675 + \epsilon)$ -approximation algorithm of Byrka et al. [4], which is a result of optimizing a part of the algorithm by Li and Svensson [23].

Approximability of CKM. As already stressed, CAPACITATED k -MEDIAN is among few remaining fundamental optimization problems for which it is not clear if there exist polynomial time constant factor approximation algorithms. All the known algorithms violate either the number of facilities or the capacities. In particular, already the algorithm of Charikar et al. [9] gave 16-approximate solution for the uniform capacitated k -median violating the capacities by a factor of 3. Then Chuzhoy and Rabani [10] considered general capacities and gave a 50-approximation algorithm violating capacities by a factor of 40.

The difficulty appears to be related to the unbounded integrality gap of the standard LP relaxation. To obtain integral solutions that are bounded with respect to the fractional solution to the standard LP, one has to either allow the integral solution to open twice as many facilities or to violate the capacities by a factor of two. LP-rounding algorithms essentially matching these limits have been obtained [1, 3].

Subsequently, Li broke this integrality gap barrier by giving a constant factor algorithm for the capacitated k -median by opening $(1 + \epsilon) \cdot k$ facilities [21, 22]. Afterwards analogous results, but violating the capacities by a factor of $(1 + \epsilon)$ were also obtained [5, 14].

The algorithms with $(1 + \epsilon)$ violations are all based on strong LP relaxations containing additional constraints for subsets of facilities. Notably, it is not clear if these relaxations can be solved exactly in polynomial time, still they suffice to construct an approximation algorithm via the “round-or-separate” technique that iteratively adds consistency constraints

for selected subsets. Although while spectacularly breaking the standard LP integrality bound, these techniques appear insufficient to yield a proper approximation algorithm that does not violate constraints.

The only true approximation for CKM known is a folklore $\mathcal{O}(\log k)$ approximation algorithm that can be obtained via the metric tree embedding with expected logarithmic distortion [15]. To the best of our knowledge, this result has not been explicitly published, but it can be obtained similarly to the $\mathcal{O}(\log k)$ -approximation for UNCAPACITATED KM by Charikar [7]. For the sake of completeness and since it follows easily from our framework, we give its proof in Section 3 without claiming credit for it. This $\mathcal{O}(\log k)$ barrier is in contrast with other capacitated clustering problems such as facility location and k -center, for which constant factor approximation algorithms are known [19, 12].

After our work was announced, Xu et al. [27] proposed a similar algorithm for Euclidean CAPACITATED k -MEANS, i.e., a constant factor approximation running in time $\text{FPT}(k)$. Both our and their approximation ratios have been very recently improved by Cohen-Addad and Li [11], who obtained $(3 + \varepsilon)$ for CAPACITATED k -MEDIAN and $(9 + \varepsilon)$ for CAPACITATED k -MEANS in general metric spaces. They have also provided a deeper insight into the problems basing on the framework of coresets.

1.2 Parameterized Complexity

A parameterized problem instance is created by associating an input instance with an integer parameter k . We say that a problem is *fixed parameter tractable* (FPT) if every instance (I, k) of the problem can be solved in time $f(k) \cdot |I|^{\mathcal{O}(1)}$, where f is an arbitrary computable function of k .

We say that a problem is FPT if it is possible to give an algorithm that solves it in running time of the required form. Such an algorithm we shall call a *parameterized algorithm*.

To show that a problem is unlikely to be FPT, we use parameterized reductions analogous to those employed in the classical complexity theory. Here, the concept of W -hardness replaces the one of NP-hardness, and we need not only construct an equivalent instance in FPT time, but also ensure that the size of the parameter in the new instance depends only on the size of the parameter in the original instance. In contrast to the NP-hardness theory, there is a hierarchy of classes $\text{FPT} = W[0] \subseteq W[1] \subseteq W[2] \subseteq \dots$ and these containments are believed to be strict. If there exists a parameterized reduction transforming a problem known to be $W[t]$ -hard for $t > 0$ to another problem Π , then the problem Π is $W[t]$ -hard as well. This provides an argument that Π is unlikely to admit an algorithm with running time $f(k) \cdot |I|^{\mathcal{O}(1)}$.

We begin with an argument that allowing FPT time for (even uncapacitated) k -MEDIAN should not help in finding the optimal solution and we still need to settle for approximation.

▷ **Fact 1.** The UNCAPACITATED k -MEDIAN problem is $W[2]$ -hard when parameterized by k , even on metrics induced by unweighted graphs.

Proof. Consider an instance (G, k) of the DOMINATING SET problem, which is $W[2]$ -hard when parameterized by the solution size k . Graph G induces a metric such that the distance between two adjacent vertices equals one and otherwise the distance between vertices is the length of the shortest path. A dominating set of size at most k exists in graph G if and only if we can find a vertex set S of size k , such that all the other vertices are at distance 1 from S . This is equivalent to the solution to UNCAPACITATED k -MEDIAN on the metric induced by G being of size exactly $|V(G)| - k$. ◁

Parameterized Approximation

In recent years new research directions emerged in the intersection of the theory of approximation algorithms and the FPT theory. It turned out that for some problems that are intractable in the exact sense, parameterization still comes in useful when we want to reduce the approximation ratio. Some examples are $(2 - \varepsilon)$ -approximation for k -CUT [17] or $f(\mathcal{F})$ -approximation for PLANAR- \mathcal{F} DELETION [16] for some implicit function f . The dependency on \mathcal{F} was later improved, leading to $\mathcal{O}(\log k)$ -approximations for, e.g., k -VERTEX SEPARATOR [20] and k -TREEWIDTH DELETION [18].

On the other hand some problems parameterized by the solution size have been proven resistant to such improvements. Chalermsook et al. [6] observed that under the assumption of Gap-ETH there can be no parameterized approximation with ratio $o(k)$ for k -CLIQUE and none with ratio $f(k)$ for k -DOMINATING SET (for any function f). Subsequently Gap-ETH has been replaced with a better established hardness assumption $\text{FPT} \neq \text{W}[1]$ for k -DOMINATING SET [25].

1.3 Organization of the paper

Our main result is stated in Theorem 16 (Section 4.3), where we present a $(7 + \varepsilon)$ -approximation algorithm for the NON-UNIFORM CKM problem running in $\text{FPT}(k)$ time.

To obtain this result we need two ingredients. The first one is a metric embedding that reduces the problem to a simpler instance, called ℓ -centered, which is described in Section 2. This reduction provides a richer structure, which can be exploited to obtain the folklore $\mathcal{O}(\log k)$ -approximation via tree embeddings [15]. As already mentioned, similar approach was presented by Charikar et al. [7] in their algorithm for the uncapacitated setting. For the sake of completeness, we present this result in Appendix 3.

The second ingredient is a parameterized algorithm for the ℓ -centered instances. Since it is simpler in the uniform setting, we first solve it in Section 4.2 as a warm up before the main result. This way the new ideas are being revealed gradually to the reader.

2 ℓ -Centered instances

Suppose we work with a graph on nodes $F \cup C$, on which we are given a metric d . In our considerations the set $F \cup C$ will be fixed throughout, however we will be modifying the metric over it. Consider an algorithm ALG which produces a solution $ALG(d)$ for a metric d . This solution can be seen as a mapping which we explicitly denote by $\phi^{ALG(d)}$. Its cost in the metric d' equals $\sum_{c \in C} d'(c, \phi^{ALG(d)})$ which we shall briefly denote by $\text{cost}(\phi^{ALG(d)}, d')$. The second argument is useful, when an algorithm ALG produces a solution (mapping) $ALG(d)$ with respect to metric d , but later on we may be interested in its cost over a different metric. Also, let $OPT(d)$ denote the optimum solution for the CKM problem on metric d .

In order to solve CKM, we shall invoke an algorithm for UNCAPACITATED KM as a subroutine. Let $ALG_{unc}^\ell(d)$ be a relaxed solution that opens up to $\ell \geq k$ facilities and can break the capacity constraints. It induces a mapping which, for consistency, we shall denote by $\phi^{ALG_{unc}^\ell(d)}$. Observe that in this mapping every client can be connected to the closest open facility. Since UNCAPACITATED KM admits constant approximation algorithms, we can work with solutions satisfying: $\text{cost}(\phi^{ALG_{unc}^\ell(d)}, d) = O(\text{cost}(\phi^{OPT(d)}, d))$. The larger ℓ we allow in the relaxation, the smaller constant we will be able to achieve in the relation above.

■ **Figure 1** An ℓ -centered instance. In the upper layer there is a set S of ℓ vertices connected as a clique. The rest of vertices are divided into separate clusters. Vertices in a single cluster are only connected to their center in the set S .

Using such an algorithm for UNCAPACITATED KM as a subroutine, we can find a simpler metric to work with. First we build a graph which will induce the metric. Let $F(\text{ALG}_{unc}^\ell(d))$ be the set of facilities opened by $\text{ALG}_{unc}^\ell(d)$. For each such a facility f we create a copy vertex s^f , which is at distance 0 from f . We denote the set of copies by S , i.e., $S = \{s^f \mid f \in F(\text{ALG}_{unc}^\ell(d))\}$. Given that we demand the distance from f to s^f to be 0, we can naturally extend the metric d to the set $C \cup F \cup S$. To distinguish facilities from $F(\text{ALG}_{unc}^\ell(d))$ from their copies S , we shall call each copy $s \in S$ a *center*.

We build a complete graph on S and preserve the metric d therein. For every node $v \notin S$, be it either a client from C or a facility from F , we place an edge to the closest (according to the extended d) center $s^v \in S$ and set its length to $d(v, s^v)$. We call such a graph ℓ -centered and refer to its induced metric as d_ℓ .

► **Definition 2.** An instance of CKM is called ℓ -centered if the metric, which we shall denote by d_ℓ , is induced by a weighted graph $G(F \cup C \cup S, E)$ such that

1. $|S| \leq \ell$,
2. $\binom{S}{2} \subseteq E$, i.e., S forms a clique,
3. for every $v \in C \cup F$ there is only one edge incident to v in E , and it connects v to some $s^v \in S$.

For a center $s \in S$ we shall say that all nodes from $F \cup C$ that are connected to s form a *cluster* of s . If we consider only nodes from F , then we talk about an f -cluster of s , denoted $F(s)$.

The idea of preprocessing that simplifies the metric by recognizing a small number of hubs resembles the notion of α -preserving metrics, that have been used as a tool to obtain coresets for the related problem BALANCED k -MEDIAN [13].

In the following lemma we relate the cost of embedding the optimum solution $\text{OPT}(d)$ from a metric d to d_ℓ .

► **Lemma 3** (Embedding d into ℓ -centered metric d_ℓ). Let $\text{ALG}_{unc}^\ell(d)$ be a solution for the UNCAPACITATED KM problem on metric d from which we construct the ℓ -centered instance. Optimal solution $\text{OPT}(d)$ can be embedded into an ℓ -centered metric d_ℓ with the cost relation being

$$\text{cost}(\phi^{\text{OPT}(d)}, d) \leq \text{cost}(\phi^{\text{OPT}(d)}, d_\ell) \leq 3 \cdot \text{cost}(\phi^{\text{OPT}(d)}, d) + 4 \cdot \text{cost}(\phi^{\text{ALG}_{unc}^\ell(d)}, d).$$

■ **Figure 2** Situation in Lemma 3. In the optimum solution to the CKM instance, client c is connected to the facility f_c . In the ℓ -centered instance c resides in a cell, where s^c is a center. The center of f_c is s^{f_c} .

Proof. Let c be a client connected to facility f_c in the optimal solution $OPT(d)$. Let s^c be the center closest to c within S (the ℓ -center), and let s^{f_c} be the center closest to f_c . First let us note that $d_\ell(c, f_c) = d(c, s^c) + d(s^c, s^{f_c}) + d(s^{f_c}, f_c)$. Next we bound the terms $d(f_c, s^{f_c})$ and $d(s^c, s^{f_c})$ separately.

▷ **Fact 4.** For every client c and its facility f_c from OPT we have $d(f_c, s^{f_c}) \leq d(f_c, c) + d(c, s^c)$.

Proof. Since s^{f_c} is the closest ℓ -center to the facility f_c , we have that $d(f_c, s^{f_c}) \leq d(f_c, s^c)$. At the same time, from the triangle inequality it follows that $d(f_c, s^c) \leq d(f_c, c) + d(c, s^c)$. ◁

▷ **Fact 5.** For each c we have $d(s^c, s^{f_c}) \leq 2(d(f_c, c) + d(c, s^c))$.

Proof. From the triangle inequality we know that

$$d(s^c, s^{f_c}) \leq d(s^c, c) + d(c, f_c) + d(f_c, s^{f_c}).$$

From Fact 4 we also know that $d(f_c, s^{f_c}) \leq d(f_c, c) + d(c, s^c)$, and combining the two inequalities we get $d(s^c, s^{f_c}) \leq d(s^c, c) + d(c, f_c) + d(f_c, s^{f_c}) \leq 2(d(f_c, c) + d(c, s^c))$. ◁

These two facts imply

$$\begin{aligned} d_\ell(c, f_c) &= d(c, s^c) + d(s^c, s^{f_c}) + d(s^{f_c}, f_c) \\ &\leq d(c, s^c) + d(s^c, s^{f_c}) + (d(f_c, c) + d(c, s^c)) && \text{(from Fact 4)} \\ &\leq d(c, s^c) + 2(d(f_c, c) + d(c, s^c)) + (d(f_c, c) + d(c, s^c)) && \text{(from Fact 5)} \\ &= 3 \cdot d(f_c, c) + 4 \cdot d(c, s^c), \end{aligned}$$

which implies the second inequality from the statement of Lemma 3. The first one directly comes from the triangle inequality $d(c, f_c) \leq d(c, s^c) + d(s^c, s^{f_c}) + d(s^{f_c}, f_c) = d_\ell(c, f_c)$, completing the whole proof. ◀

The next lemma is quite simple. Its proof follows from the fact that metric d_ℓ dominates the metric d , i.e., $d_\ell(u, v) \geq d(u, v)$ for all pairs of vertices $u, v \in C \cup F$.

► **Lemma 6** (Going back from ℓ -centered metric d_ℓ to d). *Any solution for the ℓ -centered metric d_ℓ can be embedded back into d without any loss:*

$$\text{cost}(\phi^{ALG(d_\ell)}, d_\ell) \geq \text{cost}(\phi^{ALG(d_\ell)}, d).$$

Blending together Lemmas 3 and 6 we can state the following lemma about reducing the CKM problem to ℓ -centered instances.

► **Lemma 7.** *Suppose we are given a solution $ALG_{unc}^\ell(d)$ for the UNCAPACITATED KM problem on metric d which opens ℓ centers, but β -approximates the optimum solution $OPT_{unc}^k(d)$ for UNCAPACITATED KM problem with k centers, i.e., $cost(ALG_{unc}^\ell(d), d) \leq \beta \cdot cost(OPT_{unc}^k(d), d)$. Suppose we are given an α -approximation algorithm for the CKM problem on ℓ -centered instances. If so, then we can construct an $\alpha \cdot (3 + 4\beta)$ -approximation algorithm for CKM on general instances.*

Proof. Suppose that we have an α -approximation solution for the ℓ -centered instance with metric d_ℓ , i.e., $ALG(d_\ell)$ such that

$$cost(\phi^{ALG(d_\ell)}, d_\ell) \leq \alpha \cdot cost(\phi^{OPT(d_\ell)}, d_\ell).$$

Since $OPT(d)$ is some solution for the ℓ -centered instance with metric d_ℓ we have

$$cost(\phi^{ALG(d_\ell)}, d_\ell) \leq \alpha \cdot cost(\phi^{OPT(d_\ell)}, d_\ell) \leq \alpha \cdot cost(\phi^{OPT(d)}, d_\ell).$$

And from Lemma 3 we have that

$$\begin{aligned} cost(\phi^{ALG(d_\ell)}, d_\ell) &\leq \alpha \cdot cost(\phi^{OPT(d_\ell)}, d_\ell) \\ &\leq \alpha \cdot cost(\phi^{OPT(d)}, d_\ell) \\ &\leq \alpha \left(3 \cdot cost(\phi^{OPT(d)}, d) + 4 \cdot cost(\phi^{ALG_{unc}^\ell(d)}, d) \right). \end{aligned}$$

Since solution $ALG_{unc}^\ell(d)$ β -approximates the optimal solution $OPT_{unc}^k(d)$ for UNCAPACITATED KM with k centers on metric d , we have that

$$cost(\phi^{ALG_{unc}^\ell(d)}, d) \leq \beta \cdot cost(\phi^{OPT_{unc}^k(d)}, d) \leq \beta \cdot cost(\phi^{OPT(d)}, d).$$

The second inequality $cost(\phi^{OPT_{unc}^k(d)}, d) \leq cost(\phi^{OPT(d)}, d)$ follows from an obvious fact that uncapacitated version of the problem is easier than the capacitated. Hence

$$\begin{aligned} cost(\phi^{ALG(d_\ell)}, d_\ell) &\leq \alpha \left(3 \cdot cost(\phi^{OPT(d)}, d) + 4 \cdot cost(\phi^{ALG_{unc}^\ell(d)}, d) \right) \\ &\leq \alpha \left(3 \cdot cost(\phi^{OPT(d)}, d) + 4\beta \cdot cost(\phi^{OPT(d)}, d) \right) \\ &\leq \alpha (3 + 4\beta) \cdot cost(\phi^{OPT(d)}, d). \end{aligned}$$

Since without any loss we can embed the solution $ALG(d_\ell)$ for the ℓ -centered metric d_ℓ into the initial metric d (Lemma 6) we obtain an $\alpha \cdot (3 + 4\beta)$ -approximation algorithm. The claim follows. ◀

3 $\mathcal{O}(\log k)$ -approximation in polynomial time

In this section we present a folklore polynomial-time $\mathcal{O}(\log k)$ -approximation algorithm for CKM. Since constant-factor approximation algorithms for UNCAPACITATED KM exist [9], it is a clear consequence of Lemma 7 with β being constant that it is sufficient for us to construct an $\mathcal{O}(\log k)$ -approximation algorithm for the k -centered instances.

A standard tool to provide such a guarantee is the *Probabilistic Tree Embedding* by [15]. This makes our algorithm a randomized one, but if needed, it is possible to derandomize it using the ideas from [8].

► **Definition 8.** A set of metric spaces \mathcal{T} together with a probability distribution $\pi_{\mathcal{T}}$ over \mathcal{T} probabilistically α -approximates the metric space (X, d) if

1. Every metric $\tau \in \mathcal{T}$ dominates (X, d) , that is, $d(x, y) \leq \tau(x, y) \forall x, y \in X$.
2. For every pair of points $x, y \in X$ its expected distance is not expanded by more than α , i.e.,

$$\mathbb{E}_{\tau \sim \pi_{\mathcal{T}}}[\tau(x, y)] \leq \alpha \cdot d(x, y).$$

It is a well-known fact, that any metric (X, d) , can be probabilistically $\mathcal{O}(\log |X|)$ -approximated by a distribution of tree metrics, such that the points in X are the leaves in the resulting tree [15].

As described in Definition 2, our k -centered metric d_k is induced by a graph composed of two layers – the set S of k vertices connected in a clique, and the rest of vertices, $F \cup C$, each connected to only one vertex in S . Let T be a random tree embedding of the set S (with a metric function d_T). A modified instance G_T of our problem is created by replacing the clique S with its tree approximation T .

► **Lemma 9.** An optimum solution for CKM on the instance G_T is in expectation at most $\mathcal{O}(\log k)$ times larger than the optimum for the metric d_k .

Proof. $OPT(d_k)$ denotes the optimum mapping of clients to k facilities in the k -centered metric d_k . Consider client c and facility $f = \phi^{OPT(d_k)}(c)$. Let now s^c be the center of c and s^f the center of f . The cost of connecting client c to f amounts to

$$d_k(c, f) = d_k(c, s^c) + d_k(s^c, s^f) + d_k(s^f, f)$$

in the metric d_k .

The guarantee of tree embeddings gives us an upper bound on a cost of applying the same mapping in the instance G_T ,

$$\begin{aligned} \mathbb{E}[d_T(c, f)] &= d_k(c, s^c) + \mathbb{E}[d_T(s^c, s^f)] + d_k(s^f, f) \\ &\leq d_k(c, s^c) + \mathcal{O}(\log k) \cdot d_k(s^c, s^f) + d_k(s^f, f) \\ &\leq \mathcal{O}(\log k) \cdot d_k(c, f). \end{aligned}$$

Which means that $\mathbb{E}[\text{cost}(\phi^{OPT(d_k)}, d_T)] \leq \mathcal{O}(\log k) \cdot \text{cost}(\phi^{OPT(d_k)}, d_{G_k})$. Moreover, $OPT(d_k)$ might not be the optimal solution for the metric d_T , yet its optimal solution can only have smaller cost:

$$\text{cost}(\phi^{OPT(d_T)}, d_T) \leq \text{cost}(\phi^{OPT(d_k)}, d_T) \quad \blacktriangleleft$$

► **Theorem 10.** The CKM problem admits an $\mathcal{O}(\log k)$ -approximation algorithm with polynomial running time.

Proof. After applying the probabilistic tree embedding to the graph inducing d_k – as presented in Lemma 9 – we obtain a tree instance G_T . It should come as no surprise that the problem is polynomially solvable on trees and we explain how to find the optimum solution on G_T in Lemma 12. The assignment $\phi^{OPT(d_T)}$, which yields the minimum cost on the tree G_T , can be now used to match clients to facilities in the original instance. It does not incur any additional cost, as

$$\text{cost}(\phi^{OPT(d_T)}, d_T) \geq \text{cost}(\phi^{OPT(d_T)}, d_k) \geq \text{cost}(\phi^{OPT(d_T)}, d)$$

from the property (1) of Definition 8 and Lemma 6. Combining this with a bound on $\mathbb{E}[\text{cost}(\phi^{OPT(d_k)}, d_T)]$ from Lemma 9 finishes the proof. \blacktriangleleft

3.1 CKM on a tree

The second ingredient of the $\mathcal{O}(\log k)$ -approximation for CKM is an exact algorithm solving the problem on trees. We will now describe a simple, polynomial-time procedure for this special case. In our algorithm we can assume, that all the clients and facilities reside in leaves, but the principle is easy to extend to the general problem on trees. We first turn the tree into a complete binary tree by adding dummy vertices and edges of length 0 (which may double its size).

Suppose we have a subtree t of the tree instance, hanging on an edge e_t . Once we have decided, which facilities to open inside the subtree t , we know if their total capacity is sufficient to serve all the clients inside t . If not, then we need to route some clients' connections to the facilities outside through the edge e_t . However, if the facilities we have opened in t have enough total capacity to serve some b clients from the outside, we will connect them through the edge e_t .

► **Definition 11.** $D(t, k', b)$, for subtree t , number $k' \in \{0, \dots, k\}$ of facilities and balance $b \in \{-n, \dots, n\}$, is the minimum cost of opening exactly k' facilities in t and routing exactly b clients down through e_t ($b < 0$ would mean that we are routing $-b$ clients up). The cost of routing is counted to the top endpoint of e_t .

► **Lemma 12.** The CKM problem on trees admits a polynomial time exact algorithm.

Proof. Computing $D(t, k', b)$ on t with two children t_1 and t_2 amounts to finding k'_1, k'_2, b_1 and b_2 that minimize

$$D(t_1, k'_1, b_1) + D(t_2, k'_2, b_2),$$

such that $b_1 + b_2 = b$ and $k'_1 + k'_2 = k'$. They can be trivially found in $\mathcal{O}(k \cdot n)$ time for a single pair $\langle k', b \rangle$. Once k'_1, k'_2, b_1 and b_2 are found, we set

$$D(t, k', b) = D(t_1, k'_1, b_1) + D(t_2, k'_2, b_2) + d(e_t) \cdot |b|,$$

where $d(e)$ is the length of the edge in our tree. For a leaf l , $D(l, k', b)$ is defined naturally, depending on whether the leaf holds a client or a facility. Note, that for a leaf with a facility, $D(l, 1, b)$ is finite also for b smaller than the capacity of the facility, as the optimal solution might not use it entirely. Finally, the optimum solution to the CKM problem on the entire tree T is equal to $\min_{k' \in \{1, \dots, k\}} D(T, k', 0)$. ◀

4 Constant factor approximation

In this section we present the main result of the paper which is a $(7 + \varepsilon)$ -approximation algorithm for the NON-UNIFORM CKM problem. We precede it with a $(7 + \varepsilon)$ -approximation algorithm for the UNIFORM CKM problem to introduce the ideas gradually. Both algorithms enumerate configurations of open facilities' locations, and as a subroutine we need to use an algorithm which, for a fixed configuration of k open facilities, finds the optimal assignment of clients to facilities. This subroutine is presented in the following subsection.

4.1 Optimal mapping subroutine

We are given an ℓ -centered metric instance $(F \cup C \cup S, d_\ell)$ of the k -median problem. Suppose that we have already decided to open a fixed subset $F^{open} \subseteq F$ of the facilities assume $|F^{open}| \leq k$. and we look for a mapping $\phi : C \rightarrow F^{open}$. In the uncapacitated case we

can just assign each client to the closest facility in F^{open} . It turns out that even in the capacitated setting we can find the mapping ϕ optimally in polynomial time for a given F^{open} . We state the problem of finding the optimal ϕ as an integer program:

$$\begin{aligned}
 & \text{minimize} && \sum_{c \in C} \sum_{f \in F^{open}} d_\ell(c, f) \cdot x_{c,f} && \text{(MAPPING-IP)} \\
 & \text{subject to} && \sum_{f \in F^{open}} x_{c,f} = 1 && \forall c \in C, \\
 & && \sum_{c \in C} x_{c,f} \leq u_f && \forall f \in F^{open}, \\
 & && x_{c,f} \in \{0, 1\}.
 \end{aligned}$$

In the above program $x_{c,f} = 1$ represents the fact that $\phi(c) = f$.

► **Lemma 13.** *We can find an optimal solution to the (MAPPING-IP) in polynomial time.*

Proof. The proof follows from the fact that the relaxation of the above integer program – a program which differs from (MAPPING-IP) only with the $x_{c,f} \geq 0$ constraints instead of $x_{c,f} \in \{0, 1\}$ – has an optimal solution which is integral. To see this, observe that the linear program is a formulation of the transportation problem. For such a linear program, the constraint matrix is totally unimodular, which implies the integrality of an extremal solution. See [26] for a reference. ◀

4.2 Uniform case

We begin with a parameterized algorithm for the uniform case. It is simpler than the general case, as knowing the number of facilities to open in f -cluster $F(s)$ allows us to choose them greedily.

► **Lemma 14.** *UNIFORM CKM can be solved exactly in time $\ell^k \cdot n^{\mathcal{O}(1)}$ on ℓ -centered instances.*

Proof. Let $(F \cup C \cup S, d_\ell)$ be the ℓ -centered metric. Note that the f -clusters partition the whole set of facilities, i.e., $\cup_{s \in S} F(s) = F$. Let $OPT(d_\ell)$ be an optimal solution for the CKM problem on d_ℓ . Every facility $f \in F$ belongs to exactly one f -cluster $F(s)$. Hence, the f -clusters partition the set of k facilities opened by $OPT(d_\ell)$. Let us look at all the facilities from a particular f -cluster $F(s)$ opened by $OPT(d_\ell)$, and suppose that $OPT(d_\ell)$ opens k_s of facilities in $F(s)$. Since we consider a uniform capacity case, we can assume without loss that these k_s open facilities from $F(s)$ are exactly the ones that are closest to s .

Therefore, if we know what is the number of facilities that $OPT(d_\ell)$ opens in each f -cluster, then we would know what the exact set of open facilities in $OPT(d_\ell)$ is due to the greediness in each f -cluster. To find out this allocation we can simply enumerate over all possibilities. We just need to scan over all configurations $(k_s)_{s \in S}$ where $\sum_s k_s = k$. Since there are k facilities to open, and each of them can belong to one of ℓ f -clusters $F(s)$, there are at most ℓ^k possible configurations. Of course some configurations may not be feasible since it may happen that $k_s > |F(s)|$, but these can be simply ignored.

For each configuration $(k_s)_{s \in S}$ we need to find the optimal mapping of clients to the set of open facilities that preserves their capacities. Let $F((k_s)_{s \in S})$ be the set of open facilities induced by configuration $(k_s)_{s \in S}$, that is, where we greedily open k_s facilities in f -cluster $F(s)$. Given $F((k_s)_{s \in S})$, to find the optimal mapping we use the polynomial time exact algorithm from Lemma 13 with $F^{open} = F((k_s)_{s \in S})$.

Once we know the optimal assignment for each configuration, we can simply take the cheapest one, knowing that it is the optimal one. This proves the lemma. ◀

This lemma suffices to obtain a $(7 + \varepsilon)$ -approximation for UNIFORM CKM with a reasoning that we will present in Theorem 16 in full generality.

4.3 Non-uniform case

► **Lemma 15.** NON-UNIFORM CKM can be solved with approximation ratio $(1 + \varepsilon)$ in time $\mathcal{O}\left(\ell \cdot \frac{1}{\varepsilon} \ln \frac{n}{\varepsilon}\right)^k n^{\mathcal{O}(1)}$ on ℓ -centered instances.

Proof. We begin with guessing the largest distance in d_ℓ between a client and a facility that would appear in the optimal solution – let us denote this quantity as D . There are at most $\mathcal{O}(n^2)$ choices for D , and from now we assume that it is guessed correctly. Note that $D \leq \text{cost}(OPT(d_\ell), d_\ell)$ and $D \geq d(f, s_f)$ for all facilities opened by $OPT(d_\ell)$.

Consider the set of facilities $F(s)$ in the cluster of a center s . We can remove all facilities f such that $d(s, f) > D$, because they cannot be a part of the optimal solution. Let us partition remaining facilities from $F(s)$ into buckets $F_0(s), F_1(s), \dots, F_{\lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil}(s)$, such that

$$F_i(s) = \begin{cases} \left\{ f \in F(s) \mid d(s, f) \in \left[(1 + \varepsilon)^{-(i+1)} D, (1 + \varepsilon)^{-i} D \right] \right\} & \text{for } i < \lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil \\ \left\{ f \in F(s) \mid d(s, f) \in \left[0, (1 + \varepsilon)^{-\lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil} D \right] \right\} & \text{for } i = \lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil \end{cases}$$

The number of buckets equals $\log_{1+\varepsilon} \frac{n}{\varepsilon} = \frac{1}{\ln(1+\varepsilon)} \ln \frac{n}{\varepsilon} = \mathcal{O}\left(\frac{1}{\varepsilon} \ln \frac{n}{\varepsilon}\right)$. We modify the metric again by setting $d'_\ell(s, f) = (1 + \varepsilon)^{-i} D$ for $f \in F_i(s)$. The distances within S remain untouched. Observe that the distances can only increase.

We shall guess the structure of the solution $OPT(d'_\ell)$ similarly as in Lemma 14. For each of the k facilities, we can choose its location as follows: first we choose one of the ℓ -centers s (ℓ choices), and then we choose one of the $F_i(s)$ partitions ($\mathcal{O}\left(\frac{1}{\varepsilon} \ln \frac{n}{\varepsilon}\right)$ choices). Let us denote the number of facilities in a particular partition $F_i(s)$ as $k_{s,i}$. We can assume that $k_{s,i} \leq |F_i(s)|$ because otherwise we know that the guess was incorrect. Since $d'_\ell(s, f)$ is the same for all $f \in F_i(s)$, we can assume the optimal solution opens $k_{s,i}$ facilities with the biggest capacities.

Once we establish the set of facilities to open, we can find the optimal assignment in metric d'_ℓ using the polynomial time exact subroutine from Lemma 13.

The total time complexity of solving the problem exactly over d'_ℓ equals the running time of the subroutine times the number of possible configurations, which is $\mathcal{O}\left(\ell \cdot \frac{1}{\varepsilon} \ln \frac{n}{\varepsilon}\right)^k n^{\mathcal{O}(1)}$.

It remains to prove that the algorithm yields a proper approximation. We will show that for any solution SOL it holds that

$$\text{cost}(\phi^{SOL}, d_\ell) \leq \text{cost}(\phi^{SOL}, d'_\ell) \leq (1 + \varepsilon) \cdot \text{cost}(\phi^{SOL}, d_\ell) + \varepsilon \cdot D. \quad (1)$$

By substituting $SOL = OPT(d_\ell)$ we learn that there exists a solution over metric d'_ℓ of cost at most $(1 + \varepsilon) \cdot \text{cost}(\phi^{OPT(d_\ell)}, d_\ell) + \varepsilon \cdot D \leq (1 + 2\varepsilon) \cdot \text{cost}(\phi^{OPT(d_\ell)}, d_\ell)$ for correctly guessed D . Therefore the cost of the solution found by our algorithm cannot be larger. Finally we substitute this solution as SOL to see that its cost cannot increase when returning to metric d_ℓ . The claim will follow by adjusting ε .

The first inequality in (1) is straightforward because d'_ℓ dominates d_ℓ . Consider now a pair $(c, f = \phi^{SOL}(c))$, where $f \in F_i(s)$. If $i < \lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil$, then $d_\ell(c, f) \leq d'_\ell(c, f) \leq (1 + \varepsilon) \cdot d_\ell(c, f)$, so the cost of connecting such pairs increases at most by a multiplicative factor $(1 + \varepsilon)$ during the metric switch. If $i = \lceil \log_{1+\varepsilon} \frac{n}{\varepsilon} \rceil$, then $d'_\ell(s, f) = \frac{\varepsilon D}{n}$. Since there are at most n such pairs, the total additive cost increase is bounded by $\varepsilon \cdot D$. ◀

► **Theorem 16.** NON-UNIFORM CKM can be solved with approximation ratio $(7 + \epsilon)$ in time $(k/\epsilon)^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$.

Proof. From Lemma 15 we know that we can get a $(1 + \epsilon)$ -approximation algorithm for the NON-UNIFORM CKM problem on ℓ -centered instances in time $(\mathcal{O}(\ell \cdot \frac{1}{\epsilon} \ln \frac{n}{\epsilon}))^k n^{\mathcal{O}(1)}$. We shall use the $(1 + \epsilon)$ -approximation for UNCAPACITATED KM by Lin and Vitter [24], that opens at most $\ell = (1 + \frac{1}{\epsilon}) k \cdot (\ln n + 1)$ facilities. By plugging this subroutine to find ℓ -centers into the Lemma 7 together with Lemma 15, we obtain a $(7 + \epsilon)$ -approximation algorithm for the general NON-UNIFORM CKM problem with running time

$$\mathcal{O}\left(\left(\left(1 + \frac{1}{\epsilon}\right) k \cdot (\ln n + 1) \cdot \frac{1}{\epsilon} \ln \frac{n}{\epsilon}\right)^k\right) n^{\mathcal{O}(1)} = \mathcal{O}\left(\left(\frac{1}{\epsilon^{\mathcal{O}(1)}} k \ln^2 n\right)^k\right) n^{\mathcal{O}(1)}.$$

Finally, we use standard arguments to show that $(\ln n)^{2k} \leq \max(n, k^{\mathcal{O}(k)})$. Consider two cases. If $\frac{\ln n}{2 \ln \ln n} \leq k$, then by inverting we know that $\ln n = \mathcal{O}(k \ln k)$, and so $(\ln n)^{2k} = k^{\mathcal{O}(k)}$. Suppose now that $\frac{\ln n}{2 \ln \ln n} > k$. In this case

$$(\ln n)^{2k} < (\ln n)^{\frac{\ln n}{\ln \ln n}} = e^{\ln \ln n \cdot \frac{\ln n}{\ln \ln n}} = n. \quad \blacktriangleleft$$

5 Conclusions and open problems

We have presented a $(7 + \epsilon)$ -approximation algorithm for the CKM problem, which consists of three building blocks: approximation for UNCAPACITATED KM, metric embedding into a simpler structure, and a parameterized algorithm working on ℓ -centered instances.

Whereas the first and the last ingredient are almost lossless from the approximation point of view, the embedding procedure seems to be the main bottleneck for obtaining a better approximation guarantee. One can imagine that a different technique would allow to obtain a $(1 + \epsilon)$ -approximation in FPT time. We believe that finding such an algorithm or ruling out its existence is an interesting research direction.

Another avenue for improvement is processing k -centered instances in time $2^{\mathcal{O}(k)} n^{\mathcal{O}(1)}$. Such a routine would reduce the running time of the whole algorithm to single exponential. In order to do so, one could replace the subroutine for UNCAPACITATED KM by Lin and Vitter [24] with a standard approximation algorithm that opens exactly k facilities, what would moderately increase the constant in approximation ratio.

Finally, whereas we have used the framework of ℓ -centered instances to devise an FPT approximation, it might be possible to explore the structure of special instances further and find a polynomial time approximation algorithm. This could yield an improvement over the $\mathcal{O}(\log k)$ -approximation ratio for CKM, which remains a major open problem.

Abstract

We initiate a study of algorithms with a focus on the computational complexity of individual elements, and introduce the *fragile complexity* of comparison-based algorithms as the maximal number of comparisons any individual element takes part in. We give a number of upper and lower bounds on the fragile complexity for fundamental problems, including MINIMUM, SELECTION, SORTING and HEAP CONSTRUCTION. The results include both deterministic and randomized upper and lower bounds, and demonstrate a separation between the two settings for a number of problems. The depth of a comparator network is a straight-forward upper bound on the worst case fragile complexity of the corresponding fragile algorithm. We prove that fragile complexity is a different and strictly easier property than the depth of comparator networks, in the sense that for some problems a fragile complexity equal to the best network depth can be achieved with less total work and that with randomization, even a lower fragile complexity is possible.

1 Introduction

Comparison-based algorithms is a classic and fundamental research area in computer science. Problems studied include minimum, median, sorting, searching, dictionaries, and priority queues, to name a few, and by now a huge body of work exists. The cost measure analyzed is almost always the total number of comparisons needed to solve the problem, either in the worst case or the expected case. Surprisingly, very little work has taken the viewpoint of the individual elements, asking the question: *how many comparisons must each element be subjected to?*

This question not only seems natural and theoretically fundamental, but is also practically well motivated: in many real world situations, comparisons involve some amount of destructive impact on the elements being compared, hence, keeping the maximum number of comparisons for each individual element low can be important. One example of such a situation is ranking of any type of consumable objects (wine, beer, food, produce), where each comparison reduces the available amount of the objects compared. Here, classical algorithms like QUICKSORT, which takes a single object and partitions the whole set with it, may use up this pivot element long before the algorithm completes. Another example is sports, where each comparison constitutes a match and takes a physical toll on the athletes involved. If a comparison scheme subjects one contestant to many more matches than others, both fairness to contestants and quality of result are impacted. The selection process could even contradict its own purpose – what is the use of finding a national boxing champion to represent a country at the Olympics if the person is injured in the process? Notice that in both examples above, quality of elements is difficult to measure objectively by a numerical value, hence one has to resort to relative ranking operations between opponents, i.e., comparisons. The detrimental impact of comparisons may also be of less directly physical nature, for instance if it involves a privacy risk for the elements compared, or if bias in the comparison process grows each time the same element is used.

► **Definition 1.** *We say that a comparison-based algorithm \mathcal{A} has fragile complexity $f(n)$ if each individual input element participates in at most $f(n)$ comparisons. We also say that \mathcal{A} has work $w(n)$ if it performs at most $w(n)$ comparisons in total. We say that a particular element e has fragile complexity $f_e(n)$ in \mathcal{A} if e participates in at most $f_e(n)$ comparisons.*

In this paper, we initiate the study of algorithms' fragile complexity – comparison-based complexity from the viewpoint of the individual elements – and present a number of upper and lower bounds on the fragile complexity for fundamental problems.

1.1 Previous work

One body of work relevant to what we study here is the study of sorting networks, propelled by the 1968 paper of Batcher [6]. In sorting networks, and more generally comparator networks, the notions of depth and size correspond to fragile complexity and standard worst case complexity,¹ respectively, since a network with depth $f(n)$ and size $w(n)$ easily can be converted into a comparison-based algorithm with fragile complexity $f(n)$ and work $w(n)$.

Batcher gave sorting networks with $\mathcal{O}(\log^2 n)$ depth and $\mathcal{O}(n \log^2 n)$ size, based on clever variants of the MERGESORT paradigm. A number of later constructions achieve the same bounds [10, 15, 16, 19], and for a long time it was an open question whether better results were possible. In the seminal result in 1983, Ajtai, Komlós, and Szemerédi [2, 3] answered this in the affirmative by constructing a sorting network of $\mathcal{O}(\log n)$ depth and $\mathcal{O}(n \log n)$ size. This construction is quite complex and involves expander graphs [21, 22], which can be viewed as objects encoding pseudorandomness, and which have many powerful applications in computer science and mathematics. The size of the constant factors in the asymptotic complexity of the AKS sorting network prevents it from being practical in any sense. It was later modified by others [8, 12, 17, 20], but finding a simple, optimal sorting network, in particular one not based on expander graphs, remains an open problem. Comparator networks for other problems, such as selection and heap construction have also been studied [5, 7, 14, 18, 23]. In all these problems the size of the network is super-linear.

As comparator networks of depth $f(n)$ and size $w(n)$ lead to comparison-based algorithms with $f(n)$ fragile complexity and $w(n)$ work, a natural question is, whether the two models are equivalent, or if there are problems for which comparison-based algorithms can achieve either asymptotically lower $f(n)$, or asymptotically lower $w(n)$ for the same $f(n)$.

One could also ask about the relationship between parallelism and fragile complexity. We note that parallel time in standard parallel models generally does not seem to capture fragile complexity. For example, even in the most restrictive exclusive read and exclusive write (EREW) PRAM model it is possible to create n copies of an element e in $\mathcal{O}(\log n)$ time and, thus, compare e to all the other input elements in $\mathcal{O}(\log n)$ time, resulting in $\mathcal{O}(\log n)$ parallel time but $\Omega(n)$ fragile complexity. Consequently, it is not clear whether Richard Cole's celebrated parallel merge sort algorithm [9] yields a comparison-based algorithm with low fragile complexity as it copies some elements.

1.2 Our contribution

In this paper we present algorithms and lower bounds for a number of classical problems, summarized in Table 1. In particular, we study finding the MINIMUM (Section 2), the SELECTION problem (Section 3), and SORTING (Section 4).

Minimum. The case of the deterministic algorithms is clear: using an adversary lower bound, we show that the minimum element needs to suffer $\Omega(\log n)$ comparisons and a tournament tree trivially achieves this bound (Subsection 2.1). The randomized case, however, is much more interesting. We obtain a simple algorithm where the probability of the minimum element suffering k comparisons is doubly exponentially low in k , roughly $1/2^{2^k}$ (see Subsection 2.2). As a result, the $\Theta(\log n)$ deterministic fragile complexity can be lowered to $\mathcal{O}(1)$ expected or even $\mathcal{O}(\log \log n)$ with high probability. We also show this latter high probability case is lower

¹ For clarity, in the rest of the paper we call standard worst case complexity *work*.

2:4 Fragile Complexity of Comparison-Based Algorithms

■ **Table 1** Summary of presented results. Notation: $f(n)$ means fragile complexity; $w(n)$ means work; $\langle f_m(n), f_{rem}(n) \rangle$ means fragile complexity for the selected element (minimum/median) and for the remaining elements, respectively – except for lower bounds, where it means \langle expected for the selected, limit for remaining \rangle ; \dagger means holds in expectation; \ddagger means holds with high probability $(1 - 1/n)$. $\varepsilon > 0$ is an arbitrary constant.

Problem		Upper		Lower
		$f(n)$	$w(n)$	$f(n)$
MINIMUM	Determ. (Sec. 2)	$\mathcal{O}(\log n)$ [T 2]	$\mathcal{O}(n)$	$f_{\min} = \Omega(\log n)$ [T 2]
	Rand. (Sec. 2)	$\langle \mathcal{O}(\log_{\Delta} n)^{\dagger}, \mathcal{O}(\Delta + \log_{\Delta} n)^{\dagger} \rangle$ [T 9] $\langle \mathcal{O}(1)^{\dagger}, \mathcal{O}(n^{\varepsilon}) \rangle$ (setting $\Delta = n^{\varepsilon}$) $\mathcal{O}\left(\frac{\log n}{\log \log n}\right)^{\dagger}$ [Cor 11]	$\mathcal{O}(n)$	$\langle \Omega(\log_{\Delta} n)^{\dagger}, \Delta \rangle$ [T 10] $\Omega\left(\frac{\log n}{\log \log n}\right)^{\dagger}$ [Cor 11]
		$\langle \mathcal{O}(\log_{\Delta} n \log \log \Delta)^{\ddagger}, \mathcal{O}(\Delta + \log_{\Delta} n \log \log \Delta)^{\ddagger} \rangle$ [T 9]	$\mathcal{O}(n)$ $\mathcal{O}(n)$	$f_{\min} =$ $= \Omega(\log \log n)^{\ddagger}$ [T 14]
SELECTION	Determ. (Sec. 3)	$\mathcal{O}(\log n)$ [T 15]	$\mathcal{O}(n)$ [T 15]	$\Omega(\log n)$ [Cor 3]
	Rand. (Sec. 3)	$\langle \mathcal{O}(\log \log n)^{\dagger}, \mathcal{O}(\sqrt{n})^{\dagger} \rangle$ [T 17] $\langle \mathcal{O}\left(\frac{\log n}{\log \log n}\right)^{\dagger}, \mathcal{O}(\log^2 n)^{\dagger} \rangle$ [T 17]	$\mathcal{O}(n)^{\dagger}$	$\langle \Omega(\log_{\Delta} n)^{\dagger}, \Delta \rangle$ [T 10]
MERGE		Determ. (Sec. 4)	$\mathcal{O}(\log n)$ [T 24]	$\mathcal{O}(n)$
HEAP CONSTR.	Determ. (Sec. 5)	$\mathcal{O}(\log n)$ [Obs 2]	$\mathcal{O}(n)$	$\Omega(\log n)$ [T 2]

bounded by $\Omega(\log \log n)$ (Subsection 2.3). Furthermore, we can achieve a trade-off between the fragile complexity of the minimum element and the other elements. Here $\Delta = \Delta(n)$ is a parameter we can choose freely that basically upper bounds the fragile complexity of the non-minimal elements. We can find the minimum with $\mathcal{O}(\log_{\Delta} n)$ expected fragile complexity while all the other elements suffer $\mathcal{O}(\Delta + \log_{\Delta} n)$ comparisons (Subsection 2.3). Furthermore, this is tight: we show an $\Omega(\log_{\Delta} n)$ lower bound for the expected fragile complexity of the minimum element where the maximum fragile complexity of non-minimum elements is at most Δ .

Selection. Minimum finding is a special case of the selection problem where we are interested in finding an element of a given rank. As a result, all of our lower bounds apply to this problem as well. Regarding upper bounds, the deterministic case is trivial if we allow for $\mathcal{O}(n \log n)$ work (via sorting). We show that this can be reduced to $\mathcal{O}(n)$ time while keeping the fragile complexity of all the elements at $\mathcal{O}(\log n)$ (Section 3). Once again, randomization offers a substantial improvement: e.g., we can find the median in $\mathcal{O}(n)$ expected work and with $\mathcal{O}(\log \log n)$ expected fragile complexity while non-median elements suffer $\mathcal{O}(\sqrt{n})$ expected comparisons, or we can find the median in $\mathcal{O}(n)$ expected work and with $\mathcal{O}(\log n / \log \log n)$ expected fragile complexity while non-median elements suffer $\mathcal{O}(\log^2 n)$ expected comparisons.

Sorting and other results. The deterministic selection, sorting, and heap construction fragile complexities follow directly from the classical results in comparator networks [3, 7]. However, we show a separation between comparator networks and comparison-based algorithms for the problem of MEDIAN (Section 3) and HEAP CONSTRUCTION (Section 5), in the sense that depth/fragile complexity of $\mathcal{O}(\log n)$ can be achieved in $\mathcal{O}(n)$ work for comparison-based algorithms, but requires $\Omega(n \log n)$ [5] and $\Omega(n \log \log n)$ [7] sizes for comparator networks

for the two problems, respectively. For sorting the two models achieve the same complexities: $\mathcal{O}(\log n)$ depth/fragile complexity and $\mathcal{O}(n \log n)$ size/work, which are the optimal bounds in both models due to the $\Omega(\log n)$ lower bound on fragile complexity for MINIMUM (Theorem 2) and the standard $\Omega(n \log n)$ lower bound on work for comparison-based sorting. However, it is an open problem whether these bounds can be achieved by simpler sorting algorithms than sorting networks, in particular whether expander graphs are necessary. One intriguing conjecture could be that any comparison-based sorting algorithm with $\mathcal{O}(\log n)$ fragile complexity and $\mathcal{O}(n \log n)$ work implies an expander graph. This would imply expanders, optimal sorting networks and fragile-optimal comparison-based sorting algorithms to be equivalent, in the sense that they all encode the same level of pseudorandomness.

We note that our lower bound of $\Omega(\log^2 n)$ on the fragile complexity of MERGESORT (Theorem 19) implies the same lower bound on the depth of any sorting network based on binary merging, which explains why many of the existing simple sorting networks have $\Theta(\log^2 n)$ depth. Finally, our analysis of MERGESORT on random inputs (Theorem 23) shows a separation between deterministic and randomized fragile complexity for such algorithms. In summary, we consider the main contributions of this paper to be:

- the introduction of the model of fragile complexity, which we find intrinsically interesting, practically relevant, and surprisingly overlooked
- the separations between this model and the model of comparator networks
- the separations between the deterministic and randomized setting within the model
- the lower bounds on randomized minimum finding

Due to space constraints, some proofs only appear in the full paper [1].

2 Finding the minimum

2.1 Deterministic Algorithms

As a starting point, we study deterministic algorithms that find the minimum among an input of n elements. Our results here are simple but they act as interesting points of comparison against the subsequent non-trivial results on randomized algorithms.

► **Theorem 2.** *The fragile complexity of finding the minimum of n elements is $\lceil \log n \rceil$.*

Proof. The upper bound is achieved using a perfectly balanced tournament tree. The lower bound follows from a standard adversary argument. ◀

Observe that in addition to returning the minimum, the balanced tournament tree can also return the second smallest element, without any increase to the fragile complexity of the minimum. We refer to this deterministic algorithm that returns the smallest and the second smallest element of a set X as $\text{TournamentMinimum}(X)$.

► **Corollary 3.** *For any deterministic algorithm \mathcal{A} that finds the median of n elements, the fragile complexity of the median element is at least $\lceil \log n \rceil - 1$.*

Proof. By a standard padding argument with $n - 1$ small elements. ◀

2.2 Randomized Algorithms for Finding the Minimum

We now show that finding the minimum is provably easier for randomized algorithms than for deterministic algorithms. We define f_{\min} as the fragile complexity of the minimum and f_{rem} as the maximum fragile complexity of the remaining elements. For deterministic

2:6 Fragile Complexity of Comparison-Based Algorithms

algorithms we have shown that $f_{\min} \geq \log n$ regardless of f_{rem} . This is very different in the randomized setting. In particular, we first show that we can achieve $\mathbb{E}[f_{\min}] = O(1)$ and $f_{\min} = O(1) + \log \log n$ with high probability (we later show this high probability bound is also tight, Theorem 14).

```

1: procedure SAMPLEMINIMUM( $X$ )  $\triangleright$  Returns the smallest and 2nd smallest element of  $X$ 
2:   if  $|X| \leq 8$  return TOURNAMENTMINIMUM( $X$ )
3:   Let  $A \subset X$  be a uniform random sample of  $X$ , with  $|A| = \lceil |X|/2 \rceil$ 
4:   Let  $B \subset A$  be a uniform random sample of  $A$ , with  $|B| = \lfloor |X|^{2/3} \rfloor$ 
5:    $\triangleright$  The minimum is either in (i)  $C \subseteq X \setminus A$ , (ii)  $D \subseteq A \setminus B$  or (iii)  $B$

9:   Let  $(a_1, a_2) = \text{TOURNAMENTMINIMUM}(a'_1, a'_2, b_1, b_2)$   $\triangleright$  case (ii) and (iii)
10:  Let  $C = \{x \in X \setminus A \mid x < a_2\}$   $\triangleright$  only case (i)
11:  Let  $(c_1, c_2) = \text{TOURNAMENTMINIMUM}(C)$   $\triangleright$  only case (i)
12:  return TOURNAMENTMINIMUM( $a_1, a_2, c_1, c_2$ )  $\triangleright$  always

```

First, we show that this algorithm can actually find the minimum with expected constant number of comparisons. Later, we show that the probability that this algorithm performs t comparisons on the minimum drops roughly *doubly exponentially* on t .

We start with the simple worst-case analysis.

► **Lemma 4.** *Algorithm SAMPLEMINIMUM(X) achieves $f_{\min} \leq 3 \log |X|$ in the worst case.*

Proof. First, observe that the smallest element in Lines 9 and 12 participates in at most one comparison because pairs of elements are already sorted. Then the fragile complexity of the minimum is defined by the maximum of the three cases:

- (i) One comparison each in Lines 10 and 12, plus (by Theorem 2) $\lceil \log |C| \rceil \leq \log |X|$ comparisons in Line 11.
- (ii) One comparison each in Lines 7, 9, and 12, plus the recursive call in line 8.
- (iii) One comparison each in Lines 6, 9, and 12, plus the recursive call in line 6.

The recursive calls in lines 8 and 6 are on at most $|X|/2$ elements because $B \subset A$, $D \subset A$, and $|A| = \lceil |X|/2 \rceil$. Consequently, the fragile complexity of the minimum is defined by the recurrence

$$T(n) \leq \begin{cases} \max\{3 + T(n/2), 2 + \log n\} & \text{if } n > 8 \\ 3 & \text{if } n \leq 8 \end{cases},$$

which solves to $T(n) \leq 3 \log n$. ◀

► **Lemma 5.** *Assume that in Algorithm SAMPLEMINIMUM, the minimum y is in $X \setminus A$, i.e. we are in case (i). Then $\Pr[|C| = k \mid y \notin A] \leq \frac{k}{2^k}$ for any $k \geq 1$ and $n \geq 7$.*

Proof. There are $\binom{n-1}{\lceil n/2 \rceil}$ possible events of choosing a random subset $A \subset X$ of size $\lceil n/2 \rceil$ s.t. $y \notin A$. Let us count the number of the events $\{|C| = k \mid y \notin A\}$, which is equivalent to a_2 , the second smallest element of A , being larger than exactly $k + 1$ elements of X .

For simplicity of exposition, consider the elements of $X = \{x_1, \dots, x_n\}$ in sorted order. The minimum $y = x_1 \notin A$, therefore, a_1 (the smallest element of A) must be one of the k elements $\{x_2, \dots, x_{k+1}\}$. By the above observation, $a_2 = x_{k+2}$. And the remaining $\lceil n/2 \rceil - 2$ elements of A are chosen from among $\{x_{k+3}, \dots, x_n\}$. Therefore,

$$\Pr[|C| = k \mid y \notin A] = \frac{k \cdot \binom{n-(k+2)}{\lceil n/2 \rceil - 2}}{\binom{n-1}{\lceil n/2 \rceil}} = k \cdot \frac{(n-(k+2))!}{(\lceil n/2 \rceil - k)! (\lceil n/2 \rceil - 2)!} \cdot \frac{(\lceil n/2 \rceil)! (\lceil n/2 \rceil - 1)!}{(n-1)!}$$

Rearranging the terms, we get:

$$\Pr[|C| = k \mid y \notin A] = k \cdot \frac{(n-(k+2))!}{(n-1)!} \cdot \frac{(\lceil n/2 \rceil)!}{(\lceil n/2 \rceil - 2)!} \cdot \frac{(\lceil n/2 \rceil - 1)!}{(\lceil n/2 \rceil - k)!}$$

There are two cases to consider:

$$\begin{aligned} k = 1 : \quad \Pr[|C| = k \mid y \notin A] &= 1 \cdot \frac{1}{(n-1)(n-2)} \cdot \lceil n/2 \rceil (\lceil n/2 \rceil - 1) \cdot 1 \\ &\leq \frac{1}{(n-1)(n-2)} \cdot \frac{(n+1)}{2} \cdot \frac{(n-1)}{2} \\ &= \frac{n+1}{4 \cdot (n-2)} \leq \frac{1}{2} = \frac{k}{2^k} \quad \text{for every } n \geq 5. \end{aligned}$$

$$\begin{aligned} k \geq 2 : \quad \Pr[|C| = k \mid y \notin A] &= k \cdot \frac{1}{\prod_{i=1}^{k+1} (n-i)} \cdot \lceil n/2 \rceil (\lceil n/2 \rceil - 1) \cdot \prod_{i=1}^{k-1} \left(\left\lfloor \frac{n}{2} \right\rfloor - i \right) \\ &\leq k \cdot \frac{1}{\prod_{i=1}^{k+1} (n-i)} \cdot \frac{n+1}{2} \cdot \frac{n-1}{2} \cdot \prod_{i=1}^{k-1} \frac{n-2i}{2} \\ &\leq \frac{k}{2^{k+1}} \cdot (n+1)(n-1) \cdot \frac{\prod_{i=1}^{k-1} (n-2i)}{\prod_{i=1}^{k+1} (n-i)} \\ &\leq \frac{k}{2^{k+1}} \cdot (n+1)(n-1) \cdot \frac{n-2}{(n-1)(n-2)(n-3)} \\ &= \frac{k}{2^{k+1}} \cdot \frac{n+1}{n-3} \leq \frac{k}{2^{k+1}} \cdot 2 = \frac{k}{2^k} \quad \text{for every } n \geq 7. \quad \blacktriangleleft \end{aligned}$$

► **Theorem 6.** *Algorithm SAMPLEMINIMUM achieves $\mathbb{E}[f_{\min}] \leq 9$.*

Proof. By induction on the size of X . In the base case $|X| \leq 8$, clearly $f_{\min} \leq 3$, implying the theorem.

Now assume that the calls in Line 8 and Line 6 have the property that $\mathbb{E}[f(b_1)] \leq 9$ and $\mathbb{E}[f(a'_1)] \leq 9$. Both in case (ii) and case (iii), the expected number of comparisons of the minimum is $\leq 9 + 3$. Case (i) happens with probability at least $1/2$. In this case, the expected number of comparisons is 2 plus the ones from Line 11. By Lemma 5 we have $\Pr[|C| = k \mid \text{case (i)}] \leq k2^{-k}$. Because TOURNAMENTMINIMUM (actually any algorithm not repeating the same comparison) uses the minimum at most $k-1$ times, the expected number of comparisons in Line 11 is $\sum_{k=1}^{\lceil n/2 \rceil} (k-1)k2^{-k} \leq \sum_{k=1}^{\infty} (k-1)k2^{-k} \leq 4$. Combining the bounds we get $\mathbb{E}[f_{\min}] \leq \frac{9+3}{2} + \frac{2+4}{2} = 9$. ◀

Observe that the above proof did not use anything about the sampling of B , and also did not rely on TOURNAMENTMINIMUM.

► **Lemma 7.** *For $|X| > 2$ and any $\gamma > 1$: $\Pr[|D| \geq \gamma|X|^{1/3}] < |X| \exp(-\Theta(\gamma))$*

Proof. Let $n = |X|$, $a = |A| = \lceil n/2 \rceil$ and $b = |B| = \lfloor n^{2/3} \rfloor$. The construction of the set B can be viewed as the following experiment. Consider drawing without replacement from an urn with b blue and $a - b$ red marbles. The i -th smallest element of A is chosen into B iff the i -th draw from the urn results in a blue marble. Then $|D| \geq \gamma|X|^{1/3} = \gamma n^{1/3}$ implies that this experiment results in at most one blue marble among the first $t = \gamma n^{1/3}$ draws. There are precisely $t + 1$ elementary events that make up the condition $|D| \geq t$, namely that the i -th draw is a blue marble, and where $i = 0$ stands for the event “all t marbles are red”. Let us denote the probabilities of these elementary events as p_i .

Observe that each p_i can be expressed as a product of t factors, at least $t - 1$ of which stand for drawing a red marble, each upper bounded by $1 - \frac{b-1}{a}$. The remaining factor stands for drawing the first blue marble (from the urn with $a - i$ marbles, b of which are blue), or another red marble. In any case we can bound

$$p_i \leq \left(1 - \frac{b-1}{a}\right)^{t-1} \leq \left(1 - \frac{b-1}{a}\right)^{\gamma n^{1/3} - 1} = \exp\left(-\Theta\left(\frac{b\gamma n^{1/3}}{a}\right)\right).$$

Summing the $t + 1$ terms, and observing $t + 1 < n$ if the event can happen at all, we get

$$\Pr[|D| \geq \gamma|X|^{1/3}] < n \cdot \exp\left(-\Theta\left(\frac{\gamma n^{1/3} n^{2/3}}{n/2}\right)\right) = n \cdot \exp(-\Theta(\gamma)). \quad \blacktriangleleft$$

► **Theorem 8.** *There is a positive constant c , such that for any parameter $t \geq c$, the minimum in the Algorithm `SAMPLEMINIMUM`(X) participates in at most $O(t + \log \log |X|)$ comparisons with probability at least $1 - \exp(-2^t)2 \log \log |X|$.*

Proof. Let $n = |X|$ and y be the minimum element. In each recursion step, we have one of three cases: (i) $y \in C \subseteq X \setminus A$, (ii) $y \in D \subseteq A \setminus B$ or (iii) $y \in B$. Since the three sets are disjoint, the minimum always participates in at most one recursive call. Tracing only the recursive calls that include the minimum, we use the superscript $X^{(i)}$, $A^{(i)}$, $B^{(i)}$, $C^{(i)}$, and $D^{(i)}$ to denote these sets at depth i of the recursion.

Let h be the first recursive level when $y \in C^{(h)}$, i.e., $y \notin A^{(h)}$. It follows that y will not be involved in the future recursive calls because it is in a single call to `TOURNAMENTMINIMUM`. Thus, at this level of recursion, the number of comparisons that y will accumulate is equal to $O(1) + \log |C^{(h)}|$. To bound this quantity, let $k = 4 \cdot 2^t$. Then, by Lemma 5, $\Pr[|C^{(h)}| > k] \leq k2^{-k} = 4 \cdot 2^t \cdot 2^{-4 \cdot 2^t} = 4 \cdot 2^t \cdot 4^{-2^t} \cdot 4^{-2^t}$. Since $4x4^{-x} \leq 1$ for any $x \geq 1$, $\Pr[|C^{(h)}| > k] \leq 4^{-2^t}$ for any $t \geq 0$. I.e., the number of comparisons that y participates in at level h is at most $O(1) + \log k = O(1) + t$ with probability at least $1 - 4^{-2^t} \geq 1 - \exp(-2^t)$.

Thus, it remains to bound the number of comparisons involving y at the recursive levels $i \in [1, h - 1]$. In each of these recursive levels $y \notin C^{(i)}$, which only leaves the two cases: (ii) $y \in D^{(i)} \subseteq A^{(i)} \setminus B^{(i)}$ and (iii) $y \in B^{(i)}$. The element y is involved in at most $O(1)$ comparisons in lines 7, 9 and 12. The two remaining lines of the algorithm are lines 6 and 8 which are the recursive calls. We differentiate two types of recursive calls:

- Type 1: $|X^{(i)}| \leq 2^{4t}$. In this case, by Lemma 4, the algorithm will perform $O(t)$ comparisons at the recursive level i , as well as any subsequent recursive levels.
- Type 2: $|X^{(i)}| > 2^{4t}$. In this case, by Lemma 7 on the set $X^{(i)}$ and $\gamma = |X^{(i)}|^{1/3}$ we get:

$$\Pr[|D^{(i)}| \geq \gamma|X^{(i)}|^{1/3}] < |X^{(i)}| \exp\left(-\Theta\left(|X^{(i)}|^{1/3}\right)\right) < \exp\left(-\Theta\left(|X^{(i)}|^{1/3}\right)\right)$$

Note that since $|X^{(i)}|^{1/3} > 2^t$, by the definition of the Θ -notation, there exists a positive constant c , such that $\exp\left(-\Theta\left(|X^{(i)}|^{1/3}\right)\right) < \exp(-2^t)$. Thus, it follows that with probability $1 - \exp(-2^t)$, we will recurse on a subproblem of size at most $\gamma|X^{(i)}|^{1/3} \leq |X^{(i)}|^{2/3}$. Let G_i be this (good) event, and thus $\Pr[G_i] \geq 1 - \exp(-2^t)$.

Observe that the maximum number of times we can have good events of type 2 is very limited. With every such good event, the size of the subproblem decreases significantly and thus eventually we will arrive at a recursive call of type 1. Let j be this maximum number of “good” recursive levels of type 2. The problem size at the j -th such recursive level is at most $n^{(2/3)^{j-1}}$ and we must have that $n^{(2/3)^{j-1}} > 2^{4t}$ which reveals that we must have $j = O(\log \log n)$.

We are now almost done and we just need to use a union bound. Let G be the event that at the recursive level h , we perform at most $O(1) + t$ comparisons, and all the recursive levels of type 2 are good. G is the conjunction of at most $j + 1$ events and as we have shown, each such event holds with probability at least $1 - \exp(-2^t)$. Thus, it follows that G happens with probability $1 - (j + 1) \exp(-2^t) > 1 - 2 \log \log n \exp(-2^t)$. Furthermore, our arguments show that if G happens, then the minimum will only participate in $O(t + j) = O(t + \log \log n)$ comparisons. \blacktriangleleft

The major strengths of the above algorithm is the doubly exponential drop in probability of comparing the minimum with too many elements. Based on it, we can design another simple algorithm to provide a smooth trade-off between f_{\min} and f_{rem} . Let $2 \leq \Delta \leq n$ be an integral parameter. We will design an algorithm that achieves $\mathbb{E}[f_{\min}] = O(\log_{\Delta} n)$ and $f_{\min} = O(\log_{\Delta} n \cdot \log \log \Delta)$ whp, and $f_{\text{rem}} = \Delta + O(\log_{\Delta} n \cdot \log \log \Delta)$ whp. For simplicity we assume n is a power of Δ . We build a fixed tournament tree T of degree Δ and of height $\log_{\Delta} n$ on X . For a node $v \in T$, let $X(v)$ be the set of values in the subtree rooted at v . The following code computes $m(v)$, the minimum value of $X(v)$, for every node v .

```

1: procedure TREEMINIMUM $_{\Delta}(X)$ 
2:   For every leaf  $v$ , set  $m(v)$  equal to the single element of  $X(v)$ .
3:   For every internal node  $v$  with  $\Delta$  children  $u_1, \dots, u_{\Delta}$  where the values
       $m(u_1), \dots, m(u_{\Delta})$  are known, compute  $m(v)$  using SIMPLEMINIMUM algorithm on input
       $\{m(u_1), \dots, m(u_{\Delta})\}$ .
4:   Repeat the above step until the minimum of  $X$  is computed.

```

The correctness of TREEMINIMUM $_{\Delta}$ is trivial. So it remains to analyze its fragile complexity.

► Theorem 9. *In TREEMINIMUM $_{\Delta}$, $\mathbb{E}[f_{\min}] = O(\log_{\Delta} n)$ and $\mathbb{E}[f_{\text{rem}}] = \Delta + O(\log_{\Delta} n)$. Furthermore, with high probability, $f_{\min} = O\left(\frac{\log n \log \log \Delta}{\log \Delta}\right)$ and $f_{\text{rem}} = O\left(\Delta + \frac{\log n \log \log \Delta}{\log \Delta}\right)$.*

Proof. First, observe that $\mathbb{E}[f_{\min}] = O(\log_{\Delta} n)$ is an easy consequence of Theorem 6. Now we focus on high probability bounds. Let $k = c \cdot h \log \ln \Delta$, and $h = \log_{\Delta} n$ for a large enough constant c . There are h levels in T . Let \mathbf{f}_i be the random variable that counts the number of comparisons the minimum participates in at level i of T . Observe that these are independent random variables. Let f_1, \dots, f_h be integers such that $f_i \geq 1$ and $\sum_{i=1}^h f_i = k$, and let c' be the constant hidden in the big- O notation of Theorem 8. Use Theorem 8 h times (with n set to Δ , and $t = f_i$), and also bound $2 \log \log \Delta < \Delta$ to get

$$\Pr \left[\mathbf{f}_1 \geq c'(f_1 + \log \log \Delta) \vee \dots \vee \mathbf{f}_h \geq c'(f_h + \log \log \Delta) \right] \leq \Delta^h e^{-\sum_i 2^{f_i}} \leq \Delta^h e^{-h 2^{k/h}}$$

where the last inequality follows from the inequality of arithmetic and geometric means (specifically, observe that $\sum_{i=1}^h 2^{f_i}$ is minimized when all f_i 's are distributed evenly).

2:10 Fragile Complexity of Comparison-Based Algorithms

Now observe that the total number of different integral sequences f_1, \dots, f_h that sum up to k is bounded by $\binom{h+k}{h}$ (this is the classical problem of distributing k identical balls into h distinct bins). Thus, we have

$$\begin{aligned} \Pr[f_{\min} = O(k + h \log \log \Delta)] &\leq \binom{h+k}{h} \cdot \Delta^h \frac{1}{e^{h \cdot 2^{k/h}}} \leq \left(\frac{e(h+k)}{h}\right)^h \cdot \Delta^h \frac{1}{e^{h \cdot 2^{k/h}}} \\ &\leq \left(\frac{O\left(\frac{k}{h}\right) \cdot \Delta}{e^{2^{k/h}}}\right)^h = \left(\frac{O(\Delta^2)}{e^{2^c \log \ln \Delta}}\right)^h < \left(\frac{O(\Delta^2)}{e^{\ln^c \Delta}}\right)^h < \left(\frac{\Delta^3}{\Delta^{\ln^{c-1} \Delta}}\right)^h < \Delta^{-ch} = n^{-c} \end{aligned}$$

where in the last step we bound $(\ln \Delta)^{c-1} - 3 > c$ for large enough c and $\Delta \geq 3$. This is a high probability bound for f_{\min} . To bound f_{rem} , observe that for every non-minimum element x , there exists a lowest node v such that x is not $m(v)$. If x is not passed to the ancestors of v , x suffers at most Δ comparisons in v , and below v x behaves like the minimum element, which means that the above analysis applies. This yields that whp we have $f_{\text{rem}} = \Delta + O\left(\frac{\log n \log \log \Delta}{\log \Delta}\right)$. ◀

2.3 Randomized Lower Bounds for Finding the Minimum

2.3.1 Expected Lower Bound for the Fragile Complexity of the Minimum.

The following theorem is our main result.

► **Theorem 10.** *In any randomized minimum finding algorithm with fragile complexity of at most Δ for any element, the expected fragile complexity of the minimum is at least $\Omega(\log \Delta n)$.*

Note that this theorem implies the fragile complexity of finding the minimum:

► **Corollary 11.** *Let $f(n)$ be the expected fragile complexity of finding the minimum (i.e. the smallest function such that some algorithm achieves $f(n)$ fragile complexity for all elements (minimum and the rest) in expectation). Then $f(n) = \Theta\left(\frac{\log n}{\log \log n}\right)$.*

Proof. Use Theorem 9 as the upper bound and Theorem 10, both with $\Delta = \frac{\log n}{\log \log n}$, observing that if $f(n)$ is an upper bound that holds with high probability, it is also an upper bound on the expectation. ◀

To prove Theorem 10 we give a lower bound for a *deterministic* algorithm \mathcal{A} on a random input of n values, x_1, \dots, x_n where each x_i is chosen iid and uniformly in $(0, 1)$. By Yao's minimax principle, the lower bound on the expected fragile complexity of the minimum when running \mathcal{A} also holds for any randomized algorithm.

We prove our lower bound in a model that we call “comparisons with additional information (CAI)”: if the algorithm \mathcal{A} compares two elements x_i and x_j and it turns out that $x_i < x_j$, then the value x_j is revealed to the algorithm. Clearly, the algorithm can only do better with this extra information. The heart of the proof is the following lemma which also acts as the “base case” of our proof.

► **Lemma 12.** *Let Δ be an upper bound on f_{rem} . Consider T values x_1, \dots, x_T chosen iid and uniformly in $(0, b)$. Consider a deterministic algorithm \mathcal{A} in CAI model that finds the minimum value y among x_1, \dots, x_T . If $T > 1000\Delta$, then with probability at least $\frac{7}{10}$ \mathcal{A} will compare y against an element x such that $x \geq b/(100\Delta)$.*

Proof. By simple scaling, we can assume $b = 1$. Let p be the probability that \mathcal{A} compares y against a value larger than $1/(100\Delta)$. Let I_{small} be the set of indices i such that $x_i < 1/(100\Delta)$. Let \mathcal{A}' be a deterministic algorithm in CAI model such that:

- \mathcal{A}' is given all the indices in I_{small} (and their corresponding values) except for the index of the minimum. We call these the known values.
- \mathcal{A}' minimizes the probability p' of comparing the y against a value larger than $1/(100\Delta)$.
- \mathcal{A}' finds the minimum value among the unknown values.

Since $p' \leq p$, it suffices to bound p' from below. We do this in the remainder of the proof.

Observe that the expected number of values x_i such that $x_i < 1/(100\Delta)$ is $T/(100\Delta)$. Thus, by Markov's inequality, $\Pr[|I_{\text{small}}| \leq T/(10\Delta)] \geq \frac{9}{10}$. Let's call the event $|I_{\text{small}}| \leq T/(10\Delta)$ the good event. For algorithm \mathcal{A}' all values smaller than $1/(100\Delta)$ except for the minimum are known. Let U be the set of indices of the unknown values. Observe that a value x_i for $i \in U$ is either the minimum or larger than $1/(100\Delta)$, and that $|U| = T - |I_{\text{small}}| + 1 > \frac{9}{10}T$ (using $\Delta \geq 1$) in the good event. Because \mathcal{A}' is a deterministic algorithm, the set U is split into set F of elements that have their first comparison against a known element, and set W of those that are first compared with another element with index in U . Because of the global bound Δ on the fragile complexity of the known elements, we know $|F| < \Delta \cdot |I_{\text{small}}| \leq \Delta T/(10\Delta) = T/10$. Combining this with the probability of the good event, by union bound, the probability of the minimum being compared with a value greater than $1/(100\Delta)$ is at least $1 - (1 - \frac{9}{10}) - (1 - \frac{8}{9}) \geq 7/10$. ◀

Based on the above lemma, our proof idea is the following. Let $G = 100\Delta$. We would like to prove that on average \mathcal{A} cannot avoid comparing the minimum to a lot of elements. In particular, we show that, with constant probability, the minimum will be compared against some value in the range $[G^{-i}, G^{-i+1}]$ for every integer i , $1 \leq i \leq \frac{\log_G n}{2}$. Our lower bound then follows by an easy application of the linearity of expectations. Proving this, however, is a little bit tricky. However, observe that Lemma 12 already proves this for $i = 1$. Next, we use the following lemma to apply Lemma 12 over all values of i , $1 \leq i \leq \frac{\log_G n}{2}$.

► **Lemma 13.** *For a value b with $0 < b < 1$, define $p_k = \binom{n}{k} b^k (1-b)^{n-k}$, for $0 \leq k \leq n$. Choosing x_1, \dots, x_n iid and uniformly in $(0, 1)$ is equivalent to the following: with probability p_k , uniformly sample a set I of k distinct indices in $\{1, \dots, n\}$ among all the subsets of size k . For each $i \in I$, pick x_i iid and uniformly in $(0, b)$. For each $i \notin I$, pick x_i iid and uniformly in $(b, 1)$.*

Proof. It is easy to see that choosing x_1, \dots, x_n iid uniformly in $(0, 1)$ is equivalent to choosing a point X uniformly at random inside an n dimensional unit cube $(0, 1)^n$. Therefore, we will prove the equivalence between (i) the distribution defined in the lemma, and (ii) choosing such point X .

Let Q be the n -dimensional unit cube. Subdivide Q into 2^n rectangular region defined by the Cartesian product of intervals $(0, b)$ and $(b, 1)$, i.e., $\{(0, b), (b, 1)\}^n$ (or alternatively, bisect Q with n hyperplanes, with the i -th hyperplane perpendicular to the i -th axis and intersecting it at coordinate equal to b).

Consider the set R_k of rectangles in $\{(0, b), (b, 1)\}^n$ with exactly k sides of length b and $n - k$ sides of length $1 - b$. Observe that for every choice of k (distinct) indices i_1, \dots, i_k out of $\{1, \dots, n\}$, there exists exactly one rectangle r in R_k such that r has side length b at dimensions i_1, \dots, i_k , and all the other sides of r has length $1 - b$. As a result, we know that the number of rectangles in R_k is $\binom{n}{k}$ and the volume of each rectangle in R_k is $b^k (1-b)^{n-k}$. Thus, if we choose a point X randomly inside Q , with probability p_k it will fall inside a rectangle r in R_k ; furthermore, conditioned on this event, the dimensions i_1, \dots, i_k where r has side length b is a uniform subset of k distinct indices from $\{1, \dots, n\}$. ◀

Remember that our goal was to prove that with constant probability, the minimum will be compared against some value in the range $[G^{-i}, G^{-i+1}]$ for every integer i , $1 \leq i \leq \frac{\log_G n}{2}$. We can pick $b = G^{-i+1}$ and apply Lemma 13. We then observe that it is very likely that the set of indices I that we are sampling in Lemma 13 will contain many indices. For every element x_i , $i \in I$, we are sampling x_i independently and uniformly in $(0, b)$ which opens the door for us to apply Lemma 12. Then we argue that Lemma 12 would imply that with constant probability the minimum will be compared against a value in the range $(b/G, b) = (G^{-i}, G^{-i+1})$. The lower bound claim of Theorem 10 then follows by invoking the linearity of expectations.

We are ready to prove that the minimum element will have $\Omega(\log_\Delta n)$ comparisons on average.

Proof of Theorem 10. First, observe that we can assume $n \geq (100,000\Delta)^2$ as otherwise we are aiming for a trivial bound of $\Omega(1)$.

We create an input set of n values x_1, \dots, x_n where each x_i is chosen iid and uniformly in $(0, 1)$. Let $G = 100\Delta$. Consider an integer i such that $1 \leq i < \frac{\log_G n}{2}$. We are going to prove that with constant probability, the minimum will be compared against a value in the range (G^{-i}, G^{-i+1}) , which, by linearity of expectation, shows the stated $\Omega(\log_\Delta n)$ lower bound for the fragile complexity of the minimum.

Consider a fixed value of i . Let S be the set of indices with values that are smaller than G^{-i+1} . Let p be the probability that \mathcal{A} compares the minimum against an x_j with $j \in S$ such that $x_j \geq G^{-i}$. To prove the theorem, it suffices to prove that p is lower bounded by a constant. Now consider an algorithm \mathcal{A}' that finds the minimum but for whom all the values other than those in S have been revealed and furthermore, assume \mathcal{A}' minimizes the probability of comparing the minimum against an element $x \geq G^{-i}$ (in other words, we pick the algorithm which minimizes this probability, among all the algorithms). Clearly, $p' \leq p$. In the rest of the proof we will give a lower bound for p' .

Observe that $|S|$ is a random variable with binomial distribution. Hence $\mathbb{E}[|S|] = nG^{-i+1} > \sqrt{n}$ where the latter follows from $i < \frac{\log_G n}{2}$. By the properties of the binomial distribution we have that $\Pr[|S| < \frac{\mathbb{E}[|S|]}{100}] < \frac{1}{10}$. Thus, with probability at least $\frac{9}{10}$, we will have the “good” event that $|S| \geq \frac{\mathbb{E}[|S|]}{100} \geq \frac{\sqrt{n}}{100}$.

In case of the good event, Lemma 13 implying that conditioned on S being the set of values smaller than G^{-i+1} , each value x_j with $j \in S$ is distributed independently and uniformly in the range $(0, G^{-i+1})$. As a result, we can now invoke Lemma 12 on the set S with $T = |S|$. Since $n \geq (100,000\Delta)^2$ we have $T = |S| \geq \frac{\sqrt{n}}{100} \geq \frac{100,000\Delta}{100}$. By Lemma 12, with probability at least $\frac{7}{10}$, the minimum will be compared against a value that is larger than G^{-i} .

Thus, by law of total probability, it follows that in case of a good event, with probability $\frac{7}{10}$ the minimum will be compared to a value in the range (G^{-i}, G^{-i+1}) . However, as the good event happens with probability $\frac{9}{10}$, it follows that with probability at least $1 - (1 - \frac{7}{10}) - (1 - \frac{9}{10}) = \frac{6}{10}$, the minimum will be compared against a value in the range (G^{-i}, G^{-i+1}) . ◀

2.3.2 Lower bound for the fragile complexity of the minimum whp.

With Theorem 8 in Subsection 2.2, we show in particular that `SAMPLEMINIMUM` guarantees that the fragile complexity of the minimum is at most $\mathcal{O}(\log \log n)$ with probability at least $1 - 1/n^c$ for any $c > 1$. (By setting $t = 2 \log \log n$).

Here we show that this is optimal up to constant factors in the fragile complexity.

► **Theorem 14.** *For any constant $\varepsilon > 0$, there exists a value of n_0 such that the following holds for any randomized algorithm \mathcal{A} and for any $n > n_0$: there exists an input of size n such that with probability at least $n^{-\varepsilon}$, \mathcal{A} performs $\geq \frac{1}{2} \log \log n$ comparisons with the minimum.*

Proof. We use (again) Yao’s principle and consider a fixed deterministic algorithm \mathcal{A} working on the uniform input distribution, i.e., all input permutations have probability $1/n!$. Let $f = \frac{1}{2} \log \log n$ be the upper bound on the fragile complexity of the minimum. Let $k = 2^f = \sqrt{\log n}$ and let S be the set of the k smallest input values. Let π be a uniform permutation (the input) and $\pi(S)$ be the permutation of the elements of S in π . Observe that $\pi(S)$ is a uniform permutation of the elements of S . We reveal the elements not in S to \mathcal{A} . So, \mathcal{A} only needs to find the minimum in $\pi(S)$. By Theorem 2 there is at least one “bad” permutation of S which forces algorithm \mathcal{A} to do $\log k = f$ comparisons on the smallest element. Observe $\log k! < \log k^k = k \log k = \sqrt{\log n} \frac{1}{2} \log \log n$. Observe that there exists a value of n_0 such that for $n > n_0$ the right hand side is upper bounded by $\varepsilon \log n$, so $k! \leq n^\varepsilon$, for $n > n_0$. Hence, the probability of a “bad” permutation is at least $1/k! > n^{-\varepsilon}$. ◀

3 Selection and median

The (n, t) -selection problem asks to find the t -th smallest element among n elements of the input. The simplest solution to the (n, t) -selection problem is to sort the input. Therefore, it can be solved in $\mathcal{O}(\log n)$ fragile complexity and $\mathcal{O}(n \log n)$ work by using the AKS sorting network [2]. For comparator networks, both of these bounds are optimal: the former is shown by Theorem 2 (and in fact it applies also to any algorithm) and the latter is shown in the full version of this paper [1].

In contrast, in this section we show that comparison-based algorithms can do better: we can solve SELECTION deterministically in $\Theta(n)$ work and $\Theta(\log n)$ fragile complexity, thus, showing a separation between the two models. However, to do that, we resort to constructions that are based on expander graphs. Avoiding usage of the expander graphs or finding a simpler optimal deterministic solution is an interesting open problem (see Section 6). Moreover, in Subsection 3.2 we show that we can do even better by using randomization.

3.1 Deterministic selection

► **Theorem 15.** *There is a deterministic algorithm for SELECTION which performs $\mathcal{O}(n)$ work and has $\mathcal{O}(\log n)$ fragile complexity.*

Proof sketch. It suffices to just find the median since by simple padding we can generalize the solution for the (n, t) -selection problem.

We use ε -halvers that are the central building blocks of the AKS sorting network. An ε -halver approximately performs a partitioning of an array of size n into the smallest half and the largest half of the elements. More precisely, for any $m \leq n/2$, at most εn of the m smallest elements will end up in the right half of the array, and at most εn of the m largest elements will end up in the left half of the array. Using expander graphs, a comparator network implementing an ε -halver of constant depth can be built [2, 4]. We use the corresponding comparison-based algorithm of constant fragile complexity.

The idea is to use ε -halvers to find roughly $\frac{n}{\log n}$ elements with rank between $(1 + \alpha) \frac{n}{2}$ and $(2 - \alpha) \frac{n}{2}$ and also roughly $\frac{n}{\log n}$ elements with rank between $\alpha \frac{n}{2}$ and $(1 - \alpha) \frac{n}{2}$, for some constant $0 < \alpha < 1$. This is done by repeatedly using ε -halvers but alternating between

■ **Figure 1** Illustration of the alternating division process using ε -halvers.

selecting the left half and the right half (Figure 1). Using these, we filter the remaining elements and discard a constant fraction of them. Then we recurse on the remaining elements. The details are a bit involved, as we have to guarantee that no element accumulates too many comparisons throughout the recursions. We have to do some bookkeeping as well as some additional ideas to provide this guarantee. Details can be found in the full version of the paper [1]. ◀

► **Corollary 16.** *There is a deterministic algorithm for partition which performs $\mathcal{O}(n)$ work and has $\mathcal{O}(\log n)$ fragile complexity.*

Proof. At the end of the SELECTION algorithm, the set of elements smaller (larger) than the median is the union of the respective filtered sets (sets \mathcal{L} and \mathcal{R} in the proof in the full version of the paper [1]) and the first (last) half of the sorted set in the base case of the recursion. Again, simple padding generalizes this to (n, t) -partition for arbitrary $t \neq \frac{n}{2}$. ◀

3.2 Randomized selection

In the full paper [1], we present the details of an expected work-optimal selection algorithm with a trade-off between the expected fragile complexity $f_{\text{med}}(n)$ of the selected element and the maximum expected fragile complexity $f_{\text{rem}}(n)$ of the remaining elements. In particular, we obtain the following combinations:

► **Theorem 17.** *Randomized selection is possible in expected linear work, while achieving expected fragile complexity of the median $\mathbb{E}[f_{\text{med}}(n)] = \mathcal{O}(\log \log n)$ and of the remaining elements $\mathbb{E}[f_{\text{rem}}(n)] = \mathcal{O}(\sqrt{n})$, or $\mathbb{E}[f_{\text{med}}(n)] = \mathcal{O}\left(\frac{\log n}{\log \log n}\right)$ and $\mathbb{E}[f_{\text{rem}}(n)] = \mathcal{O}(\log^2 n)$.*

4 Sorting

Recall from Section 1 that the few existing sorting networks with depth $\mathcal{O}(\log n)$ are all based on expanders, while a number of $\mathcal{O}(\log^2 n)$ depth networks have been developed based on binary merging. Here, we study the power of the mergesort paradigm with respect to fragile complexity. We first prove that any sorting algorithm based on binary merging must have a worst-case fragile complexity of $\Omega(\log^2 n)$. This provides an explanation why all existing sorting networks based on merging have a depth no better than this. We also prove that the standard mergesort algorithm on random input has fragile complexity $\mathcal{O}(\log n)$ with high probability, thereby showing a separation between the deterministic and the randomized situation for binary mergesorts. Finally, we demonstrate that the standard mergesort

algorithm has a worst-case fragile complexity of $\Theta(n)$, but that this can be improved to $\mathcal{O}(\log^2 n)$ by changing the merging algorithm to use exponential search. The omitted proofs can be found in the full paper [1].

► **Lemma 18.** *Merging of two sorted sequences A and B has fragile complexity at least $\lfloor \log_2 |A| \rfloor + 1$.*

► **Theorem 19.** *Any binary mergesort has fragile complexity $\Omega(\log^2 n)$.*

Proof. The adversary is the same as in the proof of Lemma 21, except that as scapegoat element for a merge of A and B it always chooses the scapegoat from the *larger* of A and B . We claim that for this adversary, there is a constant $c > 0$ such that for any node v in the mergetree, its scapegoat element has participated in at least $c \log^2 n$ comparisons in the subtree of v , where n is the number of elements merged by v . This implies the theorem.

We prove the claim by induction on n . The base case is $n = \mathcal{O}(1)$, where the claim is true for small enough c , as the scapegoat by Lemma 18 will have participated in at least one comparison. For the induction step, assume v merges two sequences of sizes n_1 and n_2 , with $n_1 \geq n_2$. By the base case, we can assume $n_1 \geq 3$. Using Lemma 18, we would like to prove for the induction step

$$c \log^2 n_1 + \lfloor \log n_2 \rfloor + 1 \geq c \log^2(n_1 + n_2). \quad (1)$$

This will follow if we can prove

$$\log^2 n_1 + \frac{\log n_2}{c} \geq \log^2(n_1 + n_2). \quad (2)$$

The function $f(x) = \log^2 x$ has first derivative $2(\log x)/x$ and second derivative $2(1 - \log x)/x^2$, which is negative for $x > e = 2.71\dots$. Hence, $f(x)$ is concave for $x > e$, which means that first order Taylor expansion (alias the tangent) lies above f , i.e., $f(x_0) + f'(x_0)(x - x_0) \geq f(x)$ for $x_0, x > e$. Using $x_0 = n_1$ and $x = n_1 + n_2$ and substituting the first order Taylor expansion into the right side of (2), we see that (2) will follow if we can prove

$$\frac{\log n_2}{c} \geq 2 \frac{\log n_1}{n_1} n_2,$$

which is equivalent to

$$\frac{\log n_2}{n_2} \geq 2c \frac{\log n_1}{n_1}. \quad (3)$$

Since $n_1 \geq n_2$ and $(\log x)/x$ is decreasing for $x \geq e$, we see that (3) is true for $n_2 \geq 3$ and c small enough. Since $\log(3)/3 = 0.366\dots$ and $\log 2/2 = 0.346\dots$, it is also true for $n_2 = 2$ and c small enough. For the final case of $n_2 = 1$, the original inequality (1) reduces to

$$\log^2 n_1 + \frac{1}{c} \geq \log^2(n_1 + 1). \quad (4)$$

Here we can again use concavity and first order Taylor approximation with $x_0 = n_1$ and $x = n_1 + 1$ to argue that (4) follows from

$$\frac{1}{c} \geq 2 \frac{\log n_1}{n_1}.$$

which is true for c small enough, as $n_1 \geq 3$ and $(\log x)/x$ is decreasing for $x \geq e$. ◀

► **Theorem 20.** *Standard MERGESORT with linear merging has a worst-case fragile complexity of $\Theta(n)$.*

► **Lemma 21.** *Standard MERGESORT has fragile complexity $\Omega(\log^2 n)$.*

Proof. In MERGESORT, when merging two sorted sequences A and B , no comparisons between elements of A and B have taken place before the merge. Also, the sorted order of $A \cup B$ has to be decided by the algorithm after the merge. We can therefore run the adversary argument from the proof of Lemma 18 in all nodes of the mergetree of MERGESORT. If the adversary reuses scapegoat elements in a bottom-up fashion – that is, as scapegoat for a merge of A and B chooses one of the two scapegoats from the two merges producing A and B – then the scapegoat at the root of the mergetree has participated in

$$\Omega\left(\sum_{i=0}^{\log n} \log 2^i\right) = \Omega\left(\sum_{i=0}^{\log n} i\right) = \Omega(\log^2 n)$$

comparisons, by Lemma 18 and the fact that a node at height i in the mergetree of standard MERGESORT operates on sequences of length $\Theta(2^i)$. ◀

► **Observation 1.** *Consider two sorted sequences $A = (a_1, \dots, a_n)$ and $B = (b_1, \dots, b_n)$. In linear merging, the fragile complexity of element a_i is at most $\ell + 1$ where ℓ is the largest number of elements from B that are placed directly in front of a_i (i.e. $b_j < \dots < b_{j+\ell-1} < a_i$).*

► **Lemma 22.** *Let $X = \{x_1, \dots, x_{2k}\}$ be a finite set of distinct elements, and consider a random bipartition $X_L, X_R \subset X$ with $|X_L| = |X_R| = k$ and $X_L \cap X_R = \emptyset$, such that $\Pr[x_i \in X_L] = 1/2$. Consider an arbitrary ordered set $Y = \{y_1, \dots, y_m\} \subset X$ with $m \leq k$. Then $\Pr[Y \subseteq X_L \vee Y \subseteq X_R] < 2^{1-m}$.*

Proof.

$$\Pr[Y \subseteq X_L \vee Y \subseteq X_R] = 2 \prod_{i=1}^m \Pr[y_i \in X_L \mid y_1, \dots, y_{i-1} \in X_L] = 2 \frac{(2k)^{-m} k!}{(k-m)!} \leq 2 \cdot 2^{-m}.$$

◀

► **Theorem 23.** *Standard MERGESORT with linear merging on a randomized input permutation has a fragile complexity of $\mathcal{O}(\log n)$ with high probability.*

Proof. Let $Y = (y_1, \dots, y_n)$ be the input-sequence, π^{-1} be the permutation that sorts Y and $X = (x_1, \dots, x_n)$ with $x_i = y_{\pi^{-1}(i)}$ be the sorted sequence. Wlog we assume that all elements are unique², that any input permutation π is equally likely³, and that n is a power of two.

Merging in one layer. Consider any merging-step in the mergetree. Since both input sequences are sorted, the only information still observable from the initial permutation is the bi-partitioning of elements into the two subproblems. Given π , we can uniquely retrace the mergetree (and vice-versa): we identify each node in the recursion tree with the set of elements it considers. Then, any node with elements $X_P = \{y_\ell, \dots, y_{\ell+2k-1}\}$ has children

$$\begin{aligned} X_L &= \{x_{\pi(i)} \mid \ell \leq \pi(i) \leq \ell + k - 1\} = \{y_\ell, \dots, y_{\ell+k-1}\}, \\ X_R &= \{x_{\pi(i)} \mid \ell + k \leq \pi(i) \leq \ell + 2k - 1\} = \{y_{\ell+k}, \dots, y_{\ell+2k-1}\}. \end{aligned}$$

² If this is not the case, use input sequence $Y' = ((y_1, 1), \dots, (y_n, n))$ and lexicographical compares.

³ If not shuffle it before sorting in linear time and no fragile comparisons.

Hence, locally our input permutation corresponds to an stochastic experiment in which we randomly draw exactly half of the parent's elements for the left child, while the remainder goes to right.

This is exactly the situation in Lemma 22. Let N_i be a random variable denoting the number of comparisons of element y_i in the merging step. Then, from Observation 1 and Lemma 22 it follows that $\Pr[N_i = m+1] \leq 2^{-m}$. Therefore N_i is stochastically dominated by $N_i \preceq 1+Y_i$ where Y_i is a geometric random variable with success probability $p = 1/2$.

Merging in all layers. Let $N_{j,i}$ be the number of times element y_i is compared in the j -th recursion layer and define $Y_{j,i}$ analogously. Due to the recursive partitioning argument, $N_{j,i}$ and $Y_{j,i}$ are iid in j . Let N_i^T be the total number of comparisons of element i , i.e. $N_i^T \preceq \log_2 n + \sum_{j=1}^{\log_2 n} Y_{j,i}$. Then a tail bound on the sum of geometric variables (Theorem 2.1 in [13]) yields:

$$\Pr \left[\sum_{j=1}^{\log_2 n} Y_{j,i} \geq \lambda \mathbb{E} \left[\sum_{j=1}^{\log_2 n} Y_{j,i} \right] = 2\lambda \log_2 n \right] \stackrel{[13]}{\leq} \exp \left(-\frac{1}{2} \frac{2 \ln n}{\ln 2} [\lambda - 1 - \log \lambda] \right) = n^{-2},$$

where we set $\lambda \approx 3.69$ in the last step solving $\lambda - \log \lambda = 2 \log 2$. Thus, we bound the probability $\Pr[N_i^T \geq (1+2\lambda) \log_2 n] \leq n^{-2}$.

Fragile complexity. It remains to show that with high probability no element exceeds the claimed fragile complexity. We use a union bound on N_i^T for all i :

$$\Pr \left[\max_i \{N_i^T\} = \omega(\log n) \right] \leq n \Pr[N_i^T = \omega(\log n)] \leq 1/n. \quad \blacktriangleleft$$

► **Theorem 24.** *Exponential merging of two sequences $A = (a_1, \dots, a_n)$ and $B = (b_1, \dots, b_n)$ has a worst-case fragile complexity of $\mathcal{O}(\log n)$.*

► **Corollary 25.** *Applying Theorem 24 to standard MERGESORT with exponential merging yields a fragile complexity of $\mathcal{O}(\log^2 n)$ in the worst-case.*

5 Constructing binary heaps

► **Observation 2.** *The fragile complexity of the standard binary heap construction algorithm of Floyd [11] is $\mathcal{O}(\log n)$.*

The above observation is easy to verify (shown in the full paper [1]). We note that this fragile complexity is optimal by Theorem 2, since HEAP CONSTRUCTION is stronger than MINIMUM. Brodal and Pinotti [7] showed how to construct a binary heap using a comparator network in $\Theta(n \log \log n)$ size and $\mathcal{O}(\log n)$ depth. They also proved a matching lower bound on the size of the comparator network for this problem. This, together with Observation 2 and the fact that Floyd's algorithm has work $\mathcal{O}(n)$, gives a separation between work of fragility-optimal comparison-based algorithms and size of depth-optimal comparator networks for HEAP CONSTRUCTION.

6 Conclusions

In this paper we introduced the notion of fragile complexity of comparison-based algorithms and we argued that the concept is well-motivated because of connections both to real world situations (e.g., sporting events), as well as other fundamental theoretical concepts (e.g., sorting networks). We studied the fragile complexity of some of the fundamental problems and revealed interesting behavior such as the large gap between the performance of deterministic and randomized algorithms for finding the minimum. We believe there are still plenty of interesting and fundamental problems left open. Below, we briefly review a few of them.

- The area of comparison-based algorithms is much larger than what we have studied. In particular, it would be interesting to study “geometric orthogonal problems” such as finding the maxima of a set of points, detecting intersections between vertical and horizontal line segments, kd -trees, axis-aligned point location and so on. All of these problems can be solved using algorithms that simply compare the coordinates of points.
- Is it possible to avoid using expander graphs to obtain simple deterministic algorithms to find the median or to sort?
- Is it possible to obtain a randomized algorithm that finds the median where the median suffers $O(1)$ comparisons on average? Or alternatively, is it possible to prove a lower bound? If one cannot show a $\omega(1)$ lower bound for the fragile complexity of the median, can we show it for some other similar problem?

Abstract

We present the first universal reconfiguration algorithm for transforming a modular robot between any two facet-connected square-grid configurations using pivot moves. More precisely, we show that five extra “helper” modules (“musketeers”) suffice to reconfigure the remaining n modules between any two given configurations. Our algorithm uses $O(n^2)$ pivot moves, which is worst-case optimal. Previous reconfiguration algorithms either require less restrictive “sliding” moves, do not preserve facet-connectivity, or for the setting we consider, could only handle a small subset of configurations defined by a local forbidden pattern. Configurations with the forbidden pattern do have disconnected reconfiguration graphs (discrete configuration spaces), and indeed we show that they can have an exponential number of connected components. But forbidding the local pattern throughout the configuration is far from necessary, as we show that just a constant number of added modules (placed to be freely reconfigurable) suffice for universal reconfigurability. We also classify three different models of natural pivot moves that preserve facet-connectivity, and show separations between these models.

1 Introduction

Shape shifting is a powerful idea in science fiction: T-1000 robots (from *Terminator 2: Judgement Day*), Changelings (from *Star Trek: Deep Space 9*), Symbiotes (from *Venom*), Mystique (from *X-Men*), and Metamorphagi (from *Harry Potter*) all have the ability to transform their shape nearly arbitrarily. How can we make shape shifting into science?

Modular robots [5, 19, 22] are perhaps the best answer to this question. The idea to build a single “robot” out of many small units called *modules*, each of which can attach and detach from each other, move relative to each other, communicate with each other, and compute. Modular robots offer extreme adaptability to changing environment or user needs, in particular by reconfiguring the modules into exponentially many effective shapes of the overall robot. Modularity also offers a practical future for manufacturing (identical modules can be mass-produced, making them relatively cheap) makes robots easy to repair by just replacing the broken modules, and makes it possible to re-use components from one robot/task to another.

For computational geometry, modular robots offer exciting challenges: what shapes can a modular robot self-reconfigure into, and what are good algorithms for reconfiguration? According to [19], the main difficulties in self-reconfiguration are the physical motion constraints of the modules themselves, connectivity requirements for the robot to hold together, collisions between moving and/or static modules, and “deadlocks” where no module can move or some module gets “trapped” within the configuration.

The wide diversity of mechatronic solutions to modular robots can be characterized from a geometric viewpoint by three key properties: (1) the lattice, (2) connectivity requirement, and (2) allowed moves.

Lattice. Most modular robots follow a space-filling lattice structure (e.g., squares or hexagons in 2D, or cubes in 3D), to simplify both reconfiguration and the characterization of possible shapes. Pure lattice modular robots [13, 6, 10, 17, 2, 20] have one robot per lattice element and always remain on the lattice, while hybrid modular robots [14, 18, 16, 23] also allow units move out of the lattice. We focus here on the well-studied square lattice, though we suspect our results can be generalized to cube lattices.

Connectivity requirement. A modular robot generally needs to be connected at all times while reconfiguring, so that the modules do not fall apart. The most common and practical constraint is that the modules are always *facet-connected*, meaning a connected *facet-adjacency graph* where vertices represent modules and edges represent adjacencies by shared facets (edges in 2D). The exception is that the moving module is excluded from this graph during each move, meaning that other modules must be facet-connected while the moving module may briefly disconnect during the move. A weaker connectivity constraint, considered in some theoretical research [4, Ch. 4], is that the robot is connected via shared vertices. In such case, reconfiguration is always possible. We focus here on the more challenging facet-connectivity constraint.

Allowed moves. One of the most popular models is *sliding squares/cubes* [8, 7, 1], illustrated in Figure 1 left. In this case, modules live in a square or cube lattice, move by sliding relative to each other, and require facet-connectivity. For this model, universal reconfiguration is possible between any two facet-connected configurations, in any dimension [7, 1].

■ **Figure 1** Two ways a module a starting above module s can move to the adjacent lattice position, above module s' . Left: sliding. Right: pivoting. Pivoting requires more free space to execute.

We focus here on a more challenging model, *pivoting squares/cubes* [21, 20, 4], illustrated in Figure 1 right. In this case, modules live in a square or cube lattice, move by rotating relative to each other, and require facet-connectivity. The key difference is that a module needs two additional squares/cubes of empty space in order to pivot, whereas a slide just needs the destination square/cube to be empty. Unfortunately, some configurations are *rigid* in this model, meaning that no module can move without disconnecting the robot.

Rigid configurations appear also in the sliding square model when the sliding capability is restricted to turning corners [12]. However, in this model the existence of free space around the modules does not guarantee reconfigurability, while in the pivoting squares model it does, as we will discuss.

As a consequence, all known reconfiguration algorithms for pivoting squares/cubes are somehow partial. One algorithm follows some heuristics without a termination guarantee [3] (see also [11] for heuristics for hexagons). A recent algorithm guarantees reconfiguration by forbidding one or more local patterns in both the start and goal configurations [20], essentially preventing narrow holes in the shape. (A similar result was obtained for hexagons [15].) These assumptions severely restrict the possible shapes that can be reconfigured, to a $o(1)$ fraction. The absence of such local patterns though is far from being necessary for reconfigurability. In 3D, some further strong conditions are added, such as that every hole must be orthogonally convex [20].

Our results. Our main result is that *universal* reconfiguration is possible if we allow the addition of a constant number of (five) extra “helper” modules, which we call *musketeer modules*.¹ The key is that these musketeer modules are not considered part of the initial or target shape, and thus we are free to place them where we like (in particular, along the external boundary of the robot). Surprisingly, this small amount of additional freedom is enough to achieve universal reconfiguration. In fact, we prove in Section 4 that five musketeer modules are both sufficient and sometimes necessary to solve any reconfiguration under our strategy. Our algorithm is based on the old idea of following the right-hand rule to escape a maze [9]. The number of pivots it makes is $O(n^2)$, which is optimal in the worst case by an earth-moving lower bound: each robot may need to move a distance of $\Theta(n)$.

This result can be seen as proving connectivity of the *reconfiguration graph* $\mathcal{G}_{n,k}$, where vertices represent facet-connected configurations of n modules and edges represent valid pivot moves, with the addition of $k \geq 5$ musketeer modules. With $k = 0$ musketeers, $\mathcal{G}_{n,k}$ is known to be disconnected. Surprisingly, there have been no (successful) attempts to understand

¹ *The Three Musketeers* is a story about four musketeers. This paper is a story about five musketeers.

the structure of this reconfiguration graph. In Section 3, we analyze the structure of this reconfiguration graph. Specifically, we prove that $\mathcal{G}_{n,0}$ can have an exponential number of connected components of exponential size, and in some models, can have an exponential number of singleton connected components (rigid configurations); while in other models, the reconfiguration graph cannot have any singleton connected components.

The other main contribution of this paper is to precisely define a variety of natural models for pivot moves. Pivoting is naturally defined as the rotation of one module about one of its vertices that is shared with a (static) module. But there are some subtleties in this definition depending on exactly which modules must be facet-connected at what times. (Obviously, for example, the moving module is not facet-connected to the others during the move.) In Section 2, we define three nested models, each at least as powerful as the previous, and in Section 3, we prove strict separations between these models. Our analysis of connected components in the reconfiguration space (in Section 3) also consider the effects of these different models. We conclude with open problems in Section 5.

2 Models and Definitions

2.1 Pivot Moves

In a square grid, the fact that two squares may share a vertex without actually sharing an edge opens a wider range of possibilities for the pivoting move. Refer to Figure 2. The most restrictive set of moves (Set 1 in Figure 2) requires module a to be facet-adjacent to module s and to rotate about one of the two vertices of the edge they share. Such move can be a 90° or a 180° rotation, depending on whether or not s has a neighboring module s' adjacent to it through the other edge of s incident to the rotation center, and of course, requires the goal grid position to be empty and some intermediate positions to be (at least partially) clear. These cells are depicted in white in Figure 2.

The authors of [20] propose an expanded set of moves (Set 2 in Figure 2) that allows module a to rotate 90° about module s even when s' is not present, as long as module a is again facet-adjacent to another module t at the end of the move. Since their reconfiguration algorithm relies on reversible moves, this implies allowing also the reverse move: module a can rotate 90° about a vertex of another module s incident to a , without requiring s to be facet-adjacent to a , as long as a is facet-adjacent to some module before performing the move and after performing the move. We call this enlarged set the *leapfrog* set of moves.

If the previous move is allowed (i.e., if it is feasible for a given modular robot prototype), it seems natural to allow concatenating more than one of such moves, i.e., to allow concatenating consecutive rotations about vertices incident to the pivoting module. It is easy to prove that such concatenation cannot involve more than two pivots before the moving module becomes facet-adjacent to another module. Indeed, if a module a is facet-adjacent to a module s_1 , after at most two such moves it necessarily becomes adjacent to a module s_2 (Set 3 in Figure 2). We call this complete set the *monkey* set of moves.

2.2 Reconfiguration Problem

Consider a configuration C of n robot modules in a given grid. The *facet-adjacency graph* of C has a node for each module, and an edge between a pair of nodes if the corresponding modules are facet-adjacent. Throughout this paper we will often refer to the facet-adjacency graph simply as the *adjacency graph*. We will say that a configuration C is *facet-connected* if the facet-adjacency graph of C is connected.

■ **Figure 2** The possible sets of moves for a pivoting module a about a module s , in a square grid.

Applying a pivot move from one of the three sets of moves described in the previous section to a facet-connected configuration C , means applying one of the moves to a module in C , in such a way that the configuration (without the pivoting module) stays facet-connected before, after, and during the move, and the pivoting module does not collide with any other module. Note that this implies that even deleting the moving module the configuration is still facet-connected. Reconfiguring C consists of applying a concatenation of such moves.

The (universal) reconfiguration problem asks whether it is possible to reconfigure any facet-connected configuration of n modules in a given grid into any other configuration with the same number of modules.

For any positive integer n , the *reconfiguration graph* \mathcal{G}_n has a node for each facet-connected configuration with n modules, and an edge between two nodes if the corresponding configurations can be reconfigured into each other through a single pivoting move. We call *rigid* any configuration in which no module can move, i.e., any configuration that is an isolated node of \mathcal{G}_n , forming a connected component that is a singleton. We call *locked* any configuration that cannot be reconfigured into a straight strip of modules, i.e., any configuration belonging to a connected component of \mathcal{G}_n that does not contain a strip.

■ **Figure 3** Left: a rigid configuration of edge-connected pivoting squares. Right: A configuration that can be reconfigured into a strip, in spite of containing instances of the three forbidden patterns.

3 Reconfiguration Graph

Figure 3 (left) shows an example of a configuration that is rigid under the largest possible set of pivoting moves (set 3 in Figure 2). In [20] it is proved that reconfiguration for set 2 of pivoting moves (leapfrog moves) is possible between two facet-connected configurations of the same number of squares, provided that they are both *admissible* shapes. Admissibility is defined in terms of forbidden patterns: a facet-connected configuration of squares is admissible if it does not contain any of the patterns depicted in Figure 4. However, this local separation condition is certainly not necessary, as proves the example in Figure 3 (right).

■ **Figure 4** The three forbidden patterns for facet-connected pivoting squares; solid squares represent modules, and \times -ed squares represent empty spaces.

These results raise several natural questions for facet-connected pivoting squares: Are the three sets of moves equivalent? In particular, is reconfigurability between admissible shapes also guaranteed when using the most restrictive set of pivoting moves? This latter question has been answered positively by the results from [20]. Although not explicitly stated, the reconfiguration algorithm from [20] uses only restrictive moves.

Several other interesting questions are open. Can the admissible condition be relaxed when using the largest set of pivoting moves? Do there exist rigid configurations that contain only one type of pattern? If so, are they rigid with respect to all three sets of pivoting moves? What can we say about the reconfiguration graph \mathcal{G}_n for the different sets of pivoting moves? We try to answer these questions in the remaining of this section. Due to space constraints, the proofs of the propositions in this section are omitted.

We start by showing that the three sets of moves for pivoting squares are not equivalent, as they produce three different reconfiguration graphs.

► **Proposition 1.** *The monkey set of moves for pivoting squares (set 3) is stronger than the leapfrog set (set 2), and the leapfrog set is stronger than the restrictive set (set 1). That is, the resulting reconfiguration graph \mathcal{G}_n has strictly fewer connected components for set 3 than for set 2, and fewer connected components for set 2 than for set 1.*

Let us now discuss the differences between the three forbidden patterns. From a purely geometric viewpoint, pattern Γ produces a (corner) bottleneck along the boundary of a configuration that is narrower than the one produced by pattern I (corridor bottleneck). This one is in turn narrower than the one produced by pattern Z (wide bottleneck). The next propositions show how the presence or the absence of each of such patterns influences reconfiguration under each of the 3 sets of pivoting moves.

Pattern Γ : Corner Bottleneck

We start by showing that pattern Γ alone suffices to make a configuration rigid, regardless of the set of pivoting moves used (restrictive, leapfrog, or monkey).

► **Proposition 2.** *Let \mathcal{G}_n be the reconfiguration graph of facet-connected pivoting squares. If only pattern Γ is allowed, while patterns I and Z are forbidden, the number of connected components of \mathcal{G}_n that are singletons and the number of connected components of \mathcal{G}_n of exponential size are both exponential, regardless of the set of pivoting moves used.*

Pattern I : Corridor Bottleneck

The forbidden pattern I is weaker than pattern Γ in the sense that it suffices to make a configuration rigid for the sets of moves 1 and 2 (restrictive and leapfrog) but, if the entire set 3 of moves is allowed, pattern I alone cannot make a configuration rigid, as we will see.

► **Proposition 3.** *Let \mathcal{G}_n be the reconfiguration graph of facet-connected pivoting squares under sets 1 and 2 of pivoting moves (restrictive and leapfrog). If only pattern I is allowed, and patterns Γ and Z are forbidden, the number of connected components of \mathcal{G}_n that are singletons and the number of connected components of \mathcal{G}_n of exponential size are both exponential.*

In contrast, if the entire set of monkey-pivoting moves is allowed, then no configuration can be rigid if it only contains instances of pattern I (and no instance of patterns Γ and Z).

► **Proposition 4.** *Let \mathcal{G}_n be the reconfiguration graph of facet-connected pivoting squares under the entire set 3 of monkey-pivoting moves. If only pattern I is allowed, and patterns Γ and Z are forbidden, then \mathcal{G}_n contains no singleton components.*

Pattern Z : Wide Bottleneck

The forbidden pattern Z is weaker than the forbidden patterns Γ and I in the sense that no configuration can be rigid if it contains only instances of pattern Z.

► **Proposition 5.** *Let \mathcal{G}_n be the reconfiguration graph of facet-adjacent pivoting squares. If only pattern Z is allowed, and patterns Γ and I are forbidden, then \mathcal{G}_n contains no singleton components, regardless of the set of pivoting moves allowed.*

However, there can be locked configurations containing only instances of pattern Z.

► **Proposition 6.** *Let \mathcal{G}_n be the reconfiguration graph of facet-connected pivoting squares under pivoting set of moves 1. If only pattern Z is allowed, and patterns Γ and I are forbidden, the number of connected components of \mathcal{G}_n of exponential size is exponential.*

4 Universal Reconfiguration Algorithm with $O(1)$ Musketeers

In this section, we aim for the important practical goal of universal reconfiguration, that is, connectivity of the reconfiguration graph. We have seen that the local separation condition (while sufficient) is too strong: Robot configurations can contain many instances of the forbidden patterns and still be reconfigurable. On the other hand, we proved that as soon as the local separation condition is relaxed, the reconfiguration graph breaks into at least an exponential number of connected components of exponential size.

In what follows, we propose and analyze a new approach for reconfiguring arbitrary facet-connected configurations (which may contain an arbitrary number of instances of the forbidden patterns). Our strategy is based on the addition of $O(1)$ *musketeer modules*, i.e., modules that can freely move around the boundary of our robot configuration and will be used as helpers in certain situations. These modules are not necessarily part of the specified initial or target configuration.

4.1 Preliminaries: Outer Shell

Let C be an arbitrary facet-connected configuration of pivoting squares. We start introducing a few definitions.

Let G be the facet-adjacency graph of C , and \overline{G} the facet-adjacency graph of the lattice cells that are not occupied by a module of C . Each bounded connected component of \overline{G} is a *hole* of the robot configuration C . The only unbounded connected component of \overline{G} is the *exterior* of C . The *boundary* of C is the set of lattice cells that are empty and are facet-adjacent to (at least) one module of C . If the configuration has holes, we define its *external boundary* as the subset of the boundary contained in the unbounded connected component of \overline{G} .

► **Lemma 7.** *Let C be an arbitrary and static facet-connected configuration of pivoting squares. Let m be an active module attached to C , North of the topmost rightmost module of C . Using the monkey set of moves (set 3) m can pivot along the external boundary of C following the right-hand rule and return to its initial position. If only the leapfrog set of moves (set 2) is allowed, this is not always possible.*

The proof of this lemma is omitted due to space constraints.

It is worth noticing that the proof of Lemma 7 does not require the use of diagonal monkey jumps, but only of straight monkey jumps. This is relevant from a practical viewpoint, since it allows our results to be applied to a larger class of modular robots. For example, the hardware systems modeled in [3, 20] can perform straight monkey jumps, but not diagonal ones.

We can now define the *outer shell* of a facet-connected configuration C of pivoting squares to be the subset of the external boundary of C formed by the lattice cells eventually occupied by any active robot module m initially positioned North of the topmost-rightmost module in C , in its right-hand rule traversal of the boundary of C , described in Lemma 7. Figure 5 illustrates this concept.

4.2 Algorithm Overview

Our reconfiguration algorithm transforms any initial facet-connected configuration C of pivoting squares into any goal configuration with the same number of modules.

In order to simplify the algorithm's description, we use an intermediate canonical configuration, say a strip, and describe the transformation from the initial shape to the strip. The reconfiguration from the strip to the final shape is obtained by reversing the steps of the

■ **Figure 5** A robot configuration (in gray) and its associated outer shell (striped in pink).

algorithm. The strip can be built from any lexicographically best positioned module of the configuration. For example, we will grow a horizontal strip to the left of the bottommost of the leftmost modules of the configuration.

The strategy behind the algorithm is simple. It consists of sequentially choosing a module from the configuration that is not a cut vertex of its facet-adjacency graph, and make it pivot, following the right-hand rule, along the outer shell, until it reaches the tip of the strip and stops. The problem of this strategy, as we saw in Section 3, is that the reconfiguration graph is not connected, even under the extended set of monkey moves. In order to overcome this problem, the algorithm uses *musketeer modules*. Any module from the canonical strip can serve as a musketeer module. We will prove that five musketeer modules are sufficient and sometimes necessary to solve any reconfiguration based on our strategy. Because the canonical strip is initially empty, it may be necessary to add musketeer modules to the strip if fewer than needed are available (this may happen at most once).

4.3 Algorithm Details

The description of the algorithm and the proof of its correctness make use of a *potential* function. If m is a module located in the lattice position with coordinates (x, y) , the potential function at m is defined as $\Phi(m) = (x + y, x)$. The potential being a two-dimensional function, we sort its values lexicographically. The maximum potential Φ_{max} (minimum potential Φ_{min}) of a configuration is the lexicographically largest (smallest) potential of all its modules. Note that, whenever we use the term *configuration*, we refer to the facet-connected component that includes all modules other than the ones in the canonical strip.

Given any configuration, we define NE and SW as being the modules with highest and lowest potential, respectively. Notice that in any configuration C , both NE and SW are facet-adjacent to the outer shell of C .

4.3.1 Musketeer Modules

► **Definition 8.** *We say that a module m is outer-free in a configuration C if it is facet-adjacent to the outer shell and it can pivot clockwise, without disconnecting the robot.*

The first step of the algorithm is to look for an outer-free module, and pivot it to the tip of the strip. This step is repeated until no further outer-free modules exist in the initial configuration. If at that point the configuration is a strip, the algorithm ends.

Otherwise, all the modules in the strip may be used as musketeer modules, one at a time, starting from the tip of the strip, pivoting them to the positions where they are needed, as described in next Section 4.3.2. Since our algorithm may require five such modules, it

■ **Figure 6** Top: 3×3 square S in its initial position s_0 . The outer thick line indicates the path traversed by the center of S . Dots correspond to the center positions where S is adjacent to a boundary edge. Bottom: the rectangular union R of S centered at s_k and at s_{k-1} .

may be necessary to add extra modules to the strip (or anywhere in the configuration where they are outer-free) in order to complete the necessary set of musketeer modules. This can be done at this stage or on the fly, as needed. This second option may be preferable in some cases, as not all configurations require as many as five musketeer modules.

4.3.2 Bridging Procedure

In this section we describe an operation necessary in some situations when there are no outer-free modules in the configuration. Let m be the NE module, i.e., the maximum potential module of a given configuration C . Trivially, there can be no modules of C located North, North-East, or East of m , i.e., in positions $(0, 1)$, $(1, 1)$, or $(1, 0)$ relative to m . Therefore, the degree of m in the facet-adjacency graph can only be 1 or 2. Since m is not outer-free, it must be a cut vertex and have degree 2. Let b_1 and g_1 respectively be its counterclockwise and clockwise facet-adjacent modules (see Figure 6). We color the two connected components of C connected by m blue and green, so that b_1 is blue and g_1 is green. One important procedure of our algorithm, which we call *bridging*, is the act of using musketeer modules to connect the green and blue components so that m becomes outer-free.

► **Observation 9.** *The outer shell has two green-blue changes of color, one happening at m .*

Consider a grid-aligned 3×3 square S centered at the lattice cell of coordinates $s_0 = (2, 1)$, relative to m (see top of Figure 6). Translate S orthogonally clockwise one unit at a time along the boundary of the configuration until it reaches s_0 again. Ignoring the positions where S is not adjacent to a boundary edge (i.e., the positions of S where one of its corners coincides with a convex corner of C), let s_i be the i -th position of the center of S along its boundary traversal, and let $s_m = s_0$. Refer to Figure 6. Since m is the maximum potential module of the configuration, S is empty of modules at position s_0 and all subsequent positions, and it does not share edges with the blue component when centered at s_0 , while at s_{m-2} it is facet-adjacent to the blue module b_1 . Let s_k be the first position of S along its boundary traversal where S becomes facet-adjacent to a blue module. Since S travels along the boundary of the configuration, the rectangular union R of S centered at s_k and at s_{k-1} should also be facet-adjacent to a green module (see bottom of Figure 6).

The algorithm pivots the musketeer modules clockwise, following the right-hand rule along the outer shell of the configuration, and brings them to the vicinity of s_k to connect the blue and green components, thus forming a cycle containing m .

Let g and b be the closest pair of respectively green and blue modules facet-adjacent to rectangle R , and let d be the L_1 distance between them. The bridging procedure depends on the value of d . It is easy to see that d can only be 2, 3, 4, 5, or 6. In the full version of this paper we prove the following lemma:

► **Lemma 10.** *Let m be the NE module, i.e., the maximum potential module of a given configuration C . The bridging procedure for m uses $O(n)$ pivoting operations and at most five musketeer modules, and does not change the maximum and minimum potential of the configuration. After the procedure ends, m is still the NE module of the modified configuration, but no longer a cut vertex of its facet-adjacency graph.*

Notice also that the bound of five musketeer modules for bridging is tight: Figure 7 shows an example requiring five musketeer modules for bridging.

■ **Figure 7** A rigid configuration that requires the addition of five musketeer modules for bridging.

4.3.3 Reconfiguration Step

We now need to guarantee that module m is able to move and thus it can pivot along the outer shell of C and join the canonical strip. This is clear when m is disjoint from the neighborhood of m . We also want to show that we can liberate and send to the canonical strip either the musketeers used or at least as many modules as musketeers used. In the full version of this paper we extend the analysis of the neighborhood of m , and for each of the possible cases we show that either invoking the bridging procedure or explicitly placing musketeer modules we can guarantee that.

Progress of the reconfiguration is measured in terms of the potential gap $\Delta\Phi = \Phi_{max} - \Phi_{min}$ of the configuration and the size of C (recall that C includes all modules that are not part of the canonical strip). In all the different cases we show that a reconfiguration step decreases the potential gap and/or the size of C .

4.4 Algorithm Pseudocode

Algorithm 1 solves the reconfiguration problem by combining the operations described in the previous sections:

► **Theorem 11.** *The reconfiguration algorithm (Algorithm 1) transforms a facet-connected configuration C with n modules into a canonical strip of the same size, using $O(n^2)$ monkey-move pivoting steps, which is worst-case optimal, and adding at most five extra modules.*

Proof. The input to the algorithm is a configuration C of size n and potential gap $\Delta\Phi = O(n)$. Each step of the innermost loop uses $O(n)$ pivoting operations to take an outer-free module to the end of the strip, thus decreasing the size of C by one. Each reconfiguration step uses $O(n)$ pivoting steps to decrease either the potential gap or the size of C , leaving it facet-connected

■ **Algorithm 1** Reconfiguring an arbitrary facet-connected configuration into a canonical strip.

Data: An arbitrary facet-connected configuration C with n modules
Result: A canonical strip of modules of length n

```

while there are still modules in  $C$  do
    while there exist outer-free modules do
        | pick one outer-free module and pivot it all the way to the tip of the strip;
    end
    if the strip has fewer than five modules then
        | make the strip five modules long by adding musketeer modules;
    end
    invoke the reconfiguration step;
end

```

(and never increasing the potential gap). Because the size of C never increases, the length of the canonical strip never decreases. This means that the strip can have fewer than five modules only once and the conditional does not affect the complexity of the algorithm. We conclude that the algorithm terminates after $O(n)$ iterations in total. Because each iteration takes $O(n)$ pivoting steps, the total number of pivoting steps is $O(n^2)$. Optimality comes from the $\Omega(n^2)$ pivoting steps required to reconfigure a vertical strip into a horizontal one. ◀

5 Conclusion and Open Problems

This paper addresses the problem of reconfiguring a facet-connected grid configuration of n modules into any other configuration of n modules under three increasingly more flexible sets of pivoting moves, namely restrictive, leapfrog and monkey. Previous results solve this problem under the leapfrog set of moves, as long as the initial and final configurations satisfy a strong local separating condition imposed by three forbidden patterns. We show that there exist robot configurations with many instances of the three forbidden patterns that are still reconfigurable, so the local separation condition is not necessary. On the other hand, we show that as soon as the local separation condition is relaxed, the reconfiguration graph breaks into an exponential number of connected components of exponential size. To overcome this obstacle we introduce a new pivoting move, called monkey, and a natural reconfiguration approach that does not depend on local features, but uses up to five extra modules that can freely move around the boundary of the robot configuration. These extra modules are used to unlock intermediate locked configurations so that progress can be made towards the target configuration. We show that our approach uses $O(n^2)$ monkey-pivoting moves to reconfigure any source configuration with n pivoting modules into any given target configuration.

We leave open the question of whether universal reconfiguration can be accomplished under the more restrictive set of leapfrog pivoting moves using a constant number of extra modules.

Another question is whether our approach generalizes to three or higher dimensions. For example, when the slice graphs (where the vertices are the *slices* of the configuration cut along an axis and the edges connect slices with facet-adjacent modules) of the source and target configurations are both paths, we should be able to reconfigure each to a strip of modules, one slice at a time, similar to our 2-dimensional approach does. We conjecture that a similar approach will also work for general 3-dimensional configurations, potentially after increasing the number of musketeer modules to bridge larger gaps introduced by the higher dimensionality.

Abstract

Graph spanners are well-studied and widely used both in theory and practice. In a recent breakthrough, Chechik and Wulff-Nilsen [11] improved the state-of-the-art for light spanners by constructing a $(2k - 1)(1 + \varepsilon)$ -spanner with $O(n^{1+1/k})$ edges and $O_\varepsilon(n^{1/k})$ lightness. Soon after, Filtser and Solomon [19] showed that the classic greedy spanner construction achieves the same bounds. The major drawback of the greedy spanner is its running time of $O(mn^{1+1/k})$ (which is faster than [11]). This makes the construction impractical even for graphs of moderate size. Much faster spanner constructions do exist but they only achieve lightness $\Omega_\varepsilon(kn^{1/k})$, even when randomization is used.

The contribution of this paper is deterministic spanner constructions that are fast, and achieve similar bounds as the state-of-the-art slower constructions. Our first result is an $O_\varepsilon(n^{2+1/k+\varepsilon'})$ time spanner construction which achieves the state-of-the-art bounds. Our second result is an $O_\varepsilon(m + n \log n)$ time construction of a spanner with $(2k - 1)(1 + \varepsilon)$ stretch, $O(\log k \cdot n^{1+1/k})$ edges and $O_\varepsilon(\log k \cdot n^{1/k})$ lightness. This is an exponential improvement in the dependence on k compared to the previous result with such running time. Finally, for the important special case where $k = \log n$, for every constant $\varepsilon > 0$, we provide an $O(m + n^{1+\varepsilon})$ time construction that produces an $O(\log n)$ -spanner with $O(n)$ edges and $O(1)$ lightness which is asymptotically optimal. This is the first known sub-quadratic construction of such a spanner for any $k = \omega(1)$.

To achieve our constructions, we show a novel deterministic incremental approximate distance oracle. Our new oracle is crucial in our construction, as known randomized dynamic oracles require the assumption of a non-adaptive adversary. This is a strong assumption, which has seen recent attention in prolific venues. Our new oracle allows the order of the edge insertions to not be fixed in advance, which is critical as our spanner algorithm chooses which edges to insert based on the answers to distance queries. We believe our new oracle is of independent interest.

1 Introduction

A fundamental problem in graph data structures is compressing graphs such that certain metrics are preserved as well as possible. A popular way to achieve this is through *graph spanners*. Graph spanners are sparse subgraphs that approximately preserve pairwise shortest path distances for all vertex pairs. Formally, we say that a subgraph $H = (V, E', w)$ of an edge-weighted undirected graph $G = (V, E, w)$ is a t -*spanner* of G if for all $u, v \in V$ we have $d_H(u, v) \leq t \cdot d_G(u, v)$, where d_X is the shortest path distance function for graph X and w is the edge weight function. Under such a guarantee, we say that our graph spanner H has *stretch* t . In the following, we assume that the underlying graph G is connected; if it is not, we can consider each connected component separately when computing a spanner.

Graph spanners originate from the 80's [24, 25] and have seen applications in e.g. synchronizers [25], compact routing schemes [30, 26, 8], broadcasting [18], and distance oracles [32].

The two main measures of the sparseness of a spanner H is the size (number of edges) and the *lightness*, which is defined as the ratio $w(H)/w(MST(G))$, where $w(H)$ resp. $w(MST(G))$ is the total weight of edges in H resp. a minimum spanning tree (MST) of G . It has been established that for any positive integer k , a $(2k - 1)$ -spanner of $O(n^{1+1/k})$ edges exists for any n -vertex graph [3]. This stretch-size tradeoff is widely believed to be optimal due to a matching lower bound implied by Erdős' girth conjecture [16], and there are several papers concerned with constructing spanners efficiently that get as close as possible to this lower bound [31, 5, 28].

Obtaining spanners with small lightness (and thus total weight) is motivated by applications where edge weights denote e.g. establishing cost. The best possible total weight that can be achieved in order to ensure finite stretch is the weight of an MST, thus making the definition of lightness very natural. The size lower bound of the unweighted case provides a lower bound of $\Omega(n^{1/k})$ lightness under the girth conjecture, since H must have size and weight $\Omega(n^{1+1/k})$ while the MST has size and weight $n - 1$. Obtaining this lightness has been the subject of an active line of work [2, 7, 14, 11, 19]. Throughout this paper we say that a spanner is *optimal* when its bounds coincide asymptotically with those of the girth conjecture. Obtaining an efficient spanner construction with optimal stretch-lightness trade-off remains one of the main open questions in the field of graph spanners.

Light spanners. Historically, the main approach of obtaining a spanner of bounded lightness has been through different analyses of the classic *greedy spanner*. Given $t \geq 1$, the greedy t -spanner is constructed as follows: iterate through the edges in non-decreasing order of weight and add an edge e to the partially constructed spanner H if the shortest path distance in H between the endpoints of e is greater than t times the weight of e . The study of this

spanner algorithm dates back to the early 90's with its first analysis by Althöfer et al. [2]. They showed that this simple procedure with stretch $2k - 1$ obtains the optimal $O(n^{1+1/k})$ size, and has lightness $O(n/k)$. The algorithm was subsequently analyzed in [7, 14, 19] with stretch $(1 + \varepsilon)(2k - 1)$ for any $0 < \varepsilon < 1$. Recently, a break-through result of Chechik and Wulff-Nilsen [11] showed that a significantly more complicated spanner construction obtains nearly optimal stretch, size and lightness giving the following theorem.

► **Theorem 1** ([11]). *Let $G = (V, E, w)$ be an edge-weighted undirected n -vertex graph and let k be a positive integer. Then for any $0 < \varepsilon < 1$ there exists a $(1 + \varepsilon)(2k - 1)$ -spanner of size $O(n^{1+1/k})$ and lightness $O_\varepsilon(n^{1/k})$.¹*

Following the result of [11] it was shown by Filtser and Solomon [19] that this bound is matched by the greedy spanner. In fact, they show that the greedy spanner is *existentially optimal*, meaning that if there is a t -spanner construction achieving an upper bound $m(n, t)$ resp. $l(n, t)$ on the size resp. lightness of any n -vertex graph then this bound also holds for the greedy t -spanner. In particular, the bounds in Theorem 1 also hold for the greedy spanner.

Efficient spanners. A major drawback of the greedy spanner is its $O(m \cdot (n^{1+1/k} + n \log n))$ construction time [2]. Similarly, Chechik and Wulff-Nilsen [11] only state their construction time to be polynomial, but since they use the greedy spanner as a subroutine, it has the same drawback. Addressing this problem, Elkin and Solomon [15] considered efficient construction of light spanners. They showed how to construct a spanner with stretch $(1 + \varepsilon)(2k - 1)$, size $O_\varepsilon(kn^{1+1/k})$ and lightness $O_\varepsilon(kn^{1/k})$ in time $O(km + \min(n \log n, m\alpha(n)))$. Improving on this, a recent paper of Elkin and Neiman [13] uses similar ideas to obtain stretch $(1 + \varepsilon)(2k - 1)$, size $O(\log k \cdot n^{1+1/k})$ and lightness $O(kn^{1/k})$ in expected time $O(m + \min(n \log n, m\alpha(n)))$.

Several papers also consider efficient constructions of sparse spanners, which are not necessarily light. Baswana and Sen [5] gave a $(2k - 1)$ -spanner with $O(kn^{1+1/k})$ edges in $O(km)$ expected time. This was later derandomized by Roditty et al. [27] (while keeping the same sparsity and running time). Recently, Miller et al. [23] presented a randomized algorithm with $O(m + n \log k)$ running time and $O(\log k \cdot n^{1+1/k})$ size at the cost of a constant factor in the stretch $O(k)$.

It is worth noting that for super-constant k , none of the above spanner constructions obtain the optimal $O(n^{1+1/k})$ size or $O(n^{1/k})$ lightness even if we allow $O(k)$ stretch. If we are satisfied with nearly-quadratic running time, Elkin and Solomon [15] gave a spanner with $(1 + \varepsilon)(2k - 1)$ stretch, $O_\varepsilon(n^{1+1/k})$ size and $O_\varepsilon(kn^{1/k})$ lightness in $O(kn^{2+1/k})$ time by extending a result of Roditty and Zwick [28] who got a similar result but with unbounded lightness. However, this construction still has a factor of k too much in the lightness. Thus, the fastest known spanner construction obtaining optimal size and lightness is the classic greedy spanner – even if we allow $O(k)$ stretch or $o(kn^{1/k})$ lightness.

We would like to emphasize that the case $k = \log n$ is of special interest. This is the point on the tradeoff curve allowing spanners of linear size and constant lightness. Prior to this paper, the state of the art for efficient spanner constructions with constant lightness suffered from distortion at least $O(\log^2 n)$. See the discussion after Corollary 5 for further details.

A summary of spanner algorithms can be seen in Table 1.

¹ O_ε notation hides polynomial factors in $1/\varepsilon$.

■ **Table 1** Table of related spanner constructions. In the top of the table we list non-efficient spanner constructions. In the middle we list known efficient spanner construction. In the bottom we list our contributions. Results marked * are different analyses of the greedy spanner. Results marked # are randomized. Lightness complexities marked ** appear in the full version [1] and W denotes the maximum edge weight of the input graph. The bounds hold for any constant $\varepsilon, \varepsilon' > 0$.

1.1 Our results

We present the first spanner obtaining the same near-optimal guarantees as the greedy spanner in significantly faster time by obtaining a $(1 + \varepsilon)(2k - 1)$ spanner with optimal size and lightness in $O_\varepsilon(n^{2+1/k+\varepsilon'})$ time. We also present a variant of this spanner, improving the running time to $O(m + n \log n)$ by paying a $\log k$ factor in the size and lightness. Finally, we present an optimal $O_\varepsilon(\log n)$ -spanner which can be constructed in $O(m + n^{1+\varepsilon})$ time. This special case is of particular interest in the literature (see e.g. [4, 22]). Furthermore, all of our constructions are deterministic, giving the first subquadratic deterministic construction without the additional dependence on k in the size of the spanner. As an important tool, we introduce a new deterministic approximate incremental distance oracle which works in near-linear time for maintaining small distances approximately. We believe this result is of independent interest.

More precisely, we show the following theorems.

► **Theorem 2.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, any positive integer k , and $\varepsilon, \varepsilon' > 0$ where ε arbitrarily close to 0 and ε' is a constant, one can deterministically construct an $(1 + \varepsilon)(2k - 1)$ -spanner of G with $O_\varepsilon(n^{1+1/k})$ edges and lightness $O_\varepsilon(n^{1/k})$ in $O(n^{2+1/k+\varepsilon'})$ time.*

► **Theorem 3.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, a positive integer $k \geq 640$, and $\varepsilon > 0$, one can deterministically construct a $(2k - 1)(1 + \varepsilon)$ -spanner of G with $O_\varepsilon(\log k \cdot n^{1+1/k})$ edges and lightness $O_\varepsilon(\log k \cdot n^{1/k})$ in time $O(m + n \log n)$.*

Note that in Theorem 3 we require k to be larger than 640. This is not a significant limitation, as for $k = O(1)$ [15] is already optimal.

Our $O(\log n)$ -spanner is obtained as a corollary of the following more general result.

► **Theorem 4.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, any positive integer k and constant $\varepsilon' > 0$, one can deterministically construct an $O(k)$ -spanner of G with $O(n^{1+1/k})$ edges and lightness $O(n^{1/k})$ in $O(m + n^{1+\varepsilon'+1/k})$ time.*

We note that the stretch $O(k)$ of Theorem 4 (and Corollary 5 below) hides an exponential factor in $1/\varepsilon'$, thus we only note the result for constant ε' . Bartal et. al. [4] showed that given a spanner construction that for every n -vertex weighted graph produces a $t(n)$ -stretch spanner with $m(n, t)$ edge and $l(n, t)$ lightness in $T(n, m)$ time, then for every parameter $0 < \delta < 1$ and every graph G , one can construct a t/δ -spanner with $m(n, t)$ edges and $1 + \delta \cdot l(n, t)$ lightness in $T(n, m) + (m)$ time. Plugging $k = \log n$ and using this reduction we get

► **Corollary 5.** *Let $G = (V, E, w)$ be a weighted undirected n -vertex graph, let $\varepsilon' > 0$ be a constant and $\delta > 0$ be a parameter arbitrarily close to 0. Then one can construct a spanner of G with:*

1. $O(\log n)/\delta$ stretch, $O(n)$ edges and $1 + \delta$ lightness in time $O(m + n^{1+\varepsilon'})$.
2. $O(\log n \log \log n)/\delta$ stretch, $O(n \log \log n)$ edges and $1 + \delta$ lightness in time $O(m + n \log n)$.

Corollary 5 above should be compared to previous attempts to efficiently construct a spanner with constant lightness. Although not stated explicitly, the state of the art algorithms of [15, 13], combined with the lemma from [4], provide an efficient spanner construction with $1 + \delta$ lightness, $O(n \log \log n)$ edges and only $O(\log^2 n/\delta)$ stretch.

We emphasize, that Corollary 5 is the first sub-quadratic construction of spanner with optimal size and lightness for any non-constant k .

In order to obtain Theorem 4 we construct the following deterministic incremental approximate distance oracle with near-linear total update time for maintaining small distances. We believe this result is of independent interest, and discuss it in more detail in the related work section below and in Section 3.

► **Theorem 6.** *Let G be a graph that undergoes a sequence of m edge insertions. For any constant $\varepsilon' > 0$ and parameter $d \geq 1$ there exists a data structure which processes the m insertions in total time $O(m^{1+\varepsilon'} \cdot d)$ and can answer queries at any point in the sequence of the following form. Given a pair of nodes u, v , the oracle gives, in $O(1)$ time, an estimate $\hat{d}(u, v)$ such that $\hat{d}(u, v) \geq d(u, v)$ and if $d(u, v) \leq d$ then $\hat{d}(u, v) = O(1) \cdot d(u, v)$.*

Theorem 6 assumes that ε' is constant; the O -notation hides a factor exponential in $1/\varepsilon'$ for both total update time and stretch whereas the query time bound only hides a factor of $1/\varepsilon'$.

We also obtain the following sparse, but not necessarily light, spanner in linear time as a subroutine in proving Theorem 3.

► **Theorem 7.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, a positive integer k , and $\varepsilon > 0$, one can deterministically construct a $(2k - 1)(1 + \varepsilon)$ -spanner of G with $O_\varepsilon(n^{1+1/k} \cdot \log k)$ edges in time $O(m)$.*

1.2 Related work

Closely related to graph spanners are *approximate distance oracles (ADOs)*. An ADO is a data structure which, after preprocessing a graph G , is able to answer distance queries approximately. Distance oracles are studied extensively in the literature (see e.g. [31, 33, 9, 10]) and often use spanners as a building block. The state of the art static distance oracle

is due to Chechik [10], where a construction of space $O(n^{1+1/k})$, stretch $2k - 1$, and query time $O(1)$ is given. Our distance oracle of Theorem 6 should be compared to the result of Henzinger, et al. [21], who gave a deterministic construction for incremental (or decremental) graphs with a total update time of $O_\varepsilon(mn \log n)$, a query time of $O(\log \log n)$ and stretch $1 + \varepsilon$. For our particular application, we require near-linear total update time and only good stretch for short distances, which are commonly the most troublesome when constructing spanners. It should be added that Henzinger et al. give a general deterministic data structure for choosing centers, i.e., vertices which are roots of shortest path trees maintained by the data structure. While this data structure may be fast when the total number of centers is small, we need roughly n centers and it is not clear how this number can be reduced. Having this many centers requires at least order mn time with their data structure.

To achieve our fast update time bound, we are interested in trading worse stretch for distances above parameter d for construction time. Roditty and Zwick [29] gave a randomized distance oracle for this case, however their construction does not work against an adaptive adversary as is required for our application, where the edges to be inserted are determined by the output to the queries of the oracle (see Section 3 for more discussion on this). Removing the assumption of a non-adaptive adversary in dynamic graph algorithms has seen recent attention at prestigious venues, e.g. [34, 6]. Our new incremental approximate distance oracle for short distances given in Theorem 6 is deterministic and thus is robust against such an adversary, and we believe it may be of independent interest as a building block in deterministic dynamic graph algorithms.

For unweighted graphs, there is a folklore spanner construction by Halperin and Zwick [20] which is optimal on all parameters. The construction time is $O(m)$, it has $O(n^{1+1/k})$ edges and $2k - 1$ stretch. In Section 6 we will use this spanner as a building block in proving Theorem 3.

2 Preliminaries

Consider a weighted graph $G = (V, E, w)$, we will abuse notation and refer to as E both a set of edges and the graph itself. d_G will denote the shortest path metric (that is $d_G(v, u)$ is the weight of the lightest path between v, u in G). Given a subset V' of V , $G[V']$ is the induced graph by V' . That is it has V' as its vertices, $E \cap \binom{V'}{2}$ as its edges and w as weight function. The *diameter* of a vertex set V' in a graph G' $\text{diam}_{G'}(V') = \max_{u, v \in V'} d_{G'}(u, v)$ is the maximal distance between two vertices in V' under the shortest path metric induced by G' . For a set of edges A with weight function w , the *aspect ratio* of A is $\max_{e \in A} w(e) / \min_{e \in A} w(e)$. The *sparsity* of A is simply $|A|$ its size.

We will assume that $k = O(\log n)$ as the guarantee for lightness and sparsity will not be improved by picking larger k . Instead of proving $(1 + \varepsilon)(2k - 1)$ bound on stretch, we will prove only $(1 + O(\varepsilon))(2k - 1)$ bound. This is good enough, as Post factum we can scale ε accordingly. By O_ε we denote asymptotic notation which hides polynomial factors of $1/\varepsilon$, that is $O_\varepsilon(f) = O(f) \cdot \text{poly}(\frac{1}{\varepsilon})$.

3 Paper overview

General framework. Theorems 2 to 4 are generated via a general framework. The framework is fed two algorithms for spanner constructions: A_1 , an algorithm suitable for graphs with small aspect ratio, and A_2 , an algorithm that returns a sparse spanner, but with potentially unbounded lightness. We consider a partition of the edges into groups according to their weights. For treating most of the groups we use exponentially growing clusters, partitioning

the edges according to weight. Each such group has bounded aspect ratio, and thus we can use A_1 . Due to the exponential growth rate, we show that the contribution of all the different groups is converging. Thus only the first group is significant. However, with this approach we need a special treatment for edges of small weight. This is, as using the previous approach, the number of clusters needed to treat light edges is unbounded. Nevertheless, these edges have small impact on the lightness and we may thus use algorithm A_2 , which ignores this property.

The main work in proving Theorems 2 to 4 is in designing the algorithms A_1 and A_2 described briefly below.

Approximate greedy spanner. The major time consuming ingredient of the greedy spanner algorithm is its shortest path computations. By instead considering approximate shortest path computations we significantly speed this process up. We are the first to apply this idea on general graphs, while it has previously been applied by [12, 19] on particular graph families. Specifically, we consider the following algorithm: given some parameters $t < t'$, initialize $H \leftarrow \emptyset$ and consider the edges $(u, v) \in E$ according to increasing order of weight. If $d_H(u, v) > t' \cdot w(u, v)$ the algorithm is obliged to add (u, v) to H . If $d_H(u, v) < t \cdot w(u, v)$, the algorithm is forbidden to add (u, v) to H . Otherwise, the algorithm is free to include the edge or not. As a result, we will get spanner with stretch t' , which has the same lightness and sparsity guarantees of the greedy t -spanner. Note however, that the resulting spanner is not necessarily a subgraph of any greedy spanner.

We obtain both Theorem 2 and Theorem 4 using this approach via an incremental approximate distance oracle. It is important to note that the edges inserted into H using this approach depend on the answers to the distance queries. It is therefore not possible to use approaches that do not work against an *adaptive adversary* such as the result of Roditty and Zwick [29], which is based on random sampling. Furthermore, this is the case even if we allow the spanner construction itself to be randomized. In order to obtain Theorem 2, we use our previously described framework coupled with the “approximately greedy spanner” using an incremental $(1 + \varepsilon)$ -approximate distance oracle of Henzinger et al. [21]. For Theorem 4, we present a novel incremental approximate distance oracle, which is described below. This is the main technical part of the paper and we believe that it may be of independent interest.

Deterministic distance oracle. The main technical contribution of the paper and key ingredient in proving Theorem 4 is our new deterministic incremental approximate distance oracle of Theorem 6. The oracle supports approximate distance queries of pairs within some distance threshold, d . In particular, we may set d to be some function of the stretch of the spanner in Theorem 4. Similar to previous work on distance oracles, we have some parameter, k , and maintain k sets of nodes $\emptyset = A_{k-1} \subseteq \dots \subseteq A_0 = V$, and for each $u \in A_i$ we maintain a ball of radius $r \leq d_i$. Here, d_i is a distance threshold depending on the parameter d and which set A_i we are considering, and r is chosen such that the total degree of nodes in the ball of radius r from u is relatively small. The implementation of each ball can be thought of as an incremental Even-Shiloach tree. The set A_{i+1} is then chosen as a maximal set of nodes with disjoint balls. Here we use the fact that the vertices in A_{i+1} are centers of disjoint balls in A_i to argue that A_{i+1} is much smaller than A_i . The decrease in size of A_{i+1} pays for an increase in the maximum ball radius d_i at each level. The ball of a node u may grow in size during edge insertions. In this case, we freeze the ball associated with u , shrink the radius r associated with u , and create a new ball with the new radius. Thus, for each A_i we end up with $O(\log d)$ different radii for which we pick a maximal set of nodes with disjoint balls. For

each node $u_i \in A_i$ we may then associate a node $u_{i+1} \in A_{i+1}$ whose ball intersects with u_i 's. We use these associated nodes in the query to ensure that the path distance we find is not “too far away” from the actual shortest path distance. Consider a query pair (u, v) . Then the query algorithm iteratively finds a sequence of vertices $u = u_0 \in A_0, u_1 \in A_1, \dots, u_i \in A_i$; d_i is picked such that if v is not in the ball centered at u_i with radius d_i then the shortest path distance between u and v is at least d and the algorithm outputs ∞ . Otherwise, the algorithm uses the shortest path distances stored in the balls that it encounters to output the weight of a uv -path $(u = u_0) \rightsquigarrow u_1 \rightsquigarrow \dots \rightsquigarrow u_i \rightsquigarrow v$ as an approximation of the shortest path distance between u and v .

Almost linear spanner. Chechik and Wulff-Nilsen [11] implicitly used our general framework, but used the (time consuming) greedy spanner both as their A_2 component and as a sub-routine in A_1 . We show an efficient alternative to the algorithm of [11]. For the A_2 component we provide a novel sparse spanner construction (Theorem 7, see paragraph below). For A_1 , we perform a hierarchical clustering, while avoiding the costly exact diameter computations used in [11]. Finally, we replace the greedy spanner used as a sub-routine of [11] by an efficient spanner that exploits bounded aspect ratio (see Lemma 13). This spanner can be seen as a careful adaptation of Elkin and Solomon [15] analyzed in the case of bounded aspect ratio. The idea here is (again) a hierarchical partitioning of the vertices into clusters of exponentially increasing size. However, here the growth rate is only $(1 + \varepsilon)$. Upon each clustering we construct a super graph with clusters as vertices and graph edges from the corresponding weight scale as inter-cluster edges. To decide which edges in each scale add to our spanner, we execute the extremely efficient spanner of Halperin and Zwick [20] for unweighted graphs.

Linear time sparse spanner. As mentioned above we provide a novel sparse spanner construction as a building block in proving Theorem 3. Our construction is based on partitioning edges into $O_\varepsilon(\log k)$ “well separated” sets E_1, E_2, \dots , such that the ratio between $w(e)$ and $w(e')$ for edges $e, e' \in E_i$ is either a constant or at least k . This idea was previously employed by Elkin and Neiman [13] based on [23]. For these well-separated graphs, Elkin and Neiman used an involved clustering scheme based on growing clusters according to exponential distribution, and showed that the expected number of inter-cluster edges, in all levels combined, is small enough. We provide a linear time *deterministic* algorithm with an arguably simpler clustering scheme. Our clustering is based upon the clusters defined implicitly by the spanner for unweighted graphs of Halperin and Zwick [20]. In particular, we introduce a charging scheme, such that each edge added to our spanner is either paid for by a large cluster with many coins, or significantly contributing to reduce the number of clusters in the following level.

4 A framework for creating light spanners efficiently

In this section we describe a general framework for creating spanners, which we will use to prove our main results. The framework is inspired by a standard clustering approach (see e.g. [15] and [11]). The spanner framework takes as input two spanner algorithms for restricted graph classes, A_1 and A_2 , and produces a spanner algorithm for general graphs. The algorithm A_1 works for graphs with unit weight MST edges and small aspect ratio, and A_2 creates a small spanner with no guarantee for the lightness. The main work in showing Theorems 2, 3, and 4 is to construct the algorithms, A_1 and A_2 , that go into Lemma 8 below. The framework is described in the following lemma. The proof appears in the full version [1].

► **Lemma 8.** *Let $G = (V, E)$ be a weighted graph with n nodes and m edges and let $k > 0$ be an integer, $g > 1$ a fixed parameters and $\varepsilon > 0$. Assume that we are given two spanner construction algorithms A_1 and A_2 with the following properties:*

- A_1 computes a spanner of stretch $f_1(k)$, size $O_\varepsilon(s_1(k) \cdot n^{1+1/k})$ and lightness $O_\varepsilon(l_1(k) \cdot n^{1/k})$ in time $T_1(n, m, k)$ when given a graph with maximum weight g^k , where all MST edges have weight 1. Moreover, T_1 has the property that $\sum_{i=0}^{\infty} T_1\left(\frac{n}{g^{ik}}, m_i, k\right) = O(T_1(n, m, k))$, where $\sum_i m_i = m + O(n)$.

- A_2 computes a spanner of stretch $f_2(k)$ and size $O_\varepsilon(s_2(k) \cdot n^{1+1/k})$ in time $T_2(n, m, k)$. Then one can compute a spanner of stretch $\max((1 + \varepsilon)f_1(k), f_2(k))$, size $O_\varepsilon((s_1(k) + s_2(k))n^{1+1/k})$, and lightness $O_\varepsilon((l_1(k) + s_2(k)) \cdot n^{1/k})$ in time $O(T_1(n, m, k) + T_2(n, m, k) + m + n \log n)$.

5 Efficient approximate greedy spanner

In this section we will show how to efficiently implement algorithms A_1 and A_2 of Lemma 8 in order to obtain Theorems 2 and 4. We do this by implementing an “approximate-greedy” spanner, which uses an incremental approximate distance oracle to determine whether an edge should be added to the spanner or not.

We first prove Theorem 4 and then show in Section 5.2 how to modify the algorithm to give Theorem 2. We will use Theorem 6 as a main building block, but defer the proof of this theorem to Section 8. Our A_1 is obtained by the following lemma giving stretch $O(k)$ and optimal size $O(n^{1+1/k})$ and lightness $O(n^{1/k})$ for small weights.

► **Lemma 9.** *Let $G = (V, E, w)$ be an undirected graph with $m = |E|$ and $n = |V|$ and integer edge weights bounded from above by W . Let k be a positive integer and let $\varepsilon' > 0$ be a constant. Then one can deterministically construct an $O(k)$ -spanner of G with size $O(n^{1+1/k})$ and lightness $O(n^{1/k})$ in time $O(m + kWn^{1+1/k+\varepsilon'})$.*

We note that Lemma 9 above requires integer edge weights, but we may obtain this by simply rounding up the weight of each edge losing at most a factor of 2 in the stretch. Alternatively we can use the approach of Lemma 12 in Section 5.2 to reduce this factor of 2 to $(1 + \varepsilon)$.

Our A_2 will be obtained by the following lemma, which is essentially a modified implementation of Lemma 9.

► **Lemma 10.** *Let $G = (V, E, w)$ be an edge-weighted graph with $m = |E|$ and $n = |V|$. Let k be a positive integer and let $\varepsilon' > 0$ be a constant. Then one can deterministically construct an $O(k)$ -spanner of G with size $O(n^{1+1/k})$ in time $O(m + kn^{1+1/k+\varepsilon'})$.*

Combining Lemma 8 of Section 4 with Lemmas 9 and 10 above immediately gives us a spanner with stretch $O(k)$, size $O(n^{1+1/k})$ and lightness $O(n^{1/k})$ in time $O(m + n^{1+1/k+\varepsilon''})$ for any constant $\varepsilon'' > 0$. This is true because we may assume that $k \leq \gamma \log n$ for any constant $\gamma > 0$, and thus by picking γ and ε' accordingly we have that the running time given by Lemma 8 can be bounded by

$$O\left(m + kWn^{1+1/k+\varepsilon'} + kn^{1+1/k+\varepsilon'}\right) = O\left(m + kg^k n^{1+1/k+\varepsilon'}\right) = O\left(m + n^{1+1/k+\varepsilon''}\right).$$

5.1 Details of the almost-greedy spanner

Set $\varepsilon = 1$ ². Our algorithm for Lemma 9 is described below in Algorithm 1. It computes a spanner of stretch $c_1(1 + \varepsilon)(2k - 1)$, where $c_1 = O(1)$ is the stretch of our incremental approximate distance oracle in Theorem 6. Let $t = c_1(1 + \varepsilon)(2k - 1)$ throughout the section. The proof of Lemma 9 is postponed to the full version [1].

■ **Algorithm 1** Approximate-Greedy.

input : Graph $G = (V, E, w)$, Parameters ε, k
output : Spanner H

- 1 Create $H = (V, \emptyset)$
- 2 Initialize incremental distance oracle (Theorem 6) on H with $d = t \cdot W$
- 3 **for** $(u, v) \in E$ *in non-decreasing order* **do**
- 4 **if** $\hat{d}_H(u, v) > t \cdot w(u, v)$ **then**
- 5 Add (u, v) to H
- 6 **return** H

Next, we sketch the proof Lemma 10, by explaining how to modify the proof of Lemma 9.

Proof of Lemma 10. Recall that c_1 is defined as the constant stretch provided by Theorem 6. We use Algorithm 1 with the following modifications: (1) we pick $d = c_1(2k - 1)$, (2) when adding an edge to the distance oracle we add it as an unweighted edge, (3) we add an edge if its endpoints are not already connected by a path of at most d edges according to the approximate distance oracle.

The stretch of the spanner follows by the same stretch argument as in Lemma 9 and the fact that we consider the edges in non-decreasing order. To see that the size of the spanner is $O(n^{1+1/k})$ consider an edge (u, v) added to H by the modified algorithm. Since (u, v) was added to H we know that the distance estimate was at least $c_1(2k - 1)$. It thus follows from Theorem 6 that u and v have distance at least $2k$ in H and therefore H has girth at least $2k + 1$. It now follows that H has $O(n^{1+1/k})$ edges by a standard argument. The running time of this modified algorithm follows directly from Theorem 6. ◀

5.2 Near-quadratic time implementation

The construction of the previous section used our result from Theorem 6 to efficiently construct a spanner losing a constant factor exponential in $1/\varepsilon$ in the stretch. We may instead use the seminal result of Even and Shiloach [17] to obtain the same result with stretch $(1 + \varepsilon)(2k - 1)$ at the cost of a slower running time as detailed in Theorem 2. Below is described a version of the result of [17] which we will use.

► **Theorem 11** ([17]). *There exists a deterministic incremental APSP data structure for graphs with integer edge weights, which answers distance queries within a given threshold d in $O(1)$ time and has total update time $O(mnd)$.*

Here, the threshold means that if the distance between two nodes is at most d , the data structure outputs the exact distance and otherwise it outputs ∞ (or some other upper bound).

² In Section 5.2 we let $0 < \varepsilon < 1$ here to be arbitrary small parameter.

To obtain Theorem 2 we use the framework of Section 4. For the algorithm A_2 we may simply use the deterministic spanner construction of Roditty and Zwick [28] giving stretch $2k - 1$ and size $O(n^{1+1/k})$ in time $O(kn^{2+1/k})$. For A_1 we will show the following lemma.

► **Lemma 12.** *Let $G = (V, E, w)$ be an undirected graph with $m = |E|$ and $n = |V|$, edge weights bounded from above by W and where all MST edges have weight 1. Let k be a positive integer. Then one can deterministically construct a $(1 + \varepsilon)(2k - 1)$ -spanner of G with size $O_\varepsilon(n^{1+1/k})$ and lightness $O_\varepsilon(n^{1/k})$ in time $O_\varepsilon(m \log n + kWn^{2+1/k})$.*

Proof sketch. The final spanner will be a union of two spanners. Since Theorem 11 requires integer weights. We therefore need to treat edges with weight less than $1/\varepsilon$ separately. For these edges we use the algorithm of Roditty and Zwick [28] to produce a spanner with stretch $2k - 1$, size $O(n^{1+1/k})$ and thus total weight $O(n^{1+1/k}/\varepsilon)$.

For the remaining edges with weight at least $1/\varepsilon$ we now round up the weight to the nearest integer incurring a stretch of at most a factor of $1 + \varepsilon$. We now follow the approach of Algorithm 1 using the incremental APSP data structure of Theorem 11 and a threshold in line 4 of $(1 + \varepsilon)(2k - 1) \cdot w(u, v)$ instead. We use the distance threshold $d = (1 + \varepsilon)(2k - 1) \cdot W$.

The final spanner, H , is the union of the two spanners above. The stretch, size and lightness of the spanner follows immediately from the proof of Lemma 9. For the running time, we add in the additional time to sort the edges and query the distances to obtain a total running time of

$$O_\varepsilon(m \log n + d \cdot |E(H)| \cdot |V(H)|) = O_\varepsilon\left(m \log n + kWn^{2+1/k}\right) . \quad \blacktriangleleft$$

Now, recall that $W = g^k$, where $k \leq \log n$ and $g > 1$ is a fixed parameter of our choice. By picking g such that $g^{2k} \leq n^{\varepsilon'}$ we get a running time of $O(n^{2+1/k+\varepsilon'})$ for A_1 . Theorem 2 now follows from Lemma 8.

6 Almost Linear Spanner

Our algorithm builds on the spanner of Chechik and Wulff-Nilsen [11]. Here we first describe their algorithm and then present the modifications. Chechik and Wulff-Nilsen implicitly used our general framework, and thus provide two different algorithms A_1^{CW} and A_2^{CW} . A_2^{CW} is simply the greedy spanner algorithm.

A_1^{CW} starts by partitioning the non-MST edges into k buckets, such that the i th bucket contains all edges with weight in $[g^{i-1}, g^i)$. The algorithm is then split into k levels with the i th bucket being treated in the i th level. In the i th level, the vertices are partitioned into i -clusters, where the i -clusters refine the $(i - 1)$ -clusters. Each i -cluster has diameter $O(kg^i)$ and contains at least $\Omega(kg^i)$ vertices. This is similar to the (i, ε) -clusters in Section 4 with the modification of having two types of clusters, *heavy* and *light*. A cluster is heavy if it has many incident i -level edges and light otherwise. For a light cluster, we add all the incident i -level edges to the spanner directly. For the heavy clusters, Chechik and Wulff-Nilsen [11] create a special auxiliary cluster graph and run the greedy spanner on this to decide which edges should be added.

To bound the lightness of the constructed spanner, they show that each time a heavy cluster is constructed the number of clusters in the next level is reduced significantly. Then, using a clever potential function, they show that the contribution of all the greedy spanners is bounded. It is interesting to note, that in order to bound the weight of a single greedy spanner, they use the analysis of [14]. Implicitly, [14] showed that on graphs with $O(\text{poly}(k))$ aspect ratio, the greedy $(1 + \varepsilon)(2k - 1)$ -spanner has $O_\varepsilon(n^{1/k})$ lightness and $O(n^{1+1/k})$ edges.

4:12 Constructing Light Spanners Deterministically in Near-Linear Time

There are three time-consuming parts in [11]: 1) The clustering procedure iteratively grows the i -clusters as the union of several $(i-1)$ -clusters, but uses expensive exact diameter calculations in the original graph. 2) They employ the greedy spanner several times as a subroutine during $A_1^{C^w}$ for graphs with $O(\text{poly}(k))$ aspect ratio. 3) They use the greedy spanner as $A_2^{C^w}$.

In order to handle 1) above we will grow clusters purely based on the number of nodes in the $(i-1)$ -clusters (in similar manner to (i, ε) -clusters), thus making the clustering much more efficient without losing anything significant in the analysis. To handle 2) We will use the following lemma in place of the greedy spanner.

► **Lemma 13.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, a positive integer k , $\varepsilon > 0$, such that all the weights are within $[a, a \cdot \Delta]$, and the MST have weight $O(na)$. One can deterministically construct a $(2k-1)(1+\varepsilon)$ -spanner of G with $O_\varepsilon(n^{1+\frac{1}{k}})$ edges and lightness $O_\varepsilon\left(n^{\frac{1}{k}} \cdot \log(\Delta)\right)$ in time $O(m + n \log n)$.*

The core of Lemma 13 already appears in [15], while here we analyze it for the special case where the aspect ratio is bounded by Δ . The main ingredient is an efficient spanner construction by Halperin and Zwick [20] for unweighted graphs. The proof of Lemma 13 is deferred to the full version [1]. Replacing the greedy spanner by Lemma 13 above is the sole reason for the additional $\log k$ factor in the lightness of Theorem 3.

Imitating the analysis of [11] with the modified ingredients, we are able to prove the following lemma, which we will use as A_1 in our framework.

► **Lemma 14.** *Given a weighted undirected graph $G = (V, E, w)$ with m edges and n vertices, a positive integer $k \geq 640$, and $\varepsilon > 0$, such that all MST edges have unit weight, and all weights bounded by g^k , one can deterministically construct a $(2k-1)(1+\varepsilon)$ -spanner of G with $O_\varepsilon(n^{1+1/k})$ edges and lightness $O_\varepsilon\left(\log k \cdot n^{\frac{1}{k}}\right)$ in time $O(m + nk)$.*

To address the third time-consuming part we instead use the algorithm of Theorem 7 as A_2 . Replacing the greedy algorithm by Theorem 7 is the sole reason for the additional $\log k$ factor in the sparsity of Theorem 3.

Combining Lemma 14, Theorem 7 and Lemma 8 we get Theorem 3. The proof of Lemma 14 deferred to the full version [1].

7 Proof of Theorem 7

The basic idea in the algorithm of Theorem 7, is to partition the edges E of G into $O_\varepsilon(\log k)$ sets E_1, E_2, \dots , such that the edges in E_i are “well separated”. That is, for every $e, e' \in E_i$, the ratio between $w(e)$ and $w(e')$ is either a constant or at least k . By hierarchical execution of a modified version of [20], with appropriate clustering, we show how to efficiently construct a spanner of size $O(n^{1+1/k})$ for each such “well separated” graph. Thus, taking the union of these spanners, Theorem 7 follows. The details appear in the full version [1].

8 Deterministic Incremental Distance Oracles for Small Distances

In this section, we present a deterministic incremental approximate distance oracle which can answer approximate distance queries between vertex pairs whose actual distance is below some threshold parameter d . This oracle will give us Theorem 6 and finish the proof of Theorem 4. In fact, we will show the following more general result. Theorem 6 follows directly by setting $k = 1/\varepsilon$ in the theorem below.

► **Theorem 15.** *Let $G = (V, E)$ be an n -vertex undirected graph that undergoes a series of edge insertions. Let G have positive integer edge weights and set $E = \emptyset$ initially. Let $\varepsilon > 0$ and positive integers k and d be given. Then a deterministic approximate distance oracle for G can be maintained under any sequence of operations consisting of edge insertions and approximate distance queries. Its total update time is $O_\varepsilon(m^{1+1/k}(3+\varepsilon)^{k-1}d(k+\log d)\log n)$ where m is the total number of edge insertions; the value of m does not need to be specified to the oracle in advance. Given a query vertex pair (u, v) , the oracle outputs in $O(k\log n)$ time an approximate distance $\tilde{d}(u, v)$ such that $\tilde{d}(u, v) \geq d(u, v)$ and such that if $d(u, v) \leq d$ then $\tilde{d}(u, v) \leq (2(3+\varepsilon)^{k-1} - 1)d(u, v)$.*

As discussed in Section 3, a main advantage of our oracle is that, unlike, e.g., the incremental oracle of Roditty and Zwick [29], it works against an adaptive adversary. Hence, the sequence of edge insertions does not need to be fixed in advance and we allow the answer to a distance query to affect the future sequence of insertions. This is crucial for our application since the sequence of edges inserted into our approximate greedy spanner depends on the answers to the distance queries.

We assume in the following that $m \geq n$; if this is not the case, we simply extend the sequence of updates with $n - m$ dummy updates. We will present an oracle satisfying Theorem 15 except that we require it to be given m in advance. An oracle without this requirement can be obtained from this as follows. Initially, an oracle is set up with $m = n$. Whenever the number of edge insertions exceeds m , m is doubled and a new oracle with this new value of m replaces the old oracle and the sequence of edge insertions for the old oracle are applied to the new oracle. By a geometric sums argument, the total update time for the final oracle dominates the time for all the previous oracles. Hence, presenting an oracle that knows m in advance suffices to show the theorem.

Before describing our oracle, we need some definitions and notation. For an edge-weighted tree T rooted at a vertex u , let $d_T(v)$ denote the distance from u to v in T , where $d_T(v) = \infty$ if $v \notin V(T)$. Let $r(T) = \max_{v \in V(T)} d_T(v)$. Given a graph H and $W \subseteq V(H)$, we let $\deg_H(W) = \sum_{v \in W} \deg_H(v)$ and given a subgraph S of H , we let $\deg_H(S) = \deg_H(V(S))$. For a vertex u in an edge-weighted graph H and a value $r \geq 0$, we let $B_H(u, r)$ denote the ball with center u and radius r in H , i.e., $B_H(u, r) = \{v \in V(H) \mid d_H(u, v) \leq r\}$. When H is clear from context, we simply write $B(u, r)$.

We use a superscript (t) to denote a dynamic object (such as a graph or edge set) or variable just after the t 'th edge insertion where $t = 0$ refers to the object prior to the first insertion and $t = m$ refers to the object after the final insertion. For instance, we refer to G just after the t 'th update as $G^{(t)}$.

In the following, let ε , k , and d be the values and let $G = (V, E)$ be the dynamic graph of Theorem 15. For each $i \in \{0, \dots, k-1\}$, define $m_i = 2m^{(i+1)/k}$ and let d_i be the smallest power of $(1+\varepsilon)$ of value at least $(3+2\varepsilon)^i d$. For each $u \in V$ and each $t \in \{0, \dots, m\}$, let $d_i^{(t)}(u)$ be the largest power of $(1+\varepsilon)$ of value at most d_i such that $\deg_{G^{(t)}}(B^{(t)}(u, d_i^{(t)}(u))) \leq m_i$. We let $B_i^{(t)}(u) = B^{(t)}(u, d_i^{(t)}(u))$ and let $T_i^{(t)}(u)$ be a shortest path tree from u in $B_i^{(t)}(u)$. Note that $T_i^{(t)}(u)$ need not be uniquely defined; in the following, when we say that a tree is equal to $T_i^{(t)}$, it means that the tree is equal to some shortest path tree from u in $B_i^{(t)}(u)$.

The data structure in the following lemma will be used as black box in our distance oracle. One of its tasks is to efficiently maintain trees $T_i^{(t)}(u)$. The proof of Lemma 16 is deferred to the full version [1].

► **Lemma 16.** *Let $U \subseteq V$ be a dynamic set with $U^{(0)} = \emptyset$ and let $i \in \{0, \dots, k-1\}$ be given. There is a deterministic dynamic data structure which supports any sequence of update operations, each of which is one of the following types:*

$\text{Insert-Edge}(u, v)$: this operation is applied whenever an edge (u, v) is inserted into E ,
 $\text{Insert-Vertex}(u)$: inserts vertex u into U .

Let t_{\max} denote the total number of operations and for each vertex u inserted into U , let t_u denote the update in which this happens. The data structure outputs in each update $t \in \{1, \dots, t_{\max}\}$ a (possibly empty) set of trees $\bar{T}_i^{(t)}(u)$ rooted at u for each $u \in U^{(t)}$ satisfying either $t > t_u$ and $d_i^{(t)}(u) < d_i^{(t-1)}(u)$ or $t = t_u$ and $d_i^{(t)}(u) < d_i$. For each such tree $\bar{T}_i^{(t)}(u)$, $r(\bar{T}_i^{(t)}(u)) \leq (1 + \varepsilon)d_i^{(t)}(u) \leq d_i$ and $\deg_{G^{(t)}}(\bar{T}_i^{(t)}(u)) > m_i$. Total update time is $O(m) + O_\varepsilon(|U^{(t_{\max})}|m_i d_i \log n)$.

At any point, the data structure supports in $O(1)$ time a query for the value $d_i^{(t)}(u)$ and in $O(\log n)$ time a query for the value $d_{T_i(u)}(v)$ and for whether $v \in V(T_i(u))$, for any query vertices $u \in U$ and $v \in V$.

The construction and analysis of the distance oracle appear in the full version [1].

Abstract

A string UU for a non-empty string U is called a square. Squares have been well-studied both from a combinatorial and an algorithmic perspective. In this paper, we are the first to consider the problem of maintaining a representation of the squares in a dynamic string S of length at most n . We present an algorithm that updates this representation in $n^{o(1)}$ time. This representation allows us to report a longest square-substring of S in $\mathcal{O}(1)$ time and all square-substrings of S in $\mathcal{O}(\text{output})$ time. We achieve this by introducing a novel tool – maintaining prefix-suffix matches of two dynamic strings.

We extend the above result to address the problem of maintaining a representation of all runs (maximal repetitions) of the string. Runs are known to capture the periodic structure of a string, and, as an application, we show that our representation of runs allows us to efficiently answer periodicity queries for substrings of a dynamic string. These queries have proven useful in static pattern matching problems and our techniques have the potential of offering solutions to these problems in a *dynamic* text setting.

1 Introduction

A string UU , where U is not empty, is called a *square* or a *tandem repeat*. Squares are a fundamental construct in word combinatorics, and algorithms for finding all squares have been sought as early as the 1980's [15, 10, 37]. The problem turned out to be central in computational biology causing much algorithmic work to have taken place since then [12, 27]. The approximate version is also of great interest [36, 19, 41, 40].

A run is a periodic fragment of the text that cannot be extended to either direction without increasing its period. Kolpakov and Kucherov, in their seminal paper [35], showed that there are $\mathcal{O}(n)$ runs in a text of length n , and presented an algorithm to compute them

in $\mathcal{O}(n)$ time. After a long line of research, the breakthrough result of Bannai et al. [11] showed that a string of length n can have at most n runs. Runs have been used as an algorithmic tool, for example, for extracting the k -powers in a string (note that a square is a 2-power) and for efficient computation of the periods of substrings of a string [17, 33, 34].

Due to the importance, both theoretical and practical, of squares and runs, it is surprising that the problem of computing or maintaining them in a dynamic text has not been studied. Of course, one can re-run a square/run detection algorithm after every change in the text, but this is clearly a very inefficient way of handling the problem.

In the 1990's the active field of dynamic graph algorithms was started, with the motive of answering questions on graphs that dynamically change over time. For an overview see [18]. Recently, there has been a growing interest in dynamic pattern matching. This natural interest grew from the fact that the biggest digital library in the world - the web - is constantly changing, as well as from the fact that other big digital libraries - genomes and astrophysical data, are also subject to change through mutation and time, respectively.

Historically, there has been much interest in dynamic string matching algorithms. Amir and Farach [7] introduced dynamic dictionary matching, which was later improved by Amir et al. [8]. Idury and Scheffer [29] introduced an automaton-based dynamic dictionary algorithm. Gu et al. [26] and Sahinalp and Vishkin [39] developed a dynamic indexing algorithm, where a dynamic text is indexed. Further progress in dynamic indexing and dictionary matching was achieved by Ferragina et al. [20, 21] and Mehlhorn et al. [38]. Pattern matching algorithms where the text is dynamic and the text is static were also considered [2, 9].

In the last few years there was a resurgence of interest in dynamic string matching. In 2017 a theory began to develop with its nascent set of tools. Bille et al. [13] investigated dynamic relative compression and dynamic partial sums. Amir et al. [5] considered the longest common factor (LCF) problem in the case of one revertible edit (see also [1]). Special cases of the dynamic LCF problem were discussed by Amir and Boneh [3]. An algorithm for the fully dynamic LCF problem was presented by Amir et al. [6]. (A similar line of work has taken place for the problem of maintaining a longest palindrome in a dynamic string [23, 24, 6, 4].) Gawrychowski et al. [25] settled the complexity of maintaining a dynamic collection of strings under operations: concatenate, split, makestring, lexicographic comparison, and finding the longest common prefix of two strings.

We continue this line of work by considering squares and runs in a dynamic string. We present our algorithms for the case where the allowed update operations are substitutions. We first show our techniques in the setting of the following problem.

DYNAMIC LONGEST SQUARE

Input: A string S .

Query: For given index i (and character α), set $S[i] = \alpha$ and compute $\text{LS}(S)$.

Our contributions. We make a step forward in the exciting area of dynamic pattern matching. We give efficient dynamic solutions for a number of important problems:

1. Fully dynamic pattern matching in a text and pattern where the text length is twice the pattern length. In fact, to our knowledge, this is the first known algorithm that does not require $\Omega(\text{occ})$ time to report all pattern occurrences, i.e. it may report them in time smaller than their number, by reporting occurrences via an arithmetic progression.
2. Dynamic maintenance of the *longest* square in a text in $n^{o(1)}$ time per string update, after an $\tilde{\mathcal{O}}(n)$ -time preprocessing and using $\tilde{\mathcal{O}}(n)$ space.¹

¹ The $\tilde{\mathcal{O}}(\cdot)$ notation suppresses $\log^{O(1)} n$ factors.

3. Dynamic maintenance of all *runs* in a text within the same complexities. It is noteworthy that although a single substitution can destroy/create $\Omega(n)$ squares/runs, we can maintain a compact representation of them in subpolynomial time.
4. We conclude by showing that our representation of runs can be employed to efficiently maintain k -powers in a dynamic text and answer queries about periodicity of substrings, adapting the static solutions of Crochemore et al. [17]. Detecting internal periodicities has proven useful in several static string matching applications, thus our dynamic algorithm can potentially help the dynamic version of such problems. An overview of the literature for internal queries in static texts can be found in [32].

We introduce a *new* technique, which we expect will be a powerful tool in other dynamic string matching problems, that of dynamically maintaining *prefix-suffix matches*. This enabled us to efficiently maintain all runs in a dynamic string, which, in turn, enabled the applications presented in this paper.

2 Preliminaries

We begin with basic definitions and notation generally following [16]. Let $S = S[1]S[2] \cdots S[n]$ be a *string* of length $|S| = n$ over an integer alphabet Σ . For two positions i and j on S , we denote by $S[i..j] = S[i] \cdots S[j]$ the fragment of S that starts at position i and ends at position j (it is the empty string ε if $j < i$). A string Y , of length m with $0 < m \leq n$, is a substring of S if there exists a position i in S such that $Y = S[i..i+m-1]$. In this case we say that there exists an *occurrence* of Y in S , or, more simply, that Y *occurs in* S at (*starting*) *position* i . A substring is called *proper* if it is shorter than the whole string. A fragment $S[1..j]$, $j < n$, is called a *prefix* of S , and, analogously, a fragment $S[i..n]$, $i > 1$, is called a *suffix*. A fragment of S that is neither a prefix nor a suffix of S is called an *infix*. A string B that occurs both as a proper prefix and a proper suffix of S is called a *border* of S . A positive integer p is called a *period* of S if $S[i] = S[i+p]$ for all $i = 1, \dots, n-p$. String S has a period p if and only if it has a border of length $n-p$. We refer to the smallest period $\text{per}(S)$ of S as *the period* of the string and, analogously, to the longest border as *the border* of the string. A string S is *periodic* if $\text{per}(S) \leq |S|/2$.

By ST and S^k we denote the concatenation of strings S and T and k copies of the string S , respectively. A string of the form S^2 for some $S \in \Sigma^+$ is called a *square* and a string of the form S^k is called a *k-power*.

A *run* (also known as *maximal repetition*) is a periodic fragment $R = S[a..b]$ which cannot be extended to the left nor to the right without increasing the period $p = \text{per}(R)$, that is, $S[a-1] \neq S[a+p-1]$ and $S[b-p+1] \neq S[b+1]$. The number of runs in a string of length n is at most n [11] and all runs can be computed in $\mathcal{O}(n)$ time [35].

By $\text{lcpstring}(S, T)$ we denote the longest common prefix of S and T , by $\text{lcp}(S, T)$ we denote $|\text{lcpstring}(S, T)|$, and by $\text{lcp}(r, t)$ we denote $\text{lcp}(S[r..n], S[t..n])$. The longest common suffix lcs is defined analogously. We refer to queries returning $\text{lcp}(r, s)$ or $\text{lcs}(r, s)$ as longest common extension queries (*LCE queries*).

It is known that by maintaining Karp-Rabin fingerprints [31] for the substrings of length 2^j starting at a positions $i = 1 \pmod{2^j}$ for all $1 \leq j \leq \log n$ one can obtain the following lemma. (More involved solutions with better complexities in the \mathcal{O} -notation can be obtained by applying for instance the results of [25], cf. [6].)

► **Lemma 1.** *A dynamic string can be maintained with $\tilde{\mathcal{O}}(1)$ -time per edit operation so that LCE queries can be answered in $\tilde{\mathcal{O}}(1)$ time, using $\tilde{\mathcal{O}}(n)$ space.*

3 An $\tilde{O}(n^{2/3})$ -time algorithm

In this section we present an algorithm that reports a longest square $\text{LS}(S)$ in time $\tilde{O}(n^{2/3})$ after each substitution operation. We actually present two algorithms, one for each of the cases of $\text{LS}(S)$ being short or long. Let m , which is to be chosen later, be the distinguishing threshold between those cases. We can assume that m is a power of 2.

Main idea. In order to handle the case of $\text{LS}(S)$ being short, we split our text into $\mathcal{O}(n/m)$ overlapping fragments of length $2m$. Each substitution operation affects only two of these fragments, and we thus just recompute the longest square in them in $\mathcal{O}(m)$ time. As for the case that the $\text{LS}(S)$ UU is long, we note that the first occurrence of U must contain a fragment of length $m/4$ for some $i = 1 \pmod{m/4}$. The idea is to use such fragments as anchors and maintain all of their occurrences in the string using dynamic renaming. Then for every such fragment and every occurrence of it we would like to check whether there is any square UU that contains them “aligned” in the two occurrences of U . We show how to process fragments that have many occurrences efficiently by exploiting periodicity.

3.1 $|\text{LS}(S)| \leq m$

Preprocessing. We split the string S into overlapping fragments, each of length $2m$, starting at positions $i = 1 + j \cdot m$ for $j = 0, 1, \dots, \lceil n/m \rceil$. (Note that the last two fragments could be shorter than $2m$.) We use a linear-time algorithm ([17, 28]) to compute all squares in each of these fragments, requiring time $\mathcal{O}(m \cdot n/m) = \mathcal{O}(n)$ in total. For each fragment, we will maintain a representative longest square-substring, which is chosen arbitrarily in case of ties. We store the representatives of all fragments in a max heap, with their lengths being the keys. The max heap can be built in time $\mathcal{O}(n)$.

Query. Every position of the string is contained in at most two fragments. After each substitution operation we use a linear-time algorithm to recompute all squares in the affected fragments, requiring time $\mathcal{O}(m)$. We then update the heap in time $\mathcal{O}(\log n)$ by deleting the previous representatives (to which we have stored pointers) and inserting the new ones. We then simply retrieve the longest element in the max heap in $\mathcal{O}(1)$ time. The overall query-time complexity is $\mathcal{O}(m + \log n)$.

Correctness. The correctness of the described algorithm follows directly from the observation that each substring of S of length at most m is fully contained in at least one of the $\mathcal{O}(n/m)$ $2m$ -length fragments.

3.2 $|\text{LS}(S)| \geq m = 4k$

Let us start with an observation.

► **Observation 2.** *In a square-substring UU of S , with $|U| \geq 2k$, the first occurrence of U contains $S[i..i+k-1]$ for some $i = 1 \pmod{k}$.*

This observation guarantees that long square-substrings of S can be identified using the $\mathcal{O}(n/k)$ fragments starting at positions $i = 1 \pmod{k}$ as anchors. To this end, we maintain names for all k -length fragments of the string, such that two fragments of S have the same name if and only if they are equal. We first briefly describe the renaming technique, originating from [30], and then show how to use it in the dynamic setting.

The renaming technique. We recursively (consistently) rename pairs of letters of a string S . Let us consider the original string $S = S_0$ as the string at level 0 and the resulting string S_λ after λ iterations of renaming as the string at level λ . At level λ , the letter of S_λ at position i corresponds to $S[i..i + 2^\lambda - 1]$; in other words $S_\lambda[i] = S_\lambda[j]$ if and only if $S[i..i + 2^\lambda - 1] = S[j..j + 2^\lambda - 1]$.

Given string S_λ we rename as follows. We consider the multiset V of all pairs $p_\lambda(i) = (S_\lambda[i], S_\lambda[i + 2^\lambda - 1])$ and radix sort them in $\mathcal{O}(n)$ time. We then assign a distinct integer identifier $f(v)$ from $\{1, \dots, n\}$ to each distinct element of V . Finally, we set $S_{\lambda+1}[i] = f(p_\lambda(i))$. This process terminates after $\log n$ iterations and thus requires time $\mathcal{O}(n \log n)$ in total.

Dynamic renaming. We only maintain $\log k$ levels of renaming, i.e. strings $S_0, \dots, S_{\log k}$. We maintain the different pairs of letters at each level λ in a balanced binary search tree (bBST) B_λ ; each node of B_λ stores the name given to this pair and a counter of its occurrences in the string. We also maintain a bBST C_λ storing the letters from $\{1, \dots, n\}$ that are not currently used to rename pairs at this level. Each substitution affects at most k k -length fragments. We update their names in a bottom up manner in time $\mathcal{O}(k \log n)$ as follows. For each affected pair of letters at a level λ that changed, for example, from (a, b) to (a, c) , we search for (a, b) in B_λ and decrement its counter. In addition, if the counter reaches 0, the name given to this letter is now free and we update C_λ accordingly. We then search for (a, c) in B_λ and, (a) if we find it, we increment the counter and use the stored name, (b) else we insert (a, c) to B_λ and assign to this pair of letters the smallest element of C_λ .

In addition, for each name a of a k -length fragment (i.e. letter at level $\lambda = \log k$) we store the positions of its occurrences in S_λ in a predecessor data (bBST) structure P_a . We can perform insertions and deletions as well as perform predecessor/successor queries in P_a in $\mathcal{O}(\log n)$ time each. Below, after a brief discussion on periodicity, we will present a modification on P_a in order to compactly store the occurrences of a .

Computing squares. We would like to pair each of the k -length fragments starting at a position $i = 1 \pmod k$, with name a , with all of its other occurrences in S , which can be retrieved from the predecessor structure P_a . Let $j \neq i$ be the position of such an occurrence, and denote such a pair as (i, j) . We can assume without loss of generality that $i < j$; the other case is symmetric. For each pair, we want to check whether a square $S[a..b] = UU$, such that $a \leq i < j \leq b$ and $j - i = |U|$, exists. We call each such square an (i, j) -square. Observation 2 guarantees that every square of length at least $m = 4k$ will be identified in this manner. The following lemma shows how to perform the described check efficiently.

► **Lemma 3.** *Given two positions $i < j$, we can check whether an (i, j) -square exists and report all (i, j) -squares compactly in time $\tilde{\mathcal{O}}(1)$.*

Proof. The following observation essentially reduces computing all (i, j) -squares to answering two LCE queries. Inspect Figure 1 for an illustration.

► **Observation 4.** *An (i, j) -square UU , where i is the t -th letter of the first occurrence of U exists if and only if $\text{lcs}(i, j) \geq t$ and $\text{lcp}(i, j) \geq |U| - t + 1$.*

Now $1 \leq t \leq |U|$ and $t = i - a + 1$, where a is the starting position of such a square. Hence $a = i + 1 - t$ for $1 \leq t \leq |U|$ such that $\text{lcs}(i, j) \geq t$ and $\text{lcp}(i, j) \geq |U| - t + 1$ are the starting positions of all (i, j) -squares. Equivalently, the (i, j) -squares are the fragments $S[a..a + 2|U| - 1]$, for $i + 1 - \min\{\text{lcs}(i, j), |U|\} \leq a \leq \min\{i + \text{lcp}(i, j) - |U|, i\}$. We employ Lemma 1 to efficiently answer LCE queries. ◀

■ **Figure 1** The setting in the proof of Lemma 3. The two occurrences of U in an (i, j) -square UU are denoted by dashed rectangles. The two equal k -length fragments starting at positions i and j are denoted by gray rectangles.

Aperiodic k -length substrings. If the k -length fragment $S[i..i+k-1]$ to be processed is aperiodic, it occurs $\mathcal{O}(n/k)$ times in S . We can thus afford to employ Lemma 3 for each pair (i, j) , where $j \neq i$ is a position where $S[i..i+k-1]$ occurs. The time required to process $S[i..i+k-1]$ is thus $\tilde{\mathcal{O}}(n/k)$.

Periodic k -length substrings. If the k -length substring is periodic then we cannot process each pair individually as there could be $\Omega(n)$ of them. To overcome this, we exploit periodicity to process the pairs in batches. The lemma below follows directly from the periodicity lemma, which states that if a string has a period p and a period q , such that $p + q \leq n + \gcd(p, q)$, then $\gcd(p, q)$ is also a period of this string [22].

► **Fact 5.** *The distance between the starting positions of two consecutive occurrences of a periodic string Y with period p in a string S is either p or greater than $|Y|/2$.*

We now present an algorithm to process a k -length substring Y with period p that occurs more than $3n/k$ times in S . We can treat periodic substrings that occur fewer than $3n/k$ times with the algorithm for the aperiodic ones. Note that this is in fact necessary, as we cannot afford to compute the period of each relevant substring. Instead, we identify periodic substrings that occur frequently as follows. Remember that we have stored the positions where a k -length fragment Y with name a occurs in a predecessor data structure P_a . Then, in light of Fact 5, if Y occurs more than $3n/k$ times, two of its occurrences will have to be at distance $\text{per}(Y)$. We will identify this by checking the distance of each newly inserted element in the predecessor data structure with its predecessor and successor. If it happens to be below $|Y|/2$, we store this distance, which is $\text{per}(Y)$, as satellite information in P_a .

We call a set of positions $A = \{j + t \cdot p \mid t = 0, \dots, r\}$ a p -cluster of Y in S if $p = \text{per}(Y)$, $S[a..a+k-1] = Y$ for all $a \in A$ and $S[j-p..j-p+k-1] \neq Y \neq S[j+(t+1)p..j+(t+1)p+k-1]$. It follows directly from Fact 5 that there are $\mathcal{O}(n/k)$ p -clusters of Y in S . We maintain these p -clusters by storing p -cluster A as an arithmetic progression $(\min A, p, |A|)$ with key $\min A$ in P_a . We merge p -clusters if needed by using predecessor/successor queries in P_a upon insertions, and similarly split p -clusters if needed upon deletions.

► **Observation 6.** *Let Y be a periodic string. An occurrence of Y in S is a fragment of exactly one run R with $\text{per}(R) = \text{per}(Y)$. We say that R extends Y . The p -cluster containing this occurrence of Y corresponds to the occurrences of Y in R .*

► **Lemma 7.** *Given a periodic fragment Y and $p = \text{per}(Y)$, the run R that extends Y can be computed using a constant number of LCE queries. $R = S[i-a+1..i+p+b-1]$, where $a = \text{lcs}(i, i+p)$ and $b = \text{lcp}(i, i+p)$.*

We next show how to process the pairs yielded by each of the p -clusters in $\tilde{\mathcal{O}}(1)$ time.

► **Theorem 8.** *Given a position i in S , where Y occurs, and a p -cluster A of Y in S , we can compute a longest (i, j) -square over all $j \in A$ in time $\tilde{\mathcal{O}}(1)$. In particular, if $i \notin A$, we return a superset of all (i, j) -squares for $j \in A$ that are of length at least $4k$ in a compact form.*

■ **Figure 2** An illustration of the setting in Case 1 in the proof of Theorem 8. As before, the two occurrences of U in an (i, j) -square UU are denoted by dashed rectangles and the two equal k -length fragments starting at positions i and j are denoted by gray rectangles.

Proof. If it so happens that $i \in A$, then the longest (i, j) -square can be easily retrieved as it must lie entirely within the run $R = S[a..b]$ corresponding to A . Let $r = b - a \pmod{2p}$. It can be readily verified that either $S[a+r..b]$ or $S[a..b-r]$ is a longest (i, j) -square over all $j \in A$. (See also [17].)

In the other case, that is $i \notin A$, we first compute the unique run $R_1 = S[s_1..e_1]$ that extends the occurrence of Y at position i , and similarly the run $R_2 = S[s_2..e_2]$ corresponding to the occurrences of Y in A . This can be done in time $\tilde{O}(1)$ by performing a constant number of LCE queries, cf. Lemmas 7 and 1.

Our assumption that $i < j$ implies that $s_1 < s_2$. Let UU be an (i, j) -square with $j \in A$. We have the following cases for the occurrence of U in which $S[e_1 + 1]$ lies.

1. The first occurrence, in which case the endpoints $S[e_1]$ and $S[e_2]$ of the two runs must be aligned (i.e. be at distance $|U|$), since $\text{lcp}(i, j) > e_1 + 2 - i$. In other words, $S[e_1]$ and $S[e_2]$ must both occur as the t -th letter of an occurrence of U in the square for some t – inspect Figure 2 for an illustration. In this case we compute the longest (e_1, e_2) -square (or all (e_1, e_2) -squares) in $\tilde{O}(1)$ time using Lemma 3.
2. The second occurrence, in which case, the situation is more interesting. We have the following two subcases.
 - a. If $e_1 + 1 < s_2$, by an argument symmetric to that for the first case, the starting points $S[s_1]$ and $S[s_2]$ of the two runs must be aligned – one can think of Figure 2 reversed. As in Case 1, we can compute the longest (all) (s_1, s_2) -square(s) in $\tilde{O}(1)$ time using Lemma 3.
 - b. Else, we have that the first and second occurrences of U are fragments of runs R_1 and R_2 , respectively.

We now look into the structure yielded by the condition in Case 2b and show how to compute and represent all (possibly many) squares that satisfy it, and are essentially defined by runs R_1 and R_2 , efficiently.

► **Definition 9.** For two runs R_1 and R_2 , with period $\text{per}(R_1) = \text{per}(R_2) = p$ that overlap, we define $\text{sq}(R_1, R_2)$ to be the set of squares UU of length at least $4p$ such that the first and second occurrences of U lie entirely within R_1 and R_2 , respectively.

In what follows, we show how to compute $\text{sq}(R_1, R_2)$, which is a superset of the (i, j) -squares of length at least k for $j \in A$ since $4p \leq 4k/2 \leq 2k$. We obtain a constant number of arithmetic progressions that represent all such squares. Let us start with an example that captures the structure of $\text{sq}(R_1, R_2)$.

► **Example 10.** Consider string $(\text{baa})^4\text{a}(\text{baa})^3$. There are two runs with period $p = 3$, namely $R_1 = S[1..12]$ and $R_2 = S[12..22]$. See Figure 3 for an illustration and for the squares that satisfy the condition of Case 2b. One can see that we can get $\Omega(n)$ such squares for a string of length $\mathcal{O}(n)$, by extending this paradigm and considering string $(\text{baa})^n\text{a}(\text{baa})^n$. This example shows that a single substitution can create/destroy $\Omega(n)$ squares; think of first setting $S[n + 1] := \text{c}$ and then $S[n + 1] := \text{a}$.

■ **Figure 3** The two runs with period 3 are represented by black. The squares UU of length at least $4p$, such that the two occurrences of U are fully contained in the two runs are shown in red and blue, partitioned with respect to the first letter of the second occurrence of U .

▷ **Claim 11.** Let us suppose that we are given two runs $R_1 = S[s_1 \dots e_1]$ and $R_2 = S_2[s_2 \dots e_2]$, with $\text{per}(R_1) = \text{per}(R_2) = p$, such that $R_1[f \dots f + p - 1] = R_2[1 \dots p - 1]$ for some given $f \leq s_1 + p - 1$ and such that $s_1 \leq s_2 \leq e_1 \leq e_2$. We can compute a representation of $\text{sq}(R_1, R_2)$ in $\mathcal{O}(1)$ time.

Proof. The following fact implies that Example 10 resembles the structure of the problem.

► **Fact 12** ([32]). *Two runs with period p cannot overlap by more than $p - 1$ positions.*

Due to the condition that the first and second occurrences of U must be fragments of runs R_1 and R_2 , respectively, we have that the second occurrence of U can only start at one of the positions in $C = \{s_2, \dots, e_1 + 1\}$, where $|C| \leq p$ by Fact 12. Let us consider some $c \in C$ and characterize all squares $S[a \dots b] = UU$ with $c = a + |U|$ and $|U| \geq 2p$.

$S[c - p \dots c - 1]$ is a rotation of $S[c \dots c + p - 1]$, i.e. there exists some $\delta < p$ such that $S[c - p \dots c - 1] = S[c + \delta \dots c + p - 1]S[c \dots c + \delta - 1]$. In particular, $\delta = s_2 - f \pmod{p}$.

$|U|$ must equal $t \cdot p + \delta$ in order for the two occurrences of U to start at the same offset $\text{mod } p$ from f and s_2 ; this is necessary, since otherwise we would have two different rotations of $R_2[1 \dots p - 1]$ matching, which is impossible as it would imply that $\text{per}(R_2) < p$. In addition, all $|U|$'s of the form $t \cdot p + \delta$ for $t \geq 2$ and for which the two occurrences of U lie entirely within runs R_1 and R_2 , respectively, define valid squares. We can thus compute all these squares in $\mathcal{O}(1)$ time and represent them as an arithmetic progression with respect to $|U|$.

► **Example 13** (Continued.). For position 12 of $(baa)^4 a (baa)^3$, the blue a in Figure 3, we have $\delta = 1$ and hence the squares UU that we obtain with this as starting position of the second occurrence of U are for $|U| = 1 + 3t$, for $t = 2, 3$.

Iterating over $c \in C$ in increasing order, we only have to (a) shift all squares by 1 position each time, and (b) identify the – at most two – shifts that yield an increment/decrement in the length of the arithmetic progression due to one more/less square being allowed after the shift. We can infer the values of c for which we must increment/decrement in $\mathcal{O}(1)$ time from the endpoints of the two runs and δ . These values, p , and the arithmetic progression for $c = s_2$ are our representation of $\text{sq}(R_1, R_2)$. ◀

We can straightforwardly extract the longest (i, j) -square for $j \in A$ if it is of length at least k from this representation, and this concludes the proof of the theorem. ◀

To summarize, we spend $\tilde{\mathcal{O}}(k)$ time for the dynamic renaming and then process each of the $\mathcal{O}(n/k)$ fragments starting at positions $i = 1 \pmod{k}$ in time $\tilde{\mathcal{O}}(n/k)$, using Lemma 3 and Theorem 8. The overall time complexity of this algorithm is thus $\tilde{\mathcal{O}}(n^2/k^2 + k)$.

Wrap-up. By setting $m = 4k = n^{2/3}$ and combining the algorithms for $\text{LS}(S) \leq m$ and $\text{LS}(S) \geq m$ we obtain the following result.

► **Theorem 14.** DYNAMIC LONGEST SQUARE queries can be answered in time $\tilde{O}(n^{2/3})$, using $\tilde{O}(n)$ space, after an $\tilde{O}(n)$ -time preprocessing.

4 An $n^{o(1)}$ -time algorithm

Main Idea. If we manage to get rid of the $\mathcal{O}(m)$ time dedicated to renaming in the algorithm for computing long squares, we can then recursively obtain faster algorithms. This can be achieved by using our fastest $o(m)$ query-time dynamic algorithm for each updated $2m$ -length fragment for the case that $\text{LS}(S) \leq m$ instead of recomputing them in $\mathcal{O}(m)$ time using the static algorithm. We would then obtain a faster algorithm, and could plug this in turn for the case that $\text{LS}(S) \leq m$; and so on.

Towards the goal of getting rid of renaming, we first observe that it is wasteful to keep track of the occurrences of all k -length substrings of S . It would be sufficient to keep track of the occurrences of each k -length substring that occurs at a position $i = 1 \pmod{k}$. This could be solved by maintaining $\mathcal{O}(n/m)$ instances of dynamic pattern matching with pattern $S[i..i+k-1]$, for each $i = 1 \pmod{k}$, and text S . (Note that both the pattern and the text would have to be dynamic.) The main complication stems from the need to maintain p -clusters efficiently. To the best of our knowledge, the known pattern matching algorithms in the dynamic setting require $\Omega(\text{occ})$ time to report the occ occurrences of the pattern in the text after each update, which is unsatisfactory in our case.

2-1 Dynamic Pattern Matching. A further observation, is that we can reduce the problem to an even easier one by applying the standard trick as follows. For every substring of length k occurring at a position $i = 1 \pmod{k}$, we maintain a dynamic pattern matching instance with every substring of length $2k$ starting at a position $i = 1 \pmod{k}$. Note that every possible occurrence of the k -length fragments of interest is contained in one (and at most two) of these $2k$ -length fragments. At first glance, it may seem like this partition will be less efficient to maintain because now instead of $\mathcal{O}(n/k)$ instances of dynamic pattern matching we have $\mathcal{O}((n/k)^2)$ instances of 2-1 DYNAMIC PATTERN MATCHING – to be formally defined soon. However, this is actually lossless, since every change in S only affects $\mathcal{O}(n/k)$ such instances. Let us formally define the problem in scope.

2-1 DYNAMIC PATTERN MATCHING

Given two strings P and T with $|T| = 2|P| = 2n$, return all occurrences of P in T after each substitution operation on either of P, T .

We want to exploit the constant ratio between the lengths of the pattern and the text to obtain an efficient algorithm for 2-1 DYNAMIC PATTERN MATCHING. We further reduce this problem to another, simpler one. A partition of the text T to its n -length prefix and suffix, analogously partitions any occurrence of P at some position i . Specifically, this occurrence is partitioned to the prefix $P[1..m]$ of P , corresponding to the suffix $T[i..n]$ of $T[1..2n]$ and the suffix $P[m+1..n]$ of P , corresponding to the prefix $T[n+1..i+n-1]$ of $T[n+1..2n]$. Thus, if we know all the prefixes of P that are suffixes of $T[1..n]$, we can extend each of them in order to compute all the occurrences of P in T . (This will be a bit more involved as they will be given as arithmetic progressions, see Lemma 20.) We call a prefix of P that is a suffix of T a *prefix-suffix match of P and T* .

4.1 Dynamic Prefix-Suffix

We now focus on the following problem.

DYNAMIC PREFIX-SUFFIX
 Given two strings P and S of the same length n , report all the prefixes of P that are suffixes of S , after each substitution operation on either of P , S .

We partition each of P and S to $\lfloor n/m \rfloor$ m -length fragments and possibly an extra shorter fragment. Specifically, we partition P to $P_1, P_2, \dots, P_{\lfloor n/m \rfloor}$ with $P = P_1 P_2 \dots P_{\lfloor n/m \rfloor}$ and S to $S_{\lfloor n/m \rfloor}, S_{\lfloor n/m \rfloor - 1}, \dots, S_1$ with $S = S_{\lfloor n/m \rfloor} S_{\lfloor n/m \rfloor - 1} \dots S_1$. Fragments $P_{\lfloor n/m \rfloor}$ and $S_{\lfloor n/m \rfloor}$ are allowed to be of length less than m .

► **Observation 15.** *Let X be a prefix of P that is also a suffix of S . Let $x = \lceil |X|/m \rceil$ and $r = |X| \pmod m$. Every pair of fragments (P_i, S_j) that satisfies $i + j - 1 = x$, will satisfy that the prefix of length r of P_i will be equal to the suffix of the same length of S_j . (Inspect Figure 4 for an illustration.)*

■ **Figure 4** An illustration of the setting in Observation 15 with $x = 5$.

Algorithm. Relying on Observation 15, we design a recursive algorithm. For every $1 \leq x \leq \lfloor n/m \rfloor$ we will maintain an instance of **DYNAMIC PREFIX-SUFFIX** between some pair (P_i, S_j) that satisfies $i + j - 1 = x$. Namely, for a given x , we will consider the pair $(P_{\lceil y \rceil}, S_{\lfloor y \rfloor})$, where $y = (x + 1)/2$. It can be readily verified that $\lceil y \rceil + \lfloor y \rfloor - 1 = x$. Note that each P_i, S_j is in at most two of the considered pairs. Hence, each update in P or S results in no more than 2 such pairs being affected.

The prefix-suffix matches of each pair (S_i, P_j) are witnesses for possible prefix-suffix matches between P and S . All $\mathcal{O}(|S_i|) = \mathcal{O}(m)$ witnesses of a given pair can be confirmed with a logarithmic number of LCE queries, exploiting periodicity – the details are omitted due to space constraints.

We efficiently maintain the prefix-suffix matches for all relevant pairs using predecessor structures, analogously to how we maintained all starting positions of the occurrences of a substring corresponding to some name in Section 3, relying on the following lemma.

► **Lemma 16** (cf. [34, 6]). *The prefixes of a string P that are suffixes of a string S , with $|P|, |S| = \mathcal{O}(n)$, of lengths between 2^j and $2^{j+1} - 1$ form an arithmetic progression. If it has at least three elements, all these prefix-suffix matches have the same period, equal to the difference of the progression.*

Given a change, we recursively update the witnesses for the two affected pairs. At each level of the recursion, we confirm *all* witnesses. This is necessary since a witness that was not affected by the last substitution and was not an instance of a prefix-suffix match between P and S may have just become a prefix-suffix match between P and S due to the last substitution. The opposite case is possible as well.

After obtaining all the prefix-suffix matches we iterate over them to merge consistent periodic clusters as follows. For every $j \in \{1, \dots, \lceil \log n \rceil\}$, we group the prefix-suffix matches of lengths $s \in [2^{j-1}, \dots, 2^j - 1]$ and represent them as an arithmetic progression, relying on Lemma 16. The merging is necessary for the output of the algorithm to be in a compact form at every level of the recursion. It should also then be clear that the arithmetic progressions the algorithm returns are non-overlapping, as there is a unique such progression for the elements of length between 2^{j-1} and $2^j - 1$ for each j .

Complexity. The time complexity is $T(n) = 2T(m) + \tilde{O}(\lceil n/m \rceil) = 2T(\lfloor n/k \rfloor) + \tilde{O}(k)$ for $k = \lceil n/m \rceil$. $2T(m)$ for updating the two affected pairs and $\tilde{O}(n/m)$ for confirming and merging all witnesses. We omit the proof of the following fact.

► **Fact 17.** *If $T(n) = 2T(\lfloor n/k \rfloor) + c_1 k \log^{c_2} k$ for all $n \geq N_0$, where $k = \lfloor 2\sqrt{\log n} \rfloor$, c_1, c_2 are constants, and $T(C) = \mathcal{O}(1)$ for all $C = \mathcal{O}(1)$, then $T(n) = n^{o(1)}$.*

We arrive at the following theorem for DYNAMIC PREFIX-SUFFIX.

► **Theorem 18.** *A representation of all prefix-suffix matches as $\mathcal{O}(\log n)$ arithmetic progressions of their ending positions in P can be maintained with $n^{o(1)}$ time per substitution.*

By maintaining a DYNAMIC PREFIX-SUFFIX instance for $S = P$ we obtain the following corollary, as prefix-suffix matches correspond to borders of S .

► **Corollary 19.** *The period of a string $|S|$ can be maintained with $|S|^{o(1)}$ time per substitution.*

4.2 Wrap-up and complexity

The proof of the following lemma, which uses Theorem 18 as a black box, is omitted due to space constraints.

► **Lemma 20.** *2-1 DYNAMIC PATTERN MATCHING can be solved with $n^{o(1)}$ time per substitution, reporting the starting positions of all occurrences of P in T as an arithmetic progression.*

For the computation of long squares, after each substitution we proceed as follows.

1. We update each of the $\mathcal{O}(n/k)$ affected 2-1 DYNAMIC PATTERN MATCHING instances in $f(k) = k^{o(1)}$ time, employing Lemma 20.
2. We apply Lemma 3 and Theorem 8 a total of $\mathcal{O}(n^2/k^2)$ times.

The $\tilde{O}(n^2/k^2)$ term dominates the time complexity if $n/k \geq f(k)$. We note that f is an increasing function and hence it suffices to have $k \leq n/f(n)$.

Let us express the complexity of our best algorithm for DYNAMIC LONGEST SQUARE as $n^\alpha f(n) \log^\beta n$, for $\alpha < 1$ with $n^\alpha \geq (f(n))^2$ and for β being the maximum of the powers of $\log n$ hidden by the $\tilde{O}(\cdot)$ notation in Lemma 3 and Theorems 8 and 14. (Thus Theorem 14 shows an $\mathcal{O}(n^{2/3} \log^\beta n)$ -time algorithm.) Then, for $k = (n^2/f(n))^{1/(\alpha+2)}$, we have that

$$\mathcal{O}(n^2/k^2 \log^\beta n + k^\alpha f(k) \log^\beta n) = \tilde{O}(n^{2\alpha/(\alpha+2)} ((f(n))^{2/\alpha+2} + (f(n))^{\alpha+1/\alpha+2}) \log^\beta n) = \tilde{O}(n^{2\alpha/(\alpha+2)} f(n) \log^\beta n).$$

Note that this k satisfies the condition $k \leq n/f(n)$, since

$$k = (n^2/f(n))^{1/(\alpha+2)} \leq n/f(n) \iff f(n) \leq n^{\alpha/(\alpha+1)},$$

and the latter holds due to our assumptions on the value of α .

5:12 Repetition Detection in a Dynamic String

One can show by induction that $g^{(2^t)}(1) = 1/t$ for $g(x) = 2x/(2+x)$; note that $g(1) = 2/3$. We can thus construct an algorithm requiring time arbitrarily close to $\tilde{O}((f(n))^3) = n^{o(1)}$ time per update, recursively, since we can obtain an $\tilde{O}(n^{g^{t+1}(1)} f(n))$ -time algorithm by using the $\tilde{O}(n^{g^t(1)} f(n))$ -time algorithm for short squares. We thus arrive at the following result.

► **Theorem 21.** DYNAMIC LONGEST SQUARE queries can be answered in time $n^{o(1)}$, using $\tilde{O}(n)$ space, after an $\tilde{O}(n)$ -time preprocessing.

5 Maintaining all runs and applications

In this section, we first discuss how to modify the algorithm to maintain all runs instead of computing the longest square. Afterwards, by adapting the solutions of [17] for the static setting, we show several types of queries that can be answered with our representation of runs. In particular, we show how to maintain the number of all k -powers in $n^{o(1)}$ time and report the longest k -power in S for some fixed k within the same time complexity. All – possibly $\Theta(n^2)$ – k -powers can be reported in a compact way in $\tilde{O}(\text{runs})$ time, where runs denotes the number of runs in S . Finally, we show how to answer the following queries in $\tilde{O}(1)$ time: given a fragment determine if it is periodic, and, if so, compute its period.

We start by describing how to maintain all runs in the $\tilde{O}(n^{2/3})$ -time solution.

For short runs, we use the $\mathcal{O}(m)$ -time algorithm of [35]. For each $2m$ -length fragment, we only maintain runs that do not touch its endpoints, as we do not want to maintain a run that may extend to other fragments. (We only waive this restriction for runs that are suffixes/prefixes of S and are of length smaller than m .) This is sufficient as every run R such that $|R| < m$ will be fully contained in one (and at most two) of the $2m$ -length fragments. Upon a substitution we just recompute the runs for the two affected fragments.

As for runs of length at least $m = 4k$, we recompute all of them. Let us first amend Observation 2 as follows.

► **Lemma 22.** A run $R = S[a..b]$, of length at least $4k$, contains a fragment $S[i..i+k-1]$, for some $i = 1 \pmod{k}$, that also occurs at position $i + \text{per}(R)$.

Proof. The first $2k$ -length fragment of the run must appear again somewhere in the run (otherwise it is not even a square). This fragment, being of length $2k$, must contain a fragment $S[i..i+k-1]$ with $i = 0 \pmod{k}$ and $i \leq a+k-1$. $S[i..i+k-1]$ will certainly occur at position $i + \text{per}(R)$, since $i + \text{per}(R) + k - 1 \leq a+k-1 + |R|/2 + k - 1 \leq a + |R|/4 - 1 + |R|/2 + |R|/4 - 1 \leq b$. ◀

We then proceed as in Section 3. We first define the (i,j) -run to be the unique run R containing $S[i..j]$, in which the difference between i and j is consistent with the period of the run; formally, $j = i \pmod{p}$, where $p = \text{per}(R)$. Now observe that every run R that is longer than $4k$ is an (i,j) -run for some $i = 0 \pmod{k}$ and some j for which $S[i..i+k] = S[j..j+k]$ due to Lemma 22; in particular, the smallest such j is $j = i + \text{per}(R)$.

Observation 4 can be modified analogously as follows.

► **Observation 23.** An (i,j) -run R , exists if and only if $\text{lcs}(i,j) + \text{lcp}(i,j) \geq |j-i| + 1$. If R exists it is $S[i - \text{lcs}(i,j) + 1..j + \text{lcp}(i,j) - 1]$.

The above observation allows us to efficiently process names with less than $3n/k$ occurrences in S . As for names corresponding to k -length substrings with more occurrences, the proof of Theorem 8 shows that we can process the k -length substring $S[i..i+k-1]$ with a

p -cluster A of its occurrences as follows. If $i \in A$ we are done as we simply report the run with period p corresponding to A . Otherwise, using the notation of the proof of Theorem 8, we compute the (e_1, e_2) -run and the (s_1, s_2) -run if we are in Case 1 or 2a.

Note that a run $S[a..b]$ may be identified multiple times. We remove duplicates and store $S[a..b]$ as (a, b, p) , where p is the minimum $j - i$ for which this run was obtained as the (i, j) -run; by Lemma 22 we have that $p = \text{per}(S[a..b])$.

Case 2b is again more tricky. We adapt our solution for squares (see Theorem 8) in order to compute and maintain such runs compactly using arithmetic progressions.

► **Observation 24.** *All elements of $\text{sq}(R_1, R_2)$ of equal length are extended by the same run.*

We denote the elements of $\text{sq}(R_1, R_2)$ of length $2|U|$ by $G_{|U|}$.

► **Lemma 25.** *If the minimum starting position among the elements of $G_{|U|}$ is $u > s_1$ and the maximum ending position is $v < e_2$, then the run extending the elements of $G_{|U|}$ is $R = S[u..v]$ and $\text{per}(R) = |U|$.*

Proof. We have $u + |U| = s_2$ since $u > s_1$. If the run extending the squares of $G_{|U|}$ started at some position smaller than u , this would imply $S[u - 1..s_2 - 2] = S[s_2 - 1..s_2 + |U| - 2]$, which in turn would imply that the right hand side of the equation is a string with period p . This would contradict R_2 being a run. The argument for the other side is symmetric.

As for arguing that $\text{per}(R) = |U|$, let us assume for the sake of contradiction that it has a period $q < |U|$. Then, as $|U|$ is also a period of R , the periodicity lemma implies that $q' = \text{gcd}(|U|, q) \leq |U|/2$ is also a period of R .

We can apply the periodicity lemma again, since p is also a period of U and $p + q' \leq |U|$. We then have that $p' = \text{gcd}(p, q') < |p|/2$ is a period of $S[s_2..s_2 + |U| - 1]$ and a divisor of p . This is a contradiction as $S[s_2..s_2 + p - 1]$ is a primitive string, i.e. is not of the form T^k for a string T and $k > 1$, since otherwise $p' < p$ would also be a period of R_2 . ◀

We maintain all such runs $\text{runs}(R_1, R_2)$ compactly as a constant number of arithmetic progressions with respect to $|U|$; one for each of the at most three distinct group sizes.

Only two groups of squares may contain a square that starts in the first position of R_1 or ends in the last position of R_2 . These groups of squares are the only ones such that the run extending them may not be fully contained in $S[s_1..e_2]$. This could be the case for example if we had a run R_3 with the same period and appropriate overlap with R_2 . We compute the run extending a square of each of the at most two relevant groups using LCE queries and maintain these runs explicitly.

All (explicitly or compactly represented) runs are stored in a way that allows for efficient deletion, using a key with respect to their origin, i.e. the substring at some level of the recursion for which they were computed. After each substitution, the algorithm computes all the relevant runs for the substring that contains the updated position at each level of the recursion from scratch. Thus, for every substring for which we recompute runs, we first delete all runs that have this substring as key.

► **Theorem 26.** *We can maintain all runs $R = S[a..b]$ of a string of length n , as triplets $(a, b, \text{per}(R))$ and arithmetic progressions with $n^{o(1)}$ time per operation, using $\tilde{O}(n)$ space, after $\tilde{O}(n)$ -time preprocessing.*

5.1 Application I: k -powers

Let us recall that a k -power is a string of the form U^k for some non-empty string U . The authors of [17] show that given a run R as (a, b, p) , one can compute in $\mathcal{O}(1)$ time:

1. a longest substring U^k of R with $\text{per}(R) \mid |U|$;
2. the number of all fragments $S[a..b] = V^k$, with $\text{per}(R) \mid |V|$, that lie entirely within R .

For any fixed $k \geq 3$, we can maintain the longest k -power by storing a heap keeping the longest that each explicitly stored run contributes and maintain the count on the number of k -powers (not distinct) in S within the time complexities of Theorem 26. Note that by Lemma 25 and the fact that $v - u \leq 2|U| + p$ and $|U| \geq 2p$, where u, v, p and $|U|$ are as in the statement of that lemma, we have that the runs stored as arithmetic progressions do not contribute any k -powers for $k \geq 3$. Finally, we can extract all – possibly $\Theta(n^2)$ – non-distinct k -powers in $\tilde{\mathcal{O}}(\text{runs})$ time in a compact form from the runs [17].

► **Remark 27.** As for maintaining the $\mathcal{O}(n)$ distinct k -powers efficiently, we should first be able to group runs by their Lyndon roots (the Lyndon root of a run R is the lexicographically smallest rotation of a $\text{per}(R)$ -length substring of R). It is not clear how to amend our solution to maintain the runs in this way.

5.2 Application II: 2-Period Queries

2-PERIOD QUERIES

Given a fragment $S[i..j]$ of S , decide whether $S[i..j]$ is periodic and, if so, compute its period.

2-Period Queries in a static string. 2-PERIOD QUERIES were introduced in [17], while general internal period queries were introduced in [33]. The authors of [34] showed how to optimally answer 2-PERIOD QUERIES in $\mathcal{O}(1)$ time after $\mathcal{O}(n)$ -time preprocessing. In these works, it is shown, that in order to answer the query for $S[i..j]$ it suffices to find the run R that extends $S[i..j]$, or conclude that there is no such run. In other words, it suffices to find the run R with the smallest period among the runs fully containing $S[i..j]$. Then, if $\text{per}(R) < (j - i)/2$, the fragment is periodic with period $\text{per}(R)$ and otherwise it is not.

To the best of our knowledge there is no prior work on answering internal period queries in a dynamic string. In what follows we sketch the proof of the following result – the details are omitted due to space constraints.

► **Theorem 28.** 2-PERIOD QUERIES can be answered in $\tilde{\mathcal{O}}(1)$ time in a string S of length n , with each substitution operation processed in time $n^{o(1)}$, after an $\tilde{\mathcal{O}}(n)$ -time preprocessing. The required space is $\tilde{\mathcal{O}}(n)$.

In order to compute the run with the smallest period that contains $S[i..j]$, the authors of [17] show that it is enough to be able to answer orthogonal range minimum queries in 2-d, over the following collection of points: for each run (a, b, p) we have point (a, b) with weight p . The desired run then corresponds to the point with minimum weight in the rectangle $[1, i] \times [j, n]$. A restricted version of the main result of [14], is that one can maintain a collection of $\mathcal{O}(n)$ points in $[n]^d$, for any constant d , with $\tilde{\mathcal{O}}(1)$ time per update, such that orthogonal range emptiness queries can be answered in $\tilde{\mathcal{O}}(1)$ time. We note that 2-d orthogonal range minimum queries reduce to 3-d orthogonal range emptiness queries via binary search. We maintain this data structure over the runs that are maintained explicitly, see Theorem 26. The above discussion covers the case that the run extending $S[i..j]$ has

been stored explicitly. In particular, following our discussion in Section 5.1, we are already able to answer 3-PERIOD QUERIES, i.e. whether a substring $S[i..j]$ has period at most $\lfloor j-i \rfloor/3$, and if so, return this period.

As for 2-PERIOD QUERIES, we now provide the intuition for handling the case that the run of minimum period that contains $S[i..j]$ is stored implicitly. We want to check all runs extending some square $UU \in \text{sq}(R_1, R_2)$ that is a prefix of $S[i..j]$, for some runs R_1, R_2 . Note that our definition of $\text{sq}(R_1, R_2)$ implies that $\text{per}(U) = \text{per}(R_1) \leq |U|/2$; i.e. R_1 extends U . The following lemma implies that we can only have a logarithmic number of such squares.

► **Lemma 29** ([32, Corollary 5.1.3]). *Let U_1, U_2, U_3 be periodic fragments of a text T , all starting at the same position, and being extended by runs R_1, R_2 and R_3 , respectively. If $\lfloor \log |U_1| \rfloor = \lfloor \log |U_2| \rfloor = \lfloor \log |U_3| \rfloor$, then the three runs R_1, R_2 and R_3 cannot be all distinct.*

For every set $\text{runs}(R_1, R_2)$, we add the point (s_1, e_2, p) in an initially empty 3-d grid – we use the same notation as above. We report all relevant points using 3-d dynamic orthogonal range reporting queries, again employing [14]. In particular, we first retrieve the points in the range $[1, i] \times [j, n] \times [1, \lfloor j-i \rfloor/4]$. There are $\mathcal{O}(\log n)$ of them due to the above lemma. Then, for each point, corresponding say to $\text{runs}(R_1, R_2)$, we compute in $\tilde{\mathcal{O}}(1)$ time the run of smallest period in $\text{runs}(R_1, R_2)$ containing $S[i..j]$. In particular it is the run of minimum length in $\text{runs}(R_1, R_2)$ containing $S[i..j]$ by Lemma 25.

6 Concluding remarks

We believe that, with due care, our algorithm can be adapted to handle insertions and deletions – the details are omitted due to space constraints. We leave open the questions of whether the runs of a string (or other information sufficient for answering 2-PERIOD QUERIES in $\tilde{\mathcal{O}}(1)$ time) can be maintained with $\tilde{\mathcal{O}}(1)$ time per update and whether period queries for aperiodic substrings can be answered efficiently in a dynamic string.

Abstract

Given two strings S and T , each of length at most n , the longest common substring (LCS) problem is to find a longest substring common to S and T . This is a classical problem in computer science with an $\mathcal{O}(n)$ -time solution. In the fully dynamic setting, edit operations are allowed in either of the two strings, and the problem is to find an LCS after each edit. We present the first solution to this problem requiring sublinear time in n per edit operation. In particular, we show how to find an LCS after each edit operation in $\tilde{\mathcal{O}}(n^{2/3})$ time, after $\tilde{\mathcal{O}}(n)$ -time and space preprocessing.¹

This line of research has been recently initiated in a somewhat restricted dynamic variant by Amir et al. [SPIRE 2017]. More specifically, they presented an $\tilde{\mathcal{O}}(n)$ -sized data structure that returns an LCS of the two strings after a single edit operation (that is reverted afterwards) in $\tilde{\mathcal{O}}(1)$ time. At CPM 2018, three papers (Abedin et al., Funakoshi et al., and Urabe et al.) studied analogously restricted dynamic variants of problems on strings. We show that the techniques we develop can be applied to obtain fully dynamic algorithms for all of these variants. The only previously known sublinear-time dynamic algorithms for problems on strings were for maintaining a dynamic collection of strings for comparison queries and for pattern matching, with the most recent advances made by Gawrychowski et al. [SODA 2018] and by Clifford et al. [STACS 2018].

As an intermediate problem we consider computing the solution for a string with a given set of k edits, which leads us, in particular, to answering *internal* queries on a string. The input to such a query is specified by a substring (or substrings) of a given string. Data structures for answering internal string queries that were proposed by Kociumaka et al. [SODA 2015] and by Gagie et al. [CCCG 2013] are used, along with new ones, based on ingredients such as the suffix tree, heavy-path decomposition, orthogonal range queries, difference covers, and string periodicity.

1 Introduction

Given two strings S and T , each of length at most n , the longest common substring (LCS) problem, also known as the longest common factor problem, is to find a longest substring common to S and T . This is a classical problem in theoretical computer science. Knuth had conjectured that the LCS problem was in $\Omega(n \log n)$. In 1973 Weiner solved it in the optimal $\mathcal{O}(n)$ time [49] designing a data structure that was later called the suffix tree (see also [21]). Knuth declared Weiner’s algorithm the “Algorithm of the Year” [11]. Since $\mathcal{O}(n)$ time is optimal for this problem, a series of studies have been dedicated in improving the working space [37, 44]. The LCS problem has also been studied under Hamming and edit distance. We refer the interested reader to [1, 43, 47, 16, 46, 12] and references therein.

In [43], Starikovskaya mentions that an answer to the LCS problem “is not robust and can vary significantly when the input strings are changed even by one character”, implicitly posing the following question: *Can we compute an LCS after editing S or T in $o(n)$ time?*

► **Example 1.** The length of an LCS of S and T below is *doubled* when substitution $S[4] := a$ is performed. The next substitution, $T[3] := b$, *halves* the length of an LCS.

$S = \underline{caabaaa}$	$S[4] := a$	$S = \underline{caaaaaa}$	$T[3] := b$	$S = \underline{caaaaaa}$
$T = \underline{aaaaaab}$		$T = \underline{aaaaaab}$		$T = \underline{aabaaab}$

This question poses the challenge of dynamically updating the suffix tree in the presence of edit operations (i.e. insertions, deletions and substitutions), which remains the main obstacle for answering this type of questions.

Amir et al. [8] introduced a restricted dynamic variant, where any *single* edit operation is allowed and is reverted afterwards. We call this problem LCS AFTER ONE EDIT. Amir et al. presented an $\tilde{\mathcal{O}}(n)$ -sized data structure that can be constructed in $\tilde{\mathcal{O}}(n)$ time supporting $\tilde{\mathcal{O}}(1)$ -time computation of an LCS, after one edit operation is applied on S . This work initiated a new line of research on analogously restricted dynamic variants of problems on strings [26, 27, 48]. Abedin et al. [3] improved the complexities of the data structure proposed by Amir et al. [8] by $\log^{\mathcal{O}(1)} n$ factors. Two other restricted variants of the dynamic LCS problem were considered by Amir and Boneh in [5]. In both variants substitutions were allowed in one of the strings; one was of decremental nature and in the other one the complexity was parameterized by the period of the static string.

In this paper we make substantial progress: we show a strongly sublinear-time solution for the general version of the problem, namely, the fully dynamic case of the LCS problem. Given two strings S and T , the problem is to answer the following type of queries in an on-line manner: perform an edit operation (substitution, insertion, or deletion) on S or on T and then return an LCS of the new S and T . We call this problem FULLY DYNAMIC LCS.

Below we mention some of the known results on dynamic problems on strings.

Dynamic Pattern Matching. Finding all *occ* occurrences of a pattern of length m in a *static* text can be performed in the optimal $\mathcal{O}(m + occ)$ time using suffix trees, which can be constructed in linear time [49, 21]. In the fully dynamic setting, the problem is to compute the new set of occurrences when allowing for edit operations anywhere on the text. A considerable amount of work has been carried out on this problem [31, 22, 23]. The first data structure with polylogarithmic update time and time-optimal queries was shown by Sahinalp and Vishkin [41]. The update time was later improved by Alstrup et al. [4] at the expense of slightly suboptimal query time. The state of the art is the data structure by

Gawrychowski et al. [29] supporting time-optimal queries with $\mathcal{O}(\log^2 n)$ time for updates. Clifford et al. [18] have recently shown upper and lower bounds for variants of exact matching with wildcard characters, inner product, and Hamming distance.

Dynamic String Collection with Comparison. The problem is to maintain a dynamic collection \mathcal{W} of strings of total length n supporting the following operations: adding a string to \mathcal{W} , adding the concatenation of two strings from \mathcal{W} to \mathcal{W} , splitting a string from \mathcal{W} and adding the two residual strings in \mathcal{W} , and returning the length of the longest common prefix of two strings from \mathcal{W} . This line of research was initiated by Sundar and Tarjan [45]. Data structures supporting updates in polylogarithmic time were presented by Mehlhorn et al. [40] and Alstrup et al. [4]. Finally, Gawrychowski et al. [30] proposed an optimal solution.

Longest Palindrome and Longest Lyndon Substring. A string is called *palindrome* if it is the same as its reverse. A string is called *Lyndon* if it is smaller lexicographically than all its suffixes [38]. Computing a longest palindrome and a longest Lyndon substring of a string after a single edit have been recently studied in [26] (see also [27]) and in [48], respectively.

Maintaining Repetitions. *Squares* are strings of the form XX . In [7], the authors show how to maintain squares in a dynamic string S of length n in $n^{o(1)}$ time per operation. A modification of this algorithm, with the same time complexity per operation, allows them to determine in $\tilde{\mathcal{O}}(1)$ time whether a queried substring of S is periodic, and if so, compute its period.

Our Results. We give the first fully dynamic algorithm for the LCS problem that works in *strongly sublinear* time per edit operation in any of the two strings. Specifically, for two strings, each of length up to n , it computes an LCS after each edit operation in $\tilde{\mathcal{O}}(n^{2/3})$ time after $\tilde{\mathcal{O}}(n)$ -time and space preprocessing. To ease the comprehension of the algorithm for FULLY DYNAMIC LCS, we first show a solution of an auxiliary problem called LCS AFTER ONE SUBSTITUTION PER STRING, where a single substitution is allowed in each of the strings and is reverted afterwards, with $\tilde{\mathcal{O}}(1)$ -time queries after $\tilde{\mathcal{O}}(n)$ -time and space preprocessing.

Notably, we showcase the applicability of our techniques to other string problems in the fully dynamic setting. We present a fully dynamic algorithm for computing a longest repeat of a string S of length n , i.e. a longest substring occurring more than once in S , in $\tilde{\mathcal{O}}(n^{2/3})$ time. We also present a fully dynamic algorithm for computing a longest palindrome substring of a string S requiring $\tilde{\mathcal{O}}(\sqrt{n})$ time per edit. Finally, we present a fully dynamic algorithm, requiring $\tilde{\mathcal{O}}(\sqrt{n})$ time per edit, for computing a longest Lyndon substring of string S as well as maintaining a representation of the Lyndon factorization of S that allows us to efficiently extract the t -th element of the factorization in $\tilde{\mathcal{O}}(1)$ time.

Our data structure is randomized due to the use of data structures for dynamic strings [30] and internal pattern matching [35]; the latter can be derandomized [34].

Roadmap. Section 2 provides the necessary definitions and notation used throughout as well as the standard algorithmic toolbox for string processing and the general scheme of our approach. In Section 3 we show an optimal, up to polylogarithmic factors, solution for LCS AFTER ONE SUBSTITUTION PER STRING. In Section 4 we show our main result: a solution for FULLY DYNAMIC LCS. Some technical details, including details on several special cases of internal LCS queries, are omitted in this version. A brief overview of our fully dynamic algorithms for computing the longest repeat, the longest palindrome, and the longest Lyndon substring of a string is provided in Section 5. We conclude this work in Section 6.

2 Preliminaries

Strings. Let $S = S[1]S[2] \dots S[n]$ be a *string* of length $|S| = n$ over an integer alphabet $\Sigma = \{1, \dots, n^{\mathcal{O}(1)}\}$. The elements of Σ are called *characters*. For two positions i and j on S , we denote by $S[i..j] = S[i] \dots S[j]$ the substring of S that starts at position i and ends at position j (it is empty if $i > j$). A substring of S is represented in $\mathcal{O}(1)$ space by specifying the indices i and j . A prefix $S[1..j]$ is denoted by $S^{(j)}$ and a suffix $S[i..n]$ is denoted by $S_{(i)}$. A substring of S is called *proper* if it is shorter than S . We denote the *reverse string* of S by $S^R = S[n]S[n-1] \dots S[1]$. By ST , S^k , and S^∞ we denote the concatenation of strings S and T , k copies of string S , and infinitely many copies of string S , respectively. If a string B is both a proper prefix and a proper suffix of string S , then B is called a *border* of S . A positive integer p is called a *period* of S if $S[i] = S[i+p]$ for all $i = 1, \dots, n-p$. String S has a period p if and only if it has a border of length $n-p$. We refer to the smallest period as *the period* of the string and, analogously, to the longest border as *the border* of the string.

The *suffix tree* $\mathcal{T}(S)$ of string S is a compact trie representing all suffixes of S . The suffix tree of a string of length n over an integer alphabet can be constructed in $\mathcal{O}(n)$ time and space [21]. By $\text{lcpstring}(S, T)$ we denote the longest common prefix of S and T , by $\text{lcp}(S, T)$ we denote $|\text{lcpstring}(S, T)|$, and by $\text{lcp}(r, s)$ we denote $\text{lcp}(S_{(r)}, S_{(s)})$. Further by $\text{lcssstring}(S, T)$ we denote the longest common suffix of S and T . An $\mathcal{O}(n)$ -sized lowest common ancestor data structure can be constructed over the suffix tree of S in $\mathcal{O}(n)$ time [14], supporting $\text{lcp}(r, s)$ -queries in $\mathcal{O}(1)$ time. A symmetric construction on S^R (the reverse of S) can answer the so-called *longest common suffix* (lcs) queries in the same complexity. The lcp and lcs queries are also known as *longest common extension* (LCE) queries.

General Scheme and Relation to Internal Pattern Matching. The scheme of our approach for most of the considered dynamic problems on strings is as follows. Let the input be a string S of length n (in the case of the LCS problem, this can be the concatenation of the input strings S and T separated by a delimiter). We construct a data structure that answers the following type of queries: given k edit operations on S , compute the answer to a particular problem on the resulting string S' . Assuming that the data structure occupies $\mathcal{O}(s_n)$ space, answers queries for k edits in time $\mathcal{O}(q_n(k))$ and can be constructed in time $\mathcal{O}(t_n)$ ($s_n \geq n$ and $q_n(k) \geq k$ is non-decreasing with respect to k), this data structure can be used to design a dynamic algorithm that preprocesses the input string in time $\mathcal{O}(t_n)$ and answers queries dynamically under edit operations in amortized time $\mathcal{O}(q_n(\kappa))$, where κ is such that $q_n(\kappa) = (t_n + n)/\kappa$, using $\mathcal{O}(s_n)$ space. The query time can be made worst-case using *time slicing*: for $s_n, t_n = \tilde{\mathcal{O}}(n)$ and $q_n(k) = \tilde{\mathcal{O}}(k)$ we obtain a fully dynamic algorithm with $\tilde{\mathcal{O}}(\sqrt{n})$ -time queries, whereas for $q_n(k) = \tilde{\mathcal{O}}(k^2)$ the query time is $\tilde{\mathcal{O}}(n^{2/3})$.

A *k-substring* of a string S is a concatenation of k strings, each of which is either a substring of S or a single character. A k -substring of S can be represented in $\mathcal{O}(k)$ additional space using a doubly-linked list if the string S itself is stored. The string S after k subsequent edit operations can be represented as a $(2k+1)$ -substring due to the following lemma.

► **Lemma 2.** *Let S' be a k -substring of S and S'' be S' after a single edit operation. Then S'' is a $(k+2)$ -substring of S . Moreover, S'' can be computed from S' in $\mathcal{O}(k)$ time.*

Proof. Let $S' = F_1 \dots F_k$ where each F_i is either a substring of S or a single character. We traverse the list of substrings until we find the substring F_i such that the edit operation takes place at the j -th character of F_i . As a result, F_i is decomposed into a prefix and a suffix, potentially with a single character inserted in between in case of insertion or substitution. The resulting string S'' is a $(k+2)$ -substring of S . ◀

Thus the fully dynamic version reduces to designing a data structure over a string S of length n that computes the result of a specific problem on a k -substring $F_1 \dots F_k$ of S . For the considered problems we aim at computing the longest substring of S that satisfies a certain property. Then there are two cases. Case 1: the sought substring occurs inside one of the substrings F_i (or each of its two occurrences satisfies this property in case of the LCS and the longest repeat problems). Case 2: it contains the boundary between some two substrings F_i and F_{i+1} . Case 1 requires to compute the solution to a certain problem on a substring or substrings of a specified string. This is the so-called *internal* model of queries; this name was coined by Kociumaka et al. in [35]. We call Case 2 *cross-substring* queries. Due to string periodicity, certain internal queries arise in cross-substring queries as well.

3 LCS After One Substitution Per String

Let us now consider an extended version of the LCS AFTER ONE EDIT problem, for simplicity restricted to substitutions.

LCS AFTER ONE SUBSTITUTION PER STRING

Input: Two strings S and T of length at most n

Query: For given indices i, j and characters α and β , compute $\text{LCS}(S', T')$ where S' is S after substitution $S[i] := \alpha$ and T' is T after substitution $T[j] := \beta$

To solve this problem we consider three cases depending on whether an occurrence of the LCS contains any of the changed positions in S and T . We prove the following result.

► **Theorem 3.** LCS AFTER ONE SUBSTITUTION PER STRING can be computed in $\tilde{O}(1)$ time after $\tilde{O}(n)$ -time and space preprocessing.

3.1 LCS Contains No Changed Position

We use the following lemma for a special case of internal LCS queries. Its proof is deferred to the full version. In the fully dynamic algorithm a less restrictive approach is necessary.

► **Lemma 4.** Let S and T be two strings of length at most n . After $\mathcal{O}(n \log^2 n)$ -time and $\mathcal{O}(n \log n)$ -space preprocessing, an LCS between any prefix or suffix of S and prefix or suffix of T can be computed in $\mathcal{O}(\log n)$ time.

It suffices to apply internal LCS queries of Lemma 4 four times: each time for one of $S^{(i-1)}, S_{(i+1)}$ and one of $T^{(j-1)}, T_{(j+1)}$.

3.2 LCS Contains a Changed Position in Exactly One of the Strings

We use the following lemma that encapsulates one of the main techniques of [8]. It involves computing so-called *ranges* of substrings in the *generalized suffix array* of S and T and it relies on a result by Fischer et al. [24].

► **Lemma 5.** Let S and T be strings of length at most n . After $\mathcal{O}(n \log \log n)$ -time and $\mathcal{O}(n)$ -space preprocessing, given two substrings P and Q of S or T , we can compute:

- (a) a substring of T equal to PQ , if it exists, in $\mathcal{O}(\log \log n)$ time;
- (b) the longest substring of T that is a prefix (or a suffix) of PQ in $\mathcal{O}(\log n \log \log n)$ time.

We now show how to compute the longest substring that contains the position i in S , but not the position j in T (the opposite case is symmetric). We first use Lemma 5(b) to compute two substrings, U and V , of T in $\mathcal{O}(\log n \log \log n)$ time:

- U is the longest substring of T that is equal to a suffix of $S[1 \dots i - 1]$;
- V is the longest substring of T that is equal to a prefix of $\alpha S[i + 1 \dots |S|]$.

■ **Figure 1** Occurrences of an LCS of S' and T' containing both changed positions are denoted by dashed rectangles. Occurrences of U at which an LCS is aligned are denoted by gray rectangles.

Our task then reduces to computing the longest substring of UV that crosses the boundary between U and V and is a substring of $T^{(j-1)}$ or of $T_{(j+1)}$. We can compute it using the following type of queries.

THREE SUBSTRINGS LCS
Input: A string T
Query: Given three substrings U , V , and W of T , compute the longest substring XY of W such that X is a suffix of U and Y is a prefix of V

Indeed, it suffices to ask two THREE SUBSTRINGS LCS queries: one with $W = T^{(j-1)}$ and one with $W = T_{(j+1)}$.

A solution to a special case of THREE SUBSTRINGS LCS queries with $W = T$ was already implicitly presented by Amir et al. in [8]. It is based on the *heaviest induced ancestors* (HIA) problem on trees, introduced by Gagie et al. [28], applied to the suffix tree of T . We generalize the HIA queries and use them to answer general THREE SUBSTRINGS LCS queries. The data structure for answering our generalization of HIA queries turns out to be one of the most technical parts of the paper. It relies on the construction of multidimensional grids for pairs of heavy paths (in heavy-path decompositions [42]) of the involved trees. Each query can be answered by interpreting the answer of $\mathcal{O}(\log^2 n)$ orthogonal range maximum queries over such grids.

► **Lemma 6.** *Let T be a string of length at most n . After $\tilde{\mathcal{O}}(n)$ -time preprocessing, we can answer THREE SUBSTRINGS LCS queries in $\tilde{\mathcal{O}}(1)$ time.*

3.3 LCS Contains a Changed Position in Each of the Strings

A Prefix-Suffix Query gets as input two substrings X and Y of a string S of length n and an integer d and returns the lengths of all prefixes of X of length between d and $2d$ that are suffixes of Y . It is known that such a query returns an arithmetic sequence and if it has at least three elements, then its difference equals the period of all the corresponding prefixes-suffixes. Moreover, Kociumaka et al. [35] show that Prefix-Suffix Queries can be answered in $\mathcal{O}(1)$ time using a data structure of $\mathcal{O}(n)$ size, which can be constructed in $\mathcal{O}(n)$ time. By considering $X = Y = U$, this implies the two respective points of the lemma below.

► **Lemma 7.**

- (a) *For a string U of length m , the set $\mathcal{B}_r(U)$ of border lengths of U between 2^r and $2^{r+1} - 1$ is an arithmetic sequence. If it has at least three elements, all the corresponding borders have the same period, equal to the difference of the sequence.*
- (b) *[35] Let S be a string of length n . For any substring U of S and integer r , the arithmetic sequence $\mathcal{B}_r(U)$ can be computed in $\mathcal{O}(1)$ time after $\mathcal{O}(n)$ -time and space preprocessing.*

■ **Figure 2** A border of length u is denoted by dark gray rectangles. An LCS aligned at a border of length $u - 3p$, which is in the same arithmetic sequence, is denoted by the dashed rectangle.

We next show an algorithm that finds a longest string $S'[i_\ell \dots i_r] = T'[j_\ell \dots j_r]$ such that $i_\ell \leq i \leq i_r$ and $j_\ell \leq j \leq j_r$ for the given indices i, j . Let us assume that $i - i_\ell \leq j - j_\ell$; the symmetric case can be treated analogously. We have that $U \stackrel{\text{def}}{=} S'[i + 1 \dots i_\ell + j - j_\ell - 1] = T'[j_\ell + i - i_\ell + 1 \dots j - 1]$ as shown in Figure 1. ($U = \varepsilon$ can correspond to $i - i_\ell = j - j_\ell$ or $i - i_\ell + 1 = j - j_\ell$, so both these cases need to be checked.) Note that these substrings do not contain any changed position. Any such U is a prefix of $S_{(i+1)}$ and a suffix of $T^{(j-1)}$; let U_0 denote the longest such string. Then, the possible candidates for U are U_0 and all its borders. For a border U of U_0 , we say that $\text{lcsstring}(S'^{(i)}, T'^{(j-|U|-1)}) U \text{lcpstring}(S'_{(i+|U|+1)}, T'_{(j)})$ is an *LCS aligned at U* . We compute U_0 in time $\mathcal{O}(\log n)$ by asking Prefix-Suffix Queries for $X = S_{(i+1)}$, $Y = T^{(j-1)}$ in $S\#T$ and $d = 2^r$ for all $r = 0, 1, \dots, \lfloor \log j \rfloor$. We then consider the borders of U_0 in arithmetic sequences of their lengths; see Lemma 7. If an arithmetic sequence has at most two elements, we compute an LCS aligned at each of the borders in $\mathcal{O}(1)$ time by the above formula using LCE queries. Otherwise, let p be the difference of the arithmetic sequence, ℓ be its length, and u be its maximum element. Further let:

$$\begin{aligned} X_1 &= S'_{(i+u+1)}, & Y_1 &= T'_{(j)}, & P_1 &= S'[i + u - p + 1 \dots i + u], \\ X_2^R &= T'^{(j-u-1)}, & Y_2^R &= S'^{(i)}, & P_2^R &= T'[j - u \dots j - u + p - 1]. \end{aligned}$$

The setting is presented in Figure 2. It can be readily verified (inspect Figure 2) that a longest common substring aligned at the border of length $u - wp$, for $w \in [0, \ell - 1]$, is equal to

$$\text{lcs}(X_2^R (P_2^R)^w, Y_2^R) + u - wp + \text{lcp}(P_1^w X_1, Y_1) = \text{lcp}(P_2^w X_2, Y_2) + \text{lcp}(P_1^w X_1, Y_1) + u - wp$$

which we further denote by $g(w)$. Thus, a longest LCS aligned at a border whose length is in this arithmetic sequence is $\max_{w=0}^{\ell-1} g(w)$. The following observation facilitates efficient evaluation of this formula.

► **Observation 8.** *For any strings P, X, Y , the function $f(w) = \text{lcp}(P^w X, Y)$ for integer $w \geq 0$ is piecewise linear with at most three pieces. Moreover, if P, X, Y are substrings of a string S , then the exact formula of f can be computed with $\mathcal{O}(1)$ LCE queries on S .*

Proof. Let $a = \text{lcp}(P^\infty, X)$, $b = \text{lcp}(P^\infty, Y)$, and $p = |P|$. Then:

$$f(w) = \begin{cases} a + wp & \text{if } a + wp < b \\ w + \text{lcp}(X, Y[aw + 1 \dots |Y|]) & \text{if } a + wp = b \\ b & \text{if } a + wp > b. \end{cases}$$

Note that a can be computed from $\text{lcp}(P, X)$ and $\text{lcp}(X, X[p+1 \dots |X|])$, and b analogously. Thus if P, X, Y are substrings of S , five LCE queries on S suffice. ◀

By Observation 8, $g(w)$ can be expressed as a piecewise linear function with $\mathcal{O}(1)$ pieces. Moreover, its exact formula can be computed using $\mathcal{O}(1)$ LCE queries on $S' \# T'$, hence, in $\mathcal{O}(1)$ time using LCE queries. This allows to compute $\max_{w=0}^{\ell-1} g(w)$ in $\mathcal{O}(1)$ time. Each arithmetic sequence is processed in $\mathcal{O}(1)$ time. The global maximum that contains both changed positions is the required answer. Thus the query time in this case is $\mathcal{O}(\log n)$ and the preprocessing requires $\mathcal{O}(n)$ time and space.

By combining the results of Sections 3.1 to 3.3, we arrive at Theorem 3.

4 Fully Dynamic LCS

In this section we assume that the sought LCS has length at least 2. The case that it is of unit or zero length can be easily treated separately. We use the following auxiliary problem that generalizes LCS AFTER ONE SUBSTITUTION PER STRING into the case of k edit operations:

(k_1, k_2) -SUBSTRING LCS

Input: Two strings S and T of length at most n

Query: Compute $\text{LCS}(S', T')$ where $S' = F_1 \dots F_{k_1}$ is a k_1 -substring of S , $T' = G_1 \dots G_{k_2}$ is a k_2 -substring of T , and $k_1 + k_2 = k$

As in Section 3, we consider three cases listed below. The main difference in the approach takes place in the first case since the most general internal LCS queries are probably hard to answer. Indeed, this query can be reduced via a binary search to $\mathcal{O}(\log n)$ two-range-LCP queries of Amir et al. [10]. With their Theorem 6, we can construct a data structure of size $\mathcal{O}(n)$ in $\mathcal{O}(n\sqrt{n})$ time that allows for $\tilde{\mathcal{O}}(\sqrt{n})$ -time queries. We cannot use this data structure in our scheme though due to its high preprocessing cost. In fact, Amir et al. [10] show that the two-range-LCP data structure problem is at least as hard as the *Set Emptiness* problem: preprocess a collection of sets of total cardinality n so that queries of whether the intersection of two sets is empty can be answered efficiently. The best known $\mathcal{O}(n)$ -sized data structure for this problem has $\mathcal{O}(\sqrt{n/w})$ -query-time, where w is the size of the computer word. The reduction of [10] can be adapted to show that answering general internal LCS queries is at least as hard as answering Set Emptiness queries. In light of this, in the first case, we develop a different global approach to circumvent answering such queries.

1. An LCS does not contain any position (or boundary between positions) in S or T where an edit took place. As it was mentioned before, this problem probably cannot be solved efficiently in the language of k -substrings. Instead, we compute such an LCS via an inherently dynamic algorithm for the DECREMENTAL LCS problem. See Section 4.1.
2. An LCS contains at least one position where an edit operation took place in exactly one of the strings. This corresponds to the (k_1, k_2) -SUBSTRING LCS problem when an LCS contains the boundary between some substrings of exactly one of S' and T' . We compute such an LCS by combining the techniques of Section 3.2 with a sliding window approach. See Section 4.2.
3. An LCS contains at least one position where an edit operation took place in both of the strings. This corresponds to the (k_1, k_2) -SUBSTRING LCS problem when an LCS contains the boundary between some substrings in both of S' and T' . We compute such an LCS by building upon the techniques of Section 3.3 and employing efficient LCE queries for k -substrings. See Section 4.3.

4.1 Decremental LCS

We use the following convenient formulation of the problem, where the only letter that can be inserted or substituted in S (resp. in T) is $\# \notin \Sigma$, (resp. $\$ \notin \Sigma$), with $\# \neq \$$. An insertion in S in FULLY DYNAMIC LCS corresponds to an insertion of a $\#$, while both deletions and substitutions correspond to substitutions with a $\#$. T is treated similarly. We call the problem of reporting an LCS after each such operation DECREMENTAL LCS.

We first consider the case where the sought LCS (in the fully dynamic case) is of length bounded by d ; we call this problem d -BOUNDED-LENGTH LCS.

Before we proceed to describe a solution to this problem we discuss how to answer LCE queries efficiently in a dynamic string. We resort to the main result of Gawrychowski et al. [30] to obtain the following lemma.

► **Lemma 9.** *A string S of length n can be preprocessed in $\mathcal{O}(n)$ time and space so that $k = \mathcal{O}(n)$ edit operations and $m = \mathcal{O}(n)$ lcp queries, in any order, can be processed in $\mathcal{O}(\log n)$ time each, using $\mathcal{O}(k \log n + m \log n)$ space in total.*

► **Lemma 10.** *d -BOUNDED-LENGTH LCS can be solved in $\mathcal{O}(d \log^2 n)$ time per operation after $\tilde{\mathcal{O}}(n)$ -time preprocessing, using $\tilde{\mathcal{O}}(n + kd)$ space for k performed operations.*

Proof. Let U and V be the multisets of d -length substrings and the $d - 1$ suffixes of length smaller than d of S and T , respectively. We will maintain balanced BSTs B_X , with respect to the lexicographical order, containing the elements of X , for $X = U, V$, stored as substrings. We can search in these balanced BSTs in $\mathcal{O}(\log^2 n)$ since a comparison in it is an lcp query, which requires $\mathcal{O}(\log n)$ by Lemma 9, possibly followed by a character comparison. Each node of B_X will maintain a counter denoting its multiplicity in X . Let $Y = U \cup V$; we do not use Y in the algorithm, we just introduce it for conceptual convenience.

► **Observation 11.** *The length of the LCS of length at most d is equal to the maximum lcp between pairs of consecutive substrings in (the sorted) Y that originate from different strings.*

During preprocessing, we compute the lcp of all pairs described in Observation 11 and store them in a max heap H . To each element of the heap, we store a pointer from the nodes $u \in B_U, v \in B_V$ it originates from.

Each edit in S or T yields $\mathcal{O}(d)$ deletions and $\mathcal{O}(d)$ insertions of substrings in each of U, V and Y . We first perform deletions and then insertions. For each such operation, we have to check if it destroys or creates a pair of consecutive elements in (the sorted) Y , originating from different strings. We observe that upon the insertion/deletion of a string P , only pairs involving $P, \text{pred}_U(P), \text{pred}_V(P), \text{succ}_U(P)$ and $\text{succ}_V(P)$ may be involved, where pred, succ are predecessor and successor with respect to the lexicographical order. These elements can be identified in $\mathcal{O}(\log^2 n)$ time. The max heap can then be updated using a constant number of LCE queries and heap updates. By Lemma 9, LCE queries (and heap updates) require $\mathcal{O}(\log n)$ time each. Finally, we return the maximum element of the heap. ◀

We now focus on the harder case that the sought LCS is of length at least d .

Let S' and T' be the strings S and T after p operations; for some $p \leq k$. For a position i , by $\text{succ}_{S'}^\#(i)$ we denote the smallest position $j \geq i$ such that $S'[j] = \#$. If no such position exists, we set $\text{succ}_{S'}^\#(i) = |S'| + 1$. Similarly, by $\text{pred}_{S'}^\#(i)$ we denote the greatest position $j \leq i$ such that $S'[j] = \#$, or 0 if no such position exists. Similarly we define $\text{succ}_{T'}^\$(i)$ and $\text{pred}_{T'}^\$(i)$. Such values can be computed in $\mathcal{O}(\log n)$ time if the set of replaced positions is stored in a balanced BST (note that positions of $\#$ and $\$$ can be shifted due to insertions).

■ **Figure 3** An example of a 6-cover $\mathbf{S}_{20}(6) = \{2, 3, 5, 8, 9, 11, 14, 15, 17, 20\}$, with the elements marked as black circles. For example, we may have $h(4, 11) = 4$ since $4 + 4, 11 + 4 \in \mathbf{S}_{20}(6)$.

We say that a set $\mathbf{S}(d) \subseteq \mathbb{Z}_+$ is a d -cover if there is a constant-time computable function h such that for $i, j \in \mathbb{Z}_+$ we have $0 \leq h(i, j) < d$ and $i + h(i, j), j + h(i, j) \in \mathbf{S}(d)$.

► **Lemma 12** ([39, 15]). *For each $d \in \mathbb{Z}_+$ there is a d -cover $\mathbf{S}(d)$ such that $\mathbf{S}(d) \cap [1, n]$ is of size $\mathcal{O}(\frac{n}{\sqrt{d}})$ and can be constructed in $\mathcal{O}(\frac{n}{\sqrt{d}})$ time.*

The intuition behind applying the d -cover in our string-processing setting is as follows (inspect also Figure 3). Consider a position i on S and a position j on T . Note that $i, j \in [1, n]$. By the d -cover construction, we have that $h(i, j)$ is within distance d and $i + h(i, j), j + h(i, j) \in \mathbf{S}(d)$. Thus if we want to find a longest common substring of length *at least* d , it suffices to compute longest common extensions to the left and to the right of *only* positions $i', j' \in \mathbf{S}(d)$ (black circles in Figure 3) and then merge these partial results accordingly.

For this we use the following auxiliary problem that was introduced in [16].

TWO STRING FAMILIES LCP

Input: A compact trie $\mathcal{T}(\mathcal{F})$ of a family of strings \mathcal{F} and two sets $\mathcal{P}, \mathcal{Q} \subseteq \mathcal{F}^2$

Output: The value $\text{maxPairLCP}(\mathcal{P}, \mathcal{Q})$, defined as

$\text{maxPairLCP}(\mathcal{P}, \mathcal{Q}) = \max\{\text{lcp}(P_1, Q_1) + \text{lcp}(P_2, Q_2) : (P_1, P_2) \in \mathcal{P} \text{ and } (Q_1, Q_2) \in \mathcal{Q}\}$

An efficient solution to this problem was shown in [16] (and, implicitly, in [20, 25]).

► **Lemma 13** ([16]). *TWO STRING FAMILIES LCP can be solved in $\mathcal{O}(|\mathcal{F}| + N \log N)$ time, where $N = |\mathcal{P}| + |\mathcal{Q}|$.*

► **Lemma 14.** *DECREMENTAL LCS can be solved in $\tilde{\mathcal{O}}(n^{2/3})$ time per query, using $\tilde{\mathcal{O}}(n + kn^{2/3})$ space, after $\tilde{\mathcal{O}}(n)$ -time preprocessing for k performed operations.*

Proof. Let us consider an integer $d \in [1, n]$. For lengths up to d , we use the algorithm for the BOUNDED-LENGTH LCS problem of Lemma 10. If this problem indicates that there is a solution of length at least d , we proceed to the second step. Let $A = \mathbf{S}(d) \cap [1, n]$ be a d -cover of size $\mathcal{O}(n/\sqrt{d})$ (see Lemma 12).

We consider the following families of pairs of strings: $\mathcal{P} = \{(S[\text{pred}_S^\#(i-1) + 1 \dots i - 1])^R, S[i \dots \text{succ}_S^\#(i) - 1]) : i \in A\}$ and $\mathcal{Q} = \{(T[\text{pred}_T^\$(i-1) + 1 \dots i - 1])^R, T[i \dots \text{succ}_T^\$(i) - 1]) : i \in A\}$. We define \mathcal{F} as the family of strings that occur in the pairs from \mathcal{P} and \mathcal{Q} . Then $\text{maxPairLCP}(\mathcal{P}, \mathcal{Q})$ equals the length of the sought LCS, provided that it is at least d .

Note that $|\mathcal{P}|, |\mathcal{Q}|, |\mathcal{F}|$ are $\mathcal{O}(n/\sqrt{d})$. A compact trie $\mathcal{T}(\mathcal{F})$ can be constructed in $\mathcal{O}(|\mathcal{F}| \log |\mathcal{F}|)$ time by sorting all the strings (using lcp-queries) and then a standard left-to-right construction; see [19]. Thus we can use the solution to TWO STRING FAMILIES LCP which takes $\tilde{\mathcal{O}}(n/\sqrt{d})$ time. We set $d = \lfloor n^{2/3} \rfloor$ to obtain the stated complexity. ◀

4.2 One-Sided Cross-Substring Queries

We show a solution with $\tilde{\mathcal{O}}(k^2)$ -time queries after $\tilde{\mathcal{O}}(n)$ -time preprocessing by building upon the techniques from Section 3.2.

Figure 4 Occurrences of an LCS of S' and T' crossing the boundaries in both are denoted by dashed rectangles. The starting positions f_{i+1} and g_{j+1} minimize the formula $|(f_{i+1} - p) - (g_{j+1} - q)|$. Hence the gray rectangle, denoting U , is a prefix of $S'[f_{i+1} \dots f_{i+2} - 1]$ and a suffix of $T'[g_j \dots g_{j+1} - 1]$. We thus process it as a border while processing (F_i, F_{i+1}) and (G_j, G_{j+1}) and hence find this LCS.

We present an algorithm that computes, for each $i = 1, \dots, k_1$, the longest substring of S' that contains the first character of F_i , but not of F_{i-1} and occurs in G_p for a given $p \in \{1, \dots, k_2\}$ in $\tilde{\mathcal{O}}(k)$ time. These are the possible LCSs that cross the substring boundaries.

Let us start by a global part of the computation. For convenience let us assume that $F_0 = F_{k_1+1}$ are empty strings. For an index $i \in \{1, \dots, k_1\}$, by $next(i)$ we denote the greatest index $j \geq i - 1$ for which $F_i \dots F_j$ is a substring of T . These values are computed using a sliding-window-based approach. We start with computing $next(1)$. To this end, we use Lemma 5(a) for subsequent substrings F_1, F_2, \dots as long as their concatenation is a substring of T . This takes $\mathcal{O}(k \log \log n)$ time. Now assume that we have computed $next(i)$ and we wish to compute $next(i + 1)$. Obviously, $next(i + 1) \geq next(i)$. Let $j = next(i)$. We start with $F_{i+1} \dots F_j$ which is represented as a substring of T . We keep extending this substring by F_{j+1}, F_{j+2}, \dots using Lemma 5(a) as before as long as the concatenation is a substring of T . In total, computing values $next(i)$ for all $i = 1, \dots, k_1$ takes $\tilde{\mathcal{O}}(k)$ time.

Let us now fix i and let $j = next(i)$. We use Lemma 5(b) to find the longest prefix P_i of $(F_i \dots F_j)F_{j+1}$ that occurs in T ; it is also the longest prefix of $F_i \dots F_{k_1}$ that occurs in T by the definition of $next(i)$. Then Lemma 5(b) can be used to compute the longest suffix Q_i of F_{i-1} that occurs in T . For each i it takes time $\tilde{\mathcal{O}}(1)$ time to find P_i and Q_i after $\tilde{\mathcal{O}}(n)$ time and space preprocessing.

We then compute the sought result for given $i \in \{1, \dots, k_1\}$ and $p \in \{1, \dots, k_2\}$ by a THREE SUBSTRINGS LCS query for $U = Q_i$, $V = P_i$, and $W = G_p$. With Lemma 6 this takes $\tilde{\mathcal{O}}(k^2)$ time in total after $\tilde{\mathcal{O}}(n)$ time and space preprocessing.

4.3 Two-Sided Cross-Substring Queries

We show a solution with $\mathcal{O}(k^2 \log^3 n)$ -time queries after $\mathcal{O}(n \log n)$ -time preprocessing by combining the ideas presented in Section 3.3 and efficient LCE queries in the dynamic setting (cf. Lemma 9). We consider each pair of boundaries between pairs (F_i, F_{i+1}) and (G_j, G_{j+1}) , for $1 \leq i \leq k_1 - 1$ and $1 \leq j \leq k_2 - 1$. We process the prefixes of F_{i+1} that are suffixes of G_j as in Section 3.3 (the symmetric case is treated analogously).

We next argue that we do not miss any possible LCS by only considering such prefix-suffix pairs of F_{i+1} and G_j . Let f_i and g_i be the starting positions of F_i and G_j in S' and T' , respectively. An LCS $S'[p \dots p + \ell - 1] = T'[q \dots q + \ell - 1]$ of this type will be reported when processing the pairs (F_i, F_{i+1}) and (G_j, G_{j+1}) , satisfying $p \leq f_{i+1} \leq p + \ell - 1$, $q \leq g_{j+1} \leq q + \ell - 1$, for which $|(f_{i+1} - p) - (g_{j+1} - q)|$ is minimal. Without loss of generality assume $f_{i+1} - p \leq g_{j+1} - q$. Then, $S'[f_{i+1} \dots p + g_{j+1} - q - 1]$ is a prefix of F_{i+1} and $T'[q + f_{j+1} - p + 1 \dots g_{j+1} - 1]$ is a suffix of G_j and hence it is a prefix-suffix that will be processed by our algorithm; see Figure 4.

We assume that $k = \mathcal{O}(\sqrt{n})$, which is sufficient for our main result. We consider $k_1 \times k_2 = \mathcal{O}(k^2)$ pairs $(F_i, F_{i+1}), (G_j, G_{j+1})$ and, by the analysis in Section 3.3, the time required for processing each of them (i.e. finding the longest prefix-suffix and then considering all its borders in $\mathcal{O}(\log n)$ batches) is bounded by the time required to answer $\mathcal{O}(\log n)$ LCE queries, which can be answered in time $\mathcal{O}(k^2 \log n)$ by Lemma 9. By Lemma 9 we have that $k^2 = \mathcal{O}(n)$ LCE queries over a k -substring of S , can be performed in $\mathcal{O}(k^2 \log n)$ time, using this much extra space, after $\mathcal{O}(n)$ -time preprocessing. Hence the total time required is $\mathcal{O}(k^2 \log^3 n)$ after $\tilde{\mathcal{O}}(n)$ -time preprocessing.

4.4 Main Result

By combining the results of Sections 4.1 to 4.3 we obtain the following.

► **Lemma 15.** (k_1, k_2) -SUBSTRING LCS queries can be answered in $\tilde{\mathcal{O}}(n^{2/3} + k^2)$ time, where $k = k_1 + k_2 = \mathcal{O}(\sqrt{n})$, using a data structure that can be constructed in $\tilde{\mathcal{O}}(n)$ time.

We now formalize the time slicing deamortization technique for our purposes.

► **Lemma 16.** Assume that there is a data structure \mathcal{D} over an input string of length n that occupies $\mathcal{O}(s_n)$ space, answers queries for k -substrings in time $\mathcal{O}(q_n(k))$ and can be constructed in time $\mathcal{O}(t_n)$. Assume that $s_n \geq n$ and $q(k, n) \geq k$ is non-decreasing with respect to k . We can then design an algorithm that preprocesses the input string in time $\mathcal{O}(t_n)$ and answers queries dynamically under edit operations in worst-case time $\mathcal{O}(q_n(\kappa))$, where κ is such that $q_n(\kappa) = (t_n + n)/\kappa$, using $\mathcal{O}(s_n)$ space.

By plugging Lemma 15 into Lemma 16 we arrive at our main result.

► **Theorem 17.** FULLY DYNAMIC LCS on two strings, each of length up to n , can be solved in $\tilde{\mathcal{O}}(n^{2/3})$ time per operation, using $\tilde{\mathcal{O}}(n)$ space, after $\tilde{\mathcal{O}}(n)$ -time preprocessing.

5 Applications

We present three applications of our techniques. The fully dynamic algorithm for computing the longest repeat is very similar to the fully dynamic algorithm for LCS.

Another application is a fully dynamic algorithm for the longest palindrome substring which extends the results of [26, 27]. We consider two cases. In the internal case, in which the longest palindrome occurs between edited positions, we use range queries on the set of maximal palindrome substrings of a string (which is known to have linear size). In the cross-substring case, we use the known fact that the lengths of suffix palindromes of a string can be represented as a logarithmic number of arithmetic progressions which lets us use string periodicity similarly as in Section 3.3. We remark that a more efficient algorithm for computing the longest palindrome in a dynamic string has recently been proposed [6].

The authors of [48] presented algorithms for computing a representation of a Lyndon factorization of a prefix of a string and of a suffix of a string in $\tilde{\mathcal{O}}(1)$ time after $\tilde{\mathcal{O}}(n)$ preprocessing. For the prefixes, their solution is based on the Lyndon representations of prefixes of a Lyndon string, whereas for the suffixes, it is based on the structure of a Lyndon tree (originally due to [13]). In order to devise our fully dynamic algorithm, we carefully combine these two approaches to obtain general internal computation of a representation of a Lyndon factorization in the same time bounds.

6 Final Remarks

We anticipate that the techniques presented in this paper to obtain fully dynamic algorithms for several classical problems on strings are applicable in a wider range of problems on strings.

The significance of our results is additionally highlighted by the following argument. It is known that finding an LCS when the strings have wildcard characters [2] or when $k = \Omega(\log n)$ mismatches are allowed [36] in strongly subquadratic time would refute the Strong Exponential Time Hypothesis (SETH) [33, 32] (on the other hand, pattern matching with wildcard characters can be solved in $\tilde{O}(n)$ time [17] and with k mismatches in $\tilde{O}(n\sqrt{k})$ time [9]). It is therefore unlikely that a fully dynamic algorithm with strongly sublinear-time queries exists for these problems: such an algorithm could be trivially applied as a black box to solve the problems in their static setting in strongly subquadratic time, refuting SETH.

This research could inspire more work on the lower bound side of dynamic problems. The currently known hardness (and conditional hardness) results for dynamic problems on strings have been established for dynamic pattern matching [18, 30]. It would be interesting to investigate (conditional) lower bounds for the dynamic problems considered in this paper.

Abstract

We study the classic Maximum Independent Set problem under the notion of *stability* introduced by Bilu and Linial (2010): a weighted instance of Independent Set is γ -stable if it has a unique optimal solution that remains the unique optimal solution under multiplicative perturbations of the weights by a factor of at most $\gamma \geq 1$. The goal then is to efficiently recover this “pronounced” optimal solution exactly. In this work, we solve stable instances of Independent Set on several classes of graphs: we improve upon previous results by solving $\tilde{O}(\Delta/\sqrt{\log \Delta})$ -stable instances on graphs of maximum degree Δ , $(k-1)$ -stable instances on k -colorable graphs and $(1+\varepsilon)$ -stable instances on planar graphs (for any fixed $\varepsilon > 0$), using both combinatorial techniques as well as LPs and the Sherali-Adams hierarchy.

For general graphs, we present a strong lower bound showing that there are no efficient algorithms for $O(n^{\frac{1}{2}-\varepsilon})$ -stable instances of Independent Set, assuming the planted clique conjecture. To complement our negative result, we give an algorithm for (εn) -stable instances, for any fixed $\varepsilon > 0$. As a by-product of our techniques, we give algorithms as well as lower bounds for stable instances of Node Multiway Cut (a generalization of Edge Multiway Cut), by exploiting its connections to Vertex Cover. Furthermore, we prove a general structural result showing that the integrality gap of convex relaxations of several maximization problems reduces dramatically on stable instances.

Moreover, we initiate the study of *certified* algorithms for Independent Set. The notion of a γ -certified algorithm was introduced very recently by Makarychev and Makarychev (2018) and it is a class of γ -approximation algorithms that satisfy one crucial property: the solution returned is optimal for a perturbation of the original instance, where perturbations are again multiplicative up to a factor of $\gamma \geq 1$ (hence, such algorithms not only solve γ -stable instances optimally, but also have guarantees even on unstable instances). Here, we obtain Δ -certified algorithms for Independent Set on graphs of maximum degree Δ , and $(1+\varepsilon)$ -certified algorithms on planar graphs. Finally, we analyze the algorithm of Berman and Fürer (1994) and prove that it is a $(\frac{\Delta+1}{3} + \varepsilon)$ -certified algorithm for Independent Set on graphs of maximum degree Δ where all weights are equal to 1.

1 Introduction

The Maximum Independent Set problem (simply MIS from now on) is a central problem in theoretical computer science and has been the subject of extensive research over the last few decades. As a result we now have a thorough understanding of the *worst-case* behavior of the problem. In general graphs, the problem is $n^{1-\varepsilon}$ -hard to approximate, assuming that $P \neq NP$ [34, 48], and $n/2^{(\log n)^{3/4+\varepsilon}}$ -hard to approximate, assuming that $NP \not\subseteq \text{BPTIME}(2^{(\log n)^{O(1)}})$ [37]. On the positive side, the current best algorithm is due to Feige [27] achieving a $\tilde{O}(n/\log^3 n)$ -approximation (the notation \tilde{O} hides some $\text{poly}(\log \log n)$ factors). In order to circumvent the strong lower bounds, many works have focused on special classes of graphs, such as bounded-degree graphs (see, e.g., [1, 5, 10, 11, 21, 31, 32, 33]), planar graphs ([7]) etc. In this work, we build upon this long line of research and study MIS under the beyond worst-case framework introduced by Bilu and Linial [17].

In an attempt to capture real-life instances of combinatorial optimization problems, Bilu and Linial proposed a notion of stability, which we now instantiate in the context of MIS (from now on, we will always assume weighted instances of MIS).

► **Definition 1** (γ -perturbation [17]). *Let $G = (V, E, w)$, $w : V \rightarrow \mathbb{R}_{>0}$, be an instance of MIS. An instance $G' = (V, E, w')$ is a γ -perturbation of G , for some parameter $\gamma \geq 1$, if for every $u \in V$ we have $w_u \leq w'_u \leq \gamma \cdot w_u$.*

► **Definition 2** (γ -stability [17]). *Let $G = (V, E, w)$, $w : V \rightarrow \mathbb{R}_{>0}$, be an instance of MIS. The instance G is γ -stable, for some parameter $\gamma \geq 1$, if:*

1. *it has a unique maximum independent set I^* ,*
 2. *every γ -perturbation G' of G has a unique maximum independent set equal to I^* .*
- Equivalently, G is γ -stable if it has an independent set I^* such that $w(I^* \setminus S) > \gamma \cdot w(S \setminus I^*)$ for every feasible independent set $S \neq I^*$ (we use the notation $w(Q) := \sum_{u \in Q} w_u$ for $Q \subseteq V$).*

This definition of stability is motivated by the empirical observation that in many real-life instances, the optimal solution stands out from the rest of the solution space, and thus is not sensitive to small perturbations of the parameters. This suggests that the optimal solution does not change (structurally) if the parameters of the instance are perturbed (even adversarially). Observe that the smaller the so-called *stability threshold* γ is, the less severe the restrictions imposed on the instance are; for example, $\gamma = 1$ is the case where we only require the optimal solution to be unique. Thus, the main goal in this framework is to recover the optimal solution in polynomial time, for as small $\gamma \geq 1$ as possible. An “optimal” result would translate to γ being $1 + \varepsilon$, for small $\varepsilon > 0$, since assuming uniqueness of the optimal solution is not believed to make the problems easier (see, e.g., [47]), and thus ε is unlikely to be zero. We note that perturbations are scale-invariant, and so it suffices to consider perturbations that only scale up. Moreover, we observe that an algorithm for γ -stable instances of MIS solves γ -stable instances of Minimum Vertex Cover, and vice versa.

Stability was first introduced for Max Cut [17], but the authors note that it naturally extends to other problems, such as MIS, and, moreover, they prove that the greedy algorithm for MIS solves Δ -stable instances on graphs of maximum degree Δ . The work of Bilu and Linial has inspired numerous works on stable instances of various optimization problems; we give an overview of the literature in the next page.

Prior works on stability have also studied *robust* algorithms [42, 4]; these are algorithms that either output an optimal solution or provide a polynomial-time verifiable certificate that the instance is not γ -stable (see Section 2 for a definition). Motivated by the notion of stability, Makarychev and Makarychev [41] recently introduced an intriguing class of algorithms, namely γ -certified algorithms.

► **Definition 3** (γ -certified algorithm [41]). *An algorithm for MIS is called γ -certified, for some parameter $\gamma \geq 1$, if for every instance $G = (V, E, w)$, $w : V \rightarrow \mathbb{R}_{>0}$, it computes*

1. *a feasible independent set $S \subseteq V$ of G ,*
 2. *a γ -perturbation $G' = (V, E, w')$ of G such that S is a maximum independent set of G' .*
- Equivalently, Condition (2) can be replaced by the following: $\gamma \cdot w(S \setminus I) \geq w(I \setminus S)$ for every independent set I of G .*

We highlight that a certified algorithm works for *every* instance; if the instance is γ -stable, then the solution returned is the optimal one, while if it is not stable, the solution is within a γ -factor of optimal. Hence a γ -certified algorithm is also a γ -approximation algorithm.

Motivation. Stability is especially natural for problems where the given objective function may be a proxy for a true goal of identifying a hidden correct solution. For MIS, a natural such scenario is applying a machine learning algorithm in the presence of pairwise constraints. Consider, for instance, an algorithm that scans news articles on the web and aims to extract events such as “athlete X won the Olympic gold medal in Y”. For each such statement, the algorithm gives a confidence score (e.g., it might be more confident if it saw this listed in a table rather than inferring it from a free-text sentence that the algorithm might have misunderstood). But in addition, the algorithm might also know logical constraints such as “at most one person can win a gold medal in any given event”. These logical constraints would then become edges in a graph, and the goal of finding the most likely combination of events would become a MIS problem. Stability would be natural to assume in such a setting since the exact confidence weights are somewhat heuristic, and the goal is to recover an underlying ground truth. It is also easy to see the usefulness of a certified algorithm in this setting. Given a certified algorithm that outputs a γ -perturbation, the user of the machine learning algorithm can further test and debug the system by trying to gather evidence for events on which the perturbation puts higher weight.

Related Work. There have been many works on the worst-case complexity of MIS and the current best known algorithms give $\tilde{O}(n/\log^3 n)$ -approximation [27], and $\tilde{O}(\Delta/\log \Delta)$ -approximation [31, 33, 36]), where Δ is the maximum degree. The problem has also been studied from the lens of beyond worst-case analysis. For random graphs with a planted independent set, MIS is equivalent to the classic planted clique problem. Inspired by semi-random models of [18], Feige and Killian [28] designed SDP-based algorithms for computing large independent sets in semi-random graphs. Finally, there has been work on MIS under noise [40, 12].

The notion of Bilu-Linial stability goes beyond random/semi-random models and proposes deterministic conditions that give rise to non worst-case, real-life instances. The study of this notion has led to insights into the complexity of many problems in optimization and machine learning. For MIS, Bilu [15] analyzed the greedy algorithm and showed that it recovers the optimal solution for Δ -stable instances of graphs of maximum degree Δ . The same result is also a corollary of a general theorem about the greedy algorithm and p -extendible independence systems proved by Chatziafratis et al. [22]. On the negative side, Angelidakis et al. [4] showed that there is no robust algorithm for $n^{1-\varepsilon}$ -stable instances of MIS on general graphs (unbounded degree), assuming that $P \neq NP$.

The work of Bilu and Linial has inspired a sequence of works about stable instances of various combinatorial optimization problems. There are now algorithms that solve $O(\sqrt{\log n} \log \log n)$ -stable instances of Max Cut [16, 42], $(2 - 2/k)$ -stable instances of Edge Multiway Cut, where k is the number of terminals [42, 4], and 1.8-stable instances of symmetric TSP [45]. There has also been extensive work on stable instances of clustering problems (usually called perturbation-resilient instances) with many positive results for problems such as k -median, k -means, and k -center [6, 9, 8, 4, 25, 23, 26, 30], and more recently on MAP inference [38, 39].

Our results. We explore the notion of stability in the context of MIS and significantly improve our understanding of its behavior on stable instances; we design algorithms for stable instances on different graph classes, and also initiate the study of certified algorithms for MIS. More specifically, we obtain the following results.

- **Planar graphs:** We show that on planar graphs, any constant stability suffices to solve the problem exactly in polynomial time. More precisely, we provide robust and certified algorithms for $(1 + \varepsilon)$ -stable instances of planar MIS, for any fixed $\varepsilon > 0$. To obtain these results, we utilize the Sherali-Adams hierarchy, demonstrating that hierarchies may be helpful for solving stable instances.
- **Graphs with small chromatic number or bounded degree:** We provide robust algorithms for solving $(k - 1)$ -stable instances of MIS on k -colorable graphs (where the algorithm does not have access to a k -coloring of the graph) and $(\Delta - 1)$ -stable instances of MIS on graphs of maximum degree Δ . Both results are based on LPs. For bounded-degree graphs, we then turn to combinatorial techniques and design a (non-robust) algorithm for $\tilde{O}(\Delta/\sqrt{\log \Delta})$ -stable instances; this is the first algorithm that solves $o(\Delta)$ -stable instances. Moreover, we show that the standard greedy algorithm is a Δ -certified algorithm for MIS, whereas for unweighted instances, the algorithm of Berman and Fürer (1994) is a $(\frac{\Delta+1}{3} + \varepsilon)$ -certified algorithm.
- **General graphs:** For general graphs, we show that solving $o(\sqrt{n})$ -stable instances is hard assuming the hardness of finding maximum cliques in a random graph. To the best of our knowledge, this is only the second case of a lower bound for stable instances of a graph optimization problem that applies to any polynomial-time algorithm and not only to robust algorithms [42, 4] (the first being the lower bound for Max k -Cut [42]). We complement this lower bound by giving an algorithm for (εn) -stable instances of MIS on graphs with n vertices, for any fixed $\varepsilon > 0$.
- **Convex relaxations and stability:** We present a structural result for the integrality gap of convex relaxations of maximization problems on stable instances: if the integrality gap of a relaxation is α , then it is at most $\min\left\{\alpha, 1 + \frac{1}{\beta-1}\right\}$ for $(\alpha\beta)$ -stable instances, for any $\beta > 1$. This result demonstrates a smooth trade-off between stability and the performance of a convex relaxation, and also implies $(1 + \varepsilon)$ -estimation algorithms¹ for $O(\alpha/\varepsilon)$ -stable instances.
- **Node Multiway Cut:** We give the first results on stable instances of Node Multiway Cut, a strict generalization of the well-studied (under stability) Edge Multiway Cut problem [42, 4]. In particular, we give a robust algorithm for $(k - 1)$ -stable instances, where k is the number of terminals, and show that all negative results on stable instances of MIS directly apply to Node Multiway Cut.

¹ An α -estimation algorithm returns a value that is within a factor of α from the optimum, but not necessarily a corresponding solution that realizes this value.

Organization of material. Section 2 provides definitions and related facts. Section 3 contains the algorithms for stable instances of MIS on bounded-degree, small chromatic number and planar graphs. Section 4 contains our results for stable instances on general graphs. Section 5 demonstrates how the performance of convex relaxations improves as stability increases. Section 6 contains various certified algorithms for MIS. Due to space constraints, the results for the Node Multiway Cut problem are omitted and can be found in the full version of the paper [3]. The same applies to all proofs that have been omitted.

2 Preliminaries and definitions

Given a γ -stable instance, our goal is to design polynomial-time algorithms that recover the unique optimal solution, for as small $\gamma \geq 1$ as possible. A special class of such algorithms that is of particular interest is the class of robust algorithms, introduced by Makarychev et al. [42].

► **Definition 4** (robust algorithm [42]). *Let $G = (V, E, w)$, $w : V \rightarrow \mathbb{R}_{>0}$, be an instance of MIS. An algorithm \mathcal{A} is a robust algorithm for γ -stable instances if:*

1. *it always returns the unique optimal solution of G , when G is γ -stable,*
2. *it either returns an optimal solution of G or reports that G is not stable, when G is not γ -stable.*

Note that a robust algorithm is not allowed to err, while a non-robust algorithm is allowed to return a suboptimal solution, if the instance is not γ -stable. We now present a useful lemma about stable instances of MIS that is used in several of our results. From now on, we denote the neighborhood of a vertex u of a graph $G = (V, E)$ as $N(u) = \{v : (u, v) \in E\}$, and the neighborhood of a set $S \subseteq V$ as $N(S) = \{v \in V \setminus S : \exists u \in S \text{ s.t. } (u, v) \in E\}$.

► **Lemma 5.** *Let $G = (V, E, w)$ be a γ -stable instance of MIS whose optimal independent set is I^* . Then, for any $v \in I^*$, the induced instance $\tilde{G} = G[V \setminus (\{v\} \cup N(v))]$ is γ -stable, and its unique maximum independent set is $I^* \setminus \{v\}$.*

Regarding certified algorithms (see Definition 3), it is easy to observe the following.

► **Observation 6** ([41]). *A γ -certified algorithm for MIS satisfies the following:*

1. *returns the unique optimal solution, when run on a γ -stable instance,*
2. *is a γ -certified algorithm for Vertex Cover, and vice versa,*
3. *is a γ -approximation algorithm for MIS (and Vertex Cover).*

We stress that not all algorithms for stable instances are certified, so there is no equivalence between the two notions. Some examples (communicated to us by Yury Makarychev [43]) include the algorithms for stable instances of TSP [45], Max Cut (the GW SDP with triangle inequalities), and clustering. All these algorithms solve stable instances but are not certified. Thus, designing a certified algorithm is, potentially, a harder task than designing an algorithm for stable instances.

From now on, if an algorithm for MIS only returns a feasible solution S , it will be assumed to be “candidate” γ -certified that also returns the perturbed weight function w' with $w'_u = \gamma \cdot w_u$ for $u \in S$ and $w'_u = w_u$, otherwise.

3 Stable instances of MIS on special classes of graphs

In the next few sections, we obtain algorithms for stable instances of MIS on several natural classes of graphs, by using convex relaxations and combinatorial techniques.

3.1 Convex relaxations and robust algorithms

The starting point for the design of robust algorithms via convex relaxations is the structural result of Makarychev et al. [42], that gives sufficient conditions for the integrality of convex relaxations on stable instances. We now introduce a definition and restate their theorem in the setting of MIS.

► **Definition 7** ((α, β) -rounding). *Let $x : V \rightarrow [0, 1]$ be a feasible fractional solution of a convex relaxation of MIS whose objective value for an instance $G = (V, E, w)$ is $\sum_{u \in V} w_u x_u$. A randomized rounding scheme for x is an (α, β) -rounding, for some parameters $\alpha, \beta \geq 1$, if it always returns a feasible independent set S , such that the following two properties hold for every vertex $u \in V$:*

1. $\Pr[u \in S] \geq \frac{1}{\alpha} \cdot x_u$,
2. $\Pr[u \notin S] \leq \beta \cdot (1 - x_u)$.

► **Theorem 8** ([42]). *Let $x : V \rightarrow [0, 1]$ be an optimal fractional solution of a convex relaxation of MIS whose objective value for an instance $G = (V, E, w)$ is $\sum_{u \in V} w_u x_u$. Suppose that there exists an (α, β) -rounding for x , for some $\alpha, \beta \geq 1$. Then, x is integral for (α, β) -stable instances.*

The theorem suggests a simple robust algorithm: solve the relaxation, and if the solution is integral, report it, otherwise report that the instance is not stable (observe that the rounding scheme is used only in the analysis).

3.2 A robust algorithm for $(k - 1)$ -stable instances of MIS on k -colorable graphs

In this section, we give a robust algorithm for $(k - 1)$ -stable instances of MIS on k -colorable graphs by utilizing Theorem 8 and the standard LP for MIS. For a graph $G = (V, E, w)$, the standard LP has an indicator variable x_u for each vertex $u \in V$, and is given below.

$$(\text{LP}) \quad \max : \sum_{u \in V} w_u x_u \quad \text{s.t.} : \quad x_u + x_v \leq 1 \quad \forall (u, v) \in E, \quad \text{and} \quad x_u \in [0, 1] \quad \forall u \in V.$$

The corresponding polytope is half-integral [46], and so we always have an optimal solution x with $x_u \in \{0, \frac{1}{2}, 1\}$ for every $u \in V$. This is useful for designing (α, β) -rounding schemes, as it allows us to consider randomized combinatorial algorithms and easily present them as rounding schemes.

The crucial observation that we make is that the rounding scheme in Theorem 8 is only used in the analysis and is not part of the algorithm, and so it can run in super-polynomial time. We also note that the final (polynomial-time) algorithm does not need to have a k -coloring of the graph. Let $G = (V, E, w)$ be a k -colorable graph, and let x be an optimal half-integral solution. Let $V_i = \{u \in V : x_u = i\}$ for $i \in \{0, 1/2, 1\}$. We consider the rounding scheme of Hochbaum [35] (see Algorithm 1). We use the notation $[k] = \{1, \dots, k\}$.

■ **Algorithm 1** Hochbaum's k -colorable rounding scheme.

-
1. Compute a k -coloring $f : V_{1/2} \rightarrow [k]$ of the induced graph $G[V_{1/2}]$.
 2. Pick j uniformly at random from the set $[k]$, and set $V_{1/2}^{(j)} := \{u \in V_{1/2} : f(u) = j\}$.
 3. Return $S := V_{1/2}^{(j)} \cup V_1$.
-

► **Theorem 9.** *Let $G = (V, E, w)$ be a k -colorable graph. Given an optimal half-integral solution x , the rounding scheme of Algorithm 1 is a $\left(\frac{k}{2}, \frac{2(k-1)}{k}\right)$ -rounding for x .*

Proof. The set S is feasible, as there is no edge between V_1 and $V_{1/2}$ and f is a valid coloring. For $u \in V_0$, we have $\Pr[u \in S] = 0 = x_u$ and $\Pr[u \notin S] = 1 = 1 - x_u$. For $u \in V_1$, we have $\Pr[u \in S] = 1 = x_u$ and $\Pr[u \notin S] = 0 = 1 - x_u$. Let $u \in V_{1/2}$. We have $\Pr[u \in S] \geq \frac{1}{k} = \frac{2}{k} \cdot x_u$ and $\Pr[u \notin S] \leq 1 - \frac{1}{k} = \frac{2(k-1)}{k} \cdot (1 - x_u)$. The result follows. ◀

Theorems 8 and 9 now imply the following theorem, which is tight.

► **Theorem 10.** *The standard LP for MIS is integral for $(k-1)$ -stable instances of k -colorable graphs.*

3.3 Algorithms for stable instances of MIS on bounded-degree graphs

Throughout this section, we assume that all graphs have maximum degree Δ . The only result (prior to our work) for stable instances on such graphs was using the greedy algorithm and was given by Bilu [15].

■ **Algorithm 2** The greedy algorithm for MIS.

-
1. Let $S := \emptyset$ and $X := V$.
 2. while $(X \neq \emptyset)$:
 Set $S := S \cup \{u\}$ and $X := X \setminus (\{u\} \cup N(u))$, where $u := \arg \max_{v \in X} \{w_v\}$.
 3. Return S .
-

► **Theorem 11** ([15]). *The greedy algorithm (see Algorithm 2) solves Δ -stable instances of MIS on graphs of maximum degree Δ .*

We first note that, since the maximum degree is Δ , the chromatic number is at most $\Delta + 1$, and so Theorem 10 implies a robust algorithm for Δ -stable instances, giving a robust analog of Bilu's result. In fact, we can slightly improve upon that by using Brook's Theorem [20], which states that the chromatic number is at most Δ , unless the graph is complete or an odd cycle. We can then prove following theorem.

► **Theorem 12.** *There exists a robust algorithm for $(\Delta - 1)$ -stable instances of MIS, where Δ is the maximum degree.*

We now turn to non-robust algorithms and present an algorithm that solves $o(\Delta)$ -stable instances, as long as the weights are polynomially-bounded integers. The core of the algorithm is a procedure that uses an α -approximation algorithm as a black-box in order to recover the optimal solution, when the instance is stable. Let $G = (V, E, w)$ be a graph with $n = |V|$ and $w : V \rightarrow \{1, \dots, \text{poly}(n)\}$. Let \mathcal{A} denote an α -approximation algorithm for MIS. We will give an algorithm for γ -stable instances with $\gamma = \lceil \sqrt{2\Delta\alpha} \rceil$. Note that we can assume that $\alpha \leq \Delta$ and $\gamma \leq \Delta$. These assumptions hold for the rest of this section. Algorithm 3 is the main algorithm, and it uses Algorithm 4 as a subroutine.

To prove the algorithm's correctness, we need some lemmas (see the full version [3] for their proofs).

► **Lemma 13.** *Let $G = (V, E, w)$ be γ -stable, with $w_u \geq 1$, for every $u \in V$. If $w(V) \leq \gamma$, then $E = \emptyset$.*

■ **Algorithm 3** Algorithm for γ -stable instances, where $\gamma = \lceil \sqrt{2\Delta\alpha} \rceil$.

Bounded-Alg($G(V, E, w)$):

1. If $w(V) \leq \gamma$, then return V .
2. Run α -approximation algorithm \mathcal{A} on G to get an independent set I .
3. Let $S := \text{PURIFY}(G, I, \gamma)$.
4. Let $S' := \text{Bounded-Alg}(G[V \setminus (S \cup N(S))])$.
5. Return $S \cup S'$.

■ **Algorithm 4** The PURIFY procedure.

INPUT: Graph $G = (V, E, w)$, independent set $I \subseteq V$ and factor $\gamma \geq 1$.

1. Create a bipartite unweighted graph $G_0 = (L \cup R, E_0)$, where L contains $\gamma \cdot w(u)$ copies of each $u \in I$ and R contains $w(v)$ copies of each $v \in V \setminus I$. The set E_0 is defined as follows: if (u, v) is an edge in G with $u \in I$ and $v \notin I$, then add edges from each copy of u in L to each copy of v in R .
2. Compute a maximum cardinality matching M of G_0 .
3. Return the set of all vertices $u \in I$ that have at least one unmatched copy in L w.r.t. M .

The above lemma justifies Step 1 of Algorithm 3.

► **Lemma 14.** *Let $G = (V, E, w)$ be γ -stable, and let I^* be its maximum independent set. Then $w(I^*) > \frac{\gamma}{2\Delta} \cdot w(V)$.*

► **Lemma 15.** *Let $G = (V, E, w)$ be a γ -stable instance, let I^* be its maximum independent set and let I' be an α -approximate independent set. Then $I^* \cap I' \neq \emptyset$.*

We now analyze the PURIFY procedure (Algorithm 4).

► **Lemma 16.** *Let G be a γ -stable instance that is given as input to the PURIFY procedure (see Algorithm 4), along with an α -approximate independent set I , and let I^* be its maximum independent set. If $I \neq I^*$, then the set S returned by the procedure always satisfies the following two properties:*

1. $S \neq \emptyset$,
2. $S \subseteq I^*$.

Proof. We first prove Property (1). Let's assume that $S = \emptyset$. This means that all vertices in L are matched. By construction, this implies that $\gamma \cdot w(I) \leq w(V \setminus I)$. Since I is an α -approximation, we have that $\gamma \cdot w(I) \geq \frac{\gamma}{\alpha} \cdot w(I^*) > \frac{\gamma \cdot \gamma}{2\Delta\alpha} w(V) \geq \frac{2\Delta\alpha}{2\Delta\alpha} w(V) = w(V)$, where the second inequality is due to Lemma 14. We conclude that $w(V \setminus I) > w(V)$, which is a contradiction. Thus, $S \neq \emptyset$.

We turn to Property (2). Let $A = I \setminus I^*$ and $B = I^* \setminus I$. Let $A_0 \subseteq L$ be the copies of the vertices of set A in G_0 , and let $B_0 \subseteq R$ be the copies of the vertices of set B in G_0 . We will show that for every $Z \subseteq A_0$, we have $|N(Z) \cap B_0| \geq |Z|$. To see this, let $Z \subseteq A_0$, and let $I(Z) \subseteq A$ be the distinct vertices of A whose copies (not necessarily all of them) are included in Z . Since the instance is γ -stable, this implies that the weight of the neighbors $F \subseteq B$ of $I(Z)$ in I^* is strictly larger than $\gamma \cdot w(I(Z))$. By construction, we have that $|Z| \leq \gamma \cdot w(I(Z))$, and the number of vertices in G_0 corresponding to vertices of F is equal to $w(F)$. Moreover, all of these $w(F)$ vertices are connected with at least one vertex in Z , which means that $w(F) = |N(Z) \cap B_0|$. This implies that $|N(Z) \cap B_0| > |Z|$. Thus, Hall's condition is satisfied, and so there exists a perfect matching between the vertices of A_0 and (a subset of the vertices of) B_0 .

We observe now that the neighbors of all vertices in B_0 are only vertices in A_0 and not in $L \setminus A_0$. This means that any maximum matching matches all vertices of A_0 (otherwise, we could increase the size of the matching by matching all vertices in A_0). Thus, $S \subseteq I \cap I^*$. ◀

Putting everything together, and by using the $\tilde{O}(\Delta/\log \Delta)$ -approximation algorithm of Halldórsson [31] or Halperin [33] as a black-box, it is easy to prove the following theorem.

► **Theorem 17.** *Algorithm 3 correctly solves $\lceil \sqrt{2\Delta\alpha} \rceil$ -stable instances in polynomial time. In particular, there is an algorithm that solves $\tilde{O}(\Delta/\sqrt{\log \Delta})$ -stable instances.*

3.4 Robust algorithms for $(1 + \varepsilon)$ -stable instances of MIS on planar graphs

In this section, we design a robust algorithm for $(1 + \varepsilon)$ -stable instances of MIS on planar graphs. Theorem 10 already implies a robust algorithm for 3-stable instances of planar MIS, but we will use the Sherali-Adams hierarchy (denoted as SA from now on) to reduce this threshold down to $1 + \varepsilon$, for any fixed $\varepsilon > 0$. In particular, we show that $O(1/\varepsilon)$ rounds of SA suffice to optimally solve $(1 + \varepsilon)$ -stable planar instances. We will not introduce the SA hierarchy formally, and we refer the reader to the many available surveys about it (see, e.g., [24]). The t -th level of SA for MIS has a variable Y_S for every subset $S \subseteq V$ of size at most $|S| \leq t + 1$, whose intended value is $Y_S = \prod_{u \in S} x_u$, where x_u is the indicator of whether u belongs to the independent set. The relaxation has size $n^{O(t)}$, and thus can be solved in time $n^{O(t)}$.

Our starting point is the work of Magen and Moharrami [40], which gives a SA-based PTAS for MIS on planar graphs, inspired by Baker's technique [7]. In particular, [40] gives a rounding scheme for the $O(t)$ -th round of SA that returns a $(1 + O(1/t))$ -approximation. In this section, we slightly modify and analyze their rounding scheme, and prove that it satisfies the conditions of Theorem 8. For that, we need a theorem of Bienstock and Ozbay [14]. For any subgraph H of a graph $G = (V, E)$, let $V(H)$ denote the set of vertices contained in H .

► **Theorem 18 ([14]).** *Let $t \geq 1$ and Y be a feasible vector for the t -th level SA relaxation of the standard Independent Set LP for a graph G . Then, for any subgraph H of G of treewidth at most t , the vector $(Y_{\{u\}})_{u \in V(H)}$ is a convex combination of independent sets of H .*

The above theorem implies that the t -th level SA polytope is equal to the convex hull of all independent sets of the graph, when the graph has treewidth at most t .

The rounding scheme of Magen and Moharrami [40]. Let $G = (V, E, w)$ be a planar graph and $\{Y_S\}_{S \subseteq V: |S| \leq t+1}$ be an optimal t -th level solution of SA. We denote $Y_{\{u\}}$ as y_u , for any $u \in V$. We first fix a planar embedding of G . V can then be naturally partitioned into sets V_0, V_1, \dots, V_L , for some $L \in \{0, \dots, n-1\}$, where V_0 is the set of vertices in the boundary of the outerface, V_1 is the set of vertices in the boundary of the outerface after V_0 is removed, and so on. Note that for any edge $(u, v) \in E$, we have $u \in V_i$ and $v \in V_j$ with $|i - j| \leq 1$. We will assume that $L \geq 4$, since, otherwise, the graph is at most 4-outerplanar and the problem can then be solved optimally [7].

Following [7], we fix a parameter $k \in \{1, \dots, L\}$, and for every $i \in \{0, \dots, k-1\}$, we define $B(i) = \bigcup_{j \equiv i \pmod{k}} V_j$. We now pick an index $j \in \{0, \dots, k-1\}$ uniformly at random. Let $G_0 = G[V_0 \cup V_1 \dots \cup V_j]$, and for $i \geq 1$, $G_i = G[\bigcup_{q=(i-1)k+j}^{ik+j} V_q]$, where for a subset $X \subseteq V$, $G[X]$ is the induced subgraph on X . Observe that every edge and vertex of G appears in one or two of the subgraphs $\{G_i\}$, and every vertex $u \in V \setminus B(j)$ appears in exactly one G_i .

Magen and Moharrami observe that for every subgraph $G_i = (V(G_i), E(G_i))$, the set of vectors $\{Y_S\}_{S \subseteq V(G_i): |S| \leq t+1}$ is a feasible solution for the t -th level SA relaxation of the graph G_i . This is easy to see, as the LP associated with G_i is weaker than the LP associated with G (on all common variables), since G_i is a subgraph of G , and this extends to SA as well. We need one more observation: a k -outerplanar graph has treewidth at most $3k - 1$ (see [19]). By construction, each G_i is a $(k+1)$ -outerplanar graph. Thus, by setting $t = 3k + 2$, Theorem 18 implies that the vector $\{y_u\}_{u \in V(G_i)}$ can be written as a convex combination of independent sets of G_i . Let p_i be the corresponding distribution of independent sets of G_i , implied by $\{y_u\}_{u \in V(G_i)}$.

We now consider the following rounding scheme. For each G_i , we (independently) sample an independent set S_i of G_i according to p_i . Each vertex $u \in V \setminus B(j)$ belongs to exactly one G_i and is included in the final independent set S if $u \in S_i$. A vertex $u \in B(j)$ might belong to two different graphs G_i, G_{i+1} , and is included in S only if $u \in S_i \cap S_{i+1}$. The algorithm then returns S .

Before analyzing the algorithm, we note that standard tree-decomposition based arguments show that the rounding is constructive (i.e. polynomial-time; this fact is not needed for the algorithm for stable instances of planar MIS, but will be used when designing certified algorithms).

► **Theorem 19.** *The above randomized rounding scheme always returns a feasible independent set S , such that for every vertex $u \in V$,*

1. $\Pr[u \in S] \geq \frac{k-1}{k} \cdot y_u + \frac{1}{k} \cdot y_u^2$,
2. $\Pr[u \notin S] \leq \left(1 + \frac{1}{k}\right) \cdot (1 - y_u)$.

Proof. It is easy to see that S is always a feasible independent set. We now compute the corresponding probabilities. Since the marginal probability of p_i on a vertex $u \in G_i$ is y_u , for any fixed j , for every vertex $u \in V \setminus B(j)$, we have $\Pr[u \in S] = y_u$, and for every vertex $u \in B(j)$, we have $\Pr[u \in S] \geq y_u^2$. Since j is picked uniformly at random, each vertex $u \in V$ belongs to $B(j)$ with probability exactly equal to $\frac{1}{k}$. Thus, we conclude that for every vertex $u \in V$, we have $\Pr[u \in S] \geq \frac{k-1}{k} \cdot y_u + \frac{1}{k} \cdot y_u^2$, and $\Pr[u \notin S] \leq 1 - \left(\frac{k-1}{k} \cdot y_u + \frac{1}{k} \cdot y_u^2\right) = 1 - y_u + \frac{y_u}{k} \cdot (1 - y_u) \leq \left(1 + \frac{1}{k}\right) \cdot (1 - y_u)$. ◀

The above theorem implies that the rounding scheme is a $\left(\frac{k}{k-1}, \frac{k+1}{k}\right)$ -rounding. The following theorem now is a direct consequence of Theorems 8 and 19.

► **Theorem 20.** *For every $\varepsilon > 0$, the SA relaxation of $(3 \lceil \frac{2}{\varepsilon} \rceil + 5) = O(1/\varepsilon)$ rounds is integral for $(1 + \varepsilon)$ -stable instances of MIS on planar graphs.*

4 Stable instances of MIS on general graphs

In this section, we study stable instances of general graphs. We present a strong lower bound on any algorithm (not necessarily robust) that solves $o(\sqrt{n})$ -stable instances. We complement this lower bound with an algorithm that solves (εn) -stable instances in time $n^{O(1/\varepsilon)}$.

4.1 Computational hardness of stable instances of MIS

We show that for general graphs it is unlikely to obtain efficient algorithms for solving γ -stable instances for small values of γ . Our hardness reduction is based on the *planted clique* conjecture [29, 44], which states that finding $o(\sqrt{n})$ sized planted independent sets/cliques in the Erdős-Rényi graph $G(n, \frac{1}{2})$ is computationally hard. Let $G(n, \frac{1}{2}, k)$ denote the

distribution over graphs obtained by sampling a graph from $G(n, \frac{1}{2})$ and then picking a uniformly random subset of k vertices and deleting all edges among them. The conjecture is formally stated below.

► **Conjecture 21.** *Let $0 < \varepsilon < \frac{1}{2}$ be a constant. Suppose that an algorithm \mathcal{A} receives an input graph G that is either sampled from the ensemble $G(n, \frac{1}{2})$ or $G(n, \frac{1}{2}, n^{\frac{1}{2}-\varepsilon})$. Then, no \mathcal{A} that runs in time polynomial in n can decide, with probability at least $\frac{4}{5}$, which ensemble G was sampled from.*

Our lower bound follows from the observation that planted random instances are stable up to high values of γ , and this suffices to imply our main result.

► **Theorem 22.** *Let $\varepsilon > 0$ be a constant and consider a random graph G on n vertices generated by first picking edges according to the Erdős-Rényi model $G(n, \frac{1}{2})$, followed by choosing a set I of vertices of size $n^{\frac{1}{2}-\varepsilon}$, uniformly at random, and deleting all edges inside I . Then, with probability $1 - o(1)$, the resulting instance is a $\Theta(n^{\frac{1}{2}-\varepsilon}/\log n)$ -stable instance of MIS.*

Proof. Let $G = (V, E)$ be the resulting graph (we assume that all weights are set to 1). We start by stating two well-known properties of the graph G that hold with probability $1 - o(1)$ ([2]).

1. For each vertex $u \in V \setminus I$, we have $|N(u) \cap I| \geq \frac{1}{2} \cdot n^{\frac{1}{2}-\varepsilon} (1 \pm o(1))$.
2. The size of the maximum independent set in the graph $G[V \setminus I]$ is at most $\lceil 2(1 \pm o(1)) \log n \rceil$.

Consider any other independent set $S \neq I$. By Property 1, we have that $|I \setminus S| \geq \frac{1}{2} n^{\frac{1}{2}-\varepsilon} (1 - o(1))$. By Property 2, we must have that $|S \setminus I| \leq 2(1 \pm o(1)) \log n$. Hence, $|S| < |I|$ and furthermore, $|I \setminus S| > \gamma \cdot |S \setminus I|$ for $\gamma = \frac{n^{\frac{1}{2}-\varepsilon}}{4 \log n}$. We conclude that the instance is $\left(\frac{n^{\frac{1}{2}-\varepsilon}}{4 \log n}\right)$ -stable. ◀

4.2 An algorithm for (εn) -stable instances

In this section, we design an algorithm for (εn) -stable instances on graphs of n vertices, that runs in time $n^{O(1/\varepsilon)}$; thus, $\varepsilon > 0$ is assumed to be constant. Due to space constraints, we only give an informal description of the algorithm for the special case of $(n/2)$ -stable instances; the algorithm then naturally generalizes to (n/k) -stable instances, for any integer $k \geq 2$. The base case (i.e., $k = 1$) uses the greedy algorithm.

We start by observing that either the chromatic number is at most $n/2$, in which case the LP is integral, or there are more than $n/2$ vertices of degree at least $n/2$. In the latter case, we check whether each of these high-degree vertices belongs to the optimal solution, by removing each such vertex and its neighborhood, one at a time, and using the algorithm recursively. Since their neighborhoods are large, we end up with graphs with at most $n/2$ vertices, which are still $(n/2)$ -stable if the removed vertex belongs to the optimal solution; thus, the recursion succeeds on them (in particular, the greedy algorithm solves such instances). Finally, if none of these high-degree vertices belongs to the optimal solution, then we remove all of them, and end up again with a graph with at most $n/2$ vertices that is $(n/2)$ -stable; the recursive call again solves that instance. By returning the best of all computed solutions, we are guaranteed to recover the optimal solution.

► **Theorem 23.** *There exists an algorithm that solves $(\frac{n}{k})$ -stable instances of MIS on graphs of n vertices in time $n^{O(k)}$.*

5 Stability and integrality gaps of convex relaxations

In this section, we state a general theorem about the integrality gap of convex relaxations of maximization problems on stable instances. In particular, we show that, even if the conditions of Theorem 8 are not satisfied, the integrality gap still significantly decreases as stability increases.

► **Theorem 24.** *Consider a relaxation for MIS that assigns a value $x_u \in [0, 1]$ to each vertex u of a graph $G = (V, E, w)$, and its objective function is $\sum_{u \in V} w_u x_u$. Let α be its integrality gap, for some $\alpha > 1$. Then, its integrality gap is at most $\min\{\alpha, 1 + \frac{1}{\beta-1}\}$ on $(\alpha\beta)$ -stable instances, for any $\beta > 1$.*

The proof is somewhat similar in spirit to the lemmas and analysis used for Algorithm 3. We stress that the above result is inherently non-constructive. Nevertheless, it suggests estimation algorithms for stable instances of MIS, such as the following, which is a direct consequence of Theorem 24 and the results of [31, 33].

► **Corollary 25.** *For any fixed $\varepsilon > 0$, the Lovasz θ -function SDP has integrality gap at most $1 + \varepsilon$ on $\tilde{O}\left(\frac{1}{\varepsilon} \cdot \frac{\Delta}{\log \Delta}\right)$ -stable instances of MIS of maximum degree Δ .*

We note that the theorem naturally extends to many other maximization graph problems, and is particularly interesting for relaxations that require super-constant stability for the recovery of the optimal solution (e.g., the Max Cut SDP has integrality gap $1 + \varepsilon$ for $(2/\varepsilon)$ -stable instances although the integrality gap drops to exactly 1 for $\Omega(\sqrt{\log n} \cdot \log \log n)$ -stable instances).

In general, such a theorem is not expected to hold for minimization problems, but, in our case, MIS gives rise to its complementary Minimum Vertex Cover problem, and it turns out that we can prove a very similar result for Minimum Vertex Cover as well.

6 Certified algorithms for MIS

In this section, we initiate the systematic study of certified algorithms for MIS, introduced by Makarychev and Makarychev [41].

6.1 Certified algorithms using convex relaxations

An important observation that [41] makes is that an approach very similar to the one used for the design of algorithms for weakly-stable instances [42] can be used to obtain certified algorithms. More formally, they prove the following theorem.

► **Theorem 26** ([41]). *Let $x : V \rightarrow [0, 1]$ be an optimal fractional solution of a convex relaxation of MIS whose objective value for an instance $G = (V, E, w)$ is $\sum_{u \in V} w_u x_u$. Suppose that there exists a polynomial-time (α, β) -rounding for x . Then, there exists a polynomial-time $(\alpha\beta + \varepsilon)$ -certified algorithm for MIS on instances with integer polynomially-bounded weights (for $\varepsilon \geq 1/\text{poly}(n) > 0$).*

We now combine Theorem 19 with Theorem 26 and obtain the following theorem.

► **Theorem 27.** *There exists a polynomial-time $(1 + \varepsilon)$ -certified algorithm for MIS on planar graphs with integer polynomially-bounded weights (for $\varepsilon \geq 1/\text{poly}(n) > 0$).*

6.2 Combinatorial certified algorithms

In this section, we study several combinatorial algorithms for MIS and prove that they are certified. The first result is about the greedy algorithm.

► **Theorem 28.** *The greedy algorithm (see Algorithm 2) is a Δ -certified algorithm for MIS on graphs of maximum degree Δ . More generally, the greedy algorithm is a Δ -certified algorithm for any instance of a Δ -extendible system.*

Moreover, we introduce a variant of the greedy algorithm for MIS that is a $\sqrt{\Delta^2 - \Delta + 1}$ -certified algorithm; the improvement over the greedy is moderate for small values of Δ . Finally, we show that the algorithm of Berman and Fürer [13] is $(\frac{\Delta+1}{3} + \varepsilon)$ -certified, when all weights are 1. We acknowledge that the restriction to unweighted graphs limits the scope of the algorithm, but we consider this as a first step towards obtaining $(c\Delta)$ -certified algorithms, for $c < 1$.

► **Theorem 29.** *The Berman-Fürer algorithm ([13]) is a $(\frac{\Delta+1}{3} + \varepsilon)$ -certified algorithm for MIS on graphs of maximum degree Δ , when all weights are equal to 1.*

Let $G = (V, E, w)$ be a graph of maximum degree Δ , $n = |V|$, where $w_u = 1$ for every $u \in V$. We say X is an improvement of I , if both I and $I \oplus X$ are independent sets, the subgraph induced by X is connected and $I \oplus X$ is larger than I . (The operator \oplus denotes the symmetric difference.)

The algorithm starts with a feasible independent set I' and iteratively improves the solution by checking whether there exists an improvement X with size $|X| \leq \sigma$. If so, it replaces I by $I \oplus X$ and repeats. Otherwise, if no such improvement exists, it outputs the current independent set I . Assuming that Δ is a constant, the algorithm runs in polynomial time as long as $\sigma = O(\log n)$.

► **Lemma 30** ([13]). *If Δ is a constant and $\sigma = O(\log n)$, the algorithm runs in polynomial time.*

The main result can be presented as follows. Along with Definition 3, it implies Theorem 29.

► **Lemma 31.** *Let I be the independent set returned by the algorithm with $\sigma = 32k\Delta^{4k} \log n$ and let $S \neq I$ be any feasible independent set. Then, we have $|S \setminus I| \leq (\frac{\Delta+1}{3} + \varepsilon) \cdot |I \setminus S|$, where $\varepsilon = \frac{1}{3k}$.*

Proof. Let $\bar{S} = S \setminus I$ and $\bar{I} = I \setminus S$. First, we observe that every $u \in \bar{S}$ has at least one neighbor in \bar{I} , otherwise, we could improve I by adding a new vertex from \bar{S} . We now consider the set $T = \{u \in \bar{S} : |N(u) \cap I| = 1\} \subseteq \bar{S}$. In words, T is the set of elements in \bar{S} that have exactly one neighbor in I . We also define $J = \{v \in \bar{I} : N(v) \cap T \neq \emptyset\}$ to be the set of elements of \bar{I} that have at least one neighbor in T . We will show that $|T| \leq |J|$.

To prove this, let's assume that $|T| > |J|$. Then, by the pigeonhole principle, we must have at least one vertex $v \in J$ that is connected to at least two vertices $u_1, u_2 \in T$. This implies that replacing v with u_1 and u_2 would be an improvement. Thus, we get a contradiction. Now let $I_0 = \bar{I} \setminus J$ and $S_0 = \bar{S} \setminus T$. The final step of the proof is a direct consequence of Lemma 3.5 of [13], that states that if there is no improvement over I of size at most $\sigma = 32k\Delta^{4k} \log n$, then for $\varepsilon = 1/(3k)$, $|S_0| \leq (\frac{\Delta+1}{3} + \varepsilon) |I_0|$. Recall that we have already proved $|T| \leq |J|$. Therefore,

$$\begin{aligned} |S \setminus I| &= |S_0| + |T| \leq \left(\frac{\Delta+1}{3} + \varepsilon\right) |I_0| + |J| \\ &\leq \left(\frac{\Delta+1}{3} + \varepsilon\right) (|I_0| + |J|) = \left(\frac{\Delta+1}{3} + \varepsilon\right) |I \setminus S|. \end{aligned} \quad \blacktriangleleft$$

Abstract

In the *Anchored Rectangle Packing (ARP)* problem, we are given a set of points P in the unit square $[0, 1]^2$ and seek a maximum-area set of axis-aligned interior-disjoint rectangles S , each of which is anchored at a point $p \in P$. In the most prominent variant – *Lower-Left-Anchored Rectangle Packing (LLARP)* – rectangles are anchored in their lower-left corner. Freedman [19, Unsolved Problem 11, page 345] conjectured in 1969 that, if $(0, 0) \in P$, then there is a LLARP that covers an area of at least 0.5. Somewhat surprisingly, this conjecture remains open to this day, with the best known result covering an area of 0.091 [11]. Maybe even more surprisingly, it is not known whether LLARP – or any ARP-problem with only one anchor – is NP-hard.

In this work, we first study the *Center-Anchored Rectangle Packing (CARP)* problem, where rectangles are anchored in their center. We prove NP-hardness and provide a PTAS. In fact, our PTAS applies to any ARP problem where the anchor lies in the interior of the rectangles. Afterwards, we turn to the LLARP problem and investigate two different resource-augmentation settings: In the first we allow an ε -perturbation of the input P , whereas in the second we permit an ε -overlap between rectangles. For the former setting, we give an algorithm that covers at least as much area as an optimal solution of the original problem. For the latter, we give an $(1 - \varepsilon)$ -approximation.

1 Introduction

The *lower-left-anchored rectangle packing (LLARP)* problem was first posed in 1969 by Freedman [19]: Given the unit square $U := [0, 1]^2$ in the plane and a finite set of points $P \subseteq U$, find a maximum-area set of axis-aligned and interior-disjoint rectangles \mathcal{S} , such that for each $p \in P$, there is exactly one (possibly trivial) rectangle $R \in \mathcal{S}$ that has p in its lower-left corner. It was conjectured [19, 20] that the area covered is at least 0.5 as long as $(0, 0) \in P$. The first and so far only result that achieves a constant lower bound covers an area of at least 0.091 [11].

A natural generalization of the LLARP problem looks at anchors different from the lower-left corner. Such an *anchoring* can be defined by a pair $(\alpha, \beta) \in [0, 1]^2$. The (α, β) -ARP problem then looks for a maximum-area rectangle set as above but with rectangles anchored in the relative position (α, β) (see Section 2). For example, $(0, 0)$ -ARP is LLARP, while $(1/2, 1/2)$ -ARP requires all rectangles to have a $p \in P$ at their center. We refer to the latter as *center-anchored rectangle packing (CARP)* problem.

Our Contribution. Even though the formulation of LLARP and Freedman’s conjecture [19], date back to 1969 it is still not even known whether its decision variant is NP-hard. This is why, in this work, we focus on the complexity of related ARP problems and introduce a resource augmentation setting for LLARP.

When looking at the complexity of CARP, a difference that stands out compared to LLARP is that CARP allows one to simulate “non-expandable” points: By putting four points at the corners of a tiny ε -sized square, none of their rectangles’ side lengths can exceed ε . One can think of these four points as one input point that cannot be used as an anchor but still restricts the expansion of other rectangles. These non-expandable points turn out to be a valuable asset, as they can be used to build walls and inject additional geometry into the problem. We exploit this in an elaborate construction that encodes maximum independent set into a CARP instance, proving NP-hardness of CARP (cf. Section 4). The construction of non-expandable points seems difficult or even impossible for LLARP and is the main obstacle in transferring our NP-hardness proof to that setting.

The NP-hardness is complemented by a polynomial-time approximation scheme (PTAS), which extends also to any anchoring $(\alpha, \beta) \in (0, 1)^2$. The PTAS is based on a carefully constructed input instance for a related problem called *maximum weight independent set of rectangles (MWISR)* and the usage of a known PTAS in a resource augmentation setting of MWISR (cf. Section 3).

With respect to the classical LLARP problem, we initiate the investigation of the problem with resource augmentation. We study two such settings. In the first, the algorithm is allowed to slightly perturb the input points. In the second, the rectangle set produced by the algorithm may have some (bounded) overlap. In both cases, the resulting solution is compared to an optimal solution without these augmentations. For the first setting, we develop an algorithm that produces an anchored rectangle set of total area no less than that of an optimal solution of LLARP without resource augmentation (cf. Section 5). Our analysis is combinatorial in nature and consists of transforming the optimal solution to a feasible solution for a perturbed instance by using a specific linear program with totally unimodular incidence matrix. For the second setting, we provide an algorithm that covers at least $(1 - \varepsilon)$ times the area of an optimal solution (cf. Section 5). Our algorithm is based on the one for the first setting.

Further Related Work. The best known polynomial time algorithm for the LLARP problem is due to Dumitrescu and Tóth [11] and covers an area of at least 0.091. Since the optimal solution cannot cover more than an area of 1 (the whole unit square), their analysis also implies a 0.091-approximation. In the setting where, instead of arbitrary rectangles, squares must be used, Balas et al. [5] achieve an approximation ratio of $1/3$. They also consider a setting where the algorithm can choose for each rectangle from multiple anchors (the four corners), giving a $(7/12 - \varepsilon)$ -approximation algorithm, where $\varepsilon = |P|^{-1}$, and a QPTAS for rectangles, as well as a $9/47$ -approximation algorithm and a PTAS for squares. The QPTAS and PTAS extend to the lower-left anchored variants. Recently, Akitaya et al. [4] gave the first NP-hardness result for an ARP variant where only squares may be packed and each square can be anchored at any of its four corners. They also show that, for any instance consisting of finitely many input points inside U , the union of all feasible anchored square packings covers an area of at least $1/2$. Finally, if rectangles can be anchored at any of their four corners but input points are restricted to the boundary of U , Biedl et al. [9] give a polynomial-time algorithm (based on maximum independent set for a specific class of graphs).

ARP problems fall within the more general setting of packing axis-aligned and interior-disjoint rectangles in a rectangular container. This setting captures several important and well studied optimization problems. See, for example, the (NP-hard) problems 2D-knapsack and strip packing [2, 6], as well as maximum area independent set of rectangles [3, 7, 8]. Similar problems have also been formulated by Radó and Rado [16, 13, 14, 15]. These problems differ from ARP in that the size of the packed objects is part of the input and not controllable and, in some cases, there is no anchoring of the rectangles.

2 Preliminaries

We start with some general notation. Consider a point $p \in \mathbb{R}^2$ and an axis-aligned rectangle $R \subseteq \mathbb{R}^2$ with its lower-left corner in $(x, y) \in \mathbb{R}^2$. Let w and h denote the width and height of R , respectively. For a pair $(\alpha, \beta) \in [0, 1]^2$ (called *anchoring*), we say R is (α, β) -anchored in p if $p = (x + \alpha \cdot w, y + \beta \cdot h)$. We also say that p (α, β) -spans R . If the anchoring (α, β) is clear from the context we omit it. We use $\mathcal{A}(R) = w \cdot h$ to denote the area of rectangle R . Similarly, given a set \mathcal{S} of rectangles we define $\mathcal{A}(\mathcal{S})$ as the area of $\bigcup_{R \in \mathcal{S}} R$. We use $U = [0, 1]^2$ to denote the unit square. If not stated otherwise, any rectangle is assumed to be axis-aligned.

The Anchored Rectangle Packing Problem. We now define the *anchored rectangle packing (ARP)* problem with respect to an anchoring $(\alpha, \beta) \in [0, 1]^2$. An instance consists of a finite set $P \subseteq U$ of n points. A *valid rectangle set* (also *solution*) \mathcal{S} for the ARP instance P is a set of interior-disjoint rectangles that contains one (possibly zero-sized) rectangle R_p for each $p \in P$ such that R_p is (α, β) -anchored in p and does not contain any point from $P \setminus \{p\}$ in its interior. The goal is to find a solution \mathcal{S} for P that covers as much area as possible. We use $\mathcal{S}_{\text{ARP}(P)}^*$ to denote a valid rectangle set of maximum area $\text{OPT}_{\text{ARP}(P)} := \mathcal{A}(\mathcal{S}_{\text{ARP}(P)}^*)$ and omit ARP and/or P if it is clear from context.

We will mostly consider two specific anchorings. When using the anchoring $(0, 0)$, we refer to the problem by the name *lower-left-anchored rectangle packing (LLARP)*. When the anchoring is $(1/2, 1/2)$, we refer to the problem by the name *center-anchored rectangle packing (CARP)*.

■ **Figure 1** Maximal rectangles R_{\max} and R'_{\max} and candidate rectangles $R_{\max}^{i,j}$ derived from R_{\max} for the anchoring $(1/2, 1/2)$.

3 A PTAS for ARP with Fractional Anchorings

In the following, we give a PTAS for the anchored rectangle packing problem for any anchoring $(\alpha, \beta) \in (0, 1)^2$. It is based on a result for *maximum weight independent set of rectangles (MWISR)*¹ that uses resource augmentation similar to that in Theorem 8. An instance of MWISR consists of a set of n axis-aligned, weighted rectangles. The goal is to compute a maximum-weight subset of pairwise interior-disjoint rectangles. In the relaxed variant δ -MWISR (for fixed $\delta > 0$), rectangles must be non-overlapping only *after* shrinking them by a factor of $1 - \delta$. Here, Adamaszek et al. [1] give an algorithm that, in time $n^{(\delta\varepsilon)^{-\Omega(1/\varepsilon)}}$, computes a solution which is within a $(1 + \varepsilon)$ -factor of the optimum MWISR. While the original algorithm considers shrinking only around the rectangles' centers, this can be generalized such that it also works when shrinking around an arbitrary anchoring $(\alpha, \beta) \in (0, 1)^2$. However, this does not generalize to anchors on the boundaries (in particular, not to LLARP), since [1] requires shrinking around a rectangle's center, this way the shrunken rectangle would no longer contain its anchor.

► **Theorem 1.** *For any fixed anchoring $(\alpha, \beta) \in (0, 1)^2$, the anchored rectangle packing problem admits a polynomial-time approximation scheme.*

Proof. Consider an instance $P \subseteq U$ of (α, β) -ARP with n input-points and fix $\varepsilon > 0$. Denote by ε', δ positive constants which we fix later and define $N := \lceil \log_{1-\delta}(\delta/n) \rceil + 1$.

For each point pair $p, p' \in P$, there are at most two inclusion-wise maximal rectangles that are anchored in p and have p' on their boundary, one where p' is on the left (right) side of the rectangle and one where p' is on its bottom (top) side. Thus, there are at most $2n$ inclusion-wise maximal rectangles that are anchored in a point $p \in P$ and at most $2n^2$ overall. For any such *maximal rectangle* R_{\max} , construct N^2 *candidate rectangles* $(R_{\max}^{i,j})_{i,j=0}^{N-1}$ by scaling (around the anchor) by a factor of $(1 - \delta)^i$ along the horizontal and $(1 - \delta)^j$ along the vertical axis. Denote the set of all such candidate rectangles by \mathcal{C} . See Figure 1 for an illustration.

In order to obtain a $(1 + \varepsilon)$ -approximation for the ARP instance P , we first apply the algorithm for δ -MWISR [1] to the MWISR instance $(\mathcal{C}, \mathcal{A})$ (i.e., all candidate rectangles weighted by their area). This yields a rectangle set \mathcal{S}' with $\mathcal{A}(\mathcal{S}') \geq (1 + \varepsilon')^{-1} \cdot \text{OPT}_{\text{MWISR}}$.

¹ A similar connection to MWISR has recently been used [5] to obtain a PTAS for packing squares and a QPTAS for packing rectangles when the anchors are allowed to lie in any of the four corners (and may be different for each rectangle).

where $\text{OPT}_{\text{MWISR}}$ denotes the area covered by an optimal solution for the instance $(\mathcal{C}, \mathcal{A})$ of MWISR. Note that each rectangle $R \in \mathcal{S}'$ is anchored in some point $p \in P$. By definition of δ -MWISR, scaling each rectangle in \mathcal{S}' by a factor of $1 - \delta$ in each dimension around its anchor produces a set \mathcal{S} of pairwise interior-disjoint rectangles with

$$\mathcal{A}(\mathcal{S}) \geq (1 - \delta)^2 (1 + \varepsilon')^{-1} \cdot \text{OPT}_{\text{MWISR}}. \quad (1)$$

Moreover, since the scaling happens around the anchors, the rectangles are still anchored in their associated input-points. It follows that, after possibly adding some trivial rectangles, the set \mathcal{S} is a solution for the ARP instance P . Note that for fixed δ and ε' , the total time spent to obtain \mathcal{S} is polynomial in n . The bottleneck here is the computation of \mathcal{S}' from the $|\mathcal{C}| \leq 2n^2 \cdot N^2$ candidate rectangles. By [1, Theorem 1], this can be done in time $n^{(\delta\varepsilon')^{-O(1/\varepsilon')}}$.

We now bound the area OPT_{ARP} of an optimal (α, β) -ARP solution $\mathcal{S}_{\text{ARP}}^*$ in terms of $\text{OPT}_{\text{MWISR}}$. To this end, fix a rectangle $R_p^* \in \mathcal{S}_{\text{ARP}}^*$ with anchor point $p \in P$. This rectangle is contained in at least one maximal candidate rectangle R_{max} . Let $i, j \in \{0, 1, \dots, N - 1\}$ be maximal such that $R_p^* \subseteq R_{\text{max}}^{i,j}$ and note that $\mathcal{A}(R_p^*) \leq \mathcal{A}(R_{\text{max}}) \cdot (1 - \delta)^{i+j}$. We say that R_p^* is *negligible* if $i = N - 1$ or $j = N - 1$. For each non-negligible $R_p^* \in \mathcal{S}_{\text{ARP}}^*$, define $R_p := R_{\text{max}}^{i+1, j+1}$ and denote by \mathcal{S}'' the set of all such rectangles. We consider the contribution of non-negligible and negligible rectangles to OPT_{ARP} separately.

- By construction, the contribution of non-negligible rectangles is at most $(1 - \delta)^{-2} \cdot \mathcal{A}(\mathcal{S}'')$. Furthermore, since $\mathcal{S}'' \subseteq \mathcal{C}$ and as the rectangles in \mathcal{S}'' are pairwise non-overlapping (as a shrunken subset of an ARP solution), \mathcal{S}'' is a solution to the MWISR instance \mathcal{C} . This implies that $\mathcal{A}(\mathcal{S}'') \leq \text{OPT}_{\text{MWISR}}$, which bounds the contribution of non-negligible rectangles to OPT_{ARP} by $(1 - \delta)^{-2} \cdot \text{OPT}_{\text{MWISR}}$.
- To bound the contribution of negligible rectangles, fix a negligible $R_p^* \in \mathcal{S}_{\text{ARP}}^*$ and note that $\mathcal{A}(R_p^*) \leq \mathcal{A}(R_{\text{max}}) \cdot (1 - \delta)^{N-1} \leq \text{OPT}_{\text{MWISR}} \cdot (1 - \delta)^{N-1} \leq \text{OPT}_{\text{MWISR}} \cdot \delta/n$, where the penultimate inequality holds since $\{R_{\text{max}}\}$ is a valid MWISR solution. Since there are at most n negligible rectangles in $\mathcal{S}_{\text{ARP}}^*$, they contribute at most $\delta \cdot \text{OPT}_{\text{MWISR}}$. Combined, we get that $\text{OPT}_{\text{ARP}} \leq (\delta + (1 - \delta)^{-2}) \cdot \text{OPT}_{\text{MWISR}}$. Using Equation (1), this implies

$$\mathcal{A}(\mathcal{S}) \geq (1 - \delta)^2 (1 + \varepsilon')^{-1} \cdot (\delta + (1 - \delta)^{-2})^{-1} \cdot \text{OPT}_{\text{ARP}} = (1 + \varepsilon)^{-1} \cdot \text{OPT}_{\text{ARP}}, \quad (2)$$

where the equality holds for small enough δ and appropriately chosen ε' . ◀

4 CARP is NP-Complete

In the decision variant of the center-anchored rectangle packing problem, we are given a value $A > 0$ and a finite point set $P \subseteq U$. The goal is to decide whether there is a valid rectangle set \mathcal{S} for P that covers an area of at least A . In this section we prove that this problem is NP-complete.

A useful observation is that if the input set contains four points in the corners of a tiny square with side length $\delta > 0$, then these points restrict the expansion of other points' rectangles but cannot expand their own rectangles beyond side length 2δ (see Figure 2a). This enables us to build walls that encode the graph structure of a suitable variant of maximum independent set (MIS).

► **Theorem 2.** *The center-anchored rectangle packing problem is NP-complete.*

(a) Building a wall W to the north of point p by adding four wall points. (b) Two node gadgets directly connected via a path gadget. The left node gadget is contracted, the right one expanded.

■ **Figure 2** Illustrations of the wall construction and a normalized solution for a pair of node gadgets.

The problem is easily seen to be in NP. Thus, the main challenge in proving Theorem 2 lies in the aforementioned reduction. Since the gadgets used in the construction as well as their interplay are somewhat involved, we give a high-level overview in Section 4.1. In Section 4.2, we describe in more detail how a suitable CARP instance is constructed from a given MIS instance. The analysis of this construction is given in Section 4.3.

4.1 Overview of the Reduction

The reduction is from the problem maximum independent set in 3-regular planar graphs (MIS3P), which is known to be NP-hard [12]. Given a MIS3P instance G , we use a result by Tamassia [18] to construct an orthogonal embedding of G . We then replace each node of G by a *node gadget* and each edge by a series of *path gadgets*. The number of path gadgets per edge corresponds (roughly) to the number of turns that it takes in the orthogonal embedding.

Gadgets & Rectangle Sets. Figure 2b illustrates the gadgets via a simple example where two node gadgets are directly² connected by a path gadget. Black dots represent the normal input points used to form center-anchored rectangles. Black lines represent walls built by placing four δ -spaced *wall points* at the orthogonal projections of each normal input point onto its closest wall in each direction. The horizontally striped blue areas connecting node gadget and path gadget are called *conflict areas*. The vertically striped blue areas at the entrance to the inner parts of the node gadget are called *compensation areas*. The shaded areas represent a valid example rectangle set for the (non-wall) input points. Diagonally striped red areas remain uncovered in the depicted solution.

Note that the rectangle sets of the two node gadgets in the depicted solution differ from one another. If, in a given solution, the points of a node gadget span rectangles exactly as in the right part of Figure 2b we say the node gadget is *expanded*. In particular, an expanded node gadget covers all three adjacent conflict areas. In the left part of Figure 2b, we see

² In our actual constructions, node gadgets are always connected via a chain of several path gadgets. Figure 2b neglects this technical detail in order to keep the illustration simple and instructive.

one possible example of a so called *contracted* node gadget. Such contracted node gadgets neither cover a neighboring conflict area (which is then covered by the adjacent path gadget), nor the neighboring compensation area (which is then not covered at all). A central part of our construction is that the latter case (where we loose an area of size b^2) happens only if the adjacent path gadget leads to another contracted gadget.

Normalized Solutions & Structural Properties. Our construction allows to prove the existence of a well-structured, almost optimal solution. We call a solution *normalized* if each wall point is assigned a $(\delta \times \delta)$ -square. In a normalized solution, non-wall points cannot expand their rectangles beyond adjacent walls. Additionally, we show the following properties.

- Lemma 4: There is a normalized solution approximating an optimal solution up to a factor of $1 - O(\delta/\varepsilon^2)$. Choosing δ suitably small allows us to consider normalized solutions only.
- Lemma 5: We call a solution normalized *with oriented paths* if the rectangles spanned by non-wall points are such that any series of connected path gadgets is alternatingly covered by “big” and “small” rectangles. An optimal normalized solution can be transformed into one with oriented paths without decreasing the covered area.
- Lemma 6: Given an optimal normalized solution with oriented paths, one can transform the rectangles spanned by non-wall points of node gadgets such that each node gadget is either expanded or contracted. This transformation changes only rectangles spanned by node gadgets and does not decrease the covered area.

From this, we obtain a bijection between normalized solutions \mathcal{S} with oriented paths and only either expanded or contracted node gadgets and independent sets $I \subseteq V(G)$. Nodes $u \in I$ correspond to expanded node gadgets and nodes $u \notin I$ to contracted node gadgets.

Covered Area & Size of Independent Set. We derive a formula for the area covered by \mathcal{S} in terms of the size $|I|$ of the independent set. When a contracted node gadget does not cover one (or multiple) of its compensation areas, we charge these areas to the neighboring conflict area (which has the same size, b^2). See Figure 3 for an illustration of compensation and conflict areas. By this charging, the area covered by the inner part of any node gadget (whether expanded or contracted) differs only by the number of covered ε -stripes (small diagonally striped red areas within the node gadgets of size $O(\varepsilon \cdot b) \ll b^2$). For each path gadget, we always loose an area of size $3b^2$ at one of the two ends. Additionally, for each series of path gadgets connecting two contracted node gadgets, we loose an area b^2 of one of the conflict areas (using the charging).

Thus, ignoring negligible areas from the ε -stripes and wall-points, \mathcal{S} covers an area of size $\mathcal{A}(\mathcal{S}) = A_G + 3|I| \cdot b^2$. While A_G depends only on the graph G and its embedding, the second term stems from an independent set node being the only means of covering both critical areas of an incident edge. Thus, a solution covering the maximum area yields a maximum independent set and vice versa.

4.2 Construction of the CARP Instance

We start by formalizing the ideas of walls, depicted as black lines in our images. Fix a small $\delta > 0$ (whose value we specify later) and consider a point set P , a point $p \in P$, and a wall W (an axis aligned line segment), which is closest either in x - or y -direction. We modify P by adding four wall points that form an (axis aligned) square of side length δ on the (w.r.t. p) opposite side of the wall W . We do this in such a way that p and two of the wall points lie on a straight line and the wall point closer to p is at a distance of $\delta/2$ to W . See Figure 2a for an illustration.

■ **Figure 3** Detailed illustration of node and path gadgets with the respective side lengths. Conflict areas are horizontally striped. Compensation areas are vertically striped.

► **Observation 3.** Consider a valid solution for P after adding the four wall points for p . The rectangles spanned by p and by the wall points cannot transgress the wall by more than $\delta/2$. Moreover, the rectangles spanned by the four wall points cover an area³ of at most $4\delta^2$.

Gadgets. We now formally describe the node gadgets (representing nodes of the MIS3P instance) and the path gadgets (representing edges of the MIS3P instance). Figure 3a shows the details of a node gadget. Each input point is restricted by at most four walls. A node gadget has three outgoing paths each connected to a path gadget (corresponding to an incident edge). Figure 3b shows the details of a path gadget. Path gadgets are connected either to other path gadgets via a 90° turn (the crossings in the figure) or to a node gadget. There are two global parameters, the width of a path b and a small value $\varepsilon > 0$. We choose the former such that we can fit each gadget into a small *tile* whose size depends on the MIS3P instance, and we choose the latter small enough to ensure that certain non-coverable areas of node gadgets are negligible. A path gadget g_i has two additional parameters, $d_i > 0$ (roughly the length of the straight edge it represents) and $a_i := d_i/4 - b$ (specifying the exact placement of the non-wall points depending on d_i).

Orthogonal Embedding & Connecting the Gadgets. Next, consider an MIS3P instance G (i.e., a 3-regular planar graph) consisting of n nodes. We embed G in a $(4n + 2) \times (4n + 2)$ grid. This can be done in polynomial time (a simple application of a result from [18]). We then partition the unit square U into a grid of equal-sized tiles of width and height $1/(4n + 2)$. Depending on how the embedding behaves at a grid point $(i, j) \in \{1, \dots, 4n + 2\}^2$, we construct tile (i, j) from a suitable blueprint:

- *Grid point contains a node:* Use an appropriate rotation of the tile in Figure 4a.
- *Grid point contains an edge bend:* Use an appropriate rotation of the tile from Figure 4b.
- *Grid point contains part of an edge:* Insert tiles to form a straight path of width b , either from south to north or from east to west (determined by the orientation of the edge part).

³ While the rectangles may cover all of the square formed by the wall points, an area of size δ^2 , precisely $\frac{3}{4}$ of each rectangle's area lies outside this square. Thus, the total covered area is at most $\delta^2 + 3\delta^2$.

(a) Node gadget inside a tile of U .

(b) Bend inside a tile connecting two path gadgets.

■ **Figure 4** Two tiles used in our hardness construction. Further tiles include rotations of these as well as straight horizontal and vertical paths. Both sides of each tile have size $64b + 2\varepsilon$.

Note that outgoing path gadgets always leave a tile at the center of a tile boundary and that all parts are properly connected.

It remains to fix the parameters δ , b , and ε . These are chosen such that all parts of a node gadget tile (Figure 4a) fit exactly into the $1/(4n+2) \times 1/(4n+2)$ tiles and $\delta \ll \varepsilon \ll b$. The chosen lengths (Figure 3) guarantee that tile parts do not overlap. Our analysis also requires $2a_i \geq b$ (or, equivalently, $d_i \geq 6b$) for every path gadget g_i . One can easily verify that this is the case (see Section 4.2).

We now bound the size of the constructed CARP instance P_G for a graph G consisting of n nodes. Each tile of a node gadget contains 38 points. For each bend tile we add 2 points. Since there are n nodes and at most $3n+2$ bends [18, Lemma 7], the instance P contains at most $44n+4$ non-wall points. For each non-wall point we add at most 16 wall points. Thus, the size of P is bounded by $704n+64 = \Theta(n)$, implying that P_G can be constructed in polynomial time.

4.3 Analysis of the Constructed CARP Instance

Fix a MIS3P instance $G = (V, E)$ consisting of n nodes and let P_G denote the construction from the previous section. Let $W \subseteq P_G$ be the set of all wall points in P_G . Recall that a solution \mathcal{S} for the CARP instance P_G is called normalized if all points in W span $(\delta \times \delta)$ -rectangles. Note that in such a solution the rectangles spanned by points from $P_G \setminus W$ cannot overlap the walls. An *optimal normalized solution* is a normalized solution of maximum size. In the following, we state the key results of the analysis. Due to space constraints, we do not give the proofs in all detail here. For the complete proofs, we refer the reader to the full version of this paper.

Our first lemma shows that there exists a normalized solution that approximates an optimal solution up to a factor of $1 - O(\delta/\varepsilon^2)$.

► **Lemma 4.** *There exists a normalized solution for CARP on the instance P_G of area at least $(1 - 2\delta/\varepsilon^2) \cdot \text{OPT}_{\text{CARP}(P_G)}$.*

The next pair of lemmas form the center of our arguments. They show the existence of optimal normalized solutions exhibiting useful structural properties for both the path and node gadgets.

8:10 On the Complexity of Anchored Rectangle Packing

► **Lemma 5.** *There exists an optimal normalized solution in which the two rectangles spanned by a path gadget g_i 's two non-wall points have width (or, depending on orientation, height) b , and one of them has height (width) $2a_i$, the other one $2(a_i + 4b)$. In particular, the rectangles of each path gadget cover exactly one of the gadget's two conflict areas.*

- **Lemma 6.** *There exists an optimal normalized solution such that the following holds:*
- *Each node gadget is either contracted or expanded.*
 - *No two adjacent node gadgets are expanded.*
 - *For each pair of contracted adjacent node gadgets there is a (uniquely identified) uncovered area of size b^2 inside one of the node gadgets.*

The previous two lemmas hold simultaneously. NP-hardness follows from these results as described in Section 4.1.

5 Resource Augmentation

In this section, we investigate the lower-left-anchored rectangle packing problem. We study two different types of resource augmentation. In the first type, which we call *perturbation-augmentation*, each solution rectangle does not need to be anchored exactly in the corresponding point but instead its anchor may be up to an ε distance away from that point (see Figure 5, center). We define an ε -grid $\Gamma = (V, \mathcal{L})$ as a set of points $V = \{(x, y) \in U \mid x = \varepsilon \cdot k_x \wedge y = \varepsilon \cdot k_y \wedge k_x, k_y \in \mathbb{N}\}$ together with a family of grid-cells $\mathcal{L} = \{[x, x + \varepsilon] \times [y, y + \varepsilon] \subseteq U \mid (x, y) \in V\}$. The perturbation-augmentation allows us to focus on solutions where all vertices of rectangles are points on an ε -grid Γ , thereby allowing us to enumerate all possible sets of interior-disjoint, axis-aligned rectangles with vertices in V . We call such a solution a *grid-point solution*. We show that (i) there exists a polynomial-time algorithm that finds the optimal grid-point solution and (ii) the optimal grid-point solution covers at least as much area as an optimal (unrelaxed) solution.

Before formally stating the theorem, we introduce some notation. Let $\text{dist}_\infty(x, y)$ denote the distance of two points $x, y \in \mathbb{R}^2$ in the ℓ_∞ -norm. For a set $X \subseteq \mathbb{R}^2$ and a point $y \in \mathbb{R}^2$, we write $\text{dist}_\infty(y, X) = \inf_{x \in X} \text{dist}_\infty(y, x)$ and $\overline{X} = \mathbb{R}^2 \setminus X$ for the set's complement. We say that a set of interior-disjoint rectangles $\{R_p\}_{p \in P}$ is ε -valid, if $\text{dist}_\infty(p, \ell(R_p)) < \varepsilon$ and $\text{dist}_\infty(p, \overline{R_p}) < \varepsilon$ for all $p \in P$, where $\ell(R_p)$ denotes the lower-left corner of R_p .

► **Theorem 7.** *For every $\varepsilon > 0$ and a finite point-set $P \subseteq U$, there exists a polynomial time algorithm that computes an ε -valid set of interior-disjoint rectangles that cover an area of at least $\text{OPT}_{\text{LLARP}(P)}$.*

The second type of resource augmentation we call *overlap-augmentation*. It relaxes the condition that the rectangles need to be disjoint. More specifically, each pair of rectangles is allowed to overlap by a thin strip of width at most δ . Note that this implies that a rectangle may also contain input points as long as they are no more than a δ -distance away from the boundary (see Figure 5, right).

Again, we require additional definitions. A set of rectangles $\{R_p\}_{p \in P}$ is called a δ -LLARP, if the rectangle R_p is lower-left-anchored in p and $\sup_{x \in R_{p'}} \text{dist}_\infty(x, \overline{R_p}) < \delta$, for all $p' \in P$. We show that we can transform an ε -valid grid-point solution into a δ -LLARP while only losing a small fraction of the covered area.⁴

⁴ Naturally, any area that is covered by multiple rectangles is counted only once.

■ **Figure 5** An optimal lower-left-anchored rectangle packing (left), and illustrations of the two kinds of resource augmentation that are used in the paper.

► **Theorem 8.** *For every $\varepsilon > 0$ and a finite point-set $P \subseteq U$, there exists a polynomial time algorithm that outputs an $\frac{\varepsilon}{11}$ -LLARP that covers an area of at least $(1-\varepsilon) \cdot \text{OPT}_{\text{LLARP}(P)}$.*

■ **Algorithm 1** Algorithm using resource augmentation of the perturbation-type.

```

1:  $\Gamma \leftarrow \varepsilon$ -grid in  $U$ ,  $\mathcal{H} \leftarrow \emptyset$ 
2: for every configuration  $C$  in  $\Gamma$  do
3:   if  $C$  is  $\varepsilon$ -valid for  $P$  then
4:     for every grid-point solution  $\mathcal{S} := \{R_q\}_{q \in C}$  of  $\text{LLARP}(C)$  do
5:        $\mathcal{H} \leftarrow \mathcal{H} \cup \{\mathcal{S}\}$ 
6: return  $\mathcal{S} \in \mathcal{H}$  maximizing  $\mathcal{A}(\mathcal{S})$ 

```

Proof of Theorem 7. Let $\Gamma = (V, \mathcal{L})$ be an ε -grid in U and denote by k the number of grid-cells. Without loss of generality, assume that all points of P lie in the interior of one of the $O(\varepsilon^{-2})$ grid-cells. A *grid configuration* on Γ is a subset of the grid points $C \subseteq V$. We say that a grid configuration C on Γ is ε -valid for P if there is a surjective mapping $\varphi : P \rightarrow C$, such that $\text{dist}_\infty(p, \varphi(p)) \leq \varepsilon$. Note that any LLARP for an ε -valid configuration C for P can be extended to an ε -valid solution for P by adding degenerate rectangles anchored at points in C .

Algorithm 1 enumerates all grid configurations on Γ that are ε -valid for P . Then, for each configuration C , it computes all grid-point solutions $\{R_q\}_{q \in C}$ of $\text{LLARP}(C)$. Among all enumerated solutions, we keep one that maximizes the covered area.

First, we show that the running time of this algorithm is polynomial. Note that any grid cell has four grid points as its vertices. Since any point $p \in P$ lies in the interior of some grid cell $L \in \mathcal{L}$, an ε -valid grid configuration must contain at least one of the four vertices of L . Thus, we can construct any ε -valid grid configuration by choosing for each grid cell $L \in \mathcal{L}$ and each input point $p \in P \cap L$, a vertex of L as its image in the mapping φ . However, since whenever multiple rectangles are anchored in the same point at most one can be non-degenerate, in each $L \in \mathcal{L}$ it suffices to decide on one of at most 15 cell configurations $L \cap C$ using either 0, 1, 2, 3, or 4 of the grid cell's vertices. In particular, any number of contained input points larger than 3, yields the same set of possible cell configurations. Thus, by counting the number of input points contained in each grid cell (in time $O(n)$) and then enumerating at most 15^k grid configurations, we obtain all ε -valid grid configurations. For each such configuration C , we obtain all corresponding ε -valid grid-point solutions by picking for each $q \in C$ one of the $O(\varepsilon^{-2})$ grid points above and to the right of q as the upper-right corner of the rectangle and checking interior disjointness. This amounts to at most $O(\varepsilon^{-2\varepsilon^{-2}})$ solutions per grid configuration. Thus, in total, the running time of Algorithm 1 is linear in n and doubly exponential in $\frac{1}{\varepsilon}$.

8:12 On the Complexity of Anchored Rectangle Packing

■ **Figure 6** A row B of the ε -grid F and the corresponding rectangles of \mathcal{S}_B^* .

It remains to show that the computed grid-point solution covers at least as much area as an optimal lower-left-anchored rectangle packing $\mathcal{S}_{\text{LLARP}(P)}^* = \{R_1, R_2, \dots, R_n\}$ without resource augmentation. We transform $\mathcal{S}_{\text{LLARP}(P)}^*$ to a grid-point solution by “snapping” the corners of its rectangles to Γ . We do this by first snapping the lower-left and upper-right corners of each rectangle to either of the horizontal grid-lines directly above and below the corner in question. Afterwards, the same is done analogously for the vertical grid-lines, which we omit in our discussion.

Consider one row of the grid, say $B = [0, 1] \times (y, y + \varepsilon)$, for $(x, y) \in V$ (see Figure 6). We describe how the lower-left and upper-right corners within this row can be snapped up or down without reducing the total area. Partition the row horizontally into segments x_1, x_2, \dots, x_r in-between the x -coordinates of corners of the rectangles $\mathcal{S}_B^* := \{R_i\}_{i=1}^m \subseteq \mathcal{S}_{\text{LLARP}(P)}^*$ that have a corner in the row. We associate a variable $h_i \in [0, 1]$ with each rectangle R_i denoting the height of $R_i \cap B$ relative to the height of B . Snapping the rectangles in this row can be seen as rounding each such variable h_i either up to 1 or down to 0 (i.e., expanding the rectangle to span the full row height or collapsing it such that it does not appear in the row anymore). We aim to do this in a manner, which neither introduces overlaps nor decreases the covered area. This snapping problem is represented by the following integer linear program.

$$\max \sum_{i=1, \dots, m} h_i \cdot w(R_i) \quad (3)$$

$$\text{s.t.} \quad \sum_{i: x_j \in X(R_i)} h_i \leq 1 \quad \text{for } j = 1, \dots, r \quad (4)$$

$$h_i \in \{0, 1\} \quad \text{for } i = 1, \dots, m. \quad (5)$$

Here, $w(R_i)$ denotes the width of rectangle R_i , and the set $X(R_i)$ consists of all segments x_i intersecting R_i . The objective function (3) maximizes the covered area while constraints in (4) ensure that (in an integer solution) rectangles do not overlap. The binary constraints in (5) force the rectangles to either span the entire height or nothing of the row. We note that the linear program is inspired by a similar one for the demand flow problem [10].

It is easy to verify that \mathcal{S}_B^* corresponds to a feasible solution for the linear programming relaxation of (3)–(5) and thus lower bounds the optimal value of the LP-relaxation. Since the sets $X(R_i)$ contain consecutive line segments, the LP satisfies the consecutive ones property [17]. Therefore, constraints (4) yield a totally unimodular matrix and the LP is integral [17]. It follows, that there is an integral solution that solves the relaxed linear program optimally and induces a partial snapping of area at least $\text{OPT}_{\text{LLARP}(P)}$. Repeating this argument for all rows and columns of Γ yields a grid-point solution with an area of at least $\text{OPT}_{\text{LLARP}(P)}$. ◀

■ **Algorithm 2** Algorithm using resource augmentation of the overlap-type.

-
- 1: Compute $S_I = \text{Algorithm 1}(P, \frac{\varepsilon}{22})$
 - 2: **for** all $R_p \in S_I$ **do**
 - 3: $R'_p \leftarrow$ the rectangle spanned by p and $u(R_p) + (\frac{\varepsilon}{22}, \frac{\varepsilon}{22})$
 - 4: **if** $u(R'_p) \notin U$ **then**
 - 5: $u(R'_p) \leftarrow \arg \min_{x \in U} \|x - u(R'_p)\|$
 - 6: **return** $S_{II} = \{R'_p\}_{p \in P}$
-

Proof of Theorem 8. We show that Algorithm 2 satisfies the conditions of Theorem 8, that is it runs in polynomial time and outputs a $\frac{\varepsilon}{11}$ -LLARP of area at least $(1 - \varepsilon) \cdot \text{OPT}_{\text{LLARP}}(P)$. In comparison to the previous case, input points cannot be moved, but the rectangles may somewhat overlap.

Consider the $\frac{\varepsilon}{22}$ -valid solution $S_I = \{R_p\}_{p \in P}$ of Algorithm 1 with input $(P, \frac{\varepsilon}{22})$. In constructing S_I , we move the input-points $p \in P$ to grid-points $q_p \in F$ spanning R_p , the upper-right corner of which we denote by $u(R_p)$. We transform the solution of Algorithm 1 to obtain an $\frac{\varepsilon}{11}$ -LLARP.

Shift each $u(R_p)$ up and to the right by $\frac{\varepsilon}{22}$ to obtain $u(R_p)'$. The transformed solution S'_I consists of the rectangles uniquely defined by the lower-left corners $p \in P$ and their corresponding upper-right corners $u(R_p)'$. Since $\text{dist}_\infty(p, q_p) < \frac{\varepsilon}{22}$, moving $u(R_p)$ by $(\frac{\varepsilon}{22}, \frac{\varepsilon}{22})$ ensured that transforming the solution did not decrease its size. The overlap of rectangles is bounded by $2 \cdot \frac{\varepsilon}{22} = \frac{\varepsilon}{11}$.

However, moving the solution may cause some rectangles to protrude from the unit square. We prune this excess area, by moving the respective upper-right corners back into the square to obtain our final solution S_{II} . Due to this pruning, we lose an area of size at most $2 \cdot \frac{\varepsilon}{22} = \frac{\varepsilon}{11} \leq \varepsilon \cdot \text{OPT}_{\text{LLARP}}(P)$, where the inequality follows from the lower bound of $\frac{1}{11}$ on $\text{OPT}_{\text{LLARP}}(P)$ [11]. This implies, that $\mathcal{A}(S_{II}) \geq (1 - \varepsilon) \cdot \text{OPT}_{\text{LLARP}}(P)$. ◀

simon.apers@inria.fr

Abstract

This work describes a new algorithm for creating a superposition over the edge set of a graph, encoding a quantum sample of the random walk stationary distribution. The algorithm requires a number of quantum walk steps scaling as $\tilde{O}(m^{1/3}\delta^{-1/3})$, with m the number of edges and δ the random walk spectral gap. This improves on existing strategies by initially growing a classical seed set in the graph, from which a quantum walk is then run.

The algorithm leads to a number of improvements: (i) it provides a new bound on the setup cost of quantum walk search algorithms, (ii) it yields a new algorithm for st -connectivity, and (iii) it allows to create a superposition over the isomorphisms of an n -node graph in time $\tilde{O}(2^{n/3})$, surpassing the $\Omega(2^{n/2})$ barrier set by index erasure.

1 Introduction and Summary

Sampling from the stationary distribution of a random walk is a common and valuable tool in the design of algorithms [32]. It underlies the Markov chain Monte Carlo paradigm, and plays a central role in a wide range of approximation algorithms for graph problems. In this work we investigate the quantum counterpart of this task - generating quantum samples from the random walk stationary distribution. Given query access to some graph $G = (\mathcal{V}, \mathcal{E})$ with m edges, we wish to create the quantum state

$$|\pi\rangle = \frac{1}{\sqrt{m}} \sum_{(i,j) \in \mathcal{E}} |i, j\rangle, \quad (1)$$

which is a superposition over the edges of the graph. Measuring the first register of this state, and discarding the second register, indeed returns the random walk stationary distribution. Creating such a quantum sample of a classical stationary distribution forms a crucial primitive for a range of algorithms: the so-called “setup cost” in quantum walk search algorithms [28, 25] refers to the cost of generating a state such as $|\pi\rangle$, quantum algorithms for speeding up MCMC [2, 33, 39, 30] build on the possibility of efficiently creating quantum samples, and a number of quantum algorithms for solving graph problems [38, 23] require the generation of a superposition over the edges of a graph.

We develop a new quantum algorithm for creating the quantum sample (1), given only local query access to the graph. Our algorithm improves the query and time complexity of the folklore approach to quantum sampling from $\tilde{O}(m^{1/2}\delta^{-1/2})$ to $\tilde{O}(m^{1/3}\delta^{-1/3})$. We do so by growing a classical seed set from the initial node. This incurs a payoff in the space complexity, increasing it from $\tilde{O}(1)$ to $\tilde{O}(m^{1/3}\delta^{-1/3})$. As a demonstration of our algorithm,

we discuss a new approach to solving st -connectivity: generate a superposition over the connected components of s and t , and compare these states. This approach generalizes the notorious quantum state generation strategy for solving graph isomorphism. Concerning the latter, we show that our algorithm allows to create a superposition over the isomorphisms of a given n -vertex input graph in $\tilde{O}(2^{n/3})$ steps. This surpasses the $\Omega(2^{n/2})$ index erasure barrier by Ambainis et al [6]. In a similar way we can create a superposition over the elements of a black box group in $\tilde{O}(2^{n/3})$ steps, where 2^n is the number of group elements.

1.1 Query Model

We assume throughout this work that we only have “local” query access to the graph $G = (\mathcal{V}, \mathcal{E})$: we are given an initial node $j \in \mathcal{V}$, and we can query for its degree and neighbors. Such queries fall under the so-called *adjacency array model* [20] or *bounded degree model* [21] (although we do not assume the degree is bounded), which is very natural when studying random walk algorithms. However, departing from these models, and justifying the term “local”, we will not assume direct access to or prior knowledge about \mathcal{V} , apart from the initial node. For comparison, in [20] the node set \mathcal{V} is given as a list, and in [21] access to uniformly random nodes is assumed. In this sense our work is more in line with graph exploration algorithms as considered e.g. in [34], or more recently in [17].

Since our algorithm strongly builds on the use of quantum walks, we will alternatively express the complexity of our results as a function of the number of quantum walk steps. Also in such case the denominator “local” query access is justified, since a single quantum walk step from a certain node only accesses the neighbors of that node.

1.2 Quantum Walk Sampling Algorithm

Our algorithm builds on the folklore approach to creating $|\pi\rangle$, discussed in e.g. [31, 39, 30, 29]. Starting from some initial state $|j\rangle$ localized on a node $j \in \mathcal{V}$, this approach combines quantum phase estimation and amplitude amplification on the quantum walk operator associated to the graph. We detail this scheme in Section 2.2. The scheme requires $\tilde{O}(m^{1/2}\delta^{-1/2})$ QW steps on the graph, where δ is the random walk spectral gap, and the factor $m^{1/2}$ stems from the small projection of the initial state onto $|\pi\rangle$.

In the present work we improve on this scheme by initially doing some “classical work”: we first use classical means to grow a seed set around the initial vertex. Briefly ignoring the δ -dependency, we grow the set to have size $\Theta(m^{1/3})$. We can then use a special data structure to generate and reflect around a quantum superposition over this set, which now has a $\Omega(m^{-1/3})$ overlap with the target state. Reinvoking the folklore scheme from this state then allows to retrieve $|\pi\rangle$, now only requiring $\tilde{O}(m^{1/3})$ queries. This approach leads to the following result.

► **Theorem 1.** *Given a lower bound $\gamma \leq \delta$ on the spectral gap, it is possible to create the quantum state $|\pi\rangle$ using $\tilde{O}(m^{1/3}\gamma^{-1/3})$ time, space and QW steps.*

Apart from the log-factors, the combined dependency on m and δ is optimal. Indeed it is tight on e.g. the cycle graph, which has $m = n$ and $\delta = n^{-2}$, giving an $\tilde{O}(n)$ steps algorithm. Since the diameter of the cycle is $\Omega(n)$, this is optimal when assuming local query access. We also note that, if in addition we are given a bound $D \geq d_M$ on the maximum degree (in e.g. the array model this is always given), then we can implement our algorithm using $\tilde{O}(m^{1/3}\gamma^{-1/3}D^{1/3})$ degree and neighbor queries.

The algorithm gives a direct bound on the so-called setup cost of quantum walk search algorithms in the MNRS framework [28] as a function of the update cost (i.e., the cost of implementing a quantum walk step). The increased space complexity of our algorithm, $\tilde{O}(m^{1/3}\delta^{-1/3})$ as compared to $\tilde{O}(1)$ for the folklore approach, is very similar to the payoff in space versus time or query complexity in the collision finding algorithm of Brassard et al [15] and the element distinctness algorithm of Ambainis [4].

1.3 Application to st -connectivity

Our QW sampling algorithm yields a new approach for solving st -connectivity, somewhat similar to the approach taken by Watrous in [38]: generate a superposition over the edges in the connected components of s resp. t , and compare the resulting states. As we prove in Proposition 9, this requires $\tilde{O}(m^{1/3}\gamma^{-1/3})$ QW steps, where γ is a lower bound on the spectral gaps of the connected components of s and t . Our algorithm outperforms the existing quantum algorithms for st -connectivity [20, 13, 12, 23] on for instance sparse graphs with a good spectral gap.

The approach generalizes a well-known strategy to solving graph isomorphism on a quantum computer [2] (called “component mixing” in [27]): generate superpositions over the isomorphisms of each graph, and compare the resulting states. In [6], Ambainis et al aimed to prove a lower bound on this approach by abstracting it to the so-called index erasure problem. For this generalized problem, they prove a lower bound of $\Omega(2^{n/2})$. They argue that the same bound holds for creating a superposition over graph isomorphisms, be it under the condition that the algorithm makes no use of the structure of the problem. We show that, by exploiting the structure of the problem, we can indeed use our quantum walk sampling algorithm to surpass this bound. Thereto we consider the graph whose node set consists of isomorphisms of the input graph, and whose edge set arises from performing pairwise transpositions on the nodes (i.e., on the adjacency matrices of the isomorphisms). Using our quantum walk sampling algorithm on this graph yields the following corollary.

► **Corollary 2.** *Given an n -node input graph g , it is possible to create a superposition over the isomorphisms of g in $\tilde{O}(2^{n/3})$ steps.*

Completing the associated st -connectivity algorithm, we find an $\tilde{O}(2^{n/3})$ quantum algorithm for graph isomorphism. Using the existing quantum algorithms for st -connectivity, this approach would require $\Omega(2^{n/2})$ steps. Clearly the improved performance still falls terribly short of current (classical) algorithms for graph isomorphism, most notably the quasi-polynomial algorithm by Babai [10], yet it provides a clear demonstration of how the readily accessible structure of the problem allows to surpass the index erasure bound.

A similar strategy exists for solving the group non-membership problem on a quantum computer, as proposed by Watrous [37], requiring to generate a superposition over the elements of a finite black box group. Using the random walk algorithm by Babai [9] for generating uniformly random group elements, we can similarly generate this superposition in $\tilde{O}(2^{n/3})$ steps, when 2^n is the number of group elements.

1.4 Open Questions

This work leaves open a number of questions and possible applications, some of which we summarize below:

- *Quantum sampling for general Markov chains or stoquastic Hamiltonians.* In this work we only consider the quantum sampling problem for random walks. Generalizing our approach to more general Markov chains could lead to improvements on quantum MCMC

algorithms [2, 33], or the preparation of many body ground states [30] and Gibbs states [36]. The main bottleneck to such generalization seems to be the classical construction of seed sets which have an appropriate overlap with the goal quantum state. Even more generally, one could consider the preparation of ground states of Hamiltonians. For e.g. the special case of stoquastic Hamiltonians, which are known to have a nonnegative ground state, it should be possible to construct a seed set with improved overlap with the ground state.

- *Faster quantum fast-forwarding.* In former work by the author [8], a quantum algorithm was proposed for quantum sampling a t -step Markov chain. If the Markov chain has transition matrix P , and is started from a node i , the algorithm has complexity $\tilde{O}(\|P^t |i\rangle\|^{-1} t^{1/2}) \in \tilde{O}(m^{1/2} t^{1/2})$. Using ideas from the present work, it seems very feasible that we can improve this complexity to $\tilde{O}(\|P^t |i\rangle\|^{-2/3} t^{1/2}) \in \tilde{O}(m^{1/3} t^{1/2})$. Rather than using a breadth-first search to grow the seed set, as in the present work, it seems more suitable to use random walk techniques as in [34, 7]. As a byproduct, this would yield an improved quantum expansion tester, combining the speedups of [5] and [8].
- *Quantum search in \sqrt{HT} .* Our algorithm does not suffer from the so-called “symmetry barrier” in quantum algorithms: we can go from $|j\rangle$ to $|\pi\rangle$ more easily than from $|\pi\rangle$ to $|j\rangle$. Indeed, if for instance the underlying graph is an expander, then the former takes $O(n^{1/3})$ queries, whereas the latter takes $\Omega(n^{1/2})$ queries by the search lower bound.

An open problem related to this is the following: given an initial node s in a graph, can we find a node t in $O(HT_{s,t}^{1/2})$ QW steps, with $HT_{s,t}$ the hitting time from s to t ? Currently the best algorithm for this problem is by Belovs [12], which solves it in $O(CT_{s,t}^{1/2})$, with $CT_{s,t} = H_{s,t} + H_{t,s}$ the commute time between s and t . Since the commute time is symmetric between s and t , this obeys the aforementioned symmetry barrier. However, the commute time can be much larger than the hitting time from s to t , hence the open question of whether we can improve this performance to $O(HT_{s,t}^{1/2})$, thereby necessarily breaking this symmetry e.g. by using our techniques.

1.5 Outline

In Section 2 we discuss the graph and query model (Section 2.1), and provide the necessarily preliminaries on random walks and quantum walks (Section 2.2). In Section 3 we propose an algorithm for growing a classical seed set (Section 3.1), we discuss the data structure (Section 3.2), and we propose our QW sampling algorithm (Section 3.3). Finally in Section 4 we discuss the application of our QW sampling algorithm for solving st -connectivity (Section 4.1), and we demonstrate it for the special case of graph isomorphism testing (Section 4.2).

2 Preliminaries: Queries and Walks

2.1 Graph and Query Model

Throughout the paper we assume local query access to an undirected graph $G = (\mathcal{V}, \mathcal{E})$, with \mathcal{E} a subset of the ordered pairs $\mathcal{V} \times \mathcal{V}$, such that $(i, j) \in \mathcal{E} \Leftrightarrow (j, i) \in \mathcal{E}$. We denote $|\mathcal{V}| = n$ and $|\mathcal{E}| = m$. For any $\mathcal{S} \subseteq \mathcal{V}$, we let $\mathcal{E}(\mathcal{S})$ denote the set of edges starting in \mathcal{S} , i.e.,

$$\mathcal{E}(\mathcal{S}) = \{(i, j) \in \mathcal{E} \mid i \in \mathcal{S}\}.$$

For any $i \in \mathcal{V}$, we let $d(i) = |\mathcal{E}(\{i\})|$ denote the degree of i , the maximum degree $d_M = \max_{i \in \mathcal{V}} d(i)$, and $d(\mathcal{S}) = |\mathcal{E}(\mathcal{S})| = \sum_{i \in \mathcal{S}} d(i)$ denotes the total degree of a set $\mathcal{S} \subseteq \mathcal{V}$. A single query consists of either of the following:

- *degree query:* given $i \in \mathcal{V}$, return degree $d(i)$
- *neighbor query:* given $i \in \mathcal{V}$, $k \in [d(i)]$, return k -th neighbor of i

As an alternative query model we will also consider the quantum walk model, or so-called MNRS framework, as proposed in [28] in the context of quantum walk search. The model associates abstract costs to different operations¹:

- *setup cost*: the cost of preparing the quantum sample $|\pi\rangle = m^{-1/2} \sum_{(i,j) \in \mathcal{E}} |i,j\rangle$
- *update cost*: the cost of implementing a quantum walk step. See Section 2.2 for details.

For search problems an additional *checking cost* is considered, yet this will not be relevant here. In [16] it is proven that the update cost or quantum walk step for a node i can be simulated using $O(d(i)^{1/2})$ degree and neighbor queries. From our work it follows that the setup cost can be simulated using $\tilde{O}(m^{1/3}\delta^{-1/3})$ QW steps, or $\tilde{O}(m^{1/3}d_M^{1/3}\delta^{-1/3})$ degree and neighbor queries.

2.2 Random Walks and Quantum Walks

From some initial seed vertex $j \in \mathcal{V}$, we can use degree and neighbor queries to implement a random walk over \mathcal{V} . The transition matrix P describing such a walk is defined by $P(i,j) = 1/d(i)$ if $(i,j) \in \mathcal{E}$, and $P(i,j) = 0$ elsewhere. If the graph is connected and nonbipartite, then the random walk converges to its stationary distribution π , defined by $\pi(i) = d(i)/m$ for any $i \in \mathcal{V}$. If we order the eigenvalues of P (with multiplicities) as $1 = \lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n \geq -1$, then the rate at which the walk converges to π is bounded by the spectral gap $\delta = 1 - \max\{|\lambda_2|, |\lambda_n|\}$ [26].

Quantum walks (QWs) form an elegant quantum counterpart to random walks on graphs. Following the exposition in [28], they are naturally defined over a vector space associated to the edge set

$$\mathcal{H}_{\mathcal{E}} = \text{span}_{\mathbb{C}}\{|i,j\rangle \mid (i,j) \in \mathcal{E}\}.$$

A quantum walk over $\mathcal{H}_{\mathcal{E}}$ is now defined as the unitary operator $W = SR_{\mathcal{E}}$, where $R_{\mathcal{E}}$ is a reflection around the subspace $\text{span}_{\mathbb{C}}\{|\psi_i\rangle \mid i \in \mathcal{V}\}$, with

$$|\psi_i\rangle = \frac{1}{\sqrt{d(i)}} \sum_{(i,j) \in \mathcal{E}} |i,j\rangle,$$

and S represents the swap operator defined by $S|i,j\rangle = |j,i\rangle$. The cost of implementing the QW operator W is called the update cost, but can alternatively be implemented using $O(d_M^{1/2})$ degree and neighbor queries, and $\tilde{O}(1)$ elementary operations.

The spectrum of W is carefully tied to the spectrum of the original random walk matrix P , as was seminally proven by Szegedy in [35] and Magniez et al in [28]. For the purpose of this work, we abstract the following lemma. We say that W has a phase gap Δ if for every eigenvalue $e^{i\theta} \neq 1$ of W it holds that $|\theta| \geq \Delta$. We also recall the state $|\pi\rangle = m^{-1/2} \sum_{(i,j) \in \mathcal{E}} |i,j\rangle$.

► **Lemma 3** ([35, 28]). *Let P be the random walk transition matrix having spectral gap δ . Then the quantum walk operator W has a phase gap $\Delta \in \Theta(\sqrt{\delta})$, and $|\pi\rangle$ is the unique eigenvalue-1 eigenvector in the subspace $\text{span}_{\mathbb{C}}\{|\psi_i\rangle \mid i \in \mathcal{V}\}$.*

From this lemma, combined with the quantum algorithms for phase estimation and amplitude amplification, we can derive the folklore approach to quantum walk sampling, discussed in for instance [31, 39, 30, 29]. Since we will use it as a subroutine, we summarize it below. For a general subset $\mathcal{S} \subseteq \mathcal{V}$, we denote the state $|\mathcal{S}\rangle = d(\mathcal{S})^{-1/2} \sum_{(i,j) \in \mathcal{E}(\mathcal{S})} |i,j\rangle$.

¹ They actually consider a more general model, associated to a reversible Markov chain over G . We consider the special case where the Markov chain is a random walk.

► **Proposition 4.** *Given an initial set $\mathcal{S} \subseteq \mathcal{V}$ and a lower bound $\gamma \leq \delta$, there exists a quantum routine that generates a state ϵ -close to $|\pi\rangle$. The routine finishes and outputs a success flag after an expected number of $O(d(\mathcal{S})^{-1/2}m^{1/2}\gamma^{-1/2}\log \epsilon^{-1})$ calls to W , $O(d(\mathcal{S})^{-1/2}m^{1/2})$ reflections around $|\mathcal{S}\rangle$, and requires an additional $O(\log \epsilon^{-1} \log^2 \gamma^{-1})$ time and space complexity.*

Proof. Let the operator U be defined by the amplified quantum phase estimation algorithm, as used in [28, Theorem 6]. For some integer k , this operator maps an initial state $|\mathcal{S}\rangle$ to the state

$$U|\mathcal{S}\rangle|0\rangle = \langle \pi | \mathcal{S} \rangle |\pi\rangle |0\rangle + |\Gamma\rangle,$$

where $|\Gamma\rangle$ is such that $\|(\mathbb{I} \otimes |0\rangle\langle 0|)|\Gamma\rangle\| \leq 2^{-k}$. The operator U can be implemented using $O(k\Delta^{-1}) \in O(k\gamma^{-1/2})$ calls to W and W^\dagger , and $O(k \log^2 \gamma^{-1})$ additional space and elementary gates.

On this state we can invoke the amplitude amplification scheme from [14, Theorem 3] to retrieve the projection of $U|\mathcal{S}\rangle|0\rangle$ on the image of $\mathbb{I} \otimes |0\rangle\langle 0|$, which is 2^{-k} -close to $|\pi\rangle$. This requires an expected number of $\Theta(|\langle \mathcal{S} | \pi \rangle|^{-1})$ calls to U , U^\dagger and the reflection operator $\mathbb{I} \otimes (2|0\rangle\langle 0| - \mathbb{I})$. We prove the proposition by choosing $k \in \Theta(\log \epsilon^{-1})$ and noting that $|\langle \mathcal{S} | \pi \rangle| = d(\mathcal{S})^{1/2}m^{-1/2}$. ◀

On a general graph, and starting from some initial node $\mathcal{S} = \{i\}$, this scheme requires $\tilde{O}(d(i)^{-1/2}m^{1/2}\gamma^{-1/2}) \in \tilde{O}(m^{1/2}\gamma^{-1/2})$ QW steps, or $\tilde{O}(m^{1/2}d_M^{1/2}\gamma^{-1/2})$ degree and neighbor queries.

3 Quantum Walk Sampling

In this section we elaborate our scheme for quantum walk sampling. We separately address the process for growing a seed set, the data structure that we require, and their combination with the folklore QW sampling routine.

3.1 Growing a Seed Set

We propose the below Algorithm 1 to grow a seed set in the graph. It is a variation on the breadth-first search algorithm, returning an edge set of given size.

► **Lemma 5.** *If $M \leq m$, then Algorithm 1 outputs a subset $E \subseteq \mathcal{E}$ with $|E| \geq M$. Its time and space complexity, and degree and neighbor query complexity, are $\tilde{O}(M)$.*

Proof. Assuming the lists are ordered, any of the list and queue operations (enqueueing, dequeueing, adding an element, outputting the size of a list, searching an element in a list) takes polylogarithmic time. As a consequence, the time complexity will be determined up to log-factors by the number of for-loops before the algorithm terminates.

In every for-loop an edge is considered. Since the edges are directed, every edge is encountered at most once, at which point it is added to E . Since the algorithm terminates when $|E| = M$, this implies that the algorithm terminates after less than M for-loops. ◀

Alternatively we can output the node set $\mathcal{S} \subseteq \mathcal{V}$. Since $E \subseteq \mathcal{E}(\mathcal{S})$, we have that $d(\mathcal{S}) \geq M$.

■ **Algorithm 1** Breadth-First Edge Search.

Input: initial node i and query access to a connected graph G , integer M

Do:

- 1: create lists $S = \emptyset$ and $E = \emptyset$, and queue $B = (i)$
 - 2: **while** $B \neq \emptyset$ **do**
 - 3: $i \leftarrow \text{dequeue}(B)$, $\text{add}(S \leftarrow i)$
 - 4: **for all** j s.t. $(i, j) \in \mathcal{E}$ **do**
 - 5: **if** $j \notin S$ **then**
 - 6: $\text{add}(E \leftarrow \{(i, j), (j, i)\})$
 - 7: **if** $|E| \geq M$ **then** terminate and output E
 - 8: **if** $j \notin B$ **then** $\text{enqueue}(B \leftarrow j)$
-

3.2 Kerenidis-Prakash Data Structure

After growing the seed set $\mathcal{S} \subseteq \mathcal{V}$, we wish to use it as a resource for our QW sampling algorithm. Specifically we will require the generation of and reflection around the superposition $|\mathcal{S}\rangle$ over edges starting in \mathcal{S} . By naive query access to the database containing \mathcal{S} , this requires a time complexity $\Omega(d(\mathcal{S})^{1/2})$ per generation or reflection, which follows from the bound on index erasure [6]. Since our QW sampling algorithm will require $\Omega(m^{1/3})$ such operations, the total time complexity for $d(\mathcal{S}) \in \Theta(m^{1/3})$ would become $\Omega(m^{1/2})$, thus providing no speedup on the time complexity as compared to the folklore approach. To remedy this, we use a more efficient data structure proposed by Kerenidis and Prakash [24] in their quantum recommendation algorithm. We extract the following result, abstracted from their Theorem 15 (by setting $m = 1$, $n = n^2$ and inputting entries $(1, (i, j), 1)$ for all $(i, j) \in \mathcal{S}$).

► **Theorem 6** (Kerenidis-Prakash [24]). *Assume we have query access to a set $\mathcal{S} \subseteq \mathcal{V}$. There exists a classical data structure to store the set \mathcal{S} with the following properties:*

- *the size of the structure is $O(|\mathcal{S}| \log^2(m))$,*
- *the time and query complexity to fill the structure is $O(|\mathcal{S}| \log^2(m))$,*
- *having quantum access to the data structure we can perform the mapping $U : |0\rangle \rightarrow |\mathcal{S}\rangle$ and its inverse U^\dagger in time $\text{polylog}(m)$.*

This easily implies the ability to reflect around $|\mathcal{S}\rangle$ in time $\text{polylog}(m)$: we can rewrite the reflection $2|\mathcal{S}\rangle\langle\mathcal{S}| - \mathbb{I} = U(2|0\rangle\langle 0| - \mathbb{I})U^\dagger$, so that it comes down to implementing U , U^\dagger and a reflection around the basis state $|0\rangle$.

3.3 QW Sampling Algorithm

Building on the seed set and data structure, we can now propose our quantum sampling algorithm for creating the state $|\pi\rangle$ in $\tilde{O}(m^{1/3}\delta^{-1/3})$ time, space and quantum walk steps.

► **Theorem 7** (Quantum Walk Sampling). *If we choose $\gamma \leq \delta$ then Algorithm 2 returns a state ϵ -close to $|\pi\rangle$. The algorithm requires expected space, time and quantum walk steps in*

$$\tilde{O}(m^{1/3}\gamma^{-1/3} \log \epsilon^{-1}).$$

Proof. The correctness of the algorithm follows from Proposition 4. By this proposition we know that if $\gamma \leq \delta$ and the algorithm terminates, and hence the routine from Proposition 4 finished, then it effectively outputs a state ϵ -close to $|\pi\rangle$. The complexity of the algorithm for a fixed M is also easily bounded: the complexity of steps 2 and 3 is both $\tilde{O}(M^{1/3}\gamma^{-1/3})$,

■ **Algorithm 2** Quantum Walk Sampling.

Input: parameters γ and ϵ ; initial node i and query access to a graph G

Do:

- 1: **for** $M = 1, 2, 4, \dots, 2^k, \dots$ **do**
- 2: use BFS to grow a seed set \mathcal{S} with $d(\mathcal{S}) \in \Omega(M^{1/3}\gamma^{-1/3})$
- 3: load \mathcal{S} in data structure
- 4: apply the routine from Proposition 4 on $|\mathcal{S}\rangle$
 if the routine finishes after $\tilde{O}(M^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$ steps
 then terminate algorithm and return its output
 else abort the routine and continue for-loop

which follows from Lemma 5 resp. Theorem 6. Step 4 is automatically terminated after $\tilde{O}(M^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$ steps, which by Proposition 4 directly bounds the number of calls to W and reflections around $|\mathcal{S}\rangle$. By Theorem 6 the complexity of implementing a single reflection around $|\mathcal{S}\rangle$ is $\tilde{O}(1)$. The total complexity for a fixed M is therefore $\tilde{O}(M^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$.

What remains to bound is the M -value at which the algorithm terminates. From Proposition 4 we know that if the number of steps $M^{1/3}\gamma^{-1/3} \log \epsilon^{-1}$ is sufficiently large, i.e.,

$$M^{1/3}\gamma^{-1/3} \log \epsilon^{-1} \in \Omega(|\langle \pi | \mathcal{S} \rangle|^{-1} \gamma^{-1/2} \log \epsilon^{-1}), \quad (2)$$

then the routine finishes with probability $\Omega(1)$. From the fact that $|\pi\rangle = m^{-1/2} \sum_{(i,j) \in \mathcal{E}} |i,j\rangle$ and $d(\mathcal{S}) \in \Omega(M^{1/3}\gamma^{-1/3})$ it holds that $|\langle \pi | \mathcal{S} \rangle| \in \Omega(M^{1/6}\gamma^{-1/6} m^{-1/2})$. As a consequence, if $M \geq m$ then $|\langle \pi | \mathcal{S} \rangle| \in \Omega(m^{-1/3}\gamma^{-1/6})$ and hence (2) will hold, such that the routine will finish with probability $\Omega(1)$. The expected number of for-loops is therefore $\log m + O(1)$, with the total complexity scaling as

$$\tilde{O}\left(\gamma^{-1/3} \log \epsilon^{-1} \sum_{k=0}^{\log m + O(1)} 2^{k/3}\right) \in \tilde{O}(m^{1/3}\gamma^{-1/3} \log \epsilon^{-1}). \quad \blacktriangleleft$$

Alternatively we are interested in bounding the algorithm in terms of classical queries. We can naively substitute every quantum walk step for $\tilde{O}(\sqrt{d_M})$ degree and neighbor queries, yielding a complexity $\tilde{O}(m^{1/3}d_M^{1/2}\gamma^{-1/3})$. However, if we are given an upper bound $D \geq d_M$, we can improve this complexity by slightly increasing the size of the seed set. We note that in the array model [20] the degrees are assumed to be known beforehand, so we exactly know d_M .

► **Corollary 8.** *Given an initial node i , a lower bound $\gamma \leq \delta$ and an upper bound $D \geq d_M$, we can generate a state ϵ -close to $|\pi\rangle$ in expected space, time, and degree and neighbor queries in*

$$\tilde{O}(m^{1/3}D^{1/3}\gamma^{-1/3} \log \epsilon^{-1}).$$

Proof. We adapt Algorithm 2 as follows: we slightly increase the size of the seed set in step 2 to $\Omega(M^{1/3}D^{1/3}\gamma^{-1/2})$, and limit the number of steps in step 4 to $\tilde{O}(M^{1/3}D^{-1/6}\gamma^{-1/3} \log \epsilon^{-1})$. Following the proof of Theorem 7, the algorithm then terminates after

$$\tilde{O}(m^{1/3}D^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$$

classical steps and queries, and $\tilde{O}(m^{1/3}D^{-1/6}\gamma^{-1/3})$ QW steps. Now we can substitute each QW step with $\tilde{O}(\sqrt{d_M})$ degree and neighbor queries, yielding the claimed complexity. ◀

4 Application: st-Connectivity

4.1 General Algorithm

Let $\delta^{(s)}$ and $\delta^{(t)}$ denote the spectral gaps of the connected components of s resp. t .

► **Proposition 9.** *Given $s, t \in \mathcal{V}$ and a lower bound $\gamma \leq \delta^{(s)}, \delta^{(t)}$, we can decide st -connectivity with probability $1 - \epsilon$ in $\tilde{O}(m^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$ QW steps. If we are also given an upper bound $D \geq d_M$, then we can do so in $\tilde{O}(m^{1/3}D^{1/3}\gamma^{-1/3} \log \epsilon^{-1})$ degree and neighbor queries.*

Proof. Given γ we can create an ($\epsilon' = 1/4$)-approximation $|\psi_s\rangle$ (resp. $|\psi_t\rangle$) of the superposition $|\pi^{(s)}\rangle$ (resp. $|\pi^{(t)}\rangle$) over the edges of the connected component of s (resp. t) in $\tilde{O}(m^{1/3}\gamma^{-1/3})$ QW steps. If we also have D , then we can do so in $\tilde{O}(m^{1/3}d_M^{1/3}\gamma^{-1/3})$ degree and neighbor queries.

If s and t are connected, then $|\langle \psi_s | \psi_t \rangle| \geq 1 - \epsilon'^2$, whereas if they are not, then $|\langle \psi_s | \psi_t \rangle| \leq 2\epsilon'$. We can distinguish these cases by performing the SWAP-test [2] between these states, using a single copy of both states, and $O(1)$ additional gates. If s and t are connected, then the test returns 1 with probability $(1 - |\langle \psi_s | \psi_t \rangle|)/2 \leq \epsilon'^2/2 = 1/32$, if s and t are not connected, the test returns 1 with probability $(1 + |\langle \psi_s | \psi_t \rangle|)/2 \geq 1/2 - \epsilon' = 1/4$. Repeating this scheme $O(\log \epsilon^{-1})$ times then allows to decide st -connectivity with probability $1 - \epsilon$. ◀

This approach best compares to the following classical scheme: use $\tilde{\Theta}(n^{1/2})$ independent random walks of length $\Theta(\gamma^{-1})$ from s and t to gather samples from the stationary distributions on the connected components of s resp. t . If s and t are connected then with constant probability the sample sets will overlap, which follows from the birthday paradox. This scheme requires $\tilde{O}(n^{1/2}\gamma^{-1})$ random walk steps, or equivalently, neighbor queries. It lies at the basis of the graph expansion tester by Goldreich and Ron [22], and the subsequent work on testing closeness of distributions [11] and clusterability of graphs [18].

In Table 1 we compare the query complexity of our approach to the existing quantum algorithms for st -connectivity. If no promise is given on negative instances (such as in [23] in the form of a capacitance $C_{s,t}$), then all former algorithms require $\Omega(n^{1/2})$ queries when maximized over all (s, t) -pairs of the graph. As a consequence, for the graph isomorphism problem treated in the next section, they all have a $\Omega(2^{n/2})$ complexity. Our approach however has a $\tilde{O}(2^{n/3})$ complexity.

4.2 Graph Isomorphism

We consider some given n -node graph g , described by its adjacency matrix. To this graph we can associate a new regular graph $G^{(g)} = (\mathcal{V}, \mathcal{E})$ with nodes $\mathcal{V} = \{\sigma(g) \mid \sigma \in S_n\}$, consisting of permutations of the original graph nodes, and edges $\mathcal{E} = \{(h, \sigma_{i,j}(h)) \mid h \in \mathcal{V}, i, j \in [n]\}$, corresponding to all possible transpositions of two elements. We can easily prove the following.

► **Lemma 10.** *The random walk on $G^{(g)}$ has a spectral gap $\delta \in \Omega(n^{-1} \log^{-1} n)$.*

Proof. If $|\mathcal{V}| = n!$ (i.e., $g \neq \sigma(g)$ if $\sigma \neq 1$), this graph is isomorphic to the Cayley graph derived from the symmetric group with generators given by transpositions. The mixing time of a random walk on this graph is $O(n \log n)$ by a result of Diaconis and Shashahani [19], implying a lower bound on its spectral gap $\delta \in \Omega(n^{-1} \log^{-1} n)$.

If $|\mathcal{V}| < n!$, the graph is effectively an edge contraction of the random transposition graph. Following Aldous and Fill [3, Proposition 4.44], a random walk on this graph is an *induced chain* of the random walk on the symmetric group, in particular having a spectral gap lower bounded by the spectral gap of the original walk. ◀

■ **Table 1** Query complexity of st -connectivity using different quantum algorithms in different models. The array model measures the number of degree and neighbor queries; the adjacency model measures the number of pair queries (e.g., “are i and j neighbors?”); the QW model measures the number of QW steps. The quantities $d_{s,t}$ and $R_{s,t}$ denote the length of the shortest path and the effective resistance, respectively, between s and t . The quantity $C_{s,t}$ denotes the capacitance between s and t in negative instances, i.e., if s and t are disconnected then $C_{s,t}$ quantifies “how” disconnected they are.

	query complexity	model
Dürre et al [20]	$\Theta(n)$	array
Dürre et al [20]	$\Theta(n^{3/2})$	adjacency
Belovs-Reichardt [13]	$O(m^{1/2} d_{s,t}^{1/2})$	adjacency
Belovs [12]	$O(m^{1/2} R_{s,t}^{1/2}) \in O(m^{1/2} \delta^{-1/2})$	QW
Jarret et al [23]	$O(R_{s,t}^{1/2} C_{s,t}^{1/2})$	adjacency
folklore QW sampling	$O(m^{1/2} \delta^{-1/2})$	QW
this work	$\tilde{O}(m^{1/3} \delta^{-1/3})$	QW
this work	$\tilde{O}(m^{1/3} \delta^{-1/3} d_M^{1/3})$	array

Next we show how to implement a QW step on $G^{(g)}$ in $\tilde{O}(1)$ steps. By Theorem 7 we can then create a superposition over the edges of $G^{(g)}$ (or, equivalently, its nodes) in time $\tilde{O}(m^{1/3}) = \tilde{O}(2^{n/3})$, and by Proposition 9 we can solve st -connectivity (i.e. graph isomorphism) in the same time.

► **Lemma 11.** *Implementing a quantum walk on $G^{(g)}$ takes time $\tilde{O}(1)$.*

Proof. Since we may have multi-edges, corresponding to permutations that leave the input graph invariant, we will slightly alter the QW to take place on a node+coin space (as in e.g. [1, 4]) rather than on the edge space. The relevant spectral properties from Lemma 3 however remain unchanged, as is easily seen by following for instance the proof of [25]. We define the QW node+coin space, associated to the input graph g , as $\text{span}_{\mathbb{C}}\{|\sigma(g), i, j\rangle \mid \sigma \in S_n, i, j \in [n]\}$, with S_n the symmetric group of permutations. Similarly to Section 2.2, the QW operator $W = SR_{\mathcal{E}}$ consists of a reflection $R_{\mathcal{E}}$ around a subspace $\text{span}_{\mathbb{C}}\{|\psi_{\sigma(g)}\rangle \mid \sigma \in S_n\}$, now defined as

$$|\psi_{\sigma(g)}\rangle = \frac{1}{n} \sum_{i,j \in [n]} |g, i, j\rangle,$$

and the shift operator S defined by $S|g', i, j\rangle = |\sigma_{i,j}(g'), i, j\rangle$. Each of these operators can be implemented in $\tilde{O}(1)$ steps. ◀

Abstract

We present PUFFINN, a parameterless LSH-based index for solving the k -nearest neighbor problem with probabilistic guarantees. By parameterless we mean that the user is only required to specify the amount of memory the index is supposed to use and the result quality that should be achieved. The index combines several heuristic ideas known in the literature. By small adaptations to the query algorithm, we make heuristics rigorous. We perform experiments on real-world and synthetic inputs to evaluate implementation choices and show that the implementation satisfies the quality guarantees while being competitive with other state-of-the-art approaches to nearest neighbor search. We describe a novel synthetic data set that is difficult to solve for almost all existing nearest neighbor search approaches, and for which PUFFINN significantly outperform previous methods.

1 Introduction

1.1 Our results

The k -nearest neighbor (k -NN) problem has been an object of intense research, both from theoretical and applied computer scientists. There exist many implementations of k -NN data structures that perform very well in specific scenarios (see the related work section), but all implementations that we are aware of suffer from one or more of the following drawbacks:

- Not scalable to large, high-dimensional data sets.
- Not runtime-robust in the sense that query time may degrade to that of a linear search even for input distributions that are known to allow search in sublinear time.
- Not recall-robust in the sense that there are input distributions that obtain low (less than 50%) recall.
- Performance bounds only hold for well-chosen values of certain parameters that depend on the data set as well as the query distribution.

PUFFINN combines several insights from recent theoretical research on k -NN data structures into a data structure that addresses these drawbacks. Our contributions are as follows:

1. we present a parameterless and universal locality-sensitive hashing-based (LSH) implementation that solves the k -NN problem with probabilistic guarantees (Section 3)
2. we prove the correctness of an adaptive query mechanism building on top of the LSH forest data structure described by Bawa et al. in [5] (Section 3)
3. we describe an adaptive filtering approach to decrease the number of expensive distance computations (Section 4)
4. we propose a difficult dataset for the 1-NN problem that exposes weaknesses in known heuristics (Section 5)
5. we provide a detailed experimental study of our approach, evaluating design choices and relating it to the performance of other state-of-the-art approaches to k -NN search (Section 5)

Prior to this work, only subsets of these ideas have been implemented. Our main contribution on the theoretical side is that we make certain heuristics, such as the query algorithm described in [5], rigorous. While some ideas of adaptive query algorithms have been discussed before [18], they made assumptions on the data and query distribution; our methods work for k -NN search in its full generality. On the practical side, we shed light on the empirical performance of theoretical ideas with regard to possible speed-ups of an LSH implementation. Our final implementation is parameterless in the sense that it only requires the user to specify the space available for the data structure and the required quality guarantee. Our implementation is competitive to state-of-the-art k -NN algorithms; in particular, it is as performant as previous LSH solutions that are not parameterless and do not provide guarantees on the quality of the result.

1.2 Related work

There exist many fundamentally different approaches to nearest neighbor search. Popular techniques range from approximate tree-based methods, such as kd -trees [6] and M -trees [14] with an early stopping criterion [33], to random projection trees [16], to graph-based approaches [24, 21], and finally hashing-based approaches, for example using LSH [20]. Each paradigm comes with performant implementations and we will introduce some of them in

Section 5 when we are evaluating our implementation. Since the focus of the present paper is designing a provably correct LSH implementation we will focus on existing methods in this realm. See the benchmarking paper by Aumüller et al. [4] for a more detailed overview over other approaches and their performance on real-world datasets.

Locality-sensitive hashing. LSH was introduced by Indyk and Motwani in [20]. We sketch the basic idea here. An LSH data structure consists of several independent repetitions of space partitions using LSH functions. An LSH function maps a data point to a hash code such that closer points are more likely to collide than far away points. In the LSH framework, $K \geq 1$ locality-sensitive hash functions are concatenated to increase the gap between the collision probability of “close” points and “far away” points. For solving the (c, r) -near neighbor problem [20], a certain concatenation length K is fixed according to the number of points in the data set, the approximation factor c , and the strength of the hash family at hand. From the value K and the hash family one can compute how many repetitions L (using independent hash functions) have to be made to guarantee that a close point is found with constant probability. The theoretical literature on LSH has mostly focused on solving the approximate near neighbor problem which can be used to solve the approximate *nearest* neighbor problem through a reduction [19]. In this paper we use LSH to solve the exact k -nearest neighbor problem with probabilistic guarantees.

LSH implementations. Implementations of LSH evolved over the years with new advances in the theory of LSH. One of the first popular implementations, dubbed E2LSH [2], was tailored for Euclidean space and included automatic parameter tuning of the K parameter based on subsampling the dataset. From this K parameter, other parameter such as the number of repetitions are derived. It solves the problem of reporting all points within a distance r (specified during preprocessing) from the query and uses potentially large space on large datasets [2]. The multiprobing approach introduced by Dong et al. in [18] allowed for implementations in which the space parameter can be fixed as in our approach. Their parameter tuning relies on the assumption that there is a certain distance distribution between queries and data points. LSHkit was the first implementation using this idea [17]. A new LSH family for angular distance on the unit sphere motivated the development of the FALCONN library [1]. It contains highly optimized routines for efficient hash function computation, and supports multiprobing.

None of these approaches give guarantees on the query procedure if the query set is different with respect to distance distributions from the one seen during index building. Our data structure can be seen as a modified version of the LSH forest introduced by Bawa et al. in [5]. Instead of using a single hash length K , an individual repetition is a trie built on the hash codes of the data points. Our query algorithm replaces the heuristic candidate collection of a predefined size with a rigorous termination criterion.

The cost of evaluating an LSH function differs widely. It ranges from $O(1)$ time for the bitsampling approach in Hamming space [20], over $O(d)$ for random hyperplane hashing [10], to $O(d^2)$ for cross-polytope LSH [1]. For the latter, the authors of [1] proposed a heuristic version that decreases the running time to $O(d \log d)$. Another approach to reduce hashing time is to build a hashing oracle that returns the necessary KL hash function values necessary to query the LSH data structure, but builds those from a smaller set of independent hash functions. Christiani [12] described two approaches that reduce the amount of independent hash functions needed to produce these hash values from KL to $K\sqrt{L}$ (using tensoring as in [3]) or $O(\log^2 n)$ (using the pooling approach in [15]). While the E2LSH framework uses a variant of tensoring, we are not aware of an implementation using the pooling strategy.

Another idea that is currently missing in existing LSH implementations is the use of sketches, i.e., small representations of the original data points that allow to estimate the distance between two data points via their sketches. Christiani [12] describes how to use sketches when solving the near neighbor problem, but we are not aware of existing LSH-based implementations using this idea. We remark that sketching is a well-known technique and refer to the survey [27].

Auto Tuning Approaches. Apart from the approaches mentioned above, FLANN [26] and the implementation of vantage point trees in nmslib [8] are two non-LSH based nearest neighbor search that promise to tune the data structure to guarantee a certain quality criterion. This criterion is usually the recall of the query, i.e., the fraction of true nearest neighbor among the points returned by the implementation.

FLANN contains a collection of tree-based methods. For auto-tuning, it takes a small sample of the data structure and builds indexes in a certain parameter space. It then queries the data structure with points from the data set and picks, among all the indexes that achieve at least the recall the user wishes for, the one with fastest query times. The auto tuning employed by nmslib for the vantage point tree implementation follows the same principles and explores a certain parameter space based on a model of the data set to be indexed. Both approaches require that the query and data set distribution are not too different. We will see in the experiments that both of the approaches do not satisfy the recall guarantees, even on real-world datasets.

2 Preliminaries

2.1 Problem Definition

We assume a distance space (X, dist) with distance measure $\text{dist}: X \times X \rightarrow \mathbb{R}_{\geq 0}$.

► **Definition 1.** *Given a dataset $S \subseteq X$ and an integer $k \geq 1$, the (k, δ) nearest neighbor problem $((k, \delta)$ -NN) is to build a data structure, such that for every query $q \in X$, the query algorithm returns a set of k distinct points, each one being with probability at least $1 - \delta$ among the k points in S closest to q .*

An algorithm solving the (k, δ) -NN problem guarantees an expected recall of $(1 - \delta)k$, which is usually the quality measure in the context of nearest neighbor search algorithms.

2.2 Locality-Sensitive Hashing

► **Definition 2** (LSH Family [20, 10]). *A locality-sensitive hash (LSH) family \mathcal{H} is family of functions $h: X \rightarrow R$, such that for each pair $x, y \in X$ and a random $h \in \mathcal{H}$, for arbitrary $q \in X$, whenever $\text{dist}(q, x) \leq \text{dist}(q, y)$ we have $p(q, x) := \Pr[h(q) = h(x)] \geq \Pr[h(q) = h(y)]$.*

Traditionally, LSH families are used in the LSH framework to solve the (c, r) -near neighbor problem.

While the theory provided in this paper applies to every distance space that encompasses an LSH family, we set our focus on solving the k -NN problem on the d -dimensional unit sphere under angular distance, which is equivalent to cosine similarity and inner product similarity on unit length vectors. By using the Gaussian kernel approximation method of Rahimi and Recht [29] as described by Christiani in [11], our results extend to the whole Euclidean space.

Random hyperplane (HP) LSH described by Charikar in [10] and Cross-Polytope (CP) LSH introduced by Terasawa and Tanaka [31] and analyzed by Andoni et al. in [1] are two different LSH schemes under this distance measure. A single HP LSH function produces a single bit. It works by choosing a random d -dimensional vector $a = (a_1, \dots, a_d)$ where each a_i is an independent standard normal random variable. The hash code of a point x is 1 if the inner product between a and x is at least 0, and 0 otherwise. A single CP LSH function applies a random rotation of x on the unit sphere and then maps it to the index of the closest vector out of the $2d$ signed standard basis vectors. Technically, it can be thought of as choosing d random hyperplanes a_1, \dots, a_d and mapping x to the index of the hyperplane with the largest absolute inner product, separating the two cases that the inner product is negative or not.

3 Data Structure

This section describes the basic ideas of the data structure used in our implementation. Due to space reasons we only highlight the basic data structure and some of its properties. The full description with all proofs can be found in the extended version of this paper. Note that the implementation has many differences to this clean version. These differences are discussed in Section 4.

3.1 Description

In this section we will assume that we can perform distance computations and evaluate locality-sensitive hash functions in constant time. Our data structure will be parameterized by integers $L, K \geq 1$ and will consist of a collection of L LSH tries of max depth K . This data structure is known as an LSH Forest [5]. Here we use a variant of the LSH tries with bounded depth and for completeness we include a brief description and statement of relevant properties.

LSH tries. We index the LSH tries by $j = 1, \dots, L$. The j th LSH trie is built from the set of strings $\{(h_{1,j}(x), \dots, h_{K,j}(x)) \mid x \in S\}$ where $h_{i,j} \sim \mathcal{H}$. The trie is constructed by recursively splitting the set of points S on the next (i th) character until $|S| \leq i$ or $i = K + 1$ at which point we create a leaf node in the trie that stores references to the points in S . Internal nodes store pointers to its children in a hash table where the keys are locality-sensitive hash values.

Query algorithm. Let $S_{i,j}(q)$ denote the subset of points in S that collide with q when we consider the first i hash values used in the construction of the j th trie. That is, $S_{i,j}(q) = \{x \in S \mid h_{1,j}(q) = h_{1,j}(x) \wedge \dots \wedge h_{i,j}(q) = h_{i,j}(x)\}$. For our query algorithm we wish to retrieve the points in each trie that collide with our query point in a bottom-up fashion, starting at depth $i = K$. Define $\Pi_{i,j}(q) = S_{i,j}(q) \setminus S_{i+1,j}(q)$ where $S_{K+1,j}(q) = \emptyset$.

► **Fact 1.** *LSH tries have expected construction time $O(nK)$ and use $O(n)$ words of space. For $i \in \{0, 1, \dots, K\}$ we can retrieve a set $S'_{i,j}(q) \supseteq S_{i,j}(q)$ with $|S'_{i,j}(q)| \leq |S_{i,j}(q)| + i$ using time $O(|S_{i,j}(q)| + i)$. After having retrieved $S'_{i,j}(q)$ we can retrieve $S'_{i-1,j}(q)$ using additional time $O(|\Pi_{i-1,j}(q)|)$.*

The query algorithm is described in Algorithm 1. During a query we search through the LSH Forest starting with the buckets $S_{i,j}(q)$ at depth $i = K$ and moving up one level once the L LSH tries have been explored at the current level. While searching we use a data structure PQ to keep track of the top- k closest points seen so far. We stop the search once

■ **Algorithm 1** ADAPTIVE-KNN(q, k, δ).

```

1 PQ ← empty priority queue of (point, dist) of unique points
2 for  $i \leftarrow K, K-1, \dots, 0$  do
3   for  $j \leftarrow 1, 2, \dots, L$  do
4     for  $x \in \Pi_{i,j}(q)$  do
5       /* We abbreviate  $x'_k \leftarrow \text{PQ.max}()$  for ease of notation */
6       if  $\text{dist}(q, x'_k) \geq \text{dist}(q, x)$  then
7         PQ.insert( $x, \text{dist}(q, x)$ ) // Remove largest entry if PQ contains
8         more than  $k$  elements.
9       end
10      end
11      if  $i = 0$  or  $(\text{PQ.size}() == k \text{ and } j \geq \ln(1/\delta)/p(q, x'_k)^i)$  then
12        return PQ
13      end
14    end
15  end
16 end

```

we have searched sufficiently many tries at a depth where our current k -nearest neighbor candidate would have been found with probability at least $1 - \delta$. This stopping criterion ensures that we always search far enough to find the true k -nearest neighbor with probability at least $1 - \delta$.

Insertions (Line 6) and retrieval of the k -largest distance (Lines 5 and 9) can be done in expected amortized time $O(1)$ by using an array of size $2k$ which is updated after each k insertions. For simplicity the algorithm is described as a double for-loop that iterates over the sets $\Pi_{i,j}(q)$ in a bottom-up fashion. Using LSH tries Algorithm 1 would be implemented by using a straight-forward bottom-up traversal of the tries with properties described in Fact 1.

We proceed by proving that Algorithm 1 solves the (k, δ) -NN problem as well as providing running time bounds. The idea behind an adaptive k NN algorithm with guarantees following the approach of Algorithm 1 can be attributed to Dong et al. [18]. Christiani et al. [13] show how a different stopping criteria gives a self-tuning algorithm in the regime where $\delta = 1/n$. To the best of our knowledge both the following proof of correctness (although simple) and the running time bound for Algorithm 1 is new.

► **Lemma 3.** ADAPTIVE-KNN(q, k, δ) returns a set of k points, each one being with probability at least $1 - \delta$ among the closest k points to q .

Proof. As introduced in Definition 2, we use the short notation $p(q, x) := \Pr[h(q) = h(x)]$ under the random LSH hash function choice h . Let x_1, \dots, x_k be the k closest neighbors of q in S . First, observe that at any stage the algorithm maintains the invariant “PQ.size() < k or $p(q, x'_k) \leq p(q, x_k)$ ”. This is true because at any point, the k -th closest point x'_k identified by the algorithm satisfies $\text{dist}(q, x'_k) \geq \text{dist}(q, x_k)$. Together with the monotonicity of the collision probability of LSH, cf. Definition 2, the invariant holds. Thus, the algorithm cannot terminate until j' tries have been searched at level i' where either $j' \geq \ln(1/\delta)/p(q, x_k)^{i'}$ or $i' = 0$. In the first case the probability of not finding a k NN of q is at most $(1 - p(q, x_k)^{i'})^{j'} \leq \delta$. In the case of $i' = 0$ the query algorithm degrades to a linear scan and we are guaranteed to report the true k NNs. ◀

Next, we connect the expected running time of Algorithm 1 to the optimal expected running time of an algorithm that knows optimal parameter choices for i and j . We will use $OPT(L, K, k, \delta)$ to denote the optimal expected query time that can be achieved with the natural algorithm that solves k NN queries on the LSH Forest by searching j tries at depth i where i and j are chosen to minimize the query time. In our expression for the expected the query time we use a unit cost model that counts hash function evaluations and distance computations. To ensure that each point in the k NN set is reported with probability at least $1 - \delta$ we search $j = \ln(1/\delta)/p(q, x_k)^i$ tries. The expected cost of searching one LSH trie at depth i is $i + \sum_{x \in P} p(q, x)^i$.

$$OPT(L, K, k, \delta) = \min \left\{ \frac{\ln(1/\delta)}{p(q, x_k)^i} (i + \sum_{x \in P} p(q, x)^i) \mid 0 \leq i \leq K, \frac{\ln(1/\delta)}{p(q, x_k)^i} \geq L \right\}.$$

We obtain the following lemma with a proof provided in the extended version of this paper.

► **Lemma 4.** *Let $0 < \delta \leq 1/2$ then with probability $1 - \delta$ we have that $\text{ADAPTIVE-KNN}(q, k, \delta)$ terminates in expected time $O(OPT(L, K, k, \delta/k) + L(K + k))$.*

3.2 Reducing the Number of LSH Evaluations

In [12], Christiani provides a uniform framework encompassing previous ad-hoc solutions [15, 3] to reduce the amount of hash function evaluations when solving the approximate near neighbor problem. In the extended version of this paper we describe how these techniques can be applied when solving the k -NN problem. In particular, each method requires an adaption of Algorithm 1 and comes with their own stopping criterion. We provide a succinct description of the methods next.

Tensoring. Assume that K is an even integer and L is an even power of two. Form two collections of \sqrt{L} tuples of $K/2$ LSH functions. Each trie in the LSH forest is now indexed by $j_1, j_2 \in \{1, \dots, \sqrt{L}\}$. The K LSH functions used in the (j_1, j_2) st trie are taken by interleaving the $K/2$ functions in the j_1 st tuple of the first collection and the j_2 nd tuple of the second collection. This allows us to construct L LSH tries of max depth K using only $\sqrt{L}K$ independent functions.

Pooling. Form a pool of m independent LSH functions that will be shared among LSH tries. For each LSH trie in the LSH Forest we independently sample a random subset of K LSH functions from the pool that we use in place of fully random LSH functions. The LSH pool can be viewed as a randomized construction of a smaller LSH family from our original LSH family. As m increases LSH functions sampled without replacement from the pool will work almost as well as independent samples from the LSH family.

3.3 Sketching for faster distance computations

Locality-sensitive hashing can be used to produce 1-bit sketches for efficient similarity estimation [10, 23]. The idea is to use a random hash function to hash the output of a locality-sensitive hash function to a single bit, and then packing w such bits into a w -bit machine word. We can use word parallelism (alternatively table lookups) to count the number of collisions between $w = \Theta(\log n)$ such sketches in $O(1)$ time, allowing us to efficiently estimate the similarity between points in our original space. Depending on the LSH scheme used and the distribution of distances between the query point and the data, using 1-bit sketches can replace many of the expensive distance computations performed by the query algorithm with cheaper distance estimations through sketching. See [30, 12] for more details on sketching in the context of the ANN problem.

Figure 1 Overall structure of our implementation.

4 Implementation Overview

4.1 Overall structure

Figure 1 presents an overview over our data structure. Deviating from the pointer-based trie data structure described in Section 3, we use an array of indices sorted by hash code, which improves both cache- and space-efficiency. Additionally, a sketching-based filtering approach is used to reduce the number of distance computations carried out during a query. In the following, we make the implementation precise.

A query is answered in rounds, starting at the maximum considered prefix length. A single round works as follows: Repetitions are inspected one after the other. In each repetition, all (new) candidates sharing the hash prefix with the query point are retrieved. For each such candidate point, a sketch is chosen and checked against the corresponding sketch of the query point. Let τ denote a threshold value that we will discuss how to set later. If the Hamming distance between candidate and query sketch is less than τ , the data point passes the filter, the distance computation is carried out, and the point with its distance to the query is inserted into the accumulator buffer. Once this buffer is full we discard all points not belonging to the top- k . While this can be done in time $O(k)$, we found that an implementation based on sorting was faster for the values of k we considered. The termination criterion is checked after all repetitions are inspected. If the criterion is satisfied, the algorithm returns the indices of the top- k points in the accumulator, otherwise the prefix length is decreased by one and a new round starts.

The following subsections make this process more detailed and discuss engineering choices in the case of angular distance on unit length vectors.

4.2 Engineering choices

Vector storage. We normalize the query vector and all data vectors, which means that all dot products will be between -1 and 1. This allows storing vectors in a fixed point format represented using 16-bit integers. Such a representation enables AVX2-enabled instructions that allow 16 multiplications at once. To use the AVX instructions, all vectors are stored in a 1-dimensional array with padding to ensure 256-bit alignment.

Retrieving candidate points. The j th LSH repetition is represented as a sorted array of tuples of the form $(h_{\leq i,j}(p), \text{pos}(p))$, where $\text{pos}(p)$ is the index of $p \in S$ in the original dataset, and $h_{\leq i,j}(p)$ is the hash code of p under hash functions $h_{1,j} \circ \dots \circ h_{i,j}$. We view the hash code as a bitstring. Before retrieving candidates, we first find the tuple with the longest common prefix with the hash of the query vector. This is achieved using binary search, where we tabulate the lexicographic position of each 13-bit prefix to speed up the search.

Each time more candidates are requested, all tuples whose hash code has a common prefix of length at least i are considered. Each iteration decrements i in order to increase the number of considered vectors. Since the vectors are stored in sorted order, all tuples with a common prefix of length i are stored adjacent to the tuples with common prefixes of length $i + 1$. Furthermore, they are all stored on the same side, depending on whether the removed bit was a 0 or 1. This means that the range of considered vectors can be updated efficiently.

Every access in the array is done in a segment of size $B = 12$, regardless of whether the prefix matches or not. This costs almost no time, because the random memory access is the expensive part, and only improves quality. A discussion of suitable values of B is provided in the extended version of this paper.

Filtering candidate points. The filtering step is an additional measure to reduce the number of distance computations. Fix a point $p \in S$. During the index building phase, we store M 64-bit sketches $s_1(p), \dots, s_M(p)$ obtained via HP LSH. If p is retrieved as a candidate, retrieve a sketch $s'(p)$ using a pseudorandom transformation of the repetition number j . Next, compute the Hamming distance between $s'(p)$ and $s'(q)$. If the distance is at most $\tau \in \{0, \dots, b\}$, p passes the filter and is inserted into the accumulator. A challenge in the context of k -NN queries is that the algorithm does not know the distance to the k -th nearest neighbor. This means that the threshold has to be adapted according to the points inspected so far. We set threshold τ dynamically according to the probability that a vector with Hamming distance τ or less has a dot product larger than the smallest dot product in the current top- k .

Computing distances. The accumulator takes care of the candidate points that pass the filter step. It de-duplicates the candidate list and keeps track of the top- k points found so far. The accumulator consists of a buffer of size $2k$, which contains the current top- k indices, along with their dot products, and a buffer of size k , which contains points that passed the filter along with their dot products. Once this buffer is full, the top- k list is updated.

4.3 Locality-sensitive Hash Functions

Supported LSH Functions. The supported hash functions relevant for the paper are HP LSH [10] and CP LSH [1].¹ For the latter, the implementation encompasses both the exact version and the pseudorandom version with three applications of the fast Hadamard transform, see [1] for more details. We always regard hash functions as producing an ℓ -bit string as its output. For HP LSH, we have $\ell = 1$, for CP LSH, we have $\ell = \lceil \log 2d \rceil$. In case the algorithm did not terminate after exploring all L repetitions, decreasing the prefix length by one always means that we disregard the last bit of the hash. This is to avoid a sudden increase in the number of collisions in the case of CP LSH. This is theoretically sound since the termination criteria from Section 3 only need a lower bound on the collision probability at a certain prefix-length, which can be estimated for individually bit lengths of CP LSH.

¹ PUFFINN is generic to the LSH family, but some engineering choices are different for other similarity measures, such as set similarity. At the moment, PUFFINN also support (b -bit) MinHash [9, 23].

Estimating Collision Probabilities. Recall from Section 3 that evaluating the collision probability of two points at a certain distance is a key ingredient in the query algorithm. While such a formula is easy to derive for HP LSH, we only know of the asymptotic behavior of collision probabilities for CP LSH [1]. To overcome this obstacle, we find a Monte Carlo estimate on the collision probability of unit vectors with inner product α , $-1 \leq \alpha \leq 1$, by enumerating different values of α in a window of size .05. For a fixed distance, we consider two points $x = (1, 0, \dots, 0)$ and $y = (\alpha, \sqrt{1 - \alpha^2}, 0, \dots, 0)$,² draw 1 000 random CP hash functions, count the number of collisions, and tabulate the estimate. As mentioned above, we always consider bit strings, so the probability estimation for CP LSH is made for all bit lengths up to $\ell = \lceil \log 2d \rceil$.

In the query procedure, we round the distance down to the closest distance value for which we have tabulated an estimate and use that to bound the collision probability. The evaluation in the next section will show that this yields a negligible loss in quality compared to an exact variant using HP LSH.

5 Experimental Evaluation

Implementation and Experimental Setup. PUFFINN is implemented in C++ and comes with a wrapper to the Python language. Experiments were run on 2x 14-core Intel Xeon E5-2690v4 (2.60GHz) with 512GB of RAM using Ubuntu 16.10 with kernel 4.4.0. It is compiled using g++ with the compiler flags `-std=c++14 -Wall -Wextra -Wno-noexcept-type -march=native -O3 -g -fopenmp`. Index building was multi-threaded, queries were answered sequentially in a single thread. The experiments were conducted in the `ann-benchmarks` framework from [4]. The code, raw experimental results, and the Jupyter notebook used for the evaluation are available at <https://github.com/puffinn/esa-paper>.

Quality and Performance Metrics. As quality metric we measure the individual recall of each query, i.e., the fraction of points reported by the implementation that are among the true k -NN. As performance metric, we record individual query times. We usually report on the *throughput*, i.e., the average number of queries that can be answered in one second. In plots, the throughput is dubbed QPS for *queries per second*.

Parameter Choices. PUFFINN has two parameters: the space a user is willing to allocate for the index, and the expected recall that should be achieved. We run PUFFINN with expected recall values in the set $\{.1, .2, .5, .7, .9, .95\}$. As space parameters, we use the doubling range 512 MB to 32 GB. We always retrieve the ten nearest neighbors.

Objectives of the Experiments. Our experiments are tailored to answer the following high-level questions (*HL-Q*):

(HL-Q1) Given the choices of sketching and hash function evaluation methods described in the previous two sections, how do they compare to each other w.r.t. empirical performance (Sections 5.1–5.3)?

(HL-Q2) Can a parameterless method compete with implementations that have parameters tuned to the data and query workload (Section 5.5)?

² By spherical symmetry, the collision probabilities are the same for all pairs of points with inner product α .

■ **Table 1** Datasets under consideration.

Dataset	Data Points/Query Points	Dimensions
GLOVE [28]	1 183 514/10 000	100
GLOVE-2M [28]	2 196 018/10 000	300
GNEWS-3M [25]	3 000 000/10 000	300
SYNTHETIC	1 000 000/ 1 000	300

To answer these questions, we will consider the following implementation-level questions (*IL-Q*):

(IL-Q1) What is the influence of the filtering approach to the quality/QPS (Section 5.1)?

(IL-Q2) What is the influence of the update threshold τ to quality and QPS (Section 5.1)?

(IL-Q3) How does the space parameter influence the QPS (Section 5.2)?

(IL-Q4) How does the hash function and evaluation strategy influence performance (Section 5.3)?

Real-World Datasets. Table 1 gives an overview of the datasets used in the experiments. Cosine similarity is usually used in the context of word embeddings, so we use three real-world datasets that originate from two different word embedding algorithms. Unless stated otherwise, all experiments are carried out on `Glove-1M`.

Synthetic Dataset. We describe a synthetic data set and query distribution that, as we will see, is challenging for many heuristic nearest neighbor implementations. For a fixed $d \geq 1$, we construct a dataset over \mathbb{R}^{3d} as follows. For each $i \in \{1, \dots, n-1\}$, let y_i and z_i be two d -dimensional vectors of expected length $\sqrt{1/2}$ where each coordinate is sampled independently from $\mathcal{N}(0, 1/2d)$. Define $x_i = (0^d, y_i, z_i)$. Let v and w be two more random vectors of expected length $\sqrt{1/2}$. Finally, set $x_n = (v, w, 0^d)$. We define m query vectors as follows: For each $i \in \{1, \dots, m\}$, let $q_i = (v, 0^d, r_i)$, where r_i is a random vector of length $\sqrt{1/2}$.

This construction has the property that x_n is the nearest neighbor of every query. Furthermore, all data points have unit length in expectation. The distance from each q_i to x_n is expected to be 1 (or equivalently $\mathbb{E}[\langle q_i, x_n \rangle] = \frac{1}{2}$), whereas the distance to all other points is around $\sqrt{2}$ (i.e., $\mathbb{E}[\langle q_i, x_j \rangle] = 0$). In the experiment, we choose $n = 1\,000\,000$ and $d = 100$.

Other approaches. We compare PUFFINN to the following implementations: FALCONN, a state-of-the-art LSH implementation using the theory developed in [1]; ONNG, a recent graph-based approach described in [21]; ANNOY, the best-performing implementation of a random-projection forest [7]; IVF, a k -means clustering based approach [22]; FLANN, a collection of different approaches with tuning of recall value [26]; VantagePointTree [32] as implemented in NMSlib [8] with recall guarantees.

These approaches stood out in the benchmarking paper from Aumüller et al. [4] as performing best on many datasets. We use the same parameter space as in [4] to test the performance of the different implementations. For each implementation, we report the best results achieved via a grid search over the (usually large) parameter space. We refer to that paper or the original papers for more details on these approaches. Except from FLANN and VantagePointTree, no other implementation allows to specify a guarantee on recall.

■ **Figure 2** Left: Influence of setting the threshold of sketches to $1 + \varepsilon$ times the expected difference at the distance of the k -th closest point found so far. Expected recall values: 0.1, 0.2, 0.5, 0.7, 0.9, 0.95, space: 1GB. Right: Difference between filtering/no filtering, space: 4GB.

5.1 Filtering Approach

We evaluate the filtering approach in two directions. First, we report on the quality-performance trade-off of different update strategies. Second, we benchmark the architecture against a “no filtering” approach. Experiments were done using a collection of 32 sketches using 64 bits each.

Figure 2 (top) reports on the influence of setting the passing threshold of the filtering step dynamically to a fraction of $\tau = 1 + \varepsilon$ of the expected difference³ for a point at the distance of the current k -th nearest neighbor. A ε -value of 0.0, 0.1, and 0.2 give good results in this empirical setting. Above 0.1 there is almost no gain in quality but a huge drop in QPS. Setting the threshold below the expectation results in a large loss in quality. For the remainder of the experiments, we set the threshold to the expectation, i.e., we use $\delta = 0$.

Figure 2 (bottom) allows us to see the difference between using resp. not using the filtering approach. For low recall values, the filtering approach increases the QPS by a factor of roughly 1.5. For example, the filtering approach can answer around 1 400 QPS at recall .5, without filtering this number drops to 900. At high recall, the difference is more pronounced. A recall of 97% is achieved with 122 QPS using filtering and the same recall is achieved at around 50 QPS without filtering. We can see a clear difference in the achieved quality between the two variants. The sketching approach usually decreases the recall for a fixed expected recall by .08 (for low recall) to .03 (for high recall). However, the recall is still above the guarantee in both cases.

5.2 Influence of the Index Size

We turn our focus to the third implementation-level question: How does the index size influence the performance? We note that the index size includes the whole data structure, including storage of the original dataset and the hash functions. Figure 3 reports on the quality-performance trade-off achieved by the implementation for different index sizes. We

³ The expected difference is just 64 times the probability that two points at distance r_k collide under a random hyperplane.

■ **Figure 3** Influence of index size to quality-performance trade-off.

observe that larger index sizes provide better performance, but the influence is diminishing at more than 4 GB. A small index yields a small number of repetitions, which means that the algorithm has to explore many levels in the data structure. For a recall of .9, increasing the amount of space from 512 MB to 2 GB increases the QPS from 12 to roughly 200. Doubling the allotted space to 4GB results in around 300 QPS, which is roughly the same for 8 GB as well. We can see that the achieved recall is above the set guarantee threshold for all tested index sizes. (Each data point corresponds to a recall value from the set of tested recall values.)

5.3 Choice of Hash Function and Evaluation Strategy

We start by evaluating different hash evaluation strategies. We implemented the following three different evaluation strategies in PUFFINN: independent, tensor, and pool. For the pooling strategy, we set up a pool containing 3072 bits. In the following, we fix the hash function used to be CP LSH using fast Hadamard transform. Figure 4 shows a comparison between the three evaluation strategies for different index sizes. As we can see, tensoring is never better than the pooling strategy. Furthermore, independent gives better performance for a fixed quality for large index sizes, but takes more time for initializing the hash values at low recall. We note that when using the exact CP LSH, there is a huge difference between independent and pooling, in particular for large index sizes. For example, CP using independent hash functions achieves not more than 80 QPS for the 8 GB index in the right plot in Figure 4. For all of these reasons, we fix the implementation to use the pooling strategy.

We turn our focus to the choice of hash function. Figure 5 gives an overview of three different index sizes using the pooling strategy for hash function evaluation. On the smallest index, HP LSH works well, in particular for high recall. If there is space for more repetitions, CP LSH becomes the method of choice, and FHT-CP is a bit faster than the exact method.

5.4 Summary of Implementation Choices

In light of our first high-level question, we observed that sketching provides a good performance increase at negligible cost. The larger the index size, the faster PUFFINN can answer queries. However, it works well on small index sizes as well. We fixed the pooling strategy as the evaluation strategy since it was much faster than tensoring and allows to use exact methods such as CP LSH when FHT-CP does not satisfy the guarantees one wishes for.

■ **Figure 4** Comparison of hash evaluation strategies. Left: 512 MB, center: 2 GB, right: 8 GB.

■ **Figure 5** Hash function comparison (pooling). Left: 512 MB, center: 1 GB, right: 4 GB.

5.5 Comparison to Other Approaches

We turn our focus on comparing PUFFINN to other approaches on real-world and synthetic datasets (HL-Q2). Figure 6 gives an overview of the performance-quality trade-off achieved by state-of-the-art k -NN approaches on three real-world dataset and a synthetic one. Among the implementations that support automatic parameter tuning, PUFFINN is usually by a large factor the fastest implementation. We remark that the automatic parameter tuning of FLANN failed to build an index within 6 hours on three out of the four datasets and was disregarded on those.

PUFFINN managed to obtain at least recall .95 on every dataset, whereas the tuning of the VPtree failed to achieve high recall on GNEWS-3M. PUFFINN shows better performance than FALCONN for most of the performance-quality space. It is comparable in performance to ANNOY on most of the real-world datasets, and is particular competitive in the high-recall setting. On real-world datasets, IVF and in particular ONNG show better performance than PUFFINN except for very high recall. This is an indicator that graph-based approaches perform best on these real-world datasets (for good manual parameter choices).

On the synthetic dataset, only LSH-based approaches achieve high recall at high QPS. VPtree and ONNG manage recall close to 1, but are more than a factor 10 slower than PUFFINN. IVF and ANNOY fail to achieve recall higher than 40% on the synthetic dataset.

To come back to our second high-level question: It is possible to compete with state-of-the-art implementations of k -NN using a parameterless method with guarantees. PUFFINN is easy to use and achieves performance comparable to many of its competitors. Among LSH variants, it is as fast as FALCONN which does not give guarantees. This means that our engineering choices allowed an LSH implementation with theoretical guarantees that come “for free”.

Abstract

Numerous combinatorial optimization problems (knapsack, maximum-weight matching, etc.) can be expressed as *subset maximization problems*: One is given a ground set $N = \{1, \dots, n\}$, a collection $\mathcal{F} \subseteq 2^N$ of subsets thereof such that $\emptyset \in \mathcal{F}$, and an objective (profit) function $p : \mathcal{F} \rightarrow \mathbb{R}_+$. The task is to choose a set $S \in \mathcal{F}$ that maximizes $p(S)$. We consider the *multistage* version (Eisenstat et al., Gupta et al., both ICALP 2014) of such problems: The profit function p_t (and possibly the set of feasible solutions \mathcal{F}_t) may change over time. Since in many applications changing the solution is costly, the task becomes to find a sequence of solutions that optimizes the trade-off between good per-time solutions and stable solutions taking into account an additional similarity bonus. As similarity measure for two consecutive solutions, we consider either the size of the intersection of the two solutions or the difference of n and the Hamming distance between the two characteristic vectors.

We study multistage subset maximization problems in the *online* setting, that is, p_t (along with possibly \mathcal{F}_t) only arrive one by one and, upon such an arrival, the online algorithm has to output the corresponding solution without knowledge of the future.

We develop general techniques for online multistage subset maximization and thereby characterize those models (given by the type of data evolution and the type of similarity measure) that admit a constant-competitive online algorithm. When no constant competitive ratio is possible, we employ lookahead to circumvent this issue. When a constant competitive ratio is possible, we provide almost matching lower and upper bounds on the best achievable one.

1 Introduction

In a classical combinatorial optimization setting, given an instance of a problem one needs to find a good feasible solution. However, in many situations, the data may evolve over time and one has to solve a sequence of instances. The natural approach of solving every instance independently may induce a significant transition cost, for instance for moving a system from one state to another. This cost may represent, e.g., the cost of turning on/off the servers in a data center [17, 8, 4, 1], the cost of changing the quality level in video streaming [16], or the cost for turning on/off nuclear plants [24]. Gupta et al. [15] and Eisenstat et al. [13] proposed a *multistage* model where given a time horizon $t = 1, 2, \dots, T$, the input is a sequence of instances I_1, I_2, \dots, I_T , (one for each time step), and the goal is to find a sequence of solutions S_1, S_2, \dots, S_T (one for each time step) reaching a trade-off between the quality of the solutions in each time step and the stability/similarity of the solutions in consecutive time steps. The addition of the transition cost makes some classic combinatorial optimization problems much harder. This is the case for instance for the minimum weighted perfect matching problem in the *off-line* case where the whole sequence of instances is known in advance. While the one-step problem is polynomially-time solvable, the multistage problem becomes hard to approximate even for bipartite graphs and for only two time steps [5, 15].

In this work, we focus on the *online* case, where at time t no knowledge is available for instances at times $t + 1, \dots, T$. When it is not possible to handle the online case, we turn our attention to the *k-lookahead* case, where at time t the instances at times $t + 1, \dots, t + k$ are also known. This case is of interest since in some applications like in dynamic capacity planning in data centers, the forecasts of future demands may be very helpful [18, 19]. Our goal is to measure the impact of the lack of knowledge of the future on the quality and the stability of the returned solutions. Indeed, our algorithms are limited in their knowledge of the sequence of instances. Given that the number of time steps is given, we compute the competitive ratio of the algorithm after time step T : As we focus on maximization problems, we say that a (deterministic) algorithm is (strictly) α -competitive (with competitive ratio α) if its value is at least $\frac{1}{\alpha}$ times the optimal value on all instances.

As it is usual in the online setting, we consider no limitations in the computational resources available. This implies that at every time step t , where instance I_t is known, we assume the existence of an oracle able to compute the optimal solution for that time step. Notice also that our lower bounds do not rely on any complexity assumptions. Some recent results are already known for the online multistage model [6, 15], however all these results are obtained for specific problems. In this work, we study multistage variants of a broad family of maximization problems. The family of optimization problems that we consider is the following.

► **Definition 1** (Subset Maximization Problems). *A Subset Maximization problem \mathcal{P} is a combinatorial optimization problem whose instances $I = (N, p, \mathcal{F})$ consist of*

- *A ground set N ;*
- *A set $\mathcal{F} \subseteq 2^N$ of feasible solutions such that $\emptyset \in \mathcal{F}$;*
- *A non-negative weight $p(S)$ for every $S \in \mathcal{F}$.*

The goal is to find $S^ \in \mathcal{F}$ such that $p(S^*) = \max\{p(S) : S \in \mathcal{F}\}$.*

We will consider that the empty set is always feasible, ensuring that the feasible set of solutions is non empty. This is a very general class of problems, including the maximization *Subset Selection* problems studied by Pruhs and Woeginger in [23] (they only considered linear objective functions). It contains for instance graph problems where N is the set of

vertices (as in any maximization induced subgraph problem verifying some property) or the set of edges (as in matching problems). It also contains classical set problems (knapsack, maximum 3-dimensional matching, . . .), and more generally 0-1 linear programs (with non negative profits in the objective function).

Given a problem in the previous class, we are interested in its multistage version [15, 13]. The stability over time of a solution sequence is classically captured by considering a transition cost when a modification is made in the solution. Here, dealing with maximization problems, we will consider a transition *bonus* B for taking into account the similarity of two consecutive solutions. In what follows, we will use the term *object* to denote an element of N (so an object can be a vertex of a graph, or an edge, . . ., depending on the underlying problem).

► **Definition 2** (Multistage Subset Maximization Problems). *In a Multistage Subset Maximization problem \mathcal{P} , we are given*

- a number of steps $T \in \mathbb{N}$, a set N of n objects;
- for any $t \in T$, an instance I_t of the optimization problem. We will denote:
 - p_t the objective (profit) function at time t
 - $\mathcal{F}_t \in 2^N$ the set of feasible solutions at time t
- $B \in \mathbb{R}^+$ a given transition profit.
- the value of a solution sequence $\mathcal{S} = (S_1, \dots, S_T)$ is

$$f(\mathcal{S}) = \sum_{t=1}^T p_t(S_t) + \sum_{t=1}^{T-1} b(S_t, S_{t+1})$$

where $b(S_t, S_{t+1})$ is the transition bonus for the solution between time steps t and $t + 1$. We will use the term *profit* for $p_t(S_t)$, *bonus* for the transition bonus $b(S_t, S_{t+1})$, and *value* of a solution \mathcal{S} for $f(\mathcal{S})$;

- the goal is to determine a solution sequence of maximum value.

The fact that T is known may be regarded as rather uncommon the field of online algorithms. At the end of Subsection 1.2, we relate it to our results and justify it.

There are two natural ways to define the transition bonus. We will see that these two ways of measuring the stability induce some differences in the competitive ratios one can get.

► **Definition 3** (Types of transition bonus). *If S_t and S_{t+1} denote, respectively, the solutions for time steps t and $t + 1$, then we can define the transition bonus as:*

- Intersection Bonus: B times $|S_t \cap S_{t+1}|$: in this case the bonus is proportional to the number of objects in the solution at time t that remain in it at time $t + 1$.
- Hamming Bonus: B times $|S_t \cap S_{t+1}| + |\overline{S_t} \cap \overline{S_{t+1}}|$. Here we get the bonus for each object for which the decision (to be in the solution or not) is the same between time steps t and $t + 1$. In other words, the bonus is proportional to $|N|$ minus the number of modifications (Hamming distance) in the solutions.

Note that by scaling profits (dividing them by B), we can arbitrarily fix $B = 1$. So from now on, we assume $B = 1$.

In this article, we will consider two possible ways for the data to evolve.

► **Definition 4** (Types of data evolution). ■ **Static Set of Feasible Solutions (SSFS):** *only profits may change over time, so the structure of feasible solutions remains the same: $\mathcal{F}_t = \mathcal{F}$ for all t .*

- **General Evolution (GE):** *any modification in the input sequence is possible. Both the profits and the set of feasible solutions may change over time. In this latter model, for knapsack, profits and weights of object (and the capacity of the bag) may change over time; for maximum independent set edges in the graph may change, . . .*

1.1 Related Work

A series of papers consider the online or semi-online settings, where the input changes over time and the algorithm has to modify (re-optimize) the solution by making as few changes as possible (see [3, 9, 12, 14, 20, 21] and the references therein). The multistage model considered in this paper has been introduced in Eisenstat et al. [13] and Gupta et al. [15]. Eisenstat et al. [13] studied the multistage version of facility location problems. They proposed a logarithmic approximation algorithm. An et al. [2] obtained constant factor approximation algorithms for some related problems. Gupta et al. [15] studied the MULTISTAGE MAINTENANCE MATROID problem for both the offline and the online settings. They presented a logarithmic approximation algorithm for this problem, which includes as a special case a natural multistage version of SPANNING TREE. They also considered the online version of the problem and they provide an efficient randomized competitive algorithm against any oblivious adversary. The same paper also introduced the study of the MULTISTAGE MINIMUM PERFECT MATCHING problem for which they proved that it is hard to approximate even for a constant number of stages. Bampis et al. [5] improved this negative result by showing that the problem is hard to approximate even for bipartite graphs and for the case of two time steps. When the edge costs are metric within every time step they proved that the problem remains APX-hard even for two time steps. They also showed that the maximization version of the problem admits a constant factor approximation algorithm, but is APX-hard. Olver et al. [22] studied a multistage version of the MINIMUM LINEAR ARRANGEMENT problem, which is related to a variant of the LIST UPDATE problem [25], and provided a logarithmic lower bound for the online version and a polylogarithmic upper bound for the offline version.

The MULTISTAGE MAX-MIN FAIR ALLOCATION problem has been studied in the offline and the online settings in [6]. This problem corresponds to a multistage variant of the SANTA KLAUS problem. For the off-line setting, the authors showed that the multistage version of the problem is much harder than the static one. They provided constant factor approximation algorithms for the off-line setting. For the online setting they proposed a constant competitive ratio for SSFS-type evolving instances and they proved that it is not possible to find an online algorithm with bounded competitive ratio for GE-type evolving instances. Finally, they showed that in the 1-lookahead case, where at time step t we know the instance of time step $t + 1$, it is possible to get a constant approximation ratio.

Buchbinder et al. [11] and Buchbinder, Chen and Naor [10] considered a multistage model and they studied the relation between the online learning and competitive analysis frameworks, mostly for fractional optimization problems.

1.2 Summary of Results and Overview

The contribution of our paper is a framework for online multistage maximization problems (comprising different models), a characterization of those models in which a constant competitive ratio is achievable, and almost tight upper and lower bounds on the best-possible competitive ratio for these models. The focus here is on deterministic algorithms.

We increase the complexity of the considered models over the course of the paper. We start with the arguably simplest model: Considering a static set of feasible solutions clearly restricts the general model of evolution; while such a straightforward comparison between the Hamming and intersection bonus is not possible, the Hamming bonus seems simpler in that, compared to the intersection model, there are (somewhat comparable) extra terms added on the profit of both the algorithm and the optimum. As we show in Subsection 2.1,

■ **Table 1** Our bounds on the best-possible competitive ratio c^* for the different models. The Landau symbol is with respect to $T \rightarrow \infty$.

	static set of feasible solutions	general evolution
Hamming bonus	$2 - o(1) \leq c^* \leq 2$	$1 + \sqrt{2} \leq c^* \leq 3 + o(1)$
	Theorems 6 and 5	Theorems 12 and 10
Intersection bonus	$2 \leq c^* \leq 2 + o(1)$	$c^* = \infty$
	Theorems 9 and 8	$c^* = 4$ for 1-lookahead Theorems 14, 16, and 15

there is indeed a simple 2-competitive algorithm: At each time t , it greedily chooses the set S_t that either maximizes the transition bonus w.r.t. S_{t-1} (that is, choosing $S_t = S_{t-1}$, which is possible in this model) or maximizes the value $p_t(S_t)$. We complement this observation with a matching lower bound only involving two time steps.

We then toggle the transition-bonus model and the data-evolution model separately and show that constant competitive ratios can still be achieved. First, in Subsection 2.2, we consider intersection bonus. We show that, *after* modifying the profits (internally) to make larger solutions more profitable, a $(2 + 1/(T - 1))$ -competitive algorithm can be achieved by a greedy approach again. We also give an (almost matching) lower bound of 2 again. Next, we toggle the evolution model. In Subsection 3.1, we adapt the greedy algorithm from Subsection 2.1 by reweighting to obtain a $(3 + 1/(T - 1))$ -competitive algorithm using a more complicated analysis. We complement this result with a lower bound of $1 + \sqrt{2}$.

In Subsection 3.2, we finally consider the general-evolution model with intersection bonus, where we give a simple lower bound showing that a constant-competitive ratio is not achievable. This lower bound relies on forbidding to choose any item in the second step that the algorithm chose in the first step. We circumnavigate such issues by allowing the algorithm a lookahead of one step and present a 4-competitive algorithm for that setting. A similar phase transition has been observed for a related problem [6], but our algorithm, based on a doubling approach, is different. We also give a matching lower bound of 4 on the competitive ratio of any algorithm in the same setting. We summarize all results described thus far in Table 1.

We note that the lower bounds mentioned for the Hamming model are only shown for a specific fixed number of time steps, and that in general there is no trivial way of extending these bounds to a larger number of time steps. One may however argue that the large- T regime is in fact the interesting one for both practical applications and in theory, the latter because the effect of having a first time step without bonus vanishes. At the end of the respective sections, we therefore give asymptotical lower bounds of $3/2$ and roughly 1.696 for the cases of a static set of feasible solutions and general evolutions, respectively. These bounds are non-trivial, but we do not know if they are tight.

It is plausible that the aforementioned upper bounds can be improved if extra assumptions on characteristics of the objective function and the sets of feasible solutions are made. In Subsubsection 3.1.2, we show that already very natural assumptions suffice: Assuming that at each time the feasible solutions are closed under taking subsets and the objective function is subadditive, we give a $(21/8 + o(1))$ -competitive algorithm for the model with a general evolution and Hamming bonus, improving the previous $(3 + o(1))$ -competitive ratio. Our lower bounds for general evolution and Hamming bonus in fact fulfill the extra assumptions.

We observe that all our algorithms except for the one discussed in Subsection 2.1 require that T is known in that their behavior in the last step is different from the behavior in the steps before. This assumption is crucial: In all these models, there are examples in which one can in the first time step choose either a small profit or a potentially large bonus not knowing if there is another timestep to realize the bonus. Such examples imply a superconstant lower bound on the competitive ratio in these models. This justifies our assumption that T is known.

In Section 4, we summarize our results and mention directions for future research that we consider interesting.

Due to space constraints, some proofs only appear in the full version [7].

2 Model of a Static Set of Feasible Solutions

We consider here the model of evolution where only profits change over time: $\mathcal{F}_t = \mathcal{F}$ for any t . We first consider the Hamming bonus model and show a simple 2-competitive algorithm. We will then show that a (asymptotic) competitive ratio of 2 can also be achieved in the intersection bonus model using a more involved algorithm. In both cases, this ratio 2 is shown to be (asymptotically) optimal.

2.1 Hamming-Bonus Model

► **Theorem 5.** *In the SSFS model with Hamming bonus, there is a 2-competitive algorithm.*

Proof. We consider the very simple following algorithm. At each time step t , the algorithm computes an optimal solution S_t^* with associated profit $p_t(S_t^*)$. At $t = 1$ we fix $S_1 = S_1^*$. For $t > 1$, if $p_t(S_t^*) > n$ then fix $S_t = S_t^*$, otherwise fix $S_t = S_{t-1}^*$ (which is possible thanks to the fact that the set of feasible solutions does not change).

Let f^* be the optimal value. Since any solution sequence gets profit at most $p_t(S_t^*)$ at time t , and bonus at most n between two consecutive time steps, we get $f^* \leq \sum_{t=1}^T p(S_t^*) + n(T-1)$.

By construction, at time $t > 1$, either the algorithm gets profit $p_t(S_t^*)$ when $p_t(S_t^*) > n$, or bonus (from $t-1$) n when $n \geq p_t(S_t^*)$. So in any case the algorithm gets profit plus bonus at least $\frac{p_t(S_t^*) + n}{2}$. At time 1 it gets profit at least $p_1(S_1^*)$. So

$$f(S_1, \dots, S_T) \geq p_1(S_1^*) + \sum_{t=2}^T \frac{p_t(S_t^*)}{2} + \frac{n(T-1)}{2} \geq \frac{f^*}{2},$$

which completes the proof. ◀

► **Theorem 6.** *Consider the SSFS model with Hamming bonus. For any $\epsilon > 0$, there is no $(2 - \epsilon)$ -competitive algorithm, even if there are only 2 time steps.*

Proof. We consider a set $N = \{1, 2, \dots, n\}$ of $n = 1 + \lceil \frac{1}{\epsilon} \rceil$ objects, $T = 2$ time steps, and an additive profit function. There are three feasible solutions: $S^0 = \emptyset$, $S^1 = \{1\}$ and $S^2 = \{2, \dots, n\}$. At $t = 1$, all the profits are 0. Let us consider an online algorithm A. We consider the three possibilities for the algorithm at time 1:

- At time 1, A chooses S^0 : at time 2 we give profit 1 to all objects. If A takes no object at time 2, it gets profit 0 and bonus n . If it takes S^1 , it gets profit 1 and bonus $n - 1$. If it takes S^2 , it gets profit $n - 1$ and bonus 1, so in any case the computed solution has value n . The solution consisting of taking S^2 at both time steps has profit $n - 1$ and bonus n , so value $2n - 1$.

- At time 1, A chooses S^1 : at time 2 we give profit 0 to object 1, and profit 1 to all other objects. Then, if the algorithm takes S^0 (resp, S^1 , S^2), at time 2 its gets value $n - 1$ (resp, n , $n - 1$) while the solution consisting of taking S^2 at both time steps has value $2n - 1$.
 - At time 1, A chooses S^2 : at time 2 we give profit n to object 1, and 0 to all other objects. Then if the algorithm takes S^0 (resp, S^1 , S^2) at time 2 its gets value 1 (resp, n , n), while the solution consisting of taking S^1 at both time steps has value $2n$.
- In any case, the ratio is at least $\frac{2n-1}{n} = 2 - \frac{1}{n} > 2 - \epsilon$. ◀

We complement this lower bound with an asymptotical result for large T ; the proof is provided in the full version.

► **Theorem 7.** *Consider the SSFS model with Hamming bonus. For every $\epsilon > 0$, there is a T_ϵ such that, for each number of time steps $T \geq T_\epsilon$, there is no $(3/2 - \epsilon)$ -competitive algorithm.*

2.2 Intersection-Bonus Model

In the intersection-bonus model things get harder since an optimal solution S_t^* may be of small size and then gives very small (potential) bonus for the next step. As a matter of fact, the algorithm of the previous section has unbounded competitive ratio in this case: take a large number n of objects, $\mathcal{F} = 2^N$, and at time 1 all objects have profit 0 up to one which has profit ϵ . The algorithm will take this object (instead of taking $n - 1$ objects of profit 0) and then potentially get bonus at most 1 instead of $n - 1$.

Thus we shall put an incentive for the algorithm to take solutions of large size, in order to have a chance to get a large bonus. We define the following algorithm called **MP-Algo** (for Modified Profit algorithm). Informally, at each time step t , the algorithm computes an optimal solution with a modified objective function p'_t . These modifications take into account (1) the objects taken at time $t - 1$ (2) an incentive to take a lot of objects. Formally, **MP-Algo** works as follows:

1. At $t = 1$: let $p'_1(S) = p_1(S) + |S|$. Choose S_1 as an optimal solution for the problem with modified profits p'_1 .
2. For t from 2 to $T - 1$: let $p'_t(S) = p_t(S) + |S \cap S_{t-1}| + |S|$. Choose S_t as an optimal solution for the problem with modified profit function p'_t .
3. At $t = T$: let $p'_T(S) = p_T(S) + |S \cap S_{T-1}|$. Choose S_T as an optimal solution with modified profit function p'_T .

The cases $t = 1$ and $t = T$ are specific since there is no previous solution for $t = 1$, and no future solution for $t = T$.

► **Theorem 8.** *In the SSFS model with intersection bonus, **MP-Algo** is $\left(\frac{2}{1-1/(T-1)}\right)$ -competitive.*

Proof. Let $(\hat{S}_1, \dots, \hat{S}_T)$ be an optimal sequence. Since S_t is optimal with respect to p'_t , for $t = 2, \dots, T - 1$ we have:

$$p'_t(S_t) = p_t(S_t) + |S_t \cap S_{t-1}| + |S_t| \geq p'_t(\hat{S}_t) \geq p_t(\hat{S}_t) + |\hat{S}_t|. \quad (1)$$

Since S_{t-1} is also a feasible solution at time t , we have:

$$p'_t(S_t) = p_t(S_t) + |S_t \cap S_{t-1}| + |S_t| \geq p_t(S_{t-1}) \geq 2|S_{t-1}|. \quad (2)$$

Similarly, at $t = T$ $p'_T(S) = p_T(S) + |S \cap S_{T-1}|$ so

$$p_T(S_T) + |S_T \cap S_{T-1}| \geq p_T(\hat{S}_T), \quad (3)$$

$$p_T(S_T) + |S_T \cap S_{T-1}| \geq |S_{T-1}|. \quad (4)$$

At $t = 1$, $p'_t(S) = p_t(S) + |S|$, so

$$p_1(S_1) + |S_1| \geq p_1(\hat{S}_1) + |\hat{S}_1|. \quad (5)$$

Now, note that $|S_t \cap S_{t-1}|$ is the transition bonus of the computed solution between $t - 1$ and t . By summing Equation (1) for $t = 2, \dots, T - 1$, Equation (3) and Equation (5), we deduce:

$$f(S_1, \dots, S_T) + \sum_{t=1}^{T-1} |S_t| \geq \sum_{t=1}^T p_t(\hat{S}_t) + \sum_{t=1}^{T-1} |\hat{S}_t|.$$

Since in the optimal sequence the transition bonus between time t and $t + 1$ is at most $|\hat{S}_t|$, we get:

$$f(S_1, \dots, S_T) + \sum_{t=1}^{T-1} |S_t| \geq f(\hat{S}_1, \dots, \hat{S}_T). \quad (6)$$

Now we sum Equation (2) for $t = 2, \dots, T - 1$ and Equation (4):

$$f(S_1, \dots, S_T) + \sum_{t=2}^{T-1} |S_t| \geq 2 \sum_{t=2}^{T-1} |S_{t-1}| + |S_{T-1}|.$$

From this we easily derive:

$$f(S_1, \dots, S_T) \geq \sum_{t=2}^{T-2} |S_t|. \quad (7)$$

By summing Equations (6) and (7) we have $2f(S_1, \dots, S_T) \geq f(\hat{S}_1, \dots, \hat{S}_T) - |S_{T-1}|$. The competitive ratio follows from the fact that $f(\hat{S}_1, \dots, \hat{S}_T) \geq (T - 1)|S_{T-1}|$ (since S_{T-1} is feasible for all time steps). ◀

We note that competitive ratio 2 can be derived with a similar analysis when the number of time steps is 2 or 3. In the full version, we show a matching asymptotical lower bound.

► **Theorem 9.** *Consider the SSFS model with intersection bonus. For any $\epsilon > 0$ and number of time steps $T = \lceil 1/\epsilon \rceil$, there is no $(2 - \epsilon)$ -competitive algorithm.*

3 Model of General Evolution

We consider in this section that the set of feasible solutions may evolve over time. We will show that in the Hamming bonus model, we can still get constant competitive ratios, though ratios slightly worse than in the case where only profits could change over time. Then, we will tackle the intersection bonus model, showing that no constant competitive ratio can be achieved. However, with only 1-lookahead we can get a constant competitive ratio.

3.1 Hamming-Bonus Model

In this section we consider the Hamming bonus model. We first show in Section 3.1.1 that there exists a $\left(3 + \frac{1}{T-1}\right)$ -competitive algorithm. Interestingly, we then show in Section 3.1.2 that a slight assumption on the problem structure allows to improve the competitive ratio. More precisely, we achieve a $21/8$ (asymptotic) competitive ratio if we assume that the objective function is subadditive (so including the additive case) and that a subset of a feasible solution is feasible. These assumptions are satisfied by all the problems mentioned in introduction. We finally consider lower bounds in Section 3.1.3.

3.1.1 General Case

We adapt the idea of the 2-competitive algorithm working for the Hamming bonus model for a static set of feasible solutions (Section 2.1) to the current setting where the set of feasible solutions may change. Let us consider the following algorithm **BestOrNothing**: at each time step t , **BestOrNothing** computes an optimal solution S_t^* with associated profit $p_t(S_t^*)$ and compares it to 2 times the maximum potential bonus, i.e to $2n$. It chooses S_t^* if the associated profit is at least $2n$, otherwise it chooses $S_t = \emptyset$. A slight modification is applied for the last step T .

In the full version, we define the algorithm formally and prove an upper bound on the competitive ratio achieved by this algorithm.

► **Theorem 10.** *In the GE model with Hamming bonus, **BestOrNothing** is $\left(3 + \frac{1}{T-1}\right)$ -competitive.*

3.1.2 Improvement for Sub-additivity and Subset Feasibility

In this section we assume that the problem have the following two properties:

- *subset feasibility*: at any time step, every subset of a feasible solution is feasible.
- *sub-additivity*: for any disjoint S, S' , any t , $p_t(S \cup S') \leq p_t(S) + p_t(S')$.

Note that this implies that, if a feasible set X is partitioned into (disjoint) subsets X_1, \dots, X_h , then X_1, \dots, X_h are feasible and $p_t(X) \leq \sum_i p_t(X_i)$.

We exploit this property to devise algorithms where we partition the set of objects and solve the problems on subinstances. As a first idea, let us partition the set of objects into 3 sets A, B, C of size (roughly) $n/3$; consider the algorithm which at every time step t computes the best solutions S_t^A, S_t^B, S_t^C on each subinstance on A, B and C , and chooses S_t as the one of maximum profit between these 3 solutions. By sub-additivity and subset feasibility, the algorithm gets profit at least $1/3$ of the optimal profit at each time step. Dealing with bonuses, at each time step the algorithm chooses a solution included either in A , or in B , or in C so, for any $t < T$, at least one set among A, B and C is not chosen neither at time t nor at time $t + 1$, and the algorithm gets transition bonus at least $n/3$. Hence, the algorithm is 3-competitive.

We now improve the previous algorithm. The basic idea is to remark that if for two consecutive time steps $t, t + 1$ the solution S_t and S_{t+1} are taken in the same subset, say A , then the bonus is (at least) $2n/3$ instead of $n/3$. Roughly speaking, we can hope for a ratio better than $1/3$ for the bonus. Then the algorithm makes a trade-off at every time step: if the profit is very high then it will take a solution maximizing the profit, otherwise it will do (nearly) the same as previously. More formally, let us consider the algorithm **3-Part**. We first assume that n is a multiple of 3. A parameter $x \in \mathbb{R}_+$ will be defined later.

1. Partition N in three subsets A, B, C of size $n/3$.
2. For $t \in \{1, \dots, T\}$: compute a solution S_t^* maximizing $p_t(S)$
 - Case (1): If $p_t(S_t^*) \geq xn$: define $S_t = S_t^*$
 - Otherwise ($p_t(S_t^*) \leq xn$): compute solutions with optimal profit S_t^A, S_t^B, S_t^C included in A, B and C . Let a_t, b_t and c_t the respective profits.
 - Case (2): if $t \geq 2$ and Case (1) did not occur at $t - 1$, do:
 - If $S_{t-1} \subseteq A$ (resp. $S_{t-1} \subseteq B, S_{t-1} \subseteq C$), compute $\max\{a_t + 2n/3, b_t + n/3, c_t + n/3\}$ (resp. $\max\{a_t + n/3, b_t + 2n/3, c_t + n/3\}, \max\{a_t + n/3, b_t + n/3, c_t + 2n/3\}$) and define S_t as S_t^A, S_t^B or S_t^C accordingly.
 - Case (3) ($t = 1$ or Case (1) occurred at $t - 1$) do:
 - * Define S_t as the solution with maximum profit among S_t^A, S_t^B, S_t^C .

11:10 Online Multistage Subset Maximization Problems

If N is not a multiple of 3, we add one or two dummy objects that are in no feasible solutions (at any step).

In the full version, we prove an upper bound on the competitive ratio of this algorithm.

► **Theorem 11.** *Consider the GE model with Hamming bonus. Under the assumption of subset feasibility and sub-additivity, 3-Part is $(21/8 + O(1/T + 1/n))$ -competitive.*

3.1.3 Lower Bounds

We complement the algorithmic results with a lower bound for two time steps and an asymptotical one, which we both prove in the full version. Interestingly, these bounds are also valid for the latter restricted setting with subset feasibility and sub-additivity.

► **Theorem 12.** *Consider the GE model with Hamming bonus and $T = 2$ time steps. For any $\epsilon > 0$, there is no $(1 + \sqrt{2} - \epsilon)$ -competitive algorithm.*

► **Theorem 13.** *Consider the GE model with Hamming bonus. For every $\epsilon > 0$, there is a T_ϵ such that, for each number of time steps $T \geq T_\epsilon$, there is no $(\alpha - \epsilon)$ -competitive algorithm where $\alpha = \frac{6 \cdot \sqrt[3]{9 + \sqrt{87}}}{\sqrt[3]{6 \cdot (9 + \sqrt{87})^2 - \sqrt[3]{36}}} \approx 1.696$.*

3.2 Intersection-Bonus Model

We now look at the general-evolution model with intersection bonus. This model is different from the ones considered before: We first give a simple lower bound showing that there is no constant-competitive algorithm.

► **Theorem 14.** *In the GE model with intersection bonus, there is no c -competitive algorithm for any constant c .*

Proof. We consider an instance with no profit. Let $T = 2$, $N = \{1, 2\}$, and $\mathcal{F}_1 = \{\emptyset, \{1\}, \{2\}\}$, that is, there are two items, and at time 1 it is only forbidden to take both of them. Assume w.l.o.g. that the algorithm does not pick item 2 at time 1. Then picking item 1 becomes infeasible at time 2 while picking item 2 remains feasible. Then the algorithm achieves 0 profit and bonus while the optimum can achieve a bonus of 1. ◀

Note that in this model, by adding dummy time steps giving no bonus and no profit, the previous lower bound extends to any number of time steps. This lower bound motivates considering the 1-lookahead model: at time t , besides I_t , the algorithm knows the instance I_{t+1} . It shall decide the feasible solution chosen at time t . We consider an algorithm based on the following idea: at some time step t , the algorithm computes an optimal sequence of 2 solutions $(S_{t,1}^*, S_{t,2}^*)$ of value z_t^* for the subproblem defined on time steps t and $t + 1$. Suppose it fixes $S_t = S_{t,1}^*$. Then, at time $t + 1$, it computes $(S_{t+1,1}^*, S_{t+1,2}^*)$ of value z_{t+1}^* . Depending on the values z_t^* and z_{t+1}^* , it will either choose to set $S_{t+1} = S_{t,2}^*$, confirming its choice at t (getting in this case value z_t^* for sure between time t and $t + 1$), or change its mind and set $S_{t+1} = S_{t+1,1}^*$ (possibly no value got yet, but a value z_{t+1}^* if it confirms this choice at $t + 2$). When a choice is confirmed ($S_t = S_{t,1}^*$ and $S_{t+1} = S_{t,2}^*$), then the algorithm starts a new sequence (fix $S_{t+2} = S_{t+2,1}^*, \dots$).

More formally, let $(S_{t,1}^*, S_{t,2}^*)$ be an optimal solution of the subproblem defined on time steps t and $t + 1$, and denote z_t^* its value (including profits and bonus between time t and $t + 1$). To avoid unnecessary subcases, we consider at time T $(S_{T,1}^*, S_{T,2}^*)$ where $S_{T,2} = \emptyset$ and z_T^* is the profit of the optimal solution for the single time step T , $S_{T,1}^*$. Then consider the algorithm **Balance** which:

1. At time $t = 1$ compute $(S_{1,1}^*, S_{1,2}^*)$ and fix $S_1 = S_{1,1}^*$.
2. For $t = 2$ to T : compute $(S_{t,1}^*, S_{t,2}^*)$.
 - Case (1): If at $t - 1$ the algorithm chose S_{t-1} equal to $S_{t-2,2}^*$ (i.e., Case (3) occurred), then fix $S_t = S_{t,1}^*$.
 - Case (2): Otherwise, if $z_t^* > 2z_{t-1}^*$, then fix $S_t = S_{t,1}^*$.
 - Case (3): Otherwise fix $S_t = S_{t-1,2}^*$.

► **Theorem 15.** *In the GE model with intersection bonus and 1-lookahead, Balance is a 4-competitive algorithm.*

Proof. Let V be the set of time steps in which Case (3) occurred. In the proof, intuitively we partition the time period into periods which end at some time $t \in V$, and prove the claimed ratio in each of these sub-periods.

Formally, let u, v ($u < v$) be two time steps in V such that $w \notin V$ for any $u < w < v$. Note that since Case (3) occurred at time u , Case (1) occurred at $u + 1$, so $u \neq v - 1$, and Case (2) occurred at time $u + 2, \dots, v - 1$. So $z_t^* > 2z_{t-1}^*$ for $t = u + 2, \dots, v - 1$. By an easy recurrence, this means that, for all $t \in \{u + 1, \dots, v - 1\}$, we have $z_t^* < z_{v-1}^*/2^{v-1-t}$. By taking the sum, we get $\sum_{t=u+1}^{v-1} z_t^* < 2z_{v-1}^*$. Since Case (3) occurred at v , $z_v^* \leq 2z_{v-1}^*$. Finally:

$$\sum_{t=u+1}^v z_t^* \leq 4z_{v-1}^*.$$

Now, at each time v for which case (3) occurred, we choose $S_v = S_{v-1,2}^*$. As previously said, Case (3) did not occur at $v - 1$, so we choose $S_{v-1} = S_{v-1,1}^*$. Then the algorithm gets value at least z_{v-1}^* for these two time steps. In other words $f(S_1, \dots, S_T) \geq \sum_{v \in V} z_{v-1}^*$. Consider first the case where $T \in V$ (case (3) occurred at time T). Then we get a partition of the time steps into subintervals ending in $v \in V$. So

$$\sum_{t=1}^T z_t^* \leq 4 \sum_{v \in V} z_{v-1}^* \leq 4f(S_1, \dots, S_T).$$

Let $(\hat{S}_1, \dots, \hat{S}_T)$ be an optimal solution. We have $p_t(\hat{S}_t) + p_{t+1}(\hat{S}_{t+1}) + b(\hat{S}_t, \hat{S}_{t+1}) \leq z_t^*$. So $f(\hat{S}_1, \dots, \hat{S}_T) \leq \sum_{t=1}^{T-1} z_t^*$, and:

$$f(\hat{S}_1, \dots, \hat{S}_T) \leq \sum_{t=1}^T z_t^* \leq 4f(S_1, \dots, S_T).$$

Note that this is overestimated, each $p_t(\hat{S}_t)$ appears two times in the sum.

Now, if $T \notin V$, then $T - 1 \in V$: indeed, Case (2) cannot occur at time T (since $z_T^* \leq z_{T-1}^*$). So we have in this case:

$$\sum_{t=1}^{T-1} z_t^* \leq 4 \sum_{v \in V} z_{v-1}^* \leq 4f(S_1, \dots, S_T).$$

But again since $f(\hat{S}_1, \dots, \hat{S}_T) \leq \sum_{t=1}^{T-1} z_t^*$, we have

$$f(\hat{S}_1, \dots, \hat{S}_T) \leq \sum_{t=1}^{T-1} z_t^* \leq 4f(S_1, \dots, S_T).$$

This completes the proof. ◀

In the full version, we prove a matching lower bound. The idea of the proof of the matching lower bound is as follows: As can be seen from the proof of Theorem 15, the estimate on the profit has slack for the 4-competitive algorithm. We give a construction in which there is no profit and in which the bonus when not “committing” to the solution from the previous time step is geometrically increasing over time; otherwise the bonus is 0. As it turns out, however, when the factor is 2 in each time step, we cannot show a lower bound of 4 in case the algorithm does not commit until the last time step. Interestingly, if we use the minimum factor to show a lower bound of $4 - \epsilon$ in case the algorithm commits at any time step but the last, we can find a large-enough time horizon such that, in case the algorithm commit only in the last time step, we can also show a lower bound of $4 - \epsilon$.

► **Theorem 16.** *Consider the GE model with intersection bonus. For any $\epsilon > 0$, there is a T_ϵ such that, for each number of time steps $T \geq T_\epsilon$, there is no $4 - \epsilon$ competitive ratio.*

4 Conclusion

In this paper, we have developed techniques for online multistage subset maximization problems and thereby settled the achievable competitive ratios in the various settings almost exactly. Disregarding asymptotically vanishing terms in the upper bounds, what remains open is the exact ratio in the general-evolution setting with Hamming bonus (shown to be between $1 + \sqrt{2}$ and 3 in this paper) and exact bounds for the models with Hamming bonus when $T \rightarrow \infty$. Furthermore, it is plausible that the ratios can be improved for (classes of) more specific problems.

We emphasize that we have focussed on deterministic algorithms in this work. Indeed, some of our bounds can be improved by randomization (assuming an oblivious adversary):

- In the general-evolution model with Hamming bonus assuming sub-additivity and subset feasibility, there is a simple randomized $(2 + o(1))$ -competitive algorithm (along the lines of the algorithms in Subsubsection 3.1.2): Initially partition N uniformly at random into two equal-sized sets (up to possibly one item) A and B . At each time, select the optimal solution restricted to A . Again, the algorithm is $(2 + o(1))$ -competitive separately on both profit and bonus.
- While the strong lower bound without lookahead in the general-evolution model with intersection bonus still holds, we can get a simple 2-competitive algorithm for lookahead 1: Initially flip a coin to interpret the instance as a sequence of length-2 instances either starting at time 1 or 2. Thanks to lookahead 1, the length-2 instances can all be solved optimally. The total value of all these length-2 instances adds up to at least the optimal value, and the expected value obtained by the algorithm is half of that.

While we believe that we have treated various of the most natural ways of defining value in multistage subset maximization problems, other ways can be thought of, to some of which our results extend. For instance, Theorem 5 also works for time-dependent or object-dependent bonus without major modifications (whereas, e.g., Theorem 8 does not).

We have not worried about computational complexity in this work (and therefore neither about the representation of the set of feasible solutions); indeed, often we use an oracle providing the optimal solution to instances of a potentially hard problem. However, we mention that, if only an approximation algorithm to the problem at hand was known, we would be able to obtain similar online algorithms whose competitive ratio would depend on the approximation guarantee of the approximation algorithm.

Abstract

In this paper, we consider the colorful k -center problem, which is a generalization of the well-known k -center problem. Here, we are given red and blue points in a metric space, and a coverage requirement for each color. The goal is to find the smallest radius ρ , such that with k balls of radius ρ , the desired number of points of each color can be covered. We obtain a constant approximation for this problem in the Euclidean plane. We obtain this result by combining a “pseudo-approximation” algorithm that works in any metric space, and an approximation algorithm that works for a special class of instances in the plane. The latter algorithm uses a novel connection to a certain matching problem in graphs.

1 Introduction

In the k -center problem, we are given a finite metric space (P, d) , where P is a set of n points, and $d : P \times P \rightarrow \mathbb{R}^+$ is the associated distance function. We are also given an integer $1 \leq k \leq n$. The goal is to find a subset $C \subseteq P$ of *centers*, where $|C| = k$, so as to minimize $\max_{p \in P} \min_{c \in C} d(p, c)$, the maximum distance of a point from its nearest center. Geometrically, we want to find the smallest radius ρ such that P can be covered by k balls of radius ρ (centered at points in P).

It is well known that k -center is NP-hard; furthermore, it is also NP-hard to approximate the optimal radius to within a $2 - \epsilon$ factor, for any $\epsilon > 0$. This is easily seen via a reduction from the minimum dominating set problem [16]. On the other hand, it is possible to obtain a tight approximation ratio of 2 [11, 15]. A simple greedy algorithm of [11] achieving this starts with C containing an arbitrary point in P ; in each of the subsequent $k - 1$ iterations, it finds a point $p \in P$ that maximizes $d(p, C) := \min_{c \in C} d(p, c)$, and adds that point to C .

In the k -center with outliers problem, we are given an additional parameter $1 \leq p \leq n$. The goal is to find the smallest radius ρ such that at least p points of P can be covered by k balls of radius ρ . Thus, we allow up to $n - p$ points to remain uncovered, and these

would be “outliers.” Intuitively, in comparison to k -center, an algorithm for solving this problem has to also figure out which p points to cover. Nevertheless, Charikar et al. [6], who introduced this problem, gave a simple 3-approximation using a greedy algorithm. Their algorithm guesses the optimal radius ρ ; then, for k iterations, it finds the ball of radius ρ that covers the maximum number of yet uncovered points, expands it by a factor of 3, and adds it to the solution. More recently, the approximation guarantee was improved to 2, using LP-rounding techniques [4, 13]. Note that this approximation guarantee is tight, in light of the $2 - \epsilon$ hardness result mentioned earlier.

We now introduce the *colorful k -center* problem, which is studied in this article. As in k -center, the input consists of a set P of n points in a metric space, and an integer k . Furthermore, we are given a partition $\{P_1, P_2, \dots, P_c\}$ of P into c *color classes*, and a coverage requirement $0 \leq t_i \leq |P_i|$ for each color class $1 \leq i \leq c$. The goal is to find the smallest radius ρ such that using k balls of radius ρ , centered at points of P , we can simultaneously cover at least t_i points from each class P_i . When we have only one color class, that is, when $c = 1$, we obtain the k -center with outliers problem. In much of this article, we focus on the case with two color classes, where $c = 2$. In this case, we call the colors *red* and *blue*; we denote P_1 and P_2 , respectively, by R (red points) and B (blue points), and denote the coverage requirements t_1 and t_2 , respectively, by r and b . The motivation for studying this problem is as follows. Each color class can be thought of as a certain demographic with a specific coverage requirement, which must be satisfied by the k balls chosen in the solution.

Even with two colors, the colorful k -center is quite challenging. The greedy algorithm for k -center with outliers [6] has no obvious generalization: with two color classes, what do we optimize when adding the next ball to our solution? The LP-based approaches for k -center with outliers do not generalize either – as we point out (in Example 5), the natural LP has an unbounded integrality gap.

Chakrabarty et al. [4] study a closely related problem called non-uniform k center. As input to this problem, we are given a set P of points in a metric space, λ distinct radii $r_1 > \dots > r_\lambda \geq 0$ and corresponding integers t_1, \dots, t_λ . The goal is to find the smallest *dilation* $\beta \geq 0$ such that P can be covered by a collection of balls formed by including, for each $1 \leq i \leq \lambda$, t_i balls of radius $\beta \cdot r_i$. When $\lambda = 1$, we get the regular k -center problem. When λ is unbounded, the problem is hard to approximate to within any constant factor; when $\lambda = 2$, one can get an $O(1)$ -approximation; and when λ is a constant greater than 2, it is open as to whether an $O(1)$ -approximation is possible [4].

As Chakrabarty et al. [4] observe, there is a close relationship between k -center with outliers and non-uniform k -center with $\lambda = 2$. In fact, it can be shown that the two problems are equivalent up to an $O(1)$ -approximation factor. While the relationship between the colorful k -center with c color classes and non-uniform k -center with $c + 1$ distinct radii is not known to be as close for $c \geq 2$, the study of the latter problem is one motivation that led us to the colorful k -center problem.

1.1 Other Related Work

The k -means and k -median are classic NP-hard clustering problems that are closely related to the k -center problem. Like the k -center problem, these problems have been extensively studied, resulting in different approaches guaranteeing constant factor approximations. More recently, the outlier versions of these problems were also studied; constant factor approximations were obtained for k -median with outliers [8, 19] and k -means with outliers [19]. A polynomial time bicriteria $(1 + \epsilon)$ -approximation using at most $k(1 + \epsilon)$ centers for any $\epsilon > 0$ is known in low dimensional Euclidean spaces, and metric spaces with constant doubling dimension [10].

Facility location with outliers, which is referred to as *Robust Facility Location*, is a generalization of the uncapacitated Facility Location problem; various constant approximations are known for the latter problem. The Robust Facility Location problem was introduced in [6], who gave a 3-approximation. The approximation guarantee was later improved by Jain et al. [18] to 2.

A colorful version of vertex cover is studied in [1], and colorful versions of the Set Cover and Facility Location-type problems were considered in [17]. In these problems, the cardinality of the cover (or its weight) shows up in the objective function, unlike in k -center, where the number of centers/balls k is a “hard restriction”. These problems therefore have a different flavor.

Finally, k -center and k -median have been generalized in an orthogonal direction, where there are additional constraints on the centers [12, 7, 5]. Again, the issues studied in these generalizations tend to be quite different from the ones we confront here.

1.2 Our Results

We study the colorful k -center problem when the number of colors is a constant. Our main result is a randomized polynomial time algorithm that, with high probability, outputs an $O(1)$ -approximation in the Euclidean plane. (As k -center is APX-hard even in the plane [9], we cannot hope for a PTAS.)

To describe our approach, we focus on the case with two colors. We first design a pseudo-approximation algorithm that outputs a 2-approximation, but with $k + 1$ centers instead of k . This result holds in any metric space, not just the Euclidean plane. To obtain it, we preprocess the solution to a natural LP-relaxation into a solution for a simpler LP, using ideas from [4, 13]. We then note that a basic feasible solution to the simple LP opens at most $k + 1$ centers fractionally. A pseudo-approximation for k -median with outliers was an important step in the recent work of Krishnaswamy et al. [19].

The pseudo-approximation allows us to reduce the colorful k -center problem to a special case where the balls in the optimal solution are separated – the distance between any two balls is much greater than their radii. Designing an $O(1)$ -approximation for this special case is challenging, even in the plane. For instance, partitioning into small subproblems by using a grid (such as in [14]) or other type of object does not work, because any such partitioning may intersect balls in the optimal solution, and we have a hard bound k on the number of balls allowed.

We solve separated instances in the plane by reducing to exact perfect matching on graphs. In this problem, we are given a graph in which each edge has a red weight and a blue weight, both non-negative integers. Given integers w_r and w_b , the goal is to determine if the graph has a perfect matching whose red and blue weights are, respectively, *exactly* w_r and w_b . This problem can be solved in randomized polynomial time, provided the weights are bounded by a polynomial in the input size; see [3, 21]. To our knowledge, this connection of geometric clustering and covering to exact matching is a novel one.

In its current form, the reduction from separated instances of colorful k -center to exact matching does not work even in \mathbb{R}^3 . Nevertheless, we are hopeful that this work will lead to an $O(1)$ -approximation to colorful k -center in dimensions 3 and higher, and indeed in any metric space.

Organization. We describe our pseudo-approximation in Section 2 and our $O(1)$ -approximation for the Euclidean plane in Section 3. In both these sections, we focus on the case where the number of colors is 2. We address the extension of the planar result to multiple color classes in Section 4.

Find a feasible solution (x, z) such that:	
$\sum_{i \in B(j, \rho)} x_i \geq z_j, \quad \forall j \in P$	(1)
$\sum_{i \in P} x_i \leq k,$	(2)
$\sum_{j \in R} z_j \geq r,$	(3)
$\sum_{j \in B} z_j \geq b,$	(4)
$z_j, x_i \in [0, 1], \quad \forall i, j \in P$	(5)

■ **Figure 1** The feasibility LP, parameterized by ρ .

2 Pseudo-approximation via LP Rounding

Recall that an instance of colorful k -center is a metric space $(P = R \sqcup B, d)$, where R, B are non-empty, disjoint sets of red and blue points respectively. We are also given red and blue coverage requirements $1 \leq r \leq |R|$ and $1 \leq b \leq |B|$, respectively. A solution (C, D) , where $C, D \subseteq P$, is said to be feasible, if (i) $|C| \leq k$, (ii) $|D \cap R| \geq r$, and (iii) $|D \cap B| \geq b$. The cost of a solution is defined as $\max_{j \in D} d(j, C)$. Any point in the set D is said to be *covered* by the solution. The goal of the colorful k -center problem is to find a feasible solution of the minimum cost.

In this section, we describe a pseudo-approximation algorithm for the colorful k -center problem. That is, we show how to find a solution of cost at most $2 \cdot OPT$ using at most $k + 1$ centers, where OPT is the cost of an optimal solution. This result is achieved in two steps. In the first step, we use the natural LP relaxation for the decision version of the colorful k -center problem, to partition the points in P into disjoint clusters using a simple greedy procedure. We also obtain a related fractional solution during this clustering procedure. We use this to show that a much simpler LP with a small number of constraints has a feasible solution, even though there may not exist an integral feasible solution using at most k centers. Nevertheless, we use the simplicity of the LP to show that there exists a solution using at most $k + 1$ centers.

Let ρ denote our “guess” for the optimal cost. Note that the optimal cost must be one of the $O(n^2)$ interpoint distances, therefore there are $O(n^2)$ choices for ρ . We state the feasibility LP, parameterized by ρ , in Figure 1. It is easy to see that an optimal solution satisfies all the constraints when the guess ρ is correct (i.e., when $\rho \geq OPT$). Therefore, henceforth, we assume that $\rho = OPT$.

Now, we find a feasible fractional solution (x', z') for this LP, and use it to show that a related, but a much simpler LP is feasible. To this end, we use the following “greedy clustering” procedure (see Algorithm 1), which also computes a modified LP solution (\tilde{x}, \tilde{z}) . Let P' denote the set of unclustered points, initialized to P . We also initialize S , the collection of cluster-centers, to the empty set. In each iteration, we find a point $j \in P'$ with the maximum z_j . We set $\tilde{z}_j = \tilde{x}_j \leftarrow \min\{1, \sum_{i \in B(j, \rho)} x'_i\}$ – note that the sum is over all points in the ball $B(j, \rho)$, as opposed to the points in $B(j, \rho) \cap P'$. Let C_j denote the set of unclustered points

Algorithm 1 Clustering Algorithm.

```

1:  $S \leftarrow \emptyset, P' \leftarrow P$ 
2: while  $P' \neq \emptyset$  do
3:    $j \in P'$  be a point with maximum  $z'_j$ ; let  $S \leftarrow S \cup \{j\}$ 
4:    $\tilde{x}_j \leftarrow \min\{1, \sum_{i \in B(j, \rho)} x'_i\}$ ;  $\tilde{z}_j \leftarrow \tilde{x}_j$ 
5:    $C_j \leftarrow B(j, 2\rho) \cap P'$ 
6:   For all  $j' \neq j \in C_j$ , set  $\tilde{x}_{j'} \leftarrow 0, \tilde{z}_{j'} \leftarrow \tilde{z}_j$ 
7:    $P' \leftarrow P' \setminus C_j$ 
8: end while
  
```

within distance 2ρ from j . We refer to the set C_j as a cluster. We set $\tilde{z}_{j'} \leftarrow \tilde{z}_j$ for all other points $j' \in C_j \setminus \{j\}$. Finally, we remove the points in C_j from P' and repeat this process until all points are clustered, i.e., P' becomes empty.

For any point $i \in S$, let $R_i := R \cap C_i$ and $B_i := B \cap C_i$ denote the sets of red and blue points in the “cluster” C_i respectively. Additionally, for any $i \in S$, let r_i and b_i denote the sizes of the sets R_i and B_i respectively. We start with a few simple observations that are immediate from the description of the procedure.

► **Observation 1.**

1. The “clusters” $\{C_i\}_{i \in S}$ partition the point set P . Therefore, $\{R_i\}_{i \in S}$ partition the red points R , and $\{B_i\}_{i \in S}$ partition the blue points B ,
2. For any two distinct $i, i' \in S$, $d(i, i') > 2\rho$,
3. For any $j \in P$, there is at most one $i \in S$, such that $d(i, j) \leq \rho$.

The following observation follows from the greedy nature of the clustering procedure.

► **Observation 2.** For any point $j_1 \in P$, let $j \in S$ be the point in S such that $j_1 \in C_j$. Then, $\tilde{z}_j = \tilde{z}_{j_1} \geq z'_{j_1}$

Proof. Notice that, $\tilde{z}_{j_1} = \tilde{z}_j = \min\{1, \sum_{i \in B(j, \rho)} x'_i\}$. There are two cases to consider.

$\tilde{z}_{j_1} = \tilde{z}_j = 1 \geq z'_{j_1}$, where the inequality follows from the constraint (5) of the LP.

Otherwise, $\tilde{z}_j = \sum_{i \in B(j, \rho)} x'_i$. In this case, $\tilde{z}_j = \sum_{i \in B(j, \rho)} x'_i \geq z'_j \geq z'_{j_1}$. Here, the first inequality follows from constraint (1) of the LP, and the second inequality follows from the fact that in the iteration when j_1 was removed from P' , $j \in P'$ was chosen to be a point with the maximum z' -value in line 3. ◀

The next two claims help us construct a feasible solution to a simplified LP, to be introduced later.

▷ **Claim 3.**

1. $\sum_{i \in S} r_i \tilde{x}_i \geq r$
2. $\sum_{i \in S} b_i \tilde{x}_i \geq b$

$$\begin{aligned}
 & \text{maximize} && \sum_{i \in S} r_i x_i \\
 & \text{subject to} && \sum_{i \in S} b_i x_i \geq b && (6) \\
 & && \sum_{i \in S} x_i \leq k, && (7) \\
 & && x_i \in [0, 1], \quad \forall i \in S && (8)
 \end{aligned}$$

■ **Figure 2** The Simplified LP.

Proof. We prove the first part of the claim – the second part is analogous.

$$\begin{aligned}
 \sum_{i \in S} r_i \tilde{x}_i &= \sum_{i \in S} |R_i| \cdot \tilde{x}_i \\
 &= \sum_{i \in S} \sum_{j' \in R_i} \tilde{z}_i && \text{(For any } i \in S, \tilde{x}_i = \tilde{z}_i \text{ by construction)} \\
 &\geq \sum_{i \in S} \sum_{j' \in R_i} z'_{j'} && \text{(For any } j' \in R_i \subseteq C_i, \tilde{z}_i \geq z'_{j'} \text{ from Observation 2)} \\
 &= \sum_{j \in R} z'_j && \text{(Property 1 of Observation 1)} \\
 &\geq r && \text{(By constraint (3))}
 \end{aligned}$$

◁

▷ **Claim 4.** $\sum_{i \in S} \tilde{x}_i \leq k$

Proof.

$$\begin{aligned}
 \sum_{i \in S} \tilde{x}_i &\leq \sum_{i \in S} \sum_{i' \in B(i, \rho)} x'_{i'} && (\tilde{x}_i \leq \sum_{i' \in B(i, \rho)} x'_{i'}) \\
 &\leq \sum_{i' \in P} x'_{i'} && \text{(From Property 3 of Observation 1)} \\
 &\leq k && \text{(By constraint (2))}
 \end{aligned}$$

◁

2.1 A Simplified Problem

Recall that the clusters $\{C_j\}_{j \in S}$ are disjoint, and have radius 2ρ . Now, if we can find a collection of k clusters from this set, that cover at least r red points and b blue points, then this immediately leads to a 2-approximation. Unfortunately, it is not always possible to find such a collection. However, in the following, we show that we can find a collection of $k + 1$ clusters that satisfies the coverage requirements of both colors. The LP in Figure 2 is a relaxation of the problem of finding at most k clusters that satisfy the coverage requirements of both colors.

Note that Claims 3 and 4 imply that the fractional solution (\tilde{x}) constructed above is a feasible solution for this LP, and has objective value at least r . However, there may not exist a feasible integral solution that uses at most k clusters from the set $\{C_i\}_{i \in S}$. The following example illustrates this.

► **Example 5.** In the following figure, we have two clusters C_1 and C_2 . Red points are shown as boxes, whereas blue points are shown as dots. C_1 consists of 3 red points and 1 blue point, whereas C_2 contains 3 blue points and 1 red point. Suppose that $k = 1$ and the coverage requirements of each color class is 2. Now, assigning $x_1 = x_2 = 0.5$ yields a fractional solution that satisfies the coverage requirements of each color class. However, assuming that the distance between two clusters is very large compared to the radii, 2ρ , it can be seen that there is no feasible integral solution of cost at most a constant multiple of 2ρ .

Nevertheless, we show in the following that there exists a feasible solution that uses at most $k + 1$ clusters. First, we need the following classical result from linear algebra (see Lemma 2.1.4 in [20]).

► **Lemma 6** ([20]). *In any extreme point feasible solution (or equivalently, a basic feasible solution) to a linear program, the number of linearly independent tight constraints is equal to the number of variables.*

Furthermore, an extreme point optimal solution can be computed in polynomial time. Now, we find such an optimal solution (x^*) to the simplified LP. It follows from Claim 3 that its objective value is at least r . We prove the following lemma, which is a simple consequence of Lemma 6.

► **Lemma 7.** *The number of x^* -variables in an extreme point optimal solution that are strictly fractional, is at most 2. Therefore, the number of strictly positive variables is at most $k + 1$.*

Proof. Let $m := |S|$ denote the number of variables. From Lemma 6, it follows that the number of linearly independent tight constraints is equal to m . Note that, even though there are $2m + 2$ constraints in the LP, at most $m + 2$ constraints can be simultaneously tight. Now, even if constraints (6) and (7) are tight, it follows that number of tight constraints from (8) is at least $m - 2$. That is, the number of strictly fractional variables is at most 2.

If there are k variables that are equal to 1, then constraint (7) is tight, and there are no strictly fractional variables. Otherwise, the number of variables equal to 1, is at most $k - 1$. Along with at most 2 strictly fractional variables, the number of positive variables is at most $k + 1$. ◀

Note that the red and blue coverage can only increase while rounding up the fractional variables to 1. If there is exactly one fractional variable, we round it up, giving a 2-approximation using exactly k centers. Otherwise, let x_1^*, x_2^* be the two fractional variables, corresponding to clusters C_1, C_2 respectively. Note that, although the fractional solution satisfies both red and blue coverage, adding only C_1 or C_2 to the solution may not satisfy coverage demands for both colors – recall Example 5. Therefore, we include both clusters in the solution, resulting in a pseudo-approximation of cost at most 2ρ , using at most $k + 1$ centers. We summarize the result of this section in the following theorem.

► **Theorem 8.** *There exists a polynomial time algorithm to find a 2-approximation for the colorful k -center problem (with two colors) in any metric space, using at most $k + 1$ centers.*

12:8 A Constant Approximation for Colorful k -Center

This theorem generalizes readily to an arbitrary number of color classes $c \geq 2$. Having c color classes corresponds to having $c - 1$ constraints instead of constraint (6) in the corresponding Simplified LP. As we now have constraints corresponding to $c - 1$ color classes, we obtain the following lemma for the Simplified LP, the proof of which goes along the same lines as that of Lemma 7.

► **Lemma 9.** *The number of x^* -variables in an extreme point optimal solution that are strictly fractional, is at most c . Therefore, the number of strictly positive variables is at most $k + c - 1$.*

Therefore, if we round up these fractional variables, we get a pseudo-approximation of cost at most $2 \cdot \rho$, using at most $k + c - 1$ centers.

3 A Constant Approximation Algorithm in \mathbb{R}^2

In this section, we describe a constant approximation algorithm for the colorful k -center problem with two color classes, red and blue, where the set of points lies in the Euclidean plane. Recall that $P = R \sqcup B$ denotes the input set of n points, and r and b the red and blue coverage requirements. Our algorithm consists of two subroutines which we describe in the following two subsections. The two subroutines are intended to handle two different types of instances. In order to describe these instances we need the following definitions.

► **Definition 10.** *Let $\alpha > 0$ be a parameter. A set S of balls of radius ρ' is α -separated if the distance between the centers of every two balls in S is greater than $\alpha \cdot \rho'$. An instance of colorful k -center is α -separated if the set of balls in some optimal solution is α -separated.*

The first subroutine (described in Section 3.1) gives a $2(\alpha + 1)$ -approximation algorithm for instances that are not α -separated. The second subroutine (described in Section 3.2) gives a $(0.5\alpha + 2)$ -approximation algorithm for α -separated instances where $\alpha > 4/\gamma$ for some absolute constant $\gamma > 0$, which is defined below.

Therefore for a large enough constant α , we get a $\max\{2(\alpha + 1), 0.5\alpha + 2\}$ -approximation algorithm for the colorful k -center problem with two color classes. From the geometric arguments in Section 3.2 that determine α , it is apparent that taking $\alpha = 8 + \epsilon'$ for any $\epsilon' > 0$ is sufficient. Therefore, the approximation guarantee of our algorithm is $17 + \epsilon$ for any $\epsilon > 0$.

3.1 Handling Non-Separated Instances

If an instance is not α -separated, we can use the pseudo-approximation algorithm of Section 2 to immediately get a $2(\alpha + 1)$ -approximation algorithm. This is formalized in the following lemma. It is worth pointing out that this subroutine does not require the set of points to be in \mathbb{R}^2 – it works for any metric.

► **Lemma 11.** *If an instance is not α -separated then we get a $2(\alpha + 1)$ -approximate solution to the colorful k -center problem in polynomial time.*

Proof. Let the optimal radius be ρ . Since the instance is not α -separated, there are two balls in some optimal solution whose centers are within distance $\alpha \cdot \rho$ of each other. Let C_1 and C_2 be two such balls in the optimal solution. We replace C_1 with a ball of radius $(\alpha + 1)\rho$ centered at the same point as C_1 . This allows us to remove C_2 without violating any of the coverage requirements (since the new ball replacing C_1 covers all points originally covered by C_2). This means that there exists a feasible solution using $k - 1$ centers with cost

$(\alpha + 1)\rho$. Therefore, if we run the pseudo-approximation algorithm of the previous section with number of centers being $k - 1$, we will get a solution using at most k centers having cost $2(\alpha + 1)\rho$, which proves the lemma. ◀

3.2 Reduction of Separated Instances to Exact Perfect Matching

Let us assume that the instance we are given is α -separated for some $\alpha > 4/\gamma$ for some absolute constant $\gamma > 0$. From the proof of Lemma 12, it will be clear that taking $\alpha > 8$ is sufficient. The α -separability of the instance helps us design a $(0.5\alpha + 2)$ -approximation algorithm for this problem in \mathbb{R}^2 . We do this by reducing the problem to the *Exact Perfect Matching* problem [22, 2]. In the exact perfect matching problem we are given an edge-weighted graph $G = (V, E)$ and a target weight W . The goal is to find a perfect matching in G having weight *exactly* W . The result in [3, 21] gives a randomized pseudo-polynomial algorithm for exact perfect matching. In other words, their algorithm runs in polynomial time if the largest edge weight in the input graph is bounded by a polynomial in $|V|$. We now describe our reduction from the k -center problem to exact perfect matching.

We first assume that we have guessed correctly the radius ρ of an optimal solution to the given instance. We cover \mathbb{R}^2 with a grid of equilateral triangles of side length $\ell = 0.5\alpha\rho$. See Figure 3 for an illustration. Consider the following three lines through the origin: L_1 is the x -axis, L_2 has angle 60 degrees with L_1 , and L_3 has angle 120 degrees with L_1 . The grid of side length ℓ can be formally defined as the arrangement of the collection of lines parallel to L_1 , L_2 , and L_3 , with two adjacent parallel lines having distance $\sqrt{3}\ell/2$. We can interpret the grid as an infinite graph where the edges are the sides of each atomic triangle in the grid and the vertices are the intersection points of the edges.

Define the *Voronoi region of an edge e* as the set of points that are at least as close to e as any other edge. It is easy to see that the Voronoi region of e is a rhombus whose four end points are the two end points of e and the centroids of the two triangles sharing the edge e . We are interested in the *extended Voronoi region of an edge e* which is the Minkowski sum of the Voronoi region of e and a ball of radius ρ centered at the origin.

► **Lemma 12.** *The extended Voronoi regions of two edges e and e' intersect each other iff e and e' share a common vertex.*

Proof. The reverse direction of the lemma is trivial, so we focus on the forward direction. Take two edges e and e' that are not incident on a common vertex. Note that their Voronoi regions do not intersect (see Figure 3). Thus, there is an absolute constant $\gamma > 0$ such that the distance between the closest pair of points, one in each region, is at least $\gamma \cdot \ell = \gamma \cdot 0.5\alpha\rho$. Therefore, if $\alpha > 4/\gamma$, the distance between the two Voronoi regions is greater than 2ρ .¹ Thus, the extended Voronoi regions of e and e' do not intersect because each Voronoi region “expands” by only an additive factor of ρ . ◀

For each edge define $P(e)$ as the set of points in P that lie in the extended Voronoi region of e . Let $G' = (V', E')$ be the graph where E' is the set of all grid edges such that $P(e) \neq \emptyset$, and V' is the set consisting of the endpoints of edges in E' . Define $N = 2 \max\{n, |V'|\}$, note that $N = O(n)$ because each point can belong to at most six triangles. The weight of an edge $e \in E'$ is set to $w_e = N^2 \cdot b_e + r_e$ where b_e and r_e are the number of blue and red points respectively in $P(e)$.

¹ With simple geometric calculations, one can show that $\gamma = 1/2$, which implies that $\alpha > 8$.

■ **Figure 3** Here, we show a triangular grid of side $\ell = 0.5\alpha\rho$. We also show the Voronoi region of the edge e (the area inside the dash-dotted rhombus around e), and the extended Voronoi region of e (the area inside the lightly shaded object). We also show the Voronoi regions of the “neighboring edges” that do not share a vertex with e as dashed rhombuses. Notice that the Voronoi regions (resp. extended Voronoi regions, not shown for simplicity) of the neighboring edges do not intersect with the Voronoi region (resp. extended Voronoi region) of e . We use this fact in the proof of Lemma 12. Notice that, the extended Voronoi region of e contains 2 red points and 4 blue points. Therefore, we will set the weight of the edge to be $4 \cdot N^2 + 2$.

► **Lemma 13.** *There exists a matching in G' with k edges and with weight exactly $b' \cdot N^2 + r'$ for some $|B| \geq b' \geq b$ and $|R| \geq r' \geq r$.*

Proof. Let S^* be the set of balls in an optimal solution that is α -separated. For each ball $C_i \in S^*$, $1 \leq i \leq k$, let e_i be any edge (from the infinite grid) such that the center of C_i lies in the Voronoi region of e_i . Note that the extended Voronoi region of e_i contains C_i , and thus $e_i \in E'$. We claim that if $i \neq j$, then (a) $e_i \neq e_j$, and (b) e_i and e_j are not incident on a common vertex of V' . If either (a) or (b) does not hold, the distance between the centers of C_i and C_j is at most $0.5\alpha\rho + 0.5\alpha\rho = \alpha\rho$, which violates the fact that the instance is α -separated. Therefore the set $M = \{e_i | 1 \leq i \leq k\}$ is a matching of k edges in G .

If we set b' and r' to be the total number of blue and red points in the extended Voronoi regions of the k edges, then we have a matching of weight $b' \cdot N^2 + r'$ in G . Since the extended Voronoi regions cover all the points covered by S^* , we have $b' \geq b$ and $r' \geq r$ which finishes the proof. ◀

We now define a graph G such that perfect matchings in G correspond to matchings with k edges in G' . To construct $G = (V, E)$, we start with G' and add $|V'| - 2k$ auxiliary vertices that are connected to all vertices of G' with edges of weight zero. We can do this because Lemma 13 implies that $|V'| \geq 2k$. Now G obeys the following property that is easy to prove.

► **Observation 14.** *Any matching in G' of weight W having exactly k edges can be extended to a perfect matching in G of weight exactly W . Conversely, from any perfect matching in G with weight exactly W , we can obtain a matching in G' with k edges and weight exactly W .*

Using Lemma 13 and Observation 14 we get the following Corollary.

► **Corollary 15.** *There exists a perfect matching in G of weight exactly $b' \cdot N^2 + r'$ for some $|B| \geq b' \geq b$ and $|R| \geq r' \geq r$.*

We now show how to go from a perfect matching in G to a cover for the input instance.

► **Lemma 16.** *If G has a perfect matching of weight exactly $W = b'N^2 + r'$, with $0 \leq b' \leq |B|$ and $0 \leq r' \leq |R|$, then we can place exactly k balls of radius $(0.5\alpha + 2)\rho$ that cover at least r' red points and at least b' blue points.*

Proof. Suppose G has a perfect matching M of weight W . Using Observation 14, we recover a matching M' in G' with k edges and weight W . For $e \in M'$, let $b_e = |P(e) \cap B|$ and $r_e = |P(e) \cap R|$. Thus, the weight w_e for each edge e is $b_e N^2 + r_e$. It follows that

$$\left(\sum_{e \in M'} b_e \right) N^2 + \left(\sum_{e \in M'} r_e \right) = W = b' N^2 + r'.$$

By our choice of N , both r' and $\sum_{e \in M'} r_e$ are strictly less than N^2 . It follows that $\sum_{e \in M'} r_e = r' = W \bmod N^2$, and furthermore $\sum_{e \in M'} b_e = b'$. Furthermore, since M' is a matching, by Lemma 12, the extended Voronoi regions of the edges in M' do not intersect. Thus, $\cup_{e \in M'} P(e)$ contains exactly r' red points and b' blue points.

For each $e \in M'$ such that $P(e) \neq \emptyset$, we place a ball of radius $(0.5\alpha + 2)\rho$ centered at any point in $P(e)$. These at most k balls cover all points in $\cup_{e \in M'} P(e)$. This is because the distance between any two points in $P(e)$ for an edge e is at most $(0.5\alpha + 2)\rho$. This finishes the proof of the lemma. ◀

We are now ready to state our algorithm for our α -separated instance of colorful k -center, assuming that we know the optimal radius ρ . We construct the graph G and check if it has a perfect matching of weight exactly $W = b' \cdot N^2 + r'$, for each $b \leq b' \leq |B|$ and $r \leq r' \leq |R|$. For the check, we invoke the algorithm of [3]. Corollary 15 ensures that for at least one of these guesses for W , an exact perfect matching does exist, and the algorithm of [3] returns it.² Once we find an exact perfect matching solution for any of these weight values, we convert it into a $(0.5\alpha + 2)$ -approximate solution by invoking the algorithm of Lemma 16. This completes our algorithm.

As we do not know the optimal radius for the given input instance, we will run the above algorithm for each choice of ρ from the set of $O(n^2)$ interpoint distances induced by P . Fix a particular choice of ρ . If there exists a feasible solution with balls of radius ρ that is α -separated, then the above algorithm will return a feasible solution with cost at most $(0.5\alpha + 2) \cdot \rho$. If there is no feasible solution with balls of radius ρ that is α -separated, then the above algorithm may not return a feasible cover.

Overall, we simply return the minimum cost feasible solution that we encounter after applying the above algorithm for all choices of ρ . This is a $(0.5\alpha + 2)$ -approximation for α -separated instances.

► **Remark 17.** We note that the algorithm described here generalizes to any constant number of color classes, in the following sense. Suppose we have an input instance for which there exists an α -separated solution of cost ρ' , for some ρ' . In particular, we do not assume that ρ'

² The algorithm of [3] is actually a randomized Monte-Carlo algorithm, and thus has an error probability that can be made arbitrarily small. For the sake of exposition, we ignore this eventuality of error, except in the statement of our final result.

12:12 A Constant Approximation for Colorful k -Center

is the optimal cost for the input instance. Then the algorithm computes a feasible solution of cost at most $(0.5\alpha + 2) \cdot \rho'$. Note that in this case, for any edge e of the graph G' , the weight of each edge will be of the form $\sum_{i \geq 0} P_i(e) N^{2i}$ where $P_i(e)$ is the number of points of color class i in the extended Voronoi region of that edge.

3.3 Combining Separated and Non-Separated Cases

We do not know if a given instance of colorful k -center is α -separated or not. Therefore, we do not know which subroutine to use. So we run both the subroutines and return the solution with the lowest cost. We conclude with our main result.

► **Theorem 18.** *There is a randomized polynomial time algorithm that, given any instance of colorful k -center in the plane with two colors, outputs, with high probability, an $O(1)$ -approximate solution.*

4 Multiple Color Classes in the Plane

So far we have only considered two color classes for the sake of keeping the exposition simple. We now sketch an extension to the colorful k -center problem in the plane with c color classes for any integer constant c .

For a given instance in the plane, fix the optimal set of balls S^* , and assume it has cost ρ . Let S be any maximal α -separated subset of S^* . That is, for each pair of balls in S , the distance between the centers is greater than $\alpha \cdot \rho$, whereas for every ball $B \in S^* \setminus S$, there is a ball $B' \in S$, such that the distance between the centers of B and B' is at most $\alpha \cdot \rho$. Let $\bar{S} = S^* \setminus S$. We consider two cases:

Case 1: $|\bar{S}| \geq c - 1$

Notice that if we expand each ball in S to have radius $(\alpha + 1) \cdot \rho$, and discard the balls in \bar{S} , we obtain a feasible solution with at most $k - (c - 1)$ balls and cost $(\alpha + 1) \cdot \rho$. For this case, running the pseudo-approximation algorithm on the original input, but with the number of centers set to $k - (c - 1)$, will give us a solution with k balls and cost $2(\alpha + 1) \cdot \rho$.

Case 2: $|\bar{S}| \leq c - 2$

We guess the balls in \bar{S} . Because $|\bar{S}| \leq c - 2$, and there are $O(n^2)$ choices for ρ , we have $O(n^c)$ possibilities to guess from. After guessing \bar{S} , we remove the points covered by \bar{S} , and decrease the coverage requirement for each color class by the number of points of that color class covered by \bar{S} . For this residual instance, S is an α -separated solution with $k - |\bar{S}|$ balls and cost ρ . If we run the algorithm of Section 3.2 on this residual instance, allowing $k - |\bar{S}|$ centers, we obtain a cover with $k - |\bar{S}|$ balls and cost at most $(0.5\alpha + 2) \cdot \rho$. We output the union of this cover and \bar{S} . This is a feasible solution to the original problem with k balls and cost $O(\rho)$.

The overall running time of the algorithm is $n^{O(c)}$.

5 Open Problems

One question raised by our work is whether an $O(1)$ -approximation for colorful k -center (with a constant number of colors) can be obtained in \mathbb{R}^d for $d \geq 3$, or indeed in an arbitrary metric space. Another question is whether one can obtain an $O(1)$ -approximation for non-uniform k -center in the plane (with a constant number of distinct radii).

Abstract

Deciding whether two simplicial complexes are homotopy equivalent is a fundamental problem in topology, which is famously undecidable. There exists a combinatorial refinement of this concept, called simple-homotopy equivalence: two simplicial complexes are of the same simple-homotopy type if they can be transformed into each other by a sequence of two basic homotopy equivalences, an elementary collapse and its inverse, an elementary expansion. In this article we consider the following related problem: given a 2-dimensional simplicial complex, is there a simple-homotopy equivalence to a 1-dimensional simplicial complex using at most p expansions? We show that the problem, which we call the *erasability expansion height*, is $\mathbf{W[P]}$ -complete in the natural parameter p .

1 Introduction

Homotopy theory lies at the heart of algebraic topology. In an attempt to make the concept of homotopy equivalence more amenable to combinatorial methods, Whitehead developed what turned out to be a combinatorial refinement of the theory, called *simple-homotopy theory*. Simple-homotopy theory considers sequences of elementary homotopy equivalences defined on simplicial complexes (or, more generally, CW complexes): an *elementary collapse*, which takes a face of a complex contained only in a single proper coface and removes both faces, and its inverse operation, called an *elementary expansion*. Two simplicial complexes are then said to be of the same simple-homotopy type if one can be transformed into the other by a sequence of elementary collapses and expansions. Complexes of the same simple-homotopy type are homotopy equivalent, but the converse is not always true [18], the obstruction being an element of the *Whitehead group* of the fundamental group. However, Whitehead

proved that all homotopy-equivalent complexes with a trivial fundamental group are in fact of the same simple-homotopy type [19], and thus in this particular case the notions of simple-homotopy and homotopy coincide.

A presentation of the fundamental group can be read off from a two-dimensional complex such that the presentation is balanced and describes the trivial group if and only if this complex is contractible [12]. Since the decidability of the triviality problem for balanced presentations is open [4], the same is also true for the decidability of contractibility of 2-complexes. Hence, the decidability of the existence of a simple-homotopy equivalence from a 2-complex to a point is also open. In contrast, the problem of deciding whether a given complex has trivial fundamental group is famously undecidable already for 2-complexes through its connection to the word problem, see, for instance, [5]. It follows that sequences of elementary collapses and expansions proving simple-homotopy equivalence between a 2-complex and a point can be expected to be long, if not unbounded. Nonetheless, understanding these sequences offers a great reward: the statement that any contractible 2-complex contracts to a point using only expansions up to dimension three is equivalent to a weaker variant [13, p. 34–35] of the Andrews–Curtis conjecture [1, 20].

In this article, motivated by the aforementioned problems, we investigate the computational (parametrized) complexity of a number of variants of the problem of deciding contractibility. More precisely, we focus on the problem of deciding whether a given 2-complex admits a simple-homotopy to a 1-complex using at most p expansions, called ERASIBILITY EXPANSION HEIGHT. In addition, we consider a variant, called ORDERED ERASIBILITY EXPANSION HEIGHT, which requires that all expansions come at the very beginning of the sequence. It is worth noting that ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT are equivalent for CW complexes for which one can readily swap the order of expansions and collapses [13, p. 34]. However, for simplicial complexes, the ordered and unordered expansion heights may differ.

In Section 5.1, we prove that ERASIBILITY EXPANSION HEIGHT is $\mathbf{W}[\mathbf{P}]$ -hard, see Theorem 8. The proof uses a reduction from AXIOM SET. The same reduction also establishes $\mathbf{W}[\mathbf{P}]$ -hardness of ORDERED ERASIBILITY EXPANSION HEIGHT. Note that a reduction from AXIOM SET is also used by the third author and others in [6] to establish $\mathbf{W}[\mathbf{P}]$ -hardness of a parametrized version of OPTIMAL MORSE MATCHING. However, unlike in [6], the use of combinatorial and topological properties of the dunce hat is a key ingredient of the reduction used in this paper. In particular, there is only one gadget in the reduction – a subdivision of the so-called *modified dunce hat* [3], see Figure 2. In this sense the techniques used in this paper are also related to recent work by the first and second author in [3], where they show hardness of approximation for some Morse matching problems.

In Section 5.2, we show that ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT are both in $\mathbf{W}[\mathbf{P}]$, and hence also $\mathbf{W}[\mathbf{P}]$ -complete, see Theorems 8, 13 and 14. Both results rest on the key observation that a 2-complex is erasable if and only if greedily collapsing triangles yields a 1-dimensional complex (Proposition 11), as shown by Tancer [17, Proposition 5].

In Section 6 we show that, as a consequence of the above reduction, the problem of deciding whether a 2-complex can be shown to be simple-homotopy equivalent to a 1-complex using only 3-dimensional expansions, called ERASIBILITY 3-EXPANSION HEIGHT, is \mathbf{NP} -complete, see Theorem 17.

2 Definitions and Preliminaries

2.1 Simplicial complexes

A (finite) *abstract simplicial complex* is a collection K of subsets of a finite ground set V such that if τ is an element of K , and σ is a nonempty subset of τ , then σ is an element of K . The ground set V is called the *set of vertices* of K . Since simplicial complexes are determined by their facets, we sometimes present simplicial complexes by listing their facets. A *subcomplex* of K is a subset $L \subseteq K$ which is itself a simplicial complex. Given a subset $W \subseteq V$ of the vertices of K , the *induced subcomplex on W* consists of all simplices of K that are subsets of W .

The elements of K are referred to as its *faces*. The *dimension of a face* is defined to be its cardinality minus one, and the *dimension of K* equals the largest dimension of its faces. For brevity, we sometimes refer to a d -dimensional simplicial complex as a *d -complex* and to a d -dimensional face as a *d -face*. The 0-, 1-, and 2-faces of a d -complex K are called its *vertices*, *edges*, and *triangles* respectively. Faces of K which are not properly contained in any other face are called *facets*. An $(m - 1)$ -face $\sigma \in K$ which is contained in exactly one m -face $\tau \in K$ is called *free*.

The *star* of a vertex v of complex K , written $\text{star}_K(v)$, is the subcomplex consisting of all faces of K containing v , together with their faces. If a map $\phi : V \rightarrow W$ between the vertex sets of two simplicial complexes K and L , respectively, sends every simplex $\sigma \in K$ to a simplex $\phi(\sigma) \in L$, then the induced map $f : K \rightarrow L, \sigma \mapsto \phi(\sigma)$, is said to be *simplicial*.

2.2 Simple-homotopy

We introduce the basic notions of simple-homotopy used in the present paper. The general concept of simple-homotopy can be understood independently from the notion of homotopy. In this sense this article aims to be self-contained. For further reading on homotopy theory we refer to [11].

In short, a simple-homotopy equivalence is a refinement of a homotopy equivalence. It can be described purely combinatorially with the help of the following definition.

► **Definition 1** (Elementary collapses and expansions). *Let K_0 be a simplicial complex, and let $\tau, \sigma \in K_0$ be an m -face and an $(m - 1)$ -face respectively such that $\sigma \subset \tau$, and σ is free in K_0 .*

We say that $K_1 = K_0 \setminus \{\tau, \sigma\}$ arises from K_0 by an elementary collapse of dimension m or elementary m -collapse, denoted by $K_0 \searrow K_1$. Its inverse, the operation $K_0 = K_1 \cup \{\tau, \sigma\}$ is called an elementary expansion of dimension m or elementary m -expansion, written $K_0 \nearrow K_1$. If the complex is implicit from context, we denote elementary collapses by \searrow_σ^τ and elementary expansions by \nearrow_σ^τ . An elementary collapse or an elementary expansion is sometimes referred to as an elementary move, or simply a move.

If there exists a sequence of elementary collapses turning a complex K_0 into K_1 we write $K_0 \searrow K_1$ and say that K_0 collapses to K_1 . If K_1 is one-dimensional, we say that K_0 is erasable. If K_1 is merely a point we call K_0 collapsible.

Finally, we write $K_0 \nearrow K_1$ to indicate a sequence of expansions and say that K_0 expands to K_1 .

It follows that an expansion \nearrow_σ^τ can only be performed in a simplicial complex K if all codimension 1 faces of τ except for σ are already in K . Hence, let τ be an m -face of a simplicial complex K , and let σ be one of its $(m - 1)$ -faces. An (*m -dimensional*) *horn* $\mathbf{H}(\tau, \sigma)$ associated to the pair (τ, σ) is the simplicial complex generated by the $(m - 1)$ -faces of τ apart from σ .

13:4 Parametrized Complexity of Expansion Height

All m -expansions and m -collapses with $m > 1$ leave the vertex set unchanged.

► **Definition 2** (Simple-homotopy equivalence, simple-homotopy graph). *Two simplicial complexes K and L are said to be simple homotopy equivalent or of coinciding simple-homotopy type, written $K \frown L$, if there exists a sequence \mathcal{S} of elementary moves turning one into the other. In this case, we write $\mathcal{S} : K \frown L$.*

The dimension of a simple-homotopy equivalence is the maximum of the dimensions of K , L and of any elementary expansion or collapse in the sequence.

The graph whose nodes are simplicial complexes, and two nodes are adjacent if their corresponding complexes are related by an elementary collapse is called simple-homotopy graph. Naturally, its connected components are in one-to-one correspondence with simple-homotopy types.

Two simplicial complexes of the same simple-homotopy type are homotopy equivalent, but the converse is not true, see, for instance, [18]. For simple-homotopy equivalent simplicial complexes we know the following.

► **Theorem 3** (Wall [17], Matveev [13, Theorem 1.3.5]). *Let K and L be two simplicial complexes of the same simple-homotopy type and of dimension at most $m > 2$. Then there exists a simple-homotopy equivalence of dimension at most $m + 1$, taking one to the other.*

For the case $m = 2$, Theorem 3 is still open and known as the (topological or geometric) Andrews–Curtis conjecture [2, 13, 15]. On the other hand, it is known that any contractible 2-complex is also simple-homotopy equivalent to a point [19]. Hence, any pair of contractible 2-complexes can be connected by a simple-homotopy equivalence of dimension at most four – but determining whether we can always decide if such a simple-homotopy equivalence exists is an open question [4], equivalent to the triviality problem for balanced group presentations [12].

2.3 Parametrized complexity

Parametrized complexity, as introduced by Downey and Fellows in [7], is a refinement of classical complexity theory. The theory revolves around the general idea of developing complexity bounds for instances of a problem not just based on their size, but also involving an additional *parameter*, which might be significantly smaller than the size. Specifically, we have the following definition.

► **Definition 4** (Parameter, parametrized problem). *Let Σ be a finite alphabet.*

1. *A parameter of Σ^* , the set of strings over Σ , is a function $\rho : \Sigma^* \rightarrow \mathbb{N}$, attaching to every input $w \in \Sigma^*$ a natural number $\rho(w)$.*
2. *A parametrized problem over Σ is a pair (P, ρ) consisting of a set $P \subseteq \Sigma^*$ and a parametrization $\rho : \Sigma^* \rightarrow \mathbb{N}$.*

In this article we consider the complexity class $\mathbf{W[P]}$ for parametrized problems, following the definition by Flum and Grohe [8].

► **Definition 5** (Complexity Class $\mathbf{W[P]}$). *Let Σ be an alphabet and $\rho : \Sigma^* \rightarrow \mathbb{N}$ a parametrization. A nondeterministic Turing machine \mathbb{M} with input alphabet Σ is called ρ -restricted if there are computable functions $f, h : \mathbb{N} \rightarrow \mathbb{N}$ and a polynomial p (with coefficients in the set of natural numbers) such that on every run with input $x \in \Sigma^*$ the machine \mathbb{M} performs at most $f(k) \cdot p(|x|)$ steps, at most $h(k) \cdot \log |x|$ of them being nondeterministic, where $k := \rho(x)$. $\mathbf{W[P]}$ is the class of all parametrized problems (P, ρ) that can be decided by a ρ -restricted nondeterministic Turing machine.*

3 Problems

In this article we consider the following parametrized problems.

► **Problem 1** (ERASIBILITY EXPANSION HEIGHT).

INSTANCE: A 2-dimensional simplicial complex K and a natural number p .

PARAMETER: p .

QUESTION: Is there a path in the simple-homotopy graph connecting K to a 1-complex using at most p expansions?

► **Problem 2** (ORDERED ERASIBILITY EXPANSION HEIGHT).

INSTANCE: A 2-dimensional simplicial complex K and a natural number p .

PARAMETER: p .

QUESTION: Is there a path in the simple-homotopy graph connecting K to a 1-complex using first at most p expansions, followed by a sequence of only collapses?

In Section 5, we establish $\mathbf{W[P]}$ -completeness for ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT.

The hardness proof works via a parametrized reduction using the AXIOM SET problem, which is a classical \mathbf{NP} -complete problem [9, p. 263] that is well-known to be $\mathbf{W[P]}$ -complete with respect to the appropriate parameter [7, p. 473].

► **Problem 3** (AXIOM SET).

INSTANCE: A finite set S of *sentences*, an *implication relation* R consisting of pairs (U, s) where $U \subseteq S$ and $s \in S$, and a positive integer $p \leq |S|$.

PARAMETER: p .

QUESTION: Is there a set $S_0 \subseteq S$, called an *axiom set*, with $|S_0| \leq p$ and a positive integer n such that if we recursively define

$$S_i := S_{i-1} \cup \{s \in S \mid \exists U \subseteq S_{i-1} : (U, s) \in R\}$$

for $1 \leq i \leq n$, then $S_n = S$?

► **Remark 6.** Note that every instance of AXIOM SET can be reduced in polynomial time to an instance for which every sentence must occur in at least one implication relation: First iteratively remove all sentences from the instance which do not feature in at least one implication relation. Then, for each of them, reduce p by one (note that each of them must necessarily be an axiom). It follows that solving the reduced instance is equivalent to solving the original instance.

Similarly, note that if there exists an implication $(U, s) \in R$, $s \in U$, we can simply omit it and, if this deletes s from the instance altogether, decrease p by one.

In Section 6, we show that the following variants of the expansion height problem are \mathbf{NP} -complete.

► **Problem 4** (ERASIBILITY 3-EXPANSION HEIGHT).

INSTANCE: A finite 2-dimensional simplicial complex K and a natural number p .

QUESTION: Is there a path in the simple-homotopy graph connecting K to a 1-complex using at most p expansions, all of which are 3-expansions?

► **Problem 5** (ORDERED ERASIBILITY 3-EXPANSION HEIGHT).

INSTANCE: A finite 2-dimensional simplicial complex K and a natural number p .

QUESTION: Is there a path in the simple-homotopy graph connecting K to a 1-complex using first at most p expansions, all of which are 3-expansions, followed by a sequence of only collapses?

4 Contractibility and collapsibility for 2-complexes

The main gadget used in the proof of our main result, Theorem 8, is based on the simplest 2-dimensional contractible complex which is not collapsible to a point – the *dunce hat*. Hence, before we describe our main gadget in detail, we start this section by briefly discussing minimal triangulations of the dunce hat, and a variant that is collapsible through a unique free edge, the *modified dunce hat*.

4.1 The dunce hat

In the category of CW complexes, the dunce hat can be obtained by identifying two boundary edges of a triangle to build a cone and then gluing the third edge along the seam of the first gluing. The resulting complex does not have a collapsible triangulation. On the other hand, the dunce hat is known to be contractible [21].

The smallest simplicial complexes realizing this construction have 8 vertices, 24 edges and 17 triangles. There are seven such minimal triangulations of the dunce hat [16]. One such triangulation, denoted by **D**, is shown in Figure 1. The dunce hat **D** has two horns, namely $\mathbf{H}(\{2, 7, 8\}, \{1, 2, 7, 8\})$ and $\mathbf{H}(\{3, 5, 6\}, \{1, 3, 5, 6\})$, and hence admits two 3-expansions, namely $\nearrow_{\{2,7,8\}}^{\{1,2,7,8\}}$ and $\nearrow_{\{3,5,6\}}^{\{1,3,5,6\}}$ respectively. They are shown by the shaded areas in Figure 1.

Figure 1 Left: The 8-vertex triangulation **D** of the dunce hat. The two expansions turning it collapsible are highlighted. Right: The 7-vertex triangulation **P** of the modified dunce hat.

Note that after any of these two expansions we obtain a collapsible complex: After the expansion $\nearrow_{\{2,7,8\}}^{\{1,2,7,8\}}$ and the collapses $\searrow_{\{1,7,8\}}^{\{1,2,7,8\}}$, $\searrow_{\{1,7\}}^{\{1,2,7\}}$, and $\searrow_{\{1,8\}}^{\{1,2,8\}}$, the edge $\{1, 2\}$ becomes free and thus **D** becomes collapsible. Similarly, starting with $\nearrow_{\{3,5,6\}}^{\{1,3,5,6\}}$, one may perform the collapse $\searrow_{\{1,5,6\}}^{\{1,3,5,6\}}$ and proceed in an analogous way. In particular, this shows that the dunce hat has the simple-homotopy type of a point, and in fact can be made collapsible by using a single expansion.

4.2 The modified dunce hat

Rather than working with the dunce hat directly, we base the construction of our gadget for the proof of Theorem 8 on the *modified dunce hat* [10]. More precisely, we “insert” a free edge into the dunce hat. For instance, Figure 1 depicts a triangulation of the modified dunce hat, which we denote by **P**, with $\{1, 3\}$ as the unique free edge. This particular triangulation of the modified dunce hat uses only 7 vertices, 19 edges, and 13 triangles. The modified dunce hat has previously been used as a gadget to show hardness of approximation for Morse matchings [3].

If we assume that \mathbf{P} is part of a larger complex K , in which edge $\{1, 3\}$ is glued to triangles not lying in \mathbf{P} , then $\{1, 3\}$ is not free. In this case, the triangles of \mathbf{P} can be collapsed away in essentially two distinct ways. Either, at some point in a simple-homotopy on K , the edge $\{1, 3\}$ becomes free and thus the triangles of \mathbf{P} collapse, or the triangles of \mathbf{P} become collapsible by performing one of two possible 3-expansions on \mathbf{P} . Looking at the latter case in more detail, we have the following sequences of expansions and collapses:

$$\nearrow_{\{2,5,6\}}^{\{1,2,5,6\}}, \searrow_{\{1,5,6\}}^{\{1,2,5,6\}}, \searrow_{\{1,5\}}^{\{1,2,5\}}, \searrow_{\{1,6\}}^{\{1,2,6\}}$$

and

$$\nearrow_{\{2,6,7\}}^{\{2,3,6,7\}}, \searrow_{\{3,6,7\}}^{\{2,3,6,7\}}, \searrow_{\{3,6\}}^{\{2,3,6\}}, \searrow_{\{3,7\}}^{\{2,3,7\}}.$$

In the first case, the edge $\{1, 2\}$ is freed, in the second case, the edge $\{2, 3\}$ is freed. Both sequences can be extended to a collapsing sequence of the entire complex \mathbf{P} .

4.3 The main gadget

Our gadget for the proof of Theorem 8 is a subdivided version of the modified dunce hat \mathbf{P} from Section 4.2. More precisely, it is determined by two positive integers m and ℓ , denoted by $\mathbf{P}_{m,\ell}$, and can be constructed from the complex \mathbf{P} in essentially two steps.

1. Subdivide the edge $\{1, 3\}$ of \mathbf{P} ($m - 1$) times, thereby introducing vertices x_1, \dots, x_{m-1} . Relabel $1 \rightarrow x_0$ and $3 \rightarrow x_m$ to obtain m free edges $f_i = \{x_{i-1}, x_i\}$, $1 \leq i \leq m$.
2. Remove the edge $\{4, 6\}$ and place ℓ vertex-disjoint copies of the disk

$$\{\{c_j, a_j, y_j\}, \{c_j, y_j, z_j\}, \{c_j, z_j, b_j\}, \{d_j, a_j, y_j\}, \{d_j, y_j, z_j\}, \{d_j, z_j, b_j\}\},$$

$1 \leq j \leq \ell$, inside the 4-gon in the center of \mathbf{P} bounded by 4, 5, 6, and 7. Triangulate the remaining space in the interior of the 4-gon. This creates edges $e_j = \{y_j, z_j\}$, $1 \leq j \leq \ell$, with pairwise vertex disjoint stars disjoint to 4, 5, 6, and 7 (now $\{4, 6\}$ reappears as a path from 4 to 6, and thus $\mathbf{P}_{m,\ell}$ is in fact a proper subdivision of \mathbf{P}). See Figure 2 for an illustration.

One key property of $\mathbf{P}_{m,\ell}$ is that we do not subdivide any faces of \mathbf{P} near to the two available 3-expansions. As a result, again, assuming that $\mathbf{P}_{m,\ell}$ is part of a larger complex K where all free edges of $\mathbf{P}_{m,\ell}$ are glued to other triangles of K outside of $\mathbf{P}_{m,\ell}$ and thus are not free, the triangles of $\mathbf{P}_{m,\ell}$ can be collapsed according to the following observation:

► Remark 7. Let K be a two-dimensional simplicial complex such that $\mathbf{P}_{m,\ell}$ is a subcomplex whose vertices do not span any other faces of K (i.e., $\mathbf{P}_{m,\ell}$ is an induced subcomplex of K), and $K \frown_{\searrow} L$ where L is a 1-complex. Then, at least one of the following three statements holds true at some point in $K \frown_{\searrow} L$, enabling us to eventually collapse away all the triangles of $\mathbf{P}_{m,\ell}$.

1. one of the edges $f_i \in \mathbf{P}_{m,\ell}$ becomes free;
2. one of two 3-expansions on $\mathbf{P}_{m,\ell}$: $\nearrow_{\{2,5,6\}}^{\{1,2,5,6\}}$ or $\nearrow_{\{2,6,7\}}^{\{2,3,6,7\}}$ is performed;
3. multiple expansions result in a complex in which all the triangles of $\mathbf{P}_{m,\ell}$ can be collapsed.

In other words, if one of the edges $f_i \in \mathbf{P}_{m,\ell}$ does not become free at some point in $K \frown_{\searrow} L$, then one is forced to use 3-expansions (either directly on $\mathbf{P}_{m,\ell}$, or after performing additional expansions) to collapse away the triangles of $\mathbf{P}_{m,\ell}$.

In Section 5.1 we use this gadget to reduce an instance $A = (S, R, p)$ of AXIOM SET to ERASIBILITY EXPANSION HEIGHT: Every sentence $s \in S$ is associated with one copy of $\mathbf{P}_{m,\ell}$, the edges f_i correspond to implications $(U, s) \in R$, and the edges e_j correspond to whenever $s \in U$ for some implication $(U, u) \in R$.

■ **Figure 2** The main gadget of the construction $\mathbf{P}_{m,\ell}$.

5 Parametrized complexity of Erasability Expansion Height

In this section, we first prove that ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT are $\mathbf{W[P]}$ -hard by a reduction from AXIOM SET, a problem known to be $\mathbf{W[P]}$ -complete. We then show that the two problems are also contained in $\mathbf{W[P]}$.

5.1 $\mathbf{W[P]}$ -hardness of expansion height problems

► **Theorem 8.** ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT are $\mathbf{W[P]}$ -hard problems.

The following lemma is used to assemble the gadgets in our reduction into a simplicial complex K .

► **Lemma 9** (Munkres, [14, Lemma 3.2]). *Let C be a finite set, let K be a simplicial complex with set of vertices V , and let $f : V \rightarrow C$ be a surjective map associating to each vertex of K a color from C . The coloring f extends to a simplicial map $g : K \rightarrow K_f$ where K_f has vertex set C and is obtained from K by identifying vertices with equal color.*

If for all pairs $v, w \in V$, $f(v) = f(w)$ implies that their stars $\text{star}_K(v)$ and $\text{star}_K(w)$ are vertex disjoint, then, for all faces $\tau, \sigma \in K$ we have that

- τ and $g(\tau)$ have the same dimension, and
- $g(\tau) = g(\sigma)$ implies that either $\tau = \sigma$ or τ and σ are vertex disjoint in K .

Lemma 9 provides a way of gluing faces of a simplicial complex by a simplicial quotient map obtained from vertex identifications, and tells us when this gluing does not create unwanted identifications.

Proof of Theorem 8. We want to reduce AXIOM SET to ERASIBILITY EXPANSION HEIGHT.

Fix an instance $A = (S, R, p)$ of AXIOM SET such that every sentence $s \in S$ is subject to at least one implication $(U, s) \in R$ and such that $(U, s) \in R$ implies $s \notin U$. By Remark 6, this is not a restriction, since every instance of AXIOM SET can be reduced to such an

instance in polynomial time. For every sentence $s \in S$, take a copy \mathbf{P}_s of the gadget $\mathbf{P}_{m,\ell}$ to model s , where $\ell \geq 0$ is the number of implications $(U, u) \in R$ with $s \in U$ and $m \geq 1$ is the number of implications $(U, s) \in R$. Thus, for all values $\ell \geq 0$ and $m \geq 1$ the gadget $\mathbf{P}_{m,\ell}$ is a simplicial complex without any unintended identifications. Denote the free edges of \mathbf{P}_s by $f_i^s = \{x_{i-1}^s, x_i^s\}$, $1 \leq i \leq m$, and its edges of type e_j by $e_j^s = \{y_j^s, z_j^s\}$, $1 \leq j \leq \ell$.

For a fixed $s \in S$, endow the set of implications $(U, s) \in R$ of s with an arbitrary order $(U_1, s), \dots, (U_m, s)$. Similarly, for a fixed $u \in S$, order the set of implications in R containing u arbitrarily as $(U^1, s^1), \dots, (U^\ell, s^\ell)$. Now for every $(U_i, s) \in R$ and every $u \in U_i = U^j$ (i.e., $s^j = s$), glue the edge $f_i^s = \{x_{i-1}^s, x_i^s\}$ of the gadget \mathbf{P}_s to the edge $e_j^u = \{y_j^u, z_j^u\}$ of \mathbf{P}_u by identifying x_{i-1}^s with y_j^u and x_i^s with z_j^u .

Performing these identifications for all implications in R yields a complex, which we denote by K . Note that, fixing $s \in S$, and $0 \leq i \leq m$, the only vertices to which x_i^s can possibly be identified to in K are y_j^u, z_j^u ($1 \leq j \leq \ell$).

More precisely, using the orderings from above for vertex x_i^s , let (U_i, s) and (U_{i+1}, s) be the i -th and $(i+1)$ -st implication of s in R (if $i \in \{0, m\}$ there is only one implication to consider) and denote their sentences by u_1, \dots, u_r and u^1, \dots, u^t , where $r = |U_i|$ and $t = |U_{i+1}|$. Moreover, let U_i (resp. U_{i+1}) be the j_f -th (resp. j_g -th) implication where the sentence u_f (resp. u^g) occurs, for $1 \leq f \leq r$ (resp. $1 \leq g \leq t$). Then x_i^s is identified with $z_{j_f}^{u_f}$ ($1 \leq f \leq r$) and $y_{j_g}^{u^g}$ ($1 \leq g \leq t$).

Now since every fixed edge of type e_j^u is only identified with one edge of type f_i^s , those vertices are not identified with any other vertices of K . Since, by construction, the set of the vertex stars of $z_{j_f}^{u_f}$ ($1 \leq f \leq r$), $y_{j_g}^{u^g}$ ($1 \leq g \leq t$), and x_i^s are pairwise vertex disjoint, we can apply Lemma 9 to ensure that no unwanted identifications occur in building up K . In particular, every gadget \mathbf{P}_s is a subcomplex of K via the canonical isomorphism given by the gluing map.

We now show that the following three statements are equivalent for our complex K :

- (a) there exists a simple-homotopy equivalence turning K into a 1-dimensional complex using first at most p expansions, followed by a sequence of only collapses,
- (b) there exists a simple-homotopy equivalence $K \searrow_\triangleleft L$ turning K into a 1-dimensional complex L using at most p expansions, and
- (c) there exists an axiom set $S_0 \subset S$ for $A = (S, R, p)$ using at most p elements.

We trivially have that (a) \implies (b).

In order to show that (c) \implies (a), assume that there exists an axiom set $S_0 \subset S$ of size p , and perform one 3-expansion on each gadget \mathbf{P}_u with $u \in S_0$. As described in Section 4.3, these expansions admit all triangles of these gadgets to collapse. This, in turn, frees all edges f_i^s where $s \in S$ has an implication $(U, s) \in R$ with $U \subset S_0$. Consequently, all triangles of such gadgets \mathbf{P}_s can be collapsed. Since S_0 is an axiom set, repeating this process eventually collapses away all tetrahedra and triangles, leaving a 1-complex.

In order to show that (b) \implies (c), we start with a few definitions. For a complex K' with $K \searrow_\triangleleft K'$, we say that a gadget $\mathbf{P}_s \subseteq K$ is *touched* with respect to a simple-homotopy sequence $\mathcal{S} : K \searrow_\triangleleft K'$ if at some point in the simple-homotopy sequence one of the triangles of \mathbf{P}_s is removed. Otherwise \mathbf{P}_s is said to be *untouched*. Note that even if all triangles of \mathbf{P}_s are present in K' , \mathbf{P}_s might still be touched. Being touched or untouched is a property of the sequence $\mathcal{S} : K \searrow_\triangleleft K'$, not of the complex K' .

We build the axiom set $S_0 \subset S$ for $A = (S, R, p)$ in the following way: A sentence $s \in S$ is in S_0 if and only if a triangle in \mathbf{P}_s is removed by a 3-collapse of the given simple-homotopy sequence $\mathcal{S} : K \searrow_\triangleleft L$. We first inductively prove a claim about

$$S^k = \{s \in S \mid \mathbf{P}_s \text{ is touched by a 3-collapse in the first } k \text{ moves of } K \searrow_\triangleleft L\}.$$

13:10 Parametrized Complexity of Expansion Height

We first inductively prove a claim about

$$S^k = \{s \in S_0 \mid \mathbf{P}_s \text{ is by a 3-collapse in the first } k \text{ moves of } K \frown L\}.$$

▷ **Claim 10.** For $s \in S$, if the gadget \mathbf{P}_s is touched by the first k elementary moves in $\mathcal{S} : K \frown L$, then s is implied by sentences in S^k .

Proof. First note that all gadgets are untouched in K and $S^0 = \emptyset$.

By induction hypothesis, if a gadget \mathbf{P}_s is touched by one of the first $k - 1$ moves in $\mathcal{S} : K \frown L$, then s is implied by sentences in S^{k-1} .

The induction claim is trivially true if \mathbf{P}_s is touched in the first $k - 1$ moves, or if \mathbf{P}_s is touched by a 3-collapse in the k -th move ($s \in S^k \setminus S^{k-1}$), causing the sentence s to be included in S_0 .

So, suppose that this is not the case. That is, suppose that \mathbf{P}_s is untouched in the length $k - 1$ prefix $\mathcal{S}' : K \frown K'$ of $\mathcal{S} : K \frown L$ and touched by a 2-collapse in the k -th move. This implies that $S^k = S^{k-1}$ and that \mathbf{P}_s is a subcomplex of K' and one of the edges f_i^s must be free in K' . Now let $\mathbf{P}_{u_1}, \mathbf{P}_{u_2}, \dots, \mathbf{P}_{u_q}$ be the set of other gadgets containing triangles glued to f_i^s in the original complex K (that is, there is an implication $(\{u_1, u_2, \dots, u_q\}, s) \in R$). Since none of these triangles are present in K' , all gadgets $\mathbf{P}_{u_1}, \mathbf{P}_{u_2}, \dots, \mathbf{P}_{u_q}$ must be touched in $\mathcal{S}' : K \frown K'$. Thus, either they were touched by a 3-collapse and their corresponding sentences are part of S^{k-1} , or they were touched by a 2-collapse and, by the induction hypothesis, their corresponding sentences are implied by sentences in S^k . It follows that s is implied by sentences in $S^k = S^{k-1}$, proving the claim. ◁

By assumption, K is simple homotopy equivalent to a 1-complex L . That is, $\mathcal{S}' : K \frown L$ eventually removes all triangles from K . Hence, every sentence $s \in S$ is touched as a result of a 2-collapse or a 3-collapse. Let m be the number of elementary moves needed to reach L starting from K . Then, by Claim 10, $S^m = S_0$ is the desired axiom set. Also, since a sentence s is included in S_0 only if a triangle belonging to gadget \mathbf{P}_s is removed as part of a 3-collapse, and since a triangle belonging to gadget \mathbf{P}_s does not belong to any other gadget \mathbf{P}_u for $u \neq s$, S_0 cannot contain more elements than the number of 3-collapses (and hence 3-expansions).

Finally, we infer $\mathbf{W}[\mathbf{P}]$ -hardness of ERASIBILITY EXPANSION HEIGHT and ORDERED ERASIBILITY EXPANSION HEIGHT from the above equivalence and the $\mathbf{W}[\mathbf{P}]$ -hardness of AXIOM SET [7, p. 473]. ◀

5.2 $\mathbf{W}[\mathbf{P}]$ -membership of Erasibility Expansion Height

We now show that ORDERED ERASIBILITY EXPANSION HEIGHT and ERASIBILITY EXPANSION HEIGHT are in $\mathbf{W}[\mathbf{P}]$ by describing suitable nondeterministic algorithms for deciding both problems. We begin with a well-known fact about checking collapsibility of 2-complexes.

► **Proposition 11** (Tancer [17], Proposition 5). *Let K be a 2-complex that collapses to a 1-complex L and to another 2-complex M . Then M also collapses to a 1-complex.*

► **Remark 12.** The proposition above implies that we can collapse an input 2-complex K greedily until no more 2-collapses are possible, and if K collapses to a 1-complex L , the algorithm is guaranteed to terminate with a 1-complex as well.

► **Theorem 13.** ORDERED ERASIBILITY EXPANSION HEIGHT is in $\mathbf{W}[\mathbf{P}]$.

Proof. Let K be a simplicial complex with n simplices. First, note that if there exists a simple homotopy sequence \mathcal{S} taking K to a 1-complex with p expansions that all come at the beginning of the sequence, then there also exists a simple homotopy sequence $\mathcal{S}_{\mathbb{M}}$ taking K to a 1-complex where p expansions are followed by collapses such that, for each d , all collapses of dimension $d + 1$ are executed before collapses of dimension d . This follows from observing that, for any two d -collapses \searrow_{σ}^{τ} and $\searrow_{\alpha}^{\beta}$, if the d -collapse \searrow_{σ}^{τ} is executed before the d -collapse $\searrow_{\alpha}^{\beta}$ in \mathcal{S} , then the same can be carried out in $\mathcal{S}_{\mathbb{M}}$. Also, in any simple homotopy sequence \mathcal{S} that takes K to a 1-complex, for every $d > 2$, the number of d -expansions equals the number of d -collapses in \mathcal{S} . This follows from a simple inductive argument starting with highest dimensional moves.

Denoting the total number of d -collapses, $d > 2$, in \mathcal{S} by $q \leq p$, it follows that, if there exists a simple homotopy sequence \mathcal{S} with p expansions that come at the beginning, then there exists a simple homotopy sequence $\mathcal{S}_{\mathbb{M}}$ with p expansions in the beginning followed by q collapses that gives rise to a 2-complex K' with $O(n^3)$ faces. The faces can be as many as $O(n^3)$ since \mathbb{M} does not guess any 2-collapses. Furthermore, if \mathcal{K} is erasable through the simple homotopy sequence \mathcal{S} , then K' is also erasable, once again, because the 2-collapses of \mathcal{S} can be carried out in the same order in $\mathcal{S}_{\mathbb{M}}$. Hence, the non-deterministic Turing machine \mathbb{M} can now be described as follows:

1. Guess p expansions and q collapses non-deterministically to obtain a complex K' .
2. Deterministically check if K' is erasable.

By Remark 12, erasability of K' can be deterministically checked in time polynomial in n .

Since any simplex in the desired simple homotopy sequence has at most $n + p$ vertices, the number of bits required to encode a single vertex is $O(\log(n + p))$. Also, because the dimension of the faces involved in expansions and collapses is certainly in $O(p)$, and since an expansion or a collapse can be fully described by a pair of simplices, the number of bits required to encode an expansion or a collapse is $O(p \log(n + p))$. Hence, in order to guess $p + q$ moves, it suffices for \mathbb{M} to guess $O(p^2 \cdot \log(n + p))$ bits in total since $q \leq p$. Now, assuming $n, p \geq 2$, we have

$$p^2 \log(n + p) \leq p^2 \log(np) = p^2 \log(n) + p^2 \log(p) \leq p^2(1 + \log(p)) \log(n).$$

Hence, for sufficiently large n and p , the number of bits guessed by \mathbb{M} is bounded by a function of the form $f(p) \log n$. Thus, \mathbb{M} is a p -restricted Turing machine, and ORDERED ERASIBILITY EXPANSION HEIGHT is in $\mathbf{W}[P]$. ◀

► **Theorem 14.** ERASIBILITY EXPANSION HEIGHT is in $\mathbf{W}[P]$.

Proof. Assume that there exists a simple homotopy that takes K to a 1-complex using no more than p expansions. The Turing machine \mathbb{M} needs to generate one such sequence. Below, we show that, in order to achieve this, \mathbb{M} does not have to guess an entire simple homotopy sequence, but only a subsequence, and the remaining part of the sequence can be found deterministically by \mathbb{M} .

Given a 2-dimensional complex K with n faces, \mathbb{M} first nondeterministically guesses p expansions and p collapses, and the order in which they are to be executed. These moves are referred to in the following as *prescribed moves*. While these moves are meant to appear in a specified order, they need not appear consecutively. The moves that are not prescribed are computed deterministically by \mathbb{M} . A simple homotopy sequence of K , that takes K to a 1-complex, in which all the prescribed moves occur as a subsequence, is called a sequence *compatible* with the prescribed moves. By assumption, there exists a set of prescribed moves for which a compatible sequence exists.

13:12 Parametrized Complexity of Expansion Height

In order to give a description of \mathbb{M} , we introduce some additional terminology. Let \mathcal{S}_q^j be an intermediate simple homotopy sequence computed by \mathbb{M} , such that the first j prescribed moves guessed by \mathbb{M} form a subsequence of \mathcal{S}_q^j , q is the total number of moves in \mathcal{S}_q^j , and \mathcal{S}_q^j is a prefix of a set of sequences \mathcal{S} compatible with the prescribed set of moves. Let $K \frown_{\searrow} K_q^j$ be the complex obtained by executing the moves in \mathcal{S}_q^j . Then, a collapse \searrow_{σ}^{τ} in K_q^j is *valid* for this prefix if appending the collapse still leaves a compatible prefix. That is, \mathcal{S}_q^j appended with the collapse \searrow_{σ}^{τ} (giving \mathcal{S}_{q+1}^j) continues to be a prefix of at least one compatible sequence $\mathcal{S} \in \mathcal{S}$. A collapse that is not valid is said to be *forbidden*.

Note that labelling vertices of a complex C by natural numbers determines a lexicographic order on the simplices of C . The lexicographic order $<_C$ on simplices of C can be extended to a lexicographic order \prec on collapses as follows: If $(\searrow_{\sigma}^{\tau}), (\searrow_{\alpha}^{\beta})$ are two collapses in C , then $(\searrow_{\sigma}^{\tau}) \prec (\searrow_{\alpha}^{\beta})$ if $\sigma <_C \alpha$.

The Turing machine \mathbb{M} for deciding ERASIBILITY EXPANSION HEIGHT can be described as follows:

1. Guess $2p$ prescribed moves non-deterministically.
2. Execute 2-collapses in lexicographic order until no more 2-collapses are valid.
3. Repeat until all prescribed moves have been executed:
 - a. Execute the next prescribed move.
 - b. Execute 2-collapses in lexicographic order until no more collapses are valid.

Let \mathcal{S} be a sequence compatible with an ordered set of prescribed moves X (of cardinality $2p$), and let $\mathcal{S}_{\mathbb{M}}$ be a simple homotopy sequence computed by \mathbb{M} as above such that X is a subsequence of $\mathcal{S}_{\mathbb{M}}$. Now, let σ be a free edge associated with a 2-collapse \searrow_{σ}^{τ} in \mathcal{S}_q^j for some j and q , where \mathcal{S}_q^j is a subsequence of $\mathcal{S}_{\mathbb{M}}$. If there exist future prescribed moves including cofaces of σ , then the next prescribed move including cofaces of σ that is not an expansion involving σ is denoted by m_1 . Similarly, if there exist future prescribed moves including cofaces of τ , then the next prescribed move including cofaces of τ that is not an expansion involving τ is denoted by m_2 . Note that m_2 cannot come before m_1 but we may have $m_1 = m_2$. Then, the 2-collapse \searrow_{σ}^{τ} is forbidden if and only if m_1 exists and is not preceded by a future prescribed expansion involving σ or m_2 exists, and is not preceded by a future prescribed expansion involving τ . It follows that, for each free edge, checking if a collapse is forbidden (or valid) can be done deterministically in time polynomial in p . To see this note that the most expensive atomic operation is to check if a simplex (of dimension 1 or 2) is a face of a simplex that is at most p dimensional, and the number of prescribed moves is at most $2p$. Altogether, the set of valid collapses can be computed in time polynomial in n and p , which can also be lexicographically ordered in polynomial time.

Finally, let K' denote the complex obtained from K by the sequence $\mathcal{S}_{\mathbb{M}}$. Then, the following claim establishes the effectiveness of the greedy strategy employed by \mathbb{M} .

▷ **Claim 15.** If there exists a simple homotopy sequence with at most p expansions that takes K to a 1-complex, then there exists an execution branch of the Turing machine that terminates successfully, i.e., the complex K' obtained by \mathbb{M} is a 1-complex.

Proof. Let \mathcal{S} be a simple homotopy sequence with p expansions that takes K to a 1-complex. Let X_e be the ordered set of expansions in \mathcal{S} . Thus, $|X_e| = p$. Moreover, let X_e^+ (X_e^-) denote the d -expansions (d -collapses) in \mathcal{S} with $d > 2$. As in Theorem 13, by a simple inductive argument starting from the highest dimension it can be shown that $|X_c^+| = |X_e^+|$. To the p expansions of \mathcal{S} , we associate a set X_c of collapses of \mathcal{S} as follows: If $|X_c^+| < p$, then let X_c^- be an arbitrary set of d -collapses in \mathcal{S} with $d \leq 2$, and $|X_c^-| = p - |X_c^+|$. Now, let $X_c = X_c^+ \cup X_c^-$, so that $|X_c| = p$. Finally, let the ordered set X of prescribed moves be the set containing all elements of $X_c \cup X_e$ seen as a subsequence of \mathcal{S} .

We assume that the non-deterministic Turing machine \mathbb{M} correctly guesses the specified sequence of prescribed moves X . It now suffices to show the following claim about the sequence $\mathcal{S}_{\mathbb{M}}$. \triangleleft

\triangleright **Claim 16.** $\mathcal{S}_{\mathbb{M}}$ is compatible with the prescribed moves X , and $\mathcal{S}_{\mathbb{M}}$ takes K to a 1-complex if \mathcal{S} takes K to a 1-complex.

Proof. Let $K \searrow_{\mathcal{S}} K^j$ denote the complex obtained from \mathcal{S} after executing the j -th prescribed move in \mathcal{S} . We show that there exists a complex $K_{\mathbb{M}}^j$ obtained from $\mathcal{S}_{\mathbb{M}}$ after executing the j -th prescribed move in $\mathcal{S}_{\mathbb{M}}$. Also, let $T^j (T_{\mathbb{M}}^j)$ denote the set of 2-simplices of $K^j (K_{\mathbb{M}}^j)$.

First observe that, $K_{\mathbb{M}}^0 = K$ exists and that $T_{\mathbb{M}}^0 = T^0$. We now show that the following claim is inductively true: $T_{\mathbb{M}}^j \subset T^j$ for all $j \in [1, 2p]$. Suppose we make the induction hypothesis that $T_{\mathbb{M}}^{j-1} \subset T^{j-1}$ for some $j \in [1, 2p]$. Then, the set of forbidden collapses for \mathcal{S} and $\mathcal{S}_{\mathbb{M}}$ are the same until the j -th move in X can be reached. Let τ_1 be the first 2-face of K^{j-1} that is removed as part of a 2-collapse after $j-1$ prescribed moves have been executed in \mathcal{S} . Without loss of generality, assume that the 2-collapse that removes τ_1 is non-prescribed. Then, there exists an edge $\sigma_1 \subset \tau_1$ such that τ_1 is the unique coface of σ_1 in K^{j-1} . By induction hypothesis, since $T_{\mathbb{M}}^{j-1} \subset T^{j-1}$ the same is also true for $K_{\mathbb{M}}^{j-1}$. Since \mathbb{M} greedily removes every valid collapse it can (in lexicographic order), at some appropriate lexicographic index, τ_1 is also removed from $K_{\mathbb{M}}^{j-1}$ (possibly along with σ_1). Now, let $\tau_1, \tau_2, \dots, \tau_{q-1}$ be the first $q-1$ 2-faces removed from K^{j-1} (as part of non-prescribed collapses). Assume that $\tau_1, \tau_2, \dots, \tau_{q-1}$ have also been removed from $K_{\mathbb{M}}^{j-1}$. By the same reasoning as before, if τ_q is the q -th face to be removed from K^{j-1} (as part of non-prescribed collapses), then τ_q may also be removed from $\mathcal{S}_{\mathbb{M}}$ as part of a valid collapse. Hence, by induction, $T_{\mathbb{M}}^j \subset T^j$ for all $j \in [1, 2p]$.

Finally, since by assumption, K^{2p} collapses to a 1-complex, by applying arguments analogous to the induction above, the same is true for $K_{\mathbb{M}}^{2p}$ since $T_{\mathbb{M}}^{2p} \subset T^{2p}$. \triangleleft

Since given a 2-complex with n faces, \mathbb{M} non-deterministically guesses $2p$ moves, as in Theorem 13, the number of bits guessed by \mathbb{M} is bounded by $f(p) \log(n)$, where $f(p) = O(p^2(1 + \log(p)))$. Hence, \mathbb{M} is a p -restricted Turing machine, and ERASIBILITY EXPANSION HEIGHT is in $\mathbf{W[P]}$. \blacktriangleleft

6 NP-completeness of Erasibility 3-Expansion Height

Note that the parametrized reduction from AXIOM SET to ERASIBILITY EXPANSION HEIGHT (and ORDERED ERASIBILITY EXPANSION HEIGHT) is also a polynomial-time reduction (or Karp reduction) from AXIOM SET to ERASIBILITY 3-EXPANSION HEIGHT (and ORDERED ERASIBILITY 3-EXPANSION HEIGHT), since the complexity of reduction is independent of the parameter p and depends only on the size of the input complex. This observation leads us to the following result.

\blacktriangleright **Theorem 17.** *The decision problems ERASIBILITY 3-EXPANSION HEIGHT and ORDERED ERASIBILITY 3-EXPANSION HEIGHT are NP-hard.*

Proof. Since the AXIOM SET problem is known to be NP-hard [9], it follows that ERASIBILITY 3-EXPANSION HEIGHT and ORDERED ERASIBILITY 3-EXPANSION HEIGHT are also NP-hard. \blacktriangleleft

For the rest of the section, we assume that K is a 2-complex K with n faces and m vertices. The total number of simplices that one can encounter in any simple homotopy

13:14 Parametrized Complexity of Expansion Height

sequence of K using only 3-expansions is at most $M = O(m^4)$. (Note that the ground set of K is fixed since we do not allow 1-expansions). Hence, the total number of *elementary moves* that may be available at any given point in the sequence is bounded by $O(M)$. That is, p itself is bounded by $O(M)$.

► **Theorem 18.** ERASIBILITY 3-EXPANSION HEIGHT *is in NP*.

Proof. The non-deterministic algorithm \mathbb{M} for deciding ERASIBILITY 3-EXPANSION HEIGHT first guesses at each point in the simple homotopy sequence starting with K , one elementary move (out of at most $O(M)$ available moves), and constructs a new complex from the move. The total number of moves made by \mathbb{M} is bounded by $\binom{n+2p-1}{2}$. Finally, \mathbb{M} checks if the final complex is a 1-complex. ◀

► **Theorem 19.** ORDERED ERASIBILITY 3-EXPANSION HEIGHT *is in NP*.

Proof. The non-deterministic algorithm \mathbb{M} for deciding ORDERED ERASIBILITY 3-EXPANSION HEIGHT first guesses at most p 3-expansions followed by an equal number of 3-collapses, resulting in a 2-complex K' with n faces. From Remark 12, the erasability of K' can be deterministically checked in time polynomial in n , proving the claim. ◀

Abstract

We study a multi-modal route planning scenario consisting of a public transit network and a transfer graph representing a secondary transportation mode (e.g., walking or taxis). The objective is to compute all journeys that are Pareto-optimal with respect to arrival time and the number of required transfers. While various existing algorithms can efficiently compute optimal journeys in either a pure public transit network or a pure transfer graph, combining the two increases running times significantly. As a result, even walking between stops is typically limited by a maximal duration or distance, or by requiring the transfer graph to be transitively closed. To overcome these shortcomings, we propose a novel preprocessing technique called ULTRA (UnLimited TRAnsfers): Given a complete transfer graph (without any limitations, representing an arbitrary non-schedule-based mode of transportation), we compute a small number of transfer shortcuts that are provably sufficient for computing all Pareto-optimal journeys. We demonstrate the practicality of our approach by showing that these transfer shortcuts can be integrated into a variety of state-of-the-art public transit algorithms, establishing the ULTRA-Query algorithm family. Our extensive experimental evaluation shows that ULTRA is able to improve these algorithms from limited to unlimited transfers without sacrificing query speed, yielding the fastest known algorithms for multi-modal routing. This is true not just for walking, but also for other transfer modes such as cycling or driving.

1 Introduction

Research on efficient route planning algorithms has seen remarkable advances in the past decades. For many types of transportation networks, queries can be solved in a few milliseconds, even on a continental scale [3]. However, combining schedule-based (i.e., public transit) and non-schedule-based (e.g., walking, cycling, driving) transportation modes and solving the resulting multi-modal routing problem is still a challenge [26]. In this work, we consider a multi-modal problem that augments public transit with a *transfer graph*, which represents an arbitrary non-schedule-based mode of transportation that can be used for transferring between public transit stops. Given a source and target vertex in the transfer graph and a departure time, we want to compute all Pareto-optimal journeys regarding travel time and number of used public transit trips.

Related Work. Most algorithms for public transit routing either impose technical restrictions on the included transfers or have only been evaluated on networks featuring very sparse transfer graphs. Algorithms that were only evaluated for limited transfers include the graph-based techniques in [23] and [18], frequency-based search [5], Transfer Patterns [2] and its accelerated version, Scalable Transfer Patterns [4], Public Transit Labeling [11], and SUBITO [9]. A common restriction, employed by CSA [14, 15], RAPTOR [13], and their corresponding speedup techniques ACSA [25, 15] and HypRAPTOR [12], is to require that the transfer graph is transitively closed. This eliminates the need to search within the transfer graph, as every possible destination can be reached with a single edge. To ensure a reasonably sized transfer graph, transfers are typically limited by a maximal duration (e.g., 15 minutes of walking) or distance before the transitive closure is computed. As shown in [26], choosing a higher limit for the maximal transfer duration increases the size of the resulting transitively closed graph significantly. A limit of only 20 minutes on the maximal transfer duration already leads to a graph that is unsuitable for practical applications. A special case is Trip-Based Routing [27], which precomputes transfers between pairs of trips. This precomputation involves enumerating all possible transfers and then using a limited set of pruning rules to omit some, but not all unnecessary transfers. Trip-Based Routing was only evaluated for transitively closed transfer graphs and likely has prohibitively high preprocessing times on unrestricted transfer graphs.

Using a restricted transfer graph is often justified with the argument that long transfers are rarely useful. However, experiments performed in [26, 22] show that unrestricted walking often significantly reduces the travel time of optimal journeys. This effect is likely even stronger for faster transportation modes, such as bicycle or car. The only algorithms that can handle unrestricted transfer graphs so far are multi-modal techniques such as MCR [10] and UCCH [16]. These techniques work by interleaving a public transit routing algorithm with Dijkstra’s algorithm [17] on a contracted transfer network. Accordingly, they are fairly slow compared to pure public transit algorithms. Most recently HLRaptor and HLCSA [22] have been published. Here, RAPTOR/CSA are interleaved with Hub Labeling queries [1] instead of Dijkstra. While requiring more than an hour of preprocessing, this significantly improves query times. However, it is still not as efficient as pure public transit algorithms.

Our Contribution. Preliminary experiments [24] have shown that the impact of unrestricted transfers in Pareto-optimal journeys depends heavily on their position in the journey: *Initial transfers*, which connect the source to the first public transit vehicle, and *final transfers*, connecting the final vehicle to the target, are fairly common and often have a

large impact on the travel time. In contrast, *intermediate transfers* between public transit trips are only occasionally relevant for optimal journeys. This suggests that the number of unique paths in the transfer graph that occur as intermediate transfers of a Pareto-optimal journey is small. Using this insight, we propose a new preprocessing technique called ULTRA (UnLimited TRAnsfers), which computes a set of shortcut edges representing these paths. The preprocessing step is carefully engineered to ensure that the number of shortcuts remains small. Combined with efficient one-to-many searches for the initial and final transfers, these shortcuts are sufficient to answer all queries in the network correctly. ULTRA shortcuts can be used without adjustment by any algorithm that previously required a transitively closed transfer graph. Our experiments show that this enables unrestricted multi-modal queries with roughly the same performance as restricted queries. In particular, ULTRA-CSA is the first efficient multi-modal variant of CSA. Source code for ULTRA and our experiments is available at <https://github.com/kit-algo/ULTRA>.

2 Preliminaries

In this section we establish the basic notation and terminology used in this work. Moreover, we introduce the RAPTOR and Bucket-CH algorithms, on which our work is founded.

Public Transit Network. A public transit network is a 4-tuple $(\mathcal{S}, \mathcal{T}, \mathcal{R}, G)$ consisting of a set of *stops* \mathcal{S} , a set of *trips* \mathcal{T} , a set of *routes* \mathcal{R} , and a directed, weighted *transfer graph* $G = (\mathcal{V}, \mathcal{E})$. Every stop in \mathcal{S} defines a location in the network where passengers can board or disembark a vehicle (such as buses, trains, ferries, etc.). Furthermore, we associate with each stop $v \in \mathcal{S}$ a non-negative *departure buffer time* $\tau_{\text{buf}}(v)$, which defines the minimum amount of time that has to pass after arriving at the stop before a vehicle can be boarded. A trip $T = \langle v_0, \dots, v_k \rangle \in \mathcal{T}$ is a sequence of at least two stops which are served consecutively by the same vehicle. For each stop v in the sequence, $\tau_{\text{arr}}(T, v)$ denotes the *arrival time* of the vehicle at v , and $\tau_{\text{dep}}(T, v)$ denotes its *departure time*. This, of course, implies that $\tau_{\text{arr}}(T, v) \leq \tau_{\text{dep}}(T, v)$ holds for every trip T and stop v . The i -th stop of a trip T is denoted as $T[i]$. The set of routes \mathcal{R} defines a partition of the trips such that two trips are part of the same route if they have the same stop sequence and do not overtake each other. A trip $T_a \in \mathcal{T}$ overtakes the trip $T_b \in \mathcal{T}$ if two stops $u, v \in \mathcal{S}$ exist such that T_a arrives at or departs from u before T_b and T_a arrives at or departs from v after T_b .

The transfer graph $G = (\mathcal{V}, \mathcal{E})$ consists of a set of *vertices* \mathcal{V} with $\mathcal{S} \subseteq \mathcal{V}$, and a set of *edges* $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$. For each edge $e = (u, v) \in \mathcal{E}$ we define the *transfer time* $\tau_\theta(e)$ as the time required to transfer from u to v . The notion of transfer time carries over to paths $P = (v_1, \dots, v_k)$ in G , using the definition $\tau_\theta(P) := \sum_{i=1}^{k-1} (\tau_\theta(v_i, v_{i+1}))$. Unlike in restricted walking scenarios, we require no special properties for the transfer graph G . It does not need to be transitively closed, it may be strongly connected, and transfer times may represent walking, cycling, or some other non-schedule-based mode of travel.

Journeys. A *trip leg* T^{ij} is a subsequence of the trip T , representing a passenger boarding the trip T at the i -th stop and disembarking at the j -th stop. The departure time of T^{ij} is the departure time at the first stop of the trip leg, i.e., $\tau_{\text{dep}}(T^{ij}) := \tau_{\text{dep}}(T, T[i])$. Similarly, the arrival time is defined as $\tau_{\text{arr}}(T^{ij}) := \tau_{\text{arr}}(T, T[j])$. An *intermediate transfer* ϑ between two trip legs T_a^{ij} and T_b^{mn} is a path in the transfer graph such that: (1) the path ϑ begins with the last stop of T_a^{ij} , (2) the path ends with the first stop of T_b^{mn} , and (3) the transfer time of the path is sufficient to reach T_b^{mn} . The transfer time is sufficient if after

vacating T_a^{ij} and transferring to the departure stop of T_b^{mn} , there is still sufficient buffer time to enter T_b^{mn} . We can express this formally as $\tau_{\text{arr}}(T_a^{ij}) + \tau_{\theta}(\vartheta) + \tau_{\text{buf}}(T_b^{mn}[m]) \leq \tau_{\text{dep}}(T_b^{mn})$. An *initial transfer* ϑ before a trip leg T^{ij} is a path in G from the source s to the first stop of T^{ij} . Correspondingly, a *final transfer* ϑ after a trip leg T^{ij} is a path in G from the last stop of T^{ij} to the target t . We use the term *transfer* on its own to denote the union of all transfer types, or if the actual type of the transfer can be deduced from context. We define a *journey* $J = \langle \vartheta_0, T_0^{ij}, \dots, T_{k-1}^{mn}, \vartheta_k \rangle$ as an alternating sequence of transfers and trip legs. Note that some or all of the transfers may be empty. The departure time of the journey is defined as $\tau_{\text{dep}}(J) := \tau_{\text{dep}}(T_0^{ij}) - \tau_{\text{buf}}(T_0[i]) - \tau_{\theta}(\vartheta_0)$ and the arrival time as $\tau_{\text{arr}}(J) := \tau_{\text{arr}}(T_{k-1}^{mn}) + \tau_{\theta}(\vartheta_k)$. The number of trips used by the journey is k . A journey J (weakly) *dominates* a journey J' if $\tau_{\text{dep}}(J) \geq \tau_{\text{dep}}(J')$, $\tau_{\text{arr}}(J) \leq \tau_{\text{arr}}(J')$, and J does not use more trips than J' . For strict domination, at least one criterion must be strictly better. A journey J is called *Pareto-optimal* if no other journey exists that dominates J .

In our journey definition, the departure buffer time at a stop models the time required to reach the right platform and board a trip, regardless of how the stop was reached. Many other works on public transit routing instead use a *minimum transfer time*, which only needs to be observed if the stop was reached directly via a trip instead of a transfer. This is reasonable for settings with direct transfers between stops, where the buffer time can simply be included in the transfer time. When allowing arbitrary transfers, however, it can lead to inconsistencies. For instance, given a stop with minimum transfer time τ , if a path starting and ending at this stop with a transfer time less than τ exists, then taking that path would allow passengers to circumvent the minimum transfer time.

Algorithms. Since our algorithm is strongly influenced by the RAPTOR algorithm family, we now introduce the basic concepts of these algorithms. The RAPTOR [13] algorithm can be used to solve one-to-one and one-to-many queries on a public transit network with limited transfers. The algorithm operates in *rounds*, where the i -th round finds all journeys using exactly i trips. For this, each round extends journeys found in the previous round by one trip, which can be done via a single scan of all routes in the network. An extension of this algorithm for multi-modal scenarios with unlimited transfers is MCR [10]. In this algorithm the RAPTOR rounds are alternated with Dijkstra’s algorithm on a contracted transfer graph, in order to propagate arrival times through the transfer graph. Another extension, rRAPTOR [13], can be used to answer *range queries*, which ask for all Pareto-optimal journeys that depart within a given time interval. The rRAPTOR algorithm operates in *iterations*, where every iteration handles a possible departure time using the basic RAPTOR algorithm. The possible departure times are handled in descending order, and the data structures used by RAPTOR are not cleared in between iterations. As a result, journeys found by the current iteration are implicitly pruned by journeys that depart later and neither arrive later nor have more trips. This property of the rRAPTOR algorithm is called *self-pruning*.

Besides public transit routing algorithms, we also require efficient one-to-many algorithms for the transfer graph. Especially the Bucket-CH [21, 19, 20] algorithm is useful for our purposes. This algorithm is based on Contraction Hierarchies (CH) [19, 20] and operates in three phases. First the CH is computed, requiring only the graph. Second, given the set of targets, a bucket containing distances to the targets is computed for every vertex. This is done by adding every target to the buckets of all vertices in its reverse CH search space. Finally, the distance from a source to all targets is computed by performing the forward part of a CH search. For each vertex v in the forward search space, the bucket is evaluated by combining the distance to v with the distance from v to the targets in the bucket.

3 Shortcut Computation

Our preprocessing technique aims at finding a small number of transfer shortcuts that are sufficient to answer every point-to-point query correctly. This is achieved if for every Pareto-optimal journey there exists a journey with the same departure time, arrival time, and number of trips that uses only the precomputed shortcuts to transfer between trips. Next, we present a high-level overview of the ULTRA preprocessing, followed by an in-depth description of important algorithmic details.

3.1 Overview

The basic idea of ULTRA is as follows. We enumerate all possible journeys that use exactly two trips and require neither an initial nor a final transfer. The transfers between the two trips of these journeys are then considered as *candidates* for shortcuts. For each of these *candidate journeys*, we check if there is another journey that dominates it. If this is the case, we can replace the candidate journey with the dominating journey without losing Pareto-optimality. Note that if the candidate journey is contained in a longer journey, then it still can be replaced without affecting the Pareto-optimality of the longer journey. We call such a dominating journey a *witness* since its existence proves that the candidate shortcut is not needed. Unlike the candidate journey, the witness journey can make use of the transfer graph before the first trip or after the second trip. If no witness is found, then the candidate shortcut is added to the resulting shortcut graph.

A naive implementation of this idea would be to first enumerate all candidate journeys and subsequently search for witnesses. However, this would be impractical due to the sheer number of possible journeys. We therefore propose to interweave the candidate enumeration and the witness search, with the goal of eliminating as many candidates as early as possible. Pseudocode for the result of these considerations is given by Algorithm 1. The algorithm resembles invoking rRAPTOR [13] once per stop, restricted to the first two rounds per iteration. Remember that the original rRAPTOR algorithm already answers one-to-all range queries. Restricting this algorithm to the first two rounds enables an efficient enumeration of candidate journeys. Moreover, many dominated candidates are eliminated early on, due to self-pruning. We will now continue with a detailed discussion of Algorithm 1, showing step by step what has changed in comparison to the original rRAPTOR and how this helps with computing the transfer shortcuts.

3.2 Implementation Details

A first important difference is due to the fact that rRAPTOR requires a transitively closed transfer graph. As we want to allow arbitrary transfer graphs, we replace the RAPTOR that is invoked in every iteration of rRAPTOR with MR- ∞ , the variant of MCR that optimizes arrival time and number of used trips. Because of this change, the relaxation of transfers in lines 8 and 11 is not done by relaxing outgoing edges of updated stops. Instead, Dijkstra's algorithm is performed in order to propagate arrival times found by the preceding route scanning step. Furthermore, MCR would also use Dijkstra's algorithm in order to collect all routes reachable from the source stop in line 6. In the context of rRAPTOR this leads to many redundant computations, as the source stop does not change between iterations. We therefore compute distances from the source stop to all other stops once in line 3, again using Dijkstra's algorithm. These distances can then be used in line 6.

■ **Algorithm 1** ULTRA transfer shortcut computation.

Input: Public transit network $(\mathcal{S}, \mathcal{T}, \mathcal{R}, G)$, with unrestricted transfer graph $G = (\mathcal{V}, \mathcal{E})$
Output: Shortcut graph $G' = (\mathcal{S}, \mathcal{E}')$

```

1 for each  $s \in \mathcal{S}$  do
2   Clear all arrival labels and Dijkstra queues
3    $d(s, *) \leftarrow$  Compute distances from  $s$  to all stops in  $G$  using Dijkstra
4    $D \leftarrow$  Collect departure times of trips at  $s$ 
5   for each  $\tau_{dep} \in D$  in descending order do // rRAPTOR iteration
6     Collect routes reachable from  $s$  at  $\tau_{dep}$  // first RAPTOR round
7     Scan routes
8     Relax transfers
9     Collect routes serving updated stops // second RAPTOR round
10    Scan routes
11     $C \leftarrow$  Relax transfers, thereby collecting unwitnessed candidates
12     $\mathcal{E}' \leftarrow \mathcal{E}' \cup C$ 

```

Departure Time Collection. In line 4, standard rRAPTOR would collect all departure events that are reachable from the source stop s . However, given a transfer graph without any restrictions, this could possibly be every departure event in the network. Since we are primarily interested in finding candidate journeys, which do not have initial transfers, we collect only those departure events which depart directly at the source stop s . However, in order to find witness journeys, we still need to explore initial transfers in line 6. A naive implementation would check for each stop v reachable from s and for each route containing the stop v whether a trip that was not scanned in a previous iteration can be reached given the departure time τ_{dep} at s .

A more efficient approach combines lines 4 and 6 into a single operation. For this, we first sort all departure triplets (v, τ_{dep}, r) of departure stop v , departure time τ_{dep} , and route r by their corresponding departure time at the source, $\tau_{dep} - \tau_{buf}(v) - d(s, v)$. Afterwards, we iterate through this sorted list in descending order of departure time. If the next triplet to be processed has a departure stop $v \neq s$, then its route is added to a set \mathcal{R}' . In the case that the next triplet actually has the source stop s as departure stop v , we proceed with lines 6 through 12. Now the routes that have to be collected in line 6 are exactly the routes in \mathcal{R}' . Thus we simply scan all routes in \mathcal{R}' and then reset $\mathcal{R}' = \emptyset$ for the next iteration.

Limited Transfer Relaxation. Another part of ULTRA that differs from rRAPTOR is the final relaxation of transfers in line 11. This is the part of the algorithm where we actually determine the candidate journeys for which have not found a witness. As usual, relaxing the transfers is done by Dijkstra's algorithm, initialized with the arrival times from the preceding route scanning step. Whenever a stop is settled during this execution of Dijkstra's algorithm, we look at the corresponding journey and check whether it is a candidate journey, i.e., does not require initial or final transfers. If so, we know that there is no witness journey dominating this candidate, because otherwise the search would have reached the stop via this witness journey instead. Thus, we extract the intermediate transfer of the found candidate journey and add it as an edge to the shortcut graph.

We further increase the practical performance of our algorithm by adding a stopping criterion to the final transfer relaxation in line 11. For this purpose, we count the number of stops which were newly reached via a candidate journey in the preceding route scanning

step. Whenever such a stop is settled in line 11, we decrease our counter. Once the counter reaches zero, we can stop settling further vertices as we know that no more candidates can be found in this iteration. We can apply a similar stopping criterion to the intermediate transfer relaxation in line 8. In this case, we count the stops which were reached via a route directly from s , without an initial transfer, since only these stops can later become part of a candidate journey. As in line 11, we can stop settling vertices as soon as no such stops are left in the Dijkstra queue. This does not affect the correctness of the algorithm, as we still process all candidates. However, it might cause some witnesses to be pruned and thus lead to superfluous shortcuts in the result. To counteract this, we take the arrival time τ_{arr} of the last stop representing a candidate that is settled. Instead of stopping the transfer relaxation immediately, we continue until the queue head has an arrival time greater than $\tau_{\text{arr}} + \bar{\tau}$ for some parameter $\bar{\tau}$ (which we call *witness limit*). With these changes, the only remaining part of the algorithm that performs an unlimited search on the transfer graph is the initial transfer relaxation in line 3, which is only done once per source stop.

The success of our pruning rule for the transfer relaxation in lines 8 and 11 depends on the presence of candidate journeys in the Dijkstra queues. Fewer candidate journeys could therefore lead to an earlier application of the pruning rule. We exploit this by further restricting the notion of candidate journeys. As before, a candidate journey must not contain any initial or final transfers. In addition, we now require that the intermediate transfer of a candidate journey is not contained in the set of already computed transfer shortcuts.

Cyclic Witnessing. Since witnesses are only required to dominate candidate journeys weakly, there may be journeys J, J' that dominate each other. If J has an initial transfer of length > 0 , then J without the initial transfer is not dominated by J' extended by the reverse initial transfer. Therefore, the shortcut required by J will be added. Thus, cyclic domination is only problematic between journeys with initial transfers of length 0. We prevent this by temporarily contracting groups of stops with transfer distance 0 during the preprocessing.

Transfer Graph Contraction. As shown for MCR [10], the transfer relaxation is often the bottleneck of multi-modal routing algorithms. Since ULTRA only needs to compute journeys between stops, rather than arbitrary vertices of the transfer graph, only transfers that start and end at stops are relevant. Therefore, any overlay graph that preserves the distances between all stops can be used instead of the transfer graph in our preprocessing algorithm. An easy way of obtaining such an overlay graph is to construct a partial CH that only contracts vertices that do not correspond to stops of the public transit network. This, of course, leads to a suboptimal contraction order and thus makes it infeasible to contract all vertices that are not stops. As done in many other algorithms [6, 16, 10, 8, 7], we therefore stop the contraction once the uncontracted *core* graph surpasses a certain average vertex degree.

Parallelization. Finally, we observe that ULTRA allows for trivial parallelization. Our algorithm searches for candidate journeys once for every possible source stop (line 1 of Algorithm 1). As these searches are mostly independent of each other, we can distribute them to parallel threads and combine the results in a final sequential step. Only the usage of the restricted candidate notion introduces a dependence between the searches for different source stops. As this is only a heuristic performance optimization, we simply relax the notion of candidate journeys again, only requiring that no shortcut representing the intermediate transfer has been found by the same thread yet.

■ **Algorithm 2** Query algorithm, using transfer shortcuts computed by ULTRA.

Input: Public transit network $(\mathcal{S}, \mathcal{T}, \mathcal{R}, G)$, shortcut graph $G' = (\mathcal{S}, \mathcal{E})$,
 Bucket-CH of G , source vertex s , departure time τ_{dep} , and target vertex t

Output: All Pareto-optimal journeys from s to t for departure time τ_{dep}

- 1 $d(s, *) \leftarrow$ Run Bucket-CH query from s
- 2 $d(*, t) \leftarrow$ Run reverse Bucket-CH query from t
- 3 $G'' \leftarrow G'$
- 4 **for each** $v \in \mathcal{S}$ **do**
- 5 Add edge (s, v) to G'' with travel time $d(s, v)$
- 6 Add edge (v, t) to G'' with travel time $d(v, t)$
- 7 Run black box public transit algorithm on $(\mathcal{S} \cup \{s, t\}, \mathcal{T}, \mathcal{R}, G'')$

3.3 Proof of Correctness

Before continuing with the query algorithms, we want to justify that ULTRA computes a shortcut graph that is sufficient to answer all queries correctly. For contradiction we assume that a journey $J = \langle \vartheta_0, T_0^{ij}, \dots, T_{k-1}^{mn}, \vartheta_k \rangle$ exists that requires an intermediate transfer not contained in the shortcut graph and cannot be replaced with a journey of equal travel time and number of trips that solely uses transfers from the shortcut graph. In this case, the journey J must contain at least two trips, since otherwise it would not contain any intermediate transfers. Since the journey contains two or more trips, it can be disassembled into candidate journeys $\langle T_0^{ij}, \vartheta_1, T_1^{gh} \rangle, \langle T_1^{gh}, \vartheta_2, T_2^{pq} \rangle, \dots, \langle T_{k-2}^{uv}, \vartheta_{k-1}, T_{k-1}^{mn} \rangle$. As J requires a transfer not contained in the shortcut graph, at least one of these candidates must also contain a transfer not contained in the shortcut graph. Let $J^c = \langle T_x^{gh}, \vartheta_{x+1}, T_{x+1}^{pq} \rangle$ be such a candidate journey. Since the main loop of ULTRA is executed for every stop in the network, it was also executed for the source stop $T_x[g]$ of this candidate journey. Derived from the correctness of rRAPTOR, we know that for a given source stop our algorithm computes Pareto-optimal arrival labels for all stops reachable with two trips or less. Thus we also reached the target stop $T_{x+1}[q]$ of the candidate journey. The journey J' corresponding to the target's arrival label is in this case either the candidate journey or a journey that dominates the candidate journey. In the first case, we have added the transfer ϑ_{x+1} of the candidate journey to the shortcut graph. In the second case, the candidate journey J^c can be replaced by the journey J' corresponding to the target's arrival label, leading to a journey that is not worse than the original journey and does not require the missing transfer. Therefore both cases contradict our assumption.

4 Query Algorithms

The shortcuts obtained by ULTRA can in principle be combined with any public transit query algorithm that normally requires a transitively closed transfer graph, such as RAPTOR [13], CSA [14, 15], or Trip-Based Routing [27]. The basic idea of the query algorithm is to simply use one of the above algorithms together with our precomputed shortcut graph instead of the original transfer graph. However, our shortcut graph only represents transfers between two trips, and does not provide any information for transferring from the source to the first trip or from the last trip to the target. In this section we describe how the public transit algorithms can be modified in order to handle initial and final transfers efficiently.

Basic Query Algorithm. Our approach is based on the observation that for initial and final transfers one endpoint of the transfer is fixed. All initial transfers start at the source vertex, and all final transfers end at the target vertex. Therefore, we can use two additional one-to-many queries (one of them performed in reverse) to cover initial and final transfers. These queries have to be performed on the original transfer graph, where they compute the distances from the source to all stops and from all stops to the target. While any one-to-many algorithm might be used to perform this task, we decided to use Bucket-CH, as it is one of the fastest known one-to-many algorithms and allows for optimization of local queries. Pseudocode for the resulting query algorithm using Bucket-CH and our transfer shortcuts is shown in Algorithm 2.

Our algorithm begins with performing the two Bucket-CH queries from the source and target stop in lines 1 and 2. Afterwards a temporary copy of the shortcut graph G'' is initialized. In lines 5 and 6, this temporary graph is complemented with edges from the source to all other stops and edges from all stops to the target, using the distances obtained from the Bucket-CH queries. Finally, a public transit algorithm is invoked as a black box on the public transit network with the temporary graph instead of the shortcut graph in line 7. The temporary graph is sufficient for the query to yield correct results, as it contains edges from the source to any possible first stop, all edges required to transfer between trips, and edges from any possible last stop to the target. Since there are no additional requirements on the black box public transit algorithm, it is easy to see that any existing public transit algorithm can be used with our shortcuts.

Running Time Optimizations. We can further improve the performance of this query algorithm in practice by introducing some adjustments. First, we observe that we actually do not need edges from the source to every other stop. If the distance $d(s, v)$ from s to a stop v is greater than the distance $d(s, t)$ from s to t , every journey that requires a transfer from s to v is dominated by simply transferring directly from s to t . Thus, we do not need to add the edge (s, v) to the temporary graph. The same argument can be made for edges from some stop u to the target t if the distance $d(u, t)$ is greater than $d(s, t)$. Moreover, if we know that a stop v is further away from the source than the target, then we do not even need to compute the actual distance $d(s, v)$. We can use this fact to prune the search space of the Bucket-CH queries in lines 1 and 2. For this purpose, we first perform a standard bidirectional CH query from source to target that stops settling vertices from the forward (respectively backward) queue if the corresponding key is greater than the tentative distance from the source to the target. As a result we obtain the distance $d(s, t)$, as well as the partial forward (backward) CH search space from s (t), containing no vertices that have a greater distance from s (to t) than $d(s, t)$. We then perform the second phase of the Bucket-CH query (i.e., scanning the buckets) only for the vertices in the partial search spaces of the CH query. Furthermore, we store the entries in each bucket sorted by the distance to their target. Thus we can stop scanning through the bucket of a vertex u once we reach a stop v within the bucket with $d(s, u) + d(u, v) \geq d(s, t)$. Doing so can drastically improve local queries, as we do not need to look at all stops, but only at stops that are close to the source or target.

If we do not treat the underlying public transit algorithm as a black box, we can further improve practical performance by omitting the construction of the temporary graph G'' . Instead of adding edges from s to stops v , we can directly initialize the tentative arrival times used by most public transit algorithms with $\tau_{\text{dep}} + d(s, v)$. Instead of adding edges to t , we try to update the tentative arrival time at the target with the arrival time at v plus $d(v, t)$ whenever the arrival time at v is updated.

■ **Table 1** Sizes of the used public transit networks and their transfer graphs (full and transitive).

Network	Stops	Routes	Trips	Stop events	Vertices	Full edges	Tran. edges
Switzerland	25 426	13 934	369 534	4 740 929	604 167	1 847 140	4 687 016
Germany	244 055	231 089	2 387 297	48 495 169	6 872 105	21 372 360	22 645 480

5 Experiments

All algorithms were implemented in C++17 compiled with GCC version 7.3.1 and optimization flag `-O3`. All experiments were conducted on a machine with two 8-core Intel Xeon Skylake SP Gold 6144 CPUs clocked at 3.5 GHz, 192 GiB of DDR4-2666 RAM, and 24.75 MiB of L3 cache. The shortcut preprocessing was performed in parallel on all 16 cores. The transfer graph contraction and the queries were performed on a single core.

Networks. We evaluated our technique on the public transit networks of Switzerland and Germany, which were previously used in [26]. The Switzerland network was extracted from a publicly available GTFS feed¹ and consists of two successive business days (30th and 31st of May 2017). The Germany network is based on data from `bahn.de` for Winter 2011/2012, comprising two successive identical days. For both networks, stops and connections outside of the country borders were removed. As unrestricted transfer graphs, we used the road networks of Switzerland and Germany, including pedestrian zones and stairs, which were obtained from OpenStreetMap² data. Vertices with degree one and two were contracted unless they coincided with stops. Unless stated otherwise, we used walking as the transfer mode, assuming a walking speed of 4.5 km/h on each edge. To obtain transitively closed transfer graphs (for comparison with standard RAPTOR and CSA), we inserted an edge between all stops for which the distance in the transfer graph lies below a certain threshold (15 minutes for Switzerland, 8 minutes for Germany) and then computed the transitive closure. An overview of the networks is given in Table 1.

5.1 Preprocessing

In this section we evaluate the performance of the ULTRA preprocessing phase, including the transfer graph contraction and the shortcut computation.

Core Degree and Witness Limit. The two main parameters influencing the performance of the ULTRA preprocessing are the average vertex degree of the contracted transfer graph and the witness limit $\bar{\tau}$. Figure 1 shows the impact of these two parameters on the Switzerland network. The lowest preprocessing times are achieved with a core degree of 14. While the actual shortcut computation still becomes slightly faster for higher core degrees, this is offset by the increased time required to contract the transfer graph. Contracting up to a core degree of 14 took 1:29 minutes and yielded a graph with 32 683 vertices and 466 331 edges. By contrast, the witness limit $\bar{\tau}$ only has a minor impact on the number of computed shortcuts, with a difference of fewer than 600 shortcuts between $\bar{\tau} = 0$ and $\bar{\tau} = \infty$. For all following experiments, we chose a witness limit of 15 minutes, yielding 139 669 shortcuts for Switzerland.

¹ <http://gtfs.geops.ch/>

² <http://download.geofabrik.de/>

■ **Figure 1** Impact of core degree and witness limit on the running time of the preprocessing algorithm and the number of computed shortcuts, measured on the Switzerland network. Preprocessing time includes both contracting the transfer graph and computing the shortcuts.

For the Germany network, we chose to contract up to a core degree of 20, since the share of the core computation in the overall preprocessing time decreases as the network size increases. Contraction took 24:56 minutes and produced a core graph with 314 021 vertices and 6 280 440 edges. As before, we used a witness limit of 15 minutes for the shortcut computation, which yielded 2 077 374 shortcuts.

Parallelization. We used all 16 cores of our machine in parallel to accelerate the shortcut computation. On the Switzerland network this reduced the shortcut computation time from 2:02:55 hours sequentially to 9:35 minutes, which corresponds to a speedup of 12.8. Thus, we obtain a total preprocessing time of 11:05 minutes, including the time for the contraction, which was not parallelized. This yields an overall speedup for the preprocessing phase of 11.2. For the Germany network the sequential shortcut computation would take several days, while computing the shortcuts in parallel using all 16 cores took 10:53:35 hours.

Transfer Speed. In order to test the impact of the used transfer mode on the shortcut computation, we changed the transfer speed in the Switzerland network from 4.5 km/h to different values between 1 km/h and 140 km/h. We considered two ways of applying the transfer speed: In the first version, we did not allow the transfer speed on an edge to exceed the speed limit given in the road network. This allowed us to model fast transfer modes such as cars fairly realistically. In the second version, we ignored speed limits and assumed a constant speed on every edge. Thus, we can analyze to which extend the effects observed in the first version are caused by the speed limit data. Figure 2 (left side) reports the number of computed shortcuts measured for each configuration. In all measurements, the preprocessing time remained below 15 minutes. A peak in the number of shortcuts is reached between 10 and 20 km/h, which roughly corresponds to the speed of a bicycle. If speed limits are ignored, the number of shortcuts then starts decreasing again for higher transfer speeds and reaches a plateau at around 188 000 shortcuts. If speed limits are obeyed, the number of shortcuts eventually rises again and reaches the overall peak at 140 km/h, which was the highest speed limit observed in the network.

■ **Figure 2** Impact of transfer speed, measured on the Switzerland network with a core degree of 14 and a witness limit of 15 minutes. *Left:* Number of computed shortcuts. Speed limits in the network were obeyed for the red lines and ignored for the green lines. For the two lines at the bottom, shortcuts were only added to the result if the source and target stop for which they were found were connected by a path in the transfer graph. *Right:* Query performance of MR- ∞ and ULTRA-RAPTOR, averaged over 10 000 random queries. Speed limits were obeyed. Query times are divided into route collecting/scanning, transfer relaxation, and remaining time.

For low to medium transfer speeds, the results conformed with our expectations. As the transfer speed increases, it becomes increasingly feasible to cover large distances in the transfer graph quickly, making it possible to transfer between trips that are further away from each other. Accordingly, new shortcuts appear between these trips. However, once the transfer speed becomes competitive with the public transit vehicles, we would expect the number of shortcuts to decrease sharply as it eventually becomes preferable to avoid the public transit network altogether and transfer directly from source to target. The reason why this decrease is not observed in our measurements is that not all stops in our network instances are connected to the transfer graph. Consider what happens in the shortcut computation for journeys between stops s and t that are isolated from each other and the rest of the transfer graph. In this case, a direct transfer is not possible, regardless of the transfer speed. In fact, unless there is a route that serves both s and t , any optimal journey from s to t will include at least two trips. If a transfer is necessary between these two trips, then the journey is a nondominated candidate journey and a shortcut is added for the corresponding transfer. In our Switzerland network, 625 stops are isolated from the transfer graph, usually as a result of incomplete or imperfect data. To assess the impact of these stops on the number of computed shortcuts, we repeated our experiments, this time not adding shortcuts to the result if the source and target stop of the corresponding candidate journey were not connected in the transfer graph. This resulted in much fewer shortcuts, especially for high transfer speeds. If speed limits are ignored, the amount of necessary shortcuts becomes negligible at around 60 km/h and eventually reaches 0. If speed limits are obeyed, the number of shortcuts stagnates at 17 000.

Overall, these experiments show that our shortcut computation remains feasible regardless of the speed of the used transfer mode. Moreover, if the network does not include many stops that are isolated from the transfer graph, transferring between stops is most useful for transfer speeds between 10 and 20 km/h.

■ **Table 2** Query performance for RAPTOR, MR- ∞ , and ULTRA-RAPTOR. Query times are divided into phases: initial transfers, collecting routes, scanning routes, and relaxing transfers. All results are averaged over 10 000 random queries. RAPTOR (marked with *) only supports stop-to-stop queries with transitive transfers, instead of vertex-to-vertex queries on the full graph.

Network	Algorithm	Full graph	Scans [k]		Time [ms]				
			Routes	Edges	Init.	Collect	Scan	Relax	Total
Switzerland	RAPTOR*	○	27.2	3 527	0.0	3.7	6.4	7.8	18.4
	MR- ∞	●	34.9	769	11.6	5.9	8.2	12.3	39.3
	ULTRA-RAPTOR	●	37.7	148	1.6	4.9	7.9	1.9	16.7
Germany	RAPTOR*	○	480.4	25 798	0.0	166.9	178.0	85.1	436.5
	MR- ∞	●	555.8	12 571	191.1	250.7	202.2	272.2	944.1
	ULTRA-RAPTOR	●	610.6	2 224	26.8	204.5	202.9	37.0	477.8

5.2 ULTRA Queries

To evaluate the impact of our shortcuts on the query performance, we tested them with two public transit algorithms, RAPTOR and CSA. For each algorithm, we compared three query variants: one using our ULTRA approach, one using a transitively closed transfer graph, and one using a multi-modal variant of the algorithm on an unrestricted transfer graph.

RAPTOR Queries. In the case of RAPTOR, we used the MR- ∞ variant of MCR as the multi-modal algorithm, employing the same core graph that was used by the ULTRA pre-processing. The results of our comparison are shown in Table 2. Using ULTRA-RAPTOR drastically reduces the time consumption for exploring the transfer graph compared to MR- ∞ , from 50–60% of the overall running time to 10–20%. The reason for this is that both scanning the initial/final transfers and relaxing the intermediate transfers are an order of magnitude faster in ULTRA-RAPTOR compared to MR- ∞ . For the initial and final transfers, the Core-CH search of MR- ∞ is replaced by a Bucket-CH query in ULTRA-RAPTOR. Similarly, ULTRA-RAPTOR uses shortcuts for relaxing the intermediate transfers whereas MR- ∞ performs a Dijkstra search in the core graph. Overall, ULTRA-RAPTOR is twice as fast as MR- ∞ and has a similar running time to RAPTOR with transitive transfers. Note that comparing the running times of RAPTOR and ULTRA-RAPTOR has to be done with caution, as they were measured for a different set of queries. Hence, our shortcut technique enables RAPTOR to use unrestricted transfers without incurring the performance loss that is associated with MCR.

CSA Queries. For CSA, incorporating unrestricted transfers efficiently is more challenging. Since no multi-modal variant of CSA has been published thus far, we implemented a naive multi-modal version of CSA, which we call MCSA, as a baseline for our comparison. This algorithm alternates connection scans with Dijkstra searches on the contracted core graph, in a similar manner to MCR. Query times for all three CSA variants are reported in Table 3. Note that CSA solves an easier problem than RAPTOR, since it only minimizes the arrival time and not the number of transfers. When using a transitive transfer graph, it is thus approximately three times as fast as RAPTOR. With unrestricted transfers, we observe that MCSA is slower than MR- ∞ . This is because alternating between connection scans and Dijkstra searches causes MCSA to lose the main performance advantage of CSA,

■ **Table 3** Query performance for CSA, MCSA, and ULTRA-CSA. Query times are divided into two phases: initialization including initial transfers (Init.), and connection scans including intermediate transfers (Scan). All results are averaged over 10 000 random queries. CSA (marked with *) only supports stop-to-stop queries with transitive transfers, instead of vertex-to-vertex queries on the full graph.

Network	Algorithm	Full graph	Scans [k]		Time [ms]		
			Connections	Edges	Init.	Scan	Total
Switzerland	CSA*	○	126.7	1 307	0.2	5.0	5.1
	MCSA	●	88.0	5 337	12.9	48.4	61.3
	ULTRA-CSA	●	87.3	52	1.8	3.1	4.9
Germany	CSA*	○	2 620.3	6 216	2.9	162.1	165.1
	MCSA	●	1 568.2	118 026	233.6	1462.5	1696.1
	ULTRA-CSA	●	1 562.5	665	25.7	116.8	142.5

which is its high memory locality. When using ULTRA-CSA, however, this advantage is restored because only a few shortcut edges have to be relaxed after scanning each connection. Overall, ULTRA-CSA is only slightly slower than transitive CSA and about three times as fast as RAPTOR with shortcuts, making it the only efficient multi-modal variant of CSA known so far. Moreover, our query times for ULTRA-RAPTOR and ULTRA-CSA are significantly faster than those reported for the state-of-the-art techniques HLraptor and HLCSA [22], by a factor of 3.6 and 11.1, respectively. With respect to preprocessing time and space consumption, HL-based techniques are also outperformed by ULTRA.

In addition to overall performance, we also measured how query times for RAPTOR are impacted by the transfer speed. Results are shown in Figure 2 (right side). The performance gains for ULTRA-RAPTOR compared to MR- ∞ are similar for all transfer speeds, and in fact slightly better for higher speeds. In all cases, the entire query time for ULTRA-RAPTOR is similar to or lower than the time that MR- ∞ takes for the route scanning phases only.

6 Conclusion

We developed a technique which significantly speeds up the computation of Pareto-optimal journeys in a public transit network with an unrestricted transfer graph. We achieved this by efficiently computing shortcuts that provably represent all necessary transfers. Parallelization enables fast precomputation, taking a few minutes on the network of Switzerland. Our evaluation showed that the number of computed shortcuts is low, regardless of the underlying transfer mode. The shortcuts can be used without adjustments by any public transit algorithm that previously required a transitively closed transfer graph. For RAPTOR and CSA, we showed that using shortcuts leads to similar query times as using a transitively closed transfer graph. Consequently, shortcuts enable the computation of unrestricted multi-modal journeys without incurring the performance losses of existing multi-modal algorithms. In particular, combining shortcuts with CSA yields the first efficient multi-modal variant of CSA.

For future work, we would like to develop a shortcut-based query algorithm that can answer many-to-many queries. It would also be interesting to adapt our shortcut precomputation to scenarios with additional Pareto criteria, such as walking distance or cost. Furthermore, it should be possible to extend the ULTRA approach to more complicated transfer modes, including bike or car sharing.

Abstract

A valid *edge-coloring* of a graph is an assignment of “colors” to its edges such that no two incident edges receive the same color. The goal is to find a proper coloring that uses few colors. (Note that the maximum degree, Δ , is a trivial lower bound.) In this paper, we revisit this fundamental problem in two models of computation specific to massive graphs, the *Massively Parallel Computations* (MPC) model and the *Graph Streaming* model:

Massively Parallel Computation. We give a randomized MPC algorithm that with high probability returns a $\Delta + \tilde{O}(\Delta^{3/4})$ edge coloring in $O(1)$ rounds using $O(n)$ space per machine and $O(m)$ total space. The space per machine can also be further improved to $n^{1-\Omega(1)}$ if $\Delta = n^{\Omega(1)}$. Our algorithm improves upon a previous result of Harvey et al. [SPAA 2018].

Graph Streaming. Since the output of edge-coloring is as large as its input, we consider a standard variant of the streaming model where the output is also reported in a streaming fashion. The main challenge is that the algorithm cannot “remember” all the reported edge colors, yet has to output a proper edge coloring using few colors.

We give a one-pass $\tilde{O}(n)$ -space streaming algorithm that always returns a valid coloring and uses 5.44Δ colors with high probability if the edges arrive in a random order. For adversarial order streams, we give another one-pass $\tilde{O}(n)$ -space algorithm that requires $O(\Delta^2)$ colors.

1 Introduction

Given a graph $G(V, E)$, an edge coloring of G is an assignment of “colors” to the edges in E such that no two incident edges receive the same color. The goal is to find an edge coloring that uses few colors. Edge coloring is among the most fundamental graph problems and has been studied in various models of computation, especially in distributed and parallel settings.

Denoting the maximum degree in the graph by Δ , it is easy to see that Δ colors are necessary in any proper edge coloring. On the other hand, Vizing’s celebrated theorem asserts that $\Delta + 1$ colors are always sufficient [39]. While determining whether a graph can be Δ colored is NP-hard, a $\Delta + 1$ coloring can be found in polynomial time [5, 21]. These algorithms are, however, highly sequential. As a result, in restricted settings, it is standard to consider more relaxed variants of the problem where more colors are allowed [2, 8, 20, 24, 25, 27, 29, 32, 34, 35, 36].

In this paper, we study edge coloring in large-scale graph settings. Specifically, we focus on the *Massively Parallel Computations* (MPC) model and the *Graph Streaming* model.

1.1 Massively Parallel Computation

The Model. The MPC model [10, 26, 31] is a popular abstraction of modern parallel frameworks such as MapReduce, Hadoop, Spark, etc. In this model, there are N machines, each with a space of S words¹ that all run in parallel. The input, which in our case is the edge-set of graph $G(V, E)$, is initially distributed among the machines arbitrarily. Afterwards, the system proceeds in synchronous rounds wherein the machines can perform any arbitrary local computation on their data and can also send messages to other machines. The messages are then delivered at the start of the next round so long as the total messages sent and received by each machine is $O(S)$ for local machine space S . The main parameters of interest are S and the round-complexity of the algorithm, i.e., the number of rounds it takes until the algorithm stops. Furthermore, the total available space over all machines should ideally be linear in the input size, i.e., $S \cdot N = O(|E|)$.

Related Work in MPC. We have seen a plethora of results on graph problems ever since the formalization of MPC. The studied problems include matching and vertex cover [1, 6, 14, 17, 22, 33, 12, 15], maximal independent set [22, 28, 12, 15], vertex coloring [7, 16, 28, 37, 38], as well as graph connectivity and related problems [3, 4, 13, 30, 9]. (This is by no means a complete list of the prior works.)

We have a good understanding of the complexity of vertex coloring in the MPC model, especially if the local space is near linear in n : Assadi et al. [7] gave a remarkable algorithm that using $\tilde{O}(n)$ space per machine, finds a $(\Delta + 1)$ vertex coloring in a constant number of rounds. The algorithm is based on a sparsification idea that reduces the number of edges from m to $O(n \log^2 n)$. But this algorithm alone cannot be used for coloring the edges, even if we consider the more relaxed $(2\Delta - 1)$ edge coloring problem which is equivalent to $(\Delta + 1)$ vertex coloring on the line graph. The reason is that the line-graph has $O(m)$ vertices where here m is the number of edges in the original graph. Therefore even after the sparsification step, we have $\tilde{O}(m)$ vertices in the graph which is much larger than the local space available in the machines.

¹ Throughout the paper, the stated space bounds are in the number of words that each denotes $O(\log n)$ bits.

Not much work has been done on the edge coloring problem in the MPC model. The only exception is the algorithm of Harvey et al. [28] which roughly works by random partitioning the *edges*, and then coloring each partition in a different machine using a sequential $(\Delta + 1)$ edge coloring algorithm. The choice of the number of partitions leads to a trade-off between the number of colors used and the space per machine required. The main shortcoming of this idea, however, is that if one desires a $\Delta + \tilde{O}(\Delta^{1-\Omega(1)})$ edge coloring, then a strongly super linear local space of $n\Delta^{\Omega(1)}$ is required.

Our main MPC result is the following algorithm which uses a more efficient partitioning. The key difference is that we use a *vertex* partitioning as opposed to the algorithm of Harvey et al. which partitions the edges.

► **Result 1** (Theorem 1). *There exists an MPC algorithm that using $O(n)$ space per machine and $O(m)$ total space, returns a $\Delta + \tilde{O}(\Delta^{3/4})$ edge coloring in $O(1)$ rounds.*

The algorithm exhibits a tradeoff between the space and the number of colors (see Theorem 1) and can be made more space-efficient as the maximum degree gets larger. For instance, if $\Delta > n^\epsilon$ for any constant $\epsilon > 0$, it requires a strictly sublinear space of $n^{1-\Omega(1)}$ to return a $\Delta + o(\Delta)$ edge coloring in $O(1)$ rounds. This is somewhat surprising since all previous non-trivial algorithms in the strictly sublinear regime of MPC require $\omega(1)$ rounds.

Our algorithm can also be implemented in $O(1)$ rounds of *Congested Clique*, leading to a $\Delta + \tilde{O}(\Delta^{3/4})$ edge coloring there. Prior to our work, no sublogarithmic round Congested Clique algorithm was known even for $(2\Delta - 1)$ edge coloring.

1.2 Streaming

The Model. In the standard graph streaming model, the edges of a graph arrive one by one and the algorithm has a space that is much smaller than the total number of edges. A particularly important choice of space is $\tilde{O}(n)$ – which is also known as the *semi-streaming* model [19] – so that the algorithm has enough space to store the vertices but not the edges. For edge coloring, the output is as large as the input, thus, we cannot hope to be able to store the output and report it in bulk at the end. For this, we consider a standard twist on the streaming model where the output is also reported in a streaming fashion. This model is referred to in the literature as the “W-streaming” model [18, 23]. We particularly focus on one-pass algorithms.

Designing one-pass W-streaming algorithms is particularly challenging since the algorithm cannot “remember” all the choices made so far (e.g., the reported edge colors). Therefore, even the sequential greedy algorithm for $(2\Delta - 1)$ edge coloring, which iterates over the edges in an arbitrary order and assigns an available color to each color upon visiting it, cannot be implemented since we are not aware of the colors used incident to an edge.

Our first result is to show that a natural algorithm w.h.p.² provides an $O(\Delta)$ edge coloring if the edges arrive in a random-order.

► **Result 2** (Theorem 9). *If the edges arrive in a random-order, there is a one-pass $\tilde{O}(n)$ space W-streaming edge coloring algorithm that always returns a valid edge coloring and w.h.p. uses $(2e + o(1))\Delta \approx 5.44\Delta$ colors.*

² Throughout, we use “w.h.p.” to abbreviate “with high probability” implying probability at least $1 - 1/\text{poly}(n)$.

15:4 Streaming and Massively Parallel Algorithms for Edge Coloring

If the edges arrive in an arbitrary order, we give another algorithm that requires more colors.

► **Result 3** (Theorem 10). *For any arbitrary arrival of edges, there is a one-pass $\tilde{O}(n)$ space W -streaming edge coloring algorithm that succeeds w.h.p. and uses $O(\Delta^2)$ colors.*

These are, to our knowledge, the first streaming algorithms for edge coloring.

2 The MPC Algorithm

In this section, we consider the edge coloring problem in the MPC model. Our main result in this section is an algorithm that achieves the following:

► **Theorem 1.** *For any parameter k (possibly dependent on Δ) such that $n/k \gg \log n$, there exists an MPC algorithm with $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ space per machine and $O(m)$ total space that w.h.p. returns a $\Delta + O(\sqrt{k\Delta \log n})$ edge coloring in $O(1)$ rounds.*

By setting $k = \sqrt{\Delta} + \log n$, the space required per machine will be $O(n)$ and the number of colors would be $\Delta + \tilde{O}(\Delta^{3/4})$. Using a reduction from [11], this also leads to an $O(1)$ round Congested Clique algorithm using the same number of colors.

► **Corollary 2.** *There exists a randomized MPC algorithm with $O(n)$ local space, as well as a Congested Clique algorithm, that both w.h.p. find a $\Delta + \tilde{O}(\Delta^{3/4})$ edge coloring in $O(1)$ rounds.*

Moreover, assuming that $\Delta = n^{\Omega(1)}$, by setting $k = \Delta^{0.5+\epsilon}$ for a small enough constant $\epsilon \in (0, 1)$, we get the following $O(1)$ round algorithm which requires $n^{1-\Omega(1)}$ machine space, which is notably strictly sublinear in n :

► **Corollary 3.** *If $\Delta = n^{\Omega(1)}$, there exists a randomized MPC algorithm with $O(n/\Delta^{2\epsilon}) = n^{1-\Omega(1)}$ space per machine and $O(m)$ total space that w.h.p. returns a $\Delta + \tilde{O}(\Delta^{0.75+\epsilon/2})$ edge coloring in $O(1)$ rounds.*

The Idea Behind the Algorithm. The first step in the algorithm is a random partitioning of the *vertex set* into k groups, V_1, \dots, V_k . We then introduce one subgraph for each vertex subset, called G_1, \dots, G_k , and one subgraph for every pair of groups which we denote as $G_{1,2}, \dots, G_{1,k}, \dots, G_{k-1,k}$. Any such G_i is simply the induced subgraph of G on V_i . Moreover, any such $G_{i,j}$ is the subgraph on vertices $V_i \cup V_j$, with edges with one point in V_i and the other in V_j .

The general idea is to assign different *palettes*, i.e., subsets of colors, to different subgraphs so that the palettes assigned to any two neighboring subgraphs (i.e., those that share a vertex) are completely disjoint. A key insight to prevent this from blowing up the number of colors, is that since any two edges from $G_{i,j}$ and $G_{i',j'}$ with $i \neq i'$ and $j \neq j'$ cannot share endpoints by definition, it is safe to use the same color palette for them.

To assign these color palettes, we consider a complete k -vertex graph with each vertex v_i in it corresponding to partition V_i and each edge (v_i, v_j) in it corresponding to the subgraph $G_{i,j}$. We then find a k edge coloring of this complete graph, which exists by Vizing's theorem since maximum degree in it is $k - 1$. This edge coloring can actually be constructed extremely efficiently using merely the edges' endpoint IDs. Thereafter, we map each of these k colors to a color palette. By carefully choosing k and the number of colors in each palette, we ensure that: (1) The total number of colors required is close to Δ . (2) Each subgraph $G_{i,j}$ can be

properly edge-colored with those colors in its palette. (3) Each subgraph fits the memory of a single machine so that we can put it in whole there and run the sequential edge coloring algorithm on it.

■ **Algorithm 1** An MPC algorithm for edge coloring.

Parameter: k ;

Output: An edge coloring of a given graph $G = (V, E)$ with maximum degree Δ using $\Psi := \Delta + d\sqrt{k\Delta \log n}$ colors for some large enough constant d .

Independently and u.a.r. partition V into k subsets V_1, \dots, V_k ;

For every $i \in [k]$, let G_i be the induced subgraph of G on V_i ;

For every $i, j \in [k]$ with $i \neq j$, let $G_{i,j}$ be the subgraph of G including an edge $e \in E$ iff one end-point of e is in V_i and the other is in V_j ;

Partition $[\Psi]$ into $k+1$ disjoint subsets C_1, \dots, C_k, C' , which we call *color palettes*, in an arbitrarily way such that each palette has exactly $\frac{\Psi}{k+1}$ colors;

for each graph G_i *in parallel* **do**

| Color G_i sequentially in a single machine with palette C' ;

end

// In what follows, we implicitly construct a k edge coloring of a complete k -vertex graph K_k and assign palette C_α to subgraph $G_{i,j}$ where α is the color of edge (i, j) in K_k .

for each graph $G_{i,j}$ *in parallel* **do**

| Color $G_{i,j}$ sequentially in a machine with palette C_α where

$\alpha = ((i + j) \bmod k) + 1$;

end

The algorithm outlined above is formalized as Algorithm 1. We start by proving certain bounds on subgraphs' size and degrees.

▷ **Claim 4.** W.h.p., every subgraph of type G_i or $G_{i,j}$ has maximum degree $\frac{\Delta}{k} + O(\sqrt{\Delta \log \frac{n}{k}})$ and has at most $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ edges.

Proof. Let us start with bounding the degree of an arbitrary vertex $v \in V_i$ in subgraph G_i . The degree of vertex v in G_i is precisely the number of its neighbors that are assigned to partition V_i . Since there are k partitions, the expected degree of v in G_i is $\deg_G(v)/k \leq \Delta/k$. Furthermore, since the assignment of vertices to the partitions is done independently and uniformly at random, by a simple application of Chernoff bound, v 's degree in G_i should be highly concentrated around its mean. Namely, with probability at least $1 - n^{-2}$, it holds that $\deg_{G_i}(v) \leq \frac{\Delta}{k} + O(\sqrt{\Delta \log n/k})$. Now, a union bound over the n vertices in the graph, proves that the degree of all vertices in their partitions should be at most $\frac{\Delta}{k} + O(\sqrt{\Delta \log n/k})$ with probability $1 - 1/n$.

Bounding vertex degrees in subgraphs of type $G_{i,j}$ also follows from essentially the same argument. The only difference is that we have to union bound over $n \cdot k$ choices, as we would like to bound the degree of any vertex v with say $v \in V_i$ in k subgraphs $G_{i,1}, \dots, G_{i,k}$. Nonetheless, since $k \leq n$, there are still $\text{poly}(n)$ many choices to union bound over. Thus, by changing the constants in the lower terms of the concentration bound, we can achieve the same high probability result.

Finally, we focus on the number of edges in each of the subgraphs. Each partition V_i has n/k vertices in expectation since the n vertices are partitioned into k groups independently and uniformly at random. A simple application of Chernoff and union bounds, implies that the number of vertices in each partition V_i is at most $O(\frac{n}{k})$ w.h.p., so long as $n/k \gg \log n$,

15:6 Streaming and Massively Parallel Algorithms for Edge Coloring

which is the case. Since the number of edges in each partition is less than the number of vertices times max degree, combined with the aforementioned bounds on the max degree, we can bound the number of edges in G_i and $G_{i,j}$ for any i and j by

$$O\left(\frac{n}{k}\right) \cdot O\left(\frac{\Delta}{k} + \sqrt{\frac{\Delta}{k} \log n}\right) = O\left(\frac{n\Delta}{k^2} + \frac{n}{k} \sqrt{\frac{\Delta}{k} \log n}\right),$$

which is the claimed bound. \triangleleft

Next, observe that we use palettes C_1, \dots, C_{k+1}, C' , each of size $\frac{\Psi}{k+1}$ to color the subgraphs. We need to argue that the maximum degree in each subgraph is at most $\frac{\Psi}{k+1} - 1$ to be able to argue that using Vizing's theorem in one machine, we can color any of the subgraphs with the assigned palettes. This can indeed be easily guaranteed if the constant d is large enough:

► **Observation 5.** *If constant d in Algorithm 1 is large enough, then maximum degree of every graph is at most $\frac{\Psi}{k+1} - 1$, w.h.p.*

Proof. We have $\Psi = \Delta + d\sqrt{k\Delta \log n}$ in Algorithm 1, therefore:

$$\frac{\Psi}{k+1} = \frac{\Delta}{k+1} + \frac{d\sqrt{k\Delta \log n}}{k+1} = \frac{\Delta}{k} + \Theta(\sqrt{\Delta \log n/k}),$$

where the hidden constants in the second term of the last equation can be made arbitrarily large depending on the choice of constant d . On the other hand, recall from Claim 4 that the maximum degree in any of the subgraphs is also at most $\frac{\Delta}{k} + O(\sqrt{\Delta \log n/k})$. Thus, the palette sizes are sufficient to color the subgraphs if d is a large enough constant. \blacktriangleleft

We are now ready to prove the algorithm's correctness.

► **Lemma 6.** *Algorithm 1 returns a proper edge coloring of G using $\Delta + O(\sqrt{k\Delta \log n})$ colors.*

Proof. The algorithm clearly uses $\Psi = \Delta + O(\sqrt{k\Delta \log n})$ colors, it remains to argue that the returned edge coloring is proper. Each subgraph (of type G_i or $G_{i,j}$) is sent to a single machine and edge-colored there using the palette that it is assigned to. Since by Observation 5, each palette has at least $\Delta' + 1$ colors for Δ' being the max degree in the subgraphs, there will be no conflicts in the colors associated to the edges within a partition. We only need to argue that two edges e and f sharing a vertex v that belong to two different subgraphs are not assigned the same color. Note that all subgraphs of type G_i are vertex disjoint and all receive the special color palette C' , thus there cannot be any conflict there. To complete the proof, it suffices to prove that any two subgraphs $G_{i,j}$ and $G_{i',j'}$ that share a vertex receive different palettes. Note that in this case, either $i = i'$ or $j = j'$ by the partitioning. Assume w.l.o.g. that $i = i'$ and thus $j \neq j'$. Based on Algorithm 1 for $G_{i,j}$ and $G_{i',j'}$ to be assigned the same color palette, it should hold that

$$((i+j) \bmod k) + 1 = ((i'+j') \bmod k) + 1.$$

Since $i = i'$, this would imply that $(j \bmod k) = (j' \bmod k)$, though this would not be possible given that both j and j' are in $[k]$ and that $j \neq j'$. Therefore, any two subgraphs that share a vertex receive different palettes and thus there cannot be any conflicts, completing the proof. \blacktriangleleft

Next, we turn to prove the space bounds.

► **Lemma 7** (Implementation and Space Complexity). *Algorithm 1 can be implemented with total space $O(m)$ and space per machine of $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ w.h.p.*

Proof. We start with an implementation that uses the specified space per machine but can be wasteful in terms of the total space, then describe how we can overcome this problem and also achieve an optimal total space of $O(m)$.

We can use $k + \binom{k}{2}$ machines, each with a space of size $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ to assign colors to the edges in parallel. The first m_1, \dots, m_k machines will be used for edge coloring on G_1, G_2, \dots, G_k respectively. The other $m_{k+1}, \dots, m_{k+\binom{k}{2}}$ machines will be used for edge coloring on the $G_{i,j}$ graphs. Lemma 4 already guarantees that each subgraph has size $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ w.h.p., and thus fits the memory of a single machine.

In the implementation discussed above, since the machines use $\tilde{O}(n\Delta/k^2)$ space and there are $O(k^2)$ machines, the total memory can be $\tilde{O}(n\Delta)$ which may be much larger than $O(m)$. This is because we allocate $O(n\Delta/k^2)$ space to each machine regardless of how much data it actually received. Though, observe that each edge of the graph belongs to exactly one of the subgraphs, i.e., the machines together only handle a total of $O(m)$ data. So we must consolidate into fewer machines. We do this by putting multiple subgraphs in each machine.

We start by recalling a sorting primitive in the MPC model which was proved in [26]. Basically, if there are N items to be sorted and the space per machine is $N^{\Omega(1)}$, then the algorithm of [26] sorts these items into the machines within $O(1)$ rounds. To use this primitive, we first label each edge $e = (u, v)$ of the graph by its subgraph name (e.g. G_i or $G_{i,j}$) which can be determined solely based on the end-points of the edge. After that, we sort the edges based on these labels. This way, all the edges inside each subgraph can be sent to the same machine within $O(1)$ rounds while also ensuring that the total required space remains $O(m)$. ◀

The algorithm for Theorem 1 was formalized as Algorithm 1. We showed in Lemma 6 that the algorithm correctly finds an edge coloring of the graph with the claimed number of colors. We also showed in Lemma 7 that the algorithm can be implemented with $O(m)$ total space and $O(\frac{n\Delta}{k^2} + \frac{n}{k}\sqrt{\Delta \log n/k})$ space per machine. This completes the proof of Theorem 1.

3 Streaming Algorithms

We start in Section 3.1 by describing our streaming algorithm and its analysis when the arrival order is random. Then in Section 3.2, we give another algorithm for adversarial order streams.

3.1 Random Edge Arrival Setting

In this section, we give a streaming algorithm for $O(\Delta)$ edge coloring using $\tilde{O}(n)$ space where the edges come in a random stream. That is, a permutation over the edges is chosen uniformly at random and then the edges arrive according to this permutation.

We first note that if $\Delta = O(\log n)$ then the problem is trivial as we can store the whole graph and then report a $\Delta + 1$ edge coloring (even without knowledge of Δ). As such, we assume $\Delta = \omega(\log n)$.

The algorithm – formalized as Algorithm 2 – maintains a counter c_v for each vertex v . At any point during the algorithm, this counter c_v basically denotes the highest color number used for the edges incident to v so far, plus 1. Therefore, upon arrival of an edge (u, v) , it is safe to color this edge with $\max(c_u, c_v)$ as all edges incident to u and v have a color that is

strictly smaller than this. Then, we increase the counters of both v and u to $\max(c_u, c_v) + 1$. It is not hard to see that the solution is always a valid coloring, in the remainder of this section, we mainly focus on the number of colors required by this algorithm and show that w.h.p., it is only $O(\Delta)$ for random arrivals.

■ **Algorithm 2** Edge coloring for random streams.

Result: A feasible coloring $\mathcal{C} : E \rightarrow [\Psi]$ for a given graph $G = (V, E)$ with maximum degree Δ in a random stream

$c_v \leftarrow 0 \quad \forall v \in V;$

while (u, v) is read from stream **do**

$\mathcal{C}(u, v) \leftarrow \max(c_u, c_v);$

$c_u, c_v \leftarrow \mathcal{C}(u, v) + 1;$

end

We start by noting that this algorithm can actually be extremely bad if the order is adversarial. To see this, consider a path of size n . In an adversarial stream where the edges arrive in the order of the path, Algorithm 2 uses as many as $n - 1$ colors while the maximum degree is only 2! It is easy to see why this example is very unlikely to occur in random order streams: For a fixed path, it is very unlikely that the edges are randomly ordered in this very specific way.

To make this intuition rigorous for general graphs, we first prove the following crucial lemma which gives us the correct parameter to bound.

► **Lemma 8.** *Let Ψ be the size of the longest monotone (in the order of arrival) path in the line-graph of G . Then Algorithm 2 uses exactly Ψ colors.*

Proof. Take a monotone path v_1, v_2, \dots, v_Ψ in the line-graph of G and let e_1, e_2, \dots, e_Ψ be the edges of the original graph that correspond to these vertices respectively, i.e., e_1 arrives before e_2 which arrives before e_3 and so on. Since for any i , v_i and v_{i+1} are neighbors in the line-graph, then e_i and e_{i+1} should share an end-point v . This means that at the time of arrival of e_{i+1} , we have $c_v \geq \mathcal{C}(e_i) + 1$ which in turn, implies $\mathcal{C}(e_\Psi) > \mathcal{C}(e_{\Psi-1}) > \dots > \mathcal{C}(e_1)$. Therefore, $\mathcal{C}(e_\Psi) \geq \Psi$.

On the other hand, suppose that there is an edge $e_1 = (u, v)$ for which $\mathcal{C}(e_1) = \Psi$ in Algorithm 2. This means that at least one of c_u or c_v equals Ψ when e_1 arrives, say c_u w.l.o.g. Let e_2 be the last edge incident to u that has arrived before e_1 . It should hold that $\mathcal{C}(e_2) = \Psi - 1$. Using the same argument, for each $1 < i \leq \Psi$, we can find a neighboring edge e_i such that $\mathcal{C}(e_i) = \mathcal{C}(e_{i-1}) - 1$. This way, we end up with a sequence e_1, \dots, e_Ψ of edges, the path corresponding to this sequence in the line graph will be a monotone path of length Ψ , completing the proof. ◀

► **Theorem 9.** *There is a streaming edge coloring algorithm that for any graph $G = (V, E)$ uses at most $(2e + \epsilon)\Delta \approx 5.44\Delta$ colors w.h.p. for any constant $\epsilon > 0$ given that the edges in E arrive in a random order.*

Proof. We first prove that Algorithm 2 gives us a feasible coloring of graph G . Consider two edges $e_1 = (u, v)$ and $e_2 = (u, v')$ incident to vertex u such that e_1 appears earlier than e_2 in the stream. For any edge e we represent by $\mathcal{C}(e)$ the color assigned to that by the algorithm. After the algorithm colors e_1 with $\mathcal{C}(e_1)$, it sets c_u to $\mathcal{C}(e_1) + 1$. Thus, c_u is at least $\mathcal{C}(e_1) + 1$ when e_2 arrives and $\mathcal{C}(e_2) \geq \mathcal{C}(e_1) + 1$ consequently. Therefore, $\mathcal{C}(e_2) > \mathcal{C}(e_1)$ for any pair of edges incident to a common vertex, and \mathcal{C} is a feasible coloring.

Next, for some constant α that we fix later, we show that the probability that an edge is assigned a color number at least $\alpha\Delta$ is at most n^{-c} for some constant $c \geq 2$, implying via a union bound over all the edges that indeed w.h.p., $\Psi \leq \alpha\Delta$.

We showed in Lemma 8 that if the number of colors Ψ used is $\alpha\Delta$, then there should exist a monotone path in the line-graph with size at least $\alpha\Delta$. Let $e_0, e_2, \dots, e_{\alpha\Delta}$ be the corresponding edges to this path. Thus, it suffices to bound the probability of this event. Let Π denote the set of all such paths in the line graph. For a specific path $\pi \in \Pi$, the probability that it is monotone is $1/(\alpha\Delta)!$. Call this event X_π . On the other hand, we can upper bound the number of such paths by $(2\Delta)^{\alpha\Delta}$, i.e., $|\Pi| \leq (2\Delta)^{\alpha\Delta}$. This follows from the fact that each path should start from the corresponding vertex to e_0 in the line-graph, and that maximum degree in the line graph is $2\Delta - 2$ (which is the upper bound on the number of neighboring edges to each edge). Thus:

$$\Pr[\mathcal{C}(e_0) \geq \alpha\Delta] = \Pr\left[\bigvee_{\pi \in \Pi} X_\pi\right] \leq \sum_{\pi \in \Pi} \Pr[X_\pi = 1] \leq \frac{(2\Delta)^{\alpha\Delta}}{(\alpha\Delta)!},$$

where the last inequality is obtained by replacing $\Pr[X_\pi = 1]$ and $|\Pi|$ by the aforementioned bounds. Taking the logarithm of each side of the inequality, we get

$$\begin{aligned} \ln(\Pr[\mathcal{C}(e_0) \geq \alpha\Delta]) &\leq \alpha\Delta \ln(2\Delta) - \ln((\alpha\Delta)!) \\ &\leq \alpha\Delta \ln(2\Delta) - ((\alpha\Delta + 1/2) \ln(\alpha\Delta) - \alpha\Delta) & (1) \\ &= \alpha\Delta \ln(2e/\alpha) - 1/2 \ln(\alpha\Delta) & (2) \\ &\leq \alpha\Delta \ln(2e/\alpha). & (3) \end{aligned}$$

To obtain (1), we use Stirling's approximation of factorials to lower-bound $\ln((\alpha\Delta)!)$. Finally, we rearranged terms to imply (2). By plugging in $\alpha = 2e(1 + \epsilon)$, we get

$$\begin{aligned} \ln(\Pr[\mathcal{C}(e_0) \geq 2e(1 + \epsilon)\Delta]) &\leq 2e(1 + \epsilon)\Delta \ln\left(\frac{1}{1 + \epsilon}\right) \\ &= -2e(1 + \epsilon) \ln(1 + \epsilon)\Delta \\ &\leq -2e(1 + \epsilon) \ln(1 + \epsilon) \frac{c}{2e(1 + \epsilon) \ln(1 + \epsilon)} \ln(n) & (4) \\ &= -c \ln(n) \end{aligned}$$

Since $\Delta = \omega(\log(n))$, we have $\Delta > c' \ln(n)$ for any constant c' . Inequality (4) follows from setting $c' = c/(2e(1 + \epsilon) \ln(1 + \epsilon))$ in $\Delta > c' \ln(n)$, where c is the constant for which we want to show the probability is upper-bounded by n^{-c} . Hence,

$$\Pr[\mathcal{C}(e_0) \geq 2e(1 + \epsilon)\Delta] \leq n^{-c}.$$

Thus, Algorithm 2 returns a feasible coloring of the input graph G using at most $2e(1 + \epsilon)\Delta$ colors, for any constant $\epsilon > 0$ w.h.p. if the edges arrive in a random order. \blacktriangleleft

To further evaluate the performance of Algorithm 2, we implemented and ran it for cliques of different size. The result of this experiment is provided in Table 1. The numbers are obtained by running the experiment 100 times and taking the average number of colors used. As it can be observed from Table 1, for cliques of size 100 to 1000, the number of colors used by the algorithm is in range $[3.3\Delta, 3.9\Delta]$ and it slightly increases by the size of the graph. Our analysis, however, shows that it should never exceed 5.44Δ .

15:10 Streaming and Massively Parallel Algorithms for Edge Coloring

■ **Table 1** The number of colors used by Algorithm 2 on cliques averaged over 100 trials.

Clique Size	100	200	300	400	500	600	700	800	900	1000
Colors Used	3.363 Δ	3.563 Δ	3.665 Δ	3.717 Δ	3.756 Δ	3.787 Δ	3.815 Δ	3.838 Δ	3.849 Δ	3.863 Δ

3.2 Adversarial Edge Arrival Setting

In this section, we turn to arbitrary (i.e., adversarial) arrivals of the edges. We assume that the adversary is *oblivious*, i.e., the order of the edges is determined before the algorithm starts to operate so that the adversary cannot abuse the random bits used by the algorithm. Having this assumption, we give a randomized algorithm that w.h.p., outputs a valid edge coloring of the graph using $O(\Delta^2)$ colors while using $\tilde{O}(n)$ space. The algorithm is formalized as Algorithm 3. We note that this algorithm, as stated, requires knowledge of Δ . However we later show that we can get rid of this assumption. Overall, we get the following result:

■ **Algorithm 3** Edge coloring in the adversarial order.

Result: A feasible coloring for a given graph $G = (V, E)$ with maximum degree Δ

```

for any vertex  $v \in V$  do
   $r_v \leftarrow$  a sequence of  $\log(n)$  independent random bits.
  for any  $i \in [\log n]$  do
     $c_{v,i} \leftarrow 0$ 
  end
end
for any edge  $e = (u, v)$  in the stream do
  Let  $i$  be the smallest index for which  $r_{v,i} \neq r_{u,i}$ .
  if  $\Delta 2^{-i} > \log n$  then
    if  $r_{u,i} = 1$  then
      Assign color  $(c_{u,i}, c_{v,i}, i)$  to  $e$ .
    else
      Assign color  $(c_{v,i}, c_{u,i}, i)$  to  $e$ .
    end
    Increase both  $c_{v,i}$  and  $c_{u,i}$  by one.
  else
    Store edge  $e$ .
  end
end
Color the stored edges using a new set of colors.

```

► **Theorem 10.** *Given a graph G with maximum degree Δ , there exists a one pass streaming algorithm, that outputs a valid edge coloring of the G using $O(\Delta^2)$ colors w.h.p., using $\tilde{O}(n)$ memory.*

Consider two vertices v and u and their string of random bits r_v and r_u defined in the algorithm. Let $d_{u,v}$ be the smallest index i where $r_{u,i} \neq r_{v,i}$. Upon arrival of an edge $e = (u, v)$, we first find $i := d_{u,v}$. If $\Delta 2^{-i} > \log n$, we color the edge immediately. Otherwise, we store it. We will show that all the stored edges fit in the memory thus after reading all the stream we can color them with a palette of at most $\Delta + 1$ new colors. In the algorithm, for any vertex v and any $i \in [\log n]$, we define a counter $c_{u,i}$. If $\Delta 2^{-i} > \log n$ for any edge e , then we immediately assign e a color which is represented by a tuple $(c_{u,i}, c_{v,i}, i)$. Then,

we increase counters $c_{u,i}$ and $c_{v,i}$. Note that we say two colors are the same if all three elements of them are equal. We first show that this gives us a valid coloring, which means it does not assign the same color to two edges adjacent to the same vertex. We use proof by contradiction. Assume that our algorithm assigns the same color to edges $e_1 = (u, v_1)$ and $e_2 = (u, v_2)$ adjacent to vertex u . None of them can be from the stored edges since we color them using a new palette. This means that $d_{u,v_1} = d_{u,v_2}$. Let us denote it by i . Without loss of generality, we assume that $r_{u,i} = 1$ and that in the input stream e_1 arrives before e_2 . Note that the first element of the colors (which are tuples) assigned to these edges is the value of counter $c_{u,i}$ when they arrive. However, the algorithm increases $c_{u,i}$ by one after arrival of e_1 thus the colors assigned to e_1 and e_2 cannot be the same.

Now, it suffices to show that the total number of colors used by the algorithm is $O(\Delta^2)$. Given a vertex v , and a number $l \in [\log n]$ let us compute an upper-bound for counter $c_{v,i}$. Let N_v be the set of neighbors of this vertex and let $N_{v,i}$ be the set of neighbors like u where $d_{v,u} = i$. We know that $c_{v,i} = |N_{v,i}|$, thus given any vertex v and $i \in [\log(n)]$, we need to find a bound for $|N_{v,i}|$. Given any edge $e = (v, u)$ the probability of e being in set $N_{v,i}$ is 2^{-i} which means $\mathbb{E}[|N_{v,i}|] = \deg(v)2^{-i}$ where $\deg(v)$ is the degree of vertex v in the input graph.

Using a simple application of the Chernoff bound, for any vertex v , we get:

$$\Pr\left[|N_{v,i}| \geq \deg(v)2^{-i} + O(\sqrt{\deg(v)2^{-i} \log n})\right] \leq \frac{1}{n^c}.$$

Setting c to be a large enough constant, one can use union bound and show that w.h.p., for any vertex v and $i \in [\log n]$ where $\deg(v)2^{-i} \geq \log n$, we have $|N_{v,i}| \leq O(\deg(v)2^{-i})$.

Having this, we conclude that for any $i \in [\log n]$, where $\Delta 2^{-i} > \log n$, the number of colors used by the algorithm whose third element is i is at most $O(\Delta^2 2^{-2i})$ since the first and the second element of the color can get at most $O(\Delta 2^{-i})$ different values. Therefore, the total number of colors used for any such i is at most $O(\sum_{i \in [\log n]} \Delta^2 2^{-2i}) = O(\Delta^2)$. We will also show that the stored edges fit in the memory and thus we can color them using $O(\Delta)$ new colors. As a result the total number of colors used is $O(\Delta^2)$.

To give an upper-bound for the number of stored edges we first show that the expected number of stored edges for each vertex is $O(\log n)$. Let $j := \log(\frac{\Delta}{\log n})$. Recall that we store an edge (u, v) when $\Delta 2^{-d_{u,v}} < \log n$. Thus the expected number of stored edges adjacent to a single vertex v is at most

$$\sum_{j \leq i \leq \log n} d_v 2^{-i} \leq \sum_{j \leq i \leq \log n} \Delta 2^{-i} \leq \sum_{j \leq i \leq \log n} \log(n) 2^{-i+j} = O(\log n).$$

To get the last equation we use the fact that $\Delta 2^{-j} \leq \log n$. By a similar argument that we used above (using Chernoff and Union bounds), with a high probability the total number of stored edges is $O(n \log n)$ which can be stored in the memory. Therefore the proof of this theorem is completed.

Knowledge of Δ . As written, our algorithm depends on the knowledge of Δ because we must check $\Delta 2^{-i} > \log n$. We can get rid of this condition by keeping track of the degree \deg_v^H of a vertex in the subgraph H we have seen so far, and then computing the max degree \deg_{max}^H . This only requires an additional $O(n)$ space. Thereafter, instead of checking if $\Delta 2^{-i} > \log n$, we check if $\deg_{max}^H 2^{-i} > \log n$. Whenever \deg_{max}^H increases, we iterate over all stored edges and recompute whether or not $\deg_{max}^H 2^{-i} > \log n$. If so, we color the edge and remove it from the buffer, else we keep it. It is easy to see that this will not exceed the space bounds because at any timestep, we can assume the input graph was H in the first

place. Then its max degree is $\Delta_H = \deg_{\max}^H$, and we can apply the same argument for the space bounds as before, but using Δ_H instead of Δ . All other parts of the proof still hold. Therefore our algorithm does not require knowledge of Δ .

Finally, we remark that if one allows more space, then one can modify Algorithm 3 to use fewer number of colors. Though we focused only on the $\tilde{O}(n)$ memory regime.

4 Open Problems

We believe the most notable future direction is to improve the number of colors used in our streaming algorithms. Specifically, our streaming algorithm for adversarial arrivals requires $O(\Delta^2)$ colors. A major open question is whether this can be improved to $O(\Delta)$ while also keeping the memory near-linear in n . Also for random arrival streams, we showed that Algorithm 2 achieves a 5.44Δ coloring and showed, experimentally, that it uses at least 3.86Δ colors. A particularly interesting open question is whether there is an algorithm that uses arbitrarily close to 2Δ colors using $\tilde{O}(n)$ space in random arrival streams.

Quantum Algorithms for Classical Probability Distributions

Abstract

We study quantum algorithms working on classical probability distributions. We formulate four different models for accessing a classical probability distribution on a quantum computer, which are derived from previous work on the topic, and study their mutual relationships.

Additionally, we prove that quantum query complexity of distinguishing two probability distributions is given by their inverse Hellinger distance, which gives a quadratic improvement over classical query complexity for any pair of distributions.

The results are obtained by using the adversary method for state-generating input oracles and for distinguishing probability distributions on input strings.

I am also grateful to Frederic Magniez, Shalev Ben-David, and Anurag Anshu for useful discussions, as well as to anonymous reviewers for their comments. Part of this research was performed while at the Institute for Quantum Computing in Waterloo, Canada. I would like to thank Ashwin Nayak for hospitality.

1 Introduction

It is customary for a quantum algorithm to receive its input and produce its output in the form of a classical string of symbols, quantized in the form of an oracle. This is purely classical way to store information, and, given intrinsic quantum nature of quantum algorithms, this might be not the best interface for many tasks. Moreover, even *classical* algorithms make use of other interfaces as well. For instance, classical algorithms can receive and produce *samples* from some probability distribution. In this paper we study quantum algorithms working with classical probability distributions.

1.1 Models

We analyse previously used models of accessing classical probability distributions by quantum algorithms. We prove and conjecture some relations between them. We give more detail in Section 3, but for now let us very briefly introduce the models.

In one of the models, used in, e.g., [16, 18, 27, 25], the probability distribution is encoded as a frequency of a symbol in a given input string, which the quantum algorithm accesses via the standard input oracle. In another model, e.g., [17, 2, 6], the input probability distribution

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

is given through a quantum oracle that prepares a state in the form $\sum_a \sqrt{p_a}|a\rangle$. Finally, one more model, used in [26, 20, 19], is similar but with additional state tensored with each $|a\rangle$.

This is the latter model that we champion in this paper. We find this model particularly relevant because of our belief that an input oracle should be easily interchangeable with a quantum subroutine, see discussion in [26]. It is relatively easy to see what it means for a quantum algorithm to output a probability distribution: just measure one of the registers of its final state. The latter model precisely encompasses all such subroutines. We conjecture that this model is equivalent to the first model, see also [19], where a similar conjecture is made.

1.2 Distinguishing two Probability Distributions

Additionally, we study the problem of distinguishing two probability distributions. This might be the most fundamental problem one can formulate in these settings. Given two fixed probability distributions p and q , and given an input oracle encoding one of them, the task is to detect which one, p or q , the oracle encodes. To the best of our knowledge, this particular problem has not been studied in quantum settings, although similar problems of testing the distance between two distributions [16] and testing whether the input distribution is equal to some fixed distribution [18] have been already studied.

Classically one needs $\Theta(1/d_H(p, q)^2)$ samples to solve this problem for any p and q , where d_H stands for Hellinger distance. This result is considered “folklore”, see, e.g. [7, Chapter 4]. We prove that for any p and q and for any of the models of access described above, query complexity of this problem is $\Theta(1/d_H(p, q))$. This constitutes quadratic improvement over classical algorithm for *any* pair of distributions p and q . Moreover, our algorithm also admits a simple low-level implementation, which is efficient assuming the distributions p and q can be efficiently processed.

1.3 Techniques

Our main technical tool for proving the upper bound is the version of the adversary bound for state-generating oracles, which is a special case of the adversary bound for general input oracles [11]. It is stated in the form of a relative γ_2 -norm and generalises the dual formulation of the general adversary bound [28, 29] for function evaluation, as well as for other problems [5, 24]. The dual adversary bound has been used rather successfully in construction of quantum algorithms, as in terms of span programs and learning graphs [9, 23, 13, 8, 22], as in an unrelated fashion [10, 4]. Our work gives yet another application of these techniques for construction of quantum algorithms.

Our upper bound naturally follows from the analysis of the γ_2 -norm optimisation problem associated with the task. We also compare our techniques with more standard ones involving quantum rejection sampling and amplitude amplification in the spirit of [20] and show that our techniques give a slightly better result.

As for the lower bound, we make use of the version of the adversary bound from [12]. This is a simple generalisation of the primal version of the general adversary bound [21] for function evaluation, and it is tailored for the task we are interested in: distinguishing two probability distributions on input strings. Our lower bound is surprisingly simple and gives a very intuitive justification of the significance of Hellinger distance for this problem.

2 Preliminaries

We mostly use standard linear-algebraic notation. We use ket-notation for vectors representing quantum states, but generally avoid it. We use A^* to denote conjugate operators (transposed and complex-conjugated matrices). For P a predicate, we use 1_P to denote 1 if P is true, and 0 if P is false. We use $[n]$ to denote the set $\{1, 2, \dots, n\}$.

It is unfortunate that the same piece of notation, \oplus , is used both for direct sum of matrices and direct sum of vectors, which is in conflict with each other if a vector, as it often does, gets interpreted as a column-matrix. Since we will extensively use both these operations in this paper, let us agree that \boxplus denotes direct sum of vectors, and \oplus always denotes direct sum of matrices. Thus, in particular, for $u, v \in \mathbb{R}^m$, we have

$$u \boxplus v = \begin{pmatrix} u_1 \\ \vdots \\ u_m \\ v_1 \\ \vdots \\ v_m \end{pmatrix} \quad \text{and} \quad u \oplus v = \begin{pmatrix} u_1 & 0 \\ \vdots & \vdots \\ u_m & 0 \\ 0 & v_1 \\ \vdots & \vdots \\ 0 & v_m \end{pmatrix}.$$

We often treat scalars as 1×1 -matrices which may be also thought as vectors.

2.1 Relative γ_2 -norm

In this section, we state the relative γ_2 -norm and formulate some of its basic properties. All the results are from [11].

► **Definition 1** (Relative γ_2 -norm). *Let $\mathcal{X}_1, \mathcal{X}_2, \mathcal{Z}_1$ and \mathcal{Z}_2 be vector spaces, and D_1 and D_2 be some sets of labels. Let $A = \{A_{xy}\}$ and $\Delta = \{\Delta_{xy}\}$, where $x \in D_1$ and $y \in D_2$, be two families of linear operators: $A_{xy}: \mathcal{Z}_2 \rightarrow \mathcal{Z}_1$ and $\Delta_{xy}: \mathcal{X}_2 \rightarrow \mathcal{X}_1$. The relative γ_2 -norm,*

$$\gamma_2(A|\Delta) = \gamma_2(A_{xy} \mid \Delta_{xy})_{x \in D_1, y \in D_2},$$

is defined as the optimal value of the following optimisation problem, where Υ_x and Φ_y are linear operators,

$$\text{minimise} \quad \max \left\{ \max_{x \in D_1} \|\Upsilon_x\|^2, \max_{y \in D_2} \|\Phi_y\|^2 \right\} \quad (1a)$$

$$\text{subject to} \quad A_{xy} = \Upsilon_x^*(\Delta_{xy} \otimes I_{\mathcal{W}})\Phi_y \quad \text{for all } x \in D_1 \text{ and } y \in D_2; \quad (1b)$$

$$\mathcal{W} \text{ is a vector space, } \Upsilon_x: \mathcal{Z}_1 \rightarrow \mathcal{X}_1 \otimes \mathcal{W}, \quad \Phi_y: \mathcal{Z}_2 \rightarrow \mathcal{X}_2 \otimes \mathcal{W}. \quad (1c)$$

This is a generalisation of the usual γ_2 -norm, also known as Schur (Hadamard) product operator norm [14].

In a quantum algorithm with general input oracles, the input oracle performs some unitary operation O on some fixed Hilbert space. The algorithm can execute either O or its inverse O^{-1} on some register. Each execution counts as one query. It is known that O is equal to one O_x out of a set of possible input unitaries, where x ranges over some set D of labels. If $O = O_x$, the algorithm has to perform a unitary V_x on some specified part of its work-space. The algorithm knows in advance all possible O_x and which V_x corresponds to each O_x , but it does not know which O_x it is given in a specific execution. The adversary bound corresponding to this problem is $\gamma_2(V_x - V_y \mid O_x - O_y)_{x, y \in D}$. This bound is *semi-tight*: it is a lower bound on the exact version of the problem and an upper bound on the approximate version.

16:4 Quantum Algorithms for Classical Probability Distributions

The γ_2 -norm formalism is modular in the sense that the general task of implementing a unitary can be replaced by something more specific. For instance, assume that our task is to evaluate a function $f(x)$. Then the adversary bound reads as $\gamma_2(1_{f(x) \neq f(y)} \mid O_x - O_y)_{x,y \in D}$. In this case, the bound is tight: it is also a lower bound on the approximate version of the problem.

As another example, consider the standard input oracle O_x encoding a string $x \in [q]^n$. It works as $O_x: |i\rangle|0\rangle \mapsto |i\rangle|x_i\rangle$, which can be seen as a direct sum of oracles performing transformation $|0\rangle \mapsto |x_i\rangle$. Using the modular approach, the corresponding adversary bound becomes $\gamma_2(1_{f(x) \neq f(y)} \mid \bigoplus_j 1_{x_j \neq y_j})_{x,y \in D}$, where \bigoplus stands for direct sum of matrices (resulting in a diagonal matrix). This is equivalent to the usual version of dual adversary for function evaluation (up to a constant factor).

Now we consider state-generating input oracles¹. In this case, the input to the algorithm is given by a state $\psi \in \mathbb{C}^m$, and the algorithm should work equally well for any unitary performing the transformation $O: |0\rangle \mapsto |\psi\rangle$. Without loss of generality, we may assume that $e_0 = |0\rangle$ is orthogonal to \mathbb{C}^m , thus the operator O above works in \mathbb{C}^{m+1} .

The corresponding γ_2 -object can be defined in two alternative ways:

$$L_\psi = \psi e_0^* + e_0 \psi^* \quad \text{or} \quad L_\psi = \psi \oplus \psi^*.$$

In the second expression, ψ is an $m \times 1$ -matrix and ψ^* is a $1 \times m$ -matrix, the resulting matrix being of size $(m+1) \times (m+1)$. In the case of a function-evaluation problem, the corresponding adversary bound is $\gamma_2(1_{f(x) \neq f(y)} \mid L_{\psi_x} - L_{\psi_y})_{x,y \in D}$.

Let us also state the version of the adversary bound for the decision problem with state-generating input oracles. This is the version we will use further in the paper. Assume we have a collection of states $\psi_x \in \mathcal{X}$ for $x \in D_0$, and a collection of states $\psi_y \in \mathcal{X}$ for $y \in D_1$. The task is to distinguish the two classes of states. Let $D = D_0 \cup D_1$. Using the general case, we obtain the following version of the adversary bound.

► **Theorem 2.** *The quantum query complexity of the decision problem with state-generating oracles as above is equal to $\gamma_2(1 \mid L_{\psi_x} - L_{\psi_y})_{x \in D_0, y \in D_1}$ up to a constant factor.*

An explicit optimisation problem for $\gamma_2(1 \mid L_{\psi_x} - L_{\psi_y})_{x \in D_0, y \in D_1}$ is given by

$$\begin{aligned} \text{minimise} \quad & \max_{z \in D} (\|u_z\|^2 + \|v_z\|^2) \\ \text{subject to} \quad & \langle v_x, (\psi_x - \psi_y) \otimes u_y \rangle + \langle (\psi_x - \psi_y) \otimes u_x, v_y \rangle = 1 \quad \forall x \in D_0, y \in D_1; \\ & u_z \in \mathcal{W}, \quad v_z \in \mathcal{X} \otimes \mathcal{W} \quad \forall z \in D. \end{aligned} \quad (2)$$

This result follows from general results of [11], see the full version of the paper, where we also give a stand-alone implementation and analysis of the corresponding quantum algorithm.

3 Models

In this section we formally define four different models how a quantum algorithm can access a classical probability distribution $p = (p_a)_{a \in A}$. These models were briefly explained in the introduction. We would like to understand relations between them, and, ideally, prove some equivalences between them.

¹ The results below will appear in an updated version of [11] (to appear). Alternatively, refer to the full version of the paper.

- (i) A standard input oracle encoding a string $x \in A^n$ for some relatively large n , where p_a is given as the frequency of a in x :

$$p_a = \frac{1}{n} \left| \{i \mid x_i = a\} \right|.$$

- (ii) A standard input oracle encoding a string $x \in A^n$ for some relatively large n , where each x_i is drawn independently at random from p .
 (iii) A quantum procedure that generates the state

$$\mu_p = \sum_a \sqrt{p_a} |a\rangle = \bigoplus_a \sqrt{p_a}. \quad (3)$$

- (iv) A quantum procedure that generates a state of the form

$$\sum_a \sqrt{p_a} |a\rangle |\psi_a\rangle = \bigoplus_a \sqrt{p_a} \psi_a, \quad (4)$$

where ψ_a are arbitrary unit vectors.

As mentioned in the introduction, model (i) is used in [16, 18, 27, 25]. It has a downside that the probabilities p_a must be multiples of $1/n$. All other models are free from this assumption.

Model (ii) seems like the most obvious way to encode probability distribution as a classical string, which a quantum algorithm can later gain access to. Up to our knowledge, this model has not been previously used. It has a downside that the distribution p is encoded as a probability distribution over possible input strings, which is not usual for quantum algorithms. The acceptance probability of the quantum algorithm depends both on the randomness introduced by the algorithm and the randomness in the input.

Model (iii) is the one used in [17, 2, 6]. And model (iv) is used in [26, 20, 19]. Both of these two models assume that the input oracle prepares a quantum state, which again is not very common for quantum algorithms.

► **Proposition 3.** *We have the following relations between these models.*

- (a) *Models (i) and (ii) are equivalent assuming n is large enough. More precisely, no quantum algorithm can distinguish models (i) and (ii) encoding the same probability distribution unless it makes $\Omega(n^{1/3})$ queries.*
 (b) *Model (iv) is more general than model (i). This means that any algorithm working in model (iv) can be turned into an algorithm working in model (i) with the same query complexity.*
 (c) *Model (iv) is strictly more general than model (iii). This means there exist problems where model (iii) allows substantially smaller query complexity than model (iv).*

Proof. We leave (a) for the end of the proof, and let us start with (b). Note that using one query to the input oracle of model (i), it is possible to prepare that state

$$\frac{1}{\sqrt{n}} \sum_i |i\rangle |x_i\rangle = \sum_{a \in A} \left[\frac{1}{\sqrt{n}} \sum_{i: x_i = a} |i\rangle \right] \otimes |a\rangle,$$

which is a legitimate input state in model (iv) if one swaps the registers.

Now let us prove (c). It is obvious that model (iv) is more general than model (iii). To prove that (iii) cannot simulate (iv), consider the collision problem [15]. In this problem, a function $f: [n] \rightarrow [n]$ is given, and one has to distinguish whether f is 1-to-1 or 2-to-1. In terms of model (i), this boils down to distinguishing a probability distribution p which is uniform on $[n]$ from a probability distribution q which is uniform on half of $[n]$.

16:6 Quantum Algorithms for Classical Probability Distributions

In model (iii), this problem can be solved in $O(1)$ queries because the state μ_p as in (3) has inner product $1/\sqrt{2}$ with all μ_q . On the other hand, by [1, 3], quantum query complexity of this problem in model (i) is $\Omega(n^{1/3})$. As model (iv) is more general than model (i), this gives the required lower bound.

To prove (a), we show that if one can distinguish models (i) and (ii), one can distinguish a random function from a random permutation, and the result follows from the lower bound of $\Omega(n^{1/3})$ for this task from [30]. Indeed, let p be a probability distribution and let y be a fixed string encoding p as in model (i). Let $\sigma: [n] \rightarrow [n]$ be a function, and consider the input string x given by $x_i = y_{\sigma(i)}$, which can be simulated given oracle access to σ (as the string y is fixed). If σ is a random permutation, then x is a uniformly random input string from model (i). If σ is a random function, then x is distributed as in model (ii). ◀

4 Distinguishing Two Probability Distributions

Recall the definition of Hellinger distance between two probability distributions p and q on the same space A :

$$d_H(p, q) = \sqrt{\frac{1}{2} \sum_{a \in A} (\sqrt{p_a} - \sqrt{q_a})^2}.$$

Up to a constant factor, it equals $\|\mu_p - \mu_q\|$ and $1 - \langle \mu_p, \mu_q \rangle$, where μ_p and μ_q are as in (3).

In this section, we prove the following result:

► **Theorem 4.** *For any two probability distributions p and q on the same space A , and any model of accessing them from Section 3, the quantum query complexity of distinguishing p and q is*

$$\Theta\left(\frac{1}{d_H(p, q)}\right).$$

Note that this is quadratically better than complexity of the best classical algorithm for every choice of p and q . Note also that for this problem model (iii) is equal in strength to the remaining models.

The proof of main involves proving lower and upper bounds in all four models, but, luckily, we can use relations from Proposition 3. The outline of the proof is as follows. We prove upper bound in model (iv), which implies upper bounds in all other models as model (iv) is the most general of them. As for the lower bounds, we prove it for model (ii), which implies lower bounds in models (i) and (iv). For model (iii), we prove the lower bound independently. As a bonus, we prove an upper bound in model (iii) as a warm-up for the upper bound in model (iv).

In most of the proofs, we will use α for the angle between the vectors μ_p and μ_q . Note that

$$\alpha = \Theta(\|\mu_p - \mu_q\|) = \Theta(d_H(p, q)).$$

4.1 Analysis in Model (iii)

In this section, we analyse the problem in model (iii).

▷ **Claim 5.** Quantum query complexity of distinguishing probability distributions p and q in model (iii) is $\Theta(1/d_H(p, q))$.

Proof. Let us start with the upper bound. Let O be the input oracle, and let U be a unitary that maps $|\mu_p\rangle$ into $|0\rangle$ and $|\mu_q\rangle$ into $\cos\alpha|0\rangle + \sin\alpha|1\rangle$. Now use quantum amplitude amplification on the unitary UO amplifying for the value $|1\rangle$. The algorithm can be also made exact using exact quantum amplitude amplification.

Now let us prove the lower bound. Let O_p be the input oracle exchanging $|0\rangle$ and $|\mu_p\rangle$ and leaving the vectors orthogonal to them intact. Similarly, let O_q exchange $|0\rangle$ and $|\mu_q\rangle$. Simple linear algebra shows $\|O_p - O_q\| = O(\alpha)$. Let \mathcal{A}^O be a query algorithm making t queries to O and distinguishing O_p from O_q . Then,

$$\|\mathcal{A}^{O_p} - \mathcal{A}^{O_q}\| \leq t\|O_p - O_q\| = O(t\alpha).$$

As this must be $\Omega(1)$, we get that $t = \Omega(1/\alpha)$. ◁

4.2 Upper Bound in Model (iv)

The aim of this section is to prove the following claim.

▷ **Claim 6.** Quantum query complexity of distinguishing probability distributions p and q in model (iv) is $O(1/d_H(p, q))$.

We prove this claim by constructing a feasible solution to (2). In the full version of the paper, we explain how to implement this algorithm time-efficiently and give a comparison to an algorithm using more typical techniques.

Let ψ and ϕ be some vectors encoding p and q , respectively, as in model (iv). That is,

$$\psi = \bigoplus_a \sqrt{p_a} \psi_a, \quad \text{and} \quad \phi = \bigoplus_a \sqrt{q_a} \phi_a,$$

where ψ_a and ϕ_a are some normalised vectors. Our goal is to come up with a feasible solution to (2) with ψ_x and ψ_y replaced by ψ and ϕ .

We first analyse a pair of vectors $\sqrt{p_a} \psi_a$ and $\sqrt{q_a} \phi_a$ for a fixed a . We would like to get a construction in the spirit of (2) that “erases” directions ψ_a and ϕ_a , and only depends on the norms $\sqrt{p_a}$ and $\sqrt{q_a}$. One way is to use the following identity:

$$\left\langle \sqrt{p_a} \psi_a, \sqrt{p_a} \psi_a - \sqrt{q_a} \phi_a \right\rangle + \left\langle \sqrt{p_a} \psi_a - \sqrt{q_a} \phi_a, \sqrt{q_a} \phi_a \right\rangle = p_a - q_a. \quad (5)$$

We combine this identity over all a , add weights c_a , and re-normalise:

$$\begin{aligned} & \left\langle \frac{\bigoplus_a c_a \sqrt{p_a} \psi_a}{\sqrt[4]{\sum_a c_a^2 p_a}}, (\psi - \phi) \cdot \sqrt[4]{\sum_a c_a^2 p_a} \right\rangle \\ & + \left\langle (\psi - \phi) \cdot \sqrt[4]{\sum_a c_a^2 q_a}, \frac{\bigoplus_a c_a \sqrt{q_a} \phi_a}{\sqrt[4]{\sum_a c_a^2 q_a}} \right\rangle = \sum_a c_a (p_a - q_a), \end{aligned}$$

which gives

$$\gamma_2 \left(\sum_a c_a (p_a - q_a) \mid L_\psi - L_\phi \right)_{\psi, \phi} \leq \sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a}.$$

16:8 Quantum Algorithms for Classical Probability Distributions

Dividing by $\sum_a c_a(p_a - q_a)$, we get that complexity of distinguishing p from q is at most

$$O\left(\frac{\sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a}}{\sum_a c_a(p_a - q_a)}\right). \quad (6)$$

Using triangle inequality

$$\sqrt{\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2} \leq \sqrt{\sum_a c_a^2 p_a} + \sqrt{\sum_a c_a^2 q_a} \leq 2\sqrt{\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2},$$

so (6) is equivalent to

$$O\left(\frac{\sqrt{\sum_a c_a^2 (\sqrt{p_a} + \sqrt{q_a})^2}}{\sum_a c_a(p_a - q_a)}\right).$$

Now it is easy to see that it is minimised to

$$O\left(\frac{1}{\sqrt{\sum_a (\sqrt{p_a} - \sqrt{q_a})^2}}\right) = O\left(\frac{1}{d_H(p, q)}\right)$$

when $c_a = (\sqrt{p_a} - \sqrt{q_a})/(\sqrt{p_a} + \sqrt{q_a})$.

4.3 Lower Bound in Model (ii)

We use the following version of the adversary lower bound from [12].

► **Theorem 7.** *Assume \mathcal{A} is a quantum algorithm that makes T queries to the input string $x = (x_1, \dots, x_n) \in D$, with $D = A^n$, and then either accepts or rejects. Let P and Q be two probability distributions on D , and p_x and q_y denote probabilities of x and y in P and Q , respectively. Let s_P and s_Q be acceptance probability of \mathcal{A} when x is sampled from P and Q , respectively. Then,*

$$T = \Omega\left(\min_{j \in [n]} \frac{\delta_P^* \Gamma \delta_Q - \tau(s_P, s_Q) \|\Gamma\|}{\|\Gamma \circ \Delta_j\|}\right), \quad (7)$$

for any $D \times D$ matrix Γ with real entries. Here, $\delta_P[x] = \sqrt{p_x}$ and $\delta_Q[y] = \sqrt{q_y}$ are unit vectors in \mathbb{R}^D ; for $j \in [n]$, the $D \times D$ matrix Δ_j is defined by $\Delta_j[x, y] = 1_{x_j \neq y_j}$; and

$$\tau(s_P, s_Q) = \sqrt{s_P s_Q} + \sqrt{(1 - s_P)(1 - s_Q)} \leq 1 - \frac{|s_P - s_Q|^2}{8}. \quad (8)$$

In our case, $\delta_P = \mu_p^{\otimes n}$ and $\delta_Q = \mu_q^{\otimes n}$. We construct Γ as a tensor power $G^{\otimes n}$, where G is an $A \times A$ matrix satisfying

$$G\mu_q = \mu_p, \quad \|G\| = 1, \quad \text{and} \quad \|G \circ \Delta\| \text{ is as small as possible,}$$

where Δ is the $A \times A$ matrix given by $A[a, b] = 1_{a \neq b}$. Then,

$$\delta_P^* \Gamma \delta_Q = \|\Gamma\| = 1, \quad \text{and} \quad \|\Gamma \circ \Delta_j\| = \|G \circ \Delta\|,$$

and adv gives the lower bound of $\Omega(1/\|G \circ \Delta\|)$.

We construct G as follows. Recall that α is the angle between μ_q and μ_p . Then, G is rotation by the angle α in the plane spanned by μ_q and μ_p and homothety with coefficient $\cos \alpha$ on its orthogonal complement. That is, in an orthonormal basis where the first two vectors span the plane of μ_q and μ_p , we have

$$G = \begin{pmatrix} \cos \alpha & -\sin \alpha & 0 & \cdots & 0 \\ \sin \alpha & \cos \alpha & 0 & \cdots & 0 \\ 0 & 0 & \cos \alpha & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \cos \alpha \end{pmatrix}.$$

Clearly, $G\mu_q = \mu_p$ and $\|G\| = 1$. Let $G' = G - \cos \alpha I$. We have

$$\|G \circ \Delta\| = \|G' \circ \Delta\| \leq 2\|G'\| = 2\sin \alpha = O(d_H(p, q)).$$

For the inequality we used that $\gamma_2(\Delta) \leq 2$, see [24, Theorem 3.4]. This gives the required lower bound.

5 Summary and Future Work

In this paper we considered quantum algorithms dealing with classical probability distributions. We identified four different models, and proved various relations between them. We conjecture that models (i), (ii) and (iv) are equivalent.

Also, we considered the problem of distinguishing two probability distributions and obtained precise characterisation of its quantum query complexity in all four models in terms of Hellinger distance between the probability distributions. The complexity turned out to be exactly quadratically smaller than the classical complexity of this problem for all pairs of distributions.

We showed that the corresponding algorithm can be implemented efficiently given that the probability distributions p and q can be handled efficiently. We also compared our algorithm with a more standard approach using rejection sampling and amplitude estimation.

This raises a number of interesting open problems. The first one is to prove or disprove the conjecture that models (i) and (iv) are equivalent. Another interesting problem is to come up with a nice γ_2 -characterisation of probability distribution oracles like `gamma2StatePreparing` characterises state-generating oracles. Unfortunately, we do not have any hypothesis of how this characterisation might look like. Finally, we would be interested in further quantum algorithms based on techniques of Section 4.2.

Abstract

In this paper, we design a framework to obtain efficient algorithms for several problems with a global constraint (acyclicity or connectivity) such as CONNECTED DOMINATING SET, NODE WEIGHTED STEINER TREE, MAXIMUM INDUCED TREE, LONGEST INDUCED PATH, and FEEDBACK VERTEX SET. For all these problems, we obtain $2^{O(k)} \cdot n^{O(1)}$, $2^{O(k \log(k))} \cdot n^{O(1)}$, $2^{O(k^2)} \cdot n^{O(1)}$ and $n^{O(k)}$ time algorithms parameterized respectively by clique-width, \mathbb{Q} -rank-width, rank-width and maximum induced matching width. Our approach simplifies and unifies the known algorithms for each of the parameters and match asymptotically also the running time of the best algorithms for basic NP-hard problems such as VERTEX COVER and DOMINATING SET. Our framework is based on the d -neighbor equivalence defined in [Bui-Xuan, Telle and Vatshelle, TCS 2013]. The results we obtain highlight the importance and the generalizing power of this equivalence relation on width measures. We also prove that this equivalence relation could be useful for MAX CUT: a W[1]-hard problem parameterized by clique-width. For this latter problem, we obtain $n^{O(k)}$, $n^{O(k)}$ and $n^{2^{O(k)}}$ time algorithm parameterized by clique-width, \mathbb{Q} -rank-width and rank-width.

1 Introduction

Tree-width is one of the most well-studied graph parameters in the graph algorithm community, due to its numerous structural and algorithmic properties. Nevertheless, despite the broad interest on tree-width, only sparse graphs can have bounded tree-width. But, many NP-hard problems are tractable on dense graph classes. For many graph classes, this tractability can be explained through other width measures. The most remarkable ones are certainly clique-width [8], rank-width [18], and maximum induced matching width (*a.k.a.* mim-width) [23]. We obtain most of these parameters through the notion of *rooted layout* (see Section 2).

These other width measures have a modeling power strictly stronger than the modeling power of tree-width. For example, if a graph class has bounded tree-width, then it has bounded clique-width [8], but the converse is false as cliques have clique-width at most 2

¹ Corresponding author

and unbounded tree-width. While rank-width has the same modeling power as clique-width, mim-width has the strongest one among all these width measures and is even bounded on interval graphs [1]. Despite their generality, a lot of NP-hard problems admit polynomial time algorithms when one of these width measures is fixed. But, dealing with these width measures is known to be harder than manipulating tree-width.

Concerning their computations, it is not known whether the clique-width (respectively mim-width) of a graph can be approximated within a constant factor in time $f(k) \cdot n^{O(1)}$ (resp. $n^{f(k)}$) for some function f . However, for rank-width and its variant \mathbb{Q} -rank-width [19], there are efficient FPT algorithms for computing a decomposition approximating the width of the input graph [19, 20].

Finding efficient algorithms parameterized by one of these width measures is by now standard for problems based on local constraints [7, 22]. In contrast, the task is quite complicated for problems involving a global constraint, *e.g.*, connectivity or acyclicity. For a long time, our knowledge on the parameterized complexity of this latter kind of problems, with parameters the common width measures, was quite limited even for tree-width. For a while, the FPT community used to think that for problems involving global constraints the naive $k^{O(k)} \cdot n^{O(1)}$ time algorithm, k being the tree-width of the input graph, could not be improved. But, quite surprisingly, in 2011, Cygan et al. introduced in [9] a technique called *Cut & Count* to design Monte Carlo $2^{O(k)} \cdot n^{O(1)}$ time algorithms for a wide range of problems with global constraints, including HAMILTONIAN CYCLE, FEEDBACK VERTEX SET, and CONNECTED DOMINATING SET. Later, Bodlaender et al. proposed in [5] a general toolkit, called *rank-based approach*, to design deterministic $2^{O(k)} \cdot n$ time algorithms to solve a wider range of problems.

Recently, Bergougnoux and Kanté [3] adapted the rank-based approach of [5] to obtain $2^{O(k)} \cdot n$ time algorithms, k being the clique-width of a given decomposition, for many problems with a global constraint, *e.g.* CONNECTED DOMINATING SET and FEEDBACK VERTEX SET. Unlike tree-width and clique-width, algorithms parameterized by rank-width and mim-width for problems with a global constraint, were not investigated, except for some special cases such as FEEDBACK VERTEX SET [12, 15] and LONGEST INDUCED PATH [14].

One successful way to design efficient algorithms with these width measures is through the notion of *d-neighbor equivalence*. This concept was introduced by Bui-Xuan, Telle and Vatshelle in [7]. Formally, given $A \subseteq V(G)$ and $d \in \mathbb{N}^+$, two sets $X, Y \subseteq A$ are *d-neighbor equivalent w.r.t. A* if, for all $v \in V(G) \setminus A$, we have $\min(d, |N(v) \cap X|) = \min(d, |N(v) \cap Y|)$, where $N(v)$ is the set of neighbors of v in G . Notice that X and Y are 1-neighbor equivalent *w.r.t. A* if and only if both have the same neighborhood in $V(G) \setminus A$. The *d-neighbor equivalence* gives rise to a width measure, called in this paper *d-neighbor-width* (defined in Section 2). It is worth noticing that the boolean-width of a layout introduced in [6] corresponds to the binary logarithm of the 1-neighbor-width.

These notions were used by Bui-Xuan et al. in [7] to design efficient algorithms for the family of problems called (σ, ρ) -DOMINATING SET problems. This family of problems was introduced by Telle and Proskurowski in [22] (we define this family in Section 4). Many NP-hard problems based on local constraints belong to this family, see [7, Table 1].

Bui-Xuan et al. [7] designed an algorithm that, given a rooted layout \mathcal{L} , solve any (σ, ρ) -DOMINATING SET problem in time $\text{s-nec}_d(\mathcal{L})^{O(1)} \cdot n^{O(1)}$ where d is a constant depending on the considered problem. The known upper bounds on $\text{s-nec}_d(\mathcal{L})$ and the algorithm of [7] give efficient algorithms to solve any (σ, ρ) -DOMINATING SET problem, with parameters tree-width, clique-width, (\mathbb{Q}) -rank-width, and mim-width. The running times of these algorithms are given in Table 1.

■ **Table 1** Upper bounds on $\text{s-nec}_d(\mathcal{L})^{O(1)} \cdot n^{O(1)}$ with \mathcal{L} a layout and d a constant.

Tree-width	Clique-width	Rank-width	\mathbb{Q} -rank-width	Mim-width
$2^{O(k)} \cdot n^{O(1)}$	$2^{O(k)} \cdot n^{O(1)}$	$2^{O(k^2)} \cdot n^{O(1)}$	$2^{O(k \log(k))} \cdot n^{O(1)}$	$n^{O(k)}$

Our contributions. In this paper, we design a framework based on the 1-neighbor equivalence (presented in Section 3) and using some ideas of the rank-based approach of [5] to design efficient algorithms for many problems involving a connectivity constraint. This framework provides tools to reduce the size of the sets of partial solutions we compute at each step of a dynamic programming algorithm. We prove that many ad-hoc algorithms for these problems can be unified into a single algorithm that is almost the same as the one from [7] computing a dominating set.

In Section 4, we use our framework to design an algorithm that, given a rooted layout \mathcal{L} , solves any connectivity variant (a solution must induce a connected graph) of a (σ, ρ) -DOMINATING SET problem. This includes some well-known problems such as CONNECTED DOMINATING SET, CONNECTED VERTEX COVER or NODE WEIGHTED STEINER TREE. The running time of our algorithm is polynomial in n and $\text{s-nec}_d(\mathcal{L})$, with d a constant that depends on σ and ρ . Consequently, each connectivity variant of a (σ, ρ) -DOMINATING SET problem admits algorithms with the running times given in Table 1.

In Section 5, we introduce some new concepts to deal with acyclicity. We use these concepts to deal with the *AC* variants² (a solution must induce a tree) of (σ, ρ) -DOMINATING SET problems. Both MAXIMUM INDUCED TREE and LONGEST INDUCED PATH are *AC* variants of (σ, ρ) -DOMINATING SET problems. We prove that there exist algorithms that solve these *AC* variants in the running times given in Table 1. To obtain these results, we rely heavily on the d -neighbor equivalence. However, we were not able to provide an algorithm whose running time is polynomial in n and $\text{s-nec}_d(\mathcal{L})$ for some constant d . Instead, we provide an algorithm whose behavior depends slightly on each width measure considered in Table 1. We moreover prove that we can modify slightly this algorithm to solve any acyclic variant (a solution must induce a forest) of a (σ, ρ) -DOMINATING SET problem. In particular, this shows that we can use the algorithm for MAXIMUM INDUCED TREE to solve the FEEDBACK VERTEX SET problem.

Up to a constant in the exponent, the running times of our algorithms and their algorithmic consequences match those of the best known algorithms for basic problems such as VERTEX COVER and DOMINATING SET [7, 19]. Surprisingly, our result reveal that the d -neighbor equivalence relation can be used for problems which are not based on local constraints. This highlights the importance and the generalizing power of this concept on many width measures.

We conclude in Section 6 and state our theorem for the computation of MAX CUT – a problem which is $W[1]$ -hard parameterized by clique-width – whose running time is polynomial in n and the n -neighbor width of a given rooted layout. This algorithm gives the best known algorithms parameterized by clique-width, \mathbb{Q} -rank-width and rank-width. It is worth mentioning that contrary to the algorithm for MAX CUT given in [11], there is no need to assume that the graph is given with a clique-width expression as our algorithm can be parameterized by \mathbb{Q} -rank-width, which is always smaller than clique-width and for which also a fast FPT $(3k + 1)$ -approximation algorithm exists [20].

² *AC* stands for “acyclic and connected”.

Relation to previous works. Our framework can be used on tree-decomposition to obtain $2^{O(k)} \cdot n^{O(1)}$ time algorithms parameterized by tree-width for the variants of (σ, ρ) -DOMINATING SET problems. Indeed, given a vertex separator S of size k , the number of d -neighbor equivalence classes over S (resp. $V(G) \setminus S$) is upper bounded by 2^k (resp. $(d+1)^k$). For this reason, we can consider our framework as a generalization of the rank-based approach of [5]. Our framework generalizes also the clique-width adaptation of the rank-based approach used in [3] to obtain $2^{O(k)} \cdot n$ time algorithms, k being the clique-width of a given decomposition, for CONNECTED (σ, ρ) -DOMINATING SET problem and FEEDBACK VERTEX SET. However, the constant in the running time of the algorithms in [3, 5] are better than those of our algorithms. Indeed, our approach is based on a more general parameter and is not optimized neither for tree-width nor clique-width. Our framework simplifies the algorithms in [3, 5] because contrary to [3, 5] we do not use weighted partitions to encode the partial solutions. Consequently, the definitions of the dynamic programming tables and the computational steps of our algorithms are simpler than those in [3, 5]. This is particularly true for FEEDBACK VERTEX SET where the use of weighted partitions to encode the partial solutions in [3] implies to take care of many technical details concerning the acyclicity.

The results we obtain simplify the $2^{O(k^2)} \cdot n^{O(1)}$ time algorithm parameterized by rank-width for FEEDBACK VERTEX SET from [12], and the $n^{O(k)}$ time algorithms parameterized by mim-width for FEEDBACK VERTEX SET and LONGEST INDUCED PATH from [14, 15].

Concerning mim-width, we provide unified polynomial-time algorithms for the considered problems for all well-known graph classes having bounded mim-width and for which a layout of bounded mim-width can be computed in polynomial time [1] (*e.g.*, interval graphs, circular arc graphs, permutation graphs, Dilworth- k graphs and k -polygon graphs for all fixed k). Notice that we also generalize one of the results from [17] proving that the CONNECTED VERTEX COVER problem is solvable in polynomial time for circular arc graphs.

It is worth noticing that the approach used in [9] called Cut & Count can also be generalized to the d -neighbor-width for any CONNECTED (σ, ρ) -DOMINATING SET problem with more or less the same arguments used in this paper (see the PhD thesis [2]).

2 Preliminaries

The size of a set V is denoted by $|V|$ and its power set is denoted by 2^V . We write $A \setminus B$ for the set difference of A from B . We denote by \mathbb{N} the set of non-negative integers and by \mathbb{N}^+ the set $\mathbb{N} \setminus \{0\}$. We let $\min(\emptyset) := +\infty$ and $\max(\emptyset) := -\infty$. Let V be a finite set. A set function $f : 2^V \rightarrow \mathbb{N}$ is *symmetric* if, for all $S \subseteq V$, we have $f(S) = f(V \setminus S)$.

Graphs. Our graph terminology is standard, and we refer to [10]. The vertex set of a graph G is denoted by $V(G)$ and its edge set by $E(G)$. For every vertex set $X \subseteq V(G)$, when the underlying graph is clear from context, we denote by \overline{X} , the set $V(G) \setminus X$. An edge between two vertices x and y is denoted by xy or yx . The set of vertices that is adjacent to x is denoted by $N_G(x)$. For a set $U \subseteq V(G)$, we define $N_G(U) := \bigcup_{x \in U} N_G(x)$. If the underlying graph is clear, then we may remove G from the subscript.

The subgraph of G induced by a subset X of its vertex set is denoted by $G[X]$. For $X, Y \subseteq V(G)$, we denote by $G[X, Y]$ the bipartite graph with vertex set $X \cup Y$ and edge set $\{xy \in E(G) : x \in X \text{ and } y \in Y\}$. Moreover, we denote by $M_{X,Y}$ the adjacency matrix between X and Y , *i.e.*, the (X, Y) -matrix such that $M_{X,Y}[x, y] = 1$ if $y \in N(x)$ and 0

otherwise. For a graph G , we denote by $\text{cc}(G)$ the partition $\{V(C) : C \text{ is a connected component of } G\}$. For two subsets \mathcal{A} and \mathcal{B} of $2^{V(G)}$, we define the *merging* of \mathcal{A} and \mathcal{B} , denoted by $\mathcal{A} \otimes \mathcal{B}$, as

$$\mathcal{A} \otimes \mathcal{B} := \begin{cases} \emptyset & \text{if } \mathcal{A} = \emptyset \text{ or } \mathcal{B} = \emptyset, \\ \{X \cup Y : X \in \mathcal{A} \text{ and } Y \in \mathcal{B}\} & \text{otherwise.} \end{cases}$$

Let $X \subseteq V(G)$. A *consistent cut* of X is an ordered bipartition (X_1, X_2) of X such that $N(X_1) \cap X_2 = \emptyset$. We denote by $\text{ccut}(X)$ the set of all consistent cuts of X .

The d -neighbor equivalence relation. Let G be a graph. The following definition is from [7]. Let $A \subseteq V(G)$ and $d \in \mathbb{N}^+$. Two subsets X and Y of A are *d -neighbor equivalent* w.r.t. A , denoted by $X \equiv_A^d Y$, if $\min(d, |X \cap N(u)|) = \min(d, |Y \cap N(u)|)$ for all $u \in \overline{A}$. It is not hard to check that \equiv_A^d is an equivalence relation.

For all $d \in \mathbb{N}^+$, we let $\text{nec}_d : 2^{V(G)} \rightarrow \mathbb{N}$ where, for all $A \subseteq V(G)$, $\text{nec}_d(A)$ is the number of equivalence classes of \equiv_A^d . Notice that while nec_1 is a symmetric function [16, Theorem 1.2.3], nec_d is not necessarily symmetric for $d \geq 2$.

In order to manipulate the equivalence classes of \equiv_A^d , one needs to compute a representative for each equivalence class in polynomial time. This is achieved with the following notion of a representative. Let G be a graph with an arbitrary ordering of $V(G)$ and let $A \subseteq V(G)$. For each $X \subseteq A$, let us denote by $\text{rep}_A^d(X)$ the lexicographically smallest set $R \subseteq A$ such that $|R|$ is minimized and $R \equiv_A^d X$. Moreover, we denote by \mathcal{R}_A^d the set $\{\text{rep}_A^d(X) : X \subseteq A\}$. It is worth noticing that the empty set always belongs to \mathcal{R}_A^d , for all $A \subseteq V(G)$ and $d \in \mathbb{N}^+$. Moreover, we have $\mathcal{R}_{V(G)}^d = \mathcal{R}_\emptyset^d = \{\emptyset\}$ for all $d \in \mathbb{N}^+$. In order to compute \mathcal{R}_A^d , we use the following lemma.

► **Lemma 1** ([7]). *For every $A \subseteq V(G)$ and $d \in \mathbb{N}^+$, one can compute in time $O(\text{nec}_d(A) \cdot \log(\text{nec}_d(A)) \cdot |V(G)|^2)$, the sets \mathcal{R}_A^d and a data structure, that given a set $X \subseteq A$, computes $\text{rep}_A^d(X)$ in time $O(\log(\text{nec}_d(A)) \cdot |A| \cdot |V(G)|)$.*

Graph width measures. A *rooted binary tree* is a binary tree with a distinguished vertex called the *root*. Since we manipulate at the same time graphs and trees representing them, the vertices of trees will be called *nodes*. A *rooted layout* of G is a pair $\mathcal{L} = (T, \delta)$ of a rooted binary tree T and a bijective function δ between $V(G)$ and the leaves of T . For each node x of T , let L_x be the set of all the leaves l of T such that the path from the root of T to l contains x . We denote by $V_x^\mathcal{L}$ the set of vertices that are in bijection with L_x , i.e., $V_x^\mathcal{L} := \{v \in V(G) : \delta(v) \in L_x\}$. When \mathcal{L} is clear from the context, we may remove \mathcal{L} from the superscript.

All the width measures dealt with in this paper are special cases of the following one, the difference being in each case the used set function. Given a set function $f : 2^{V(G)} \rightarrow \mathbb{N}$ and a rooted layout $\mathcal{L} = (T, \delta)$, the f -width of a node x of T is $f(V_x^\mathcal{L})$ and the f -width of (T, δ) , denoted by $f(T, \delta)$ (or $f(\mathcal{L})$), is $\max\{f(V_x^\mathcal{L}) : x \in V(T)\}$. Finally, the f -width of G is the minimum f -width over all rooted layouts of G .

For a graph G , we let $\text{s-nec}_d, \text{mw}, \text{mim}, \text{rw}, \text{rw}_\mathbb{Q}$ be functions from $2^{V(G)}$ to \mathbb{N} such that for every $A \subseteq V(G)$, $\text{s-nec}_d(A) = \max\{\text{nec}_d(A), \text{nec}_d(\overline{A})\}$, $\text{mw}(A)$ is the cardinality of $\{N(v) \cap \overline{A} : v \in A\}$, $\text{mim}(A)$ is the size of a maximum induced matching of the graph $G[A, \overline{A}]$ and $\text{rw}(A)$ (resp. $\text{rw}_\mathbb{Q}(A)$) is the rank over $GF(2)$ (resp. \mathbb{Q}) of the matrix $M_{A, \overline{A}}$. The *d -neighbor-width*, *module-width*, *mim-width*, *rank-width* and *\mathbb{Q} -rank-width* of G , are respectively, its s-nec_d -width, mw -width, mim -width, rw -width and $\text{rw}_\mathbb{Q}$ -width [23].

Observe that, for every graph G , $\text{mw}(G) \leq \text{cw}(G) \leq 2\text{mw}(G)$ where $\text{cw}(G)$ is the clique-width of G [21], and one can moreover translate, in time at most $O(n^2)$, a given decomposition into the other one with width at most the given bounds.

In the following, we fix G an n -vertex graph, (T, δ) a rooted layout of G , and $w : V(G) \rightarrow \mathbb{Q}$ a weight function over the vertices of G . We also assume that $V(G)$ is ordered.

3 Representative sets

In this section, we define a notion of representativity between sets of partial solutions *w.r.t.* the connectivity. Our notion of representativity is defined *w.r.t.* some node x of T and the 1-neighbor equivalence class of some set $R' \subseteq \overline{V}_x$. In our algorithms, R' will always belong to $\mathcal{R}_{\overline{V}_x}^d$ for some $d \in \mathbb{N}^+$. Our algorithms compute a set of partial solutions for each $R' \in \mathcal{R}_{\overline{V}_x}^d$. The partial solutions computed for R' will be completed with sets equivalent to R' *w.r.t.* $\equiv_{\overline{V}_x}^d$. Intuitively, the R' 's represent some expectation about how we will complete our sets of partial solutions. For the connectivity and the domination, $d = 1$ is enough but if we need more information for some reasons (for example the (σ, ρ) -domination or the acyclicity), we may take $d > 1$. This is not a problem as the d -neighbor equivalence class of R' is included in the 1-neighbor equivalence class of R' . Hence, in this section, we fix a node x of T and a set $R' \subseteq \overline{V}_x$ to avoid to overload the statements by the sentence “let x be a node of T and $R' \subseteq \overline{V}_x$ ”. We let $\text{opt} \in \{\min, \max\}$; if we want to solve a maximization (or minimization) problem, we use $\text{opt} = \max$ (or $\text{opt} = \min$). We use it also, as here, in the next sections.

► **Definition 2** ((x, R') -representativity). *For every $\mathcal{A} \subseteq 2^{V(G)}$ and $Y \subseteq V(G)$, we define $\text{best}(\mathcal{A}, Y) := \text{opt}\{w(X) : X \in \mathcal{A} \text{ and } G[X \cup Y] \text{ is connected}\}$.*

Let $\mathcal{A}, \mathcal{B} \subseteq 2^{V_x}$. We say that \mathcal{B} (x, R') -represents \mathcal{A} if, for every $Y \subseteq \overline{V}_x$ such that $Y \equiv_{\overline{V}_x}^1 R'$, we have $\text{best}(\mathcal{A}, Y) = \text{best}(\mathcal{B}, Y)$.

Notice that the (x, R') -representativity is an equivalence relation. The set \mathcal{A} is meant to represent a set of partial solutions of $G[V_x]$ associated with R' which have been computed. If a $\mathcal{B} \subseteq \mathcal{A}$ (x, R') -represents \mathcal{A} , then we can safely substitute \mathcal{A} by \mathcal{B} because the quality of the output of the dynamic programming algorithm will remain the same. Indeed, for every subset Y of \overline{V}_x such that $Y \equiv_{\overline{V}_x}^1 R'$, an optimum solution obtained by the union of a partial solution in \mathcal{A} and Y will have the same weight as an optimum solution obtained from the union of a set in \mathcal{B} and Y .

The following theorem presents the main tool of our framework: a function `reduce` that, given a set of partial solutions \mathcal{A} , outputs a subset of \mathcal{A} that (x, R') -represents \mathcal{A} and whose size is upper bounded by $\text{s-nec}_1(\mathcal{L})^2$. To design this function, we use ideas from the rank-based approach of [5]. That is, we define a small matrix \mathcal{C} with $|\mathcal{A}|$ rows and $\text{s-nec}_1(V_x)^2$ columns. Then, we show that a basis of maximum weight of the row space of \mathcal{C} corresponds to an (x, R') -representative set of \mathcal{A} . Since \mathcal{C} has $\text{s-nec}_1(\mathcal{L})^2$ columns, the size of a basis of \mathcal{C} is smaller than $\text{s-nec}_1(\mathcal{L})^2$. By calling `reduce` after each computational step, we keep the sizes of the sets of partial solutions polynomial in $\text{s-nec}_1(\mathcal{L})$.

In order to compute a small (x, R') -representative set of a set $\mathcal{A} \subseteq 2^{V_x}$, the following theorem requires that the sets in \mathcal{A} are pairwise equivalent *w.r.t.* $\equiv_{\overline{V}_x}^1$. This is useful since in our algorithm we classify our sets of partial solutions with respect to this property. We need this to guarantee that the partial solutions computed for R' will be completed with sets equivalent to R' *w.r.t.* $\equiv_{\overline{V}_x}^d$. However, if one wants to compute a small (x, R') -representative set of a set \mathcal{A} that does not respect this property, then it is enough to compute an (x, R') -representative set for each 1-neighbor equivalence class of \mathcal{A} . The union of these (x, R') -representative sets is an (x, R') -representative set of \mathcal{A} . In the following, ω is the matrix multiplication exponent.

► **Theorem 3.** *Let $R \in \mathcal{R}_{V_x}^1$ and $R' \subseteq \overline{V_x}$. Then, there exists an algorithm `reduce` that, given $\mathcal{A} \subseteq 2^{V_x}$ such that $X \equiv_{V_x}^1 R$ for all $X \in \mathcal{A}$, outputs in time $O(|\mathcal{A}| \cdot \text{nec}_1(V_x)^{2(\omega-1)} \cdot n^2)$ a subset $\mathcal{B} \subseteq \mathcal{A}$ such that \mathcal{B} (x, R') -represents \mathcal{A} and $|\mathcal{B}| \leq \text{nec}_1(V_x)^2$.*

Sketch of proof. We assume w.l.o.g. that $\text{opt} = \max$ (the case $\text{opt} = \min$ is symmetric). If $R' \equiv_{V_x}^1 \emptyset$, then, from Definition 2, it is enough to output $\{X\}$ where X is a set in \mathcal{A} of maximum weight such that $G[X]$ is connected.

Assume that R' is not equivalent to \emptyset w.r.t. $\equiv_{V_x}^1$. Observe that, for every $X \in \mathcal{A}$ which admits a connected component C with $N(C) \cap R' = \emptyset$, the graph $G[X \cup Y]$ is not connected for every $Y \equiv_{V_x}^1 R'$. Thus, we can safely remove from \mathcal{A} all such sets, this can be done in time $|\mathcal{A}| \cdot n^2$. Let \mathcal{D} be the set of all subsets Y of $\overline{V_x}$ such that $Y \equiv_{V_x}^1 R'$ and, for all $C \in \text{cc}(Y)$, we have $N(C) \cap R' \neq \emptyset$. It is easy to check that the sets in $2^{\overline{V_x}} \setminus \mathcal{D}$ do not matter in the (x, R') -representativity: they will not give a solution with a set in \mathcal{A} .

For every $Y \in \mathcal{D}$, we let v_Y be one fixed vertex of Y . In the following, we denote by \mathfrak{R} the set $\{(R'_1, R'_2) \in \mathcal{R}_{V_x}^1 \times \mathcal{R}_{V_x}^1\}$. Let \mathcal{C} , and $\overline{\mathcal{C}}$ be, respectively, an $(\mathcal{A}, \mathfrak{R})$ -matrix and an $(\mathfrak{R}, \mathcal{D})$ -matrix such that

$$\mathcal{C}[X, (R'_1, R'_2)] := \begin{cases} 1 & \text{if } \exists (X_1, X_2) \in \text{ccut}(X) \text{ such that } N(X_1) \cap R'_2 = \emptyset \wedge N(X_2) \cap R'_1 = \emptyset, \\ 0 & \text{otherwise.} \end{cases}$$

$$\overline{\mathcal{C}}[(R'_1, R'_2), Y] := \begin{cases} 1 & \text{if } \exists (Y_1, Y_2) \in \text{ccut}(Y) \text{ such that } v_Y \in Y_1, Y_1 \equiv_{V_x}^1 R'_1, \text{ and } Y_2 \equiv_{V_x}^1 R'_2, \\ 0 & \text{otherwise.} \end{cases}$$

Owing to the partial solutions we have removed from \mathcal{A} and the definition of \mathcal{D} , we can prove that a basis of maximum weight of the row space of \mathcal{C} is an (x, R') -representative set of \mathcal{A} . This follows from the fact that $(\mathcal{C} \cdot \overline{\mathcal{C}})[X, Y]$ equals the number of consistent cuts (W_1, W_2) in $\text{ccut}(X \cup Y)$ such that $v_Y \in W_1$. Consequently, $(\mathcal{C} \cdot \overline{\mathcal{C}})[X, Y] = 2^{|\text{cc}(G[X \cup Y])| - 1}$ and thus $(\mathcal{C} \cdot \overline{\mathcal{C}})[X, Y]$ is odd if and only if $G[X \cup Y]$ is connected. The running time of `reduce` and the size of `reduce`(\mathcal{A}) follows from the size of \mathcal{C} (i.e. $|\mathcal{A}| \cdot \text{nec}_1(V_x)^2$) and the fact that both \mathcal{C} and a basis of maximum weight of \mathcal{C} are easy to compute. ◀

Now to boost up a dynamic programming algorithm P on some rooted layout (T, δ) of G , we can use the function `reduce` to keep the size of the sets of partial solutions bounded by $\text{s-nec}_1(T, \delta)^2$. We call P' the algorithm obtained from P by calling the function `reduce` at every step of computation. We can assume that the set of partial solutions \mathcal{A}_r computed by P and associated with the root r of (T, δ) contains an optimal solution (this will be the cases in our algorithms). To prove the correctness of P' , we need to prove that \mathcal{A}'_r (r, \emptyset) -represents \mathcal{A}_r where \mathcal{A}'_r is the set of partial solutions computed by P' and associated with r . For doing so, we need to prove that at each step of the algorithm the operations we use preserve the (x, R') -representativity. The following fact states that we can use the union without restriction, it follows directly from Definition 2 of (x, R') -representativity.

► **Fact 4.** *If \mathcal{B} and \mathcal{D} (x, R') -represents, respectively, \mathcal{A} and \mathcal{C} , then $\mathcal{B} \cup \mathcal{D}$ (x, R') -represents $\mathcal{A} \cup \mathcal{C}$.*

The second operation we use in our dynamic programming algorithms is the merging operator \otimes . In order to safely use it, we need the following notion of compatibility that just tells which partial solutions from V_a and V_b can be joined to possibly form a partial solution in V_x . (It was already used in [7] without naming it.)

► **Definition 5** (d - (R, R') -compatibility). Suppose that x is an internal node of T with a and b as children. Let $d \in \mathbb{N}^+$ and $R \in \mathcal{R}_{V_x}^d$. We say that $(A, A') \in \mathcal{R}_{V_a}^d \times \mathcal{R}_{V_a}^d$ and $(B, B') \in \mathcal{R}_{V_b}^d \times \mathcal{R}_{V_b}^d$ are d - (R, R') -compatible if we have (1) $A \cup B \equiv_{V_x}^d R$, (2) $A' \equiv_{V_a}^d B \cup R'$, and (3) $B' \equiv_{V_b}^d A \cup R'$.

► **Lemma 6.** Suppose that x is an internal node of T with a and b as children. Let $d \in \mathbb{N}^+$ and $R \in \mathcal{R}_{V_x}^d$. Let $(A, A') \in \mathcal{R}_{V_a}^d \times \mathcal{R}_{V_a}^d$ and $(B, B') \in \mathcal{R}_{V_b}^d \times \mathcal{R}_{V_b}^d$ that are d - (R, R') -compatible. Let $\mathcal{A} \subseteq 2^{V_a}$ such that, for all $X \in \mathcal{A}$, we have $X \equiv_{V_a}^d A$, and let $\mathcal{B} \subseteq 2^{V_b}$ such that, for all $W \in \mathcal{B}$, we have $W \equiv_{V_b}^d B$. If $\mathcal{A}' \subseteq \mathcal{A}$ (a, A')-represents \mathcal{A} and $\mathcal{B}' \subseteq \mathcal{B}$ (b, B')-represents \mathcal{B} , then $\mathcal{A}' \otimes \mathcal{B}'$ (x, R')-represents $\mathcal{A} \otimes \mathcal{B}$.

4 Connected (Co)- (σ, ρ) -Dominating Sets

Let σ and ρ be two (non-empty) finite or co-finite subsets of \mathbb{N} . We say that a subset D of $V(G)$ (σ, ρ)-dominates a subset $U \subseteq V(G)$ if, for every vertex $u \in U \cap D$, we have $|N(u) \cap D| \in \sigma$, and, for every vertex $u \in U \setminus D$, we have $|N(u) \cap D| \in \rho$. A subset D of $V(G)$ is a (σ, ρ)-dominating set (resp. co- (σ, ρ) -dominating set) if D (resp. $V(G) \setminus D$) (σ, ρ)-dominates $V(G)$. A problem is a CONNECTED (σ, ρ) -DOMINATING SET if it consists in finding a connected (σ, ρ) -dominating set of maximum (or minimum) weight. Similarly, one can define the CONNECTED CO- (σ, ρ) -DOMINATING SET problems. Examples are CONNECTED PERFECT DOMINATING SET and CONNECTED VERTEX-COVER³.

Let $d(\mathbb{N}) := 0$, and for a finite or co-finite subset μ of \mathbb{N} , let $d(\mu) := \min(\max(\mu), \max(\mathbb{N} \setminus \mu)) + 1$. Let $d := \max\{1, d(\sigma), d(\rho)\}$. The definition of d is motivated by the following lemma.

► **Lemma 7** ([7]). Let $A \subseteq V(G)$. Let $X \subseteq A$ and $Y, Y' \subseteq \bar{A}$ such that $Y \equiv_A^d Y'$. Then $(X \cup Y)$ (σ, ρ)-dominates A if and only if $(X \cup Y')$ (σ, ρ)-dominates A .

In this section, we present an algorithm that computes a maximum (or minimum) connected (σ, ρ) -dominating set with a graph G and a layout (T, δ) as inputs. Its running time is $O(\text{s-nec}_d(T, \delta)^{O(1)} \cdot n^3)$. The same algorithm, with some little modifications, will be able to find a minimum Steiner tree or a maximum (or minimum) connected co- (σ, ρ) -dominating set as well.

To deal with the local constraint, *i.e.*, the (σ, ρ) -domination, we use the ideas of Bui-Xuan et al. [7]. For every $x \in V(T)$ and all pairs $(R, R') \in \mathcal{R}_{V_x}^d \times \mathcal{R}_{V_x}^d$, we let $\mathcal{A}_x[R, R'] := \{X \subseteq V_x : X \equiv_{V_x}^d R \text{ and } X \cup R' \text{ } (\sigma, \rho)\text{-dominates } V_x\}$. To compute a maximum (or minimum) (σ, ρ) -dominating set, Bui-Xuan et al. [7] proved that it is enough to compute, for each node $x \in V(T)$ and each pair (R, R') , a partial solution X in $\mathcal{A}_x[R, R']$ of maximum (or minimum) weight. Indeed, by Lemma 7, if a partial solution $X \in \mathcal{A}_x[R, R']$ could be completed into a (σ, ρ) -dominating set of G with a set $Y \equiv_{V_x}^d R'$, then it is the case for every partial solution in $\mathcal{A}_x[R, R']$. To deal with the connectivity constraint, for each node x of $V(T)$ and each pair (R, R') , our algorithm will compute a set $\mathcal{D}_x[R, R']$ that satisfies the following invariant.

Invariant. For every $(R, R') \in \mathcal{R}_{V_x}^d \times \mathcal{R}_{V_x}^d$, the set $\mathcal{D}_x[R, R']$ is a subset of $\mathcal{A}_x[R, R']$ of size at most $\text{s-nec}_1(T, \delta)^2$ that (x, R') -represents $\mathcal{A}_x[R, R']$.

Notice that, by the definition of $\mathcal{A}_r[\emptyset, \emptyset]$ (r being the root of T) and the definition of (x, R') -representativity, if G admits a connected (σ, ρ) -dominating set, then $\mathcal{D}_r[\emptyset, \emptyset]$ must contain a maximum (or minimum) connected (σ, ρ) -dominating set.

³ More can be found in [7, Table 1] by adding a connectivity constraint to the sets or their complements.

We compute the tables \mathcal{D}_x 's by a usual bottom-up dynamic programming algorithm, starting at the leaves of T . The computational steps are trivial for the leaves, and for each internal node x with children a and b , and for each $(R, R') \in \mathcal{R}_{V_x}^d \times \mathcal{R}_{V_x}^d$ we let $\mathcal{D}_x[R, R']$ be an (x, R') -representative set of $\left(\bigcup_{(A, A'), (B, B') \text{ } d\text{-}(R, R')\text{-compatible}} \mathcal{A}_a[A, A'] \otimes \mathcal{A}_b[B, B']\right)$ computed with the function `reduce` defined in Section 3. This guarantees that each set $\mathcal{D}_x[R, R']$ contains at most $\mathfrak{s}\text{-nec}_1(T, \delta)^2$ partial solutions. Thanks to Lemma 6, we can state.

► **Theorem 8.** *There exists an algorithm that, given an n -vertex graph G and a rooted layout (T, δ) of G , computes a maximum (or minimum) connected (σ, ρ) -dominating set in time $O(\mathfrak{s}\text{-nec}_d(T, \delta)^3 \cdot \mathfrak{s}\text{-nec}_1(T, \delta)^{2(\omega+1)} \cdot \log(\mathfrak{s}\text{-nec}_d(T, \delta)) \cdot n^3)$ with $d := \max\{1, d(\sigma), d(\rho)\}$.*

As a corollary, we can solve in time $\mathfrak{s}\text{-nec}_1(T, \delta)^{O(1)} \cdot n^3$ the NODE-WEIGHTED STEINER TREE problem that asks, given a subset of vertices $K \subseteq V(G)$ called *terminals*, a subset T of minimum weight such that $K \subseteq T \subseteq V(G)$ and $G[T]$ is connected.

► **Corollary 9.** *There exists an algorithm that, given an n -vertex graph G , a subset $K \subseteq V(G)$, and a rooted layout (T, δ) of G , computes a minimum node-weighted Steiner tree for (G, K) in time $O(\mathfrak{s}\text{-nec}_1(T, \delta)^{2\omega+5} \cdot \log(\mathfrak{s}\text{-nec}_1(T, \delta)) \cdot n^3)$.*

Observe that Corollary 9 simplify and generalize the algorithm from [5] for (EDGE-WEIGHTED) STEINER TREE. Indeed the incidence graph of a graph of tree-width k has tree-width at most $k + 1$, and one can reduce the computation of a edge-weighted Steiner tree on a graph to the computation of a node-weighted Steiner tree on its incidence graph.

With few modifications of the algorithm from Theorem 8, we can state the following.

► **Corollary 10.** *There exists an algorithm that, given an n -vertex graph G and a rooted layout (T, δ) of G , computes a maximum (or minimum) connected $\text{co-}(\sigma, \rho)$ -dominating set in time $O(\mathfrak{s}\text{-nec}_d(T, \delta)^3 \cdot \mathfrak{s}\text{-nec}_1(T, \delta)^{2\omega+5} \cdot \log(\mathfrak{s}\text{-nec}_d(T, \delta)) \cdot n^3)$ with $d := \max\{1, d(\sigma), d(\rho)\}$.*

5 Acyclic variants of (Connected) (σ, ρ) -Dominating Set

We call AC- (σ, ρ) -DOMINATING SET (resp. ACYCLIC (σ, ρ) -DOMINATING SET) the family of problems which consists in finding a subset $X \subseteq V(G)$ of maximum (or minimum) weight such that X is a (σ, ρ) -dominating set of G and $G[X]$ is a tree (resp. a forest). Examples are LONGEST INDUCED PATH and FEEDBACK VERTEX SET.

In this section, we present an algorithm that solves any AC- (σ, ρ) -DOMINATING SET problem. Unfortunately, we were not able to obtain an algorithm whose running time is polynomial in n and the d -neighbor-width of the given layout (for some constant d). But, for the other parameters, by using their respective properties, we get the running time presented in Table 1. Moreover, we show, via a polynomial reduction, that we can use our algorithm for AC- (σ, ρ) -DOMINATING SET problems (with some modifications) to solve any ACYCLIC (σ, ρ) -DOMINATING SET problem.

Let us first explain why we cannot use the same trick as in [5] on the algorithms of Section 4 to ensure the acyclicity, that is classifying the partial solutions X – associated with a node $x \in V(T)$ – with respect to $|X|$ and $|E(G[X])|$. Indeed, for two sets $X, W \subseteq V_x$ with $|X| = |W|$ and $|E(G[X])| = |E(G[W])|$, we have $|E(G[X \cup Y])| = |E(G[W \cup Y])|$, for all $Y \subseteq \overline{V_x}$, if and only if $X \equiv_{V_x}^n W$. Hence, the trick used in [5] would imply to classify the partial solutions with respect to their n -neighbor equivalence class. But, the upper bounds we have on $\text{nec}_n(V_x)$ with respect to module-width, (\mathbb{Q}) -rank-width would lead to an XP algorithm.

17:10 Connectivity and Acyclicity Constraints Versus d -Neighbor Equivalence

In the following, we introduce some new concepts that extends the framework designed in Section 3 in order to manage acyclicity. All along, we give intuitions on these concepts through a concrete example: MAXIMUM INDUCED TREE. Finally, we present the algorithms for the AC- (σ, ρ) -DOMINATING SET problems and the algorithms for ACYCLIC (σ, ρ) -DOMINATING SET problems. We start by defining a new notion of representativity to deal with the acyclicity constraint. This new notion of representativity is defined *w.r.t.* to the 2-neighbor equivalence class of a set $R' \subseteq \overline{V_x}$. We consider 2-neighbor equivalence classes instead of 1-neighbor equivalence classes in order to manage the acyclicity (see the following explanations). Similarly to Section 3, every concept introduced in this section is defined with respect to a node x of T and a set $R' \subseteq \overline{V_x}$. To simplify this section, we fix a node x of T and $R' \subseteq \overline{V_x}$. In our algorithm, R' will always belong to $\mathcal{R}_{\overline{V_x}}^d$ for some $d \in \mathbb{N}^+$ with $d \geq 2$. For MAXIMUM INDUCED TREE $d = 2$ is enough and in general, we use $d := \max\{2, d(\sigma), d(\rho)\}$. The following definition extends Definition 2 of Section 3 to deal with the acyclicity.

► **Definition 11** ((x, R') -acy-representativity). *For every $\mathcal{A} \subseteq 2^{V(G)}$ and $Y \subseteq V(G)$, we define $\text{best}(\mathcal{A}, Y)^{\text{acy}} := \text{opt}\{\text{w}(X) : X \in \mathcal{A} \text{ and } G[X \cup Y] \text{ is a tree}\}$.*

Let $\mathcal{A}, \mathcal{B} \subseteq 2^{V_x}$. We say that \mathcal{B} (x, R') -acy-represents \mathcal{A} if, for every $Y \subseteq \overline{V_x}$ such that $Y \equiv_{\overline{V_x}}^2 R'$, we have $\text{best}^{\text{acy}}(\mathcal{A}, Y) = \text{best}^{\text{acy}}(\mathcal{B}, Y)$.

In order to compute a maximum induced tree, we design an algorithm similar to those of Section 4. That is, for each $(R, R') \in \mathcal{R}_{V_x}^2 \times \mathcal{R}_{\overline{V_x}}^2$, our algorithm will compute a set $\mathcal{D}_x[R, R'] \subseteq 2^{V_x}$ that is an (x, R') -acy-representative set of small size of the set $\mathcal{A}_x[R] := \{X \subseteq V_x \text{ such that } X \equiv_{\overline{V_x}}^2 R\}$. This is sufficient to compute a maximum induced tree of G since we have $\mathcal{A}_r[\emptyset] = 2^{V(G)}$ with r the root of T . Thus, by Definition 11, any $(r, \emptyset)^{\text{acy}}$ -representative set of $\mathcal{A}_r[\emptyset]$ contains a maximum induced tree.

The key to compute the tables of our algorithm is a function that, given $\mathcal{A} \subseteq 2^{V_x}$, computes a small subset of \mathcal{A} that (x, R') -acy-represents \mathcal{A} . This function starts by removing from \mathcal{A} some sets that will never give a tree with a set $Y \equiv_{\overline{V_x}}^2 R'$. For doing so, we characterize the sets $X \in \mathcal{A}$ such that $G[X \cup Y]$ is a tree for some $Y \equiv_{\overline{V_x}}^2 R'$. The following gives a formal definition of these important and unimportant partial solutions.

► **Definition 12** (R' -important). *We say that $X \subseteq V_x$ is R' -important if there exists $Y \subseteq \overline{V_x}$ such that $Y \equiv_{\overline{V_x}}^2 R'$ and $G[X \cup Y]$ is a tree, otherwise, we say that X is R' -unimportant.*

By definition, any set obtained from a set \mathcal{A} by removing R' -unimportant sets is an (x, R') -acy-representative set of \mathcal{A} . The following lemma gives some necessary conditions on R' -important sets. It follows that any set which does not respect one of these conditions can safely be removed from \mathcal{A} . These conditions are the key to obtain the running times of Table 1. At this point, we need to introduce the following notations. For every $X \subseteq V_x$, we define $X^0 := \{v \in X : N(v) \cap R' = \emptyset\}$, $X^1 := \{v \in X : |N(v) \cap R'| = 1\}$, and $X^{2+} := \{v \in X : |N(v) \cap R'| \geq 2\}$. Notice that, for every $Y \equiv_{\overline{V_x}}^2 R'$ and $X \subseteq V_x$, the vertices in X^0 have no neighbor in Y , those in X^1 have exactly one neighbor in Y and those in X^{2+} have at least 2 neighbors in Y .

► **Lemma 13.** *If $X \subseteq V_x$ is R' -important, then $G[X]$ is a forest and the following properties are satisfied:*

1. *for every pair of distinct vertices a and b in X^{2+} , we have $N(a) \cap \overline{V_x} \neq N(b) \cap \overline{V_x}$,*
2. *$|X^{2+}|$ is upper bounded by $2\text{mim}(V_x)$, $2\text{rw}(V_x)$ and $2\text{rw}_{\mathbb{Q}}(V_x)$.*

In order to prove these two necessary conditions, we need the properties of the 2-neighbor equivalence relation. More precisely, we use the fact that, for all $X \subseteq V_x$ and $Y \equiv_{\overline{V_x}}^2 R'$, the vertices in X having at least two neighbors in Y corresponds exactly to those having

at least two neighbors in R' . These vertices play a major role in the acyclicity and the computation of representatives in the following sense. By removing from \mathcal{A} the sets that do not respect the two above properties, we are able to decompose \mathcal{A} into a small number of sets $\mathcal{A}_1, \dots, \mathcal{A}_t$ such that an (x, R') -representative set of \mathcal{A}_i is an $(x, R')^{\text{acy}}$ -representative set of \mathcal{A}_i for each $i \in \{1, \dots, t\}$. We find an $(x, R')^{\text{acy}}$ -representative set of \mathcal{A} , by computing an (x, R') -representative set \mathcal{B}_i for each \mathcal{A}_i with the function `reduce`. This is sufficient because $\mathcal{B}_1 \cup \dots \cup \mathcal{B}_t$ is an $(x, R')^{\text{acy}}$ -representative set of \mathcal{A} . The following definition gives a characterization of the subsets of 2^{V_x} for which an (x, R') -representative set is also an $(x, R')^{\text{acy}}$ -representative set.

► **Definition 14.** We say that $\mathcal{A} \subseteq 2^{V_x}$ is R' -consistent if, for each $Y \subseteq \overline{V_x}$ such that $Y \equiv_{\overline{V_x}}^2 R'$, if there exists $W \in \mathcal{A}$ such that $G[W \cup Y]$ is a tree, then, for each $X \in \mathcal{A}$, either $G[X \cup Y]$ is a tree or $G[X \cup Y]$ is not connected.

The following lemma proves that an (x, R') -representative set of an R' -consistent set is also an $(x, R')^{\text{acy}}$ -representative set of this latter.

► **Lemma 15.** Let $\mathcal{A} \subseteq 2^{V_x}$. For all $\mathcal{D} \subseteq \mathcal{A}$, if \mathcal{A} is R' -consistent and \mathcal{D} (x, R') -represents \mathcal{A} , then \mathcal{D} $(x, R')^{\text{acy}}$ -represents \mathcal{A} .

The next lemma proves that, for each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$, we can decompose a set $\mathcal{A} \subseteq 2^{V_x}$ into a small collection $\{\mathcal{A}_1, \dots, \mathcal{A}_t\}$ of pairwise disjoint subsets of \mathcal{A} such that each \mathcal{A}_i is R' -consistent. Even though some parts of the proof are specific to each parameter, the ideas are roughly the same. First, we remove the sets X in \mathcal{A} that do not induce a forest. If $f = \text{mw}$, we remove the sets in \mathcal{A} that do not respect Condition (1) of Lemma 13, otherwise, we remove the sets that do not respect the upper bound associated with f from Condition (2) of Lemma 13. These sets can be safely removed as, by Lemma 13, they are R' -unimportant. After removing these sets, we obtain the decomposition of \mathcal{A} by taking the equivalence classes of some equivalence relation that is roughly the n -neighbor equivalence relation. Owing to the set of R' -unimportant sets we have removed from \mathcal{A} , we prove that the number of equivalence classes of this latter equivalence relation respects the upper bound associated with f that is described in Table 2.

► **Lemma 16.** Let $\mathcal{A} \subseteq 2^{V_x}$. For each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$, there exists a collection $\{\mathcal{A}_1, \dots, \mathcal{A}_t\}$ of pairwise disjoint subsets of \mathcal{A} computable in time $O(|\mathcal{A}| \cdot \mathcal{N}_f(T, \delta) \cdot n^2)$ such that (1) $\mathcal{A}_1 \cup \dots \cup \mathcal{A}_t$ $(x, R')^{\text{acy}}$ -represents \mathcal{A} , (2) \mathcal{A}_i is R' -consistent for each $i \in \{1, \dots, t\}$, and (3) $t \leq \mathcal{N}_f(T, \delta)$; where $\mathcal{N}_f(T, \delta)$ is the term defined in Table 2.

■ **Table 2** Upper bounds $\mathcal{N}_f(T, \delta)$ on the size of the decomposition of Lemma 16 for each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$.

f	mw	rw _Q	rw	mim
$\mathcal{N}_f(T, \delta)$	$2^{\text{mw}(T, \delta)} \cdot 2n$	$2^{\text{rw}_{\mathbb{Q}}(T, \delta) \log_2(2\text{rw}_{\mathbb{Q}}(T, \delta) + 1)} \cdot 2n$	$2^{2\text{rw}(T, \delta)^2} \cdot 2n$	$2n^{2\text{mim}(T, \delta) + 1}$

We are now ready to give an adaptation of Theorem 3 to the notion of $(x, R')^{\text{acy}}$ -representativity.

► **Theorem 17.** Let $R \in \mathcal{R}_{V_x}^2$. For each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$, there exists an algorithm `reducefacy` that, given a set \mathcal{A} such that $X \equiv_{V_x}^2 R$ for every $X \in \mathcal{A}$, outputs in time $O((\text{nec}_1(V_x)^{2(\omega-1)} + \mathcal{N}_f(T, \delta)) \cdot |\mathcal{A}| \cdot n^2)$, a subset $\mathcal{B} \subseteq \mathcal{A}$ such that \mathcal{B} $(x, R')^{\text{acy}}$ -represents \mathcal{A} and $|\mathcal{B}| \leq \mathcal{N}_f(T, \delta) \cdot \text{nec}_1(V_x)^2$.

17:12 Connectivity and Acyclicity Constraints Versus d -Neighbor Equivalence

Now, The algorithm for any AC- (σ, ρ) -DOMINATING SET problem is essentially the same as the algorithm from Theorem 8, except that we use $\text{reduce}_f^{\text{acy}}$ instead of reduce .

► **Theorem 18.** *For each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$, there exists an algorithm that, given an n -vertex graph G and a rooted layout (T, δ) of G , solves any AC- (σ, ρ) -DOMINATING SET problem, in time $O(\text{s-nec}_d(T, \delta)^3 \cdot \text{s-nec}_1(T, \delta)^{2(\omega+1)} \cdot \mathcal{N}_f(T, \delta)^2 \cdot \log(\text{s-nec}_d(T, \delta)) \cdot n^3)$, with $d := \max\{2, d(\sigma), d(\rho)\}$.*

By constructing for any graph G a graph G' such that the width measure of G' is linear in the width measure of G , and any optimum acyclic (σ, ρ) -dominating set of G corresponds to an optimum AC- (σ, ρ) -dominating set of G' and vice-versa, we obtain the following which allows for instance to compute a feedback vertex set in time $n^{O(c)}$, c the mim-width.

► **Theorem 19.** *For each $f \in \{\text{mw}, \text{rw}, \text{rw}_{\mathbb{Q}}, \text{mim}\}$, there exists an algorithm that, given an n -vertex graph G and a rooted layout (T, δ) of G , solves any ACYCLIC (σ, ρ) -DOMINATING SET problem in time $O(\text{s-nec}_d(T, \delta)^{O(1)} \cdot \mathcal{N}_f(T, \delta)^{O(1)} \cdot n^3)$ with $d := \max\{2, d(\sigma), d(\rho)\}$.*

6 Conclusion

Prior to this work, the d -neighbor-equivalence relation was used only for problems with a locally checkable property like DOMINATING SET [7, 13, 19]. We prove that the d -neighbor-equivalence relation can also be useful for problems with a connectivity constraint and an acyclicity constraint. Is this notion also useful for other kinds of problems? Can we use it for the problems which are unlikely to admit FPT algorithms parameterized by clique-width, \mathbb{Q} -rank-width or rank-width? This is the case for well-known problems such as HAMILTONIAN CYCLE, EDGE DOMINATING SET, and MAX CUT. The complexity of these problems parameterized by clique-width is well-known. Indeed, for each of these problems, we have an ad-hoc $n^{O(k)}$ time algorithm with k the clique-width of a given k -expression [4, 11]. On the other hand, little is known concerning rank-width and \mathbb{Q} -rank-width. For mim-width, we know that HAMILTONIAN CYCLE is para-NP-hard parameterized by the mim-width of a given rooted layout [15].

As these problems are W[1]-hard parameterized by clique-width, we cannot expect to rely only on the d -neighbor equivalence relation for d a constant. Maybe, we can avoid this dead-end by using the n -neighbor equivalence relation. In fact, we prove the following theorem for MAX CUT.

► **Theorem 20.** *There exists an algorithm that, given an n -vertex graph G and a rooted layout (T, δ) , solves MAX CUT in time $O(\text{s-nec}_n(T, \delta)^2 \cdot \log(\text{s-nec}_n(T, \delta)) \cdot n^3)$.*

Consequently, this theorem implies the existence of $n^{O(\text{mw}(\mathcal{L}))}$, $n^{O(\text{rw}_{\mathbb{Q}}(G))}$ and $n^{2^{O(\text{rw}(G))}}$ time algorithms for MAX CUT. Notice that, unless ETH fails, there are no $n^{o(\text{mw}(\mathcal{L}))}$ and $n^{o(\text{rw}_{\mathbb{Q}}(G))}$ time algorithms for MAX CUT [11].

Abstract

Semi-online models where decisions may be revoked in a limited way have been studied extensively in the last years.

This is motivated by the fact that the pure online model is often too restrictive to model real-world applications, where some changes might be allowed. A well-studied measure of the amount of decisions that can be revoked is the migration factor β : When an object o of size $s(o)$ arrives, the decisions for objects of total size at most $\beta \cdot s(o)$ may be revoked. Usually β should be a constant. This means that a small object only leads to small changes. This measure has been successfully investigated for different, classical problems such as bin packing or makespan minimization. The dual of makespan minimization – the Santa Claus or machine covering problem – has also been studied, whereas the dual of bin packing – the bin covering problem – has not been looked at from such a perspective.

In this work, we extensively study the bin covering problem with migration in different scenarios. We develop algorithms both for the static case – where only insertions are allowed – and for the dynamic case, where items may also depart. We also develop lower bounds for these scenarios both for amortized migration and for worst-case migration showing that our algorithms have nearly optimal migration factor and asymptotic competitive ratio (up to an arbitrary small ε). We therefore resolve the competitiveness of the bin covering problem with migration.

1 Introduction

Online algorithms aim to maintain a competitive solution without knowing future parts of the input. The competitive ratio of such an algorithm (for a maximization problem) is thus defined as the worst-case ratio between the value of an optimal solution produced by an offline algorithm knowing the complete input and the value of the solution produced by the online algorithm. Furthermore, once a decision is made by these algorithms, this decision is fixed and irreversible. While a surprisingly large number of problems do have such algorithms, the complete irreversibility requirement is often too strict, leading to high competitive ratios. Furthermore, if the departure of objects from the instance is also allowed, irreversible online algorithms are rarely able to be competitive at all. From a practical point of view, this is quite alarming, as the departure of objects is part of many applications. We call such a problem *dynamic* and the version with only insertions *static*.

A number of different scenarios to loosen the strict requirement of irreversibility – called *semi-online* scenarios – have been developed over time in order to find algorithms that achieve good competitive ratios for some of the scenarios with bounded reversibility. In the last few years, the concept of the *migration factor* has been studied intensively [3, 10, 11, 12, 13, 16, 19, 21, 22]. Roughly speaking, a migration factor of β allows to reverse a total size of $\beta \cdot s(o)$ decisions, where $s(o)$ denotes the *size* of the newly arrived object o . For a packing problem, this means that the algorithm is allowed to repack objects with a total size of $\beta \cdot s(o)$. This notion of reversibility is very natural, as it guarantees that a small object can only lead to small changes in the solution structure. Furthermore, algorithms with bounded migration factor often show a very clear-cut tradeoff between their migration and the competitive ratio: Many algorithms in this setting have a bounded migration factor which can be defined as a function $f(\varepsilon)$ (growing with $\frac{1}{\varepsilon}$) and a small competitive ratio $g(\varepsilon)$ (growing with ε), where the functions f and g can be defined for all $\varepsilon > 0$ [3, 10, 13, 16, 19, 21, 22]. Such algorithms are called *robust*, as the amount of reversibility allowed only depends on the solution guarantee that one wants to achieve. Such robust algorithms thus serve as evidence for the possibility for sensitivity analysis in approximated settings.

Many different problems have been studied in online and semi-online scenarios, but two problems that have been considered in nearly every scenario are classical scheduling problems: The *bin packing* problem and the *makespan minimization* problem. Both of these problems have been studied intensively in the migration model [3, 10, 12, 13, 19, 21, 22]. Both of these problems also have corresponding dual maximization variants. The dual version of the makespan minimization problem, often called the *Santa Claus* or *machine covering* problem, has also been studied with migration [16, 22]. In contrast, the dual version of bin packing, called *bin covering* has not yet been studied in this model. The aim of this paper is to remedy this situation by taking a look at this classical scheduling problem in the migration model.

Formal Problem Statement. In the *bin covering problem*, a set of items Γ with sizes $s: \Gamma \rightarrow (0, 1]$ is used to cover as many unit sized bins as possible, that is, Γ has to be partitioned maximizing the number of partitions with summed up item size of at least one. An instance of the problem will usually be denoted as I and is given as a sequence of entries $(i, s(i))$ where i is the identifier of the item and $s(i)$ is the size of the item. A *solution* to such an instance I with items Γ is a partition $P: \Gamma \rightarrow \mathbb{N}$ and a set $B = P^{-1}(k)$ with $B \neq \emptyset$ is called a *bin* and we say that the items in B are packed into the k -th bin. A bin B is *covered* if $s(B) := \sum_{i \in B} s(i) \geq 1$, where $s(B)$ is called the load of B , and the goal is to maximize the number of such covered bins. The optimal (maximum) number of covered bins of instance I is denoted as $\text{OPT}(I)$.

We also use the following notation throughout our work: The smallest size of an item in bin B is defined as $s_{\min}(B) := \min_{i \in B} \{s(i)\}$ and the largest size is defined as $s_{\max}(B) := \max_{i \in B} \{s(i)\}$. If \mathcal{B} is a set of bins, we also define its total size $s(\mathcal{B}) := \sum_{B \in \mathcal{B}} s(B)$, its minimal size $s_{\min}(\mathcal{B}) := \min_{B \in \mathcal{B}} s_{\min}(B)$, and its maximal size $s_{\max}(\mathcal{B}) := \max_{B \in \mathcal{B}} s_{\max}(B)$. Furthermore, we define $s_{\min}(\emptyset) = +\infty$ and $s_{\max}(\emptyset) = 0$.

We consider variants of static and dynamic online bin covering in which algorithms are allowed to reassign a bounded amount of previously assigned items. In particular, an algorithm has a *migration factor* of β , if the total size of items that it reassigns upon arrival or departure of an item of size s is bounded by βs . Moreover, it has an *amortized migration factor* of β , if at any time the total size of items that have been reassigned by the algorithm in total is bounded by βS , where S is the total size of all items that arrived before. Intuitively, an item of size s creates a migration potential of size βs upon arrival, and this potential may be used by an algorithm to reassign items right away (non-amortized) or anytime from then on (amortized). Note that if an algorithm has a non-amortized migration factor of β , it also has an amortized migration factor of at most β . Thus, we study four variants in this work.

Offline bin covering is NP-hard and therefore there is little hope for a polynomial time algorithm solving the problem to optimality, and in the online setting there is no algorithm that can maintain an optimal solution regardless of its running time. We prove that this non-existence of algorithms that maintain an optimal solution holds also for (static or dynamic) algorithms with bounded amortized migration factor (and thus also for algorithms with bounded non-amortized migration factor).

Hence, algorithms satisfying some performance guarantee are studied. In particular an offline algorithm ALG for a maximization problem has an *asymptotic performance guarantee* of $\alpha \geq 1$, if $\text{OPT}(I) \leq \alpha \cdot \text{ALG}(I) + c$, where $\text{OPT}(I)$ and $\text{ALG}(I)$ are the objective values of an optimal solution or the one produced by ALG respectively for some instance I , and c is an input independent constant. If $c = 0$ holds, α is called *absolute* rather than asymptotic. An online algorithm has a (asymptotic or absolute) *competitive ratio* of α , if after each arrival or departure an (asymptotic or absolute) performance guarantee of α for the instance of the present items holds. Note that we use the convention of competitive ratios larger than 1 for maximization problems. For minimization problems similar definitions are used but they use the required inequality $\text{ALG}(I) \leq \alpha \cdot \text{OPT}(I) + c$. As we study asymptotic competitive ratios in this paper, we will sometimes omit the word asymptotic (and we always use the word absolute for absolute competitive ratios).

Our Results. We present competitive algorithms using both amortized migration and non-amortized migration and develop nearly matching lower bounds (up to an arbitrarily small additive term of ε). These bounds show the optimality of all of our algorithms for both the static and the dynamic version of the bin covering problem. The main technical contribution of our work is an algorithm with competitive ratio $3/2 + \varepsilon$ and non-amortized migration of $\mathcal{O}(1/\varepsilon^5 \cdot \log^2(1/\varepsilon))$ for the dynamic bin covering problem where items arrive and depart. A major obstacle in the design of competitive algorithms for dynamic problems is the impossibility of moving large items on the arrival or departure of small items. We overcome this obstacle by developing a delicate technique to combine the packing of large and small items. The main results of this work are summarized in the following table. Note that the lower bound of 1 in the third row indicates that there is no online algorithm that maintains an optimal solution with amortized migration factor $\mathcal{O}(1)$. All of our algorithms run in polynomial time. Curiously, we achieve a polynomial migration factor, while most known migration factors are exponential (e.g. for the makespan minimization problem [21]) with the exception of bin packing [3, 18].

Amortization	Departures	Lower Bound	Competitive Ratio	Migration
✘	✘	3/2	$3/2 + \varepsilon$	$\mathcal{O}(1/\varepsilon)$
✘	✓	3/2	$3/2 + \varepsilon$	$\mathcal{O}(1/\varepsilon^5 \cdot \log^2(1/\varepsilon))$
✓	✘	1	$1 + \varepsilon$	$\mathcal{O}(1/\varepsilon)$
✓	✓	3/2	$3/2 + \varepsilon$	$\mathcal{O}(1/\varepsilon^5 \cdot \log^2(1/\varepsilon))$

Due to space constraints, we focus on the non-amortized case with only insertions (described in the first row) and prove most of the corresponding results here. The remaining results are shortly described and a full presentation of them is given in the appendix.

Related Results

Bin Covering. The offline bin covering problem was first studied by Assmann et al. [1]. It was shown that a simple greedy strategy achieves approximation ratio 2. For the online version of the bin covering problem, Csirik and Totik showed in [6] that this simple greedy algorithm also works in the online setting and that the competitive ratio of 2 reached by this algorithm is the best possible. Csirik, Johnson, and Kenyon presented an asymptotic polynomial time approximation scheme (APTAS) with approximation ratio $1 + \varepsilon$ in [5]. This was improved to an asymptotic fully polynomial time approximation scheme (AFPTAS) by Jansen and Solis-Oba in [20]. Many different variants of this problem have also been investigated: If a certain number of classes needs to be part of each bin [9, 15]; if items are drawn probabilistically [14, 15]; if bins have different sizes [7, 23]; if the competitiveness is not measured with regard to an optimal offline algorithm [4, 8]. More variants are e. g. discussed in [17] and lower bounds for several variants are studied in [2].

Makespan Minimization and Santa Claus. The migration factor model was introduced by Sanders, Sivadasan, and Skutella in [21]. The paper investigated several algorithms for the makespan minimization problem and also presents an approximation scheme with absolute competitive ratio $1 + \varepsilon$ and non-amortized migration factor $2^{O(1/\varepsilon \log^2(1/\varepsilon))}$. Skutella and Verschae [22] studied a dynamic setting with amortized migration, where jobs may also depart from the instance. They achieved the same absolute competitive ratio, but their algorithm needs an amortized migration of $2^{O(1/\varepsilon \log^2(1/\varepsilon))}$. Their algorithm also works for the Santa Claus (or machine covering) problem, for which they show that even in the static setting no algorithm has absolute competitive ratio $1 + \varepsilon$ and a bounded migration factor. If one aims for a polynomial migration factor for the Santa Claus problem, Gálvez, Soto, and Verschae presented an online variant of the LPT (longest processing time) algorithm achieving an absolute competitive ratio of $4/3 + \varepsilon$ with non-amortized migration factor $O(1/\varepsilon^3 \log(1/\varepsilon))$ [16]. For the makespan minimization problem with preemption, Epstein and Levin showed in [12] that an optimal algorithm with a non-amortized migration factor of $1 - 1/m$ is achievable and best possible.

Bin Packing. Epstein and Levin presented an approximation scheme with the same ratio $1 + \varepsilon$ and the same non-amortized migration factor $2^{O(1/\varepsilon \log^2(1/\varepsilon))}$ as in the makespan minimization for the bin packing problem in [10]. This result was improved by Jansen and Klein in [18], who drastically reduced the migration factor to $O(1/\varepsilon^4)$. Berndt, Jansen, and Klein used a similar approach to also handle the dynamic bin packing problem, where items may also depart over time [3]. They also showed that a non-amortized migration factor of $\Omega(1/\varepsilon)$ is needed for this. A generalized model, where an item i has arbitrary

movement costs c_i – not necessarily linked to the size of an item – was studied by Feldkord et al. [13]. They showed that for $\alpha \approx 1.387$ and every $\varepsilon > 0$, a competitive ratio of $\alpha + \varepsilon$ is achievable with migration $O(1/\varepsilon^2)$, but no algorithm with migration $o(n)$ and ratio $\alpha - \varepsilon$ exists. Strengthening the lower bound of [3], they also showed an amortized migration factor of $\Omega(1/\varepsilon)$ is needed for the standard model, where movement costs c_i equal items sizes s_i , if one wants to achieve competitive ratio $1 + \varepsilon$. A generalization of bin packing – packing d -dimensional cubic items into unit size cubes – was studied by Epstein and Levin [11].

2 Non-amortized Migration in the Static Case

We begin our study by analyzing the static case with non-amortized migration. We will first present a lower bound showing that no algorithm with constant non-amortized migration factor can have a competitive ratio below $3/2$. Then, we present an algorithm that achieves for all $\varepsilon > 0$ a competitive ratio of $3/2 + \varepsilon$ with non-amortized migration factor $O(1/\varepsilon)$.

We start with a simple lower bound on the asymptotic competitive ratio of all algorithms with constant non-amortized migration factor. This lower bound can also be proved for a different definition of the asymptotic competitive ratio α , where we require $\text{OPT}(I) \leq \alpha \cdot \text{ALG}(I) + o(\text{OPT}(I))$.

► **Proposition 1.** *There is no algorithm for static online bin covering with a constant non-amortized migration factor and an asymptotic competitive ratio smaller than $3/2$.*

Proof sketch. Fix a migration factor β and an integer N . First, insert $6N$ items of size $1 - \varepsilon$ and then $6N$ items of size ε , where $\varepsilon = \min\{(2\beta + 2)^{-1}\}$. ◀

We will now give our algorithm ALG for this scenario. In addition to the instance I , a parameter $\varepsilon > 0$ is also given that regulates the asymptotic competitive ratio and the used migration. The assumption $\varepsilon \leq 0.5$ is justified as for $\varepsilon \geq 0.5$, the result follows by the online algorithm with an asymptotic competitive ratio of 2 presented in [6], or by using the algorithm below with $\varepsilon = \frac{1}{2}$.

► **Theorem 2.** *For each $\varepsilon \in (0, 0.5]$, there is an algorithm ALG for static online bin covering with polynomial running time, an asymptotic competitive ratio of $1.5 + \varepsilon$ with additive constant 3, and a non-amortized migration factor of $\mathcal{O}(1/\varepsilon)$.*

The algorithm distinguishes between big, medium and small items. For each item, it calls a corresponding insertion procedure based on this classification into three classes. An item i is called *big* if $s(i) \in (0.5, 1]$, *medium* if $s(i) \in (\varepsilon, 0.5]$, and *small* otherwise. For a bin B , let $\text{small}(B)$ be the set of small items of B . We define $\text{medium}(B)$ and $\text{big}(B)$ accordingly and also extend these notions to sets of bins \mathcal{B} . Furthermore, we call a covered bin *barely covered*, if removing the biggest item of the smallest class of items, i. e. big, medium or small, contained in the bin, results in the bin not being covered anymore. For instance, consider a bin containing four items with sizes $0.65, 0.3, \varepsilon$ and 0.25ε , for $\varepsilon \geq 0.04$. This bin contains items of all three classes if $\varepsilon < 0.3$. In this case, the biggest item of the smallest class has size ε , and if $\varepsilon = 0.1$, the bin is indeed barely covered. However, if $\varepsilon = 0.22$, the bin is not barely covered. If $\varepsilon = 0.3$, the bin only has items of two classes, and it is not barely covered, since removing one item of size 0.3 results in a total size above 1. Note that showing that removing an arbitrary item of the smallest class of items for a given covered bin results in an uncovered bin is sufficient for showing that it is barely covered.

Let B be a barely covered bin. If B contains at most one big item, its load is bounded from above by 1.5, and if B additionally contains no medium item the bound is reduced to $1 + \varepsilon$. This holds due to the following. Since the big item has size below 1, the bin contains at

least one medium or small item. If the bin has no small items, removing the largest medium item reduces the load to below 1, and together with the medium item the load is below 1.5. If it has a small item, a similar calculation shows that the load is below $1 + \varepsilon$.

The last two types of bins are benign in the sense that they allow analysis using arguments that are based on sizes. This is not the case for bins containing two big items. Such bins could have a size arbitrarily close to 2 (even if they have no other items). Bins of this type are needed for instances with many big items (for an example we refer to the construction of the lower bound in Proposition 1). However, they cause problems not only because they are wastefully packed, but also because they exclusively contain big items that should only be moved if suitably large items arrive in order to bound migration. The basic idea of the algorithm is to balance the number of bins containing two big items and the number of bins containing one big item and no medium items. The two numbers will be roughly the same, which is obtained using migration on arrivals of big and medium items. As described in the previous paragraph, the guarantees of these bins that are based on loads cancel each other out in the sense that an average load not exceeding $1.5 + \varepsilon/2$ can be achieved. In order to keep the number of bins with two big items in check, our algorithm will only produce very few bin types and we will maintain several invariants. This structured approach allows us also to bound the migration needed. We elaborate on the details of the algorithm.

Bin Types and Invariants

We distinguish different types of bins packed by the algorithm.

The bins are partitioned into bins containing two big items (and no other items) **BB**; barely covered bins containing one big item and some medium items **BM**; *barely covered* bins containing one big item and some small items **BSC**; bins that are not covered (*partially covered*) and contain one big item and no medium items (but it could contain small items) **BSP**; and bins that are at most barely covered (they are barely-covered, or not covered) and exclusively contain small or medium items **S** or **M** respectively. Furthermore, let $MC \subseteq M$ and $SC \subseteq S$ be the corresponding subsets of barely covered bins (while $M \setminus MC$ and $S \setminus SC$ are sets of bins that are not covered). We denote the (disjoint) union of **BSC** and **BSP** as **BS**. The set of bins packed by the algorithm (covered or not covered) is denoted as **Bins**. All bins covered by the algorithm are in fact barely covered, and no bin (covered or not) contains items of all three classes. Among bins that are not covered, there are no bins containing a big item and a non-empty set of medium items.

We will now introduce the invariants needed. The first invariant of the algorithm ensures that this bin structure is maintained and the second invariant was already indicated above ($A \dot{\cup} B$ denotes the disjoint union of A and B):

I1 The solution has the proposed bin type structure, i. e. $\text{Bins} = \text{BB} \dot{\cup} \text{BM} \dot{\cup} \text{BS} \dot{\cup} \text{M} \dot{\cup} \text{S}$ and $\text{BS} = \text{BSC} \dot{\cup} \text{BSP}$.

I2 The sets **BB** and **BS** are balanced in size, i. e. $||\text{BB}| - |\text{BS}|| \leq 1$.

Therefore we have $\text{ALG}(I) = |\text{BB}| + |\text{BM}| + |\text{BSC}| + |\text{MC}| + |\text{SC}|$. Furthermore, we have several invariants concerning the distribution of items to different bin types. The intuition behind these invariants is always the same: We have to ensure that no other algorithm is able to use the small and medium items to cover too many bins.

I3 The big items contained in **BM** are at least as big as the ones in **BSC** which in turn are at least as big as the ones in **BSP**, and the smallest big items are placed in **BB**, i. e. $s(i) \geq s(i')$ for each (i) $i \in \text{big}(\text{BM})$ and $i' \in \text{big}(\text{BS} \cup \text{BB})$; each (ii) $i \in \text{big}(\text{BM} \cup \text{BSC})$ and $i' \in \text{big}(\text{BSP} \cup \text{BB})$; each (iii) $i \in \text{big}(\text{BM} \cup \text{BS})$ and $i' \in \text{big}(\text{BB})$. Informally, $\text{BB} \leq \text{BSP} \leq \text{BSC} \leq \text{BM}$.

I4 The items in M cannot be used to cover a bin together with a big item from BS or BB , i. e. $BS \cup BB \neq \emptyset \implies s(M) < 1 - s_{\max}(BS \cup BB)$.

I5 If a bin containing only small items exists, all bins in BS are covered, i. e. $|S| > 0 \implies |BSP| = 0$.

Lastly, there are some bin types with bins that are not covered, and we have to make sure that they are not wastefully packed:

I6 If there are small items in BSP , they are all included in the bin containing the biggest item in BSP .

I7 Both S and M each contain at most one bin that is not covered.

This concludes the definition of all invariants. It is easy to see that the invariants all hold in the beginning when no item has arrived yet. Next, we describe the insertion procedures and argue that the invariants are maintained.

Insertion Procedures

We start with the definition of two simple auxiliary procedures used in the following:

- **GreedyPush**(i, \mathcal{B}) is given an item i and a set of bins \mathcal{B} . If all the bins contained in \mathcal{B} are covered, it creates a new bin containing item i , and otherwise it inserts i into the most loaded bin that is not covered.
- **GreedyPull**(B, \mathcal{B}) is given bin B and a set of bins \mathcal{B} . It successively removes a largest non-big item from a least loaded bin from $\{B' \in \mathcal{B} \mid \text{small}(B') \cup \text{medium}(B') \neq \emptyset\}$ and inserts it into B . This is repeated until B is covered or \mathcal{B} does not contain non-big items.

Consider one application of **GreedyPull** such that B already has a big item. The total size of moved items is smaller than 1. Both procedures are used to insert and repack non-big items. Note that calling **GreedyPush** for a small item and bin set BSP or S , or a medium item and bin set M , the last two invariants **I6** and **I7** are maintained. For BSP , the most loaded bin always contains the largest big item, and if there is at least one small item, such a bin is unique. It could happen that as a result of inserting a small item into this bin of BSP the bin is covered and moves to BSC .

For each insertion procedure, we will argue that the invariants are maintained and focus on the critical ones, that is, in each context the invariants, that are not discussed explicitly, trivially hold. For example, we do not discuss **I1** in the following, because it will always be easy to see that it is maintained.

Insertion of Small Items. If the arriving item i^* is small, we call **GreedyPush**(i^*, BSP), if $BSP \neq \emptyset$, and **GreedyPush**(i^*, S) otherwise. Insertion into a bin of BSP (the most loaded one) may lead to a covered bin, in which case the bin becomes a bin of BSC (but remains in BS). It is easy to verify, that all invariants, and **I5**, **I6** and **I7** in particular, are maintained by this. As mentioned above, **I3** holds, as the most loaded bin in BSP always contains the largest big item. Furthermore, there is no migration in this case. The insertion of a medium or big item, however, is more complicated.

Insertion of Big Items. In the case that a big item i^* arrives, we have to be careful where we place it exactly, because, on the one hand, the distributions of big and medium items, that is, invariants **I3** and **I4**, have to be maintained, and, on the other hand, we have to balance out BS and BB (**I2**). We consider placing the item in BM , BS or BB in this order, i. e. we first try to insert i^* into BM , then into BS and finally into BB . Figure 1 illustrates this.

Insertion into BM. We insert i^* into BM, if either $s(i^*) + s(\mathbf{M}) \geq 1$ or $s(i^*) > s_{\min}(\text{big}(\mathbf{BM}))$. Note that the first condition implies $s(i^*) \geq s_{\max}(\text{big}(\mathbf{BB} \cup \mathbf{BS}))$, because of I4, and therefore the insertion of i^* into BM maintains I3 in both situations. The second condition implies $\mathbf{BM} \neq \emptyset$, because we set $s_{\min}(\emptyset) = +\infty$. In either of these cases, we create a new bin $B^* = \{i^*\}$ and call $\text{GreedyPull}(B^*, \mathbf{M})$, thereby ensuring that I4 is maintained if the new bin is covered. If the first condition did hold, B^* is covered afterwards and we do nothing else. Otherwise, there is a bin $B \in \mathbf{BM}$ containing a big item i with $s(i) = s_{\min}(\text{big}(\mathbf{BM})) < s(i^*)$, and we have $\mathbf{M} = \emptyset$. We remove i from B , yielding $\mathbf{M} = \{B\}$, and call $\text{GreedyPull}(B^*, \mathbf{M})$ a second time. Afterwards, B^* is covered, because $s(i^*) > s(i)$. Furthermore, $s(i) + s(\mathbf{M}) < 1$, because B was barely covered before and the biggest medium item was removed from B due to the second call of GreedyPull . This ensures I4, since by I3, item i is no smaller than any big item packed in BS or BB. The item i is reinserted using a recursive call to the procedure of inserting a big item. However, item i will not be considered for insertion into BM, because neither the first nor second condition holds for this item, and the other insertion options have no recursive calls for insertion into BM. It is easy to verify that the distribution of medium items in \mathbf{M} (I7) is maintained.

Insertion into BS. This step is possible only for item i^* that satisfies $s(i^*) + s(\mathbf{M}) < 1$ and $s(i^*) \leq s_{\min}(\text{big}(\mathbf{BM}))$. Thus, \mathbf{BM} will have the largest big items as required in Invariant I3 after the insertion is performed. In this case there is no recursive call for inserting a big item.

We insert i^* into BS, if either $s(i^*) > s_{\min}(\text{big}(\mathbf{BS}))$ or the following two conditions hold: $s(i^*) \geq s_{\max}(\text{big}(\mathbf{BB}))$ and $|\mathbf{BS}| \leq |\mathbf{BB}|$. Note that $s(i^*) \geq s_{\max}(\text{big}(\mathbf{BB}))$ trivially holds, if $\mathbf{BB} = \emptyset$. Inserting i^* into BS under these conditions already ensures the correct distribution of big items (I3) with respect to BS and BB, but we still have to be careful concerning the distribution within the two subsets of BS. The procedure is divided into three simple steps. As a first step, we create a new bin $B^* = \{i^*\}$ and call $\text{GreedyPull}(B^*, \mathbf{S})$. No matter whether B^* is now covered or not, Invariant I5 is satisfied as either B^* is covered and therefore $\mathbf{BSP} = \emptyset$ both before and after the call, or B^* is not covered but now $\mathbf{S} = \emptyset$ (it is possible that both will hold). Note that all properties of the invariants are satisfied, if B^* is already covered. In particular, Invariant I3 holds within BS because $\mathbf{BSP} = \emptyset$. In the remainder of the second step of the insertion into BS algorithm we deal with the case that B^* is not covered.

Let \mathbf{XB} denote the set of bins $B \in \mathbf{BS}$ that include small items as well as a big item i with $s(i) < s(i^*)$. Recall that any bin of BSC has at least one small item, while at most one bin of BSP has small items.

First, assume that $\mathbf{XB} = \emptyset$ but B^* is not covered. There are two cases. In the first case, at least one item of \mathbf{S} was moved. In this case before we started dealing with i^* , the set \mathbf{BSP} was empty, and now B^* is the unique bin of \mathbf{BSP} , and its big item is not larger than those of BSC (if the last set is not empty) so the invariants I3 and I6 are maintained. In the second case, \mathbf{S} was empty, and B^* is now a bin of \mathbf{BSP} with only a big item. Since $\mathbf{XB} = \emptyset$, adding B^* to \mathbf{BSP} maintains the invariants I3 and I6. Thus, it is left to deal with the case $\mathbf{XB} \neq \emptyset$. In the remainder of the second step of the insertion into BS algorithm we deal with the case that \mathbf{XB} is not empty.

As B^* is not yet covered, we now have $\mathbf{S} = \emptyset$, and this might have been the case before the call of GreedyPull , in particular if we had $\mathbf{BSP} \neq \emptyset$. Due to the existence of a big item that is smaller than i^* in BS (such items exist in all bins of \mathbf{XB}), we have to be careful in order to maintain the correct distribution of big and small items inside of BS (I3 and I6).

In the second step, we construct a set of bins $\tilde{\mathbf{B}} \subseteq \mathbf{BS}$ from which small items are removed in order to cover B^* . If $\mathbf{BSP} \cap \mathbf{XB} \neq \emptyset$, this set has exactly one bin (containing small items) by Invariant I6. If such a bin exists, we denote it by B_1 . If $\mathbf{BSC} \cap \mathbf{XB} \neq \emptyset$, the set BSC includes

a bin that contains a big item i' with $s_{\min}(\text{big}(\text{BSC})) = s(i') < s(i^*)$ and we denote one such bin (with a big item of minimum size in BSC) by B_2 . As $\text{XB} \neq \emptyset$, at least one of the bins B_1 or B_2 must exist, but it can also be the case that both exist. Let $\tilde{\text{B}}$ be the set of cardinality 1 or 2, which contains these bins. The next operation of the second step is to call $\text{GreedyPull}(B^*, \tilde{\text{B}})$. It is easy to see that no matter whether B^* is covered or not after this operation, the invariants I3 and I6 hold. Specifically, if B_2 does not exist, B^* is not necessarily covered, but I3 and I6 hold as all big items of BSC are not smaller than i^* (as every such bin has at least one small item). If B_2 exists, then B^* keeps receiving items coming first from B_1 and then possibly also from B_2 , until it is covered. As the total size of small items of B_2 is sufficient for covering B^* since the big item of B_2 is smaller than i^* , B^* will be covered, so all big items of BSP are not larger than i^* .

Lastly, we describe the third step, which is performed for all cases above, after i^* has been inserted. The insertion of i^* might have violated I2, that is, we now have $|\text{BS}| = |\text{BB}| + 2$. In this case, we perform the last step, namely, we select two bins $B_3, B_4 \in \text{BS}$ with minimal big items, merge the big items into a BB bin and remove and reinsert all small items from B_3 and B_4 , using insertion of small items. This yields, $|\text{BS}| = |\text{BB}| - 1$ and I2 holds.

Insertion into BB. If i^* was not inserted in any of the last steps, it is inserted into BB. In this case, we know from the conditions above that $s(i^*) \leq s_{\min}(\text{big}(\text{BS} \cup \text{BM}))$, and additionally that $s(i^*) \geq s_{\max}(\text{big}(\text{BB}))$ implies $|\text{BS}| = |\text{BB}| + 1$. We consider two cases.

If $|\text{BS}| = |\text{BB}| + 1$ (and hence $\text{BS} \neq \emptyset$), we select a bin $B \in \text{BS}$ with a big item of minimal size. We insert i^* into B to obtain a BB bin and remove and reinsert all small items from B . This yields $|\text{BS}| = |\text{BB}| - 1$ and I2 holds.

If $|\text{BS}| < |\text{BB}| + 1$, we have $s(i^*) < s_{\max}(\text{big}(\text{BB}))$ (and hence $\text{BB} \neq \emptyset$). In this case, we select a bin $B \in \text{BB}$ with a big item i of maximal size, insert i^* into B , and remove and reinsert i . Because of its size and invariant I4, the item i will be inserted into BS. Note that in both cases invariant I3 is maintained.

Figure 1 Insertion of a big item i^* . Big items are drawn in dark gray, medium items in light gray, and small items in white.

Insert into BM: open a new bin B^* for i^* ; pull M into B^* ; pull from bin $B \in \text{BM}$ containing the smallest big item i ; remove and reinsert i .

Insert into BS: open a new bin B^* for i^* ; pull S into B^* ; pull from bin $B \in \text{BS}$ containing the smallest big item i .

► **Lemma 3.** *The overall size of items migrated due to the insertion of a big item i^* is upper bounded by 11.*

Proof sketch. First, note that an insertion into BS can not trigger the reinsertion of a big item. The insertion into BB can only trigger the reinsertion of a single big item into BS and the insertion into BM can only trigger the reinsertion into BB or BS. Hence, each insertion of a big item can trigger at most two other insertions in total and thus only move a total size of 2 this way. The direct reassignments are bounded by 5. ◀

Insertion of Medium Items. If a medium item i^* arrives, $\text{GreedyPush}(i^*, M)$ is called. Afterwards, the invariant I4 may be infringed and if this happens, we have $BS \cup BB \neq \emptyset$ and $s(M) \geq 1 - s_{\max}(BS \cup BB)$, and we continue as follows. We will now describe how to pack a barely covered bin using the items from M and a largest big item from $BS \cup BB$ to maintain I4.

If $BS = \emptyset$, I2 implies that BB contains a single bin B including two items i and i' with $s_{\max}(BS \cup BB) = s(i) \geq s(i')$. We remove i' from B , and call $\text{GreedyPull}(B, M)$ to create a BM bin. Afterwards, $s(M)$ and $s_{\max}(BS \cup BB)$ are at most as big as they were before i^* arrived as the first item we pulled from M is at least as big as i^* , and therefore I4 holds. Furthermore $BS = BB = \emptyset$ and I2 still holds. Lastly, we reinsert the big item i' .

If, on the other hand, $BS \neq \emptyset$, the corresponding big item i with $s_{\max}(BS \cup BB) = s(i)$ is contained in a bin $B \in BS$, because of I3. In this case, we remove the small items from B and call $\text{GreedyPull}(B, M)$. Afterwards I4 holds, but I2 may be infringed due to the removal of a bin from BS , i.e. $|BB| = |BS| + 2$. In this case, we remove the two biggest items i_1 and i_2 from the bins $B_1, B_2 \in BB$ and if $B_1 \neq B_2$ merge the two bins. This yields $|BB| = |BS| + 1$ and I2 holds. Afterwards, we reinsert the two items i_1 and i_2 , which both will be inserted in BS due to their sizes. No matter whether we had to rebalance $|BB|$ and $|BS|$ or not, we reinsert the removed small items from B as a last step. Figure 2 contains an illustration of this process.

■ **Figure 2** Insertion of a medium item i^* . Big items are drawn in dark gray, medium items in light gray, and small items in white.

► **Lemma 4.** *The overall size of items migrated due to the insertion of a medium item i^* is upper bounded by 27.*

Analysis. The migration bound stated in Theorem 2 or more precisely $\frac{27}{\varepsilon}$ is already implied by Lemma 3 and Lemma 4, as a medium item has size above ε . It is easy to see that:

► **Remark 5.** The presented algorithm for static bin covering has polynomial running time.

Hence, the only thing left to show is the stated asymptotic competitive ratio:

► **Lemma 6.** *The presented algorithm has an asymptotic competitive ratio of $1.5 + \varepsilon$ with additive constant 3.*

Proof. First, we consider the case $BSP = \emptyset$. In this case, the claim holds because the bins on average have not too much excess size. More precisely, we obviously have $\text{OPT}(I) \leq s(I)$, and invariants I1 and I7 imply $s(I) < 2|BB| + (1 + \varepsilon)|BS| + 1.5|BM| + 1.5|MC| + (1 + \varepsilon)|SC| + 2$. Furthermore, we have $0.5|BB| \leq 0.5(|BS| + 1)$, due to Invariant I2, and $|BS| = |BSC|$, as $BSP = \emptyset$ holds in the case we are currently considering. Hence $\text{OPT}(I) < (1.5 + \varepsilon)(|BB| + |BSC| + |BM| + |MC| + |SC|) + 2.5 < (1.5 + \varepsilon) \text{ALG}(I) + 3$.

A similar argument holds, if $BSP \neq \emptyset$ but $BB = \emptyset$. In this case, we have $|BSP| = |BS| = 1$, because of invariant I2; and $S = \emptyset$, because of Invariant I5. Hence $\text{OPT}(I) \leq s(I) < 1.5|BM| + 1.5|MC| + 2 = 1.5 \text{ALG}(I) + 2$.

Next, we consider the case $\text{BSP} \neq \emptyset$ and $\text{BB} \neq \emptyset$. Here, we have $\text{MC} = \emptyset$, because of Invariant I4, and $\text{S} = \emptyset$, because of Invariant I5. Note that every bin of $\text{BSC} \cup \text{BM}$ has at least one item that is not big, since big items have sizes below 1, and these bins are covered. Let $\xi = s_{\max}(\text{BSP})$ be the size of a big item from BSP with maximal size. Then all items in $\text{BB} \cup \text{BSP}$ have size at most ξ (I3) and $\xi > 0.5$. We construct a modified instance I^* as follows:

1. The size of each big item with size below ξ is increased to ξ .
2. Every big item of size larger than ξ is split into a big item of size ξ and a medium or small item, such that the total size of these two items is equal to the size of the original item. Let X be the set of items with sizes of ξ , which we will call ξ -items in the instance after these transformations (X includes also items whose sizes were ξ in I).
3. For each bin from $\text{BSC} \cup \text{BM}$, select the largest item of I that is not big and call it *special*. By increasing item sizes if necessary, change the sizes of all special items to 0.5. Let Y be the set of special items (whose sizes are now all equal to 0.5). Let Z be the set of the remaining items not belonging to X or Y (in the instance I^* after the transformations, so there may be items that did not exist in I resulting from splitting a big item).

The set of items in I^* is just $X \cup Y \cup Z$. For instance I^* , any bin of BB contains only two items of X . Any bin of BSP has an item of X , and one of these bins may also have small items of Z , but it is not covered. Any bin of $\text{BSC} \cup \text{BM}$ has one item of X , one item of Y , and possibly items of Z . There may be one uncovered bin of M , containing items of Z .

Note that $\text{OPT}(I) \leq \text{OPT}(I^*)$, since any packing for I can be used as a packing for I^* with at least the same number of covered bins. Next, we investigate the relationship between $\text{OPT}(I^*)$ and the packing of the algorithm for the original instance I . For some optimal solution for I^* without overpacked bins (more than barely covered), let k_2 , k_1 and k_0 be the number of covered bins with 2, 1 and 0 items from $X \cup Y$, respectively. Then we have $\text{OPT}(I^*) = k_2 + k_1 + k_0$ and due to counting $2k_2 + k_1 = |X \cup Y| = (2|\text{BB}| + |\text{BS}| + |\text{BM}|) + (|\text{BM}| + |\text{BSC}|)$. Since each item in $X \cup Y$ is upper bounded by ξ , we have: $(1 - \xi)k_1 + k_0 \leq s(Z)$.

The total size of items (of Z only) packed into the bin of M is below $1 - \xi$ since BSP has a big item of size ξ in I and by Invariant I4, since every item of $\text{BS} \cup \text{BB}$ is smaller than $1 - s(\text{M})$. For BSP only one bin may contain items of Z by Invariant I6, and this bin has an item of size ξ in I (and it is not covered), so it also has items of Z of total size below $1 - \xi$. Consider a bin of $\text{BSC} \cup \text{BM}$. The total size of items excluding the special item is the same for I and I^* . Since such a bin is barely covered and for I it has items of one class except for the big item (small or medium), removing the special item results in a load below 1. The total size of items of I^* in such a bin excluding the ξ -item and the special item is below $1 - \xi$.

Therefore, we find that $s(Z) \leq (1 - \xi)(|\text{BM}| + |\text{BSC}| + 2)$. Hence:

$$\begin{aligned} 2 \text{OPT}(I) &\leq 2(k_2 + k_1 + k_0) \leq (2k_2 + k_1) + (k_1 + (1 - \xi)^{-1}k_0) \\ &\leq (2|\text{BB}| + |\text{BS}| + |\text{BM}| + |\text{BM}| + |\text{BSC}|) + (|\text{BM}| + |\text{BSC}| + 2) \\ &\stackrel{\text{Invariant I2}}{\leq} 3|\text{BB}| + 3|\text{BM}| + 2|\text{BSC}| + 3 \leq 3 \text{ALG}(I) + 3. \end{aligned} \quad \blacktriangleleft$$

Extending Our Results

Non-amortized Migration in the Dynamic Case. We are able to extend the result of the static case and show that we can also handle the case of departing items.

► **Theorem 7.** *For each $\varepsilon < 1$ with $1/\varepsilon \in \mathbb{Z}$, there is an algorithm ALG for dynamic online bin covering with polynomial running time, an asymptotic competitive ratio of $1.5 + \varepsilon$ with additive constant $\mathcal{O}(\log 1/\varepsilon)$, and a non-amortized migration factor of $\mathcal{O}((1/\varepsilon)^5 \log^2(1/\varepsilon))$.*

18:12 Online Bin Covering with Limited Migration

This is the most elaborate result of the paper and its proof can be found in the long version of the paper (see appendix). In the following, we briefly discuss this the result and give some intuition for the developed techniques.

The main challenge in the dynamic case arises from small items: Let N be some positive integer. Consider the case that N^2 items of size $1/N$ arrived and were placed into N bins, covering each of them perfectly. Next, one item from each bin leaves yielding a solution without any covered bin while the optimum is still $N - 1$. Hence, a migration strategy for the small items is needed. Now, coming up with such a strategy to deal with the present example is rather simple, since all the items are of the same size, but in principle small items may differ in size by arbitrary factors. Still, the case with only small items can be dealt with adapting a technique for online bin packing with migration [3]. The basic idea is to sort the items non-increasingly and maintain a packing that corresponds to a partition of this sequence into barely covered bins. If an item arrives, it is inserted into the correct bin and excess items are pushed to the right, that is, to the neighboring bin containing the next items in the ordering, and this process is repeated until the packing is restored. Correspondingly, if an item departs, items are pulled in from the next bin to the right. In this process the arrival or departure of a small item can only cause movements of items at most as big as the original one. While this is useful, it does not suffice to bound migration: Too many bins have to be repacked. In order to deal with this, the bins are partitioned into *chains* of appropriate constant length with a *buffer bin* at the end, which is used to interrupt the migration process. This technique can be applied for the bins \mathbf{S} containing only small items, but for bins \mathbf{BS} containing big items as well problems arise. The main reason for this is that in order to adapt our analysis, we need to cover the bins in \mathbf{BS} containing larger big items with higher priority and furthermore guarantee that there are no (or only few) bins contained in \mathbf{S} if there are bins containing big items that are not covered, i.e., $\mathbf{BSP} \neq \emptyset$. It is not hard to see that spreading one sequence of chains out over the bins of \mathbf{BS} and \mathbf{S} will not suffice.

To overcome these problems, we develop a novel technique: We partition the bins of \mathbf{BS} into few, that is, $\mathcal{O}(\log 1/\varepsilon)$ many, *groups*. Each of the groups is in turn partitioned into *parallel chains* of length $\mathcal{O}(1/\varepsilon)$. The groups are defined such that they comply with a non-increasing ordering of both the big and the small items: the first group contains the largest big and small items, the next group the remaining largest, and so on. A similar ordering holds for each single parallel chain, but no such structure is maintained in between the parallel chains of the same group. Now, whenever a buffer bin of a parallel chain becomes overfilled, items are pushed directly into the next group. However, to maintain the described structure, these have to be the smallest items of the group, and to guarantee this we introduce some additional structure for the buffer bins in each group. While there may be a chain reaction caused by such a push or pull, the migration can still be bounded, because there are only few groups. We are able to guarantee that there is at most one group \mathbf{G} containing uncovered bins and that that all bins of \mathbf{BS} are barely covered, if $\mathbf{S} \neq \emptyset$. These are the essential properties we need in order to adapt our approach to the dynamic case.

Amortized Migration. First of all, we can strengthen the lower bound of Theorem 1 if items can depart and show that the same bound also holds for amortized migration in this case.

► **Proposition 8.** *There is no algorithm for dynamic online bin covering with a constant amortized migration factor β and an asymptotic competitive ratio smaller than $3/2$.*

If items never depart, we can use the amortization by repacking the completely instance every once in a while with the help of an AFPTAS of Jansen and Solis-Oba [20]. We can also show that we need to be contended with a non-optimal solution by making use of a highly non-trivial construction.

► **Theorem 9.** *For every $\varepsilon > 0$, there is an algorithm for static bin covering with polynomial running time, asymptotic competitive ratio $1 + \varepsilon$, and amortized migration factor $\mathcal{O}(1/\varepsilon)$. Additionally, there is no (possibly exponential time) algorithm for static online bin covering that maintains an optimal solution with constant amortized migration factor β .*

Abstract

Given a planar digraph G and a positive even integer k , an embedding of G in the plane is k -modal, if every vertex of G is incident to at most k pairs of consecutive edges with opposite orientations, i.e., the incoming and the outgoing edges at each vertex are grouped by the embedding into at most k sets of consecutive edges with the same orientation. In this paper, we study the k -MODALITY problem, which asks for the existence of a k -modal embedding of a planar digraph. This combinatorial problem is at the very core of a variety of constrained embedding questions for planar digraphs and flat clustered networks.

First, since the 2-MODALITY problem can be easily solved in linear time, we consider the general k -MODALITY problem for any value of $k > 2$ and show that the problem is NP-complete for planar digraphs of maximum degree $\Delta \geq k+3$. We relate its computational complexity to that of two notions of planarity for flat clustered networks: Planar Intersection-Link and Planar NodeTrix representations. This allows us to answer in the strongest possible way an open question by Di Giacomo et al. [GD17], concerning the complexity of constructing planar NodeTrix representations of flat clustered networks with small clusters, and to address a research question by Angelini et al. [JGAA17], concerning intersection-link representations based on geometric objects that determine complex arrangements. On the positive side, we provide a simple FPT algorithm for partial 2-trees of arbitrary degree, whose running time is exponential in k and linear in the input size. Second, motivated by the recently-introduced planar L-drawings of planar digraphs [GD17], which require the computation of a 4-modal embedding, we focus our attention on $k = 4$. On the algorithmic side, we show a complexity dichotomy for the 4-MODALITY problem with respect to Δ , by providing a linear-time algorithm for planar digraphs with $\Delta \leq 6$. This algorithmic result is based on decomposing the input digraph into its blocks via BC-trees and each of these blocks into its triconnected components via SPQR-trees. In particular, we are able to show that the constraints imposed on the embedding by the rigid triconnected components can be tackled by means of a small set of reduction rules and discover that the algorithmic core of the problem lies in special instances of NAESAT, which we prove to be always NAE-satisfiable – a result of independent interest that improves on Porschen et al. [SAT03]. Finally, on the combinatorial side, we consider outerplanar digraphs and show that any such a digraph always admits a k -modal embedding with $k = 4$ and that this value of k is best possible for the digraphs in this family.

1 Introduction

Computing k -modal embeddings of planar digraphs, for some positive even integer k called *modality*, is an important algorithmic task at the basis of several types of graph visualizations. In *2-modal embeddings*, also called *bimodal embeddings*, the outgoing and the incoming edges at each vertex form two disjoint sequences. Bimodal embeddings are ubiquitous in Graph Drawing. For instance, level planar drawings [15, 22] and upward-planar drawings [8, 17] – two of the most deeply-studied graph drawing standards – determine bimodal embeddings. *4-modal embeddings*, where the outgoing and the incoming edges at each vertex form up to four disjoint sequences with alternating orientations, arise in the context of planar L-drawings of digraphs. In an *L-drawing* of an n -vertex digraph, introduced by Angelini et al. [1], vertices are placed on the $n \times n$ grid so that each vertex is assigned a unique x -coordinate and a unique y -coordinate and each edge uv (directed from u to v) is represented as a 1-bend orthogonal polyline composed of a vertical segment incident to u and of a horizontal segment incident to v . Recently, Chaplick et al. [13] addressed the question of deciding the existence of *planar L-drawings*, i.e., L-drawings whose edges might possibly overlap but do not cross and observe that the existence of a 4-modal embedding is a necessary condition for a digraph to admit such a representation (Fig. 1a).

To the best of our knowledge, no further relationships have been explicitly pointed out in the literature between modal embeddings and notable drawing models for modality values greater than four, yet they do exist. Da Lozzo et al. [14] and Di Giacomo et al. [18] study the planarity of *NodeTrix representations* of flat clustered networks, a hybrid representational model introduced by Henry, Fekete, and McGuffin [19], where clusters and intra-cluster edges are represented as adjacency-matrices, with rows and columns for the vertices of each cluster, and inter-cluster edges are Jordan arcs connecting different matrices (Fig. 1b). For clusters containing only two vertices, it is possible to show that the problem of computing planar NodeTrix representations coincides with the one of testing whether a special digraph, called the *canonical digraph*, associated to the network admits a 6-modal embedding. For higher values of modality, k -modal embeddings occur in the context of Intersection-Link representations of flat clustered networks. In an *intersection-link representation* [3, 5], vertices are represented as translates of the same polygon, intra-cluster edges are represented

Figure 1 (a) A planar L-drawing, which determines a 4-modal embedding. (b) A planar NodeTrix representation. (c) A planar intersection-link representation using comb-shaped polygons.

via intersections between the polygons corresponding to their endpoints, and inter-cluster edges – similarly to NodeTrix representations – are Jordan arcs connecting the polygons corresponding to their endpoints. For any modality $k \geq 2$, it can be shown that testing the existence of a k -modal embedding of the canonical digraph of a flat clustered network with clusters of size two is equivalent to testing the existence of an intersection-link representation in which the curves representing inter-cluster edges do not intersect, when vertices are drawn as comb-shaped polygons (Fig. 1c).

Related Work. It is common knowledge that the existence of bimodal embeddings can be tested in linear time: Split each vertex v that has both incoming and outgoing edges into two vertices v_{in} and v_{out} , assign the incoming edges to v_{in} and the outgoing edges to v_{out} , connect v_{in} and v_{out} with an edge, and test the resulting (undirected) graph for planarity using any of the linear-time planarity-testing algorithms [11, 20]. Despite this, most of the planarity variants requiring bimodality are NP-complete; for instance, upward planarity [17], windrose planarity [6], partial-level planarity [12], clustered-level planarity and T -level planarity [4, 23], ordered-level planarity and bi-monotonicity [23]. In this scenario, a notable exception is represented by the classic level planarity problem, which can be solved in linear time [22], and its generalizations on the standing cylinder [7], rolling cylinder and the torus [2]. Although the existence of a bimodal embedding is easy to test, Binucci, Didimo, and Giordano [9] prove that the related problem of finding the maximum bimodal subgraph of an embedded planar digraph is an NP-hard problem. Moreover, Binucci, Didimo, and Patrignani [10] show that, given a *mixed planar graph*, i.e., a planar graph whose edge set is partitioned into a set of directed edges and a set of undirected edges, orienting the undirected edges in such a way that the whole graph admits a bimodal embedding is an NP-complete problem. On the other hand, the question regarding the computational complexity of constructing k -modal embedding for $k \geq 4$ has not been addressed, although the related problem of testing the existence of planar L-drawings has been recently proved NP-complete [13].

Our results. We study the complexity of the k -MODALITY problem, which asks for the existence of k -modal embeddings of planar digraphs – with an emphasis on $k = 4$. Our results are as follows:

- We demonstrate a complexity dichotomy for the 4-MODALITY problem with respect to the maximum degree Δ of the input digraph. Namely, we show NP-completeness when $\Delta \geq 7$ (see [21, Section 9]) and give a linear-time testing algorithm for $\Delta \leq 6$ (Theorem 19). Further, we extend the hardness result to any modality value larger than or equal to 4, by proving that the k -MODALITY problem is NP-complete for $k \geq 4$ when $\Delta \geq k + 3$.
- We provide an FPT-algorithm for k -MODALITY that runs in $f(k)O(n)$ time for the class of directed partial 2-trees (Theorem 16), which includes series-parallel and outerplanar digraphs.
- In Section 3, we relate k -modal embeddings with hybrid representations of flat clustered graphs, and exploit this connection to give new complexity results (Theorems 4 and 8) and algorithms (Theorems 3 and 7) for these types of representations. In particular, our NP-hardness results allow us to answer two open questions. Namely, we settle in the strongest possible way an open question, posed by Di Giacomo et al. [18, Open Problem (i)], about the complexity of computing planar NodeTrix representations of flat clustered graphs with clusters of size smaller than 5. Also, we address a research question by Angelini et al. [3, Open Problem (2)] about the representational power of intersection-link representations based on geometric objects that give rise to complex combinatorial structures, and solve it when the considered geometric objects are k -combs.
- Finally, in [21, Section 10], we show that not every outerplanar digraph admits a bimodal embedding, whereas any outerplanar (multi-)digraph admits a 4-modal embedding.

The algorithms presented in this paper employ the SPQ- and SPQR-tree data structures to succinctly represent the exponentially-many embeddings of series-parallel and biconnected planar digraphs, respectively, and can be easily modified to output an embedding of the input digraph in the same time bound. In particular, our positive result for $\Delta \leq 6$ is based on a set of simple reduction rules that exploit the structure of the rigid components of bounded-degree planar digraphs. These rules allow us to tackle the algorithmic core of the problem, by enabling a final reduction step to special instances of NAESAT, previously studied by Porschen et al. [26], which we prove to be always NAE-satisfiable [21, Section 7].²

2 Definitions

We assume familiarity with basic concepts concerning directed graphs, planar embeddings, connectivity and the BC-tree data structure; see the full version [21] for more details.

Directed graphs. A *directed graph* (for short *digraph*) $G = (V, E)$ is a pair, where V is the set of vertices and E is the set of (*directed*) *edges* of G , i.e., ordered pairs of vertices. We also denote the sets V and E by $V(G)$ and $E(G)$, respectively. The *underlying graph* of G is the undirected graph obtained from G by disregarding edge directions. Let v be a vertex, we denote by $E(v)$ the set of edges of G incident to v and by $\deg(v) = |E(v)|$ the *degree* of v . For an edge $e = uv$ directed from u to v and an end-point $x \in \{u, v\}$ of e , we define the *orientation* $\sigma(e, x)$ of e at x as $\sigma(e, x) = \uparrow$, if $x = u$, and $\sigma(e, x) = \downarrow$, if $x = v$, and we say that uv is *outgoing from* u and *incoming at* v .

Modality. Let G be a planar digraph and let \mathcal{E} be an embedding of G . A pair of edges e_1, e_2 that appear consecutively in the circular order around a vertex v of G is *alternating* if they do not have the same orientation at v , i.e., they are not both incoming at or both outgoing from v . Also, we say that vertex v is *k -modal*, or that v has *modality k* , or that the *modality of v is k* in \mathcal{E} , if there exist exactly k alternating pairs of edges incident to v in \mathcal{E} . Clearly, the value k needs to be a non-negative even integer. An embedding of a digraph G is *k -modal*, if each vertex is at most k -modal; see Fig. 3(left).

We now define an auxiliary problem, called k -MAXMODALITY (where k is a positive even integer), which will be useful to prove our algorithmic results. We denote the set of non-negative integers by \mathbb{Z}^* and the set of non-negative even integers smaller than or equal to k as $\mathbb{E}_k^+ = \{b : b = 2a, b \leq k, a \in \mathbb{Z}^*\}$. Given a graph G , we call *maximum-modality function* an integer-valued function $m : V(G) \rightarrow \mathbb{E}_k^+$. We say that an embedding \mathcal{E} of G *satisfies m at a vertex v* if the modality of v in \mathcal{E} is at most $m(v)$.

Problem: k -MAXMODALITY
Input: A pair $\langle G, m \rangle$, where G is a digraph and m is a maximum-modality function.
Question: Is there an embedding \mathcal{E} of G that <i>satisfies</i> m at every vertex?

² In “Stefan Porschen, Bert Randerath, Ewald Speckenmeyer: Linear Time Algorithms for Some Not-All-Equal Satisfiability Problems. SAT 2003: 172-187” [26], the authors state in the abstract “First we show that a NAESAT model (if existing) can be computed in linear time for formulas in which each variable occurs at most twice.” We give a strengthening of this result by showing that the only negative formulas with the above properties are those whose variable-clause graph contains components isomorphic to a simple cycle and provide a recursive linear-time algorithm for computing a NAE-truth assignment for formulas in which each variable occurs at most twice, when one exists, which is also considerably simpler than the one presented in [26].

■ **Figure 2** (a) Illustrations for the duality between the canonical digraph and the canonical c-graph. Correspondence (b) between 6-modal embeddings and planar NodeTrix representations, and (c) between 4-modal embeddings and clique-planar representations using 2-combs as geometric objects.

3 Implications on Hybrid Representations

A *flat clustered graph* (for short, *c-graph*) is a pair $\mathcal{C} = (G = (V, E), \mathcal{P} = (V_1, V_2, \dots, V_c))$, where G is a graph and \mathcal{P} is a partition of V into sets V_i , for $i = 1, \dots, c$, called *clusters*. An edge $(u, v) \in E$ with $u \in V_i$ and $v \in V_j$ is an *intra-cluster edge*, if $i = j$, and is an *inter-cluster edge*, if $i \neq j$. The problem of visualizing such graphs so to effectively convey both the relation information encoded in the set E of edges of G and the hierarchical information given by the partition \mathcal{P} of the clusters has attracted considerable research attention. In a *hybrid representation* of a graph different conventions are used to represent the dense and the sparse portions of the graph [3, 5, 14, 18, 19, 24, 27]. We present important implications of our results on some well-known models for hybrid-representations of c-graphs.

Let \mathcal{C} be a c-graph whose every cluster forms a clique of size at most 2, that is, each cluster contains at most two vertices connected by an intra-cluster edge. Starting from \mathcal{C} we define an auxiliary digraph G° , called the *canonical digraph* for \mathcal{C} , as follows. Without loss of generality, assume that, for $i = 1, \dots, c$, each cluster V_i contains two vertices denoted as $v^i[\uparrow]$ and $v^i[\downarrow]$. The vertex set of G° contains a vertex v^i , for $i = 1, 2, \dots, c$, and a dummy vertex d_e , for each inter-cluster edge $e \in E$. The edge set of G° contains two directed edges, for each inter-cluster edge $e = (v_x^i, v_y^j) \in E$, with $x, y \in \{\uparrow, \downarrow\}$ and $i \neq j$; namely, $E(G^\circ)$ contains (i) either the directed edges $v_x^i d_e$, if $x = \downarrow$, or the directed edge $d_e v_x^i$, if $x = \uparrow$, and (ii) either the directed edges $v_y^j d_e$, if $y = \downarrow$, or the directed edge $d_e v_y^j$, if $y = \uparrow$.

Let now $D = (V, E)$ be a digraph. We construct a c-graph $\mathcal{C}^* = (G^* = (V^*, E^*), \mathcal{P}^*)$ from D whose every cluster forms a clique of size at most 2, called the *canonical c-graph* for D , as follows. For each vertex $v^i \in V$, G^* contains two vertices $v^i[\uparrow]$ and $v^i[\downarrow]$, which form the cluster $V_i = \{v^i[\uparrow], v^i[\downarrow]\}$ in \mathcal{P}^* . For each (directed) edge $v^i v^j$ of D , G^* contains an (undirected) edge $(v^i[\downarrow], v^j[\uparrow])$; that is, each directed edge in E that is incoming (outgoing) at a vertex v^i and outgoing (incoming) at a vertex v^j corresponds to an inter-cluster edge in E^* incident to $v^i[\uparrow]$ (to $v^i[\downarrow]$) and to $v^j[\downarrow]$ (to $v^j[\uparrow]$). Finally, for each vertex $v^i \in V$, G^* contains an intra-cluster edge $(v^i[\uparrow], v^i[\downarrow])$. The canonical digraph and the canonical c-graph form dual concepts, as illustrated in Fig. 2a; the canonical c-graph of G° is the original c-graph \mathcal{C} (neglecting clusters originated by dummy vertices) and the canonical digraph of \mathcal{C}^* is the original digraph D (suppressing dummy vertices).

NodeTrix Planarity. A *NodeTrix representation* of a c-graph $\mathcal{C} = (G, \mathcal{P})$ is a drawing of \mathcal{C} such that: (i) each cluster $V_i \in \mathcal{P}$ is represented as a symmetric adjacency matrix M_i (with $|V_i|$ rows and columns), drawn in the plane so that its boundary is a square Q_i with sides parallel to the coordinate axes; (ii) no two matrices intersect, that is, $Q_i \cap Q_j = \emptyset$, for

all $1 \leq i < j \leq c$; (iii) each intra-cluster edge is represented by the adjacency matrix M_i ; and (iv) each inter-cluster edge (u, v) with $u \in V_i$ and $v \in V_j$ is represented as a simple Jordan arc connecting a point on the boundary of Q_i with a point on the boundary of Q_j , where the point on Q_i (on Q_j) belongs to the column or to the row of M_i (resp. of M_j) associated with u (resp. with v). A NodeTrix representation is *planar* if no inter-cluster edge intersects a matrix or another inter-cluster edge, except possibly at a common end-point; see Figs. 1b and 2b. The NODETRIX PLANARITY problem asks whether a c-graph admits a planar NodeTrix representation. NODETRIX PLANARITY has been proved NP-complete for c-graphs whose clusters have size larger than or equal to 5 [18].

We are ready to establish our main technical lemmas.

- **Lemma 1.** *C-graph \mathcal{C} is NodeTrix planar if and only if G^\diamond admits a 6-modal embedding.*
- **Lemma 2.** *Digraph D admits a 6-modal embedding if and only if \mathcal{C}^* is NodeTrix planar.*

Proof sketch for Lemmas 1 and 2. Let M_i be the matrix representing cluster $V_i = \{v^i[\uparrow], v^i[\downarrow]\}$. We have that, independently of which of the two possible permutations for the rows and columns of M_i is selected, the boundary of Q_i is partitioned into three maximal portions associated with $v^i[\uparrow]$ and three maximal portions associated with $v^i[\downarrow]$; that is, they form the pattern [1, 2, 1, 2, 1, 2], see Fig. 2b. Therefore, any planar NodeTrix representation of \mathcal{C} (of \mathcal{C}^*) can be turned into a 6-modal embedding of G^\diamond (of D) via a local redrawing procedure which operates in the interior of Q_i ; also, any 6-modal embedding of G^\diamond (of D) can be turned into a planar NodeTrix representation of \mathcal{C} (of \mathcal{C}^*) via a local redrawing procedure which operates in a small disk centered at v_i that contains only v_i and intersects only edges incident to v_i .

Since G^\diamond can be constructed in linear time from \mathcal{C} , Lemma 1 and the algorithm of Theorem 16 for solving k -MODALITY of directed partial 2-trees give us the following.

- **Theorem 3.** *NODETRIX PLANARITY can be solved in linear time for flat clustered graphs whose clusters have size at most 2 and whose canonical digraph is a directed partial 2-tree.*

Note that (i) \mathcal{C}^* can be constructed in polynomial time from D , (ii) \mathcal{C}^* only contains clusters of size 2 (although clusters corresponding to vertices of D incident to incoming or outgoing edges only could be simplified into clusters of size 1), and (iii) each cluster $V_i \in \mathcal{P}^*$, with $v^i \in V(D)$, is incident to α inter clusters edges, where α is the degree of v^i in D . These properties and the fact that in [21, Section 9] we prove the k -MODALITY problem to be NP-complete for digraphs of maximum degree $\Delta \geq k + 3$ give us the following.

- **Theorem 4.** *NODETRIX PLANARITY is NP-complete for flat clustered graphs whose clusters have size at most 2, even if each cluster is incident to at most 9 inter-cluster edges.*

We remark that the above NP-completeness result is best possible in terms of the size of clusters, as clusters of size 1 do not offer any advantage to avoid intersections between inter-cluster edges. Also, it solves [18, Open Problem (i)], which asks for the complexity of NODETRIX PLANARITY for c-graphs whose clusters have size between 2 and 5.

Clique Planarity. Hybrid representations have also been recently studied in the setting in which clusters are represented via intersections of geometric objects. In particular, Angelini et al. [3] introduced the following type of representations. Suppose that a c-graph (G, \mathcal{P}) is given, where \mathcal{P} is a set of cliques that partition the vertex set of G . In an *intersection-link representation*, the vertices of G are represented by geometric objects that are translates

of the same rectangle. Consider an edge (u, v) and let $R(u)$ and $R(v)$ be the rectangles representing u and v , respectively. If (u, v) is an intra-cluster edge (called *intersection-edge* in [3]), we represent it by drawing $R(u)$ and $R(v)$ so that they intersect, otherwise if (u, v) is an inter-cluster edge (called *link-edge* in [3]), we represent it by a Jordan arc connecting $R(u)$ and $R(v)$. A *clique-planar* representation is an intersection-link representation in which no inter-cluster edge intersects the interior of any rectangle or another inter-cluster edge, except possibly at a common end-point. The CLIQUE PLANARITY problem asks whether a c-graph (G, \mathcal{P}) admits a clique-planar representation.

Angelini et al. proved the CLIQUE PLANARITY problem to be NP-complete, when \mathcal{P} contains a cluster V^* with $|V^*| \in O(|G|)$, and asked, in [3, Open Problem (2)], about the implications of using different geometric objects for representing vertices, rather than translates of the same rectangle. We address this question by considering k -combs as geometric objects, where a k -comb is the simple polygon with k spikes illustrated in Fig. 2c. We have the following.

► **Lemma 5.** *C-graph \mathcal{C} is a positive instance of CLIQUE PLANARITY using k -combs as geometric objects if and only if G^\diamond admits a $2k$ -modal embedding.*

► **Lemma 6.** *Digraph D admits an 4-modal embedding if and only if \mathcal{C}^* is a positive instance of CLIQUE PLANARITY using 2-combs as geometric objects.*

Proof sketch for Lemmas 5 and 6. Let A_i be an arrangements of 2-combs representing cluster $V_i = \{v^i[\uparrow], v^i[\downarrow]\}$. We have that, the boundary of A_i is partitioned into at most two maximal portions associated with $v^i[\uparrow]$ and at most two maximal portions associated with $v^i[\downarrow]$; that is, they form the pattern $[1, 2, 1, 2]$, see Fig. 2c. Therefore, as for Lemmas 1 and 2, we can exploit a local redrawing procedure to transform a clique-planar representation of \mathcal{C} (of \mathcal{C}^*) into a 4-modal embedding of G^\diamond (of D), and vice versa.

Combining Lemma 5 and the algorithm of Theorem 16 gives us the following positive result.

► **Theorem 7.** *CLIQUE PLANARITY using r -combs, with $r \geq 1$, as geometric objects can be solved in linear time for flat clustered graphs whose clusters have size at most 2 and whose canonical digraph is a directed partial 2-tree.*

Finally, Lemma 6 and the discussion preceding Theorem 4 imply the following.

► **Theorem 8.** *CLIQUE PLANARITY using 2-combs as geometric objects is NP-complete, even for flat clustered graphs with clusters of size at most 2 each incident to at most 7 inter-cluster edges.*

4 Polynomial-time Algorithms

In this section, we present an algorithmic framework to devise efficient algorithms for the k -MODALITY problem for notable families of instances. First, in Section 4.1, we show how to efficiently reduce the k -MODALITY problem in simply-connected digraphs to the k -MAXMODALITY problem in biconnected digraphs. Then, in Section 4.2, we introduce preliminaries and definitions concerning SPQR-trees and k -modal embeddings of biconnected digraphs.

4.1 Simply-Connected Graphs

We first observe that the k -MAXMODALITY problem is a generalization of the k -MODALITY problem. In fact, a directed graph $G = (V, E)$ admits a k -modal embedding if and only if the pair $\langle G, m \rangle$, with $m(v) = k, \forall v \in V(G)$, is a positive instance of the k -MAXMODALITY problem.

■ **Figure 3** (left) A 4-modal embedding of a simply-connected planar digraph G . (right) The SPQR tree \mathcal{T} of the block β of G rooted at the edge $e = uv$. The extended skeletons of all non-leaf nodes of \mathcal{T} are shown; virtual edges corresponding to S-, P-, and R-nodes are thick.

► **Observation 1.** k -MODALITY reduces in linear time to k -MAXMODALITY.

Let $\langle G, m : V(G) \rightarrow \mathbb{E}_4^+ \rangle$ be an instance of 4-MAXMODALITY; also, let β be a leaf-block of the BC-tree \mathcal{T} of G and let v be the parent cut-vertex of β in \mathcal{T} . We denote by G_β^- the subgraph of G induced by v and the vertices of G not in β , i.e., $G_\beta^- = G - (\beta - \{v\})$. Also, let $B(\mathcal{T})$ be the set of blocks in \mathcal{T} . We show that k -MAXMODALITY (and k -MODALITY, by Observation 1) in simply-connected digraphs is Turing reducible to k -MAXMODALITY in biconnected digraphs.

► **Theorem 9.** *Given a subroutine TESTBICONNECTED that tests k -MAXMODALITY for biconnected instances, there exists a procedure TESTSIMPLYCONNECTED that tests k -MAXMODALITY for simply-connected digraphs. Further, given an instance $\langle G, m \rangle$ of k -MAXMODALITY, the runtime of TESTSIMPLYCONNECTED($\langle G, m \rangle$) is*

$$O(|G| + \log k \sum_{\beta \in B(\mathcal{T})} r(\beta)),$$

where $r(\beta)$ is the runtime of TESTBICONNECTED($\langle \beta, m \rangle$) and \mathcal{T} is the BC-tree of G .

Sketch. The algorithm selects a leaf-block β of \mathcal{T} , with parent cut-vertex v , and finds an embedding of β with the minimum modality at v satisfying m at all vertices, by performing a binary search using the TESTBICONNECTED procedure. We then remove β , replace G with G_β^- , and update the value of $m(v)$, so to account for the alternations at v introduced by β . The procedure terminates when all the blocks have been processed. Therefore, since the total number of calls to subroutine TESTBICONNECTED is bounded by the number of blocks of G , which is $O(|\mathcal{T}|) = O(|G|)$ multiplied by $\log k$, the overall running time is $O(|G| + \log k \sum_{\beta \in B(\mathcal{T})} r(\beta))$. ◀

4.2 Biconnected Graphs

To handle the decomposition of a biconnected digraph into its triconnected components, we use SPQR-trees, a data structure introduced by Di Battista and Tamassia [16].

SPQR-trees. Let G be a biconnected digraph. We consider SPQR-trees that are rooted at an edge e of G , called the *reference edge*. The rooted SPQR-tree \mathcal{T} of G with respect to e describes a recursive decomposition of G induced by its split pairs. The nodes of \mathcal{T} are of four types: S, P, Q, and R. Each node μ of \mathcal{T} has an associated undirected multigraph $\text{skel}(\mu)$, called the *skeleton* of μ , with two special nodes u_μ and v_μ (the *poles* of μ), and an associated subgraph $\text{pert}(\mu)$ of G , called *pertinent* of μ . The skeleton graph equipped with the edge $u_\mu v_\mu$, called the *parent edge*, is the *extended skeleton* of μ . Refer to Fig. 3(right).

Each edge of $\text{skel}(\mu)$, called *virtual edge*, is associated with a child of μ in \mathcal{T} . The skeleton of μ describes how the pertinent graphs of the children of μ have to be “merged” via their poles to obtain $\text{pert}(\mu)$. The extended skeleton of an S-, P-, R-, and Q-node is a cycle, parallel, triconnected graph, and a 2-gon, respectively. It follows that skeleton and pertinent graphs are always biconnected once the parent edge is added. A *series-parallel digraph* is a biconnected planar digraph whose SPQR-tree only contains S-, P-, and Q-nodes. A *partial 2-tree* is a digraph whose every block is a series-parallel digraph.

A digraph G is planar if and only if the skeleton of each R-node in the SPQR-tree of G is planar. By selecting *regular embeddings* for the skeletons of the nodes of \mathcal{T} , that is, embeddings in which the parent edge is incident to the outer face, we can construct any embedding of G with the edge e on the outer face, where the choices for the embeddings of the skeletons are all and only the (i) flips of the R-nodes and the (ii) permutations for the virtual edges of the P-nodes.

Consider a pair $\langle G, m \rangle$ such that G is biconnected and let \mathcal{E} be a planar embedding of G . Also, let \mathcal{T} be the SPQR-tree of G rooted at an edge e of G incident to the outer face of \mathcal{E} . We will assume that the virtual edges of the skeletons of the nodes in \mathcal{T} are oriented so that the extended skeleton of each node μ is a DAG with a single source u_μ and a single sink v_μ . Let μ be a node of \mathcal{T} and let \mathcal{E}_μ be the planar (regular) embedding of $\text{skel}(\mu)$ induced by \mathcal{E} . For an oriented edge $d = uv$ of $\text{skel}(\mu)$, the *left* and *right face* of d in \mathcal{E}_μ is the face of \mathcal{E}_μ seen to the left and to the right of d , respectively, when traversing this edges from u to v . We define the *outer left (right) face* of \mathcal{E}_μ as the left (right) face of the edge $u_\mu v_\mu$ in \mathcal{E}_μ .

Embedding tuples. An *embedding tuple* (for short, *tuple*) is a 4-tuple $\langle \sigma_1, a, \sigma_2, b \rangle$, where $\sigma_1, \sigma_2 \in \{\uparrow, \uparrow\}$ are orientations and $a, b \in \mathbb{N}$ are non-negative integers. Consider two tuples $t = \langle \sigma_1, a, \sigma_2, b \rangle$ and $t' = \langle \sigma'_1, a', \sigma'_2, b' \rangle$. We say that t *dominates* t' , denoted as $t \preceq t'$, if $\sigma_1 = \sigma'_1$, $\sigma_2 = \sigma'_2$, $a \leq a'$, and $b \leq b'$. Also, we say that t and t' are *incompatible*, if none of them dominates the other. Since the relationship \preceq is reflexive, antisymmetric, and transitive, it defines a poset (T, \preceq) , where T is the set of embedding tuples. A subset $S \subseteq T$ is *succinct* or an *antichain*, if the tuples in S are pair-wise incompatible. Consider two subsets $S, S' \subseteq T$ of tuples. We say that S *dominates* S' , denoted as $S \preceq S'$, if for any tuples $t' \in S'$ there exists at least one tuple $t \in S$ such that $t \preceq t'$. Also, S *reduces* S' if $S \preceq S'$ and $S \subseteq S'$. Finally, S is a *gist* of S' , if S is succinct and reduces S' .

Let e_u and e_v be the edges of $\text{pert}(\mu)$ incident to the outer left face of \mathcal{E}_μ and to u_μ and v_μ , respectively, possibly $e_u = e_v$. Also, let a and b be non-negative integers. We say that the embedding \mathcal{E}_μ *realizes* tuple $\langle \sigma_1, a, \sigma_2, b \rangle$, if $\sigma_1 = \sigma(e_u, u_\mu)$, $\sigma_2 = \sigma(e_v, v_\mu)$, and a and b are the number of inner faces of \mathcal{E}_μ whose (two) edges incident to u_μ and to v_μ , respectively, form an alternating pair. A tuple $t = \langle \sigma_1, a, \sigma_2, b \rangle$ is *realizable by* μ , if there exists an embedding of $\text{pert}(\mu)$ that realizes t , and *admissible*, if $a \leq m(u)$ and $b \leq m(v)$. A tuple is *good for* μ if it is both admissible and realizable by μ . We denote by $S(\mu)$ the gist of the set of good tuples for a node μ . Let e_μ be the virtual edge representing μ in the skeleton of the parent of μ in \mathcal{T} , with a small overload of notation, we also denote $S(\mu)$ by $S(e_\mu)$. For a tuple $t = \langle \sigma_1, a, \sigma_2, b \rangle \in S(e_\mu)$, where $e = u_\mu v_\mu$, the pair (σ_1, a) is the *embedding pair* of t at u_μ ; likewise, the pair (σ_2, b) is the *embedding pair* of t at v_μ . We have the following substitution lemma.

► **Lemma 10.** *Let \mathcal{E} be a planar embedding of G satisfying m . Let μ be a node of \mathcal{T} and let \mathcal{E}_μ be the embedding of $\text{pert}(\mu)$ induced by \mathcal{E} . Also, let $\mathcal{E}'_\mu \neq \mathcal{E}_\mu$ be an embedding of $\text{pert}(\mu)$ satisfying m . Then, G admits an embedding \mathcal{E}' satisfying m in which the embedding of $\text{pert}(\mu)$ is \mathcal{E}'_μ , if $t' \preceq t$, where t and t' are the embedding tuples realized by \mathcal{E}_μ and by \mathcal{E}'_μ , respectively.*

19:10 Computing k -Modal Embeddings of Planar Digraphs

■ **Figure 4** Illustration for the proof of Lemma 10. The parity of t and t' is the same at u_μ and different at v_μ ; in particular, even if a new alternation is introduced between the pair (e, e') at v_μ , the different parity guarantees that the modality at v_μ does not increase from \mathcal{E} to \mathcal{E}' .

Sketch. We show how to construct a drawing Γ'_G of G satisfying m in which the embedding of $\text{pert}(\mu)$ is \mathcal{E}'_μ ; see Fig. 4. Let Γ_G be a drawing of G whose embedding is \mathcal{E} . Remove from Γ_G the drawing of all the vertices of $\text{pert}(\mu)$ different from u_μ and v_μ and the drawing of all the edges of $\text{pert}(\mu)$. Denote by f the face of the resulting embedded graph G^- that used to contain the removed vertices and edges. We obtain Γ'_G by inserting a drawing of $\text{pert}(\mu)$ whose embedding is \mathcal{E}'_μ in the interior of f so that vertices u_μ and v_μ are identified with their copies in G^- . We can prove that the embedding \mathcal{E}' of Γ'_G satisfies m by exploiting the interplay between the parity and the number of alternations at u_μ (at v_μ) in t' and t when $t' \preceq t$. ◀

Let \mathcal{T} be the SPQR-tree \mathcal{T} of G rooted at a reference edge e . In the remainder of the section, we show how to compute the gist $S(\mu)$ of the set of good tuples for μ , for each non-root node μ of \mathcal{T} . In the subsequent procedures to compute $S(\mu)$ for S-, P-, and R-nodes, we are not going to explicitly avoid set $S(\mu)$ to contain dominated tuples. In fact, this can always be done at the cost of an additive $O(k^2)$ factor in the running time, by maintaining an hash table that stores the tuples that have been constructed (possibly multiple times) by the procedures and by computing the gist of the constructed set as a final step.

► **Property 1.** For each node $\mu \in \mathcal{T}$, it holds that $|S(\mu)| \in O(k)$.

Proof. By the definition of gist, any embedding pair (σ, a) has at most two tuples $t', t'' \in S(\mu)$ such that (σ, a) is the embedding pair of t' and t'' at u_μ ; also, the embedding pairs (σ', a') of t' and (σ'', a'') of t'' at v_μ are such that $\sigma' \neq \sigma''$. Since there exist at most $2k$ realizable embedding pairs (σ, a) at u_μ (as $\sigma \in \{\ddagger, \dagger\}$, $a \in \{0, 1, \dots, k\}$), and the existence of tuple whose embedding pair at u_μ is $(\sigma, 0)$ implies that all tuples have such an embedding pair at u_μ , we have $|S(\mu)| \leq 4k$. ◀

If μ is a leaf Q-node of \mathcal{T} , then $S(\mu) = \{\langle \sigma(u_\mu v_\mu, u_\mu), 0, \sigma(u_\mu v_\mu, v_\mu), 0 \rangle\}$. If μ is an internal node of \mathcal{T} , we visit \mathcal{T} bottom-up and compute the set $S(\mu)$ for μ assuming to have already computed the sets $S(\mu_1), \dots, S(\mu_k)$ for the children μ_1, \dots, μ_k of μ (where μ_i is the child of μ corresponding to the edge e_i in $\text{skel}(\mu)$). Let ρ be the unique child of the root of \mathcal{T} . Once the set $S(\rho)$ has been determined, we can efficiently decide whether G admits an embedding satisfying m in which the reference edge e is incident to the outer face by means of the following lemma.

► **Lemma 11.** Given $S(\rho)$, we can test whether G has an embedding that satisfies m in $O(k^2)$ time.

5 Partial 2-trees

In the following, we describe how to compute $S(\mu)$, if μ is an S-node (Lemma 12) and a P-node (Lemma 13) in $O(f(k)|\text{skel}(\mu)|)$ time, where f is a computable function.

► **Lemma 12.** *Set $S(\mu)$ can be constructed in $O(k^2|\text{skel}(\mu)|)$ time for an S-node μ .*

Sketch. Let μ be an S-node with skeleton $\text{skel}(\mu) = (e_1, e_2, \dots, e_h)$. We define τ_j as the S-node obtained by the series composition of $\mu_1, \mu_2, \dots, \mu_j$, with $j \leq h$. Initially we set $S(\tau_1) = S(e_1)$. Then, we construct $S(\tau_j)$, for $j = 2, \dots, h$, by verifying the compatibility of the embedding pairs of the good tuples of the virtual edges of $\text{skel}(\tau_j)$ at the internal vertices of $\text{skel}(\tau_j)$. As $S(\tau_j) = S(\tau_{j-1}) \cup e_j$, we can compute $S(\tau_j)$ by considering all the tuples obtained by combining every tuple $t' \in S(\tau_{j-1})$ with every tuple $t'' \in S(e_j)$. Since both these sets contain $O(k)$ tuples, by Property 1, and since the tuple resulting from the combination of t' and t'' can be determined in $O(1)$ time, we have that $S(\tau_j)$ can be computed in $O(k^2)$ time. Therefore, the overall running time for computing $S(\mu) = S(\tau_h)$ is $O(k^2|\text{skel}(\mu)|)$. ◀

► **Lemma 13.** *Set $S(\mu)$ can be constructed in $O((2k+4)!k^3 + |\text{skel}(\mu)|)$ time for a P-node μ .*

Sketch. Let μ be a P-node with poles u_μ and v_μ , whose skeleton $\text{skel}(\mu)$ consists of h parallel virtual edges e_1, e_2, \dots, e_h . It can be shown that the computation of $S(\mu)$ reduces in $O(|\text{skel}(\mu)|)$ time to the computation of $S(\tau)$, where τ is a P-node whose skeleton consists of at most $2k$ virtual edges of $\text{skel}(\mu)$ that contribute with at least one alternating pair of edges at u_μ or v_μ , plus up to 4 virtual edges of $\text{skel}(\mu)$ that contribute with no alternating pair at u_μ or at v_μ . For any permutation π of the virtual edges of $\text{pert}(\tau)$, let τ_i^π be the P-node obtained by restricting τ to the first i virtual edges in π . We fix the embedding of $\text{skel}(\tau_i^\pi)$ in such a way that the virtual edges of $\text{skel}(\tau_i^\pi)$ are ordered according to π . Then, in a fashion similar to the S-node case, we can compute $S(\tau_i^\pi)$ for the given embedding of $\text{skel}(\tau_i^\pi)$ by combining $S(\tau_{i-1}^\pi)$ and $S(e_i)$ in $O(k^2)$ time (recall that both these sets have size $O(k)$, by Property 1). Clearly, for any fixed π , we can compute $S(\tau_\pi^h)$ in $O(k^3)$ time. Thus, by performing the above computation for all the $(2k+4)!$ possible permutations for the virtual edges of $\text{pert}(\tau)$, we can construct $S(\tau)$ in $O((2k+4)!k^3 + |\text{skel}(\mu)|)$ time. ◀

Altogether, Lemmas 12 and 13 yield the following main result.

► **Lemma 14.** *k -MAXMODALITY can be solved in $O((2k+4)!k^3n)$ for series-parallel digraphs.*

Observation 1, Lemma 14, and Theorem 9 immediately imply the following.

► **Corollary 15.** *k -MODALITY can be solved in $O(((2k+4)!k^3 \log k)n)$ for directed partial 2-trees.*

Due to the special algorithmic framework we are employing, we can however turn the multiplicative $O(\log k)$ factor in the running time into an additive $O(k)$ factor by modifying Theorem 9 as follows. When considering a cut-vertex v , we will execute “only once” the function TESTBICONNECTED by rooting the SPQ-tree at a Q-node η corresponding to an edge incident to v . This will allow us to compute the minimum modality for cut-vertex v in an embedding that satisfies m at every vertex, by simply scanning the set $S(\eta)$, which takes $O(k)$ time by Property 1, rather than by exploiting a logarithmic number of calls to TESTBICONNECTED.

► **Theorem 16.** *k -MODALITY can be solved in $O((2k+4)!k^3n)$ for directed partial 2-trees.*

6 A Linear-time Algorithm for 4-MaxModality when $\Delta \leq 6$

In this section, we show that in the special case when $k = 4$ and G has maximum degree $\Delta \leq 6$, it is possible to compute the set $S(\mu)$ when μ is an R-node in linear time in the size of $\text{skel}(\mu)$.

Our strategy to compute $S(\mu)$ is as follows. We select a single tuple from the admissible set of each virtual edge incident to u_μ and v_μ , in every possible way. Each selection determines a “*candidate tuple*” t for $S(\mu)$. First, we check if t is admissible at both u and v . Second, we restrict the tuples of the edges incident to the poles to only the tuples that form t and check if there is a way of satisfying m at the (inner) vertices of $\text{skel}(\mu)$. If both the poles and the inner vertices are satisfiable, then we add t to $S(\mu)$. Since the degrees of the poles are bounded, there is at most a constant number of candidate tuples which must be checked. The complexity lies in this check.

We now formally describe how to compute $S(\mu)$. First, for each virtual edge e_i of $\text{skel}(\mu)$ incident to the poles of μ , we select a tuple t_i from $S(\mu_i)$. Let $T_u = [t_{u,1}, t_{u,2}, \dots, t_{u,\ell}]$ and $T_v = [t_{v,1}, t_{v,2}, \dots, t_{v,h}]$ be the list of tuples selected for the virtual edges incident to u_μ and to v_μ , respectively. Each pair of lists T_u and T_v yields a *candidate tuple* $t = \langle \sigma_1, a, \sigma_2, b \rangle$ for μ . However, the tuples selected to construct T_u and T_v allow for an admissible embedding of $\text{pert}(\mu)$ realizing tuple t *if and only if*: **(Condition 1)** tuple t satisfies m at u_μ and at v_μ , and **(Condition 2)** it is possible to select tuples for each of the remaining virtual edges of $\text{skel}(\mu)$ that satisfy m at every internal vertex of $\text{skel}(\mu)$. Let $\mathcal{P}(\mu)$ be the set of candidate tuples for μ constructed as described above. We can easily filter out the candidate tuples that do not satisfy Condition 1. In the remainder of the section, for each pair of lists T_u and T_v yielding a tuple $t \in \mathcal{P}(\mu)$, we will show how to test Condition 2 for μ in linear time. This and the fact that $|\mathcal{P}(\mu)| \in O(1)$ imply the following.

► **Lemma 17.** *Set $S(\mu)$ can be constructed in $O(|\text{skel}(\mu)|)$ time for an R-node μ , if $\Delta \leq 6$.*

Altogether, Lemmas 12, 13 and 17 yield the following main result.

► **Lemma 18.** *4-MAXMODALITY can be solved in linear time for biconnected digraphs with $\Delta \leq 6$.*

Observation 1, Lemma 18, and Theorem 9 immediately imply the following.

► **Theorem 19.** *4-MODALITY can be solved linear time for digraphs with $\Delta \leq 6$.*

To prove Lemma 17, we show how to solve the following auxiliary problem for special instances.

Problem: 4-MAXSKELMODALITY
<p>Input: A triple $\langle G = (V, E), \mathcal{S} = \{S(e_1), \dots, S(e_{ E })\}, m \rangle$ where G is an embedded directed graph, each $S(e_i)$ is a set containing embedding tuples for the virtual edge $e_i \in E$, and $m : V \rightarrow \mathbb{E}_4^+$ is the <i>maximum-modality function</i>.</p> <p>Question: Can we select a tuple from each set $S(e_i)$ in such a way that the modality at each vertex $v \in V$ is at most $m(v)$?</p>

For each pair of lists T_u and T_v yielding a candidate tuple in $\mathcal{P}(\mu)$, we will construct an instance $I_\mu(T_u, T_v) = (G, \mathcal{S}, m)$ of 4-MAXSKELMODALITY as follows. First, we set $G = \text{skel}(\mu)$ and we fix the embedding of G to be equal to the unique regular embedding of $\text{skel}(\mu)$. Second, for each virtual edge $e_{u,i}$ incident to u_μ , with $i = 1, \dots, \ell$, we set $S(e_{u,i}) = \{t_{u,i}\}$; for each virtual edge $e_{v,j}$ incident to v_μ , with $j = 1, \dots, h$, we set $S(e_{v,j}) = \{t_{v,j}\}$; and, for each of the remaining virtual edges e_d of $\text{skel}(\mu)$, we set $S(e_d) = S(\mu_d)$. Finally, the maximum-modality function of I_μ coincides with m .

Clearly, $I_\mu(T_u, T_v)$ is a positive instance of 4-MAXSKELMODALITY if and only if, given the constraints imposed by the tuples in T_u and in T_v , there exists a selection of tuples for the edges of G not incident to u_μ or v_μ that satisfies m at all the internal vertices of G , i.e., Condition 2 holds.

Let v be a vertex of G and let e be an edge in $E(v)$, we denote by $A_v(e)$ the maximum number of alternations at v over all the tuples in $S(e)$.

► **Definition 20** (Good instances). *An instance of 4-MAXSKELMODALITY is good if, for any vertex v in G , it holds $\sum_{e \in E(v)} (A_v(e) + 1) \leq 6$.*

Note that, for each edge e in $\text{ske}(\mu)$ incident to a vertex v , $\text{pert}(e)$ contributes at least $A_v(e) + 1$ edges to $d_{\text{pert}(e)}(v)$. Thus, we have $\sum_{e \in E(v)} (A_v(e) + 1) \leq \sum_{e \in E(v)} d_{\text{pert}(e)}(v) \leq 6$. Therefore, instance $I_\mu(T_u, T_v)$ is good. Although 4-MAXSKELMODALITY turns out to be NP-complete in general [21, Section 9], we are now going to show the following main positive result.

► **Theorem 21.** *4-MAXSKELMODALITY is linear-time solvable for good instances.*

The outline of the linear-time algorithm to decide whether a good instance $I = \langle G = (V, E), \mathcal{S} = \{S(e_1), \dots, S(e_{|E|})\}, m \rangle$ of 4-MAXSKELMODALITY is a positive instance is as follows.

- We process I by means of a set of *reduction rules* applied locally at the vertices of G and their incident edges. Each of these rules, if applicable, either detects that the instance I is a negative instance or transforms it into an equivalent smaller instance $I' = \langle G', \mathcal{S}', m' \rangle$. Each rule can be applied when specific conditions are satisfied at the considered vertex. A rule may additionally set a vertex as *marked*. Any marked vertex v has the main property that **any selection** of tuples from the admissible sets of the edges incident to v satisfies m' at v .
- Let I^* be the instance of 4-MAXSKELMODALITY obtained when no reduction rule may be further applied. We prove that instance I^* has a special structure that allows us to reduce the problem of testing whether I^* is a positive instance of 4-MAXSKELMODALITY to that of verifying the NAE-satisfiability of a constrained instance of NAESAT, in fact, of PLANAR NAESAT. Since PLANAR NAESAT is in P [25], this immediately implies that 4-MAXSKELMODALITY is also in P. However, in [21, Section 7], by strengthening a result of Porschen et al. [26], we are able to show that the constructed instances of NAESAT are always satisfiable and that a satisfying NAE-truth assignment can be computed in linear time.

In [21, Section 8], we provide three reduction rules that turn a good instance I into an equivalent smaller good instance I' . Let $I^* = \langle G^*, \mathcal{S}^*, m^* \rangle$ be the good instance, equivalent to I , produced by applying a maximal sequence of reduction rules to I . We say that I^* is *irreducible*. The following lemma will prove useful.

► **Lemma 22.** *For each unmarked vertex $v \in V(G^*)$, it holds that: (i) v has degree 3, (ii) $m^*(v) = 4$, and (iii) there exist tuples $t_1, t_2 \in S^*(e)$ such that the embedding pair of t_1 and of t_2 at v are $(\text{?}, 1)$ and $(\text{!}, 1)$, respectively, for each edge e incident to v .*

Our next and final tool is the following, quite surprising, result.

► **Lemma 23.** *Any irreducible good instance I^* is a positive instance.*

Theorem 21 immediately follows from Lemma 23. We conclude the section by providing a sketch of the proof of Lemma 23. A detailed proof can be found in [21, Section 8].

Outline of the proof of Lemma 23. If a vertex is marked then any combination of tuples will satisfy m^* at it. So the proof is mainly concerned with unmarked vertices. By Lemma 22, edges where both endpoints are unmarked have one of the following tuple sets: $S_A = \{(\uparrow, 1, \uparrow, 1), (\downarrow, 1, \downarrow, 1)\}$, $S_B = \{(\downarrow, 1, \uparrow, 1), (\uparrow, 1, \downarrow, 1)\}$, or $S_A \cup S_B$. In the last case we arbitrarily remove either S_A or S_B . Taking advantage of the structure of irreducible instances, the problem of solving I^* is reduced in linear time to the one of testing the NAE-satisfiability of a CNF-formula ϕ in which every variable occurs in at most two clauses. Each edge incident to an unmarked vertex has the two possible embedding pairs $(\uparrow, 1)$ or $(\downarrow, 1)$ at the vertex. We create a variable for each incidence between an edge and an unmarked vertex. For each edge with two unmarked endpoints, we introduce an *edge clause* to ensure that the embedding pairs for each endpoint are selected in a consistent way. Consider an unmarked vertex v and assume, for simplicity of description, that its three incident edges have the same orientation at v . A selection of embedding pairs for the edges incident to v will not satisfy $m^*(v)$ if and only if all such pairs coincide. Therefore, we can introduce a *vertex clause* to model such constraint as a NAESAT clause that is the disjunction of the three boolean variables for the endpoints of the edges incident to v . The NAE-formula ϕ has the property that each variable occurs in at most two clauses. Moreover, the variable-clause graph G_ϕ of ϕ contains no connected component that is isomorphic to a simple cycle, since vertex clauses have degree 3. In [21, Section 7], we prove that such instances are always NAE-satisfiable and provide a linear-time algorithm to construct a NAE-truth assignment for such formulas. This proves that I^* is always a positive instance.

7 Conclusions

In this paper, we studied the complexity of the k -MODALITY problem, with special emphasis on $k = 4$. We provided complexity, algorithmic, and combinatorial results. Our main algorithmic contribution for $k = 4$ and $\Delta \leq 6$ leverages an elegant connection with the NAE-satisfiability of special CNF formulas, whose study allowed us to strengthen a result in [26]. Moreover, we showed notable applications of the previous results to some new interesting embedding problems for clustered networks, some of which solve open problems in this area [3, 18].

Abstract

We study mechanism design for combinatorial cost sharing models. Imagine that multiple items or services are available to be shared among a set of interested agents. The outcome of a mechanism in this setting consists of an assignment, determining for each item the set of players who are granted service, together with respective payments. Although there are several works studying specialized versions of such problems, there has been almost no progress for general combinatorial cost sharing domains until recently [7]. Still, many questions about the interplay between strategyproofness, cost recovery and economic efficiency remain unanswered.

The main goal of our work is to further understand this interplay in terms of budget balance and social cost approximation. Towards this, we provide a refinement of cross-monotonicity (which we term *trace-monotonicity*) that is applicable to iterative mechanisms. The trace here refers to the order in which players become finalized. On top of this, we also provide two parameterizations (complementary to a certain extent) of cost functions which capture the behavior of their average cost-shares. Based on our trace-monotonicity property, we design a scheme of ascending cost sharing mechanisms which is applicable to the combinatorial cost sharing setting with symmetric submodular valuations. Using our first cost function parameterization, we identify conditions under which our mechanism is weakly group-strategyproof, $O(1)$ -budget-balanced and $O(H_n)$ -approximate with respect to the social cost. Further, we show that our mechanism is budget-balanced and H_n -approximate if both the valuations and the cost functions are symmetric submodular; given existing impossibility results, this is best possible. Finally, we consider general valuation functions and exploit our second parameterization to derive a more fine-grained analysis of the Sequential Mechanism introduced by Moulin. This mechanism is budget balanced by construction, but in general only guarantees a poor social cost approximation of n . We identify conditions under which the mechanism achieves improved social cost approximation guarantees. In particular, we derive improved mechanisms for fundamental cost sharing problems, including Vertex Cover and Set Cover.

1 Introduction

How to share the cost of a common service (or public good) among a set of interested agents constitutes a fundamental problem in mechanism design that has been studied intensively for at least two decades. Several deep and significant advancements have been achieved throughout this period, notably also combining classical mechanism design objectives (such as incentive compatibility, economic efficiency, etc.) with theoretical computer science objectives (such as approximability and computational efficiency).

However, in the vast majority of the cost sharing models that have been proposed and analyzed in the literature, it is assumed that the mechanism designer is offering a single service and that each agent has a private value describing the willingness to pay for the service. At the same time, there is also a publicly known cost function which describes the total cost for offering the service to each possible subset of agents. Said differently, this results in a single-parameter mechanism design problem, where the goal is to select a subset of the players that will be granted service, subject to covering the cost and achieving an economically efficient outcome.

Although significant progress has been made for such single-parameter domains, moving towards more general *combinatorial domains* has been almost elusive so far. Imagine that there are multiple goods to be shared among the agents who now have more complex valuation functions, expressing their willingness to pay for different subsets (or bundles) of goods. The cost function now depends on the subsets of agents sharing each of the items. An outcome of a mechanism under this setting, consists of an allocation, which specifies for each agent the goods for which she is granted service, together with a payment scheme.

The desired properties in designing a cost-sharing mechanism (be it combinatorial or not) are three-fold: (i) *group-strategyproofness*: we would like resistance to misreporting preferences by individual agents or coalitions, (ii) *budget-balance*: the payments of the players should cover the incurred cost, (iii) *economic efficiency*: the allocation should maximize a measure of social efficiency. The fundamental results in [10, 16] rule out the possibility that all three properties can be achieved. As a result, if we insist on any variant of strategyproofness, we are forced to settle with approximate notions of at least one of the other two criteria. In this context, approximate budget balance means that the mechanism may overcharge the agents, but not by too much. In terms of efficiency, considering a social cost objective instead of the classical social welfare objective (definitions are given in Section 2) seems more amenable for multiplicative approximation guarantees.

These adapted objectives have been investigated thoroughly for single-parameter problems, especially for cost-sharing variants of well-known optimization problems. In the context of more general combinatorial cost-sharing mechanisms, a restricted model with multiple levels of service was first studied in [13]. Ever since, for almost a decade, there was no additional progress along these lines. It was only recently that a step forward was made by Dobzinski and Ovadia [7]. In their work, they introduce a combinatorial cost-sharing model and derive the first mechanisms guaranteeing good budget balance and social cost approximation guarantees for different classes of valuation and cost functions. As already pointed out in [7], however, several important questions concerning our understanding of the approximability of these objectives remain open and deserve further study. This constitutes the starting point of our investigations reported in this work.

Our Contributions. We make further advancements on the design and analysis of mechanisms for combinatorial cost-sharing models. To begin with, the analysis of the mechanisms we study asks for new conceptual ideas which might be interesting on their own:

- We first provide a refinement of the well-known notion of *cross-monotonic* cost sharing functions, which is key in the intensively studied class of Moulin-Shenker mechanisms [15] for the single-parameter domain. We introduce the notion of *trace-monotonic* cost sharing functions which is applicable for mechanisms that proceed iteratively and evict agents one-by-one. Trace-monotonicity formalizes the fact that the cost-shares observed by a player for an item do not decrease throughout the *course* of the mechanism. That is, these cost shares may depend on the specific order (or *trace* as we will call it) in which the mechanism considers the agents.
- We identify two different and (to some extent) complementary parameterizations of the cost functions. Intuitively, these parameters measure the “variance” of the average cost-share $c(S)/|S|$, over all agent sets S . We introduce two such notions, which we term α -average decreasing and α -average min-bounded (see Definition 5 and Definition 15, respectively). We note that for every cost function, there exist respective values of α (possibly different for each definition) for which these properties are satisfied. These definitions provide an alternative way to classify cost functions and their respective approximation guarantees in terms of budget balance and social cost.

Using the above ideas, in Section 3, we derive a scheme for ascending cost sharing mechanisms, which can be seen as a (non-trivial) adaptation of the Moulin-Shenker mechanisms from the binary accept/reject setting to combinatorial cost sharing. Our notion of trace-monotonic cost shares plays a crucial role here. We show that our proposed mechanism is applicable for any non-decreasing cost function and for symmetric submodular valuations (i.e., submodular functions whose value depends only on the cardinality of the set).

By exploiting the first parameterization of α -average decreasing cost functions, our main result of Section 3 is that for $\alpha = O(1)$, our mechanism is polynomial-time, weakly group-strategyproof, $O(1)$ -budget-balanced and $O(H_n)$ -approximate with respect to social cost, where n is the number of agents.¹ As a consequence, if both the valuation and cost functions are symmetric submodular ($\alpha = 1$), the mechanism is budget-balanced and H_n -approximate. This is best possible even for a single item, as there exist corresponding inapproximability results by Dobzinski et al. [6]. Prior to our work, the best known mechanism for symmetric submodular valuation and cost functions is H_n -budget balanced and H_n -approximate [7]. We anticipate that further extensions and generalizations might be feasible through our framework and this type of ascending mechanisms.

In Section 4, we exploit our second parameterization of α -average min-bounded cost functions, and provide results for general valuation functions. As it turns out, our parameterization enables us to obtain a more fine-grained analysis of the Sequential Mechanism introduced by Moulin [14]. This mechanism is budget-balanced by construction, but in general only guarantees a poor social cost approximation of factor n . We show that for α -average min-bounded cost functions with $\alpha = O(1)$, the Sequential Mechanism is budget balanced and H_n -approximate with respect to social cost. Interestingly, this result does not even require monotonicity of the valuation functions. In addition, we can push our results even a bit further by introducing a refinement of this class of cost functions (see Definition 20) for which we show that the Sequential Mechanism is $O(1)$ -approximate. The refinement allows us to obtain improved mechanisms for several cost functions originating from combinatorial optimization problems. For example, our result implies that the Sequential Mechanism is d -approximate for certain cost-sharing variants of Vertex Cover and Set Cover, where d is the maximum degree of a node or the maximum size of a set, respectively; this improves upon existing results, even in the well-studied single-item case, when d is constant.

¹ We use H_n to denote the n -th *Harmonic number* defined as $H_n = 1 + \frac{1}{2} + \dots + \frac{1}{n}$.

In general, the two parameterizations of the cost functions introduced in this work seem to be suitable means to accurately capture the approximation guarantees of both the ascending cost-sharing mechanism of Section 3, and the Sequential Mechanism of Section 4. In fact, we have not managed to construct natural examples of cost functions which do not admit an $O(H_n)$ -approximation by neither of the mechanisms studied here. See also the discussion in Section 5, where some examples are constructed but they are rather artificial (Proposition 25). As such, these parameterizations help us to narrow down the class of cost functions which are not yet known to admit a good social cost approximation and enhance our understanding towards further progress in combinatorial cost sharing.

Related Work. For the single-item setting and with submodular cost functions, the best known group-strategyproof and budget balanced cost-sharing mechanism is arguably the Shapley value mechanism, introduced by Moulin and Shenker [14, 15]. This was also the first work that tried to quantify the efficiency loss of budget balanced cost-sharing mechanisms. Later, Feigenbaum et al. [9] showed that if one insists on truthfulness, there is no mechanism that achieves a finite approximation of the social welfare objective, even if one relaxes the budget balance property to cost recovery. To overcome this impossibility result, Roughgarden et al. [17] introduced the notion of *social cost* as an alternative means to quantify the efficiency of a mechanism. In the same work, they showed that the Shapley value mechanism is H_n -approximate with respect to this objective. Dobzinski et al. [6] established another impossibility result for the social cost objective, and showed that every mechanism satisfying truthfulness and cost recovery cannot achieve a social cost approximation guarantee better than $\Omega(\log n)$. The problem of deriving mechanisms with the best possible budget balance and social cost approximation guarantees for different cost functions arising from combinatorial optimization problems has been extensively studied in various works, see e.g., [2, 3, 4, 11].

Moving beyond the single-item case, Mehta et al. [13] introduced a new family of truthful mechanisms (called *acyclic mechanisms*) which apply to general demand settings of multiple identical items when players have symmetric submodular valuations. For additional works that consider the general demand setting, the reader is referred to [2, 3, 5, 14]. Birmpas et al. [1] also studied families of valuation and cost functions for the multiple item setting, under cost sharing models that are motivated by applications in participatory sensing environments.

Most related to our work is the recent work by Dobzinski and Ovadia [7]. To the best of our knowledge, this is the only prior work that considers a more general approach for combinatorial cost sharing. They studied a multi-parameter setting and proposed a new VCG-based mechanism. Basically, the idea is to run a VCG mechanism with respect to a modified objective function which is defined as the sum of the player valuations minus a potential. Intuitively, the latter ensures that the payments computed by the mechanism cover the actual cost. They showed that this mechanism is strategyproof and H_n -approximate with respect to social cost. They also identified several classes of valuation and cost functions for which the mechanism is H_n -budget balanced. In particular, this is the case if the valuation and cost functions are symmetric.² Additionally, they established that their mechanism is optimal with respect to the social cost approximation among all symmetric VCG-based mechanisms that always cover the cost.

² We note that their definition of symmetry for the cost function differs from the one we use here.

2 Definitions and Notation

We assume there is a set $N = \{1, 2, \dots, n\}$ of players and a set $M = \{1, 2, \dots, m\}$ of items. Each item can be viewed as a public good or some service that can be shared by the players. Each player i has a *private valuation function* $v_i : 2^M \rightarrow \mathbb{R}_{\geq 0}$ specifying the value that she derives from each subset of items.

A *cost-sharing mechanism* takes as input the declared (possibly false) valuation functions $\vec{b} = (b_i)_{i \in N}$ of the players and outputs (i) an allocation that determines which players share each item and (ii) a payment p_i for each player i . An allocation is denoted by a tuple $A = (A_1, \dots, A_n)$, where $A_i \subseteq M$ is the set of items provided to player i . For notational convenience, we also represent an allocation $A = (A_i)_{i \in N}$ as a tuple over the items space (T_1, \dots, T_m) such that for every item $j \in M$, $T_j \subseteq N$ is the subset of players sharing item j , i.e., $T_j = \{i \in N : j \in A_i\}$.

In this paper, we consider mostly *separable* cost functions. In the *separable setting*, we assume that the overall cost of an allocation decomposes into the cost for providing each item separately. Hence, every item j is associated to a known cost function $c_j : 2^N \rightarrow \mathbb{R}_{\geq 0}$, which specifies for each set of players $T \subseteq N$, the cost $c_j(T)$ of providing item j to the players in T . Thus, the total cost of an allocation A is defined as $C(A) = \sum_{j \in M} c_j(T_j)$. In Section 4.3, we also consider the *non-separable setting*, where we are given a more general cost function $C : (2^M)^n \rightarrow \mathbb{R}_{\geq 0}$, specifying for every allocation $A = (A_i)_{i \in N}$ the corresponding cost $C(A)$. Non-separable functions can capture dependencies among different items.

We assume that the utility functions of the players are *quasilinear*, i.e., given an allocation $A = (A_i)_{i \in N}$ and payments $(p_i)_{i \in N}$ determined by the mechanism for valuation functions $\vec{v} = (v_i)_{i \in N}$, the utility of player i is defined as $u_i(\vec{v}) = v_i(A_i) - p_i$. All our mechanisms have *no positive transfers* (NPT), i.e., $p_i \geq 0$, and satisfy *individual rationality* (IR), i.e., $p_i \leq v_i(A_i)$.

In addition to the above, we are also interested in the following properties:

- **Weak Group-Strategyproofness (WGSP):** We insist on a stronger notion of resistance to manipulation than truthfulness: A mechanism is *weakly group-strategyproof* if there is no deviation by a coalition of players that makes all its members strictly better off. More formally, we require that for every coalition $Q \subseteq N$ of players, every profile \vec{v}_{-Q} of the other players, there is no deviation \vec{b}_Q of the players in Q such that $u_i(\vec{b}_Q, \vec{v}_{-Q}) > u_i(\vec{v}_Q, \vec{v}_{-Q})$ for every $i \in Q$, where \vec{v}_Q is the profile of the actual valuation functions of Q .
- **Budget Balance:** We are interested in mechanisms whose payments cover the allocation cost, ideally exactly. However, the latter is not always possible as it may be incompatible with the other objectives. We therefore consider an approximate budget balance notion: A mechanism is *β -budget-balanced* ($\beta \geq 1$) if for every valuation profile $\vec{v} = (v_i)_{i \in N}$, the outcome (A, p) computed by the mechanism satisfies

$$C(A) \leq \sum_{i \in N} p_i \leq \beta \cdot C(A).$$

Clearly, we want β to be as small as possible to not overcharge players too much for covering the cost. We say that the mechanism is *budget balanced* if $\beta = 1$.

- **Economic Efficiency:** Our goal is to compute outcomes that are (approximately) efficient. To this aim, we use the *social cost objective*, originally defined in [17]. Adapted to our combinatorial setting, the *social cost* of an allocation $A = (A_i)_{i \in N}$ is defined as the actual cost of the outcome plus the value missed by not serving all items to all players, i.e.,

$$\pi(A) = \sum_{j \in M} c_j(T_j) + \sum_{i \in N} [v_i(M) - v_i(S_i)].^3$$

A mechanism is said to be α -approximate with respect to the social cost objective if for every valuation profile $\vec{v} = (v_i)_{i \in N}$, the allocation A output by the mechanism satisfies $\pi(A) \leq \alpha \cdot \pi(A^*)$, where A^* is an allocation of minimum social cost.

We assume that both the valuation functions $(v_i)_{i \in N}$ and the cost functions $(c_j)_{j \in M}$ are non-decreasing (see below for formal definitions). Further, we focus on certain classes of valuation and cost functions: More specifically, we consider *submodular* and *subadditive* cost functions, both naturally modeling economies of scale. As to the valuation functions, we consider *submodular* valuation functions in Section 3 and general valuation functions in Section 4. Further, the class of *symmetric XOS* functions play a prominent role in Section 3.⁴ Below we summarize all relevant definitions (see also Lehman et al. [12]).

► **Definition 1.** Let $f : 2^U \rightarrow \mathbb{R}_{\geq 0}$ be a function defined over subsets of a universe U .

1. f is non-decreasing if $f(S) \leq f(T)$ for every $S \subseteq T \subseteq U$.
2. f is symmetric if $f(S) = f(T)$ for every $S, T \subseteq U$ with $|S| = |T|$.
3. f is submodular if $f(S \cup \{i\}) - f(S) \geq f(T \cup \{i\}) - f(T)$ for every $S \subseteq T \subseteq U$ and $i \notin S$.
4. f is XOS if there are additive functions f^1, \dots, f^k such that $f(S) = \max_{i \in [k]} f^i(S)$ for all $S \subseteq U$.
5. f is subadditive if $f(S \cup T) \leq f(S) + f(T)$ for every $S, T \subseteq U$.
6. f is symmetric XOS if it is symmetric and $f(S)/|S| \geq f(T)/|T|$ for every $S \subseteq T \subseteq U$.

Some of our mechanisms make use of cross-monotonic cost-sharing functions defined as follows:

► **Definition 2.** Let $c : 2^N \rightarrow \mathbb{R}_{\geq 0}$ be a cost function. A cost-sharing function⁵ $\chi : N \times 2^N \rightarrow \mathbb{R}_{\geq 0}$ with respect to c specifies for each subset $S \subseteq N$ and every player $i \in S$ a non-negative cost share $\chi(i, S)$ such that $\sum_{i \in S} \chi(i, S) \geq c(S)$.⁶ χ is cross-monotonic if for all $S \subseteq T \subseteq N$ and every $i \in S$, we have $\chi(i, S) \geq \chi(i, T)$.

3 An Iterative Ascending Cost Sharing Mechanism

In this section, we present our *Iterative Ascending Cost Sharing Mechanism (IACSM)* for the combinatorial cost sharing setting with symmetric submodular valuations and general cost functions. We first provide a generic description of our mechanism and identify two properties which are sufficient for our main result to go through. We then show that these properties are satisfied if the valuations are symmetric submodular.

3.1 Definition of IACSM and Two Crucial Properties

Mechanism IACSM can be viewed as a generalization of the *Moulin-Shenker* mechanism [15] to the combinatorial setting in the sense that it simulates in parallel an ascending iterative auction for each item. To our knowledge this is the first ascending price mechanism for the combinatorial setting which is not VCG-based and as we will describe below, this adaptation is not straightforward since there are several obstacles we need to overcome. A description of our mechanism IACSM is given in Algorithm 1.

⁴ It is not hard to verify that these functions can equivalently be defined as stated in Definition 1 (see also [8]).

⁵ We stress here that we allow cost-sharing functions to overcharge the actual cost $c(\cdot)$. As a result, this will lead to approximately budget balanced mechanisms.

⁶ For notational convenience, we define $\chi(i, S) = \infty$ for $i \notin S$.

■ **Algorithm 1** Iterative Ascending Cost Sharing Mechanism (IACSM).

Input: Declared valuation functions $(b_i)_{i \in N}$.
Output: Allocation $A = (A_i)_{i \in N}$ and payments $p = (p_i)_{i \in N}$.

- 1 **Initialization:** Let $X = N$ be the set of active players and define $T_j = N$ for every item $j \in M$.
- 2 **while** $X \neq \emptyset$ **do**
- 3 Compute an *optimal bundle* A_i for every player $i \in X$:

$$A_i \in \arg \max_{S \subseteq M} \{b_i(S) - p_i(S)\}, \quad \text{where} \quad p_i(S) = \sum_{j \in S} \chi_j(T_j) \quad (1)$$

(If there are several optimal bundles, resolve ties as described within Section 3.1.)
- 4 Let $i^* \in X$ be a player such that $|A_{i^*}| \leq |A_i|$ for every $i \in X$.
- 5 Assign the items in A_{i^*} to player i^* and remove player i^* from X .
- 6 For every item $j \in M \setminus A_{i^*}$, set $T_j = T_j \setminus \{i^*\}$, and update the cost shares $\chi_j(T_j)$.
- 7 **return** $A = (A_i)_{i \in N}$ and $p = (p_i)_{i \in N}$, where $p_i = \sum_{j \in A_i} \chi_j(T_j)$.

The mechanism maintains a set of *active* players X and for each item $j \in M$ a set of players T_j who are *tentatively* assigned to j . Initially, each player is active and tentatively assigned to all the items, i.e., $X = N$ and $T_j = N$ for all $j \in M$. The mechanism then proceeds in iterations. In each iteration, each item j is offered to each active player $i \in X$ at a price that only depends on the set of tentatively assigned players T_j . For this, we use a player-independent *cost sharing function* $\chi_j(\cdot, T_j)$ for every item j , and since we require that $\chi_j(i, T_j) = \chi_j(k, T_j)$ for every $i, k \in T_j$, we will simply denote by $\chi_j(T_j)$ the cost share that each player $i \in T_j$ tentatively assigned to j has to pay. Based on these cost shares, every active player $i \in X$ computes an *optimal bundle* A_i with respect to the payments $p_i(\cdot)$, as defined in Equation (1). If there are ties, we resolve them according to the following *tie-breaking rule*: if there are several optimal bundles, then player i chooses one of maximum size. If there are multiple optimal bundles of maximum size k , then she chooses the bundle consisting of the k cheapest items (where ties between equal cost share items are resolved consistently, say by index of the items).

After determining the optimal bundle for each active player, the mechanism then chooses an active player i^* whose optimal bundle has minimum size. Again, we break ties consistently, say by index of the players. The items in A_{i^*} are assigned to player i^* and i^* becomes inactive. Finally, for every item j that does not belong to the optimal bundle A_{i^*} , i^* is removed from the tentative set T_j . The mechanism terminates when all players are inactive.

We next identify two crucial properties that our mechanism has to satisfy for our main result to go through. To formalize these properties, we introduce first some more notation.

Trace of IACSM. Note that the execution of our mechanism IACSM on an instance of the problem induces an order $\tau = (\tau_1, \dots, \tau_n)$ on the players. Without loss of generality, we may assume that the players are renamed such that $\tau = (1, \dots, n)$, i.e., player i becomes inactive in iteration i ; however, we emphasize that this order is determined by the run of our mechanism.

The order $\tau = (1, \dots, n)$ together with the final bundle A_i assigned to each player i at the end of iteration i induces an order of player withdrawals for each item j . More precisely, for every $j \in M$ we let τ_j be the subsequence of τ consisting only of the players who withdrew from item j (at the end of the iteration when they became inactive). We refer to τ_j as the *trace of item j* . Recall that initially $T_j = N$ and hence all players are tentatively assigned to j . The length of τ_j can vary from 0, when nobody withdraws from item j and τ_j is the null sequence, all the way to n , when everybody withdraws from j and $\tau_j = \tau$. Given a trace τ_j

in the form $\tau_j = (i_1, i_2, \dots, i_\ell)$ and $k \in \{0, 1, \dots, |\tau_j|\}$, let $R_j^k = N \setminus \{i_1, i_2, \dots, i_k\}$; define $R_j^0 = N$. Note that the set R_j^k is precisely the set of players tentatively assigned to j after k players have withdrawn from j during the execution of the mechanism. We note that the notion of trace is valid also for any other iterative mechanism where the assignment of one player becomes finalized at each iteration, e.g., [13].

Trace-monotonic cost sharing functions. We introduce a new property of cost sharing functions which will turn out to be crucial below. Intuitively, it is a refinement of the standard cross-monotonicity property which has to hold only for *certain* subsets of players encountered by the mechanism, namely for the sets $\{R_j^k\}$. More precisely, given a trace τ_j for an item $j \in M$, we say that the cost sharing function χ_j is *cross-monotonic with respect to τ_j* (or, *trace-monotonic* for short), if for every $k \in \{0, \dots, |\tau_j| - 1\}$, we have $\chi_j(R_j^k) \leq \chi_j(R_j^{k+1})$. Note that this ensures that the cost share of item j (weakly) increases during the execution of the mechanism, as we consider the sequence of sets $R_j^0 \supset R_j^1 \supset \dots \supset R_j^{|\tau_j|}$. A subtle point here is that the definition of the cost share $\chi_j(R_j^k)$ may not only depend on the set of players R_j^k , but also on the trace τ_j specifying how the set R_j^k has been reached by the mechanism.⁷ It will become clear below that this additional flexibility enables us to implement our mechanism for *arbitrary* cost functions.

Properties (P1) and (P2). Our first property is rather intuitive: An item j needs to be offered to all active players at the same price and this price can only increase in subsequent iterations. In particular, this ensures that if at the end of iteration i , player i withdraws from an item $j \in M \setminus A_i$, then the price of j for the remaining players in $T_j \setminus \{i\}$ does not decrease. This is crucial to achieve strategyproofness, and it is captured precisely by trace-monotonic cost sharing functions.⁸

(P1) For each item $j \in M$ the cost sharing function χ_j is trace monotonic for every trace τ_j .

The first property alone is not sufficient to ensure that our mechanism IACSM is weakly group-strategyproof (or even strategyproof). Additionally, we need to enforce the following refinement property on the final bundles assigned to the players. We prove below that Property (P2) is satisfied for symmetric submodular valuation functions.

(P2) The final bundles $(A_i)_{i \in N}$ assigned to the players satisfy the following *refinement property*: $A_i \subseteq A_{i+1}$ for every $i \in \{1, \dots, n-1\}$.

Feasibility of (P1) and (P2). We next define the cost sharing function that we use. The intuition is as follows: Suppose that $S = T_j$ is the set of players who are tentatively allocated to item j at the beginning of iteration i for some $i \in [n]$. Ideally, we would like to charge the average cost $c_j(S)/|S|$ to each player in S , but we cannot simply do this because the average cost might decrease with respect to the previous iteration, and this will destroy Property (P1). Given our new notion of trace-monotonicity, we can resolve this by defining the cost share of item j as the maximum average cost over all player sets which were tentatively allocated to j so far.

⁷ Notationally, we would have to write here $\chi_j^{\tau_j}$ to indicate the dependency on τ_j . However, in the analysis we focus on a fixed trace produced by an execution of the mechanism and omit the explicit reference to it for notational convenience.

⁸ Note that we have to require trace-monotonicity with respect to an *arbitrary* trace of item j here, because we cannot control the trace τ_j that will be realized by IACSM.

More formally, let τ_j be the trace of item j induced by IACSM when executed on a given instance. Let S be the set of players tentatively assigned to item j at the beginning of iteration i , and fix k such that $R_j^k = S$ (by the definition of our mechanism, such a k must exist and $k \leq i - 1$). We define

$$\chi_j(S) = \max_{\ell \in \{0, \dots, k\}} \frac{c_j(R_j^\ell)}{|n - \ell|}. \quad (2)$$

Note that by using this definition we may end up overcharging the actual cost $c_j(S)$ of item j in the sense that $|S| \cdot \chi_j(S) > c_j(S)$. As we show in Section 3.2, the budget balance and social cost approximation guarantees depend on the magnitude by which we might overcharge.

It is now trivial to show that Property (P1) holds.

► **Lemma 3.** *Consider some item $j \in M$ and let $c_j : 2^N \rightarrow \mathbb{R}_{\geq 0}$ be an arbitrary cost function. Let τ_j be an arbitrary trace of j . The cost sharing function χ_j defined in (2) is trace-monotonic.*

We turn to Property (P2). In general, it seems difficult to guarantee (P2), but it is not hard to see that it holds if the valuation functions are symmetric submodular.

► **Lemma 4.** *Suppose the valuation functions are symmetric submodular. Then $A_i \subseteq A_{i+1}$ for every $i \in \{1, \dots, n - 1\}$.*

3.2 Main result for IACSM

In order to state our main result of this section, we need to introduce a crucial parameter that determines the budget balance and social cost approximation guarantees of our mechanism.

► **Definition 5.** *A cost function $c : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is α -average-decreasing, for some $\alpha \geq 1$, if for every $S \subseteq T \subseteq N$, $\alpha \cdot \frac{c(S)}{|S|} \geq \frac{c(T)}{|T|}$.*

Note that for every cost function c there exists some $\alpha \geq 1$ such that c is α -average decreasing. However, here we are particularly interested in α -average decreasing cost functions for which the parameter α is small, as can be seen by Theorem 6 below. Average decreasing functions with small values of α arise naturally in the domains of digital goods and public goods. For digital goods the cost of serving a non-empty set of customers is typically assumed to be constant because there is a cost for producing the good and then it can be shared with no additional cost (hence the definition is satisfied with $\alpha = 1$). The same is applicable for some public good models. Note also that *symmetric XOS cost functions* (see Definition 1) are average-decreasing (i.e., $\alpha = 1$).

The following is the main result of this section.

► **Theorem 6.** *Suppose the valuation functions are symmetric submodular and the cost functions are α -average decreasing, for some $\alpha \geq 1$. Then the mechanism IACSM runs in polynomial time, satisfies IR, NPT, WGSP and is α -budget balanced and $2\alpha^3 H_n$ -approximate.*

Symmetric submodular cost functions are average decreasing (i.e., $\alpha = 1$) since they are a subclass of symmetric XOS functions. As a consequence, we obtain the following corollary from Theorem 6 (with an additional improvement on the social cost approximation).

► **Corollary 7.** *Suppose the valuation functions and the cost functions are symmetric submodular. Then the mechanism IACSM runs in polynomial time, satisfies IR, NPT, WGSP and is budget balanced and H_n -approximate.*

Note that the approximation factor of H_n for symmetric submodular functions is tight: The impossibility result of Dobzinski et al. [6] for a single public good implies that achieving a better approximation ratio is impossible, even in the single-item case ($m = 1$).

Finally we point out that α -average-decreasing functions are subadditive when $\alpha = 1$, while this is not necessarily true for $\alpha > 1$.

► **Lemma 8.** *Let $c(\cdot)$ be an α -average-decreasing cost function where $\alpha = 1$. Then $c(\cdot)$ is subadditive and in addition, not necessarily symmetric, or submodular. In case $c(\cdot)$ is α -average-decreasing with $\alpha > 1$, then $c(\cdot)$ is not necessarily subadditive.*

3.3 Proof of Social Cost Approximation

Due to lack of space, we will only establish the social cost approximation stated in Theorem 6. In this section, we will show that our mechanism IACSM is $2\alpha^3 H_n$ -approximate with respect to the social cost objective for symmetric submodular valuation functions.

Let $A = (A_i)_{i \in N}$ be the allocation computed by the mechanism, where $A_i \subseteq M$ is the subset of items that player i receives. As before, without loss of generality we assume that the player order induced by IACSM is $\tau = (1, \dots, n)$. Recall that for every item $j \in M$, $T_j = \{i \in N : j \in A_i\}$ is the final set of players that receive item j . We also use T_j^i to refer to the subset of players who are allocated to item j at the beginning of iteration i . Clearly, $T_j^i \supseteq T_j$ for every player i and item j .

We first state some simple lemmas which will be helpful to establish the social cost approximation guarantee.

► **Lemma 9.** *Fix an item $j \in M$ and let i be the first player in τ such that $j \in A_i$. Then $T_j = \{i, \dots, n\}$.*

► **Lemma 10.** *Consider player i who becomes inactive in iteration i . We have*

$$v_i(A_i) - \sum_{j \in A_i} \chi_j(T_j) \geq v_i(S) - \sum_{j \in S} \chi_j(T_j) \quad \forall S \subseteq M.$$

Proof. In iteration i , the final bundle A_i is chosen as the set of items maximizing the utility of player i with respect to the current cost shares, i.e.,

$$v_i(A_i) - \sum_{j \in A_i} \chi_j(T_j^i) \geq v_i(S) - \sum_{j \in S} \chi_j(T_j^i) \quad \forall S \subseteq M. \quad (3)$$

Recall that T_j^i is the set of players that are allocated to item j in iteration i . Note that by Lemma 9, $T_j^i = T_j$ for every $j \in A_i$. Further, $T_j^i \supseteq T_j$ for every $j \in M \setminus A_i$ as additional players might withdraw from j in subsequent iterations. Note that the final set T_j is reached from T_j^i by following the trace τ_j of item j . The claim now follows from the trace-monotonicity of χ_j (Property (P1)). ◀

► **Lemma 11.** *Consider player i who becomes inactive in iteration i . For every item $j \in M$,*

$$\chi_j(T_j^i) \leq \alpha \frac{c_j(\{i, \dots, n\})}{n - i + 1}.$$

► **Lemma 12.** *Let c be an α -average decreasing cost function. Let $S, T \subseteq N$ be arbitrary subsets with $|S| \leq |T|$. Then $c(S) \leq 2\alpha c(T)$.*

We are now ready to prove the approximation guarantee.

► **Lemma 13.** *Mechanisms IACSM is $2\alpha^3 H_n$ -approximate.*

Proof. Let $A^* = (A_1^*, \dots, A_n^*)$ be an optimal allocation and let T_j^* be the respective set of players that receive item j in A^* . We have

$$\begin{aligned} \pi(A) &= \sum_{i \in N} (v_i(M) - v_i(A_i)) + \sum_{j \in M} c_j(T_j) \\ &\leq \sum_{i \in N} v_i(M) - \sum_{i \in N} \left(v_i(A_i) - \sum_{j \in A_i} \chi_j(T_j) \right) \\ &\leq \sum_{i \in N} v_i(M) - \sum_{i \in N} \left(v_i(A_i^*) - \sum_{j \in A_i^*} \chi_j(T_j^i) \right) \\ &= \sum_{i \in N} (v_i(M) - v_i(A_i^*)) + \sum_{i \in N} \sum_{j \in A_i^*} \chi_j(T_j^i), \end{aligned}$$

where the first inequality holds because χ_j is α -budget balanced and the second inequality follows from Equation (3) in the proof of Lemma 10.

The proof follows if we can show that

$$\sum_{i \in N} \sum_{j \in A_i^*} \chi_j(T_j^i) \leq 2\alpha^3 H_n \sum_{j \in M} c_j(T_j^*). \quad (4)$$

We use a charging argument to prove (4). Fix some item $j \in M$ and order the players in T_j^* according to the player order $\tau = (1, \dots, n)$ induced by IACSM; let $T_j^* = \{i_1, \dots, i_{k_j^*}\}$ be the ordered set with $k_j^* := |T_j^*|$. We now “tag” each player i in T_j^* with a fraction of the cost $c_j(T_j^*)$ for item j as follows: For the l th player $i = i_l$ in T_j^* with $1 \leq l \leq k_j^*$, define

$$\text{tag}_i(j) := \frac{c_j(T_j^*)}{k_j^* - l + 1}. \quad (5)$$

That is, the first player i_1 in T_j^* is tagged with $c_j(T_j^*)/k_j^*$, the second player i_2 with $c_j(T_j^*)/(k_j^* - 1)$ and so forth, and the last player $i_{k_j^*}$ is tagged with $c_j(T_j^*)$.

We first derive two lower bounds on the tagged cost:

► **Claim 14.** For every player $i \in N$ and for every item $j \in A_i^*$:

$$\text{tag}_i(j) \geq \frac{c_j(T_j^*)}{n - i + 1} \quad \text{and} \quad \text{tag}_i(j) \geq \frac{c_j(T_j^*)}{|T_j^*|}.$$

Proof. The latter bound holds by definition (5). To see that the former bound holds, observe that the k th last player ($1 \leq k \leq k_j^*$) in the ordered set T_j^* is tagged by $c_j(T_j^*)/k$. The claim now follows because there are at most $n - i$ players succeeding i in T_j^* according to the order. ◁

Note that the total tagged cost of item j satisfies

$$\sum_{i \in T_j^*} \text{tag}_i(j) = \sum_{l=1}^{k_j^*} \frac{c_j(T_j^*)}{k_j^* - l + 1} \leq H_n c_j(T_j^*). \quad (6)$$

Thus, to prove (4) it suffices to show that the total cost share sum is upper bounded by the total tagged cost, i.e.,

$$\sum_{i \in N} \sum_{j \in A_i^*} \chi_j(T_j^i) \leq 2\alpha^3 \sum_{j \in M} \sum_{i \in T_j^*} \text{tag}_i(j). \quad (7)$$

20:12 Cost Sharing over Combinatorial Domains

We show that for every i and every $j \in A_i^*$, $\chi_j(T_j^i) \leq \text{tag}_i(j)$. Summing over all $i \in N$ and $j \in A_i^*$ then proves (4). We distinguish two cases:

Case 1: $|T_j^*| \geq n - i + 1$: Let $S \subseteq T_j^*$ be a set such that $|S| = n - i + 1$. We have

$$\chi_j(T_j^i) \leq \alpha \frac{c_j(\{i, \dots, n\})}{n - i + 1} \leq 2\alpha^2 \frac{c_j(S)}{|S|} \leq 2\alpha^2 \frac{c_j(T_j^*)}{n - i + 1} \leq 2\alpha^2 \text{tag}_i(j), \quad (8)$$

where the first inequality follows from Lemma 11, the second inequality follows from Lemma 12, the third inequality holds because c_j is non-decreasing and the last inequality follows from Claim 14.

Case 2: $|T_j^*| < n - i + 1$: Let $S \supset T_j^*$ be a set such that $|S| = n - i + 1$. We have

$$\chi_j(T_j^i) \leq \alpha \frac{c_j(\{i, \dots, n\})}{n - i + 1} \leq 2\alpha^2 \frac{c_j(S)}{|S|} \leq 2\alpha^3 \frac{c_j(T_j^*)}{|T_j^*|} \leq 2\alpha^3 \text{tag}_i(j), \quad (9)$$

where the first inequality follows from Lemma 11, the second inequality follows from Lemma 12, the third inequality holds because c_j is α -average-decreasing and the last inequality follows from Claim 14. This concludes the proof. \blacktriangleleft

4 Mechanisms for General Valuations and Subadditive Cost Functions

In this section, we move away from symmetric submodular valuation functions and derive results for more general functions. In particular, we investigate the performance of the *Sequential Mechanism* [14] for general valuations and subadditive cost functions. Although for arbitrary subadditive cost functions this mechanism does not provide favorable approximation guarantees, we identify conditions on the cost functions under which it achieves significantly better approximation factors. This is based on considering a different parameterization of cost functions with regard to their average cost shares.

4.1 The Sequential Mechanism

The *Sequential Mechanism* (SM) was introduced by Moulin [14] and was also studied in [7]. A description of the mechanism SM is given in Algorithm 2. We note that this mechanism is applicable both to separable and non-separable cost functions. Here, we first focus on separable cost functions, and in Section 4.3, we consider generalizations to the non-separable setting.

It is trivial to see that SM is budget-balanced and it is also known that it is WGSP [7]. However, for arbitrary monotone subadditive cost functions, the mechanism achieves a (poor) social cost approximation guarantee of n (see [7]). Despite this, we show that SM has better guarantees under certain conditions. Namely, we identify a crucial parameter of each cost function c_j with $j \in M$ that allows us to quantify this improvement. The parameterization introduced here is different from the one used in Section 3 and it compares the average cost of a set $T \subseteq N$ with the minimum standalone cost of a player in T .

► Definition 15. A cost function $c : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is α -average min-bounded, for some $\alpha \geq 1$, if for every set $T \subseteq N$, we have $\alpha \cdot \frac{c(T)}{|T|} \geq c_{\min}(T)$, where $c_{\min}(T) = \min_{j \in T} c(\{j\})$.

Definition 15 may look contrived at first glance and we thus provide some more intuition on how we arrived at this parameterization. Given that IACSM performs well for α -average decreasing functions and small values of α , as we established in Section 3, it is natural to

■ **Algorithm 2** Sequential Mechanism (SM).

Input: Declared valuation functions $(b_i)_{i \in N}$.
Output: Allocation $A = (A_i)_{i \in N}$ and payments $p = (p_i)_{i \in N}$.

- 1 **Initialization:** Fix an order on the set of players $N = \{1, \dots, n\}$.
- 2 **for** $i = 1, \dots, n$ **do**
- 3 Compute an *optimal bundle* A_i for player i :

$$A_i \in \arg \max_{S \subseteq M} \{b_i(S) - p_i(S)\}, \quad \text{where}$$

$$p_i(S) = C(A_1, \dots, A_{i-1}, S, \emptyset, \dots, \emptyset) - C(A_1, \dots, A_{i-1}, \emptyset, \dots, \emptyset).$$

(If there are multiple optimal bundles, choose the lexicographically smallest one.)
- 4 **return** $A = (A_i)_{i \in N}$ and $p = (p_i)_{i \in N}$, where $p_i = p_i(A_i)$.

focus on the complement of this class. For example, fix $\alpha = 1$ for now. Then the exact complement is not easy to characterize because it involves two existential quantifiers. We therefore consider a subset of this complement (with only one existential quantifier) by demanding that for every T , there exists $S \subseteq T$ such that $c(S)/|S| < c(T)/|T|$. It is not hard to verify that this definition is equivalent to the class of 1-average min-bounded functions. For larger values of α , we can see that α -average-min-bounded functions still capture a chunk of the complement of α -average-decreasing functions. Thus, a positive result for α -average-min-bounded functions narrows down on the cost functions that are not yet known to admit good approximation guarantees.

Note that for every cost function we can find an $\alpha \geq 1$ such that it is α -average min-bounded. As the next theorem reveals, the Sequential Mechanism attains a favorable performance for small values of α .

► **Theorem 16.** *Suppose we have general valuation functions and for each item $j \in M$, the cost function $c_j : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is non-decreasing, subadditive, and α -average min-bounded for some $\alpha \geq 1$. Then the Sequential Mechanism satisfies IR, NPT, WGSP, and is budget balanced and $\alpha \cdot H_n$ -approximate.*

For the proof of Theorem 16, we will use the following proposition:

► **Proposition 17.** *If $c : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is non-decreasing and α -average min-bounded, then $\sum_{i \in T} c(\{i\}) \leq \alpha H_{|T|} \cdot c(T)$ for every $T \subseteq N$.*

Proof of Theorem 16. We only need to prove that SM is αH_n -approximate. All the other properties have been established in [7, 14]. Let $A = (A_i)_{i \in N}$ be the allocation output by the mechanism and let $A^* = (A_i^*)_{i \in N}$ be an optimal allocation. Further, let T_j^* be the respective set of players that receive item j in A^* . To simplify notation in the analysis, we also let $A_{<i}$ denote the tuple $(A_1, \dots, A_{i-1}, \emptyset, \dots, \emptyset)$. Define now the incremental cost of a player i for a bundle $S \subseteq M$, with respect to the allocation constructed by the Sequential Mechanism before i 's turn as $\Delta_i(A_{<i}, S) = C(A_1, \dots, A_{i-1}, S, \emptyset, \dots, \emptyset) - C(A_1, \dots, A_{i-1}, \emptyset, \dots, \emptyset)$.

We have

$$\begin{aligned} \pi(A) &= \sum_{i \in N} [v_i(M) - v_i(A_i)] + C(A) = \sum_{i \in N} v_i(M) - \sum_{i \in N} [v_i(A_i) - \Delta_i(A_{<i}, A_i)] \\ &\leq \sum_{i \in N} [v_i(M) - v_i(A_i^*)] + \sum_{i \in N} \Delta_i(A_{<i}, A_i^*). \end{aligned}$$

20:14 Cost Sharing over Combinatorial Domains

Note that the inequality holds because A_i was chosen as the optimal bundle for i . The next step is to prove a bound on the incremental costs in the form

$$\sum_{i \in N} \Delta_i(A_{<i}, A_i^*) \leq \beta \cdot C(A^*). \quad (10)$$

The proof follows if we can show that (10) holds for $\beta = \alpha H_n$ because we then have

$$\pi(A) \leq \sum_{i \in N} [v_i(M) - v_i(A_i^*)] + \alpha \cdot H_n C(A^*) \leq \alpha H_n \cdot \pi(A^*).$$

By exploiting the subadditivity of the cost functions c_j , we obtain

$$\Delta_i(A_{<i}, A_i^*) = C(A_{<i}, A_i^*) - C(A_{<i}) \leq C(A_{<i}) + C(A_i^*, \emptyset_{-i}) - C(A_{<i}) = \sum_{j \in A_i^*} c_j(\{i\}).$$

Summing over over all $i \in N$, and using Proposition 17, we get:

$$\sum_{i \in N} \Delta_i(A_{<i}, A_i^*) \leq \sum_{i \in N} \sum_{j \in A_i^*} c_j(\{i\}) = \sum_{j \in M} \sum_{i \in T_j^*} c_j(\{i\}) \leq \sum_{j \in M} \alpha H_{|T_j^*|} c_j(T_j^*) \leq \alpha H_n C(A^*).$$

This proves (10) and concludes the proof of Theorem 16. \blacktriangleleft

By going through the proof of Theorem 16 more carefully, we realize the following:

► **Remark 18.** For any subclass of non-decreasing, subadditive cost functions, it suffices to establish inequality (10) to prove that the Sequential Mechanism has a social cost approximation guarantee of β .

Finally we have that for $\alpha = 1$ the approximation factor is tight.

► **Proposition 19.** *Even for the single item setting, there exists a 1-average min-bounded cost function, under which the Sequential Mechanism provides an H_n -approximation.*

4.2 Improved Approximation Guarantees and Applications

We continue with a natural refinement of Definition 15 which turns out to provide even better approximation factors of the Sequential Mechanism.

► **Definition 20.** *A cost function $c : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is α -average max-bounded, for some $\alpha \geq 1$, if for every set $T \subseteq N$, we have $\alpha \cdot \frac{c(T)}{|T|} \geq c_{\max}(T)$, where $c_{\max}(T) = \max_{j \in T} c(\{j\})$.*

Clearly, any function that is α -average max-bounded is also α -average min-bounded. Thus, we already have an αH_n -approximation for non-decreasing, subadditive and α -average max-bounded cost functions. Below we show that we can achieve a much better guarantee.

► **Theorem 21.** *Suppose we have general valuation functions and for each item $j \in M$, the cost function $c_j : 2^N \rightarrow \mathbb{R}_{\geq 0}$ is non-decreasing, subadditive, and α -average max-bounded for some $\alpha \geq 1$. Then the Sequential Mechanism satisfies IR, NPT, WGSP, and is budget-balanced and α -approximate.*

Example applications of combinatorial cost functions. We give some examples of combinatorial cost functions below and show that they are α -average max-bounded (possibly depending on some parameters of the combinatorial problem). In particular, by applying Theorem 21 we obtain attractive social cost approximation guarantees for these problems. For simplicity, all examples consider a single item only; but clearly, we can consider more general multiple item settings (e.g., when for each item $j \in M$, c_j captures one of the problems below).

- **Set Cover.** We are given a universe of elements U and a family $\mathcal{F} \subseteq 2^U$ of subsets of U . The players correspond to the elements of U and the cost $c(S)$ for serving a set of players $S \subseteq U$ is defined as the size of a minimum cardinality set cover for S .
- **Vertex Cover.** This is a special case of Set Cover. We are given an undirected and unweighted graph $G = (V, E)$ and the players are the edges of the graph. The cost $c(S)$ for serving a set $S \subseteq E$ of players is defined as the size of a minimum vertex cover in the subgraph induced by S .
- **Matching.** We are given an undirected and unweighted graph $G = (V, E)$ and the players correspond to the edges. The cost $c(S)$ for serving a set S of players is defined as the size of a maximum cardinality matching in the subgraph induced by S .

Using our α -average max-bounded notion, it is now easy to prove that these problems admit constant social cost approximation guarantees (under certain restrictions).

► **Theorem 22.** *The Sequential Mechanism is α -approximate for the above problems, where*

1. $\alpha = d$ for the Set Cover problem, where d is the maximum cardinality of the sets in \mathcal{F} ;
2. $\alpha = k$ for the Vertex Cover problem in graphs of maximum degree k ;
3. $\alpha = k$ for the Matching problem in bipartite graphs of maximum degree k ;
4. $\alpha = (5k + 3)/4$ for the Matching problem in general graphs of maximum degree k .

We can now compare these bounds with the existing results in the literature. For Vertex Cover, there is a mechanism that is 2-budget-balanced and $O(\log n)$ -approximate [13]. Thus, for graphs with maximum degree less than $\log n$, we obtain a better guarantee. For Set Cover, there is a mechanism that is $O(\log n)$ -budget-balanced and $O(\log n)$ -approximate [13]. Hence, we obtain an improvement if the sets in \mathcal{F} have a size that is no more than $o(\log n)$. Finally, we note that our results do not apply to the weighted versions of these problems.

4.3 Guarantees of the Sequential Mechanism for Non-Separable Cost Functions

We extend our results to non-separable cost functions. Recall that in this setting, the cost $C(A)$ of an allocation $A = (A_i)_{i \in N}$ is given by some general (not necessarily separable) cost function $C : (2^M)^n \rightarrow \mathbb{R}_{\geq 0}$. In particular, C may encode dependencies among different items.

We introduce some more notation. Given two allocations $S = (S_i)_{i \in N}$ and $T = (T_i)_{i \in N}$, we define $S \cup T$ as the componentwise union of S and T , i.e., $S \cup T = (S_1 \cup T_1, \dots, S_n \cup T_n)$. Similarly, we write $S \subseteq T$ if this relation holds componentwise, i.e., $S_i \subseteq T_i$ for every $i \in N$. Given an allocation $A = (A_i)_{i \in N}$ and a set of players $S \subseteq N$, we define $A|_S = (A_S, \emptyset_{-S})$ as the allocation in which each player $i \in S$ receives the items in A_i and all other players receive nothing. If $S = \{i\}$ is a singleton set, we also write $A|_i$ instead of $A|_{\{i\}}$. Throughout this section, we remain in the domain of non-decreasing and subadditive cost functions. In the non-separable case, a cost function $C : (2^M)^n \rightarrow \mathbb{R}_{\geq 0}$ is non-decreasing if $C(S) \leq C(T)$ for every pair of allocations S, T , with $S \subseteq T$. Also, it is subadditive if for every two allocations $S = (S_i)_{i \in N}$ and $T = (T_i)_{i \in N}$, we have $C(S \cup T) \leq C(S) + C(T)$.

We now adapt Definitions 15 and 20 to non-separable cost functions.

- **Definition 23.** Let $C : (2^M)^n \rightarrow \mathbb{R}_{\geq 0}$ be a non-separable cost function.
- C is α -average min-bounded, for some $\alpha \geq 1$, if for every allocation A and every subset $T \subseteq N$ with $|T| \geq 2$, it holds $\alpha \frac{C(A|_T)}{|T|} \geq C_{\min}(T)$, where $C_{\min}(T) = \min_{j \in T} C(A|_j)$.
 - C is α -average max-bounded, for some $\alpha \geq 1$, if for every allocation A and every subset $T \subseteq N$ with $|T| \geq 2$, it holds $\alpha \frac{C(A|_T)}{|T|} \geq C_{\max}(T)$, where $C_{\max}(T) = \max_{j \in T} C(A|_j)$.

As before, if a non-separable function is α -average max-bounded, then it is also α -average min-bounded.

We remark that it has been shown in [14, 7] that the Sequential Mechanism is weakly group-strategyproof and budget balanced for the non-separable setting. By adapting Proposition 17 for the non-separable setting and by using the same reasoning as in the proof of Theorem 16, we obtain the same approximation guarantee of αH_n as in the separable setting. Further, the improvement we obtained in Theorem 21 also goes through in this setting. We summarize these observations in the following corollary.

- **Corollary 24.** Suppose we have general valuation functions and a non-decreasing, subadditive, and α -average min-bounded cost function $C : (2^M)^n \rightarrow \mathbb{R}_{\geq 0}$. Then the Sequential Mechanism satisfies IR, NPT, WGSP, and is budget balanced and $\alpha \cdot H_n$ -approximate. Furthermore, if C is also α -average max-bounded, then the Sequential Mechanism is α -approximate.

5 Discussion

In Section 3, we proposed the mechanism IACSM, which is weakly group-strategyproof under general cost functions and symmetric submodular valuations. Moreover it is α -budget balanced and $2\alpha^3 H_n$ -approximate when we restrict the cost functions to the α -average-decreasing class. The social cost approximation guarantee further improves to H_n if the cost functions are symmetric submodular and this is best possible (due to the known lower bound for public-excludable goods [6]). It would be very interesting to explore mechanisms that go beyond symmetric submodular valuation functions. It seems that entirely new ideas are needed for this setting. It would also be interesting to extend our mechanism to non-separable cost functions. We note that separability of the costs in Section 3 is needed for IACSM only to argue that the cost share per item increases as players withdraw (with respect to the trace). One would need to investigate how to adapt the mechanism and enforce this property in the non-separable setting. Technically, this seems far from obvious and we leave a proper treatment of this issue for future work.

In Section 4, we studied the (partially) complementary class of α -average min bounded cost functions. We showed that the well-known Sequential Mechanism is budget balanced and αH_n -approximate even for general valuation functions. These results also extend to non-separable cost functions. A very natural question is whether SM is optimal in this setting and we note that the answer is not yet clear: The impossibility result of [6] holds for the public-excludable good cost function which is symmetric submodular and thus 1-average-decreasing. However, it is not hard to see that this does not fall within the α -average min bounded class for any constant α . This leads to the question of whether there exists a WGSP mechanism that breaks the $\Omega(\log(n))$ -approximation in terms of social cost for α -average-min bounded functions with small values of α .

Finally, what we also find very interesting is to identify the class of cost functions for which neither of the two mechanisms studied here perform well. Recall that, for any constant value of α , if a cost function is either α -average decreasing or α -average min-bounded, then a good performance is guaranteed. Thus, we need look at the complement of the set of

α -average decreasing functions and the set of α -average min-bounded functions for small value of α and examine whether these complements have a non-empty intersection. The following proposition shows that this intersection is indeed non-empty.

► **Proposition 25.** *Given $\alpha \geq 1$, the intersection of the complements of α -average-decreasing and α -average min-bounded functions is non-empty.*

The proof of this proposition follows by constructing a cost function that requires non-constant values of α to be captured by either of our parameterizations. Although the intersection turns out to be non-empty, the constructed cost function is rather artificial and more natural examples are elusive so far. In fact, for most of the known cost functions that have been studied in the literature, at least one of our mechanisms achieves an $O(H_n)$ -approximation. To make further progress, we believe it is important to understand better the class of functions defined by the intersection of the two complements, as it would help us to identify the missing elements for deriving mechanisms for a wider class of cost functions.

Abstract

Hyperbolic random graphs (HRG) and geometric inhomogeneous random graphs (GIRG) are two similar generative network models that were designed to resemble complex real world networks. In particular, they have a power-law degree distribution with controllable exponent β , and high clustering that can be controlled via the temperature T .

We present the first implementation of an efficient GIRG generator running in expected linear time. Besides varying temperatures, it also supports underlying geometries of higher dimensions. It is capable of generating graphs with ten million edges in under a second on commodity hardware. The algorithm can be adapted to HRGs. Our resulting implementation is the fastest sequential HRG generator, despite the fact that we support non-zero temperatures. Though non-zero temperatures are crucial for many applications, most existing generators are restricted to $T = 0$. We also support parallelization, although this is not the focus of this paper. Moreover, we note that our generators draw from the correct probability distribution, i.e., they involve no approximation.

Besides the generators themselves, we also provide an efficient algorithm to determine the non-trivial dependency between the average degree of the resulting graph and the input parameters of the GIRG model. This makes it possible to specify the desired expected average degree as input.

Moreover, we investigate the differences between HRGs and GIRGs, shedding new light on the nature of the relation between the two models. Although HRGs represent, in a certain sense, a special case of the GIRG model, we find that a straight-forward inclusion does not hold in practice. However, the difference is negligible for most use cases.

1 Introduction

Network models play an important role in different fields of science [8]. From the perspective of network science, models can be used to explain observed behavior in the real world. To mention one example, Watts and Strogatz [26] observed that few random long-range connections suffice to guarantee a small diameter. This explains why many real-world networks exhibit the small-world property despite heavily favoring local over long-range connections. From the perspective of computer science, and specifically algorithmics, realistic random networks can provide input instances for graph algorithms. This facilitates theoretical approaches (e.g., average-case analysis), as well as extensive empirical evaluations by providing an abundance of benchmark instances, solving the pervasive scarcity of real-world instances.

There are some crucial features that make a network model useful. The generated instances have to resemble real-world networks. The model should be as simple and natural as possible to facilitate theoretical analysis, and to prevent untypical artifacts. And it should be possible to efficiently draw networks from the model. This is particularly important for the empirical analysis of model properties and for generating benchmark instances.

A model that has proven itself useful in recent years is the *hyperbolic random graph (HRG)* model [17]. HRGs are generated by drawing vertex positions uniformly at random from a disk in the hyperbolic plane. Two vertices are joined by an edge if and only if their distance lies below a certain threshold; see Section 2.2. HRGs resemble real-world networks with respect to crucial properties. Most notable are the *power-law degree distribution* [15] (i.e., the number of vertices of degree k is roughly proportional to $k^{-\beta}$ with $\beta \in (2, 3)$), the high *clustering coefficient* [15] (i.e., two vertices are more likely to be connected if they have a common neighbor), and the small diameter [11, 19]. Moreover, HRGs are accessible for theoretical analysis (see, e.g., [15, 11, 19, 4]). Finally there is a multitude of efficient generators with different emphases [2, 24, 23, 25, 21, 13, 12]; see Section 1.2 for a discussion.

Closely related to HRGs is the *geometric inhomogeneous random graph (GIRG)* model [7]. Here every vertex has a position on the d -dimensional torus and a weight following a power law. Two vertices are then connected if and only if their distance on the torus is smaller than a threshold based on the product of their weights. When using positions on the circle ($d = 1$), GIRGs approximate HRGs in the following sense: the processes of generating a HRG and a GIRG can be coupled such that it suffices to decrease and increase the average degree of the GIRG by only a constant factor to obtain a subgraph and a supergraph of the corresponding HRG, respectively. Compared to HRGs, GIRGs are potentially easier to analyze, generalize nicely to higher dimensions, and the weights allow to directly adjust the degree distribution.

Above, we described the idealized *threshold variants* of the models, where two vertices are connected if and only if their distance is small enough. Arguably more realistic are the *binomial variants*, which allow longer edges and shorter non-edges with a small probability. This is achieved with an additional parameter T , called *temperature*. For $T \rightarrow 0$, the binomial and threshold variants coincide. Many publications focus on the threshold case, as it is typically simpler. This is particularly true for generation algorithms: in the threshold variants one can ignore all vertex pairs with sufficient distance, which can be done using geometric data structures. In the binomial case, any pair of vertices could be adjacent, and the search space cannot be reduced as easily. For practical purposes, however, a non-zero temperature is crucial as real-world networks are generally assumed to have positive temperature. Moreover, from an algorithmic perspective, the threshold variants typically produce particularly well-behaved instances, while a higher temperature leads to difficult problem inputs. Thus, to obtain benchmark instances of varying difficulty, generators for the binomial variants are key.

1.1 Contribution & Outline

Based on the algorithm by Bringmann, Keusch, and Lengler [7], we provide an efficient and flexible GIRG generator. It includes the binomial case and allows higher dimensions. Its expected running time is linear. To the best of our knowledge, this is the first efficient generator for the GIRG model. Moreover, we adapt the algorithm to the HRG model, including the binomial variant. Compared to existing HRG generators (most of which only support the threshold variant), our implementation is the fastest sequential HRG generator.

A refactoring of the original GIRG algorithm [7] allows us to parallelize our generators. They do not use multiple processors as effectively as the threshold-HRG generator by Penschuck [21], which was specifically tailored towards parallelism. However, in a setting realistic for commodity hardware (8 cores, 16 threads), we still achieve comparable run times.

Our generators come as an open-source C++ library¹ with documentation, command-line interface, unit tests, micro benchmarks, and OpenMP [6] parallelization using shared memory. An integration into NetworkKit [22] is available.

Besides the efficient generators, we have three secondary contributions. (I) We provide a comprehensible description of the sampling algorithm that should make it easy to understand how the algorithm works, why it works, and how it can be implemented. Although the core idea of the algorithm is not new [7], the previous description is somewhat technical. (II) The expected average degree can be controlled via an input parameter. However, the dependence of the average degree on the actual parameter is non-trivial. In fact, given the average degree, there is no closed formula to determine the parameter. We provide a linear-time algorithm to estimate it. (III) We investigate how GIRGs and HRGs actually relate to each other by measuring how much the average degree of the GIRG has to be decreased and increased to obtain a subgraph and supergraph of the HRG, respectively.

In the following we first discuss our main contribution in the context of existing HRG generators. In Section 2, we formally define the GIRG and HRG models. Afterwards we describe the sampling algorithm in Section 3. In Section 4 we discuss implementation details, including the parameter estimation for the average degree (Section 4.1) as well as multiple performance improvements. Section 5 contains our experiments: we investigate the scaling behavior of our generator in Section 5.1, compare our HRG generator to existing ones in Section 5.2, and compare GIRGs to HRGs in Section 5.3.

1.2 Comparison with Existing Generators

We are not aware of previous GIRG implementations. Concerning HRGs, most algorithms only support the threshold case; see Table 1. The only published exceptions are the trivial quadratic algorithm [2], and an $O((n^{3/2} + m) \log n)$ algorithm [23] based on a quad-tree data structure [24]. The latter is part of NetworkKit; we call it NKQUAD. Moreover, the code for a hyperbolic embedding algorithm [5] includes an HRG generator implemented by Bringmann based on the GIRG algorithm [7]; we call it EMBEDDER in the following. EMBEDDER has been widely ignored as a high performance generator. This is because it was somewhat hidden, and it is heavily outperformed by other threshold generators. Experiments show that our generator HYPERGIRGs is much faster than NKQUAD, which is to be expected considering the asymptotic running time. Moreover, on a single processor, we outperform EMBEDDER by an order of magnitude for $T = 0$ and by a factor of 4 for higher temperatures. As EMBEDDER does not support parallelization, this speed-up increases for multiple processors.

■ **Table 1** Existing hyperbolic random graph generators. The columns show the names used throughout the paper; the conference appearance; a reference (journal if available); whether the generator supports the binomial model; and the asymptotic running time. The time bounds hold in the worst case (wc), with high probability (whp), in expectation (exp), or empirically (emp).

Name	First Published	Ref.	Binom.	Running Time
PAIRWISE	CPC'15	[2]	✓	$\Theta(n^2)$ (wc)
QUADTREE	ISAAC'15	[24]		$O((n^{3/2} + m) \log n)$ (wc)
NKQUAD	IWOCA'16	[23]	✓	$O((n^{3/2} + m) \log n)$ (wc)
NKGEN, NKOPT	HPEC'16	[25]		$O(n \log n + m)$ (emp)
EMBEDDER	ESA'16	[5]	✓	$\Theta(n + m)$ (exp)
HYPERGEN	SEA'17	[21]		$O(n \log \log n + m)$ (whp)
RHG	IPDPS'18	[13]		$\Theta(n + m)$ (exp)
SRHG	JPDC'19	[12]		$\Theta(n + m)$ (exp)
HYPERGIRGS	this paper		✓	$\Theta(n + m)$ (exp)

For the threshold variant of HRGs, there are the following generators. The quad-tree data structure mentioned above was initially used for a threshold generator (QUADTREE) [24]. It was later improved leading to the algorithm currently implemented in NetworKit (NKGEN) [25]. A later re-implementation by Penschuck [21] improves it by about a factor of 2 (NKOPT). However, the main contribution of [21] was a new generator that features sublinear memory and near optimal parallelization (HYPERGEN). Up to date, HYPERGEN was the fastest threshold-HRG generator on a single processor. Our generator, HYPERGIRGS, improves by a factor of 1.3 – 2 (depending on the parameters) but scales worse for more processors. Finally, Funke et al. [13] provide a generator designed for a distributed setting to generate enormous instances (RHG). Its run time was later further reduced (SRHG) [12].

2 Models

2.1 Geometric Inhomogeneous Random Graphs

GIRGs [7] combine elements from random geometric graphs [14] and Chung-Lu graphs [10, 9]. Let $V = \{1, \dots, n\}$ be a set of vertices with positive weights w_1, \dots, w_n following a power law with exponent $\beta > 2$. Let W be their sum. Let \mathbb{T}^d be the d -dimensional torus for a fixed dimension $d \geq 1$ represented by the d -dimensional cube $[0, 1]^d$ where opposite boundaries are identified. For each vertex $v \in V$, let $x_v \in \mathbb{T}^d$ be a point drawn uniformly and independently at random. For $x, y \in \mathbb{T}^d$ let $\|x - y\|$ denote the L_∞ -norm on the torus, i.e. $\|x - y\| = \max_{1 \leq i \leq d} \min\{|x_i - y_i|, 1 - |x_i - y_i|\}$. Two vertices $u \neq v$ are independently connected with probability p_{uv} . For a positive temperature $0 < T < 1$,

$$p_{uv} = \min \left\{ 1, c \left(\frac{w_u w_v / W}{\|x_u - x_v\|^d} \right)^{1/T} \right\} \quad (1)$$

while for $T = 0$ a threshold variant of the model is obtained with

$$p_{uv} = \begin{cases} 1 & \text{if } \|x_u - x_v\| \leq c(w_u w_v / W)^{1/d}, \\ 0 & \text{else.} \end{cases}$$

The constant $c > 0$ controls the expected average degree. We note that the above formulation slightly deviates from the original definition; see Section 2.3 for more details.

2.2 Hyperbolic Random Graphs

HRGs [17] are generated by sampling random positions in the hyperbolic plane and connecting vertices that are close. More formally, let $V = \{1, \dots, n\}$ be a set of vertices. Let $\alpha > 1/2$ and $C \in \mathbb{R}$ be two constants, where α controls the power-law degree distribution with exponent $\beta = 2\alpha + 1 > 2$, and C determines the average degree \bar{d} . For each vertex $v \in V$, we sample a random point $p_v = (r_v, \theta_v)$ in the hyperbolic plane, using polar coordinates. Its angular coordinate θ_v is chosen uniformly from $[0, 2\pi)$ while its radius $0 \leq r_v < R$ with $R = 2 \log(n) + C$ is drawn according to the density function $f(r) = \frac{\alpha \sinh(\alpha r)}{\cosh(\alpha R) - 1}$. In the threshold case of HRGs two vertices $u \neq v$ are connected if and only if their distance is below R . The hyperbolic distance $d(p_u, p_v)$ is defined via $\cosh(d(p_u, p_v)) = \cosh(r_u) \cosh(r_v) - \sinh(r_u) \sinh(r_v) \cos(\theta_u - \theta_v)$.

The binomial variant adds a temperature $T \in [0, 1]$ to control the clustering, with lower temperatures leading to higher clustering. Two nodes $u, v \in V$ are then connected with probability $p_T(d(p_u, p_v))$ where $p_T(d) = (\exp[(d - R)/(2T)] + 1)^{-1}$. For $T \rightarrow 0$, the two definitions (threshold and binomial) coincide.

2.3 Comparison of GIRGs and HRGs

Bringmann et al. [7] show that the HRG model can be seen as a special case of the GIRG model in the following sense. Let d_{HRG} be the average degree of a HRG. Then there exist GIRGs with average degree d_{GIRG} and D_{GIRG} with $d_{\text{GIRG}} \leq d_{\text{HRG}} \leq D_{\text{GIRG}}$ such that they are sub- and supergraphs of the HRG, respectively. Moreover, d_{GIRG} and D_{GIRG} differ only by a constant factor. Formally, this is achieved by using the big- O notation instead of a single constant c for the connection probability. We call this the *generic GIRG framework*. It basically captures any specific model whose connection probabilities differ from Equation (1) by only a constant factor. From a theoretical point of view this is useful as proving something for the generic GIRG framework also proves it for any manifestation, including HRGs.

To see how HRGs fit into the generic GIRG framework, consider the following mapping [7]. Radii are mapped to weights $w_v = e^{(R-r_v)/2}$, and angles are scaled to fit on a 1-dimensional torus $x_v = \theta_v/(2\pi)$. One can then see that the hyperbolic connection probability $p_T(d)$ under the provided mapping deviates from Equation (1) by only a constant. Thus, c in Equation (1) can be chosen such that all GIRG probabilities are larger or smaller than the corresponding HRG probabilities, leading to the two average degrees d_{GIRG} and D_{GIRG} mentioned above. Bringmann et al. [7] note that the two constants, which they hide in the big- O notation, do not have to match. They leave it open if they match, converge asymptotically, or how large the interval between them is in practice. We investigate this empirically in Section 5.3.

3 Sampling Algorithm

As mentioned in the introduction, the core of our sampling algorithm is based on the algorithm by Bringmann et al. [7]. In the following, we first give a description of the core ideas and then work out the details that lead to an efficient implementation.

To explain the idea, we make two temporary assumptions and relax them in Section 3.1 and Section 3.2, respectively. For now, assume that all weights are equal and consider only the threshold variant $T = 0$. The task is to find all vertex pairs that form an edge, i.e., their distance is below the threshold $c(w_u w_v / W)^{1/d}$. Since all weights are equal, the threshold in this restricted scenario is the same for all vertex pairs. One approach to quickly identify adjacent vertices is to partition the ground space into a grid of cells. The size of the cells should be chosen, such that (I) the cells are as small as possible and (II) the diameter

■ **Figure 1** (a),(b) The grid used by weight bucket pairs with a connection probability threshold between 2^{-3} and 2^{-4} in two dimensions. (a) Each pair of colored cells represent neighbors. Note that the ground space is a torus and a cell is also a neighbor to itself. (b) The eight gray cells represent multiple distant cell pairs, which are replaced by one pair consisting of the red outlined parent cell pair. (c) Linearization of the cells on level 1 (left) and 2 (right) for $d = 2$.

of cells is larger than the threshold $c(w_u w_v / W)^{1/d}$. The latter implies that only vertices in neighboring cells can be connected thus narrowing down the search space. The former ensures that neighboring cells contain as few vertex pairs as possible reducing the number of comparisons. Figure 1a shows an example of such a grid for a 2-dimensional ground space.

3.1 Inhomogeneous Weights

Assume that we have vertices with two different weights w_1, w_2 , rather than one. As before, the cells should still be as small as possible while having a diameter larger than the connection threshold. However, there are three different thresholds now, one for each combination of weights. To resolve this, we can group the vertices by weight and use three differently sized grids to find the edges between them.

As GIRGs require not only two but many weights, considering one grid for every weight pair is infeasible. The solution is to discretize the weights by grouping ranges of weights into *weight buckets*. When searching for edges between vertices in two weight buckets, the pair of largest weights in these buckets provides the threshold for the cell diameter. This choice of the cell diameter satisfies property (II). Property (I) is violated only slightly, if the weight range within the bucket is not too large. Thus, each combination of two weight buckets uses a grid of cells, whose granularity is based on the maximum weight in the respective buckets.

As a tradeoff, we choose $\lceil \log_2 n \rceil$ many buckets which yields a sublinear number of grids. Moreover, the largest and smallest weight in a bucket are at most a factor two apart. Thus, the diameter of a cell is too large by at most a factor of four.

With this approach, a single vertex has to appear in grids of different granularity. To do this in an efficient manner, we recursively divide the space into ever smaller grid cells, leading to a hierarchical subdivision of the space. This hierarchy is naturally described by a tree. For a 2-dimensional ground space, each node has four children, which is why we call it *quadtree*. Note that each level of the quadtree represents a grid of different granularity. Moreover, the side length of a grid cell on level ℓ is $2^{-\ell}$. For a pair (i, j) of weight buckets, we then choose the level that fits best for the corresponding weights, i.e., the deepest level such that the diameter of each grid cell is above the connection threshold for the largest weights in bucket i and j , respectively. We call this level the *comparison level*, denoted by $CL(i, j)$. It suffices to insert vertices of a bucket into the deepest level among all its comparison levels. This level is called the *insertion level* and we denote it by $I(i)$. In Section 3.4, we discuss in detail how to efficiently access all vertices in a given grid cell belonging to a given weight bucket.

3.2 Binomial Variant of the Model

For $T > 0$, neighboring cell pairs are still easy to handle: a constant fraction of vertex pairs will have an edge and one can sample them by explicitly checking every pair. For distant cell pairs and a fixed pair of weight buckets, the distance between the cells yields an upper bound on the connection probability of included vertices; see Equation (1). The probability bound depends on both, the weight buckets and the cell pair distance, using the maximum weight within the buckets and the minimum distance between points in the cells. We note that the individual connection probabilities are only a constant factor smaller than the upper bound.

Knowing this, we can use geometric jumps to skip most vertex pairs [1]. The approach works as follows. Assume that we want to create an edge with probability \bar{p} for each vertex pair. For this process, we define the random variable X to be the number of vertex pairs we see until we add the next edge. Then X follows a geometric distribution. Thus, instead of throwing a coin for each vertex pair, we can do a single experiment that samples X from the geometric distribution and then skip X vertex pairs ahead. Since not all vertex pairs reach the upper bound \bar{p} , we accept encountered pairs with probability p_{uv}/\bar{p} to get correct results.

Although distant cell pairs are handled efficiently, their number is still quadratic, most of which yield no edges. To circumvent this problem, the sampling algorithm, yet again, uses a quadtree. In the quadratic set of cell pairs to compare for one weight bucket pair, non-neighboring cells are grouped together along the quadtree hierarchy. They are replaced by their parents as shown in Figure 1b until their parents become neighbors.

In conclusion, for each pair of weight buckets (i, j) the following two types of cell pairs have to be processed. Any two neighboring cell pairs on the comparison level $CL(i, j)$; and any distant cell pair with level larger or equal $CL(i, j)$ that has neighboring parents. The resulting set of distant and neighboring cell pairs for a fixed bucket pair partitions $\mathbb{T}^d \times \mathbb{T}^d$.

3.3 Efficiently Iterating Over Cell Pairs

The previous description sketches the algorithm as originally published. Here, we propose a refactoring that greatly simplifies the implementation and enables parallelization. We attribute a significant amount of HYPERGIRGS' speed up over EMBEDDER to this change.

Instead of first iterating over all bucket pairs and then over all corresponding cell pairs, we reverse this order. This removes the need to repeatedly determine the cell pairs to process for a given bucket pair. Instead it suffices to find the bucket pairs that process a given cell pair. This only depends on the level of the two cells and their type (neighboring or distant). Inverting the mapping from bucket pairs to cell pairs in the previous section yields the following. A neighboring cell pair on level ℓ is processed for bucket pairs with a comparison level of exactly ℓ . A distant cell pair on level ℓ (with neighboring parents) is processed for bucket pairs with a comparison level larger than or equal to ℓ . Thus, for each level of the quadtree we must enumerate all neighboring cell pairs, as well as distant cell pairs with neighboring parents. Algorithm 1 recursively enumerates exactly these cell pairs.

3.4 Efficient Access to Vertices by Bucket and Cell

A crucial part of the algorithm is to quickly access the set of vertices restricted to a weight bucket i and a cell A , which we denote by V_i^A . To this end, we linearize the cells of each level as illustrated in Figure 1c. This linearization is called Morton code [18] or z-order curve [20]. It has the nice properties that (I) for each cell in level ℓ , its descendants in level $\ell' > \ell$ in the quadtree appear consecutively; and (II) it is easy to convert between a cell's position in the linear order and its d -dimensional coordinates (see Section 4.2).

■ **Algorithm 1** Sample GIRG by Recursive Iteration of Cell Pairs.

Input: cell pair (A,B) ; initially called with A,B set to the root of the quadtree

```

1 forall bucket pairs  $(i, j)$  that process the cell pair  $(A, B)$  do
2   if  $A$  and  $B$  are neighbors then
3     emit each edge  $(u, v) \in V_i^A \times V_j^B$  with probability  $p_{uv}$ 
4   else
5     choose candidates  $S \subseteq V_i^A \times V_j^B$  using geometric jumps and  $\bar{p}$ 
6     emit each edge  $(u, v) \in S$  with probability  $p_{uv}/\bar{p}$ 
7 if  $A$  and  $B$  are neighbors and not maximum depth reached then
8   forall children  $X$  of  $A$  do
9     forall children  $Y$  of  $B$  do
10    recur( $X, Y$ )

```

We sort the vertices of a fixed weight bucket i by the Morton code of their containing cell on the insertion level $I(i)$, using arbitrary tie-breaking for vertices in the same cell. This has the effect that for any cell A with $\text{level}(A) \leq I(i)$, the vertices of V_i^A appear consecutive. Thus, to efficiently enumerate them, it suffices to know for each cell A the index of the first vertex in V_i^A . This can be precomputed using prefix sums leading to the following lemma.

► **Lemma 1.** *After linear preprocessing, for all cells A and weight buckets i with $\text{level}(A) \leq I(i)$, vertices in the set V_i^A can be enumerated in $\mathcal{O}(|V_i^A|)$.*

4 Implementation Details

The description in the previous section is an idealized version of the algorithm. For an actual implementation, there are some gaps to fill in. Omitting many minor tweaks, we want to sketch optimizations that are crucial to achieve a good practical run time in the following. More details on the sketched approaches can be found in the long version of this paper [3].

4.1 Estimating the Average Degree Parameter

Here, we sketch how to estimate the parameter c in Eq. (1) to achieve a given expected average degree. We estimate the constant based on the actual weights, not on their probability distribution. This leads to lower variance and allows user-defined weights.

We start with an arbitrary constant c , calculate the resulting expected average degree $\mathbb{E}[\bar{d}]$ and adjust c accordingly, using a modified binary search. This is possible, as $\mathbb{E}[\bar{d}]$ is monotone in c . We derive an exact formula for $\mathbb{E}[\bar{d}]$, depending on c and the weights. It cannot simply be solved for c , which is why we use binary search instead of a closed expression.

For the binary search, we need to evaluate $\mathbb{E}[\bar{d}]$ for different values of c . This is potentially problematic, as the formula for $\mathbb{E}[\bar{d}]$ sums over all vertex pairs. The issue preventing us from simplifying this formula is the minimum in the connection probability. Therefore, we first ignore the minimum and subtract an error term for those vertex pairs, where the minimum takes effect. The remaining hard part is to calculate this error term. Let E_S be the set of vertex pairs appearing in the error term and let S be the set of vertices with at least one partner in E_S . Although $|E_S|$ itself is sufficiently small, S is too large to determine E_S by iterating over all pairs in $S \times S$. We solve this by iterating over the vertices in S , sorted by weight. Then, for each vertex we encounter, the set of partners in E_S is a superset of the partners of the previous vertex with smaller weight, allowing us to compute $\mathbb{E}[\bar{d}]$ in $O(S)$.

4.2 Efficiently Encoding and Decoding Morton Codes

Recall from Section 3.4 that we linearize the d -dimensional grid of cells using Morton code. As vertex positions are given as d -dimensional coordinates, we have to convert the coordinates to Morton codes (i.e., the index in the linearization) and vice versa. This is done by bitwise interleaving the coordinates. For example, the 2-dimensional Morton code of the four-bit coordinates $a = a_3a_2a_1a_0$ and $b = b_3b_2b_1b_0$ is $a_3b_3a_2b_2a_1b_1a_0b_0$. We evaluated different encoding and decoding approaches via micro benchmarks. The fastest approach, at least on Intel processors, was an assembler instruction from BMI2 proposed by Intel in 2013 [16].

4.3 Generating HRGs Avoiding Expensive Mathematical Operations

The algorithm from Section 3 can be used to generate HRGs. The algorithm works conceptually the same, except that most formulas change. This has for example the effect that we no longer get a closed formula to determine the insertion level of a weight bucket or the comparison level of a bucket pair. Instead, one has to search them, by iterating over the levels of the quadtree. Furthermore, HRGs introduce many computationally expensive mathematical operations like the hyperbolic cosine. This can be mitigated as follows.

For the threshold model, an edge exists if the distance d is smaller than R . Considering how the hyperbolic distance is defined (Section 2.2), reformulating it to $\cosh(d) < \cosh(R)$ avoids the expensive $\operatorname{arccosh}$, while $\cosh(R)$ remains constant during execution and can thus be precomputed. Similar to recent threshold HRG generators, we compute intermediate values per vertex such that $\cosh(d)$ can be computed using only multiplication and addition [12, 21].

For the binomial model, evaluating the connection probability is a performance bottleneck. The straightforward way to sample edges is: compute the connection probability $p_T(d)$ depending on the distance, sample a uniform random value $u \in [0, 1]$, and create the edge if and only if $u < p_T(d)$. We can improve this by precomputing the inverse of $p_T(d)$ for equidistant values in $[0, 1]$. This lets us, for small ranges in $[0, 1]$, quickly access the corresponding range of distances. Changing the order, we first sample $u \in [0, 1]$, which falls in a range between two precomputed values, which in turn yields a range of distances. If the actual distance lies below that range, there has to be an edge and if it lies above, there is no edge. Only if it lies in the range, we actually have to compute the probability $p_T(d)$.

4.4 Parallelization

The algorithm has five steps: generate weights, generate positions, estimate the average degree constant, precompute the geometric data structure, and sample edges. The first two are trivial to parallelize. For estimating the constants, we parallelize the dominant computations with linear running time. To sample the edges, we make use of the fact that we iterate over cell pairs in a recursive manner. This can be parallelized by cutting the recursion tree at a certain level and distributing the loose ends among multiple processors.

For the preprocessing we have to do three subtasks: compute for each vertex its containing cells on its insertion level, sort the vertices according to their Morton code index, and compute the prefix sum for all cells. We parallelize all three tasks and optimize them by handling all weight buckets together, sorting by weight bucket first and Morton code second. This is done by encoding this criterion into integers that are sorted with parallel radix sort.

■ **Figure 2** Sequential run time for the steps of the GIRG sampling algorithm averaged over 10 iterations. Each plot varies a different model parameter deviating from a base configuration $d = 1$, $n = 2^{15}$, $T = 0$, $\beta = 2.5$, and $\bar{d} = 10$. The base configuration is indicated by a dashed vertical line.

5 Experimental Evaluation

We perform three types of experiments. In Section 5.1 we investigate the scaling behavior of our GIRG generator, broken down into the different tasks performed by the algorithm. In Section 5.2 we compare our HRG generator with existing generators. In Section 5.3 we experimentally investigate the difference between HRGs and their GIRG counterpart. Whenever a data point represents the mean over multiple iterations, our plots include error bars that indicate the standard deviation. Besides the implementation itself, all benchmarks and analysis scripts are also accessible in our source repository.

5.1 Scaling of the GIRG Generator

We investigate the scaling of the generator, broken down into five steps. 1. **(Weights)** Generate power-law weights. 2. **(Positions)** Generate points on \mathbb{T}^d . 3. **(Binary)** Estimate the constant controlling the average degree. 4. **(Pre)** Preprocess the geometric data structure (Section 3.4). 5. **(Edges)** Sample edges between all vertex pairs as described in Algorithm 1.

Figure 2 shows the sequential run time over the number of nodes n (top left), number of edges m (top right), temperature T (bottom right), and dimension d (bottom right). The performance is measured in nanoseconds per edge. Each data point represents the mean over 10 iterations. To make the measurements independent of the graph representation, we do not save the edges into RAM, but accumulate a checksum instead. Note that the top right plot increases the average degree, resulting in a decreased time per edge.

The empirical run times match the theoretical bounds: it is linear in n and m , grows exponentially in the dimension d , and is unaffected by the temperature T . The overall time is dominated by the edge sampling. Generating the weights includes expensive exponential functions, making it the slowest step after edge sampling. Generating the positions is significantly faster even for higher dimensions. For the parameter estimation using binary search, one can see that the run time never exceeds the time to generate the weights. For

Figure 3 Comparison of HRG generators averaged over 5 iterations. (a), (b) Threshold variant for different average degrees \bar{d} and power-law exponents β . (c) Binomial variant with temperature $T = 0.5$. (d) The same configuration as (b) but utilizing multiple cores.

non-zero temperature T the performance of the binary search is similar to the generation of the weights, as it also requires exponential functions. The lower run times per edge for the increasing number of edges (top right) show that the run time is dominated by the number of nodes n . Only for very high average degrees, the cost per edge outgrows the cost per vertex.

5.2 HRG Run Time Comparison

We evaluate the run time performance of HYPERGIRGs compared to the generators in Table 1, excluding the generators with high asymptotic run time as well as RHG and SRHG. RHG and SRHG are designed for distributed machines. Executed on a single compute node, the performance of the faster SRHG is comparable to HYPERGEN [12]. To avoid systematic biases between different graph representations, the implementations are modified² not to store the resulting graph. Instead, only the number of edges produced is counted and we ensure that the computation of incident nodes is not optimized away by the compiler.

We used different machines for our sequential and parallel experiments. The former are done on an *Intel Core i7-8700K* with 16 GB RAM, the latter on an *Intel Xeon CPU E5-2630 v3* with 8 cores (16 threads) and 64 GB RAM.

Our generator HYPERGIRGs is consistently faster than the competitors, independent of the parameter choices; see Figure 3a and 3b. Only for unrealistic average degrees (1k), HYPERGEN slightly outperforms HYPERGIRGs. Moreover, HYPERGIRGs beats EMBEDDER, the only other efficient generator supporting non-zero temperature, by an order of magnitude.

² The modifications are publicly available and referenced in our GitHub repository.

■ **Figure 4** Relation between the HRG and the GIRG model. (a) The values for d_{HRG} , d_{GIRG} , D_{GIRG} averaged over 50 iterations. (b) The number of missing ($\text{HRG} \setminus \text{GIRG}$) and additional ($\text{GIRG} \setminus \text{HRG}$) edges depending on the expected degree of the corresponding GIRG. It can be interpreted as a cross-section of one iteration in (a).

For higher temperatures, we compare our algorithm with the two other non-quadratic generators NKQUAD (included in NetworkKit) and EMBEDDER; see Figure 3c. We note that EMBEDDER uses a different estimation for R , which leads to an insignificant left-shift of the corresponding curve. In Figure 3c, one can clearly see the worse asymptotic running time of NKQUAD. Compared to EMBEDDER, HYPERGIRGS is consistently 4 times faster.

Figure 3d shows measurements for parallel experiments using 16 threads. The parameters coincide with Figure 3b. EMBEDDER does not support parallelization and is outperformed even more. For sufficiently large graphs, the fastest generator in this multi-core setting is HYPERGEN, which is specifically tailored towards parallel execution. Nonetheless, HYPERGIRGS shows comparable performance and overtakes the other two generators NKGGEN and NKOPT. We note that even on parallel machines, the sequential performance is of high importance: one often needs a large collection of graphs rather than a single huge instance. In this case, it is more efficient to run multiple instances of a sequential generator in parallel.

5.3 Difference Between HRGs and GIRGs

Recall from Section 2.3 that a HRG with average degree d_{HRG} has a corresponding GIRG sub- and supergraphs with average degrees d_{GIRG} and D_{GIRG} , respectively.

We experimentally determine, for given HRGs, the values for d_{GIRG} by decreasing the average degree of the corresponding GIRGs until it is a subgraph of the HRG. Analogously, we determine the value for D_{GIRG} . We focus on the threshold variant of the models, as this makes the coupling between HRGs and GIRGs much simpler (the graph is uniquely determined by the coordinates). Figure 4a shows d_{GIRG} and D_{GIRG} , compared to d_{HRG} for growing n . One can see that d_{GIRG} and D_{GIRG} are actually quite far apart. They in particular do not converge to the same value for growing n . However, at least d_{GIRG} seems to approach d_{HRG} . This indicates that every HRG corresponds to a GIRG subgraph that is missing only a sublinear fraction of edges. On the other hand, the average degree of the GIRG has to be increased by a lot to actually contain all edges also contained in the HRG.

Figure 4b gives a more detailed view for a single HRG. Depending on the average degree of the GIRG, it shows how many edges the GIRG lacks and how many edges the GIRG has in addition to the HRG. For degree 100, the GIRG contains about 38k additional and lacks about 42k edges. These are rather small numbers compared to the 50 M edges of the graphs.

Abstract

Randomized incremental construction (RIC) is one of the most important paradigms for building geometric data structures. Clarkson and Shor developed a general theory that led to numerous algorithms that are both simple and efficient in theory and in practice.

Randomized incremental constructions are most of the time space and time optimal in the worst-case, as exemplified by the construction of convex hulls, Delaunay triangulations and arrangements of line segments. However, the worst-case scenario occurs rarely in practice and we would like to understand how RIC behaves when the input is nice in the sense that the associated output is significantly smaller than in the worst-case. For example, it is known that the Delaunay triangulations of nicely distributed points on polyhedral surfaces in E^3 has linear complexity, as opposed to a worst-case quadratic complexity. The standard analysis does not provide accurate bounds on the complexity of such cases and we aim at establishing such bounds in this paper. More precisely, we will show that, in the case of nicely distributed points on polyhedral surfaces, the complexity of the usual RIC is $O(n \log n)$, which is optimal. In other words, without any modification, RIC nicely adapts to good cases of practical value.

Our proofs also work for some other notions of nicely distributed point sets, such as (ε, κ) -samples. Along the way, we prove a probabilistic lemma for sampling without replacement, which may be of independent interest.

1 Introduction

The *randomized incremental construction* (RIC) is an algorithmic paradigm introduced by Clarkson and Shor [10], which has since found immense applicability in computational geometry, e.g., [21, 20]. The general idea is to process the input points sequentially in a random order, and to analyze the expected complexity of the resulting procedure. The theory developed by Clarkson and Shor is quite general and has led to numerous algorithms that are simple and efficient, both in theory and in practice. On the theory side, randomized incremental constructions are most of the time space and time optimal in the worst-case, as exemplified by the construction of convex hulls, Delaunay triangulations and arrangements of line segments. Randomized incremental constructions appear also to be very efficient in practice, which, together with their simplicity, make them the most popular candidates for implementations. Not surprisingly, the CGAL library includes several randomized incremental algorithms, e.g., for computing Delaunay triangulations [22].

This paper aims at extending the analysis of RIC to the case of *nice-case* complexity. More precisely, our goal is to understand how randomized incremental constructions behave when the input is nice in the sense that the associated construction is significantly smaller than in the worst-case.

In this paper, we shall consider the case where the underlying space is a polyhedral surface in \mathbb{E}^3 . This is a commonly-occurring practical scenario in e.g., surface reconstruction [1, 6], and has been studied by several authors [2, 4, 5, 17]. Further, we need a model of good point sets to describe the input data and analyze the algorithm. This will be done through the notion of ε -nets. When we enforce such a hypothesis of “nice” distribution of the points in space, a result of Attali and Boissonnat [4] ensures that the complexity of the Delaunay triangulation is linear in the number of points. Unfortunately, to be able to control the complexity of the usual randomized incremental algorithms [3, 9, 10, 12], it is not enough to control the final complexity of the Delaunay triangulation. We need to control also the complexity of the triangulation of random subsets. One might expect that a random subsample of size k of an ε -net is also an ε' -net for $\varepsilon' = \varepsilon\sqrt{\frac{n}{k}}$. Actually this is not quite true, it may happen with reasonable probability that a ball of radius $O(\varepsilon')$ contains $\Omega(\log k / \log \log k)$ points or that a ball of radius $\Omega(\varepsilon'\sqrt{\log k})$ does not contain any point. However, it can only be shown that such a subsample is an $(\frac{\varepsilon'}{\log(1/\varepsilon)})$ -covering and an $(\varepsilon' \log(1/\varepsilon))$ -packing, with high probability. Thus this approach can transfer the complexity of an ε -net to the one of a random subsample of an ε -net but with an extra multiplicative factor of $\Omega(\log 1/\varepsilon) = \Omega(\log n)$. It follows that, in the case we consider, the standard analysis does not provide accurate bounds on the complexity of the (standard) randomized incremental construction. Our results are based on proving that the above bad scenarios occur rarely, and the algorithm achieves optimal run-time complexity, in expectation.

Related Work

The Delaunay triangulations of nicely-distributed points have been studied since the 50's, e.g., by Meijering [18], and later by Møller [19], Dwyer [13, 14], and others. Erickson [15, 16] proved upper and lower bounds for point samples with bounded *spread* (the ratio between the maximum to minimum distance between any two points) in \mathbb{E}^3 . For polyhedral surfaces, Golin and Na [17] gave an $O(n \log^4 n)$ bound for Poisson-distributed points. Attali and Boissonnat [4] showed that for (ε, κ) -samples, the complexity of the Delaunay triangulation is linear. Under some extra assumptions, this was extended by Amenta, Attali, and Devillers [2] to higher-dimensional polyhedral surfaces. Attali, Boissonnat, and Lieutier [5] proved an $O(n \log n)$ bound for (ε, κ) -samples on *smooth* surfaces in \mathbb{E}^3 .

Except for a few authors such as Dwyer [14] and Erickson [16], most of the above results discuss only the combinatorial aspects and not the algorithmic ones. For Poisson and uniformly distributed point samples, we observe that the standard analysis of the RIC procedure immediately implies an optimal bound on the expected run-time. However, for deterministic notions of nice distributions such as ε -nets, (ε, κ) -samples, and bounded spread point sets, the standard RIC analysis is not optimal, since, as we observed, it gives at least an extra logarithmic factor for (ε, κ) -samples and even worse for bounded spread point-sets, as stated in an open problem by Erickson [16].

Our Contribution

For ε -nets on polyhedral surfaces in \mathbb{E}^3 , we establish tight bounds on the complexity of random subsamples of any given size. Using this, we show that the complexity of the usual RIC is $O(n \log n)$, which is optimal. Hence, without any modification, the standard RIC nicely adapts to polyhedral surfaces in \mathbb{E}^3 .

Our technical developments rely on a general bound for the probability of certain non-monotone events in sampling without replacement, which may be of independent interest. We use this together with a geometric construction that, given a point p on a plane P , and a threshold radius r , allows us to bound the probability of existence of any empty disk in P with radius at least r , having p on its boundary. Lastly, the boundary effects need to be explicitly controlled, which requires a careful handling along the lines of the result of Attali and Boissonnat [4], along with some new ideas which we develop. (For a more detailed outline of the ideas, see the discussion in Section 3).

We remark that though we focus on polyhedral surfaces in \mathbb{E}^3 in this paper, our techniques are more general, and can be extended to e.g., ε -nets on d -dimensional flat torii, etc., which we do in the full version of this paper.

Outline

The rest of the paper is as follows. In Section 2, we define the basic concepts of Delaunay triangulation, ε -nets and random samples. We state our theorems and their proofs in Section 3. In Section 4, we give the proofs of some technical lemmas needed for the proofs of our theorems. Proofs missing from the main sections can be found in the full version of this paper [7].

2 Background

2.1 Notations

We shall use $\|\cdot\|$ to denote the Euclidean ℓ_2 norm. We denote by $\Sigma(p, r)$, $B(p, r)$ and $B[p, r]$, the sphere, the open ball, and the closed ball of center p and radius r respectively. For $x \in \mathbb{E}^2$, $y \geq 0$, $D(x, r)$ denotes the disk with center x and radius r , i.e. the set of points $\{y \in \mathbb{E}^2 : \|y - x\| < r\}$, and similarly $D[x, r]$ denotes the corresponding closed disk.

For an event \mathcal{E} in some probability space Ω , we use $\mathbb{1}_{[\mathcal{E}]}$ to denote the indicator variable $\mathbb{1}_{[\mathcal{E}]} = \mathbb{1}_{[\mathcal{E}]}(\omega)$ which is 1 whenever $\omega \in \mathcal{E}$, and zero otherwise. We use $[n]$ to mean the set $\{1, 2, \dots, n\}$. Given a discrete set A , $\#(A)$ denotes its cardinality and, for $k \in \mathbb{Z}^+$, $\binom{A}{k}$ denotes the set of k -sized subsets of A . Given an event A in some probability space, $\mathbb{P}[A]$ denotes the probability of A occurring. For a random variable Z in a probability space, $\mathbb{E}[Z]$ denotes the expected value of Z . Lastly, $e = 2.7182\dots$ denotes the base of the natural logarithm.

2.2 ε -nets

A set \mathcal{X} of n points in a metric space \mathcal{M} , is an ε -packing if any pair of points in \mathcal{X} are at least distance ε apart, and an ε -cover if each point in \mathcal{M} is at distance at most ε from some point of \mathcal{X} . \mathcal{X} is an ε -net if it is an ε -cover and an ε -packing simultaneously.

The definition of an ε -net applies for any metric space. In the case of the Euclidean metric, we can prove some additional properties, which will be given in Section 3.

2.3 Delaunay Triangulation

For simplicity of exposition and no real loss of generality, all finite point sets considered in this paper will be assumed to be in *general position*, i.e. there are no 5 points lying on a sphere in \mathbb{E}^3 , and no plane has a set of 4 points lying on a circle. Given a set \mathcal{X} in some ambient topological space, the *Delaunay complex* of \mathcal{X} is the (abstract) simplicial complex with vertex set \mathcal{X} which is the nerve of the Voronoi diagram of \mathcal{X} , that is, a simplex σ (of arbitrary dimension) belongs to $Del(\mathcal{X})$ iff the Voronoi cells of its vertices have a non empty common intersection. Equivalently, σ can be circumscribed by an empty ball, i.e. a ball whose bounding sphere contains the vertices of σ and whose interior contains no points of \mathcal{X} .

For point sets in \mathbb{E}^3 in general position, the Delaunay complex embeds in \mathbb{E}^3 and is a triangulation of the space.

2.4 Polyhedral Surfaces in \mathbb{E}^3

A *polyhedral surface* \mathcal{S} in \mathbb{E}^3 is a collection of a finite number of polygons $F \subset \mathcal{S}$, called *facets*, which are pairwise disjoint or meet along an edge. In this paper, \mathcal{S} will denote an arbitrary but fixed polyhedral surface, with C facets, and having total length of the boundaries of its faces L and total area of its faces A . Any non-convex polygonal facet $F \in \mathcal{S}$ can be triangulated and replaced in \mathcal{S} by the collection of triangular facets obtained. This will only change the total length L of the boundaries, which, for a given triangulation, still depends only on the original surface \mathcal{S} . Thus without any real loss of generality, we can (and shall) assume the facets of \mathcal{S} are convex.

2.5 Randomized Incremental Construction and Random Subsamples

For the algorithmic complexity aspects, we state a version of a standard theorem for the RIC procedure, (see e.g., [11]). We first need a necessary condition for the theorem. When a new point p is added to an existing triangulation, a *conflict* is defined to be a previously existing simplex whose circumball contains p .

► **Condition 1.** *At each step of the RIC, the set of simplices in conflict can be removed and the set of newly introduced conflicts can be computed in time proportional to the number of conflicts.*

We now come to the general theorem on the algorithmic complexity of RIC using the Clarkson-Shor technique (see e.g., Devillers [11] Theorem 5(1,2)).

► **Theorem 2.** *Let $F(s)$ denote the expected number of simplices that appear in the Delaunay triangulation of a uniform random sample of size s , from a given point set P . Then, if Condition 1 holds and $F(s) = O(s)$, we have*

- (i) *The expected space complexity of computing the Delaunay triangulation is $O(n)$.*
- (ii) *The expected time complexity of computing the Delaunay triangulation is $O(n \log n)$.*

A subset \mathcal{Y} of set \mathcal{X} is a *uniform random sample* of \mathcal{X} of size s if \mathcal{Y} is any possible subset of \mathcal{X} of size s with equal probability.

In order to work with uniform random samples, we shall prove a lemma on the uniformly random sampling distribution or *sampling without replacement*, which is stated below, and will be a key probabilistic component of our proofs. The lemma provides a bound on the probability of a non-monotone compound event, that is, if the event holds true for a fixed set of k points, there could exist supersets as well as subsets of the chosen set for which the event does not hold. This may well be of general interest, as most natural contiguity results with Bernoulli (i.e. independent) sampling, are for monotone events.

► **Lemma 3.** *Given $a, b, c \in \mathbb{Z}^+$, with $2b \leq a \leq c$, $t \leq c$. Let C be a set, and B and T two disjoint subsets of C . If A is a random subset of C , chosen uniformly from all subsets of C having size a , the probability that A contains B and is disjoint from T , is at most $(\frac{a}{c})^b \left(1 - \frac{t}{c-b}\right)^{a-b} \leq (\frac{a}{c})^b \cdot \exp\left(-\frac{at}{2c}\right)$, where a, b, c are the cardinalities of A, B , and C respectively, and the cardinality of T is at least t .*

Proof. The total number of ways of choosing the random sample A is $\binom{c}{a}$. The number of ways of choosing A such that $B \subset A$ and $T \cap A = \emptyset$, is $\binom{c-b-t}{a-b}$. Therefore the required probability is

$$\begin{aligned} \mathbb{P}[B \subset A, T \cap A = \emptyset] &= \frac{\binom{c-b-t}{a-b}}{\binom{c}{a}} \\ &= \frac{\prod_{i=0}^{b-1} (a-i) \prod_{i=b}^{a-1} (a-i)}{\prod_{i=0}^{b-1} (c-i) \prod_{i=b}^{a-1} (c-i)} \cdot \frac{\prod_{i=0}^{a-b-1} (c-b-t-i)}{\prod_{i=0}^{a-b-1} (a-b-i)} \\ &= \frac{\prod_{i=0}^{b-1} (a-i) \prod_{i=0}^{a-b-1} (c-b-t-i)}{\prod_{i=0}^{b-1} (c-i) \prod_{i=0}^{a-b-1} (c-b-i)} \\ &= (a/c)^b \frac{\prod_{i=0}^{b-1} (1-i/a)}{\prod_{i=0}^{b-1} (1-i/c)} \left(1 - \frac{t}{c-b}\right)^{a-b} \left(\frac{\prod_{i=0}^{a-b-1} (1 - \frac{i}{c-b-t})}{\prod_{i=0}^{a-b-1} (1 - \frac{i}{c-b})}\right) \\ &\leq (a/c)^b \left(1 - \frac{t}{c-b}\right)^{a-b}, \end{aligned}$$

where in the last step, observe that for the product $\frac{\prod_{i=0}^{b-1} (1-i/a)}{\prod_{i=0}^{b-1} (1-i/c)}$ for each i , the term $(1-i/a)$ in the numerator is smaller than the corresponding term $(1-i/c)$ in the denominator, since $a \leq c$. A similar observation holds for the product $\left(\frac{\prod_{i=0}^{a-b-1} (1 - \frac{i}{c-b-t})}{\prod_{i=0}^{a-b-1} (1 - \frac{i}{c-b})}\right)$.

Now, observe that $\left(1 - \frac{t}{c-b}\right)^{a-b} \leq \exp\left(-\left(\frac{t(a-b)}{c-b}\right)\right) \leq \exp\left(-\left(\frac{at}{2c}\right)\right)$, if $b \leq a/2$ and $b < c$. ◀

3 Results and Main Proofs

We show that the expected complexity of the Delaunay triangulation of a uniformly random subsample of an ε -net on a polyhedral surface is linear in the size of the subsample:

► **Theorem 4.** *Let $\varepsilon \in (0, 1]$, \mathcal{X} be an ε -net on a polyhedral surface \mathcal{S} , having n points and let $\mathcal{Y} \subset \mathcal{X}$ be a random sub-sample of \mathcal{X} having size s . Then, in expectation, the Delaunay triangulation $Del(\mathcal{Y})$ of \mathcal{Y} on \mathcal{S} has $O(s)$ simplices.*

Algorithmic Bounds

We next use the above combinatorial bound to get the space and time complexity of the randomized incremental construction of the Delaunay triangulation of an ε -net on a polyhedral surface in \mathbb{E}^3 .

► **Theorem 5** (Randomized incremental construction). *Let $\varepsilon \in (0, 1]$, and let \mathcal{X} be an ε -net in general position over a fixed polyhedral surface $\mathcal{S} \subset \mathbb{E}^3$, then the randomized incremental construction of the Delaunay triangulation takes $O(n \log n)$ expected time and $O(n)$ expected space, where $n = \#\mathcal{X}$ and the constant in the big O depends on (and only on) \mathcal{S} .*

► **Remark 6.** Theorem 4 also works for the case when the random sample is a Bernoulli sample of parameter $q := \frac{s}{n}$.

► **Remark 7.** Our results can be extended to other types of good samples, e.g., the weaker notion of (ε, κ) -samples for which any ball of radius ε contains at least one point and at most κ points. If we fix $\kappa = \kappa_0 = 2^{O(d)}$, we get exactly the same result. The bounds can be straightforwardly adapted to accommodate other values of κ .

Before presenting the proof of Theorem 4, we briefly discuss the outline of the proof.

Main Ideas

Our overall strategy will be to mesh the proof of Attali and Boissonnat [4] with some new ideas which are needed for random subsamples of ε -nets. Briefly, Attali and Boissonnat reduce the problem to counting the Delaunay edges of the point sample, which they do by distinguishing between *boundary* points, which lie in a strip of width ε near the boundaries of the facets of the polyhedral surface, and the other points, called *interior* points. For boundary points, they allow all possible edges. For interior points, the case of edges with endpoints on the same facet is easy to handle, while geometric constructions are required to handle the case of endpoints on different facets, or that of edges with one endpoint in the interior and another on the boundary.

However, we shall need to introduce a couple of new ideas. Firstly, an edge can have multiple balls passing through its endpoints and, as soon as one of these balls is empty, the edge is in the triangulation. To bound therefore, the probability of a potential edge appearing in the triangulation, we need to simultaneously bound the probability of any of these balls being empty. To ensure this, we use a geometric construction (see Lemma 17). Basically, the idea is to build a constant-sized packing of a sphere centered on a given point, using large balls, such that any sphere of a sufficiently large radius which passes through the point, must contain a ball from the packing.

Secondly, since we have randomly spaced points at the boundaries, boundary effects are no longer necessarily contained in the fixed strip of width ε around the boundary, and could potentially penetrate deep into the interior. To handle this, we generalize the fixed-width strip using the notion of *levels* of a facet. We then use a probabilistic, rather than deterministic, classification of boundary and interior points. The new classification is based on the level of a point and the radius of the largest empty disk passing through it.

Recall the definitions of \mathcal{X} , \mathcal{Y} and \mathcal{S} from Theorem 4. We shall use κ to denote the maximum number of points of a given point set in a disk of radius 2ε . When \mathcal{X} is an ε -net, κ is at most 25, using a packing argument (the maximum number of disjoint discs of radius $\varepsilon/2$ that can be packed in a disc of radius $2\varepsilon + \varepsilon/2$, is $\frac{\pi(5\varepsilon/2)^2}{\pi(\varepsilon/2)^2} \leq 25$). We define $q := \frac{s}{n}$, and $\delta := \varepsilon/\sqrt{q}$. For a curve Γ , $l(\Gamma)$ denotes its length. For a subset of a surface $R \subset \mathcal{S}$, $a(R)$ denotes the area of R . For sets $A, B \subset \mathbb{E}^3$, $A \oplus B$ denotes the Minkowski sum of A and B , i.e. the set $\{x + y : x \in A, y \in B\}$. For convenience, the special case $A \oplus B(0, r)$ shall be denoted by $A \oplus r$.

We next present some general lemmas, which will be needed in the proofs of the main lemmas.

Level Sets, Boundary Points and Interior Points

We now introduce some definitions which will play a central role in the analysis. First we define the notion of levels. Given facet $F \in \mathcal{S}$ and $k \geq 0$, define the *level set* $L_{\leq k} := F \cap (\partial F \oplus 2^k \delta)$. $L_{=k} := L_{\leq k} \setminus L_{\leq k-1}$. For $x \in \mathcal{X}$, the *level* of x , denoted $Lev(x)$, is k such that $x \in L_{=k}$. Let $L_{\leq k}(\mathcal{X}), L_{=k}(\mathcal{X})$ denote $L_{\leq k} \cap \mathcal{X}, L_{=k} \cap \mathcal{X}$ respectively. Note that for $x \in L_{=k}, k \geq 1$, the distance $d(x, \partial F) \in (2^{k-1}\delta, 2^k\delta]$. Hence, if $Lev(x) = k, D(x, 2^{k-1}\delta) \subset F$. For $k = 0, d(x, \partial F) \in [0, \delta]$.

Given $x \in F$ having $Lev(x) = k, x$ is a *boundary point* or $x \in Bd_F(\mathcal{Y})$ if $k = 0$ or if there exists an empty disk (w.r.t. \mathcal{Y}) of radius greater than $2^{k-1}\delta$, whose boundary passes through x . x is an *interior point* or $x \in Int_F(\mathcal{Y})$ if and only if $x \in \mathcal{Y} \setminus Bd_F(\mathcal{Y})$. In general, $x \in Bd_{\mathcal{S}}(\mathcal{Y})$ if $x \in Bd_F(\mathcal{Y})$ for some $F \in \mathcal{S}$, and $x \in Int_{\mathcal{S}}(\mathcal{Y})$ is defined similarly.

The above bi-partition induces a classification of potential edges of $Del(\mathcal{Y})$, depending on whether the end-points are boundary or interior points. Let E_1 denote the set of edges whose end points are two boundary points. Let E_2 denote the set of edges having as end-points, two interior points of the same facet of \mathcal{S} . Let E_3 denote the set of edges having as end-points, two interior points of different facets of \mathcal{S} . Let E_4 denote the set of edges having an interior point and a boundary point as end-points.

We have the following lemmas, to be proved in section 4.2.

► **Lemma 8.** $\mathbb{E}[\#(E_1)] \leq O(1) \cdot (\kappa^2 L^2 / A) \cdot s$.

► **Lemma 9.** $\mathbb{E}[\#(E_2)] \leq O(1) \cdot \kappa s$.

► **Lemma 10.** $\mathbb{E}[\#(E_3)] \leq O(1) \cdot (C - 1) \cdot \kappa s$.

► **Lemma 11.** $\mathbb{E}[\#(E_4)] \leq O(1) \cdot \frac{\kappa^2 L^2}{A} s$.

Given the above lemmas, the proof of Theorem 4 follows easily.

Proof of Theorem 4. As in [4] (Section 4), by Euler's formula, the number of tetrahedra $t(Del(\mathcal{Y}))$ in the Delaunay triangulation of \mathcal{S} , is at most $e(Del(\mathcal{Y})) - \#(\mathcal{Y}) = e(Del(\mathcal{Y})) - s$, where $e(Del(\mathcal{Y}))$ is the number of edges in the Delaunay triangulation. Therefore, it suffices to count the edges of $Del(\mathcal{Y})$. Next, observe that any point $x \in \mathcal{Y}$ is either a boundary or an interior point, that is $Bd_{\mathcal{S}}(\mathcal{Y}) \sqcup Int_{\mathcal{S}}(\mathcal{Y}) = \mathcal{Y}$. An edge in $Del(\mathcal{Y})$, therefore, can be either between two points in $Bd_{\mathcal{S}}(\mathcal{Y})$, or two points in $Int_{\mathcal{S}}(\mathcal{Y})$, or between a point in $Bd_{\mathcal{S}}(\mathcal{Y})$ and another in $Int_{\mathcal{S}}(\mathcal{Y})$. The case of a pair of points in $Int_{\mathcal{S}}(\mathcal{Y})$ is further split based on whether the points belong to the same facet of \mathcal{S} or different facets. Thus using the above exhaustive case analysis, the proof follows simply by summing the bounds of Lemmas 8 to 11. ◀

Next, we show how Theorem 4 implies bounds on the computational complexity of constructing Delaunay triangulations of ε -nets. Our main tool shall be Theorem 2. However, we need to show first that Condition 1 holds. The standard proof of this (see e.g., [10], [9], also the discussion in [8](Section 2.2 D)) is sketched below.

Now we come to the proof of Theorem 5.

Proof of Theorem 5. To verify that Condition 1 indeed holds in the case of polyhedral surfaces, observe first that the union \mathcal{C}_p of the simplices in conflict with a new point p is a connected set. Therefore, walking on the adjacency graph of the simplices by rotating around the edge or triangle shared between two adjacent faces on the boundary of \mathcal{C}_p , is enough to yield the set of new conflicts. Now Theorem 2 can be applied to get the claimed result. ◀

4 Proofs of Lemmas 8–11

Before proving Lemmas 8–11, we need a few technical lemmas.

4.1 Some Technical Lemmas

The following geometric and probabilistic lemmas prove certain properties of ε -nets on polyhedral surfaces and random subsets, as well as exploit the notion of boundary and interior points to get an exponential decay for boundary effects penetrating into the interior.

► **Lemma 12.** *Given $a > 0$, $b \in (0, 1)$, the sum $\sum_{n \in \mathbb{Z}_+} 2^{an} \cdot \exp(-b \cdot 2^{an})$ is at most $\frac{2 \log_2(1/b)}{eab}$.*

► **Proposition 13 ([4]).** *Let F be a (convex)¹ facet of \mathcal{S} . For any convex Borel set $R \subset F$, we have*

$$\left(\frac{a(R)}{4\pi\varepsilon^2}\right) \leq \#(R \cap \mathcal{X}) \leq \left(\frac{\kappa \cdot a(R \oplus \varepsilon)}{\pi\varepsilon^2}\right), \text{ and therefore,} \tag{1}$$

$$\left(\frac{A}{4\pi\varepsilon^2}\right) \leq \#(\mathcal{S} \cap \mathcal{X}) = n. \tag{2}$$

► **Proposition 14 ([4]).** *Let F be a facet of \mathcal{S} , let $\Gamma \subset F$ be a curve contained in F , and $k \in \mathbb{N}$. Then*

$$\#((\Gamma \oplus k\varepsilon) \cap \mathcal{X}) \leq \kappa \frac{l(\Gamma)(2k+2)\varepsilon}{\pi\varepsilon^2} \leq \left(2k\kappa \frac{l(\Gamma)}{\varepsilon}\right), \text{ when } k \geq 1. \tag{3}$$

► **Lemma 15.** *Given a circle $\Sigma_1 \subset \mathbb{E}^2$ of unit radius centered at the origin, seven disks having centers in Σ_1 and radius $1/2$, are necessary and sufficient to cover Σ_1 .*

► **Lemma 16 (Level Size).** $\#(L_{=k} \cap \mathcal{X}) \leq \#(L_{\leq k} \cap \mathcal{X}) \leq 9\kappa L \left(\frac{2^k \delta}{\varepsilon^2}\right)$.

► **Lemma 17.** *Let F be a facet of \mathcal{S} with supporting plane P , and $x \in F$ with $Lev(x) > 0$. Then given any $k \in [0, Lev(x))$, $k \in \mathbb{N}$, there exists a collection \mathcal{D}_x of at most $c_B = 7$ disks in F , such that*

- (i) *Each $D \in \mathcal{D}_x$ is contained in F ,*
- (ii) *Each $D \in \mathcal{D}_x$ has radius $r_0/4$, where $r_0 = 2^k \delta$ and $k \in \mathbb{N}$ such that $0 \leq k < Lev(x)$, and*
- (iii) *Any disk $D \subset P$ of radius at least r_0 , such that $x \in \partial D$, contains at least one disk in \mathcal{D}_x .*

¹ Recall our assumption in 2.4.

► **Lemma 18** (Decay Lemma). *Given $x_1, \dots, x_t \in \mathcal{X}$, with x_i contained in the facet F_i with supporting plane P_i , such that $\text{Lev}(x_i) > 0$, $1 \leq i \leq t$, then for all $0 \leq k_i < \text{Lev}(x_i)$, with $r_i^* := 2^{k_i} \delta$, the probability of the event*

$$E := \{\forall i \in [t] : \exists D_i = D(y_i, r_i) \subset P_i : r_i \geq r_i^*, x_i \in \mathcal{Y}, x_i \in \partial D_i \text{ and } \text{int}(D_i) \cap \mathcal{Y} = \emptyset\},$$

is given by

$$\mathbb{P}[E] \leq \begin{cases} q^t, & \text{if } k_{\max} = 0, \\ c_1 \cdot q^t \cdot \exp(-c_2 \cdot 2^{2k_{\max}}), & \text{if } k_{\max} > 0, \end{cases}$$

where $c_1 = c_B^t$, $c_2 \geq 2^{-7}$, and $k_{\max} := \max_i \{k_i\}$. Thus

$$\mathbb{P}[E] \leq c_1 \cdot q^t \cdot \exp(-c_2 \cdot 2^{2k_{\max}}), \quad k_{\max} \geq 0.$$

► **Lemma 19** (Growth Lemma). *Given any point $x \in \mathcal{S}$ in a facet F , and $0 \leq k < \text{Lev}(x)$, we have*

- (i) $2^{2k-2}/q \leq \#(D(x, 2^k \delta) \cap \mathcal{X}) \leq 4 \cdot (2^{2k}/q)$.
- (ii) $2^{2k-2} \leq \mathbb{E}[\#(D(x, 2^k \delta) \cap \mathcal{Y})] \leq 4 \cdot (2^{2k})$.

4.2 Proofs of Lemmas 8–11

The proofs of Lemmas 8 and 9 now follow by adapting the analysis of [4] to random subsamples of ε -nets, using the Decay and Growth lemmas.

Proof of Lemma 8. To bound the expected number of edges in E_1 , we simply bound the number of pairs $(x_1, x_2) \in \text{Bd}_{\mathcal{S}}(\mathcal{Y}) \times \text{Bd}_{\mathcal{S}}(\mathcal{Y})$. Consider a pair of points $x_1, x_2 \in \mathcal{X}$. Let $l_1 := \text{Lev}(x_1)$ and $l_2 := \text{Lev}(x_2)$, and let $l := \max\{l_1, l_2\}$. By definition, if $l = 0$, then $x_1, x_2 \in \text{Bd}_{\mathcal{S}}(\mathcal{Y})$. For $l \geq 1$, we get that $x_1 \in \text{Bd}_{\mathcal{S}}(\mathcal{Y})$ and $x_2 \in \text{Bd}_{\mathcal{S}}(\mathcal{Y})$ only if there exists a disk of radius at least $2^{l-1} \delta$ passing through x_1 or x_2 , and containing no points of \mathcal{Y} . Therefore to bound the probability that $(x_1, x_2) \in (\text{Bd}_{\mathcal{S}}(\mathcal{Y}))^2$, we can apply the Decay Lemma 18, with $t = 2$, for $i \in \{1, 2\}$. We get

$$\begin{aligned} \mathbb{P}[(x_1, x_2) \in E_1] &\leq \mathbb{P}[(x_1, x_2) \in (\text{Bd}_{\mathcal{S}}(\mathcal{Y}))^2] \\ &\leq c_1 q^2 \cdot \exp(-c_2 \cdot 2^{2l-2}) \leq c_1 q^2 \cdot \exp(-c'_2 \cdot 2^{2l}), \end{aligned} \quad (4)$$

where $c'_2 = c_2/4 = 2^{-9}$. Summing over all choices of levels of x_1 and x_2 , we have

$$\mathbb{E}[\#(E_1)] \leq \sum_{l_1 \geq 0} \#(L_{=l_1} \cap \mathcal{X}) \sum_{l_2 \geq 0} \#(L_{=l_2} \cap \mathcal{X}) \mathbb{P}[(x_1, x_2) \in (\text{Bd}_{\mathcal{S}}(\mathcal{Y}))^2].$$

By symmetry, it is enough to assume without loss of generality that $l_1 \geq l_2$, i.e. $l = l_1$. Thus,

$$\mathbb{E}[\#(E_1)] \leq 2 \sum_{l_1 \geq 0} \#(L_{=l_1} \cap \mathcal{X}) \sum_{l_2=0}^{l_1} \#(L_{=l_2} \cap \mathcal{X}) \mathbb{P}[(x_1, x_2) \in (\text{Bd}_{\mathcal{S}}(\mathcal{Y}))^2].$$

Applying equation (4) and the Level Size Lemma 16, we get

$$\begin{aligned} \mathbb{E}[\#(E_1)] &\leq 2 \sum_{l_1 \geq 0} \#(L_{\leq l_1} \cap \mathcal{X}) \sum_{l_2=0}^{l_1} \#(L_{\leq l_2} \cap \mathcal{X}) \cdot c_1 q^2 \cdot \exp(-c'_2 \cdot 2^{2l_1}) \\ &\leq 2c_1 q^2 \sum_{l_1 \geq 0} (9\kappa L \cdot (2^{l_1} \delta / \varepsilon^2)) \sum_{l_2=0}^{l_1} (9\kappa L \cdot (2^{l_2} \delta / \varepsilon^2)) \cdot \exp(-c'_2 \cdot 2^{2l_1}) \\ &\leq 2c_1 q^2 (9\kappa L \left(\frac{\delta}{\varepsilon^2}\right))^2 \sum_{l_1 \geq 0} 2^{l_1} \cdot \exp(-c'_2 \cdot 2^{2l_1}) \sum_{l_2=0}^{l_1} 2^{l_2}. \end{aligned}$$

22:10 RIC of Delaunay Triangulations of Nice Point Sets

Using the definitions of q and δ , together with Proposition 13, and writing the terms outside the summation as N_1 , we get $N_1 := 2 \cdot c_1 q^2 (9\kappa L (\frac{\delta}{\varepsilon^2}))^2 = 2c_1 \cdot (9\kappa L)^2 (\frac{s}{n\varepsilon^2}) \leq 4c_1 \cdot (\frac{4\pi(9\kappa L)^2}{A}) \cdot s$. We get

$$\mathbb{E} [\#(E_1)] \leq N_1 \sum_{l_1 \geq 0} 2^{l_1} \cdot \exp(-c'_2 \cdot 2^{2l_1}) \cdot 2 \cdot 2^{l_1} \leq 2N_1 \sum_{l_1 \geq 0} 2^{2l_1} \cdot \exp(-c'_2 \cdot 2^{2l_1}).$$

The summation can be bounded using Lemma 12, to get

$$\mathbb{E} [\#(E_1)] \leq 2N_1 \cdot \left(2 \cdot \frac{\log 1/c'_2}{2ec'_2} \right) = 2N_1 \cdot \frac{\log 1/c'_2}{e \cdot c'_2}.$$

Now substituting $c'_2 = 2^{-9}$ gives $\mathbb{E} [\#(E_1)] \leq 2 \cdot 10^4 \cdot c_1 \cdot (\frac{4\pi(9\kappa L)^2}{A}) \cdot s$. \blacktriangleleft

The proof of Lemma 9 follows simply from the fact that for any given face, the Delaunay graph formed by the points in \mathcal{Y} is planar, and therefore the number of edges is at most 3 times the number of points. The total number of such edges, summed over all faces of \mathcal{S} , is at most $3s$. The proof of Lemma 10 is based on combining a construction of Attali-Boissonnat with Lemma 9, and is omitted here. For the proofs of Lemmas 10 and 11, we need some more geometric ideas of [4]. Before proving Lemma 11, we briefly describe a construction, which will be central to our analysis.

► **Construction 20** (Attali-Boissonnat [4]). *Let P be a plane and Z be a finite set of points. To each point $x \in Z$, assign the region $V(x) = V_x(Z) \subset P$ of points $y \in P$ such that the sphere tangent to P at y and passing through x encloses no point of Z . Let $\mathcal{V} := \{V(x) : x \in Z\}$.*

We summarize some conclusions of Attali-Boissonnat regarding the construction. The proofs of these propositions can be found in [4].

► **Proposition 21.**

- (i) \mathcal{V} is a partition of P .
- (ii) For each $x \in Z$, $V(x)$ is an intersection of regions that are either disks or complements of disks.
- (iii) The total length of the boundary curves in \mathcal{V} is equal to the total length of the convex boundaries.

For the rest of this subsection, we shall apply Construction 20 on the plane P , and the points in $Bd_{\mathcal{S}}(\mathcal{Y})$ as Z . Let $\mathcal{T} := \text{Int}_F(\mathcal{Y})$ for some facet $F \in \mathcal{S}$. Given $x \in Z$, $y \in P \setminus V(x)$, let $k_y = k_y(x)$ denote the least $k \geq 0$ such that $y \in \partial V(x) \oplus 2^k \delta$.

► **Proposition 22** (Attali-Boissonnat [4]). *Suppose there exists a ball $B \subset \mathbb{E}^3$ and $y \in P$, such that $y, x \in \partial B$, and $B \cap \mathcal{T} = \emptyset$. Then the disk $D_y = P \cap B$ satisfies $D_y \cap \mathcal{T} = \emptyset$, $y \in \partial D_y$ and $D_y \cap V_x \neq \emptyset$.*

► **Lemma 23.** *If $\{x, y\} \in E_4$ with $x \in Bd_{\mathcal{S}}(\mathcal{Y})$, $y \in \text{Int}(F)$, then $k_y \leq \text{Lev}(y)$.*

Proof. Suppose $\{x, y\} \in E_4$. Then there exists a ball $B \in \mathbb{E}^3$ with $x, y \in \partial B$, and $\text{int}(B) \cap \mathcal{Y} = \emptyset$. Therefore $D_y := B \cap P$ also satisfies $\text{int}(D_y) \cap \mathcal{Y} = \emptyset$. By Proposition 22 we have that $D_y \cap V(x) \neq \emptyset$. Therefore, $y \in V(x) \oplus 2r_y$, where r_y is the radius of D_y . But since $y \in \text{Int}(F)$, we have that any disk having y on its boundary and containing no point of \mathcal{Y} in its interior can have radius at most $2^{\text{Lev}(y)-1} \delta$. Therefore $r_y \leq 2^{\text{Lev}(y)-1} \delta$. Now taking k_y such that $2^{k_y} \delta = 2r_y$, we get that $k_y \leq \text{Lev}(y)$. \blacktriangleleft

Now we partition the pairs of vertices $\{x, y\} \in E_4$ with $x \in Bd_S(\mathcal{Y})$, depending on whether $y \in V_F(x)$ or $y \in \partial V_F(x) \oplus 2^{k_y}\delta$. That is, given a facet $F \in \mathcal{S}$, let $E_4(Int(F))$ denote the set of edges $\{x, y\} \in E_4$ with $y \in int(V_F(x))$, and $E_4(Bd(F))$ denote the set of edges in E_4 with $y \in \partial(V_F(x)) \oplus 2^k\delta$, for $k \in [0, k_y]$. Define $E_4(Int) := \bigcup_{F \in \mathcal{S}} E_4(Int(F))$ and $E_4(Bd) := \bigcup_{F \in \mathcal{S}} E_4(Bd(F))$ respectively.

Lemma 11. The proof follows from Lemmas 24 and 25, which bound the expected number of edges in $E_4(Int)$ and $E_4(Bd)$ respectively. \blacktriangleleft

► **Lemma 24.** *Given a facet $F \in \mathcal{S}$, $\mathbb{E}[E_4(Int(F))] \leq q \cdot \#(\mathcal{X} \cap F)$. As a consequence, $\mathbb{E}[E_4(Int)] \leq s$.*

Proof. Let $x \in \mathcal{X}$ and $y \in \mathcal{X} \cap F$. Let $\mathcal{E}_{x,y}$ denote the event $\{x, y\} \in E_4(Int(F))$. Then $\mathcal{E}_{x,y}$ can occur only if (i) $x \in Bd_S(\mathcal{Y})$ and, (ii) $y \in Int_S(Y) \cap V_F(x)$. Fix a choice of \mathcal{Y} , say $Y \in \binom{\mathcal{X}}{s}$. Conditioning on this choice of \mathcal{Y} , $Bd_S(\mathcal{Y})$ is a fixed set of points. The number of pairs contributing to $E_4(Int(F))$ is at most $\#(\{(x, y) \in Y \times Y \mid x \in Bd_S(\mathcal{Y}), y \in V_F(x)\})$. The main observation is now that since \mathcal{V} restricted to F is a sub-division of F , for each $y \in \mathcal{X} \cap F$, there is a unique $x = x_y \in Bd_S(\mathcal{Y})$ such that $y \in V_F(x)$. Therefore we get

$$E_4(Int(F)) \leq \sum_{V_F(x) \in \mathcal{V}: x \in Bd_S(\mathcal{Y})} \#(V_F(x) \cap Y) \leq \#(Y \cap F).$$

Since the last bound holds for any choice of Y , taking expectation over all choices we get

$$\mathbb{E}[E_4(Int(F))] \leq \mathbb{E}[\#(\mathcal{Y} \cap F)] = q \cdot \#(\mathcal{X} \cap F).$$

Now summing over all faces gives $\mathbb{E}[E_4(Int)] \leq \mathbb{E}[\#(\mathcal{Y})] = s$. \blacktriangleleft

► **Lemma 25.** *Given a facet $F \in \mathcal{S}$, $\mathbb{E}[E_4(Bd(F))] \leq \left(O(1) \cdot \frac{\kappa^2 L \cdot l(\partial F) s}{A}\right)$. As a consequence, $\mathbb{E}[E_4(Bd(\mathcal{S}))] \leq \left(O(1) \cdot \frac{\kappa^2 L^2 s}{A}\right)$.*

Proof. To compute the expected value of $E_4(Bd(\mathcal{S}))$, fix a face $F \in \mathcal{S}$. Consider a pair of points $x, y \in \mathcal{X}$, such that $y \in F$. Let $\mathcal{E}_{x,y}$ denote the event $\{x, y\} \in E_4(Bd(F))$.

The value of $E_4(Bd)$ is the number of $x, y \in \mathcal{X}$, such that $\mathcal{E}_{x,y}$ occurs. Taking expectations,

$$\mathbb{E}[E_4(Bd(F))] \leq \sum_{x \in \mathcal{X}} \sum_{y \in \mathcal{X} \cap F} \mathbb{P}[\mathcal{E}_{x,y}]. \quad (5)$$

Observe that $\mathcal{E}_{x,y}$ occurs only if (i) $x \in Bd_S(\mathcal{Y})$ and (ii) $k_y(x) \leq Lev(y)$, by applying Construction 20, on the plane P , $Z = Bd_S(\mathcal{Y})$, and $\mathcal{T} = \mathcal{Y} \cap P$, and using Proposition 22. By Lemma 23, $k_y(x) \in [0, Lev(y)]$.

Let P_{l_1, l_2} denote the probability that $\{x, y\} \in E_4(Bd(F))$, with $Lev(x) = l_1$, and $k_y(x) = l_2$. Equation (5) can be rewritten in terms of l_1 and l_2 as

$$\mathbb{E}[E_4(Bd(F))] \leq \sum_{l_1 \geq 0} \#(L_{=l_1} \cap \mathcal{X}) \sum_{l_2 \geq 0} \sum_{V_F \in \mathcal{V}} \#((\partial V_F \oplus 2^{l_2}\delta) \cap \mathcal{X}) \cdot P_{l_1, l_2}.$$

Applying the Decay Lemma 18 with $t = 2$, $x_1 = x$, $x_2 = y$, $k_1 = \max\{0, l_1 - 1\}$ (since $x \in Bd_S(\mathcal{Y})$), and $k_2 = \max\{0, l_2 - 1\}$, we get

$$P_{l_1, l_2} \leq c_1 q^2 \cdot \exp(-f(l^*)),$$

where $l^* := \max\{0, l_1 - 1, l_2 - 1\}$, and $f(l^*) = 0$ if $l^* = 0$, and $c'_2 \cdot 2^{2l^*}$ otherwise, with $c'_2 = c_2/4$. As in the proof of Lemma 8, we shall use symmetry to combine the cases $l_1 \geq l_2$ and $l_2 > l_1$ together.

$$\begin{aligned} \mathbb{E}[E_4(Bd(F))] &\leq 2 \sum_{l_1 \geq 0} \#(L_{=l_1} \cap \mathcal{X}) \cdot \\ &\quad \sum_{l_2 \leq l_1} \sum_{V(x) \in \mathcal{V}} \#((\partial V(x) \oplus 2^{l_2} \delta) \cap \mathcal{X}) \cdot c_1 q^2 \cdot \exp(-c'_2 2^{2l_1}). \end{aligned}$$

By the Level Size Lemma 16, we get that $\#(L_{=l_1} \cap \mathcal{X}) \leq \frac{2\kappa L 2^{l_1} \delta}{\varepsilon^2}$. Using Proposition 14, we get that $\#(\{\partial V(x) \oplus 2^{l_2} \delta\} \cap \mathcal{Y}) \leq \frac{2\kappa \cdot l(\partial V(x)) 2^{l_2} \delta}{\varepsilon^2}$. By Proposition 21 (iii), each boundary in the partition \mathcal{V} is convex for some $x \in Bd_S(\mathcal{Y})$, and so we need to sum $l(\partial V(x))$ only over the convex curves in $\partial V(x)$, $x \in Bd_S(\mathcal{Y})$, whose length we observe is at most $l(\partial F)$. Thus,

$$\mathbb{E}[E_4(Bd(F))] \leq 2L \cdot l(\partial F) \cdot \left(\frac{2\kappa \delta q}{\varepsilon^2}\right)^2 \sum_{l_1 \geq 0} 2^{l_1} \sum_{l_2 \leq l_1} 2^{l_2} c_1 \cdot \exp(-c'_2 \cdot 2^{2l_1}).$$

Using Lemma 12, the above summation is bounded by a constant. This comes to $c_1 \cdot O(1) \left(\frac{(2\kappa)^2 L \cdot l(\partial F) \delta^2 q^2}{\varepsilon^4}\right) = O\left(\frac{\kappa^2 L \cdot l(\partial F) s}{A}\right)$, where the last step followed from the lower bound on n in Proposition 13 (2), and the identities $q = s/n = \delta^2/\varepsilon^2$. Summing y over all facets F in \mathcal{S} , we get $\mathbb{E}[E_4(Bd(\mathcal{S}))] = \left(O(1) \cdot \frac{\kappa^2 L^2 s}{A}\right)$. ◀

Abstract

The TRAVELING SALESMAN PROBLEM asks to find a minimum-weight Hamiltonian cycle in an edge-weighted complete graph. Local search is a widely-employed strategy for finding good solutions to TSP. A popular neighborhood operator for local search is k -opt, which turns a Hamiltonian cycle \mathcal{C} into a new Hamiltonian cycle \mathcal{C}' by replacing k edges. We analyze the problem of determining whether the weight of a given cycle can be decreased by a k -opt move. Earlier work has shown that (i) assuming the Exponential Time Hypothesis, there is no algorithm that can detect whether or not a given Hamiltonian cycle \mathcal{C} in an n -vertex input can be improved by a k -opt move in time $f(k)n^{o(k/\log k)}$ for any function f , while (ii) it is possible to improve on the brute-force running time of $\mathcal{O}(n^k)$ and save linear factors in the exponent. Modern TSP heuristics are very successful at identifying the *most promising* edges to be used in k -opt moves, and experiments show that very good global solutions can already be reached using only the top- $\mathcal{O}(1)$ most promising edges incident to each vertex. This leads to the following question: can improving k -opt moves be found efficiently in graphs of bounded degree? We answer this question in various regimes, presenting new algorithms and conditional lower bounds. We show that the aforementioned ETH lower bound also holds for graphs of maximum degree three, but that in bounded-degree graphs the best improving k -move can be found in time $\mathcal{O}(n^{(23/135+\epsilon_k)k})$, where $\lim_{k \rightarrow \infty} \epsilon_k = 0$. This improves upon the best-known bounds for general graphs. Due to its practical importance, we devote special attention to the range of k in which improving k -moves in bounded-degree graphs can be found in *quasi-linear* time. For $k \leq 7$, we give quasi-linear time algorithms for general weights. For $k = 8$ we obtain a quasi-linear time algorithm when the weights are bounded by $\mathcal{O}(\text{polylog } n)$. On the other hand, based on established fine-grained complexity hypotheses about the impossibility of detecting a triangle in edge-linear time, we prove that the $k = 9$ case does not admit quasi-linear time algorithms. Hence we fully characterize the values of k for which quasi-linear time algorithms exist for polylogarithmic weights on bounded-degree graphs.

1 Introduction

1.1 Motivation

The TRAVELING SALESMAN PROBLEM (TSP) hardly needs an introduction; it is one of the most important problems in combinatorial optimization, which asks to find a Hamiltonian cycle of minimum weight in an edge-weighted complete graph. Local search is widely used in practical TSP solvers [10, 11]. The most commonly used neighborhood is a k -move (or k -opt move). A k -move on a Hamiltonian cycle \mathcal{C} is a pair (E^-, E^+) of edge sets such that $E^- \subseteq E(\mathcal{C})$, $|E^-| = |E^+| = k$ and $(\mathcal{C} \setminus E^-) \cup E^+$ is also a Hamiltonian cycle. Marx [13] showed that finding an improving k -move (i.e., a k -move that results in a lighter Hamiltonian cycle) is W[1]-hard parameterized by k , and this result was refined by Guo et al. [6] to obtain an $f(k)n^{\Omega(k/\log k)}$ lower bound under the Exponential Time Hypothesis (ETH). For small values of k , the current fastest running time is $\mathcal{O}(n^k)$ for $k = 2, 3$ (by exhaustive search), $\mathcal{O}(n^3)$ for $k = 4$ [4], and $\mathcal{O}(n^{3.4})$ for $k = 5$ [3]. Moreover, de Berg et al. [4] and Cygan et al. [3] showed that improving the running time to $\mathcal{O}(n^{3-\epsilon})$ for $k = 3$ or $k = 4$ implies a breakthrough result of an $\mathcal{O}(n^{3-\delta})$ -time algorithm for ALL-PAIRS SHORTEST PATHS.

From the hardness shown by the theoretical studies, it seems that local search can be applied only to small graphs. Nevertheless, state-of-the-art local search TSP solvers can deal with large graphs with tens of thousands of vertices. This is mainly due to the following two heuristics.

1. They sparsify the input graph by picking the top- d important incident edges for each vertex according to an appropriate importance measure. For example, Lin-Kernighan [12] picks the top-5 nearest neighbors, and its extension LKH [8] picks the top-5 α -nearest neighbors, where the α -distance of an edge is the increase of the Held-Karp lower bound [7] by including the edge. The empirical evaluation by Helsgaun [8] showed that the sparsification by the α -nearest neighbors can preserve almost optimal solutions.
2. They mainly focus on *sequential* k -moves. In general, $E^- \cup E^+$ is a set of edge-disjoint closed walks, each of which alternately uses edges in E^- and E^+ . If it consists of a single closed walk, the move is called sequential. Graphs of maximum degree d with n vertices have at most $n(2(d-2))^{k-1}$ sequential k -moves (n choices for the starting point, 2 choices for the next edge in E^- , and at most $d-2$ choices for the next edge in E^+), which is linear in n when considering d and k as constants. On the other hand, linear-time computation of non-sequential k -moves appears non-trivial. Lin-Kernighan does not search for non-sequential moves at all, and after it finds a local optimum, it applies special non-sequential 4-moves called *double bridges* to get out of the local optimum. LKH-2 [9] improves Lin-Kernighan by heuristically searching for non-sequential moves during the local search.

This state of affairs raises the following questions: what is the complexity of finding improving k -moves in bounded-degree graphs? How does the complexity scale with k , and can it be done efficiently for small values of k ? Since improving *sequential moves* can be found in linear time for fixed k and d , to answer these questions we have to investigate non-sequential k -moves in bounded-degree graphs.

1.2 Our contributions

We classify the complexity of finding improving k -moves in bounded-degree graphs in various regimes. We present improved algorithms that exploit the degree restrictions using the structure of k -moves, treewidth bounds, color-coding, and suitable data structures. We also give new lower bounds based on the Exponential Time Hypothesis (ETH) and hypotheses from fine-grained complexity concerning the complexity of detecting triangles. To state our results in more detail, we first introduce the two problem variants we consider; a weak variant to which our lower bounds already apply, and a harder variant which can be solved by our algorithms.

k -OPT DETECTION

Parameter: k .

Input: An undirected graph G , a weight function $w: E(G) \rightarrow \mathbb{Z}$, an integer k , and a Hamiltonian cycle $\mathcal{C} \subseteq E(G)$.

Question: Can \mathcal{C} be changed into a Hamiltonian cycle of strictly smaller weight by a k -move?

The related optimization problem k -OPT OPTIMIZATION is to compute, given a Hamiltonian cycle in the graph, a k -move that gives the largest cost improvement, or report that no improving k -move exists. With this terminology, we describe our results.

We show that k -OPT DETECTION is unlikely to be fixed-parameter tractable on bounded-degree graphs: we give a new constant-degree lower-bound construction to show that there is no function f for which k -OPT DETECTION on subcubic graphs with weights $\{1, 2\}$ can be solved in time $f(k) \cdot n^{o(k/\log k)}$, unless ETH fails. Hence the running time lower bound for general graphs by Guo et al. [6] continues to hold in this very restricted setting. While the degree restriction does not make the problem fixed-parameter tractable, it is possible to obtain faster algorithms. By adapting the approach of Cygan et al. [3], exploiting the fact that the number of sequential moves is linear in n in bounded-degree graphs, and proving a new upper bound on the pathwidth of an k -edge even graph, we show that k -OPT OPTIMIZATION in n -vertex graphs of maximum degree $\mathcal{O}(1)$ can be solved in time $\mathcal{O}(n^{(23/135+\epsilon_k)k}) = \mathcal{O}(n^{(0.1704+\epsilon_k)k})$, where $\lim_{k \rightarrow \infty} \epsilon_k = 0$. This improves on the behavior for general graphs, where the current-best running time [3] is $\mathcal{O}(n^{(1/4+\epsilon_k)k})$.

Since quasi-linear running times are most useful for dealing with large inputs, we perform a fine-grained analysis of the range of k for which improving k -moves can be found in time $\mathcal{O}(n \text{ polylog } n)$ on n -vertex graphs. Observe that in the bounded-degree setting, the number of edges m is $\mathcal{O}(n)$. We prove lower bounds using the hypothesis that detecting a triangle in an unweighted graph cannot be done in nearly-linear time in the number of edges m , which was formulated in several ways by Abboud and Vassilevska Williams [1, Conjectures 2–3]. By an efficient reduction from TRIANGLE DETECTION, we show that an algorithm with running time $\mathcal{O}(n \text{ polylog } n)$ for 9-OPT DETECTION in subcubic graphs with weights $\{1, 2\}$ implies that a triangle in an m -edge graph can be found in time $\mathcal{O}(m \text{ polylog } m)$, contradicting popular conjectures. We complement these lower bounds by quasi-linear algorithms for all $k \leq 8$ to obtain a complete dichotomy for the case of integer weights bounded by $\mathcal{O}(\text{polylog } n)$. When the weights are not bounded, we obtain quasi-linear time algorithms for all $k \leq 7$, leaving open only the case $k = 8$.

1.3 Organization

Preliminaries are presented in Section 2. In Section 3 we give faster XP algorithms for varying k . By refining these ideas, we give quasi-linear-time algorithms for $k \leq 8$ in Section 4. Section 5 gives the reduction from TRIANGLE DETECTION to establish a superlinear lower bound on subcubic graphs for $k = 9$. In Section 6 we describe the lower bound for varying k .

2 Preliminaries

Given a graph G edge-weighted by $w: E(G) \rightarrow \mathbb{Z}$, and a subset $F \subseteq E(G)$ of its edges, $w(F) := \sum_{e \in F} w(e)$. A k -move on a Hamiltonian cycle \mathcal{C} is pair (E^-, E^+) of edge sets such that $|E^-| = |E^+| = k$ and $(\mathcal{C} \setminus E^-) \cup E^+$ is also a Hamiltonian cycle. A k -move is called *improving* if $w((\mathcal{C} \setminus E^-) \cup E^+) < w(\mathcal{C})$, or equivalently and more simply $w(E^+) < w(E^-)$. A necessary condition for a pair (E^-, E^+) to be a k -move is that the multiset of endpoints of E^- is equal to the multiset of endpoints of E^+ . An exchange (E^-, E^+) that satisfies this condition is called a k -swap. We say that a k -swap *results* in the graph $(\mathcal{C} \setminus E^-) \cup E^+$. Note that a k -swap always results in a spanning disjoint union of cycles. A k -swap resulting in a graph with a single connected component is therefore a k -move. An *infeasible* k -swap is a k -swap which is not a k -move.

We say that a k -swap (E^-, E^+) *induces* the graph $E^- \cup E^+$. As a slight abuse of notation, a k -swap will sometimes directly refer to this graph. A k -swap (E^-, E^+) such that all edges $E^- \cup E^+$ are visited by a single closed walk alternating between E^- and E^+ is called *sequential*. In particular, in a simple graph, every 2-swap is sequential. One can notice that an infeasible (sequential) 2-swap results in a disjoint union of exactly two cycles. A k -move can always be decomposed into sequential k_i -swaps (with $\sum k_i = k$) but some k -moves cannot be decomposed into sequential k_i -moves. The quantity $w(E^-) - w(E^+)$ is called the *gain* of the swap (E^-, E^+) . We distinguish *neutral* swaps, with gain 0, *improving* swaps, with strictly positive gain, and *worsening* swaps, with strictly negative gain.

For an integer n , we denote $[n] = \{1, \dots, n\}$. A k -embedding (or shortly: *embedding*) is an increasing function $f: [k] \rightarrow [n]$. A *connection k -pattern* (or shortly: *connection pattern*) is a perfect matching in the complete graph on the vertex set $[2k]$. A pair (f, M) where f is a k -embedding and M is a connection k -pattern, is an alternative description of a k -swap. Indeed, let e_1, \dots, e_n be subsequent edges of \mathcal{C} . Then, $E^- = \{e_{f(i)}: i \in [k]\}$. Vertices of the connection pattern correspond to endpoints of E^- , i.e., vertices $2i - 1, 2i \in [2k]$ correspond to the left and right (in the clockwise order) endpoint of $e_{f(i)}$, respectively. Thus, edges of the connection pattern correspond to a set E^+ of $|M|$ edges in G . We say that a k -swap (E^-, E^+) *fits into* M if there is an embedding f such that (f, M) describes (E^-, E^+) . Note that every pair of an embedding and a connection pattern (f, M) describes exactly one swap (E^-, E^+) . Conversely, for a swap (E^-, E^+) the corresponding embedding f is also unique (and determined by E^-). However, in case E^- contains incident edges, the swap fits into more than one matching M (see Fig. 1). See [3] for a more formal description of the equivalence.

The notion of a connection pattern can be extended to represent k' -swaps, for $k' < k$, as follows. Note that a matching N in the complete graph on the vertex set $[2k]$ corresponds to an $|N|$ -swap if and only if there is a set $\iota(N) \subseteq [k]$ such that $V(N) = \{2i - 1, 2i: i \in \iota(N)\}$. For a set $X \subseteq [k]$, by $M[X]$ we denote the swap N such that $\iota(N) = X$. We say that a connection pattern M *decomposes* into swaps N_1, \dots, N_t when $M = \bigsqcup_{i=1}^t N_i$ and each N_i is a connection pattern of a swap. The notion of fitting extends to k' -swaps in the natural way.

Consider a connection pattern N of a swap, for $V(N) \subseteq [2k]$. We call N *sequential* if $N \cup \{\{2i - 1, 2i\}: i \in \iota(N)\}$ forms a simple cycle. In particular, every connection pattern can be decomposed into sequential connection patterns of (possibly shorter) swaps. The correspondence between sequential swaps and sequential connection patterns is somewhat delicate, so let us explain it in detail.

Let N be a sequential connection pattern, $V(N) \subseteq [2k]$. Recall that for every embedding f there is exactly one $|N|$ -swap (E^-, E^+) that fits into N . Clearly, this swap is sequential, since every edge in $\{\{2i - 1, 2i\}: i \in \iota(N)\}$ corresponds to an edge of E^- and every edge in

Figure 1 A sequential swap (left) which fits two connection patterns (center, right). The pattern in the center is not sequential, while the pattern on the right is sequential. On the left the solid red edges are in E^- , the dashed green edges are in E^+ , and the thin black edges are the remaining edges of the Hamiltonian cycle C . In the central and right pictures, the dashed green edges form some connection patterns.

N corresponds to an edge in E^+ . Thus the resulting set of edges $E^- \cup E^+$ forms a single closed walk. In particular, if the image of f contains two neighboring indices $i, i + 1 \in [n]$, the closed walk is not a simple cycle.

Conversely, it is possible that a sequential swap fits into a connection pattern which is not sequential, see Fig. 1 for an example. However, every sequential ℓ -swap (E^-, E^+) fits at least one sequential connection pattern. This sequential connection pattern is determined by the closed walk which certifies the sequentiality of the swap. Indeed, let $E^- = \{e_{i_1}, \dots, e_{i_\ell}\}$, where i_1, \dots, i_ℓ is an increasing sequence. Let $v_0, \dots, v_{2\ell-1}$ be the closed walk alternating between E^- and E^+ , in particular assume that $E^- = \{v_i v_{i+1} : i \text{ is even}\}$. Consider any $i = 0, \dots, \ell - 1$ and the corresponding edge $e_{i_j} = v_{2i} v_{2i+1}$ in E^- , for some $j \in [\ell]$. If v_{2i} is the left endpoint of e_{i_j} , we put $w_{2i} = 2j - 1$ and $w_{2i+1} = 2j$, otherwise $w_{2i} = 2j$ and $w_{2i+1} = 2j - 1$. Then $w_0, \dots, w_{2\ell-1}$ is a simple cycle and $N = \{w_i w_{i+1} : i \text{ is odd}\}$ is a sequential connection pattern. By construction, (E^-, E^+) fits N , as required. Keeping in mind the nuances in the notions of sequential swaps and corresponding sequential connection patterns, for simplicity, we will often just say “a sequential swap M ” for a matching M , instead of the more formal “a sequential connection pattern M of a swap”.

Fix a connection pattern M and let $f: S \rightarrow [n]$ be a partial embedding, for some $S \subseteq [k]$. For every $j \in S$, let v_{2j-1} and v_{2j} be the left and right endpoint of $e_{f(j)}$, respectively. We define

$$E_f^- = \{e_{f(i)} \mid i \in S\},$$

$$E_f^+ = \{\{v_{i'}, v_{j'}\} \mid i, j \in S, i' \in \{2i - 1, 2i\}, j' \in \{2j - 1, 2j\}, \{i', j'\} \in M\}.$$

Then, $\text{gain}_M(f) = w(E_f^-) - w(E_f^+)$.

3 Fast XP algorithms

For all fixed integers k and d , the number of sequential k -swaps in a graph of maximum degree d is $\mathcal{O}(n)$, and we can enumerate all of them in the same running time. Therefore, we can find the best improving k -move that can be decomposed into at most c sequential k -swaps in $\mathcal{O}(n^c)$ time. Because c is at most $\lfloor \frac{k}{2} \rfloor$, we obtain an $\mathcal{O}(n^{\lfloor \frac{k}{2} \rfloor})$ -time algorithm for k -OPT OPTIMIZATION. In what follows, we will improve this naive algorithm. Below we present a relatively simple algorithm which exploits the range tree data structure [15] and achieves running time roughly the same as the more sophisticated algorithm of Cygan et al. [3] for general graphs.

► **Theorem 1.** *For all fixed integers k , c , and d , there is an $\mathcal{O}(n^{\lceil \frac{c}{2} \rceil})$ polylog n -time algorithm to compute the best improving k -move that can be decomposed into c sequential swaps in graphs of maximum degree d .*

Proof. When $c = 1$, we can use the naive algorithm. Suppose $c \geq 2$ and let $h := \lceil \frac{c}{2} \rceil$.

For each possible connection pattern M consisting of c sequential swaps, we find the best embedding as follows. Let $M = \bigcup_{i=1}^c N_i$, where each N_i corresponds to a sequential swap. We split M into two parts $M_L = \bigcup_{i=1}^h N_i$ and $M_R = \bigcup_{i=h+1}^c N_i$ and we define $L = \bigcup_{i=1}^h \iota(N_i)$ and $R = \bigcup_{i=h+1}^c \iota(N_i)$. Note that $L \uplus R = [k]$. Let $f_L: L \rightarrow [n]$ and $f_R: R \rightarrow [n]$ be embeddings of L and R , respectively. The union of these two embeddings results in an embedding of $[k]$ if and only if the following conditions hold.

- For each $i \in [k-1]$ with $i \in L$ and $i+1 \in R$, $f_L(i) < f_R(i+1)$ holds.
- For each $i \in [k-1]$ with $i \in R$ and $i+1 \in L$, $f_R(i) < f_L(i+1)$ holds.

We can efficiently compute a pair of embeddings satisfying these conditions using an orthogonal range maximum data structure as follows. Let $\{l_1, \dots, l_p\} = \{i: l_i \in L \text{ and } l_i + 1 \in R\}$ and let $\{r_1, \dots, r_q\} = \{i: r_i - 1 \in R \text{ and } r_i \in L\}$. We first enumerate all the $|L|$ -swaps that fit into M_L and all the $|R|$ -swaps that fit into M_R , in $\mathcal{O}(n^h)$ time. For each such $|L|$ -swap (f_L, M_L) , we create a $(p+q)$ -dimensional point $(f_L(l_1), \dots, f_L(l_p), f_L(r_1), \dots, f_L(r_q))$ with a priority gain $_{M_L}(f_L)$, and we collect these points into a data structure. It stores $\mathcal{O}(n^h)$ points. For each $|R|$ -swap (f_R, M_R) , we query for the embedding f_L of maximum priority satisfying $f_L(l_i) < f_R(l_i + 1)$ for every $i \in [p]$ and $f_R(r_i - 1) < f_L(r_i)$ for every $i \in [q]$, and we answer the pair maximizing the total gain, i.e., the sum $\text{gain}_{M_L}(f_L) + \text{gain}_{M_R}(f_R)$. Using the range tree data structure [15], each query takes $\mathcal{O}(\log^{p+q} n^h) = \mathcal{O}(\text{polylog } n)$ time, so the total running time is $\mathcal{O}(n^h \text{ polylog } n)$. ◀

Since $c \leq \lfloor \frac{k}{2} \rfloor$ we get the following corollary.

► **Corollary 2.** *For all fixed integers k and d , k -OPT OPTIMIZATION in graphs of maximum degree d can be solved in time $\mathcal{O}(n^{\lceil \frac{k-1}{4} \rceil})$ polylog n .*

Let us take another look at the proof of Theorem 1. Recall that for merging embeddings f_L and f_R , we were interested only in values $f_L(i)$ for $i \in L$ such that $i+1 \in R$ or $i-1 \in R$. The embeddings of the remaining elements of L were forgotten at that stage, but we knew that it is possible to embed them and we stored the gain of embedding them. This suggests the following, different approach. We decompose the connection pattern into sequential swaps and we scan the swaps in a carefully chosen order. Assume we scanned t swaps already and there are $c-t$ swaps ahead. Assume that only $p \ll t$ of the t “boundary” swaps interact with the remaining $c-t$ swaps, where two swaps N_1 and N_2 interact when there is $i \in \iota(N_1)$ such that $i-1 \in \iota(N_2)$ or $i+1 \in \iota(N_2)$. Then it suffices to compute, for every embedding f_L of the p swaps, the gain of the best (i.e., giving the highest gain) embedding g_L of the t swaps, such that f_L matches g_L on the boundary swaps. This amounts to $\mathcal{O}(n^p)$ values to compute, since each sequential swap can be embedded in $\mathcal{O}(n)$ ways, if k and the maximum degree are $\mathcal{O}(1)$. The idea is to (1) compute these values quickly (in time linear in their number) using analogous values computed for the prefix of $t-1$ swaps, (2) find an order of swaps so that p is always small, namely $p \leq (23/135 + \epsilon_k)k$. The readers familiar with the notion of pathwidth recognize that p here is just the pathwidth of the graph obtained from the path $1, 2, \dots, k$ by identifying vertices in the set $\iota(N)$ for every sequential swap N in M , and that (2) is just dynamic programming over the path decomposition. The resulting algorithm is summarized in Theorem 3, and due to space limits, its formal proof is deferred to the full version.

► **Theorem 3.** *For all fixed integers k and d , k -OPT OPTIMIZATION in graphs of maximum degree d can be solved in time $\mathcal{O}(n^{(23/135+\epsilon_k)k}) = \mathcal{O}(n^{(0.1704+\epsilon_k)k})$, where $\lim_{k \rightarrow \infty} \epsilon_k = 0$.*

4 Fast algorithms for small k

Note that the algorithm for k -OPT OPTIMIZATION from Corollary 2 is quasi-linear for $k \leq 5$. In this section we extend the quasi-linear-time solvability to $k \leq 7$ for k -OPT DETECTION. Under an additional assumption of bounded weights, we are able to reach quasi-linear time for $k = 8$ as well, but the details of this part are deferred to the full version because of space constraints. To be precise, in the $k = 7$ case we prove the following stronger statement than just finding an arbitrary improving k -move.

► **Theorem 4.** *For $k \leq 7$, there is a quasi-linear-time algorithm to compute the best improving k -move in bounded-degree graphs under the assumption that there are no improving k' -moves for $k' < k$.*

We say that a connection pattern M of k -swaps is *reducible* if it can be decomposed into two moves. Note that if M is improving, then at least one of the two moves is improving, contradicting the assumption of Theorem 4.

► **Observation 5.** *If there are no improving k' -moves for $k' < k$, then no improving k -swap fits into a reducible connection pattern.*

Before we formulate our algorithm, we need two lemmas. We can prove these lemmas by case analysis, and because of the space constraints, their proofs are deferred to the full version. Let $M[X]$ and $M[Y]$ be two swaps in a connection pattern M , for some disjoint $X, Y \subseteq [k]$. *Interaction* between $M[X]$ and $M[Y]$ is any $i \in [k-1]$ such that $i \in X$ and $i+1 \in Y$ or $i \in Y$ and $i+1 \in X$.

► **Lemma 6.** *For any $k \geq 6$, there is no feasible and irreducible connection k -pattern that contains two 2-swaps that interact at least twice.*

Let M be a connection pattern, i.e., a perfect matching on vertices $[2k]$. We say that M' is obtained from M by swapping i and $i+1$, for $i \in [k]$, when M' is obtained from M by swapping the mates of $2i-1$ and $2i+1$ and swapping the mates of $2i$ and $2i+2$.

► **Lemma 7.** *Let M be a feasible irreducible connection k -pattern. Assume that M decomposes into three sequential swaps $M[X]$, $M[Y]$, and $M[Z]$, such that $|X| = |Y| = 2$. If there is exactly one index $i \in [k-1]$ with $i \in X$ and $i+1 \in Y$ or $i \in Y$ and $i+1 \in X$, the connection pattern M' obtained from M by swapping i and $i+1$ is either feasible or reducible.*

Now we are ready to describe the algorithm from Theorem 4 (see also Pseudocode 1). For each feasible and irreducible connection k -pattern M , we compute the best embedding as follows. If M consists of at most two sequential swaps, we can use the algorithm in Theorem 1. Otherwise, M consists of three sequential swaps $M[X]$, $M[Y]$, $M[Z]$ such that $X \uplus Y \uplus Z = [k]$, $|X| = |Y| = 2$ and $|Z| = k-4$. For each embedding $f_X : X \rightarrow [n]$ of $X = \{i, j\}$ we create a 2-dimensional point $(f_X(i), f_X(j))$ with priority $\text{gain}_X(f_X)$ and we put all the points in a range tree data structure D_X [15]. We build an analogous data structure for Y . Next, for each embedding f_Z for Z , we compute the best pair of embeddings (f_X, f_Y) for X and Y as follows.

If there are no interactions between X and Y , we can find the best pair in $\mathcal{O}(\text{polylog } n)$ time by independently picking the best embeddings for X and Y by querying the range trees D_X and D_Y . Indeed, first note that there is no index $i \in [k-1]$ such that $X = \{i, i+1\}$ because

■ **Algorithm 1** Quasi-linear-time algorithm for $k \leq 7$.

```

1: for each feasible irreducible connection  $k$ -pattern  $M$  do
2:   if  $M$  consists of at most two sequential swaps then
3:     Apply the algorithm in Theorem 1.
4:   else
5:     Let  $M = M[X] \uplus M[Y] \uplus M[Z]$  where  $|X| = |Y| = 2$  and  $|Z| = k - 4$ .
6:     if there are no interactions between  $X$  and  $Y$  then
7:       for each embedding  $f_Z$  for  $Z$  do
8:         Independently compute the best embeddings  $f_X$  for  $X$  and  $f_Y$  for  $Y$ .
9:       else
10:        Relax the constraint  $f_X(i) < f_Y(i+1)$  to  $f_X(i) \neq f_Y(i+1)$ .
11:        for each embedding  $f_Z$  for  $Z$  do
12:          Compute the best pair  $(f_X, f_Y)$  satisfying the relaxed constraints.

```

in such a case, both the 2-swap and the remaining $(k-2)$ -swap have to be feasible (similarly for Y). Since there are no interactions between X and Y , we must have $i-1 \in Z \cup \{0\}$ and $i+1 \in Z \cup \{k+1\}$ for every $i \in X \cup Y$. To find the best embedding f_X of $X = \{i, j\}$, we query D_X with the constraints $f_Z(i-1) < f_X(i) < f_Z(i+1)$ and $f_Z(j-1) < f_X(j) < f_Z(j+1)$, where we define $f_Z(0) := 0$ and $f_Z(k+1) := n+1$. We proceed analogously for Y .

Finally, assume there are interactions between X and Y , so from Lemma 6, there is exactly one interaction. W.l.o.g. $i \in X$ and $i+1 \in Y$. Note that $i-1 \in Z \cup \{0\}$ and $i+2 \in Z \cup \{k+1\}$. We first relax the constraint $f_Z(i-1) < f_X(i) < f_Y(i+1) < f_Z(i+2)$, where we define $f_Z(0) := 0$ and $f_Z(k+1) := n+1$, to three constraints $f_Z(i-1) < f_X(i) < f_Z(i+2)$, $f_Z(i-1) < f_Y(i+1) < f_Z(i+2)$, and $f_X(i) \neq f_Y(i+1)$. We then drop the disturbing inequality constraint $f_X(i) \neq f_Y(i+1)$ by color-coding¹. We color each vertex in $[n]$ in red or blue, and we independently pick the best embedding for X (resp. Y) that uses only red (resp. blue) vertices. By using a family of perfect hash functions [5], we can construct a set of $\mathcal{O}(\log^2 n)$ colorings such that, for every pair of embeddings f_X and f_Y , there is at least one coloring that colors all the vertices in f_X red and all the vertices in f_Y blue.

We now obtain the best pair of embeddings (f_X, f_Y) satisfying the relaxed constraints. If the obtained k -swap is not improving, we immediately know that there are no improving k -moves that fit into M . If it is improving and satisfies the original constraint, we are done. Finally, if it is improving but does not satisfy the original constraint, it fits into the connection pattern M' that is obtained from M by swapping i and $i+1$. By Lemma 7, M' is either feasible or reducible. Because no improving k -swaps fit into reducible connection patterns, M' has to be feasible. We therefore obtain a k -move that is as good as the best k -move that fits into M . This completes the proof of Theorem 4.

We finally consider the case of $k = 8$. Note that, because Lemma 6 and 7 do not assume $k \leq 7$, the above algorithm can also compute the best improving k -move that can be decomposed into three sequential swaps of size $(2, 2, k-4)$ for any fixed k under the same assumption. Moreover, any connection patterns of 8-moves consisting of four 2-swaps are reducible because it always induces a pair of two 2-swaps that interact at least twice. The

¹ Instead of color-coding, we can adapt the range tree to support orthogonal range maximum queries with an additional constraint of the form $x \neq i$ by keeping one additional point in each node. With this approach, we can avoid the additional $\log^2 n$ factor. Because this paper does not focus on optimizing the polylog n factor, we do not touch on the details.

■ **Figure 2** An instance of TRIANGLE DETECTION.

remaining case for $k = 8$ is only when the 8-move can be decomposed into three sequential swaps of size $(2, 3, 3)$. In order to tackle this case, we exploit the bounded-weight assumption as follows. For each connection pattern $M = M[X] \uplus M[Y] \uplus M[Z]$ with $|X| = 2$ and $|Y| = |Z| = 3$, and for each embedding f_Z for Z , we want to compute the best pair of embeddings f_X for X and f_Y for Y . When all the weights are integers from $[W]$, the gain of $(f_X, M[X])$ is an integer from $[-2W, 2W]$, and the gain $(f_Y, M[Y])$ is an integer from $[-3W, 3W]$. We therefore have only $\mathcal{O}(W^2)$ pairs of gains. By guessing the pair of gains, the query of finding the *best* pair can be reduced to the query of finding an *arbitrary* pair, and the latter query can be efficiently answered by adapting the range tree. This leads to the following algorithm, whose detailed description is deferred to the full version.

► **Theorem 8.** *When all the weights are integers from $[W]$, there is an $\mathcal{O}(W^2 n \text{ polylog } n)$ -time algorithm to compute the best improving 8-move under the assumption that there are no improving k' -moves for $k' < 8$.*

5 Lower bound for $k = 9$

The starting point for our reduction is the following problem (see Fig. 2 for an exemplary instance).

<p>TRIANGLE DETECTION</p> <p>Input: An undirected graph H whose vertex set $V(H)$ is partitioned into $A \cup B \cup C$.</p> <p>Question: Is there a triple $(a, b, c) \in A \times B \times C$ such that $\{ab, ac, bc\} \subseteq E(H)$?</p>	<p>Parameter: $m := E(H)$.</p>
---	--

We assume without loss of generality that A , B , and C are three independent sets, so that finding such a triple is equivalent to finding a triangle in the graph H . By simple reductions that incur only a constant blow-up in the number of vertices and edges, this problem is equivalent to determining whether a graph has a triangle or not.

► **Assumption 1** (Triangle hypothesis [1]). *There is a fixed $\delta > 0$ such that, in the Word RAM model with words of $\mathcal{O}(\log n)$ bits, any algorithm requires $m^{1+\delta-o(1)}$ time in expectation to detect whether an m -edge graph contains a triangle.*

It should be noted that one can solve TRIANGLE DETECTION in time $\mathcal{O}(n^\omega)$ where n is the number of vertices and $\omega \leq 2.373$ is the best-known exponent for matrix multiplication. Alon et al. [2] found an elegant win-win argument to solve TRIANGLE DETECTION in time $\mathcal{O}(m^{\frac{2\omega}{\omega+1}})$: the 3-vertex paths in which the middle vertex has degree less than $m^{\frac{\omega-1}{\omega+1}}$ can be listed in time $\mathcal{O}(m \cdot m^{\frac{\omega-1}{\omega+1}}) = \mathcal{O}(m^{\frac{2\omega}{\omega+1}})$, and for each, one can check if they form a triangle, whereas the number of vertices of degree greater than $m^{\frac{\omega-1}{\omega+1}}$ is at most $m^{\frac{2}{\omega+1}}$, so one can detect a triangle in time $\mathcal{O}(m^{\frac{2\omega}{\omega+1}})$ in the subgraph that they induce. After more than two decades, this is still the best worst-case running time (when $n^\omega = \Omega(m^{\frac{2\omega}{\omega+1}})$). This suggests

that the triangle hypothesis is likely to hold. Moreover, if one thinks that the above scheme yields the best possible running time and that ω will eventually reach 2, then exponent $4/3$ could be the *right answer* for TRIANGLE DETECTION parameterized by the number of edges. The following is implied by [1, Conjecture 2] (since $\omega \geq 2$), in the regime $m = \Theta(n^{3/2})$ (so that $\mathcal{O}(n^2)$ and $\mathcal{O}(m^{4/3})$ coincide).

► **Assumption 2.** *In the Word RAM model with words of $\mathcal{O}(\log n)$ bits, any algorithm requires $m^{4/3-o(1)}$ time in expectation to detect whether an m -edge $\Theta(m^{2/3})$ -node graph contains a triangle.*

We show that SUBCUBIC 9-OPT DETECTION parameterized by the number of vertices is as hard as TRIANGLE DETECTION parameterized by the number of edges, by providing a linear-time reduction from the latter to the former. In light of Theorem 4, this implies that BOUNDED-DEGREE 8-OPT DETECTION is the only remaining open case where a quasi-linear algorithm is not known but also not ruled out by a standard fine-grained complexity assumption.

► **Lemma 9.** *There is an $\mathcal{O}(m)$ -time reduction from TRIANGLE DETECTION on m -edge graphs to SUBCUBIC 9-OPT DETECTION on $\mathcal{O}(m)$ -vertex undirected graphs with edge weights in $\{1, 2\}$.*

Proof. From a tripartitioned instance of TRIANGLE DETECTION $H = (A \cup B \cup C, E(H))$ with m edges, we build a subcubic graph G with $\Theta(m)$ vertices, an edge-weight function $w : E(G) \rightarrow \{1, 2\}$, and a Hamiltonian cycle \mathcal{C} . From \mathcal{C} , there is a swap of up to 9 edges (i.e., up to 9 deletions and the same number of additions) which results in a lighter Hamiltonian cycle if and only if H has a triangle.

Overall construction of G . We will build G by adding chords to the cycle \mathcal{C} . Henceforth, a *chord* is an edge of G which is not in \mathcal{C} . It is helpful to think of \mathcal{C} as a (subdivided) triangle whose three sides correspond to A , B , and C , which we call the A -side (left), B -side (right), and C -side (bottom), respectively. We will only name the edges of G (and not the vertices), since the problem is more efficiently described in terms of edges. We will define some sequential 3-swaps (we recall that a sequential i -swap is a closed walk of length $2i$ alternating edges of $E(\mathcal{C})$ and edges of $E(G) \setminus E(\mathcal{C})$). Eventually, all the edges that are not in a described sequential 3-swap are incident to a vertex of degree 2, making them undeletable. (One can also enforce that by subdividing every irrelevant edge once.)

The improving 9-move, should there be a triangle abc in H , will consist of a sequence of three 3-swaps. More precisely, it consists of one improving 3-swap, which splits \mathcal{C} into three cycles respectively containing:

- (1) a part of the vertex gadget of some $a \in A$,
- (2) the part of the B -side below the vertex gadget of b , as well as the C -side, and
- (3) the part of the B -side above the vertex gadget of some $b \in N_H(a) \cap B$.

This decreases the total weight by 1. Then a neutral 3-swap reconnects (1) and (2) together, but also detaches (4) a part of the vertex gadget of some $c \in N_H(a) \cap C$. Finally a neutral 3-swap glues (3), (1)+(2), and (4) together, provided $bc \in E(H)$. This results in a new Hamiltonian cycle of length $w(\mathcal{C}) - 1$.

There will be relatively few edges of weight 2. To simplify the presentation, every edge is of weight 1, unless specified otherwise. Let \vec{H} be the directed graph obtained from H by orienting its edges from A to B , from B to C , and from C to A . Note that finding a directed triangle in \vec{H} is equivalent to finding a triangle in H .

Vertex scopes, extended scopes, and nested chords. For $(X, Y) \in \{(A, B), (B, C), (C, A)\}$, we set $Z := \{A, B, C\} \setminus \{X, Y\}$ and we do the following as a preparatory step to encode the arcs of \vec{H} . Each vertex $v \in X$ is given a (pairwise vertex-disjoint) subpath I_v of \mathcal{C} , called the *extended scope* of v , with $|I_v| := 6(|N_H(v) \cap Y|) + 3(|N_H(v) \cap Z|) - 1$ vertices. We think of I_v as being displayed from left to right with the leftmost vertex of index 1, and the rightmost one of index $|I_v|$. The extended scopes of the vertices of A , B , and C occupy respectively the A -side, B -side, and C -side. In what follows, it will be more convenient to have a *circular* notion of *left* and *right*. Starting from the bottom corner of the A -side, and going clockwise to the top corner of the A -side, then down to the bottom corner of the B -side, the relative left and right within the A -side and the B -side coincide with the usual notion as displayed in Figure 3a. But then closing the loop from the right corner of the C -side to its left corner, left and right are switched: the closer to the bottom corner of A (resp. B), the more “right” (resp. “left”).

Each vertex $v \in X$ has $|N_H(v) \cap Y|$ nested chords spaced out every three vertices. More precisely, the second vertex of I_v is adjacent to the penultimate, the fifth to the one of index $|I_v| - 4$, the eighth to the one of index $|I_v| - 7$, and so on, until $|N_H(v) \cap Y|$ chords are drawn. Each of these chords is associated to an edge $vy \in E(\{v\}, Y)$, and is denoted by \underline{vy} . A vertex just to the right of the left endpoint, or just to the left of the right endpoint, of such a chord will remain of degree 2 in G . This is the case of the vertices of index 3, 6, ... and $|I_v| - 2, |I_v| - 5, \dots$ in I_v . We call $l^-(v, y)$ (resp. $r^-(v, y)$) the edge of I_v incident to both the left endpoint of \underline{vy} and the vertex just to its left (resp. right endpoint of \underline{vy} and the vertex just to its right). Both endpoints of $l^-(v, y)$ and of $r^-(v, y)$ will eventually have degree 3 in G .

The chord linking the most distant vertices in I_v is called the *outermost* chord, while the one linking the closest pair is called the *innermost* chord. We also say that a chord e is *wider* than a chord e' if e links a farther pair on I_v than e' does. The central path $J_v \subset I_v$ on $|I_v| - (6|N_H(v) \cap Y| - 4) = 3(|N_H(v) \cap Z| + 1)$ vertices, surrounded by the innermost chord, is called the *scope* of v . We map in one-to-one correspondence the edges of $E(\{v\}, Z)$ to every three edges of J_v starting from the third edge (that is, the third, sixth, and so on). Note that we have the exact space to do so, since $|J_v| = 3(|N_H(v) \cap Z| + 1)$. We denote by \underline{zv} the edge in J_v corresponding to the edge $vz \in E(\{v\}, Z)$.

Encoding the arcs of \vec{H} . The last step to encode the arcs of \vec{H} , or equivalently the edges of H , is the following. Keeping the notations of the previous paragraphs, for every edge $xy \in E(X, Y)$, we add two chords (of weight 1): one chord $l^+(x, y)$ between the left endpoint of $l^-(x, y)$ and the right endpoint of \underline{xy} and one chord $r^+(x, y)$ between the right endpoint of $r^-(x, y)$ and the left endpoint of \underline{xy} . We finish the construction of G (and \mathcal{C}) by subdividing each edge between consecutive extended scopes once, to make the resulting edges undeletable. The edges $l^-(a, b)$ for $(a, b) \in A \times B$ get weight 2, while all the other edges of $E(G)$ get weight 1. This finishes the construction of (G, w, \mathcal{C}) . See Figure 3a for an illustration.

Improving and neutral 3-swaps. For each $(x, y) \in E(\vec{H})$, denote by $S(x, y)$ the 3-swap $(\{\underline{xy}, l^-(x, y), r^-(x, y)\}, \{\underline{xy}, l^+(x, y), r^+(x, y)\})$. For $(X, Y) \in \{(A, B), (B, C), (C, A)\}$, we define the set of 3-swaps $S(X, Y) := \bigcup_{xy \in E(X, Y)} S(x, y)$, and $\mathcal{S} := S(A, B) \cup S(B, C) \cup S(C, A)$.

Note that all the 3-swaps of $S(A, B)$ are improving. They gain 1 since $l^-(a, b)$ has weight 2 for any $(a, b) \in A \times B$. On the other hand, all the 3-swaps of $S(B, C)$ and $S(C, A)$ are neutral. The edges added in swaps of \mathcal{S} partition the chords of G , and the open neighborhood

(a) The construction for the instance of Figure 2. Edges of \mathcal{C} are in black, chords are in red, bold edges are the ones with weight 2. The three chords in blue are the edges to add to perform the neutral 3-swap $S(5, 1)$ of $S(\mathcal{C}, A)$.

(b) The 9-move corresponding to the triangle 135 results in a Hamiltonian cycle using one less edge of weight 2. Note that after the swaps $S(1, 3)$ and $S(5, 1)$ are performed, the only 3-swap that can reconnect the three cycles into one, is $S(3, 5)$, implying the existence of the edge 35, and thereby of the triangle 135.

■ **Figure 3** Illustration of the reduction (left) and of a potential solution (right).

of the six vertices involved in every swap are six vertices of degree 2 in G . Therefore, all the possible swaps are in the set \mathcal{S} , they are on vertex-disjoint sets of vertices, and any move is a sequence of 3-swaps of \mathcal{S} .

The vertices of \mathcal{C} are incident to at most one chord. Hence the graph G is subcubic. It has $\sum_{v \in V(H)} 1 + |I_v| \leq 9|E(H)| + |V(H)| = \Theta(m)$ vertices and (G, w, \mathcal{C}) takes $\Theta(m)$ -time to build. To summarize, we defined a linear reduction from TRIANGLE DETECTION with parameter m to SUBCUBIC 9-OPT DETECTION with parameter n . So a quasi-linear algorithm for the latter would yield an unlikely quasi-linear algorithm for the former. We now check that the reduction is correct.

A triangle in H implies an improving 9-move for (G, w, \mathcal{C}) . Let abc be a triangle in H . In particular, all three swaps $S(a, b)$, $S(b, c)$, and $S(c, a)$ exist. Performing these three 3-swaps results in a spanning union of (vertex-disjoint) cycles, whose total weight is $w(\mathcal{C}) - 1$. Indeed $S(a, b)$ is swap of weight -1 , while $S(b, c)$, and $S(c, a)$ are both neutral.

We thus only need to show that the three swaps result in a connected graph (hence, Hamiltonian cycle of lighter weight). By performing the 3-swap $S(a, b)$, we create three components: (1) one on a vertex set $K_{a,b}$ such that $J_a \subseteq K_{a,b} \subseteq I_a$, (2) one containing the scopes of vertices of the B -side to the right (lower part) of the scope of b , and (3) one containing the scopes of vertices of the B -side to the left (upper part) of the scope of b . Then the swap $S(c, a)$ glues (1) and (2) together, but also disconnects (4) a cycle on a vertex set $K_{c,a}$ such that $J_c \subseteq K_{c,a} \subseteq I_c$. At this point, there are three cycles: (3), (1)+(2), and (4). It turns out that the 3-swap $S(b, c)$ deletes exactly one edge in each of these three cycles: b_c in (4), $l^-(b, c)$ in (3), and $r^-(b, c)$ in (1)+(2). Therefore, $S(b, c)$ reconnects these three components into one Hamiltonian cycle.

An improving k -move for (G, w, \mathcal{C}) with $k \leq 9$ implies a triangle in H . We assume that there is an improving k -move $\mathcal{M} = (E^-, E^+)$ for (G, w, \mathcal{C}) with $k \leq 9$. Being improving, the k -move has to contain at least one improving 3-swap of $S(A, B)$. Let $S(a, b)$ be a 3-swap of

$S(A, B)$ in \mathcal{M} such that for every other (improving) 3-swap $S(a, b')$ in \mathcal{M} , the chord ab' is wider than ab . Since $S(a, b)$ exists, it holds in particular that $ab \in E(H)$. Performing $S(a, b)$ results in the union of three cycles: (1) on a vertex set $K_{a,b}$ with $J_a \subseteq K_{a,b} \subseteq I_a$, and cycles (2) and (3) as described in the previous paragraph.

By the choice of b , the only remaining swaps of \mathcal{M} touching $K_{a,b}$ are in $S(C, A)$. So \mathcal{M} has to contain a neutral 3-swap $S(c, a)$ for some $c \in C$. This implies that $ac \in E(H)$. Performing this swap results in three cycles: (3), (1)+(2), and (4), as described above. To reconnect all three components into one Hamiltonian cycle, the 3-swap has to delete exactly one edge in (3), (1)+(2), and (4). The only 3-swap that does so is $S(b, c)$. This finally implies that $bc \in E(H)$. Thus abc is a triangle in H . ◀

We obtain the following theorem as a direct consequence of the previous lemma.

► **Theorem 10.** SUBCUBIC 9-OPT DETECTION *requires time:*

- (1) $n^{1+\delta-o(1)}$ for a fixed $\delta > 0$, under the triangle hypothesis, and
 - (2) $n^{4/3-o(1)}$, under the strong triangle hypothesis,
- in expectation, even in undirected graphs with edge weights in $\{1, 2\}$.

If we use general integral weights and not just $\{1, 2\}$, we can show a stronger lower bound, by reducing from NEGATIVE EDGE-WEIGHTED TRIANGLE. Again, we can assume that the instance is partitioned into three sets A, B, C , and we look for a triangle abc such that $w'(ab) + w'(bc) + w'(ac) < 0$, where w' gives an integral weight to each edge. A truly subcubic (in the number of vertices) algorithm for this problem would imply one for ALL-PAIRS SHORTEST PATHS, which would be considered a major breakthrough. The assumption that such an algorithm is not possible is called the APSP hypothesis.

We only change the above construction in the weight of the edges $l^-(x, y)$. Now each edge $l^-(x, y)$ gets weight $-w'(xy)$. From a NEGATIVE EDGE-WEIGHTED TRIANGLE-instance with n vertices, we obtain an equivalent instance of SUBCUBIC 9-OPT DETECTION with $\mathcal{O}(n^2)$ vertices, in time $\mathcal{O}(n^2)$. So we derive the following.

► **Theorem 11.** SUBCUBIC 9-OPT DETECTION *requires time* $n^{3/2-o(1)}$, *under the APSP hypothesis.*

6 Lower bound for varying k

In this section we describe the main ideas behind the lower bound for k -OPT DETECTION in subcubic graphs for varying k . The details are deferred to the full version due to space restrictions. The overall approach is similar to the lower bound of Guo et al. [6], in that we give a linear-parameter reduction from the k -PARTITIONED SUBGRAPH ISOMORPHISM problem parameterized by the number of edges k . Marx [14] proved that, assuming the Exponential Time Hypothesis, the problem cannot be solved in time $f(k) \cdot n^{o(k/\log k)}$ for any function f .

The instance created in the reduction of Guo et al. [6] may contain vertices of arbitrarily large degrees. To obtain such a reduction to k -OPT DETECTION in subcubic graphs, an essential ingredient is a *choice gadget* with terminal pairs $(x_0, y_0), \dots, (x_\ell, y_\ell)$ which enforces that sufficiently cheap Hamiltonian cycles that enter at x_i , must leave via the corresponding y_i . The gadget can be implemented by suitable weight settings and vertices of degree at most three. This gadget allows us to enforce synchronization properties, which enforce that an improved Hamiltonian cycle first selects which vertices to use in the image of the subgraph isomorphism,

and then selects incident edges for each selected vertex. By carefully coordinating the gadgets, this allows us to implement the hardness proof by an edge selector strategy. It leads to a proof of the following theorem.

► **Theorem 12.** *There is no function f for which k -OPT DETECTION on n -vertex graphs of maximum degree 3 with edge weights in $\{1, 2\}$ can be solved in time $f(k) \cdot n^{o(k/\log k)}$, unless ETH fails.*

We remark that the lower bound also holds for *permissive* local search algorithms which output an improved Hamiltonian cycle of arbitrarily large Hamming distance to the starting cycle \mathcal{C} , if a cheaper cycle exists in the k -OPT neighborhood of \mathcal{C} .

Abstract

Let k and d be such that $k \geq d + 2$. Consider two k -colorings of a d -degenerate graph G . Can we transform one into the other by recoloring one vertex at each step while maintaining a proper coloring at any step? Cereceda et al. answered that question in the affirmative, and exhibited a recolouring sequence of exponential length.

If $k = d + 2$, we know that there exists graphs for which a quadratic number of recolorings is needed. And when $k = 2d + 2$, there always exists a linear transformation. In this paper, we prove that, as long as $k \geq d + 4$, there exists a transformation of length at most $f(\Delta) \cdot n$ between any pair of k -colorings of chordal graphs (where Δ denotes the maximum degree of the graph). The proof is constructive and provides a linear time algorithm that, given two k -colorings c_1, c_2 computes a linear transformation between c_1 and c_2 .

1 Introduction

Reconfiguration problems consist in finding step-by-step transformations between two feasible solutions of a problem such that all intermediate states are also feasible. Such problems model dynamic situations where a given solution already in place has to be modified for a more desirable one while maintaining some properties throughout the transformation. Reconfiguration problems have been studied in various fields such as discrete geometry [6], optimization [1] or statistical physics [22] in order to transform, generate, or count solutions. In the last few years, graph reconfiguration received a considerable attention, e.g. reconfiguration of independent sets [3, 21], matchings [7, 20], dominating sets [24] or fixed-degree sequence graphs [9]. For a complete overview of the reconfiguration field, the reader is referred to the two recent surveys on the topic [23, 25].

Two main questions are at the core of combinatorial reconfiguration. (i) Is it possible to transform any solution into any other? (ii) If yes, how many steps are needed to perform this transformation? These two questions and their algorithmic counterparts received considerable attention.

Graph recoloring

Throughout the paper, $G = (V, E)$ denotes a graph, $n = |V|$, Δ denotes the maximum degree of G , and k is an integer. For standard definitions and notations on graphs, we refer the reader to [15]. A (proper) k -coloring of G is a function $f : V(G) \rightarrow \{1, \dots, k\}$ such that, for every edge $xy \in E$, we have $f(x) \neq f(y)$. Since we will only consider proper colorings, we will then omit the proper for brevity. The *chromatic number* $\chi(G)$ of a graph G is the smallest k such that G admits a k -coloring. Two k -colorings are *adjacent* if they differ on exactly one vertex. The k -reconfiguration graph of G , denoted by $\mathcal{G}(G, k)$ and defined for any $k \geq \chi(G)$, is the graph whose vertices are k -colorings of G , with the adjacency condition defined above. Cereceda, van den Heuvel and Johnson provided an algorithm to decide whether, given two 3-colorings, one can transform one into the other in polynomial time and characterized graphs for which $\mathcal{G}(G, 3)$ is connected [12, 13]. Given any two k -colorings of a graph, it is **PSPACE**-complete to decide whether one can be transformed into the other for $k \geq 4$ [5].

The k -recoloring diameter of a graph G is the diameter of $\mathcal{G}(G, k)$ if $\mathcal{G}(G, k)$ is connected and is $+\infty$ otherwise. In other words, it is the minimum D for which any k -coloring can be transformed into any other one through a sequence of at most D recolorings. Bonsma and Cereceda [5] proved that there exists a class \mathcal{C} of graphs and an integer k such that, for every graph $G \in \mathcal{C}$, there exist two k -colorings whose distance in the k -reconfiguration graph is finite and super-polynomial in n .

A graph G is d -degenerate if any subgraph of G admits a vertex of degree at most d . In other words, there exists an ordering v_1, \dots, v_n of the vertices such that for every i , v_i has at most d neighbors in v_{i+1}, \dots, v_n . It was shown independently by Dyer et al [16] and by Cereceda et al. [12] that for any d -degenerate graph G and every $k \geq d + 2$, $\mathcal{G}(G, k)$ is connected. Note that the bound on k is the best possible since the $\mathcal{G}(K_n, n)$ is not connected. Cereceda [11] conjectured the following:

► **Conjecture 1** (Cereceda [11]). *For every d , every $k \geq d + 2$, and every d -degenerate graph G , the diameter of $\mathcal{G}(G, k)$ is at most $C_d \cdot n^2$.*

If true, the quadratic function is the best possible, even for paths, as shown in [2]. Bousquet and Heinrich [8] recently proved that the diameter of $\mathcal{G}(G, k)$ is $O(n^{d+1})$. In the general case, Cereceda's conjecture is only known to be true for $d = 1$ (trees) [2] and $d = 2$ and $\Delta \leq 3$ [18]. The diameter of $\mathcal{G}(G, k)$ is $O(n^2)$ when $k \geq \frac{3}{2}(d + 1)$ as shown in [8]. Even if Cereceda's conjecture is widely open for general graphs, it has been proved for a few graph classes, e.g. chordal graphs [2], bounded treewidth graphs [4], and bipartite planar graphs [8].

Jerrum conjectured that if $k \geq \Delta + 2$, the mixing time (time needed to approach the stationary distribution) of the Markov chain of graph colorings¹ is $O(n \log n)$. So far, the conjecture has only been proved if $k \geq (\frac{11}{6} - \epsilon)\Delta$ [14]. Since the diameter of the reconfiguration graph is a lower bound of the mixing time, a lower bound on the diameter is of interest to study the mixing time of the Markov chain. In order to obtain such a mixing time, we need an (almost) linear diameter.

The diameter of $\mathcal{G}(G, k)$ is linear if $k \geq 2d + 2$ [10] or if k is at least the Grundy number of G plus 1 [4]. When $k = d + 2$, the diameter of $\mathcal{G}(G, k)$ may be quadratic, even for paths [2]. But it might be true that the diameter of $\mathcal{G}(G, k)$ is linear whenever $k \geq d + 3$. In this paper, we investigate the following question, raised for instance in [8]: when does the k -recoloring diameter of d -degenerate graphs become linear?

¹ A random walk on $\mathcal{G}(G, k)$. For more details on Markov chains on graph colorings, the reader is for instance referred to [14].

Our results

A graph is *chordal* if it does not contain any induced cycle of length at least 4. Chordal graphs admit a *perfect elimination ordering*, i.e. there exists an ordering v_1, \dots, v_n of V such that, for every i , $N[v_i] \cap \{v_{i+1}, \dots, v_n\}$ is a clique. Chordal graphs are $(\omega(G) - 1)$ -degenerate where $\omega(G)$ is the size of a maximum clique of G . Our main result is the following:

► **Theorem 2.** *Let Δ be a fixed integer. Let G be a d -degenerate chordal graph of maximum degree Δ . For every $k \geq d+4$, the diameter of $\mathcal{G}(G, k)$ is at most $O_\Delta(n)$. Moreover, given two colorings c_1, c_2 of G , a transformation of length at most $O_\Delta(n)$ can be found in linear time.*

Theorem 2 improves the best existing upper bound on the diameter of $\mathcal{G}(G, k)$ (where G is chordal) which was quadratic up to $k = 2d + 1$ [10].

Note that the bound on k is almost the best possible since we know that this result cannot hold for $k \leq d + 2$ [2]. So there is only one remaining case which is the case $k = d + 3$.

► **Question 3.** *Is the diameter of $\mathcal{G}(G, d + 3)$ at most $f(\Delta(G)) \cdot n$ for any d -degenerate graph G ?*

In some very restricted cases (such as power of paths), our proof technique can be extended to $k = d + 3$, but this is mainly due to the very strong structure of these graphs. For chordal graphs (or even interval graphs), we need at least $d + 4$ colors at several steps of the proof and decreasing k to $d + 3$ seems to be a challenging problem.

We also ask the following question: is it possible to remove the dependency on Δ to only obtain a dependency on the degeneracy? More formally:

► **Question 4.** *Is the diameter of $\mathcal{G}(G, d + 3)$ at most $f(d) \cdot n$ for any d -degenerate chordal graph G ?*

The best known result related to that question is the following: $\mathcal{G}(G, k)$ has linear diameter if $k \geq 2d + 2$ (and f is a constant function) [10].

► **Question 5.** *Is the diameter of $\mathcal{G}(G, d + 3)$ at most $f(\Delta(G)) \cdot n$ for any bounded treewidth graph G ?*

Our proof cannot be immediately adapted for bounded treewidth graphs since we use the fact that all the vertices in a bag have distinct colors. Feghali [17] proposed a method to “chordalize” bounded treewidth graphs for recoloring problems. However his proof technique does not work here since it may increase the maximum degree of the graph. We nevertheless think that our proof technique can be adapted in order to study many well-structured graph classes.

Proof outline

In order to prove Theorem 2, we introduce a new proof technique to obtain linear diameters for recoloring graphs. The existing results (e.g. [10]) ensuring that $\mathcal{G}(G, k)$ has linear diameter are based on inductive proofs that completely fail when k is close to d . On the other hand, in the proofs giving quadratic diameters (e.g. [2]), the technique usually consists in finding two vertices that can be “identified” and then applying induction on the reduced graph. In that case, even if we can identify two vertices after a constant number of single vertex recolorings, we only obtain a quadratic diameter (since each vertex might “represent” a linear number of initial vertices). Both approaches are difficult to adapt to obtain linear transformations since they do not use or “forget” the original structure of the graph.

Let us roughly describe the idea of our method on interval graphs. A buffer \mathcal{B} is a set of vertices contained in $f(\omega)$ consecutive cliques of the clique path. We assume that at the left of the buffer, the coloring of the graph already matches the target coloring. We moreover assume that the coloring of \mathcal{B} is special in the sense that, for every vertex v in \mathcal{B} , at most $d + 2$ colors appear in the neighborhood of v ². Note that in order to satisfy this property (and several others detailed in Section 2), the buffer has to be “long enough”. The main technical part of the proof consists in showing that if the buffer is “long enough”, then we can modify the colors of vertices of the buffer in such a way that the same assumptions hold for the buffer starting one clique to the right of the starting clique of \mathcal{B} . We simply have to repeat at most n times this operation to guarantee that the coloring of the whole graph is the target coloring. Since a vertex is recolored only if it is in the buffer and a vertex is in the buffer a constant (assuming Δ constant) number of times, every vertex is recolored a constant number of times.

The structure of this special coloring of the buffer, which is the main novelty of this paper, is described in Sections 2.2 to 2.4. We actually show that this graph recoloring problem can be rephrased into a “vectorial recoloring problem” (Section 2.5) which is easier to manipulate. And we finally prove that this vectorial recoloring problem can be solved by recoloring every element (and then every vertex of the graph) at most a constant number of times in Section 3.

2 Buffer and vectorial coloring

Throughout this section, $G = (V, E)$ is a chordal graph on n vertices of maximum clique number ω and maximum degree Δ . Let $k \geq \omega + 3$ be the number of colors denoted by $1, \dots, k$. Given two integers $x \leq y$, $\llbracket x, y \rrbracket$ is the set $\{x, x + 1, \dots, y\}$. The *closed neighbourhood* of a set $S \subseteq V$ is $N[S] := S \cup (\cup_{v \in S} N(v))$.

2.1 Chordal graphs and clique trees

Vertex ordering and canonical coloring

Let v_1, v_2, \dots, v_n be a perfect elimination ordering of V . A greedy coloring of v_n, v_{n-1}, \dots, v_1 gives an optimal coloring c_0 of G using only ω colors. The coloring c_0 is called the *canonical coloring of G* . The colors $c \in 1, 2, \dots, \omega$ are called the *canonical colors* and the colors $c > \omega$ are called the *non-canonical colors*. Note that the independent sets $X_i := \{v \in V \text{ such that } c_0(v) = i\}$ for $i \leq \omega$, called the *classes* of G , partition the vertex set V .

Clique tree

Let $G = (V, E)$ be a chordal graph. A *clique tree* of G is a pair (T, B) where $T = (W, E')$ is a tree and B is a function that associates to each node U of T a subset of vertices B_U of V (called *bag*) such that: (i) every bag induces a clique, (ii) for every $x \in V$, the subset of nodes whose bags contain x forms a non-empty subtree in T , and (iii) for every edge $(U, W) \in T$, $B_U \setminus B_W$ and $B_W \setminus B_U$ are non empty. Note that the size of every bag is at most $\omega(G)$. A clique-tree of G can be found in linear time [19]. Throughout this section, $T = (V_T, E_T)$ is a clique tree of G . We assume that T is rooted on an arbitrary node. Given a rooted tree T and a node C of T , the *height* of C denoted by $h(C)$ is the length of the path from the root to C .

² Our condition is actually even more restrictive.

■ **Figure 1** The nodes represent cliques of G . The vertices v and w belong to Q_i . The vertex u does not belong to Q_i even if it intersects cliques of Q_i , and the vertex x belongs to Q_{i+1} .

► **Observation 6.** Let G be a chordal graph of maximum degree Δ and T be a clique tree of G rooted in an arbitrary node. Let x be a vertex of G and C_i, C_j be two bags of T that contain x . Then $h(C_j) - h(C_i) \leq \Delta$.

Proof. We can assume without loss of generality (free to replace the one with the smallest height by the first common ancestor of C_i and C_j) that C_i is an ancestor of C_j (indeed, this operation can only increase the difference of height). Let P be the path of T between C_i and C_j and (U, W) be an edge of P with $h(U) < h(W)$. By assumption on the clique tree, there is a vertex y that appears in B_W and that does not appear in B_U . Since this property is true for every edge of T and since all the bags of P induce cliques and contain x , the vertex x has at least $|P|$ neighbors. ◀

2.2 Buffer, blocks and regions

Let C_e be a clique of T . We denote by T_{C_e} the subtree of T rooted in C_e and by $h_{C_e}(C)$ the height of the clique $C \in T_{C_e}$. Given a vertex $v \in T_{C_e}$, we say that v starts at height h if the maximum height of a clique of T_{C_e} containing v is h (in T_{C_e}).

Let $s := 3\binom{\omega}{2} + 2$ and $N = s + k - \omega + 1$ where k is the number of colors. The *buffer* \mathcal{B} rooted in C_e is the set of vertices of G that start at height at most $3\Delta N - 1$ in T_{C_e} . For every $0 \leq i \leq 3N - 1$, the *block* Q_{3N-i} of \mathcal{B} is the set of vertices of G that start at height h with $i\Delta \leq h \leq (i+1)\Delta - 1$. Finally, for $0 \leq i \leq N - 1$, the *region* R_i of \mathcal{B} is the set of blocks $Q_{3i+1}, Q_{3i+2}, Q_{3(i+1)}$. Unless stated otherwise, we will always denote the three blocks of R_i by A_i, B_i and C_i , and the regions of a buffer \mathcal{B} by R_1, \dots, R_N . Given a color class X_p and $S \subseteq V$, we denote by $N[S, p]$ the set $N[S \cap X_p]$. By definition of a block and Observation 6 we have:

► **Observation 7.** Let C_e be a clique of T and \mathcal{B} be the buffer rooted in T_{C_e} . Let Q_{i-1}, Q_i, Q_{i+1} be three consecutive blocks of \mathcal{B} . Then $N[Q_i] \subseteq Q_{i-1} \cup Q_i \cup Q_{i+1}$. In particular for each region $R_i = (A_i, B_i, C_i)$ of \mathcal{B} , $N[B_i] \subseteq R_i$.

Proof. Let v be a vertex of Q_i . By definition of Q_i , v starts at height h with $(3N - i)\Delta \leq h \leq (3N - i + 1)\Delta - 1$. Let u be a neighbour of v . By Observation 6, u starts at height h' with $h - \Delta \leq h' \leq h + \Delta$, thus we have $(3N - i - 1)\Delta \leq h' \leq (3N - i + 2)\Delta - 1$. It follows that u belongs either to Q_{i-1}, Q_i , or Q_{i+1} . ◀

We refer to this property as the *separation property*. It implies that when recoloring a vertex of Q_i , one only has to show that the coloring induced on Q_{i-1}, Q_i, Q_{i+1} remains proper.

2.3 Vectorial coloring

Let \mathcal{B} be a buffer. We denote the set of vertices of class p that belong to the sequence of blocks Q_i, \dots, Q_j of \mathcal{B} by (Q_i, \dots, Q_j, p) . A *color vector* ν is a vector of size ω such that $\nu(p) \in \llbracket 1, k \rrbracket$ for every $p \in \llbracket 1, \omega \rrbracket$, and $\nu(p) \neq \nu(q)$ for every $p \neq q \leq \omega$. A block Q

■ **Figure 2** The buffer \mathcal{B} rooted at C_e . The dots represent cliques of T and the dashed lines separates the blocks of \mathcal{B} .

is *well-colored* for a color vector ν_Q if all the vertices of (Q, p) are colored with $\nu_Q(p)$. It does not imply that all the colors are $\leq \omega$ but just that all the vertices of a same class have the same color (and vertices of different classes have different colors). For brevity, we say that (Q, ν_Q) is *well-colored* and when ν_Q is clear from context we just say that Q is *well-colored*. In particular, a well-colored block is properly colored. Since the set (Q, p) may be empty, a block may be well-colored for different vectors. However, a color vector defines a unique coloring of the vertices of a block (if (Q, ν_Q) is well-colored then every vertex of (Q, p) has to be colored with $\nu_Q(p)$). The color vector ν is *canonical* if $\nu(p) = p$ for every $p \leq \omega$. A sequence of blocks Q_1, \dots, Q_r is *well-colored* for (ν_1, \dots, ν_r) if (Q_i, ν_i) is well-colored for every $i \leq r$.

► **Definition 8** (Waiting region). A region R well-colored for vectors ν_A, ν_B, ν_C is a *waiting region* if $\nu_A = \nu_B = \nu_C$.

► **Definition 9** (Color region). A region R well-colored for vectors ν_A, ν_B, ν_C is a *color region* if there exist a canonical color c_1 , a non-canonical color z and a class p such that:

1. $\nu_A(m) = \nu_B(m) = \nu_C(m) \notin \{c_1, z\}$ for every $m \neq p$.
2. $\nu_A(p) = c_1$ and $\nu_B(p) = \nu_C(p) = z$.

In other words, the color of exactly one class is modified from a canonical color to a non-canonical color between blocks A and C . We say that the color c_1 *disappears* in R and that the color z *appears* in R . For brevity we say that R is a color region for the class X_p and colors c_1, z .

► **Definition 10** (Transposition region). A region R well-colored for vectors ν_A, ν_B, ν_C is a *transposition region* if there exist two canonical colors $c_1 \neq c_2$, two non-canonical colors $z \neq z'$ and two distinct classes p, q such that:

1. $\nu_A(m) = \nu_B(m) = \nu_C(m) \notin \{c_1, c_2, z, z'\}$ and is canonical for every $m \notin \{p, q\}$.
2. $\nu_A(p) = c_1, \nu_B(p) = z, \nu_C(p) = c_2$.
3. $\nu_A(q) = c_2, \nu_B(q) = z', \nu_C(q) = c_1$.

Note that ν_A and ν_C only differ on the coordinates p and q which have been permuted. The colors z and z' are called the *temporary colors* of R . Note that the coloring induced on R is proper since the separation property ensures that $N[A \cap R] \subseteq A \cup B$, $N[C \cap R] \subseteq B \cap C$ and no class in B is colored with c_1 nor c_2 .

Let ν be a color vector. The color vector ν' is obtained from ν by *swapping the coordinates* $p, \ell \leq \omega$ if for every $m \notin \{p, \ell\}$, $\nu'(m) = \nu(m)$, $\nu'(p) = \nu(\ell)$, and $\nu'(\ell) = \nu(p)$. In other words, ν' is the vector obtained from ν by permuting the coordinates p and ℓ .

	A_i	B_i	C_i		A_i	B_i	C_i		A_i	B_i	C_i
X_1	1	1	1		1	1	1		1	<u>5</u>	3
X_2	3	3	3		3	5	5		3	<u>6</u>	1
X_3	4	4	4		4	4	4		4	4	4
X_4	2	2	2		2	2	2		2	2	2
	Waiting region				Color region				Transposition region		

■ **Figure 3** Example of waiting, color, and transposition regions with $\omega = 4$. Each square represents a region, the dotted lines separate the blocks and the dashed lines separate the classes. The colors 1 to 4 are the canonical colors and the colors 5 and 6 are non-canonical colors. The underlined colors in the transposition region indicate the temporary colors.

Swapping the coordinates p and ℓ in a region R well-colored for (ν_A, ν_B, ν_C) means that for every block $Q \in \{A, B, C\}$, we replace ν_Q by the color vector ν'_Q obtained by swapping the coordinates p and ℓ of ν_Q . It does not refer to a reconfiguration operation but just to an operation on the vectors.

► **Observation 11.** *Swapping two coordinates in a waiting (resp. color, resp. transposition) region leaves a waiting (resp. color, resp. transposition) region.*

Using the following lemma, we can assume that all the transposition regions use the same temporary colors.

► **Lemma 12.** *Let R be a transposition region with temporary colors z, z' . Let $z'' \notin \{z, z'\}$ be a non-canonical color. By recoloring the vertices of R at most once, we can assume the temporary colors are z, z'' .*

Proof. Let p and q be the coordinates which are permuted in R . By definition of transposition regions, no vertex of R is colored with z'' . As any class is an independent set and by the separation property, we can recolor (B, q) with z'' to obtain the desired coloring of R . ◀

2.4 Valid and almost valid buffers

In what follows, a bold symbol ν always denote a tuple of vectors and a normal symbol ν always denotes a vector. Let $\mathcal{B} = R_1, R_2, \dots, R_N$ be a buffer such that all the regions $R_i = A_i, B_i, C_i$ are well-colored for the vectors $\nu_{A_i}, \nu_{B_i}, \nu_{C_i}$. So \mathcal{B} is well-colored for $\nu = (\nu_{A_1}, \nu_{B_1}, \nu_{C_1}, \nu_{A_2}, \dots, \nu_{C_N})$. The buffer (\mathcal{B}, ν) is *valid* if:

1. [Continuity property] For every $i \in 1, 2, \dots, N - 1$, $\nu_{C_i} = \nu_{A_{i+1}}$.
2. The vectors ν_{A_1}, ν_{B_1} and ν_{C_1} are canonical (and then R_1 is a waiting region).
3. The regions R_2, \dots, R_{s-1} define a *transposition buffer*, that is a sequence of consecutive regions that are either waiting regions or transposition regions using the same temporary colors.
4. The regions R_{s+1}, \dots, R_{N-1} define a *color buffer*, that is a sequence of consecutive regions that are either color regions or waiting regions.
5. The regions R_s and R_N are waiting regions.

Note that Property 1 along with the definition of well-colored regions enforce “continuity” in the coloring of the buffer: the coloring of the last block of R_i and the first block of R_{i+1} in a valid buffer have to be the same.

An *almost valid buffer* (\mathcal{B}, ν) is a buffer that satisfies Properties 1 to 4 of a valid buffer and for which Property 5 is relaxed as follows:

5'. The region R_s is a transposition region or a waiting region. R_N is a waiting region.

Let us make a few observations.

► **Observation 13.** *Let (\mathcal{B}, ν) be an almost valid buffer. For every $i \leq s$, the color vectors ν_{A_i} and ν_{C_i} are permutations of the canonical colors.*

Proof. By induction on i . By Property 2 of almost valid buffers, it is true for every $i \leq r$. Suppose now that the property is verified for R_i with $2 < i < s$. By assumption ν_{C_i} is a permutation of $\llbracket 1, \omega \rrbracket$ and the continuity property (Property 1 of almost valid buffer) ensures that $\nu_{A_{i+1}} = \nu_{C_i}$. By Property 3 we only have two cases to consider, either R_{i+1} is a waiting region and by definition $\nu_{C_{i+1}} = \nu_{A_{i+1}}$, or R_{i+1} is a transposition region. In the later case, by definition of a transposition region, $\nu_{C_{i+1}}$ is equal to $\nu_{A_{i+1}}$ up to a transposition of some classes k, ℓ and thus is a permutation of the canonical colors. ◀

► **Observation 14.** *Let (\mathcal{B}, ν) be an almost valid buffer and c be a non-canonical color. There exists a unique class $p \leq \omega$ such that $\nu_{C_s}(p) = c$. Furthermore, either the class p is colored with c on all the blocks of R_{s+1}, \dots, R_N , or the color c disappears in a color region for the class p .*

Proof. By Observation 13, ν_{C_s} is a permutation of the canonical colors. Thus there exists a unique class $p \leq \omega$ such that $\nu_{C_s}(p) = c$. Furthermore, by Property 4 of almost valid buffer, the regions R_{s+1}, \dots, R_N are either waiting or color regions. The continuity property then ensures that either the class p is colored with c on R_{s+1}, \dots, R_N or that the color c disappears in a color region if there exists a color region for the class p . ◀

Since only non-canonical colors can appear in a color region, we have the following observation:

► **Observation 15.** *Let (\mathcal{B}, ν) be an almost valid buffer and z be a non-canonical color. Either no vertex of R_{s+1}, \dots, R_N is colored with z , or there exists a color region R_i with $s < i < N$ for the class p in which z appears. In the latter case, the vertices of the color buffer of \mathcal{B} colored with z are exactly the vertices of $(B_i, C_i, \dots, C_N, p)$.*

Finally, since the number of regions in the color buffer is the number of non-canonical colors, we have:

► **Observation 16.** *Let (\mathcal{B}, ν) be an almost valid buffer. There exists a waiting region in R_{s+1}, \dots, R_{N-1} if and only if there exists a non-canonical color that does not appear in R_{s+1}, \dots, R_{N-1} .*

2.5 Vectorial recoloring

Let (\mathcal{B}, ν) be a buffer. The tuple of color vectors $\nu = (\nu_{Q_1}, \dots, \nu_{Q_{3\Delta N}})$ is a (proper) *vectorial coloring* of \mathcal{B} if for every color c and every $i \leq 3\Delta N - 1$ such that c is in both ν_{Q_i} and $\nu_{Q_{i+1}}$, then there exists a unique class $p \leq \omega$ such that $\nu_{Q_i}(p) = \nu_{Q_{i+1}}(p) = c$.

► **Observation 17.** *Any proper vectorial coloring (\mathcal{B}, ν) induces a proper coloring of $G[\mathcal{B}]$.*

Proof. Indeed, two different classes in two consecutive blocks cannot have the same color in a proper vectorial coloring. Since for any block Q_i of \mathcal{B} and for any class p , $N[Q_i, p] \subseteq Q_{i-1} \cup Q_i \cup Q_{i+1}$, the coloring induced on $G[\mathcal{B}]$ is proper. ◀

Note that if (\mathcal{B}, ν) is an almost valid buffer then ν is a proper vectorial coloring of \mathcal{B} by the continuity property and the definition of waiting, color, and transposition regions. Since we will only consider proper vectorial colorings, we will omit the term proper for brevity.

Let ν_Q be a color vector. A color vector ν'_Q is *adjacent to* ν_Q if there exist a class p and a color $c \notin \nu_Q$ such that $\nu'_Q(p) = c$ and $\nu'_Q(m) = \nu_Q(m)$ for every $m \neq p$.

► **Observation 18.** *Let Q be a block well-colored for ν_Q and let ν'_Q be a color vector adjacent to ν_Q such that $\nu'_Q(p) = c \neq \nu_Q(p)$. Then recoloring the vertices of (Q, p) one by one is a proper sequence of recolorings of $G[Q]$ after which Q is well-colored for ν'_Q .*

Let (ν, ν') be two vectorial colorings of a buffer \mathcal{B} . The coloring ν' is a *vectorial recoloring* of ν if there exists a unique $i \in \llbracket 1, 3\Delta N \rrbracket$ such that ν'_{Q_i} is adjacent to ν_{Q_i} and $\nu'_{Q_j} = \nu_{Q_j}$ for $j \neq i$. By Observation 18, we have:

► **Observation 19.** *Let $t \geq 1$ and (ν^1, ν^t) be two (proper) vectorial colorings of a buffer \mathcal{B} . If there exists a sequence of adjacent (proper) vectorial recolorings $\nu^1, \nu^2, \dots, \nu^t$, then there exists a sequence of (proper) single vertex recolorings of $G[\mathcal{B}]$ after which the coloring of \mathcal{B} is well-colored for ν^t .*

Given a sequence of vectorial recolorings $\nu^1, \nu^2, \dots, \nu^t$, we say that each coordinate is recolored at most ℓ times if for every coordinate $p \leq \omega$ and every $r \in \llbracket 1, 3\Delta N \rrbracket$, there exist at most ℓ indices t_1, \dots, t_ℓ such that the unique difference between ν^{t_i} and $\nu^{t_{i+1}}$ is the p -th coordinate of the r -th vector of the tuples.

3 Algorithm outline

Let G be a chordal graph of maximum degree Δ and maximum clique size ω , T be a clique tree of G , and ϕ be any k -coloring of G . We propose an iterative algorithm that recolors the vertices of the bags of T from the leaves to the root until we obtain the canonical coloring defined in Section 2.1. Let S be a clique of T . A coloring α of G is *treated up to* S if:

1. Vertices starting at height more than $3\Delta N$ in T_S are colored canonically, and
2. The buffer rooted at S is valid.

Let C be a clique of T . We associate a vector ν_C of length ω to the clique C as follows. We set $\nu_C(\ell) = \alpha(v)$ if there exists $v \in X_\ell \cap C$. Then we arbitrarily complete ν_C in such a way all the coordinates of ν_C are distinct (which is possible since $|\nu_C| < k$).

Given two vectors ν and ν' the *difference* $D(\nu, \nu')$ between ν and ν' is $|\{p : \nu(p) \neq \nu'(p)\}|$, i.e. the number of coordinates on which ν and ν' differ. Given an almost valid buffer (\mathcal{B}, ν) and a vector ν_C , the *border error* $D_{\mathcal{B}}(\nu_C, \nu)$ is $D(\nu_{C_N}, \nu_C)$.

Let \mathcal{B} be a buffer. The class $p \leq \omega$ is *internal* to \mathcal{B} if $N[R_N, p] \subseteq R_{N-1} \cup R_N$.

We first state the main technical lemmas of the paper with their proof outlines and finally explain how we can use them to derive Theorem 2. The complete proofs of the lemmas annotated with (*) are included in the full version of the article (see related version).

► **Lemma 20 (*)**. *Let C be a clique associated with ν_C . Let S be a child of C , \mathcal{B} be the buffer rooted at S and ν be a tuple of vectors such that (\mathcal{B}, ν) is valid. If $D_{\mathcal{B}}(\nu_C, \nu) > 0$, then there exists a recoloring sequence of $\cup_{i=s}^N R_i$ such that the resulting coloring ν' satisfies $D_{\mathcal{B}}(\nu_C, \nu') < D_{\mathcal{B}}(\nu_C, \nu)$, and (\mathcal{B}, ν') is almost valid. Moreover, every coordinate of $\cup_{i=s}^N R_i$ is recolored at most 3 times and only internal classes are recolored.*

Outline of the proof. Let ℓ be a class on which ν_C and ν_{C_N} are distinct. Then, in particular, no vertex of X_ℓ is in $C_N \cap C$ thus the class ℓ is internal. Given an internal class ℓ , if we modify $\nu_{C_N}(\ell)$ and maintain a proper vectorial coloring of the buffer \mathcal{B} , then the corresponding recoloring of the graph is proper. So, if we only recolor internal classes of R_N , then we simply have to check that the vectorial coloring of \mathcal{B} remains proper. The proof is then based on a case study depending on whether $\nu_C(\ell)$ is canonical or not. A more complete sketch is given in Section 3.1 ◀

► **Lemma 21 (*)**. *Let (\mathcal{B}, ν) be an almost valid buffer. There exists a recoloring sequence of $\cup_{i=2}^s R_i$ such that every coordinate is recolored at most 6 times and the resulting coloring ν' is such that (\mathcal{B}, ν') is valid.*

Outline of the proof. The proof distinguishes two cases: either there exists a waiting region in the transposition buffer or not. In the first case, we show that we can “slide” the waiting regions to the right of the transposition buffer and then ensure that R_s is a waiting region. Otherwise, because of the size of the transposition buffer, then some pair of colors has to be permuted twice. In this case, we show that these two transpositions can be replaced by waiting regions (and we can apply the first case). A more complete sketch is given in Section 4. ◀

Note that given a clique C and its associated vector ν_C , applying Lemma 21 to an almost valid buffer (\mathcal{B}, ν) rooted at a child S of C does not modify $D_{\mathcal{B}}(\nu_C, \nu)$ since the region R_N is not recolored.

Let C be a clique and S_1, S_2 be two children of C . For every $i \leq 2$, let \mathcal{B}_i be the buffer of S_i and assume that \mathcal{B}_i is valid for ν^i . We say that \mathcal{B}_1 and \mathcal{B}_2 have *the same coloring* if $\nu^1 = \nu^2$.

► **Lemma 22 (*)**. *Let C be a clique associated with ν_C . Let S_1, S_2, \dots, S_e be the children of C , and for every $i \leq e$, \mathcal{B}_i be the buffer rooted at S_i . Let ν^i be a vectorial coloring such that (\mathcal{B}_i, ν^i) is valid. If $D_{\mathcal{B}_i}(\nu_C, \nu^i) = 0$ for every $i \leq e$, then there exists a recoloring sequence of $\cup_{j=2}^{N-1} R_j^i$ such that every coordinate is recolored $O(\omega^2)$ times, the final coloring of all the \mathcal{B}_i s is the same coloring ν' , $D_{\mathcal{B}_i}(\nu_C, \nu') = 0$, and (\mathcal{B}_i, ν') is valid for every $i \leq e$.*

Outline of the proof. First, we prove that it is possible to transform the coloring of \mathcal{B}_i in such a way that all the color buffers have the same coloring, and that $\nu_s^1 = \nu_s^i$ for $i \in [2, e]$. We then have to ensure that the vectors of the transposition buffers are the same, which is more complicated. Indeed, even if we know that the vectors ν_s^1 and ν_s^i are the same, we are not sure that we use the same sequence of transpositions in the transposition buffers of \mathcal{B}_1 and \mathcal{B}_i to obtain it. Let τ_1, \dots, τ_r be the set of transpositions of \mathcal{B}_1 . The proof consists in showing that we can add to \mathcal{B}_i the transpositions $\tau_1, \dots, \tau_r, \tau_r^{-1}, \dots, \tau_1^{-1}$ at the beginning of the transposition buffer. It does not modify ν_{A_s} since this sequence of transpositions gives the identity. Finally, we prove that $\tau_r^{-1}, \dots, \tau_1^{-1}$ can be cancelled with the already existing transpositions of \mathcal{B}_i . And then the transposition buffer of \mathcal{B}_i only consists of τ_1, \dots, τ_r . ◀

► **Lemma 23 (*)**. *Let C be a clique of T with children S_1, S_2, \dots, S_e and let α be a k -coloring of G treated up to S_i for every $i \in [1, e]$. Let ν_C be a vector associated with C and $\mathcal{B}_i = R_1^i, \dots, R_N^i$ denote the buffer rooted at S_i . Assume that there exists ν such that (\mathcal{B}_i, ν) is valid and satisfies $D_{\mathcal{B}_i}(\nu_C, \nu) = 0$ for every $i \leq e$. Then there exists a recoloring sequence of $\cup_{j=2}^{N-1} R_j^i$ such that, for every $i \leq e$, every vertex of \mathcal{B}_i is recolored at most one time and such that the resulting coloring of G is treated up to C .*

Outline of the proof. This proof “only” consists in shifting the buffer of one level. We simply recolor the vertices that now start in another region (of the buffer rooted at C) with their new color. We prove that the recoloring algorithm cannot create any conflict. ◀

Given Lemmas 20, 21, 22 and 23 we can prove our main result:

► **Theorem 24.** *Let Δ be a fixed constant. Let $G(V, E)$ be a d -degenerate chordal graph of maximum degree Δ and ϕ be any k -coloring of G with $k \geq d + 4$. Then we can recolor ϕ into the canonical coloring c_0 in at most $O(d^4 \Delta \cdot n)$ steps. Moreover the recoloring algorithm runs in linear time.*

Proof. Let c_0 be the canonical coloring of G as defined in Section 2.1, and T be a clique tree of G . Let us first show that given a clique $C \in T$ with children S_1, \dots, S_e and a coloring α treated up to S_i for every $i \leq e$, we can obtain a coloring of G treated up to C . Let ν_C be a vector associated with C . For every $i \leq e$, let \mathcal{B}_i be the buffer rooted in S_i and ν^i be a vectorial coloring of \mathcal{B}_i such that (\mathcal{B}_i, ν^i) is valid. For every $i \leq e$, by applying Lemmas 20 and 21 at most $D_{\mathcal{B}_i}(\nu_C, \nu^i)$ times to (\mathcal{B}_i, ν^i) , we obtain a vectorial coloring ν^i such that (\mathcal{B}_i, ν^i) is valid and $D_{\mathcal{B}_i}(\nu_C, \nu^i) = 0$. By Lemma 22, we can recolor each ν^i into ν' such that for every i , (\mathcal{B}_i, ν') is valid and $D_{\mathcal{B}_i}(\nu_C, \nu') = 0$. Then we can apply Lemma 23 to obtain a coloring of G such that the buffer (\mathcal{B}, ν) rooted in C is valid. Since no vertex starting in cliques $W \in T_C$ with $h_C(W) > 3\Delta N$ is recolored, these vertices remain canonically colored and the resulting coloring of G is treated up to C . Note that only vertices of T_C that start in cliques of height at most $3\Delta N$ are recolored at most $O(\omega^2)$ times to obtain a coloring treated up to C .

Let us now describe the recoloring algorithm and analyze its running time. We root T at an arbitrary node C_r and orient the tree from the root to the leaves. We then do a breadth-first-search starting at C_r and store the height of each node in a table h such that $h[i]$ contains all the nodes of T of height i . Let i_h be the height of T . We apply Lemmas 20 to 23 to every $C \in h[i]$ for i from i_h to 0. Let us show that after step i , the coloring of G is treated up to C for every $C \in h[i]$. It is true for $i = i_h$ since for any $C \in h[i_h]$ the sub-tree T_C of T only contains C . Suppose it is true for some $i > 0$ and let $C \in h[i - 1]$. Let S_1, \dots, S_e be the children of C . For all $j \in 1, \dots, e$, $S_j \in h[i]$ and by assumption the current coloring is treated up to S_j after step i . Thus we can apply Lemmas 20 to 23 to C . After iteration i_h we obtain a coloring of G that is treated up to C_r . Up to adding “artificial” vertices to G , we can assume that C_r is the only clique of T adjacent to a clique path of length $3\Delta N$ (in fact we only need a tuple of $3N$ color vectors) in T and apply Lemmas 20 to 23 until we obtain a coloring such that C_r is canonically colored, and the algorithm terminates. A clique tree of G can be computed in linear time [19], as well as building the table h via a breadth-first-search. Given a clique C , we can access to the cliques of the buffer rooted at T_C in constant time by computing their height and using the table h . Furthermore, a vertex of height i is recolored during the iterations $i + 1, \dots, i + 3\Delta N$ only. As each vertex is recolored at most $O(\omega^2)$ times at each iteration, it follows that the algorithm runs in linear time. Finally, as $N = 3\binom{\omega}{2} + k - \omega + 3$, each vertex is recolored at most $O(\omega^4 \Delta)$ times, and thus the algorithm recolors ϕ to c_0 in at most $O(\omega^4 \Delta \cdot n)$ steps. ◀

The proof of Theorem 2 immediately follows:

Proof of Theorem 2. Let ϕ and ψ be two k -colorings of G with $k \geq d + 4$ and let c_0 be the canonical coloring of G defined in Section 2.1. By Theorem 24, there exists a recoloring sequence from ϕ (resp. ψ) to c_0 of length $O((d + 1)^4 \Delta \cdot n)$. Thus there exists a sequence of length $O_\Delta(n)$ that recolors ϕ to ψ . Furthermore the recoloring sequences from ϕ to c_0 and from ψ to c_0 can be found in linear time by Theorem 24, which concludes the proof. ◀

3.1 Proof of Lemma 20

Recall that in a buffer \mathcal{B} , R_s is the region that sits between the transposition buffer and the color buffer. Before proving Lemma 20, let us first start with some observations.

► **Observation 25.** *Let R be a well-colored region that does not contain color c . If we set $\nu_Q(p) = c$ for every block Q of R , then we obtain a waiting region if R was a waiting region or a color region for the class p , and we obtain a color region if R was a color region for a class $q \neq p$.*

► **Lemma 26 (*)**. *Let (\mathcal{B}, ν) be an almost valid buffer and R_i, R_j be two regions of \mathcal{B} with $1 \leq i \leq j$. Let X be a block in $\{B_i, C_i\}$ and let $Y = B_j$ or $Y = C_N$. Then recoloring (X, \dots, Y, p) with c preserves the continuity property.*

Given a color c , a class p , and a sequence of consecutive blocks (Q_i, \dots, Q_j) , we say that (Q_i, \dots, Q_j, p) is c -free if no vertex of $N[\cup_{t=i}^j Q_t \cap X_p]$ is colored with c . Note that a sequence of (proper) vectorial recolorings of a buffer (\mathcal{B}, ν) that does not recolor A_1 and such that all the classes recolored on C_N are internal to \mathcal{B} yields a (proper) sequence of single vertex recolorings of G by Observation 19. With the definition of clique-tree we can make the following observation:

► **Observation 27.** *Let C be a clique associated with ν_C , S be a child of C , and (\mathcal{B}, ν) be the buffer rooted at S . If $\nu_{C_N}(\ell) \neq \nu_C(\ell)$ for some $\ell \leq \omega$, then the class ℓ is internal to \mathcal{B} .*

Proof. Suppose that the class $\ell \leq \omega$ is not internal to \mathcal{B} . Then there exists a vertex $u \in X_\ell \cap R_N$ which has a neighbor v that does not belong to $R_{N-1} \cup R_N$. Thus u and v must be contained in C or in a clique C' that is an ancestor of C . In the latter case, Property (ii) of clique tree ensures that u must also be contained in C . Then, by definition of ν_C , it must be that $\nu_C(\ell) = \nu_{C_n}(\ell)$. ◀

We also need the following technical lemma:

► **Lemma 28.** *Let (\mathcal{B}, ν) be an almost valid buffer. Let $s < i < N$, c be a color and p be an internal class. If one of the following holds:*

1. R_i is a waiting region, c is a non-canonical color that does not appear in R_s, \dots, R_N and the class p is not involved in a color region, or
2. R_i is a color region for the class p . Moreover c is non-canonical and does not appear in R_s, \dots, R_N , or
3. R_i is a color region for the class p where c is the canonical color that disappears.

Then changing the color of (B_i, \dots, C_N, p) by c also gives an almost valid buffer and a proper coloring of G .

We can now give the flavour of Lemma 20. For a complete proof, the reader is referred to the full version of the article.

Proof of Lemma 20. Let C be the clique associated with vector ν_C and S be a child of C . Let (\mathcal{B}, ν) be the valid buffer rooted at S . Assume that $D_{\mathcal{B}}(\nu_c, \nu) > 0$. Then there exists $p \leq \omega$ such that $\nu_{C_N}(p) \neq \nu_C(p) := c$ and by Observation 27 the class p is internal to \mathcal{B} .

The following sequences of recolorings only recolor blocks of R_s, \dots, R_N and all the recolorings fit in the framework of Lemma 26. Thus Properties 1, 2 and 3 of almost valid buffers are always satisfied. We then only have to check Properties 4 and 5' to conclude the proof. The proof is then based on a case distinction. Let us give a couple of simple cases to give an idea of the general proof:

Case 1. No class is colored with c on R_s, \dots, R_N in ν .

Then c is not canonical since ν_{A_s} is a permutation of the canonical colors by Observation 13. Suppose first that there does not exist a color region for the class p in ν . Since c does not appear in the color buffer, Observation 16 ensures that there exists a waiting region R_i with $s < i < N$. Then by Lemma 28.1, we can recolor (B_i, \dots, C_N, p) with c and obtain an almost valid buffer. Suppose otherwise that there exists a color region R_j for class p in ν . By Lemma 28.2, we can recolor (B_j, \dots, C_N, p) with c and obtain an almost valid buffer. In both cases, the border error decreases.

Case 2. A class $\ell \neq p$ is colored with c , c is canonical, and c disappears in the color region R_j for class ℓ where the non-canonical color z appears (see Figure 4 for an illustration). Let $z' \neq z$ be a non-canonical color and let $c_1 = \nu_{A_s}(p)$. We apply the following recolorings:

- (1) Recolor (B_s, \dots, A_j, ℓ) with z ,
- (2) Recolor (B_s, p) with z' ,
- (3) Recolor (C_s, \dots, C_N, p) with c ,
- (4) Recolor (C_s, \dots, A_j, ℓ) with c_1 .

Recoloring 1 is proper since Observation 15 ensures that the only class colored with z in R_s, \dots, R_N is the class ℓ on (B_j, \dots, C_N) . By the separation property, (B_s, \dots, A_j, ℓ) is z -free in ν . Recoloring 2 is proper as the only non-canonical color in R_s after recoloring 1 is $z \neq z'$. Recoloring 3 is proper as the class p is internal and thus after recoloring 1, (C_s, \dots, C_N, p) is c -free by the separation property. Finally, recoloring 4 is proper as after recolorings 2 and 3, (C_s, \dots, A_j, ℓ) is c_1 -free by the separation property.

Let us show that the resulting coloring defines an almost valid buffer. First note that regions R_{j+1}, \dots, R_N are only modified by recoloring 3 and Observation 25 ensures they remain either waiting or color regions. In particular R_N remains a waiting region. Note that after recolorings 3 and 4, ν' on regions R_{s+1}, \dots, R_{j-1} is obtained from ν by swapping coordinates p and ℓ (on these regions). Thus the nature of these regions is maintained by Observation 11. Since R_j was a color region for the class ℓ and colors c, z in ν , B_j, C_j are not modified and since $\nu'_{A_j}(\ell) = c_1$, R_j is a color region for class ℓ and colors c_1, z in ν' . So the regions R_{s+1}, \dots, R_N remain either waiting or color regions. Furthermore no new color region is created and colors c_1, z are involved in exactly one color region thus Property 4 is satisfied. Finally, R_s is indeed a transposition region in ν' since ν is a valid buffer and z and z' are non-canonical colors, thus Property 5' holds. Furthermore, $\nu'_{C_N}(p) = c$ thus the border error has decreased. ◀

■ **Figure 4** The initial coloring ν for case 2 in the proof of Lemma 20. The rows represent the classes. A blank indicates a color region for the class. The vertical segment at the end of the buffer indicates that the class is internal. The dotted vertical lines separate the different regions.

4 Proof of Lemma 21

The proof distinguishes two cases:

Case 1. there is a region of the transposition buffer of \mathcal{B} that is a waiting region.

The core of the proof consists in iteratively applying the following lemma:

► **Lemma 29 (*)**. *Let (\mathcal{B}, ν) be an almost valid buffer and R_i, R_{i+1} be two consecutive regions with $1 < i < s$ such that R_i is a waiting region and R_{i+1} is a transposition region. Then there exists a recoloring sequence of $R_i \cup R_{i+1}$ such that, in the resulting coloring ν' , R_i is a transposition region, R_{i+1} is a waiting region, and (\mathcal{B}, ν') is almost valid. Moreover only coordinates of $R_i \cup R_{i+1}$ are recolored at most twice.*

Case 2. All the regions of the transposition buffer of \mathcal{B} are transposition regions.

As there are $3\binom{\omega}{2}$ regions in the transposition buffer and only $\binom{\omega}{2}$ distinct transpositions of $\llbracket 1, \omega \rrbracket$, there must exist two distinct regions R_i and R_j with $1 < i < j < s$ for which the same pair of colors is permuted (note that the colors might be associated to different classes in R_i and R_j but it does not matter). The proof consists in applying the following lemma and then applying Case 1.

► **Lemma 30 (*)**. *Let (\mathcal{B}, ν) be an almost valid buffer and c_1, c_2 be two canonical colors. If there exist two transposition regions R_i and R_j where colors c_1 and c_2 are transposed, then there exists a sequence of recolorings of $\cup_{t=i}^j R_t$ such that each coordinate is recolored at most twice, R_i and R_j are waiting regions in the resulting coloring ν' , and (\mathcal{B}, ν') is almost valid.*

Patching Colors with Tensors

Cornelius Brand

Abstract

We describe a generic way of exponentially speeding up algorithms which rely on Color-Coding by using the recently introduced technique of Extensor-Coding (Brand, Dell and Husfeldt, STOC 2018). To demonstrate the usefulness of this “patching” of Color-Coding algorithms, we apply it *ad hoc* to the exponential-space algorithms given in Gutin et al. (Journal Comp. Sys. Sci. 2018) and obtain the fastest known deterministic algorithms for, among others, the k -internal out-branching and k -internal spanning tree problems. To realize these technical advances, we make qualitative progress in a special case of the detection of multilinear monomials in multivariate polynomials: We give the first deterministic fixed-parameter tractable algorithm for the k -multilinear detection problem on a class of arithmetic circuits that may involve cancellations, as long as the computed polynomial is promised to satisfy a certain natural condition.

Furthermore, we explore the limitations of using this very approach to speed up algorithms by determining exactly the dimension of a crucial subalgebra of extensors that arises naturally in the instantiation of the technique: It is equal to F_{2k+1} , the k th odd term in the Fibonacci sequence. To determine this dimension, we use tools from the theory of Gröbner bases, and the studied algebraic object may be of independent interest.

We note that the asymptotic bound of $F_{2k+1} \approx \phi^{2k} = O(2.619^k)$ curiously coincides with the running time bound on one of the fastest algorithms for the k -path problem based on representative sets due to Fomin et al. (JACM 2016). Here, ϕ is the golden ratio.

1 Introduction

The research in parameterized algorithms has brought forth a vast toolbox of techniques to tackle an ever-growing list of hard computational problems, and provided solutions for those problems in a multitude of shapes and flavors. Recently, Brand, Dell and Husfeldt [9] added another item to the box: A technique called *Extensor-Coding*, based on the properties of the so-called *exterior algebra*, a fundamental object in multilinear algebra.

Extensor-Coding allows us to understand a variety of key approaches in the design of parameterized algorithms in a common language, including the celebrated and by now classic *Color-Coding*-approach of Alon, Yuster and Zwick [1], the *algebraic fingerprints* due to Koutis [24] and Koutis and Williams [25], the representative families from Fomin et al. [19, 18], and the labeled walks of Björklund et al. [5].

While this yields unification on a conceptual level, the main technical advance made in [9] was with respect to the approximate counting of solutions in the longest path (or k -path) problem. Despite the fact that the technique suggests a straightforward algebraic and *deterministic* algorithm for the k -path problem, its running time was only very slightly (infinitesimally, in fact) below the older bound achieved by Chen et al. [10], and thus at significant distance from Zehavi’s current record bound [36]. In this paper, we will identify several problems where Extensor-Coding *does* improve over the state-of-the-art. To this end, we start from a novel and natural variant of the ubiquitous multilinear detection problem on polynomials computed by arithmetic circuits that is more general than the very well-studied case of cancellation-free circuits. This leads us to a rather generic approach of patching, if you will, algorithms involving Color-Coding, by replacing the Colors used in the algorithm by Extensors, i.e., elements of the exterior algebra.¹ This then yields an exponential speed-up. While this improvement is certainly incremental in nature, the novelty of the approach laid out in this work is of a more conceptual nature. This is discussed further below.

On the other hand, we demonstrate an algebraic barrier, limiting the potential progress that can be made by applying Extensor-Coding in a more or less straightforward manner – just as we do it in this paper for the considered algorithmic problems. This barrier is based on the dimension of a certain subalgebra of the exterior algebra, which presents a lower bound for the cost of computation in the algebra and hence for the entire algorithm. It is noteworthy that the resulting bound, which is exactly the $(2k + 1)$ th Fibonacci number on an underlying vector space of dimension k , asymptotically coincides with the square of the golden ratio, which also appears in the approach of Fomin et al. to the k -path problem, which is based on the very different, purely combinatorial method of representative families [19]. One might argue that this connection is not entirely surprising, since the approaches can be used to solve the same problem and the representative families in fact have their origin in exterior algebra. This, however, is an argument that only bears on a superficial level: It is by no means clear how the very algebraic object studied in this article relates in any way to the use of the exterior algebra in the representative families-approach, and indeed, one can consider uncovering such a precise connection as an intriguing avenue for further research. Therefore, one may regard studying this algebraic object as a first step to tighten the ties between combinatorics and algebra in the study of rather general parameterized algorithms, and not just for the k -path problem.

1.1 Contributions

1.1.1 New and Improved Algorithms

The algorithmic problems we study are the following: The k -*internal out-branching* (k -*IOB*) problem asks for the existence of an out-branching (also called a directed spanning tree or arborescence, among others) with at least k internal, i.e., non-leaf, nodes. The k -*internal spanning* (k -*IST*) tree problem is formulated analogously for undirected graphs. A subset of edges in an edge-colored graph is k -*colorful* if it contains edges of at least k distinct colors, and the definitions of the problems k -*colorful perfect matching* and k -*colorful out-branching* are self-evident.

Our algorithmic advances in these problems are borne by progress in another domain: The k -*multilinear detection* (k -*MLD*) problem has as an input a multivariate polynomial represented through an arithmetic circuit, and asks whether the polynomial contains a

¹ Extensors are often also referred to as antisymmetric tensors, hence the title.

monomial of degree k in which no variable appears with degree more than one. We focus our attention on the restriction of the problem to those instances where a multilinear monomial may only appear with positive coefficient. Since there is no known way to efficiently test this property, this turns the problem into a promise problem. The promise, however, is typically satisfied in combinatorial applications, where the studied polynomials are usually *multivariate generating functions* of the sought combinatorial objects. The decisive subtlety here is that, while the *polynomial* that is computed by the input circuit may not have negative coefficients in its multilinear part, the circuit *itself* may very well contain negative constants and make use of cancellations, and, in particular, it need *not* be monotone. We will make heavy use of this property in the above application problems, and the above point is decisive here for the following reason: These problems can be expressed using determinantal generating functions, and by a theorem of Jerrum and Snir, determinants do *not* have monotone circuits of subexponential size, such that cancellations are actually crucial for their efficient computation. To the best of our knowledge, this is the first fixed-parameter tractable algorithm for the problem.

We prove the following deterministic, exponential-space² record time bounds, and defer the reader to Sect. 4 for a formal statement of the theorem.

► **Theorem 1 (Informal).** *There are deterministic algorithms to solve*

1. *the k -internal out-branching problem and the k -internal spanning tree problem in time $3.21^k \cdot \text{poly}(n)$, and*
2. *the k -colorful perfect matching problem on planar graphs and the k -colorful out-branching problem in time $4^k \cdot \text{poly}(n)$.*

Furthermore, there is a deterministic algorithm that solves the restriction of the multilinear detection problem to circuits computing polynomials with positive coefficients in their multilinear part (as laid out above) in time $4^k \cdot \text{poly}(n)$ on skew arithmetic circuits, and in time $2^{\omega k} \cdot \text{poly}(n) < 5.19^k \cdot \text{poly}(n)$ on general circuits, where ω is the exponent of matrix multiplication.

► **Remark 2.** The bound of 5.19 is not competitive; indeed it is easy to prove that an exponential basis of 4.312 can be obtained using a derandomization of Color-Coding, and Pratt [28] gives a randomized algorithm achieving 4.075. Note, however, that our bound depends on ω , and one can make the point (albeit moot in the foreseeable future) of this dependency making our bound potentially competitive.

► **Remark 3.** Skewness, i.e., the syntactic restriction of each multiplication gate having an input as an operand seems rather strong at a first glance. At a second glance, this impression does not hold up: Without concerning ourselves with the technicalities of algebraic complexity theory, suffice it to say that the polynomials that can be computed by efficient skew circuits are precisely those that are efficient projections of determinants, and determinantal generating functions are known for a variety of combinatorial objects. Equivalently, they are those polynomials that are computed by efficient algebraic branching programs (which is a widely studied and very natural computational model).

The algorithms for the problems of detecting a k -internal as well as k -colorful out-branching (and spanning tree) are established, as demonstrated by Björklund et al. , via the Directed Matrix-Tree Theorem [7]. We reuse the meticulous and very careful analysis of the

² We are aware of the doubtful practical usefulness of exponential-space algorithms in some settings and ask the skeptical reader to think of our results as being motivated theoretically.

parallel monomial sieving technique by Gutin et al. [22]. We can relatively easily replace the employed pseudorandom objects by extensors. This suggests a rather generic way in which to speed up algorithms based on Color-Coding by instead using Extensor-Coding.

As far as the k -colorful planar matching problem is concerned, as in [22], we use a Pfaffian computation. However, we cannot perform the square root extraction that is necessary to make use of the determinantal identities for the Pfaffian, but rely on a result of Flarup et al. [15] for a direct computation of Pfaffians with skew arithmetic circuits.

Let us conclude the discussion of our algorithmic contributions with a comment on their relevance. As far as combinatorial problems are concerned, the obtained technical improvements are incremental. However, focusing on these individual results is, in a way, a red herring: The important point is that we can obtain speed-ups in sophisticated algorithms for well-studied problems in a simple, *ad hoc* manner by replacing colors with extensors. The only requirement here is the, as argued, rather mild one of the combinatorial objects in question being described through a determinantal formula. This is not primarily a technical, but a *conceptual* insight that is meant to guide the design of deterministic exponential-space algorithms in the future, and to encourage revisiting existing bounds using extensors. To demonstrate how to go about this, we do so for k -IOB, a very well-studied problem where the current state-of-the-art was obtained through a sequence of incremental improvements, each more involved than the previous one.

A similar case can be made for the monomial detection algorithms, which are obtained in an admittedly straightforward manner by an application of the Extensor-Coding method, which was certainly available at the time of writing of [9]. The takeaway here, however, is that polynomials with positive coefficients computed by efficient skew circuits are not some arbitrary, but instead very natural class of polynomials, namely those that arise as determinantal generating functions for combinatorial objects, which are of central interest in algebraic combinatorics.

1.1.2 Algebraic Limitations

Broadly speaking, when aiming towards deterministic decision algorithms, Extensor-Coding essentially works by evaluating a multivariate polynomial associated with the input over an exterior algebra. This algebra is of dimension 4^k , where k will typically be the parameter of the input instance (while it formally is half the dimension of the underlying vector space).

In this way, it is similar to a method introduced by Koutis [24]. It differs, however, in the points at which the polynomial associated with the input instance is evaluated. While Koutis, and later, Williams [33], rely on random evaluation points, in [9], certain carefully constructed vectors are used. One can readily observe that “evaluating a polynomial” involves, on an arithmetic level, nothing but multiplications and additions. In particular, if one evaluates a polynomial over any algebraic structure that is closed under multiplication and addition, one will always obtain again an element of this algebraic structure after evaluation. Turning this around, one can always restrict one’s attention to the closure of (i.e., the substructure generated by) the set of evaluation points. In particular, it might be far easier to actually implement the arithmetic operations only over this substructure than over the entire structure.

In this paper, we will examine the subalgebra generated by the aforementioned special evaluation points (i.e., the smallest set closed under addition, scaling with a field constant, and multiplication containing all the evaluation points). Note now that the dimension of an algebra provides a trivial lower bound on the cost of general computation in it, simply because one has to write down its elements’ coordinates at some point. Conversely, the dimension itself can be used to derive a trivial upper bound for the cost of computation as

well, just by a look-up of the structural constants of the algebra, but this bound is generally far from optimal. For example, naive multiplication of degree- d polynomials (which can be modeled as objects of a $O(d)$ -dimensional algebra over some field) takes around $O(d^2)$ field operations, while (over compatible fields) the Fast Fourier Transform method yields the classic bound of $O(d \log d)$. A running time of the latter form, i.e., quasilinear in the dimension of the algebra, is of course the best one can hope for. Note however that, in general, it is a highly nontrivial, and sometimes impossible, task to come up with such fast multiplication algorithms in any kind of algebraic structure.

We prove that, surprisingly (for reasons that will be expanded on later), the dimension of the subalgebra generated by the evaluation points used in Extensor-Coding is of dimension *exponentially smaller* than 4^k , i.e., the dimension of the full algebra. At first, this seems to open up a tantalizing new point of attack on one of the most prominent open problems in the area of parameterized algorithms: To exhibit a *deterministic* algorithm for the k -path problem that matches the running time of $2^k \cdot \text{poly}(n)$ for the best *randomized* algorithms [33, 24]. Now, *a priori*, we could hope for the studied subalgebra to be of dimension 2^k (but not much smaller, by a result of Koutis-Williams [26]). Then, a quasilinear multiplication algorithm would give a bound of $2^k \cdot \text{poly}(k)$ field operations, and (assuming all coefficients stay of moderate size) hence produce a deterministic algorithm solving the problem in time $2^k \cdot \text{poly}(n)$.

Unfortunately, we share the fate of Tantalos:

► **Theorem 4 (Informal).** *The dimension of the subalgebra of the exterior algebra over the complex vector space of dimension $2k$ generated by the evaluation points used in Extensor-Coding is of dimension exactly F_{2k+1} , which is the $(2k + 1)$ th Fibonacci number, and this is asymptotically bounded as $2.618^k \leq F_{2k+1} \leq 2.619^k$.*

Again, it will be stated formally in Sect. 5. Somewhat unluckily, this does also not suffice to improve the state-of-the-art for k -path, even if we had a sufficiently fast multiplication algorithm, since Zehavi's [36] intricate algorithm has an exponential basis of 2.597 in its running time.

This result can be interpreted in two ways: On the one hand, as laid out above, it can be seen as a negative result, ruling out one approach for solving the k -path problem deterministically and fast. On the other hand, while a quasilinear multiplication algorithm for the subalgebra might be a lot to hope for, even an algorithm using, say, $2.619^{\omega k/2} < 3.136^k$ field operations would mean significant improvements for all the problems studied in this paper, including in particular deterministic multilinear detection for a subclass of circuits with cancellations. It is not at all clear how to implement multiplication over this algebra faster than trivially, and we leave this as a challenging open problem.

Let us comment on the bound of $2.619^{k\omega/2}$, which might at first seem arbitrary. This is simply the bound one would obtain from a matrix representation of dimension at most d , i.e., having dimension $\sqrt{2.619^{k/2}} \times \sqrt{2.619^{k/2}}$. For this reason, it appears in the recent breakthrough work of Umans [32] and Ching-Yun Hsu and Umans [12] on generalized Fast Fourier Transforms on arbitrary finite groups. Therefore, our result nurtures the hope for even further, significant improvement for a variety of parameterized problems, conditional on the development of fast multiplication algorithms over this algebraic structure.

Furthermore, we exhibit a whole family of subalgebras that enjoy all the desired properties of the subalgebra that is used in [9], and that obey the same upper bound on their dimension, while the lower bound argument does not easily carry over, and it is an exciting possibility that, somewhere among these subalgebras, there is one that has even lower dimension.

As for our algorithmic contributions, let us comment on the relevance of the algebraic barrier, and in particular, why this highly special algebraic object is of wider interest. Given the apparent connection to the work of Fomin et al. as well as the recent insights of Pratt [28], the study of algebraic approaches may have much closer ties to the classic combinatorial techniques than is currently visible. Establishing the dimension bounds as done here is clearly necessary and important in order to uncover these ties; ties which, eventually, might make the study of parameterized algorithms and their limitations appealing to a more diverse audience even outside of parameterized algorithms and complexity, in a way similar (even if not as ambitious by far) to how algebraic geometers found interest in complexity theory through its geometric reformulation. Furthermore, as stated, exhibiting fast multiplication algorithms for this problem would directly imply massive speed-ups for problems that are amenable to be “patched” using extensors.

1.2 Related work

The k -internal out-branching and spanning tree problems have attracted a significant amount of attention over the last years [17, 22, 6, 7, 27, 38, 37, 16, 13, 11, 21, 14, 29]. The current deterministic record bounds for all the aforementioned graph problems were recently given in Gutin et al. [22], using monomial sieving in combination with Color-Coding and suitable pseudorandom objects. The bounds they obtain (in the exponential-space setting) for the k -internal out-branching and spanning tree problems are $3.41^k \cdot \text{poly}(n)$, and $4.32^k \cdot \text{poly}(n)$ for the k -colorful perfect matching and out-branching problems.

The detection of k -multilinear terms in polynomials computed by arithmetic circuits lies at the heart of the design of the fastest randomized algorithms for a host of parameterized problems, such as the longest path problem on directed graphs, the k -tree problem, the t -dominating set problem and the m -dimensional k -matching problem, with a record bound of $2^k \cdot \text{poly}(n)$ for randomized k -multilinear detection [26, 33]. The crux is that, for the arithmetic circuits in these algorithms, it is required that they be *monotone*, i.e., do not involve any cancellations of terms. On this class of monotone arithmetic circuits, the k -multilinear detection problem can be solved deterministically in time $3.85^k \cdot \text{poly}(n)$, using the combinatorial notion of representative sets [18].

Recently, the first fixed-parameter tractable *randomized* algorithms were developed for the problem on general arithmetic circuits [9], which has sparked further work in the area, announcing a polynomial-space version and $4.08^k \cdot \text{poly}(n)$ as a new record bound on general circuits [3, 2, 28].

Due to the particularity of the algebraic object studied for the dimension barrier, it is highly doubtful whether any work directly related to it has been done – at the least, we are not aware of such work. However, the idea of proving dimension lower bounds in order to limit the use of certain parameterized algorithmic techniques was already present in work by Koutis and Williams [26]. Their work, however, gives a more general lower bound and relies on entirely different technical ideas, making it akin to our work only in a broader conceptual sense.

Omitted proofs and details will appear in [8], which we call the full version.

2 Preliminaries

In what follows, $2 \leq \omega < 2.374$ [30, 34] is the exponent of matrix multiplication.

An *arithmetic circuit* is a directed acyclic graph with a single vertex of out-degree 0, called the *output*, a set of vertices with in-degree 0 which are labeled with variables or complex numbers, called the *inputs* and labels $+$ and \times on all vertices that are not inputs.

A vertex labeled with $+$ or \times is, respectively, called a $+$ -gate or \times -gate. All \times -gates are required to have in-degree at most two. We call an arithmetic circuit *skew* if, for all \times -gates, at least one of the arcs ending at the gate comes from an input. The *polynomial computed by an arithmetic circuit* is defined in the obvious inductive way: It is equal to the label of the inputs, and for a gate that is not an input, it is defined as the result of the operation indicated by the label of the gate, applied to its two inputs.

Given a directed graph $D = (V, A)$, we call a subgraph B of D *out-branching* if B is an oriented tree with exactly one vertex r of in-degree zero, the *root*, and B is spanning. Vertices of out-degree zero are called *leaves*, and vertices that are not leaves are *internal*. For an integer k , an out-branching is *k-internal* if it contains at least k internal vertices.

A set of arcs is called a *matching* if no vertex of V is contained in two arcs, and a matching is *perfect* if every vertex is contained in some arc of the matching.

For an edge-colored graph G , directed or undirected, we call a subgraph S of G *k-colorful*, if the edge set of S contains at least k differently colored edges.

2.1 A Review of Extensor-Coding

Although not a strict prerequisite, some knowledge of the technique and its uses for the longest path problem make the following certainly more digestible. An elementary exposition of the employed algebraic objects can be found in the original work [9]. However, we will demonstrate the technique in the appropriate brevity. This should, in principle, suffice to understand everything that happens here. For a more mathematically concise and thorough treatment of the algebraic background material, we encourage the interested reader to consult any given textbook on algebra, for example the one by Birkhoff and Mac Lane [4].

Let us first review some basic algebraic notions. A complex unital associative *algebra* is a ring A that is simultaneously a complex vector space, such that scalar multiplication is compatible with the multiplication in the ring. That is, for any $\lambda \in \mathbb{C}$ and $a, b \in A$, it holds that $\lambda(ab) = (\lambda a)b = a(\lambda b)$ and there is an element $1 \in A$ with $1a = a = a1$ for all $a \in A$. Since complex unital associative algebras are the only types of algebras we will encounter henceforth, we understand all these properties whenever we speak merely of an algebra. The dimension of an algebra A is the dimension of A as a complex vector space.

2.1.1 The Exterior Algebra

Let V be the complex vector space \mathbb{C}^k , endowed with its canonical basis $\{e_1, \dots, e_k\}$. We can now consider the set of formal, *non-commutative* polynomials $\mathbb{C}\langle e_1, \dots, e_k \rangle$ that can be formed in the “indeterminates” (or *generators*) e_1, \dots, e_k .

Let us define a kind of multiplication on these generators that is denoted as \wedge , called the *wedge product*. The wedge product operation on the generators is defined to satisfy the anti-commutativity relation: $e_i \wedge e_j = -e_j \wedge e_i$ for all $1 \leq i, j \leq k$. For $i = j$, this means that $e_i \wedge e_i = -e_i \wedge e_i$, which over \mathbb{C} implies $e_i \wedge e_i = 0$ for all i .

By repeatedly applying this rule, we can understand the multiplication of more than two generators as follows. Let $1 \leq i_1, \dots, i_t \leq k$ be natural numbers, and consider the wedge product $e_{i_1} \wedge \dots \wedge e_{i_t}$. Exhaustive application of the rules now implies that this product becomes zero if $i_j = i_{j'}$ for any distinct j, j' . Otherwise, it is equal to $\text{sgn}(\sigma)e_{i_{\sigma(1)}} \wedge \dots \wedge e_{i_{\sigma(t)}}$, where σ is the permutation that brings the sequence i_1, \dots, i_t in ascending order.

This multiplication is extended to linear combinations of wedge products of the generators by distributivity and bilinearity. The vector space generated by all such wedge products of generators is called the *exterior algebra* over V and is denoted by $\Lambda(V)$. The vector space $\Lambda(V)$ is turned into an algebra by equipping it with the wedge product as multiplication. We have seen that any reordering of the factors either leaves the original wedge product intact

or leads to a sign change. Hence, the set of ordered wedge products $\{e_{i_1} \wedge \cdots \wedge e_{i_t} \mid 0 \leq t \leq k, i_1 < \cdots < i_t\}$ form a linear basis of $\Lambda(V)$. This shows that $\Lambda(V)$ is of dimension 2^k . For any set $S \subseteq \{1, \dots, k\}$, we write e_S to denote $e_{i_1} \wedge \cdots \wedge e_{i_{|S|}}$, where the elements of S are assumed to be in ascending order, i.e., $i_1 < \cdots < i_{|S|}$. We remark that we can regard V as a linear subspace of $\Lambda(V)$ via a vector's basis representation, i.e., $(x_1, \dots, x_k)^T \in \mathbb{C}^k$ corresponds uniquely to $x_1 e_{\{1\}} + \cdots + x_k e_{\{k\}}$.

Let us quickly comment on the cost of computation in $\Lambda(V)$. It is clear that addition of two elements of $\Lambda(V)$ can be performed using 2^k arithmetic operations, namely by pointwise addition, over \mathbb{C} . Clearly, this can be performed in time polynomial in the length of the basis coefficients of the two summands.

For a restricted but crucial variant of multiplication in $\Lambda(V)$, called *skew multiplication*, we recall the following observation:

► **Proposition 5** ([9], Sect. 2.3). *Given an element $x \in \Lambda(\mathbb{C}^k)$ and $y \in \mathbb{C}^k \subseteq \Lambda(\mathbb{C}^k)$ as a list of basis coefficients, their product $x \wedge y \in \Lambda(\mathbb{C}^k)$ as a list of basis coefficients can be computed using $2^k \cdot \text{poly}(k)$ arithmetic operations over \mathbb{C} .*

Additionally, if the bitlength of coefficients of x and y is bounded in by τ , then their product can be computed in $2^k \cdot \text{poly}(\tau)$ bit operations.

As for general multiplication, let us record what Włodarczyk [35] showed implicitly:

► **Theorem 6** ([35]). *Given two elements $x, y \in \Lambda(\mathbb{C}^k)$ as a list of basis coefficients, their product $x \wedge y \in \Lambda(\mathbb{C}^k)$ as a list of basis coefficients can be computed using $2^{\omega k/2} \cdot \text{poly}(k)$ arithmetic operations over \mathbb{C} .*

Additionally, if the bitlength of coefficients of x and y is bounded by τ , then their product can be computed in $2^{\omega k/2} \cdot \text{poly}(\tau)$ bit operations.

Since the connection to the exterior algebra in [35] is not made explicitly, we give a self-contained (and somewhat simpler) proof of Włodarczyk's result, adapted to our terminology, in the full version.

► **Remark 7.** The best known way to compute a general wedge product is due to insights of Włodarczyk: This goes by reducing the wedge product to the product in a so-called Clifford algebra, which is an algebra that, filtered by degree, gives rise to the exterior algebra as its associated graded algebra. This is surprising from a mathematical perspective: The exterior algebra is an especially degenerate Clifford algebra, and yet the latter is used to compute in the former. Finding other, possibly faster approaches for the computation of wedge products is an independent research direction that we feel worth pursuing in the future, given that the wedge product is the epitomic operation in all of multilinear algebra.

An easy, but fundamental standard observation is that, for any $t \leq k$, the t -factor wedge multiplication map

$$V^t \rightarrow \Lambda(V), \quad x_1, \dots, x_t \mapsto x_1 \wedge \cdots \wedge x_t \in \Lambda(V) \tag{1}$$

can be written down in coordinates as the determinants of the $t \times t$ -minors of the matrix $(x_1 \mid x_2 \mid \dots \mid x_t)$ obtained as the juxtaposition of x_1, \dots, x_t :

$$x_1 \wedge \cdots \wedge x_t = \sum_{S \in \binom{[k]}{t}} \det(x_1 \mid x_2 \mid \dots \mid x_t)_S e_S,$$

where $(x_1 \mid x_2 \mid \dots \mid x_t)_S$ is the $t \times t$ -minor of the matrix $(x_1 \mid x_2 \mid \dots \mid x_t)$ indexed at the rows S . In particular, this entails that the k -fold wedge product is just the determinant map:

$$x_1 \wedge \cdots \wedge x_k = \det(x_1 \mid x_2 \mid \dots \mid x_k) e_{[k]}.$$

2.1.2 Lifts

Consider the direct sum of vector spaces $V \oplus V \cong \mathbb{C}^{2k}$, and let $\iota_1, \iota_2 : V \rightarrow V \oplus V$ be the canonical embeddings of V into $V \oplus V$ as the left and right summand, respectively. In coordinates, this corresponds respectively to pre- or appending k zeros to a vector. Consider the *lift mapping* $\Lambda(V) \rightarrow \Lambda(V \oplus V)$, $x \mapsto \bar{x} := \iota_1(x) \wedge \iota_2(x)$. We now have (see also [9, Sect. 3.4]) the following.

$$\bar{x}_1 \wedge \cdots \wedge \bar{x}_k = \pm \det(x_1 \mid \cdots \mid x_k)^2 e_{[2k]},$$

where the sign only depends on k .

2.1.3 Vandermonde Codings

Determinants vanish on singular matrices. To prevent unwanted vanishing of determinants later on, we will use a set of vectors that are, in a sense, maximally linearly independent: Vandermonde vectors. To this end, consider the mapping

$$\phi : \mathbb{C} \rightarrow V, c \mapsto (1, c, c^2, \dots, c^{k-1})$$

and its lifted variant

$$\bar{\phi} : \mathbb{C} \rightarrow V \oplus V, c \mapsto \overline{\phi(c)}.$$

This has the nice property that, on the image of ϕ (or $\bar{\phi}$ for that matter), the k -fold wedge product map as in Eq. (1) is zero only when two factors are *equal*. In particular, the mapping $\mathbb{C}^k \rightarrow \Lambda(V \oplus V)$, $(c_1, \dots, c_k) \mapsto \bar{\phi}(c_1) \wedge \cdots \wedge \bar{\phi}(c_k)$ is zero exactly on the set of points that have at least two coordinates equal. Indeed, the coordinates of this map witness this in the clearest way possible: It is the well-known Vandermonde-determinant $\prod_{i < j} (c_i - c_j)$. An analogous statement of course holds for $\bar{\phi}$.

3 Monomial Detection Problems

As a kind of warm-up, we will give a rather direct, but very useful first application to a special kind of monomial detection problem. The general problem presents itself as follows: As input, it obtains a multivariate (and now again commutative) polynomial $f \in \mathbb{C}[X_1, \dots, X_n]$ in n indeterminates. Our task is now to decide whether or not f contains a monomial of degree k such that no indeterminate appears twice. A variation of this is to ask whether f contains a monomial such that at least k distinct indeterminates appear in it. The degree of hardness of this problem obviously hinges on the way in which f is represented. When f is given in its sparse representation as a list of monomials and coefficients, then deciding this question is trivial.

This not the case, however, if f is represented by an arithmetic circuit, which is the setting we are interested in. Indeed, we are interested only in a semantically defined subclass of arithmetic circuits: Those that compute a polynomial f such that every multilinear monomial that appears in f does so with positive coefficient. As stated before, it is crucial to note that this does *not* mean a monotonicity restriction for the input circuit, and it may well involve cancellations of terms and negative constants. Let us formally define the set of circuits we are interested in:

► **Definition 8.** *Let C be an arithmetic circuit that computes a polynomial f . We call C combinatorial if f has non-negative coefficients on its multilinear part, and C can be evaluated over \mathbb{Z} at numbers of absolute value at most τ using $\text{poly}(\tau)$ bit operations.*

We remark that the last condition of this definition is a barely concealed crutch to avoid having to think about subtleties regarding a possible doubly exponential blowup of inputs in general arithmetic circuits, which are irrelevant in our applications. For a very similar reason, we only speak about evaluation over \mathbb{Z} ; namely, in order to ignore potential issues with representations of complex numbers.

3.1 Multilinear Detection

As promised, we will now start out with an easy application of Extensor-Coding. Speaking of promises, it is again in order to remark that the problems discussed henceforth are promise problems, in the sense that there is no known efficient method of checking whether an input circuit satisfies the condition of being combinatorial.

► **Theorem 9.** *There is a deterministic algorithm that, given a combinatorial arithmetic circuit C of size s and an integer k , decides whether or not the polynomial computed by C contains a multilinear monomial of degree k in time $2^{\omega k} \cdot \text{poly}(s) < 5.19^k \cdot \text{poly}(s)$.*

Proof. Consider the lifted Vandermonde coding $\bar{\phi}$, and assume that the polynomial computed by C is n -variate.

The algorithm then simply evaluates C at $(\bar{\phi}(1), \dots, \bar{\phi}(n))$, and outputs “yes” if and only if the coefficient of $e_{[2k]}$ in the resulting element of $\Lambda(V \oplus V)$ is non-zero.

The running time is immediate from the definition and Theorem 6, and correctness can be seen as follows. We first have to take care of the fact that our algebra is not commutative, strictly speaking, but nevertheless we evaluate a commutative polynomial over it. This is remedied either by a standard degree- k homogenization argument on C , and, depending on k , a subsequent single sign correction of the result. Alternatively, one can observe that the signs are consistent across each degree individually, and monomials of different degrees are linearly independent, so that the different signature arising when evaluation over the image of $\bar{\phi}$ will not make a difference. From the fact mentioned in discussion about Vandermonde codings, every monomial containing an indeterminate twice will vanish. The parts of degree less than k do not enter into the coefficient of $e_{[2k]}$, and parts of degree more than k will go to zero anyways. Now, let L be the set of multilinear monomials in the polynomial computed by f . Each such monomial m identifies a subset of $\{1, \dots, n\}$, and by abuse of notation, we will not distinguish between a monomial and a subset. Furthermore, we denote with c_m the coefficient of m , which is non-negative by the assumption on C , and let V_m be the $2k \times 2k$ matrix $(\bar{\phi}(i))_{i \in m}$. Then the coefficient of $e_{[2k]}$ can be seen to be equal to $\sum_{m \in L} c_m \cdot \det(V_m)^2$, which is non-zero if and only if one of the determinants is non-zero. This in turn happens if and only if there is a multilinear monomial of degree k in the polynomial computed by C . ◀

We also obtain the more useful skew variant:

► **Theorem 10.** *There is a deterministic algorithm that, given a skew combinatorial arithmetic circuit C of size s and an integer k , decides whether or not the polynomial computed by C contains a multilinear monomial of degree k in time $4^k \cdot \text{poly}(s)$.*

Proof. Follows verbatim like Theorem 9 after replacing Theorem 6 by Proposition 5. ◀

3.2 k -Distinct Detection

We will now turn to the monomial detection problem that will later on be used in applications, namely the k -distinct detection problem. Again, the input here is an arithmetic circuit, but this time, the task is to decide whether there exists a monomial containing at least k distinct

indeterminates. Using the folklore trick of replacing every variable x_i by $1 + t \cdot x_i$ with a formal indeterminate t , turning a nilpotent variable x_i into an (almost) idempotent one, and then extracting the coefficient of t^k , we obtain:³

► **Theorem 11.** *There is a deterministic algorithm that, given a skew combinatorial arithmetic circuit C of size s that computes a polynomial that only has non-negative coefficients, and an integer k , decides whether or not the polynomial computed by C contains a monomial with at least k different variables in time $4^k \cdot \text{poly}(s)$.*

A proof sketch is given in the full version. Equipped with these observations, we may now turn to our application problems.

4 Graph Problems

We will make use of the classic Directed Matrix-Tree Theorem, following the presentation in [7]. Let us first define the *Laplacian* of a directed graph $G = (D, A)$. To this end, let $X = \{x_a \mid a \in A\}$ be a set of formal indeterminates labeled with the arcs of a graph, and define the matrix $L = (\ell_{uv})_{u,v \in V}$ through

$$\ell_{uv} = \begin{cases} \sum_{w \in V: wu \in A} x_{wu} & \text{if } u = v \\ -x_{uv} & \text{if } uv \in A \\ 0 & \text{if } uv \notin A \end{cases}.$$

After fixing a root $r \in V$, we will consider L_r , the *Laplacian punctured at r* , which is defined as the matrix obtained from L by striking row r and column r . With these definitions in place, we have the following well-known theorem, and just as [7], we refer to the corresponding chapter of Gessel and Stanley in the Handbook of Combinatorics [20] for a proof.

► **Theorem 12 (Directed Matrix-Tree Theorem).** *Let $G = (D, A)$ be a directed graph. For all $r \in V$, the following holds.*

$$\det L_r = \sum_{\substack{T = (V, B) \text{ is an} \\ \text{out-branching of } G \\ \text{rooted at } r}} \prod_{b \in B} x_b.$$

In other words, the determinant of L_r is the multivariate generating function of the set of out-branchings rooted at r . The important insight is now the following: All known (randomized) efficient algorithms for detecting k -multilinear terms – and, by extension, k -distinct terms – in the polynomial computed by an arithmetic circuit rely on this circuit not involving cancellations in their computation, i.e., they need to be *monotone*.

However, by a theorem of Jerrum and Snir [23], computing $\det L_r$ using such a monotone circuit requires circuits of *exponential size* in n .

On the other hand, there are efficient skew arithmetic circuits (this time with cancellations) for computing the $n \times n$ determinant polynomial:

► **Theorem 13 ([31]).** *There is a family of skew arithmetic circuits $(C_n)_{n \in \mathbb{N}}$ such that C_n computes the $n \times n$ determinant polynomial, and the size $s(n)$ of C_n satisfies $s(n) \leq \text{poly}(n)$. Furthermore, there is an algorithm that, upon input 1^n , outputs a description of C_n in time $\text{poly}(n)$, and every circuit can be evaluated over \mathbb{Z} in polynomial time in the length of the input representation.*

³ We might just replace the indeterminate t by 1, and extract the degree- k term of the result in the exterior algebra. Using an extra indeterminate t allows us to avoid explaining how *degree* is a well-defined concept even over exterior algebras.

In fact, the $n \times n$ determinant polynomial is complete – for a suitable notion of reduction – for the adequately named class VDET of polynomial families computable by $\text{poly}(n)$ -sized skew arithmetic circuits, defined *ibid.* Importantly, this together with the Matrix-Tree Theorem 12 also shows that $\det L_r$ is a combinatorial polynomial.

4.1 Out-Branchings

Let us now proceed gently with a first application of what we have gathered so far.

► **Theorem 14.** *There is a deterministic algorithm that, given a directed edge-colored graph D on n vertices and an integer k , decides whether D has a k -colorful out-branching in time $4^k \cdot \text{poly}(n)$.*

Proof. First, replace every variable x_a by a fresh variable corresponding to its color $c(a)$, say $y_{c(a)}$, and denote the corresponding symbolic matrix with $L_r(y)$. Since $\det L_r$ is combinatorial and skew, so is $\det L_r(y)$, and we can perform the k -distinct detection from Theorem 11 in the claimed running time. The existence of a monomial with k distinct variables in $\det L_r(y)$ is now clearly equivalent to the existence of a k -colorful out-branching in D . ◀

Theorems 12, 13 and Theorem 11 immediately yield a deterministic algorithm for the problem, running in time $4^k \cdot \text{poly}(n)$. We note that this is already a significant improvement over the time bound of $5 \cdot 14^k \cdot \text{poly}(n)$ on the runner-up algorithm of [37].

► **Proposition 15** (Superseded by [22]). *There is a deterministic algorithm that, given a directed graph D on n vertices and an integer k , decides whether D has a k -internal out-branching in time $4^k \cdot \text{poly}(n)$.*

Proof. First, replace every variable x_{uv} by a fresh variable corresponding to its tail, say y_u , and denote the corresponding symbolic matrix with $L_r(y)$. Since $\det L_r$ is combinatorial and skew, so is the n -variate polynomial $\det L_r(y)$, and we can perform the k -distinct detection from Theorem 11 in the claimed running time. It has been observed by Björklund et al. [7] that this is neatly equivalent to the input instance containing a k -internal out-branching. ◀

To speed this up, we can more or less just plug in an Extensor-Coding into the analysis from [22] and set a new record bound for the k -internal out-branching problem. We defer the proof to the full version.

► **Theorem 16.** *There is a deterministic algorithm that, given a directed graph D on n vertices and an integer k , decides whether D has a k -internal out-branching in time $3.21^k \cdot \text{poly}(n)$.*

The corresponding results for k -internal spanning trees of undirected graphs follow immediately by standard reductions to the directed case (see [22]).

4.2 Colorful Planar Perfect Matchings

Just like out-branchings, perfect matchings in planar graphs have an efficiently computable multivariate generating function, namely the *Pfaffian* $\text{Pf } A$ of a suitable skew-symmetric matrix A . Gutin et al. [22] employ a determinantal identity for the Pfaffian, and do so by evaluating the determinant polynomial in question over the integers in a black-box fashion. Namely, they exploit that $\text{Pf}(A)^2 = \det(A)$. In the very last step, this requires a square root extraction, which is a perfectly viable path over the integers, but not over more general algebras. Therefore, instead of construing $\text{Pf}(A)$ as $\sqrt{\det(A)}$, we rely on an observation of Flarup et al. [15], who show that the Pfaffian has efficient skew circuits. Putting this together, we immediately obtain:

► **Theorem 17.** *There is a deterministic algorithm that, given an undirected edge-colored planar graph G on n vertices and an integer k , decides whether G has a k -colorful perfect matching in time $4^k \cdot \text{poly}(n)$.*

5 The Dimension Barrier

In this section, we will explain Theorem 4. The entire proof is deferred to the full version.

5.1 The Subalgebra Generated by Evaluation Points

Let us first elaborate on the fundamental insight that motivates this result and that was alluded to already in the introduction: Let f be a complex polynomial, such as the polynomial computed by a circuit in, say, Theorem 11. During the evaluation of this polynomial f (or rather the circuit computing it) at points from the image of $\bar{\phi}$, only sums and wedge products of elements of the image of $\bar{\phi}$ are ever formed. Note that this is what we do in all our applications: We only plug in points of the form $\bar{\phi}(c)$ for some $c \in \mathbb{C}$. We can say this rigorously and concisely by stating that during such an evaluation, all computation may only occur in the *subalgebra of $\Lambda(V \oplus V)$ generated by the image of $\bar{\phi}$* , which is – by definition – the set of all sum-wedge product combinations of the generating set. It is precisely the subalgebra generated by these elements $\bar{\phi}(c)$ that we will study. The fundamental quantity associated with this subalgebra is its dimension, that is, the dimension of the subalgebra as a complex vector space. Let us stress again the argument from the introduction that any potential progress on the technique in its present form hinges on the dimension of this subalgebra: It provides both strict lower bounds and a good guide towards the upper bounds one can hope for when solving problems using Extensor-Coding.

5.2 A Family of Related Subalgebras

The decisive property that makes Vandermonde codings so useful is that any distinct k of them are linearly independent, which is commonly referred to the set of Vandermonde vectors being in general position. This, however, is not only a property enjoyed by Vandermonde vectors. First of all, any finite random set of vectors is in general position almost certainly.

This suggests that instead of considering the subalgebra generated by Vandermonde codings, one might as well just take any n random vectors and proceed with them. Extensive computational experiments have shown, however, that the expected dimension of this subalgebra is almost as high as the dimension of the full algebra. Curiously, it seems to be equal (and in fact this was the only case that ever occurred during all our experiments) to the k -th Catalan number, which grows asymptotically faster than $4^{(1-\varepsilon)k}$ for all $\varepsilon > 0$.

It is worth pondering about this phenomenon for a little while. From a matroid perspective, the Vandermonde codings just correspond to a representation of the k -uniform matroid over an n -element universe. One might now hope that the dimension of the subalgebra generated by the lifts of the columns of this representation matrix is a matroid invariant; however, this is *not* the case. Even more, most representations are just as bad as the worst case.

Remarkably, the extraordinarily well-behaved case of the Vandermonde representation transfers quite directly to a related family of subalgebras. Consider any set $P = \{p_1, \dots, p_k\}$ of formal univariate polynomials that are linearly independent and of degree less than k . In other words, a basis of the set of polynomials of degree less than k . We can form, for any n , a $k \times n$ evaluation matrix of this set P , where the i -th row is given as $(p_i(1), p_i(2), \dots, p_i(n))$. If we pick as P the standard monomial basis, this is just the Vandermonde representation.

However, we may as well pick any other basis, and the resulting matrix will again have the property that any subset of k columns is linearly independent. This works, provided the p_i do not have a common root at the evaluation point. We can take care of this easily by just picking a different, appropriate set of evaluation points. Note that this set exists (and in fact, almost certainly, any random set will do) by the fact that the p_i are distinct polynomials. Now, we can again study the subalgebra of $\Lambda(V \oplus V)$ generated by the lifts of the column vectors of this evaluation matrix. Surprisingly, the argument for the upper dimension bound carries over immediately, but we could not find a corresponding proof for the lower bound. This opens up the exciting possibility of finding lower-dimensional algebras in this family, that could lead to even faster algorithms. Note that despite the main motivation for studying this algebra may stem from the flagship k -path problem, due to the connection to multilinear detection, finding these algorithms has impacts for all the problems that reduce to this special case of multilinear detection, including those studied in this paper.

5.3 The Barrier

As announced, we will merely state the relevant theorem. A full, detailed proof can be found in the full version.

► **Theorem 18.** *Let $V = \mathbb{C}^k$ and let F_{2k+1} be the $(2k+1)$ th Fibonacci number. The subalgebra of $\Lambda(V \oplus V)$ generated by the image $\{\overline{\phi}(c) \mid c \in \mathbb{C}\}$ of $\overline{\phi}$ is of dimension exactly equal to F_{2k+1} .*

Furthermore, for any linear basis P of the univariate polynomials of degree at most k , denote for $c \in \mathbb{C}$ with $P(c)$ the column vector obtained by evaluating all polynomials in P at c . Then, the subalgebra generated by $\{\overline{P}(c) \mid c \in \mathbb{C}\}$ is of dimension at most F_{2k+1} .

Abstract

We study SET COVER for orthants: Given a set of points in a d -dimensional Euclidean space and a set of orthants of the form $(-\infty, p_1] \times \dots \times (-\infty, p_d]$, select a minimum number of orthants so that every point is contained in at least one selected orthant. This problem draws its motivation from applications in multi-objective optimization problems. While for $d = 2$ the problem can be solved in polynomial time, for $d > 2$ no algorithm is known that avoids the enumeration of all size- k subsets of the input to test whether there is a set cover of size k . Our contribution is a precise understanding of the complexity of this problem in any dimension $d \geq 3$, when k is considered a parameter:

- For $d = 3$, we give an algorithm with runtime $n^{\mathcal{O}(\sqrt{k})}$, thus avoiding exhaustive enumeration.
- For $d = 3$, we prove a tight lower bound of $n^{\Omega(\sqrt{k})}$ (assuming ETH).
- For $d \geq 4$, we prove a tight lower bound of $n^{\Omega(k)}$ (assuming ETH).

Here n is the size of the set of points plus the size of the set of orthants. The first statement comes as a corollary of a more general result: an algorithm for SET COVER for half-spaces in dimension 3. In particular, we show that given a set of points U in \mathbb{R}^3 , a set of half-spaces \mathcal{D} in \mathbb{R}^3 , and an integer k , one can decide whether U can be covered by the union of at most k half-spaces from \mathcal{D} in time $|\mathcal{D}|^{\mathcal{O}(\sqrt{k})} \cdot |U|^{\mathcal{O}(1)}$.

We also study approximation for SET COVER for orthants. While in dimension 3 a PTAS can be inferred from existing results, we show that in dimension 4 and larger, there is no 1.05-approximation algorithm with runtime $f(k) \cdot n^{o(k)}$ for any computable f , where k is the optimum.

1 Introduction

Motivated by applications in multi-objective optimization, we study a geometric variant of the classic SET COVER problem. In general, SET COVER is defined as follows. Let \mathbb{U} be a universe; typically, \mathbb{U} is a finite collection of elements or \mathbb{R}^d for some constant $d \geq 1$. Given a finite set $U \subseteq \mathbb{U}$ and a finite set \mathcal{T} of subsets of \mathbb{U} , the goal is to find a set $S \subseteq \mathcal{T}$ of minimum size such that for each $u \in U$ it holds that $u \in F$ for some $F \in S$. We let $n = |\mathcal{T}| + |U|$.

SET COVER can be approximated within factor $\ln |\mathcal{T}|$ by a greedy algorithm [13, 29, 34], but, unless $P = NP$, no polynomial-time algorithm can attain an approximation factor of $(1 - \varepsilon) \ln |\mathcal{T}|$ for any $\varepsilon > 0$ [20]. Moreover, when parameterized by the expected solution size k (formally, here we consider a decision problem), the problem is W[2]-hard [21] and there is no $\mathcal{O}(n^{k-\varepsilon})$ -time algorithm for any $\varepsilon > 0$, unless the Strong Exponential Time Hypothesis (SETH) fails [50]. Recently, it was even shown that, unless the Gap Exponential Time Hypothesis (Gap-ETH) fails, SET COVER has no $f(\text{OPT})|\mathcal{T}|^{o(\text{OPT})}$ -time algorithm that approximates the optimum OPT within a factor of $a(\text{OPT})$, for any computable a and f [9]. This makes SET COVER a very hard algorithmic problem in general.

Fortunately, through years of research, we know that SET COVER becomes much easier when geometry is involved. If the universe \mathbb{U} is equal to \mathbb{R}^d for some $d \geq 1$, the set U is a set of points, and the sets in \mathcal{T} are defined by geometric objects, then the problem is known as GEOMETRIC SET COVER. Then various restrictions on the shapes of objects allowed in \mathcal{T} may lead to different tractability results. While for $d = 1$ the problem is polynomial-time solvable when \mathcal{T} is required to consist of intervals, there are easy cases in $d = 2$ that are NP-hard, such as when \mathcal{T} is defined by sets of unit squares or disks [24, 30]. However, the approximability of GEOMETRIC SET COVER in $d = 2$ is significantly better than in general. Approaches like the shifting technique [23], ε -nets [1, 2, 8, 14, 33, 41, 47], local search [3, 25, 44], sampling techniques [11, 55] and separator techniques [43] have proven successful in obtaining constant-factor approximation algorithms and approximation schemes. Recently, Govindarajan et al. [25] showed a very general approximability result, namely that GEOMETRIC SET COVER admits a PTAS when the underlying sets in \mathcal{T} are non-piercing regions, which includes the case of pseudo-disks. From a parameterized perspective, Marx and Pilipczuk [39] showed that GEOMETRIC SET COVER has a $|\mathcal{T}|^{\mathcal{O}(\sqrt{k})}$ -time algorithm when \mathcal{T} is a set of disks or a set of squares. Moreover, no $n^{o(\sqrt{k})}$ -time algorithm exists for these cases unless the Exponential Time Hypothesis fails [36, 39]. For piercing regions, such as axis-parallel rectangles and fat triangles, GEOMETRIC SET COVER is APX-hard [10, 27] and admits no $|\mathcal{T}|^{o(k)}$ -time algorithm unless ETH fails [39]. For $d = 3$, a generic PTAS is also unlikely, as GEOMETRIC SET COVER is APX-hard even for unit balls [10], although constant-factor approximation algorithms do exist in certain cases [33]. This makes the complexity of GEOMETRIC SET COVER highly interesting for $d \geq 3$.

Orthant Cover. In this paper, we contribute to the knowledge about GEOMETRIC SET COVER by considering the case when the sets in \mathcal{T} are orthants, which we call ORTHANT COVER. An *orthant* is a subset $T \subset \mathbb{R}^d$ of the form $T = \{(x_1, \dots, x_d) \in \mathbb{R}^d : x_i \leq p_i \text{ for all } i \in [d]\}$ for some $(p_1, \dots, p_d) \in \mathbb{R}^d$. Alternatively, an orthant can be defined as $(-\infty, p_1] \times \dots \times (-\infty, p_d]$.

Our interest in ORTHANT COVER is motivated by multi-objective optimization. Here an optimization problem (like shortest path) is associated with $d > 1$ objectives (e.g. every edge has a cost and transition time), see, e.g., [5, 22, 26, 45, 48, 49]. We identify each possible solution of the optimization problem with the vector in \mathbb{R}^d that lists all of its d objectives. A solution $p \in \mathbb{R}^d$ is called *Pareto-optimal* if there is no solution $q \in \mathbb{R}^d$ with $q \geq p$ (i.e., $q_i \geq p_i$ for all $1 \leq i \leq d$). The set of all Pareto-optimal solutions $F \subseteq \mathbb{R}^d$ is called the *Pareto front* [32] (or *trade-off curve* [56] or *skyline* [4]), and computing it is the standard goal of multi-objective optimization.

However, the Pareto front can be prohibitively large to display to the end user. Therefore, a typical relaxation is to compute a $(1 + \varepsilon)$ -approximation of the Pareto front. This is defined as a subset F' of the Pareto front F such that for every $p \in F$ there exists a $q \in F'$ with $p \leq (1 + \varepsilon)q$ [48]. The question then becomes to find a Pareto front approximation of minimum size. This problem has been studied in multi-objective optimization under different names like “approximately dominating representatives” (ADR) [32] and “ ε -indicator subset selection” [6, 7, 57]. Observe that we can solve ADR using an algorithm for ORTHANT COVER by setting

$$U := F \quad \text{and} \quad \mathcal{T} := \{(-\infty, (1 + \varepsilon)f_1] \times \dots \times (-\infty, (1 + \varepsilon)f_d] : (f_1, \dots, f_d) \in F\}.$$

Therefore, ORTHANT COVER can be seen as an asymmetric variant of ADR. This provides strong motivation to gain an algorithmic understanding of ORTHANT COVER.

We already know that in dimension $d = 2$, ORTHANT COVER can be solved in polynomial time, and even in near-linear time in n [7, 32]. For $d \geq 3$, however, the problem becomes NP-hard [32]. Moreover, if we focus on looking for a solution of size at most k , no algorithm is known that avoids the enumeration of all size- k subsets of \mathcal{T} . In fact, no $n^{o(k)}$ -time algorithm is known, even for $d = 3$. Therefore, we ask *in which dimensions can the naive algorithm for ORTHANT COVER with running time $n^{O(k)}$ be significantly improved upon?*

Our Contribution. In this paper, we resolve the parameterized complexity of ORTHANT COVER when parameterized by the size of the solution. We present an algorithm for $d = 3$ that improves on the naive $n^{O(k)}$ -time algorithm, and rule out any further significant improvements in any dimension. Our lower bounds are conditional on the Exponential Time Hypothesis (ETH) by Impagliazzo, Paturi, and Zane [28], which (avoiding technical details) states that 3-SAT has no algorithm with running time $2^{o(n)}$, where n is the number of variables.

► **Theorem 1.** *Consider the ORTHANT COVER problem in dimension d . Then:*

1. *for $d = 3$, it can be solved in time $|\mathcal{T}|^{O(\sqrt{k})} \cdot |U|^{O(1)}$, in particular in time $n^{O(\sqrt{k})}$;*
2. *for $d = 3$, it cannot be solved in time $f(k)n^{o(\sqrt{k})}$ for any computable f , assuming ETH;*
3. *for $d \geq 4$, it cannot be solved in time $f(k)n^{o(k)}$ for any computable f , assuming ETH.*

In the above and for all the results stated in this paper, we measure the running time in the number of arithmetic operations over the reals given on input, i.e., in the strong fashion. Note that $n = |\mathcal{T}| + |U|$.

Thus, we determine the optimal time complexity of ORTHANT COVER as $n^{\Theta(\sqrt{k})}$ for $d = 3$ and $n^{\Theta(k)}$ for $d \geq 4$, assuming ETH. This dependence on d is somewhat surprising, since many previous conditional lower bounds for geometric problems are of the form $n^{\Omega(k^{1-1/d})}$ [40, 52]. We are only aware of one other work establishing problems to be easier for $d = 3$, but for $d = 4$ to be as hard as in any high dimension, namely k -means and k -median [15].

The algorithm of Theorem 1.1 actually follows from a more general result.

► **Theorem 2.** *Given a set of points U in \mathbb{R}^3 , a set of half-spaces \mathcal{D} in \mathbb{R}^3 , and an integer k , one can decide whether U can be covered by the union of at most k half-spaces from \mathcal{D} in time $|\mathcal{D}|^{\mathcal{O}(\sqrt{k})} \cdot |U|^{\mathcal{O}(1)}$.*

It is known that ORTHANT COVER can be reduced to this case (see [46, Lemma 2.3] or [12, Section A.3]). We observe that GEOMETRIC SET COVER for disks in \mathbb{R}^2 (DISK COVER) can also be reduced to this case, as follows. Consider an instance of DISK COVER where the point set U and the disk set \mathcal{T} are in the plane $z = 0$, and let p be a point in \mathbb{R}^3 outside this plane. For each disk $D \in \mathcal{T}$, we can define a ball $B(D)$ whose intersection with the plane $z = 0$ is D and that has p on its boundary. We apply an inversion with center p . As a result, each ball $B(D)$ is mapped to a half-space that contains the inverse of a point $x \in U$ if and only if x is covered by D . Hence, Theorem 2 also generalizes the known $n^{\mathcal{O}(\sqrt{k})}$ -time algorithm for DISK COVER [39].

We also study the approximability of ORTHANT COVER. Previous work implies a PTAS for $d = 3$ running in $n^{\mathcal{O}(1/\varepsilon^2)}$ time by a reduction (see [46, Lemma 2.3] or [12, Section A.3]) to the known PTAS for half-spaces in dimension 3 [44], and APX-hardness for $d \geq 4$ by a reduction (see Section 4) to the known APX-hardness of RECTANGLE COVER [54]. In this paper, we rule out any significant improvement for $d = 3$, particularly the existence of an Efficient PTAS. For $d \geq 4$, we establish a stronger inapproximability result conditional on Gap-ETH [19, 35].

► **Theorem 3.** *Consider the ORTHANT COVER problem in dimension d . Then:*

1. *for $d = 3$, it has no PTAS with running time $f(\varepsilon) n^{\mathcal{O}(\sqrt{1/\varepsilon})}$ for any computable f , assuming ETH;*
2. *for any $d \geq 4$, it has no 1.05-approximation algorithm running in time $f(k)n^{\mathcal{O}(k)}$ for any computable f , assuming Gap-ETH.*

Technical Overview. Our algorithm for half-spaces in \mathcal{R}^3 is a branching algorithm that attempts to split the input point set based on a balanced separator \mathcal{S}_0 of the optimum solution, where the separator should be small: of size $\mathcal{O}(\sqrt{k})$. However, we do not know the optimum solution and thus we cannot know the separator. Instead, we show that we can enumerate a set of candidate separators in time $|\mathcal{T}|^{\mathcal{O}(\sqrt{k})}$, in which the separator \mathcal{S}_0 is guaranteed to be contained. Similar approaches to obtain a subexponential-time algorithm for geometric and planar problems are known to exist (e.g. [31, 39]). However, the existence of the balanced separator of size $\mathcal{O}(\sqrt{k})$ is somewhat surprising here, since in 3 dimensions only separators of size $\mathcal{O}(k^{2/3})$ are known (see e.g. [53]). In order to get the desired separator size, we work on the surface of the convex polytope which is defined as the complement of the union of half-spaces in the solution. The edge graph of this polytope is planar, which allows us to define an appropriately small separator of the input point set.

For the $n^{\Omega(\sqrt{k})}$ lower bound, the first observation is that ORTHANT COVER for $d = 3$ is at least as hard as GEOMETRIC SET COVER in the plane where the objects are translates of an equilateral triangle. For the problem of GEOMETRIC SET COVER for squares, an $n^{\Omega(\sqrt{k})}$ conditional lower bound is known via a reduction from the GRID TILING problem [37, 40]. In this reduction, it is crucial that a gadget of (shifts of) a square can “transport” a value a from its left side to its right side, and a value b from its top side to its bottom side. For the related DOMINATING SET problem on intersection graphs of triangle translates, the proof strategy does generalize [18]. However, triangle translates are not flexible enough to naively follow this proof strategy for GEOMETRIC SET COVER: in a sense they have too few sides. Therefore, while our lower bound is also a reduction from GRID TILING, it is much more

subtle. Our most crucial construction is a “sumcheck” gadget that obtains “input values” a and b at two sides of the involved triangles and results in the value $a + b$ at the “output side”, while disallowing certain combinations. Using the “sumcheck” gadget on the values $a + b$ and $-a$ allows us to recover value b , and similarly we can recover a . Hence, we can use an essentially planar layout of triangles to transfer a value a from left to right and a value b from top to bottom; see Figure 3 for illustrations. Using this construction we can then simulate GRID TILING, obtaining the claimed lower bound.

The $n^{\Omega(k)}$ lower bound for $d = 4$ as well as our results on approximation algorithms all follow by relatively simple reductions to or from known results.

Organization. We prove Theorem 2 in Section 2, which implies Theorem 1.1 as per [46, Lemma 2.3] or [12, Section A.3]. We prove the remainder of Theorem 1 in Sections 3 and 4, which respectively contain a sketch of the lower bound for $d = 3$ and the lower bound for $d = 4$. Details of the lower bound for $d = 3$ as well as the proof of Theorem 3 are deferred to the full version of the paper.

2 Half-spaces in dimension 3

In this section, we prove Theorem 2 (and by extension, Theorem 1.1) by giving an algorithm for GEOMETRIC SET COVER for half-spaces in \mathbb{R}^3 . An instance of this problem consists of a set of half-spaces \mathcal{D} in \mathbb{R}^3 , a set of points U in \mathbb{R}^3 , and an integer k . The question is whether one can select k half-spaces from \mathcal{D} so that every point of U is covered by at least one of them.

We shall say that a set of half-spaces \mathcal{D} in \mathbb{R}^3 is *in general position* if no two boundaries of half-spaces in \mathcal{D} are parallel, and no four boundaries of half-spaces in \mathcal{D} meet at one point. Note that given an instance (\mathcal{D}, U, k) of GEOMETRIC SET COVER for half-spaces, one may slightly perturb the half-spaces of \mathcal{D} so that every half-space still covers the same subset of points in U as before, but after the perturbation they are in general position. Hence, we shall assume this property in all the considered instances of GEOMETRIC SET COVER for half-spaces.

2.1 Algorithm

Our algorithm will rely on the following balanced separator lemma.

► **Lemma 4.** *Suppose (\mathcal{D}, U, k) is an instance of GEOMETRIC SET COVER for half-spaces in \mathbb{R}^3 where \mathcal{D} is in general position, and let $\mathcal{S} \subseteq \mathcal{D}$ be an optimum solution to this instance, whose size ℓ satisfies $4 < \ell \leq k$. Then there exists a subset $\mathcal{S}_0 \subseteq \mathcal{S}$ with $|\mathcal{S}_0| \leq \mathcal{O}(\sqrt{k})$ and a partition \mathcal{P} of $U \setminus \bigcup \mathcal{S}_0$ with $|\mathcal{P}| \leq k$, such that the following property holds: For each $W \in \mathcal{P}$, if ℓ_W is the optimum size of a solution to the instance (\mathcal{D}, W, k) , then $\ell_W \leq \frac{2}{3}\ell$ and $|\mathcal{S}_0| + \sum_{W \in \mathcal{P}} \ell_W \leq \ell$.*

Moreover, given (\mathcal{D}, U, k) , one can in time $|\mathcal{D}|^{\mathcal{O}(\sqrt{k})} \cdot |U|^{\mathcal{O}(1)}$ enumerate a family \mathcal{N} consisting of at most $|\mathcal{D}|^{\mathcal{O}(\sqrt{k})}$ pairs $(\mathcal{S}_0, \mathcal{P})$ with $\mathcal{S}_0 \subseteq \mathcal{D}$, \mathcal{P} a partition of $U \setminus \bigcup \mathcal{S}_0$ with $|\mathcal{P}| \leq k$, and the guarantee that \mathcal{N} contains at least one pair satisfying the property above.

Before we give a proof of Lemma 4, we show how it can be used to construct an algorithm as promised in Theorem 2. The algorithm is presented below using pseudo-code as Algorithm `halfSpaceCoverDim3`.

Algorithm 1 Algorithm `halfSpaceCoverDim3`.

Input: Instance (\mathcal{D}, U, k) of GEOMETRIC SET COVER for half-spaces in \mathbb{R}^3 with \mathcal{D} in general position

Output: An optimum solution $\mathcal{S} \subseteq \mathcal{D}$ provided it has size $\leq k$, or \perp otherwise

```

 $\mathcal{S} \leftarrow \perp$ 
for each  $\mathcal{C} \subseteq \mathcal{D}$  with  $|\mathcal{C}| \leq \min(k, 4)$  do
    if  $U \subseteq \bigcup \mathcal{C}$  and  $|\mathcal{C}| < |\mathcal{S}|$  then // convention:  $|\perp| = \infty$ 
         $\mathcal{S} \leftarrow \mathcal{C}$ 
if  $k \leq 4$  then
    return  $\mathcal{S}$ 
 $\mathcal{N} \leftarrow$  family enumerated using the algorithm of Lemma 4 for  $(\mathcal{D}, U, k)$ 
for each  $(\mathcal{S}_0, \mathcal{P}) \in \mathcal{N}$  do
    for each  $W \in \mathcal{P}$  do
         $\mathcal{S}_W \leftarrow$  halfSpaceCoverDim3 $(\mathcal{D}, W, \lfloor 2k/3 \rfloor)$ 
         $\mathcal{C} \leftarrow \mathcal{S}_0 \cup \bigcup_{W \in \mathcal{P}} \mathcal{S}_W$  // convention:  $\perp \cup X = \perp$ 
        if  $|\mathcal{C}| \leq k$  and  $|\mathcal{C}| < |\mathcal{S}|$  then
             $\mathcal{S} \leftarrow \mathcal{C}$ 
return  $\mathcal{S}$ 

```

As argued, we may assume that \mathcal{D} is in general position. First, we look through all candidates \mathcal{C} for a solution with $|\mathcal{C}| \leq 4$. In case any such \mathcal{C} covering U is found, we store the smallest one as the optimum solution. Next, provided $k > 4$, we apply the algorithm of Lemma 4 to the instance (\mathcal{D}, U, k) and enumerate a suitable family of pairs \mathcal{N} . For each $(\mathcal{S}_0, \mathcal{P}) \in \mathcal{N}$ we apply the algorithm recursively to all instances $(\mathcal{D}, W, \lfloor \frac{2}{3}k \rfloor)$ for $W \in \mathcal{P}$, yielding solutions \mathcal{S}_W . We then consider $\mathcal{C} = \mathcal{S}_0 \cup \bigcup_{W \in \mathcal{P}} \mathcal{S}_W$ as a candidate solution, provided none of \mathcal{S}_W is equal to \perp . Finally, we output the smallest candidate solution of size at most k found.

The correctness of the algorithm follows immediately from Lemma 4. Indeed, if (\mathcal{D}, U, k) admits a solution of size at most 4, then an optimum solution will be found in the initial search. Otherwise, Lemma 4 ensures us that for some pair $(\mathcal{S}_0, \mathcal{P}) \in \mathcal{N}$, the recursive calls of the algorithm will find solutions \mathcal{S}_W for $W \in \mathcal{P}$ which together with \mathcal{S}_0 form an optimum solution to (\mathcal{D}, U, k) .

We are left with bounding the time complexity of the algorithm. Let $C > 0$ be such that the algorithm of Lemma 4 always returns a family \mathcal{N} satisfying $|\mathcal{N}| \leq |\mathcal{D}|^{C\sqrt{k}}$. Let $T[d, k]$ be the maximum number of leaves of the recursion tree produced by the algorithm when applied to an instance with $|\mathcal{D}| = d$ and parameter k . Then $T[d, k] = 1$ for $k \leq 4$, while for $k > 4$ we have the following recursive inequality:

$$T[d, k] \leq k \cdot d^{C\sqrt{k}} \cdot T[d, \lfloor 2k/3 \rfloor].$$

Here, factor $k \cdot d^{C\sqrt{k}}$ comes from the fact that for at most $d^{C\sqrt{k}}$ pairs $(\mathcal{S}_0, \mathcal{P}) \in \mathcal{N}$ we apply the algorithm recursively to $|\mathcal{P}| \leq k$ instances with parameter $\lfloor 2k/3 \rfloor$. Unraveling the recursion, we have

$$T[d, k] \leq k^{\log_{3/2} k} \cdot d^{C\sqrt{k} \cdot (1 + (2/3)^{1/2} + (2/3)^{2/2} + (2/3)^{3/2} + \dots)} = k^{\log_{3/2} k} \cdot d^{C'\sqrt{k}} = d^{\mathcal{O}(\sqrt{k})},$$

where $C' = C \cdot \frac{1}{1 - (2/3)^{1/2}}$.

We conclude that the recursion tree for an instance with $d = |\mathcal{D}|$ and parameter k has at most $d^{\mathcal{O}(\sqrt{k})}$ leaves, so it also has $d^{\mathcal{O}(\sqrt{k})}$ nodes. The internal computation for each node takes time $d^{\mathcal{O}(\sqrt{k})} \cdot |U|^{\mathcal{O}(1)}$, so the total running time of $d^{\mathcal{O}(\sqrt{k})} \cdot |U|^{\mathcal{O}(1)}$ follows.

2.2 Balanced separator lemma

We now move to the proof of Lemma 4, which spans the remainder of this section.

Since \mathcal{S} is an optimum solution to (\mathcal{D}, U, k) , we have that \mathcal{S} is *minimal* in the following sense: there is no $S \in \mathcal{S}$ such that $S \subseteq \bigcup_{T \in \mathcal{S} \setminus \{S\}} T$. It turns out that this minimality condition together with the assumption $|\mathcal{S}| > 4$ implies that \mathcal{S} cannot cover the whole space; this is implied by the following result.

► **Theorem 5** (Danzer et al. [17]). *If a set of half-spaces \mathcal{S} in \mathbb{R}^3 is minimal and $\bigcup \mathcal{S} = \mathbb{R}^3$, then $|\mathcal{S}| \leq 4$.*

For every half-space $S \in \mathcal{S}$ we may choose an affine function $\varphi_S: \mathbb{R}^3 \rightarrow \mathbb{R}$ so that

$$S = \{x \in \mathbb{R}^3: \varphi_S(x) \leq 0\}.$$

In particular, we set $\varphi_S(x) = \langle x - v_S, n_S \rangle$, where v_S is a point in the boundary of S , the vector n_S is the normal of the boundary plane of S pointing away from S , and $\langle \cdot, \cdot \rangle$ denotes the inner product in \mathbb{R}^3 . Let $\bar{S} = \{x \in \mathbb{R}^3: \varphi_S(x) \geq 0\}$; that is, \bar{S} is the closure of the complement of S . Then the complement of $\bigcup \mathcal{S}$ is the interior of the polytope P defined as follows:

$$P = \bigcap_{S \in \mathcal{S}} \bar{S} = \{x \in \mathbb{R}^3: \varphi_S(x) \geq 0 \text{ for all } S \in \mathcal{S}\}.$$

By Theorem 5 we infer that P is non-empty.

We shall also assume from now on that the polytope P is bounded. This can be achieved by adding to \mathcal{S} up to 6 *dummy* half-spaces of the form $\{(x_1, x_2, x_3) \in \mathbb{R}^3: x_i \geq M\}$ and $\{(x_1, x_2, x_3) \in \mathbb{R}^3: x_i \leq -M\}$ for $i = 1, 2, 3$ and some large M , so that none of the dummy half-spaces covers any point of U . These may be perturbed slightly so that \mathcal{S} remains in general position. As we will not use the optimality of \mathcal{S} from now on, this can be safely done at the cost of replacing ℓ with $\ell + 6$ in all asymptotic bounds. Note that we do ensure that minimality of \mathcal{S} is maintained, and thus possibly less than 6 dummy half-spaces are added.

Recall that we denote $|\mathcal{S}| = \ell$. Thus, P is a bounded convex polytope in \mathbb{R}^3 with ℓ faces, one for each half-space of \mathcal{S} (this follows by minimality). Since \mathcal{S} is in general position, at each vertex of P three faces meet. Let H be a graph whose vertices are the vertices of P and whose edges are the edges of P . Observe that the boundary of P – which consists of its faces – is homeomorphic to a sphere, so this homeomorphism shows that H admits a drawing in the sphere with ℓ faces. In the following, we identify faces of H with the faces of P . Since every face f of P is a polygon, the boundary of f is a simple cycle in H . Therefore, H is a simple 3-regular plane graph (i.e. without loops and multiple edges connecting the same pair of vertices) that is connected and bridgeless.

Let H' be the *radial graph* of H : the vertex set of H' consists of vertices and faces of H , and in H' a vertex u is adjacent to a face f if and only if u lies on the boundary of f . Note that H' is bipartite, with the vertices and faces of H being the bipartition. Also, H' admits an embedding into a sphere constructed from the embedding of H as follows: for every face f pick an arbitrary point $x_f \in f$ representing it, and connect x_f with all vertices u lying on f using pairwise non-crossing curves within f . Observe that every face of H' is a 4-cycle, induced by two faces of H and the endpoints of an edge shared by them. Since H is connected and bridgeless, a straightforward argument shows that H' is 2-connected. Since H is 3-regular, it follows that $3|V(H)| = 2|E(H)|$, so by Euler's formula for polyhedra ($|V(H)| - |E(H)| + \ell = 2$), we have that $|V(H)| = 2\ell - 4$. Consequently, $|V(H')| = 3\ell - 4$.

We may now apply the following Cycle Separator Theorem of Miller.

► **Theorem 6** ([42], with simplified formulation). *Let G be a 2-connected plane graph on n vertices and let d be the maximum length of a face in G . Suppose $\mu: V(G) \rightarrow [0, 1]$ is a weight function on the vertices of G such that $\mu(V(G)) = \sum_{v \in V(G)} \mu(v) = 1$. Then there exists a simple cycle C in G of length at most $2\sqrt{2\lfloor d/2 \rfloor n}$ such that if R_1 and R_2 are the (open) connected regions of the plane with C removed, then the vertices contained in R_1 have total weight at most $2/3$, and the same holds for R_2 .*

On the vertex set of H' define the following weight function: $\mu(f) = \frac{1}{\ell}$ for every face f of H , and $\mu(u) = 0$ for every vertex u of H . By Theorem 6, in H' there exists a simple cycle C of length at most $4\sqrt{|V(H')|} = 4\sqrt{3\ell - 4}$ such that every connected component of $H' - C$ contains at most $\frac{2}{3}\ell$ vertices that correspond to faces of H . Let

$$C = (z_1, f_1, z_2, f_2, \dots, z_q, f_q),$$

where $2q$ is the length of C (thus $q \leq 2\sqrt{3\ell - 4}$), z_1, \dots, z_q are consecutive vertices of H visited by C , and f_1, \dots, f_q are consecutive faces of H visited by C .

Let Q be a closed poly-line in \mathbb{R}^3 with vertices z_1, \dots, z_q , connected with straight line segments in this order (cyclically). Then the segment between z_i and z_{i+1} (with indices behaving cyclically modulo q) is entirely contained in the face f_i of P . Thus, Q is a curve contained in the boundary of P (denoted further ∂P), so it splits ∂P (which is homeomorphic to a sphere) into two regions, say A_1 and A_2 .

We now color the faces of P in three colors as follows:

- faces incident to any of the vertices z_1, z_2, \dots, z_q are colored green;
- remaining faces are colored red or blue, depending whether they are contained in A_1 or A_2 .

Note that since three faces meet at each vertex z_i , there are at most $4\sqrt{3\ell - 4}$ green faces: f_1, \dots, f_q and at most one additional face per each vertex z_i . Also, red faces do not share edges with blue faces, because all faces intersecting Q (even at one point) are colored green. We treat the above coloring of faces of P also as a coloring of all the points of ∂P . Here, points on edges of P are colored green if any face incident to the edge is colored green, and they are colored red or blue if all incident faces are red or blue, respectively.

Let $X = \text{conv}\{z_1, \dots, z_q\}$. The asserted properties of C immediately yield the following.

▷ **Claim 7.** There are at most $4\sqrt{3\ell - 4}$ green faces, at most $\frac{2}{3}\ell$ red faces, and at most $\frac{2}{3}\ell$ blue faces. No red face shares any edge with any blue face. Moreover, if x is any blue point on ∂P and y is any red point on ∂P , then the straight line segment with endpoints x and y intersects X .

As faces of P are in one-to-one correspondence with the half-spaces of \mathcal{S} , we may talk about red, green, and blue half-spaces of \mathcal{S} . We next observe that the separating properties of C carry over to the points of U .

▷ **Claim 8.** If a point $u \in U$ is simultaneously covered by a red half-space from \mathcal{S} and by a blue half-space from \mathcal{S} , then it is also covered by a green half-space from \mathcal{S} .

Proof. Let A and B be respectively the red and the blue half-space covering u , and let f_A and f_B be the faces of P that correspond to A and B , respectively. Pick any point $x_A \in f_A$ and $x_B \in f_B$ and let Π be a plane through u , x_A , and x_B . We may choose x_A and x_B so that Π does not contain any vertex of P . Then $P \cap \Pi$ is a nonempty convex polygon, whose sides are colored red, green, and blue so that no red side is adjacent to any blue side. Moreover, the side containing x_A is red, while the side containing x_B is blue. Call these sides s_A and s_B , respectively.

Call a side s of $P \cap \Pi$ *separating* if its extension to a line separates u from $P \cap \Pi$ in the plane Π . Since $P \cap \Pi$ is convex, separating sides form an interval on the perimeter of $P \cap \Pi$. Moreover, since A and B cover u , it follows that s_A and s_B are separating. As s_A is red and s_B is blue, from the two claims above we conclude that there exists a green side s of $P \cap \Pi$ that is also separating. Then the half-space corresponding to the face of P containing s is green and it covers u , as required. \triangleleft

By Claim 8, we may partition U into three subsets:

- *green points* of U that are covered by some green half-space from \mathcal{S} ;
- *red points* of U that are covered only by red half-spaces from \mathcal{S} ;
- *blue points* of U that are covered only by blue half-spaces from \mathcal{S} .

Denote the above sets by U_G, U_R, U_B , respectively. In the following claims, roughly speaking we show that X can be used to separate red points of U from blue points of U . Call two points $u, v \in U$ *separated* by X if the straight line segment with endpoints u and v intersects X .

▷ **Claim 9.** For all $u \in U_R$ and $v \in U_B$, we have that u and v are separated by X .

Proof. Let I be the straight line segment with endpoints u and v .

Suppose first that I does not intersect the polytope P . Since both I and P are convex, there exists an affine functional $\psi: \mathbb{R}^3 \rightarrow \mathbb{R}$ such that $\psi(u) < 0$, $\psi(v) < 0$, but $\psi(x) \geq 0$ for all $x \in P$. We may moreover choose ψ so that there exists a vertex w of P for which $\psi(w) = 0$. Let the faces of P incident to w be contained in the boundaries of half-spaces S_1, S_2, S_3 . Since ψ is nonnegative on P , it follows that ψ can be written as a nonnegative linear combination of $\varphi_{S_1}, \varphi_{S_2}, \varphi_{S_3}$. Then $\varphi_{S_i}(u) < 0$ holds for some index $i \in \{1, 2, 3\}$, and similarly condition $\varphi_{S_j}(v) < 0$ holds for some index $j \in \{1, 2, 3\}$. Thus S_i covers u and S_j covers v , so S_i is necessarily red and S_j is necessarily blue. However, the faces corresponding to S_i and S_j share an edge incident to the vertex w . This contradicts Claim 7.

Now we know that I indeed intersects P . Let $J = I \cap P$. Note that since $u \in U_R$, the endpoint of J closer to u has to be red, for the half-space corresponding to the face of P containing this endpoint covers u . Similarly, the endpoint of J closer to v has to be blue. We conclude that, by Claim 7, the segment J has to intersect X . \triangleleft

▷ **Claim 10.** Suppose $u, v \in U \setminus U_G$ are separated by X . Then there is no half-space in \mathcal{S} that would simultaneously cover both u and v .

Proof. Let I be the straight line segment with endpoints u and v , and let x be any point of $I \cap X$.

Suppose first that x lies on ∂P . Since $x \in X$ and all faces of P incident to z_1, \dots, z_q are colored green, it follows that x is green. Let S be any half-space of \mathcal{S} corresponding to a green face on which x lies. As $x \in I$, we conclude that S either covers u or v , which contradicts the assumption that $u, v \notin U_G$.

Suppose now that x lies in the interior of P . If there was a half-space $S \in \mathcal{S}$ containing both u and v , then S would contain the whole segment I , and x in particular, so S would intersect the interior of P . This is a contradiction with the definition of P . \triangleleft

Consider now a graph L with vertex set $U \setminus U_G$, where different $u, v \in U \setminus U_G$ are considered adjacent if and only if they are not separated by X . Then Claims 9 and 10 directly imply the following.

▷ **Claim 11.** Every connected component of L is entirely contained either in U_R or in U_B . Moreover, no half-space in \mathcal{S} covers points from two different connected components of L .

26:10 On Geometric Set Cover for Orthants

The existential part of Lemma 4 follows now if we take \mathcal{S}_0 to be the set of green half-spaces and \mathcal{P} to be the partition of $U \setminus U_G$ into the connected components of L . Here, if any half-space from \mathcal{S}_0 turns out to be one of the at most six dummy half-spaces, we may safely remove it from \mathcal{S}_0 , as it does not cover any point in U anyway. Let us check that the required properties are indeed satisfied by the pair $(\mathcal{S}_0, \mathcal{P})$. First, by Claim 7 we have $|\mathcal{S}_0| \leq 2q \leq \mathcal{O}(\sqrt{k})$. Next, for a connected component W of L , let us denote by \mathcal{S}_W the set of half-spaces from \mathcal{S} that cover at least one point of $U \setminus U_G$ belonging to W . Clearly, \mathcal{S}_W is a solution to the instance (\mathcal{D}, W, k) , hence $|\mathcal{S}_W| \geq \ell_W$. By Claim 10, the sets \mathcal{S}_W are pairwise disjoint, and they are clearly disjoint from \mathcal{S}_0 . Hence, we have

$$\ell = |\mathcal{S}| \geq |\mathcal{S}_0| + \sum_{W \in \text{cc}(L)} |\mathcal{S}_W| \geq |\mathcal{S}_0| + \sum_{W \in \text{cc}(L)} \ell_W,$$

where $\text{cc}(L)$ is the set of connected components of L . Also, the sets \mathcal{S}_W are non-empty, because every connected component of L requires at least one half-space to be covered, so $\sum_{W \in \text{cc}(L)} |\mathcal{S}_W| \leq \ell$ entails that $|\mathcal{P}| = |\text{cc}(L)| \leq \ell \leq k$. Finally, by Claim 9, for each $W \in \text{cc}(L)$ the half-spaces of \mathcal{S}_W are either all red or all blue, which by Claim 7 implies that $|\mathcal{S}_W| \leq \frac{2}{3}\ell$ for all $W \in \text{cc}(L)$.

We are left with providing an algorithm enumerating a suitable family \mathcal{N} . The algorithm proceeds as follows. Let \mathcal{D}' be \mathcal{D} augmented by adding the six dummy half-spaces of the form $\{(x_1, x_2, x_3) \in \mathbb{R}^3 : x_i \geq M\}$ and $\{(x_1, x_2, x_3) \in \mathbb{R}^3 : x_i \leq -M\}$ for $i = 1, 2, 3$ and some large M , so that none of the added half-spaces covers any point of U . Say that a point $x \in \mathbb{R}^3$ is *important* if it is the intersection of some triple of planes that are boundaries of some half-spaces in \mathcal{D}' . Note that all vertices of the polytope P are important points, while the total number of important points is at most $(|\mathcal{D}| + 6)^3$ and they can be enumerated in time $\mathcal{O}(|\mathcal{D}|^3)$.

Next, for every $q \leq 2\sqrt{3 \cdot (k+6)} - 4 = 2\sqrt{3k+14}$, iterate through

- every choice of $2q$ half-spaces from \mathcal{D} , say $\mathcal{S}_0 = \{S_1, \dots, S_{2q}\}$;
- and every choice of q important points z_1, \dots, z_q .

Note that there are at most $|\mathcal{D}|^{4\sqrt{3k+14}}$ choices for \mathcal{S}_0 and at most $(|\mathcal{D}| + 6)^{6\sqrt{3k+14}}$ choices for z_1, \dots, z_q , hence we iterate through at most $(|\mathcal{D}| + 6)^{10\sqrt{3k+14}}$ choices in total.

Let $X = \text{conv}\{z_1, \dots, z_q\}$ and let U_G be the set of all points of U that are covered by some half-space of \mathcal{S}_0 . Construct the graph L as described before: the vertex set of L is $U \setminus U_G = U \setminus \bigcup \mathcal{S}_0$, and two points $u, v \in U \setminus U_G$ are adjacent if and only if u and v are not separated by X . Observe that whether u and v are separated by X can be checked in strongly polynomial time. Indeed, this question boils down to the verifying whether, in 3-dimensional Euclidean space, a given segment intersects a polyhedron defined as the convex hull of a given set of points, which can be solved by any strongly polynomial-time procedure for intersecting two convex polyhedra in \mathbb{R}^3 , see e.g. [51, Section 7.3 and notes and comments to Chapter 7]. Therefore, L can be computed in (strongly) polynomial time. Finally, if L has at most k connected components, then include in the constructed family \mathcal{N} the pair $(\mathcal{S}_0, \mathcal{P})$, where \mathcal{P} is the partition of $U \setminus U_G$ into the connected components of L .

The bound on the size of \mathcal{N} and the running time of the algorithm follow immediately from the description. The correctness is also clear, as some choice of \mathcal{S}_0 and z_1, \dots, z_q considered by the algorithm is the same as the one considered in the existential argument. This finishes the proof of Lemma 4.

3 Lower bound for dimension 3

The goal of this section is to prove Theorem 1, assertion 2. We can restrict our attention to the case where all points lie on the plane $\Pi = \{(x, y, z) : x + y + z = 0\}$ and the corners of all orthants lie on the plane $\{(x, y, z) : x + y + z = 1\}$. In such a setting, the intersections of the orthants with Π form equilateral triangles on Π , which all have the same size and orientation. In essence, this setting of ORTHANT COVER is equivalent to finding a geometric set cover of size k among m translates of some triangle. We call this problem TRIANGLE TRANSLATE COVER. Therefore, Theorem 1.2 is implied by the following theorem.

► **Theorem 12.** *There is no $f(k)n^{o(\sqrt{k})}$ algorithm for TRIANGLE TRANSLATE COVER for any computable function f , unless ETH fails.*

Here n is m plus the number of points.

Our reduction is from GRID TILING [38, 16], which is defined as follows. We are given as input an integer k , an integer n , and a collection \mathcal{S} of k^2 non-empty sets $S_{i,j} \subseteq \{1, \dots, n\} \times \{1, \dots, n\}$ for $i, j \in \{1, \dots, k\}$. The goal is to select an element $s_{i,j} \in S_{i,j}$ for each $i, j \in \{1, \dots, k\}$ such that:

- If $i < k$, $s_{i,j} = (x, y)$, and $s_{i+1,j} = (x', y')$, then $x = x'$.
- If $j < k$, $s_{i,j} = (x, y)$, and $s_{i,j+1} = (x', y')$, then $y = y'$.

One can picture these sets in a $k \times k$ matrix: in each cell (a, b) , we need to select a representative from the set $S_{i,j}$ so that the representatives selected from horizontally neighboring cells agree in the first coordinate, and representatives from vertically neighboring cells agree in the second coordinate. Observe that due to equality conditions, the goal in the GRID TILING problem can be stated equivalently as follows: select elements $x_1, \dots, x_k, y_1, \dots, y_k \in [n]$ such that $(x_i, y_j) \in S_{i,j}$ for all $i, j \in [k]$. Note that $s_{i,j} = (x_i, y_j)$ in this case. In the following, we will treat the selection $x_1, \dots, x_k, y_1, \dots, y_k$ also as a *solution* to a GRID TILING instance.

Our goal is to create a parameterized reduction where the constructed instance of TRIANGLE TRANSLATE COVER has a cover of size ck^2 for some constant c if and only if the original GRID TILING instance has a solution. This is sufficient due to the following theorem.

► **Theorem 13** ([38, 16]). *There is no $f(k)n^{o(k)}$ algorithm for GRID TILING for any computable function f , unless ETH fails.*

3.1 Gadgets

Due to lack of space, we only give a short intuitive overview of our construction. The complete construction and all proofs can be found in the full version of the paper.

Let $\varepsilon = \frac{1}{100n}$. In the TRIANGLE TRANSLATE COVER problem, the input triangles are equilateral triangles; we assume the side lengths are precisely 1. This means our construction can effectively use three directions, namely along the vectors $\bar{\mathbf{e}} = (1, 0)$, $\acute{\mathbf{e}} = (1/2, \sqrt{3}/2)$, and $\grave{\mathbf{e}} = (1/2, -\sqrt{3}/2)$. For convenience, we let $E = \{\bar{\mathbf{e}}, -\bar{\mathbf{e}}, \acute{\mathbf{e}}, -\acute{\mathbf{e}}, \grave{\mathbf{e}}, -\grave{\mathbf{e}}\}$. Given a positive integer N , we use $[N]$ to denote $\{1, \dots, N\}$ and $[-N]$ to denote $\{-1, \dots, -N\}$.

Bundles. We first establish a gadget to represent an integer value. Let $N = 2n$ and $\mathbf{e} \in E$. A *bundle* is a set of N triangles $B = \{t_1, \dots, t_N\}$ such that t_1 has its lower-left corner on the origin and t_{i+1} is t_i translated by $i\varepsilon \cdot \mathbf{e}$. The bundle also contains a point p_B on the incenter of $t_{N/2}$ ensuring that at least one triangle is selected from B . The idea behind the construction is that each solution will select exactly one triangle from the bundle. In this manner, the index of the selected triangle represents an integer in $[N]$. In the figures, each bundle has an arrow that indicates the direction along which the translation is done, and the indices (i.e. the represented integer) increase.

■ **Figure 1** Left, middle: transportation gadgets. Arrows indicate the direction of increasing indices within the bundle. Right: negation gadget.

■ **Figure 2** Integer gadgets with some transportation to the outside.

A *negative bundle* uses a different indexing, and represents the integer $-N + i - 1$. Hence, the index of the selected triangle represents an integer in $[-N]$. (In figures, such bundles are indicated with a minus sign.)

Transportation gadget. We now establish a gadget to transport an integer value over some distance; this is built on a pair of bundles B and B' as in Figure 1. Observe that the boundaries of the triangles of B and B' induce an $(N - 1) \times (N - 1)$ lattice with directions \bar{e} and \bar{e} . Now place points in the cells of this lattice as indicated in the figure. In this way, we are able to transport the integer value i represented by the triangle selected from B to an integer value of at most i for the bundle B' . Note that within certain limits, we can translate B' at will, so that we can “lengthen” or “shorten” as needed for the rest of the construction. By switching the sign of the values represented by one bundle of the transportation gadget, we get a *negation gadget* (see right hand side of Figure 1); if we make a cycle by joining transportation gadgets, we get an *integer gadget*, within which the selected triangles of each bundle must represent the same integer value (see Figure 2).

Sum and sumcheck gadget. We can create a *sum gadget*, which has three bundles, two of which are considered input bundles and one an output bundle. The gadget has the property that if the triangles selected in the two input bundles represent a and b respectively, then the output bundle must have a triangle representing some value that is at most $a + b$. Such a gadget is depicted in Figure 3. By adding extra points (indicated by red crosses), we can also disable the selection of certain triplets $(a, b, a + b)$. For a set $S \subseteq [n] \times [n]$, this allows us to create a *sumcheck gadget* where given inputs a, b the output is at most $a + b$, where equality can occur if and only if $(a, b) \in S$. This is the crucial step that eventually allows us to check for the sets $S_{i,j}$ corresponding to the cell i, j of the GRID TILING instance.

■ **Figure 3** Left: summation gadget. Adding the points indicated by the red crosses creates an S -sumcheck gadget for $S = \{(1, 1); (1, 3); (2, 2)\}$. Right: schematic representation of a cell (i, j) of the GRID TILING instance. The transportation gadgets (blue) carry inequalities involving $a = a_{i,j}$ and $b = b_{i,j}$.

3.2 The complete construction

The idea of the reduction is to have for any pair of neighboring tiles an integer gadget which contains the value that these neighboring tiles must agree on. Given such integer gadgets, we can realize a single tile $(i, j) \in [k] \times [k]$ using our gadgetry the following way. We want to transfer the value a that is our horizontal selection and the value b which is our vertical selection between these integer gadgets. At the same time, we want to ensure that $(a, b) \in S_{i,j}$. We do this as explained schematically in Figure 3. From the integer gadgets on the left and on the top, we extract the integer values stored there, say $a_{i,j}$ and $b_{i,j}$ respectively, and transport these values (using transportation gadgets) to an $S_{i,j}$ -sumcheck gadget. The output of this gadget will be an integer c satisfying $c \leq a_{i,j} + b_{i,j}$, and moreover $c < a_{i,j} + b_{i,j}$ if $(a_{i,j}, b_{i,j}) \notin S_{i,j}$. Using negation gadgets, we can extract $-a_{i,j}$ and $-b_{i,j}$ from the left and top integer gadgets, respectively. Each of these values can be combined with c through a sum gadget, whose output (i.e., third bundle) recovers integer values $a_{i,j+1} \leq a_{i,j}$ and $b_{i+1,j} \leq b_{i,j}$ that can be passed along to the right hand side and bottom integer gadgets respectively.

Let G be the construction thus far. Note that the construction ensures that left-to-right and top-to-bottom we have non-increasing values stored in our integer gadgets. To ensure equality holds, we need to wrap the rows and columns into cycles, just as we did for a single integer gadget. Doing this in a naive manner would lead to further crossings, so instead we create a construction H that is similar to G , but the rows are in reverse order, and the gadgetry of every tile is mirrored on the vertical axis; this construction is then translated below G (see Figure 4). In particular, the cell in row i and column j of H corresponds to the cell in row $k - i + 1$ and column j of the GRID TILING instance. As Figure 4 indicates, we can create transportation gadgets in a suitable manner to realize this construction.

We remark that it is tempting to use a known variant of GRID TILING called GRID TILING WITH \leq as the starting point of the reduction, which enjoys the same complexity lower bound as GRID TILING; see [16, Theorem 14.30]. In this variant, the equality conditions are replaced with the requirement that one coordinate behaves non-decreasingly along rows, while the second behaves non-decreasingly along columns. The variant looks convenient, as our

■ **Figure 4** Schematic representation of the complete construction for $k = 3$.

gadgets directly implement inequalities between coordinates, not equalities. This thinking, however, is problematic for the following reason: in our construction, in order to implement the check $(a, b) \in S_{i,j}$ we have to enforce equality in the sumcheck gadget created for the cell (i, j) , as in case of any slackness, this condition is not checked by the gadget. Therefore, starting the reduction from GRID TILING WITH \leq would not simplify the reasoning.

4 Lower bound for dimension 4 and higher

Consider the RECTANGLE COVER problem: Given points $P \subseteq \mathbb{R}^2$, a set R of axis-parallel rectangles in the plane, and a number k , decide whether there is a subset $R' \subseteq R$ of size k such that P is contained in the union of all rectangles in R' . RECTANGLE COVER is not solvable in time $f(k)n^{o(k)}$ for any computable f assuming ETH [39], where $n = |P| + |R|$. We obtain the same lower bound for ORTHANT COVER in dimension $d \geq 4$ by an easy reduction.

Proof of Theorem 1.3. Given points P and rectangles R in the plane, we construct a 4-dimensional ORTHANT COVER instance (U, \mathcal{T}) : For each point $p = (x, y) \in P$, we add the point $(-x, x, -y, y)$ to U . For each rectangle $r = [x_1, x_2] \times [y_1, y_2] \in R$, we add the orthant with corner $(-x_1, x_2, -y_1, y_2)$ to \mathcal{T} . Note that p is contained in r if and only if $x_1 \leq x \leq x_2$ and $y_1 \leq y \leq y_2$, which is equivalent to $-x \leq -x_1$, $x \leq x_2$, $-y \leq -y_1$, and $y \leq y_2$. For points $p, q \in \mathbb{R}^d$, note that q is contained in the orthant $T = (-\infty, p_1] \times \dots \times (-\infty, p_d]$ if and only if every coordinate of p is not larger than the corresponding coordinate of q . This proves the correctness of our reduction. We thus ruled out time $f(k)n^{o(k)}$ assuming ETH for ORTHANT COVER in dimension $d = 4$, and also for any $d \geq 4$ (by a trivial embedding). ◀

Together with the reasoning presented in [39], the above argument yields a chain of reductions from CLIQUE to ORTHANT COVER in $d = 4$. Using recent hardness of approximation for CLIQUE [9] and carefully tracking the gap through this chain of reductions, we obtain that ORTHANT COVER in $d = 4$ has no 1.05-approximation with running time $f(k)n^{o(k)}$ for any computable f , assuming Gap-ETH (Theorem 3.2). This result is presented in the full version of the paper.

Abstract

Recently, Chakrabarty and Swamy (STOC 2019) introduced the *minimum-norm load-balancing* problem on unrelated machines, wherein we are given a set J of jobs that need to be scheduled on a set of m unrelated machines, and a monotone, symmetric norm; We seek an assignment $\sigma : J \rightarrow [m]$ that minimizes the norm of the resulting load vector $\vec{\text{load}}_\sigma \in \mathbb{R}_+^m$, where $\vec{\text{load}}_\sigma(i)$ is the load on machine i under the assignment σ . Besides capturing all ℓ_p norms, symmetric norms also capture other norms of interest including top- ℓ norms, and ordered norms. Chakrabarty and Swamy (STOC 2019) give a $(38 + \varepsilon)$ -approximation algorithm for this problem via a general framework they develop for minimum-norm optimization that proceeds by first carefully reducing this problem (in a series of steps) to a problem called min-max ordered load balancing, and then devising a so-called deterministic oblivious LP-rounding algorithm for ordered load balancing.

We give a direct, and simple $4 + \varepsilon$ -approximation algorithm for the minimum-norm load balancing based on rounding a (near-optimal) solution to a novel convex-programming relaxation for the problem. Whereas the natural convex program encoding minimum-norm load balancing problem has a large non-constant integrality gap, we show that this issue can be remedied by including a key constraint that bounds the “norm of the job-cost vector.” Our techniques also yield a (essentially) 4-approximation for: (a) *multi-norm load balancing*, wherein we are given multiple monotone symmetric norms, and we seek an assignment respecting a given budget for each norm; (b) the best *simultaneous approximation factor* achievable for all symmetric norms for a given instance.

1 Introduction

In the *minimum-norm load-balancing* (MinNormLB) problem, we are given a set J of n jobs, a set of m machines, and processing times $p_{ij} \geq 0$ for all $i \in [m]$ and $j \in J$. We use $[m]$ to denote $\{1, \dots, m\}$. We are also given a monotone, symmetric norm $f : \mathbb{R}^m \rightarrow \mathbb{R}_+$. Recall that by definition of norm, this means that f satisfies: (i) $f(x) = 0$ iff $x = 0$; (ii) $f(x + y) \leq f(x) + f(y)$ for all $x, y \in \mathbb{R}^m$ (triangle inequality); and (iii) $f(\lambda x) = |\lambda|f(x)$ for all $x \in \mathbb{R}^m, \lambda \in \mathbb{R}$ (homogeneity). (Properties (ii) and (iii) imply that f is convex.) Monotonicity means that $f(x) \leq f(y)$ for all $x, y \in \mathbb{R}^m$ such that $x_i(y_i - x_i) \geq 0$ for all $i \in [m]$; symmetry means that permuting the coordinates of x does not affect its norm, i.e., $f(x) = f(\{x_{\pi(i)}\}_{i \in [m]})$ for every $x \in \mathbb{R}^m$ and every permutation $\pi : [m] \mapsto [m]$.

The goal is to find an assignment $\sigma : J \rightarrow [m]$ that minimizes the norm (under f) of the induced load vector. More precisely, an assignment σ induces the m -dimensional load vector $\vec{\text{load}}_\sigma \in \mathbb{R}_+^m$ where $\vec{\text{load}}_\sigma(i) := \sum_{j:\sigma(j)=i} p_{ij}$. The objective is to find σ that minimizes $f(\vec{\text{load}}_\sigma)$.

Besides ℓ_p -norms, monotone symmetric norms capture **Top- ℓ** norms – sum of ℓ largest coordinates in absolute value – and ordered norms (which are a nonnegative linear combination of **Top- ℓ** norms). The minimum-norm load-balancing problem was recently introduced by Chakrabarty and Swamy [8]. They develop a general framework for minimum-norm optimization problems based on reducing the problem to a special case called min-max ordered optimization, and devise a so-called deterministic oblivious rounding [8] to tackle the latter problem, which results in a $(38 + \varepsilon)$ -approximation algorithm for **MinNormLB**.

Our main result is a simpler $4(1 + \varepsilon)$ -approximation algorithm for **MinNormLB** that runs in time $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$.

► **Theorem 1.** *One can achieve a $4(1 + \varepsilon)$ -approximation for **MinNormLB** in time $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$, assuming we have a value-oracle and subgradient-oracle for the norm f . More generally, if we have ω -approximate value- and subgradient- oracles for f (see Section 4), then one can compute a $4(1 + 5\omega)(1 + \varepsilon)$ -approximation to **MinNormLB** in time $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$.*

This is a substantial improvement over the approximation factor of 38 obtained in [8]. Moreover, our algorithm is also simpler and more direct than the one in [8]. Notably, our approximation factor is close to the best-known approximation factor (of 2) known for the ℓ_∞ norm (wherein **MinNormLB** becomes the classical minimum-makespan problem). Our algorithm proceeds by rounding the solution to a novel convex-programming relaxation of the problem. The convex program can be solved (approximately) using an (approximate) first-order oracle for f that returns the function value, and its subgradient at a given point.

Our techniques also yield a $4(1 + \varepsilon)$ -approximation for (see Section 5): (a) *multi-norm load balancing*, wherein we are given multiple monotone, symmetric norms and budgets for each norm, and we seek an assignment (approximately) respecting these budgets; and (b) the best *simultaneous approximation factor* achievable for all symmetric norms for a given instance.

Motivation and perspective

One of the reasons for studying **MinNormLB** is that it generalizes various load-balancing problems considered in the literature, and its study therefore yields a unified methodology for dealing with monotone, symmetric norms.

Load balancing under the ℓ_∞ norm, that is, minimizing the maximum load (also called the makespan) is a classical scheduling problem that has been extensively studied [18, 23, 10, 24, 6, 15] over the past three decades, both in its full generality for unrelated machines and for various special cases. The best known approximation factor for the unrelated-machines setting is still 2 [18], and it is *NP*-hard to obtain an approximation factor better than $3/2$ [18]. For general ℓ_p -norms, Azar and Epstein [3] obtain a 2-approximation, and improved guarantees have been obtained for constant p [3, 16, 19]. More recently, the load-balancing problem has also been considered for other monotone, symmetric norms. **Top- ℓ** - and ordered-norms have been proposed in the location-theory literature (see “Other related work”) as a means of interpolating between the ℓ_1 and ℓ_∞ norms (and an alternative to using ℓ_p norms), and motivated by this, Chakrabarty and Swamy [8] studied the **Top- ℓ** load-balancing

problem – minimize the total load on the ℓ most loaded machines – and the ordered load-balancing problem. They give a $(2 + \varepsilon)$ -approximation algorithm in both settings, and also (as noted earlier) devise a $(38 + \varepsilon)$ -approximation algorithm for an arbitrary monotone, symmetric norm.

For load balancing, there has been considerable interest in *simultaneous optimization*. Given an instance, the objective is to find an assignment that *simultaneously* approximates a large suite of objective functions. Building upon previous works [2, 4], Goel and Meyerson [11] describe a 2-approximation for the problem of simultaneously approximating all monotone symmetric norms in the *restricted assignment* setting. However, it is known that such an $O(1)$ -factor is *impossible* in the unrelated-machines setting [4, 11]. As a byproduct of their MinNormLB algorithm, in the unrelated-machines setting, Chakrabarty and Swamy [8] give an *instance-wise* $(38 + \varepsilon)$ -approximation to the best simultaneous approximation-factor possible for the instance. To elaborate, let $\alpha_{\mathcal{I}}^*$ denote the smallest factor for instance \mathcal{I} such that there exists a schedule that achieves an $\alpha_{\mathcal{I}}^*$ -approximation for all monotone, symmetric norms; [8] returns a schedule for \mathcal{I} that achieves a $38(1 + \varepsilon)\alpha_{\mathcal{I}}^*$ -approximation for all monotone, symmetric norms. As mentioned above, we devise an algorithm that for every instance \mathcal{I} returns a schedule that simultaneously achieves a $(4 + O(\varepsilon))\alpha_{\mathcal{I}}^*$ -approximation for all monotone, symmetric norms (see Theorem 13).

Our techniques

Since a norm is a convex function, a natural convex-programming relaxation for MinNormLB is to minimize the norm of the fractional load vector $\vec{L} = L(\vec{x}) := \{\sum_j p_{ij}x_{ij}\}_{i \in [m]}$, where the x_{ij} s are the usual variables denoting if job j is assigned to machine i , and we have the usual job-assignment constraints encoding that every job is assigned to some machine. This convex program, however, has a large integrality gap, even when f is the ℓ_∞ -norm due to the issue that the convex program could split a large job across multiple machines.

In the case of the ℓ_∞ norm (the makespan minimization problem), the typical way of circumventing the above issue is to “guess” the optimal value, say T , and add constraints to encode that no single job contributes more than T to the objective. The usual way of capturing this is to explicitly set $x_{ij} = 0$ if $p_{ij} > T$. A less common, and weaker, way of encoding this is to enforce that $\sum_i p_{ij}x_{ij} \leq T$ for all j , that is, the total processing time contribution of any job j across the machines cannot exceed T .

For an arbitrary (monotone, symmetric) norm, it is unclear how to extend either of the above approaches, since the contribution of a job to the objective is now a somewhat vague notion. One way to generalize things would be to encode (either explicitly or in the alternate weaker sense above) that the “norm” of the job-cost vector is at most T , where the job-cost vector is indexed by jobs and the cost for job j (under x) is $P_j := \sum_i p_{ij}x_{ij}$. But the norm f is defined over \mathbb{R}^m , whereas the job-cost vector lies in \mathbb{R}^n . For certain specific (families of) norms – e.g., ℓ_p -norms, top- ℓ norm, ordered norm – there is a natural version of the norm over \mathbb{R}^n ,¹ but what does such a constraint mean in general, and how can one encode this?

Our key insight, which leads to our convex program, is that one can capture the above consideration by examining the vector $\vec{P} \in \mathbb{R}^m$ comprising the *costs of the m most-costly jobs* and enforcing the constraint $f(\vec{P}) \leq T$; since f is monotone, this can be equivalently encoded as $f(\{P_j\}_{j \in S}) \leq T$ for all $S \subseteq J$ with $|S| = m$. It is not apparent that such a

¹ For ℓ_p -norms, a variant of this that considers the ℓ_p^p expression does work, but this crucially exploits the separability of ℓ_p^p [3].

constraint is valid, but we derive some insights about symmetric norms and show that this is indeed the case (see Theorem 3). This yields our convex program (CP), which can be solved efficiently (within ε additive error, for any $\varepsilon > 0$, in time $\text{poly}(\text{input size}, \ln(1/\varepsilon))$) using the ellipsoid method provided we have a value oracle and subgradient oracle for f .

Rounding a solution x to the convex program is now quite easy. Let $\vec{L} \in \mathbb{R}^m$ denote the load-vector arising from x . We use a filtering step to ensure that each job j is only assigned to machines i for which $p_{ij} \leq 2P_j$. This causes a factor-2 blowup in the machine loads. Now we use the rounding algorithm of Shmoys and Tardos [23] for the generalized assignment problem (GAP). The resulting assignment σ has load-vector at most $2\vec{L} + \vec{Z}$, where $\vec{Z} \in \mathbb{R}^m$ and $Z_i = \max_{j:\sigma(j)=i} p_{ij}$; the filtering step and our constraints ensure that $f(\vec{Z}) \leq 2T$, so $f(2\vec{L} + \vec{Z}) \leq 4T$. Our algorithm is much more direct than the one in [8]: it avoids the sequence of steps (and the associated approximation-factor losses) used in [8], wherein MinNormLB is reduced to a special case, called min-max ordered load balancing, which is then tackled by a deterministic oblivious rounding procedure.

Other related work

The algorithmic problem of finding minimum-norm solutions has also been investigated in the context of k -clustering, wherein the goal is to open k “facilities” in a metric space to serve a set of clients, and the cost vector induced by a solution is the vector of distances of clients to their nearest open facility. The setting of ℓ_p -norms, especially when $p \in \{1, 2, \infty\}$ (where the problem is called the k -{median, means, center} problem) has been extensively studied, and $O(1)$ -approximations are known in these settings [13, 9, 14, 1]. Top- ℓ and ordered norms have been proposed in the context of k -clustering in the Operations Research literature (see, e.g., [21, 17]), but constant-factor approximations for these norms were obtained quite recently [5, 7, 8]. Furthermore, Chakrabarty and Swamy [8] utilize their general framework to obtain an $O(1)$ -approximation for the k -clustering problem under any monotone, symmetric norm. We do not know of any alternate approach that works in the k -clustering setting.

2 A convex-programming relaxation

By possibly adding dummy jobs with zero processing times, we may assume without loss of generality that $n \geq m$. A natural convex program for MinNormLB has non-negative variables x_{ij} denoting if job j is assigned to machine i (or the extent of j assigned to i) with the constraint (1) encoding that every job is assigned to a machine. These x -variables define a load vector $\vec{L} = (L_i = L_i(x))_{i \in [m]}$ where $L_i(x) = \sum_{j \in J} p_{ij} x_{ij}$. The objective seeks to minimize $T := f(\vec{L})$. As noted earlier, this convex program has a large integrality gap (even when f is the ℓ_∞ norm). We *strengthen* the convex program as follows.

Given the x -assignment, define $P_j = P_j(x) := \sum_i p_{ij} x_{ij}$, which is the load incurred by the fractional solution for scheduling job j . Fix any subset $S \subseteq J$ with $|S| = m$. Note that this is well-defined since we have assumed $n \geq m$. This defines the m -dimensional vector $\vec{P}_S := \{P_j\}_{j \in S}$. We add the constraints (6) enforcing that $f(\vec{P}_S) \leq T$ for each such subset S . Throughout, we use i to index the machines in $[m]$, and j to index the jobs in J .

$$\begin{aligned}
 \min \quad & T & & \text{(CP)} \\
 \text{s.t.} \quad & \sum_i x_{ij} \geq 1 & \forall j \in J & \text{(1)} \\
 & x \geq 0 & & \text{(2)} \\
 & L_i = \sum_{j \in J} p_{ij} x_{ij} \quad \forall i \in [m] & & \text{(3)} \\
 & P_j = \sum_{i \in [m]} p_{ij} x_{ij} \quad \forall j \in J & & \text{(4)} \\
 & f(\vec{L}) \leq T & & \text{(5)} \\
 & f(\vec{P}_S) \leq T \quad \forall S \subseteq J, |S| = m & & \text{(6)}
 \end{aligned}$$

Let $\text{OPT} := \text{OPT}_{\text{CP}}$ denote the optimal value of (CP), and let O^* be the optimal value of the minimum-norm load-balancing problem. Since the x_{ij} -variables completely determine a solution to (CP), we will sometimes abuse notation and say that x is a feasible solution to (CP). We argue that (CP) is a valid relaxation. The proof uses the following simple observation about symmetric convex functions.

▷ **Claim 2.** Let $h : \mathbb{R}^m \rightarrow \mathbb{R}$ be a symmetric convex function. Let $v \in \mathbb{R}_+^m$, and $i, j \in [m]$. Let $w \in \mathbb{R}_+^m$ be the vector where $w_i = v_i + v_j$, $w_j = 0$, and $w_k = v_k$ otherwise. Then, $h(v) \leq h(w)$.

Proof. Consider the vector w' constructed in a symmetric fashion to w : set $w'_j = v_i + v_j$, $w'_i = 0$, and $w'_k = v_k$ otherwise. Observe that v is a convex combination of w and w' (we have $v = \frac{v_i}{v_i+v_j} \cdot w + \frac{v_j}{v_i+v_j} \cdot w'$), and $h(w) = h(w')$ since h is symmetric. By convexity and symmetry, $h(v) \leq \max\{h(w), h(w')\} = h(w)$. ◁

► **Theorem 3.** Constraints (6) are valid, and so for any instance of MinNormLB, we have $\text{OPT} \leq O^*$.

Proof. Let $\sigma^* : J \rightarrow [m]$ be an optimal assignment, so $f(\text{load}_{\sigma^*}) = O^*$. We now describe a feasible solution to (CP) with $T = O^*$. Set $x_{ij} = 1$ if $\sigma^*(j) = i$, and 0 otherwise. Clearly, constraints (1) hold. Note, $L_i = \text{load}_{\sigma^*}(i)$ for all i , and $P_j = p_{\sigma^*(j)j}$ for all j . Therefore, (5) holds with equality.

The interesting bit is to show that (6) holds. To that end, fix a subset $S \subseteq J$ of m jobs. Consider the load vector induced by jobs in S . That is, define $L'_i := \sum_{j \in S: \sigma^*(j)=i} p_{ij}$. Note that \vec{L} coordinate wise dominates \vec{L}' , so by monotonicity of f , we have $f(\vec{L}') \leq f(\vec{L}) = T$.

We argue that $f(\vec{P}_S) \leq f(\vec{L}')$, which will complete the proof. To see this, first note that if σ^* assigns the jobs in S to distinct machines, then \vec{P}_S is simply a permutation of \vec{L}' , so $f(\vec{P}_S) = f(\vec{L}')$. Otherwise, observe that \vec{L}' can be obtained from \vec{P}_S by applying the operation in Claim 2 to pairs of jobs in S assigned to the same machine; therefore, we have $f(\vec{P}_S) \leq f(\vec{L}')$. ◀

The proof above relied only on convexity, monotonicity, and symmetry of the function f . In Section 3 (see Theorem 4) we describe a rounding procedure which takes a feasible solution for (CP) and returns an assignment with a factor-4 blow-up in the objective. This will utilize the homogeneity of the norm f . In Section 4, we show how to (approximately) solve (CP) given an (approximate) first-order oracle for the underlying norm (see Theorem 9). Combining these two results yields Theorem 1.

3 The rounding algorithm

We now describe and analyze our simple rounding algorithm, which yields the following guarantee.

► **Theorem 4.** Given a feasible fractional solution $(x = \{x_{ij}\}_{i,j}, \vec{L}, \vec{P}, T)$ to (CP), there is a polynomial time algorithm to obtain a schedule σ with $f(\text{load}_{\sigma}) \leq 4T$.

Proof. First, we filter x . For every i, j , we set $\hat{x}_{ij} = 2x_{ij}$ if $p_{ij} \leq 2P_j$, and 0 otherwise. A standard Markov-inequality style argument shows that \hat{x} satisfies (1). Now we apply the Shmoys-Tardos GAP-rounding algorithm [23] to \hat{x} . This yields an assignment $\sigma : J \rightarrow [m]$ such that: for every job j , we have $\sigma(j) = i$ only if $\hat{x}_{ij} > 0$, and for every machine i , we have $\text{load}_{\sigma}(i) \leq \sum_{j \in J} p_{ij} \hat{x}_{ij} + Z_i \leq 2L_i + Z_i$, where $Z_i = \max_{j: \sigma(j)=i} p_{ij}$. Thus, $\text{load}_{\sigma} \leq 2\vec{L} + \vec{Z}$.

Let j_i be a maximum-length job assigned to machine i in σ , i.e., $\sigma(j_i) = i$ and $Z_i = p_{j_i}$. By our filtering step, we know that $Z_i \leq 2P_{j_i}$. Let $S = \{j_i : i \in [m]\}$. Then $\vec{Z} := (Z_i)_{i \in [m]} \leq 2\vec{P}_S$. By monotonicity, the triangle inequality, and homogeneity of f , we then obtain that

$$f(\text{load}_\sigma) \leq 2f(\vec{L}) + f(\vec{Z}) \leq 2T + 2f(\vec{P}_S) \leq 4T. \quad \blacktriangleleft$$

Interestingly, and notably, observe that the rounding procedure above is *oblivious to the norm* f : given a fractional solution x , the same rounding procedure works for all monotone, symmetric norms. This will be useful in Section 5, where we seek an assignment that is simultaneously good for multiple norms.

4 Solving the convex program

We now discuss how to solve the convex program (CP). To maintain the flow of reading, proofs of certain technical claims are deferred to Section 6. It is well known [20, 12] that we can efficiently solve a convex program $\min_{x \in S} h(x)$ (where $S \subseteq \mathbb{R}^n$ is convex) to within any additive error $\varepsilon > 0$ using the ellipsoid method provided that (we state things more precisely below): (i) S has non-zero volume and is contained in some ball; (ii) we have a separation oracle for S ; (iii) we have a *first-order* oracle for h that given input $x \in S$, returns $h(x)$, and a subgradient of h at x . More generally, we show that by utilizing the machinery of Shmoys and Swamy [22], even an approximate value and subgradient oracle suffices (see Theorem 9). This is particularly relevant since the norm and/or components of the subgradient vector may involve irrational numbers.

By scaling we may assume that all p_{ij} s are integers. Let O^* denote the optimal value for the MinNormLB instance. We can easily detect if $O^* = 0$, since this implies an assignment with 0 load on every machine. Therefore, we assume $O^* \geq 1$. It will be convenient to reformulate (CP) as follows. Let $\mathcal{P} := \{x \in \mathbb{R}^{[m] \times J} : \sum_i x_{ij} \geq 1 \ \forall j \in J, \ 0 \leq x_{ij} \leq 1 \ \forall i \in [m], j \in J\}$ denote the feasible region for the assignment variables.

$$\min g(x) := \max \left\{ f(L(\vec{x})), \max_{S \subseteq J: |S|=m} f(P(\vec{x})_S) \right\} \quad \text{s.t.} \quad x \in \mathcal{P}. \quad (\text{CP}')$$

Note that the x_{ij} s are the only variables above. Recall that OPT is the optimal value of (CP) (and (CP')).

We recall a few standard concepts from optimization. Let $h : \mathbb{R}^k \mapsto \mathbb{R}$ and let $\|u\|$ denote the ℓ_2 norm of u .

- We say that h has *Lipschitz constant* (at most) K if $|h(v) - h(u)| \leq K\|v - u\|$ for all $u, v \in \mathbb{R}^k$.
- We say that $d \in \mathbb{R}^k$ is a *subgradient* of h at $u \in \mathbb{R}^k$ if we have $h(v) - h(u) \geq d \cdot (v - u)$ for all $v \in \mathbb{R}^k$. We say that \hat{d} is an ω -*subgradient* of h at $u \in \mathbb{R}^k$ if for every $v \in \mathbb{R}^k$, we have $h(v) - h(u) \geq \hat{d} \cdot (v - u) - \omega h(u)$; we call this the approximate-subgradient inequality.
- An ω -*first-order oracle* for h is an algorithm that at any point $u \in \mathbb{R}^k$, returns an estimate est such that $h(u) \leq \text{est} \leq (1 + \omega)h(u)$, and an ω -subgradient of h at u .

(In the optimization literature, the notions of approximate first-order oracle and approximate subgradient typically involve additive errors; since our problems are scale-invariant, multiplicative approximations, where the error at u is measured relative to $h(u)$, are more apt here.)

We remark that since f is a norm, an ω -subgradient \hat{d} of f at u also yields an estimate of $f(u)$ as follows: taking $v = \vec{0}$ and $v = 2u$ respectively in the approximate-subgradient inequality, we obtain the bounds $\hat{d} \cdot u \geq (1 - \omega)f(u)$ and $\hat{d} \cdot u \leq (1 + \omega)f(u)$. (Thus, an ω -first-order oracle for f boils down to an ω -subgradient oracle for f .)

By input size, we mean the total encoding length of the p_{ij} s. It is easy to separate over \mathcal{P} , and easy to find radii R , and $0 < V \leq 1$ such that $\mathcal{P} \subseteq B(0, R) := \{x : \|x\| \leq R\}$, \mathcal{P} contains a ball of radius V , and $\log(\frac{R}{V}) = \text{poly}(m, n)$. In particular, $R = \sqrt{mn}$ suffices, and \mathcal{P} contains a ball of radius $V = \frac{0.5}{m}$ around the point x with $x_{ij} = \frac{1.5}{m}$ for all i, j . (We may assume $m \geq 2$ as otherwise the problem is trivial.) Throughout, we use K_f to denote an efficiently-computable upper bound on the Lipschitz constant of f ; Lemma 8 shows how to obtain this. Given a bound on the Lipschitz constant of f , one can compute an upper bound on the Lipschitz constant of g .

▷ **Claim 5.** The Lipschitz constant of g is at most $K = \sqrt{mn} \cdot \max_{i,j} p_{ij} \cdot K_f$.

► **Theorem 6** (Follows from [20]; see also [12]). *Let alg be a first-order oracle for f . Then, for any $\eta > 0$, we can compute $x^* \in \mathcal{P}$ such that $g(x^*) \leq \text{OPT} + \eta$ in $\text{poly}(\text{input size}, \log(\frac{K_f R}{\eta V}))$ time and using $\text{poly}(\text{input size}, \log(\frac{K_f R}{\eta V}))$ calls to alg .*

Theorem 6 follows from the ellipsoid method for convex optimization, due to the bound on the Lipschitz constant of g obtained from Claim 5, and since one can use alg to obtain a first-order oracle for g . We next use [22] to obtain a stronger result that utilizes only an approximate first-order oracle for f .

► **Theorem 7** (Lemma 4.5 in [22] paraphrased). *Consider a convex optimization problem: $\min_{x \in \mathcal{P}} h(x)$. Let K_h be a known bound on the Lipschitz constant of h . Let $\omega < 1$ and $\eta > 0$. In $\text{poly}(m, n, \log(\frac{K_h R}{V \eta}))$ time and using $\text{poly}(m, n, \log(\frac{K_h R}{V \eta}))$ calls to an ω -first-order oracle for h , one can compute a solution $x^* \in \mathcal{P}$ such that $h(x^*) \leq \frac{1+\omega}{1-\omega} \cdot (\min_{x \in \mathcal{P}} h(x) + \eta)$.*

To utilize Theorem 7 to solve (CP), we show how to obtain an approximate first-order oracle for g given one for f . Also, in order to convert the additive error in Theorem 7 (and Theorem 6) into a multiplicative guarantee, we show how to obtain a lower bound lb on O^* such that K_f/lb is small.

► **Lemma 8.** *Let alg be an ω -first-order oracle for f (where $\omega < 1$).*

- *We can obtain a 2ω -first-order oracle for g using $O(1)$ calls to alg .*
- *Using alg , we can efficiently compute $\text{lb} \leq O^*$, and an upper bound K_f on the Lipschitz constant of f such that $\frac{K_f}{\text{lb}} \leq 2\sqrt{m}$.*

► **Theorem 9.** *Let alg be an ω -first-order oracle for f with $\omega \leq \frac{1}{10}$. Given a MinNormLB instance with optimum value O^* , there is an algorithm that, for any $\varepsilon > 0$, computes a feasible solution x^* to (CP) of objective value $g(x^*) \leq (1 + 5\omega)(1 + \varepsilon)O^*$. The algorithm runs in $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ time and makes $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ calls to alg .*

Proof. This follows by combining Theorem 7 and Lemma 8. Recall that we are assuming that $O^* \geq 1$. By part 8 of Lemma 8, we can compute a 2ω -first-order oracle for g . We use part 8 of Lemma 8 to obtain lb and K_f . Now we apply Theorem 7 to the problem $\min_{x \in \mathcal{P}} g(x)$, taking $\eta = \varepsilon \text{lb}$. The point x^* returned satisfies $g(x^*) \leq \frac{1+2\omega}{1-2\omega} \cdot (\text{OPT} + \varepsilon \text{lb}) \leq (1 + 5\omega)(1 + \varepsilon)O^*$.

Recall that $\log(R/V) = \text{poly}(m, n)$. Since we have an upper bound K on the Lipschitz constant of g , where $\log K = \text{poly}(\text{input size}) \cdot \log K_f$ (Claim 5), the running time and number of calls to the first-order oracle for g (and hence alg) is at most $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$. ◀

5 Extensions: multi-norm load balancing and simultaneous approximation

5.1 Multi-norm load balancing

In the *multi-norm load-balancing problem*, we are given a load-balancing instance $(J, m, \{p_{ij}\}_{i \in [m], j \in J})$, multiple monotone, symmetric norms f_1, \dots, f_k , and budgets T_1, \dots, T_k for these norms respectively. The goal is to find an assignment $\sigma : J \rightarrow [m]$ such that $f_r(\vec{\text{load}}_\sigma) \leq T_r$ for all $r \in [k]$. Our approximation guarantee extends easily to this problem.

► **Theorem 10.** *Let $(J, m, \{p_{ij}\}_{i \in [m], j \in J})$ be a load-balancing instance. Let f_1, \dots, f_k be k monotone, symmetric norms, with associated budgets T_1, \dots, T_k . Given an ω -first-order oracle for each norm, for any $\varepsilon > 0$, in $\text{poly}(\text{input size}, k, \log(1/\varepsilon))$ time, one can either determine that there is no feasible solution to the multi-norm load-balancing problem, or return an assignment $\sigma : J \rightarrow [m]$ such that $f_r(\vec{\text{load}}_\sigma) \leq 4(1 + 7\omega)(1 + \varepsilon)T_r$ for all $r \in [k]$.*

The convex-programming relaxation for this problem is a variant of (CP) where there is no objective function, and constraints (5), (6) are replaced with

$$f_r(\vec{L}) \leq T_r, \quad f_r(\vec{P}_S) \leq T_r \quad \forall S \subseteq J : |S| = m, \quad \forall r = 1, \dots, k \quad (7)$$

Let (Multi-CP) denote the resulting feasibility problem: find (x, \vec{L}, \vec{P}) satisfying (1)–(4), and (7). As noted earlier, the rounding procedure in Section 3 is *oblivious* to the underlying norm, and so our task boils down to finding an (approximately) feasible solution to (Multi-CP).

In order to solve (Multi-CP), as with (CP), it will be convenient to move the nonlinear constraints to the objective and consider the following reformulation:

$$\min q(x) := \max \left\{ \max_{r \in [k]} \frac{f_r(\vec{L}(x))}{T_r}, \max_{r \in [k]} \max_{S \subseteq J : |S| = m} \frac{f_r(\vec{P}(x)_S)}{T_r} \right\} \quad \text{s.t.} \quad (1), (2). \quad (\text{MNCP})$$

Observe that finding a feasible solution to (Multi-CP) is equivalent to finding a feasible solution to (MNCP) with objective value at most 1. As before, we may assume that the p_{ij} s are integers, and can determine if there is an assignment σ such that $\vec{\text{load}}_\sigma = \vec{0}$ (which clearly satisfies (7)). So assume otherwise. We prove the following.

► **Theorem 11.** *Let alg_r be an ω -first-order oracle for f_r for all $r \in [k]$, where $\omega \leq \frac{1}{18}$. For any $\varepsilon > 0$, in $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ time and using $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ calls to each alg_r oracle, we can determine that either (Multi-CP) is infeasible, or compute $x^* \in \mathcal{P}$ such that $q(x^*) \leq (1 + 7\omega)(1 + \varepsilon)$.*

Using Theorem 11, for any $\varepsilon > 0$, we can determine in time $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ that (Multi-CP) is infeasible, or return a fractional assignment x^* satisfying

$$f_r(L(\vec{x}^*)) \leq \kappa T_r, \quad f_r(P(\vec{x}^*)_S) \leq \kappa T_r \quad \forall S \subseteq J : |S| = m, \quad \forall r = 1, \dots, k$$

where $\kappa = (1 + 7\omega)(1 + \varepsilon)$. As noted earlier, the rounding procedure in Section 3 is *oblivious* to the underlying norm, and so by utilizing this to round x^* , we obtain an assignment σ such that $f_r(\vec{\text{load}}_\sigma) \leq 4\kappa T_r$ for all $r \in [k]$. This yields Theorem 10.

In the rest of this section, we discuss the proof of Theorem 11. If the multi-norm problem is feasible, we must have $T_r \geq f_r(e_1)$ for all $r \in [k]$. We assume in the sequel that T_r is at least the estimate of $f_r(e_1)$ returned by alg_r scaled by $(1 + \omega)$, for all $r \in [k]$; if this

does not hold, then we declare infeasibility. Given this, the proof of Lemma 8.8 shows that $K_r = (1 + \omega)\sqrt{m} \cdot T_r$ is an upper bound on the Lipschitz constant of f_r , for all $r \in [k]$. We assume this bound in the sequel. Similar to Claim 5 and Lemma 8, we show that the Lipschitz constant of q can be bounded in terms of the K_r s, and we can obtain a 2ω -first-order oracle for q using the alg_r oracles.

► **Lemma 12.** (i) *The Lipschitz constant of q is bounded by $K = \text{poly}(m, n, \max_{i,j} p_{ij})$. (ii) We can obtain a 2ω -first order oracle for q by making $O(1)$ calls to alg_r for each $r \in [k]$.*

Proof of Theorem 11. We utilize Lemma 12 in conjunction with Theorem 7. Part (ii) of Lemma 12 shows how to obtain a 2ω -first-order oracle, alg , for q . So invoking Theorem 7 with $\eta = \varepsilon$, and the bound K on the Lipschitz constant of q obtained from part (i) of Lemma 12, we obtain $\bar{x} \in \mathcal{P}$ such that

$$q(\bar{x}) \leq \frac{1 + 2\omega}{1 - 2\omega} \left(\min_{x \in \mathcal{P}} q(x) + \eta \right). \quad (8)$$

The running time is $\text{poly}(\text{input size}, \log(\frac{1}{\varepsilon}))$ (since $\log(R/V)$, $\log K = \text{poly}(\text{input size})$), and this is also a bound on the number of calls to the alg_r oracles. Using alg , we obtain an estimate est such that $q(\bar{x}) \leq \text{est} \leq (1 + 2\omega)q(\bar{x})$. If $\text{est} > \frac{(1+2\omega)^2}{1-2\omega} \cdot (1 + \eta)$, then (8) implies that $(\min_{x \in \mathcal{P}} q(x)) > 1$, and so (Multi-CP) is infeasible. Otherwise, taking $x^* = \bar{x}$, we obtain that $q(x^*) \leq \text{est} \leq \frac{(1+2\omega)^2}{1-2\omega} \cdot (1 + \varepsilon) \leq (1 + 7\omega)(1 + \varepsilon)$ since $\omega \leq \frac{1}{18}$. ◀

5.2 Simultaneous approximation

Given a load-balancing instance $\mathcal{I} = (J, m, \{p_{ij}\}_{i \in [m], j \in J})$, let $\alpha_{\mathcal{I}}^*$ be the smallest α such that there *exists* an assignment σ^* satisfying $f(\text{load}_{\sigma^*}) \leq \alpha (\min_{\sigma: J \rightarrow [m]} f(\text{load}_{\sigma}))$ for every monotone, symmetric norm. That is, $\alpha_{\mathcal{I}}^*$ is the best *simultaneous approximation factor* achievable on instance \mathcal{I} . Instead of seeking absolute bounds on $\alpha_{\mathcal{I}}^*$ over a class of instances [2, 4, 11], as discussed in [8], another pertinent problem is to seek *instance-wise* guarantees: given an instance \mathcal{I} , we want to find a polytime-computable assignment $\bar{\sigma}$ such that, for some factor $\gamma \geq 1$, we have $f(\text{load}_{\bar{\sigma}}) \leq \gamma \alpha_{\mathcal{I}}^* (\min_{\sigma: J \rightarrow [m]} f(\text{load}_{\sigma}))$ for every monotone, symmetric norm; i.e., the simultaneous approximation factor of $\bar{\sigma}$ at most γ times the best simultaneous approximation factor achievable for \mathcal{I} .

Our techniques coupled with insights from [11, 8] yields a $4(1 + O(\varepsilon))$ -approximation to the best simultaneous approximation factor, in time $\text{poly}(\text{input size}, (\frac{m}{\varepsilon})^{O(1/\varepsilon)})$. To obtain this guarantee, following [11, 8], incurring a $(1 + \varepsilon)$ -factor loss, it suffices to obtain a 4-approximation to the best simultaneous-approximation achievable for **Top- ℓ -norms** – $\text{Top-}\ell(x) := \max_{S \subseteq [m]: |S|=\ell} \sum_{i \in S} |x_i|$ – for the $O(\log m)$ indices ℓ in $\text{POS} := \{\min\{\lceil (1 + \varepsilon)^s \rceil, m\} : s \geq 0\}$. If we knew the optimal value opt_{ℓ} for each such **Top- ℓ** norm, then we can set a budget $T_{\ell} = \alpha \text{opt}_{\ell}$ for each $\ell \in \text{POS}$, and utilize our result for multi-norm load balancing to do a binary search for α . Importantly, notice that the resulting feasibility problem (Multi-CP) can now be cast as an *linear-programming* feasibility problem, since a budget constraint of the form $\text{Top-}\ell(\vec{v}) \leq T_{\ell}$ can be modeled using exponentially many linear constraints that one can separate over. Thus, this would yield a $4(1 + \varepsilon)$ -approximation. To make this idea work, we enumerate all choices for the opt_{ℓ} values in powers of $(1 + \varepsilon)$. As argued in [8], there are at most $\text{poly}(\text{input size}, (\frac{m}{\varepsilon})^{O(1/\varepsilon)})$ candidates to enumerate over, and this yields the stated guarantee.

► **Theorem 13.** *Given a load-balancing instance $\mathcal{I} = (J, m, \{p_{ij}\}_{i \in [m], j \in J})$, let α_I^* be the smallest α such that there is an assignment σ^* satisfying $f(\vec{\text{load}}_{\sigma^*}) \leq \alpha (\min_{\sigma: J \rightarrow [m]} f(\vec{\text{load}}_{\sigma}))$ for every monotone, symmetric norm f . In $\text{poly}(\text{input size}, (\frac{m}{\varepsilon})^{O(1/\varepsilon)})$ time, we can find an assignment $\hat{\sigma}$ such that we have $f(\vec{\text{load}}_{\hat{\sigma}}) \leq (4 + O(\varepsilon)) \alpha_I^* (\min_{\sigma: J \rightarrow [m]} f(\vec{\text{load}}_{\sigma}))$ for every monotone, symmetric norm f .*

6 Proofs from Sections 4 and 5

Proof of Claim 5. The bound follows easily from the definition of g . Let $x, y \in \mathbb{R}^{[m] \times J}$. Let $\vec{L}, \vec{L}' \in \mathbb{R}^m$ be the load vectors induced by x, y respectively; let \vec{P}_S, \vec{P}'_S be the job-cost vectors for the jobs in S induced by x, y respectively. Then, $g(y) - g(x) \leq \max\{f(L') - f(L), \max_{S \subseteq J: |S|=m} f(P'_S) - f(P_S)\}$. So $g(y) - g(x) \leq K_f \|L' - L\|_2$ or $g(y) - g(x) \leq K_f \|P'_S - P_S\|$ for some $S \subseteq J$ with $|S| = m$. Let $p_{\max} := \max_{i,j} p_{ij}$. In the former case, we have $g(y) - g(x) \leq K_f p_{\max} \sum_{i,j} |y_{ij} - x_{ij}| \leq \sqrt{mn} \cdot K_f p_{\max} \|y - x\|_2$; the same bound also applies in the latter case. This shows that $K = \sqrt{mn} \cdot K_f p_{\max}$ is a bound on the Lipschitz constant of g . ◀

The following claim will be useful in proving part 8 of Lemma 8, as also part (ii) of Lemma 12.

▷ **Claim 14.** Let $h : \mathbb{R}^n \mapsto \mathbb{R}$ be defined by $h(x) := \max_{r \in [k]} h_r(x)$, where $h_r : \mathbb{R}^n \mapsto \mathbb{R}$ is convex for all $r \in [k]$. Let alg_r be an ω -first order oracle for h_r for all $r \in [k]$ (where $\omega < 1$).

- One can obtain a 2ω -first order oracle for h using $O(1)$ calls to $\text{alg}_1, \dots, \text{alg}_k$.
- More generally, suppose that given $x \in \mathbb{R}^n$, one can identify $I(x) \subseteq [k]$ such that $h(x) = \max_{r \in I(x)} h_r(x)$. Then, one can compute a 2ω -first-order oracle for h that, on input $x \in \mathbb{R}^n$, makes $O(1)$ calls to alg_r for all $r \in I(x)$.

Proof. We focus on proving part (i); part (ii) follows from a very similar argument. Fix $x \in \mathbb{R}^n$. For every $r \in [k]$, we call alg_r to obtain an estimate est^r of $h_r(x)$. We set the estimate for $h(x)$ to be $\text{est} := \max_{r \in [k]} \text{est}^r$. From the properties of est^r , it is easy to see that $h(x) \leq \text{est} \leq (1 + \omega)h(x)$.

Let d^r be the ω -subgradient of f_r at x returned by alg_r . Let $s \in [k]$ be such that $\text{est} = \text{est}^s$. We set $\mu = d^s$. We now argue that μ is a 2ω -subgradient of h at x . Consider any $y \in \mathbb{R}^n$. We have

$$\begin{aligned} \mu^T(y - x) &= (y - x)^T d^s \leq h_s(y) - h_s(x) + \omega h_s(x) \leq h(y) - \frac{1-\omega}{1+\omega} \cdot \text{est}^s = h(y) - \frac{1-\omega}{1+\omega} \cdot \text{est} \\ &\leq h(y) - \frac{1-\omega}{1+\omega} \cdot h(x) \leq h(y) - (1 - 2\omega)h(x). \end{aligned}$$

The first two inequalities follow due to the fact that (est^s, d^s) was returned by the ω -first order oracle for h_s ; the next equality follows from the definition of index s ; and the penultimate inequality follows since $\text{est} \geq h(x)$ as established earlier.

The proof of the more general statement in (ii) is essentially identical: on input x , we now run alg^r for all $r \in I(x)$; we set $\text{est} = \max_{r \in I(x)} \text{est}^r$, and $d = d^s$, where $s \in I(x)$ is an index such that $\text{est} = \text{est}^s$. ◀

Proof of Lemma 8. For part 8, fix $x \in \mathbb{R}^{[m] \times J}$. Recall that $P_j = P_j(x) := \sum_i p_{ij} x_{ij}$. Let S^* be the set of m jobs with the highest P_j values. Let $\vec{L} = L(x)$ and $\vec{P}_{S^*} = P(x)_{S^*}$. Then, $g(x) = \max\{f(\vec{L}), f(\vec{P}_{S^*})\}$. Observe that alg can be used to obtain an ω -first-order oracle for both $f(L(x))$ and $f(P(x)_{S^*})$. Thus, by using Claim 14 (ii), we obtain a 2ω -first-order oracle for g using $O(1)$ calls to alg .

We now justify the observation. A $(1 + \omega)$ -approximate value oracle is obtained by simply calling `alg` to obtain estimates of $f(\vec{L})$ and $f(\vec{P}_{S^*})$. Let $d^L = (d_i^L)_{i \in [m]}$, and $d^P = (d_j^P)_{j \in S^*}$ be the ω -subgradients of f at \vec{L} at \vec{P}_{S^*} respectively returned by `alg`.

$$\text{For all } i \in [m], j \in J, \text{ define } \quad \beta_{ij} = p_{ij}d_i^L, \quad \gamma_{ij} = \begin{cases} p_{ij}d_j^P & \text{if } j \in S^*; \\ 0 & \text{otherwise.} \end{cases}$$

Then, for any $y \in \mathbb{R}^{[m] \times J}$, we have $\beta^T(y - x) = \sum_{i,j} d_i^L p_{ij}(y_{ij} - x_{ij}) = (L(\vec{y}) - L(\vec{x}))^T d^L$ showing that β is an ω -subgradient of $f(L(\vec{\cdot}))$ at x . Similarly, $\gamma^T(y - x) = (P(\vec{y})_{S^*} - P(\vec{x})_{S^*})^T d^P$ showing that γ is an ω -subgradient of $f(P(\vec{\cdot}))$ at x .

For part 8, Let σ^* be an optimal assignment. Since we are assuming that $O^* \geq 1$, we have $\text{load}_{\sigma^*}(i) \geq 1$ for some $i \in [m]$. Let $e_i \in \mathbb{R}^m$ be the vector with 1 in coordinate i and 0s everywhere else. Then, $O^* \geq f(e_i)$. Let `lb` be the estimate of $f(e_i)$ obtained by `alg` scaled down by $(1 + \omega)$. So we have $f(e_i)/(1 + \omega) \leq \text{lb} \leq O^*$. Consider any $x, y \in \mathbb{R}^m$. We have $y = x + \sum_{i=1}^m (y_i - x_i)e_i$, so by the triangle inequality and symmetry, we have $|f(y) - f(x)| \leq \sum_{i=1}^m |y_i - x_i|f(e_i)$. Therefore, $|f(y) - f(x)| \leq (1 + \omega)\text{lb} \sum_{i=1}^m |y_i - x_i| \leq (1 + \omega)\sqrt{m} \cdot \text{lb} \cdot \|y - x\|$. So we can set $K_f = (1 + \omega)\sqrt{m} \cdot \text{lb}$. ◀

Proof of Lemma 12. Part (i) follows by applying Claim 5 to each norm f_r , and since the Lipschitz constant of the maximum of a collection of functions is bounded by the maximum of the Lipschitz constants of the functions in the collection. Let $p_{\max} = \max_{i,j} p_{ij}$. By Claim 5, for each $r \in [k]$, and $S \subseteq J$ with $|S| = m$, both $f_r(L(\vec{x}))/T_r$ and $f_r(P(\vec{x})_S)/T_r$ have Lipschitz constant at most $\sqrt{mn} \cdot p_{\max} \cdot K_r/T_r \leq (1 + \omega)m\sqrt{n}p_{\max}$. Hence, the Lipschitz constant of q is at most $K = (1 + \omega)m\sqrt{n}p_{\max}$.

For part (ii), we mimic the proof of part 8 of Lemma 8. Fix $x \in \mathbb{R}^{[m] \times J}$. Let S^* be the set of m jobs with the highest $P_j(x)$ values, where $P_j(x) := \sum_i p_{ij}x_{ij}$. Let $\vec{L} = L(\vec{x})$ and $\vec{P}_{S^*} = P(\vec{x})_{S^*}$. Then,

$$q(x) = \max \left\{ \max_{r \in [k]} f_r(\vec{L})/T_r, \max_{r \in [k]} f_r(\vec{P}_{S^*})/T_r \right\}.$$

As in the proof of Lemma 8 8, for each $r \in [k]$, we can use `algr` to obtain an ω -first-order oracle for $f_r(L(\vec{x}))/T_r$ and $f_r(P(\vec{x})_{S^*})/T_r$. Thus, by using Claim 14 (ii), we obtain a 2ω -first-order oracle for q using $O(1)$ calls to `algr`, for each $r \in [k]$. ◀

Abstract

In this paper we consider the p -NORM HAMMING CENTROID problem which asks to determine whether some given strings have a centroid with a bound on the p -norm of its Hamming distances to the strings. Specifically, given a set S of strings and a real k , we consider the problem of determining whether there exists a string s^* with $(\sum_{s \in S} d^p(s^*, s))^{1/p} \leq k$, where $d(\cdot)$ denotes the Hamming distance metric. This problem has important applications in data clustering and multi-winner committee elections, and is a generalization of the well-known polynomial-time solvable CONSENSUS STRING ($p = 1$) problem, as well as the NP-hard CLOSEST STRING ($p = \infty$) problem.

Our main result shows that the problem is NP-hard for all fixed rational $p > 1$, closing the gap for all rational values of p between 1 and ∞ . Under standard complexity assumptions the reduction also implies that the problem has no $2^{o(n+m)}$ -time or $2^{o(k \frac{p}{p+1})}$ -time algorithm, where m denotes the number of input strings and n denotes the length of each string, for any fixed $p > 1$. The first bound matches a straightforward brute-force algorithm. The second bound is tight in the sense that for each fixed $\varepsilon > 0$, we provide a $2^{k \frac{p}{p+1} + \varepsilon}$ -time algorithm. In the last part of the paper, we complement our hardness result by presenting a fixed-parameter algorithm and a factor-2 approximation algorithm for the problem.

1 Introduction

The *Hamming distance between two strings* of equal length is the number of positions at which the corresponding symbols in the strings differ. In other words, it measures the number of substitutions of symbols required to change one string into the other, or the number of errors that could have transformed one string into the other. This is perhaps the most fundamental string metric known, named after Richard Hamming who introduced the concept in 1950 [24].

While Hamming distance has a variety of applications in a plethora of different domains, a common usage for it appears when clustering data of various sorts. Here, one typically wishes to cluster the data into groups that are centered around some centroid, where the notion of centroid varies from application to application. Two prominent examples in this context are: **Consensus String**, where the centroid has a bound on the sum of its (Hamming) distance to all strings, and

Closest String, where the centroid has a bound on the maximum distance to all strings.

In functional analysis terms, these two problems can be formalized using the p -norms of the Hamming distance vectors associated with the clusters. That is, if $S \subseteq \{0, 1\}^n$ is a cluster and $s^* \in \{0, 1\}^n$ is its centroid, then the p -norm of the corresponding Hamming distance vector is defined by

$$\|(s^*, S)\|_p := \left(\sum_{s \in S} d^p(s^*, s) \right)^{1/p},$$

where $d(s^*, s) = |\{i: s^*[i] \neq s[i], 1 \leq i \leq n\}|$ denotes the Hamming distance between s^* and s . Using this notation, we can formulate **CONSENSUS STRING** as the problem of finding a centroid s^* with a bound on $\|(s^*, S)\|_1$ for a given set S of strings, while **CLOSEST STRING** can be formulated as the problem of finding a centroid s^* with a bound on $\|(s^*, S)\|_\infty$.

The following cluster S with 5 strings, each of length 7, shows that for different p , we indeed obtain different optimal centroids. For each $p \in \{1, 2, \infty\}$, string s_p^* is an optimal p -norm centroid but it is not an optimal q -norm centroid, where $q \in \{1, 2, \infty\} \setminus \{p\}$. Moreover, one can verify that s_2^* is the only optimal 2-norm centroid and no optimal ∞ -norm centroid is an optimal 2-norm centroid.

$S :$		p		
	centroid	$\ \cdot\ _1$	$\ \cdot\ _2$	$\ \cdot\ _\infty$
1111 111	$s_1^* = 0000\ 000$	14	$\sqrt{68}$	7
1111 000	$s_2^* = 0011\ 000$	16	$\sqrt{56}$	5
0000 100	$s_\infty^* = 0011\ 001$	17	$\sqrt{61}$	4
0000 010				
0000 001				

The notion of p -norms for distance vectors is very common in many different research fields [33, 30, 21, 34, 20, 2, 27, 3, 17, 39]. In cluster analysis of data mining and machine learning, one main goal is to partition m observations (i.e., m real vectors of the same dimension) into K groups so that the sum of “discrepancies” between each observation and its nearest center is minimized. Here, two highly prominent clustering methods are K -means [32] and K -medians [25, 4] clustering, each using a slightly different notion of discrepancy measure. The first method aims to minimize the *sum of squared Euclidean distances* between each observation and the “mean” of its respective group. In other words, it minimizes the squared 2-norm of the Euclidean-distance vector. K -medians, on the other hand, uses the 1-norm instead of the squared 2-norm to define the discrepancy to the mean. Thus, instead of calculating the mean for each group to determine its centroid, one calculates the median.

In committee elections from social choice theory [17, 39, 35, 16], the p -norm is used to analyze how well a possible committee represents the voter's choices. In a fundamental approval-based procedure to select a t -person committee from n candidates, each voter either approves or disapproves each of the candidates, which can be expressed as a binary string of length n . An optimal committee is a length- n binary string containing exactly t ones and which minimizes the p -norm of the vector of the Hamming distances to each voter's preference string [39].

Problem Definition, Notation, and Conventions

Since the Hamming distance is frequently used in various applications, e.g., in computational biology [36], information theory, coding theory and cryptography [24, 11, 37], in social choice [26, 1] and since the notion of p -norm is very prominent in clustering tools [38, 6, 30, 40] and preference aggregation rules [1, 5, 35], where often $p = 1, 2, \infty$ but also other values of p are used, it is natural to consider computational problems associated with the p -norm of the Hamming distance metric. This is the main purpose of this paper. Specifically, we consider the following problem:

p -NORM HAMMING CENTROID (p -HDC)

Input: A set S of strings $s_1, \dots, s_m \in \{0, 1\}^n$ and a real k .

Question: Is there a string $s^* \in \{0, 1\}^n$ such that $\|(s^*, S)\|_p \leq k$?

Throughout, we will call a string s^* as above a *solution*. Note that there is nothing special about using the binary alphabet in the definition above, but for ease of presentation we use it throughout the paper. When $p = 1$, our p -HDC problem is precisely the CONSENSUS STRING problem, and when $p = \infty$ it becomes the CLOSEST STRING problem.

In the following, we list some notation and conventions that we use. By p -distance we mean the p^{th} -power of the Hamming distance. For each natural number t by $[t]$ we denote the set $\{1, 2, \dots, t\}$. Unless stated otherwise, by *strings* we mean binary strings over alphabet $\{0, 1\}$. Given a string s , we use $|s|$ to denote the length of this string. For two binary strings s and s' , let $s \circ s'$ denote the concatenation of s and s' . By $s[j]$ we denote the j th value or the value in the j^{th} character of string s . By $\bar{s} = (1 - s[j])_{j \in [|s|]}$ we denote the complement of the (binary) string s . Given two integers $j, j' \in \{1, 2, \dots, |s|\}$ with $j \leq j'$, we write $s|_j^{j'}$ for the substring $s[j]s[j+1] \cdots s[j']$. Given a number ℓ , we use $\mathbf{0}_\ell$ and $\mathbf{1}_\ell$ to denote the length- ℓ all-zero string and the length- ℓ all-one string, respectively.

Our Contributions

Our main result is a tight running time bound on the p -HDC problem for all fixed rationals $p > 1$. Specifically, we show that the problem is NP-hard and can be solved in $2^{k^{p/(p+1)+\varepsilon}} \cdot |I|^{O(1)}$ time for arbitrary small $\varepsilon > 0$ where $|I|$ denotes the size of the instance, but cannot be solved in $2^{o(k^{p/(p+1)})}$ time unless the Exponential Time Hypothesis (ETH) [12] fails. The lower bounds are given in Theorem 3 and Proposition 6 and the upper bound in Theorem 10. While the upper bound in this result is not very difficult, the lower bound uses an intricate construction and some delicate arguments to prove its correctness. In particular, the construction extensively utilizes the fact that since $p > 1$, the p -norm of Hamming distances is convex and always admits a second derivative. We believe that this kind of technique is of interest on its own. As another consequence of the hardness construction, we also obtain a $2^{o(n+m)}$ running time lower bound assuming ETH, which gives evidence that the trivial brute-force $2^n \cdot |I|$ -time algorithm for the problem cannot be substantially

improved. Moreover, the lower bounds also hold when we constrain the solution string to have a prescribed number of ones. That is, we also show hardness for the committee election problem mentioned above (Corollary 7).

In the final part of the paper we present two more algorithms for p -HDC. First, we provide an $m^{O(m^2)} \cdot |I|^{O(1)}$ time algorithm (see Theorem 13), by first formulating the problem as a so-called Combinatorial n -fold Integer Program, and then applying the algorithm developed by Knop et al. [28]. Second, we show that the problem can be approximated in polynomial time within a factor of 2, using an extension of the well known 2-approximation algorithm for CLOSEST STRING (see Proposition 14).

Related Work

The NP-complete CLOSEST STRING [18, 29] problem (aka. MINIMUM RADIUS) is a special case of p -HDC with $p = \infty$. It seems, however, difficult to adapt this hardness reduction to achieve our hardness results for every fixed rational p (see also the beginning of Section 2 for some more discussion). CLOSEST STRING has been studied extensively under the lens of parameterized complexity and approximation algorithmics. The first fixed-parameter algorithm for parameter k , the maximum Hamming distance bound, was given by Gram et al. [22], runs in $O(k^k \cdot km + mn)$ time where m and n denote the number and the length of input strings, respectively. This algorithm works for arbitrary alphabet Σ . For small alphabets Σ , there are algorithms with $O(mn + n \cdot |\Sigma|^{O(k)})$ running time [31, 9]. Both types of running time are tight under the ETH [12, Theorem 14.17]. For arbitrary alphabet Σ , Knop et al. [28] gave an algorithm with $m^{O(m^2)} \cdot \log n$ running time based on so-called n -fold integer programming. As for approximability, CLOSEST STRING admits a PTAS with running time $O(n^{O(\epsilon^{-2})})$ [31] but no EPTAS unless $\text{FPT} = \text{W}[1]$ [13].

Our problem falls into the general framework of convex optimization with binary variables. If the input and the output are allowed to have fractional values, then the underlying convex optimization problem, called L_p -NORM CONVEX MINIMIZATION, can be solved in polynomial time for each fixed value $p \leq 2$ [34, Chapter 6.3.2]. This convex optimization problem is a special variant of the in general NP-hard L_p SUBSPACE APPROXIMATION problem [14, 23]. This problem has as input m points s_1, \dots, s_m in \mathbb{R}^n and an integer k' , and asks to find a subspace H of \mathbb{R}^n of dimension k' that minimizes the following $\sum_{i=1}^m (\text{dist}^p(H, a_i))^{1/p}$, where $\text{dist}(H, a_i)$ is the minimum Euclidean distance between a_i and any point in H . For $k = 0$, L_p SUBSPACE APPROXIMATION is equivalent to the L_p -NORM CONVEX MINIMIZATION.

For $p \in \{2, 3\}$, maximizing (instead of minimizing) the p -norm reduces to MIRKIN MINIMIZATION in consensus clustering with input and output restricted to two-clusters, which was shown to be NP-hard [15] under Turing reductions. Recently, Chen et al. [7] showed that the simple 2^n -time algorithm by brute-force searching all possible outcome solutions is essentially tight under ETH. They also provided some efficient algorithms and showed that the problem admits an FPTAS using a simple rounding technique.

2 NP-hardness for the p -Norm of Hamming Distance Vectors

We now show that p -HDC is NP-hard for each fixed rational number $p > 1$ (Theorem 3 and Proposition 6) and that algorithms with running time $2^{o(n+m)}$ or $2^{o(k^{p/(p+1)})}$ would contradict the ETH. We reduce from the NP-hard 3-COLORING problem [19] in which, given an undirected graph $G = (V, E)$, we ask whether there is a *proper vertex coloring* $\text{col}: V \rightarrow \{0, 1, 2\}$, that is, no two *adjacent* vertices receive the same color.

The first challenge we need to overcome when designing the reduction is to produce some regularity in the solution string: Given $\hat{n} \in \mathbb{N}$, in Lemma 1, we show how to construct a set of strings to enforce a solution string to have exactly \hat{n} ones which only occur in the columns of some specific range. This allows us later on to build gadgets that have several discrete states. Indeed, after controlling the overall number of ones in the solution in this way, we can allocate three columns (one for each color) for each vertex v in G and build a gadget for v such that this gadget induces minimum p -distance to the solution if and only if there is exactly 1 one in the solution in the columns allocated for v . This column determines the color for v . Then, for each edge, we will introduce an edge gadget consisting of six strings which induce minimum p -distance in the solution if and only if they are “covered” by the ones in the solution exactly twice, corresponding to different colors.

In general, the design of gadgets for p -HDC is quite different from the known NP-hard case CLOSEST STRING ($p = \infty$) [18, 29]: In CLOSEST STRING every optimal solution s^* must regard the “worst” possible input string while in our case s^* can escape such constraints by distributing some of its Hamming distance from the “worst” to other strings.

In the remainder of this section, let a and b be two fixed integers such that a and b are coprime, $a > b$, and $p = a/b > 1$. To better capture the Hamming distance, we introduce the notion of the *Hamming set* of two strings s and s' of equal length n , which consists of the indices of the columns at which both strings differ: $\text{hs}(s, s') = \{j \in [n] \mid s[j] \neq s'[j]\}$.

As mentioned, we first show how to construct a set of strings to enforce some structure on the optimal solution, that is, a binary string with minimum sum of the p -distances.

► **Lemma 1** (\star^1). *Let $p > 1$ be a fixed rational number, and a and b be two coprime fixed integers with $p = a/b$. Let S consist of one string $\mathbf{1}_{(2^b+1)\hat{n}}\mathbf{0}_{\hat{n}}$ and 2^{a-b} copies of string $\mathbf{0}_{(2^b+2)\hat{n}}$, where \hat{n} is a positive integer. For each string $s^* \in \{0, 1\}^{(2^b+2)\hat{n}}$, the following holds.*

- (1) *If $d(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) = \hat{n}$ and $\text{hs}(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \subseteq [(2^b+1)\hat{n}]$, then $\|(s^*, S)\|_p^p = (2^a + 2^{a-b}) \cdot \hat{n}^p$.*
- (2) *If $d(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \neq \hat{n}$ or $\text{hs}(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \not\subseteq [(2^b+1)\hat{n}]$, then $\|(s^*, S)\|_p^p > (2^a + 2^{a-b}) \cdot \hat{n}^p$.*

To show Lemma 1 we crucially use the fact that $p > 1$. In contrast, if $p = 1$, then taking the majority value in each column yields an optimal solution, and thus it is impossible to force every optimal solution to have a certain number of ones without at the same time specifying in which precise columns these ones should occur.

In the reduction we make heavy use of specific pairs of strings whose Hamming distances to an arbitrary string always sum up to some lower bound. They will enforce local structure in some columns of the solution, while being somewhat immune to changes elsewhere. As a tool in the reduction we derive the following lower bound on the p -distance of an arbitrary string to a pair of strings which are quite far from each other, in terms of Hamming distances.

► **Lemma 2** (\star). *Let s_1 and s_2 be two strings of the same length R such that the Hamming distance between s_1 and s_2 is $d(s_1, s_2) = 2L$. For each rational $p > 1$ and each length- R string \hat{s} the following holds.*

- (1) $d^p(\hat{s}, s_1) + d^p(\hat{s}, s_2) \geq 2 \cdot L^p$.
- (2) *If $d(\hat{s}, s_1) = d(\hat{s}, s_2) = L$, then $d^p(\hat{s}, s_1) + d^p(\hat{s}, s_2) = 2 \cdot L^p$.*
- (3) *If $d(\hat{s}, s_1) \neq L$ or $d(\hat{s}, s_2) \neq L$, then $d^p(\hat{s}, s_1) + d^p(\hat{s}, s_2) > 2 \cdot L^p$.*

Using Lemmas 1 and 2, we can show NP-hardness of p -HDC for each fixed rational $p > 1$. For better readability, we will first show hardness for the case with multiple identical strings (Theorem 3) and then extend the construction to also include the case where no two strings are the same (Proposition 6).

¹ Proofs for results marked by \star can be found in [8].

► **Theorem 3.** For each fixed rational number $p > 1$, p -HDC (with possibly multiple identical strings) is NP-hard.

Proof. First of all, let a and b be two fixed coprime integers such that $p = a/b$. To show the hardness result, we reduce from the NP-hard 3-COLORING problem [19] defined above. Let $G = (V, E)$ be an instance of 3-COLORING. Let n be the number of vertices in G and m the number of edges. Denote $V = \{v_1, v_2, \dots, v_n\}$ and $E = \{e_1, e_2, \dots, e_m\}$.

Construction. We introduce three groups of strings of length $(2^b + 2) \cdot \hat{n}$ each, where $\hat{n} = n + m$. The first group ensures that each optimal solution string must have exactly \hat{n} ones which appear in the first $3\hat{n}$ columns (using Lemma 1), the second group ensures that an optimal solution enforces that each vertex has exactly one of the three colors, and the third group, combined with the second group, ensures that no two adjacent vertices obtain the same color.

Group 1. Construct one string $\mathbf{1}_{(2^b+1)\hat{n}} \circ \mathbf{0}_{\hat{n}}$ and 2^{a-b} copies of the same string $\mathbf{0}_{(2^b+2)\hat{n}}$.

Group 2. This group consists of one pair of strings for each vertex. Each pair consists of two strings which are mostly complements to each other. This ensures that the Hamming distance to the solution induced by a pair is somewhat homogeneous, regardless where exactly the ones in the solution occur. However, in each pair there are three columns, corresponding to the vertex, which will skew the pairs of Hamming distances in a way to induce minimum p -distances only if the solution has exactly 1 one in these three columns. Formally, for each vertex $v_i \in V$, let u_i be a string of length $3\hat{n}$ which has exactly 3 ones in the columns $3i - 2, 3i - 1, 3i$, and let \bar{u}_i be the complement of u_i . Deriving from u_i , we construct two *vertex strings* s_i and r_i with $s_i := u_i \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{0} \circ \mathbf{1}_{\hat{n}-1}$ and $r_i := \bar{u}_i \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{1} \circ \mathbf{0}_{\hat{n}-1}$. Note that both strings s_i and r_i have all zeros in the columns $\{3\hat{n}, \dots, (2^b + 1)\hat{n}\}$ such that $d(s_i, r_i) = 4\hat{n}$.

For an illustration, the strings s_2 and r_2 , which correspond to the vertex v_2 , are as follows:
 $s_2 = \mathbf{000111} \circ \mathbf{0}_{3\hat{n}-6} \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{0} \circ \mathbf{1}_{\hat{n}-1}$, $r_2 = \mathbf{111000} \circ \mathbf{1}_{3\hat{n}-6} \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{1} \circ \mathbf{0}_{\hat{n}-1}$.

Group 3. We now use three pairs of strings for each edge to ensure relatively homogeneous distributions of Hamming distances to the solution and then skew them. This time, we aim to skew distances to the solution so that their corresponding p -distances are minimum only if the solution distributes exactly three ones (corresponding to the colors) over three special regions: two corresponding to the endpoints of the edge and one extra dummy region.

Formally, for each edge $e_j \in E$ let $e_j^{(0)}, e_j^{(1)}$, and $e_j^{(2)}$ denote three strings, each of length $3\hat{n}$, that ensure that the edge and both of its endpoints each have a distinct color:

$$\forall \ell \in \{1, 2, \dots, \hat{n}\}: e_j^{(0)}[3\ell - 2, 3\ell - 1, 3\ell] := \begin{cases} 100, & 1 \leq \ell \leq n \text{ with } v_\ell \in e_j, \text{ or } \ell = j + n, \\ 000, & \text{otherwise.} \end{cases}$$

$$e_j^{(1)}[3\ell - 2, 3\ell - 1, 3\ell] := \begin{cases} 010, & 1 \leq \ell \leq n \text{ with } v_\ell \in e_j, \text{ or } \ell = j + n, \\ 000, & \text{otherwise.} \end{cases}$$

$$e_j^{(2)}[3\ell - 2, 3\ell - 1, 3\ell] := \begin{cases} 001, & 1 \leq \ell \leq n \text{ with } v_\ell \in e_j, \text{ or } \ell = j + n, \\ 000, & \text{otherwise.} \end{cases}$$

Now, we construct the following six *edge strings* for edge e_j :

$$\forall z \in \{0, 1, 2\}: t_j^{(z)} := e_j^{(z)} \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{0} \circ \mathbf{1}_{\hat{n}-1} \text{ and } w_j^{(z)} := \bar{e}_j^{(z)} \circ \mathbf{0}_{(2^b-2)\hat{n}} \circ \mathbf{1} \circ \mathbf{0}_{\hat{n}-1}.$$

Just as for group 2, the two strings $t_j^{(z)}$ and $w_j^{(z)}$ have all zeros in the columns $\{3\hat{n}, \dots, (2^b + 1)\hat{n}\}$ such that $d(t_j^{(z)}, w_j^{(z)}) = 4\hat{n}$.

■ **Figure 1** Illustration of the reduction used in Theorem 3. The left figure depicts a graph G that admits a proper vertex coloring col (see the labels on the vertices). For instance, vertex v_1 has color 0, i.e., $\text{col}(v_1) = 0$. The right figure shows the crucial part of an instance of p -HDC with $p = 2$ (i.e., $a = 2$ and $b = 1$) that we will construct according to the proof for Theorem 3. For each pair of constructed strings we only show the first one. A solution string s^* corresponding to the coloring col is depicted at the bottom of the right figure.

For an example, assume that $a = 3$, $b = 2$, $n = 3$, and $m = 2$, and there is an edge of the form $e_2 = \{v_1, v_3\}$. Then, the two triples of strings that we construct for e_2 have each length $(2^b + 2)(n + m) = 30$ and are

$$\begin{aligned}
 t_j^{(0)} &= 100\ 000\ 100\ 000\ 100\ 0000000000\ 01111, & w_j^{(0)} &= 011\ 111\ 011\ 111\ 011\ 0000000000\ 10000, \\
 t_j^{(1)} &= 010\ 000\ 010\ 000\ 010\ 0000000000\ 01111, & w_j^{(1)} &= 101\ 111\ 101\ 111\ 101\ 0000000000\ 10000, \\
 t_j^{(2)} &= 001\ 000\ 001\ 000\ 001\ 0000000000\ 01111, & w_j^{(2)} &= 110\ 111\ 110\ 111\ 110\ 0000000000\ 10000.
 \end{aligned}$$

Summarizing, the instance I' of p -HDC consists of the following strings, each of length $(2^b + 2)\hat{n} = (2^b + 2)(n + m)$:

- (1) Add the $2^{a-b} + 1$ strings in group 1 to I' .
- (2) For each vertex $v_i \in V$, add the vertex strings s_i and r_i to I' .
- (3) For each edge $e_j \in E$, add two triples $t_j^{(0)}, t_j^{(1)}, t_j^{(2)}$ and $w_j^{(0)}, w_j^{(1)}, w_j^{(2)}$ to I' .

See Figure 1 for an illustration.

Finally, we define k such that $k^p = (2^a + 2^{a-b}) \cdot \hat{n}^p + 2(n + 3m) \cdot (2\hat{n})^p$. This completes the construction, which can clearly be done in polynomial time.

Correctness of the construction. Before we show the correctness of our construction, we define a notion and make an observation. Let s and s' be two strings of equal length. We say that s covers s' exactly once if there is exactly one integer $\ell \in \{1, 2, \dots, |s|\}$ with $s[\ell] = s'[\ell] = 1$.

▷ Claim 4 (★). Let s^* and s be two strings, both of length $4\hat{n}$, such that

(i) s^* has exactly \hat{n} ones and each of them is in the first $3\hat{n}$ columns, and

(ii) in s , the first $3\hat{n}$ columns have exactly 3 ones and the last \hat{n} columns are $0 \circ \mathbf{1}_{\hat{n}-1}$.

Then, if s^* covers s exactly once, then $d^p(s^*, s) + d^p(s^*, \bar{s}) = 2 \cdot (2\hat{n})^p$; else $d^p(s^*, s) + d^p(s^*, \bar{s}) > 2 \cdot (2\hat{n})^p$.

We show that G has a proper 3-coloring if and only if there is a string s^* such that the sum of the p -distances from s^* to all strings in I' is at most $k^p = (2^a + 2^{a-b}) \cdot \hat{n}^p + 2(n+3m) \cdot (2\hat{n})^p$.

For the “if” direction, let s^* be a string which has a sum of p -distances of at most k^p to all strings in I' . Before we define a coloring for the vertices and show that it is proper we observe several properties of the solution string s^* .

By Lemma 2(1), the sum of p -distances to all strings from group 2 and group 3 is at least $2 \cdot (2\hat{n})^p \cdot (n+3m)$ since these groups consist of $n+3m$ pairs of strings, and the strings in each of these pairs have Hamming distance exactly $4\hat{n}$ to each other. By the definition of k , the sum of p -distances from s^* to the first of group of strings is thus at most $(2^a + 2^{a-b}) \cdot \hat{n}^p$. Hence, by the contra-positive of Lemma 1(2), the solution string s^* has exactly \hat{n} ones, which all appear in the first $(2^b + 1)\hat{n}$ columns, i.e., $d(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) = \hat{n}$ and $\text{hs}(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \subseteq [(2^b + 1)\hat{n}]$. By Lemma 1(1), this implies that

$$\sum_{s \in \text{group 1}} d^p(s^*, s) = (2^a + 2^{a-b}) \cdot \hat{n}^p. \quad (1)$$

Next, we claim that the ones in the solution s^* indeed all appear in the first $3\hat{n}$ columns, i.e., $\text{hs}(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \subseteq [3\hat{n}]$. Suppose, for the sake of contradiction, that solution s^* contains x ones which appear in columns ranging from $3\hat{n} + 1$ to $(2^b + 1)\hat{n}$ with $x > 0$. Consider an arbitrary pair of strings s_i and r_i from group 2 or an arbitrary pair of strings $t_i^{(z)}$ and $w_i^{(z)}$ from group 3; for the sake of readability, represent them by s and s' . By construction, strings s and s' have Hamming distance exactly $4\hat{n}$ to each other, but have all zeros in the columns between $3\hat{n} + 1$ and $(2^b + 1)\hat{n}$. Since $x > 0$, by the triangle inequality of Hamming distances, it follows that at least one string from the pair, s or s' , has Hamming distance more than $2\hat{n}$ from s^* . However, by Lemma 2(3), this means that the sum of p -distances from s^* to $\{s, s'\}$ exceeds $2 \cdot (2\hat{n})^p$. Since there are in total $n + 3m$ such pairs in groups 2 and 3, the sum of p -distances from s^* to these groups exceeds $2(n + 3m) \cdot (2\hat{n})^p$, a contradiction to equation (1) and the defined bound k . Thus, indeed, it holds that

$$d(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) = \hat{n} \text{ and } \text{hs}(s^*, \mathbf{0}_{(2^b+2)\hat{n}}) \subseteq [3\hat{n}]. \quad (2)$$

This implies that, when determining the p -distance of s^* to the strings from group 2 and group 3, we can ignore, the values in the columns ranging from $3\hat{n} + 1$ to $(2^b + 1)\hat{n}$, in each string, which includes the solution s^* , because s^* also has only zeros in these columns. We will hence from now on treat these columns as if they do not exist. In this way, we obtain strings of length $4\hat{n}$. Again, consider an arbitrary pair of strings s_i and r_i from group 2 (resp. an arbitrary pair of strings $t_i^{(z)}$ and $w_i^{(z)}$ from group 3), and represent them by s and s' . Since we ignore columns $3\hat{n} + 1$ to $(2^b + 1)\hat{n}$, string s' is the complement of s . By construction, the Hamming distance between s and s' is exactly $4\hat{n}$. Using Claim 4 on s^* , s, s' , the sum of p -distances from s^* to the pair $\{s, s'\}$ is indeed equal to $2 \cdot (2\hat{n})^p$. By the same claim, it follows that s^* covers each string s_i (resp. $t_j^{(z)}$) from group 2 (resp. group 3) exactly once.

Having this property, we are ready to color the vertices. Let $\text{col}: V \rightarrow \{0, 1, 2\}$ be a mapping defined as follows. For each $v_i \in V$, set $\text{col}(v_i) = z$ where $z \in \{0, 1, 2\}$ such that $s^*[3i - 2 + z] = 1$. Note that, since s^* covers s_i exactly once and since s_i has exactly three

ones in the columns $3i - 2$, $3i - 1$, and $3i$, there is indeed such a z with $\text{col}(v_i)$. We claim that col is a proper coloring for G . Suppose, towards a contradiction, that there is an edge $e_j = \{v_i, v_{i'}\} \in E$ such that v_i and $v_{i'}$ have the same color from col , say $z \in \{0, 1, 2\}$. By the definition of col , this means that $s^*[3i - 2 + z] = s^*[3i' - 2 + z] = 1$. However, by the definition of the string $t_j^{(z)}$ which corresponds to the edge e_j , we also have that $t_j^{(z)}[3i - 2 + z] = t_j^{(z)}[3i' - 2 + z] = 1$. This implies that $t_j^{(z)}$ is not covered by s^* exactly once – a contradiction to our reasoning above that s^* covers each string from the third group exactly once.

For the “only if” direction, let $\text{col}: V \rightarrow \{0, 1, 2\}$ be a proper coloring for G . For an edge $e \in E$ with two endpoints $v_i, v_{i'}$, let $\text{col}(e) = \{\text{col}(v_i), \text{col}(v_{i'})\}$. We claim that string s^* , defined as follows, has the desired bound on the sum of the p -distances to all strings of I' .

$$\forall i \in \{1, 2, \dots, n\}: s^*[3i - 2, 3i - 1, 3i] := \begin{cases} 100, & \text{col}(v_i) = 0, \\ 010, & \text{col}(v_i) = 1, \\ 001, & \text{col}(v_i) = 2. \end{cases}$$

$$\forall j \in \{n + 1, n + 2, \dots, \hat{n}\}: s^*[3j - 2, 3j - 1, 3j] := \begin{cases} 100, & \text{col}(e_j) = \{1, 2\}, \\ 010, & \text{col}(e_j) = \{0, 2\}, \\ 001, & \text{col}(e_j) = \{0, 1\}. \end{cases}$$

$$s^* \Big|_{3\hat{n}+1}^{(2^b+2)\hat{n}} := \mathbf{0}_{\hat{n}}.$$

First of all, since col is a proper coloring, s^* is well defined in all $(2^b + 2)\hat{n}$ columns. Moreover, it has exactly n ones in the first $3n$ columns and exactly m ones in the next $3m$ columns, and all zeros in the remaining columns. Thus, by Lemma 1(2), the sum of the p -distances from s^* to the first group of strings is $(2^a + 2^{a-b}) \cdot \hat{n}^p$.

Now, we focus on strings from group 2 and group 3. Since the solution s^* and each string in these groups have only zeros in the columns between $3\hat{n} + 1$ and $(2^b + 1)\hat{n}$, we can simply ignore the values in these columns and assume from now on that the strings have length $4\hat{n}$. Moreover, for each $i \in [n]$, the pair s_i and r_i can be considered as complement to each other. Thus, for each string s_i from group 2, s^* and s_i fulfill the properties stated in Claim 4. Moreover, by definition, s^* covers s_i exactly once. Thus, by the same claim, we have that the sum of the p -distances from s^* to all strings in group 2 is $n \cdot 2 \cdot (2\hat{n})^p$.

Analogously, consider a string $t_j^{(z)}$ from group 3, $j \in \{1, 2, \dots, m\}$ and $z \in \{0, 1, 2\}$. Recall that $t_j^{(z)}$ corresponds to the edge e_j , and let v_i and $v_{i'}$ be the two endpoints of edge e_j . We claim that s^* covers $t_j^{(z)}$ exactly once. Observe that $t_j^{(z)}$ has exactly 3 ones in the first $3\hat{n}$ columns, namely at columns $3i - 2 + z$, $3i' - 2 + z$, and $3n + 3j - 2 + z$. To prove that s^* covers $t_j^{(z)}$ exactly once, it suffices to show that s^* has 1 one in exactly one of these three columns. To show this, we consider the substrings $t_j^{(z)} \Big|_{3n+3j-2}^{3n+3j}$ and $s^* \Big|_{3n+3j-2}^{3n+3j}$.

Case 1: $s^* \Big|_{3n+3j-2}^{3n+3j} = t_j^{(z)} \Big|_{3n+3j-2}^{3n+3j}$. By the definition of s^* , this implies that $s^*[3n + 3j - 2 + z] = 1$ and $\text{col}(e_j) = \{0, 1, 2\} \setminus \{z\}$. We claim that $s^*[3i - 2 + z] = s^*[3i' - 2 + z] = 0$. By the definition of s^* regarding the columns that correspond to the endpoint v_i of edge e_j , we have that $s^*[3i - 2 + \text{col}(v_i)] = 1$ while $s^*[3i - 2 + z] = 0$ (since $z \notin \text{col}(e_j) = \{\text{col}(v_i), \text{col}(v_{i'})\}$). Analogously, by the definition of s^* regarding the columns that correspond to the other endpoint $v_{i'}$ of edge e_j , we have that $s^*[3i' - 2 + \text{col}(v_{i'})] = 1$ while $s^*[3i' - 2 + z] = 0$ (since $z \notin \text{col}(e_j) = \{\text{col}(v_i), \text{col}(v_{i'})\}$). Thus, $3n + 3j - z$ is the only column in which both s^* and $t_j^{(z)}$ have 1 one, implying that s^* covers $t_j^{(z)}$ exactly once.

Case 2: $s^*|_{3n+3j-2}^{3n+3j} \neq t_j^{(z)}|_{3n+3j-2}^{3n+3j}$. This means that $s^*[3n+3j-2+z] = 0$ and that $z \in \text{col}(e_j)$. To show that s^* covers $t_j^{(z)}$ exactly once in this case, it suffices to show that either $s^*[3i-2+z] = 1$ and $s^*[3i'-2+z] = 0$, or $s^*[3i-2+z] = 0$ and $s^*[3i'-2+z] = 1$.

- Assume that $s^*[3i-2+z] = 1$. Then, by the definition of s^* regarding the columns that correspond to the endpoint v_i of edge e_j , this means that $\text{col}(v_i) = z$. Since col is a proper coloring, it follows that $\text{col}(v_{i'}) \neq z$. Thus, again by the definition of s^* regarding the columns that correspond to the other endpoint $v_{i'}$ of edge e_j , it follows that $s^*[3i'-2+z] = 0$.
- Assume that $s^*[3i-2+z] = 0$. Then, by the definition of s^* regarding the columns that correspond to the endpoint v_i of edge e_j , we have $\text{col}(v_i) \neq z$. Since $z \in \text{col}(e_j)$ and col is a proper coloring, the other endpoint $v_{i'}$ of edge e_j must have color $\text{col}(v_{i'}) = z$. Again, by the definition of s^* regarding the columns that correspond $v_{i'}$, it follows that $s^*[3i'-2+z] = 1$.

We have just shown that s^* covers $t_j^{(z)}$ exactly once. Since s^* and $t_j^{(z)}$ fulfill the property stated in Claim 4, it follows from the same claim that the sum of p -distances from s^* to $t_j^{(z)}$ and to $w_j^{(z)}$ is $2 \cdot (2\hat{n})^p$. There are $3m$ pairs in this group. So, the sum of the p -distances from s^* to all strings of this group is $3m \cdot 2 \cdot (2\hat{n})^p$.

In total, the sum of the p -distances from s^* to all strings of I' is $(2^a + 2^{a-b}) \cdot \hat{n}^p + 2 \cdot (2\hat{n})^p \cdot (n + 3m) = k^p$, as required. ◀

Our NP-hardness reduction implies the following running time lower bounds [12].

► **Corollary 5** (★). *For each fixed rational number $p > 1$, unless the ETH fails, no $2^{o(\hat{n}+\hat{m})} \cdot |I'|^{O(1)}$ -time or $2^{o(k^{p/(p+1)})} \cdot |I'|^{O(1)}$ -time algorithm exists that decides every given instance I' of p -HDC where \hat{n} is the length of the input strings, \hat{m} is the number of input strings, and k is the p -norm bound.*

Using a slight modification of the construction, we can show that our results are not idiosyncratic to instances which contain some strings multiple times. (Recall that the gadget from Lemma 1 in the construction contains 2^{a-b} copies of the all-zero string.) The basic idea is to append an identity matrix to the strings we need to distinguish, and then to show using a slightly more involved analysis that the gadgets still work in the same way.

► **Proposition 6** (★). *Theorem 3 and Corollary 5 hold even if all input strings are distinct.*

Let p -NORM APPROVAL COMMITTEE be the variant of p -HDC in which we additionally get $t \in \mathbb{N}$ as an input and require the number of ones in the solution string s^* to be exactly t [39]. Note that in the proof of Theorem 3 we have first shown that each solution string contains exactly \hat{n} ones. Thus, the reduction works in the same way for p -NORM APPROVAL COMMITTEE when we specify $t = \hat{n}$ in the constructed instance. We hence obtain the following.

► **Corollary 7**. *For each fixed rational $p > 1$, p -NORM APPROVAL COMMITTEE is NP-hard and admits no algorithm running in $2^{o(\hat{n}+\hat{m})} \cdot |I'|^{O(1)}$ -time or in $2^{o(k^{p/(p+1)})} \cdot |I'|^{O(1)}$ -time unless the ETH fails, where \hat{n} is the number of candidates, \hat{m} is the number of voters, and k is the p -norm bound.*

3 Algorithmic Results

We now turn to our positive results. In Section 3.1 we provide an efficient algorithm when the objective value k is small. In Section 3.2, we derive an integer convex programming formulation to obtain an efficient algorithm for instances where the number m of input strings is small. Finally, we give a simple 2-approximation in Section 3.3.

3.1 A Subexponential-Time Algorithm

In this section, we present an algorithm with running time $2^{k^{p/(p+1)+\epsilon}} \cdot |I|^{O(1)}$ for any $\epsilon > 0$ and input instance I with distance bound k . By the lower bound result given in Corollary 5, we know that under ETH, the running time of the obtained algorithm is tight.

The algorithm is built on two subcases, distinguishing on a relation between the number m of input strings and the distance bound k . In each subcase we use a distinct algorithm that runs in subexponential time when restricted to that subcase. To start with, a dynamic programming algorithm which keeps track of the achievable vector of Hamming distances to each input string after columns 1 to $j \leq n$ has running time $O(n \cdot k^m)$.

► **Lemma 8** (\star). *p -HDC can be solved in $O(n \cdot k^m)$ time and space, where m and n are the number and the length of the input strings, respectively, and k is the p -norm distance bound.*

The dynamic program given in Lemma 8 is efficient if there is a small number m of input strings only. In particular, if m satisfies $m \leq \frac{k^{p/(p+1)}}{\log k}$, then we immediately obtain an $O(n \cdot 2^{k^{p/(p+1)}})$ -time algorithm. Otherwise, we can use Lemma 9. The algorithm behind Lemma 9 is based on a different but related idea as the fixed-parameter algorithm for CLOSEST STRING given by Gramm et al. [22]: We use data reduction to shrink the length of the strings by k^p , observe that one of the input strings must be close to a solution with bound k if it exists, and then find the solution by a search tree.

► **Lemma 9**. *p -HDC can be solved in $O(nm^2 \cdot k^{\frac{p \cdot k}{\sqrt[p]{m}}})$ time, where m and n are the number and the length of the input strings, respectively, and k is the p -norm distance bound.*

Proof. Let $I = (S, k)$ be an instance of p -HDC with $S = (s_1, \dots, s_m)$ being the input strings of length n and k being the p -norm distance bound. To show the statement, we first observe that if a column is an all-zero (resp. an all-one) column, then we can simply assume that an optimal solution will also have zero (resp. one) in this column as our objective function is convex. By preprocessing all columns that are either an all-zero or an all-one vector, we obtain an equivalent instance, where each column has at least a zero and at least a one. Thus, for each column, no matter which value a solution has at this column, it will always induce Hamming distance of at least one to some input string. Consequently, if there are more than k^p columns remaining, then we can simply answer “no” as any string will have cost more than k to the input. Otherwise, there remain at most k^p columns.

If I is a yes-instance, meaning that there is a solution s^* for I with $\|(s^*, S)\|_p \leq k$, then there is an input string $s^{**} \in S$ whose Hamming distance satisfies $d(s^{**}, s^*) \leq \sqrt[p]{\frac{k^p}{m}} = \frac{k}{\sqrt[p]{m}}$. Thus, we iterate over all input strings in S , assuming in each iteration that the current string is the aforementioned s^{**} . For each string s_i that we assume to be the aforementioned s^{**} , we go over all strings \hat{s} that differ from s_i by k' columns with $k' \leq \frac{k}{\sqrt[p]{m}}$. We check whether $\|(\hat{s}, S)\|_p \leq k$. We answer “no” if for each input string $s_i \in S$, no length- n string \hat{s} with $d(s_i, \hat{s}) \leq \frac{k}{\sqrt[p]{m}}$ exists which satisfies $\|(\hat{s}, S)\|_p \leq k$.

It remains to show the running-time bound. Observe that the preprocessing for all-zero and all-one columns can be done in $O(nm)$ time. After that, for each of the m input strings s_i , we search all strings of Hamming distance at most $k' \leq \frac{k}{\sqrt[p]{m}}$ to s_i , and there are $O(n^{\frac{k}{\sqrt[p]{m}}})$ such strings. For each of them, we compute the objective function, which can be accomplished in $O(nm)$ time. As already reasoned, after the preprocessing, n is upper-bounded by k^p . Thus, the overall running time bound is $O(nm + nm^2 \cdot n^{\frac{k}{\sqrt[p]{m}}}) = O(nm^2 \cdot k^{\frac{p \cdot k}{\sqrt[p]{m}}})$, as claimed. ◀

Combining Lemma 8 with Lemma 9, we obtain a subexponential algorithm with respect to k .

► **Theorem 10.** *For each fixed positive value $\varepsilon > 0$, p -HDC can be solved in $O(nm^2 \cdot 2^{k^{p/(p+1)+\varepsilon}})$ time, where n and m denote the length and the number of input strings, and k is the p -norm distance bound with $p > 1$.*

Proof. Let $I = (S, k)$ be an instance of p -HDC with $S = (s_1, \dots, s_m)$ being the input strings of length n and k being the p -norm distance bound. As already discussed, to solve our problem we distinguish between two cases, depending on whether $m \leq \frac{k^{p/(p+1)}}{\log k}$ holds.

If $m \leq \frac{k^{p/(p+1)}}{\log k}$, then $k^m \leq k^{\frac{k^{p/(p+1)}}{\log k}} \leq 2^{k^{p/(p+1)}}$. In this case, we use the dynamic programming approach given in the proof of Lemma 8, which has the desired running time $O(n \cdot k^m) = O(n \cdot 2^{k^{p/(p+1)}})$.

Otherwise, $m > \frac{k^{p/(p+1)}}{\log k}$, meaning that $\frac{p \cdot k \cdot \log k}{\sqrt[p]{m}} < p \cdot k \cdot \log k / \sqrt[p]{\frac{k^{p/(p+1)}}{\log k}} = p \cdot k^{p/(p+1)} \cdot (\log k)^{(p+1)/p}$. For each fixed positive $\varepsilon \in \mathbb{R}$ there exists $k_0 = k_0(p, \varepsilon) \in \mathbb{R}$ such that, for each $k \geq k_0$, we have $p \cdot (\log k)^{(p+1)/p} < k^\varepsilon$. If $k < k_0$, then the algorithm in the proof of Lemma 9 runs in $O(nm^2)$ time. Otherwise $k \geq k_0$, which implies $\frac{p \cdot k \cdot \log k}{\sqrt[p]{m}} < k^{p/(p+1)+\varepsilon}$. Thus, the algorithm given in the proof of Lemma 9 has a running time of $O(nm^2 \cdot k^{\frac{p \cdot k}{\sqrt[p]{m}}}) = O(nm^2 \cdot 2^{\frac{p \cdot k \cdot \log k}{\sqrt[p]{m}}}) = O(nm^2 \cdot 2^{k^{p/(p+1)+\varepsilon}})$.

Altogether we presented an algorithm which has the desired running time bound. ◀

3.2 A Fixed-Parameter Algorithm for the Number of Input Strings

In this section, we show that minimizing the sum of the p -distances is fixed-parameter tractable for the number m of input strings. The idea is to formulate our problem as a combinatorial n -fold integer program (CnIP) with $O(2^m)$ variables and $O(m)$ constraints. We then apply the following simplified result of Knop et al. [28]:

► **Proposition 11** ([28, Theorem 3]). *Let $E \in \mathbb{Z}^{(r+1) \times t}$ be a matrix such that the last row equals $(1, 1, \dots, 1) \in \mathbb{Z}^t$. Let $b \in \mathbb{Z}^{r+1}$, $\ell, u \in \mathbb{Z}^t$, and let $f: \mathbb{R}^t \rightarrow \mathbb{R}$ be a separable convex function given by an evaluation oracle². Then, there is an algorithm that solves³ $P := \min\{f(x) \mid Ex = b \wedge \ell \leq x \leq u \wedge x \in \mathbb{Z}^t\}$ in $t^{O(r)} \cdot ((1 + \|E\|_\infty) \cdot r)^{O(r^2)} \cdot L + T$ time, where L is the total bit-length of b, ℓ, u , and the oracle of f , and T is the time that an algorithm needs to solve the continuous relaxation of P .*

To get a useful running time bound from Proposition 11, we need a bounded number of variables. To do this, we group columns in the input strings with the same “type” together and introduce an integer variable for each column type. To this end, given a set $S = \{s_1, \dots, s_m\}$ of length- n strings, we say that two columns $j, j' \in [n]$ have the *same type* if for each $i \in [m]$ it holds that $s_i[j] = s_i[j']$. The *type* of column j is its equivalence class in the same-type relation. Thus, each type is represented by a vector in $\{0, 1\}^m$. Let n' denote the number of different (column) types in S . Then, $n' \leq \min(2^m, n)$. Enumerate the n' column types as $t_1, \dots, t_{n'}$. Below we identify a column type with its index for easier notation. Using this, we can encode the set S succinctly by introducing a constant $e(j)$ for each column type $j \in [n']$ that denotes the number of columns with type j . Given a solution string s^* , we can also encode this string s^* via an integer vector $x \in \{0, 1, \dots, n\}^{n'}$, where for each type $j \in [n']$ we define $x[j]$ as the number of ones in the solution s^* whose corresponding columns are of type j . Note that this encodes all essential information in a solution, since the actual

² A function is separable convex if it is the sum of univariate convex functions.

³ The algorithm correctly reports either a minimizer $x \in P$ or that P is infeasible or unbounded.

order of the columns is not important (see Example 12). Vice versa, each integer vector in $x \in \{0, 1, \dots, n\}^{n'}$ satisfying $0 \leq x[j] \leq e(j)$ for each $j \in [n']$ yields a length- n binary string $s^*(x)$; it remains to add constraints and a suitable objective function to ensure that $s^*(x)$ has minimum sum of p -distances to the input strings.

► **Example 12.** For an illustration, let $S = \{0000, 0001, 1110\}$. The set S has two different column types, represented by $(0, 0, 1)^T$, call it type 1, and $(0, 1, 0)^T$, call it type 2. There are three columns of type 1 and one column of type 2. The solution 0110 for S can be encoded by two variables $x[1] = 2$ and $x[2] = 0$.

We next introduce m variables $y \in \{0, 1, \dots, n\}^m$ that shall be equal to the Hamming distances of each input string s_i , $i \in [m]$, to the solution $s^*(x)$ selected by x . To achieve this, we need a formula specifying the Hamming distance between the two strings s_i and $s^*(x)$, and this formula needs to be linear in x . This can be achieved as follows; for the sake of simplicity, we let $s_i[j] = 1$ if the column of type j has one in the i^{th} row and $s_i[j] = 0$ if it has zero in the i^{th} row: $d(s_i, s^*(x)) = \sum_{j=1}^{n'} (s_i[j] \cdot (e(j) - x[j]) + (1 - s_i[j]) \cdot x[j]) = \sum_{j=1}^{n'} (e(j) \cdot s_i[j] + (1 - 2s_i[j]) \cdot x[j]) = w_i + \sum_{j=1}^{n'} x[j] \cdot (1 - 2s_i[j])$, where we define $w_i := \sum_{j=1}^{n'} e(j) \cdot s_i[j]$, which denotes the number of ones in string s_i .

We can now formulate an appropriate CnIP. The variables are $x \in \mathbb{R}^{n'}$, $y \in \mathbb{R}^m$, and a dummy variable $z \in \mathbb{Z}$. The bounds ℓ, u for the variables are defined such that

- (1) for each $j \in [n']$ it holds that $0 \leq x[j] \leq e(j)$,
- (2) for each $i \in [m]$ it holds that $0 \leq y[i] \leq n$, and
- (3) there is virtually no constraint on z , that is, $-n' \cdot n + mn \leq z \leq n' \cdot n + mn$.

The objective function is defined as $f(x, y, z) = \sum_{i=1}^m y[i]^p$ which is clearly separable convex over the domain specified by ℓ and u . Finally, the constraint system $Et = b$, where $t^T = (x^T y^T z)$ is defined such that the first m constraints are $\sum_{j=1}^{n'} (x[j] \cdot (1 - 2s_i[j])) - y[i] = -w_i$, for each $i \in [m]$, and the last constraint is $\sum_{j=1}^{n'} x[j] + \sum_{i=1}^m y[i] + z = 0$ (note that this constraint can always be fulfilled by setting z accordingly).

By the above reasoning, an instance of p -HDC is a yes-instance if and only if $\min\{f(x) \mid Et = b \wedge \ell \leq t \leq u \wedge t \in \mathbb{Z}^{n'+n+1}\}$ is at most k^p . Plugging in the running time of Proposition 11, and using a polynomial-time algorithm for the continuous relaxation of the CnIP above [10], we obtain the following.

► **Theorem 13.** p -NORM HAMMING CENTROID can be solved in $m^{O(m^2)} \cdot (n \cdot m)^{O(1)}$ time.

3.3 A Factor-2 Approximation

It is known that by taking an input string that minimizes the largest Hamming distance over all input strings, CLOSEST STRING can be approximated within factor 2. Indeed, using a similar idea, we show that the minimization version of our p -HDC problem can also be approximated within factor 2. More specifically, we show that an input string which has minimum p -norm to all other input strings is a 2-approximate solution.

► **Proposition 14** (*). *The minimization variant of p -HDC can be approximated within factor 2 in polynomial time.*

4 Conclusion and Outlook

We analyzed the complexity of p -NORM HAMMING CENTROID for all fixed rational values p between $p = 1$ and $p = \infty$. We believe that the running time bounds established in this paper, of essentially $2^{\Theta(k^{\frac{p}{p+1}})} \cdot (nm)^{O(1)}$, connect the extreme points $p = 1$ and $p = \infty$ in

a very satisfying way. We did not consider the non-norm case of $0 < p < 1$, as it does not fit our clustering motivation very well. But this non-convex case might be of independent interest, and may be the subject of future work. Furthermore, we have focused here on the case where p is a fixed constant. It would also be interesting to study the case where p is part of the input.

An interesting generalization of CLOSEST STRING is CLOSEST SUBSTRING in which we seek a string s^* of a certain specified length such that each of the input strings has a substring which is close to s^* (see, e.g., Ma and Sun [31]). It would be interesting to see how our results carry over to this and other similar variants. Finally, the fact that the simple 2-factor approximation for CLOSEST STRING carries over to p -HDC may imply that there are similar connections for approximation algorithms. This warrants further investigation into whether p -HDC admits a PTAS.

Abstract

Interactive-proof games model the scenario where an honest party interacts with powerful but strategic provers, to elicit from them the correct answer to a computational question. Interactive proofs are increasingly used as a framework to design protocols for computation outsourcing.

Existing interactive-proof games largely fall into two categories: either as games of cooperation such as multi-prover interactive proofs and cooperative rational proofs, where the provers work together as a team; or as games of conflict such as refereed games, where the provers directly compete with each other in a zero-sum game. Neither of these extremes truly capture the strategic nature of service providers in outsourcing applications. How to design and analyze non-cooperative interactive proofs is an important open problem.

In this paper, we introduce a mechanism-design approach to define a multi-prover interactive-proof model in which the provers are *rational* and *non-cooperative* – they act to maximize their expected utility given others’ strategies. We define a strong notion of backwards induction as our solution concept to analyze the resulting extensive-form game with imperfect information.

We fully characterize the complexity of our proof system under different *utility gap* guarantees. (At a high level, a utility gap of u means that the protocol is robust against provers that may not care about a utility loss of $1/u$.) We show, for example, that the power of non-cooperative rational interactive proofs with a polynomial utility gap is exactly equal to the complexity class P^{NEXP} .

complexity classes (e.g., [4, 16, 22–24, 26, 27, 37]). From a modern perspective, these games capture the essence of computation outsourcing – the honest party is a client outsourcing his computation to powerful rational service providers in exchange for money.

In this paper, we consider a natural type of interactive-proof game. For the moment, let us call our client Arthur. Arthur hires a service provider Merlin to solve a computational problem for him, and hires a second service provider Megan to cross-check Merlin’s answer. Arthur wants the game (and associated payments) to be designed such that if Merlin gives the correct answer, Megan agrees with him; however, if Merlin cheats and gives a wrong answer, Megan is incentivized to contradict him, informing Arthur of Merlin’s dishonesty. This means that Merlin and Megan are not purely cooperative nor purely competitive. Each is simply a rational agent who wants to maximize their own utility.

This is a mechanism design problem – how can Arthur incentivize non-cooperative rational agents (Merlin and Megan) to give truthful answers to his questions, helping him solve a computational problem? This problem is the focus of our paper.

Structure of the game

We borrow the structure and terminology of interactive proofs [3, 6, 29], as was done in previous work on rational proofs [1, 2, 11, 12, 17–19, 31, 32] and refereed games [16, 22, 24–26, 35, 40]. We call Arthur the **verifier** and assume that he is computationally bounded (he may be probabilistic, but must run in polynomial time). Arthur’s coin flips are treated as Nature moves in the game. We call Merlin and Megan the **provers**; they have unbounded computational power.

The verifier exchanges messages with the provers in order to determine the answer to a decision problem. The exchange proceeds in rounds: in a round, either a verifier sends a message to all provers or receives a response from each. The provers cannot observe the messages exchanged between the verifier and other provers.

At the end, the verifier gives a payment to *each* prover. Our goal is to design protocols and payments such that, under an appropriate solution concept of the resulting game, the provers’ best strategies lead the verifier to the correct answer.

The interactive protocols described above form an extensive-form game of imperfect information. To analyze them, we essentially use a strong notion of backward induction as our solution concept. We refine it further by eliminating strategies that are weakly dominated on “subgames” within the entire game. We define the solution concept formally in Section 2.1.

Comparison to previous work

The model of our games is based on interactive proof systems [3, 29], in which a verifier exchanges messages with untrustworthy provers and at the end either accepts or rejects their claim. Interactive proofs guarantee that, roughly speaking, the verifier accepts a truthful claim with probability at least $2/3$ (**completeness**) and no strategy of the provers can make the verifier accept a false claim with probability more than $1/3$ (**soundness**).

The study of interactive proofs has found extensive applications in both theory and practice. Classical results on IPs have led us to better understand complexity classes through characterizations such as $IP = PSPACE$ [37, 43] and $MIP = NEXP$ [4, 23, 27], and later led to the important area of probabilistically checkable proofs [44]. More recently, the study of IPs has resulted in extremely efficient (e.g., near linear or even logarithmic time) protocols for delegation of computation [7, 9, 15, 30, 41]. Such super-efficient IPs have brought theory closer to practice, resulting in “nearly practical” systems (e.g., see [8, 13, 45, 47]).

Indeed, interactive proofs are not only a fundamental theoretical concept but an indispensable framework to design efficient computation-outsourcing protocols.

Existing interactive-proof games

Interactive-proof systems with multiple provers have largely been studied as games that fall into two categories: either as games of cooperation such as MIP [6], cooperative multi-prover rational proofs (MRIP) [18], and variants [4, 10, 27, 30, 33], where the provers work together to convince the verifier of their joint claim; or as games of conflict such as refereed games [14–16, 22, 24, 26, 34], where the provers directly compete with each other to convince the verifier of their conflicting claims.

Both of these categories have limitations. In a game of cooperation, provers cannot be leveraged directly against each other. That is, the verifier cannot directly ask one prover if another prover is lying. On the other hand, in a game of conflict, such as refereed games, one prover must “win” the zero-sum game. Thus, such games need to assume that at least one prover – who must be the winning prover in a correct protocol – can be trusted to always tell the truth. Despite their limitations, both models have proved to be fundamental constructs to understand and characterize important complexity classes [4, 16, 18, 22, 26], and to design efficient computation outsourcing protocols [7, 8, 14, 15, 30].

1.1 Contributions and Results

In this paper, we introduce a new interactive-proof game, *non-cooperative rational interactive proofs* (*ncRIP*). This model generalizes multi-prover rational proofs [17–19].

Solution concept for ncRIP

We define a refinement of sequential equilibrium [36], **strong sequential equilibrium** (SSE), that essentially says that players’ beliefs about the histories that led them to an unreachable information set should be irrelevant to their best response. From a mechanism-design perspective, we want to design the protocols and payments that allow this strong guarantee to hold – letting the players’ best responses be unaffected by their beliefs.¹

Finally, we eliminate SSE strategies that are suboptimal within “subgames” by defining and enforcing a backward-induction-compatible notion of dominance. Roughly speaking, we say a protocol is a ncRIP if there exists a strategy profile of the provers that is a dominant SSE among the *subforms* of the extensive form game, and under this strategy the provers’ lead the verifier to the correct answer. We define the model formally in Section 2.

Utility gap for non-cooperative provers

Utility gap is a fundamental concept for rational proofs [2, 18, 19, 31] which is analogous to *soundness gap* in interactive proofs. It measures how robust a protocol is against the provers’ possible deviations from the desired strategy.

This notion is straightforward to define for cooperative rational protocols – they have a utility gap of u if the *total* expected payment decreases by $1/u$ whenever the provers report the wrong answer. In non-cooperative protocols, however, it is not a priori clear how to define such a payment loss or to choose which prover should incur the loss. A payment loss

¹ We believe that SSE is of independent interest as a solution concept for designing extensive-form mechanisms (e.g. [21, 28, 46]). In the full version of the paper, we prove important properties of SSE that may prove useful in future studies.

solely imposed on the total payment may not prevent some provers from deviating, and a loss solely imposed on the provers' final payments may not prevent them from deviating within subgames.

We define a meaningful notion of utility gap for ncRIP that is naturally incorporated in a backward-induction-compatible way to the dominant SSE concept.

Tight characterizations of ncRIP classes

In this paper, we completely characterize the power of non-cooperative rational proofs under different utility-gap guarantees.

We construct ncRIP protocols with constant, polynomial, and exponential utility gaps for powerful complexity classes, demonstrating the strength of our solution concept. Our protocols are simple and intuitive (requiring only a few careful tweaks from their cooperative counterparts), and are thus easy to explain and implement. However, proving their correctness involves analyzing the extensive-game (including subtleties in the incentives and beliefs of each player at each round) to show that the protocol meets the strong solution-concept and utility-gap requirements.

We then prove tight upper bounds for all three ncRIP classes. Proving tight upper bounds is the most technically challenging part of the paper. We prove the upper bounds by simulating the decisions of the verifier and provers with a Turing Machine. However, there are several obstacles to attain the correct bounds. For example, the polynomial randomness of the verifier can induce an exponential-sized game tree, which is too large to be verified by the polynomial-time machine in Theorems 1 and 2. Furthermore, an NEXP oracle cannot itself verify whether a strategy profile is a dominant SSE. The key lemma that helps us overcome these challenges is the pruning lemma (Lemma 13). At a high level, it shows that we can prune the nature moves of the verifier in the resulting game tree, while preserving the dominant-SSE and utility-gap guarantees.

Our results are summarized in Figure 1, where we use $O(1)$ -ncRIP, $\text{poly}(n)$ -ncRIP and $\text{exp}(n)$ -ncRIP to denote ncRIP classes with constant, polynomial and exponential utility gaps respectively. The notations are analogous for MRIP [17] (the cooperative variant). We characterize ncRIP classes via oracle Turing machines. In particular, $\mathbf{P}^{\text{NEXP}[O(1)]}$ is the class of languages decided by a polynomial-time Turing machine that makes $O(1)$ queries to an NEXP oracle, and $\text{EXP}^{\text{poly-NEXP}}$ is the class decided by an exponential-time Turing machine with polynomial-length queries to an NEXP oracle.

Note that lower and upper bounds for the case of exponential utility gap (that is, Theorem 3 and Corollary 6) are deferred to the full version of the paper.

▶ Theorem 1. $O(1)$ -ncRIP = $\mathbf{P}^{\text{NEXP}[O(1)]}$	▶ Corollary 4. $O(1)$ -ncRIP = $O(1)$ -MRIP
▶ Theorem 2. $\text{poly}(n)$ -ncRIP = \mathbf{P}^{NEXP}	▶ Corollary 5. $\text{poly}(n)$ -ncRIP \supseteq $\text{poly}(n)$ -MRIP
▶ Theorem 3. $\text{exp}(n)$ -ncRIP = $\text{EXP}^{\text{poly-NEXP}}$	▶ Corollary 6. $\text{exp}(n)$ -ncRIP = $\text{exp}(n)$ -MRIP

■ **Figure 1** Summary of our results.

Power of non-cooperative vs. cooperative and competitive provers

Interestingly, in the case of constant and exponential utility gap, the power of ncRIP and MRIP coincide. This can be explained by the power of adaptive versus non-adaptive queries in oracle Turing machines.

Indeed, our results reveal the main difference between non-cooperative and cooperative provers: the former can be used to handle adaptive oracle queries, the latter cannot (see [17, 18]). Intuitively, this makes sense – cooperative provers may collude across adaptive queries, answering some of them incorrectly to gain on future queries. On the other hand, non-cooperativeness allows us to treat the subgame involving the oracle queries as a separate game from the rest.

Our results also show that non-cooperative provers are more powerful than competing provers. Feige and Kilian [22] proved that the power of refereed games with imperfect information and perfect recall is equal to EXP.

2 Non-Cooperative Rational Interactive Proofs

In this section we introduce the model for ncRIP.

Notation

First, we review the structure of ncRIP protocols and related notation; this is largely the same as [18].

The decision problem being solved by an interactive proof is modeled as whether a given string x is in language L . An interactive protocol is a pair (V, \vec{P}) , where V is the **verifier**, $\vec{P} = (P_1, \dots, P_{p(n)})$ is the vector of $p(n)$ **provers**, where $p(n)$ is polynomial in $n = |x|$. The verifier runs in polynomial time and flips private coins. Each P_i is computationally unbounded. The verifier and provers are given the input x . Similar to classical multi-prover interactive proofs, the verifier can communicate with each prover privately, but no two provers can communicate with each other once the protocol begins.

In a **round**, either each prover sends a message to V , or V sends a message to each prover, and these two cases alternate. The length of each message $\ell(n)$, and the number of rounds $k(n)$ are both polynomial in n . The final transcript \vec{m} of the protocol is a random variable depending on r , the random string used by V . At the end of the communication, the verifier computes an **answer bit** $c \in \{0, 1\}$ for the membership of x in L based on x , r , and \vec{m} . V also computes a payment vector $\vec{R} = (R_1, R_2, \dots, R_{p(n)})$, where R_i is the payment given to P_i , $R_i \in [-1, 1]$, and the total $\sum_{i=1}^{p(n)} R_i \in [-1, 1]$ as well.² The protocol and the payment function \vec{R} are public knowledge.

Each prover P_i 's **strategy** at round j maps the transcript seen at the beginning of round j to the message he sends in that round. Let $s_i = (s_{i1}, \dots, s_{ik(n)})$ be the strategy of prover P_i , and $s = (s_1, \dots, s_{p(n)})$ be the **strategy profile** of the provers. Given input x , and strategy profile s , let $u_k(x, s, (V, \vec{P}))$ denote the expected payment of prover P_k in the protocol (V, \vec{P}) based on randomness r , input x and s ; if (V, \vec{P}) is clear from context, we shorten this to $u_k(x, s)$ or $u_k(s)$.

The protocol forms an extensive-form game with imperfect information and should be designed such that the provers are incentivized to reach an equilibrium that leads V to the correct answer bit c . We formalize the solution concept next.

² Negative payments are used to reflect punishment. The individual payments and the total payment can be shifted and scaled to lie in $[0, 1]$.

2.1 Solution concept for ncRIP

We want the solution concept for ncRIP to satisfy a strong notion of backward induction [39], a standard criterion applied to extensive-form games based on the common knowledge of rationality. Backwards induction refers to the condition of being “sequentially rational” in an extensive-form game, that is, each player must play his best response at each node where he has to move, even if his rationality implies that such a node will not be reached.

If an interactive protocol forms an extensive-form game of perfect information, it is easy to formalize this condition. A strategy s is **sequentially rational** or satisfies **backward induction**, if for every player i and every decision node of i , conditioned on reaching the decision node, s_i is a best response to s_{-i} , that is, $u_i(s_i, s_{-i}) \geq u_i(s'_i, s_{-i})$ for any strategy s'_i of prover i . In other words, s induces a best response at every subgame.³

In a game of imperfect information, the decision nodes corresponding to a player’s turn are partitioned into **information sets**, where the player is unable to distinguish between the possible histories within an information set. To reason about sequential rationality we need a probability distribution u_I on each information set I , so as to determine the players’ expected utility conditioned on reaching I and thus their best response at I . The probability distribution μ_I is referred to as the player’s **beliefs** about the potential histories leading to I .

Given a strategy profile s , beliefs u_I at **reachable information sets** (reached with non-zero probability under s) are derived from s using Bayes’ rule; this is a standard derivation used in most solution concepts for extensive-form games [39]. We sometimes write μ_I^s to emphasize that the beliefs depend on s .

Past work has introduced a variety of methods for defining the beliefs u_I^s at **unreachable information sets** I (i.e. information sets reached with probability zero under s); see e.g. [20, 36, 38, 42]. The most well-known is sequential equilibrium [36], which demands an explicit system of beliefs that satisfies a (somewhat artificial) consistency condition. Other equilibria, like trembling hand [42], reason implicitly about beliefs at unreachable information sets by assigning a negligible probability with which the player’s hand “trembles,” and reaches an otherwise-unreachable information set. Further refinements of these take the structure and payoffs of the game into account [5, 20, 38].

The treatment of beliefs at unreachable information sets in these solution concepts is often focused on ensuring that they can be used to analyze *every* extensive-form game. From a mechanism-design perspective, our focus is different – we want to design mechanisms in such a way that they admit much stronger equilibrium requirements, even if such an equilibrium cannot be used to analyze every game.

At a high-level, we want the players’ beliefs to be irrelevant in determining their best response at unreachable information sets. We call this notion **strong sequential rationality**. A strategy profile s is **strongly sequentially rational** if for every information set I , conditioned on reaching I , s_i is a best response to s_{-i} with respect to μ_I^s , where

- μ_I^s is derived using Bayes’s if I is reachable under s , and
- μ_I^s is *any* arbitrary probability distribution if I is unreachable under s .

In the full version of the paper, we show that this requirement is equivalent to saying that, at an unreachable information set I , s_i must be a best response to s_{-i} conditioned on reaching each history $h \in I$. In other words, at an unreachable information set I , each player must have a *single* action that is the best response to every possible history in I . We say a strategy profile is a **strong sequential equilibrium** (SSE) if it satisfies strong sequential rationality.

³ A subgame is a subtree that can be treated as a separate well-defined game. In a perfect-information game, every node starts a new subgame. “Backward induction” and “subgame-perfect equilibrium” are used interchangeably in the literature [28].

We refine our solution concept further to eliminate strategies that are weakly dominated within “subgames” of the entire game. This is crucial to deal with equilibrium selection, in particular, because the players’ cannot unilaterally deviate out of a suboptimal equilibria. We say an SSE s **weakly dominates** another SSE s' if, for any player i , $u_i(s) \geq u_i(s')$. A strategy s is **weakly dominant** if it dominates all SSEs. Next we eliminate SSEs that are weakly dominated in subgames of the entire game. We use the generalized notion of subgames, called **subforms**, defined by Kreps and Wilson [36] for extensive-form games with imperfect information.

To review the definition of subforms, we need further notation. Let H be the set of histories of the game. Recall that a history is a sequence (a^1, \dots, a^K) of actions taken by the players.⁴ For histories $h, h' \in H$, we say h has h' as a **prefix** if there exists some sequence of actions b^1, \dots, b^L (possibly empty) such that $h = (h', b^1, \dots, b^L)$. For a history $h \in H$, let $I(h)$ be the unique information set containing h .

For an information set I , let H_I be the set of all histories following I , that is, H_I is the set of all histories $h \in H$ such that h has a prefix in I . We say that H_I is a **subform rooted at I** if for every information set I' such that $I' \cap H_I \neq \emptyset$, it holds that $I' \subseteq H_I$. Roughly speaking, a subform H_I “completely contains” all histories of the information sets following I , so there is no information asymmetry between the players acting within H_I .

Thus, given a strategy profile, the subform H_I together with the probability distribution μ_I^s on I , can be treated as a well-defined game.

We say an SSE s **weakly dominates** SSE s' **on a subform H_I** if, for any player j acting in H_I , the expected utility of j under s_I in the game (H_I, μ_I^s) is greater than or equal to their utility under s'_I in the game $(H_I, \mu_I^{s'})$.

We eliminate weakly dominated strategies by imposing this dominance condition in a backward-induction-compatible way on the subforms as follows.

► **Definition 7** (Dominant Strong Sequential Equilibrium). *A strategy profile s is a dominant strong sequential equilibrium if s is an SSE and*

- *for every subform H_I of height 1: s weakly dominates s' on H_I for any SSE s'*
- *for every subform H_I subgame of height > 1 : s weakly dominates s' on H_I for any SSE s' that is a dominant SSE in all subforms of height at most $h - 1$.*

We are ready to define non-cooperative rational interactive proofs.

► **Definition 8** (Non-Cooperative Rational Interactive Proof). *Fix an arbitrary string x and language L . An interactive protocol (V, \vec{P}) is a non-cooperative rational interactive proof (ncRIP) protocol for L if there exists a strategy profile s of the provers that is a dominant SSE in the resulting extensive-form game, and under any dominant SSE, the answer bit c output by the verifier is correct (i.e., $c = 1$ iff $x \in L$) with probability 1, where the probability is taken over the verifier’s randomness.*

2.2 Utility Gap in ncRIP Protocols

In game theory, players are assumed to be perfectly rational and “sensitive” to arbitrarily small utility losses. In reality, some provers may not care about small losses. Such provers may not have sufficient incentive to reach a dominant SSE, and could end up leading the verifier to the wrong answer. To design ncRIP protocols that are robust against such “insensitive” provers, we define the notion of **utility gap**.

⁴ In the full version of the paper, we present a more formal treatment of the underlying extensive-form game, based on [39].

Informally, a utility gap of u means that if a strategy profile s leads the verifier to the wrong answer, there must exist a subform, such that some provers must lose at least a $1/u$ amount in their final individual payments (compared to their optimal strategy in that subform). As a consequence, these provers will not deviate to s , as long as they care about $1/u$ payment losses. We formalize this notion below. (We say a subform H_I is reachable under s if the information set I is reached under s with non-zero probability.)

► **Definition 9 (Utility Gap).** *Let (V, \vec{P}) be an ncRIP protocol for a language L and s^* be a dominant SSE of the resulting game. The protocol (V, \vec{P}) has an $\alpha(n)$ -utility gap or $\alpha(n)$ -gap, if for any strategy profile s' under which the answer bit c' is wrong, there exists a subform H_I reachable under s' , and a prover P_j acting in H_I who has deviated from s^* such that*

$$u_j(x, (s'_{-I}, s_I^*), (V, \vec{P})) - u_j(x, (s'_{-I}, s'_I), (V, \vec{P})) > 1/\alpha(n),$$

where s'_{-I} denotes the strategy profile s' outside subform H_I , that is, $s'_{-I} = s' \setminus s'_I$.

The class of languages that have an ncRIP protocol with **constant**, **polynomial** and **exponential** utility gap, are denoted by $O(1)$ -ncRIP, $\text{poly}(n)$ -ncRIP, and $\text{exp}(n)$ -ncRIP respectively.⁵ Note that $\alpha(n)$ gap corresponds to a payment loss of $1/\alpha(n)$, so an exponential utility gap is the weakest guarantee.

3 Lower Bounds: ncRIP Protocols with Utility Gap

In this section, we give an $O(1)$ -utility gap ncRIP protocol for the class NEXP and use it to give an $O(\alpha(n))$ -utility gap ncRIP protocol for the class $\text{P}^{\text{NEXP}[\alpha(n)]}$. Setting $\alpha(n)$ to be a constant or polynomial in n gives us $\text{P}^{\text{NEXP}[O(1)]} \subseteq O(1)\text{-ncRIP}$ and $\text{P}^{\text{NEXP}} \subseteq \text{poly}(n)\text{-ncRIP}$ respectively.

Here we argue correctness of our protocols at a high level; see the full version of the paper for formal proofs.

A constant-gap ncRIP protocol for NEXP

The ncRIP protocol for any language in NEXP is in Figure 2. The protocol uses the 2-prover 1-round MIP for NEXP [23] as a blackbox.⁶ The protocol in Figure 2 essentially forces the non-cooperative provers to coordinate by giving them identical payments. As a result, it is almost identical to the MRIP protocol for NEXP [18].

While the payment scheme is simple, in the analysis we have to open up the black-box MIP. In particular, if P_1 sends $c = 0$ in round 1, all the information sets of P_1 and P_2 in round 3 become unreachable. To show that an SSE exists, we show that the provers have a best response at these unreachable sets, which is argued based on the messages exchanged in the MIP protocol.

► **Lemma 10.** *Any language $L \in \text{NEXP}$ has a 2-prover 3-round $6/5$ -gap ncRIP protocol.*

⁵ These classes are formally defined by taking the union over languages with $\alpha(n)$ utility gap, for every $\alpha(n)$ that is constant, polynomial and exponential in n respectively.

⁶ It is also possible to give a scoring-rule based ncRIP protocol for NEXP, similar to MRIP [18]. However, such a protocol has an exponential utility gap.

For any input x and language $L \in \text{NEXP}$, the protocol (V, P_1, P_2) for L is:

1. P_1 sends a bit c to V . V outputs c at the end of the protocol.
2. If $c = 0$, then the protocol ends and the payments are $R_1 = R_2 = 1/2$.
3. Otherwise, V runs the classic 2-prover 1-round MIP protocol for NEXP [23] with P_1 and P_2 to prove if $x \in L$. If the MIP protocol accepts then $R_1 = 1, R_2 = 1$; else, $R_1 = -1, R_2 = -1$.

■ **Figure 2** A simple $O(1)$ -utility gap ncRIP protocol for NEXP .

An $O(\alpha(n))$ -gap ncRIP protocol for $\text{P}^{\text{NEXP}[\alpha(n)]}$

Using the above NEXP protocol as a subroutine, we give an ncRIP protocol with $O(\alpha(n))$ -utility gap for the class $\text{P}^{\text{NEXP}[\alpha(n)]}$. This protocol works for any function $\alpha(n)$ which (1) is a positive integer for all n , (2) is upper-bounded by a polynomial in n , and (3) is polynomial-time computable.⁷

► **Lemma 11.** *Any language $L \in \text{P}^{\text{NEXP}[\alpha(n)]}$ has a 3-prover 5-round ncRIP protocol that has a utility gap of $6/(5\alpha(n))$.*

The ncRIP protocol for any $L \in \text{P}^{\text{NEXP}[\alpha(n)]}$ is in Figure 3. It is fairly intuitive – V simulates the polynomial-time Turing machine directly, and uses the ncRIP protocol for NEXP for the oracle queries.

For any input x of length n , the protocol (V, \vec{P}) works as follows.

1. P_1 sends $(c, c_1, \dots, c_{\alpha(n)}) \in \{0, 1\}^{\alpha(n)+1}$ to V . V outputs c at the end of the protocol.
2. V simulates M on x using the bits $c_1, \dots, c_{\alpha(n)}$ as answers to NEXP queries $\phi_1, \dots, \phi_{\alpha(n)}$ generated by M respectively. If M accepts and $c = 0$ or M rejects and $c = 1$, then the protocol ends and $R_1 = -1, R_2 = R_3 = 0$.
3. V picks a random index i' from $\{1, \dots, \alpha(n)\}$ and sends $(i', \phi_{i'})$ to P_2 and P_3 .
4. V runs the 2-prover 3-round $O(1)$ -gap ncRIP protocol for NEXP (Figure 2) with P_2 and P_3 on $\phi_{i'}$. P_2 and P_3 get payments R_2 and R_3 based on the protocol. Let $c_{i'}^*$ be the answer bit in the NEXP protocol. If $c_{i'}^* \neq c_{i'}$, then $R_1 = 0$; otherwise $R_1 = 1$.

■ **Figure 3** An $O(\alpha(n))$ -utility gap ncRIP protocol for $\text{P}^{\text{NEXP}[\alpha(n)]}$.

We argue the correctness of this protocol at a high-level. Under any strategy of P_1 , the resulting NEXP queries in the protocol in Figure 3 are the roots of non-trivial subforms. Which of these subforms are reachable under a strategy profile s is determined solely by the strategy of P_1 . However, because weak dominance is imposed on all subforms in a bottom-up fashion, P_2 and P_3 must play their optimal strategy in these subforms regardless of their reachability – and therefore, they must play optimally for any strategy of P_1 . (This is one example of why ruling out weakly-dominated strategies in subforms in the definition of dominant SSEs is crucial to arguing correctness.) From the correctness of the NEXP protocol in Figure 2, we know that the optimal strategy of P_2 and P_3 is to compute the NEXP queries correctly. Given that the best response of P_2 and P_3 is to solve the NEXP queries correctly, and given that V randomly verifies 1 out of $\alpha(n)$ queries, P_1 must commit to correct answer bits in the first round, or risk losing a $O(1/\alpha(n))$ amount from his expected payment.

⁷ For Theorem 1 and Theorem 2, $\alpha(n)$ need only be a constant or polynomial in n . However, Lemma 11 holds for all $\alpha(n)$'s that are polynomial-time computable (given 1^n) and polynomially bounded, such as $\log n, \sqrt{n}$, etc.

If P_1 gives the correct answer bits in step 1, but P_2 or P_3 deviate within a subform corresponding to an NEXP query ϕ_q , then with probability $1/\alpha(n)$, V simulates the protocol in Figure 3 on ϕ_q , in which case they lose a constant amount of their expected payment.

4 Upper Bounds: ncRIP Protocols with Utility Gap

In this section, we prove matching upper bounds on the classes of ncRIP protocols with constant and polynomial utility gaps. In particular, we show that any language in $O(1)$ -ncRIP (or $\text{poly}(n)$ -ncRIP) can be decided by a polynomial-time Turing machine with a constant (resp. polynomial) number of queries to an NEXP oracle.

To simulate an ncRIP protocol, we need to find a strategy profile “close enough” to the dominant SSE so that the answer bit is still correct, i.e. a strategy profile that satisfies the utility-gap guarantee. We formalize this restatement of Definition 9 below.

► **Observation 12.** *Given input x and an ncRIP protocol (V, \vec{P}) with $\alpha(n)$ -utility gap, let s be a strategy profile such that for all reachable subforms H_I and all provers P_j acting in H_I ,*

$$u_j(x, r, (V, \vec{P}), (s_{-I}, s_I^*)) - u_j(x, r, (V, \vec{P}), (s_{-I}, s_I)) < \frac{1}{\alpha(n)},$$

where s^* is a dominant SSE. Then, the answer bit c under s must be correct.

There are several challenges involved in finding a strategy profile satisfying Observation 12.

First, the size of the game tree of any ncRIP protocol – small gap notwithstanding – can be exponential in n . Even if the polynomial-time machine considers a single strategy profile s at a time, since V can flip polynomially many coins, the part of the tree “in play” – the number of decision nodes reached with positive probability under s – can be exponential in n .

The second (and related) challenge is that of verifying whether a strategy profile is a dominant SSE. While the NEXP oracle can guess and verify an SSE, it cannot directly help with dominant SSEs. The polynomial-time machine must check using backward induction if an SSE is dominant on all its reachable subforms, which can again be exponential in n .

Finally, the polynomial-time machine needs to search through the exponentially large strategy-profile space in an efficient way to find one which leads to the correct answer.

In the remainder of the section we address these challenges. In Lemma 13 we show that we can prune the game tree, resolving the first two challenges. Then in Lemmas 17 and 18, we show how to efficiently search through the strategy-profile space.

Pruning Nature moves in ncRIP protocols

We now give our main technical lemma for the upper bound, which shows that we can limit ourselves to examining protocols with bounded game trees without loss of generality.

Recall that a verifier’s coin flips in an ncRIP protocol represent Nature moves in the resulting game. The problem is that a polynomial-time verifier can result in Nature moves that impose nonzero probabilities over exponentially many outcomes.

We prune the Nature moves of a verifier so that a polynomial-time Turing machine simulating an $\alpha(n)$ -utility-gap protocol can traverse the game tree reachable under a given s . This pruning operation takes exponential time (linear in the size of the game tree), and can be performed by the NEXP oracle.

► **Lemma 13 (Pruning Lemma).** *Let $L \in \alpha(n)$ -ncRIP and let (V, \vec{P}) be an ncRIP protocol for L with $\alpha(n)$ utility gap and $p(n)$ provers. Given an input x and a strategy s , the protocol (V, \vec{P}) can be transformed in exponential time to a new protocol (V', \vec{P}') , where*

- the probability distribution on the outcomes imposed by the Nature moves of V' for input x has $O(\alpha(n))$ support,
- if s is a dominant SSE of (V, \vec{P}) , then s induces a dominant SSE in (V', \vec{P}) ,
- $|u_j(x, s, (V, \vec{P})) - u_j(x, s, (V', \vec{P}))| < 1/(4\alpha(n))$ for all $j \in \{1, \dots, p(n)\}$, and
- the utility gap guarantee is preserved, that is, if the answer bit under s is wrong, then there exists a subform H_I in the game (V', \vec{P}) (reachable under s) and a prover P_j acting at H_I , such that P_j loses a $1/(2\alpha(n))$ amount in his expected payment compared to a strategy profile where s_I (induced by s on H_I) is replaced by s_I^* (the dominant SSE on H_I), keeping the strategy profile outside H_I , s_{-I} , fixed.

We prove Lemma 13 in several parts. First, given an input x and a strategy s of the provers, we show how to transform any verifier V that imposes a probability distribution over outcomes with exponential support into a verifier V' that imposes a probability distribution with $O(\alpha(n))$ support.

Let (V, \vec{P}) use $p(n)$ provers and let the running time of V be n^k for some constant k . There can be at most 2^{n^k} different payments that V can generate for a particular prover given input x . Given x and s , fix a prover index $j \in \{1, \dots, p(n)\}$. Let R_1, R_2, \dots, R_m be the payments generated by V on s for P_j . Let V 's randomness assign probability distribution $\mu = (p_1, p_2, \dots, p_m)$ to R_1, R_2, \dots, R_m respectively. Then, the expected payment of P_j under s is $u_j(x, s, (V, \vec{P})) = \sum_{i=1}^m p_i R_i$.

Recall that $u_j(x, s, (V, \vec{P})) \in [-1, 1]$ for all $1 \leq j \leq p(n)$. For each prover P_j , divide the interval $[-1, 1]$ into $4\alpha(n)$ intervals, each of length $1/(2\alpha(n))$. In other words, prover P_j 's i th interval is $[i/2\alpha(n), (i+1)/2\alpha(n)]$,⁸ for each $i \in \{-2\alpha(n), \dots, 2\alpha(n) - 1\}$.

We round the possible payments for P_j to a representative of the their corresponding interval. Specifically, we map each payment R_i to r_j as described in Equation 1. There

$$r_j = \begin{cases} \frac{4\ell+1}{4\alpha(n)} & \text{if } R_i \in \left[\frac{\ell}{2\alpha(n)}, \frac{2\ell+1}{4\alpha(n)} \right) \\ \frac{4\ell+3}{4\alpha(n)} & \text{if } R_i \in \left[\frac{2\ell+1}{4\alpha(n)}, \frac{\ell+1}{2\alpha(n)} \right) \end{cases} \quad (1) \quad p'_i = \begin{cases} \sum_{k \in T_j} p_k & \text{if } i = f(S(i)) \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

are potentially exponentially many different payments R_i , and only polynomially many different payments r_j , so several R_i must map to the same r_j . Let $T_j = \{i : R_i \text{ maps to } r_j\}$. Let $\mathcal{T} = \cup_j \{T_j\}$. Thus the total number of distinct r_j is $8\alpha(n)$, so $|\mathcal{T}| = O(\alpha(n))$. Let $S : \{1, \dots, m\} \rightarrow \mathcal{T}$ such that $S(i) = T_j$ if and only if $i \in T_j$.

For each $T_j \in \mathcal{T}$, let $f(T_j)$ denote a unique index in the set T_j . Without loss of generality, let $f(T_j)$ be the lowest index in T_j . We define a new probability distribution $\mu' = (p'_1, \dots, p'_h)$ over the payments R_1, \dots, R_h respectively, given by Equation 2. In particular, for every $T_j \in \mathcal{T}$, assign $R_{f(T_j)}$ probability $\sum_{k \in T_j} p_k$ and for every other index $\ell \in T_j$, $\ell \neq f(T_j)$, assign R_ℓ probability 0.

Define V' as a polynomial-time verifier that simulates all deterministic computation of V . For a fixed input x , V' imposes a probability distribution μ' with $O(\alpha(n))$ support for any probability distribution μ imposed by V . For other inputs, V' simulates V without any modification.

⁸ To include 1 as a possible payment, interval $2\alpha(n) - 1$ should be closed on both sides; we ignore this for simplicity.

29:12 Non-Cooperative Rational Interactive Proofs

Note that given input x , a strategy profile s and the protocol (V, \vec{P}) , transforming the distribution μ to μ' takes time linear in the size of the game tree, and thus exponential in n . (This means that an NEXP oracle, given x , can guess a particular s and perform the transformation.)

The remainder of the proof of Lemma 13 consists of the following three claims. We argue their correctness at a high-level and defer formal proofs to the full version.

First, we show that if the strategy profile s is a dominant SSE of (V, \vec{P}) , then s restricted to the pruned game tree of (V', \vec{P}) imposes a dominant SSE on (V', \vec{P}) as well.

► **Claim 14.** *Any dominant SSE s of the game formed by (V, \vec{P}) induces a dominant SSE in the game formed by (V', \vec{P}) .*

First, we prove that s is an SSE of (V', \vec{P}) . Suppose by contradiction that s is not a SSE of (V', \vec{P}) . Then there exists an information set I , such that, conditioned on reaching I , the prover acting at I can improve his expected payment by deviating (given his belief u'_I at I if I is reachable under s and for any belief he may hold at I if I is unreachable under s). Writing out their expected payments, accounting for the probabilistic transformation between V and V' , in both cases leads to a contradiction to the assumption that s was an SSE in (V, \vec{P}) . We then argue that a similar contradiction holds for proving that s is a dominant SSE of (V', \vec{P}) .

The following claim states that for a given s , the expected payments of the provers under (V, \vec{P}) and under (V', \vec{P}) are not too far off. This claim is one of the bullet points in Lemma 13, and will be used to prove Claim 16.

► **Claim 15.** *For all $j \in \{1, \dots, p(n)\}$, $|u_j(x, s, (V, \vec{P})) - u_j(x, s, (V', \vec{P}))| < 1/(4\alpha(n))$.*

With the above, we show that (V', \vec{P}) preserves utility gap guarantees.

► **Claim 16.** *Given input x , if the answer bit under s is wrong, then there exists a subform H_I reachable under s in (V', \vec{P}) and P_j acting at H_I , such that P_j 's expected payment under s is $\frac{1}{2\alpha(n)}$ less than his expected payment under (s_{-I}, s_I^*) , where s_I^* is a dominant SSE on H_I .*

Consider a strategy profile s^* that is a dominant SSE in the game tree of (V, \vec{P}) . Since s gives the wrong answer bit, from the $\alpha(n)$ -utility gap guarantee of (V, \vec{P}) and Definition 9, there exists a subform H_I reachable under s , such that a prover P_j acting in H_I loses $1/\alpha(n)$ in his expected payment under s compared to the strategy profile (s_{-I}, s_I^*) .

Using Claim 14, s^* also induces a dominant SSE in the game tree of (V', \vec{P}) . And since H_I is reachable under s in (V, \vec{P}) , it is reachable under s in (V', \vec{P}) as well. Finally, Claim 16 follows by applying Claim 15 twice: once to show that payments under V and V' are similar under s , and once to show that the payments are similar under (s_{-I}, s_I^*) . In the worst case this leads to a payment difference of $1/(4\alpha(n)) + 1/(4\alpha(n)) = 1/(2\alpha(n))$.

Using Lemma 13, given an $O(\alpha(n))$ -gap nCRIP protocol (where $\alpha(n)$ is constant or polynomial), a polynomial-time oracle Turing machine can use its NEXP oracle to guess a strategy profile s , prune the verifier's Nature moves, and report the resulting $O(\alpha(n))$ -support distribution bit-by-bit. Thus, it can simulate the new distribution and find the decision nodes that are reachable under s .

Searching through the strategy-profile space efficiently

The next question is: how should the polynomial-time Turing machine navigate the potential strategy-profile space (in polynomial time) to find the strategy profile that satisfies Observation 12? To cut down on the search space, we invoke a recurring idea: divide each prover's expected payment interval $[-1, 1]$, evenly into $8\alpha(n)$ **subintervals** of length $1/(4\alpha(n))$, and consider **subinterval profiles** (a tuple of subintervals, one for each prover).

► **Lemma 17.** *Given an input x and an ncRIP protocol (V, \vec{P}) with $\alpha(n)$ -utility gap, consider a subinterval profile $(L_1, \dots, L_{p(n)})$, where each $L_i = [k/(4\alpha), (k+1)/(4\alpha+1))$ denotes a subinterval of prover P_i in $[-1, 1]$, for some $k \in \{-2\alpha(n), \dots, 2\alpha(n) - 1\}$. Let s be an SSE that has an expected payment profile $\tilde{u}(x, s)$ such that $u_i(x, s) \in L_i$ for all $1 \leq i \leq p(n)$, and s does not satisfy Observation 12. Then the expected payment profile $\tilde{u}(x, s^*)$ under a dominant SSE s^* cannot lie in the same subinterval profile, that is, there exists a prover index j such that $u_j(x, s^*) \notin L_j$.*

Using Lemma 17, if the polynomial-time Turing machine is able to test *any* SSE s with $\tilde{u}(x, s)$ in a subinterval profile, for all subinterval profiles, then it is guaranteed to find one that satisfies Observation 12. This is because a dominant SSE of an ncRIP protocol is guaranteed to exist and its expected payment profile must belong to some subinterval profile.

However, there are still $O(\alpha(n))$ subintervals for each prover, and thus $O(\alpha(n)^{p(n)})$ total subinterval profiles. A polynomial-time machine cannot test SSEs for each of them.

To reduce the search space further, we show that it is sufficient to consider subintervals of the total expected payment rather than individual and test an SSE s for each of them. Recall that a SSE s is weakly dominant if for any player i and SSE s' , $u_i(s) \geq u_i(s')$.

► **Lemma 18.** *If a weakly-dominant SSE exists, then a strategy profile s is a weakly-dominant SSE if and only if s is an SSE and s maximizes the sum of utilities of all players among all SSEs.*

We are now ready to prove the upper bound for ncRIP classes with constant and polynomial utility gap. We defer formal details of the proof to the full version of the paper.

Constant utility gap

Using Lemma 13 and Lemma 18, simulating a constant-gap protocol using a $\text{P}^{\text{NEXP}[O(1)]}$ machine M is straightforward. We give a high-level overview below.

There are at most $O(1)$ subforms that are reachable under any strategy profile s , and the total expected payment of the provers conditioned on reaching these subforms will be in one of the $O(1)$ subintervals. Thus, there are $O(1)$ combinations of total expected payments on all subforms (including the whole game). M queries its NEXP oracle whether there exists an SSE that achieves that combination of total expected payments on those subforms, for all combinations. Then, M finds the maximum among all of the combinations that got a “yes.” Such a maximum is guaranteed to exist for an ncRIP protocol. Finally, M queries the oracle for the answer bit of the corresponding SSE by giving the dominant profile of total expected payments over the subgames.

► **Lemma 19.** $O(1)\text{-ncRIP} \subseteq \text{P}^{\text{NEXP}[O(1)]}$.

Polynomial utility gap

To simulate a polynomial-utility gap ncRIP protocol (V, \vec{P}) , using a P^{NEXP} machine M , we put to use all the structure we have established in this section.

For each of the $O(\alpha(n))$ total payment subintervals of the interval $[-1, 1]$ that correspond to an SSE, M does a recursive search to find an exact total expected payment $u(x, s)$ that is generated by an SSE. (We can restrict ourselves to $O(\alpha(n))$ oracle queries due to Lemma 18.) In particular, M queries the NEXP oracle: *Does there exist an SSE with total expected payment in the first half of the i th interval?* If the answer is *yes* then M recurses on the first half of the i th interval; M does not need to search the second half by Lemma 17. Otherwise

(if the answer is *no*) then M recurses on the second half. Thus, in polynomial time and with polynomial queries, M can find an exact $u(x, s)$ for an SSE s in the subinterval using the power of its *adaptive* queries.

Next, M simulates the protocol (V, \vec{P}) with the help of the oracle, under the SSE s for a given subinterval. Lemma 13 is crucial for M to simulate the verifier’s moves, because V in general can induce exponential-size distributions. M traverses the tree reachable under s “top-down” using the oracle to learn the pruned distributions and provers’ moves. Finally, M goes “bottom-up” to test whether s satisfies Observation 12 on all its reachable subgames.

► **Lemma 20.** $\text{poly}(n)\text{-ncRIP} \subseteq \text{P}^{\text{NEXP}}$.

Abstract

The minimum genus of a graph is an important question in graph theory and a key ingredient in several graph algorithms. However, its computation is NP-hard and turns out to be hard even in practice. Only recently, the first non-trivial approach – based on SAT and ILP (integer linear programming) models – has been presented, but it is unable to successfully tackle graphs of genus larger than 1 in practice.

Herein, we show how to improve the ILP formulation. The crucial ingredients are two-fold. First, we show that instead of modeling rotation schemes explicitly, it suffices to optimize over partitions of the (bidirected) arc set A of the graph. Second, we exploit the cycle structure of the graph, explicitly mapping short closed walks on A to faces in the embedding.

Besides the theoretical advantages of our models, we show their practical strength by a thorough experimental evaluation. Contrary to the previous approach, we are able to quickly solve many instances of genus > 1 .

1 Introduction

The (orientable) genus of a graph G is the smallest number γ such that G can be embedded on an orientable surface of genus γ . The problem of determining γ is the *graph genus problem*.

Algorithmically exploiting a low graph genus is a vivid research field that spawned many results. It plays a key role for the complexity of certain problems, in particular w.r.t. polynomial-time approximation schemes (PTAS) and fixed parameter tractability (FPT) [8]. Algorithms tailored to achieve faster runtime on planar graphs can often be extended for the bounded genus setting (given a corresponding embedding, see below). For example, a bounded graph genus leads to: linear-time graph isomorphism testing [7]; FPT runtime for dominating set [15]; subexponential FPT runtime for many bidimensional problems, including vertex cover and variants of dominating set [13]; a quasi-PTAS for capacitated vehicle routing [1]; stronger preprocessing for several Steiner problems [29]; and many more.

Apart from such algorithmic uses, the problem is of independent interest in graph theory, where one is concerned with finding the genus of certain graph families (or even single graphs) [3–5, 12, 17, 18, 21, 22, 24, 26, 30–33, 37]. Typically, this involves induction and tedious arguments for the base cases.

Although genus is one of the best-established measures for non-planarity, its NP-hardness was proved relatively late in 1989 by Thomassen [35]. In contrast to other non-planarity measures like crossing number or skewness (or equivalently, maximum planar subgraph), and even compared to the *maximum* graph genus problem, there has been little algorithmic

progress. In 1988, Thomassen gave an algorithm that computes the genus of a restricted class of graphs in polynomial time [36] (graphs that have so-called LEW-embeddings). The problem is in FPT w.r.t. its natural parameterization due to Robertson and Seymour [34]; Mohar gave a constructive proof for such an FPT-algorithm [25]. Still, the proof spans seven papers of more than 100 pages in total. It was later simplified and extended to graphs with bounded treewidth [19]. It remains open to find a practically feasible FPT-algorithm [27]. No general approximation algorithm is known, although some progress was recently made for restricted variants and closely related problems [6, 20, 23]. The first general exact algorithm – beyond explicit enumeration – was described only recently [2]. It uses ILP/SAT solving to optimize over all rotation systems of the input, but fails to compute genera higher than 1 in practice. Overall, there is no practical, non-trivial algorithm to find low-genus embeddings, not even heuristically. Clearly, this is a main stumbling block for applying any of the genus-based algorithms mentioned above in practice.

Contribution. In this paper, we use the existing ILP as a starting point to develop a practically feasible model. To this end, we establish two novel core ideas. The original approach needs to model the embedding’s rotation scheme (see below) explicitly, essentially considering a Hamiltonian cycle problem for each graph node. We show how to only consider partitions of the bidirected arc set to deduce a rotation scheme; among other benefits, this allows us to use fewer variables. The second concept is to explicitly consider the cycle structure of the graph, by examining short, closed walks of the graph. Overall, we obtain both theoretically and practically stronger LP-relaxations. We thus present the first approach to compute the genus of (reasonably sized) graphs in practice, even for genera > 1 .

2 Preliminaries

We only need to consider biconnected (since genus is additive over biconnected components), simple graphs where each node has degree ≥ 3 : Given an undirected graph, we obtain its *bidirected* counterpart by creating two oppositely directed arcs uv, vu for each edge $\{u, v\}$. Given a graph H , we denote its nodes, edges, and arcs by $V(H)$, $E(H)$, and $A(H)$, respectively. For the input graph G , we may simply write V , E , and A . A *closed walk* c on a bidirected graph G is a set of arcs such that the induced subgraph $G[c]$ is connected and for each node the number of entering arcs is equal to that of leaving arcs. A *cycle* is a closed walk that visits no node more than once. For a node v , we refer to the arcs entering (leaving) v as $\delta_+(v)$ ($\delta_-(v)$, respectively). Let $N(v)$ be the nodes adjacent to node v . Given two subsets W, U of nodes, we define $W \times_A U := (W \times U) \cap A$ as the arcs from W to U . Given a partition, we refer to its partition sets as *cells*; this term should not be confused with faces of an embedding. For $k \in \mathbb{N}$, let $[k] := \{1, \dots, k\}$.

Graph Embeddings. A *drawing* \mathcal{D} of an undirected graph $G = (V, E)$ on an orientable surface S is a set of points \mathcal{P} and curves \mathcal{C} on S , such that there are bijections $\mathcal{D}_V: V \rightarrow \mathcal{P}$ and $\mathcal{D}_E: E \rightarrow \mathcal{C}$. We require that for each edge uv the two endpoints of $\mathcal{D}_E(uv)$ are $\mathcal{D}_V(u), \mathcal{D}_V(v)$. A drawing is *crossing free* if for any two edges e, f , $\mathcal{D}_E(e)$ is disjoint from $\mathcal{D}_E(f)$ except for common endpoints. We say that a graph is *planar* if it admits a crossing free drawing on the sphere. A crossing free drawing \mathcal{D} induces a cyclic rotation scheme Π of edges around each node, an *embedding*. From a combinatorial perspective, Π fully specifies \mathcal{D} and the genus minimal surface that \mathcal{D} can be drawn on. The regions bounded by edges are the *faces* of Π .

Given an embedding Π , we may identify its faces by tracing them as follows: Consider the bidirected counterpart of G . Starting at a node v , we traverse an arc vw and continue with the cyclically succeeding arc leaving w (w.r.t. the order of the undirected edges in Π). We iterate this until we again arrive at vw , closing the traced face's boundary. Repeating this operation until all edges are traversed exactly once in both directions gives all faces of Π . The traversed arcs of a face form a closed walk. If a node (or edge) appears more than once on the walk, we call this node (or edge) *singular*. The face tracing will allow us to count the number f_Π of faces. Using the Euler characteristic $|V| + f_\Pi - |E| = 2 - 2\gamma$, we are able to determine the lowest-genus (i.e., γ) surface that Π can be drawn on. Algorithmically, we thus ask for an embedding yielding the maximum number of faces.

Integer Linear Programming. A *linear program* (LP) consists of a cost vector $c \in \mathbb{Q}^d$ together with a set of linear inequalities, called *constraints*, that define a polyhedron P in \mathbb{R}^d . In polynomial time, we can find a point $x \in P$ that maximizes the *objective value* $c^\top x$. Unless $P = NP$, this is no longer true when restricting x to have integral components; the so-modified problem is an *Integer Linear Program* (ILP). Conversely, the *LP-relaxation* of an ILP is obtained by dropping the integrality constraints on its variables. Typically, there are several ways to reduce a given NP-hard problem to an ILP. These reductions are referred to as *models*. To achieve good practical performance, one aims for a small model where the objective value of the LP-relaxation is close to that of the ILP. This is crucial, as ILP solvers rely on iteratively computing LP-relaxations to obtain dual bounds on the integral objective. When a model has too many constraints to be solved in its entirety, it is often sufficient to use only a reasonably sized constraint subset to achieve a provably optimal solution. Hence, we may dynamically add constraints, during the solving process; this is called *separation*. We say that model A is *at least as strong* as model B , if for all instances, the LP-relaxation's value of model A is no worse than that of B . If there also exists an instance for which A 's LP-relaxation yields a tighter value than that of B , we call A *stronger* than B .

Common Foundation and Predecessor Model. As the known model [2], ours will simulate the face tracing algorithm. As such, both models share a common foundation that we borrow from [2]. For the sake of completeness, we repeat its definition below: We use variables x_i that are 1 if and only if face i exists, and variables x_i^a that are 1 if and only if arc a participates in the boundary of face i . Let \bar{f} be an upper bound on the number of faces. We use the shorthands $x(I, A) := \sum_{i \in I, a \in A} x_i^a$ and $x(A) := x([\bar{f}], A)$; thereby, we may omit curly braces when providing sets of cardinality one. Consider the following (by itself insufficient!) model (1a–1e) that we call ILP_{Base} .

$$\max \quad \sum_{i=1}^{\bar{f}} x_i \tag{1a}$$

$$\text{s.t.} \quad 3x_i \leq x(i, A) \quad \forall i \in [\bar{f}] \tag{1b}$$

$$x(a) = 1 \quad \forall a \in A \tag{1c}$$

$$x(i, \delta_-(v)) = x(i, \delta_+(v)) \quad \forall i \in [\bar{f}], v \in V \tag{1d}$$

$$x_i, x_i^a \in \{0, 1\} \quad \forall i \in [\bar{f}], a \in A \tag{1e}$$

Following [2], ILP_{Base} ensures that the faces form a partition of the arc set such that each cell consists of at least three arcs and is a collection of closed walks.

It remains to ensure that the faces are consistent with some rotation scheme of the edges around the nodes. In [2], this is achieved via *predecessor* variables, and we denote the model by ILP_{Pre} in the following. It uses ILP_{Base} and additionally (2a–2d). The idea is to establish

30:4 Stronger ILPs for the Graph Genus Problem

a cyclic order of the incident edges of each node by a cut-based sub-ILP known from the traveling salesman problem.

$$x_i^{vw} \geq x_i^{uv} + p_{u,w}^v - 1, \quad x_i^{uv} \geq x_i^{vw} + p_{u,w}^v - 1 \quad \forall i \in [\bar{f}], v \in V, u, w \in N(v) : u \neq w \quad (2a)$$

$$\sum_{\substack{u \in N(v) \\ u \neq w}} p_{w,u}^v = 1, \quad \sum_{\substack{u \in N(v) \\ u \neq w}} p_{u,w}^v = 1 \quad \forall v \in V, w \in N(v) \quad (2b)$$

$$\sum_{u \in W, w \in N(v) \setminus W} p_{u,w}^v \geq 1 \quad \forall v \in V, W \subsetneq N(v) : \emptyset \neq W \quad (2c)$$

$$p_{u,w}^v \in \{0, 1\} \quad \forall v \in V, u, w \in N(v) : u \neq w \quad (2d)$$

3 Realizability Model

In contrast to the explicit modeling of an embedding in ILP_{Pre} , we establish the existence of an embedding *implicitly*. Our *realizability constraints* (see (3) later) require only the variables of ILP_{Base} . We first need some auxiliary concepts. A graph $G = (V, A)$ is *loopy* if it is directed, connected, each node has at least one incoming arc, and for each arc $uv \in A$ it holds that $\mathcal{K}(uv) := G[\{s : sv \in A\} \cup \{t : ut \in A\}]$ is a complete bipartite graph $K_{k,k}$ for some $k \in \mathbb{N}$, such that each arc is directed from the cell of u to that of v w.r.t. the bipartition.

► **Lemma 1.** *Loopy graphs are Hamiltonian, i.e., they contain a cycle traversing all nodes.*

Proof. We first show that any loopy graph allows a cycle cover of pairwise node-disjoint cycles. Assume it does not, consider a collection \mathcal{C} of pairwise node-disjoint cycles covering as many nodes as possible, and let v be an uncovered node. By loopiness, there exists a bipartition that induces two cells, an arc uv , and $\mathcal{K}(uv)$ has a node w (possibly $u = w$) in the cell of u , such that w is not contained in any cycle of \mathcal{C} : for any ℓ nodes of one cell in a cycle $c \in \mathcal{C}$, c also contains ℓ nodes of the other cell. As there are only finitely many nodes, we find a new cycle by iterating our argument, i.e., traversing the cycle's arcs in reverse order, thus increasing our cycle cover; a contradiction.

Now, let \mathcal{C} be a node-disjoint cycle cover. For a cycle $c \in \mathcal{C}$, an arc a connecting $V(c)$ with $V \setminus V(c)$ exists by connectivity. Hence, $\mathcal{K}(a)$ contains an arc uv of c and another arc wx of a different cycle $c' \in \mathcal{C}$. We join c with c' to a single cycle by replacing uv, wx with ux, wv . Iterating this yields the claim. ◀

► **Theorem 2.** *A graph G allows an embedding Π with at least ξ faces if and only if there exists a partition P of $A(G)$, such that*

- (a) *P consists of at least ξ cells;*
- (b) *every cell of P is a set of pairwise node-disjoint closed walks; and*
- (c) *for all subsets $X \subseteq P$, nodes $v \in V(G)$, and non-empty subsets $W \subsetneq N(v)$, we have $\{wv, vw : w \in W\} \neq \bigcup_{x \in X} \{a \in x : v \text{ incident to } a\}$.*

Before giving the formal proof, let us provide some intuition on property (c): It models that the rotation around each node v is consistent. While in ILP_{Pre} constraints (2a–2d) model the rotation explicitly, property (c) ensures the *existence* of a feasible rotation by preventing subcycles. In the rotation around v , any two subsequent arcs must share an edge or a face. Hence, there cannot exist a *proper* subset W of v 's neighbors, such that *exactly* the arcs between v and W belong to a subset X of faces. As shown below this is also sufficient.

Proof (of Theorem 2). (\implies) We obtain P by creating a cell for each face f of Π : it contains exactly the arcs traversed by f . This satisfies (a) and (b). Assume that (c) is not satisfied, i.e., there exist X, v, W (following the above selection rules) such that

$\{wv, vw : w \in W\} = \bigcup_{x \in X} \{a \in x : v \text{ incident to } a\}$. Since W is a proper subset of $N(v)$, X cannot span all faces incident with v . We choose any face contained (not contained) in X and denote it by f (resp. g). Since Π is an embedding, there exists a sub-sequence of edges incident with v that corresponds to a dual path from f to g . But according to (c), all edges incident with X join two faces in X .

(\Leftarrow) We find an embedding Π by forming a face from each component of each cell of P . We establish feasible rotations around each node v in the following way: Let D_v be a directed graph with nodes $N(v)$ such that $uw \in A(D_v)$ if and only if uv and vw are in the same cell of P (i.e., the arcs could be traversed in that order when tracing the face corresponding to v 's component of the cell). A feasible rotation around v corresponds to a Hamiltonian cycle in D_v . We show that D_v is loopy, and hence Hamiltonian by Lemma 1: By construction of D_v , $\mathcal{K}(a)$ is a $K_{k,k}$ for some $k \in \mathbb{N}$, for each $a \in A(D_v)$. By property (b), all nodes of D_v have at least one incoming arc. For disconnected D_v , let W denote the nodes of a single component of D_v , and X the cells that induce $A(D_v[W])$. Then X, v, W contradict property (c). \blacktriangleleft

The above theorem shows that it suffices to optimize over all partitions of arcs into faces. Given a feasible partition (w.r.t. Theorem 2), a corresponding embedding is easily determined in polynomial time following our proof. We can now establish our new model ILP_{Real} , which extends ILP_{Base} with constraints (3). While the former already establishes properties (a) and (b), the latter models property (c): the connectivity of the ‘‘local dual graph’’ D_v around each primal node. Here, index set I corresponds to X from Theorem 2.

$$x(I, v \times_A (N(v) \setminus W)) \geq 1 + x(I, v \times_A W) - 2|W| \quad \forall v \in V, I \subseteq [\bar{f}], W \subsetneq N(v) : W \neq \emptyset \quad (3)$$

Separation. Clearly, it is impractical to add all exponentially many constraints (3) when solving ILP_{Real} . We use a heuristic separation routine to identify a relevant subset of these constraints. For each LP-feasible solution encountered during the solving process, we proceed as follows: For each node v we check if all variables x_a^i of its incident arcs a are integral. If this holds, but the corresponding D_v is disconnected, we found a new violation of (3).

4 Small Faces

The following approach is inspired by the cycle model for the maximum planar subgraph problem [11]. There, a mapping between small faces and short cycles was used to (only) strengthen the LP-relaxation of another, by itself sufficient, model. Thus, it was possible to mostly disregard longer cycles. In our setting we have to be more careful: On the one hand, we need to consider a far wider range of drawings as we embed on surfaces of higher genera. On the other hand, we have to directly adapt the core model itself; to continue to have a sufficient model, we need to *precisely* encode *all*, even very large, faces. We will model ‘‘short’’ faces by new binary y -variables, one for each specific feasible set of arcs. We continue to use the x -variables for *generic*, i.e., ‘‘large’’ faces. On sparse graphs, this yields a reduction of x -variables, as we may drastically decrease the upper bound on the number of generic faces. Both models, ILP_{Pre} and ILP_{Real} , can be extended in this way.

Let \mathcal{C}_χ denote the maximal set of closed walks such that each walk’s length satisfies property χ . Expanding on ILP_{Base} , we parameterize our new model $\text{ILP}_{\text{Base}}^D$ by some $D \geq 2$ and obtain (4a–4g) below. We introduce a new decision variable y_c for each $c \in \mathcal{C}_{\leq D}$. Let $y(a) := \sum_{c \in \mathcal{C}_{\leq D} : a \in c} y_c$ and $\bar{f}_{>d}$ any upper bound on the number of faces with length $> d$.

$$\begin{aligned}
 \max \quad & \sum_{i=1}^{\bar{f}_{>D}} x_i + \sum_{c \in \mathcal{C}_{\leq D}} y_c & (4a) \\
 \text{s.t.} \quad & (D+1)x_i \leq x(i, A) & \forall i \in [\bar{f}_{>D}] & (4b) \\
 & x(a) + y(a) = 1 & \forall a \in A & (4c) \\
 & x(i, \delta_-(v)) = x(i, \delta_+(v)) & \forall i \in [\bar{f}_{>D}], v \in V & (4d) \\
 & \sum_{i=1}^{\bar{f}_{>D}} x_i + \sum_{c \in \mathcal{C}_{\leq D}: |c| > d} y_c \leq \bar{f}_{>d} & \forall d \in \{2, \dots, D\} & (4e) \\
 & x_i \in \{0, 1\}, x_i^a \in \{0, 1\} & \forall i \in [\bar{f}_{>D}], a \in A & (4f) \\
 & y_c \in \{0, 1\} & \forall c \in \mathcal{C}_{\leq D} & (4g)
 \end{aligned}$$

Each arc is contained either in one of the generic faces that each form a set of closed walks (as for ILP_{Base}), or in a closed walk c with dedicated variable y_c , see constraints (4c). Generic faces are large, as required by constraints (4b). Constraints (4d) are essentially (1d). Albeit not required for integral solutions, constraints (4e) enforce the previously implicit upper bound on the total number of faces and bound the number of gradually smaller faces.

Predecessor Model. To obtain $\text{ILP}_{\text{Pre}}^D$, we add equations (2a–2d) to $\text{ILP}_{\text{Base}}^D$, i.e., the same set as for the transition from ILP_{Base} to ILP_{Pre} . Additionally, we require

$$\sum_{c \in \mathcal{C}_{\leq D}: uv, vw \in c} y_c \geq p_{u,w}^v - x([\bar{f}], uv) \quad \forall v \in V, u, w \in N(v). \quad (5)$$

Similar to (2a), this ensures that if an arc uv is contained in a face modeled by a y -variable, the succeeding arc vw has to be contained in the same face.

Realizability Model. We obtain $\text{ILP}_{\text{Real}}^D$ by starting with $\text{ILP}_{\text{Base}}^D$ and adding the following constraints to realize property (c) of Theorem 2.

$$\begin{aligned}
 x(I, \overline{A_W^v}) &\geq 1 + x(I, A_W^v) + \sum_{c \in \mathcal{C}_{\leq D}: c \cap \overline{A_W^v} = \emptyset} |c \cap A_W^v| y_c - 2|W| \\
 &\forall v \in V, I \subseteq [\bar{f}], W \subsetneq N(v) : W \neq \emptyset, A_W^v := v \times_A W, \overline{A_W^v} := v \times_A (N(v) \setminus W)
 \end{aligned} \quad (6)$$

They ensure there is no subset W of arcs at a common node v that is fully assigned to a set (consisting of I and a subset of $\mathcal{C}_{\leq D}$) of face variables that do not have an arc outside of W .

D-Hierarchy: Strength of LP-Relaxations. Clearly $\text{ILP}_{\text{Base}} = \text{ILP}_{\text{Base}}^2$. The value of \bar{f} has a strong influence on the dual bounds obtained by LP-relaxations. Hence, we describe how to determine \bar{f} and $\bar{f}_{>D}$ on general graphs. Let $n := |V(G)|$ and $m := |E(G)|$. Let $f_{\text{UB}}(a, b) := \min\{a, b - \mathbb{1}_{a-b=1 \pmod{2}}\}$, $\bar{f} := f_{\text{UB}}(m - n, \lfloor 2m/3 \rfloor)$, $\bar{f}_{>2} := \bar{f}$, and $\bar{f}_{>d} := \min\{\bar{f}_{>d-1}, \lfloor 2m/(d+1) \rfloor\}$ for $d > 2$. The validity of these bounds follows directly from Euler's formula (assuming non-planar G). We are not aware of any better, general, dual bounds. In the following comparison of LP-relaxations we always assume the above bounds.

► **Lemma 3.** *For every graph G , the LP-relaxation of ILP_{Base} has objective value \bar{f} .*

Proof. The domains (1e) establish \bar{f} as an upper bound. Set $\tilde{x}_a^i = 1/\bar{f}$ and $\tilde{x}^i = 1$ for all $i \in \bar{f}, a \in A$. Clearly \tilde{x} is an LP-feasible solution and achieves the claimed objective. ◀

► **Lemma 4.** *For every graph G , $\text{ILP}_{\text{Base}}^D$ admits an LP-feasible solution with objective value $\bar{f}_{>D}$. If G contains no closed walk of length at most D , this value is optimal.*

Proof. The first claim follows from the LP-feasible solution $\tilde{x}_i^a = 1/\bar{f}_{>D}$ and $\tilde{x}_i = 1$ for all $i \in \bar{f}_{>D}$, $a \in A$, and $\tilde{y} = 0$. When $\mathcal{C}_{\leq D} = \emptyset$, there are no y variables and the domains (4f) bound the objective from above, yielding the second claim. \blacktriangleleft

► **Lemma 5.** *Model $\text{ILP}_{\text{Base}}^{D+1}$ is at least as strong as $\text{ILP}_{\text{Base}}^D$ for any $D \geq 2$.*

Proof. Observe that $\text{ILP}_{\text{Base}}^{D+1}$ generally contains more y - but fewer x -variables than $\text{ILP}_{\text{Base}}^D$. Consider an LP-feasible solution (\hat{x}, \hat{y}) for $\text{ILP}_{\text{Base}}^{D+1}$. We derive an LP-feasible solution (\tilde{x}, \tilde{y}) for $\text{ILP}_{\text{Base}}^D$ that achieves no smaller objective value. For notational simplicity, let $\hat{x}_i = \hat{x}_i^a = 0$ for all $i > \bar{f}_{>D+1}$ and $\beta := \sum_{c \in \mathcal{C}_{=D+1}} \hat{y}_c$. For $\beta = 0$, already (\hat{x}, \hat{y}) , when interpreted for $\text{ILP}_{\text{Base}}^D$, is LP-feasible. Assume $\beta > 0$. Let $\alpha := \bar{f}_{>D} - \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i$ and $\beta_a := \sum_{c \in \mathcal{C}_{=D+1}: a \in c} \hat{y}_c \forall a \in A$. From $\alpha < \beta$ it would follow that $\bar{f}_{>D} < \sum_{i=1}^{\bar{f}_{>D+1}} \bar{f}_{>D+1} \hat{x}_i + \beta$, a direct contradiction of constraint (4e) for $d = D$ in $\text{ILP}_{\text{Base}}^{D+1}$. Thus, $\alpha \geq \beta$. We define (\tilde{x}, \tilde{y}) by $\tilde{x}_i := \hat{x}_i + (1 - \hat{x}_i)\beta/\alpha, \forall i \in [\bar{f}_{>D}]$; $\tilde{x}_i^a := \hat{x}_i^a + (\hat{x}_i - \hat{x}_i^a)\beta_a/\beta, \forall i \in [\bar{f}_{>D}], a \in A$; and $\tilde{y}_c := \hat{y}_c, \forall c \in \mathcal{C}_{\leq D}$. The objective value (4a) for (\tilde{x}, \tilde{y}) in $\text{ILP}_{\text{Base}}^D$ is

$$\begin{aligned} \sum_{i=1}^{\bar{f}_{>D}} \tilde{x}_i + \sum_{c \in \mathcal{C}_{\leq D}} \tilde{y}_c &= \sum_{i=1}^{\bar{f}_{>D}} (\hat{x}_i + (1 - \hat{x}_i)\beta/\alpha) + \sum_{c \in \mathcal{C}_{\leq D}} \hat{y}_c \\ &\stackrel{\text{(by } x_i = 0 \forall i > \bar{f}_{D+1})}{=} \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i + \beta/\alpha \cdot (\bar{f}_{>D} - \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i) + \sum_{c \in \mathcal{C}_{\leq D}} \hat{y}_c \\ &\stackrel{\text{(by def. of } \alpha, \beta)}{=} \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i + \sum_{c \in \mathcal{C}_{\leq D+1}} \hat{y}_c, \end{aligned}$$

i.e., equal to that of (\hat{x}, \hat{y}) in $\text{ILP}_{\text{Base}}^{D+1}$. Assuming constraint (4b) to be violated, we obtain $(D+1)\tilde{x}_i > (D+1)(\tilde{x}_i - \hat{x}_i) + \sum_{a \in A} \hat{x}_i^a \beta_a/\beta$, since $\sum_{a \in A} \beta_a/\beta = D+1$. This implies $(D+1)\tilde{x}_i > \sum_{a \in A} \hat{x}_i^a$, a violation of constraint (4b) already by (\hat{x}, \hat{y}) . Let us show the feasibility of (\tilde{x}, \tilde{y}) w.r.t. constraints (4c) by expanding their left-hand side.

$$\begin{aligned} \tilde{x}(a) + \tilde{y}(a) &= \sum_{i=1}^{\bar{f}_{>D}} (\hat{x}_i^a + (1 - \hat{x}_i)\beta_a/\alpha) + \sum_{c \in \mathcal{C}_{\leq D}: a \in c} \hat{y}_c \\ &\stackrel{\text{(by def. of } \alpha)}{=} \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i^a + \beta_a + \sum_{c \in \mathcal{C}_{\leq D}: a \in c} \hat{y}_c \\ &\stackrel{\text{(by def. of } \beta_a)}{=} \sum_{i=1}^{\bar{f}_{>D+1}} \hat{x}_i^a + \sum_{c \in \mathcal{C}_{\leq D+1}: a \in c} \hat{y}_c \stackrel{\text{(by feasibility of (4c) in } (\hat{x}, \hat{y}))}{=} 1 \end{aligned}$$

Since $\mathcal{C}_{=D+1}$ contains only closed walks, we have $\sum_{u \in N(v)} (\beta_{uv} - \beta_{vu}) = 0$ for all nodes v . Constraints (4d) hold, as we see by expanding their left-hand side:

$$\begin{aligned} \sum_{vu \in A} \tilde{x}_i^{vu} &= \sum_{vu \in A} \hat{x}_i^{vu} + (\tilde{x}_i - \hat{x}_i)/\beta \cdot \sum_{vu \in A} \beta_{vu} \\ &\stackrel{\text{(by (4d) in } \text{ILP}_{\text{Base}}^{D+1} \text{ and the above)}}{=} \sum_{uv \in A} \hat{x}_i^{uv} + (\tilde{x}_i - \hat{x}_i)/\beta \cdot \sum_{uv \in A} \beta_{uv} = \sum_{uv \in A} \hat{x}_i^{uv} \end{aligned}$$

Constraints (4e) maintain their slack, as the first term increases by $\sum_{i=1}^{\bar{f}_{>D}} (\tilde{x}_i - \hat{x}_i) = \beta$ while the second decreases by β . Clearly, $\tilde{x}_i \geq \hat{x}_i$ and $\tilde{x}_i^a \geq \hat{x}_i^a$. By $\alpha \geq \beta$ we have $\tilde{x}_i \leq 1$. By (4c) we have $\hat{x}_i^a + \beta_a \leq 1$. Thus, $\tilde{x}_i^a > 1$ would imply $\tilde{x}_i - \hat{x}_i > \beta$. Clearly, we keep $0 \leq \tilde{y}_c \leq 1$. \blacktriangleleft

► **Theorem 6.** *Model $\text{ILP}_{\text{Base}}^{D+1}$ is stronger than $\text{ILP}_{\text{Base}}^D$ for any $D \geq 2$.*

Proof. Restricting ourselves to dense graphs of girth $> D+1$, the claim immediately follows from Lemmata 3–5. An example of such graphs are the complete graphs on D nodes, where we subdivide each edge D times. They have girth $3(D+1)$ and are dense enough such that the respective bounds differ: $f_{>D} > f_{>D+1}$. We note that there are also dense graphs with high girth that do not allow any general preprocessing techniques. \blacktriangleleft

5 Additional Tuning (“Add-Ons”)

In addition to the new models described above, there is a set of supplemental constraints that may be applied to several of these models. We discuss them in alphabetical order.

Arc-Face. We may require the below trivial constraints explicitly.

$$x_i \geq x_i^a \quad \forall a \in A, i \in [\bar{f}] \quad (7)$$

Branching Rule. To facilitate the fast generation of strong primal bounds, we may initially restrict the solution space to explicitly modeled faces, e.g., by branching on

$$\sum_{i \in \bar{f}_{>D}} x_i \stackrel{?}{=} 0. \quad (8)$$

deg-3-Model. There are only two possible rotations around any degree-3 node v . In ILP_{Pre} , this can be modeled by a single binary variable for v and alternative constraints, partially replacing (2a–2d), as discussed in [2]. The same holds for $\text{ILP}_{\text{Pre}}^D$, and we use this improvement in our benchmarks.

Long Faces. In several cases we can establish lower bounds on the length of faces modeled by the x -variables. Let $s(v, w)$ denote the length of the shortest path between nodes v and w .

► **Lemma 7.** *For arcs uv, wx that traverse the same face f , we have $s(v, w) + s(x, u) + 2 \leq |f|$.*

Proof. Tracing any such face f yields a path from v to w that neither contains arc uv (it may contain arc vu) nor arc vx . Similarly, an arc-disjoint path from x to u must exist in f . The total length of these paths is lower bounded by $s(v, w) + s(x, u)$. ◀

► **Lemma 8.** *Any face with a singular edge contains at least eight arcs and this is tight.*

Proof. Let uv denote the edge that is traversed in both directions when tracing face f . If tracing f would additionally yield a path from u to v that does not contain uv , the tracing would similarly yield a path from v to u that does not contain vu . This contradicts the assumption since f would contain two oppositely directed, closed walks that form two separate faces. Hence, there exist two arc-disjoint closed walks on the boundary of f , one for each node u, v . Since there are no deg-1 nodes in a biconnected graph, any subcycle in a face requires at least three arcs and the claim follows. Considering a genus-1 embedding of the K_4 we can see that it indeed contains such a face of length eight. ◀

► **Lemma 9.** *Any face with a singular node contains at least six arcs and this is tight.*

Proof. If the face f also traverses an edge twice, the bound follows from Lemma 8. Otherwise, the doubly traversed node has at least four arcs in f , belonging to pairwise different edges, and hence four incident nodes. A closed walk on this $K_{1,4}$ requires at least two additional arcs and the claimed bound follows. A face of length six can be observed in a genus-1 embedding of the following graph: Take two copies of the K_5 , remove one edge each, join the graphs by identifying two deg-3 nodes, and add a new edge between the remaining two deg-3 nodes. ◀

Let $\ell_{uv,wx} := \max\{s(v, w) + s(x, u) + 2, 6 \cdot \mathbf{1}_{k=3}, 8 \cdot \mathbf{1}_{k=2}\}$ with $k := |\{u, v, w, x\}|$. Lemmata 7–9 yield the following constraints. When using them in our benchmarks, we separate them.

$$\ell_{uv,wx} (x_i^{uv} + x_i^{wx} - 1) \leq x(i, A) \quad \forall i \in [\bar{f}_{>D}], uv, wx \in A : uv \neq wx \quad (9)$$

Objective Parity. All above ILPs maximize the number f of faces and deduce γ via Euler’s formula $n + f - m = 2 - 2\gamma$. Thus the parity of f is fixed. This gives room for improved bounding and cutting by the ILP solver. Using a new variable $z \in \mathbb{N}$ we may demand

$$(m - n \bmod 2) + 2z = \sum_{i=1}^{\bar{f} > D} f_i + \sum_{c \in \mathcal{C}_{\leq D}} y_c. \quad (10)$$

Symmetry Breaking. For ILP_{Pre} it was observed in [2] that symmetry breaking does not seem to pay off. However, ILP_{Pre} only solves genus-1 instances in practice (see below). Symmetry breaking may hinder heuristics from identifying trivially optimal solutions, but may be beneficial for harder instances. The approach in [2] enforces that face i has at most as many arcs as face $i + 1$. However, there are typically many faces with the same length in a low-genus embedding. We consider breaking symmetries by restricting the set of faces that may contain a given arc. Let \prec denote an arbitrary but fixed order on the arc set A .

$$y(a) + x(\{1, \dots, \ell\}, a) \geq 1 - x(\ell, \{a' \in A : a' \prec a\}) \quad \forall \ell \in [\bar{f}], a \in A \quad (11)$$

These constraints ensure that any arc is contained either in an explicitly modeled closed walk or in the lowest-indexed face that it can be placed into. For ILP_{Pre} and ILP_{Real} , i.e., when there are no explicitly modeled closed walks, we simply set $y(a) = 0$.

6 Experiments

All algorithms are implemented in C++, compiled with gcc 6.3.0, and use the OGDF (snapshot 2018-03-28) [9]. We use SCIP 6.0.0 [16] for solving ILPs, with CPLEX 12.8.0 as the underlying LP solver. Each computation uses a single physical core of a Xeon Gold 6134 CPU (3.2 GHz) with a memory speed of 2666 MHz. We employ a time limit of 10 minutes and a memory limit of 8 GB per computation. All instances and results, giving runtime and genus (if solved), are available for download at <http://tcs.uos.de/research/min-genus>. In our experiments, we increase parameter D – separately on each graph – until we obtain at least 1000 y -variables. As they are not required for integral solutions, we omit constraints (4e) by default.

Instance Sets. We consider the 423 and 8249 non-planar graphs of the two established real-world sets NORTH [28] and ROME [14], respectively. In addition, we use the set of 600 EXPANDER graphs, as established in [10, 11] for a related non-planarity measure (skewness): there are 20 graphs for each feasible parameterization $(|V(G)|, \Delta) \in \{10, 20, 30, 50, 100\} \times \{4, 6, 10, 20, 40\}$, where Δ denotes the node degree.

Discussion of SAT-based algorithms. In [2], the SAT-based approach was faster than the ILP-based one. However, we do not need to directly compare with it.

Both previous approaches solve only instances with genus ≤ 1 in practice. Since the respective dual bound is trivially given by planarity testing (and enforced in all previous models), the runtime difference can be attributed to the SAT-solver quickly finding a satisfying solution. In contrast, standard primal heuristics of ILP-solvers are weaker, and the comparably time-consuming LP-relaxations are rarely profitable. However, w.r.t. success-rate, SAT is only marginally in the lead, if at all: on the ROME graphs, the ILP and SAT solve 2595 and 2667 instances, respectively. For NORTH, “the success-rates of both approaches are [...] comparable” [2].

(a) Solved ROME graphs by number of nodes.

(b) Solved NORTH graphs by number of nodes.

■ **Figure 1** Detailed success-rates of algorithms on established benchmark sets. We provide the relative number of solved instances over the number of nodes, clustered to the nearest multiple of 10. The gray bars denote the number of instances in each cluster.

Since we can neither employ separation nor LP-relaxations in the setting of SAT-solvers, there also is no immediate way of using our strengthening results for SAT-based algorithms. We will see that the new ILP variants clearly dominate the SAT-based variants; e.g., we solve up to 6797 ROME instances.

Results. The experiments confirm that our new model is not only theoretically stronger but also better in practice: Using $\text{ILP}_{\text{Real}}^D$, we are now able to solve 82% instead of just 28% of the ROME graphs, cf. Table 1. Depending on the instance set, we achieve an average speed-up of factor 82 to 248. In [2], only graphs with genus 1 (and not all of them) could be solved. Surprisingly, and in contrast to the observations made in [2], the deg 3-model does not perform better than the respective base variant: SCIP’s built-in preprocessing reduces the variable space to essentially the same dimension as obtained when manually applying the deg 3-model (while possibly retaining some additional information that helps in the solving process). Also somewhat to our surprise, none of the add-ons (8–11) pay off *reliably*.

Taking a closer look at the number of solved instances (Figure 1 and Table 2), we see that – on average – $\text{ILP}_{\text{Real}}^D$ is superior to all other variants for any graph size. We now solve real-world instances with non-trivial dual bounds, i.e., when the genus is > 1 , e.g., we have solved a genus-7 instance on ROME and even a genus-21 instance on NORTH. We see very clearly, in particular on ROME, that we may order the models ILP_{Pre} , ILP_{Real} , $\text{ILP}_{\text{Pre}}^D$, $\text{ILP}_{\text{Real}}^D$ by increasing success rate. This means that, independent on whether we apply the small-faces model extension or not, the realizability model is more successful than

■ **Table 1** Average success-rate s and runtime t on each instance set. Considering the runtime, we restrict the instances to those solved by all variants. Of the graphs solved by ILP_{Pre} , all variants solved at least 94% (ROME), 99% (NORTH), and 100% (EXPANDER). Particularly, algorithms based on ILP_{Base}^D always solved all of the instances solved by ILP_{Pre} .

	ROME		NORTH		EXPANDER	
	s [%]	t [s]	s [%]	t [s]	s [%]	t [s]
ILP_{Pre}	27.79	190.23	45.86	139.09	5.26	58.29

■ **Figure 2** Final primal vs. dual bounds on the genus, generated by algorithmic variants on ROME (without any add-ons). Color and size indicate the number of instances with the respective bounds. We note that these bounds do not apply to the values of the formal objective value, i.e., the number of attained faces, but to the genus, which allows a more sensible comparison. Note that without the small faces extension, neither ILP_{Pre} nor ILP_{Real} obtains lower bounds > 1 (i.e., only trivial ones).

30:12 Stronger ILPs for the Graph Genus Problem

(a) genus bound of LP-relaxation.

(b) number of generated y -variables.

■ **Figure 3** Average values of ILP_{Base}^D on the solved ROME graphs, depending on the maximum length D of explicitly modeled cycles and the genus of the graph. Note that we only solved one instance with genus 7 on ROME.

■ **Table 2** Number of solved instances in the EXPANDER set for selected variants without add-ons.

# nodes	10		20			30		≥ 50
	4	6	4	6	10	4	6-20	4-40
ILP_{Pre}	20	0	0	0	0	0	0	0
ILP_{Real}	20	1	0	0	0	0	0	0
ILP_{Pre}^D	20	20	20	0	0	6	0	0
ILP_{Real}^D	20	20	20	18	0	13	0	0

the predecessor model. The most progress, however, is achieved by activating the small-faces model extension ILP_{Base}^D . As the shapes of the success-rate curves demonstrate, it benefits both underlying models roughly equally. In particular, we see (cf. also Figure 2 which shows the final bounds of our core variants on ROME) that even ILP_{Real} , like ILP_{Pre} , can only solve genus 1 instances. This is in accordance with Lemma 3, i.e., that the LP-relaxation of ILP_{Base} always yields value \bar{f} . Nonetheless, the success-rates 46% and 51% on NORTH for ILP_{Pre} and ILP_{Real} , respectively, demonstrate that ILP_{Pre} is far from solving all toroidal instances. More complex instances require the small-faces extension ILP_{Base}^D . This is also reflected by the root relaxations of ILP_{Base}^D for different values of D , cf. Figure 3. Consistent with theory, increasing the minimum length D leads to stronger LP-relaxations also in practice, but may drastically increase the number of variables. Interestingly, generating only triangles, i.e., $D = 3$, yields only a very slight increase on the average dual bound compared to ILP_{Base} on ROME, possibly caused by the graphs' sparsity.

Genera in Graph Theory. Our new approach allows us to confirm results from literature, all with non-trivial dual bounds: In 2015, the circulants of genus ≤ 2 were characterized [12]. Thereby, the authors need to show that 12 specific graphs have genus ≥ 3 . For these arguments alone, they require about nine pages, supplemented by several hours of computation. Using ILP_{Real}^D , we are able to confirm these results (and compute the respective genera) in a matter of seconds without employing any graph-specific theory. Before, using ILP_{Pre} , the arguably hardest case $C_{11}(1, 2, 4)$ required 180 hours [2]. In 2005, a full paper was dedicated to showing that the Gray graph has genus 7 [24]. Our tool confirms this result within 42 hours. Similarly, we confirm a result from 1989 [4] in 250 seconds: the group that is the semidirect product of \mathbb{Z}_9 with \mathbb{Z}_3 has genus 4 (the genus of group Γ is the smallest genus of a Caley graph of Γ).

7 Conclusion

We have presented novel ILP models for the graph genus problem, proved their theoretical strength, the existence of a hierarchy of ever stronger LP-relaxations, and positively evaluated them in practice, e.g., by solving 82% instead of the previous 28% of the ROME instances. We are now able to solve real-world instances with genera up to 21. This is in stark contrast to the previous models that – on the same set of instances – succeeded only on toroidal graphs.

It remains open whether even stronger models can be found by a more careful examination of the face structure. What additional properties of the embedding may be modeled? Is it possible to better exploit singular nodes or edges, particularly when they are adjacent? Further, we expect that our algorithms would benefit from strong primal heuristics but we are not aware of any general such algorithms. Currently, optimal dual bounds are often identified long before an optimal solution is found.

Abstract

For a graph F , a graph G is F -free if it does not contain an induced subgraph isomorphic to F . For two graphs G and H , an H -coloring of G is a mapping $f : V(G) \rightarrow V(H)$ such that for every edge $uv \in E(G)$ it holds that $f(u)f(v) \in E(H)$. We are interested in the complexity of the problem H -COLORING, which asks for the existence of an H -coloring of an input graph G . In particular, we consider H -COLORING of F -free graphs, where F is a fixed graph and H is an odd cycle of length at least 5. This problem is closely related to the well known open problem of determining the complexity of 3-COLORING of P_t -free graphs.

We show that for every odd $k \geq 5$ the C_k -COLORING problem, even in the precoloring-extension variant, can be solved in polynomial time in P_9 -free graphs. On the other hand, we prove that the extension version of C_k -COLORING is NP-complete for F -free graphs whenever some component of F is not a subgraph of a subdivided claw.

1 Introduction

For graphs G and H , a *homomorphism from G to H* is a mapping $f : V(G) \rightarrow V(H)$ such that $f(u)f(v) \in E(H)$ for every edge $uv \in E(G)$. It is straightforward to see that if H is a complete graph with k vertices, then every homomorphism to H is in fact a k -coloring of G (and vice versa). This shows that homomorphisms can be seen as a generalization of graph colorings. Because of that, a homomorphism to H is often called an *H -coloring*, and vertices of H are called *colors*. We also say that G is *H -colorable* if G has an H -coloring.

In what follows, the target graph H is always fixed. We are interested in the complexity of the H -COLORING problem, which asks whether the input graph G has an H -coloring.

1.1 Complexity of variants of H -Coloring

Since H -COLORING is a generalization of k -COLORING, it is natural to try to extend results for k -COLORING to target graphs H which are not complete graphs. For example, it is well-known that k -COLORING enjoys a complexity dichotomy: it is polynomial-time solvable if $k \leq 2$, and NP-complete otherwise. The complexity dichotomy for H -COLORING was described by Hell and Nešetřil in their seminal paper [23]: they proved that the problem is polynomial-time solvable if H is bipartite, and NP-complete otherwise.

Since then, there have been numerous studies on variants of H -COLORING. Our main focus will be on the H -PRECOLORING EXTENSION problem, in which we are given a triple (G, W, h) , where G is a graph, W is a subset of $V(G)$, and h is a mapping from W to $V(H)$. The problem is to decide if h can be extended to an H -coloring of G , that is, if there is an H -coloring f of G such that $f|_W = h$.

Note that this problem is closely related to the LIST H -COLORING problem, where the input consists of a graph G with an *H -list assignment*, which is a function $L : V(G) \rightarrow 2^{V(H)}$ that assigns a subset of $V(H)$ (called *list*) to each vertex of G . We ask if there is an H -coloring f of G such that $f(v) \in L(v)$ for each $v \in V(G)$. In such a case we say that (G, L) is *H -colorable* and f is an *H -coloring of (G, L)* . Clearly H -PRECOLORING EXTENSION can be seen as a restriction of LIST H -COLORING, in which every list is either a singleton, or contains all vertices of H . This is the reason why it is sometimes called *one-or-all list homomorphism (coloring) problem* [13].

In general, variants of H -COLORING can be seen in a wider context of Constraint Satisfaction Problems (CSP). A full complexity dichotomy for this family of problems has been a long-standing open question, known as the *CSP dichotomy conjecture* of Feder and Vardi [15]. After a long series of partial results, the problem was finally solved very recently, independently by Bulatov [5] and by Zhuk [33].

A natural approach in dealing with computationally hard problems is to consider restricted instances, in hope to understand the boundary between easy and hard cases. For example, it is known that H -COLORING can be solved in polynomial time for perfect graphs, because it suffices to test whether $\omega(G) > \omega(H)$, which can be done in $O(|V(G)|^{|V(H)|})$ time. If $\omega(G) > \omega(H)$, then the answer is no, as there is no way to map the largest clique of G to H . Otherwise the answer is yes, since $\omega(G)$ -coloring of G can be translated to a homomorphism of G to the largest clique of H , and thus to H . The situation changes when we consider the more general setting of H -PRECOLORING EXTENSION and LIST H -COLORING. For any fixed graph H , LIST H -COLORING (and thus H -PRECOLORING EXTENSION and H -COLORING) can be solved in polynomial time for input graphs with bounded tree-width. Combining this with an observation that any graph with a clique larger than $\omega(H)$ has no H -coloring, we obtain polynomial-time algorithms for chordal graphs [14]. For permutations graphs, LIST

H -COLORING can also be solved in polynomial time via a recursive branching algorithm [11]. For bipartite input graphs, however, 3-PRECOLORING EXTENSION (i.e., K_3 -PRECOLORING EXTENSION) is already NP-complete [29]. Other restricted inputs have been studied too, e.g. bounded-degree graphs [16]. For more results on graph homomorphisms, we refer to the monograph by Hell and Nešetřil [22].

1.2 Graphs with forbidden induced subgraphs

A rich family of restricted graph classes comes from forbidding some small substructures. For graphs G and F , we say that G *contains* F if F is an induced subgraph of G . By F -free graphs we mean the class of graphs that do not contain F . Note that this class is *hereditary*, that is, it is closed under taking induced subgraphs.

The complexity of k -COLORING for hereditary graph classes has received much attention in the past two decades and significant progress has been made. Of particular interest is the class of F -free graphs for a fixed graph F . For any fixed $k \geq 3$, the k -COLORING problem remains NP-complete for F -free graphs whenever F is not a linear forest (a collection of disjoint paths) [25, 31]. The simplest linear forests are paths, and the complexity of k -COLORING in P_t -free graphs has been studied by many researchers.

On the positive side, Hoàng, Kamiński, Lozin, Sawada, and Shu [24] gave a recursive algorithm showing that k -COLORING can be solved in polynomial time for P_5 -free graphs for any fixed k . Bonomo, Chudnovsky, Maceli, Schaudt, Stein, and Zhong [4] showed that 3-COLORING can be solved in polynomial time in P_7 -free graphs. Moreover, very recently, Chudnovsky, Spirkl, and Zhong proved that 4-COLORING is polynomial-time solvable in P_6 -free graphs [7, 8, 9].

On the negative side, Woeginger and Sgall [32] demonstrated the NP-completeness of 5-COLORING for P_8 -free graphs and 4-COLORING for P_{12} -free graphs. Later on, these NP-completeness results were improved by various researchers and the strongest result is due to Huang [26] who proved that 4-COLORING is NP-complete for P_7 -free graphs and 5-COLORING is NP-complete for P_6 -free graphs. These results settle the complexity of k -COLORING for P_t -free graphs for all pairs (k, t) , except for the complexity of 3-COLORING for P_t -free graphs when $t \geq 8$. Interestingly, all polynomial-time results carry over to the list variant, except for the case of LIST 4-COLORING of P_6 -free graphs, which was shown to be NP-complete by Golovach, Paulusma, and Song [18]. We refer the reader to the survey by Golovach, Johnson, Paulusma, and Song [17] for more information about coloring graphs with forbidden subgraphs.

Understanding the complexity of 3-COLORING in P_t -free graphs seems a hard problem – on the one hand, algorithms even for small values of t are difficult to construct, and on the other hand all our hardness reductions appear to introduce long induced paths. Let us mention a problem whose complexity is equally elusive: INDEPENDENT SET. Alekseev [1] observed that INDEPENDENT SET is NP-complete in F -free graphs whenever F is not a path or a subdivided claw. For P_t -free graphs, polynomial-time algorithms are known only for small values of t : currently, the best result is the recent polynomial-time algorithm for P_6 -free graphs by Grzesik, Klimošova, Pilipczuk, and Pilipczuk [20, 21]. On the other hand, the problem is not known to be NP-hard for any fixed t .

A natural question to ask is if the similar behavior of 3-COLORING and INDEPENDENT SET in P_t -free graphs is a part of a more general phenomenon. Recently, Groenland, Okrasa, Rzażewski, Scott, Seymour, and Spirkl [19] shed some light on this question by showing that if H does not contain two vertices with two common neighbors, then a very general, weighted variant of H -COLORING can be solved in time $2^{O(\sqrt{tn \log n})}$ for P_t -free graphs. Clearly K_3

does not have two vertices with two common neighbors. Moreover, INDEPENDENT SET can be expressed as a weighted homomorphism to $\textcircled{1}-\textcircled{1}$, which has the same property, and thus, for every t , both 3-COLORING and INDEPENDENT SET can be solved in subexponential time in P_t -free graphs (we note that a subexponential algorithm for INDEPENDENT SET in P_t -free graphs was known before [2]). This implies that if one attempts to prove NP-completeness of any of these problems in P_t -free graphs, then, assuming the Exponential Time Hypothesis [27, 28], such a reduction should be sufficiently complicated to introduce at least a quadratic blow-up of the instance.

In this paper, we study the complexity of variants of H -COLORING when H is an odd cycle of length at least five. Note that by the result of Groenland *et al.* [19], this problem can be solved in subexponential time in P_t -free graphs. We are interested in better classification of polynomial and NP-hard cases.

1.3 Our contribution

The contribution of the paper is twofold: First, we show that the C_k -PRECOLORING EXTENSION problem can be solved in polynomial time in P_9 -free graphs.

► **Theorem 1.1.** *Let $k \geq 5$ be odd, G be a P_9 -free graph of order n , W be a subset of its vertices, and h be a mapping from W to $V(C_k)$. Then one can determine in $O(n^{12k+3})$ time if h can be extended to a C_k -coloring of G , and find such a C_k -coloring if one exists.*

The algorithm is described in detail in Section 3. It builds on the recent work on 3-COLORING P_7 -free graphs [4]. The high-level idea of the algorithm is the following: First, we partition the graph into a so-called *layer structure* and guess the colors of a constant number of vertices. This precoloring propagates to other vertices using the layer structure, reducing the lists of possible colors. We keep guessing the colors of other vertices, transforming the input instance into a set of $n^{O(k)}$ subinstances of LIST H -COLORING, such that:

- (i) (G, W, f) is a yes-instance of C_k -PRECOLORING EXTENSION if and only if one of these subinstances is a yes-instance of LIST C_k -COLORING; and
- (ii) each subinstance can be solved in polynomial time by a reduction to 2-SAT.

In Section 4, we study the complexity of variants of H -COLORING in F -free graphs and prove the following theorem.

► **Theorem 1.2.** *Let F be a connected graph. If F is not a subgraph of a subdivided claw, then for every odd $k \geq 5$ the C_k -PRECOLORING EXTENSION problem is NP-complete for F -free graphs.*

We prove the theorem in several steps, analyzing the possible structure of F and trimming the hard cases. Observe that the statement of Theorem 1.2 is similar to the previously mentioned result of Alekseev for INDEPENDENT SET [1]. In most cases, we actually prove hardness for the more restricted C_k -COLORING problem.

Finally, in Section 5, we state some open questions for future research.

2 Preliminaries

Let G be a simple graph. For $X \subseteq V(G)$, we denote by $G|X$ the subgraph induced by X , and denote by $G \setminus X$ the graph $G|(V(G) \setminus X)$. We say that X is *connected* if $G|X$ is connected. For two disjoint subsets $A, B \subset V(G)$, we say that A is *complete* to B if every vertex of A is adjacent to every vertex of B , and that A is *anticomplete* to B if every

vertex of A is nonadjacent to every vertex of B . If $A = \{a\}$ we write a is complete (or anticomplete) to B to mean that $\{a\}$ is complete (or anticomplete) to B . For $X \subseteq V(G)$, we say that $e \in E(G)$ is *an edge of X* if both endpoints of e are in X . For $v \in V(G)$ we write $N_G(v)$ (or $N(v)$ when there is no danger of confusion) to mean the set of vertices of G that are adjacent to v . Observe that since G is simple, $v \notin N(v)$. For $X \subseteq V(G)$ we define $N(X) = (\bigcup_{v \in X} N(v)) \setminus X$. We say that the set S *dominates X* , or S is a *dominating set* of X if $X \subseteq S \cup N(S)$. We write that S dominates G when we mean that it dominates $V(G)$. A component of G is *trivial* if it has only one vertex and *nontrivial* otherwise.

We use $[k]$ to denote the set $\{1, 2, \dots, k\}$. We denote by P_t the path with t vertices. A *path in a graph G* is a sequence $v_1 - \dots - v_t$ of pairwise distinct vertices such that for any $i, j \in [t]$, $v_i v_j \in E(G)$ if and only if $|i - j| = 1$. The *length* of this path is t . We denote by $V(P)$ the set $\{v_1, \dots, v_t\}$. If $a, b \in V(P)$, say $a = v_i$ and $b = v_j$ with $i < j$, then $a - P - b$ is the path $v_i - v_{i+1} - \dots - v_j$, and $b - P - a$ is the path $v_j - v_{j-1} - \dots - v_i$.

Let $k \geq 3$ be an odd integer. We denote by C_k a cycle with k vertices $1, 2, \dots, k$ that appear along the cycle in this order. The calculations on vertices of C_k will be preformed modulo k , with 0 unified with vertex k .

We say that (G, L') is a *subinstance* of (G, L) if $L'(v) \subseteq L(v)$ for every $v \in V(G)$. Two C_k -list assignments L and L' of G are *equivalent* if (G, L) is C_k -colorable if and only if (G, L') is C_k -colorable. A C_k -list assignment L is *equivalent* to a set \mathcal{L} of C_k -list assignments of a graph G if there is $L' \in \mathcal{L}$ such that (G, L) is equivalent to (G, L') .

Let (G, L) be an instance of LIST C_k -COLORING. We say that the list $L(x)$ of a vertex x is *good* if $|L(x)| \in \{1, 2, 3, k\}$ and in addition

- if $|L(x)| = 2$, then $L(x) = \{i - 1, i + 1\}$ for some $i \in [k]$, and
- if $|L(x)| = 3$, then $L(x) = \{i, i - 2, i + 2\}$ for some $i \in [k]$.

We say that L is *good* if $L(v)$ is good for all $v \in V(G)$.

For an edge $vw \in E(G)$, we *update v from w* if one of the following is performed.

- If $L(w) = \{i\}$ for some $i \in [k]$, then replace the list of v by $\{i - 1, i + 1\} \cap L(v)$.
- If $L(w) = \{i - 1, i + 1\}$ for some $i \in [k]$, then replace the list of v by $\{i, i + 2, i - 2\} \cap L(v)$.
- If $L(w) = \{i, i - 2, i + 2\}$, $L(v) = \{j, j + 2, j - 2\}$ for some $i, j \in [k]$, then replace the list of v by $\{i - 1, i + 1, i - 3, i + 3\} \cap L(v)$.

Clearly, any update creates an equivalent subinstance of (G, L) . Note that in the graph homomorphism literature this operation is usually referred to as *edge (or arc) consistency* and it is performed in the beginning of most algorithms solving variants of H -COLORING [22, 30]. However, we keep the name “update” to emphasize that we will only perform it at certain points in our algorithm. We say that an update of v from w is *effective* if the size of the list of v decreases by at least 1, and *ineffective* otherwise. Note that an update is effective if and only if there exists an element $c \in L(v)$ which is not an element of $\{i - 1, i + 1\}$, $\{i, i + 2, i - 2\}$ or $\{i - 1, i + 1, i - 3, i + 3\}$ depending on the case in the definition of an update. We observe that the update does not change the goodness of the list².

► **Lemma 2.1** (♠). *If the lists of v and w are good before updating v from w , then the list of v is good or empty after the update.*

A C_k -list assignment L is said to be *reduced* if no effective update can be performed. It is well-known that one can obtain a reduced list assignment in polynomial time.

² The proofs of theorems and lemmas marked with ♠ are omitted due to space constraints.

► **Lemma 2.2** (♠). *Let G be a graph of order n , and L be a C_k -list assignment. There exists an $O(n^3)$ -time algorithm to obtain an equivalent reduced subinstance (G, L') of (G, L) or determine that (G, L) has no C_k -coloring.*

We now introduce two more tools that are important for our purpose. The first one is purely graph-theoretic and describes the structure of P_t -free graphs.

► **Theorem 2.3** ([6]). *Let G be a connected P_t -free graph with $t \geq 4$. Then G has a connected dominating set D such that $G|D$ is either P_{t-2} -free or isomorphic to P_{t-2} .*

The next observation generalizes the observation by Edwards [10] that LIST k -COLORING can be solved in polynomial time, whenever the size of each list is at most two. This was already noted by e.g. Feder and Hell [12].

► **Theorem 2.4** (♠). *Let (G, L) be an instance of LIST H -COLORING where G is of order n and $|L(v)| \leq 2$ for every $v \in V(G)$. Then one can determine in $O(n^2)$ time if (G, L) is H -colorable and find an H -coloring if one exists.*

3 Polynomial algorithm for P_9 -free graphs

In this section, we show that C_k -PRECOLORING EXTENSION can be solved in polynomial time for P_9 -free graphs.

► **Theorem 1.1.** *Let $k \geq 5$ be odd, G be a P_9 -free graph of order n , W be a subset of its vertices, and h be a mapping from W to $V(C_k)$. Then one can determine in $O(n^{12k+3})$ time if h can be extended to a C_k -coloring of G , and find such a C_k -coloring if one exists.*

Outline of the proof

The overall strategy is to reduce the instance (G, W, h) , in polynomial time, to a set \mathcal{I} of polynomially many instances of LIST C_k -COLORING, in which every list has size at most 2, and (G, W, h) is a yes-instance if and only if at least one instance from \mathcal{I} is a yes-instance. We then apply Theorem 2.4 to solve each instance from \mathcal{I} in polynomial time.

More specifically, our algorithm, at a high level, consists of five phases. In the first three of them, we focus on processing the graph $G' := G \setminus W$. First, we apply Theorem 2.3 to show that the vertex set of G' can be partitioned into four sets (S, X, Y, Z) such S is connected and dominates X , X dominates Y , and Y dominates Z . Second, we branch on every possible C_k -coloring of $G'|S$. For each of these colorings of $G'|S$, we propagate the coloring of S to the vertices of $G' \setminus S$ via updates. After updating, the vertices in $S \cup X$ will have lists of size at most 2, but the vertices in $Y \cup Z$ may still have larger lists. In the third phase, we reduce the instance to polynomially many subinstances via branching in such a way that each of the subinstances avoids certain configurations, which we call *bad paths*. Finally, using the fact that each subinstance has no bad paths, in the last two phases we reduce the list size of vertices in $Y \cup Z$ to at most 2, restore the set W , creating a set of instances, which is equivalent to (G, W, h) , and use Theorem 2.4 to solve the created instances in polynomial time.

Proof of Theorem 1.1. We view (G, W, h) as an equivalent instance (G, L) of LIST C_k -COLORING where $L(v) = \{h(v)\}$ if $v \in W$ and $L(v) = [k]$ otherwise.

Clearly, h can be extended to an C_k -coloring of G if and only if (G, L) is C_k -colorable. Moreover, observe that if G contains a triangle, then we can immediately report a no-instance. Checking for existence of triangles can clearly be done in $O(n^3)$ time, so from now on we assume that G is triangle-free.

For the first three phases we consider the graph $G' := G \setminus W$. We may assume that G' is connected, for otherwise we can apply the same reasoning to every connected component.

Phase I. Obtaining a layer structure

Let us start with imposing some structure on the vertices of G' .

▷ **Claim 3.1.** There exists $S \subseteq V(G')$ such that $|S| \leq 7$, the graph $G'|S$ is connected, and $S \cup N(S) \cup N(N(S))$ dominates G' .

Proof. We apply Theorem 2.3 to G' : G' has a connected dominating set D that induces a subgraph that is either P_7 -free or isomorphic to a P_7 . If $G'|D$ is isomorphic to a P_7 , then D is the desired set S . Otherwise we apply Theorem 2.3 on $G'|D$ to conclude that $G'|D$ has a connected dominating set D' that induces a subgraph that is either P_5 -free or isomorphic to a P_5 . If $G'|D'$ is isomorphic to a P_5 , then D' is the desired set S . Otherwise $G'|D'$ is P_5 -free. We again apply Theorem 2.3 on $G'|D'$: $G'|D'$ has a connected dominating set D'' that induces a subgraph that is either P_3 -free or isomorphic to P_3 . Then $D'' \cup N(D'') \cup N(N(D''))$ dominates G' . Since G' is triangle-free, if $G'|D''$ is P_3 -free, then D'' is a clique of size at most 2. It follows that $|D''| \leq 3$ and thus we can choose D'' for S . ◁

Let S be the set given by Claim 3.1. Define $X = N(S)$, $Y = N(N(S)) \setminus S$ and $Z = V(G') \setminus (X \cup Y \cup Z)$. Then (S, X, Y, Z) is a partition of $V(G')$, where S dominates X , X dominates Y and Y dominates Z , and there is no edge between S and $Y \cup Z$ or between X and Z . Moreover, S is connected. Such a quadruple $\mathcal{P} = (S, X, Y, Z)$ is called a *layer structure* of G' . The set S is called the *seed* of \mathcal{P} .

Phase II. Obtaining a canonical C_k -list assignment via updates

We now branch on every possible C_k -coloring of $G'|S$, there are at most k^7 such colorings since $|S| \leq 7$. Note that k^7 is a constant since k is a fixed number. To prove the theorem, therefore, it suffices to determine whether there is a branch, in which the precoloring of $S \cup W$ can be extended to a C_k -coloring of (G, L) in polynomial time.

In the following, we consider a fixed coloring $f : S \rightarrow [k]$, and we continue with the instance (G', L') of LIST C_k -COLORING, where $L'(v) = \{f(v)\}$ if $v \in S$ and $L'(v) = [k]$ otherwise.

We further partition the sets S , X , and Y as follows. For $1 \leq i \leq k$, we define

$$\begin{aligned} S_i &:= \{s \in S : L(s) = \{i\}\}, \\ X_i &:= \{x \in X \setminus (\bigcup_{j=1}^{i-1} X_j) : N(x) \cap S_i \neq \emptyset\}, \\ Y_i &:= \{y \in Y \setminus (\bigcup_{j=1}^{i-1} Y_j) : N(y) \cap X_i \neq \emptyset\}. \end{aligned}$$

Clearly, (X_1, X_2, \dots, X_k) is a partition of X and (Y_1, Y_2, \dots, Y_k) is a partition of Y .

We now perform the following updates for all $1 \leq i \leq k$ in the following order.

- For every edge sx with $s \in S_i$ and $x \in X_i$, we update x from s .
- For every edge xy with $x \in X_i$ and $y \in Y_i$, we update y from x .

We continue to denote the resulting C_k -list assignment by L' . Then $|L'(s)| = 1$ for every $s \in S$, $L'(x) \subseteq \{i-1, i+1\}$ for every $x \in X_i$ and $L'(y) \subseteq \{i, i-2, i+2\}$ for every $y \in Y_i$. We call such a C_k -list assignment L' *canonical* for $\mathcal{P} = (S, \bigcup_{i=1}^k X_i, \bigcup_{i=1}^k Y_i, Z)$.

▷ **Claim 3.2 (♠).** If X_i is not stable, then (G', L') is not C_k -colorable.

Note that one can determine in $O(n^2)$ time if there exists an X_i that is not stable. If so, we stop and correctly determine that (G', L') is not C_k -colorable by Claim 3.2. Otherwise, we may assume that X_i is stable for all $1 \leq i \leq k$ from now on.

Phase III. Eliminating bad paths via branching ($O(n^{12k})$ branches)

In this phase, we shall reduce the instance (G', L') to an equivalent set of polynomially many subinstances so that every subinstance has no bad paths, which we define now.

An induced path $a - b - c$ is a *bad path* in $\mathcal{P} = (S, X, Y, Z) = (S, \bigcup_{i=1}^k X_i, \bigcup_{i=1}^k Y_i, Z)$ if for some $i \in [k]$ we have $a \in Y_i$, $b, c \in (Y \cup Z) \setminus Y_i$, and $\{b, c\}$ is anticomplete to X_i . We call a the *starter* of $a - b - c$. Let \mathcal{Q}_i be the set of all bad paths with starters in Y_i , clearly $|\mathcal{Q}_i| = O(n^3)$.

A vertex $v \in Y_i$ is of *depth at least ℓ* in \mathcal{P} if for every $x \in N(v) \cap X_i$, there exists an induced path $v - x - P$ of length at least ℓ such that $V(P) \subseteq S$. Observe that every vertex in Y is of depth at least 3 to S (because we may assume that $|S| \geq 2$ and so no vertex in X is complete to S since G is triangle-free), and that the starter of a bad path is of depth at most 7 to S since G' is P_9 -free.

Note that for any C_k -coloring of (G', L') and every $i \in [k]$, either there exists a bad path in \mathcal{Q}_i whose starter is colored with a color in $\{i-2, i+2\}$ or the starters of all bad paths in \mathcal{Q}_i are colored with i . This leads to the following branching scheme, which only updates the lists.

Branching.

■ ($2^k = O(1)$ branches.) For every subset $I \subseteq [k]$, we have a branch B_I intended to find possible colorings such that there exists a bad path in \mathcal{Q}_i whose starter is colored with a color in $\{i-2, i+2\}$ if $i \in I$, and all starters of bad paths in \mathcal{Q}_i are colored with color i if $i \notin I$. Clearly, (G', L') is C_k -colorable if and only if at least one of the B_I is a yes-instance. In the following, we fix a branch B_I .

■ ($O(2^k n^{3k}) = O(n^{3k})$ branches.) We further branch to obtain a set of size $O(n^{3k})$ of subinstances within B_I by guessing, for each $i \in I$, a bad path in \mathcal{Q}_i , and guessing the color of its starter from $\{i-2, i+2\}$. The union over all branches B_I of these subinstances is equivalent to (G', L') .

Specifically, for each element $(a_i - b_i - c_i)_{i \in I}$ in $\prod_{i \in I} \mathcal{Q}_i$, we have one branch where we set $L''(a_i) := L'(a_i) \cap \{i-2, i+2\}$ for every $i \in I$, and we set $L''(a) := L'(a) \cap \{i\}$ for every starter a of a bad path in \mathcal{Q}_i for every $i \notin I$. We denote the resulting C_k -list assignment by L'' . For each such branch and for every element $(q_i)_{i \in I}$ in $\prod_{i \in I} L''(a_i)$, we have one branch where $L''(a_i) = \{q_i\}$ for all $i \in I$. It follows that for all $i \in I$ and $x \in X_i \cap N(a_i)$, the only possible color for x is $(q_i + i)/2$, and so we set $L''(x) = \{(q_i + i)/2\}$. Since $L''(a_i) \subseteq \{i-2, i+2\}$ for all $i \in I$, it follows that there are $2^{|I|} \leq 2^k$ branches. Let us fix one such branch and denote the resulting instance by (G', L'') .

■ ($O(k^{3k}) = O(1)$ branches.) We let I^* be the subset of $[k] \setminus I$ of indices i such that \mathcal{Q}_i contains a bad path. For each $i \in I^*$, we choose a bad path $a_i - b_i - c_i$ in \mathcal{Q}_i such that $|N(a_i) \cap X_i|$ is minimum, where the minimum is taken over all bad paths in \mathcal{Q}_i . Choose a vertex $x_i \in N(a_i) \cap X_i$ for each $i \in I^*$. Define

$$Q := \bigcup_{i \in I} \{b_i, c_i\} \cup \bigcup_{i \in I^*} \{b_i, c_i, x_i\},$$

where for $i \in I$, b_i, c_i are two vertices on the bad path we guessed in the previous bullet. We branch on every possible coloring of Q . Since $|Q| \leq 3k$, the number of branches is at most k^{3k} . In the following, we fix a coloring g of Q and denote the resulting subinstance by (G', L''') , where $L'''(v) = \{g(v)\}$ if $v \in Q$ and $L'''(v) = L''(v)$ otherwise.

Obtaining a new layer structure with a canonical C_k -list assignment. We now deal with (G', L''') . Define

$$A = \bigcup_{i \in I} ((N(a_i) \cap X_i) \cup \{a_i, b_i, c_i\}) \cup \bigcup_{i \in I^*} \{x_i, a_i, b_i, c_i\},$$

and note that in L''' , every vertex in A has a list of size at most 1. We update all vertices of G' from all vertices in A and continue to denote the resulting C_k -list assignment by L''' . We now obtain a new partition $\mathcal{P}' = (S', X', Y', Z')$ of G' as follows.

- Let $S' := S \cup A$.
- For each $1 \leq j \leq k$, let $K_j := \emptyset$. For each vertex $v \in Y \cup Z$, if v has a neighbor in S' , let j be the smallest integer in $[k]$ such that there exists a vertex $s \in N(v) \cap S'$ with $L(s) = \{j\}$, and add v to K_j . For each $1 \leq j \leq k$, let $X'_j = (X_j \cup K_j) \setminus A$. Let $X' := \bigcup_{i=1}^k X'_i$.
- For $1 \leq i \leq k$, let Y'_i be the set of vertices in $V(G') \setminus (S' \cup X' \cup (\bigcup_{j < i} Y'_j))$ that have a neighbor in X'_i . Let $Y' := \bigcup_{i=1}^k Y'_i$.
- Let $Z' := V(G') \setminus (S' \cup X' \cup Y')$.

▷ **Claim 3.3 (♠).** The new partition $\mathcal{P}' := (S', X', Y', Z')$ is a layer structure of G' and L''' is a canonical C_k -list assignment for \mathcal{P}' .

▷ **Claim 3.4 (♠).** For every $i \in [k]$ it holds that

1. $X'_i \setminus X_i \subseteq Y \cup Z$.
2. If a vertex in $Y' \cup Z'$ is anticomplete to X'_i , then it is anticomplete to X_i .
3. $Y'_i \setminus Y_i$ is anticomplete to X_i .

The following claim is the key to our branching algorithm.

▷ **Claim 3.5.** Let a be a starter of a bad path in \mathcal{P}' . If the depth of the starter of any bad path in \mathcal{P} is at least ℓ , then the depth of a in \mathcal{P}' is at least $\ell + 1$.

Proof. Let $a' - b' - c'$ be a bad path in \mathcal{P}' with $a' \in Y'_i$. Consider the following cases.

Case 1: $a' \in Y_i \cap Y'_i$. Then $\emptyset \neq N(a') \cap X_i \subseteq X'_i$. By item 2. in Claim 3.4, $\{b', c'\}$ is anticomplete to X_i and so $a' - b' - c'$ is also a bad path in $\mathcal{P} = (S, X, Y, Z)$. This implies that $\mathcal{Q}_i \neq \emptyset$. Therefore, there exist $a, b, c, x \in S'$ such that $a - b - c$ is a bad path in \mathcal{P} with $a \in Y_i$ and $x \in N(a) \cap X_i$.

We first claim that it is possible to pick a vertex $x' \in N(a') \cap X_i$ that is not adjacent to a . Recall that the branch we consider corresponds to a set $I \subseteq [k]$. If $i \in I$, then all vertices in $N(a) \cap X_i$ are in A and hence are now in S' . So every vertex in $N(a') \cap X_i$ is not adjacent to a , and our claim holds. If $i \notin I$, then $i \in I^*$, and so $a = a_i$. By the choice of a_i , it follows that $|N(a) \cap X_i| \leq |N(a') \cap X_i|$. Since $a' \in Y'_i$, it follows that a' is not adjacent to x . Therefore, there exists a vertex $x' \in N(a') \cap X_i$ such that x' is not adjacent to a .

Note that x and x' are not adjacent by Claim 3.2. Moreover, x' is anticomplete to $\{b', c', b, c\}$ by the definition of bad path. Let P' be the shortest path from x to x' with internal vertices contained in S . Note that P' exists since S is connected. Then P' is an

31:10 Complexity of C_k -Coloring in Hereditary Classes of Graphs

induced path. Since $V(P') \setminus \{x, x'\} \subseteq S$, it follows that $V(P') \setminus \{x, x'\}$ is anticomplete to $\{a, b, c, a', b', c'\}$. Therefore, $c - b - a - x - P' - x' - a' - b' - c'$ is an induced path of order at least 9, a contradiction.

Case 2: $a' \in Y'_i \setminus Y_i$. It follows from Claim 3.4, item 3. that $N(a') \cap X'_i \subseteq X'_i \setminus X_i$. Pick a vertex $x' \in N(a') \cap X'_i$. Since $x \in X'_i \setminus X_i$, x' has a neighbor $s' \in S'$ by the definition of X'_i . By Claim 3.4, item 1., $x' \in Y \cup Z$ and so $s' \in S' \setminus S = A$. Thus there exists $j \in I$ such that x' is not anticomplete to $Q = \{x_j, a_j, b_j, c_j\}$, where $x_j \in N(a_j) \cap X_j$. Let $a_j - x_j - P$ be an induced path of length ℓ with $V(P) \subseteq S$. Note that $x' \in Y \cup Z$ is anticomplete to $V(P) \subseteq S$. Let $x' - P'' - x_j$ be the shortest path from x' to x_j such that $V(P'') \subseteq Q$. Since a' is anticomplete to $\{x\} \cup V(P) \cup V(P'') \subseteq S'$, it follows that $a' - x' - P'' - x_j - P$ is an induced path of length at least $\ell + 1$. This proves the claim. \triangleleft

Therefore, we have obtained an equivalent set of subinstances of size $O(n^{3k})$. For each such subinstance, the minimum depth of the starter of a bad path has increased by at least 1 compared to \mathcal{P} due to Claim 3.5. Note that the depth of any starter of a bad path in \mathcal{P} is at least 3. Moreover, since G' is P_9 -free, the depth of any starter of a bad path is at most 7.

By branching 4 times, therefore, we obtain an equivalent set of $O(n^{12k})$ subinstances such that each subinstance has no bad paths.

Phase IV. Reducing the list size of vertices in Z

Now we go back to processing the graph G . Let us fix an instance of LIST C_k -COLORING on G' , created in the previous phase, and let (G, L) denote the instance obtained by restoring the vertices of W . By $\mathcal{P} = (S, X, Y, Z)$ we denote the layer structure of G' with no bad paths and L is canonical for \mathcal{P} . We first reduce the list size of vertices in Z .

\triangleright **Claim 3.6** (\spadesuit). The set Z is stable and each $z \in Z$ has neighbors in at most one of $\{Y_1, Y_2, \dots, Y_k\}$.

\triangleright **Claim 3.7** (\spadesuit). Let $z \in Z$ be anticomplete to W and have a neighbor in Y_i . If (G, L) has a C_k -coloring, then (G, L) has a C_k -coloring c such that $c(z) \in \{i - 1, i + 1\}$.

We now modify the lists of vertices in Z : let $L(z) := L(z) \cap \{i - 1, i + 1\}$ for every $z \in Z$ that is anticomplete to W and has a neighbor in Y_i . It follows from Claim 3.7 that the resulting list is equivalent to the original one. We still denote by the resulting list L .

Phase V. Reducing the list size of vertices in Y

We now apply Lemma 2.2 to obtain a reduced C_k -list assignment L' . Then (G, L') is an equivalent subinstance of (G, L) . If $L'(v) = \emptyset$ for some $v \in V(G)$, we stop and report a no-instance. Define:

$$\begin{aligned} S' &:= \{v \in V(G') : |L'(v)| = 1\}, \\ X'_i &:= \{v \in V(G') \setminus S' : L'(v) \subseteq \{i - 1, i + 1\}\}, 1 \leq i \leq k, \\ Y'_i &:= \{v \in V(G') \setminus (S' \cup X' \cup \bigcup_{j < i} Y'_j) : L'(v) \subseteq \{i, i - 2, i + 2\}\}, 1 \leq i \leq k, \\ X' &:= \bigcup_{i=1}^k X'_i, \\ Y' &:= \bigcup_{i=1}^k Y'_i. \end{aligned}$$

Note $W \subseteq S'$ and that (S', X', Y', \emptyset) is almost a layer structure of G except that S' is not necessarily connected. It follows from the definition of (S', X', Y') and Lemma 2.1 that $L'(x) = \{i-1, i+1\}$ for every $x \in X'_i$ and $L'(y) = \{i-2, i, i+2\}$ for every $y \in Y'_i$. For $1 \leq i \leq k$, we partition Y'_i into two subsets Y_i^1 and Y_i^2 , where Y_i^2 is the set of isolated vertices in $G|Y'_i$ and $Y_i^1 = Y'_i \setminus Y_i^2$. We prove a few properties for S' , X' and Y' .

▷ **Claim 3.8** (♠). The following hold for S' , X' and Y' .

1. $V(G) = S' \cup X' \cup Y'$.
2. For every $i \in [k]$ and $y \in Y'_i$, we have $N(y) \cap X' \subseteq X'_i$.
3. For every $i \in [k]$, we have $X_i \subseteq X'_i \cup S'$ and $Y'_i \subseteq Y_i$.
4. For every $i \in [k]$ and $y \in Y_i^2$, the vertex y is anticomplete to $Y' \setminus (Y_{i+1}^2 \cup Y_{i-1}^2)$.

▷ **Claim 3.9.** If (G, L') is C_k -colorable, then there exists a C_k -coloring c of (G, L') such that for each $1 \leq i \leq k$, $c(y) = i$ for all $y \in Y_i^2$ and $c(y) \in \{i-2, i+2\}$ for all $y \in Y_i^1$.

Proof. Suppose that c' is a C_k -coloring of (G, L') . Note that each $u \in Y_i^1$ has a neighbor $v \in Y_i^1$ by the definition. Since $L'(u), L'(v) \subseteq \{i-2, i, i+2\}$ and c' is a C_k -coloring of (G, L') , it follows that $c'(u) \neq i$ and $c'(v) \neq i$. So $c'(u) \in \{i-2, i+2\}$.

Let $u \in Y_i^2$. Note that u can only have neighbors in X'_i or in $Y_{i+1}^2 \cup Y_{i-1}^2$ by item 2. and item 4. of Claim 3.8. Define $c : V(G) \rightarrow [k]$ such that $c(v) := i$ if $v \in Y_i^2$ and $c(v) := c'(v)$ if $v \notin \bigcup_{i=1}^k Y_i^2$.

Then c is a C_k -coloring of (G, L') , since $c'(x) \in \{i-1, i+1\}$ for every $x \in X'_i$. This completes the proof. ◁

Let us point out that the special treatment of the sets Y_i^1 is needed only for the case $k = 5$. For $k > 5$, if one Y_i contains two adjacent vertices, one can observe that there is no way to color them. Thus we can immediately report a no-instance (or let it be reported when we solve the corresponding 2-SAT instance).

Let us now modify the lists as follows. For each $1 \leq i \leq k$ and each $y \in Y'_i$, let $L'(y) := L'(y) \cap \{i-2, i+2\}$ if $y \in Y_i^1$ and $L'(y) := L'(y) \cap \{i\}$ if $y \in Y_i^2$. By Claim 3.9, the new list assignment is equivalent to the original one. Now for each $v \in V(G)$ we have $|L'(v)| \leq 2$ and so Theorem 2.4 applies.

This completes the proof of correctness of our algorithm. Clearly, the most expensive part of our algorithm is Phase III where we branch into $O(n^{12k})$ subinstances. Since each subinstance can be constructed in $O(n^3)$ time by Lemma 2.2 and each 2-SAT instance can be solved in $O(n^2)$ time by Theorem 2.4, the total running time is $O(n^{12k+3})$. ◀

4 Hardness results

In this section we prove the following theorem.

▶ **Theorem 1.2.** *Let F be a connected graph. If F is not a subgraph of a subdivided claw, then for every odd $k \geq 5$ the C_k -PRECOLORING EXTENSION problem is NP-complete for F -free graphs.*

We will prove Theorem 1.2 in several steps in which we analyze possible structure of F . We start with the following simple observation that will be repeatedly used. For the rest of this section, let $k = 2s + 1$ for $s \geq 2$.

▶ **Observation 4.1.** *Let $s \geq 2$ be an integer and P be a $2s$ -vertex path with endvertices a and b . Then the following holds.*

- *In any C_{2s+1} -coloring h of P we have $h(a) \neq h(b)$.*
- *For any distinct $i, j \in \{1, 2, \dots, 2s+1\}$, there exists a C_{2s+1} -coloring h of P such that $h(a) = i$ and $h(b) = j$.*

4.1 Eliminate cycles

The *girth* of a graph G , denoted by $\text{girth}(G)$, is the length of a shortest cycle in G . A vertex in a graph is called a *branch vertex* if its degree is at least 3. By Γ_p we denote the class of graphs, in which the number of edges in any path joining two branch vertices is divisible by p .

We first show that the problem is NP-hard in F -free graphs, unless F is a tree in Γ_{2s-1} .

► **Theorem 4.2.** *For each fixed integer $s \geq 2$ and each connected graph F , C_{2s+1} -COLORING is NP-complete for F -free graphs whenever F contains a cycle or is not in Γ_{2s-1} .*

Proof. It is known (see e.g. [31]) that the $(2s+1)$ -COLORING problem is NP-complete for graphs of girth at least g for each fixed $g \geq 3$. We reduce this problem to C_{2s+1} -COLORING. Given a graph G , we obtain a graph G' by replacing each edge of G by a $(2s-1)$ -edge path. Then it follows from Observation 4.1 that G is $(2s+1)$ -colorable if and only if G' is C_{2s+1} -colorable. Clearly, $\text{girth}(G') = \text{girth}(G) \cdot (2s-1) \geq g(2s-1)$. Thus, if we choose $g \geq 3$ such that $g(2s-1) > \text{girth}(F)$, e.g., $g = |V(F)| + 1$, it follows that all graphs of girth at least $g(2s-1)$ are F -free. Moreover, it is easy to see that the number of edges in any path joining two branch vertices of G' is divisible by $2s-1$, so if $F \notin \Gamma_{2s-1}$, then G' does not contain F . ◀

4.2 Eliminate vertices of degree at least 4

From now on it suffices to consider trees with branch vertices at distance divisible by $2s-1$. We now show that C_k -COLORING is NP-complete for F -free graphs if F contains a vertex of degree at least 4. Note that in this case every subcubic graph is F -free.

► **Theorem 4.3 (♠).** *For each fixed $s \geq 2$, C_{2s+1} -COLORING is NP-complete for subcubic graphs.*

4.3 Eliminate multiple branch vertices

Before we prove the main theorem we need one more intermediate step that allows us to eliminate those F in which there are two branch vertices that are at distance not divisible by s . The proof is a reduction from the problem called NON-RAINBOW COLORING EXTENSION, whose instance is a 3-uniform hypergraph H and a partial coloring f of some of its vertices with colors $\{1, 2, 3\}$. We ask whether f can be extended to a 3-coloring of $V(H)$ such that no hyperedge is *rainbow* (i.e., contains three distinct colors). This problem is known to be NP-complete [3].

► **Theorem 4.4.** *For each fixed integer $s \geq 2$, C_{2s+1} -PRECOLORING EXTENSION is NP-complete for bipartite graphs in Γ_s .*

Proof. We reduce from NON-RAINBOW COLORING EXTENSION. Let $H = (V, E)$ be a 3-uniform hypergraph and let f be a partial 3-coloring of H . We construct an instance of C_{2s+1} -PRECOLORING EXTENSION as follows.

- For each vertex $v \in V$, we introduce a variable vertex, denoted by v' . If v is precolored by f , we precolor v' with the color $f(v)$.
- For each v that is not precolored by f , we introduce $2s-2$ new vertices and precolor them with $4, 5, \dots, 2s+1$, respectively. Then each of these new vertices is joined by a $(2s-1)$ -edge path to v' . It follows from Observation 4.1 that each vertex v' can only be mapped to one of $1, 2, 3$, and any of these three choices is possible.
- For each hyperedge $e = \{x, y, z\} \in E$, we add a new vertex v_e and three s -edge paths connecting v_e to x', y' , and z' , respectively. This whole subgraph is called an *edge gadget*.

Observe that if x' is mapped to $i \in \{1, 2, 3\}$, then the possible colors for v_e are $\{s+i, s+i-2, \dots, s+i-2\lfloor s/2 \rfloor\} \cup \{s+i+1, s+i+3, \dots, s+i+1+2\lfloor s/2 \rfloor\}$. Thus, if each of x', y', z' is mapped to a different vertex from $\{1, 2, 3\}$, then there is no way to extend this mapping to the whole edge gadget. On the other hand, such an extension is possible whenever x', y', z' receive at most two distinct colors.

We denote by G the resulting graph. By the properties of variable vertices and edge gadgets, (H, f) is a yes-instance of NON-RAINBOW COLORING EXTENSION if and only if the precoloring of G can be extended to a C_{2s+1} -coloring of G . Clearly, G is bipartite and belongs to Γ_s . ◀

By Theorems 4.2, 4.3, and 4.4, the C_{2s+1} -PRECOLORING EXTENSION problem is NP-complete for F -free graphs unless F is a tree in $\Gamma_{s(2s-1)}$ (observe that s and $2s-1$ are relatively prime). We are now ready to show that the problem is NP-hard if F has more than one branch vertex.

► **Theorem 4.5.** *Let $s \geq 2$ be an integer and let F be a tree. If F contains two branch vertices, then C_{2s+1} -COLORING is NP-complete for F -free graphs.*

Proof. Let d be the distance between two closest branch vertices in F . We reduce from POSITIVE NOT-ALL-EQUAL SAT with all clauses containing exactly three literals. Consider an instance with variables x_1, x_2, \dots, x_n and clauses D_1, D_2, \dots, D_m .

- We start our construction by introducing one special vertex z .
- For each variable x_i , we introduce a vertex v_i , adjacent to z .
- For each clause $D_\ell = \{x_i, x_j, x_k\}$, we introduce three new vertices $y_{\ell,i}, y_{\ell,j}$, and $y_{\ell,k}$, and join each pair of them with a $(2s-1)$ -edge path. This guarantees that in every C_{2s+1} -coloring, they get three distinct colors. These three paths constitute the *clause gadget*.
- For each variable x_i belonging to a clause D_ℓ , we join each $y_{\ell,i}$ to v_i by a path $P_{\ell,i}$ with $2d(2s-1) + 1$ edges. Let $v_i = p_1, p_2, \dots, p_{2d(2s-1)+2} = y_{\ell,i}$ be the consecutive vertices of $P_{\ell,i}$. We add edges joining z and $p_{1+j(2s-1)}$ for every $1 \leq j \leq 2d$.

This completes the construction of a graph G . We claim that G is C_{2s+1} -colorable if and only if the initial formula is satisfiable, and that G belongs to our class.

▷ Claim 4.6 (♠). G is C_{2s+1} -colorable if and only if the initial formula is satisfiable.

▷ Claim 4.7 (♠). G is F -free.

This completes the proof of Theorem 4.5. ◀

Now Theorem 1.2 comes from combining the Theorems 4.2, 4.3, 4.4, and 4.5. We observe that all reductions in our hardness proofs are linear in the number of vertices (the target graph is assumed to be fixed, so s is a constant). Moreover, all problems we are reducing from can be shown to be NP-complete by a linear reduction from 3-SAT. Thus we get the following result, conditioned on the Exponential Time Hypothesis (ETH), which, along with the *sparsification lemma*, implies that 3-SAT with n variables and n clauses cannot be solved in time $2^{o(n+m)}$ [27, 28].

► **Corollary 4.8.** *Unless the ETH fails, the following holds. If F is a connected graph that is not a subgraph of a subdivided claw, then for every $s \geq 2$, the C_{2s+1} -PRECOLORING EXTENSION problem cannot be solved in time $2^{o(n)}$ in F -free graphs with n vertices.*

5 Conclusion

In this paper, we initiate a study of C_{2s+1} -COLORING for F -free graphs for a fixed graph F . We prove that C_{2s+1} -PRECOLORING EXTENSION is NP-complete for F -free graphs if some component of F is not a subdivided claw. Moreover, we show that C_{2s+1} -PRECOLORING EXTENSION is polynomial-time solvable for P_9 -free graphs. Note that all our hardness results work for C_{2s+1} -COLORING, except for Theorem 4.4. Thus it is natural to ask whether analogous hardness results holds for C_{2s+1} -COLORING too. Moreover, the following questions seem natural to explore.

- Are there values of s and t such that C_{2s+1} -COLORING is NP-complete for P_t -free graphs?
- Is C_{2s+1} -COLORING polynomial for F -free graphs when F is a subdivided claw?
- Is C_{2s+1} -COLORING FPT for P_t -free graphs, when parameterized by s ?

Abstract

Representing a family of geometric objects in the digital world where each object is represented by a set of pixels is a basic problem in graphics and computational geometry. One important criterion is the consistency, where the intersection pattern of the objects should be consistent with axioms of the Euclidean geometry, e.g., the intersection of two lines should be a single connected component. Previously, the set of linear rays and segments has been considered. In this paper, we extended this theory to families of curved rays going through the origin. We further consider some pseudoline arrangements obtained as unions of such families of rays.

1 Introduction

The representation of geometric objects in the pixel world does not always satisfy geometric properties such as Euclidean axioms. Figure 1 shows that a naive definition of digital lines may cause inconsistency. In Figure 1, the intersection of a pair of digital lines is divided into three connected components (in the 4-neighbor topology), while it is desired that the intersection should be connected to imitate the Euclidean axiom that two non-parallel lines intersect at a point. Thus, it is important to seek for a digital representation of a family of geometric objects such that they satisfy a digital version of geometric axioms.

Geometric consistency is important in implementation of algorithms of computational geometry. In geometric computation, we often experience that finite-precision computation is suffered by geometric inconsistency. For example, the divide and conquer algorithm to construct a Voronoi diagram given in the textbook of Preparata and Shamos [6] is known to be difficult to implement. The algorithm needs to compute the intersection point of two (possibly nearly parallel) lines, and then later decides whether the intersection point is above or below another line. Therefore, we may need to compute the intersection point precisely beyond the precision of the system to avoid inconsistency causing a wrong decision. It is a difficult task to avoid such geometric inconsistency. After the seminal paper of Greene and Yao [7], many approaches to overcome the geometric inconsistency in finite precision computation have been proposed. Snap rounding [10, 8, 9] is one of the approaches, which systematically replaces line segments with piecewise linear segments. Another approach implemented in several softwares is the dynamic control of the precision [15, 13].

The pixel-based consistent representation of digital objects would lead to an additional methodology for consistent geometric computation. In general, it is a difficult task to convert families of geometric objects into families of digital objects without geometric inconsistency. However, we have hope if we restrict the task on some fundamental curves to represent basic geometric objects.

In this paper, we propose the *consistent digital curved rays* generalizing consistent digital rays for straight lines [5, 14]. We also show constructions of digital rays that consistently approximate some pseudoline arrangements in the first quadrant.

We consider the triangular region Δ defined by $\{(x, y) : x \geq 0, y \geq 0, x + y \leq n\}$ in the plane, and the integer grid $G = \{(i, j) : i, j \in \{0, 1, \dots, n\}, i + j \leq n\}$ in the region. We can also handle a square region, but use Δ to make the description easier.

Each element of G is called a *pixel* (usually, a pixel is a square, but we represent it by its lower-left-corner grid point in this paper). A pixel is called a *boundary pixel* if it lies on $x + y = n$. We consider an undirected graph structure under the four-neighbor topology such that $(i, j) \in G$ is connected to $(k, \ell) \in G$ if $(k, \ell) \in \{(i - 1, j), (i, j - 1), (i + 1, j), (i, j + 1)\}$.

A *digital ray* $S(p)$ is a path in G from the origin o to p , where $S(o) = \{o\}$ is a zero-length path. Let us consider a family $\{S(p) : p \in G\}$ of digital rays, where a digital ray is uniquely assigned to each $p \in G$. The family is called *consistent* if the following three conditions hold:

1. If $q \in S(p)$, then $S(q) \subseteq S(p)$.
2. For each $S(p)$, there is a (not necessarily unique) boundary pixel r such that $S(p) \subseteq S(r)$.
3. Each $S(p)$ is a shortest path from o to p in G .

The consistency implies that the union of paths $S(p)$ form a spanning tree T of G such that all leaves are boundary pixels, and accordingly the intersection of two digital rays consists of single connected component. See the pictures (a) and (b) of Figure 2 for the illustration. The tree T and also the family of digital rays are called CDR (*Consistent Digital Rays*).

Previously, the theory has been considered only for digital straightness[11]. Lubby [14] first gave a construction of CDR where each $S(p)$ simulates a linear ray within Hausdorff distance $O(\log n)$, and showed that the bound is asymptotically tight. Here, the Hausdorff distance between objects P and Q is $\max\{\max_{p \in P} \min_{q \in Q} d(p, q), \max_{q \in Q} \min_{p \in P} d(p, q)\}$, where $d(p, q)$ is the Euclidean distance between p and q . The construction was re-discovered by Chun et al.[5] to give further investigation, and Christ et al.[4] gave a construction of consistent digital line segments where the lines need not go through the origin. There are several works on different characterizations and variations [1, 2, 3].

■ **Figure 2** CDR for linear rays and parabolic rays in the triangular region of a 20×20 grid, and sampled linear and parabola digital rays in a 300×300 square grid.

We will extend the theory to families of curves with the same topology as linear rays. In Figure 2, the combinatorial difference between two CDRs can be observed. The difference leads to the visual difference of digital rays illustrated in Figure 2, where it can be seen that the digital rays in (b) approximate parabolas as shown in (d) extended to a sufficiently large grid, while (a) approximates linear rays as shown in (c).

A family \mathcal{F} of nondecreasing curves in Δ is called a *ray family* if each curve goes through the origin o , and for each point $(x, y) \in \Delta \setminus \{o\}$ there exists a unique curve of \mathcal{F} going through it. We call an element of \mathcal{F} a *ray*. Accordingly, each pair of rays intersect each other only at the origin. A typical example is the family of parabolas $y = ax^2$ for $a \geq 0$.

We give a construction method of CDR $T_{\mathcal{F}}$ in G such that the (unique) ray of \mathcal{F} connecting o and a pixel p is approximated by the path $S(p)$ of $T_{\mathcal{F}}$ well. In order to theoretically guarantee the goodness of the approximation, we give an $O(\sqrt{n \log n})$ bound of the Hausdorff distance for several ray families, where the unit is given by the pixel size. Although the theoretical bound is much worse than the known $\Theta(\log n)$ optimal bound for the linear ray [5, 14], it is the first nontrivial result for curved rays as far as the authors know.

Then, we investigate the structure of unions of CDRs. Our results include a new interpretation of CDS, and generalize it to a digitized pseudoline arrangement (i.e. set of paths intersecting at most once to each other) given as union of translated copies of a ray family. Moreover, we deal with digitization of the arrangement given as a union of families of constant degree homogeneous polynomial curves to show that they can be consistently discretized to form a pseudoline arrangement in a subregion of Δ excluding a constant number of rows and columns, and a constant-area triangle.

We have implemented our construction algorithm of CDR for several families of rays, and our experimental result shows that the Hausdorff distance is only 12 for $n = 2^{14}$ for the parabola rays.

2 Consistent digital rays and their properties

The set of pixels of G on the diagonal $x + y = k$ for $k = 0, 1, \dots, n$ is called the level set $L(k)$. We implicitly give a direction of edges from lower towards higher levels, and call an edge of G between nodes $u \in L(k - 1)$ and $v \in L(k)$ an incoming edge to (resp. outgoing edge from) v (resp. u).

Consider a CDR T . Any node of T has exactly one incoming edge, and at most two outgoing edges of T . The following observation was given by Chun et al.[5] (see Figure 3 for its illustration).

■ **Figure 3** The branching nodes (colored yellow) and partition of incoming edges to the 5th level (left picture) of the CDR (right picture) of linear rays.

► **Lemma 1.** *In the level set $L(k)$ for $k \geq 1$, there exists a real value $0 < x(k) < k$ such that the incoming edge of T to each node whose x -value is smaller than (resp. larger than or equal to) $x(k)$ is vertical (resp. horizontal). Accordingly, there exists a unique branching node of T in $L(k - 1)$ (colored yellow in Figure 3).*

Thus, a CDR is completely characterized by the integer sequence $\lceil x(1) \rceil, \lceil x(2) \rceil, \dots, \lceil x(n) \rceil$, where $1 \leq x(i) \leq i$. We call $x(k)$ the *separating position* on $L(k)$. The following lemma is easy to verify.

► **Lemma 2.** *A (unique) CDR exists for each of $(n - 1)!$ possible sequences as above.*

Our task is to find a CDR among those candidates to approximate a given family of rays as good as possible.

2.1 CDR for linear rays revisited

The CDR of linear rays can be obtained by selecting $x(k)$ as uniformly as possible from $[1, k]$.

Let us consider the binary representation $k = \sum_{i=0}^{\infty} a(i)2^i$ of a natural number k . The van der Corput sequence (see [12]) is the sequence that is defined by a function $V(k) = \sum_{i=1}^{\infty} a(i)2^{-i}$ from natural numbers to $[0, 1]$. We remove $V(0) = 0$ from our consideration so that the range becomes $(0, 1]$. For example, for $6 = 2 + 4 = 110_2$, $V(6) = 0.11_2 = \frac{1}{2} + \frac{1}{4} = \frac{3}{4}$. Here, a sequence of digits with subscript 2 means 2-adic representation of numbers.

The van der Corput sequence is known to be a low discrepancy sequence: There is a nonnegative constant c such that for each n and a range $[a, b]$ in $(0, 1]$, the number of $k \leq n$ satisfying $V(k) \in [a, b]$ differs from $(b - a)n$ at most $c \log n$. In particular, for each $m < n$, the set $\{V(i) : m \leq i \leq n\}$ gives an almost uniform distribution on $[0, 1]$.

We can set $x(k) = kV(k)$ to obtain a CDR. This CDR is exactly same as the one given by Chun et al.[5], and it has been shown that it approximates the linear rays emanating from the origin with the optimal $\Theta(\log n)$ distance bound. In order to generalize to the curved rays, we give the following interpretation.

Consider a line $y = ax$ intersecting $x + y = k$ at $q = (x_0, k - x_0)$. By definition, its slope is a , which is $\frac{k-x_0}{x_0}$. Naturally, we need to approximate the line segment of slope $\frac{k-x_0}{x_0}$ with a grid path in a neighborhood of q in order to globally approximate a line by the path. Ideally the ratio of vertical edges to the horizontal edges in the path should be $\frac{k-x_0}{x_0}$ in the neighborhood. If we set $x_0 = kt_0$, the ratio is $\frac{1-t_0}{t_0}$.

By the definition of the separating position $x(k)$, the edge incoming to q is vertical if and only if q lies on the left of $x(k)$. Let $x(k) = kt(k)$ and we take $t(k) = \theta$ for a uniformly random variable θ on $(0, 1]$. Then, q is on the left of $x(k)$ if and only if $t_0 < \theta$, and its probability is $1 - t_0$. Thus, the incoming edge becomes horizontal and vertical with probabilities t_0 and $1 - t_0$, respectively. Hence, the ratio between them is $\frac{1-t_0}{t_0}$ as desired.

The construction can be derandomized by replacing θ by $V(k)$ for each k . This derandomization also improves the Hausdorff distance bound.

We would like to extend this argument for other families of curves.

3 CDR for families of curves

Let us give a construction method of CDR applicable to several families of curves. We start with a family of parabolas as a typical example for improving the readability, and then discuss more general cases for which we will prove an upper bound for the Hausdorff distance between rays and digital rays.

3.1 CDR for a family of parabolas

3.1.1 Construction of CDR

■ **Figure 4** CDR T_{para} . Green nodes are branching nodes. Red path gives a digital parabolic ray.

Let us consider the family $y = ax^2$ ($a \geq 0$) of parabolas that have the origin o as their apex. We include the y -axis $x = 0$ in the family (this convention is applied to all other cases).

Consider a parabola $C : y = ax^2$ intersecting the level $x + y = k$ at $q = (x_0, k - x_0)$. The slope of tangent at q is $2ax_0$, which is $\frac{2y_0}{x_0} = \frac{2(k-x_0)}{x_0} = \frac{2(1-t_0)}{t_0}$ if we set $x_0 = kt_0$.

Analogously to the linear case, if we would like to have a digital ray nicely approximate C , the curve C in a neighborhood of q should be approximated by a path that contains the horizontal and vertical edges with the probabilities $\frac{t_0}{2-t_0}$ and $\frac{2(1-t_0)}{2-t_0}$, respectively.

Thus, we should select the separating position $x(k) = kt(k)$ to be located on the left of q with probability $\frac{t_0}{2-t_0}$. We consider a monotonically increasing function F_k in the range $[0, 1]$ and set $t(k) = F_k(\theta)$ for the uniformly random variable θ on $(0, 1]$. The probability that $x_0 = kt_0 < x(k)$ is the probability that $F_k^{-1}(t_0) < \theta$ from the monotonicity of F_k . Because of uniformity, this probability equals to $F_k^{-1}(t_0)$.

Thus, we should set $F_k^{-1}(t) = \frac{t}{2-t}$ to meet our requirement, and $F_k(\theta) = \frac{2\theta}{\theta+1}$. This is indeed monotonically increasing as we desired¹. We then derandomize the process by replacing θ with $V(k)$, and we set $t(k) = \frac{2V(k)}{V(k)+1}$ and hence $x(k) = \frac{2kV(k)}{V(k)+1}$ to construct a CDR T_{para} illustrated in Figure 4 deterministically.

The bound for the Hausdorff distance between a parabola ray and its corresponding digital ray in T_{para} is given in the following theorem, although its proof will be given later for a more general form.

► **Theorem 3.** *For each node $p \in G$, the Hausdorff distance between the parabola ray going through p and the path $S(p)$ from p towards the origin in the CDR T_{para} is $O(\sqrt{n \log n})$.*

3.2 Homogeneous polynomials

Let us consider the family \mathcal{F}_j of curves defined by $y = f_a(x) = ax^j$ for $a \geq 0$. Here, the slope of tangent of a curve at (x, y) is $f'_a(x) = jax^{j-1}$, which equals jy/x . Thus, analogously to the parabola case, we have $F_k^{-1}(t) = \frac{t}{j-(j-1)t}$ and $F_k(\theta) = \frac{j\theta}{1+(j-1)\theta}$. Applying derandomization to replace θ by $V(k)$, we set $x(k) = \frac{jkV(k)}{(j-1)V(k)+1}$ for $k = 1, 2, \dots, n$ to define a CDR $T_{\mathcal{F}_j}$. The following theorem is analogously obtained to the parabola case.

► **Theorem 4.** *For each node $p \in G$, the Hausdorff distance between the ray in \mathcal{F}_j going through p and the path $S(p)$ from p towards the origin in the CDR $T_{\mathcal{F}_j}$ is $O(\sqrt{n \log n})$.*

3.3 Handling general ray families

3.3.1 Framework for a diffused ray family

Recall that a family \mathcal{F} of nondecreasing curves in Δ is called *ray family* if each curve (called ray) goes through the origin o , and for each point $(x, y) \in \Delta \setminus \{o\}$ there exists a unique curve of \mathcal{F} going through it. We call a ray family *smooth* if every curve is differentiable. Let us consider the slope $\tau(t, z)$ at $p = (tz, z - tz)$ ($0 < t \leq 1$) of the unique curve of \mathcal{F} going through p . We assume that we can compute $\tau(t, z)$ for a given p efficiently, and its computation time will be regarded as the unit of the time complexity.

► **Definition 5.** *A smooth ray family \mathcal{F} is called *diffused* (resp. *weakly diffused*) if $\tau(t, z)$ is continuous and decreasing (resp. nonincreasing) in t for each fixed $z > 0$.*

Intuitively, the diffusedness means that the rays always expand: The distance between two curves along the off-diagonal $x + y = k$ is increasing in k , since the right curve has a smaller slope than the left one. It can be considered as a continuous counterpart of the property of CDR given in Lemma 1 that vertical edges are incoming to the left of $x(k) = kt(k)$ while horizontal edges incoming to the right of it in each level $L(k)$. The families of parabolas and homogeneous polynomials are diffused.

Now, we consider construction of a CDR for a diffused family \mathcal{F} . We want to control so that the probability that the edge incoming to a pixel $q = (tk, k - tk)$ in $L(k)$ is horizontal with probability $g_k(t) = \frac{1}{1+\tau(t, k)}$, so that the ratio of probabilities to have a vertical edge against a horizontal edge becomes $\tau(t, k)$ for each of $t = j/k$ ($j = 1, 2, \dots, k$).

We would like to find a monotonically increasing function F_k such that $t(k) = F_k(\theta)$ for a uniformly random variable θ on $(0, 1]$ so that the incoming edge to $(tk, k - tk)$ becomes horizontal with probability $g_k(t)$.

¹ The function F_k is independent of k , but it is not always true for the more general cases.

Since the family is diffused, $\tau(t, k)$ is decreasing in t , and hence g_k is increasing. Therefore, it has the inverse function g_k^{-1} that is also increasing.

We set $F_k = g_k^{-1}$ to attain our requirement. Indeed, the condition that $x(k)$ lies on the left of q is that $t(k) < t$, which means $g_k(t(k)) \leq g_k(t)$ because of the monotonicity of g_k . Since $g_k(t(k)) = g_k(F_k(\theta)) = \theta$, this happens if the value of θ is smaller than $g_k(t)$, and hence the probability is $g_k(t)$ as we desire.

By evaluating $F_k(\theta)$ at a given θ , we have $t(k)$ for $k = 1, 2, \dots, n$, and hence obtain a CDR for \mathcal{F} . Approximate evaluation is sufficient for our purpose, since only the value $\lceil x(k) \rceil = \lceil kt(k) \rceil$ is necessary for the construction of CDR. Since $\tau(t, z)$ can be computed in the unit time, we can compute $g_k(t)$. Since $g_k(t)$ is an increasing function, the value $\lceil kt(k) \rceil$ for $t(k) = t_\theta = F_k(\theta)$ can be computed by binary searching over $t \in \{1/k, 2/k, \dots, k - 1/k\}$ to find the value t_0 such that $g(t_0 - 1/k) < \theta \leq g(t_0)$.

We then derandomize the process replacing θ by $V(k)$ for each k .

3.3.2 Upper bound of the Hausdorff distance

We give the analysis for the Hausdorff distance between a curved ray and its digitized ray. We consider the derandomized version here, and the analysis for the randomized version is given later.

For a differentiable curve $C \in \mathcal{F}$, consider the intersection point $p_C(z) = (x_C(z), z - x_C(z))$ with the line $x + y = z$ for $0 < z \leq n$. Let $s_C(z)$ be the slope of C at $p_C(z)$. Our analysis depends on the property of the function $s_C(z)$.

► **Definition 6.** *Given a function $y = f(x)$ defined on an interval I , if I can be decomposed into a minimum number of consecutive subintervals such that $f(x)$ is monotone (either nonincreasing or nondecreasing) on each subinterval, the number of subintervals is called the wave number of f . It is infinity if there is no such decomposition into a finite number of subintervals.*

The wave number of $s_C(z)$ is intuitively the length of the alternating sequence of consecutive convex segments and concave segments of C .

► **Definition 7.** *The wave number of \mathcal{F} is the supremum of the wave numbers of $s_C(z)$ over all $C \in \mathcal{F}$ on the interval $(0, n]$ of z .*

► **Theorem 8.** *If \mathcal{F} is a diffused family of rays with the wave number w , the Hausdorff distance between the ray C going through p in \mathcal{F} and the path $P = S(p)$ from p towards the origin in $T_{\mathcal{F}}^{\text{det}}$ is bounded by $O(\sqrt{wn \log n})$ for any node $p \in G$.*

For the families of parabolas and homogeneous polynomials, we can verify that the wave number is 1, and thus we have Theorems 3 and 4 as corollaries.

In order to prove Theorem 8, we prepare two lemmas. The first one (Lemma 9) is well-known (see e.g. [12]). The area of a planar region X is denoted by $A(X)$.

► **Lemma 9.** *Consider the set of points $S = \{(k, V(k)) : k = 0, 1, 2, \dots, n\}$ in the region $X = [0, n] \times [0, 1]$. Then, for any axis parallel rectangle R in X , the difference (called discrepancy) between the number of points in $S \cap R$ and the area of $A(R)$ is $O(\log n)$.*

The following Lemma 10 gives a discrepancy bound of S with respect to a region below a curve of a function.

► **Lemma 10.** Consider the set of points $S = \{(k, V(k)) : k = 0, 1, 2, \dots, n\}$. Let $f(x)$ be a continuous function from $[0, n]$ to $[0, 1]$ with a wave number w , and let $Q_I(f) = \{(x, y) : 0 \leq y \leq f(x), x \in I\}$ for any given interval $I \subset [0, 1]$. Then, the discrepancy $||S \cap Q_I(f)| - A(Q_I(f))|$ is bounded by $c\sqrt{wn \log n}$ for a suitable constant c .

Proof. Since we can decompose the interval I into w subintervals such that f is monotone on each of them, it suffices to consider the case $w = 1$. Indeed, if subintervals have lengths n_1, n_2, \dots, n_w and has discrepancies $c\sqrt{n_i \log n_i}$ for $i = 1, 2, \dots, w$, the sum $\sum_{i=1}^w c\sqrt{n_i \log n_i}$ is bounded by $c\sqrt{wn \log n}$, where the minimum it attained if $n_i = n/w$ for every i . If $w = 1$, f is either nonincreasing or nondecreasing, and without loss of generality, we assume f is nondecreasing.

We divide $Q_I(f)$ into its intersections with consecutive vertical strips of width $\sqrt{n \log n}$ (possibly the last one is skinnier). Let A_i for $i = 1, 2, \dots, M = \lceil \sqrt{n \log n} \rceil$ be the strips.

Suppose s_i and t_i are x -values of the leftmost and rightmost boundary of A_i , respectively. Now, within the strip A_i , $Q_I(f)$ is contained in a rectangle R_i whose height is $f(t_i)$, and contains another rectangle R'_i whose height is $f(s_i)$. Since $0 \leq f(x) \leq 1$ and f is nondecreasing we can easily see that the difference of areas of $\cup_{i=1}^M R_i$ and $\cup_{i=1}^M R'_i$ is at most the area of a rectangle of height 1 and width $\sqrt{n \log n}$. For a union of M rectangles, we can apply Lemma 9, and the number of points of S in $\cup_{i=1}^M R_i$ is at most $A(Q_I(f)) + \sqrt{n \log n} + O(M \log n)$, and that in $\cup_{i=1}^M R'_i$ is at least $A(Q_I(f)) - \sqrt{n \log n} - O(M \log n)$. Since $M < \sqrt{n \log n} + 1$, we have the lemma. ◀

We remark that for the discrepancy in Lemma 10, an $\Omega(\sqrt{n})$ lower bound is known even if f is a linear function (see [12]).

Now let us give a proof for Theorem 8.

The basic idea is that if P goes too far from C on a level, then it cannot come back to the same destination point p without violating the discrepancy condition given in Lemma 10.

Without loss of generality, we can assume that p is a boundary element located on $L(n)$. For each diagonal $x + y = k$, the intersection of C (resp. P) with it is denoted by $q_C(k) = (x_C(k), y_C(k))$ and $q_P(k) = (x_P(k), y_P(k))$, respectively. Then, the Hausdorff distance is bounded by $\sqrt{2} \max_{1 \leq k \leq n} |x_C(k) - x_P(k)|$, and it suffices to show that there is a constant c' such that $|x_C(k) - x_P(k)| \leq c' \sqrt{wn \log n}$. We take $c' > c$, where c is the constant given in Lemma 10.

Assume on the contrary there exists an index s such that $|x_C(s) - x_P(s)| > c' w \sqrt{n \log n}$. Without loss of generality, we can assume that $x_C(s) > x_P(s)$, since the other case can be handled analogously.

There exists an index m such that $x_C(i) - x_P(i) > 0$ for $s \leq i < m$ and $x_C(m) - x_P(m) \leq 0$ because $x_P(n) = x_C(n)$ (both P and C need to go through p). In other words, the path P lies on the left of C in $L(k)$ for $s \leq k < m$ and first comes back to the (almost) same position on $L(m)$. Let I be the interval $(s, m]$. Thus, we have

$$x_P(m) - x_P(s) > x_C(m) - x_C(s) + c' \sqrt{wn \log n}. \quad (*)$$

In the derandomized construction, $V(k)$ is used (instead of θ) to determine $t(k)$. In our construction method, P has a horizontal incoming edge at $L(k)$ if and only if $g_k(t_P(k)) \geq V(k)$, where $t_P(k) = \frac{x_P(k)}{k}$. By the monotonicity of g_k , $g_k(t_C(k)) \geq g_k(t_P(k))$ if $k \in I$, and this implies $g_k(t_C(k)) \geq V(k)$.

The integer-valued function $x_C(k)$ is extended to a continuous function $x_C(z)$ that gives the x -value of the intersection point of $x + y = z$ and the ray C for a real value $z \in (0, n]$. Moreover, the function $g_k(t) = \frac{1}{1+\tau(t,k)}$ can be extended to $g(t, z) = \frac{1}{1+\tau(t,z)}$.

We define $\varphi_C(z) = g(t_C(z), z) = \frac{1}{1 + \tau(t_C(z), z)}$. Recall that $\tau(t_C(z_0), z_0) = dy/dx|_{z=z_0}$ is the slope of C at $z = z_0$, and hence

$$\varphi_C(z_0) = \frac{1}{1 + \frac{dy}{dx}|_{z=z_0}} = \frac{dx}{dx + dy}|_{z=z_0} = \frac{dx}{dz}|_{z=z_0}.$$

Thus, $\varphi_C(z)$ is the ratio of the increase of $x_C(z)$ to the increase of z in the infinitesimal neighbor of z_0 . The wave number of $\varphi_C(z)$ is the same as that of $\tau(t_C(z), z)$, since $\varphi_C(z)$ is increasing in an interval I if and only if $\tau(t_C(z), z)$ is decreasing. We can observe that $\tau(t_C(z), z) = s_C(z)$ by definition, and hence the wave number of $\varphi_C(z)$ is the same as that of $s_C(z)$, and bounded by w . Also, the range of $\varphi_C(z)$ is in $(0, 1]$.

If the incoming edge of P is horizontal, $\varphi_C(k) = g_k(t_C(k)) \geq V(k)$ as shown above, and this condition is equivalent to $(k, V(k)) \in Q_I(\varphi_C)$, since $Q_I(\varphi_C) = \{(z, x) : 0 \leq x \leq \varphi_C(z), s < z \leq m\}$. Let S be the set of points $(k, V(k))$ for $k = s, s + 1, \dots, m - 1$. The difference of the x -values of P at $z = s$ and $z = m$ is the number of horizontal edges in the interval, which is hence bounded by $|Q_I(\varphi_C) \cap S|$.

On the other hand, $A(Q_I(\varphi_C))$ equals the difference of x -value of C at s and m , since

$$A(Q_I(\varphi_C)) = \int_{s < z < m} \varphi_C(z) dz = \int_{s < z < m} \frac{dx_C(z)}{dz} dz = x_C(m) - x_C(s).$$

Since the wave number of φ_C is bounded by w and its range is in $(0, 1]$, Lemma 10 says that $|Q_I(\varphi_C) \cap S| - A(Q_I(\varphi_C)) < c\sqrt{wn \log n}$. Thus, we have

$$x_P(m) - x_P(s) \leq |Q_I(\varphi_C) \cap S| \leq A(Q_I(\varphi_C)) + c\sqrt{wn \log n} = x_C(m) - x_C(s) + c\sqrt{wn \log n}.$$

Therefore, $x_P(m) - x_P(s) \leq x_C(m) - x_C(s) + c\sqrt{wn \log n}$. Compared with (*), we have $c > c'$, and obtain a contradiction.

3.3.3 Analysis for the randomized version

We would like to mention the quality of the randomized construction of a CDR.

► **Definition 11.** Consider a continuous function f defined on an interval $I = (k, m]$ with the range $[0, 1]$, where $0 < k < m < n$ are positive integers. let \bar{f} be the linear interpolation using the values of f on integer abscissae, which is the piecewise linear curve connecting $(k, f(k)), (k + 1, f(k + 1)), \dots, (m, f(m))$ by linear segments of width 1. The discretization error of f on I is $|A(Q_I(f)) - A(Q_I(\bar{f}))|$.

The following is easy to see.

► **Lemma 12.** If the wave number of f is bounded by w , the discretization error of f is at most w .

Now, given a function f from $[0, n]$ to $[0, 1]$, consider a $\{0, 1\}$ -valued random variable $X_f(i)$ for each $i = 1, 2, \dots, n$ such that it becomes 1 if and only if a uniformly random number (chosen independently for each i) in $[0, 1]$ becomes less than or equals to $f(i)$. Let $X_f = \sum_{i=1}^n X_f(i)$. Then the expected value $E(X) = \sum_{i=1}^n E(X_i)$ equals $\sum_{i=1}^n f(i) = A(Q_I(\bar{f})) + \frac{f(m) - f(k)}{2}$. Note that $A(Q_I(\bar{f})) \leq n$, thus $E(X) \leq n + 1/2$.

We can apply Chernoff's inequality, and obtain a constant $c(r)$ such that $|X - Q(\bar{f})| \geq c(r)\sqrt{n \log n}$ with a probability $1 - n^{-r-3}$ for any given constant r . Now we are ready to analyze the randomized construction of CDR.

► **Theorem 13.** *If \mathcal{F} is a diffused family of rays with the wave number w , the largest Hausdorff distance between a ray and the corresponding digital ray in $T_{\mathcal{F}}^{rand}$ is $O(\sqrt{n} \log n + w)$ with probability $1 - n^{-r}$ for any fixed $r > 0$.*

Proof. Analogously to the deterministic version, For any path p in the CDR corresponding a curve $C = C(p) \in F$, the Hausdorff distance from p to C is bounded by the maximum difference of $A(Q_I(\varphi(C)))$ and $X_{Q_I(\varphi(C))}$ over all I . Since there are $O(n)$ paths from the root to leaves, and there are $O(n^2)$ intervals $[k, m]$, there are $O(n^3)$ choices. Thus, with probability $1 - n^{-r}$, $|A(Q_I(\varphi(\bar{C}(p)))) - X(Q_I(\varphi(C(p))))| \leq c(r)\sqrt{n} \log n$ for all p and I . Thus, we have the theorem. ◀

The above upper bound is worse than the deterministic version by a $\sqrt{\log n}$ factor if w is a small constant, while it is theoretically better if $w > \log n$.

3.4 Family of curves linear in a parameter

Let us consider a nondecreasing differentiable function $y = f(x)$ for $x \in [0, n]$ such that $f(0) = 0$ and $f(x) > 0$ for $x > 0$. We define the family $\mathcal{F} = \{C_a : a \geq 0\}$ of curves, where C_a is defined by $y = af(x)$. It is clear that this gives a ray family.

If C_a goes through (x_0, y_0) , then $a = \frac{y_0}{f(x_0)}$. The slope of the curve C_a at (x_0, y_0) is $af'(x_0)$, which is (eliminating a) $\frac{f'(x_0)y_0}{f(x_0)}$. We consider the slope $\tau(x, k) = \frac{(k-x)f'(x)}{f(x)}$ along the diagonal $x + y = k$ for each k .

If \mathcal{F} is diffused, the framework in the previous subsection works. Although the explicit form of F_k might not be obtained, we can apply binary search to compute $F_k(z)$ for a given z utilizing the monotonicity. Thus, we can compute $x(k) = kF_k(V(k))$ within the pixel precision in $O(\log n)$ time.

Diffusedness and the wave number depend on f . The following lemma is easy to observe.

► **Lemma 14.** *If f is a strictly increasing and concave function, the family \mathcal{F} is diffused, and its wave number is 1.*

Note that the family of rays $\{y = f(a^{-1}x) : a > 0\}$ for a convex function f can be also handled, since this family is $\{x = af^{-1}(y)\}$ and $f^{-1}(y)$ is a concave function, e.g., the families of parabolas and homogeneous polynomials could be regarded in this form. Let us see some typical examples.

► **Example 15.** Let \mathcal{F}_{sig} be the family of curves $y = a\sigma(x)$, $0 \leq a$, where $\sigma(x) = \frac{1}{1+e^{-x}} - \frac{1}{2}$ is the shifted sigmoid function. The curve $y = \sigma(x)$ is strictly increasing and concave; hence, the family is diffused with the wave number 1, and we have the $O(\sqrt{n} \log n)$ bound.

Here, $\tau(x, k) = \frac{(k-x)e^{-x}}{(1+e^{-x})^2\sigma(x)}$. The function $g_k = F_k^{-1}$ can be analytically given, but it is a complicated function such that it is difficult to find an explicit formula for F_k . Thus, we apply the binary searching method to find a value of $F_k(V(k))$ in our experiment.

► **Example 16.** Consider the family of curves $y = a \log(x + 1)$, then similarly we have a CDR with the $O(\sqrt{n} \log n)$ distance bound.

► **Example 17.** The sine curve $y = \sin(x)$ is not monotone. Therefore, we define $\tilde{\sin}(x)$ by $\tilde{\sin}(x) = 0$ for $x < 0$, $\tilde{\sin}(x) = \sin x$ for $0 \leq x \leq \pi/2$ and $\tilde{\sin}(x) = 1$ for $x > \pi/2$. The curve $y = \tilde{\sin}(x)$ is monotonically nondecreasing and differentiable, and we will apply our CDR construction for the family of curves $y = a \tilde{\sin}(x)$ for $a \geq 0$.

Here, the family is weakly-diffused but not diffused, since there are many parallel horizontal lines intersecting each level. However, it is clear that in the region $x > \pi/2$ where the rays becomes horizontal, we can set all edges horizontal. Thus, we can still apply our method to have the $O(\sqrt{n \log n})$ bound.

The obtained CDRs are illustrated in Figure 6 in the section to give experimental results.

4 Union of CDRs with consistency

A CDR is characterized by the sequence $\mathbf{m} : m(1), m(2), \dots, m(n)$ where $1 \leq m(i) = \lceil x(k) \rceil \leq k$, and we denote the CDR by $T(\mathbf{m})$. We denote $\mathbf{m} \succeq \mathbf{m}'$ if $m(i) \geq m'(i)$ for all $1 \leq i \leq n$. \succeq is a partial ordering. We write $\mathbf{m} \succ \mathbf{m}'$ if $\mathbf{m} \succeq \mathbf{m}'$ and $\mathbf{m} \neq \mathbf{m}'$.

Consider $\mathcal{P}(T(\mathbf{m})) \cup \mathcal{P}(T(\mathbf{m}'))$, where $\mathcal{P}(T)$ means the set of paths from the root towards leaf vertices in T .

Let $x_P(k)$ be the x -value of the pixel of a path P (from the root to a leaf) in a CDR on the level $L(k)$.

► **Definition 18.** We say a path P_1 is steeper than another path P_2 in a different CDR if there is an index $0 \leq k \leq n$ such that $x_{P_1}(i) \leq x_{P_2}(i)$ for $i \leq k$ and $x_{P_1}(i) > x_{P_2}(i)$ for $i > k$. We say the level $L(k)$ the break level of P_1 and P_2 .

The above definition implies that P_1 lies below or on P_2 up to the break level, and it lies strictly above P_2 after it. We allow $k = n$, which means P_1 never goes above P_2 . We say the pair of paths have a *singular separation* on a level $L(i)$ if $x_{P_1}(i) = x_{P_2}(i)$ and $x_{P_1}(i+1) > x_{P_2}(i+1)$. Thus, the paths cross each other at most once, although they may touch and singularly separate several times before the break level. We say P_1 and P_2 *semi-consistently intersect* if one is steeper than the other. Moreover, if there is no singular separation, we say they *consistently intersect* each other.

► **Theorem 19.** If $\mathbf{m} \succ \mathbf{m}'$, any path $P_1 \in \mathcal{P}(T(\mathbf{m}))$ is steeper than any path $P_2 \in \mathcal{P}(T(\mathbf{m}'))$. Moreover, if a singular separation happens on a level $L(i)$, $m(i+1) = m'(i+1) = x_{P_1}(i) + 1 = x_{P_2}(i) + 1$.

Proof. Since $\mathbf{m} \succ \mathbf{m}'$, if a vertical edge comes in $p \in L(k)$ in $T_{\mathbf{m}'}$, a vertical edge comes in p in $T_{\mathbf{m}}$, too. This further implies that if such p is located on the right of another pixel q on $L(k)$, every incoming edge to q must be also vertical in both trees.

Therefore, if P_2 lies strictly on the right of P_1 on a level $L(k)$, whenever P_2 selects a vertical incoming edge in $L(k+1)$, P_1 also must select a vertical edge. Thus, inductively the horizontal distance never decreases after the break level, and hence P_1 never meets P_2 again.

Next, we consider what happens at a singular separation. Then, P_1 and P_2 goes through a same point $p = (x, k-x)$ in a level $L(k)$, and P_1 selects a horizontal and P_2 selects a vertical edge towards $L(k+1)$. Then, the vertices of P_1 and P_2 are at positions $q = (x+1, k-x)$ and $q' = (x, k+1-x)$, respectively. Since the incoming edge of $T_{\mathbf{m}}$ to q is horizontal and that of $T_{\mathbf{m}'}$ to q' is vertical, $m(i+1) \leq x+1$ and $m'(i+1) > x$. Since $m(i+1) \geq m'(i+1)$, this happens only if $m(i+1) = m'(i+1) = x+1$. ◀

We note that the condition $m(i+1) = m'(i+1) = x_{P_1} + 1 = x_{P_2} + 1$ for a singular level $L(i)$ means that both $T_{\mathbf{m}}$ and $T_{\mathbf{m}'}$ have the branching node $p = (m(i+1) - 1, i - m(i+1) + 1)$ on the level $L(i)$ simultaneously. Both P_1 and P_2 goes through p , and P_1 selects the horizontal while P_2 selects the vertical branch. We say a node p a *singular point* if it is a shared branching node of $T_{\mathbf{m}}$ a $T_{\mathbf{m}'}$, and hence a singular separation only occurs at a singular point.

A region $R \subseteq \Delta$ is called a *slanted-quadrant* if it is defined as $\{(x, y) \in \Delta \mid x \geq a, y \geq b, x + y \geq c\}$ for nonnegative numbers a, b , and c . We say a set of digital rays semi-consistently (resp. consistently) approximates a family of curves intersecting at most once to each other in a slanted-quadrant R if each pair of digital rays semi-consistently (resp. consistently) intersect each other if they are restricted to $G \cap R$.

Suppose that families \mathcal{F} and \mathcal{F}' has CDRs $T(\mathbf{m})$ and $T(\mathbf{m}')$ for $\mathbf{m} \succ \mathbf{m}'$, respectively. Assume that $\mathcal{F} \cup \mathcal{F}'$ forms a pseudoline arrangement in a slanted quadrant R . Theorem 19 assures that $\mathcal{P}(T(\mathbf{m})) \cup \mathcal{P}(T(\mathbf{m}'))$ consistently approximates $\mathcal{F} \cup \mathcal{F}'$ in R if there is no singular point in R .

4.1 Union of translated copies of a CDR

For the sequence \mathbf{m} and a nonnegative integer s , we define a new sequence \mathbf{m}^s by $m^s(k) = \min(m(k) + s, k)$. Similarly, for a negative integer s , we define \mathbf{m}^s by $m^s(k) = \max(m(k) + s, 1)$. The following lemma is obvious.

► **Lemma 20.** *If $s \geq 1$, $\mathbf{m}^s \succ \mathbf{m}$. If $s \leq -1$, $\mathbf{m} \succ \mathbf{m}^s$.*

► **Theorem 21.** *Suppose that \mathcal{F} and \mathcal{F}^s are ray families digitized by $T(\mathbf{m})$ and $T(\mathbf{m}^s)$, respectively. Assume that $\mathcal{F} \cup \mathcal{F}^s$ forms a pseudoline arrangement in $\Delta_1 : \{(x, y) \in \Delta \mid x \geq 1, y \geq 1\}$. Then $\mathcal{P}(T(\mathbf{m})) \cup \mathcal{P}(T(\mathbf{m}^s))$ consistently approximate $\mathcal{F} \cup \mathcal{F}^s$ in Δ_1 .*

Proof. Semi-consistency is clear from Theorem 19 and Lemma 20. Consider the location of a singular point $p = (m(i+1) - 1, i - m(i+1) + 1)$ for a pair of paths. However, Theorem 19 says that $m(i+1) = m^s(i+1)$. This only happens either $m(i+1) = m^s(i+1) = 1$ or $m(i+1) = m^s(i+1) = i+1$, and hence $p = (0, i)$ or $p = (i, 0)$. Thus the singular points only locate on the coordinate axes. Thus, we have the theorem. ◀

For a CDR $T = T(\mathbf{m})$, we define $\mathcal{U}^K(T) = \cup_{-K \leq i \leq K} \mathcal{P}(T(\mathbf{m}^s))$. It follows from Theorem 21 that $\mathcal{U}^K(T)$ consistently approximates a pseudoline arrangement represented as a union of associated ray families.

► **Example 22 (Consistent digital line arrangement).** Let us consider the family \mathcal{F}_1 of linear rays. Define \mathcal{F}_1^s for $s \geq 0$ (resp. $s \leq -1$) to be the set of rays starting with horizontal (resp. vertical) rays, and continue to linear rays with positive slopes emanating from $(s, -s)$. Let T be the CDR for \mathcal{F}_1 constructed in Section 2.1. Then $\mathcal{U}^K(T)$ consistently digitize $\cup_{-K \leq s \leq K} \mathcal{F}_1^s$ in Δ_1 with the $O(\log n)$ distance bound.

Indeed, for $s > 0$, the structure of $T(\mathbf{m}^s)$ in $\Delta \cap \{(x, y) : x \geq s\}$ is same as the tree obtained by connecting the forest of $T \cap \{(x, y) : y \geq s\}$ by a horizontal path. The case $s < 0$ is similar. Thus, the discrepancy bound remains as same as the one for T .

Note that although we only consider the lines with positive slopes, we can easily mix it with those with negative slopes (obtained by a mirror construction) without losing consistency. The above example shows that we can consistently digitize the line segments in the first quadrant. However, it is weaker than [4] since we only deal with segments on the lines going through $(s, -s)$ for integers s , and we need a finer precision to represent short segments.

► **Example 23 (Consistent digital pseudoline arrangement of shifted parabola rays).** Let us consider the family \mathcal{F}_2 consisting of curves defined by $y = ax^2$ ($a > 0$). Define \mathcal{F}_2^s to be the set of the right halves of parabolas with the apex $(s, -s)$. Then $\mathcal{U}^K(T_{para})$ consistently digitize $\cup_{-K \leq s \leq K} \mathcal{F}_2^s$ in Δ_1 with the $O(\sqrt{n \log n})$ distance bound.

4.2 Union of homogeneous polynomial families

In this section, we assume that the CDRs are constructed deterministically. Let us consider $\mathcal{F}_{i,j} = \mathcal{F}_i \cup \mathcal{F}_j$ for $1 \leq i \leq j$, where \mathcal{F}_i is the family of homogeneous polynomial curves of degree i . Let $\mathbf{m}^{(i)}$ be the sequence (do not confuse this with \mathbf{m}^s given above) corresponding to $T_{\mathcal{F}_i}$ deterministically constructed. Naturally, each pair of curves $f \in \mathcal{F}_i$ and $g \in \mathcal{F}_j$ intersect once in the first quadrant other than the origin, and thus behaves as a pseudoline arrangement in the region $x > 0, y > 0$. We consider the union $\mathcal{T}_{i,j} = \mathcal{P}(T_{\mathcal{F}_i}) \cup \mathcal{P}(T_{\mathcal{F}_j})$ to approximate curves in $\mathcal{F}_{i,j}$.

► **Lemma 24.** $\mathbf{m}^{(j)} \succeq \mathbf{m}^{(i)}$ for $1 \leq i \leq j$.

Proof. Recall that $x(k) = \frac{jkV(k)}{(j-1)V(k)+1}$ in the construction of $T_{\mathcal{F}_j}$. Thus, $m^{(j)}(k) = \lceil \frac{jkV(k)}{(j-1)V(k)+1} \rceil$. Since $\frac{ikV(k)}{(i-1)V(k)+1} \leq \frac{jkV(k)}{(j-1)V(k)+1}$ if $i < j$, we have the lemma. ◀

► **Theorem 25.** $\mathcal{T}_{1,2}$ consistently approximates $\mathcal{F}_{1,2}$ in the region $\{(x, y) \in \Delta \mid x \geq 3, y \geq 3\}$. For $i \geq 2$, $\mathcal{T}_{i,i+1}$ consistently approximates $\mathcal{F}_{i,i+1}$ in the region $R(i) = \{(x, y) \in \Delta \mid x + y \geq 4(i+1)(i+2), x \geq 4i, y \geq 4(i+1)\}$.

Proof. $\mathcal{T}_{i,i+1}$ semi-consistently approximates $\mathcal{F}_{i,i+1}$ in Δ , although the existence of multiple singular points prevents the consistency.

Thus, we study location of singular points to find a subregion R to attain the consistency.

Consider a singular point p in a level $L(k)$. Recall that $p = (m^{(i)}(k+1), k - m^{(i+1)}(k+1))$ and $m^{(i)}(k+1) = m^{(i+1)}(k+1)$ at a singular point p in a level $L(k)$. Since $m^{(i)}(k+1) = m^{(i+1)}(k+1)$, we have

$$\frac{(i+1)(k+1)V(k+1)}{iV(k+1)+1} - \frac{i(k+1)V(k+1)}{(i-1)V(k+1)+1} < 1.$$

For the case $i = 1$, suppose that a singular point appears on $L(k)$, and let $v = V(k+1)$, and $K = k+1$. Then we have $\frac{2Kv}{v+1} - Kv < 1$, which means $Kv(1-v) < v+1$. We assume that $K \geq 6$ and $\frac{3}{K} \leq v \leq 1 - \frac{3}{K}$. Then, $Kv(1-v) \geq 3(1 - \frac{3}{K}) = 3 - \frac{9}{K}$ and hence $3 - \frac{9}{K} < 1 + 1 - \frac{3}{K}$ and hence $K < 6$, and we have contradiction.

Thus, $k+1 < 6$ or $(k+1)v < 3$ or $(k+1)v > k+1-3 = k-2$. The position of the singular point p is $\lceil (k+1)v \rceil, k - \lceil (k+1)v \rceil$, and hence it is located either in the region $x+y \leq 4, x \leq 2$ or $y \leq 2$. Thus, we have the theorem for $\mathcal{T}_{1,2}$.

For $i \geq 2$, $p = (m^{(i)}(k+1), k - m^{(i)}(k+1))$ and $m^{(i)}(k+1) = m^{(i+1)}(k+1)$ at the singular point p . For simplifying the formulas, we set $K = k+1, v = V(k+1)$, and $c = 2(i+1)(i+2)$. We assume $K > 2c$ since otherwise the singular point is outside R .

Now, we have

$$\frac{(i+1)Kv}{iv+1} - \frac{iKv}{(i-1)v+1} < 1.$$

This is transformed to

$$Kv(1-v) < (iv+1)((i+1)v+1). \quad (*)$$

We will first show that it gives a contradiction if $\frac{4}{K} \leq v \leq 1 - \frac{c}{K}$.

For the case where $1/2 \leq v \leq 1 - \frac{c}{K}$, $v(1-v)$ take its minimum at $v = 1 - \frac{c}{K}$, and the right hand side is at most $(i+1)(i+2)$. Thus we have

$$K \frac{c}{K} (1 - \frac{c}{K}) = c(1 - \frac{c}{K}) < (i+1)(i+2)$$

32:14 Digital Curved Rays

Since $K > 2c$, $c(1 - 1/2) < (i + 1)(i + 2)$ and hence $c < 2(i + 1)(i + 2)$ and it contradicts the definition of c .

If $\frac{1}{i+1} \leq v < \frac{1}{2}$, substituting $K > 4(i + 1)(i + 2)$, (*) implies that

$$4(i + 1)(i + 2)v(1 - v) < (iv + 1)((i + 1)v + 1).$$

Cleaning up the formula, we have

$$-(5i^2 + 13i + 8)v^2 + (4i^2 + 10i + 7)v - 1 < 0.$$

Since $v < 1/2$, we replace v^2 by $v/2$, we have

$$-(5i^2 + 13i + 8)\frac{v}{2} + (4i^2 + 10i + 7)v - 1 < 0.$$

And hence $(3i^2 + 7i + 6)v < 2$. This does not happen if $v \geq \frac{1}{i+1}$.

If $\frac{4}{K} \leq v \leq \frac{1}{i+1}$, the left hand of (*) takes minimum at $v = \frac{4}{K}$, and the right hand takes maximum at $v = \frac{1}{i+1}$, and we have

$$4\left(1 - \frac{4}{K}\right) < 2\frac{2i + 1}{i + 1}.$$

Since $K > 4(i + 1)(i + 2)$,

$$1 - \frac{1}{(i + 1)(i + 2)} < 1 - \frac{1}{2(i + 1)}.$$

This does not happen since $i + 2 > 2$.

Thus, we have either $v < \frac{4}{K}$ or $v > 1 - \frac{c}{K}$.

In the former case that $v < \frac{4}{K}$. The x -value of the singular point is $\lceil \frac{iKv}{(i-1)v+1} \rceil \cdot \frac{iKv}{(i-1)v+1}$ is monotonically increasing in v (if $v > 0$). Thus, we have it is less than $\frac{4i}{1+4(i-1)/K}$, which takes maximum at $K = \infty$. Thus, the x -value of the singular point is less than $4i$.

In the latter case, consider the y -value $k - \lceil \frac{(i+1)Kv}{iv+1} \rceil$ of the singular point, which is at most $K - \frac{(i+1)Kv}{iv+1} = \frac{K-Kv}{iv+1}$. It takes the maximum $\frac{c}{i(1-\frac{c}{K})+1}$ at $v = 1 - \frac{c}{K}$, and since $K > 2c$ it is less than $\frac{2c}{i+2} = 4(i + 1)$. ◀

The following is a straightforward corollary.

► **Corollary 26.** $\mathcal{T}_{i,j}$ consistently approximates $\mathcal{F}_{i,j}$ for any $j > i$ in the region $R(i)$. Accordingly, $\mathcal{T}_{\leq d} = \cup_{1 \leq i \leq d} \mathcal{P}(T_i)$ consistently approximates $\mathcal{H}_d = \cup_{1 \leq i \leq d} \mathcal{F}_i$ in the region $R(d - 1)$.

5 Experimental results

We have implemented our method and constructed CDR for the constant-multiplied curves. Figure 5 and Figure 6 illustrate CDRs for polynomial curves, sine, sigmoid, and logarithmic rays.

Figure 7 shows the selected paths approximating the curves towards equally-spaced sampled points on the boundary of square regions.

For each grid width $n = 2^m$ up to $n = 2^{14}$, the worst-case Hausdorff distance between parabolas and digital rays in T_{para} is given in Figure 8, where it is about 12 for $n = 2^{14}$. The dependency of worst-case Hausdorff distance on n have the similar behavior for each of other types of curve.

The error for $n = 2^{14}$ is about 11.2, 13.4, 15.0 for sine, sigmoid and logarithmic curves, respectively. Note that the values are real numbers since we consider Hausdorff distance based on Euclidean distance.

■ **Figure 5** CDRs for (a) $y = ax^2$, (b) $y = ax^3$, and (c) $y = ax^4$. Green nodes are branching nodes. Red paths are the digital curves towards $p = (15, 15)$.

■ **Figure 6** CDRs for (d) $y = a\tilde{\sin}x$ ($0 \leq x \leq \pi/2$), (e) $y = a\sigma(x)$ ($x \leq 6$), and (f) $y = a \log(x + 1)$. Green nodes are branching nodes. Red paths are the digital curves towards $p = (15, 15)$.

■ **Figure 7** Sampled Curves of CDRs for (a) $y = ax^2$, (b) $y = ax^3$, (c) $y = ax^4$, (d) $y = a\tilde{\sin}x$ ($0 \leq x \leq \pi/2$), (e) $y = a\sigma(x)$ ($x \leq 6$), and (f) $y = a \log(x + 1)$ in the 300×300 grid.

■ **Figure 8** The largest distance from a parabola and the corresponding digital ray in T_{para} .

6 Concluding remarks

The experimental result suggests that our $O(\sqrt{n \log n})$ bound seems to be loose. Although currently the lower bound mentioned for Lemma 10 prevents us to improve it beyond $O(\sqrt{n})$, recent progress on low-discrepancy sequences [16] might be applied.

For the line segments, a construction of consistent digital segments (CDS) is known [4] with $O(\log n)$ distance error bound. Although we have a generalization of CDS to handle some families of curves, there are a lot of questions to invest further: For example, we do not know how to handle the set of all axis parallel parabolas.

Abstract

We consider the k -MEDIAN problem on planar graphs: given an edge-weighted planar graph G , a set of clients $C \subseteq V(G)$, a set of facilities $F \subseteq V(G)$, and an integer parameter k , the task is to find a set of at most k facilities whose opening minimizes the total connection cost of clients, where each client contributes to the cost with the distance to the closest open facility. We give two new approximation schemes for this problem:

- *FPT Approximation Scheme*: for any $\varepsilon > 0$, in time $2^{\mathcal{O}(k\varepsilon^{-3} \log(k\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ we can compute a solution that has connection cost at most $(1 + \varepsilon)$ times the optimum, with high probability.
- *Efficient Bicriteria Approximation Scheme*: for any $\varepsilon > 0$, in time $2^{\mathcal{O}(\varepsilon^{-5} \log(\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ we can compute a set of at most $(1 + \varepsilon)k$ facilities whose opening yields connection cost at most $(1 + \varepsilon)$ times the optimum connection cost for opening at most k facilities, with high probability.

As a direct corollary of the second result we obtain an EPTAS for UNIFORM FACILITY LOCATION on planar graphs, with same running time.

Our main technical tool is a new construction of a “coreset for facilities” for k -MEDIAN in planar graphs: we show that in polynomial time one can compute a subset of facilities $F_0 \subseteq F$ of size $k \cdot (\log n / \varepsilon)^{\mathcal{O}(\varepsilon^{-3})}$ with a guarantee that there is a $(1 + \varepsilon)$ -approximate solution contained in F_0 .

1 Introduction

We study approximation schemes for classic clustering objectives, formalized as follows. Given an edge-weighted graph G together with a set C of vertices called *clients*, a set F of vertices called *candidate facilities*, and an *opening cost* $\text{open} \in \mathbb{R}_{\geq 0}$, the UNIFORM FACILITY LOCATION problem asks for a subset of facilities (also called centers) $D \subseteq F$ that minimizes

the cost defined as $|D| \cdot \text{open} + \sum_{c \in C} \min_{f \in D} \text{dist}(c, f)$. In the NON-UNIFORM FACILITY LOCATION variant, the opening costs may vary between facilities.

We also consider the related k -MEDIAN problem, where the tuple (G, F, C) comes with a hard budget k for the number of open facilities (as opposed to the opening cost `open`). That is, the problem asks for a set $D \subseteq F$ of size at most k that minimizes the connection cost $\sum_{c \in C} \text{dist}(c, D)$. Note that UNIFORM FACILITY LOCATION can be reduced to k -MEDIAN by guessing the number of open facilities in an optimal solution.

FACILITY LOCATION and k -MEDIAN model in an abstract way various clustering objectives appearing in applications. Therefore, designing approximation algorithms for them and their variants is a vibrant topic in the field of approximation algorithms. For NON-UNIFORM FACILITY LOCATION, a long line of work [1, 15, 22, 16] culminated with the 1.488-approximation algorithm by Li [18]. On the other hand, Guha and Khuller [13] showed that the problem cannot be approximated in polynomial time within factor better than 1.463 unless $\text{NP} \subseteq \text{DTIME}[n^{\mathcal{O}(\log \log n)}]$, which gives almost tight bounds on the best approximation factor achievable in polynomial time. For k -MEDIAN, the best known approximation ratio achievable in polynomial time is 2.67 due to Byrka et al. [3], while the lower bound of 1.463 due to Guha and Khuller [13] holds here as well.

Given the approximation hardness status presented above, it is natural to consider restricted metrics. In this work we consider *planar metrics*: we assume that the underlying edge-weighted graph G is planar.

It was a long-standing open problem whether FACILITY LOCATION admits a polynomial-time approximation scheme (PTAS) in planar metrics. For the uniform case, this question has been resolved in affirmative by Cohen-Addad et al. [8] in an elegant way: they showed that local search of radius $\mathcal{O}(1/\varepsilon^2)$ actually yields a $(1 + \varepsilon)$ -approximation, giving a PTAS with running time $n^{\mathcal{O}(1/\varepsilon^2)}$. This approach also gives a PTAS for k -MEDIAN with a similar running time, and works even in metrics induced by graphs from any fixed proper minor-closed class.

Very recently, Cohen-Addad et al. [9] also gave a PTAS for NON-UNIFORM FACILITY LOCATION in planar metrics using a different approach. Roughly, the idea is to first apply Baker layering scheme to reduce the problem to the case when in all clusters (sets of clients connected to the same facility) in the solution, all clients are within distance between 1 and r from the center, for some constant r depending only on ε . This case is then resolved by another application of Baker layering scheme, followed by a dynamic programming on a hierarchical decomposition of the graph using shortest paths as balanced separators.

Both the schemes of [8] and of [9] are PTASes: they run in time $n^{g(\varepsilon)}$ for some function g . It is therefore natural to ask for an *efficient PTAS* (EPTAS): an approximation scheme with running time $f(\varepsilon) \cdot n^{\mathcal{O}(1)}$ for some function f . Such an EPTAS was given by Cohen-Addad [5] for k -MEANS in low-dimensional Euclidean spaces; this is a variant of k -MEDIAN where every client contributes to the connection cost with the *square* of its distance from the closest open facility. Here, the idea is to apply local search as in [8], but to use the properties of the metric to explore the local neighborhood faster. Unfortunately, this technique mainly relies on the Euclidean structure (or on the bounded doubling dimension of the input) and seems hard to lift to the general planar case. Also the techniques of [9] are far from yielding an EPTAS: essentially, one needs to use a logarithmic number of portals at every step of the final dynamic programming in order to tame the accumulation of error through $\log n$ levels of the decomposition. Recently, a near-linear time EPTAS was given by Cohen-Addad et al. [6] for k -median, k -means and non-uniform facility location where the input points lie in a metric of bounded doubling dimension. This result is obtained using a randomized dissection of the metric, a technique that is not available for planar inputs.

The goal of this work is to circumvent these difficulties and give an EPTAS for UNIFORM FACILITY LOCATION in planar metrics.

Our results. Our main technical contribution is the following theorem. In essence, it states that when solving k -MEDIAN on a planar graph one can restrict the facility set to a subset of size $k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$, at the cost of losing a multiplicative factor of $(1 + \varepsilon)$ on the optimum connection cost. This can be seen as the planar version of the classic result by Matoušek [20] who showed that for Euclidean metrics of dimension d , it is possible to reduce the number of candidate centers to $\text{poly}(k)\varepsilon^{-\mathcal{O}(d)}$ at the cost of losing a multiplicative factor of $(1 + \varepsilon)$ on the optimum connection cost (through the use of coresets as well). For general metrics, obtaining such a result seems challenging, since this would imply a $(1 + \varepsilon)$ -approximation algorithm with running time $f(k, \varepsilon)n^{\mathcal{O}(1)}$, which would contradict Gap-ETH [7].

From now on, by *with constant probability* we mean with probability at least $1/2$; this can be boosted by independent repetition.

► **Theorem 1.** *Given a k -Median instance (G, F, C, k) , where G is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized polynomial time compute a set $F_0 \subseteq F$ of size $k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$ satisfying the following condition with constant probability: there exists a set $D_0 \subseteq F_0$ of size at most k such that for every set $D \subseteq F$ of size at most k it holds that $\sum_{c \in C} \min_{u \in D_0} \text{dist}(u, c) \leq (1 + \varepsilon) \sum_{c \in C} \min_{u \in D} \text{dist}(u, c)$.*

A direct corollary of Theorem 1 is a fixed-parameter approximation scheme for the k -MEDIAN problem in planar graphs. This continues the line of work on fixed-parameter approximation schemes for k -median and k -means in Euclidean spaces [12, 17], where the goal is to design an algorithm running in time $f(k, \varepsilon) \cdot n^{\mathcal{O}(1)}$ for a computable function f .

► **Corollary 2.** *Given a k -Median instance (G, F, C, k) , where G is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{\mathcal{O}(k\varepsilon^{-3} \log(k\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ compute a solution $D \subseteq F$ that has connection cost at most $(1 + \varepsilon)$ times the minimum possible connection cost with constant probability.*

Proof. Apply the algorithm of Theorem 1 and let $F_0 \subseteq F$ be the obtained subset of facilities. Then run a brute-force search through all subsets of F_0 of size at most k and output one with the smallest connection cost. Thus, the running time is

$$\left(k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}\right)^k \cdot n^{\mathcal{O}(1)} \leq 2^{\mathcal{O}(k\varepsilon^{-3} \log(k\varepsilon^{-1}))} \cdot (\log n)^{\mathcal{O}(k\varepsilon^{-3})} \cdot n^{\mathcal{O}(1)}$$

which is at most $2^{\mathcal{O}(k\varepsilon^{-3} \log(k\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ since $(\log n)^d \leq 2^{\mathcal{O}(d \log d)} \cdot n^{\mathcal{O}(1)}$: if $n \leq 2^{d^2}$ then $(\log n)^d \leq d^{2d} \leq 2^{\mathcal{O}(d \log d)}$, and if $n > 2^{d^2}$ then $(\log n)^d \leq 2^{\sqrt{\log n} \cdot \log \log n} \leq n^{\mathcal{O}(1)}$. ◀

Using Theorem 1 we can also give an efficient bicriteria PTAS for k -MEDIAN in planar graphs. This time, the proof is more involved and uses the local search techniques of [5].

► **Theorem 3.** *Given a k -Median instance (G, F, C, k) , where G is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{\mathcal{O}(\varepsilon^{-5} \log(\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ compute a set $D \subseteq F$ of size at most $(1 + \varepsilon)k$ such that its connection cost is at most $(1 + \varepsilon)$ times the minimum possible connection cost for solutions of size k with constant probability.*

A direct corollary of Theorem 3 is an efficient PTAS for UNIFORM FACILITY LOCATION in planar graphs.

► **Theorem 4.** *Given a Uniform Facility Location instance (G, F, C, open) , where G is a planar graph, and an accuracy parameter $\varepsilon > 0$, one can in randomized time $2^{\mathcal{O}(\varepsilon^{-5} \log(\varepsilon^{-1}))} \cdot n^{\mathcal{O}(1)}$ compute a solution $D \subseteq F$ that has total cost at most $(1 + \varepsilon)$ times the optimum cost with constant probability.*

Proof. Iterate over all possible choices of k being the number of facilities opened by the optimum solution, and for every k invoke the algorithm of Theorem 3 for the k -MEDIAN instance (G, F, C, k) . From the obtained solutions output one with the smallest cost. ◀

Note that the approach presented above fails for the non-uniform case, where each facility has its own, distinct opening cost.

In this extended abstract we focus on proving the main result, Theorem 1. The proof of Theorem 3, on which Theorem 4 also relies, is fully deferred to the full version of the paper [10].

Our techniques. The first step in the proof of Theorem 1 is to reduce the number of relevant clients using the coreset construction of Feldman and Langberg [11]. By applying this technique, we may assume that there are at most $k \cdot \mathcal{O}(\varepsilon^{-2} \log n)$ clients in the instance, however they are weighted: every client c is assigned a nonnegative weight $\omega(c)$, and it contributes to the connection cost of any solution with $\omega(c)$ times the distance to the closest open facility in the solution.

We now examine the Voronoi diagram induced in the input graph G by the *clients*: vertices of G are classified into *cells* according to the closest client. This Voronoi diagram has one cell per every client, thus it can be regarded as a planar graph with $|C|$ faces, where each face accommodates one cell. To formally define the Voronoi diagram, and in particular the boundaries between neighboring cells, we use the framework introduced by Marx and Pilipczuk [19] and its extension used in [21].

Consider now all the *spokes* in the diagram, where a spoke is the shortest path connecting the center of a cell (i.e. a client) with a branching node of the diagram incident to the cell (which is a face of G). Removing all the spokes and all the branching nodes from the plane divides it into *diamonds*, where each diamond is delimited by four spokes, called further the *perimeter* of the diamond. See Figure 1 for an example. Since the diagram is a planar graph with $|C|$ faces, there are $\mathcal{O}(|C|) = k \cdot \mathcal{O}(\varepsilon^{-2} \log n)$ diamonds altogether. Moreover, since no diamond contains a client in its interior, whenever P is a path connecting a client with a facility belonging to some diamond Δ , P has to cross the perimeter of Δ .

Now comes the key and most technical part of the proof. We very carefully put $\mathcal{O}(\varepsilon^{-2} \log n)$ portals on the perimeter of each diamond. The idea of placement is similar to that of the resolution metric used in the QPTAS for FACILITY LOCATION. Namely, on a spoke Q starting at client c we put portals at distance $1, (1 + \varepsilon), (1 + \varepsilon)^2, \dots$ from c , so that the further we are on the spoke from c , the sparser the portals are. As a diamond is delimited by four spokes, we may thus use only $\mathcal{O}(\varepsilon^{-2} \log n)$ portals per diamond, while the cost of snapping a path crossing Q to the portal closest to the crossing point can be bounded by ε times the distance from the crossing point to c .

For a facility f in a diamond Δ , we define the *profile* of f as follows. For every spoke Q in the perimeter of Δ , we look at the closest portal π from f on Q . We record approximate (up to $(1 + \varepsilon)$ multiplicative error) distances from f to π and $\mathcal{O}(\varepsilon^{-3})$ neighboring portals, as well as the distance to the client endpoint of the spoke Q . The crux lies in the following fact: for every two facilities f, f' in Δ with the same profile, replacing f with f' increases the connection cost of any client c connected to f only by a multiplicative factor of $(1 + \varepsilon)$. Hence, for every profile in every diamond it suffices to keep just one facility with that profile. Since there are $k \cdot \mathcal{O}(\varepsilon^{-2} \log n)$ diamonds and $\mathcal{O}(\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$ possible profiles in each of them, we keep at most $k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$ facilities in total. This proves Theorem 1.

For the proof of Theorem 3, we first apply Theorem 1 to reduce the number of facilities to $k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$. Then we again inspect the Voronoi diagram, but now induced by the *facilities*. Having contracted every cell to a single vertex, we compute an r -division of the

obtained planar graph to cover it with regions of size $r = (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$ so that only $\mathcal{O}(\varepsilon)k$ facilities are on boundaries of the regions. We open all the facilities in all the boundaries – thus exceeding the quota for open facilities by $\mathcal{O}(\varepsilon)k$ – run the PTAS of Cohen-Addad et al. [8] in each region independently, and at the end assemble regional solutions using a knapsack dynamic programming. Since within each region there are only polylogarithmically many facilities, each application of the PTAS actually works in time $f(\varepsilon) \cdot n^{\mathcal{O}(1)}$.

2 Preliminaries on Voronoi diagrams and coresets

In this section we recall some tools about Voronoi diagrams in planar graphs and coresets that will be used in the proof of Theorem 1. We will consider undirected graphs with positive edge lengths embedded in a sphere, with the standard shortest-paths metric $\text{dist}(u, v)$ for $u, v \in V(G)$. Contrary to the previous section, the metric is defined on the vertex set of G only, i.e., we do not consider G as a metric space with points in the interiors of edges. For $X, Y \subseteq V(G)$, we denote $\text{dist}(X, Y) = \min_{x \in X, y \in Y} \text{dist}(x, y)$ and similarly we define $\text{dist}(u, X)$ for $u \in V(G)$ and $X \subseteq V(G)$.

Recall that for a set $D \subseteq V(G)$ of *open facilities* and a set $C \subseteq V(G)$, we define the *connection cost* as

$$\text{conn}(D, C) = \sum_{v \in C} \text{dist}(v, D).$$

If the input is additionally equipped with opening costs $\text{open}: F \rightarrow \mathbb{R}_{\geq 0}$, then the *opening cost* of D is defined as $\sum_{w \in D} \text{open}(w)$.

2.1 Voronoi diagrams in planar graphs

We now recall the construction of Voronoi diagrams and related notions in planar graphs used by Marx and Pilipczuk [19]. The setting is as follows. Suppose G is an n -vertex simple graph embedded in a sphere Σ whose edges are assigned nonnegative real lengths. We consider the shortest path metric in G : for two vertices u, v , their *distance* $\text{dist}(u, v)$ is equal to the smallest possible total length of a path from u to v . We will assume that G is triangulated (i.e. every face of G is a cycle of length 3), for this may always be achieved by triangulating the graph using edges of infinite weight.

Further, we assume that shortest paths are unique in G and that finite distances between distinct vertices in G are pairwise different: for all vertices u, v, u', v' with $u \neq v$, $u' \neq v'$ and $\{u, v\} \neq \{u', v'\}$, we have $\text{dist}(u, v) \neq \text{dist}(u', v')$ or $\text{dist}(u, v) = \text{dist}(u', v') = +\infty$. This can be achieved by adding small perturbations to the edge lengths. Since we never specify degrees of polynomials in the running time of our algorithms, we may ignore the additional complexity cost incurred by the need of handling the perturbations in arithmetic operations.

Voronoi diagrams and their properties. Suppose that S is a subset of vertices¹ of G . First, define the *Voronoi partition*: for a vertex $p \in S$, the *Voronoi cell* $\text{Cell}_S(p)$ is the set of all those vertices $u \in V(G)$ whose distance from p is smaller than the distance from any other vertex $q \in S$; note that ties do not occur due to the distinctness of distances in G . Note that $\{\text{Cell}_S(p)\}_{p \in S}$ is a partition of the vertex set of G . For each $p \in S$, let $T(p)$ be the union of

¹ In [19] a more general setting is considered where objects inducing the diagram are connected subgraphs of G instead of single vertices. We will not need this generality here.

■ **Figure 1** A part of the Voronoi diagram with various features distinguished. Branching nodes of the diagram are grayed triangular faces, edges of the diagram are dashed. Solid paths of respective colors are spokes. (The interior of) one diamond is grayed in order to highlight it.

shortest paths from vertices of $\text{Cell}_S(p)$ to p ; recall here that shortest paths in G are unique. Note that, due to the distinctness of distances in G , $T(p)$ is a spanning tree of the subgraph of G induced by the cell $\text{Cell}_S(p)$.

The diagram Vor_S induced by G is a multigraph constructed as follows. First, take the dual G^* of G and remove all edges dual to the edges of all the trees $T(p)$, for $p \in S$. Then, exhaustively remove vertices of degree 1. Finally, for every maximal 2-path (i.e. path with internal vertices of degree 2), say with endpoints u and v , we replace this path by the edge uv ; note that this creates a loop at u in case $u = v$. The resulting multigraph Vor_S is the Voronoi diagram induced by S . Note that the vertices of Vor_S are faces of G ; for clarity we shall call them *branching nodes*. Furthermore, Vor_S inherits an embedding in Σ from the dual G^* , where an edge uv that replaced a maximal 2-path P is embedded precisely as P , i.e., as the concatenation of (the embeddings of) the edges comprising P . From now on we will assume this embedding of Vor_S .

We recall several properties of Vor_S , observed in [19]

► **Lemma 5** (Lemmas 4.4 and 4.5 of [19]). *The diagram Vor_S is a connected and 3-regular multigraph embedded in Σ , which has exactly $|S|$ faces, $2|S| - 4$ branching nodes, and $3|S| - 6$ edges. The faces of Vor_S are in one-to-one correspondence with vertices of S : each $p \in S$ corresponds to a face of Vor_S that contains all vertices of $\text{Cell}_S(p)$ and no other vertex of G .*

Spokes and diamonds. We now introduce further structural elements that can be distinguished in the Voronoi diagram, see Figure 1 for reference. The definitions and basic observations presented below are taken from Pilipczuk et al. [21], and were inspired by the Euclidean analogues due to Har-Peled [14].

An *incidence* is a triple $\tau = (p, u, f)$ where $p \in S$, f is a branching node of the diagram Vor_S , and u is a vertex of G that lies on f (recall that f is a triangular face of G) and belongs to $\text{Cell}_S(p)$. The *spoke* of the incidence τ , denoted $\text{Spoke}(\tau)$, is the shortest path in G between p and u . Note that all the vertices of $\text{Spoke}(\tau)$ belong to $\text{Cell}_S(p)$.

Let $e = f_1 f_2$ be an edge of the diagram Vor_S , where f_1, f_2 are branching nodes (possibly $f_1 = f_2$ if e is a loop in Vor_S). Further, let p_1 and p_2 be the vertices from S that correspond to faces of Vor_S incident to e (possibly $p_1 = p_2$ if e is a bridge in Vor_S). Suppose for a moment that $f_1 \neq f_2$. Then, out of the three edges of f_1 (these are edges in G) there is

exactly one that crosses the edge e of Vor_S ; say it is the edge $u_{1,1}u_{1,2}$ where $u_{1,1} \in \text{Cell}_S(p_1)$ and $u_{1,2} \in \text{Cell}_S(p_2)$. Symmetrically, there is one edge of f_2 that crosses e , say it is $u_{2,1}u_{2,2}$ where $u_{2,1} \in \text{Cell}_S(p_1)$ and $u_{2,2} \in \text{Cell}_S(p_2)$. In case $f_1 = f_2$, the edge e crosses two different edges of $f_1 = f_2$ and we define $u_{1,1}, u_{1,2}, u_{2,1}, u_{2,2}$ analogously for these two crossings; note that then, provided p_1 corresponds to the face enclosed by the loop e , we have $u_{1,1} = u_{1,2}$. For all $i, j \in \{1, 2\}$, consider the incidence $\tau_{i,j} = (p_i, u_{i,j}, f_j)$.

Consider removing the following subsets from the sphere Σ : interiors of faces f_1, f_2 and spokes $\text{Spoke}(\tau_{i,j})$ for all $i, j \in \{1, 2\}$. After this removal the sphere breaks into two regions, out of which exactly one, say R , intersects (the embedding of) e . Let the *diamond* of e , denoted $\text{Diam}(e)$, be the subgraph of G consisting of all features (vertices and edges) embedded in $R \cup \bigcup_{i,j \in \{1,2\}} \text{Spoke}(\tau_{i,j})$. The region R as above is the *interior* of the diamond $\text{Diam}(e)$. Note that in particular, the spokes $\text{Spoke}(\tau_{i,j})$ for $i, j \in \{1, 2\}$ and the edges $u_{1,1}u_{1,2}$ and $u_{2,1}u_{2,2}$ belong to $\text{Diam}(e)$. The *perimeter* of the diamond of e is the closed walk obtained by concatenating spokes $\text{Spoke}(\tau_{i,j})$ for $i, j \in \{1, 2\}$ and edges $u_{1,1}u_{1,2}, u_{2,1}u_{2,2}$ in the natural order around $\text{Diam}(e)$. The following observation is immediate:

► **Proposition 6.** *Consider removing all the spokes (considered as curves on Σ) and all the branching nodes (considered as interiors of faces on Σ) of the diagram Vor_S from the sphere Σ . Then Σ breaks into $3|S| - 6$ regions that are in one-to-one correspondence with edges of Vor_S : a region corresponding to the edge e is the interior of the diamond $\text{Diam}(e)$. Consequently, the intersection of diamonds of two different edges of Vor_S is contained in the intersection of their perimeters.*

Finally, we note that the perimeter of a diamond separates it from the rest of the graph. Since vertices of S are never contained in the interior of a diamond, this yields the following.

► **Lemma 7.** *Let $p \in S$ and u be a vertex of G belonging to the diamond $\text{Diam}(e)$ for some edge e of Vor_S . Then every path in G connecting u and p intersects the perimeter of $\text{Diam}(e)$.*

2.2 Coresets

In most our algorithms, the starting point is the notion of a *coreset* and a corresponding result of Feldman and Langberg [11]. To this end, we need to slightly generalize the notion of a client set in a k -MEDIAN instance. A *client weight function* is a function $\omega: C \rightarrow \mathbb{R}_{\geq 0}$. Given a set $D \subseteq F$ of open facilities, the (weighted) connection cost is defined as

$$\text{conn}(D, \omega) = \sum_{v \in C} \text{dist}(v, D) \cdot \omega(v).$$

That is, every client v is assigned a weight $\omega(v)$ with which it contributes to the objective function. The *support* of a weight function ω is defined as $\text{supp}(\omega) = \{v \in C \mid \omega(v) > 0\}$. From now on, whenever we speak about a k -MEDIAN instance without specified client weight function, we assume the standard function assigning each client weight 1.

The essence of coresets is that one can find weight functions with small support that well approximate the original instance. Given a k -MEDIAN instance (G, F, C, k) (without weights) and an accuracy parameter $\varepsilon > 0$, a *coreset* is a weight function ω such that for every set $D \subseteq F$ of size at most k , it holds that

$$|\text{conn}(D, C) - \text{conn}(D, \omega)| \leq \varepsilon \cdot \text{conn}(D, C).$$

We rely on the following result of Feldman and Langberg [11].

► **Theorem 8** (Theorem 15.4 of [11]). *Given a k -Median instance (G, F, C, k) with $n = |V(G)|$ and accuracy parameter $\varepsilon > 0$, one can in randomized polynomial time find a weight function ω with support of size $\mathcal{O}(k\varepsilon^{-2} \log n)$ that is a coreset with constant probability.*

We note that Ke Chen [4] gave a construction of a strong coreset with support of size $\mathcal{O}(k^2\varepsilon^{-2} \log n)$ that is much simpler than the later construction of Feldman and Langberg [11]. By using this construction instead, we would obtain a weaker version of Theorem 1, with a bound on $|F_0|$ that is quadratic in k instead of linear. This would be perfectly sufficient to derive an FPT approximation scheme as in Corollary 2, but for Theorem 3 we will vitally use the stronger statement. A construction of coresets with similar size guarantees, but maintainable in the streaming model, has been proposed by Braverman et al. [2].

3 Facility coreset for k -Median in planar graphs

In this section we give a coreset for centers for the k -MEDIAN problem, that is, we prove Theorem 1. We shall focus on the following lemma, which in combination with Theorem 8 yields Theorem 1.

► **Lemma 9.** *Given a k -Median instance (G, F, C, k) with a weight function ω and an accuracy parameter $\varepsilon > 0$, one can in polynomial time compute a set $F_0 \subseteq F$ of size $|\text{supp}(\omega)| \cdot (\varepsilon^{-1} \log |V(G)|)^{\mathcal{O}(\varepsilon^{-3})}$ satisfying the following condition with constant probability: there exists a set $D_0 \subseteq F_0$ of size at most k such that for every set $D \subseteq F$ of size at most k it holds that $\text{conn}(D_0, \omega) \leq (1 + \varepsilon) \cdot \text{conn}(D, \omega)$.*

Before we proceed, let us verify that Theorem 8 and Lemma 9 together imply Theorem 1. Given an instance (G, F, C, k) of k -MEDIAN, we first apply Theorem 8 to obtain a coreset ω with support of size $\mathcal{O}(k\varepsilon^{-2} \log n)$. Next, we pass this coreset to Lemma 9, thus obtaining a set $F_0 \subseteq F$ of size $k \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})}$. Let D_0 be the subset of F_0 of size at most k that minimizes $\text{conn}(D_0, \omega)$. Then using the approximation guarantees of Theorem 8 and Lemma 9, for any $D \subseteq F$ we have

$$\text{conn}(D_0, C) \leq (1 + \varepsilon)\text{conn}(D_0, \omega) \leq (1 + \varepsilon)^2\text{conn}(D, \omega) \leq (1 + \varepsilon)^3\text{conn}(D, C).$$

It remains to rescale ε . Hence, for the rest of this section we focus on proving Lemma 9.

Let $\mathcal{I} = (G, F, C, k)$ be an input k -MEDIAN instance with a weight function ω , where G is planar. Let $\varepsilon > 0$ be an accuracy parameter and without loss of generality assume that $\varepsilon < 1/4$. Let $n = |V(G)|$ and $m = |E(G)|$. Without loss of generality assume that $n = \Theta(m)$.

We assume that G is embedded in a sphere Σ and apply the necessary modifications explained in the beginning of Section 2.1 to fit into the framework of Voronoi diagrams. Denote $S = \text{supp}(\omega)$. We compute the Voronoi partition Cell_S induced by S and the Voronoi diagram Vor_S induced by S . By Proposition 6, Vor_S has $\mathcal{O}(|S|)$ vertices, faces, and edges.

Distance levels. We first compute an $\mathcal{O}(1)$ -approximate solution $\tilde{D} \subseteq F$ using the algorithm given by Feldman and Langberg [11, Theorem 15.1]; this algorithm outputs an $\mathcal{O}(1)$ -approximate solution with constant probability. Let us scale all the edge lengths in G by the same ratio so that

$$\text{conn}(\tilde{D}, \omega) = |S|/\varepsilon. \tag{1}$$

Next, we assign length $+\infty$ to every edge of length larger than $\text{conn}(\tilde{D}, \omega)$; clearly, they are not used in the computation of the connection cost of an optimum solution. Without loss of

generality we assume that all the distances between vertices in G are finite: otherwise we can split the instance into a number of independent ones, compute a suitable set F_0 for each of them and take the union.

The next step is to assign levels to distances in the graph. For any $c \in [0, +\infty)$, define the *level* of c , denoted $\text{level}(c)$, to be the smallest nonnegative integer ℓ such that $c < (1 + \varepsilon)^\ell$. Note that $\text{level}(c) = 0$ if and only if $c < 1$. Let $L = 1 + \text{level}(m \cdot \text{conn}(\tilde{D}, \omega))$, then we have

$$\text{level}(\text{dist}(u, v)) \in \{0, 1, \dots, L - 1\} \quad \text{for all } u, v \in V(G).$$

Observe that since $m = \Theta(n)$, by (1) we have

$$L \leq \mathcal{O}(\varepsilon^{-1} \log(m|S|/\varepsilon)) \leq \mathcal{O}(\varepsilon^{-2} \log n). \quad (2)$$

Portals and profiles. Let $\tau = (p, u, f)$ be an incidence in Vor_S . Let $d(\tau) = \text{dist}(p, u)$ and let $\ell(\tau) = \text{level}(d(\tau))$; note that $\text{Spoke}(\tau)$ has length exactly $d(\tau)$. For every integer $\iota \in \{1, \dots, \ell(\tau)\}$, we define the *portal* $\mathbf{p}\langle\tau, \iota\rangle$ as a vertex on $\text{Spoke}(\tau)$ at distance exactly $(1 + \varepsilon)^{\iota-1}$ from p ; we subdivide an edge and create a new vertex to accommodate $\mathbf{p}\langle\tau, \iota\rangle$ if necessary. Furthermore, we add also a portal $\mathbf{p}\langle\tau, 0\rangle = p$. Since $\ell(\tau) = \text{level}(d(\tau)) < L$, there are at most L portals on the spoke $\text{Spoke}(\tau)$.

Consider a diamond $\text{Diam}(e)$ induced by some edge e of Vor_S , and a vertex w in $\text{Diam}(e)$. Recall that the perimeter of $\text{Diam}(e)$ consists of spokes $\text{Spoke}(\tau_{i,j})$ for four incidence $\tau_{i,j}$, where $i, j \in \{1, 2\}$. The *profile* of a vertex w belonging to the diamond $\text{Diam}(e)$ consists of the following information, for all $\tau \in \{\tau_{i,j} : i, j \in \{1, 2\}\}$:

1. The minimum index $\lambda \in \{0, 1, \dots, \ell(\tau)\}$ satisfying

$$\text{dist}(\mathbf{p}\langle\tau, \lambda\rangle, p) > \varepsilon \cdot \text{dist}(\mathbf{p}\langle\tau, \lambda\rangle, w),$$

where $p = \mathbf{p}\langle\tau, 0\rangle$ is the vertex of S involved in τ . If no such index exists, we set $\lambda = \ell(\tau)$.

2. Letting

$$I = (\{0\} \cup \{\iota : |\iota - \lambda| \leq 1/\varepsilon^3\}) \cap \{0, 1, \dots, \ell(\tau)\},$$

the profile records the value of $\text{level}(\text{dist}(w, \mathbf{p}\langle\tau, \iota\rangle))$ for all $\iota \in I$.

Whenever speaking about a vertex w and incidence τ , we use $\lambda(\tau, w)$ and $I(\tau, w)$ to denote λ and I as above. We note that in total there are only few possible profiles.

▷ **Claim 10.** The number of possible different profiles of vertices in $\text{Diam}(e)$ is $L^{\mathcal{O}(\varepsilon^{-3})}$.

Proof. Since $0 \leq \ell(\tau) < L$ for every incidence τ , there are at most L^4 choices for the four values $\lambda(\tau_{i,j}, w)$ for $i, j \in \{1, 2\}$. Further, we have $|I(\tau_{i,j}, w)| \leq \mathcal{O}(\varepsilon^{-3})$, so there are at most $L^{\mathcal{O}(\varepsilon^{-3})}$ choices for the values $\text{level}(\text{dist}(w, \mathbf{p}\langle\tau_{i,j}, \iota\rangle))$ for $i, j \in \{1, 2\}$ and $\iota \in I(\tau_{i,j}, w)$. ◁

For future reference, we state the key property of profiles: having the same profile implies having approximately same distances to the profiles with indices in I .

▷ **Claim 11.** Suppose w and w' are two vertices of $\text{Diam}(e)$ that have the same profile. Then for each $\tau \in \{\tau_{i,j} : i, j \in \{1, 2\}\}$ and $\iota \in I(\tau, w)$, we have

$$\text{dist}(w', \mathbf{p}\langle\tau, \iota\rangle) \leq (1 + \varepsilon) \cdot \text{dist}(w, \mathbf{p}\langle\tau, \iota\rangle) + 1.$$

Proof. Let $\ell = \text{level}(\text{dist}(w, \mathbf{p}\langle\tau, \iota\rangle)) = \text{level}(\text{dist}(w', \mathbf{p}\langle\tau, \iota\rangle))$, as recorded in the common profile. If $\ell = 0$, then $\text{dist}(w', \mathbf{p}\langle\tau, \iota\rangle) < 1$ and we are done. Otherwise, $\text{dist}(w, \mathbf{p}\langle\tau, \iota\rangle)$ and $\text{dist}(w', \mathbf{p}\langle\tau, \iota\rangle)$ are both contained in the interval $[(1 + \varepsilon)^{\ell-1}, (1 + \varepsilon)^\ell]$. This interval has length $\varepsilon \cdot (1 + \varepsilon)^{\ell-1} \leq \varepsilon \cdot \text{dist}(w, \mathbf{p}\langle\tau, \iota\rangle)$, hence the claim follows. ◁

33:10 Efficient Approximation Schemes for Planar Clustering

Construction of the set F_0 . We now construct the set F_0 as follows: for every diamond $\text{Diam}(e)$ and every possible profile in $\text{Diam}(e)$, include in F_0 one facility with that profile (if one exists). Since there are $\mathcal{O}(|S|)$ diamonds, by Claim 10 and (10) we have

$$|F_0| \leq \mathcal{O}(|S|) \cdot L^{\mathcal{O}(\varepsilon^{-3})} = |\text{supp}(\omega)| \cdot (\varepsilon^{-1} \log n)^{\mathcal{O}(\varepsilon^{-3})},$$

as claimed. It remains to prove that F_0 has the claimed approximation properties.

For every facility $w \in F$, pick a diamond $\text{Diam}(e)$ containing w and let $f(w)$ to be the facility $f(w) \in F_0 \cap \text{Diam}(e)$ that has the same profile as w . Fix a solution $D^* \subseteq F$ with $|D^*| \leq k$ minimizing $\text{conn}(D^*, \omega)$. Let $D_0 = \{f(w) : w \in D^*\}$. Clearly, $|D_0| \leq |D^*| \leq k$. To finish the proof of Lemma 9 it suffices to show that

$$\text{conn}(D_0, \omega) \leq (1 + \mathcal{O}(\varepsilon))\text{conn}(D^*, \omega). \quad (3)$$

To this end, consider any client $v \in S = \text{supp}(\omega)$ and let $w \in D^*$ be the facility in D^* serving v , that is, $\text{dist}(v, w) = \text{dist}(v, D^*)$. To show (3), it suffices to prove that

$$\text{dist}(v, f(w)) \leq (1 + \mathcal{O}(\varepsilon))\text{dist}(v, w) + \mathcal{O}(1). \quad (4)$$

Indeed, by summing (4) through all $v \in S$ and using (1) we obtain

$$\begin{aligned} \text{conn}(D_0, \omega) &\leq (1 + \mathcal{O}(\varepsilon))\text{conn}(D^*, \omega) + \mathcal{O}(1) \cdot |S| \\ &\leq (1 + \mathcal{O}(\varepsilon))\text{conn}(D^*, \omega) + \mathcal{O}(\varepsilon) \cdot \text{conn}(\tilde{D}, \omega) \leq (1 + \mathcal{O}(\varepsilon))\text{conn}(D^*, \omega), \end{aligned}$$

where the last inequality is due to \tilde{D} being an $\mathcal{O}(1)$ -approximate solution.

Hence, from now on we focus on proving (4). Let $\text{Diam}(e)$ be the diamond containing w and $f(w)$. Consider the shortest path P from w to v in G . By Lemma 7, the path P intersects the perimeter of the diamond $\text{Diam}(e)$. Let u be the vertex on the perimeter of $\text{Diam}(e)$ that lies on P and, among such, is closest to w on P . Since P is a shortest path, the length of the subpaths of P between v and u and between u and w equal $\text{dist}(v, u)$ and $\text{dist}(u, w)$, respectively, and in particular $\text{dist}(v, w) = \text{dist}(v, u) + \text{dist}(u, w)$.

We now observe that to prove (4), it suffices show the following.

$$\text{dist}(u, f(w)) \leq \text{dist}(u, w) + \mathcal{O}(\varepsilon)\text{dist}(v, w) + \mathcal{O}(1). \quad (5)$$

Indeed, assuming (5) we have

$$\begin{aligned} \text{dist}(v, f(w)) &\leq \text{dist}(v, u) + \text{dist}(u, f(w)) \\ &\leq \text{dist}(v, u) + \text{dist}(u, w) + \mathcal{O}(\varepsilon)\text{dist}(v, w) + \mathcal{O}(1) \\ &= \text{dist}(v, w) + \mathcal{O}(\varepsilon)\text{dist}(v, w) + \mathcal{O}(1). \end{aligned}$$

Hence, from now on we focus on proving (5).

Let $\tau_{i,j}$ for $i, j \in \{1, 2\}$, be the four incidences involved in the diamond $\text{Diam}(e)$. Since u lies on the perimeter of $\text{Diam}(e)$, actually u lies on $\text{Spoke}(\tau)$, where $\tau = \tau_{i,j}$ for some $i, j \in \{1, 2\}$. Let $p = \mathbf{p}\langle \tau, 0 \rangle$ be the vertex of S involved in the incidence τ . Since $u \in \text{Cell}_S(p)$ while $v \in S$, we have that $\text{dist}(u, p) \leq \text{dist}(u, v)$. Consequently, we have $\text{dist}(u, w) \leq \text{dist}(v, w)$ and $\text{dist}(u, p) \leq \text{dist}(v, w)$, so to prove (5) it suffices to prove the following:

$$\text{dist}(u, f(w)) \leq \text{dist}(u, w) + \mathcal{O}(\varepsilon)(\text{dist}(u, w) + \text{dist}(u, p)) + \mathcal{O}(1). \quad (6)$$

Let $\mathbf{p}_u = \mathbf{p}\langle \tau, \iota \rangle$ be the portal on the subpath of $\text{Spoke}(\tau)$ between u and p that is closest to u . Intuitively, \mathbf{p}_u is a good approximation of u and distances from \mathbf{p}_u are almost the same as distances from u . As this idea will be repeatedly used in this sequel, we encapsulate it in a single claim.

▷ Claim 12. Suppose for some vertices x and y we have

$$\text{dist}(\mathbf{p}_u, x) \leq A \cdot \text{dist}(\mathbf{p}_u, y) + B,$$

for some A, B . Then

$$\text{dist}(u, x) \leq A \cdot \text{dist}(u, y) + B + (A + 1)\varepsilon \cdot \text{dist}(u, p) + (A + 1).$$

Proof. By the choice of \mathbf{p}_u we have

$$\text{dist}(\mathbf{p}_u, p) \leq \text{dist}(u, p) \leq (1 + \varepsilon)\text{dist}(\mathbf{p}_u, p) + 1,$$

so $\text{dist}(u, \mathbf{p}_u) \leq \varepsilon \cdot \text{dist}(u, p) + 1$. Therefore, we have

$$\begin{aligned} \text{dist}(u, x) &\leq \text{dist}(\mathbf{p}_u, x) + \text{dist}(\mathbf{p}_u, u) \leq A \cdot \text{dist}(\mathbf{p}_u, y) + B + \text{dist}(\mathbf{p}_u, u) \\ &\leq A \cdot (\text{dist}(u, y) + \text{dist}(\mathbf{p}_u, u)) + B + \text{dist}(\mathbf{p}_u, u) \\ &= A \cdot \text{dist}(u, y) + B + (A + 1) \cdot \text{dist}(\mathbf{p}_u, u) \\ &\leq A \cdot \text{dist}(u, y) + B + (A + 1) \cdot \varepsilon \cdot \text{dist}(u, p) + (A + 1), \end{aligned}$$

as claimed. ◁

Since w and $f(w)$ have the same profile, we may denote $\lambda = \lambda(\tau, w) = \lambda(\tau, f(w))$ and $I = I(\tau, w) = I(\tau, f(w))$. Further, let $\mathbf{p}_\lambda = \mathbf{p}(\tau, \lambda)$. We now consider a number of cases depending on the relative values of ι and λ , with the goal on proving that (6) holds in each case. See Figure 2 for an illustration.

■ **Figure 2** The diamond $\text{Diam}(e)$ with vertices v, u, w, p , and $f(w)$. Red vertices are clients, black squares are portals. The case distinction in the proof corresponds to relative order of \mathbf{p}_λ and \mathbf{p}_ι .

Middle case: $\iota \in I$. As profiles of w and $f(w)$ are the same and $\iota \in I$, by Claim 11 we have

$$\text{dist}(\mathbf{p}_u, f(w)) \leq (1 + \varepsilon)\text{dist}(\mathbf{p}_u, w) + 1.$$

It suffices now to apply Claim 12 to infer inequality (6).

Close case: $\iota < \lambda - 1/\varepsilon^3$. Since $\iota < \lambda - 1/\varepsilon^3$, by the choice of λ we have

$$\text{dist}(\mathbf{p}_u, p) \leq \varepsilon \cdot \text{dist}(\mathbf{p}_u, w).$$

By applying Claim 12, we infer that

$$\text{dist}(u, p) \leq \varepsilon \cdot \text{dist}(u, w) + (1 + \varepsilon)\varepsilon \cdot \text{dist}(u, p) + \mathcal{O}(1) \leq \varepsilon \cdot \text{dist}(u, w) + \text{dist}(u, p)/2 + \mathcal{O}(1),$$

33:12 Efficient Approximation Schemes for Planar Clustering

which entails

$$\text{dist}(u, p) \leq 2\varepsilon \cdot \text{dist}(u, w) + \mathcal{O}(1).$$

Since $0 \in I$ and the profiles of w and $f(w)$ are equal, by Claim 11 we have

$$\text{dist}(p, f(w)) \leq (1 + \varepsilon) \cdot \text{dist}(p, w) + 1.$$

By combining the last two inequalities, we conclude that

$$\begin{aligned} \text{dist}(u, f(w)) &\leq \text{dist}(u, p) + \text{dist}(p, f(w)) \\ &\leq \text{dist}(u, p) + (1 + \varepsilon)\text{dist}(p, w) + 1 \\ &\leq \text{dist}(u, p) + (1 + \varepsilon)(\text{dist}(u, p) + \text{dist}(u, w)) + 1 \\ &= (2 + \varepsilon)\text{dist}(u, p) + (1 + \varepsilon)\text{dist}(u, w) + 1 \\ &\leq (1 + \mathcal{O}(\varepsilon))\text{dist}(u, w) + \mathcal{O}(1). \end{aligned}$$

Thus, inequality (6) holds in this case.

Far case: $\iota > \lambda + 1/\varepsilon^3$. By the definition of λ and since $\iota > \lambda + 1/\varepsilon^3$, we have in particular $\lambda < \ell(\tau)$ and hence

$$\varepsilon \cdot \text{dist}(\mathbf{p}_\lambda, w) < \text{dist}(\mathbf{p}_\lambda, p).$$

On the other hand, we have

$$\text{dist}(p, \mathbf{p}_\lambda) = (1 + \varepsilon)^{\lambda - \iota} \text{dist}(p, \mathbf{p}_u) \leq (1 + \varepsilon)^{-1/\varepsilon^3} \text{dist}(p, \mathbf{p}_u) \leq \varepsilon^2 \cdot \text{dist}(p, \mathbf{p}_u),$$

where the last step follows from Bernoulli's inequality. By combining the above two inequalities we obtain

$$\text{dist}(\mathbf{p}_\lambda, w) \leq \varepsilon \cdot \text{dist}(p, \mathbf{p}_u),$$

implying

$$\text{dist}(p, w) \leq \text{dist}(p, \mathbf{p}_\lambda) + \text{dist}(\mathbf{p}_\lambda, w) \leq (\varepsilon + \varepsilon^2) \cdot \text{dist}(p, \mathbf{p}_u) \leq 2\varepsilon \cdot \text{dist}(p, \mathbf{p}_u) \leq 2\varepsilon \cdot \text{dist}(p, u).$$

As before, by Claim 11 we have $\text{dist}(p, f(w)) \leq (1 + \varepsilon)\text{dist}(p, w) + 1$ due to $0 \in I$, hence

$$\begin{aligned} \text{dist}(u, f(w)) &\leq \text{dist}(u, p) + \text{dist}(p, f(w)) \\ &\leq (\text{dist}(u, w) + \text{dist}(p, w)) + (1 + \varepsilon)\text{dist}(p, w) + 1 \\ &\leq \text{dist}(u, w) + (2 + \varepsilon) \cdot (2\varepsilon) \cdot \text{dist}(u, p) + 1 \\ &\leq \text{dist}(u, w) + \mathcal{O}(\varepsilon)\text{dist}(u, p) + \mathcal{O}(1). \end{aligned}$$

We conclude that inequality (6) holds in this case.

As the case investigation presented above covers all the possibilities, the proof of Lemma 9 is complete, so we have also proved Theorem 1.

Abstract

Treedepth, a more restrictive graph width parameter than treewidth and pathwidth, plays a major role in the theory of sparse graph classes. We show that there exists a constant C such that for every integers $a, b \geq 2$ and a graph G , if the treedepth of G is at least $Cab \log a$, then the treewidth of G is at least a or G contains a subcubic (i.e., of maximum degree at most 3) tree of treedepth at least b as a subgraph.

As a direct corollary, we obtain that every graph of treedepth $\Omega(k^3 \log k)$ is either of treewidth at least k , contains a subdivision of full binary tree of depth k , or contains a path of length 2^k . This improves the bound of $\Omega(k^5 \log^2 k)$ of Kawarabayashi and Rossman [SODA 2018].

We also show an application for approximation algorithms of treedepth: given a graph G of treedepth k and treewidth t , one can in polynomial time compute a treedepth decomposition of G of width $\mathcal{O}(kt \log^{3/2} t)$. This improves upon a bound of $\mathcal{O}(kt^2 \log t)$ stemming from a tradeoff between known results.

The main technical ingredient in our result is a proof that every tree of treedepth d contains a subcubic subtree of treedepth at least $d \cdot \log_3((1 + \sqrt{5})/2)$.

1 Introduction

For an undirected graph G , the *treedepth* of G is the minimum height of a rooted forest whose ancestor-descendant closure contains G as a subgraph. Together with more widely known related width notions such as treewidth and pathwidth, it plays a major role in structural graph theory, in particular in the study of general sparse graph classes [8, 7, 6].

An important property of treedepth is that it admits a number of equivalent definitions. Following the definition of treedepth above, a *treedepth decomposition* of a graph G consists of a rooted forest F and an injective mapping $f : V(G) \rightarrow V(F)$ such that for every $uv \in E(G)$ the vertices $f(u)$ and $f(v)$ are in ancestor-descendant relation in F . The *width* of a treedepth decomposition (F, f) is the height of F (the number of vertices on the longest leaf-to-root path in F) and the treedepth of G is the minimum possible height of a treedepth decomposition

of G . A *centered coloring* of a graph G is an assignment $\alpha : V(G) \rightarrow \mathbb{Z}$ such that for every connected subgraph H of G , α has a *center* in H : a vertex $v \in V(H)$ of unique color, i.e., $\alpha(v) \neq \alpha(w)$ for every $w \in V(H) \setminus \{v\}$. A *vertex ranking* of a graph G is an assignment $\alpha : V(G) \rightarrow \mathbb{Z}$ such that in every connected subgraph H of G there is a unique vertex of *maximum* rank (value $\alpha(v)$). Clearly, each vertex ranking is a centered coloring. It turns out that the minimum number of colors (minimum size of the image of α) needed for a centered coloring and for a vertex ranking are equal and equal to the treedepth of a graph [6].

While there are multiple examples of algorithmic usage of treedepth in the theory of sparse graphs [7, 8], our understanding of the complexity of computing minimum width treedepth decompositions is limited. For a graph G , let $\text{td}(G)$ and $\text{tw}(G)$ denote the treedepth and the treewidth of G , respectively. An algorithm of Reidl, Rossmanith, Villaamil, and Sikdar [9] computes exactly the treedepth of an input graph G in time $2^{\mathcal{O}(\text{td}(G) \cdot t)} n^{\mathcal{O}(1)}$, given a tree decomposition of G of width t . Combined with the classic constant-factor approximation algorithm for treewidth that runs in $2^{\mathcal{O}(\text{tw}(G))} n^{\mathcal{O}(1)}$ time [10], one obtains an exact algorithm for treedepth running in time $2^{\mathcal{O}(\text{td}(G)\text{tw}(G))} n^{\mathcal{O}(1)}$. No faster exact algorithm is known.

For approximation algorithms, the following folklore lemma (presented with full proof in [4]) is very useful.

► **Lemma 1.** *Given a graph G and a tree decomposition (T, β) of G of maximum bag size w , one can in polynomial time compute a treedepth decomposition of G of width at most $w \cdot \text{td}(T)$.*

Using Lemma 1, one can obtain an approximation algorithm for treedepth with a cheap tradeoff trick.¹

► **Lemma 2.** *Given a graph G , one can in polynomial time compute a treedepth decomposition of G of width $\mathcal{O}(\text{td}(G) \cdot \text{tw}(G)^2 \log \text{tw}(G))$.*

Proof. Let $n = |V(G)|$. Using the polynomial-time approximation algorithm for treewidth [3], compute a tree decomposition (T, β) of G of width $t = \mathcal{O}(\text{tw}(G) \sqrt{\log \text{tw}(G)})$ and $\mathcal{O}(n)$ bags. For every integer $1 \leq k \leq (\log n)/t$, use the algorithm of [9] to check in polynomial time if the treedepth of G is at most k . Note that if this is the case, the algorithm finds an optimal treedepth decomposition and we can conclude. Otherwise, we have $\log n \leq \text{td}(G) \cdot t$ and we apply Lemma 1 to G and (T, β) obtaining a treedepth decomposition of G of width

$$\mathcal{O}(t \log n) \leq \mathcal{O}(\text{td}(G) \cdot t^2) \leq \mathcal{O}(\text{td}(G) \cdot \text{tw}(G)^2 \log \text{tw}(G)). \quad \blacktriangleleft$$

Lemma 2 is the only polynomial approximation algorithm for treedepth running in polynomial time we are aware of.

A related topic to exact and approximation algorithms computing minimum-width treedepth decomposition is the study of obstructions to small treedepth. Dvořák, Giannopoulou, and Thilikos [2] proved that every minimal graph of treedepth k has the number of vertices at most double-exponential in k . More recently, Kawarabayashi and Rossman showed an excluded-minor theorem for treedepth.

► **Theorem 3** ([4]). *There exists a universal constant C such that for every integer k every graph of treedepth at least $Ck^5 \log^2 k$ is either of treewidth at least k , contains a subdivision of a full binary tree of depth k as a subgraph, or contains a path of length 2^k .*

¹ This trick has been observed and communicated to us by Michał Pilipczuk. We thank Michał for allowing us to include it in this paper.

While neither the results of [2] nor [4] have a direct application in the approximability of treedepth, these topics are tightly linked with each other and we expect that a finer understanding of treedepth obstructions is necessary to provide more efficient algorithms computing or approximating the treedepth of a graph.

Our results

Our main result is the following statement, improving upon the work of Kawarabayashi and Rossman [4].

► **Theorem 4.** *Let G be a graph of treewidth $\text{tw}(G)$ and treedepth $\text{td}(G)$. Then there exists a subcubic tree H that is a subgraph of G and is of treedepth $\Omega(\text{td}(G)/(\text{tw}(G) \log \text{tw}(G)))$.*

In other words, Theorem 4 states that there exists a constant C such that for every graph G and integers $a, b \geq 2$, if the treedepth of G is at least $Cab \log a$, then the treewidth of G is at least a or G contains a subcubic tree of treedepth b . Since every subcubic tree of treedepth d contains either a simple path of length $2^{\Omega(\sqrt{d})}$ or a subdivision of a full binary tree of depth $\Omega(\sqrt{d})$ [4], we have the following corollary.

► **Corollary 5.** *Let G be a graph of treewidth $\text{tw}(G)$ and treedepth $\text{td}(G)$. Then for some*

$$h = \Omega\left(\sqrt{\text{td}(G)/(\text{tw}(G) \log \text{tw}(G))}\right)$$

G contains either a simple path of length 2^h or a subdivision of a full binary tree of depth h .

Consequently, there exists an absolute constant C such that for every integer $k \geq 1$ and a graph G of treedepth at least $Ck^3 \log k$, either

- *G has treewidth at least k ,*
- *G contains a subdivision of a full binary tree of depth k as a subgraph, or*
- *G contains a path of length 2^k .*

In other words, Corollary 5 improves the bound $k^5 \log^2 k$ of Kawarabayashi and Rossman [4] to $k^3 \log k$. We remark here that there are subcubic trees of treedepth $\Omega(h^2)$ that contains neither a path of length 2^h nor a subdivision of a full binary tree of depth h ,² and thus the quadratic loss between the statements of Theorem 4 and Corollary 5 is necessary.

Inside the proof of Theorem 4 we make use of the following lemma that may be of independent interest. This lemma is the main technical improvement upon the work of Kawarabayashi and Rossman [4].

► **Lemma 6.** *Every tree of treedepth d contains a subcubic subtree of treedepth at least $\frac{\log((1+\sqrt{5})/2)}{\log(3)}d$.*

Furthermore, such a subtree can be found in polynomial time.

The techniques developed to prove Theorem 4 have some implications on the approximability of treedepth. We improve upon Lemma 2 as follows.

► **Theorem 7.** *Given a graph G , one can in polynomial time compute a treedepth decomposition of G of width $\mathcal{O}(\text{td}(G) \cdot \text{tw}(G) \log^{3/2} \text{tw}(G))$.*

² It is straightforward to deduce such an example from the proof of [4]. We provide such an example in Section 6.

34:4 Improved Bounds for the Excluded-Minor Approximation of Treedepth

The result of Kawarabayashi and Rossman [4] has been also an important ingredient in the study of *linear colorings* [5]. A coloring $\alpha : V(G) \rightarrow \mathbb{Z}$ of a graph G is a *linear coloring* if for every (not necessarily induced) path P in G there exists a vertex $v \in V(P)$ of unique color $\alpha(v)$ on P . Clearly, each centered coloring is a linear coloring, but the minimum number of colors needed for a linear coloring can be much smaller than the treedepth of a graph. Kun et al. [5] provided a polynomial relation between the treedepth and the minimum number of colors in a linear coloring; by replacing their usage of [4] by our result (and using an improved bound for the excluded grid theorem [1]) we obtain an improved bound.

► **Theorem 8.** *There exists a polynomial p such that for every integer k and graph G , if the treedepth of G is at least $k^{19}p(\log k)$, then every linear coloring of G requires at least k colors.*

The previous bound of [5] is $k^{190}p(\log k)$.

After proving Lemma 6 in Section 2, we prove Theorem 4 in Section 3. Theorem 7 is proven in Section 3 while Theorem 8 is proven in Section 5. The symbol \log_p stands for base- p logarithm and \log stands for \log_2 . We denote $\varphi = \frac{1+\sqrt{5}}{2}$; note that φ is chosen in a way so that $\varphi^2 = \varphi + 1$ and $\varphi > 1$.

2 Subcubic subtrees of trees of large treedepth

This section focuses on proving Lemma 6.

Schäffer [11] proved that there is a linear time algorithm for finding a vertex ranking with minimum number of colors of a tree T . We follow [5] for a good description of its properties.

In original Schäffer's algorithm ranks are starting from 1, however for the ease of exposition let us assume that ranks are starting from 0. That is, the algorithm constructs a vertex ranking $\alpha : V(T) \rightarrow \{0, 1, 2, \dots\}$ trying to minimize the maximum value attained by α . Assume that T is rooted in an arbitrary vertex and for every $v \in V(T)$ let T_v be the subtree rooted at v .

Of central importance to Schäffer's algorithm are what we will refer to as *rank lists*. For a rooted tree T , the rank list $L(T)$ for vertex ranking α consists of these ranks i for which there exists a path P starting from the root and ending in a vertex v with $\alpha(v) = i$ such that for every $u \in V(P) \setminus \{v\}$ we have $\alpha(u) < \alpha(v)$, that is, v is the unique vertex of maximum rank on P . More formally:

► **Definition 9.** *For a vertex ranking α of tree T , the rank list of T , denoted $L(T)$, can be defined recursively as $L(T) = L(T \setminus T_v) \cup \{\alpha(v)\}$ where v is the vertex of maximum rank in T .*

Schäffer's algorithm arbitrarily roots T and builds the ranking from the leaves to the root of T , computing the rank of each vertex from the rank lists of each of its children. For brevity, we denote $L(v) = L(T_v)$ for every v in T .

► **Proposition 10.** *Let α be a vertex ranking of T produced by Schäffer's algorithm and let $v \in T$ be a vertex with children u_1, \dots, u_l . If x is the largest integer appearing on rank lists of at least two children of v (or -1 if all such rank lists are pairwise disjoint) then $\alpha(v)$ is the smallest integer satisfying $\alpha(v) > x$ and $\alpha(v) \notin \bigcup_{i=1}^l L(u_i)$.*

For a node $v \in V(T)$, and vertex ranking α , the following potential is pivotal to the analysis of Schäffer's algorithm. Let $l_0 > l_1 > \dots > l_{|L(v)|-1}$ be the elements of $L(v)$ sorted in decreasing order.

$$\zeta(v) = \sum_{r \in L(v)} 3^r = \sum_{i=0}^{|L(v)|-1} 3^{l_i}.$$

When we write $\zeta(T)$ for some tree T we refer to $\zeta(s)$ where s is a root of T . For our purposes, we will also use a skewed version of potential function with a different base

$$\sigma(v) = \sum_{i=0}^{|L(v)|-1} \varphi^{l_i-i},$$

where again $l_0 > l_1 > \dots > l_{|L(v)|-1}$ are elements of $L(v)$ sorted in decreasing order. Throughout this section, when focusing on one node $v \in V(T)$, we use notation that l_i is i -th element of set $L(v)$ when sorted in decreasing order and when 0-based indexed.

Let us start with proving following two bounds that estimate $\text{td}(T)$ in terms of $\zeta(T)$ and $\sigma(T)$.

▷ **Claim 11.** $\log_{\varphi}(\sigma(T)) \geq \text{td}(T) - 1$.

Proof. We know that $L(T)$ is nonempty and its biggest element is equal to $\text{td}(T) - 1$ (we need to subtract one because we use nonnegative numbers as ranks, not positive). Therefore we have

$$\sigma(T) = \sum_{i=0}^{|L(T)|-1} \varphi^{l_i-i} \geq \varphi^{l_0} = \varphi^{\text{td}(T)-1}.$$

Hence, $\log_{\varphi}(\sigma(T)) \geq \text{td}(T) - 1$, as desired. ◁

▷ **Claim 12.** $\log_3(\zeta(T)) + \log_3(2) < \text{td}(T)$.

Proof. We have that

$$\begin{aligned} \zeta(T) &= \sum_{r \in L(v)} 3^r \leq \sum_{r=0}^{\text{td}(T)-1} 3^r = \frac{3^{\text{td}(T)} - 1}{2}, \\ 2\zeta(T) &\leq 3^{\text{td}(T)} - 1 < 3^{\text{td}(T)} \end{aligned}$$

$\log_3(2) + \log_3(\zeta(T)) < \text{td}(T)$. ◁

We are ready to prove Lemma 6. Given tree T we want to produce a subcubic (i.e., maximum degree at most 3) tree S which is a subtree of T and that fulfills $\text{td}(S) > \text{td}(T) \log_3(\varphi)$.

Let us start our algorithm by arbitrary rooting T and computing rank lists using Schäffer's algorithm. Then for every vertex $v \in T$ we define $C(v)$ as a set of two children of v that have the biggest value of ζ in case v has at least two children, or all children otherwise. Let us now define forest F whose vertex set is the same as vertex set of T where for every v we put edges between v and all elements of $C(v)$. Clearly this is a forest consisting of subcubic trees which are subtrees of T (where *subtree* is understood as subgraph, not necessarily as some vertex t along with all its descendants in a rooted tree). Let S be a tree of this forest containing root of T . We claim that S is that subcubic subtree of T we are looking for. Note that computing F and thus S can be trivially done in polynomial time. Hence, we are left with proving that $\text{td}(S) > \text{td}(T) \log_3(\varphi)$.

34:6 Improved Bounds for the Excluded-Minor Approximation of Treedepth

Let us root every tree of F in a vertex that was closest to root of T in T . Then compute rank lists for these trees using Schäffer's algorithm. So now, for every vertex we have two rank lists, one for T and one for F . Let us now denote these second ranklists as $\tilde{L}(v)$ for $v \in V(T)$ and let us define function $\tilde{\zeta}$ which will be similar potential function as ζ , but operating on rank lists $\tilde{L}(v)$ instead of $L(v)$. Following claim will be crucial.

▷ **Claim 13.** For every $v \in V(T)$ it holds that $\tilde{\zeta}(v) \geq \sigma(v)$.

We first verify that Claim 13 implies Lemma 6.

Proof of Lemma 6. Using also Claims 12 and 11 we infer that

$$\begin{aligned}
 \text{td}(S) &> \log_3(\tilde{\zeta}(S)) + \log_3(2) && \text{by Claim 12 for } S \\
 &\geq \log_3(\sigma(T)) + \log_3(2) && \text{by Claim 13} \\
 &= \log_\varphi(\sigma(T)) \cdot \log_3(\varphi) + \log_3(2) && \text{logarithm base change} \\
 &\geq (\text{td}(T) - 1) \cdot \log_3(\varphi) + \log_3(2) && \text{by Claim 11 for } T \\
 &= \text{td}(T) \cdot \log_3(\varphi) - \log_3(\varphi) + \log_3(2) > \text{td}(T) \cdot \log_3(\varphi). && \blacktriangleleft
 \end{aligned}$$

Thus it remains to prove Claim 13. To this end, we prove two auxiliary inequalities.

▷ **Claim 14.** For every $v \in V(T)$ it holds that $\tilde{\zeta}(v) \geq 1 + \sum_{s \in C(v)} \tilde{\zeta}(s)$

Proof. We express every $\tilde{\zeta}(x)$ for $x \in \{v\} \cup C(v)$ as a sum of powers of 3 and count how many times each power occurs on both sides of this claimed inequality. Consider a summand 3^c . If $c > \alpha(v)$ then, by the choice of $\alpha(v)$, 3^c appears at most once on the right side and if it appears there, then it appears on the left side as well, so contributions of summands of form 3^c for $c > \alpha(v)$ to both sides are equal. The summand $3^{\alpha(v)}$ appears once on the left side and does not appear on the right side. For $c < \alpha(v)$, the summands of form 3^c appear at most twice in $\sum_{s \in C(v)} \tilde{\zeta}(s)$, so their contribution to right side can be bounded from above by $\sum_{c=0}^{\alpha(v)-1} 2 \cdot 3^c = 3^{\alpha(v)} - 1$, so in fact $3^{\alpha(v)}$ from the left side contributes at least as much as remaining summands from the right side. This finishes the proof of the claim. ◀

▷ **Claim 15.** For every $v \in V(T)$ it holds that $\sigma(v) \leq 1 + \sum_{s \in C(v)} \sigma(s)$

Proof. Recall that by the definition $C(v)$ is a set of two children of v in T with the biggest values of ζ or a set of all children of v in case it has less than two of them. Observe that having bigger value of $\zeta(v)$ is another way of expressing having the set $L(v)$ bigger lexicographically when sorted in decreasing order.

If v is a leaf then $C(v)$ is empty and $\sigma(v) = 1$, so the inequality is obvious. Henceforth we focus on a vertex v that is not a leaf. In our proof following equation will come handy:

$$\varphi = \sum_{i=0}^{\infty} \varphi^{-2i}$$

It holds since $\sum_{i=0}^{\infty} \varphi^{-2i} = \frac{1}{1-\varphi^{-2}} = \frac{\varphi^2}{\varphi^2-1} = \frac{\varphi^2}{\varphi} = \varphi$.

Let us now analyze $L(v)$. It consists of some prefix P of values that appeared exactly once in children of v , then $\alpha(v)$ and then nothing (when enumerated from the biggest to the smallest). Let us now denote by A_i intersection of $L(u_i)$ and P , where u_i is i -th child of v when sorted in nonincreasing order by their values $\zeta(u_i)$ (1-based). We distinguish two cases:

Case 1: A_2 is nonempty. If A_2 is nonempty then in particular it means that v has at least two children. Let us denote the biggest element of $L(u_2)$ by d . We have that $d \in P$, but d is not the biggest element of P . Its contribution to $\sigma(u_2)$ is φ^d , however its contribution to $\sigma(v)$ is at most φ^{d-1} (because of the skew and since d is not the biggest element of P). Contribution to $\sigma(v)$ of elements smaller than d can be bounded from above by $\varphi^{d-3} + \varphi^{d-5} + \dots$. We know that $d = l_j$ for some j , where $j \geq 1$ and $L(v)$ consists of elements $l_0 > l_1 > \dots > l_{|L(v)-1|}$. We have that $l_k \in L(u_1)$ for $k < j$ and that $l_j \geq l_i + (i - j)$ for $i \geq j$, so $l_i - i \leq l_j - j - 2(i - j) = d - j - 2(i - j)$. We can deduce that

$$\begin{aligned} \sigma(v) &= \sum_{i=0}^{|L(v)|-1} \varphi^{l_i-i} = \sum_{i=0}^{j-1} \varphi^{l_i-i} + \sum_{i=j}^{|L(v)|-1} \varphi^{l_i-i} \leq \sigma(u_1) + \sum_{i=j}^{|L(v)|-1} \varphi^{d-j-2(i-j)} \\ &\leq \sigma(u_1) + \varphi^{d-j} \sum_{i=j}^{\infty} \varphi^{-2(i-j)} = \sigma(u_1) + \varphi^{d-j} \sum_{i=0}^{\infty} \varphi^{-2i} = \sigma(u_1) + \varphi^{d-j+1} \\ &\leq \sigma(u_1) + \varphi^d \leq \sigma(u_1) + \sigma(u_2) < 1 + \sigma(u_1) + \sigma(u_2), \end{aligned}$$

which is what we wanted to prove.

Case 2: A_2 is empty. Let us now introduce a few variables:

- d - the biggest integer number smaller than $\alpha(v)$ that is not an element of $L(u_1)$. We know that elements from $d + 1$ to $\alpha(v) - 1$ belong to $L(u_1)$.
- k - shorthand for number of these elements (which is equal to $\alpha(v) - 1 - d$). k can be zero, but cannot be negative.
- g - the number of elements of $L(v)$ that are bigger than $\alpha(v)$.

Then from the definition of $\alpha(v)$ either

- $d = -1$; or
- v has at least two children and $L(u_2)$ contains a number that is at least d .

Because of that we have $1 + \sum_{s \in C(v)} \sigma(s) \geq \sigma(u_1) + \varphi^d$. We know that $\sum_{s \in C(v)}$ is either $\sigma(u_1)$ or $\sigma(u_1) + \sigma(u_2)$, depending on whether v has only one child or more. If $d = -1$ then $1 \geq \varphi^d$ and stated inequality holds. If $d \neq -1$ then u_2 exists and $\sigma(u_2) \geq \varphi^d$.

Note that either $k > 0$ or $g > 0$, because if $k = g = 0$ then $d = \alpha(v) - 1$ and $L(u_1)$ cannot contain elements bigger than $\alpha(v)$ (because $g = 0$), cannot contain $\alpha(v)$ (from the definition of $\alpha(v)$) and cannot contain $\alpha(v) - 1$ (since $d = \alpha(v) - 1$), so its biggest element is at most $d - 1$. If $d = -1$ then it means that v is a leaf, but we already assumed it is not one. However, if v has at least two children and $L(u_2)$ contains a number that is at least d , then it contradicts the assumption that $\zeta(u_1) \geq \zeta(u_2)$. So indeed it holds that $k > 0$ or $g > 0$ and therefore $k + g \geq 1$.

We have that

$$\sigma(v) - \sigma(u_1) \leq \varphi^{\alpha(v)-g} - (\varphi^{\alpha(v)-g-1} + \varphi^{\alpha(v)-g-3} + \dots + \varphi^{\alpha(v)-g-2k+1}),$$

which is because summands coming from numbers bigger than $\alpha(v)$ in $L(v)$ and $L(u_1)$ cancel out (A_2 is empty, so all elements of $L(v)$ different than $\alpha(v)$ come from $L(u_1)$) and new rank $\alpha(v)$ contributes $\varphi^{\alpha(v)-g}$ to $\sigma(v)$ whereas $L(u_1)$ contains numbers from $d + 1$ up to $\alpha(v) - 1$ and their contribution to $\sigma(u_1)$ is $\varphi^{\alpha(v)-g-1} + \varphi^{\alpha(v)-g-3} + \dots + \varphi^{\alpha(v)-g-2k+1}$. We conclude that $\sigma(v) - \sigma(u_1) \leq \varphi^{-g}(\varphi^{\alpha(v)} - (\varphi^{\alpha(v)-1} + \varphi^{\alpha(v)-3} + \dots + \varphi^{\alpha(v)-2k+1}))$.

On the other hand since $\varphi^2 = \varphi + 1$ we have that

$$\begin{aligned} \varphi^{\alpha(v)} &= \varphi^{\alpha(v)-1} + \varphi^{\alpha(v)-2} = \varphi^{\alpha(v)-1} + \varphi^{\alpha(v)-3} + \varphi^{\alpha(v)-4} = \dots = \\ &= (\varphi^{\alpha(v)-1} + \varphi^{\alpha(v)-3} + \dots + \varphi^{\alpha(v)-2k+1}) + \varphi^{\alpha(v)-2k}. \end{aligned}$$

34:8 Improved Bounds for the Excluded-Minor Approximation of Treedepth

Because of that we have

$$\sigma(v) - \sigma(u_1) \leq \varphi^{-g} \cdot \varphi^{\alpha(v) - 2k} = \varphi^{\alpha(v) - 2k - g} = \varphi^{\alpha(v) - (\alpha(v) - 1 - d) - k - g} = \varphi^{d+1 - (k+g)} \leq \varphi^d.$$

From that we conclude that $\sigma(v) \leq \sigma(u_1) + \varphi^d \leq 1 + \sum_{s \in C(v)} \sigma(s)$, what concludes proof of this claim. \triangleleft

Now, having claims 15 and 14 proven, we can wrap our reasoning up. If v is a leaf then $\sigma(v) = \tilde{\zeta}(v) = 1$. If v is not a leaf then we know that $\sigma(v) \leq 1 + \sum_{s \in C(v)} \sigma(s)$ and $\tilde{\zeta}(v) \geq 1 + \sum_{s \in C(v)} \tilde{\zeta}(s)$, so by straightforward induction we get that $\sigma(v) \leq \tilde{\zeta}(v)$ for every $v \in V(T)$, as desired by Claim 13.

3 Proof of Theorem 4

Let G be a nonempty graph and let $r = \text{td}(G)/(\text{tw}(G) + 1)$. Recall that our goal is to show existence of a subcubic tree H being a subgraph of G such that $\text{td}(H)$ is $\Omega(r/\log(\text{tw}(G) + 1))$. Without loss of generality we may assume that G is connected, as otherwise we focus on the connected component of G of maximum treedepth. Also, the statement is trivial for $\text{tw}(G) \leq 1$ (when G is a tree) and when $r \leq 2$, so assume otherwise.

We consider a greedy tree decomposition of G , as defined in [4]. A greedy tree decomposition is a tree decomposition that can be also interpreted as a treedepth decomposition.

Recall that a tree decomposition of a graph G is a pair (T, β) where T is a rooted tree and $\beta : V(T) \rightarrow 2^{V(G)}$ is such that for every $v \in V(G)$ the set $\{t \in V(T) \mid v \in \beta(t)\}$ induces a connected nonempty subtree of T and for every $uv \in E(G)$ there exists $t \in V(T)$ with $u, v \in \beta(t)$. A tree decomposition (T, β) of a graph G is *greedy* if

1. $V(T) = V(G)$,
2. for every $uv \in E(G)$, the nodes u and v in T are in ancestor-descendant relation in T , and
3. for every vertex $u \in V(T)$ and its child v there is some descendant w of v in T such that $uw \in E(G)$.

Lemma 3.6. in [4] states that for every connected graph G there exists a greedy tree decomposition (T, β) of width $\text{tw}(G)$, that is, all bags $\beta(t)$ for $t \in V(T)$ have size bounded by $\text{tw}(G) + 1$. Let (T, β) be such a decomposition of our graph G . By Lemma 1 we get that $\text{td}(T) \geq r$, as otherwise we would be able to construct treedepth decomposition of too low treedepth.

In the remainder of the proof we show the following lemma.

► **Lemma 16.** *Let G be a connected graph, (T, β) be a greedy tree decomposition of G , and let $\tau \geq 2$ be such that $|\beta(t)| \leq \tau$ for every $t \in V(T)$. Then G contains a subcubic tree of treedepth $\Omega(\text{td}(T)/\log \tau)$.*

Theorem 4 follows immediately from Lemma 16 applied to the tree decomposition (T, β) of G . Thus, it remains to prove Lemma 16.

To this end, we first apply Lemma 6 to tree T and obtain a subcubic tree S such that

$$\text{td}(S) \geq r \cdot \log_3(\varphi). \tag{1}$$

Second, we apply the core part of the reasoning of Kawarabayashi and Rossman [4]. The construction of Section 5 of [4] can be encapsulated in the following lemma.

► **Lemma 17** (Section 5 of [4]). *Let (T, β) be a greedy tree decomposition of graph G and let $\tau = \max_{t \in V(T)} |\beta(t)|$. Then for every subcubic subtree S of T there exists a subtree F of G such that $V(S) \subseteq V(F)$ and the maximum degree of F is bounded by $\tau + 2$.*

By application of Lemma 17 to our decomposition (T, β) and subtree S we get a tree F in G , which has large treedepth, as we show in a moment. To this end, we need the following simple bound on treedepth of trees.

► **Lemma 18.** *For every tree H with maximum degree bounded by $d \geq 2$ it holds that*

$$\log_d |V(H)| \leq \text{td}(T) \leq 1 + \log_2 |V(H)|.$$

Proof. We use the following equivalent recursive definition of treedepth: Treedepth of an empty graph is 0, treedepth of a disconnected graph equals the maximum of treedepth over its connected components, while for nonempty connected graphs G we have $\text{td}(G) = 1 + \min_{v \in V(G)} \text{td}(G - v)$.

For the lower bound, for $k \geq 1$ let $f_d(k)$ be the maximum possible number of vertices of a tree of maximum degree at most d and treedepth at most k . Clearly, $f_d(1) = 1$. Since removing a single vertex from a tree of maximum degree at most d results in at most d connected components, we have that

$$f_d(k+1) \leq 1 + d \cdot f_d(k).$$

Consequently, we obtain by induction that

$$f_d(k) \leq d^k - 1.$$

This proves the lower bound. For the upper bound, note that in every tree T there exists a vertex $v \in V(T)$ such that every connected component of $T - \{v\}$ has at most $|V(T)|/2$ vertices. Consequently, if we define $g(n)$ to be the maximum possible treedepth of an n -vertex tree, then $g(1) = 1$ and we have that

$$g(n) \leq 1 + g(\lfloor n/2 \rfloor).$$

This proves the upper bound. ◀

By (1) and Lemma 18 we get that $|V(S)| \geq 2^{r \cdot \log_3(\varphi) - 1}$. This implies that also

$$|V(F)| \geq 2^{r \cdot \log_3(\varphi) - 1}. \quad (2)$$

As S is subcubic, by Lemma 17 we know that the maximum degree of F is bounded by $\text{tw}(G) + 3$. Therefore Lemma 18 and (2) jointly imply that

$$\text{td}(F) \geq \log_{(\text{tw}(G)+3)} 2^{r \cdot \log_3(\varphi) - 1} \geq \frac{r \cdot \log_3(\varphi) - 1}{\log(\text{tw}(G) + 3)} \geq \frac{\log_3(\varphi)}{20} \cdot r / \log(\text{tw}(G) + 1). \quad (3)$$

Here, the last inequality follows from the assumptions $r > 2$ and $\text{tw}(G) \geq 2$; note that the constant 20 is sufficiently large constant for the estimations to work.

As tree F is not necessarily subcubic, we apply one more time Lemma 6 and get a subcubic subtree H of F such that

$$\text{td}(H) \geq \text{td}(F) \cdot \log_3(\varphi) \geq \frac{\log_3(\varphi)^2}{20} \cdot r / \log(\text{tw}(G) + 1), \quad (4)$$

which finishes the proof of Lemma 16 and of Theorem 4.

4 Proof of Theorem 7

Proof of Theorem 7. Without loss of generality we can assume that the input graph G is connected. As in the proof of Lemma 2, we apply the polynomial-time approximation algorithm for treewidth [3], to compute a tree decomposition (T_0, β_0) of G with $\mathcal{O}(n)$ nodes of T_0 and $|\beta(t)| \leq \tau$ for every $t \in V(T_0)$ and some $\tau = \mathcal{O}(\text{tw}(G)\sqrt{\log \text{tw}(G)})$. As discussed in [4], one can in polynomial time turn (T_0, β_0) into a greedy tree decomposition (T, β) of G without increasing the maximum size of a bag, that is, still $|\beta(t)| \leq \tau$ for every $t \in V(T)$. We apply Lemma 1 to (T, β) , returning a treedepth decomposition of G of width at most $\tau \cdot \text{td}(T) = \mathcal{O}(\text{td}(T)\text{tw}(G)\sqrt{\log \text{tw}(G)})$.

It remains to bound $\text{td}(T)$. Lemma 16 asserts that G contains a subcubic tree H of treedepth $\Omega(\text{td}(T)/\log \tau)$. Therefore $\text{td}(T) = \mathcal{O}(\text{td}(H) \log \tau) = \mathcal{O}(\text{td}(G) \log \text{tw}(G))$ and thus the width of the computed treedepth decomposition is $\mathcal{O}(\text{td}(G)\text{tw}(G) \log^{3/2} \text{tw}(G))$. This finishes the proof of Theorem 7. \blacktriangleleft

5 Proof of Theorem 8

Here we show how to assemble the proof of Theorem 8 from Theorem 4, a number of intermediate results of [5], and an improved excluded grid theorem due to Chuzhoy and Tan [1]:

► **Theorem 19** ([1]). *There exists a polynomial p_{GMT} such that for every integer k if a graph G has treewidth at least $k^9 p_{\text{GMT}}(\log k)$ then G contains a $k \times k$ grid as a minor.*

The following two results were proven in [5].

► **Lemma 20** ([5]). *If a graph G contains a $k \times k$ grid as a minor, then every linear coloring of G requires $\Omega(\sqrt{k})$ colors.*

► **Lemma 21** ([5]). *If G is a tree of treedepth d and maximum degree Δ , then every linear coloring of G requires at least $d/\log_2(\Delta)$ colors.*

Recall that Theorem 4 asserts that there exists a constant C such that for every graph G and integers $a, b \geq 2$, if the treedepth of G is at least $Cab \log a$, then either the treewidth of G is at least a or G contains a subcubic tree of treedepth at least b . Applying this theorem to $a = \theta(k^2)$ and $b = k \log_2(3)$, one obtains that if the treedepth of G is $\Omega(k^{19} p_{\text{GMT}}(\log k) \log k)$, then G contains either a $\theta(k^2) \times \theta(k^2)$ grid minor or a subcubic tree of treedepth at least $k \log_2(3)$. In the first outcome, Lemma 20 gives the desired number of colors of a linear coloring, while in the second outcome the same result is obtained from Lemma 21. This concludes the proof of Theorem 8.

6 An example of a tree with treedepth quadratic in the height of the binary tree or logarithm of a length of a path

In this section we provide a construction of a family of trees $(G_n)_{n \geq 1}$ such that

1. The tree G_n does not contain a path with 2^{n+2} vertices.
2. The tree G_n does not contain a subdivision of a full binary tree of depth $n + 2$.
3. The treedepth of G_n is at least $\binom{n+1}{2}$.

We will consider each tree G_n as a rooted tree. The tree G_1 consists of a single vertex. For $n \geq 2$, the tree G_n is defined recursively as follows. We take a path P_n with 2^n vertices and for each $v \in V(P_n)$ we create a copy G_n^v of G_{n-1} and attach its root to v . We root G_n in one of the endpoints of P_n ; see Figure 1. We now proceed with the proof of the properties of G_n .

■ **Figure 1** Construction of G_n .

Since every path in G_n is contained in at most two root-to-leaf paths (not necessarily edge-disjoint), to show Property (1) it suffices to show the following.

► **Lemma 22.** *Every root-to-leaf path in G_n contains less than 2^{n+1} vertices.*

Proof. We prove the statement by induction on n . For $n = 1$ the statement is straightforward. For the inductive step, observe that every root-to-leaf path in G_n consists of a subpath of P_n (which has 2^n vertices) and a root-to-leaf path in one of the copies C_n^v of G_{n-1} (which has less than 2^n vertices by the inductive assumption). ◀

We say that a subtree H of G_n that is a subdivision of a full binary tree of height $h \geq 1$ is *aligned* if $h = 1$ or $h \geq 2$ and the closest to the root vertex of H is of degree 2 in H and its deletion breaks H into two subtrees containing a subdivision of a full binary tree of height $h - 1$. In other words, an aligned subtree has the same ancestor-descendant relation as the tree G_n . Observe that any subtree H_0 of G_n that is a subdivision of a full binary tree of height $h \geq 2$ contains a subtree that is an aligned subdivision of a full binary tree of height $h - 1$. Therefore, to prove Property (2), it suffices to show the following.

► **Lemma 23.** *G_n does not contain an aligned subdivision of a full binary tree of height $n + 1$.*

Proof. We prove the claim by induction on n . It is straightforward for $n = 1$. For $n \geq 2$, let H be such an aligned subtree of G_n and let w be the closest to the root of G_n vertex of H . If $w \in V(C_n^v)$ for some $v \in V(P_n)$, then H is completely contained in C_n^v , which is a copy of G_{n-1} . Otherwise, $w \in V(P_n)$ and thus one of the components of $H - \{w\}$ lies in C_n^w . However, this component contains an aligned subdivision of a full binary tree of height n . In both cases, we obtain a contradiction with the inductive assumption. ◀

We are left with the treedepth lower bound of Property (3). To this end, we consider the following families of trees. For integers $a, b \geq 1$, the family $\mathcal{G}_{a,b}$ contains all trees H that are constructed from a path P_H with at least 2^a vertices by attaching, for every $v \in V(P_H)$, a tree T_v of treedepth at least b by an edge to v . We show the following.

► **Lemma 24.** *For every $H \in \mathcal{G}_{a,b}$ we have $\text{td}(H) \geq a + b$.*

Proof. We prove the lemma by induction on a . For $a = 1$ we have $\text{td}(H) \geq a + 1$ and H contains two vertex-disjoint subtrees of treedepth at least b each. Assume then $a > 1$ and $H \in \mathcal{G}_{a,b}$. Then for every $v \in V(H)$, $H - v$ contains a connected component that contains a subtree belonging to $\mathcal{G}_{a-1,b}$. This finishes the proof. ◀

We show Property (3) by induction on n . Clearly, $\text{td}(G_1) = 1 = \binom{1+1}{2}$. Consider $n \geq 2$. Since the treedepth of G_{n-1} is at least $\binom{n}{2}$, we have that $G_n \in \mathcal{G}_{n, \binom{n}{2}}$. By Lemma 24, we have that

$$\text{td}(G_n) \geq n + \binom{n}{2} = \binom{n+1}{2}.$$

This finishes the proof of Property (3).

7 Conclusions

We have provided improved bounds for the excluded minor approximation of treedepth of Kawarabayashi and Rossman [4]. Our main result, Theorem 4, is close to being optimal in the following sense: as witnessed by the family of trees, if one considers the measure $r := \text{td}(G)/\text{tw}(G)$, one cannot hope to find a tree in G of treedepth larger than r . We pose getting rid of the $\log(\text{tw}(G) + 1)$ factor in Theorem 4 as an open problem. Improving the $Ck^3 \log k$ bound of Corollary 5 to $Ck^{3-\varepsilon}$ for some $\varepsilon > 0$ seems much more challenging.

Our main result can be applied to a polynomial-time treedepth approximation algorithm, improving upon state-of-the-art tradeoff trick. As a second open problem, we ask for a polynomial-time or single-exponential in treedepth parameterized algorithm for constant or polylogarithmic approximation of treedepth.

Abstract

A robot modeled as a deterministic finite automaton has to build a structure from material available to it. The robot navigates in the infinite oriented grid $\mathbb{Z} \times \mathbb{Z}$. Some cells of the grid are full (contain a brick) and others are empty. The subgraph of the grid induced by full cells, called the *field*, is initially connected. The (Manhattan) distance between the farthest cells of the field is called its *span*. The robot starts at a full cell. It can carry at most one brick at a time. At each step it can pick a brick from a full cell, move to an adjacent cell and drop a brick at an empty cell. The aim of the robot is to construct the most compact possible structure composed of all bricks, i.e., a *nest*. That is, the robot has to move all bricks in such a way that the span of the resulting field be the smallest.

Our main result is the design of a deterministic finite automaton that accomplishes this task and subsequently stops, for every initially connected field, in time $O(sz)$, where s is the span of the initial field and z is the number of bricks. We show that this complexity is optimal.

1 Introduction

The problem

A mobile agent (robot) modeled as a deterministic finite automaton has to build a structure from material available to it. The robot navigates in the infinite oriented grid $\mathbb{Z} \times \mathbb{Z}$ represented as the set of unit square cells in the two-dimensional plane, with all cell sides vertical or horizontal. The robot has a compass enabling it to move from a currently occupied cell to one of the four cells (to the North, East, South, West) adjacent to it. Some cells of the grid contain a brick, i.e., are *full*, other cells are *empty*. The subgraph of the grid induced by full cells, called the *field*, is initially connected. The (Manhattan) distance between the farthest cells of the field is called its *span*. Notice that the span of any current field may be much smaller than its diameter as a subgraph of the grid. In fact, this diameter may be sometimes undefined, if the field becomes disconnected. The robot starts at a full cell. It

can carry at most one brick at a time. At each step, the robot can pick up a brick from the currently occupied full cell (if it does not carry any brick at this time), moves to an adjacent cell, and can drop a brick at the currently occupied empty cell (if it carries a brick). The robot has no a priori knowledge of the initial field, of its span or of the number of bricks.

The aim of the robot is to construct the most compact possible structure composed of all bricks, i.e., a *nest*. That is, the robot has to move all bricks in such a way that the span of the resulting field be the smallest. The above task has many real applications. In the natural world, animals use material scattered in a territory (pieces of wood, small branches, leaves) to build a nest, and minimizing the span is important to better protect it. A mobile robot may be used to clean a territory littered by hazardous material, in which case minimizing the span of the resulting placement of contaminated pieces facilitates subsequent decontamination. A more mundane example is the everyday task of sweeping the floor, whose aim is to gather all trash in a small space and then get rid of it.

Our results

Our main result is the design of a deterministic finite automaton that accomplishes the task of building a nest and subsequently stops, for every initially connected field, in time $O(sz)$, where s is the span of the initial field and z is the number of bricks. The time is defined as the number of moves of the robot. We show that this complexity is optimal.

The essence of our nest building algorithm is to instruct the robot to make a series of trips to get consecutive bricks, one at a time, and carry them to some designated compact area. This approach ensures the optimal complexity. (In order to show where the problem is, we also sketch a much simpler algorithm that uses another approach but has significantly larger complexity). There are two major difficulties to carry out this plan. The first is that the span of the initial field may be much larger than the memory of the robot, and hence the robot that already put several bricks in a compact area and goes for the next brick cannot remember the way back to the area where it started building. Thus we need to prepare the way, so that the robot can recognize the backtrack path locally at each decision point. The second problem is that, while we temporarily disconnect the field during the execution of the algorithm, special care has to be taken so that the connected components of intermediary fields be close to each other, to prevent the robot from getting lost in large empty spaces.

To the best of our knowledge, the task of constructing structures from available material using an automaton, has never been studied before in the algorithmic setting. It is interesting to compare this task to that of exploration of mazes by automata, that is a classic topic with over 50 years of history (see the section “Related work”). It follows from the result of Budach [9] (translated to our terminology) that if an automaton can only navigate in the field without moving bricks then it cannot explore all connected fields, even without the stop requirement, i.e., it cannot even see all bricks. By contrast, it follows from our result that the ability of moving bricks enables the automaton not only to see all bricks but to build a potentially useful structure using all of them and stop, and to accomplish all of that with optimal complexity.

The model

We consider the infinite oriented grid $\mathbb{Z} \times \mathbb{Z}$ represented as the set of unit square cells tiling the two-dimensional plane, with all cell sides vertical or horizontal. Each cell has 4 adjacent cells, North, East, South and West of it. Some cells of the grid contain a brick, i.e., are *full*, other cells are *empty*. The subgraph of the grid induced by full cells is initially connected.

At each step of the algorithm this subgraph can change, due to the actions of the robot, described below. At each step, the subgraph induced by the full cells is called the current *field*. Any maximal connected subgraph of the current field is called a *component*. Throughout the paper, the *distance* between two cells (x, y) and (x', y') of the grid is the Manhattan distance between them, i.e., $|x - x'| + |y - y'|$. The number of cells of a field is called its *size*, and the distance between two farthest cells of a field is called its *span*. A nest of size z is a field that has the minimum span among all fields of size z .

We are given a mobile entity (robot) starting in some cell of the initial field and traveling in the grid. The robot has a priori no knowledge of the field, of its size or of its span. The robot is formalized as a finite deterministic Mealy automaton $\mathcal{R} = (X, Y, \S, \delta, \lambda, S_0, S_f)$. $X = \{e, f\} \times \{l, h\}$ is the input alphabet, $Y = \{N, E, S, W\} \times \{e, f\} \times \{l, h\}$ is the output alphabet. \S is a finite set of states with two special states: S_0 called initial and S_f called final. $\delta : \S \times X \rightarrow \S$ is the state transition function, and $\lambda : \S \times X \rightarrow Y$ is the output function.

The meaning of the input and output symbols is the following. At each step of its functioning, the robot is at some cell of the grid and has some weight: it is either light, denoted by l (does not carry a brick) or heavy, denoted by h (carries a brick). Moreover, the current cell is either empty, denoted by e or full, denoted by f . The input $x \in \{e, f\} \times \{l, h\}$ gives the automaton information about these facts. The robot is in some state S . Given this state and the input x , the robot outputs the symbol $\lambda(x, S) \in \{N, E, S, W\} \times \{e, f\} \times \{l, h\}$ with the following meaning. The first term indicates the adjacent cell to which the robot moves: North, East, South or West of the current cell. The second term determines whether the robot leaves the current cell empty or full, and the third term indicates whether the robot transits as heavy or as light to the adjacent cell. Since the robot can only either leave the current cell intact and not change its own weight, or pick a brick from a full cell leaving it empty (in the case when the robot was previously light), or drop a brick on an empty cell leaving it full (in the case when the robot was previously heavy), we have the following restrictions on the possible values of the output function λ :

- $\lambda(S, e, l)$ must be (\cdot, e, l)
- $\lambda(S, e, h)$ must be either (\cdot, e, h) or (\cdot, f, l)
- $\lambda(S, f, l)$ must be either (\cdot, f, l) or (\cdot, e, h)
- $\lambda(S, f, h)$ must be (\cdot, f, h)

Seeing the input symbol x and being in a current state S , the robot makes the changes indicated by the output function (it goes to the indicated adjacent cell, possibly changes the filling of the current cell as indicated and possibly changes its own weight as indicated), and transits to state $\delta(x, S)$. The robot starts light in a full cell in the initial state S_0 (hence its initial input symbol is (f, l)) and terminates its action in the final state S_f .

Related work

Problems concerning exploration and navigation performed by mobile agents or robots in an unknown environment have been studied for many years (cf. [7, 21, 26]). The relevant literature can be divided into two parts, according to the environment where the robots operate: it can be either a geometric terrain, possibly with obstacles, or a network modeled as a graph in which the robot moves along edges.

In the geometric context, a closely related problem is that of pattern formation [12, 14, 28]. Robots, modeled as points freely moving in the plane have to arrange themselves to form a pattern given as input. This task has been mostly studied in the context of asynchronous oblivious robots having full visibility of other robots positions.

The graph setting can be further specified in two different ways. In [1, 3, 4, 13, 19] the robot explores strongly connected directed graphs and it can move only in the tail-to-head direction of an edge, not vice-versa. In [2, 5, 9, 15, 16, 17, 25, 27] the explored graph is undirected and the robot can traverse edges in both directions. Graph exploration scenarios can be also classified in another important way. It is either assumed that nodes of the graph have unique labels which the robot can recognize (as in, e.g., [13, 17, 25]), or it is assumed that nodes are anonymous (as in, e.g., [3, 4, 9, 10, 27]). In our case, we work with the infinite anonymous grid, hence it is an undirected anonymous graph scenario. The efficiency measure adopted in papers dealing with graph exploration is either the completion time of this task, measured by the number of edge traversals, (cf., e.g., [25]), or the memory size of the robot, measured either in bits or by the number of states of the finite automaton modeling the robot (cf., e.g., [15, 20, 19]). We are not concerned with minimizing the memory size but we assume that this memory is bounded, i.e., it is constant as a function of the input grid size. However we want to minimize the time of our construction task.

The capability of a robot to explore anonymous undirected graphs has been studied in, e.g., [6, 9, 15, 20, 23, 27]. In particular, it was shown in [27] that no finite automaton can explore all cubic planar graphs (in fact no finite set of finite automata can cooperatively perform this task). Budach [9] proved that a single automaton cannot explore all mazes (that we call connected fields in this paper). Hoffmann [22] proved that one pebble does not help to do it. By contrast, Blum and Kozen [6] showed that this task can be accomplished by two cooperating automata or by a single automaton with two pebbles. The size of port-labeled graphs which cannot be explored by a given robot was investigated in [20].

Recently a lot of attention has been devoted to the problem of searching for a target hidden in the infinite anonymous oriented grid by cooperating agents modeled as either deterministic or probabilistic automata. Such agents are sometimes called ants. It was shown in [18] that 3 randomized or 4 deterministic automata can accomplish this task. Then matching lower bounds were proved: the authors of [11] showed that 2 randomized automata are not enough for target searching in the grid, and the authors of [8] proved that 3 deterministic automata are not enough for this task. Searching for a target in the infinite grid with obstacles was considered in [24].

Our present paper adopts the same model of environment as the above papers, i.e., the infinite anonymous oriented grid. However the task we study is different: instead of searching for a target, the robot has to build some structure from the available material. To the best of our knowledge, such construction tasks performed by automata have never been studied previously in the algorithmic setting.

2 Terminology and preliminaries

In the description and analysis of our algorithm we will categorize full cells. A full cell is said to be a *border cell* if it is adjacent to an empty cell. A full cell that has only one full adjacent cell is called a *leaf*. A full cell is called *special*, if it is either a leaf, or has at least two full cells adjacent to it, sharing a corner.

A finite deterministic automaton may remember a constant number of bits by encoding them in its states. We will use this fact to define several simple procedures and simplifications that we use in the sequel. The first simplification is as follows. We formulate the actions of the robot based on the configuration of bricks in its neighborhood. More precisely, at any step, the robot knows whether each cell at distance at most $r = 8$ from its current cell is full or empty. This can be achieved by performing a bounded local exploration with return, after each move of the robot.

We will use the notion of current *orientation* of the robot. At the beginning of its navigation, the robot goes in one of the four cardinal directions. Then its orientation is determined in one of the two ways: either by its last step (North, East, South or West) or by a *turn*: we say that the robot *turns left* (respectively *right*) meaning that it changes its orientation in the appropriate way while remaining at the same cell. Clearly the robot can remember its orientation, using its states. We refer to cardinal directions with respect to this current orientation. Thus, e.g., if the robot is oriented East then we say that its adjacent North (resp. East, South or West) cell is *left* (resp. *in front*, *right*, *back*) of it.

Whenever we say that the robot located at a cell c and not carrying a brick *brings* a brick from a full cell c' to c we mean that the robot moves from c to c' , picks the brick from c' , moves back to c and restores its original orientation. Whenever we say that the robot located at a cell c and carrying a brick *places* it at an empty cell c' we mean that the robot moves from c to c' , drops the brick at c' , moves back to c and restores its original orientation.

Whenever the robot selects a cell according to some condition that is fulfilled by more than one cell, the robot selects the cell that is minimal with respect to the following total order \prec on the set of all cells. For cells $c = (x, y)$ and $c' = (x', y')$, $c \prec c'$ holds if and only if either $y < y'$, or $y = y'$ and $x \leq x'$. We denote by $|S|$ the number of cells in a sequence or a set S of cells.

We define a *disc* of radius $r \geq 0$ with center c to be the set of all cells at distance at most r from c , see Fig. 1. A disc of radius r contains $z_r = 2(1 + 3 + 5 + \dots + (2r - 1)) + (2r + 1) = 2r^2 + 2r + 1$ cells and has span $2r$. A *rough disc* of size z , where $z_r \leq z < z_{r+1}$ is defined as follows. If $z = z_r$, then the rough disc is the disc of radius r . Otherwise, let F be the set of cells not belonging to the disc D of radius r but adjacent to some cell of it. Add to D exactly $z - z_r$ cells belonging to F , starting from the North neighbor of the East-most cell of D and going counterclockwise. If $z_r < z \leq z_r + 2r + 2$ then the rough disc of size z has span $2r + 1$ and if $z_r + 2r + 2 < z < z_{r+1}$ then the rough disc of size z has span $2r + 2$, the same as the disc of radius $r + 1$ that has size z_{r+1} .

■ **Figure 1** (a) disc of size z_r for $r = 3$; (b) a rough disc of size $z_r + 7$ and span $2r + 1$, $r = 3$; (c) a rough disc of size $z_r + 11$ and span $2r + 2$, $r = 3$.

The proofs of the next two propositions are omitted due to space limitation.

► **Proposition 1.** *Any rough disc is a nest.*

The nests built by our automaton will be rough discs. The following proposition shows that the complexity of our nest-building algorithm is optimal, regardless of the relation between the size of the initial field and its span (recall that, by definition, the span must be smaller than the size z and it must be in $\Omega(\sqrt{z})$). Our lower bound on complexity follows from geometric properties of the grid, and hence it holds regardless of the machine that builds the nest, i.e., even if the robot is a Turing machine knowing a priori the initial field.

► **Proposition 2.** *Let $s' < z$ be positive integers such that $s' \in \Omega(\sqrt{z})$. There exists an initial field of size z and span $s \in \Theta(s')$, such that any algorithm that builds a nest starting from this field must use time $\Omega(sz)$.*

3 The algorithm

The robot will move bricks from the original field and build two special components. One of them will be a rough disc that will be gradually extended. The second one will be a one-cell component whose only cell is called the *marker*. The robot will periodically get at large distances from the rough disc being built, and the role of the marker will be to indicate to the robot that it got back in the vicinity of the rough disc. Any component that is different from the rough disc and from the marker will be called a *free component*. During the execution of the entire algorithm, the robot will not ensure that the full cells outside of the rough disc and of the marker form one component – they may form several components – but after adding a new brick to the rough disc these components will be always at a bounded distance, i.e., at distance $O(1)$, from the rough disc that the robot is constructing.

We are now ready to sketch the high-level idea of the algorithm, whose pseudo-code is presented at the end of this section as algorithm Nest. First the robot performs some preliminary actions by establishing the marker and the initial rough disc and by calling procedure Sweep, which together result in constructing the first rough disc D (of size one), placing the marker next to it and ensuring that no full cells other than the marker are at distance at most 7 from D . Then each iteration of the main loop of algorithm Nest performs three actions. First, it executes procedure FindNextBrick that allows the robot to find a brick in a free component \mathcal{C} . This brick must be carefully chosen. For example, greedily picking the closest available brick would soon result in creating large empty spaces between components of the field, in which the robot could get lost. This brick will be later used to extend the rough disc. However, this procedure may lead the robot far from the rough disc and may also disconnect \mathcal{C} into many components. Disconnecting \mathcal{C} is one of the main tools in our construction. It is done by the robot on purpose to allow it to find its way back to the marker and so that it is possible to recover the connectivity of \mathcal{C} on the way back. Such a walk back to the marker is the second action performed in the main loop and described as procedure ReturnToMarker. The third action is done once the robot is back at the marker, and it is given as procedure ExtendRoughDisc. This procedure extends the rough disc, ensuring the property that there are no full cells at a prescribed bounded distance from the rough disc, except the marker. While restoring this property, the robot may again disconnect some components but all of them are at a bounded distance from the rough disc and thus the robot will be able to find them easily. Additionally, it may happen that the cell brought to the rough disc was the last cell of \mathcal{C} . In such a case, as the last part of procedure ExtendRoughDisc, the robot places the marker near another component close to the rough disc, if one exists. This will be the new free component \mathcal{C} in which the robot will find the next brick in the next iteration of the main loop. If no such \mathcal{C} exists, then the robot adds the brick from the marker to the rough disc, thus completing the construction of the nest.

Many of the difficulties described above come from our desire to keep the complexity of the algorithm optimal, i.e., $O(sz)$. If complexity were not an issue, the following much simpler algorithm would be sufficient. The robot first builds a horizontal line at the level of a South-most cell of the initial field, by gradually squeezing down the field, keeping it connected at all times. Then it transforms the line into a nest. The squeezing down can be performed by iteratively repeating the following steps. First, the robot makes sure that it is not on the lowest level (if the line is not yet constructed, this can be done by finding a full cell with a full South neighbor). Then the robot goes to some North-West extremity of the field, i.e., to any full cell that has empty cells to the North and to the West of it. Then it picks the brick from this cell and drops it one level down, ensuring the connectivity. This

can be done by first moving one level down and then iteratively going West until an empty cell is encountered, where the robot drops the brick. When the field is squeezed down to a line, the robot will recognize this and easily transform it into a nest.

This idea potentially requires time $\Theta(z)$ to lower a brick by one level. Since there are z bricks possibly on $\Theta(s)$ levels, the entire time would be $\Theta(sz^2)$ in the worst case, which is suboptimal. Thus we proceed with the detailed description of the optimal algorithm Nest whose high-level idea was described before.

3.1 Moving bricks out of the way

One of the challenges in constructing the rough disc is to have enough room so that, while expanding, it does not merge with the remainder of the field. This is one of the goals of procedure Sweep. Its high-level idea is the following. It ensures an invariant that has to hold whenever the agent goes to retrieve the next brick in order to extend the rough disc. This invariant is that there are no full cells, other than the cell M that is the marker, within a given bounded distance from the current rough disc D . This procedure is called when the robot is at the marker, in two situations. The first one is right before the main loop: in this case the marker, the rough disc (of size one) and its corresponding neighborhood occupy a constant number of cells and hence in this case the robot is able to decide whether a given cell is in $D \cup \{M\}$. The second situation occurs after each extension of the rough disc. In this case, the size of D may be unbounded but a walk around its border (which can be done with stop, using the marker) allows to determine if there is a full cell c within a bounded distance from D , that does not belong to the rough disc itself. Whenever such a full cell c is found, the robot picks the brick from c and searches for an empty cell at distance at least 7 from the rough disc. This searching walk is done in such a way as to ensure the return to the rough disc. At the end of the procedure, the robot places the marker next to some free component. Below is the pseudo-code of procedure Sweep. In this pseudo-code, we use

■ **Procedure Sweep** sweeping away bricks that are close to the rough disc.

```

1  $M :=$  the marker
2 go to the closest cell of the rough disc  $D$ 
3 perform a full counterclockwise traversal of the border of  $D$ , executing the following
  actions after each step:
4   for each full cell  $c \notin D \cup \{M\}$  at distance at most 7 from the robot do
5      $c' :=$  the cell currently occupied by the robot
6     go to  $c$  and pick the brick
7     move in direction away from  $D$  and stop at the first empty cell at distance at
      least 7 from  $D$ 
8     drop the brick and return to  $c'$ 
9 if there exists a free component  $\mathcal{C}$  then
10  pick the brick from marker and place it at distance 3 from the rough disc and at
    distance 4 from  $\mathcal{C}$ , creating a new marker
11 go to the marker

```

the notion of the robot going *in direction away* from the rough disc D . This is the direction which strictly increases the distance between the robot and the rough disc. In the case where there are two such directions, we use priority North, East, South, West.

3.2 Finding the next brick

The high-level idea of procedure FindNextBrick is the following. It may happen that the cells that belong to a free component \mathcal{C} and are close to the marker cannot be rearranged in such a way that the robot be able to obtain a brick that it can then use to extend the rough disc and at the same time keep the connectivity of \mathcal{C} and ensure that \mathcal{C} remains close to the marker. Thus, the robot has to retrieve the needed brick by following a potentially long walk; we will call it a *search walk* and formally define it below. The search walk needs to be carefully chosen to ensure that it ends at a location where it is possible to find the desired brick and so that the robot be able to return to the marker. Moreover, this walk has to be sufficiently short to guarantee the time $O(sz)$ of the algorithm, i.e., the length of each walk must be $O(s)$. We ensure the latter as follows: each search walk \mathcal{W} leads alternately in two non-opposite directions, e.g., North and West. The return is guaranteed by repeatedly performing an action called *switch* while walking along \mathcal{W} , which we formally describe later. Intuitively speaking, the switch eliminates the cells adjacent to \mathcal{W} at which the robot may incorrectly turn on its way back to the marker. The switch potentially disconnects the component but the robot is able to recover the connectivity while backtracking along \mathcal{W} . Finally, we will describe how the desired brick can be found at the end of \mathcal{W} .

3.2.1 Search walks

Suppose that the robot is currently at a full cell and there is a full cell in front of the robot. A *left-free* (respectively *right-free*) segment consists of all full cells that will be visited by the robot that moves without changing its direction until one of the following conditions holds:

- (S1) the robot arrives at a full cell that has an empty cell in front of it and has an empty cell to the left (respectively right) of it; such a segment is called *terminal*,
- (S2) the robot arrives at the first special cell such that the cell to the left (respectively right) of the robot is full.

Whenever the orientation is not important or clear from the context we will refer to a left-free or right-free segment by saying *segment*. Note that not every special cell terminates the above sequence of moves.

We now define a *search walk* \mathcal{W} of the robot in an arbitrary component \mathcal{C} (cf. the example in Fig. 2). A search walk depends on the initial position of the robot in \mathcal{C} and on its orientation. We make two assumptions in the definition: the robot is initially located at a full cell of \mathcal{C} and, if $|\mathcal{C}| > 1$, then there is a full cell in front of the robot. The search walk \mathcal{W} is a concatenation of segments. The first segment is both left-free and right-free. If the cell c at the end of this segment is a leaf, then the construction of \mathcal{W} is completed. Otherwise, note that there is a full cell to the left of the robot located at c or to the right of it. In the former case, the search walk is called *left-oriented* and in the latter it is *right-oriented*. Intuitively, a left-oriented search walk prescribes going straight until it is possible to go left, then going straight until it is possible to go right, and so on, alternating directions, until a stop condition is satisfied. A similar intuition concerns right-oriented search walks.

More formally, if $|\mathcal{C}| > 1$, then the search walk \mathcal{W} consists of a single cell. Otherwise, in a right-oriented (respectively left-oriented) search walk, the segments are sequentially added to \mathcal{W} , cyclically alternating the following construction steps.

- (W1) The robot traverses a right-free (respectively left-free) segment, adding it to \mathcal{W} . This segment becomes the last segment in \mathcal{W} if it is a terminal. If the segment is not the last one, then the robot turns right (respectively left).

- (W2) The robot traverses a left-free (respectively right-free) segment, adding it to \mathcal{W} . This segment becomes the last segment in \mathcal{W} if it is a terminal. If the segment is not the last one, then the robot turns left (respectively right).

■ **Figure 2** An example of a search walk $\mathcal{W} = (w_1, \dots, w_{20})$ that is constructed by the robot initially located at w_1 and facing North. This search walk is left-oriented, and has three left-free segments $S_1 = (w_1, w_2, w_3)$, $S_3 = (w_8, w_9, w_{10})$, $S_5 = (w_{11}, w_{12})$ and three right-free segments $S_2 = (w_3, \dots, w_8)$, $S_4 = (w_{10}, w_{11})$, $S_6 = (w_{12}, \dots, w_{20})$.

3.2.2 Ensuring the return from a search walk

We start with a high-level idea of the mechanism that will ensure the return from a search walk. Whenever the robot follows a search walk \mathcal{W} , it may a priori not be able to return to the origin of \mathcal{W} . This is due to the fact that, e.g., if \mathcal{W} is left-oriented, then any segment that is right-free may have an unbounded number of special cells such that each of them is adjacent to a cell that does not belong to \mathcal{W} . Thus, the returning robot is not able to remember, using its bounded memory, which of such cells do not belong to the search walk and should be skipped. To overcome this difficulty, the robot will make small changes in the field close to the search walk while traversing it for the first time. These changes may disconnect the component in which the robot is walking, and this may result in creating many new components. While doing so, we will ensure two properties. First, thanks to the modifications in the field performed while traversing \mathcal{W} , the robot is able to return to the first cell of this search walk. Second, while backtracking on \mathcal{W} , the robot is able to undo earlier changes and recover the connectivity of the component.

Each cell c at which the robot stops to perform the above-mentioned modification will be called a *break point* and is defined as follows. First, we require that c be an internal cell of a segment S , i.e., neither the first nor the last cell of S . Second, if S is left-free (respectively right-free), then when the robot traversing S is at c , there is a full cell f to the right (respectively left) of it. Clearly, the cell e to the left (respectively right) of the robot is empty. The following couple of actions performed by the robot located at such a cell c are called a *switch*: if the robot is not carrying a brick, then the robot brings the brick from f and then places it at e , and if the robot is carrying a brick, then the robot places it at e and then brings the brick from f . Note that the switch may disconnect the component in which the robot is located thus creating two new components. One new component is the one in which the robot is located and this is the component that contains the search walk. The second new component is the one that contains the cell f' adjacent to f and at

distance two from c , if f' is full. If the cell f' is full and belongs to a separate component, then this second component containing f' will be called a *switch-component*. Whenever the robot traversing a segment performs the switch at each internal special cell of the segment, we say that this is a *switch-traversal* (cf. the example in Fig. 3).

■ **Figure 3** The field from Figure 2 after switch-traversal of the search walk from Figure 2. The cells $w_6, w_7, w_9, w_{13}, w_{15}$ and w_{16} are the break points at which the robot moves a brick from a cell f_i to e_i for $i \in \{1, \dots, 6\}$. Note that a brick is moved from f_2 to e_2 while traversing the second segment and then the same brick is moved to e_3 while traversing the third segment.

3.2.3 Obtaining a brick at the end of a search walk

Informally, the purpose of traversing the entire search walk by a robot is to arrive at a location in the current component \mathcal{C} of the robot, where the robot can start a procedure aimed at obtaining a brick whose removal will not disconnect \mathcal{C} . We will say that such a brick is *free*. In our algorithm, we check the condition (S1) to learn if the last segment is terminal. According to the condition, the terminal segment may end with a leaf, and in such a case the robot is at a cell with a free brick. If the terminal segment does not end with a leaf, then there need not exist a free brick located in a close neighborhood of the robot. However, we will prove that it is possible to perform a series of changes to the field that results in creating a configuration of bricks that does contain a free brick.

We now define the behavior of the robot that ended the switch-traversal of the last segment S of a search walk \mathcal{W} and arrived at a cell that is not a leaf. The following series of moves is called *shifting* (cf. Fig. 4). Suppose that the cell to the right (respectively left) of the robot is full. Note that this implies that S is left-free (respectively right-free). First the robot changes its direction so that a cell of S is in front of it (i.e., the robot turns back). The following three actions are performed until the stop condition specified in the third action occurs. First, the robot picks the brick from the currently occupied cell. Second, the robot moves one step forward – thus backtracking along S . Third, when the robot is at a special cell, then the shifting is completed, and otherwise the robot places the brick at the cell to the left (respectively right) of it. Note that when the robot arrives at a special cell, it is carrying a brick and this is the desired free brick.

We now give the pseudo-code of procedure FindNextBrick that obtains this brick.

■ **Figure 4** The field from Fig. 3 at the end of shifting. The shifting ends with a right-free segment, at the cell w_{16} because it has a full neighbor, the cell e_6 . There is one fewer brick than in Fig. 3 and this is the free brick obtained and carried by the robot.

■ **Procedure FindNextBrick** finding a free brick.

-
- 1 $\mathcal{W} :=$ the search walk that starts at the cell where the robot is located
 - 2 go to the nearest cell belonging to a free component
 - 3 perform a switch-traversal of \mathcal{W}
 - 4 **if** the robot is at a leaf **then**
 - 5 pick the brick
 - 6 **else**
 - 7 perform shifting
-

3.3 Back to the marker

Before presenting the high-level idea of procedure ReturnToMarker that takes the robot carrying a brick back to the marker, we need the following definitions. If S is a segment, then the *reversal* of S , denoted by $\varphi(S)$, is the segment composed of the same cells as S but in the reversed order. For a search walk \mathcal{W} that is a concatenation of segments S_1, \dots, S_l , define the *reversal* of \mathcal{W} , denoted by $\varphi(\mathcal{W})$, to be the walk that is the concatenation of segments $\varphi(S_l), \varphi(S_{l-1}), \dots, \varphi(S_1)$, in this order. Thus, following $\varphi(\mathcal{W})$ means backtracking along \mathcal{W} , and in this section we give a procedure performing it, that reconnects the previous free component on the way. We also define the orientation of $\varphi(\mathcal{W})$ as follows. If the last segment of \mathcal{W} is left-free, then $\varphi(\mathcal{W})$ is left-oriented, and otherwise $\varphi(\mathcal{W})$ is right-oriented. Thus, if \mathcal{W} ended with a left-free (respectively right-free) segment, then $\varphi(\mathcal{W})$ also starts with a left-free (respectively right-free) segment.

At a high level, the robot will perform a switch-traversal along $\varphi(\mathcal{W})$, stopping at each break point to reconnect the corresponding switch-component with the component in which the robot is walking. However, we need to ensure that, at the end, the robot stops at the right point, i.e., at the marker. In order to ensure this, we define the following condition:

(S1') the robot arrives at a cell at distance at most 4 from the marker.

We define a *return switch-traversal* of $\varphi(\mathcal{W})$ to be a switch-traversal of $\varphi(\mathcal{W})$ in which each verification of condition (S1) is replaced by the verification of condition (S1'). Recall that the condition (S1) is checked in the definition of a switch-traversal to determine the termination of a segment and consequently the termination of the entire search walk. Intuitively, by replacing condition (S1) with (S1') we change the behavior of the robot so that it is looking for the marker while backtracking along \mathcal{W} , i.e., going along $\varphi(\mathcal{W})$.

35:12 Building a Nest by an Automaton

A high-level sketch of procedure `ReturnToMarker` is the following. As indicated earlier, the robot essentially follows $\varphi(\mathcal{W})$ and, as the return switch-traversal dictates, reconnects the switch components. However, there is one special case in which the robot should not perform a switch while being at a cell c' of $\varphi(\mathcal{W})$, although c' satisfies the definition of a break point. This case occurs if the shifting moved all internal cells of the last segment of \mathcal{W} . In this case, it is enough for the robot to move to the next cell after c' and start the return switch-traversal of $\varphi(\mathcal{W})$ from there. This is feasible because the cell c and its neighbors are at a bounded distance from the robot when the shifting is completed. Below is the pseudo-code of procedure `ReturnToMarker`.

■ **Procedure `ReturnToMarker`** going back to the marker.

```
1  $\mathcal{W} :=$  the search walk traversed in the last call to FindNextBrick
2 let  $S_1, \dots, S_l$  be the segments in  $\mathcal{W}$ 
3 if the robot is at the first cell of  $S_l$  then
4   turn towards the penultimate cell of  $S_{l-1}$ 
5   move  $\min\{2, |S_{l-1}| - 1\}$  cells forward
6   if  $|S_{l-1}| = 2$  and  $l > 2$ , then make a turn towards the penultimate cell of  $S_{l-2}$ 
7 starting at the current location, perform a return switch-traversal of  $\varphi(\mathcal{W})$ 
8 go to the marker
```

3.4 Extending the rough disc

The aim of procedure `ExtendRoughDisc` is double: it adds a new brick to the current rough disc in a specific place, and it calls procedure `Sweep` to extend, if necessary, the empty space around the rough disc and to ensure that the marker is close to some free component. Whenever procedure `ExtendRoughDisc` is called, the following conditions will be satisfied: the robot is at the marker and it is carrying a brick.

Below is the pseudo-code of procedure `ExtendRoughDisc`.

■ **Procedure `ExtendRoughDisc`** adding one brick to the rough disc D .

```
1 place the brick at the unique cell  $e$  such that  $D \cup \{e\}$  is a rough disc
2 call procedure Sweep
```

Now the pseudo-code of the entire algorithm can be succinctly formulated as follows.

■ **Algorithm `Nest`** building a nest from any connected field.

```
1 if the span of the field is at most 2 then
2   exit ▷ the field is already a nest
3 the cell occupied by the robot becomes the marker
4 a full cell at distance 2 from the marker becomes the initial rough disc
5 call procedure Sweep
6 while there exists a free component  $\mathcal{C}$  do
7   call procedure FindNextBrick
8   call procedure ReturnToMarker
9   call procedure ExtendRoughDisc ▷ moves the marker if necessary
10 pick the brick (the marker) and place it at the unique cell  $e$  of the rough disc  $D$  such
    that  $D \cup \{e\}$  is a rough disc
```

The following is the main result of this paper. Its proof is omitted due to space limitation.

► **Theorem 3.** *Algorithm Nest builds a nest starting from any connected field of size z and span s in time $O(sz)$. This time is worst-case optimal.*

4 Conclusion

We designed a finite deterministic automaton that builds the most compact structure starting from any connected field of bricks, and does it in optimal time. An interesting problem yielded by our research is to characterize the classes of target structures that can be built by a single automaton, starting from any connected field of bricks in the grid. Another problem is that of how the building task parallelizes, i.e., how much time many automata use to build some structure.

Abstract

In this work we consider three well-studied broadcast protocols: *push*, *pull* and *push&pull*. A key property of all these models, which is also an important reason for their popularity, is that they are presumed to be very robust, since they are simple, randomized, and, crucially, do not utilize explicitly the global structure of the underlying graph. While sporadic results exist, there has been no systematic theoretical treatment quantifying the robustness of these models. Here we investigate this question with respect to two orthogonal aspects: (adversarial) modifications of the underlying graph and message transmission failures.

We explore in particular the following notion of *local resilience*: beginning with a graph, we investigate up to which fraction of the edges an adversary may delete at each vertex, so that the protocols need significantly more rounds to broadcast the information. Our main findings establish a separation among the three models. On one hand *pull* is robust with respect to all parameters that we consider. On the other hand, *push* may slow down significantly, even if the adversary is allowed to modify the degrees of the vertices by an arbitrarily small positive fraction only. Finally, *push&pull* is robust when no message transmission failures are considered, otherwise it may be slowed down.

On the technical side, we develop two novel methods for the analysis of randomized rumour spreading protocols. First, we exploit the notion of self-bounding functions to facilitate significantly the round-based analysis: we show that for any graph the variance of the growth of informed vertices is bounded by its expectation, so that concentration results follow immediately. Second, in order to control adversarial modifications of the graph we make use of a powerful tool from extremal graph theory, namely Szemerédi's Regularity Lemma.

1 Introduction

Randomized broadcast protocols are highly relevant for data distribution in large networks of various kinds, including technological, social and biological networks. Among many others there are three basic models in the literature, introduced in [19, 9, 24], namely *push*, *pull* and *push&pull* (or short *pp*). Consider a connected graph in which some vertex holds a piece of information; we call this vertex (initially) informed. All three models have the common characteristic that they proceed in rounds. In the *push* model, in every round every informed vertex chooses a neighbour independently and uniformly at random (iuar) and informs it; this of course has only an effect if the target vertex was previously uninformed. Contrary, in the *pull* model every round every uninformed vertex chooses a neighbour iuar and asks for the information. If the asked vertex has the information, then the asking vertex becomes

informed as well. The third model *push&pull* combines both worlds: in each round, each vertex chooses a neighbour *uar*, and if one of both vertices is informed, then afterwards both become so. We additionally assume that each message transmission succeeds independently with probability $q \in (0, 1]$. For these algorithms, the main parameter that we consider is the random variable that counts how many rounds are needed until all vertices are informed, and we call these quantities the *runtimes* of the respective algorithms.

In the remainder we will denote the runtime of *push* by $T_{push}(G, v, q)$ where G is the underlying graph, initially the vertex v is informed and we have a transmission success probability of $q \in (0, 1]$. Analogously we denote the runtimes of *pull* and *push&pull* by $T_{pull}(G, v, q)$ and $T_{pp}(G, v, q)$ respectively. If the choice of v does not matter we will omit it in our notation. The most basic case is when G is the complete graph K_n with n vertices. Then, see for example Doerr and Kostrygin [11], it is known that for $\mathcal{P} \in \{push, pull, pp\}$ and $q \in (0, 1]$ in expectation and with probability tending to 1 as $n \rightarrow \infty$

$$T_{\mathcal{P}}(K_n, q) = c_{\mathcal{P}}(q) \log n + o(\log n),$$

where, for $q \in (0, 1)$,

$$c_{push}(q) := \frac{1}{\log(1+q)} + \frac{1}{q}, \quad c_{pull}(q) := \frac{1}{\log(1+q)} - \frac{1}{\log(1-q)},$$

$$c_{pp}(q) := \frac{1}{\log(1+2q)} + \frac{1}{q - \log(1-q)},$$

and where we set $c_{\mathcal{P}}(1) := \lim_{q \rightarrow 1} c_{\mathcal{P}}(q)$. If q is clear from the context, we write $c_{\mathcal{P}}$ instead of $c_{\mathcal{P}}(q)$. Actually, the results in [11] and also [12] are much more precise, but the stated forms will be sufficient for what follows.

Contribution & Related Work

In this article our focus is on quantifying the *robustness* of all three models. Indeed, robustness is a key property that is often attributed to them, since they are simple, randomized, and, crucially, do not exploit explicitly the structure of the underlying graph (apart, of course, from considering the neighborhoods of the vertices). Clearly, the runtime can vary tremendously between different graphs with the same number of vertices. Hence it is essential to understand which structural characteristics of a graph influence in what way the runtime of rumour spreading algorithms.

One result in this spirit for the *push* model was shown in [25]. Roughly speaking, in that paper it is shown that even on graphs with low density, if the edges are distributed rather uniformly, then *push* is as fast as on the complete graph. This can be interpreted as a robustness result: starting with a complete graph, one can delete a vast amount of edges and as long as this is done rather uniformly, the runtime of *push* is affected insignificantly. To state the result more precisely, we need the following notion.

► **Definition 1** ($(n, \delta, \Delta, \lambda)$ -graph). *Let G be a connected graph with n vertices that has minimum degree δ and maximum degree Δ . Let $\mu_1 \geq \mu_2 \geq \dots \geq \mu_n$ be the eigenvalues of the adjacency matrix of G , and set $\lambda = \max_{2 \leq i \leq n} |\mu_i| = \max\{|\mu_2|, |\mu_n|\}$. We will call G an $(n, \delta, \Delta, \lambda)$ -graph.*

In this paper we are interested in the case where G gets large, that is, when $n \rightarrow \infty$. Hence all asymptotic notation in this paper is with respect to n ; in particular “with high probability”, or short whp, means with probability $1 - o(1)$ when $n \rightarrow \infty$.

► **Definition 2** (Expander Sequence). Let $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be a sequence of graphs, where G_n is a $(n, \delta_n, \Delta_n, \lambda_n)$ -graph for each $n \in \mathbb{N}$. We say that \mathcal{G} is an expander sequence if $\Delta_n/\delta_n = 1 + o(1)$ and $\lambda_n = o(\Delta_n)$.

Note that if we consider any sequence $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ of graphs this always implicitly defines δ_n, Δ_n and λ_n as in Definition 2. Expander graphs have found numerous applications in computer science and mathematics, see for example the survey [23]. If \mathcal{G} is an expander sequence, then intuitively this means that for n large enough, the edges of G_n are rather uniformly distributed. For a more formal statement see Lemma 16. Moreover, note that our definition of expander sequences excludes the case when Δ_n is bounded; this is actually a necessary condition for our robustness results to hold, see [13]. With all these definitions at hand we can state the result from [25] that quantifies the robustness of *push* with respect to the network topology, that is, the runtime is asymptotically the same as on the complete graph K_n .

► **Theorem 3.** Let $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be an expander sequence. Then whp

$$T_{push}(G_n) = c_{push}(1) \log n + o(\log n).$$

Apart from expander sequences, results in the form of Theorem 3 (where the asymptotic runtimes of one or more of these algorithms are determined) were also shown for sufficiently dense Erdős-Renyi random graphs [16], random regular graphs [15] as well as hypercubes [25]. Moreover, the order of the runtime on various models that describe social networks was investigated. In [17] the Chung-Lu model was studied, [10] explored preferential attachment graphs and [18] examined geometric graphs. A somewhat different approach is to derive general runtime bounds that hold for all graphs and depend only on some graph parameter, e.g. conductance [20, 6], vertex expansion [21] or diameter [14, 5, 22]. Furthermore, several variants of *push*, *pull* and *push&pull* were studied. These include vertices being restricted to answer only one *pull* request per round [7], vertices being allowed to contact multiple neighbours per round [25, 11], vertices not calling the same neighbour twice [10] and asynchronous versions [4, 26, 1, 2]. Finally, besides [11], robustness of these rumor spreading algorithms with respect to message transmission failures was also studied by Elsässer and Sauerwald in [13]. It was shown for any graph that if a message fails with probability $1 - p$, then the runtime of *push* increases at most by a factor of $6/p$.

In this work our focus is on three subjects concerning the robustness of rumour spreading. Our first (and not unexpected) result extends Theorem 3 to the runtimes of *pull* and *push&pull*. In particular, we show that none of the three protocols slows down or speeds up on graphs with good expansion properties compared to its runtime on the complete graph. This motivates to investigate how severely a graph with good expansion properties has to be modified to increase the respective runtimes.

In our second contribution, which is also the main result and which differs from what was treated in previous works, we propose and study a novel approach to quantifying robustness. In particular, we investigate the impact of adversarial edge deletions, where we use the well-known concept of *local resilience*, see e.g. [28, 8]. To be specific, we explore up to which fraction of edges an adversary may delete at each vertex to slow down the process by a significant amount of time, i.e., by $\Omega(\log n)$ rounds. Here we discover a surprising dichotomy in the following sense. On the one hand, we show that both *pull* and *push&pull* cannot be slowed down by such adversarial edge deletions – in essentially all but trivial cases, where the fraction is so large that the graph may become (almost) disconnected. On the other hand, we demonstrate that even a small number of edge deletions is sufficient to slow down

push by $\Omega(\log n)$ rounds. In other words, we find that in contrast to *pull* and *push&pull*, the *push* protocol is not resilient to adversarial deletions and lacks (in this specific sense) the robustness of the other two protocols.

As our third subject, we generalise the previous results by additionally considering message transmission failures that occur independently with probability $1 - q \in [0, 1)$. On the positive side, we show that for arbitrary $q \in (0, 1]$ all three algorithms inform *almost* all vertices at least as fast as when run on expander sequence in spite of adversarial edge deletions. However, if we want to inform all vertices, only *pull* is not slowed down by adversarial edge deletions for all values of q ; *push* can be slowed down as before; and *push&pull* is a mixed bag, for $q = 1$ it cannot be slowed down, for $q < 1$ it can. Furthermore, in general it is also possible to speed *push&pull* up by deleting edges, which is however not surprising as the star-graph deterministically finishes in at most 2 rounds.

Summarizing, this work expands previous (robustness) results, particularly the ones concerning precise asymptotic runtimes and random transmission failures. Crucially, we introduce and study the concept of local resilience as a method to investigate robustness. However, apart from that, in this paper we develop two new general methods for the analysis of rumour spreading algorithms.

- The most common approach in the current literature for the study of the runtime is to determine the expected number of newly informed vertices in one or more rounds and to show concentration, for example by bounding the variance. Achieving this, however, is often quite complex and makes laborious and lengthy technical arguments necessary. Here we use the theory of *self-bounding* functions, see Section 2, that allows us to cleanly upper bound the variance by the *expected value*. The argument works for all three investigated algorithms and the bound is valid for all graphs. We are certain that this method will also facilitate future work on the analysis of rumour spreading algorithms.
- Studying the robustness of the protocols is a challenging task, as the adversary (as described previously) has various options to modify the graph, for example by introducing a high variance in the degrees of the vertices; this turns out to be particularly problematic in the case of *push&pull*. Here we demonstrate that such types of irregularities can be handled universally by applying a powerful tool from a completely different area, namely extremal graph theory. In particular, we use Szemerédi’s regularity lemma (see e.g. [27]), which allows us to partition the vertex set of a graph such that nearly all pairs of sets in the partition behave nearly like perfect regular bipartite graphs. This allows us to apply our methods on these regular pairs; eventually we obtain a linear recursion that can be solved by analysing the maximal eigenvalue of the underlying matrix.

1.1 Results

Our first result addresses the question about how fast rumours spread on expander graphs; in order to obtain a concise statement also the occurrence of independent message transmission failures is considered.

► **Theorem 4.** *Let $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be an expander sequence and let $q \in (0, 1]$. Then whp*

- (a) $T_{push}(G_n, q) = c_{push}(q) \log n + o(\log(n))$,
- (b) $T_{pull}(G_n, q) = c_{pull}(q) \log n + o(\log(n))$,
- (c) $T_{pp}(G_n, q) = c_{pp}(q) \log n + o(\log(n))$.

The first statement is an extension of Theorem 3 and its proof is a straightforward adaptation of the proof in [25]. We omit it. The contribution here is the proof of (b) and (c). Next we consider the case with edge deletions in addition to the message transmission failures.

► **Theorem 5.** *Let $0 < \varepsilon < 1/2, q \in (0, 1]$ and $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be an expander sequence. Let $\tilde{\mathcal{G}} = (\tilde{G}_n)_{n \in \mathbb{N}}$ be such that each \tilde{G}_n is obtained by deleting edges of G_n such that each vertex keeps at least a $(1/2 + \varepsilon)$ fraction of its edges. Then whp*

(a) $T_{pull}(\tilde{G}_n, q) = c_{pull}(q) \log n + o(\log n)$.

(b) $T_{pp}(\tilde{G}_n, 1) \leq c_{pp}(1) \log n + o(\log n)$, when additionally assuming that $\delta(G_n) \geq \alpha n$ for some constant $0 < \alpha \leq 1$.

This result demonstrates unconditionally the robustness of *pull*, and conditionally on $q = 1$ the robustness of *push&pull* on dense graphs, in the case of edge deletions, that is, the runtime is asymptotically the same as in the complete graph. It even shows that *push&pull* may potentially profit from edge deletions in contrast to being slowed down. The proof of this result, especially the statement about *push&pull*, is rather involved, since the original graph may become quite irregular after the edge deletions. Here we use, among many other ingredients, the aforementioned decomposition of the graph given by Szemerédi's regularity lemma.

Note that Theorem 5 does not consider *push* and *push&pull* (when $q \neq 1$) at all. Indeed, our next result states that in these cases the behaviour is rather different and that the algorithms may be slowed down.

► **Theorem 6.** *Let $\varepsilon > 0$ and $q \in (0, 1]$. Then there is an expander sequence $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ and a sequence of graphs $\tilde{\mathcal{G}} = (\tilde{G}_n)_{n \in \mathbb{N}}$ with the following properties. Each \tilde{G}_n is obtained by deleting edges of G_n such that each vertex keeps at least a $(1 - \varepsilon)$ fraction of its edges. Moreover, whp*

(a) $T_{push}(\tilde{G}_n, q) \geq c_{push}(q) \log n + \varepsilon/(2q) \log n + o(\log n)$.

(b) $T_{pp}(\tilde{G}_n, q) \geq c_{pp}(q) \log n + (\varepsilon/(8q) - \varepsilon q^3/5) \log n + o(\log n)$.

Nevertheless, not all hope is lost. On the positive side, the next result states that *push* and *push&pull* are able to inform *almost* all vertices as fast as on the complete graph in spite of adversarial edge deletions. In this sense, we obtain an almost-robustness result for these cases.

► **Theorem 7.** *Let $0 < \varepsilon < 1/2, q \in (0, 1]$ and $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be an expander sequence. Let $\tilde{\mathcal{G}} = (\tilde{G}_n)_{n \in \mathbb{N}}$ be such that each \tilde{G}_n is obtained by deleting edges of G_n such that each vertex keeps at least a $(1/2 + \varepsilon)$ fraction of its edges. For $\mathcal{P} \in \{\text{push}, \text{pp}\}$ let $\tilde{T}_{\mathcal{P}}$ denote the number of rounds needed to inform at least $n - n/\log n$ vertices. Then whp*

(a) $\tilde{T}_{push}(\tilde{G}_n) = \log_{1+q}(n) + o(\log n)$.

(b) $\tilde{T}_{pp}(\tilde{G}_n) \leq \log_{1+2q}(n) + o(\log n)$, when additionally assuming that $\delta(G_n) \geq \alpha n$ for some constant $0 < \alpha \leq 1$.

We conjecture that there is also a version of Theorem 7b that is true for *push&pull* on sparse graphs; to be precise we conjecture that in the setting of Theorem 7b it is $\tilde{T}_{pp}(\tilde{G}_n) \leq \log_{1+2q}(n) + o(\log n)$, without further restrictions on G_n , i.e. that *push&pull* cannot be slowed down informing *almost* all vertices.

As a final remark note that Theorems 5 and 7 are tight in the sense that if an adversary may delete up to half of the edges at each vertex, then there are expander graphs that become disconnected. On those graphs a linear fraction of the vertices will remain uninformed forever.

Outline

The rest of this paper is structured as follows. The first part of Section 2 contains our technical contribution concerning the analysis through self-bounding functions. In the second part we state the Expander Mixing Lemma and give some applications to our setting with

deleted edges. The remaining sections contain the proofs to the main theorems. The proof of Theorem 4 has two steps: determining the expected growth rates of the number of informed vertices after performing one round, then concluding the proof for the runtime by using the tools developed in Section 2. This proof is not included in this version, here instead we focus on the case with edge deletions, where for every protocol we use a different method to show the claimed results. In Subsection 3.1 we show that edge deletions do not slow down *pull*, by analysing the number of edges between informed and uninformed vertices. Showing that adversarial edge deletions cannot slow down the time until *push* has informed almost all vertices will be archived in Section 3.2 by giving a coupling to the case without edge deletions. Then, in Subsection 3.3 we show that *push&pull* informs almost all vertices of dense graphs fast in spite of adversarial edge deletions. We utilize a version of Szemerédi Regularity Lemma to get a well-behaved partition of the vertex set that is suitable for performing a round based analysis. However, if $q < 1$, adversarial edge deletions can slow down the time until *push&pull* has informed all vertices for nearly all values of q ; we show this in Section 3.4. The same example as given there also yields Theorem a. Finally, an unabridged version of this paper, that contains any proofs that are omitted here, is available at <https://arxiv.org/abs/1902.07618>.

Further Notation

Let $G = (V, E)$ denote a graph with vertex set V and edge set $E \subseteq \binom{V}{2}$. Consider $v \in V$ and $U, W \subseteq V$ with $U \cap W = \emptyset$. We will denote the set of neighbours of v in G by $N_G(v)$ or by $N(v)$ and we will denote its degree by $d_G(v) := |N_G(v)|$ or by $d(v)$; δ_G or δ and Δ_G or Δ denote minimum and maximum degree of G . Similarly the neighbourhood of any set of vertices $S \subseteq V$ is defined by $N_G(S) := \cup_{v \in S} N_G(v)$. Furthermore let $E(U, W) = E_G(U, W)$ denote the set of edges with one vertex in U and one vertex in W and let $e(U, W) := e_G(U, W) := |E_G(U, W)|$. With $E_G(U)$ we denote the set of edges with both vertices in U ; $e_G(U) = |E_G(U)|$. For any round $t \in \mathbb{N}$ and $\mathcal{P} \in \{\text{push}, \text{pull}, \text{pp}\}$, we denote by $I_t^{(\mathcal{P})}(G)$ the set of vertices of G informed by *push*, *pull* and *push&pull* respectively at the beginning of round t and $|I_1^{(\mathcal{P})}| = 1$; if the underlying graph is clear from the context we will omit it; if we consider a sequence of graphs $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ and a sequence of times $t = (t(n))_{n \in \mathbb{N}}$, then $I_t^{(\mathcal{P})}(\mathcal{G}) = (I_{t(n)}^{(\mathcal{P})}(G_n))_{n \in \mathbb{N}}$ is also a sequence. Similarly, $U_t^{(\mathcal{P})} := V \setminus I_t^{(\mathcal{P})}$ denotes the set of uninformed vertices. With \log we refer to the natural logarithm. For any event A we will write $\mathbb{E}_t[A]$ instead of $\mathbb{E}[A|I_t]$ for the conditional expectation and $P_t[A]$ instead of $P[A|I_t]$ for the conditional probability. Finally we want to clarify our use of Landau symbols. Let $a, b \in \mathbb{R}$ and f be a function. The terms $a \leq b + o(f)$ and $a \geq b - o(f)$ mean that there exist positive functions $g, h \in o(f)$ such that $a \leq b + g$ and $a \geq b - h$. Consequently $a = b + o(f)$ means that there exists a positive function $g \in o(f)$ such that $a \in [b - g, b + g]$

2 Tools & Techniques

In this section we collect and prove statements about our protocols and properties of expander sequences. We begin with applying the previously mentioned notion of self-bounding functions to derive universal and simple-to-apply concentration results for our random variables, i.e., the number of informed vertices after a particular round. Then we extend the concentration results to more than one round. In the last part we recall the well known Expander Mixing Lemma and utilize it to derive properties (weak expansion, path enumeration) for the case where we delete edges from our graphs.

Self-bounding functions

Our main technical new result in this section is the following bound on the variance for the number of informed vertices in any given round; it is true for any graph and any set of informed vertices.

► **Lemma 8.** *Let G be a graph, $t \in \mathbb{N}$ and $I_t = I_t^{(\mathcal{P})}(G)$ for $\mathcal{P} \in \{\text{push}, \text{pull}, \text{pp}\}$. Then*

$$\text{Var}[|I_{t+1}| | I_t] \leq \mathbb{E}[|I_{t+1}| | I_t].$$

Lemma 8 follows directly from Lemmas 10 and 11. Before stating them we introduce the notion of self-bounding functions.

► **Definition 9** (Self-bounding function). *Let X be a set and $m \in \mathbb{N}$. A non-negative function $f : X^m \rightarrow \mathbb{R}$ is self-bounding, if there exist functions $f_i : X^{m-1} \rightarrow \mathbb{R}$ such that for all $x_1, \dots, x_m \in X$ and all $i = 1, \dots, m$*

$$0 \leq f(x_1, \dots, x_m) - f_i(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_m) \leq 1$$

and

$$\sum_{1 \leq i \leq m} (f(x_1, \dots, x_m) - f_i(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_m)) \leq f(x_1, \dots, x_m).$$

A striking property of self-bounding function is the following bound on the variance.

► **Lemma 10** ([3]). *For a self-bounding function f and independent random variables X_1, \dots, X_m , $m \in \mathbb{N}$*

$$\text{Var}[f(X_1, \dots, X_m)] \leq \mathbb{E}[f(X_1, \dots, X_m)].$$

► **Lemma 11.** *Let G be a graph, $t \in \mathbb{N}$, and let $I_t = I_t^{(\mathcal{P})}(G)$ for $\mathcal{P} \in \{\text{push}, \text{pull}, \text{pp}\}$. Then, conditional on I_t , there exist $m \in \mathbb{N}$, independent random variables X_1, \dots, X_m and a self-bounding function $f = f^{(\mathcal{P})}$ such that $|I_{t+1}| = f(X_1, \dots, X_m)$.*

► **Remark 12.** Let $G = (V, E)$ be a graph. Lemma 11 also applies to subsets of I_{t+1} , i.e. for any $U \subset V$ and conditioned on I_t we have that $|I_{t+1} \cap U|$ and $|(I_{t+1} \cap U) \setminus I_t|$ are self-bounding.

The following lemma gives a tool that we will use in order to extend our round-wise analysis to longer phases.

► **Proposition 13.** *Let $\mathcal{P} \in \{\text{push}, \text{pull}, \text{pp}\}$, $I_t = I_t^{(\mathcal{P})}$ and $t_1 \geq t_0 \geq 1$ such that $|I_{t_0}| \geq \sqrt{\log n}$. Let further $(\mathcal{A}_i)_{i \in \mathbb{N}}$ be a sequence of events, $c > 1$, and $\delta > 0$ such that*

$$P_{t_0}[\mathcal{A}_t | \mathcal{A}_{t_0}, \dots, \mathcal{A}_{t-1}] \geq 1 - \delta (c^{t-t_0} |I_{t_0}|)^{-1/3} \quad \text{for all } t_0 \leq t \leq t_1.$$

Then

$$P_{t_0} \left[\bigcap_{t=t_0}^{t_1} \mathcal{A}_t \right] \geq 1 - O(|I_{t_0}|^{-1/3})$$

We give two typical example applications of this lemma below. The first example addresses the case where we have a lower bound for the expected number of informed vertices after one round.

► **Example 14.** Let $\mathcal{P} \in \{\text{push}, \text{pull}, \text{pp}\}$, $I_t = I_t^{(\mathcal{P})}$. Assume that there is some $c > 1$ such that $\mathbb{E}_t [|I_{t+1}|] \geq c|I_t|$ for all t as long as $n/f(n) \leq |I_t| \leq n/g(n)$ for some functions $1 \leq f, g \leq n$, $f = o(n)$. Let t_0 be such that $|I_{t_0}| \geq n/f(n)$. Then according to Lemma 8 we have that $\text{Var}_t [|I_{t+1}|] \leq \mathbb{E}_t [|I_{t+1}|]$ and applying Chebychev's inequality gives

$$P_t \left[\left| |I_{t+1}| - \mathbb{E}_t [|I_{t+1}|] \right| \leq \mathbb{E}_t [|I_{t+1}|]^{2/3} \right] \geq 1 - \mathbb{E}_t [|I_{t+1}|]^{-1/3} \geq 1 - |I_t|^{-1/3}. \quad (1)$$

Consider the events

$$\mathcal{A}_t = \left[|I_t| \geq \mathbb{E}_{t-1} [|I_t|] - \mathbb{E}_{t-1} [|I_t|]^{2/3} \quad \text{or} \quad |I_t| \geq n/g(n) \right]$$

The intersection of $\mathcal{A}_{t_0+1}, \dots, \mathcal{A}_t$ implies inductively that either $|I_t| \geq n/g(n)$ or

$$|I_t| \geq \left(1 - \mathbb{E}_{t-1} [|I_t|]^{-1/3} \right) \mathbb{E}_{t-1} [|I_t|] \geq \left((1 - (c|I_{t_0}|)^{-1/3})c \right)^{t-t_0} |I_{t_0}|.$$

We obtain with (1)

$$P_{t_0} [\mathcal{A}_{t+1} \mid \mathcal{A}_{t_0+1}, \dots, \mathcal{A}_t, |I_t| < n/g(n)] \geq 1 - \left((1 - (c|I_{t_0}|)^{-1/3})c \right)^{-(t-t_0)/3} |I_{t_0}|^{-1/3},$$

and otherwise $P_{t_0} [\mathcal{A}_{t+1} \mid \mathcal{A}_{t_0+1}, \dots, \mathcal{A}_t, |I_t| \geq n/g(n)] = 1$. Choose $\tau := t - t_0 = \log_c(f(n)/g(n)) + o(\log n)$ as small as possible such that this lower bound for $|I_{t+1}|$ is $\geq n/g(n)$, that is, this lower bound is $< n/g(n)$ for $t = t_0 + \tau$. Combining the two conditional probabilities we obtain for all $t_0 \leq t \leq t_0 + \tau$

$$P_{t_0} [\mathcal{A}_{t+1} \mid \mathcal{A}_{t_0+1}, \dots, \mathcal{A}_t] \geq 1 - \left((1 - (c|I_{t_0}|)^{-1/3})c \right)^{-(t-t_0)/3} |I_{t_0}|^{-1/3}.$$

Applying Proposition 13 then yields whp

$$|I_{t_0+\tau+1}| \geq n/g(n).$$

In the second example we make the stronger assumption that we can determine asymptotically the expected number of informed vertices after one round. Here we assume that we begin with a “small” set of informed vertices, say of size $\sqrt{\log n}$, and want to reach a set of size nearly linear in n .

► **Example 15.** Assume that there is some $c > 1$ such that $\mathbb{E}_t [|I_{t+1}|] = (1 + o(1))c|I_t|$ for all t as long as $\sqrt{\log n} \leq |I_t| \leq n/\log n$. Let \mathcal{A}_t be the event “ $\left| |I_t| - \mathbb{E}_{t-1} [|I_t|] \right| \leq \mathbb{E}_{t-1} [|I_t|]^{2/3}$ ” and let t_0 be such that $|I_{t_0}| \geq \sqrt{\log n}$. There is $h(n) \in o(1)$ such that for $c^- := (1 - h(n))c$ and $c^+ := (1 + h(n))c$ we have that $\mathbb{E}_t [|I_{t+1}|] \leq c^+ |I_t|$ and $\mathbb{E}_t [|I_{t+1}|] \geq c^- |I_t|$. Using this notation, the events $\mathcal{A}_{t_0+1}, \dots, \mathcal{A}_{t+1}$ imply together inductively that

$$|I_{t+1}| \leq \left(1 + \mathbb{E}_t [|I_{t+1}|]^{-1/3} \right) \mathbb{E}_t [|I_{t+1}|] \leq \left((1 + (c^- |I_{t_0}|)^{-1/3})c^+ \right)^{t-t_0} |I_{t_0}|$$

for all t such that the right-hand side is bounded by $n/\log n$. Moreover, for all such t

$$|I_{t+1}| \geq \left(1 - \mathbb{E}_t [|I_{t+1}|]^{-1/3} \right) \mathbb{E}_t [|I_{t+1}|] \geq \left((1 - (c^- |I_{t_0}|)^{-1/3})c^- \right)^{t-t_0} |I_{t_0}|.$$

Thus, as \mathcal{A}_t only depends on I_t it follows with (1)

$$P_{t_0} [\mathcal{A}_{t+1} \mid \mathcal{A}_{t_0+1}, \dots, \mathcal{A}_t] \geq 1 - \left((1 - (c^- |I_{t_0}|)^{-1/3})c^- \right)^{-(t-t_0)/3} |I_{t_0}|^{-1/3}.$$

Applying Proposition 13 then immediately gives that there is $\tau_1 = \log_c(n/|I_{t_0}|) + o(\log n)$ such that whp $|I_{t_0+\tau_1}| \leq n/\log n$. Example 14, setting $f = n/\sqrt{\log n}$ and $g = \log n$, gives an additional $\tau_2 = \log_c(n/|I_{t_0}|) + o(\log n)$ such that $|\tau_1 - \tau_2| = o(\log n)$ and whp

$$|I_{t_0+\tau_1}| \leq \frac{n}{\log n} \leq |I_{t_0+\tau_2}|.$$

Expander Sequences

In this section we collect some important properties of expander sequences that we are going to use later. We start by stating a version of the well-known expander mixing lemma applied to our setting of expander sequences.

► **Lemma 16** ([25, Cor. 2.4]). *Let $\mathcal{G} = (G_n)_{n \in \mathbb{N}} = ((V_n, E_n))_{n \in \mathbb{N}}$ be an expander sequence. Then for $S_n \subseteq V_n$ such that $1 \leq |S_n| \leq n/2$ it is*

$$\left| e(S_n, V_n \setminus S_n) - \frac{\Delta_n |S_n| (n - |S_n|)}{n} \right| = o(\Delta_n) |S_n|.$$

The following result is a consequence of the Expander Mixing Lemma that applies to graphs in which some edges were removed. It seems very simple but it turns out to be surprisingly useful.

► **Lemma 17.** *Let $\mathcal{G} = (G_n)_{n \in \mathbb{N}} = ((V_n, E_n))_{n \in \mathbb{N}}$ be an expander sequence. Let $\varepsilon > 0$ and set $\tilde{\mathcal{G}} = (\tilde{G}_n)_{n \in \mathbb{N}}$, where each \tilde{G}_n it is obtained from G_n by deleting edges such that each vertex keeps at least a $(1/2 + \varepsilon)$ fraction of its edges. For each $n \in \mathbb{N}$ let further $S_n \subseteq V_n$, then there is $n_0 \in \mathbb{N}$ such that for all $n \geq n_0$*

$$e_{\tilde{G}_n}(S_n, V_n \setminus S_n) \geq \varepsilon e_{G_n}(S_n, V_n \setminus S_n).$$

3 Proofs

3.1 Proof of Theorems 4b, 5a – edge deletions do not slow down pull

Let $0 < \varepsilon \leq 1/2$. In this section we study the runtime of *pull* in the case in which the input graph is an expander, and where at each vertex at most an $(1/2 - \varepsilon)$ fraction of the edges is deleted. The runtime on expander sequences without edge deletions, that is, the setting in Theorem 4b, is included as the special case where we set $\varepsilon = 1/2$. In contrast to previous proofs, in the analysis of *pull* the “standard” approach that consists of showing, for example, that $\mathbb{E}_t[|I_{t+1} \setminus I_t|] \approx |I_t|$ fails. The main reason is that the graph between I_t and U_t might be quite irregular, so that, depending on the actual state, $\mathbb{E}_t[|I_{t+1} \setminus I_t|] \approx c|I_t|$ for some $c < 1$. However, we discover a different invariant that is preserved, namely that the number of edges between I_t and U_t behaves in an exponential way. With Lemmas 16 and 17 we can then relate this to the number of informed vertices.

► **Lemma 18.** *Consider the setting of Theorem 5a and let $I_t = I_t^{(pull)}$.*

(a) *Let $\sqrt{\log n} \leq |I_t| \leq n/\log n$. Then $|e(U_{t+1}, I_{t+1}) - (1+q)e(U_t, I_t)| \leq |I_t|^{-1/3} e(U_t, I_t)$ with probability at least $1 - O(|I_t|^{-1/3})$.*

(b) *Let $|U_t| \leq n/\log n$. Then $\mathbb{E}_t[|U_{t+1}|] = (1 - q + o(1))|U_t|$.*

Lemma 19 gives a lower bound, that together with an upper bound provided by Lemma 20 imply Theorems 4b and 5a.

► **Lemma 19** (Upper bound in Theorem 5a). *Consider the setting of Theorem 5a and let $I_t = I_t^{(pull)}$, then the following statements hold whp.*

(a) *Let $\sqrt{\log n} \leq |I_t| \leq n/\log n$. Then there are $\tau_1, \tau_2 = \log_{1+q}(n/|I_t|) + o(\log n)$ such that $|I_{t+\tau_2}| < n/\log n < |I_{t+\tau_1}|$.*

(b) *Let $n/\log n \leq |I_t| \leq n - n/\log n$. Then there is $\tau = o(\log n)$ such that $|I_{t+\tau}| > n - n/\log n$.*

(c) *Let $|I_t| \geq n - n/\log n$.*

1. *Case $q = 1$: Then there is $\tau = o(\log n)$ such that $|I_{t+\tau}| = n$.*

2. *Case $q \neq 1$: Then there is $\tau \leq -\log n / \log(1 - q) + o(\log n)$ such that $|I_{t+\tau}| = n$.*

36:10 Robustness of Randomized Rumour Spreading

Note that for $q = 1$ this already implies Theorems 4b and 5a. This leaves the case for $q \neq 1$.

► **Lemma 20.** *Let $0 < \varepsilon \leq 1/2, q \in (0, 1]$ and $\mathcal{G} = (G_n)_{n \in \mathbb{N}}$ be an expander sequence. Let $\tilde{\mathcal{G}} = (\tilde{G}_n)_{n \in \mathbb{N}}$ be such that each \tilde{G}_n is obtained by deleting edges of G_n such that each vertex keeps at least a $(1/2 + \varepsilon)$ fraction of its edges and abbreviate $I_t = I_t^{(pull)}$. Let further $q \in (0, 1)$ and $|I_t| \leq n/2$. Then for $\tau = -\log n / \log(1 - q)$ and all $c < 1$ whp $|I_{t+c\tau}| < n$.*

3.2 Proof of Theorem 7a – push informs almost all vertices fast in spite of edge deletions

To shorten the notation let us call the setting with deleted edges “new model” and the setting without “old model”, that is, the term new model corresponds to the graphs in $\tilde{\mathcal{G}}$, while old model refers to the (original) graphs in \mathcal{G} . We prove Lemma 21 that directly implies Theorem a. We write $I_t = I_t^{(push)}$ throughout.

► **Lemma 21.** *Under the assumptions of Theorem 7a the following holds for the new model:*

(a) *There are $\tau, \tilde{\tau} = \log_{1+q}(n) + o(\log n)$ such that whp $|I_{\tilde{\tau}}| < n / \log n < |I_{\tau}|$.*

(b) *Assume $|I_t| \geq n / \log n$. Then there is a $\tau = o(\log n)$ such that whp $|I_{t+\tau}| \geq n - n / \log n$.*

For the proof of Lemma 21 we will need the following statements, the first one taken from [25].

► **Lemma 22** (Proof of Lemma 2.5 in [25]). *Consider the old model. Assume $|I_t| < n / \log n$ and $q = 1$. Then*

$$P_t[|I_{t+1}| = |I_t| + (1 - o(1))|I_t|] = 1 - o(1). \quad (2)$$

► **Lemma 23.** *Consider push on a sequence of graphs $(G_n)_{n \in \mathbb{N}}$, where G_n has n vertices. Assume that $|I_t| = \omega(1)$ and that (2) holds for $q = 1$, that is, assume that $P_t[|I_{t+1}| = |I_t| + (1 - o(1))|I_t|] = 1 - o(1)$ for $q = 1$. Then for $q \in (0, 1]$*

$$P_t[|I_{t+1}| = |I_t| + (q - o(1))|I_t|] = 1 - o(1). \quad (3)$$

Moreover, assume that whenever $|I_t| < n / \log n$, for $q = 1$, (2) holds. Then there are $\tau, \tilde{\tau} = \log_{1+q}(n) + o(\log n)$ such that whp

$$|I_{\tilde{\tau}}| < n / \log n < |I_{\tau}|. \quad (4)$$

3.3 Proof of Theorems 5b, 7b – push&pull informs almost all vertices fast in spite of edge deletions

Before we show the actual proof we will first present an informal argument that contains all relevant ideas and important observations. Let $\sqrt{\log n} \leq |I_t| \leq n / \log n$ and assume $q = 1$. In Section 3.2 we proved that for *push* the informed vertices nearly double in every round for an arbitrary expander sequence with edge deletions and an otherwise arbitrary set I_t . For *pull* this is not true; however, we proved in Section 3.1 that the number of edges between the informed and the uninformed vertices nearly doubles in every round. The first attempt towards the proof of Theorems b, b then seems obvious: one would try to show that either the vertices triple every round, or the edges do so, or for example that the product of the two quantities increases by a factor of 9. As it turns out, this is in general not the case; indeed, it is possible to choose an expander sequence, to delete edges such that each vertex keeps at least an $(1/2 + \varepsilon)$ -fraction of its neighbors, and to choose a (large) set of informed vertices I_t such that after one round whp either $|I_{t+1}| < c|I_t|$ or $e(I_{t+1}, U_{t+1}) < ce(I_t, U_t)$ or

$|I_{t+1}|e(I_{t+1}, U_{t+1}) < c^2|I_t|e(I_t, U_t)$ for some $c < 3$. On the other hand and although we have no explicit description of these “malicious” sets, it seems rather unlikely that such sets will occur several times during the execution of *push&pull*.

In order to show the claimed running time of *push&pull* we will impose some additional structure. Let $\varepsilon > 0$. In the subsequent exposition we assume that our graph G – obtained from an expander by deleting edges such that each vertex keeps at least an $(1/2 + \varepsilon)$ fraction of the edges – has a *very special* structure. In particular, we assume that there is a partition $\Pi = (V_i)_{i \in [k]}$ of the vertex set of G into a bounded number k of equal parts such that $E_G(V_i) = \emptyset$ for all $1 \leq i \leq k$ and such that the induced subgraph (V_i, V_j) looks like a random regular bipartite graph for all $1 \leq i < j \leq k$. Of course, not every relevant G admits such a partition; however, Szemerédi’s regularity lemma guarantees that every sufficiently large graph has a partition that is in a well-defined sense *almost* like the one described previously, and a substantial part of our proof is concerned with showing that being “almost special” does not hurt significantly.

Assuming that G is very special let us collect some easy facts. Denote the degree of $u \in V_i$ in the induced subgraph (V_i, V_j) with d_{ij} ; this immediately gives that $d_G(u) = \sum_{\ell=1}^k d_{i\ell}$, and note that $d_{ii} = 0$ as there are no edges in V_i . Moreover, regular bipartite random graphs satisfy an expander property, that is, for all $W_i \subseteq V_i, W_j \subseteq V_j, 1 \leq i < j \leq k$ we have

$$e(W_i, W_j) = d_{i,j}|W_i||W_j|/|V_j| + o(d_{i,j})|W_i| \approx |W_i||W_j|d_{ij}k/n$$

where we used that all $|V_i|$ ’s are of equal size. This is quite similar to the property that we used in our preceding analysis on expander sequences, see Lemma 16. As a pair in Π behaves like a bipartite expander sequence we can easily compute the expected number of informed vertices. We do so now for *pull*. Let $|I_{t+1}^{i,j}|$ be the number of vertices in V_i informed after round $t + 1$ by *pull* from vertices only in V_j and set $I_t^i := I_t \cap V_i, U_t^i := U_t \cap V_i \forall 1 \leq i \leq k$. Thus, as long as I_t^i is much smaller than V_i (and thus also $U_t^i \approx |V_i| = n/k$) we get

$$\mathbb{E}_t \left[|I_{t+1}^{(pull),i,j} \setminus I_t^i| \right] = \sum_{u \in U_t^i} \frac{|N(u) \cap I_t^j|}{d(u)} = \frac{e(U_t^i, I_t^j)}{\sum_{1 \leq \ell \leq k} d_{i\ell}} \approx \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{i\ell}} |I_t^j|.$$

A similar calculation, which we don’t perform in detail, yields for *push*

$$\mathbb{E}_t \left[|I_{t+1}^{(push),i,j} \setminus I_t^i| \right] \approx \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{\ell j}} |I_t^j|.$$

Moreover, as in previous proofs it turns out that the number of vertices informed simultaneously by *push* as well as *pull* is negligible. Thus we obtain that more or less

$$\mathbb{E}_t \left[|I_{t+1}^{(pp),i,j}| \right] \approx |I_t^i| + \left(\frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{i\ell}} + \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{\ell j}} \right) |I_t^j|$$

and by linearity of expectation

$$\mathbb{E}_t \left[|I_{t+1}^{(pp),i}| \right] \approx |I_t^i| + \sum_{1 \leq j \leq k} \left(\frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{i\ell}} + \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{\ell j}} \right) |I_t^j|.$$

Set $X_t = (|I_t^i|)_{i \in [k]}$ and $A = (A_{ij})_{1 \leq i, j \leq k}$, the matrix with entries

$$A_{ij} = \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{i\ell}} + \frac{d_{ij}}{\sum_{1 \leq \ell \leq k} d_{\ell j}} \quad \text{for } 1 \leq i \neq j \leq k$$

36:12 Robustness of Randomized Rumour Spreading

and $A_{ii} = 1$ for $1 \leq i \leq k$. With this notation we obtain the recursive relation

$$\mathbb{E}_t[X_{t+1}] \approx A \cdot X_t, \quad (5)$$

that is, we may expect that $X_t \approx \mathbb{E}_t[X_t] \approx A^t X_0$. If we then denote by λ_{\max} the greatest eigenvalue of A , then we obtain that in leading order

$$|I_t| \approx \lambda_{\max}^t.$$

Our aim is to show that *push&pull* is (at least) as fast as on the complete graph, that is, $|I_t| \lesssim 3^t$, and so we take a closer look at the eigenvalues of A . By construction A is symmetric, so that the largest eigenvalue equals $\sup_{\|x\|=1} \|x^T A x\|$, and the simple choice $x = k^{-1/2} \mathbf{1}$ yields

$$\begin{aligned} \lambda_{\max} &\geq \frac{\sum_{(i,j)} A_{i,j}}{k} \\ &= \frac{\sum_{j=1}^k 1 + \sum_{i=1}^k \sum_{j=1}^k d_{ij} / \left(\sum_{\ell=1}^k d_{i\ell} \right) + \sum_{j=1}^k \sum_{i=1}^k d_{ij} / \left(\sum_{\ell=1}^k d_{\ell j} \right)}{k} = 3. \end{aligned}$$

This neat property leads us to the expected result $T_{pp}(G) = (1 + o(1)) \log_{\lambda_{\max}} n \leq (1 + o(1)) \log_3 n$, and it also completes the informal argument that justifies the claim made in Theorems 5b and 7b. In the unabridged version we turn this argument step by step into a formal proof by filling in all missing pieces.

3.4 Proof of Theorem 6b – edge deletions may slow down *push&pull*

For any $0 < \varepsilon < 1/2$, $q \in (0, 1)$ we consider a sequence of graphs $(G_n(\varepsilon))_{n \in \mathbb{N}} = ((V_n, E_n))_{n \in \mathbb{N}}$. Let $V_n = A_n \cup B_n$ with $A_n := \{1, \dots, \lfloor n/2 \rfloor\}$, $B_n := \{\lfloor n/2 \rfloor + 1, \dots, n\}$ and $\deg(v) = n - 1$ for all $v \in A_n$. Let the induced subgraph of B_n be a random graph in which each edge is included independently with probability $p = 1 - 2\varepsilon$. We know and it is easy to show, see for example [15, Section IV], that whp this subgraph is almost regular, i.e.,

$$d_{B_n}(v) = (1 + o(1))(1 - 2\varepsilon)n/2 \quad \text{for all } v \in B_n, \quad (6)$$

and is an expander, which means that for every $S_n \subseteq B_n$, $1 \leq |S_n| \leq n/4$ and $d_{B_n} := (1 - 2\varepsilon)n/2$ we have

$$e(S_n, B_n \setminus S_n) = (1 + o(1)) \frac{d_{B_n} |S_n| |B_n \setminus S_n|}{|B_n|} = (1 - 2\varepsilon + o(1)) |S_n| |B_n \setminus S_n|. \quad (7)$$

At first we give a statement that describes the expected number of informed vertices after performing one round of *push&pull*.

► **Lemma 24.** *Let $G_n(\varepsilon) = (A_n \cup B_n, E_n)$ be as above.*

(a) *Let $\sqrt{\log n} \leq |I_t| \leq n/\log n$ and set*

$$X_t = \left(|I_t^{(pp),(A)}|, |I_t^{(pp),(B)}| \right) := \left(|I_t^{(pp)} \cap A_n|, |I_t^{(pp)} \cap B_n| \right).$$

Then $\mathbb{E}_t[X_{t+1}] = (1 + o(1)) M X_t$, where

$$M = \begin{pmatrix} 1 + q & q(1 + \varepsilon/(2 - 2\varepsilon)) \\ q(1 + \varepsilon/(2 - 2\varepsilon)) & 1 + q(1 - 2\varepsilon/(2 - 2\varepsilon)) \end{pmatrix}.$$

(b) *Let $|U_t^{(pp)}| \leq n/\log n$. Then $\mathbb{E}_t[|U_{t+1}^{(pp)}|] \leq (1 + o(1)) e^{-q(1/2 + (1/2 - \varepsilon)/(1 - \varepsilon))} (1 - q) |U_t|$.*

► Remark 25. Let λ_{\max} be the greatest eigenvalue of M as defined in Lemma 24a. Then

$$\lambda_{\max} = 1 + 2q + (2q(\sqrt{(\varepsilon^2/2 - \varepsilon + 1)} - 1) + q\varepsilon)/(2 - 2\varepsilon) > 1 + 2q.$$

Next comes a lemma that bounds the runtime of *push&pull* on $G_n(\varepsilon)$. In particular, Lemma 26 a) and c) provide a lower bound on the runtime and Lemma 26 a), b) and d) provides an upper bound.

► **Lemma 26.** Let $I_t = I_t^{(pp)}$, $\varepsilon > 0$ and $\lambda = \lambda_{\max}(M)$ be the greatest eigenvalue of M as given in Lemma 24a. Consider $G_n(\varepsilon)$.

- (a) Let $\sqrt{\log n} \leq |I_t| \leq n/\log n$. Then there are $\tau_1, \tau_2 = \log_\lambda(n/|I_t|) + o(\log n)$ such that $|I_{t+\tau_1}| < n/\log n < |I_{t+\tau_2}|$.
- (b) Let $n/\log n \leq |I_t| \leq n - n/\log n$. Then there is $\tau = o(\log n)$ such that $|I_{t+\tau}| > n - n/\log n$.
- (c) Let $|I_t| \leq n/\log n$. Then there is $\tau \geq \log n / \log((1 - q)^{-1} \exp(q(1/2 + (1/2 - \varepsilon)/(1 - \varepsilon)))) - o(\log n)$ such that $|I_{t+\tau}| < n$.
- (d) Let $|I_t| \geq n - n/\log n$ and $q \in (0, 1)$. Then there is $\tau \leq \log n / \log((1 - q)^{-1} \exp(q(1/2 + (1/2 - \varepsilon)/(1 - \varepsilon)))) + o(\log n)$ such that $|I_{t+\tau}| = n$.

Lemma 26 gives that

$$T_{pp}(G_n(\varepsilon), q) = \log_\lambda n + \frac{1}{q(1 - 1.5\varepsilon)/(1 - \varepsilon) - \log(1 - q)} \log n + o(\log n)$$

where $\lambda = 1 + 2q + (2q(\sqrt{(\varepsilon^2/2 - \varepsilon + 1)} - 1) + q\varepsilon)/(2 - 2\varepsilon) > 1 + 2q$. To see whether *push&pull* actually slowed down (in terms of order $\log n$) one has to compare the runtime on this sequence of graphs to $c_{pp}(q) \log n$; the runtime on expander sequences. In the Figure 1 we can see that it slows down for nearly all values of ε and q in question; however, there are admissible values of ε and q such that the process even speeds up.

■ **Figure 1** Plotted values of Δ in $T_{pp}(G_n(\varepsilon), q) - c_{pp} \log n = \Delta \log n + o(\log n)$, for $0.9 < q < 1$ and $0 < \varepsilon < 1/2$.

Abstract

We develop a framework for generalizing approximation algorithms from the structural graph algorithm literature so that they apply to graphs somewhat close to that class (a scenario we expect is common when working with real-world networks) while still guaranteeing approximation ratios. The idea is to **edit** a given graph via vertex- or edge-deletions to put the graph into an algorithmically tractable class, apply known approximation algorithms for that class, and then **lift** the solution to apply to the original graph. We give a general characterization of when an optimization problem is amenable to this approach, and show that it includes many well-studied graph problems, such as INDEPENDENT SET, VERTEX COVER, FEEDBACK VERTEX SET, MINIMUM MAXIMAL MATCHING, CHROMATIC NUMBER, (ℓ) -DOMINATING SET, EDGE (ℓ) -DOMINATING SET, and CONNECTED DOMINATING SET.

To enable this framework, we develop new editing algorithms that find the approximately-fewest edits required to bring a given graph into one of a few important graph classes (in some cases these are bicriteria algorithms which simultaneously approximate both the number of editing operations and the target parameter of the family). For bounded degeneracy, we obtain an $O(r \log n)$ -approximation and a bicriteria $(4, 4)$ -approximation which also extends to a smoother bicriteria trade-off. For bounded treewidth, we obtain a bicriteria $(O(\log^{1.5} n), O(\sqrt{\log w}))$ -approximation, and for bounded pathwidth, we obtain a bicriteria $(O(\log^{1.5} n), O(\sqrt{\log w} \cdot \log n))$ -approximation. For treedepth 2 (related to bounded expansion), we obtain a 4-approximation. We also prove complementary hardness-of-approximation results assuming $P \neq NP$: in particular, these problems are all log-factor inapproximable, except the last which is not approximable below some constant factor 2 (assuming UGC).

1 Introduction

Network science has empirically established that real-world networks (social, biological, computer, etc.) exhibit sparse structure. Theoretical computer science has shown that graphs with certain structural properties enable significantly better approximation algorithms for hard problems. Unfortunately, the experimentally observed structures and the theoretically required structures are generally not the same: mathematical graph classes are rigidly defined, while real-world data is noisy and full of exceptions. This paper provides a framework for extending approximation guarantees from existing rigid classes to broader, more flexible graph families that are more likely to include real-world networks.

Specifically, we hypothesize that most real-world networks are in fact **small perturbations of graphs from a structural class**, that is, a family of graphs which adhere to some specified structure (e.g. treewidth at most w) [9, 29]. Intuitively, these perturbations may be exceptions caused by unusual/atypical behavior (e.g., weak links rarely expressing themselves), natural variation from an underlying model, or noise caused by measurement error or uncertainty. Formally, a graph is γ -close to a structural class \mathcal{C} , where $\gamma \in \mathbb{N}$, if some γ edits (e.g., vertex deletions, edge deletions, or edge contractions) bring the graph into class \mathcal{C} ¹. (Other papers call this the “noisy setting” [44, 12, 4].)

Our goal is to extend existing approximation algorithms for a structural class \mathcal{C} to apply more broadly to graphs γ -close to \mathcal{C} . To achieve this goal, we need two algorithmic ingredients:

1. **Editing algorithms.** Given a graph G that is γ -close to a structural class \mathcal{C} , find a sequence of $f(\gamma)$ edits that result in a member of \mathcal{C} . When the structural class is parameterized (e.g., treewidth $\leq w$), we may also approximate those parameters.
2. **Structural rounding algorithms.** Develop approximation algorithms for optimization problems on graphs γ -close to a structural class \mathcal{C} by converting ρ -approximate solutions on an edited graph in class \mathcal{C} into $g(\rho, \gamma)$ -approximate solutions on the original graph.

1.1 Our Results: Structural Rounding

In Section 4, we present a general metatheorem giving sufficient conditions for an optimization problem to be amenable to the structural rounding framework. Specifically, if a problem Π has an approximation algorithm in structural class \mathcal{C} , the problem and its solutions are “stable” under an edit operation, and there is an α -approximate algorithm for editing to \mathcal{C} , then we get an approximation algorithm for solving Π on graphs γ -close to \mathcal{C} . The new approximation algorithm incurs an additive error of $O(\gamma)$, so we preserve PTAS-like $(1 + \varepsilon)$ approximation factors provided $\gamma \leq \delta \text{OPT}_{\Pi}$ for a suitable constant $\delta = \delta(\varepsilon, \alpha) > 0$. Our metatheorem generalizes previous analysis of two specific problems [4].

¹ Note that the number of these edits could be super-constant. The number of edits could be as large as $O(m + n)$, the size of the graph.

For example, we obtain $(1 + O(\delta \log^{1.5} n))$ -approximation algorithms for VERTEX COVER, FEEDBACK VERTEX SET, MINIMUM MAXIMAL MATCHING, and CHROMATIC NUMBER on graphs $(\delta \cdot \text{OPT}_{\Pi}(G))$ -close to having treewidth w via vertex deletions (generalizing exact algorithms for bounded treewidth graphs); and we obtain a $(1 - 4\delta)/(4r + 1)$ -approximation algorithm for INDEPENDENT SET on graphs $(\delta \cdot \text{OPT}_{\Pi}(G))$ -close to having degeneracy r (generalizing a $1/r$ -approximation for degeneracy- r graphs). These results use our new algorithms for editing to treewidth- w and degeneracy- r graph classes as summarized next.

1.2 Our Results: Editing

We develop editing approximation algorithms and/or hardness-of-approximation results for six well-studied graph classes: bounded degeneracy, bounded treewidth and pathwidth, bounded clique number, bounded treedepth, bounded weak c -coloring number, and bounded degree. Refer to the full version of this paper ([18]) for details about these classes. Table 1 summarizes our results for the bounded degeneracy and bounded treewidth classes which we use in our structural rounding framework to find approximate solutions for some classic problems. Refer to the full version of this paper ([18]) for an overview of our results for the rest of the aforementioned graph classes.

■ **Table 1** Summary of results for $(\mathcal{C}_{\lambda}, \psi)$ -EDIT problems, i.e. finding the minimum number of ψ -edits needed to obtain a graph in class \mathcal{C}_{λ} (including abbreviations and standard parameter notation). For each combination we give a shorthand problem name in bold (e.g. r -DE-V). “Approx.” denotes a polynomial-time approximation or bicriteria approximation algorithm (see Section 3); “inapprox.” denotes inapproximability assuming $P \neq NP$ unless otherwise specified.

1.3 Related Work

Editing to approximate optimization problems. The most closely related results are in the “noisy setting” introduced by Magen and Moharrami [44], which imagines that the “true” graph lies in the structural graph class that we want, and any extra edges observed in the given graph are “noise.” In this model, Magen and Moharrami [44] developed a PTAS for estimating the *size* of INDEPENDENT SET (IS) in graphs that are δn edits away from a minor-closed graph family (for sufficiently small values of δ). However, they provide no method for actually finding a solution set of vertices that achieves this approximation [44]. Later, Chan and Har-Peled [12] developed a PTAS that returns a $(1 + \varepsilon)$ -approximation to IS in noisy planar graphs. More recently, Bansal et al. [4] developed an LP-based approach for noisy minor-closed IS whose runtime and approximation factor achieve better dependence on δ but only for edge edits. Moreover, they provide a similar guarantee for noisy Max k -CSPs also for edge edits [4]. Their approximation analysis resembles our general analysis of the structural rounding framework.

Another related set of approximation algorithms near a graph class are **parameterized approximations**, meaning that they run in polynomial time only when the number of edits is very small (constant or logarithmic input size). This research direction was initiated by Cai [11]; see the survey and results of Marx [46, Section 3.2] and e.g. [30, 45]. An example of one such result is a $\frac{7}{3}$ -approximation algorithm to Chromatic Number in graphs that become planar after γ vertex edits, with a running time of $f(\gamma) \cdot O(n^2)$, where $f(\gamma)$ is at least $2^{2^{2^{\Omega(\gamma)}}}$ (from the use of Courcelle’s Theorem), limiting its polynomial-time use to when the number of edits satisfies $\gamma = O(\lg \lg \lg n)$. In contrast, our algorithms allow up to δOPT_Π edits.

Editing algorithms. Editing graphs into a desired graph class is an active field of research and has various applications outside of graph theory, including computer vision and pattern matching [28]. In general, the editing problem is to delete a minimum set X of vertices (or edges) in an input graph G such that the result $G[V \setminus X]$ has a specific property. Previous work studied this problem from the perspective of identifying the maximum induced subgraph of G that satisfies a desired “nontrivial, hereditary” property [39, 41, 42, 56]. A graph property π is nontrivial if and only if infinitely many graphs satisfy π and infinitely many do not, and π is hereditary if G satisfying π implies that every induced subgraph of G satisfies π . The vertex-deletion problem for any nontrivial, hereditary property has been shown to be NP-complete [42] and even requires exponential time to solve, assuming the ETH [37]. Approximation algorithms for such problems have also been studied in this domain [27, 43, 52], but in general this problem requires additional restrictions on the input graph and/or output graph properties in order to develop fast algorithms [17, 20, 22, 33, 38, 48, 49, 55].

Much past work on editing is on parameterized algorithms. For example, Dabrowski et al. [17] found that editing a graph to have a given degree sequence is W[1]-complete, but if one additionally requires that the final graph be planar, the problem becomes Fixed Parameter Tractable (FPT). Mathieson [48] showed that editing to degeneracy d is W[P]-hard (even if the original graph has degeneracy $d + 1$ or maximum degree $2d + 1$), but suggests that classes which offer a balance between the overly rigid restrictions of bounded degree and the overly global condition of bounded degeneracy (e.g., structurally sparse classes such as H -minor-free and bounded expansion [51]) may still be FPT. Some positive results on the parameterized complexity of editing to classes can be found in Drange’s 2015 PhD thesis [20]; in particular, the results mentioned include parameterized algorithms for a variety of NP-complete editing problems such as editing to threshold and chain graphs [22], star forests [22], multipartite cluster graphs [25], and \mathcal{H} -free graphs given finite \mathcal{H} and bounded indegree [21].

Our approach differs from this prior work in that we focus on approximations of edit distance that are **polynomial-time approximation algorithms**. There are previous results about approximate edit distance by Fomin et al. [26] and, in a very recent result regarding approximate edit distance to bounded treewidth graphs, by Gupta et al. [31]. Fomin et al. [26] provided two types of algorithms for vertex editing to planar \mathcal{F} -minor-free graphs: a randomized algorithm that runs in $O(f(\mathcal{F}) \cdot mn)$ time with an approximation constant $c_{\mathcal{F}}$ that depends on \mathcal{F} , as well as a fixed-parameter algorithm parameterized by the size of the edit set whose running time thus has an exponential dependence on the size of this edit set. Agrawal et al. [1] recently provided a $O(\log^{1.5} n)$ -approximation via a parameterized algorithm for the WEIGHTED \mathcal{F} VERTEX DELETION problem (among some other problems) where \mathcal{F} is a minor-closed family excluding at least one planar graph.

Gupta et al. [31] strengthen the results in [26] but only in the context of **parameterized approximation algorithms**. Namely, they give a deterministic fixed-parameter algorithm for PLANAR \mathcal{F} -DELETION that runs in $f(\mathcal{F}) \cdot n \log n + n^{O(1)}$ time and an

$O(\log k)$ -approximation where k is the maximum number of vertices in any planar graph in \mathcal{F} ; this implies a fixed-parameter $O(\log w)$ -approximation algorithm with running time $2^{O(w^2 \log w)} \cdot n \log n + n^{O(1)}$ for w -TW-V and w -PW-V. They also show that w -TW-E and w -PW-E have parameterized algorithms that give an absolute constant factor approximation but with running times parameterized by w and the maximum degree of the graph [31]. Finally, they show that when \mathcal{F} is the set of all connected graphs with three vertices, deleting the minimum number of edges to exclude \mathcal{F} as a subgraph, minor, or immersion is APX-hard for bounded degree graphs [31]. Again, these running times are weaker than our results, which give bicriteria approximation algorithms that are polynomial without any parameterization on the treewidth or pathwidth of the target graphs. Here, bicriteria relates to the number of editing operations and the target parameter.

In a similar regime, Bansal et al. [4] studied w -TW-E (which implies an algorithm for w -PW-E) and designed an LP-based bicriteria approximation for this problem. For a slightly different set of problems in which the goal is to exclude a single graph H of size k as a subgraph (H -VERTEX-DELETION), there exists a simple k -approximation algorithm. On the hardness side, Guruswami and Lee [32] proved that whenever H is 2-vertex-connected, it is NP-hard to approximate H -VERTEX-DELETION within a factor of $(|V(H)| - 1 - \varepsilon)$ for any $\varepsilon > 0$ ($|V(H)| - \varepsilon$ assuming UGC). Moreover, when H is a star or simple path with k vertices, $O(\log k)$ -approximation algorithms with running time $2^{O(k^3 \log k)} \cdot n^{O(1)}$ are known [32, 40].

An important special case of the problem of editing graphs into a desired class is the *minimum planarization* problem, in which the target class is planar graphs, and the related application is approximating the well-known *crossing number* problem [15]. Refer to [7, 13, 14, 34, 36, 35, 47, 54] for the recent developments on minimum planarization and crossing number.

2 Techniques

This section summarizes the main techniques, ideas, and contributions in the paper.

2.1 Structural Rounding Framework

The main contribution of our structural rounding framework (Section 4) is establishing the right definitions that make for a broadly applicable framework with precise approximation guarantees. Our framework supports arbitrary graph edit operations and both minimization and maximization problems, provided they jointly satisfy two properties: a combinatorial property called “stability” and an algorithmic property called “structural lifting”. Roughly, these properties bound the amount of change that OPT can undergo from each edit operation, but they are also parameterized to enable us to derive tighter bounds when the problem has additional structure. With the right definitions in place, the framework is simple: edit to the target class, apply an existing approximation algorithm, and lift.

The rest of Section 4 shows that this framework applies to many different graph optimization problems. In particular, we verify the stability and structural lifting properties, and combine all the necessary pieces, including our editing algorithms from Section 5 and existing approximation algorithms for structural graph classes. We summarize all of these results in Table 2 and formally define the framework in Section 4.1.

■ **Table 2** Problems for which structural rounding (Theorem 4.4) results in approximation algorithms for graphs near the structural class \mathcal{C} , where the problem has a $\rho(\lambda)$ -approximation algorithm. We also give the associated stability (c') and lifting (c) constants, which are class-independent. The last column shows the running time of the $\rho(\lambda)$ -approximation algorithm for each problem provided an input graph from class \mathcal{C}_λ . We remark that vertex^* is used to emphasize the rounding process has to pick the set of annotated vertices in the edited set carefully to achieve the associated stability and lifting constants. We provide precise problem statements in the full version of this paper ([18]).

Problem	Edit ψ	c'	c	Class \mathcal{C}_λ	$\rho(\lambda)$	runtime
INDEPENDENT SET (IS)	vertex del.	1	0	degeneracy r	$\frac{1}{r+1}$	polytime
ANNOTATED DOMINATING SET (ADS)	vertex^* del.	0	1	degeneracy r	$O(r)$	polytime [5] ^a
INDEPENDENT SET (IS)	vertex del.	1	0	treewidth w	1	$O(2^w n)$ [2]
ANNOTATED DOMINATING SET (ADS)	vertex^* del.	0	1	treewidth w	1	$O(3^w n)$
ANNOTATED (ℓ -)DOMINATING SET (ADS)	vertex^* del.	0	1	treewidth w	1	$O((2\ell + 1)^w n)$ [10]
CONNECTED DOMINATING SET (CDS)	vertex^* del.	0	3	treewidth w	1	$O(n^w)^b$
VERTEX COVER (VC)	vertex del.	0	1	treewidth w	1	$O(2^w n)$ [2]
FEEDBACK VERTEX SET (FVS)	vertex del.	0	1	treewidth w	1	$2^{O(w)} n^{O(1)}$ [16]
MINIMUM MAXIMAL MATCHING (MMM)	vertex del.	0	1	treewidth w	1	$O(3^w n)^c$
CHROMATIC NUMBER (CRN)	vertex del.	0	1	treewidth w	1	$w^{O(w)} n^{O(1)}$
INDEPENDENT SET (IS)	edge del.	0	1	degeneracy r	$\frac{1}{r+1}$	polytime
DOMINATING SET (DS)	edge del.	1	0	degeneracy r	$O(r)$	polytime [5]
(ℓ -)DOMINATING SET (DS)	edge del.	1	0	treewidth w	1	$O((2\ell + 1)^w n)$ [10]
EDGE (ℓ -)DOMINATING SET (EDS)	edge del.	1	1	treewidth w	1	$O((2\ell + 1)^w n)$ [10]
MAX-CUT (MC)	edge del.	1	0	treewidth w	1	$O(2^w n)$ [19]

^a The approximation algorithm of [5] is analyzed only for DS; however, it is straightforward to show that the same algorithm achieves $O(r)$ -approximation for ADS as well.

^b Our rounding framework needs to solve an annotated version of CDS which can be solved in $O(n^w)$ by modifying the $O(w^w n)$ dynamic-programming approach of DS.

^c The same dynamic-programming approach of DS can be modified to solve ADS and MMM in $O(3^w n)$.

2.2 Editing to Bounded Degeneracy and Degree

We first present a $O(r \log n)$ -approximation algorithm for finding the fewest vertex or edge deletions to reduce the **degeneracy** to a target threshold r . The algorithm is a greedy algorithm over a type of **min-degree ordering** computed via the classic algorithm for finding the degeneracy of a graph G given by Matula and Beck [50]. In addition, we present two constant-factor bicriteria approximation algorithms for the same editing problem to degeneracy r . We provide a summary of the techniques used to obtain our results here; refer to the full version of this paper to see a detailed description of our techniques ([18]). The first approach uses the local ratio technique by Bar-Yehuda et al. [6] to establish that good-enough local choices result in a guaranteed approximation. The second approach is based on rounding a linear-programming relaxation of an integer linear program and works even when the input graph is **weighted** (both vertices and edges are weighted) and the goal is to minimize the total weight of the edit set.

On the lower bound side, we show $o(\log(n/r))$ -approximation is impossible for vertex or edge edits when we forbid bicriteria approximation, i.e., when we must match the target degeneracy r exactly. This result is based on a reduction from SET COVER. A similar reduction proves $o(\log d)$ -inapproximability of editing to maximum degree d , which proves tightness (up to constant factors) of a known $O(\log d)$ -approximation algorithm [23].

2.3 Editing to Bounded Treewidth

We present a bicriteria approximation algorithm in the full version ([18]) for finding the fewest vertex edits to reduce the **treewidth** to a target threshold w . Our approach builds on the deep separator structure inherent in treewidth. We combine ideas from Bodlaender’s $O(\log n)$ -approximation algorithm for treewidth with Feige et al.’s $O(\sqrt{\log w})$ -approximation algorithm for vertex separators [24] (where w is the target treewidth). In the end, we obtain a bicriteria $(O(\log^{1.5} n), O(\sqrt{\log w}))$ -approximation that runs in polynomial time on all graphs (in contrast to many previous treewidth algorithms). The tree decompositions that we generate are guaranteed to have $O(\log n)$ height. As a result, we also show a bicriteria $(O(\log^{1.5} n), O(\sqrt{\log w} \cdot \log n))$ -approximation result for pathwidth, based on the fact that the **pathwidth** is at most the width times the height of a tree decomposition.

On the lower bound side, we prove a $o(\log w)$ -inapproximability result by another reduction from SET COVER. By a small modification, this lower bound also applies to editing to **bounded clique number**.

3 Preliminaries

This section defines several standard notions and graph classes, and is probably best used as a reference. The one exception is Section 3.1, which formally defines the graph-class editing problem $(\mathcal{C}_\lambda, \psi)$ -EDIT introduced in this paper.

Graph notation. We consider finite, loopless, simple graphs. Unless otherwise specified, we assume that graphs are undirected and unweighted. We denote a graph by $G = (V, E)$, and set $n = |V|$, $m = |E|$. Given $G = (V, E)$ and two vertices $u, v \in V$ we denote edges by $e(u, v)$ or (u, v) . We write $N(v) = \{u \mid (u, v) \in E\}$ for the set of neighbors of a vertex v ; the degree of v is $\deg(v) = |N(v)|$. In digraphs, in-neighbors and out-neighbors of a vertex v are defined using edges of the form (u, v) and (v, u) , respectively, and we denote in- and out-degree by $\deg^-(v)$, $\deg^+(v)$, respectively. For the maximum degree of G we use $\Delta(G)$, or just Δ if context is clear. The clique number of G , denoted $\omega(G)$, is the size of the largest clique in G . Given some subset E' of the edges in G , we define $G[E']$ to be the subgraph of G induced on the edge set E' . Note that if every edge adjacent to some vertex v is in $E \setminus E'$, then v does not appear in the vertex set of $G[E']$.

We present below our definitions of editing problems that we consider in this paper. Please refer to the full version of this paper ([18]) for complete definitions of the structural graph classes, hardness reduction techniques, and hard optimization problems for which we provide approximation algorithms.

3.1 Editing Problems

This paper is concerned with algorithms that edit graphs into a desired structural class, while guaranteeing an approximation ratio on the size of the edit set. Besides its own importance, editing graphs into structural classes plays a key role in our structural rounding framework for approximating optimization problems on graphs that are “close” to structural graph classes (see Section 4). The basic editing problem is defined as follows relative to an edit operation ψ such as vertex deletion, edge deletion, or edge contraction:

(\mathcal{C}, ψ) -EDIT parametrised by

Input: An input graph $G = (V, E)$, family \mathcal{C} of graphs, edit operation ψ
Problem: Find k edits $\psi_1, \psi_2, \dots, \psi_k$ such that $\psi_k \circ \psi_{k-1} \circ \dots \circ \psi_2 \circ \psi_1(G) \in \mathcal{C}$.
Objective: Minimize k

We can also loosen the graph class we are aiming for, and approximate the parameter value λ for the family \mathcal{C}_λ . Thus we obtain a **bicriteria problem** which can be formalized as follows:

$(\mathcal{C}_\lambda, \psi)$ -EDIT parametrised by

Input: An input graph $G = (V, E)$, parameterized family \mathcal{C}_λ of graphs, a target parameter value λ^* , edit operation ψ
Problem: Find k edits $\psi_1, \psi_2, \dots, \psi_k$ such that $\psi_k \circ \psi_{k-1} \circ \dots \circ \psi_2 \circ \psi_1(G) \in \mathcal{C}_\lambda$ where $\lambda \geq \lambda^*$.
Objective: Minimize k .

► **Definition 3.1.** An algorithm for $(\mathcal{C}_\lambda, \psi)$ -EDIT is a **(bicriteria) (α, β) -approximation** if it guarantees that the number of edits is at most α times the optimal number of edits into \mathcal{C}_λ , and that $\lambda \leq \beta \cdot \lambda^*$.

See the full version of this paper for a complete list of the problems considered, along with their abbreviations. Recall that $\rho(\lambda)$ is the approximation factor for a problem in class \mathcal{C} . We assume that $\mathcal{C}_i \subseteq \mathcal{C}_j$ for $i \leq j$, or equivalently, that $\rho(\lambda)$ is monotonically increasing in λ .

4 Structural Rounding

In this section, we show how approximation algorithms for a structural graph class can be extended to graphs that are near that class, provided we can find a certificate of being near the class. These results thus motivate our results in later sections about editing to structural graph classes. Our general approach, which we call **structural rounding**, is to apply existing approximation algorithms on the edited (“rounded”) graph in the class, then “lift” that solution to solve the original graph, while bounding the loss in solution quality throughout.

4.1 General Framework

First we define our notion of “closeness” in terms of a general family ψ of allowable graph edit operations (e.g., vertex deletion, edge deletion, edge contraction):

► **Definition 4.1.** A graph G' is **γ -editable** from a graph G under edit operation ψ if there is a sequence of $k \leq \gamma$ edits $\psi_1, \psi_2, \dots, \psi_k$ of type ψ such that $G' = \psi_k \circ \psi_{k-1} \circ \dots \circ \psi_2 \circ \psi_1(G)$. A graph G is **γ -close** to a graph class \mathcal{C} under ψ if some $G' \in \mathcal{C}$ is γ -editable from G under ψ .

To transform an approximation algorithm for a graph class \mathcal{C} into an approximation algorithm for graphs γ -close to \mathcal{C} , we will need two properties relating the optimization problem and the type of edits:

► **Definition 4.2.** A graph minimization (resp. maximization) problem Π is **stable** under an edit operation ψ with constant c' if $\text{OPT}_\Pi(G') \leq \text{OPT}_\Pi(G) + c'\gamma$ (resp. $\text{OPT}_\Pi(G') \geq \text{OPT}_\Pi(G) - c'\gamma$) for any graph G' that is γ -editable from G under ψ . In the special case where $c' = 0$, we call Π **closed** under ψ . When ψ is vertex deletion, closure is equivalent to the graph class defined by $\text{OPT}_\Pi(G) \leq \lambda$ (resp. $\text{OPT}_\Pi(G) \geq \lambda$) being **hereditary**; we also call Π **hereditary**.

► **Definition 4.3.** A minimization (resp. maximization) problem Π can be **structurally lifted** with respect to an edit operation ψ with constant c if, given any graph G' that is γ -editable from G under ψ , and given the corresponding edit sequence $\psi_1, \psi_2, \dots, \psi_k$ with $k \leq \gamma$, a solution S' for G' can be converted in polynomial time to a solution S for G such that $\text{Cost}_\Pi(S) \leq \text{Cost}_\Pi(S') + c \cdot k$ (resp. $\text{Cost}_\Pi(S) \geq \text{Cost}_\Pi(S') - c \cdot k$).

Now we can state the main result of structural rounding:

► **Theorem 4.4 (Structural Rounding Approximation).** Let Π be a minimization (resp. maximization) problem that is stable under the edit operation ψ with constant c' and that can be structurally lifted with respect to ψ with constant c . If Π has a polynomial-time $\rho(\lambda)$ -approximation algorithm in the graph class \mathcal{C}_λ , and $(\mathcal{C}_\lambda, \psi)$ -EDIT has a polynomial-time (α, β) -approximation algorithm, then there is a polynomial-time $((1 + c'\alpha\delta) \cdot \rho(\beta\lambda) + c\alpha\delta)$ -approximation (resp. $((1 - c'\alpha\delta) \cdot \rho(\beta\lambda) - c\alpha\delta)$ -approximation) algorithm for Π on any graph that is $(\delta \cdot \text{OPT}_\Pi(G))$ -close to the class \mathcal{C}_λ .

Proof. We write $\text{OPT}(G)$ for $\text{OPT}_\Pi(G)$. Let G be a graph that is $(\delta \cdot \text{OPT}(G))$ -close to the class \mathcal{C}_λ . By Definition 3.1, the polynomial-time (α, β) -approximation algorithm finds edit operations $\psi_1, \psi_2, \dots, \psi_k$ where $k \leq \alpha\delta \cdot \text{OPT}(G)$ such that $G' = \psi_k \circ \psi_{k-1} \circ \dots \circ \psi_2 \circ \psi_1(G) \in \mathcal{C}_{\beta\lambda}$. Let $\rho = \rho(\beta\lambda)$ be the approximation factor we can attain on the graph $G' \in \mathcal{C}_{\beta\lambda}$.

We prove the case when Π is a minimization problem. The proof of the maximization case can be found in the full version of this paper. Because Π has a ρ -approximation in $\mathcal{C}_{\beta\lambda}$ (where $\rho > 1$), we can obtain a solution S' with cost at most $\rho \cdot \text{OPT}(G')$ in polynomial time. Applying structural lifting (Definition 4.3), we can use S' to obtain a solution S for G with $\text{Cost}(S) \leq \text{Cost}(S') + ck \leq \text{Cost}(S') + c\alpha\delta \cdot \text{OPT}(G)$ in polynomial time. Because Π is stable under ψ with constant c' ,

$$\text{OPT}(G') \leq \text{OPT}(G) + c'k \leq \text{OPT}(G) + c'\alpha\delta \cdot \text{OPT}(G) = (1 + c'\alpha\delta) \text{OPT}(G),$$

and we have

$$\text{Cost}(S) \leq \rho \cdot \text{OPT}(G') + c\alpha\delta \cdot \text{OPT}(G) = (\rho + \rho c'\alpha\delta + c\alpha\delta) \text{OPT}(G),$$

proving that we have a polynomial time $(\rho + (c + c'\rho)\alpha\delta)$ -approximation algorithm as required. ◀

To apply Theorem 4.4, we need four ingredients: (a) a proof that the problem of interest is stable under some edit operation (Definition 4.2); (b) a polynomial-time (α, β) -approximation algorithm for editing under this operation (Definition 3.1); (c) a structural lifting algorithm (Definition 4.3); and (d) an approximation algorithm for the target class \mathcal{C} .

In the remainder of this section, we show how this framework applies to many problems and graph classes, as summarized in Table 2 on page 6. Most of our approximation algorithms depend on our editing algorithms described in Section 5.

Structural rounding for annotated problems. We refer to graph optimization problems where the input consists of both a graph and subset of annotated vertices/edges as **annotated** problems. Hence, in our rounding framework, we have to carefully choose the set of annotated vertices/edges in the edited graph to guarantee small **lifting** and **stability** constants. To emphasize the difference compared to “standard” structural rounding, we denote the edit operations as vertex^* and edge^* in the annotated cases. Moreover, we show that we can further leverage the flexibility of annotated rounding to solve **non-annotated** problems that cannot normally be solved via structural rounding. In the full version of this paper ([18]), we consider applications of annotated rounding for both annotated problems such as ANNOTATED DOMINATING SET and non-annotated problems such as CONNECTED DOMINATING SET.

4.2 Applications: Vertex and Edge Deletions

For each problem, we show stability and structural liftability, and use these to conclude approximation algorithms. Using our structural rounding framework above, we obtain the following results on a broad set of problems for a number of different target classes. We point out that these problems are hard-to-solve on general graphs. Table 2 shows a summary of the set of problems we can obtain efficient approximation algorithms using structural rounding. The full version of this paper ([18]) contains the stability and structural liftability proofs used to obtain the corresponding results stated below.

We first use our structural rounding framework with vertex deletions to obtain the following approximation results.

- **Theorem 4.5.** *For graphs $(\delta \cdot \text{OPT}(G))$ -close to degeneracy r via vertex deletions,*
- INDEPENDENT SET has a $(1 - 4\delta)/(4r + 1)$ -approximation.
 - ANNOTATED DOMINATING SET has $O(r + \delta)$ -approximation.
- For graphs $(\delta \cdot \text{OPT}(G))$ -close to treewidth w via vertex deletions:*
- ANNOTATED (ℓ) -DOMINATING SET has a $(1 + O(\delta \log^{1.5} n))$ -approximation for the case $w\sqrt{\log w} = O(\log_\ell n)$.
 - INDEPENDENT SET has a $(1 - O(\delta \log^{1.5} n))$ -approximation when $w\sqrt{\log w} = O(\log n)$.
 - The problems VERTEX COVER, CHROMATIC NUMBER, and FEEDBACK VERTEX SET have $(1 + O(\delta \log^{1.5} n))$ -approximations when $w\sqrt{\log w} = O(\log n)$.
 - MINIMUM MAXIMAL MATCHING has a $(1 + O(\delta \log^{1.5} n))$ -approximation for the case $w \log^{1.5} w = O(\log n)$.
 - CONNECTED DOMINATING SET has a $(1 + O(\delta \log^{1.5} n))$ -approximation when $w = O(1)$.
- Finally, for graphs $(\delta \cdot \text{OPT}(G))$ -close to planar- H -minor-free via vertex deletions,*
- INDEPENDENT SET has a $(1 - c_H \delta)$ -approximation.
 - The problems VERTEX COVER, MINIMUM MAXIMAL MATCHING, CHROMATIC NUMBER, and FEEDBACK VERTEX SET have $(1 + c_H \delta)$ -approximations.

We now use our structural rounding framework with edge deletions to obtain the following approximation results.

- **Theorem 4.6.** *For graphs $(\delta \cdot \text{OPT}(G))$ -close to degeneracy r via edge deletions,*
- INDEPENDENT SET has a $(1/(3r + 1) - 3\delta)$ -approximation.
 - DOMINATING SET has an $O((1 + \delta)r)$ -approximation.
- For graphs $(\delta \cdot \text{OPT}(G))$ -close to treewidth w via edge deletions,*
- (ℓ) -DOMINATING SET and EDGE (ℓ) -DOMINATING SET have $(1 + O(\delta \log n \log \log n))$ -approximations when $w \log w = O(\log_\ell n)$.
 - MAX-CUT has a $(1 - O(\delta \log n \log \log n))$ -approximation when $w \log w = O(\log n)$.

Although we do not present any editing algorithms for edge contractions, we point out that such an editing algorithm would enable our framework to apply to additional problems such as (WEIGHTED) TSP TOUR, and to apply more efficiently to other problems such as DOMINATING SET (reducing c' from 1 to 0).

5 Editing Algorithms

5.1 Degeneracy: Greedy $O(r \log n)$ -Approximation

In this section, we give a polytime $O(\log n)$ -approximation for reducing the degeneracy of a graph by one using either vertex deletions or edge deletions. More specifically, given a graph $G = (V, E)$ with degeneracy $r + 1$, we produce an edit set X such that $G' = G \setminus X$ has degeneracy r and $|X|$ is at most $O(\log |V|)$ times the size of an optimal edit set. Note that this complements an $o(\log \frac{n}{r})$ -inapproximability result for the same problem.

In general, the algorithm works by computing a vertex ordering and greedily choosing an edit to perform based on that ordering. In our algorithm, we use the **min-degree ordering** of a graph. The **min-degree ordering** is computed via the classic greedy algorithm given by Matula and Beck [50] that computes the degeneracy of the graph by repeatedly removing a minimum degree vertex from the graph. The degeneracy of G , $\text{degen}(G)$, is the maximum degree of a vertex when it is removed. In the following proofs, we make use of the observation that given a min-degree ordering L of the vertices in $G = (V, E)$ and assuming the edges are oriented from smaller to larger indices in L , $\text{deg}^+(u) \leq \text{degen}(G)$ for any $u \in L$.

The first ordering L_0 is constructed by taking a min-degree ordering on the vertices of G where ties may be broken arbitrarily. Using L_0 , an edit is greedily chosen to be added to X . Each subsequent ordering L_i is constructed by taking a min-degree ordering on the vertices of $G \setminus X$ where ties are broken based on L_{i-1} . Specifically, if the vertices u and v have equal degree at the time of removal in the process of computing L_i , then $L_i(u) < L_i(v)$ if and only if $L_{i-1}(u) < L_{i-1}(v)$. The algorithm terminates when the min-degree ordering L_j produces a witness that the degeneracy of $G \setminus X$ is r .

In order to determine which edit to make at step i , the algorithm first computes the forward degree of each vertex u based on the ordering L_i (equivalently, $\text{deg}^+(u)$ when edges are oriented from smaller to larger index in L_i). Each vertex with forward degree $r + 1$ is marked, and similarly, each edge that has a marked left endpoint is also marked. The algorithm selects the edit that **resolves** the largest number of marked edges. We say that a marked edge is **resolved** if it will not be marked in the subsequent ordering L_{i+1} .

We observe that given an optimal edit set (of size k), removing the elements of the set in any order will resolve every marked edge after k rounds (assuming that at most one element from the optimal edit set is removed in each round). If it does not, then the final ordering L_k must have a vertex with forward degree $r + 1$, a contradiction. Let m_i be the number of marked edges based on the ordering L_i . We show that we can always resolve at least $\frac{m_i}{k}$ marked edges in each round, giving our desired approximation (all proofs of this section are deferred to the full version of this paper).

By repeatedly applying the $O(\log n)$ approximation given above, we can edit a graph with arbitrary degeneracy to the class of graphs with degeneracy r .

► **Theorem 5.1.** *There exists an $O(r \cdot \log n)$ -approximation for finding the minimum size edit set to reduce the degeneracy of a graph to r .*

5.2 Treewidth: bicriteria-approximation for vertex deletion

Our method for editing to bounded treewidth exploits the general recursive approach of the approximation algorithms for constructing a tree decomposition [3, 8, 24, 53]. Our algorithm iteratively subdivides the graph, considering $G[V_i]$ in iteration i . We first apply the result of [8, 24] (see Theorem 5.2) to determine if $G[V_i]$ has a tree decomposition with “small” width; if yes, the algorithm removes nothing and terminates. Otherwise, we compute an approximate vertex $(3/4)$ -separator S of $G[V_i]$, remove it from the graph, and recurse on the connected components of $G[V_i \setminus S]$. The full exposition of our results for editing to bounded treewidth and pathwidth graphs are given in the full version of this paper.

■ **Algorithm 1** Approximation for Vertex Editing to Bounded Treewidth Graphs.

```

1: procedure TREEWIDTHNODEEDIT( $G = (V, E), w$ )
2:    $t \leftarrow$  compute  $\text{tw}(G)$   $\triangleright$  refer to Theorem 5.2
3:   if  $t \leq 32c_1 \cdot w\sqrt{\log w}$  then
4:     return  $\emptyset$ 
5:   else
6:      $S \leftarrow$  compute a vertex  $(\frac{3}{4})$ -separator of  $G$  by invoking the algorithm of [24]
7:     let  $G[V_1], \dots, G[V_\ell]$  be the connected components of  $G[V \setminus S]$ .
8:     return  $(\bigcup_{i \leq \ell} \text{TREEWIDTHNODEEDIT}(G[V_i], w)) \cup S$ 
9:   end if
10: end procedure

```

► **Theorem 5.2** ([8, 24]). *There exists an algorithm that, given an input graph G , in polynomial time returns a tree decomposition of G of width at most $c_2 \cdot \text{tw}(G)\sqrt{\log \text{tw}(G)}$ and height $O(\log |V(G)|)$ for a sufficiently large constant c_2 .*

Next, we analyze the performance of Algorithm 1. Our approach relies on known results for **vertex c -separators**, structures which are used extensively in many other algorithms for finding an approximate tree decomposition.

► **Definition 5.3.** *For a subset of vertices W , a set of vertices $S \subseteq V(G)$ is a **vertex c -separator** of W in G if each component of $G[V \setminus S]$ contains at most $c|W|$ vertices of W . The minimum sized vertex c -separator of a graph is a separator with size k , denoted $\text{sep}_c(G)$, where k is the minimum integer such that for any subset $W \subseteq V$ there exists a vertex c -separator of W in G of size k .*

► **Theorem 5.4.** *Algorithm 1 removes at most $O(\log^{1.5} n) \text{OPT}_{w\text{-TW-V}}(G)$ vertices from any n -vertex graph G . The treewidth of the subgraph of G returned by Algorithm 1 is $O(w \cdot \sqrt{\log w})$.*

Abstract

We describe a new family of k -uniform hypergraphs with independent random edges. The hypergraphs have a high probability of being *peelable*, i.e. to admit no sub-hypergraph of minimum degree 2, even when the edge density (number of edges over vertices) is close to 1.

In our construction, the vertex set is partitioned into linearly arranged *segments* and each edge is incident to random vertices of k consecutive segments. Quite surprisingly, the linear geometry allows our graphs to be peeled “from the outside in”. The density thresholds f_k for peelability of our hypergraphs ($f_3 \approx 0.918$, $f_4 \approx 0.977$, $f_5 \approx 0.992$, ...) are well beyond the corresponding thresholds ($c_3 \approx 0.818$, $c_4 \approx 0.772$, $c_5 \approx 0.702$, ...) of standard k -uniform random hypergraphs.

To get a grip on f_k , we analyse an idealised peeling process on the random weak limit of our hypergraph family. The process can be described in terms of an operator on $[0, 1]^{\mathbb{Z}}$ and f_k can be linked to thresholds relating to the operator. These thresholds are then tractable with numerical methods.

Random hypergraphs underlie the construction of various data structures based on hashing, for instance invertible Bloom filters, perfect hash functions, retrieval data structures, error correcting codes and cuckoo hash tables, where inputs are mapped to edges using hash functions. Frequently, the data structures rely on peelability of the hypergraph, or peelability allows for simple linear time algorithms. Memory efficiency is closely tied to edge density while worst and average case query times are tied to maximum and average edge size.

To demonstrate the usefulness of our construction, we used our 3-uniform hypergraphs as a drop-in replacement for the standard 3-uniform hypergraphs in a retrieval data structure by Botelho et al. [8]. This reduces memory usage from $1.23m$ bits to $1.12m$ bits (m being the input size) with almost no change in running time. Using $k > 3$ attains, at small sacrifices in running time, further improvements to memory usage.

1 Introduction

The *core* of a hypergraph $H = (V, E)$ is the largest sub-hypergraph of H with minimum degree at least 2. The core can be obtained by *peeling*, which means repeatedly choosing a vertex of degree 0 or 1 and removing it (and the incident edge if present) from the hypergraph, until no such vertex exists. If the core of H is empty, then H is called *peelable*.

The significance of peelability. Hypergraphs underlie many hashing based data structures and peelability is often necessary for proper operation or allows for simple linear time algorithms. We list a few examples.

- **Invertible Bloom Lookup Tables.** IBLTs [22] are based on Bloomier filters [10] which are based on Bloom filters [4]. Each element is inserted in several random positions in a hash table. Any cell stores the XOR of all elements that have been inserted into it. A LIST-ENTRIES query on an IBLT can recover all elements of the table precisely if the underlying hypergraph is peelable. Among other things, IBLTs have been used to construct error correcting codes [34] and to solve the set reconciliation and straggler identification problems [16].
- **Erasur Correcting Codes.** To construct capacity achieving erasure codes, the authors of [28] consider a hypergraph where V corresponds to parity check bits and E to message bits that were lost during transmission. A message bit is incident to precisely those check bits to which it contributed. Correct decoding hinges on peelability of the hypergraph.
- **Cuckoo Hashing and XORSAT.** In the context of cuckoo hash tables [14, 31, 36] and solving random XORSAT formulas [15, 19, 37], (partial) peelability of the underlying hypergraph makes placing all (some) keys or solving the linear system (eliminating some variables) particularly simple.
- **Retrieval and Perfect Hashing.** The retrieval problem (considered later in Section 7) occurs in the context of constructing perfect hash functions [3, 6, 7, 8, 30]. The known approaches involve finding a solution $z : V \rightarrow R$ for a system $(\sum_{v \in e} z(v) = f(e))_{e \in E}$ of equations where $H = (V, E)$ is a hypergraph, $f : E \rightarrow R$ a function and R a small set. If R is a field, then the incidence matrix of H needs to have full rank over R to guarantee the existence of a solution. If H is peelable however, then the existence of a solution is guaranteed even if R only has a group structure. Moreover, it can be computed in linear time.

In these contexts, the hypergraph typically has vertex set $[n] = \{1, \dots, n\}$ and for each element x of an input set S , an edge $e_x \subset [n]$ is created with incidences chosen via hash functions. For theoretical considerations, the edges $(e_x)_{x \in S}$ are often assumed to be independent random variables. This has proven to be a good model for practical settings, even though perfect independence is not achieved by most practical hash functions. An important choice left to the algorithm designer is the distribution of e_x .

Previous work. If the distribution is such that $\mathcal{O}(n)$ edges have size 2 or less (in particular if H is a graph with $\mathcal{O}(n)$ edges), then – due to the well-known “birthday paradox” – there is a constant probability that an edge is repeated. In that case, H is clearly not peelable. The simplest workable candidate for the distribution of e_x is therefore to pick a constant $k \geq 3$ and let e_x contain k vertices chosen independently and uniformly at random. We refer to these standard hypergraphs as *k-uniform Erdős-Renyi hypergraphs* $H_{n,cn}^k$ where c is the *edge density*, i.e. the number of edges over the number of vertices. Corresponding *peelability thresholds* c_k have been determined in [35] meaning if $c < c_k$ then $H_{n,cn}^k$ is peelable with high probability (whp), i.e. with probability approaching 1 as $n \rightarrow \infty$ and if $c > c_k$ then $H_{n,cn}^k$ is not peelable whp. The largest threshold is $c_3 \approx 0.818$. Since the edge density is often tightly linked to a performance metric (e.g. memory efficiency of a dictionary, rate of a code) a density closer to 1 would be desirable, but we know of only two alternative constructions.

To obtain erasure codes with high rates the authors of [28] construct for any $D \in \mathbb{N}$ hypergraphs with edge sizes in $\{5, \dots, D + 4\}$, average edge size $\approx \ln D + 3$ and edge density $1 - 1/D$ that are peelable whp. In particular, this yields peelable hypergraphs with edge densities arbitrarily close to 1. A downside is that the high maximum edge size can lead to worst case query times of $\Theta(D)$ in certain contexts. Motivated by this, the author of

■ **Table 1** The erosion thresholds er_k and peelability thresholds f_k for k -ary fuse graphs satisfy $b_k \leq er_k \leq f_k \leq c_k^*$. The values B_k play a role in Section 5.

k	3	4	5	6	7
b_k	0.9179352469	0.9767692112	0.9924345766	0.9973757381	0.9990561294
c_k^*	0.9179352767	0.9767701649	0.9924383913	0.9973795528	0.9990637588
B_k	0.9179353065	0.9767711186	0.9924422067	0.9973833675	0.9990713882
$\Rightarrow f_k \approx$	0.917935	0.97677	0.99243	0.99738	0.99906

[39] looked into non-uniform hypergraphs with constant maximum edge size. Focusing on hypergraphs with two admissible edge sizes, he found for example that mixing edges of size 3 and size 21 yields a family of hypergraphs with peelability threshold ≈ 0.92 .

Our construction. In this paper we introduce and analyse a new distribution on edges that yields k -uniform hypergraphs with high peelability thresholds that perform well in practical algorithms.

We call our hypergraphs *fuse graphs* (as in the cord attached to a firecracker). There is an underlying linear geometry and similar to how fire proceeds linearly through a lit fuse, the peeling process proceeds linearly through our hypergraphs, in the sense that vertices on the inside of the line tend to only become peelable after vertices closer to the end of the line have already been removed.

Formally, for $k \geq 3$, $\ell \in \mathbb{N}$ and $c \in \mathbb{R}^+$ we define the family $(F(n, k, c, \ell))_{n \in \mathbb{N}}$ of k -uniform fuse graphs as follows. The vertex set is $V = \{1, \dots, n(\ell + k - 1)\}$ where for $i \in I := \{0, \dots, \ell + k - 2\}$ the vertices $\{in + 1, \dots, (i + 1)n\}$ form the i -th *segment*¹. The edge set E has size $cn\ell$. Each edge $e \in E$ is independently determined by one uniformly random variable $j \in J := \{0, \dots, \ell - 1\}$ denoting the *type* of e and k independent random variables o_0, \dots, o_{k-1} uniformly distributed in $[n]$, yielding $e = \{(j + t)n + o_t \mid t \in \{0, \dots, k - 1\}\}$. In other words, e contains one uniformly random vertex from each segment $j, j + 1, \dots, j + k - 1$. There may be repeating edges but the probability that this happens is $\mathcal{O}(1/n)$. The edge density $c \frac{\ell}{\ell + k - 1}$ approaches c for $\ell \gg k$.

Results. Let the *peelability threshold* for k -ary fuse graphs be defined as

$$f_k := \sup\{c \in \mathbb{R}^+ \mid \forall \ell \in \mathbb{N} : \Pr[F(n, k, c, \ell) \text{ is peelable}] \xrightarrow{n \rightarrow \infty} 1\}.$$

Our Main Theorem relates f_k to the *orientability threshold* c_k^* of k -ary Erdős-Rényi hypergraphs and the *erosion threshold* er_k defined in the technical part of our paper.

► **Theorem 1.** *For any $k \geq 3$ we have $er_k \leq f_k \leq c_k^*$.*

The orientability thresholds c_k^* are known exactly [11, 19, 20] and we determine lower bounds on the erosion thresholds er_k . As shown in Table 1, this makes it possible to narrow down f_k to an interval of size 10^{-5} for all $k \in \{3, \dots, 7\}$.

¹ Denoting the segment size by n instead of the number of vertices is more convenient. Note that $|V| = \Theta(n)$ still holds.

Outline. The paper is organised as follows. In Section 2 we idealise the peeling process by switching to the *random weak limit* of our hypergraphs, and capture the essential behaviour of the process in terms of an operator $\hat{\mathbf{P}}$ acting on functions $q : \mathbb{Z} \rightarrow [0, 1]$. For this operator, we identify the properties of being *eroding* and *consolidating* as well as corresponding thresholds er_k and co_k in Section 3. We then prove the “ $\text{er}_k \leq f_k$ ” part of our theorem in Section 4 and give numerical approximations of er_k and co_k in Section 5. The comparatively simple “ $f_k \leq c_k^*$ ” part of our theorem is independent of these considerations and is proved in Section 6. Finally, in Section 7 we demonstrate how using our hypergraphs can improve the performance of practical retrieval data structures.

2 The Peeling Process and Idealised Peeling Operators

In this section we consider how the probabilities for vertices to “survive” $r \in \mathbb{N}$ rounds of peeling changes from one round to the next. In the classical setting this could be described by a function, mapping the old probability to the new one [35]. In our case, however, there are distinct probabilities for each segment of the graph. Thus we need a corresponding operator $\hat{\mathbf{P}}$ that acts on *sequences* of probabilities. Conveniently, it will be independent of n and ℓ .

We almost always suppress n, k, c, ℓ in notation outside of definitions, assuming n to be large. Big- \mathcal{O} notation refers to $n \rightarrow \infty$ while k, c, ℓ are constant.

Consider the parallel peeling process $\text{peel}(F)$ on $F = F(n, k, c, \ell)$. In each *round* of $\text{peel}(F)$, all vertices of degree 0 or 1 are determined and then deleted simultaneously. Deleting a vertex implicitly deletes incident edges. We also define the *rooted peeling process* $\text{peel}_v(F)$ for any vertex $v \in V$, which behaves exactly like $\text{peel}(F)$ except that the special vertex v may only be deleted if it has degree 0, not if it has degree 1. For any $i \in I$ and $r \in \mathbb{N}_0$ we let $q^{(r)}(i) = q^{(r)}(i, n, k, c, \ell)$ be the probability that a vertex v of segment i survives r rounds of $\text{peel}_v(F)$, i.e. is not deleted. Note that the probability is well-defined as vertices of the same segment are symmetric.

By definition, $q^{(0)}(i) = 1$ for all $i \in I$. Whether a vertex v of segment $i \in I$ survives $r > 0$ rounds is a function of its r -neighbourhood $N(n, v, r)$, i.e. the set of vertices and edges of F that can be reached from v by traversing at most r hyperedges.

It is standard to consider the *random weak limit* of F to get a grip on the distribution of $N(n, v, r)$ and thus on $q^{(r)}(i)$. Intuitively, we identify a (possibly infinite) random tree that captures the local characteristics of F for $n \rightarrow \infty$. See [1] for a good survey with examples and details on how to formally define the underlying topology and metric space. In the limit, the binomially distributed vertex degrees (e.g. $\text{Bin}(cn\ell, \frac{1}{n\ell})$ for vertices of segment 0) become Poisson distributed ($\text{Po}(c)$ for segment 0). Short cycles are not only rare but non-existent and certain weakly correlated random variables become perfectly independent.

► **Definition 2 (Limiting Tree).** *Let $k, \ell \in \mathbb{N}$, $c \in \mathbb{R}^+$ and $i \in I$. The random (possibly infinite) hypertree $T_i = T_i(k, c, \ell)$ is distributed as follows.*

T_i has a root vertex $\text{root}(T_i)$ of segment² i which for each $j \in \{i - k + 1, \dots, i\} \cap J$ has $d_j \sim \text{Po}(c)$ child edges of type j . Each child edge of type j is incident to $k - 1$ (fresh) child vertices of its own, one for each segment $i' \in \{j, \dots, j + k - 1\} \setminus \{i\}$. The sub-hypertree at such a child vertex of segment i' is distributed recursively (and independently of its sibling-subtrees) according to $T_{i'}$.

² In the current context, the segment of a vertex is an abstract label. There can be an unbounded number of vertices of each segment.

Since all arguments are standard in contexts where local weak convergence plays a role, we state the following lemma without proof. For instance, a full argument to show a similar convergence is given in [25]. See also [24] for the related technique of Poissonisation.

► **Lemma 3.** *Let $r \in \mathbb{N}$ be constant. Let further $N(n, v, r)$ be the r -neighbourhood of a vertex v of segment i in F and $T_i^{(r)}$ the r -neighbourhood of $\text{root}(T_i)$, both viewed as undirected and unlabelled hypergraphs. Then $N(n, v, r)$ converges in distribution to $T_i^{(r)}$ as $n \rightarrow \infty$.*

We now direct our attention to survival probabilities in the idealised peeling processes $(\text{peel}_{\text{root}(T_i)}(T_i))_{i \in I}$, which are easier to analyse than those of $\text{peel}_v(F)$.

► **Lemma 4.** *Let $r \in \mathbb{N}_0$ be constant and $q_T^{(r)}(i) = q_T^{(r)}(i, k, c, \ell)$ be the probability that $\text{root}(T_i)$ survives r rounds of $\text{peel}_{\text{root}(T_i)}(T_i)$ for $i \in I$. Then*

$$q_T^{(r+1)}(i) = 1 - \exp\left(-c \sum_{j \in \{i-k+1, \dots, i\} \cap J} \prod_{\substack{j \leq i' < j+k \\ i' \neq i}} q_T^{(r)}(i')\right) \quad \text{for } i \in I.$$

Proof. Let $i \in I$ and $v = \text{root}(T_i)$. Assume $j \in \{i-k+1, \dots, i\} \cap J$ is the type of some edge e incident to v . Edge e survives r rounds of $\text{peel}_v(T_i)$ if and only if all of its incident vertices survive these r rounds. Since v itself may not be deleted by $\text{peel}_v(T_i)$ as long as e exists, the relevant vertices are the $k-1$ child vertices, one for each segment $i' \in \{j, \dots, j+k-1\} - \{i\}$. Call these w_1, \dots, w_{k-1} and denote the subtrees rooted at those vertices by W_1, \dots, W_{k-1} . Now consider the peeling processes $\text{peel}_{w_1}(W_1), \dots, \text{peel}_{w_{k-1}}(W_{k-1})$. Assume one of them, say $\text{peel}_{w_s}(W_s)$, deletes w_s in round $r' \leq r$, meaning w_s has degree 0 before round r' . It follows that w_s has degree at most 1 before round r' in $\text{peel}_v(T_i)$, meaning $\text{peel}_v(T_i)$ deletes e in round r' (or earlier). Conversely, if none of $\text{peel}_{w_1}(W_1), \dots, \text{peel}_{w_{k-1}}(W_{k-1})$ delete their root vertex within r rounds, then w_1, \dots, w_{k-1} have degree at least 2 after round r of $\text{peel}_v(T_i)$ and e survives round r of $\text{peel}_v(T_i)$. This makes the probability for e to survive r rounds of $\text{peel}_v(T_i)$ equal to $p_{ij} := \prod_{j \leq i' < j+k, i' \neq i} q_T^{(r)}(i')$. Since the number m_{ij} of edges of type j incident to v has distribution $m_{ij} \sim \text{Po}(c)$, the number m'_{ij} of edges of type j incident to v surviving r rounds of $\text{peel}_v(T_i)$ is a correspondingly *thinned out* variable, namely $m'_{ij} \sim \text{Bin}(m_{ij}, p_{ij})$, which means $m'_{ij} \sim \text{Po}(cp_{ij})$.

The claim now follows by observing that v survives $r+1$ rounds of $\text{peel}_v(T_i)$ if and only if at least one of its child edges survives r rounds of $\text{peel}_v(T_i)$:

$$\begin{aligned} q_T^{(r+1)}(i) &= \Pr[v \text{ survives } r+1 \text{ rounds of } \text{peel}_v(T_i)] = 1 - \Pr\left[\bigcap_{j \in \{i-k+1, \dots, i\} \cap J} \{m'_{ij} = 0\}\right] \\ &= 1 - \prod_{j \in \{i-k+1, \dots, i\} \cap J} \Pr[m'_{ij} = 0] = 1 - \prod_{j \in \{i-k+1, \dots, i\} \cap J} \exp(-cp_{ij}) = 1 - \exp\left(-c \sum_{j \in \{i-k+1, \dots, i\} \cap J} p_{ij}\right). \end{aligned}$$

Replacing p_{ij} with its definition completes the proof. ◀

For convenience we define, for $k \geq 3, \ell \in \mathbb{N}$ and $c \in \mathbb{R}^+$, the operator $\mathbf{P} = \mathbf{P}(k, c, \ell)$, which maps any $q : I \rightarrow [0, 1]$ to $\mathbf{P}q : I \rightarrow [0, 1]$ with

$$(\mathbf{P}q)(i) = 1 - \exp\left(-c \sum_{j \in \{i-k+1, \dots, i\} \cap J} \prod_{\substack{j \leq i' < j+k \\ i' \neq i}} q(i')\right) \quad \text{for } i \in I.$$

Together Lemmas 3 and 4 imply that \mathbf{P} can be used to approximate survival probabilities.

► **Corollary 5.** *Let $r \in \mathbb{N}_0$ be constant. Then for all $i \in I$*

$$\mathbf{P}^r q^{(0)}(i) \stackrel{\text{def}}{=} \mathbf{P}^r q_T^{(0)}(i) \stackrel{\text{Lem 4}}{=} q_T^{(r)}(i) \stackrel{\text{Lem 3}}{=} q^{(r)}(i) \pm o(1).$$

To obtain *upper* bounds on survival probabilities, we may remove the awkward restriction “ $\cap J$ ” in the definition of \mathbf{P} . We define $\hat{\mathbf{P}} = \hat{\mathbf{P}}(k, c)$ as mapping $q : \mathbb{Z} \rightarrow [0, 1]$ to $\hat{\mathbf{P}}q : \mathbb{Z} \rightarrow [0, 1]$ with

$$(\hat{\mathbf{P}}q)(i) = 1 - \exp\left(-c \sum_{j=i-k+1}^i \prod_{\substack{j \leq i' < j+k \\ i' \neq i}} q(i')\right) \quad \text{for } i \in \mathbb{Z}.$$

Note that $\hat{\mathbf{P}}$ does not depend on ℓ or n . To simplify notation, we assume that the old operator \mathbf{P} also acts on functions $q : \mathbb{Z} \rightarrow [0, 1]$, ignoring $q(i)$ for $i \notin I$, and producing $\mathbf{P}q : \mathbb{Z} \rightarrow [0, 1]$ with $\mathbf{P}q(i) = 0$ for $i \notin I$. We also extend $q^{(0)}$ to be $\mathbf{1}_I : \mathbb{Z} \rightarrow [0, 1]$, i.e. the characteristic function on I , essentially introducing vertices of segments $i \notin I$ which are, however, already deleted with probability 1 before the first round begins. Note that while $q^{(r)}(i)$ and $q_T^{(r)}(i)$ are by definition non-increasing in r , this is not the case for $(\hat{\mathbf{P}}^r q^{(0)})(i)$. For instance, $\hat{\mathbf{P}}^r q^{(0)}$ has support $\{-r, -r+1, \dots, \ell+k-2+r\}$, which grows with r .³ The following lemma lists a few easily verified properties of $\hat{\mathbf{P}}$. All inequalities between functions should be interpreted point-wise.

► **Lemma 6.**

- (i) $\forall q : \mathbb{Z} \rightarrow [0, 1] : \mathbf{P}q \leq \hat{\mathbf{P}}q$.
- (ii) $\hat{\mathbf{P}}$ commutes with the shift operators \ll and \gg defined via $(\ll q)(i) = q(i+1)$ and $(\gg q)(i) = q(i-1)$. In other words, we have $\forall q : \mathbb{Z} \rightarrow [0, 1] : \hat{\mathbf{P}}(\ll q) = \ll(\hat{\mathbf{P}}q) \wedge \hat{\mathbf{P}}(\gg q) = \gg(\hat{\mathbf{P}}q)$.
