- (iii) $\hat{\mathbf{P}}$ is monotonic, i.e. $\forall q, q' : \mathbb{Z} \rightarrow [0, 1] : q \leq q' \Rightarrow \hat{\mathbf{P}}q \leq \hat{\mathbf{P}}q'$.
- (iv) $\hat{\mathbf{P}}$ respects monotonicity, i.e. if $q(i)$ is (strictly) increasing in i , then so is $(\hat{\mathbf{P}}q)(i)$.

3 Two Fixed Points Battling for Territory

In this section we define the *erosion* and *consolidation thresholds* at which the behaviour of $\hat{\mathbf{P}}$ changes in crucial ways.

First, we require a few facts about the function $f : [0, 1] \rightarrow [0, 1]$ mapping $x \mapsto 1 - e^{-ckx^{k-1}}$. It appears in the analysis of cores in k -ary Erdős-Renyi hypergraphs $H_{n, cn}^k$, essentially mapping the probability ρ_r for a vertex to survive r rounds of peeling to the probability $\rho_{r+1} = f(\rho_r)$ to survive $r+1$ rounds of peeling, see [35, page 5]⁴.

The threshold c_k for the appearance of a core in $H_{n, cn}^k$ turns out to be the threshold for the appearance of a non-zero fixed point of f . The following is implicit in the analysis.

► **Fact 7** ([35, Proofs of Lemmas 3 and 4]).

- (i) For $c < c_k$, f has only the fixed point $f(0) = 0$, with $f'(0) < 1$.
- (ii) For $c > c_k$, there are exactly three fixed points 0 , $\xi_1 = \xi_1(k, c)$ and $\xi_2 = \xi_2(k, c)$ where $f'(\xi_1) > 1$ while $f'(0), f'(\xi_2) < 1$.

³ It is still possible to interpret $\hat{\mathbf{P}}^r q^{(0)}(i)$ as survival probabilities in more symmetric extended versions \hat{T}_i of the tree T_i , but we will not pursue this.

⁴ Our setting corresponds to the choices $(r_{\text{Molloy}}, k_{\text{Molloy}}, c_{\text{Molloy}}) = (k, 2, c \cdot (k-1)!)$.

This implies the following behaviour of applying f repeatedly to a starting value x . This should be immediately clear from the sketches on the right.

Note that f captures the behaviour of $\hat{\mathbf{P}}$ on constant functions $\text{const}_x(i) := x$, in the sense that $\hat{\mathbf{P}}\text{const}_x = \text{const}_{f(x)}$. For $c < c_k$ we therefore have for all $i \in I$

$$\mathbf{P}^r q^{(0)}(i) \stackrel{\text{Cor 5}}{=} q^{(r)}(i) \pm o(1) \text{ and } \mathbf{P}^r q^{(0)} \leq \hat{\mathbf{P}}^r q^{(0)} \leq \hat{\mathbf{P}}^r \text{const}_1 = \text{const}_{f^r(1)} \xrightarrow{r \rightarrow \infty} \text{const}_0.$$

In conjunction with a later lemma, this is sufficient to show that F is peelable whp in this case. A similar argument for $c = c_k$ is possible as well. Our focus from now on is therefore on the interesting case $c > c_k$ where the three distinct fixed points $0, \xi_1, \xi_2$ of f exist.

We give an intuitive account of the phenomenon underlying the following steps before continuing formally. Due to (1) we have

$$\hat{\mathbf{P}}^r \text{const}_x \xrightarrow{r \rightarrow \infty} \begin{cases} \text{const}_0 & \text{for } x < \xi_1 \\ \text{const}_{\xi_2} & \text{for } x > \xi_1. \end{cases}$$

Now consider what happens if we iterate $\hat{\mathbf{P}}$ on a function that is “torn” between these two cases. Concretely, let us consider the function step_0^1 where we define $\text{step}_x^y : \mathbb{Z} \rightarrow [0, 1]$ to have value y on \mathbb{N}_0 and value x on negative inputs. Should we expect $\hat{\mathbf{P}}^r \text{step}_0^1$ to converge to const_0 or const_{ξ_2} as r increases? It turns out both is possible, depending on c .

Speaking more generally, let $q : \mathbb{Z} \rightarrow [0, 1]$ be any function. If $N(i) := \{i - k + 1, \dots, i + k - 1\} \setminus \{i\}$ then $\hat{\mathbf{P}}q(i)$ depends (monotonically) on $(q(i'))_{i' \in N(i)}$. It is clear that if $q(i') < \xi_1$ for all $i' \in N(i)$, then $\hat{\mathbf{P}}q(i) < \xi_1$ as well. Similarly, if $q(i') > \xi_1$ for all $i' \in N(i)$ then $\hat{\mathbf{P}}q(i) > \xi_1$. If, however, there are indices $i'_1, i'_2 \in N(i)$ with $q(i'_1) < \xi_1 < q(i'_2)$ then $\hat{\mathbf{P}}q(i)$ could be above or below ξ_1 ; in this case we call the index i *contested*.

The contested area of step_0^1 is $[-k + 1, k - 2]$. Iterating $\hat{\mathbf{P}}$ we obtain $\hat{\mathbf{P}}^r \text{step}_0^1$ for $r \in \mathbb{N}_0$. For all $r \in \mathbb{N}_0$ the contested area is an interval of size $2k - 2$ with all values to the left of it (towards $-\infty$) less than ξ_1 and all values to the right of it (towards ∞) bigger than ξ_1 . However, the contested area may *shift*. If the domain of values bigger than ξ_1 is shrinking (“*eroding*”), then we see convergence to const_0 . If conversely it is growing (“*consolidating*”), then we see convergence to const_{ξ_2} . In Figure 1 we visualise these effects. There is only a small range of values c where both fixed points seem equally “strong” and the same area remains perpetually contested.

With this in mind, we make the following definitions. For a compact formulation in the coarse terms of shifts (“ \ll ”, “ \gg ”) and point-wise inequalities (“ $<$ ”, “ $>$ ”) we use slightly different step functions.

► **Definition 8.** Let $k \geq 3, c \in \mathbb{R}^+$ and $\hat{\mathbf{P}} = \hat{\mathbf{P}}(k, c)$ as above. We say

$$\hat{\mathbf{P}} \text{ is eroding if } \exists R \in \mathbb{N} : \hat{\mathbf{P}}^R \text{step}_{\xi_1/2}^1 < \gg \text{step}_{\xi_1/2}^1$$

$$\text{and } \hat{\mathbf{P}} \text{ is consolidating if } \exists R \in \mathbb{N} : \hat{\mathbf{P}}^R \text{step}_0^{(\xi_1+\xi_2)/2} > \ll \text{step}_0^{(\xi_1+\xi_2)/2}.$$

■ **Figure 1** Depiction of $\hat{\mathbf{P}}^r \text{step}_0^1$ for $c \in \{0.85, 0.95\}$ and $r \in \{0, 5, 25\}$ on the range $i \in \{-10, \dots, 10\}$. The phenomenon of *erosion* can be seen on the top with the plot seemingly moving towards the right between $r = 5$ and $r = 25$. Similarly, *consolidation* can be seen on the bottom.

We define the corresponding *erosion* and *consolidation thresholds* as

$$\text{er}_k = \sup\{c \in \mathbb{R}^+ \mid \hat{\mathbf{P}}(k, c) \text{ is eroding}\}, \quad \text{co}_k = \inf\{c \in \mathbb{R}^+ \mid \hat{\mathbf{P}}(k, c) \text{ is consolidating}\}.$$

Note that $c < \text{er}_k$ implies that $\hat{\mathbf{P}}(k, c)$ is eroding and $c > \text{co}_k$ implies $\hat{\mathbf{P}}(k, c)$ is consolidating as would be expected. This uses that the definition of $\hat{\mathbf{P}}$ is monotonic in c .

The following lemma states that erosion (consolidation) are sufficient conditions for const_0 (const_{ξ_2}) to “win the battle” when iterating $\hat{\mathbf{P}}$ on step_0^1 .

► **Lemma 9.** *Let $k \geq 3$.*

- (i) *If $c < \text{er}_k$ and $i \in \mathbb{Z}$, then $\hat{\mathbf{P}}^r \text{step}_0^1(i) \xrightarrow{r \rightarrow \infty} 0$.*
- (ii) *If $c > \text{co}_k$ and $i \in \mathbb{Z}$, then $\hat{\mathbf{P}}^r \text{step}_0^1(i) \xrightarrow{r \rightarrow \infty} \xi_2$.*
- (iii) $\text{er}_k \leq \text{co}_k$.

Proof.

- (i) Let $R \in \mathbb{N}$ be the witness to the fact that $\hat{\mathbf{P}}(k, c)$ is eroding and $i \in \mathbb{Z}$ arbitrary.

$$\begin{aligned} \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r \text{step}_0^1)(i) &\leq \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r \text{step}_{\xi_1/2}^1)(i) = \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r ((\hat{\mathbf{P}}^R)^{kr} \text{step}_{\xi_1/2}^1))(i) \\ &\leq \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r (\gg^{kr} \text{step}_{\xi_1/2}^1))(i) = \lim_{r \rightarrow \infty} (\gg^{kr} (\hat{\mathbf{P}}^r \text{step}_{\xi_1/2}^1))(i) \\ &= \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r \text{step}_{\xi_1/2}^1)(i - kr) = \lim_{r \rightarrow \infty} (\hat{\mathbf{P}}^r \text{const}_{\xi_1/2})(i - kr) \\ &= \lim_{r \rightarrow \infty} \text{const}_{f^r(\xi_1/2)}(i - kr) = \lim_{r \rightarrow \infty} f^r(\xi_1/2) = 0. \end{aligned}$$

When replacing $\text{step}_{\xi_1/2}^1$ by $\text{const}_{\xi_1/2}$ we exploited that $(\hat{\mathbf{P}}^r q)(i)$ depends only on the values $q(i')$ for $i' \in \{i - k + 1, \dots, i + k - 1\}$ and thus $(\hat{\mathbf{P}}^r q)(i)$ depends only on the values $q(i')$ for $i' \in [i - (k - 1)r, i + (k - 1)r]$.

- (ii) The proof is analogous to the proof of (i).
- (iii) This is clear, since the implications of (i) and (ii) are mutually exclusive. ◀

4 Erosion is Sufficient for Peeling

We now connect the phenomenon of erosion to the survival probabilities $q^{(R)}(i)$ we were originally interested in. For $c < \text{er}_k$ and any $\ell \in \mathbb{N}$, they can be made smaller than any $\delta > 0$ in $R = R(\delta, \ell)$ rounds. For $c > \text{co}_k$ and ℓ sufficiently large, no constant number of rounds suffices to reduce all survival probabilities below ξ_1 .

► **Lemma 10.** *Let $k \geq 3$.*

- (i) *If $c < \text{er}_k$ then $\forall \ell \in \mathbb{N}, \delta > 0: \exists R, N \in \mathbb{N}: \forall n \geq N, i \in I: q^{(R)}(i) < \delta$.*
- (ii) *If $c > \text{co}_k$ then $\exists L = L(k, c): \forall \ell \geq L: \exists i \in I: \lim_{r \rightarrow \infty} \lim_{n \rightarrow \infty} q^{(r)}(i) > \xi_1$.*

Proof.

- (i) Let $\ell \in \mathbb{N}$ and $\delta > 0$ be arbitrary constants. Using (i) from Lemma 9, there exists a constant R such that $\hat{\mathbf{P}}^R \text{step}_0^1(i) \leq \delta/2$ for all $i \in I$. Therefore for $i \in I$:

$$q^{(R)}(i) \stackrel{\text{Cor 5}}{=} (\mathbf{P}^R q^{(0)})(i) + o(1) \leq (\hat{\mathbf{P}}^R q^{(0)})(i) + o(1) \leq (\hat{\mathbf{P}}^R \text{step}_0^1)(i) \leq \delta/2 + o(1).$$

which implies the existence of an appropriate $N \in \mathbb{N}$.

- (ii) Let $R \in \mathbb{N}$ be the witness to the fact that $\hat{\mathbf{P}}(k, c)$ is consolidating and let $\ell \geq L(k, c) := 4d$ for $d = (k - 1)R$. Consider the function $q^* : \mathbb{Z} \rightarrow [0, 1]$ defined as $q^* = \mathbb{1}_{\{d, \dots, \ell - d - 1\}} \cdot (\xi_1 + \xi_2)/2$, i.e. the function with value $(\xi_1 + \xi_2)/2$ on its support $\{d, \dots, \ell - d - 1\}$ and 0 outside of it. For any $d \leq i < \ell - 2d$ we have

$$\begin{aligned} \mathbf{P}^R q^*(i) &= \hat{\mathbf{P}}^R q^*(i) = \hat{\mathbf{P}}^R \text{step}_0^{(\xi_1 + \xi_2)/2}(i - d) \geq \llcorner \text{step}_0^{(\xi_1 + \xi_2)/2}(i - d) \\ &= (\xi_1 + \xi_2)/2 = q^*(i). \end{aligned}$$

For the first equality, we exploited that i is so far from the borders of $I = \{0, \dots, \ell - 1\}$ that there is no difference between \mathbf{P} and $\hat{\mathbf{P}}$. For the second equality we used that only the values of q^* on $\{i - d, \dots, i + d\}$ play a role and q^* is a (shifted) step function on that domain. By mirroring, the same argument can be made to get $\mathbf{P}^R q^*(i) \geq q^*(i)$ for $2d \leq i < \ell - d$ as well and thus the point-wise inequality $\mathbf{P}^R q^* \geq q^*$. Since $q^{(0)} \geq q^*$ we get

$$\lim_{r \rightarrow \infty} \lim_{n \rightarrow \infty} q^{(r)} \stackrel{\text{Cor 5}}{=} \lim_{r \rightarrow \infty} \mathbf{P}^r \mathbb{1}_I \geq \lim_{r \rightarrow \infty} \mathbf{P}^r q^* \geq q^*.$$

Since q^* exceeds ξ_1 on $\{d, \dots, \ell - d - 1\}$, this implies the claim. ◀

While Lemma 10(i) is sufficient to show that all but a δ -fraction of the vertices is peeled whp if $c < \text{er}_k$, we still need the following combinatorial argument that shows that whp no non-empty core is contained within the remaining vertices. Arguments such as these are standard, many similar ones can be found for instance in [18, 19, 23, 27, 29, 35, 32].

► **Lemma 11.** *For any $k \geq 3$, $\ell \in \mathbb{N}$ and $c \in (0, 1)$ there exists $\delta = \delta(k, \ell) > 0$ such that the following holds whp. For any non-empty set $V' \subseteq V$ of at most $\delta|V|$ vertices of $F = (V, E)$, there exists $v \in V'$ of degree at most 1 in the sub-hypergraph of H induced by V' .*

Proof. In the course of the proof we will implicitly encounter positive upper bounds on δ in terms of k and ℓ . Any $\delta > 0$ small enough to respect these bounds is suitable. We consider the events $(W_{s,t})_{k \leq s \leq \delta|V|, \frac{2s}{k} \leq t \leq |E|}$ that some small set V' of size s induces t edges. If none of these events occurs, then all such V' induce less than $2|V'|/k$ edges and therefore induce hypergraphs with average degree less than 2, so a vertex of degree at most 1 exists in each of them.

It is thus sufficient to show that $\Pr[\bigcup_s \bigcup_t W_{s,t}] = \mathcal{O}(1/n)$. We shall use a first moment argument. First note that F has duplicate edges with probability $\binom{cn\ell}{2} (\ell n^k)^{-1} = \mathcal{O}(n^{-1})$, so we restrict our attention to F without duplicate edges. Given s and t there are $\binom{(\ell+k-1)n}{s}$ ways to choose V' and at most $\binom{s^k}{t}$ ways to choose which k -tuples of vertices in V' induce an edge. The probability that any given k -tuple actually does induce an edge is either zero if the k vertices are not of consecutive segments or $1 - (1 - (\ell n^k)^{-1})^{cn\ell} \leq \frac{cn}{n^k} = \frac{1}{n^{k-1}}$. Thus, using constants $C, C', C'', C''' \in \mathbb{R}^+$ (that may depend on k and ℓ) where precise values do not matter, we get

$$\begin{aligned}
 \Pr\left[\bigcup_{s=k}^{\delta|V|} \bigcup_{t=\frac{2s}{k}}^{|E|} W_{s,t}\right] &\leq \sum_{s=k}^{\delta|V|} \sum_{t=\frac{2s}{k}}^{|E|} \Pr[W_{s,t}] \leq \sum_{s=k}^{\delta|V|} \sum_{t=\frac{2s}{k}}^{|E|} \binom{(\ell+k-1)n}{s} \binom{s^k}{t} \left(\frac{1}{n^{k-1}}\right)^t \\
 &\leq \sum_{s=k}^{\delta|V|} \sum_{t=\frac{2s}{k}}^{|E|} \left(\frac{e(\ell+k-1)n}{s}\right)^s \left(\frac{es^k}{tn^{k-1}}\right)^t \leq \sum_{s=k}^{\delta|V|} \sum_{t=\frac{2s}{k}}^{|E|} \left(C\frac{n}{s}\right)^s \left(C'\frac{s^{k-1}}{n^{k-1}}\right)^t \\
 &\leq 2 \sum_{s=k}^{\delta|V|} \left(C\frac{n}{s}\right)^s \left(C'\frac{s^{k-1}}{n^{k-1}}\right)^{\frac{2s}{k}} = 2 \sum_{s=k}^{\delta|V|} \left(C''\frac{n^k s^{2k-2}}{s^k n^{2k-2}}\right)^{\frac{s}{k}} = 2 \sum_{s=k}^{\delta|V|} \left(C'''\frac{s}{n}\right)^{\frac{s(k-2)}{k}}.
 \end{aligned}$$

To get rid of the summation over t , we assumed $(s/n)^{k-1} \leq \delta^{k-1} \leq \frac{1}{2C'}$. Elementary arguments show that in the resulting bound, the contribution of summands for $s \in \{k, \dots, 2k\}$ is of order $\mathcal{O}(\frac{1}{n})$, the contribution of the summands with $s \in \{2k+1, \dots, \mathcal{O}(\log n)\}$ are of order $\mathcal{O}(\frac{\log n}{n^2})$ (using $\frac{s}{n} \leq \frac{\log n}{n}$) and the contribution of the remaining terms with $s \geq 3 \log_2 n$ is of order $\mathcal{O}(2^{-\log_2 n}) = \mathcal{O}(\frac{1}{n})$ (using $C'''\frac{s}{n} \leq C'''\delta(\ell+2) \leq \frac{1}{2}$).

This gives $\Pr[\bigcup_{s,t} W_{s,t}] = \mathcal{O}(n^{-1})$, proving the claim. \blacktriangleleft

We are ready to prove the “ $\text{er}_k \leq f_k$ ” of Theorem 1, stated here as a theorem of its own.

► **Theorem 12.** *For all $k \geq 3$ we have $\text{er}_k \leq f_k$.*

Proof. We need to prove that for any $c < \text{er}_k$ and any $\ell \in \mathbb{N}$ the fuse graph $F = F(n, k, c, \ell)$ is peelable whp.

First, let $\delta = \delta(k, \ell)$ be the constant from Lemma 11 and $R = R(\delta/2, \ell)$ as well as $N = N(\delta/2, \ell)$ the corresponding constants from Lemma 10(i).

Assuming $n \geq N$ we have $q^{(R)}(i) \leq \delta/2$ for all $i \in I$, meaning any vertex v from F is *not* deleted within R rounds of $\text{peel}_v(F)$ with probability at most $\delta/2$. Since $\text{peel}(F)$ deletes at least the vertices that any $\text{peel}_v(F)$ for $v \in V$ deletes, the expected number of vertices not deleted by $\text{peel}(F)$ within R rounds is at most $\delta|V|/2$.

Now standard arguments using Azuma’s inequality (see e.g. [33, Theorem 13.7]) suffice to conclude that whp at most $\delta|V|$ vertices are not deleted by $\text{peel}(F)$ within R rounds.

By Lemma 11 whp neither the remaining $\delta|V|$ vertices, nor any of its subsets induces a hypergraph of minimum degree 2. Therefore the core of F is empty. \blacktriangleleft

A natural follow-up question to Theorem 12 would be whether $\text{er}_k = f_k$, which would also imply $f_k \leq \text{co}_k$. To establish this stronger claim, we would have to exclude the possibility that for certain densities c there is a function $r(n) = \omega(1)$ such that a constant fraction of vertices survive $r(n)$ rounds but are nevertheless deleted eventually. It seems plausible that arguments similar to [35, Lemma 4] can be used, but since our main goal is reached we do not pursue this now.

5 Approximating the Erosion and Consolidation Thresholds

We now approximate the thresholds er_k (and analogously co_k) with numerical methods. Note that if $c < \text{er}_k$ (if $c > \text{co}_k$), then this can be verified in a finite computation, because the correct value of R , together with a bound on the required precision of floating point operations (when rounding conservatively), constitutes a witness. Moreover, the function $\hat{\mathbf{P}}^r \text{step}_{\xi, 1/2}^1$ can be represented by a finite number of reals, since it is constant on $(-\infty, -(k-1)r]$ and constant on $[(k-1)r, \infty)$.

To approximate er_k (and co_k) with high precision, more efficient approaches are required, however. We compute upper bounds on $\hat{\mathbf{P}}^r \text{step}_{\xi_1/2}^1$ by focusing on a finite domain $[-D, D]$ for some $D \in \mathbb{N}$ and rounding conservatively outside of it. Concretely we define $(a_r : \mathbb{Z} \rightarrow [0, 1])_{r \in \mathbb{N}_0}$ (dependent on k, c and D) with $a_0 := \text{step}_{\xi_1/2}^1$ (analogously $(b_r : \mathbb{Z} \rightarrow [0, 1])_{r \in \mathbb{N}_0}$ with $b_0 := \text{step}_0^{(\xi_1 + \xi_2)/2}$). For $r \geq 0$ we let

$$a_{r+1}(i) := \begin{cases} a_{r+1}(-D) & \text{if } i < -D, \\ \hat{\mathbf{P}}a_r(i) & \text{if } -D \leq i \leq D, \\ 1 & \text{if } i > D. \end{cases} \quad b_{r+1}(i) := \begin{cases} 0 & \text{if } i < -D, \\ \hat{\mathbf{P}}b_r(i) & \text{if } -D \leq i \leq D, \\ \hat{\mathbf{P}}b_r(D) & \text{if } i > D. \end{cases}$$

Due to the limited effective domain, each a_r is given by $2D + 2$ values. It is easy to see that each a_r is monotonous and fulfils $a_{r+1} \leq \hat{\mathbf{P}}a_r$, which implies $\hat{\mathbf{P}}^r \text{step}_{\xi_1/2}^1 \leq a_r$. If we find $a_r(0) < \xi_1/2$, then by monotonicity we have $a_r \leq \gg \text{step}_{\xi_1/2}^1$ and therefore:

$$\exists R \in \mathbb{N} : a_R(0) < \xi_1/2 \quad \Rightarrow \quad \exists R \in \mathbb{N} : \hat{\mathbf{P}}^R \text{step}_{\xi_1/2}^1 < \gg \text{step}_{\xi_1/2}^1 \stackrel{\text{def}}{\Rightarrow} c < \text{er}_k.$$

(Analogously if $b_R(-1) > (\xi_1 + \xi_2)/2$ then $c > \text{co}_k$ follows.)

Experimental Results. For $D = 50$ and all $k \in \{3, \dots, 7\}$ we computed, using double-precision floating point values, a_1, a_2, \dots and b_1, b_2, \dots for various c . For each pair (k, c) , we either find that $\hat{\mathbf{P}}(k, c)$ is consolidating, it is eroding, or none of the two can be verified. The results suggest that $\text{er}_k < c_k^* < \text{co}_k$ where c_k^* is the orientability threshold for k -ary Erdős-Renyi hypergraphs.

Concretely, we considered for $j = 1, 2, 3, \dots$ the values $c_k^* - 2^{-j}$ and tried to verify that they are less than er_k . The largest for which we succeeded is reported as b_k in Table 1 on page 3. The largest number of iterations required was $6 \cdot 10^7$. For the first value that could not be shown to be less than er_k , our approximations of the sequence of $(a_i)_{i \in \mathbb{N}}$ became stationary with $a[0] > \xi_1/2$, i.e. the double-precision floats did not change any more (the highest number of iterations to reach this point was $2 \cdot 10^8$). It is possible that the value is still less than er_k and our choice of D or the precision of our floats is simply insufficient. Further experiments with 128-bit floats and larger values of D suggest however, that there is a tiny but real gap between er_k, c_k^* and co_k and the natural conjecture of equality is misplaced.

In the same way we report the smallest value of the form $c_k^* + 2^{-j}$ for which we verified that it exceeds co_k as B_k in Table 1.

6 Peeling Necessitates Orientability of Erdős-Renyi Hypergraphs

We now prove the “ $f_k \leq c_k^*$ ”-half of Theorem 1, stated as Theorem 14. Recall that an *orientation* of a hypergraph $H = (V, E)$ is an injective map $f : E \rightarrow V$ with $f(e) \in e$ for all $e \in E$ and that c_k^* is the threshold for orientability of k -uniform Erdős-Renyi hypergraphs.

After classical (2-ary) cuckoo hashing was discovered [36] (relying on $c_2^* = \frac{1}{2}$), the thresholds for $k > 2$ were determined independently by [11, 19, 20], with generalisations to other graphs and hypergraphs studied in [9, 17, 25, 26, 40].

Note that if H is peelable then it is also orientable: Just orient each edge e to a vertex $v \in e$ such that v and e are deleted in the same round of $\text{peel}(H)$.

Our proof of Theorem 14 relies strongly on a deep and remarkable theorem due to Lelarge [27]. To clarify its role in our proof, we restate it in weaker but sufficient form.

38:12 Dense Peelable Hypergraphs

► **Theorem 13** (Lelarge [27, Theorem 4.1]). *Let $(G_n = (A_n, B_n, E_n))_{n \in \mathbb{N}}$ be a sequence of bipartite graphs with $|E_n| = O(|A_n|)$. Let further $M(G_n)$ be the size of a maximum matching in G_n . If the random weak limit ρ of $(G_n)_{n \in \mathbb{N}}$ is a bipartite unimodular Galton-Watson tree, then $\lim_{n \rightarrow \infty} \frac{M(G_n)}{|A_n|}$ exists almost surely and depends only on ρ .*

To see the connection, note that an orientation of a hypergraph is a left-perfect matching in its (bipartite) incidence graph.

► **Theorem 14.** *For all $k \geq 3$ we have $f_k \leq c_k^*$.*

Proof. Let $c = c_k^* + \varepsilon$. We need to show that there exists $\ell \in \mathbb{N}$ such that the fuse graph $F = F(n, k, c, \ell)$ is not peelable whp.

Let $H = H_{n, cn}^k$ be the k -ary Erdős-Renyi random hypergraph with density c . By choice of c , H is not orientable whp. More strongly even, there exists $\delta = \delta(\varepsilon) > 0$ such that the largest *partial orientation*, i.e. the largest subset of the edges that can be oriented, has size $(1 - \delta)cn + o(n)$ whp, see for instance [27].

We set $\ell = \frac{k}{\delta c}$ and consider F as well as the hypergraph \tilde{F} where the vertices i and $i + n\ell$ for all $i \in \{1, \dots, (k - 1)n\}$ are merged. This “glues” the last $k - 1$ segments of F on top of the first $k - 1$ segments of F , making \tilde{F} a “seamless” version of our construction. Crucially, the *random weak limit* of \tilde{F} and H coincide, i.e. for any constant $R \in \mathbb{N}$ the distribution of the R -neighbourhood $N_{\tilde{F}}(v, R)$ of a random vertex v of \tilde{F} has the same limit (as $n \rightarrow \infty$) as the distribution of the R -neighbourhood $N_H(v, R)$ of a random vertex v of H .⁵ It now follows from [27, Theorem 4.1] that the size of the largest partial orientation of \tilde{F} is essentially also a $(1 - \delta)$ -fraction of the number of edges, namely $(1 - \delta)c\ell n + o(n)$ whp. Switching from \tilde{F} back to F can increase the size of a largest partial orientation by at most $(k - 1)n$ to $(1 - \delta + \frac{k-1}{c\ell})c\ell n + o(n) = (1 - \frac{\delta}{k})c\ell n + o(n)$ whp. Thus F is not orientable whp and therefore not peelable whp. ◀

7 Experiments

We used our hypergraphs to implement retrieval data structures and compare it to existing implementations.

A *1-bit retrieval data structure* for a universe \mathcal{U} is a pair of algorithms **construct** and **query**, where the input of **construct** is a set $S \subseteq \mathcal{U}$ of size $m = |S|$ and $f : S \rightarrow \{0, 1\}$. If **construct** succeeds, then the output is a data structure D_f such that $\text{query}(D_f, x) = f(x)$ for all $x \in S$. The output of $\text{query}(D_f, y)$ for $y \in \mathcal{U} \setminus S$ may yield an arbitrary element of $\{0, 1\}$. The interesting setting is when the data structure may only occupy $\mathcal{O}(m)$ bits. See [8, 7, 12, 21, 38].

One approach is to map each element $x \in S$ to a set $e_x \subset [N]$ via a hash function, where $N = m/c$ for some desired edge density c . One then seeks a solution $z : [N] \rightarrow \{0, 1\}$ satisfying $\bigoplus_{v \in e_x} z(v) = f(x)$ for all $x \in S$. The bit-vector z and the hash function then form D_f . A query simply evaluates the left hand side of the equation for x to recover $f(x)$. To compute z , we consider the hypergraph $H = ([N], \{e_x, x \in S\})$. A peelable vertex $v \in [N]$ only contained in one edge e_x corresponds to a variable $z(v)$ only occurring in the equation associated with x . It is thus easy to see that if H is peelable, repeated elimination and back-substitution yields z in $\mathcal{O}(m)$ time.

⁵ The common limit of the incidence graphs of \tilde{F} and H is the bipartite unimodular Galton-Watson tree described in [27, Section 4]. Standard arguments, e.g. from [24, 25] suffice to establish the identity.

■ **Table 2** Overheads and average running times per key of various practical retrieval data structures.

	Configuration	Overhead	construct [μs/key]	query [ns]
Botelho et al. [8]	$c = 0.81$	23.5%	0.32	59
⟨Fuse Graphs⟩	$c = 0.910, k = 3, \ell = 100$	12.1%	0.29	55
⟨Fuse Graphs⟩	$c = 0.960, k = 4, \ell = 200$	5.7%	0.29	60
⟨Fuse Graphs⟩	$c = 0.985, k = 7, \ell = 500$	2.7%	0.38	74
Luby et al. [28]	$c = 0.9, D = 12$	11.1%	0.79	94
Luby et al. [28]	$c = 0.99, D = 150$	1.1%	0.87	109
Genuzio et al. [21]	$c = 0.91, k = 3, C = 10^4$	10.2%	1.30	58
Genuzio et al. [21]	$c = 0.97, k = 4, C = 10^4$	3.4%	2.20	64
the authors [13]	$c = 0.9995, \ell = 16, C = 10^4$	0.25%	2.47	56

We implemented the following peeling-based variations and report results in⁶ Table 2. By the *overhead* of an implementation we mean $\frac{N'}{m} - 1$ where $N' \geq N$ is the total number of bits used, including auxiliary data structures.

Botelho et al. [8] H is a 3-ary Erdős-Renyi hypergraph with an edge density below the peelability threshold $c_3 \approx 0.818$. Construction via peeling and queries are very fast, but the overhead of 23% is sizeable (i.e. D_f occupies roughly $1.23m$ bits).

Fuse Graphs. The edges are distributed such that H is a fuse graph. Recall that the edge density is $c \frac{\ell}{\ell+k-1}$. Note that we let ℓ grow with k to keep the density close to c . We still keep ℓ in a moderate range, as our construction relies on $n \gg \ell$.

Luby et al. [28] The edges are distributed such that H is the peelable hypergraph from [28] already mentioned on page 2. To our knowledge these hypergraphs have not been considered in the context of retrieval. They seem to be particularly well suited to achieve very small overheads at the cost of larger construction and mean query times compared to our other approaches. Note that the largest edge size is $D + 4$ and the worst-case query time is therefore much larger than the reported average query time.

For reference, we also implemented two recent retrieval data structures that do not rely on peeling but solve linear systems [13, 21]. There, to counteract cubic solving time, the input is partitioned into chunks of size C . Especially [13] achieves much smaller overheads than what is feasible with peeling approaches, with the downside of being much slower and more complicated.

Overall, it seems using fuse graphs in retrieval data structures has a chance of outperforming existing approaches when moderate memory overheads of $\approx 5\%$ are acceptable.

However, more research is required to explore the complex space of possible input sizes, configurations of the data structures and trade-offs between overhead and runtime. Our implementations are configured reasonably, but arbitrary in some aspects. A full discussion is beyond the scope of this paper.

⁶ Experiments were performed on a desktop computer with an Intel® Core i7-2600 Processor @ 3.40GHz. In all cases, the data set S contains the first $m = 10^7$ URLs from the `eu-2015-host` dataset gathered by [5] with ≈ 80 bytes per key, and $f: \mathcal{U} \rightarrow \{0, 1\}$ is taken to be the parity of the string length. As hash function we used MURMURHASH3_x64_128 [2]. If more than 128 hash bits were needed, techniques resembling double-hashing were used to generate additional bits to avoid another execution of murmur. Reported query times are averages obtained by querying all elements of the data set once. They include the roughly 25 ns needed to evaluate murmur on average. The reported numbers are medians of 5 executions.

8 Conclusion

We introduced for all $k \in \mathbb{N}$ a new family of k -uniform hypergraphs where the vertex set is partitioned into a large but constant number of segments. Each edge chooses a random range of k consecutive segments and one random incidence in each of them.

While we have no asymptotic results on the resulting peelability thresholds f_k , at least for small k they are remarkably close to c_k^* with $0 \leq c_k^* - f_k \leq 10^{-5}$ for $k \in \{3, 4, 5, 6, 7\}$. In other words, f_k almost coincides with the *orientability* threshold c_k^* of Erdős-Renyi hypergraphs and significantly exceeds their peelability threshold c_k . Note that $c_k^* = 1 - (1 + o_k(1))e^{-k} \xrightarrow{k \rightarrow \infty} 1$ (see [19, page 3]) while $c_k \xrightarrow{k \rightarrow \infty} 0$ (see e.g. [35]). When plugging our hypergraphs into the retrieval framework by [8], we obtained corresponding improvements with respect to memory usage, with no discernible downsides.

Future Experiments. While our experiments on retrieval data structures are promising, it is unclear how robustly the advantages translate to other practical settings where peelable hypergraphs are used, say when implementing Invertible Bloom Lookup Tables [22]. There are hidden disadvantages of our hypergraphs not considered in this paper – for instance the number of rounds needed to peel our hypergraphs is higher, possibly hurting parallel peeling algorithms – as well as hidden advantages – peeling in external memory, a setting considered in [3], is easy due to the locality of the edges.

A Theoretical Question. Given our results, it is natural to suspect a fundamental connection between f_k and c_k^* . Quite possibly, the tiny gap that seems to remain between the values – clearly negligible from a practical perspective – is merely an artefact of the discreteness of segments in our construction.

This discreteness, while heavily used in our arguments, may in fact be dispensable. Indeed, we believe the key idea behind our hypergraphs is *limited bandwidth* where a hypergraph on vertex set $[n]$ has bandwidth at most d if each edge e satisfies $\max_{v \in e} v - \min_{v \in e} v < d$ (the incidence matrix can then be sorted to resemble a bandmatrix). Such a hypergraph can be generated by choosing for each edge a random range of d consecutive vertices and k incidences independently and uniformly at random from that range. In experiments with $k = 3$ and $d = \varepsilon n$, such hypergraphs performed similar to the hypergraphs we analysed (with $k = 3$ and $\ell \approx 1/\varepsilon$). Note that there are no discrete segments in the modified construction. It would be nice to see whether in such a variation peelability and orientability are more elegantly and more intimately linked.

Abstract

In this paper we identify a new class of sparse near-quadratic random Boolean matrices that have full row rank over $\mathbb{F}_2 = \{0, 1\}$ with high probability and can be transformed into echelon form in almost linear time by a simple version of Gauss elimination. The random matrix with dimensions $n(1 - \varepsilon) \times n$ is generated as follows: In each row, identify a block of length $L = O((\log n)/\varepsilon)$ at a random position. The entries outside the block are 0, the entries inside the block are given by fair coin tosses. Sorting the rows according to the positions of the blocks transforms the matrix into a kind of band matrix, on which, as it turns out, Gauss elimination works very efficiently with high probability. For the proof, the effects of Gauss elimination are interpreted as a (“coin-flipping”) variant of Robin Hood hashing, whose behaviour can be captured in terms of a simple Markov model from queuing theory. Bounds for expected construction time and high success probability follow from results in this area. They readily extend to larger finite fields in place of \mathbb{F}_2 .

By employing hashing, this matrix family leads to a new implementation of a *retrieval* data structure, which represents an arbitrary function $f: S \rightarrow \{0, 1\}$ for some set S of $m = (1 - \varepsilon)n$ keys. It requires $m/(1 - \varepsilon)$ bits of space, construction takes $\mathcal{O}(m/\varepsilon^2)$ expected time on a word RAM, while queries take $\mathcal{O}(1/\varepsilon)$ time and access only one contiguous segment of $\mathcal{O}((\log m)/\varepsilon)$ bits in the representation ($\mathcal{O}(1/\varepsilon)$ consecutive words on a word RAM). The method is readily implemented and highly practical, and it is competitive with state-of-the-art methods. In a more theoretical variant, which works only for unrealistically large S , we can even achieve construction time $\mathcal{O}(m/\varepsilon)$ and query time $\mathcal{O}(1)$, accessing $\mathcal{O}(1)$ contiguous memory words for a query. By well-established methods the retrieval data structure leads to efficient constructions of (static) perfect hash functions and (static) Bloom filters with almost optimal space and very local storage access patterns for queries.

1 Introduction

1.1 Sparse Random Matrices

In this paper we introduce and study a new class of sparse random matrices over finite fields, which give rise to linear systems that are efficiently solvable with high probability¹. For concreteness and ease of notation, we describe the techniques for the field $\mathbb{F}_2 = \{0, 1\}$. (The analysis applies to larger fields as well, as will be discussed below.) A matrix A from this class has n columns and $m = (1 - \varepsilon)n$ rows for some small $\varepsilon > 0$. We always imagine that a right hand side $\vec{b} \in \{0, 1\}^m$ is given and that we wish to solve the system $A\vec{z} = \vec{b}$ for the vector of unknowns \vec{z} .

The applications (see Section 1.2) dictate that the rows of A are stochastically independent and are all chosen according to the same distribution \mathcal{R} on $\{0, 1\}^n$. Often, but not always, \mathcal{R} is the uniform distribution on some pool $R \subseteq \{0, 1\}^n$ of admissible rows. The following choices were considered in the literature.

- (1) If $R = \{0, 1\}^n$, then A has full row rank whp for any $\varepsilon = \omega(1/n)$. In fact, the probability for full row rank is > 0.28 even for $\varepsilon = 0$, see e.g. [11, 35]. Solving time is $\tilde{O}(n^3)$.
- (2) A popular choice for R is the set of vectors with 1's in precisely k positions, for constant k . Then $\varepsilon = e^{-\theta(k)}$ is sufficient for solvability whp [34]. Solving time is still $\tilde{O}(n^3)$ if Gauss elimination is used and $\mathcal{O}(n^2)$ if Wiedemann's algorithm [37] is used, but heuristics exploiting the sparsity of A help considerably [22].
- (3) In the previous setting with $k = 3$ and $\varepsilon \geq 0.19$, linear running time can be achieved with a simple greedy algorithm, since then the matrix can be brought into echelon form by row and column *exchanges* alone [7, 24, 32]. Using $k > 3$ is pointless here, as then the required value of ε increases.
- (4) Luby et al. [29, 30] study "loss-resilient codes" based on certain random bipartite graphs. Translating their considerations into our terminology shows that at the core of their construction is a distribution on $(1 - \varepsilon)n \times n$ -matrices with randomly chosen sparse rows as well. Simplifying a bit, a number $D = \mathcal{O}(1/\varepsilon)$ is chosen and a weight sequence is carefully selected that will give a row at most D many 1's and on average $\mathcal{O}(\log D)$ many 1's (in random positions). It is shown in [29, 30] that such matrices not only have full row rank with high probability, but that, as in (3), row and column *exchanges* suffice to obtain an echelon form whp. This leads to a solving time of $\mathcal{O}(n \log(1/\varepsilon))$ for the corresponding linear system.
- (5) The authors of the present work describe in a simultaneous paper [18] the construction of sparse $(1 - \varepsilon)n \times n$ matrices for very small (constant) ε , with a fixed number of 1's per row, which also allow solving the corresponding system by row and column exchanges. (While behaviour in experiments is promising, determining the behaviour of the construction for arbitrarily small ε is an open problem.)
- (6) In a recent proposal [17] by the authors of the present paper, a row $r \sim \mathcal{R}$ contains two *blocks* of $\Theta(\log n)$ random bits at random positions (block-aligned) in a vector otherwise filled with 0's. It turned out that in this case even $\varepsilon = \mathcal{O}((\log n)/n)$ will give solvability with high probability. Solution time is again about cubic (Gauss) resp. quadratic (Wiedemann), with heuristic pre-solvers cushioning the blow partly in practice.

Motivated by the last construction, we propose an even simpler choice for the distribution \mathcal{R} : A row r consists of 0's except for one randomly placed block of some length L , which consists of random bits. It turns out that $L = \mathcal{O}((\log n)/\varepsilon)$ is sufficient to achieve solvability

¹ Events occur "with high probability (whp)" if they occur with probability $1 - \mathcal{O}(m^{-1})$.

with high probability. The L -bit block fits into $\mathcal{O}(1)$ memory words as long as ε is constant. Our main technical result (Theorem 2) is that the resulting random matrix has full row rank whp. Moreover, if this is the case then sorting the rows by starting points of the blocks followed by a simple version of Gauss elimination produces an echelon form of the matrix and a solution to the linear system. The expected number of field operations is $\mathcal{O}(nL/\varepsilon)$, which translates into expected running time $\mathcal{O}(n/\varepsilon^2)$ on a word RAM. For the proof, we establish a connection to a particular version of Robin Hood hashing, whose behaviour in turn can be understood by reducing it to a well-known situation in queuing theory. (A detailed sketch of the argument is provided in Section 2.1.)

To our knowledge, this class of random matrices has not been considered before. However, *deterministic* versions of matrices similar to these random ones have been thoroughly studied in the last century, for both infinite and finite fields. Namely, sorting the rows of our matrices yields matrices that with high probability resemble *band matrices*, where the nonzero entries in row i are within a restricted range around column $\lfloor i/(1 - \varepsilon) \rfloor$. In the study of band matrices one usually has $\varepsilon = 0$ and assumes that the matrix is nonsingular. Seemingly the best known general upper time bound for the number of field operations needed for solving band quadratic systems with bandwidth L are $\mathcal{O}(nL^{\omega-1}) = \mathcal{O}(n((\log n)/\varepsilon)^{\omega-1})$, where ω is the matrix multiplication exponent, see [20, 23, 33].

1.2 Retrieval

One motivation for studying random systems as described above comes from data structures for solving the *retrieval problem*, which can be described as follows: Some “*universe*” \mathcal{U} of possible keys is given, as is a function $f: S \rightarrow W$, where $S \subseteq \mathcal{U}$ has finite size m and $W = \{0, 1\}^r$ for some $r \geq 1$. A *retrieval data structure* [6, 10, 15, 35] makes it possible to recover $f(x)$ quickly for arbitrary given $x \in S$. We do not care what the result is when $x \notin S$, which makes the retrieval situation different from a dictionary, where the question “ $x \in S$?” must also be decided. A retrieval data structure consists of

- an algorithm **construct**, which takes f as a list of pairs (and maybe some parameters) as input and constructs an object DS_f , and
- an algorithm **query**, which on input $x \in \mathcal{U}$ and DS_f outputs an element of W , with the requirement that $\text{query}(\text{DS}_f, x) = f(x)$ for all $x \in S$.

The essential performance parameters of a retrieval data structure are:

- the space taken up by DS_f (ideally $(1 + \varepsilon)m$ bits of memory for some small $\varepsilon > 0$),
- the running time of **construct** (ideally $\mathcal{O}(m)$), and
- the running time of **query** (ideally a small constant in the worst case, possibly dependent on ε , and good cache behaviour).

In this paper we concentrate on the case most relevant in practice, namely the case of small constant r , in particular on² $r = 1$.

A standard approach is as follows [6, 10, 15, 35]. Let $f: S \rightarrow \{0, 1\}$ be given and let $n = m/(1 - \varepsilon)$ for some $\varepsilon > 0$. Use hashing to construct a mapping $\text{row}: \mathcal{U} \rightarrow \{0, 1\}^n$ such that $(\text{row}(x))_{x \in S}$ is (or behaves like) a family of independent random variables drawn from a suitable distribution \mathcal{R} on $\{0, 1\}^n$. Consider the linear system $(\langle \text{row}(x), \vec{z} \rangle = f(x))_{x \in S}$. In case the vectors $\text{row}(x)$, $x \in S$, are linearly independent, this system is solvable for \vec{z} .

² Every solution for this case gives a solution for larger r as well, with a slowdown not larger than r . In our case, this slowdown essentially only affects queries, not construction, since the Gauss elimination based algorithm can trivially be extended to simultaneously handle r right hand sides $\vec{b}_1, \dots, \vec{b}_r$ and produce r solution vectors $\vec{z}_1, \dots, \vec{z}_r$. This change slows down **construct** by a factor of $1 + r/L = 1 + \mathcal{O}(\varepsilon r / \log n)$.

Solve the system and store the bit vector \vec{z} of n bits (and the hash function used) as DS_f . Evaluation is by $\text{query}(\text{DS}_f, x) = \langle \text{row}(x), \vec{z} \rangle$, for $x \in \mathcal{U}$. The running time of **construct** is essentially the time for solving the linear system, and the running time for **query** is the time for evaluating the inner product.

A common and well-explored trick for reducing the construction time [5, 16, 35, 22] is to split the key set into “chunks” of size $\Theta(C)$ for some suitable C and constructing separate retrieval structures for the chunks. The price for this is twofold: In queries, one more hash function must be evaluated and the proper part of the data structure has to be located; regarding storage space one needs an array of $\Omega(m/C)$ pointers. In this paper, we first concentrate on a “pure” construction. The theoretical improvements possible by applying the splitting technique will be discussed briefly in Section 4. The splitting technique is also used in experiments for our construction in Section 5 to keep the block length small. In this context it will also be noted the related “split-and-share” technique from [16, 19] can be used to get rid of the assumption that fully random hash functions are available for free.

Our main result regarding the retrieval problem follows effortlessly from the analysis of the new random linear systems (formally stated as Theorem 2).

► **Theorem 1.** *Let \mathcal{U} be a universe. Assume the context of a word RAM with oracle access to fully random hash functions on \mathcal{U} . Then for any $\varepsilon > 0$ there is a retrieval data structure such that for all $S \subseteq \mathcal{U}$ of size m*

- (i) *construct succeeds with high probability.*
- (ii) *construct has expected running time $\mathcal{O}(\frac{m}{\varepsilon^2})$.*
- (iii) *The resulting data structure DS_f occupies at most $(1 + \varepsilon)m$ bits.*
- (iv) *query has running time $\mathcal{O}(\frac{1}{\varepsilon})$ and accesses $\mathcal{O}(\frac{1}{\varepsilon})$ consecutive words in memory.*

1.3 Machine Model and Notation

For a positive integer k we denote $\{1, \dots, k\}$ by $[k]$. The number m always denotes the size of a domain – the number of keys to hash, the size of a function for retrieval or the number of rows of a matrix. A (small) real number $\varepsilon > 0$ is also given. The number n denotes the size of a range. We usually have $m = (1 - \varepsilon)n$. In asymptotic considerations we always assume that ε is constant and m and n tend to ∞ , so that for example the expression $\mathcal{O}(n/\varepsilon)$ denotes a function that is bounded by cm/ε for a constant c , for all m bigger than some $m(\varepsilon)$. By $\langle \vec{y}, \vec{z} \rangle$ we denote the inner product of two vectors \vec{y} and \vec{z} . As our computational model we adopt the word RAM with memory words comprising $\Omega(\log m)$ bits, in which an operation on a word takes constant time. In addition to AC_0 instructions we will need the **PARITY** of a word as an elementary operation. For simplicity we assume this can be carried out in constant time, which certainly is realistic for standard word lengths like 64 or 128. In any case, as the word lengths used are never larger than $\mathcal{O}(\log m)$, one could tabulate the values of **PARITY** for inputs of size $\frac{1}{2} \log m$ in a table of size $\mathcal{O}(\sqrt{m} \log m)$ bits to achieve constant evaluation time for inputs comprising a constant number of words.

1.4 Techniques Used

We use *coupling* of random variables X and Y (or of processes $(X_i)_{i \geq 1}$ and $(Y_i)_{i \geq 1}$). By this we mean that we exhibit a single probability space on which X and Y (or $(X_i)_{i \geq 1}$ and $(Y_i)_{i \geq 1}$) are defined, so that there are interesting *pointwise* relations between them, like $X \leq Y$, or $X_i \leq Y_i + a$ for all $i \geq 1$, for a constant a . Sometimes these relations hold only conditioned on some (large) part of the probability space. We will make use of the following

observation. If we have random variables U_0, \dots, U_k with couplings, i.e. joint distributions, of $U_{\ell-1}$ and U_ℓ , for $1 \leq \ell \leq k$, then there is a common probability space on which all these random variables are defined and the joint distribution of $U_{\ell-1}$ and U_ℓ is as given.³

2 Random Band Systems that Can be Solved Quickly

The main topic of this paper are matrices generated by the following random process. Let $0 < \varepsilon < 1$ and $n \in \mathbb{N}$. For a number $m = (1 - \varepsilon)n$ of rows and some number $L \geq 1$ we consider a matrix $A = (a_{ij})_{i \in [m], j \in [n+L-1]}$ over the field \mathbb{F}_2 , chosen at random as follows. For each row $i \in [m]$ a *starting position* $s_i \in [n] = \{1, \dots, n\}$ is chosen uniformly at random. The entries a_{ij} , $s_i \leq j < s_i + L$ form a *block* of fully random bits, all other entries in row i are 0.

In this section we show that for proper choices of the parameters such a random matrix will have full row rank and the corresponding systems $A\vec{z} = \vec{b}$ will be solvable very efficiently whp. Before delving into the technical details, we sketch the main ideas of the proof.

2.1 Proof Sketch

As a starting point, we formulate a simple algorithm, a special version of Gaussian elimination, for solving linear systems $A\vec{z} = \vec{b}$ as just described. We first sort the rows of A by the starting position of their block. The resulting matrix resembles a band matrix, and we apply standard Gaussian elimination to it, treating the rows in order of their starting position. Conveniently, there is no “proliferation of 1’s”, i.e. we never produce a 1-entry outside of any row’s original block. In the round for row i , the entries a_{ij} for $j = s_i, \dots, s_i + L - 1$ are scanned. If column j has been previously chosen as pivot then $a_{ij} = 0$. Otherwise, a_{ij} is a random bit. While this bit may depend in a complex way on the original entries of rows $1, \dots, i$ (apart from position (i, j)), for the analysis we may simply imagine that a_{ij} is only chosen now by flipping a fair coin. This means that we consider eligible columns from left to right, and the first j for which the coin flip turns up 1 becomes the pivot column for row i . This view makes it possible to regard choosing pivot columns for the rows as probabilistically equivalent to a slightly twisted version of Robin Hood hashing. Here this means that m keys x_1, \dots, x_m with random hash values in $\{1, \dots, n + L - 1\}$ are given and, in order of increasing hash values, are inserted in a linear probing fashion into a table with positions $1, \dots, n + L - 1$ (meaning that for x_i cells s_i, s_{i+1}, \dots are inspected). The twist is that whenever a key probes an empty table cell flipping a fair coin decides whether it is placed in the cell or has to move on to the next one. The resulting position of key x_i is the same as the position of the pivot for row i . As is standard in the precise analysis of linear probing hashing we switch perspective and look at the process from the point of view of cells $1, 2, \dots, n, \dots, n + L - 1$. Associated with position (“time”) j is the set of keys that probe cell j (the “queue”), and the quantity to study is the length of this queue. It turns out that the average queue length determines the overall cost of the row additions, and that the probability for the maximum queue length to become too large is decisive for bounding the success probability of the Gaussian elimination process. The first and routine step in

³ We do not prove this formally, since arguments like this belong to basic probability theory or measure theory. The principle used is that the pairwise couplings give rise to conditional expectations $\mathbb{E}(U_\ell \mid U_{\ell-1})$. Arguing inductively, given a common probability space for $U_1, \dots, U_{\ell-1}$ and $\mathbb{E}(U_\ell \mid U_{\ell-1})$, one can obtain a common probability space for U_1, \dots, U_ℓ so that $(U_1, \dots, U_{\ell-1})$ is distributed as before and $\mathbb{E}(U_\ell \mid U_1, \dots, U_{\ell-1}) = \mathbb{E}(U_\ell \mid U_{\ell-1})$. – This is practically the same as the standard argument that shows that a sequence of conditional expectations gives rise to a corresponding Markov chain on a joint probability space.

the analysis of the queue length is to “Poissonise” arrivals such that the evolution of the queue length becomes a Markov chain. A second step is needed to deal with the somewhat annoying possibility that in a cell all keys that are eligible for this cell reject it because of their coin flips. We end up with a standard queue (an “M/D/1 queue” in Kendall notation) and can use existing results from queuing theory to read off the bounds regarding the queue length needed to complete the analysis.

The following subsections give the details.

2.2 A Simple Gaussian Solver

We now describe the algorithm to solve linear systems involving the random matrices described above. This is done by a variant of Gauss elimination, which will bring the matrix into echelon form (up to leaving out inessential column exchanges) and then apply back substitution.

Given a random matrix $A = (a_{ij})_{i \in [m], j \in [n+L-1]}$ as defined above, with blocks of length L starting at positions s_i , for $i \in [m]$, as well as some $\vec{b} \in \{0, 1\}^m$, we wish to find a solution \vec{z} to the system $A\vec{z} = \vec{b}$. Consider algorithm SGAUSS (Algorithm 1). If A has linearly independent rows, it will return a solution \vec{z} and produce intermediate values $(\text{piv}_i)_{i \in [m]}$. (These will be important only in the analysis of the algorithm.) If the rows of A are linearly dependent, the algorithm will fail.

■ **Algorithm 1** A simple Gaussian solver.

```

1 Algorithm SGAUSS( $A = (a_{ij})_{i \in [m], j \in [n+L-1]}$ ,  $(s_i)_{i \in [m]}$ ,  $\vec{b} \in \{0, 1\}^m$ ):
2   sort the rows of the system  $(A, \vec{b})$  by  $s_i$  (in time  $\mathcal{O}(m)$ )
3   relabel such that  $s_1 \leq s_2 \leq \dots \leq s_m$ 
4    $\text{piv}_1, \text{piv}_2, \dots, \text{piv}_m \leftarrow 0$ 
5   for  $i = 1, \dots, m$  do
6     for  $j = s_i, \dots, s_i + L - 1$  do } // search for leftmost 1 in row  $i$ . Can be done
7     if  $a_{ij} = 1$  then } // in time  $\mathcal{O}(L/\log m)$  on a word RAM.
8        $\text{piv}_i \leftarrow j$ 
9       for  $i'$  with  $i' > i \wedge s_{i'} \leq \text{piv}_i$  do
10        if  $a_{i', \text{piv}_i} = 1$  then
11           $a_{i'} \leftarrow a_{i'} \oplus a_i$  // row addition (= subtraction)
12           $b_{i'} \leftarrow b_{i'} \oplus b_i$ 
13        break
14     if  $\text{piv}_i = 0$  // row  $i$  is 0
15     then return FAILURE
    // back substitution:
16    $\vec{z} \leftarrow \vec{0}$ 
17   for  $i = m, \dots, 1$  do
18      $z_{\text{piv}_i} \leftarrow \langle \vec{z}, a_i \rangle \oplus b_i$  // note:  $a_{ij} = 0$  for  $j$  outside of  $\{s_i, \dots, s_i + L - 1\}$ 
19   return  $\vec{z}$  // solution to  $A\vec{z} = \vec{b}$ 

```

Algorithm SGAUSS starts by sorting the rows of the system (A, \vec{b}) by their starting positions s_i in linear time, e.g. using counting sort [13, Chapter 8.2]. We suppress the resulting permutation in the notation, assuming $s_1 \leq s_2 \leq \dots \leq s_m$. Rows are then processed sequentially. When row i is treated, its leftmost 1-entry is found, if possible, and

the corresponding column index is called the *pivot* piv_i of row i . Row additions are used to eliminate 1-entries from column piv_i in subsequent rows. Note that this operation never produces nonzero entries outside of any row's original block, i.e. for no row i are there ever any 1's outside of the positions $\{s_i, \dots, s_i + L - 1\}$. To see this, we argue inductively on the number of additions performed. Assume $i > 1$ and row i' with $i' < i$ is added to row i . By choice of $\text{piv}_{i'}$ and the induction hypothesis, nonzero entries of row i' can reside only in positions $\text{piv}_{i'}, \dots, s_{i'} + L - 1$. Again by induction and since row i contains a 1 in position $\text{piv}_{i'}$, we have $s_i \leq \text{piv}_{i'}$; moreover we have $s_{i'} + L - 1 \leq s_i + L - 1$, due to sorting. Thus, row i' contains no 1's outside of the block of row i and the row addition maintains the invariant.

If an all-zero row is encountered, the algorithm fails (and returns FAILURE). This happens if and only if the rows of A are linearly dependent⁴. Otherwise we say that the algorithm succeeds. In this case a solution \vec{z} to $A\vec{z} = \vec{b}$ is obtained by back-substitution.

It is not hard to see that the expected running time of SGAUSS is dominated by the expected cost of row additions.

The proof of the following statement, presented in the rest of this section, is the main technical contribution of this paper.

► **Theorem 2.** *There is some $L = \mathcal{O}((\log m)/\varepsilon)$ such that a run of SGAUSS on the random matrix $A = (a_{ij})_{i \in [m], j \in [n+L-1]}$ and an arbitrary right hand side $\vec{b} \in \{0, 1\}^m$ succeeds whp. The expected number of row additions is $\mathcal{O}(m/\varepsilon)$. Each row addition involves entries inside one block and takes time $\mathcal{O}(1/\varepsilon)$ on a word RAM.*

2.3 Coin-Flipping Robin Hood Hashing

Let $\{x_1, \dots, x_m\} \subseteq \mathcal{U}$ be some set of *keys* to be stored in a hash table T . Each key x_i has a uniformly random *hash value* $h_i \in [n]$. An (injective) placement of the keys in T fulfils the *linear probing* requirement if each x_i is stored in a cell $T[\text{pos}_i]$ with $\text{pos}_i \geq h_i$ and all cells $T[j]$ for $h_i \leq j < \text{pos}_i$ are non-empty. In *Robin Hood hashing* there is the additional requirement that $h_i > h_{i'}$ implies $\text{pos}_i > \text{pos}_{i'}$. Robin Hood hashing is interesting because it minimises the variance of the displacements $\text{pos}_i - h_i$. It has been studied in detail in several papers [9, 14, 25, 27, 36].

Given the hash values $(h_i)_{i \in [m]}$, a placement of the keys obeying the Robin Hood linear probing conditions can be obtained as follows: Insert the keys in the order of increasing hash values, by the usual linear probing insertion procedure, which probes (i.e. inspects) cells $T[h_i], T[h_i + 1], \dots$ until the first empty cell is found, and places x_i in this cell. We consider a slightly “broken” variation of this method, which sometimes delays placements. In the placing procedure for x_i , when an empty cell $T[j]$ is encountered, it is decided by flipping a fair coin whether to place x_i in cell $T[j]$ or move on to the next cell. (No problem is caused by the fact that the resulting placement violates the Robin Hood requirement and even the linear probing requirement, since the hash table is only used as a tool in our analysis.) For this insertion method we assume we have an (idealised) unbounded array $T[1, 2, \dots]$. The position in which key x_i is placed is called pos_i . At the end the algorithm itself checks whether any of the displacements $\text{pos}_i - h_i$ is larger than L , in which case it reports FAILURE.⁵ Algorithm 2 gives a precise description of this algorithm, which we term CFRH.

⁴ Depending on \vec{b} , the system $A\vec{z} = \vec{b}$ may still be solvable. We will not pursue this.

⁵ The reason we postpone checking for FAILURE until the very end of the execution is that it is technically convenient to have the values $(\text{pos}_i)_{i \in [m]}$ even if failure occurs.

■ **Algorithm 2** The *Coin-Flipping Robin Hood hashing* algorithm. Without the condition “ $\text{coinFlip}() = 1$ ” it would compute a Robin Hood placement with maximum displacement L , if one exists.

```

1 Algorithm CFRH ( $\{x_1, \dots, x_m\} \subseteq \mathcal{U}$ ):
2   sort  $x_1, \dots, x_m$  by hash value  $h_1, \dots, h_m$ 
3   relabel such that  $h_1 \leq \dots \leq h_m$ 
4    $T \leftarrow [\perp, \perp, \dots]$  // empty array, “ $\perp$ ” means “undefined”
5    $\text{pos}_1, \dots, \text{pos}_m \leftarrow 0$ 
6   for  $i = 1, \dots, m$  do
7     for  $j = h_i, h_i + 1, \dots$  do
8       if  $T[j] = \perp \wedge \text{coinFlip}() = 1$  (“HEADS”) then
9          $\text{pos}_i \leftarrow j$ 
10         $T[j] \leftarrow x_i$ 
11        break
12  if  $\exists i \in [m] : \text{pos}_i - h_i \geq L$  then return FAILURE
13  return  $T$ 

```

2.4 Connection between SGAUSS and CFRH

We now establish a close connection between the behaviour of algorithms SGAUSS and CFRH, thus reducing the analysis of SGAUSS to that of CFRH. The algorithms have been formulated in such a way that some structural similarity is immediate. A run of SGAUSS on a matrix with random starting positions $(s_i)_{i \in [m]}$ and random entries yields a sequence of pivots $(\text{piv}_i)_{i \in [m]}$; a run of CFRH on a key set with random hash values $(h_i)_{i \in [m]}$ performing random coin flips yields a sequence of positions $(\text{pos}_i)_{i \in [m]}$. We will see that the distributions of $(\text{piv}_i)_{i \in [m]}$ and $(\text{pos}_i)_{i \in [m]}$ are essentially the same and that moreover two not so obvious parameters of the two random processes are closely connected. For this, we will show that outside the FAILURE events we can use the probability space underlying algorithm SGAUSS to describe the behaviour of algorithm CFRH. This yields a coupling of the involved random processes.

The first step is to identify $s_i = h_i$ for $i \in [m]$ (both sequences are assumed to be sorted and then renamed). The connection between pos_i and piv_i is achieved by connecting the coin flips of CFRH to certain events in applying SGAUSS to matrix A . We construct this correspondence by induction on i . Assume rows $1, \dots, i-1$ have been treated, x_1, \dots, x_{i-1} have been placed, and $\text{piv}_{i'} = \text{pos}_{i'}$ for all $1 \leq i' < i$.

Now row a_i (transformed by previous row additions) is treated. It contains a 0 in columns that were previously chosen as pivots, so possible candidates for piv_i are only indices from $J_i := \{s_i, \dots, s_i + L - 1\} \setminus \{\text{piv}_1, \dots, \text{piv}_{i-1}\}$. For each $j \in J_i$, the initial value of a_{ij} was a random bit. The bits added to a_{ij} in rounds $1, \dots, i-1$ are determined by the original entries of rows $1, \dots, i-1$ alone. We order the entries of J_i as $j^{(1)} < j^{(2)} < \dots < j^{(|J_i|)}$. Then, conditioned on all random choices in rows $1, \dots, i-1$ of A , the current values $a_{i,j^{(1)}}, \dots, a_{i,j^{(k)}}$ still form a sequence of fully random bits. We use these random bits to run round i of CFRH, in which x_i is placed. Since each cell can only hold one key, and by excluding runs where finally FAILURE is declared, we may focus on the empty cells with indices in $\{h_i, \dots, h_i + L - 1\} \setminus \{\text{pos}_1, \dots, \text{pos}_{i-1}\} = \{s_1, \dots, s_i + L - 1\} \setminus \{\text{piv}_1, \dots, \text{piv}_{i-1}\} = J_i$. We use (the current value) a_{ij} as the value of the coin flip for cell j , for $j = j^{(1)}, j^{(2)}, \dots, j^{(|J_i|)}$. The minimal j in this sequence (if any) with $a_{ij} = 1$ equals piv_i and pos_i . If all these bits are 0, algorithm SGAUSS will fail immediately, and key x_i will be placed in a cell $T[j]$ with $j \geq h_i + L$, so CFRH will eventually fail as well.

Thus we have established that the random variables needed to run algorithm CFRH (outside of FAILURE) can be taken to belong to the probability space defined by $(s_i)_{i \in [m]}$ and the entries in the blocks of A for algorithm SGAUSS, so that (outside of FAILURE) the random variables pos_i and piv_i are the same. In the following lemma we state this connection as Claim (i). In addition, we consider other random variables central for the analysis to follow. First, we define the *height* of position $j \in [n + L - 1]$ in the hash table as

$$H_j := \#\{i \in [m] \mid h_i \leq j < \text{pos}_i\}.$$

This is the number of keys probing table cell j without being placed in it, either because the cell is occupied or because it is rejected by the coin flip. Claim (ii) in the next lemma shows that $\sum_{j \in [n+L-1]} H_j$ essentially determines the running time of SGAUSS, so that we can focus on bounding $(H_j)_{j \in \mathbb{N}}$ from here on. Further, with Claim (iii), we get a handle on the question how large we have to choose L in order to keep the failure probability small.

► **Lemma 3.** *With the coupling just described, we get*

- (i) SGAUSS succeeds iff CFRH succeeds. On success we have $\text{piv}_i = \text{pos}_i$ for all $i \in [m]$.
- (ii) A successful run of SGAUSS performs at most $\sum_{j \in [n+L-1]} H_j$ row additions.
- (iii) Conditioned on the event $\max_{j \in [n]} H_j \leq L - 2 \log m$, the algorithms succeed whp.

Proof. (ii) (Note that a similar statement with a different proof can be found in [26, Lemma 2.1].) Consider the sets $\text{Add} := \{(i, i') \in [m]^2 \mid \text{SGAUSS adds row } i \text{ to row } i'\}$ and $\text{Displ} := \{(i, j) \in [m] \times [n + L - 1] \mid h_i \leq j < \text{pos}_i\}$. Since H_j simply counts the pairs $(i, j) \in \text{Displ}$ with $i \in [m]$, we have $|\text{Displ}| = \sum_{j \in [n+L-1]} H_j$. To prove the claim we exhibit an injection from Add into Displ .

Assume $(i, i') \in \text{Add}$. If $\text{pos}_i < \text{pos}_{i'}$, we map (i, i') to (i', pos_i) . This is indeed an element of Displ , since $h_{i'} \leq \text{piv}_i = \text{pos}_i < \text{pos}_{i'}$ (if piv_i were smaller than $s_{i'}$, row i would not be added to row i'). On the other hand, if $\text{pos}_i > \text{pos}_{i'}$, we map (i, i') to $(i, \text{pos}_{i'})$. This is in Displ since $h_i = s_i \leq s_{i'} \leq \text{pos}_{i'} < \text{pos}_i$ (recall that rows are sorted by starting position).

The mapping is injective since from the image of $(i, i') \in \text{Add}$ we can recover the set $\{i, i'\}$ with the help of the injective mapping $i \mapsto \text{pos}_i$, $i \in [m]$. The fact that $i < i'$ fixes the ordering in the pair.

(iii) In CFRH, for an arbitrary $i \in [m]$ consider the state before key x_i probes its first position $j := h_i$. Any previous key $x_{i'}$ with $i' < i$ has a hash value $h_{i'} \leq h_i$. Hence it either was inserted in a cell $j' < j$ or it has probed cell j . Since at most H_j keys have probed cell j , at most H_j positions in $T[j, \dots, j + L - 1]$ are occupied and at least $2 \log m$ are free. The probability that x_i is not placed in this region is therefore at most $2^{-2 \log m} = m^{-2}$. By the union bound we obtain a failure probability of $\mathcal{O}(1/m)$. ◀

2.5 Bounding Heights in CFRH by a Markov Chain

Lemma 3 tells us that we must analyse the heights in the hashing process CFRH. In this subsection, we use “Poissonisation” of the hashing positions to majorise the heights in CFRH by a Markov chain, i.e. a process that is oblivious to the past, apart from the current height. Poissonisation is a common step in the analysis of linear probing hashing, see e.g. [36]. Further, we wish to replace randomized placement by deterministic placement: Whenever a key is available for a position, one is put there (instead of flipping coins for all available keys). By this, the heights may decrease, but only by a bounded amount whp. The details of these steps are given in this subsection.

In analysing CFRH (without regard for the event FAILURE), it is inconvenient that the starting positions h_i are determined by random choices with subsequent sorting. Position j is hit by a number of keys given by a binomial distribution $\text{Bin}(m, \frac{1}{n})$ with expectation $\frac{m}{n} = 1 - \varepsilon$, but there are dependencies. We approximate this situation by ‘‘Poissonisation’’ [31, Sect. 5.4]. Here this means that we assume that cell $j \in [n]$ is hit by k_j keys, independently for $j = 1, \dots, m$, where $k_j \sim \text{Po}(1 - \varepsilon')$ is Poisson distributed, for $\varepsilon' = \varepsilon/2$. Then the total number $m' = \sum_{j \in [n]} k_j$ of keys is distributed as $m' \sim \text{Po}((1 - \varepsilon')n)$. Given k_1, \dots, k_n , we can imagine we have m' keys with nondecreasing hash values $(h_i)_{i \in [m']}$, and we can apply algorithm CFRH to obtain key positions $(\text{pos}'_i)_{i \in [m']}$ in $\{1, 2, \dots\}$ and cell heights $(H'_j)_{j \geq 1}$.

Conveniently, with Poissonisation, the heights $(H'_j)_{j \in [n]}$ turn out to form a Markov chain. This can be seen as follows. Recall that H'_{j-1} is the number of keys probing cell $j - 1$ without being placed there. Hence the number of keys probing cell j is $H'_{j-1} + k_j$. One of these keys will be placed in cell j , unless $H'_{j-1} + k_j$ coin flips all yield 0, so if $g_j \sim \text{Geom}(\frac{1}{2})$ is a random variable with geometric distribution with parameter $\frac{1}{2}$ (number of fair coin flips needed until the first 1 appears) and b_j is the indicator function $\mathbb{1}_{\{g_j > H'_{j-1} + k_j\}}$, we have $H'_j = H'_{j-1} + k_j - 1 + b_j$. (Note that the case $H'_{j-1} + k_j = 0$ is treated correctly by this description. Conditioned on $H'_{j-1} + k_j$, the value b_j is a Bernoulli variable.) The Markov property holds since H'_j depends only on H'_{j-1} and the two ‘‘fresh’’ random variables k_j and g_j .

The following lemma allows us to shift our attention from (H_j) to (H'_j) .

► **Lemma 4.** *Let $m = (1 - \varepsilon)n$ and $m' \sim \text{Po}((1 - \varepsilon')m)$ for $\varepsilon' = \varepsilon/2$. There is a coupling between an ordinary run of CFRH (with m , n and H_j) and a Poissonised run (with m' , n and H'_j) such that conditioned on the high probability event $E_{\geq m} = \{m' \geq m\}$ we have $H'_j \geq H_j$ for all $j \in [n + L - 1]$.*

Proof. Because ε and $\varepsilon' = \varepsilon/2$ are constants, the event $E_{\geq m}$ has indeed high probability, as can be seen by well-known concentration bounds for the Poisson distribution (e.g. [31, Th. 5.4]). For $m_0 \geq m$ fixed the distribution of the number of hits in the cells in $T[1, \dots, n]$ conditioned on $\{m' = m_0\}$ is the same as what we get by throwing m_0 balls randomly into n bins [31, Th. 5.6]. Thus, we may assume the Poissonised run has to deal with the m keys of the ordinary run plus $m' - m$ additional keys with random hash values in $[n]$. We apply algorithm CFRH to both inputs. After sorting, the new keys are inserted in some interleaved way with the ordinary keys. Now if one of the ordinary keys x probes an empty cell $T[j]$, we use the same coin flip in both runs to decide whether to place it there; for the probing of the additional keys we use new, independent coin flips. With this coupling it is clear that for all ordinary keys x the displacement ‘‘(position of x) – (hash value of x)’’ in the Poissonised run is at least as big as in the ordinary run. As the additional keys can only increase heights, $H'_j \geq H_j$ follows. ◀

As a further simplification, we eliminate the geometrically distributed variable g_j and the derived variable b_j in the Markov chain $(H'_j)_{j \geq 0}$. For this, let $(X_j)_{j \geq 0}$ be the Markov chain defined as

$$X_0 := 0 \quad \text{and} \quad X_j := \max(0, X_{j-1} + d_j - 1) \quad \text{for } j \geq 1, \quad (1)$$

where $d_j \sim \text{Po}(1 - \varepsilon'/2)$ are independent random variables.

► **Lemma 5.** *There is a coupling between $(X_j)_{j \geq 0}$ and $(H'_j)_{j \geq 0}$ such that $X_j + \log(4/\varepsilon') \geq H'_j$ for all $j \in [n + L - 1]$.*

Proof. Assume wlog that $\log(1/\varepsilon')$ is an integer. Let $b'_j \sim \text{Po}(\varepsilon'/2)$ be a random variable on the same probability space as g_j such that $g_j > \log(4/\varepsilon')$ implies $b'_j \geq 1$. This is possible because

$$\Pr[g_j > \log(4/\varepsilon')] = 2^{-\log(4/\varepsilon')} = \varepsilon'/4 \leq 1 - e^{-\varepsilon'/2} = \Pr[b'_j \geq 1].$$

We then define $d_j := k_j + b'_j$ which gives $d_j \sim \text{Po}(1 - \varepsilon'/2)$. Proceeding by induction, and using (1), we can define $(X_j)_{j \geq 0}$ and $(H'_j)_{j \geq 0}$ on a common probability space. Then we check $X_j + \log(4/\varepsilon') \geq H'_j$, also by induction: In the case $H'_{j-1} + k_j \leq \log(4/\varepsilon')$ we simply get

$$X_j + \log(4/\varepsilon') \geq \log(4/\varepsilon') \geq H'_{j-1} + k_j \geq H'_{j-1} + k_j + b_j - 1 = H'_j.$$

Otherwise we can use the inequality $b_j = \mathbb{1}_{\{g_j > H'_{j-1} + k_j\}} \leq \mathbb{1}_{\{g_j > \log(4/\varepsilon')\}} \leq b'_j$ to obtain

$$\begin{aligned} X_j + \log(4/\varepsilon') &\geq X_{j-1} + d_j - 1 + \log(4/\varepsilon') \stackrel{(\text{Ind.Hyp.})}{\geq} H'_{j-1} + d_j - 1 \\ &= H'_{j-1} + k_j + b'_j - 1 \geq H'_{j-1} + k_j + b_j - 1 = H'_j. \end{aligned} \quad \blacktriangleleft$$

2.6 Enter Queuing Theory

It turns out that, in essence, the behaviour of the Markov chain $(X_j)_{j \geq 0}$ has been studied in the literature under the name “M/D/1 queue”, which is Kendall notation [28] for queues with “Markovian arrivals, Deterministic service times and 1 server”. We will exploit what is known about this simple queuing situation in order to finish our analysis.

Formally, an M/D/1 queue is a Markov process $(Z_t)_{t \in \mathbb{R}_{\geq 0}}$ in continuous time and discrete space $\mathbb{N}_0 = \{0, 1, 2, \dots\}$. The random variable Z_t is usually interpreted as the number of *customers* waiting in a FIFO queue at time $t \in \mathbb{R}_{\geq 0}$. Initially the queue is empty ($Z_0 = 0$). Customers arrive independently, i.e. arrivals are determined by a Poisson process with a rate we set to $\rho = 1 - \varepsilon'/2$ (which implies that the number of customers arriving in any fixed time interval of length 1 is $\text{Po}(\rho)$ -distributed). The *server* requires one time unit to process a customer which means that if $t \in \mathbb{R}_{\geq 0}$ is the time of the first arrival, then customers will leave the queue at times $t + 1, t + 2, \dots$ until the queue is empty again.

Now consider the discretisation $(Z_j)_{j \in \mathbb{N}_0}$ of the M/D/1 queue. For $j \geq 1$, the number d_j of arrivals in between two observations Z_{j-1} and Z_j has distribution $d_j \sim \text{Po}(\rho)$, and one customer was served in the meantime if and only if $Z_{j-1} > 0$. We can therefore write

$$Z_j = \begin{cases} d_j & \text{if } Z_{j-1} = 0, \\ Z_{j-1} + d_j - 1 & \text{if } Z_{j-1} > 0. \end{cases}$$

By reusing the variables $(d_j)_{j \geq 1}$ that previously occurred in the definition of $(X_j)_{j \geq 0}$, we already established a coupling between the processes $(X_j)_{j \geq 0}$ and $(Z_j)_{j \geq 0}$. A simple induction suffices to show

$$X_j = \max(0, Z_j - 1) \text{ for all } j \geq 0. \quad (2)$$

Intuitively, the server in the X -process is ahead by one customer because customers are processed at integer times “just in time for the observation”.

The following results are known in queuing theory:

► **Fact 1.**

(i) The average number of customers in the Z -queue at time $t \in \mathbb{R}_{\geq 0}$ is

$$\mathbb{E}[Z_t] \leq \lim_{\tau \rightarrow \infty} \mathbb{E}[Z_\tau] = \rho + \frac{1}{2} \left(\frac{\rho^2}{1 - \rho} \right) = \Theta(1/\varepsilon).$$

(Precise values are known even for general service-time distributions, see [12, Chapter 5.4].)

(ii) [21, Prop 3.4] We have the following tail bound for the event $\{Z_t > k\}$ for any $k \in \mathbb{N}$:

$$\Pr[Z_t > k] \leq \lim_{\tau \rightarrow \infty} \Pr[Z_\tau > k] = e^{-k \cdot \Theta(\varepsilon)}, \text{ for all } t \geq 0.$$

2.7 Putting the Pieces Together

We now have everything in place to prove Theorem 2 regarding solving our linear systems.

Proof of Theorem 2. By the observation made in Section 1.4, we may assume that the random variables $(H_j)_{j \in [n+L-1]}$, $(H'_j)_{j \in [n+L-1]}$, $(X_j)_{j \geq 0}$ and $(Z_j)_{j \geq 0}$ and the three corresponding couplings are realized on one common probability space.

By Fact 1(ii) it is possible to choose $L = \Theta((\log m)/\varepsilon)$ while guaranteeing $\Pr[Z_j > L/2] = \mathcal{O}(m^{-2})$ for all $j \geq 0$.

By the choice of L and the union bound, the event $E_{\max Z} = \{\forall j \in [n+L-1]: Z_j \leq L/2\}$ occurs whp. Conditioned on $E_{\max Z}$ and the high probability event $E_{\geq m}$ from Lemma 4 we have

$$H_j \stackrel{\text{Lem. 4}}{\leq} H'_j \stackrel{\text{Lem. 5}}{\leq} X_j + \log(4/\varepsilon') \stackrel{\text{Eq. 2}}{\leq} Z_j + \log(4/\varepsilon') \stackrel{E_{\max Z}}{\leq} L/2 + \log(4/\varepsilon') \leq L - 2 \log m.$$

By using Lemma 3(iii) we conclude that SGAUSS succeeds with high probability.

Along similar lines we get, for each $j \in [n+L-1]$:

$$\begin{aligned} \mathbb{E}[H_j] &\stackrel{\text{Lem. 4}}{\leq} \mathbb{E}[H'_j \mid E_{\geq m}] \leq \frac{1}{\Pr[E_{\geq m}]} \mathbb{E}[H'_j] \stackrel{\text{Lem. 5}}{\leq} \frac{1}{\Pr[E_{\geq m}]} \mathbb{E}[X_j + \log(4/\varepsilon')] \\ &\stackrel{\text{Eq. 2}}{\leq} \frac{1}{\Pr[E_{\geq m}]} \mathbb{E}[Z_j + \log(4/\varepsilon')] \stackrel{\text{Fact 1(i)}}{\leq} \frac{1}{\Pr[E_{\geq m}]} (\mathcal{O}(1/\varepsilon) + \log(4/\varepsilon')) = \mathcal{O}(1/\varepsilon). \end{aligned}$$

By Lemma 3(ii) the expected number of row additions performed by a successful run of SGAUSS is therefore at most $\mathbb{E}[\sum_{j \in [n+L-1]} H_j] = \mathcal{O}(m/\varepsilon)$. Since unsuccessful runs happen with probability $\mathcal{O}(1/m)$ and can perform at most mL additions (each row can only be the target of L row additions), the overall expected number of additions is not skewed by unsuccessful runs, hence is also in $\mathcal{O}(m/\varepsilon)$. This finishes the proof of Theorem 2. ◀

► **Remark.** The analysis described in this section works in exactly the same way if instead of \mathbb{F}_2 a larger finite field \mathbb{F} is used. A row in the random matrix is determined by a random starting position and a block of L random elements from \mathbb{F} . A row operation in the Gaussian elimination now consists of a division, a multiplication of a block with a scalar and a row addition. The running time of the algorithm will increase at least by a factor of $\log(|\mathbb{F}|)$ (the bitlength of a field element), and further increases depend on how well word parallelism in the word RAM can be utilized for operations like row additions, scalar multiplications and scalar products. (In [22], efficient methods are described for the field of three elements.) The queue length will become a little smaller, but not significantly, since even the M/D/1 queue with arrivals with a Poisson($1 - \varepsilon$) distribution will lead to average queue length $\Theta(1/\varepsilon)$.

► **Remark.** An interesting question was raised by a reviewer of the submission: Is anything gained if we fix the first bit of each block to be 1? When checking our analysis for this case we see that this 1-bit need not survive previous row operations. However, such a change does improve success probabilities in the Robin Hood insertion procedure. If a key x_i finds cell h_i empty, it occupies this cell, without a coin being flipped. From the point of view of the queues, we see that now the derived variable b_j in Section 2.5 is 1 if $k_j > 0$ and geometrically distributed only if $k_j = 0$. As in the preceding remark, this brings the process closer to the M/D/1 queue with arrivals with a $\text{Poisson}(1 - \varepsilon)$ distribution and deterministic service time 1, but the average queue length remains $\Theta(1/\varepsilon)$. Still, it may be interesting to check by experiments if improvements result by this change.

3 A New Retrieval Data Structure

With Theorem 2 in place we are ready to carry out the analysis of the retrieval data structure based on the new random matrices as described in Section 1.2. The proof of Theorem 1 is more or less straightforward.

Proof of Theorem 1. Denote the m elements of S by x_1, \dots, x_m , let $n = \frac{1}{1-\varepsilon}m$, $L = \Theta(\frac{\log m}{\varepsilon})$ the number from Theorem 2 and $h: \mathcal{U} \rightarrow [n] \times \{0, 1\}^L$ a fully random hash function. For construct, we associate the values $(s_i, p_i) := h(x_i)$ with each x_i for $i \in [m]$ and interpret them as a random band matrix $A = (a_{ij})_{i \in [m], j \in [n+L-1]}$, where for all $i \in [m]$ row a_i contains the pattern p_i starting at position s_i and 0's everywhere else. Moreover, let $\vec{b} \in \{0, 1\}^m$ be the vector with entries $b_i = f(x_i)$ for $i \in [m]$. We call SGAUSS (Algorithm 1) with inputs A and \vec{b} , obtaining (in case of success) a solution $\vec{z} \in \{0, 1\}^{n+L-1}$ of $A\vec{z} = \vec{b}$. The retrieval data structure is simply $\text{DS}_f = \vec{z}$.

By Theorem 2 construct succeeds whp⁶ (establishing (i)) and performs $\mathcal{O}(m/\varepsilon)$ row additions. Since additions affect only $L = \mathcal{O}(\frac{\log m}{\varepsilon})$ consecutive bits, and since a word RAM can deal with $\mathcal{O}(\log m)$ bits at once, a single row addition costs $\mathcal{O}(1/\varepsilon)$ time, leading to total expected running time $\mathcal{O}(m/\varepsilon^2)$ (which establishes (ii)).

The data structure $\text{DS}_f = \vec{z}$ occupies exactly $\frac{1}{1-\varepsilon}m + L - 1 < (1 + 2\varepsilon)m$ bits. Replacing ε with $\varepsilon/2$ yields the literal result (iii).

To evaluate $\text{query}(\text{DS}_f, y)$ for $y \in \mathcal{U}$, we compute $(s_y, p_y) = h(y)$ and the scalar product $b_y = \langle \vec{z}[s_y \dots s_y+L-1], p_y \rangle := \bigoplus_{j=1}^L \vec{z}_{s_y+j-1} \cdot p_{y_j}$. By construction, this yields $b_i = f(x_i)$ in the case that $y = x_i$. To obtain (iv), observe that the scalar product of two binary sequences of length $L = \mathcal{O}(\log(n)/\varepsilon)$ can be computed using $\mathcal{O}(1/\varepsilon)$ bit parallel AND and XOR operations, as well as a single PARITY operation on $\mathcal{O}(\log m)$ bits, which can be assumed to be available in constant time. ◀

► **Remark.** As the proof of Theorem 2 remains valid for arbitrary fixed finite fields in place of \mathbb{F}_2 , the same is true for Theorem 1. This is relevant for the compact representation of functions with small ranges like [3], where binary encoding of single symbols implies extra space overhead. Such functions occur in data structures for perfect hash functions [7, 22].

⁶ If success with probability 1 is desired, then in case the construction fails with hash function $h_0 = h$, we just restart the construction with different hash functions h_1, h_2, \dots . In this setup, DS_f must also contain the seed $s \in \mathbb{N}_0$ identifying the first hash function h_s that led to success.

4 Input Partitioning

We examine the effect of a simple trick to improve construction and query times of our retrieval data structure. We partition the input into *chunks* using a “first-level hash function” and construct a separate retrieval data structure for each chunk. Using this with chunk size $C = m^\varepsilon$ will reduce the time bounds for construction and query by a factor of ε . The main reason for this is that we can use smaller block sizes L , which in turn makes row additions and inner products cheaper. Note that the idea is not new. Partitioning the input has previously been applied in the context of retrieval to reduce construction times, especially when “raw” construction times are superlinear [15, 22, 35] or when performance in external memory settings is an issue [3, 7]. Partitioning also allows us to get rid of the full randomness assumption, which is interesting from a theoretical point of view [7, 19, 16].

► **Remark.** The reader should be aware that the choice $C = m^\varepsilon$, which is needed to obtain a speedup of $1/\varepsilon$, is unlikely to be a good choice in practice and that this improvement only works for unrealistically large m . Namely, we use that $\frac{\log m}{m^\varepsilon} \ll \varepsilon$ for sufficiently large m . While the left term is indeed $o(1)$ and the right a constant, even for moderate values of ε like 0.05 implausibly large values of m are needed to satisfy the weaker requirement $\frac{\log m}{m^\varepsilon} < \varepsilon$. In this sense, Theorem 6 taken literally is of purely theoretical value. Still, the general idea is sound and it can give improvements in practice when partitioning less aggressively, say with $C \approx \sqrt{m}$. For example, the good running times reported in Section 5 are only possible with this splitting approach.

► **Theorem 6.** *The result of Theorem 1 can be strengthened in the following ways.*

- (i) *The statements of Theorem 1 continue to hold without the assumption of fully random hash functions being available for free.*
- (ii) *The expected construction time is $\mathcal{O}(m/\varepsilon)$ (instead of $\mathcal{O}(m/\varepsilon^2)$).*
- (iii) *The expected query time is $\mathcal{O}(1)$ (instead of $\mathcal{O}(1/\varepsilon)$). Queries involve accessing a (small) auxiliary data structure, so technically not all required data is “consecutive in memory”.*

Proof Sketch. Let $C = m^\varepsilon$ be the *desired chunk size*. In [7, Section 4] it is described in detail how a splitting function can be used to obtain chunks that have size within a constant factor of C with high probability, and how fully random hash functions on each individual chunk can be provided by a randomized auxiliary structure \mathcal{H} that takes only $o(m)$ space. New functions can be generated by switching to new seeds. (This construction is a variation of what is described in [16, 19].) This fully suffices for our purposes. We construct an individual retrieval data structure for each chunk with $L = \mathcal{O}(\frac{\log C}{\varepsilon}) = \mathcal{O}(\log m)$. Such a construction succeeds in expected time $\mathcal{O}(C/\varepsilon)$ with probability $1 - \mathcal{O}(1/C)$. In case the construction fails for a chunk, it is repeated with a different seed. At the end we save the concatenation of all m/C retrieval data structures, the data structure \mathcal{H} and an auxiliary array. This array contains, for each chunk, the offset of the corresponding retrieval data structure in the concatenation and the seed of the hash function used for the chunk. It is easy to check that the size of all auxiliary data is asymptotically negligible.

The total expected construction time is $\mathcal{O}((m/C) \cdot C/\varepsilon) = \mathcal{O}(m/\varepsilon)$, and since $L = \mathcal{O}(\log m)$, a retrieval query can be evaluated in constant time. ◀

► **Remark.** The construction from [30] described in item (4) in the list in Section 1.1 can also be transformed in a retrieval data structure. (This does not seem to have been explored up to now.) The expected running time for **construct** is $\mathcal{O}(m \log(1/\varepsilon))$ (better than our $\mathcal{O}(m/\varepsilon)$), the expected running time for **query** is $\mathcal{O}(\log(1/\varepsilon))$, with $\mathcal{O}(\log(1/\varepsilon))$ random accesses in

memory. (Worst case is $\mathcal{O}(1/\varepsilon)$.) In our preliminary experiments, see Section 5, for $m = 10^7$, both construction and query times of our construction seem to be able to compete well with the construction following [30].

5 Experiments

We implemented our retrieval data structure following the approach explained in the proof of Theorem 6, except that we used `MurmurHash3` [1] for all hash functions. This is a heuristic insofar as we depart from the full randomness assumption of Theorem 1. We report⁷ running times and space overheads in Table 1, with the understanding that a retrieval data structure occupying N bits of memory in total and accommodating m keys has overhead $\frac{N}{m} - 1$. Concerning the choice of parameters, $L = 64$ has practical advantages on a 64-bit machine and $C = 10^4$ seems to go well with it experimentally. As $\varepsilon \in \{7\%, 5\%, 3\%\}$ decreases, the measured construction time increases as would be expected. This is partly due to the higher number of row additions in successful constructions, but also due to an increased probability for a chunk's construction to fail, which prompts a restart for that chunk with a different seed. Note that, in our implementation, querying an element in a chunk with non-default seed also prompts an additional hash function evaluation.

Competing Implementations. For comparison, we implemented the retrieval data structures from [7, 17, 22] and the one arising from the construction in [29]. (The number D in Table 1 is the maximum number of 1's in a row; the average is then $\Theta(\log D)$.)

In [7], the rows of the linear systems contain three 1's in independent and uniformly random positions. If the number of columns is $n = m/(1 - \varepsilon)$ for $\varepsilon > 18.2\%$, the system can be solved in linear time by row and column *exchanges* alone. Compared to that method, we achieve smaller overheads at similar running times.

The approaches from [22] and [17] are different in that they construct linear systems that require cubic solving time with Gaussian elimination. This is counteracted by partitioning the input into chunks as well as by a heuristic *LazyGauss*-phase of the solver that eliminates many variables before the Method of Four Russians [2] is used on what remains. Construction times are higher than ours, but the tiny space overhead achieved in [17] is beyond the reach of our approach. The systems considered in [22] resemble those in [7], except at higher densities. The systems studied in [17] resemble our systems, except with *two* blocks of random bits per row instead of one.

We remark that our approach is easier to implement than those of [17, 22] but more difficult than that of [7].

6 Conclusion

This paper studies the principles of solving linear systems given by a particular kind of sparse random matrices, with one short random block per row, in a random position. The proof works by the point of view from Gaussian elimination to Robin Hood hashing and then to queuing theory. It might be interesting to find a direct, simpler proof for the main

⁷ Experiments were performed on a desktop computer with an Intel® Core i7-2600 Processor @ 3.40GHz. Following [22], we used as data set S the first $m = 10^7$ URLs from the `eu-2015-host` dataset gathered by [4] with ≈ 80 bytes per key. As hash function we used `MURMURHASH3_X64_128` [1]. Reported query times are averages obtained by querying all elements of the data set once and include the evaluation of `murmur`, which takes about 25 ns on average. The reported figures are medians of 5 executions.

■ **Table 1** Space overhead and running times per key of some practical retrieval data structures.

	Configuration	Overhead	construct [$\mu\text{s}/\text{key}$]	query [ns]
[7]	$\varepsilon = 19\%$	23.5%	0.32	59
$\langle\text{NEW}\rangle$	$\varepsilon = 7\%, L = 64, C = 10^4$	8.8%	0.24	52
$\langle\text{NEW}\rangle$	$\varepsilon = 5\%, L = 64, C = 10^4$	6.5%	0.27	54
$\langle\text{NEW}\rangle$	$\varepsilon = 3\%, L = 64, C = 10^4$	4.3%	0.43	61
[29]	$c = 0.9, D = 12$	11.1%	0.79	94
[29]	$c = 0.99, D = 150$	1.1%	0.87	109
[22]	$\varepsilon = 9\%, k = 3, C = 10^4$	10.2%	1.30	58
[22]	$\varepsilon = 3\%, k = 4, C = 10^4$	3.4%	2.20	64
[17]	$\varepsilon = 0.05\%, \ell = 16, C = 10^4$	0.25%	2.47	56

theorem. Preliminary experiments concerning an application with retrieval data structures are promising. The most intriguing property is that evaluation of a retrieval query requires accessing only one (short) block in memory.

The potential of the construction in practice should be explored more fully and systematically, taking all relevant parameters like block size and chunk size into consideration. Constructions of perfect hash functions like in [7, 22] or Bloom filters that combine perfect hashing with fingerprinting [8, 15] might profit from our construction.

Abstract

We study the problem of k -center clustering with outliers in arbitrary metrics and Euclidean space. Though a number of methods have been developed in the past decades, it is still quite challenging to design quality guaranteed algorithm with low complexity for this problem. Our idea is inspired by the greedy method, Gonzalez’s algorithm, for solving the problem of ordinary k -center clustering. Based on some novel observations, we show that this greedy strategy actually can handle k -center clustering with outliers efficiently, in terms of clustering quality and time complexity. We further show that the greedy approach yields small coreset for the problem in doubling metrics, so as to reduce the time complexity significantly. Our algorithms are easy to implement in practice. We test our method on both synthetic and real datasets. The experimental results suggest that our algorithms can achieve near optimal solutions and yield lower running times comparing with existing methods.

1 Introduction

Clustering is one of the most fundamental problems in data analysis [25]. Given a set of elements, the goal of clustering is to partition the set into several groups based on their similarities or dissimilarities. Several clustering models have been extensively studied, such as k -center, k -median, and k -means clustering [9]. In reality, datasets often are noisy and contain outliers. Moreover, outliers could seriously affect the final results in data analysis [14]. Clustering with outliers can be viewed as a generalization of ordinary clustering problems; however, the existence of outliers makes the problems to be much more challenging.

We focus on the problem of *k -center clustering with outliers* in this paper. Given a metric space with n vertices and a pre-specified number of outliers $z < n$, the problem is to find k balls to cover at least $n - z$ vertices and minimize the maximum radius of the balls. The problem also can be defined in Euclidean space so that the cluster centers can be any points in the space (i.e., not restricted to be selected from the input points). The

2-approximation algorithms for ordinary k -center clustering (without outliers) were given in [18, 22], and it was proved that any approximation ratio lower than 2 implies $P = NP$. A 3-approximation algorithm for k -center clustering with outliers in arbitrary metrics was proposed by Charikar et al. [15]; for the problem in Euclidean space, their approximation ratio becomes 4. A following streaming $(4 + \epsilon)$ -approximation algorithm was proposed by McCutchen and Khuller [33]. Recently, Chakrabarty et al. [13] proposed a 2-approximation algorithm for metric k -center clustering with outliers (but it is unclear of the resulting approximation ratio for the problem in Euclidean space). Existing algorithms often have high time complexities. For example, the complexities of the algorithms in [15, 33] are $O(kn^2 \log n)$ and $O(\frac{1}{\epsilon}(kzn + (kz)^2 \log \Phi))$ respectively, where Φ is the ratio of the optimal radius to the smallest pairwise distance among the vertices; the algorithm in [13] needs to solve a complicated model of linear programming and the exact time complexity is not provided. The coreset based idea of Badoiu et al. [7] needs to enumerate a large number of possible cases and also yields a high complexity. Several distributed algorithms for k -center clustering with outliers were proposed recently [12, 19, 30, 32]; most of these distributed algorithms, to our best knowledge, rely on the sequential algorithm [15].

In this paper, we aim to design quality guaranteed algorithm with low complexity for the problem of k -center clustering with outliers. Our idea is inspired by the greedy method from Gonzalez [18] for solving ordinary k -center clustering. Based on some novel insights, we show that this greedy method also works for the problem with outliers (Section 2). Our approach can achieve the approximation ratio 2 with respect to the clustering cost (i.e., the radius); moreover, the time complexity is linear in the input size. Charikar et al. [16] showed that if more than z outliers are allowed to remove, the random sampling technique can be applied to reduce the data size for metric k -center clustering with outliers. Recently, Huang et al. [23] showed a similar result for instances in Euclidean space (and they name the sample as “robust coreset”). In Section 2.3, we prove that the sample size of [23] can be further reduced.

We also consider the problem in doubling metrics, motivated by the fact that many real-world datasets often manifest low intrinsic dimensions [8]. For example, image sets usually can be represented in low dimensional manifold though the Euclidean dimension of the image vectors can be very high. “Doubling dimension” is widely used for measuring the intrinsic dimensions of datasets [35] (the formal definition is given in Section 1.1). Rather than assuming the whole (X, d) has a low doubling dimension, we only assume that **the inliers of the given data have a low doubling dimension $\rho > 0$** . We do not have any assumption on the outliers; namely, the outliers can scatter arbitrarily in the space. We believe that this assumption captures a large range of high dimensional instances in reality.

With the assumption, we show that our approach can further improve the clustering quality. In particular, the greedy approach is able to construct a coreset for the problem of k -center clustering with outliers; as a consequence, the time complexity can be significantly reduced if running existing algorithms on the coreset (Section 3). *Coreset* construction is a technique for reducing data size so as to speedup the algorithms for many optimization problems; we refer the reader to the surveys [5, 34] for more details. The size of our coreset is $2z + O((2/\mu)^\rho k)$, where μ is a small parameter measuring the quality of the coreset; the construction time is $O((\frac{2}{\mu})^\rho kn)$. Note that z and k are often much smaller than n in practice; the coefficient 2 of z actually can be further reduced to be arbitrarily close to 1, by increasing the coefficient of the second term $(2/\mu)^\rho k$. Moreover, our coreset is a natural “composable coreset” [24] which could be potentially applied to distributed clustering with outliers. Very recently, Ceccarello et al. [12] also provided a coreset for k -center clustering

with z outliers in doubling metrics, where their size is $T = O((k+z)(\frac{24}{\mu})^\rho)$ with $O(nT)$ construction time. Thus our result is a significant improvement in terms of coreset size and construction time. Huang et al. [23] considered the coreset construction for k -median/means clustering with outliers in doubling metrics, however, their method cannot be extended to the case of k -center. Aghamolaei and Ghodsi [2] considered the coreset construction in doubling metrics for ordinary k -center clustering without outliers.

Our proposed algorithms are easy to implement in practice. To study the performance of our algorithms, we test them on both synthetic and real datasets in Section 4. The experimental results suggest that our method outperforms existing methods in terms of clustering quality and running time. Also, the running time can be significantly reduced via building coreset where the clustering quality can be well preserved simultaneously.

Due to the space limit, some details are omitted here, and we refer the reader to the full version of our paper.

1.1 Preliminaries

We consider the problem of k -center with outliers in arbitrary metrics and Euclidean space \mathbb{R}^D . Let (X, d) be a metric, where X contains n vertices and $d(\cdot, \cdot)$ is the distance function; with a slight abuse of notation, we also use the function d to denote the shortest distance between two subsets $X_1, X_2 \subseteq X$, i.e., $d(X_1, X_2) = \min_{p \in X_1, q \in X_2} d(p, q)$. We assume that the distance between any pair of vertices in X is given in advance; for the problem in Euclidean space, it takes $O(D)$ time to compute the distance between any pair of points. Below, we introduce several important definitions that are used throughout the paper.

► **Definition 1** (k -Center Clustering with Outliers). *Given a metric (X, d) with two positive integers k and $z < n$, k -center clustering with outliers is to find a subset $X' \subseteq X$, where $|X'| \geq n - z$, and k centers $\{c_1, \dots, c_k\} \subseteq X$, such that $\max_{p \in X'} \min_{1 \leq j \leq k} d(p, c_j)$ is minimized. If given a set P of n points in \mathbb{R}^D , the problem is to find a subset $P' \subseteq P$, where $|P'| \geq n - z$, and k centers $\{c_1, \dots, c_k\} \subset \mathbb{R}^D$, such that $\max_{p \in P'} \min_{1 \leq j \leq k} \|p - c_j\|$ is minimized.*

Note. For the sake of convenience, we describe the following definitions only in terms of metric space. In fact, the definitions can be easily modified for the problem in Euclidean space.

In this paper, we always use X_{opt} , a subset of X with size $n - z$, to denote the subset yielding the optimal solution. Also, let $\{C_1, \dots, C_k\}$ be the k clusters forming X_{opt} , and the resulting clustering cost be r_{opt} ; that is, each C_j is covered by an individual ball with radius r_{opt} .

Usually, optimization problems with outliers are challenging to solve. Thus we often relax our goal and allow to miss a little more outliers in practice. Actually the same relaxation idea has been adopted by a number of works on clustering with outliers before [3, 16, 23, 30].

► **Definition 2** ($(k, z)_\epsilon$ -Center Clustering). *Let (X, d) be an instance of k -center clustering with z outliers, and $\epsilon \geq 0$. $(k, z)_\epsilon$ -center clustering is to find a subset X' of X , where $|X'| \geq n - (1 + \epsilon)z$, such that the corresponding clustering cost of Definition 1 on X' is minimized.*

(i) *Given a set A of cluster centers ($|A|$ could be larger than k), the resulting clustering cost,*

$$\min \left\{ \max_{p \in X'} \min_{c \in A} d(p, c) \mid X' \subseteq X, |X'| \geq n - (1 + \epsilon)z \right\} \quad (1)$$

is denoted by $\phi_\epsilon(X, A)$.

- (ii) If $|A| = k$ and $\phi_\epsilon(X, A) \leq \alpha r_{opt}$ with $\alpha > 0^1$, it is called an α -approximation. Moreover, if $|A| = \beta k$ with $\beta > 1$, it is called an (α, β) -approximation.

Obviously, the problem in Definition 1 is a special case of $(k, z)_\epsilon$ -center clustering with $\epsilon = 0$. Further, Definition 1 and 2 can be naturally extended to **weighted case**: each vertex p has a non-negative weight w_p and the total weight of outliers should be equal to z ; the distance $d(p, c_j)$ in the objective function is replaced by $w_p \cdot d(p, c_j)$. Then we have the following definition of coreset.

► **Definition 3 (Coreset).** Given a small parameter $\mu \in (0, 1)$ and an instance (X, d) of k -center clustering with z outliers, a set $S \subseteq X$ is called a μ -coreset of X , if each vertex of S is assigned a non-negative weight and $\phi_0(S, H) \in (1 \pm \mu)\phi_0(X, H)$ for any set $H \subseteq X$ of k vertices.

Given a large-scale instance (X, d) , we can run existing algorithm on its coreset S to compute an approximate solution for X ; if $|S| \ll n$, the resulting running time can be significantly reduced. Formally, we have the following claim.

▷ **Claim 4.** If the set H yields an α -approximation of the μ -coreset S , it yields an $\alpha \times \frac{1+\mu}{1-\mu}$ -approximation of X .

As mentioned before, we also consider the case with low doubling dimension. Roughly speaking, doubling dimension describes the expansion rate of the metric. For any $p \in X$ and $r \geq 0$, we use $Ball(p, r)$ to denote the ball centered at p with radius r .

► **Definition 5 (Doubling Dimension).** The doubling dimension of a metric (X, d) is the smallest number $\rho > 0$, such that for any $p \in X$ and $r \geq 0$, $X \cap Ball(p, 2r)$ is always covered by the union of at most 2^ρ balls with radius r .

2 Algorithms for $(k, z)_\epsilon$ -Center Clustering

For the sake of completeness, let us briefly introduce the algorithm of [18] for ordinary k -center clustering first. Initially, it arbitrarily selects a vertex from X , and iteratively selects the following $k - 1$ vertices, where each j -th step ($2 \leq j \leq k$) chooses the vertex having the largest minimum distance to the already selected $j - 1$ vertices; finally, each input vertex is assigned to its nearest neighbor of these selected k vertices. It can be proved that this greedy strategy results in a 2-approximation of k -center clustering; the algorithm also works for the problem in Euclidean space and results in the same approximation ratio. In this section, we show that a modified version of Gonzalez's algorithm yields approximate solutions for $(k, z)_\epsilon$ -center clustering.

In Section 2.1 and 2.2, we present our results for metric k -center with outliers. Actually, it is easy to see that Algorithm 1 and 2 yield the same approximation ratios if the input instance is a set of points in Euclidean space (the analysis is almost identical, and we omit the details due to the space limit); only the running times are different, since it takes $O(D)$ time to compute distance between two points in \mathbb{R}^D .

¹ Since we remove more than z outliers, it is possible to have an approximation ratio $\alpha < 1$, i.e., $\phi_\epsilon(X, A) < r_{opt}$.

■ **Algorithm 1** Bi-criteria Approximation Algorithm.

Input: An instance (X, d) of metric k -center clustering with z outliers, and $|X| = n$; parameters $\epsilon > 0$, $\eta \in (0, 1)$, and $t \in \mathbb{Z}^+$.

1. Let $\gamma = z/n$ and initialize a set $E = \emptyset$.
2. Initially, $j = 1$; randomly select $\frac{1}{1-\gamma} \log \frac{1}{\eta}$ vertices from X and add them to E .
3. Run the following steps until $j = t$:
 - a. $j = j + 1$ and let Q_j be the farthest $(1 + \epsilon)z$ vertices of X to E (for each vertex $p \in X$, its distance to E is $\min_{q \in E} d(p, q)$).
 - b. Randomly select $\frac{1+\epsilon}{\epsilon} \log \frac{1}{\eta}$ vertices from Q_j and add them to E .

Output E .

2.1 $(2, O(\frac{1}{\epsilon}))$ -Approximation

Here, we consider bi-criteria approximation that returns more than k cluster centers. The main challenge for implementing Gonzalez's algorithm is that the outliers and inliers are mixed in X ; for example, the selected vertex, which has the largest minimum distance to the already selected vertices, is very likely to be an outlier, and therefore the clustering quality could be arbitrarily bad. Instead, our strategy is to take a small sample from the farthest subset. We implement our idea in Algorithm 1. For simplicity, let γ denote z/n in the algorithm; usually we can assume that γ is a value much smaller than 1. We prove the correctness of Algorithm 1 below.

► **Lemma 6.** *With probability at least $1 - \eta$, the set E in Step 2 of Algorithm 1 contains at least one point from X_{opt} .*

Since $|X_{opt}|/|X| = 1 - \gamma$, Lemma 6 can be easily obtained by the following folklore claim.

▷ **Claim 7.** Let U be a set of elements and $V \subseteq U$ with $\frac{|V|}{|U|} = \tau > 0$. Given $\eta \in (0, 1)$, if one randomly samples $\frac{1}{\tau} \log \frac{1}{\eta}$ elements from U , with probability at least $1 - \eta$, the sample contains at least one element from V .

Recall that $\{C_1, C_2, \dots, C_k\}$ are the k clusters forming X_{opt} . Denote by $\lambda_j(E)$ the number of the clusters which have non-empty intersection with E at the beginning of j -th round in Step 3 of Algorithm 1. For example, initially $\lambda_1(E) \geq 1$ by Lemma 6. Obviously, if $\lambda_j(E) = k$, i.e., $C_l \cap E \neq \emptyset$ for any $1 \leq l \leq k$, E yields a 2-approximation for k -center clustering with outliers through the triangle inequality.

▷ **Claim 8.** If $\lambda_j(E) = k$, then $\phi_0(X, E) \leq 2r_{opt}$.

► **Lemma 9.** *In each round of Step 3 of Algorithm 1, with probability at least $1 - \eta$, either (1) $d(Q_j, E) \leq 2r_{opt}$ or (2) $\lambda_j(E) \geq \lambda_{j-1}(E) + 1$.*

Proof. Suppose that (1) is not true, i.e., $d(Q_j, E) > 2r_{opt}$, and we prove that (2) is true. Let \mathcal{J} include all the indices $l \in \{1, 2, \dots, k\}$ with $E \cap C_l \neq \emptyset$. We claim that $Q_j \cap C_l = \emptyset$ for each $l \in \mathcal{J}$. Otherwise, let $p \in Q_j \cap C_l$ and $p' \in E \cap C_l$; due to the triangle inequality, we know that $d(p, p') \leq 2r_{opt}$ which is in contradiction to the assumption $d(Q_j, E) > 2r_{opt}$. Thus, $Q_j \cap X_{opt}$ only contains the vertices from C_l with $l \notin \mathcal{J}$. Moreover, since the number of outliers is z , we know that $\frac{|Q_j \cap X_{opt}|}{|Q_j|} \geq \frac{\epsilon}{1+\epsilon}$. By Claim 7, if randomly selecting $\frac{1+\epsilon}{\epsilon} \log \frac{1}{\eta}$ vertices from Q_j , with probability at least $1 - \eta$, the sample contains at least one vertex from $Q_j \cap X_{opt}$; also, the vertex must come from $\cup_{l \notin \mathcal{J}} C_l$. That is, (2) $\lambda_j(E) \geq \lambda_{j-1}(E) + 1$ happens. ◀

40:6 Greedy Strategy for k -Center Clustering with Outliers

If (1) of Lemma 9 happens, i.e., $d(Q_j, E) \leq 2r_{opt}$, then it implies that

$$\max_{p \in X \setminus Q_j} d(p, E) \leq 2r_{opt}; \quad (2)$$

moreover, since $|Q_j| = (1 + \epsilon)z$, we have $\phi_\epsilon(X, E) \leq 2r_{opt}$. Next, we assume that (1) in Lemma 9 never happens, and prove that $\lambda_j(E) = k$ with constant probability when $j = \Theta(k)$. The following idea actually has been used by Aggarwal et al. [1] for achieving a bi-criteria approximation for k -means clustering. Define a random variable x_j : $x_j = 1$ if $\lambda_j(E) = \lambda_{j-1}(E)$, or 0 if $\lambda_j(E) \geq \lambda_{j-1}(E) + 1$, for $j = 1, 2, \dots$. So $\mathbb{E}[x_j] \leq \eta$ by Lemma 9 and

$$\sum_{1 \leq s \leq j} (1 - x_s) \leq \lambda_j(E). \quad (3)$$

Also, let $J_j = \sum_{1 \leq s \leq j} (x_s - \eta)$ and $J_0 = 0$. Then, $\{J_0, J_1, J_2, \dots\}$ is a super-martingale with $J_{j+1} - J_j < 1$ (more details are shown in the full version of our paper). Through *Azuma-Hoeffding inequality* [4], we have $Pr(J_t \geq J_0 + \delta) \leq e^{-\frac{\delta^2}{2t}}$ for any $t \in \mathbb{Z}^+$ and $\delta > 0$. Let $t = \frac{k + \sqrt{k}}{1 - \eta}$ and $\delta = \sqrt{k}$, the inequality implies that

$$Pr\left(\sum_{1 \leq s \leq t} (1 - x_s) \geq k\right) \geq 1 - e^{-\frac{1-\eta}{4}}. \quad (4)$$

Combining (3) and (4), we know that $\lambda_t(E) \geq k$ with probability at least $1 - e^{-\frac{1-\eta}{4}}$. Moreover, $\lambda_t(E) = k$ directly implies that E is a 2-approximate solution by Claim 8. Together with Lemma 6, we have the following theorem.

► **Theorem 10.** *Let $\epsilon > 0$. If we set $t = \frac{k + \sqrt{k}}{1 - \eta}$ for Algorithm 1, with probability at least $(1 - \eta)(1 - e^{-\frac{1-\eta}{4}})$, $\phi_\epsilon(X, E) \leq 2r_{opt}$.*

Quality and Running time. If $\frac{1}{\eta}$ and $\frac{1}{1-\eta}$ are constant numbers, $|E|$ will be $O(\frac{k}{\epsilon})$ and Theorem 10 implies that E is a $(2, O(\frac{1}{\epsilon}))$ -approximation for $(k, z)_\epsilon$ -center clustering of X with constant probability. In each round of Step 3, there are $O(\frac{1}{\epsilon})$ new vertices added to E , thus it takes $O(\frac{1}{\epsilon}n)$ time to update the distances from the vertices of X to E ; to select the set Q_j , we can apply the linear time selection algorithm [10]. Overall, the running time of Algorithm 1 is $O(\frac{k}{\epsilon}n)$. If the given instance is in \mathbb{R}^D , the running time will be $O(\frac{k}{\epsilon}nD)$.

Further, we consider the instances under some practical assumption, and provide new analysis of Algorithm 1. In reality, the clusters are usually not too small, compared with the number of outliers. For example, it is rare to have a cluster C_l that $|C_l| \ll z$.

► **Theorem 11.** *If each optimal cluster C_l has size at least ϵz for $1 \leq l \leq k$, the set E of Algorithm 1 is a $(4, O(\frac{1}{\epsilon}))$ -approximation for the problem of $(k, z)_0$ -center clustering with constant probability.*

Compared with Theorem 10, Theorem 11 shows that we can exactly exclude z outliers (rather than $(1 + \epsilon)z$), though the approximation ratio with respect to the radius becomes 4.

Proof of Theorem 11. We take a more careful analysis on the proof of Lemma 9. If (1) never happens, eventually $\lambda_j(E)$ will reach k and thus $\phi_0(X, E) \leq 2r_{opt}$ (Claim 8). So we focus on the case that (1) happens before $\lambda_j(E)$ reaching k . Suppose at j -th round, $d(Q_j, E) \leq 2r_{opt}$ but $\lambda_j(E) < k$. We consider two cases (i) there exists some $l_0 \notin \mathcal{J}$ such that $C_{l_0} \subseteq Q_j$ and (ii) otherwise.

■ **Algorithm 2** 2-Approximation Algorithm.

Input: An instance (X, d) of metric k -center clustering with z outliers, and $|X| = n$; a parameter $\epsilon > 0$.

1. Initialize a set $E = \emptyset$.
2. Let $j = 1$; randomly select one vertex from X and add it to E .
3. Run the following steps until $j = k$:
 - a. $j = j + 1$ and let Q_j be the farthest $(1 + \epsilon)z$ vertices to E .
 - b. Randomly select one vertex from Q_j and add it to E .

Output E .

For (i), we have $C_{l_0} \subseteq Q_j$ for some $l_0 \notin \mathcal{J}$. Note that we assume $|C_{l_0}| \geq \epsilon z$, i.e., $\frac{|C_{l_0}|}{|Q_j|} \geq \frac{\epsilon}{1+\epsilon}$. Using the same manner in the proof of Lemma 9, we know that (2) $\lambda_j(E) \geq \lambda_{j-1}(E) + 1$ happens with probability $1 - \eta$. Thus, if (i) is always true, we can continue Step 3 and eventually $\lambda_j(E)$ will reach k , that is, a $(2, O(\frac{1}{\epsilon}))$ -approximation of $(k, z)_0$ -center clustering is obtained with constant probability.

For (ii), we have $C_l \setminus Q_j \neq \emptyset$ for all $l \notin \mathcal{J}$. Together with the assumption $d(Q_j, E) \leq 2r_{opt}$, we know that there exists $q_l \in C_l \setminus Q_j$ (for each $l \notin \mathcal{J}$) such that $d(q_l, E) \leq d(Q_j, E) \leq 2r_{opt}$. Consequently, we have that $\forall q \in C_l$,

$$d(q, E) \leq \|q - q_l\| + d(q_l, E) \leq 4r_{opt} \text{ (see the left of Figure. 1).} \quad (5)$$

Note that for any $l \in \mathcal{J}$, $d(E, C_l) \leq 2r_{opt}$ by the triangle inequality. Thus,

$$\phi_0(X, E) \leq \max_{q \in \cup_{l=1}^k C_l} d(q, E) \leq 4r_{opt}. \quad (6)$$

So a $(4, O(\frac{1}{\epsilon}))$ -approximation of $(k, z)_0$ -center clustering is obtained. ◀

2.2 2-Approximation

If k is a constant, we show that a single-criterion 2-approximation can be achieved. Actually, we use the same strategy as Section 2.1, but run only k rounds with each round sampling only one vertex. See Algorithm 2.

■ **Figure 1** Left: p_e is a point of E having distance $\leq 2r_{opt}$ to p_l ; right: p_e is any point of E , o_e and o_p are the centers taking charge of p_e and p .

Denote by $\{v_1, \dots, v_k\}$ the k sampled vertices of E . Actually, the proof of Theorem 12 is similar to the analysis in Section 2.1. The only difference is that the probability that (2) $\lambda_j(E) \geq \lambda_{j-1}(E) + 1$ happens is at least $\frac{\epsilon}{1+\epsilon}$. Also note that $v_1 \in X_{opt}$ with probability $1 - \gamma$ ($\gamma = z/n$). If all of these events happen, either we obtain a 2-approximation before k steps

(i.e., $d(E, X \setminus Q_j) \leq 2r_{opt}$ for some $j < k$), or $\{v_1, \dots, v_k\}$ fall into the k optimal clusters C_1, C_2, \dots, C_k separately (i.e., $\lambda_k(E) = k$). No matter which case happens, we always obtain a 2-approximation with respect to $(k, z)_\epsilon$ -center clustering. So we have Theorem 12.

► **Theorem 12.** *Algorithm 2 returns a 2-approximation for the problem of $(k, z)_\epsilon$ -center clustering on X , with probability at least $(1 - \gamma)(\frac{\epsilon}{1+\epsilon})^{k-1}$. The running time is $O(kn)$. If the given instance is in \mathbb{R}^D , the running time will be $O(knD)$.*

To boost the probability of Theorem 12, we just need to repeatedly run the algorithm; the success probability is easy to calculate by taking the union bound.

► **Corollary 13.** *If we run Algorithm 2 $O(\frac{1}{1-\gamma}(\frac{1+\epsilon}{\epsilon})^{k-1})$ times, with constant probability, at least one time the algorithm returns a 2-approximation for the problem of $(k, z)_\epsilon$ -center clustering.*

Similar to Theorem 11, we consider the practical instances. We show that the quality of Theorem 12 can be preserved even exactly excluding z outliers, if the optimal clusters are “well separated”. The property was also studied for other clustering problems in practice [17, 26]. Let $\{o_1, \dots, o_k\}$ be the k cluster centers of the optimal clusters $\{C_1, \dots, C_k\}$.

► **Theorem 14.** *Suppose that each optimal cluster C_l has size at least ϵz and $\|o_l - o_{l'}\| > 4r_{opt}$ for $1 \leq l \neq l' \leq k$. Then with probability at least $(1 - \gamma)(\frac{\epsilon}{1+\epsilon})^{k-1}$, Algorithm 2 returns a 2-approximation for the problem of $(k, z)_0$ -center clustering.*

Proof. Initially, we know that $\lambda_1(E) = 1$ with probability $1 - \gamma$. Suppose that at the beginning of the j -th round of Algorithm 2 with $2 \leq j \leq k$, E already has $j - 1$ vertices separately falling in $j - 1$ optimal clusters; also, we still let \mathcal{J} be the set of the indices of these $j - 1$ clusters. Then we have the following claim.

▷ **Claim 15.** $|Q_j \cap (\cup_{l \notin \mathcal{J}} C_l)| \geq \epsilon z$.

Proof. For any $p \in \cup_{l \notin \mathcal{J}} C_l$, we have

$$d(p, E) > 4r_{opt} - r_{opt} - r_{opt} = 2r_{opt} \quad (7)$$

from triangle inequality and the assumption $\|o_l - o_{l'}\| > 4r_{opt}$ for $1 \leq l \neq l' \leq k$ (see the right of Figure. 1). In addition, for any $p \in \cup_{l \in \mathcal{J}} C_l$, we have

$$d(p, E) \leq 2r_{opt}. \quad (8)$$

We consider two cases. If $d(Q_j, E) \leq 2r_{opt}$ at the current round, then (7) directly implies that $\cup_{l \notin \mathcal{J}} C_l \subseteq Q_j$ (recall Q_j is the set of farthest vertices to E); thus $|Q_j \cap (\cup_{l \notin \mathcal{J}} C_l)| = |\cup_{l \notin \mathcal{J}} C_l| \geq \epsilon z$ by the assumption that any $|C_l| \geq \epsilon z$. Otherwise, $d(Q_j, E) > 2r_{opt}$. Then $Q_j \cap (\cup_{l \in \mathcal{J}} C_l) = \emptyset$ by (8). Moreover, since there are only z outliers and $|Q_j| = (1 + \epsilon)z$, we know that $|Q_j \cap (\cup_{l \notin \mathcal{J}} C_l)| \geq \epsilon z$. ◁

Claim 15 reveals that with probability at least $\frac{\epsilon}{1+\epsilon}$, the new added vertex falls in $\cup_{l \notin \mathcal{J}} C_l$, i.e., $\lambda_j(E) = \lambda_{j-1}(E) + 1$. Overall, we know that $\lambda_k(E) = k$, i.e., E is a 2-approximation of $(k, z)_0$ -center clustering (by Claim 8), with probability at least $(1 - \gamma)(\frac{\epsilon}{1+\epsilon})^{k-1}$. ◀

2.3 Reducing Data Size via Random Sampling

Given a metric (X, d) , Charikar et al. [16] showed that we can use a random sample S to replace X . Recall $\gamma = z/n$. Let $|S| = O(\frac{k}{\epsilon^2 \gamma} \ln n)$ and E be an α -approximate solution of $(k, z)_\epsilon$ -center clustering on (S, d) , then E is an α -approximate solution of $(k, z)_{O(\epsilon)}$ -center clustering on (X, d) with constant probability. In D -dimensional Euclidean space, Huang et al. [23] showed a similar result, where the sample size $|S| = \tilde{O}(\frac{1}{\epsilon^2 \gamma^2} kD)^2$ (to be consistent with our paper, we change the notations in their theorem). In this section, we show that the sample size of [23] can be further improved to be $\tilde{O}(\frac{1}{\epsilon^2 \gamma} kD)$, which can be a significant improvement if $\frac{1}{\gamma} = \frac{n}{z}$ is large.

Let P be a set of n points in \mathbb{R}^D . Consider the range space $\Sigma = (P, \Pi)$ where each range $\pi \in \Pi$ is the complement of union of k balls in \mathbb{R}^D . We know that the VC dimension of balls is $O(D)$ [4], and therefore the VC dimension of union of k balls is $O(kD \log k)$ [11]. That is, the VC dimension of the range space Σ is $O(kD \log k)$. Let $\epsilon \in (0, 1)$, and an “ ϵ -sample” S of P is defined as follows: $\forall \pi \in \Pi$, $|\frac{|\pi \cap P|}{|P|} - \frac{|\pi \cap S|}{|S|}| \leq \epsilon$; roughly speaking, S is an approximation of P with an additive error inside each range π . Given a range space with VC dimension m , an ϵ -sample can be easily obtained via uniform sampling [4], where the success probability is $1 - \lambda$ and the sample size is $O(\frac{1}{\epsilon^2} (m \log \frac{m}{\epsilon} + \log \frac{1}{\lambda}))$ for any $0 < \lambda < 1$. For our problem, we need to replace the “ ϵ ” of the “ ϵ -sample” by $\epsilon\gamma$ to guarantee that the number of uncovered points is bounded by $(1 + O(\epsilon))\gamma n$ (we show the details below); the resulting sample size will be $\tilde{O}(\frac{1}{\epsilon^2 \gamma^2} kD)$ that is the same as the sample size of [23] (we assume that the term $\log \frac{1}{\lambda}$ is a constant for convenience).

Actually, the front factor $\frac{1}{\epsilon^2 \gamma^2}$ of the sample size can be further reduced to be $\frac{1}{\epsilon^2 \gamma}$ by a more careful analysis. We observe that there is no need to guarantee the additive error for each range π (as the definition of ϵ -sample). Instead, only a multiplicative error for the ranges covering at least γn points should be sufficient. Note that when a range covers more points, the multiplicative error is weaker than the additive error and thus the sample size is reduced. For this purpose, we use *relative approximation* [21, 31]: let $S \subseteq P$ be a subset of size $\tilde{O}(\frac{1}{\epsilon^2 \gamma} kD)$ chosen uniformly at random, then with constant probability,

$$\forall \pi \in \Pi, \left| \frac{|\pi \cap P|}{|P|} - \frac{|\pi \cap S|}{|S|} \right| \leq \epsilon \times \max \left\{ \frac{|\pi \cap P|}{|P|}, \gamma \right\}. \quad (9)$$

We formally state our result below.

► **Theorem 16.** *Let P be an instance for the problem of k -center clustering with outliers in \mathbb{R}^D as described in Definition 1, and $S \subseteq P$ be a subset of size $\tilde{O}(\frac{1}{\epsilon^2 \gamma} kD)$ chosen uniformly at random. Suppose $\epsilon \leq 0.5$. Let S be a new instance for the problem of k -center clustering with outliers where the number of outliers is set to be $z' = (1 + \epsilon)\gamma|S|$. If E is an α -approximate solution of $(k, z')_\epsilon$ -center clustering on S , then E is an α -approximate solution of $(k, z)_{O(\epsilon)}$ -center clustering on P , with constant probability.*

Proof. We assume that S is a relative approximation of P and (9) holds (this happens with constant probability). Let \mathbb{B}_{opt} be the set of k balls covering $(1 - \gamma)n$ points induced by the optimal solution for P , and \mathbb{B}_S be the set of k balls induced by an α -approximate solution of $(k, z')_\epsilon$ -center clustering on S . Suppose the radius of each ball in \mathbb{B}_{opt} (resp., \mathbb{B}_S) is r_{opt} (resp., r_S). We denote the complements of \mathbb{B}_{opt} and \mathbb{B}_S as π_{opt} and π_S , respectively.

² The asymptotic notation $\tilde{O}(f) = O(f \cdot \text{polylog}(\frac{kD}{\epsilon\gamma}))$.

40:10 Greedy Strategy for k -Center Clustering with Outliers

First, since \mathbb{B}_{opt} covers $(1 - \gamma)n$ points of P and S is a relative approximation of P , we have

$$\frac{|\pi_{opt} \cap S|}{|S|} \leq \frac{|\pi_{opt} \cap P|}{|P|} + \epsilon \times \max \left\{ \frac{|\pi_{opt} \cap P|}{|P|}, \gamma \right\} = (1 + \epsilon)\gamma \quad (10)$$

by (9). That is, the set balls \mathbb{B}_{opt} cover at least $(1 - (1 + \epsilon)\gamma)|S|$ points of S , and therefore it is a feasible solution for the instance S with respect to the problem of k -center clustering with z' outliers. Since \mathbb{B}_S is an α -approximate solution of (k, z') -center clustering on S , we have

$$r_S \leq \alpha r_{opt}; \quad |\pi_S \cap S| \leq (1 + \epsilon)z' = (1 + \epsilon)^2 \gamma |S|. \quad (11)$$

Now, we claim that

$$|\pi_S \cap P| \leq \frac{(1 + \epsilon)^2}{1 - \epsilon} \gamma |P|. \quad (12)$$

Assume that (12) is not true, then (9) implies $\left| \frac{|\pi_S \cap P|}{|P|} - \frac{|\pi_S \cap S|}{|S|} \right| \leq \epsilon \times \max \left\{ \frac{|\pi_S \cap P|}{|P|}, \gamma \right\} = \epsilon \frac{|\pi_S \cap P|}{|P|}$. So $\frac{|\pi_S \cap S|}{|S|} \geq (1 - \epsilon) \frac{|\pi_S \cap P|}{|P|} > (1 + \epsilon)^2 \gamma$, which is in contradiction with the second inequality of (11), and thus (12) is true. We assume $\epsilon \leq 0.5$, so $\frac{1}{1 - \epsilon} \leq 1 + 2\epsilon$ and $\frac{(1 + \epsilon)^2}{1 - \epsilon} = 1 + O(\epsilon)$. Consequently (12) and the first inequality of (11) together imply that \mathbb{B}_S is an α -approximate solution of $(k, z)_{O(\epsilon)}$ -center clustering on P . ◀

3 Coreset Construction in Doubling Metrics

In this section, we always assume the following is true by default:

Given an instance (X, d) of k -center clustering with outliers, the metric (X_{opt}, d) , i.e., the metric formed by the set of inliers, has a constant doubling dimension $\rho > 0$.

We do not have any restriction on the outliers $X \setminus X_{opt}$. Thus the above assumption is more relaxed and practical than assuming the whole (X, d) has a constant doubling dimension. From Definition 5, we directly know that each optimal cluster C_l of X_{opt} can be covered by 2^ρ balls with radius $r_{opt}/2$ (see the left figure in Figure. 2). Imagine that the instance (X, d) has $2^\rho k$ clusters, where the optimal radius is at most $r_{opt}/2$. Therefore, we can just replace k by $2^\rho k$ when running Algorithm 1, so as to reduce the approximation ratio (i.e., the ratio of the resulting radius to r_{opt}) from 2 to 1.

■ **Figure 2** Illustrations for Theorem 17 and 18.

► **Theorem 17.** *If we set $t = \frac{2^\rho k + 2^{\rho/2} \sqrt{k}}{1 - \eta}$ for Algorithm 1, with probability $(1 - \eta)(1 - e^{-\frac{1 - \eta}{4}})$, $\phi_\epsilon(X, E) \leq r_{opt}$. So the set E is a $(1, O(\frac{2^\rho}{\epsilon}))$ -approximation for the problem of $(k, z)_\epsilon$ -center clustering, and the running time is $O(2^\rho \frac{k}{\epsilon} n)$.*

■ **Algorithm 3** The Coreset Construction.

Input: An instance (X, d) of metric k -center clustering with z outliers, and $|X| = n$; parameters η and $\mu \in (0, 1)$.

1. Let $l = (\frac{2}{\mu})^\rho k$.
2. Set $\epsilon = 1$ and run Algorithm 1 $t = \frac{l + \sqrt{l}}{1 - \eta}$ rounds. Denote by \tilde{r} the maximum distance between E and X by excluding the farthest $2z$ vertices, after the final round of Algorithm 1.
3. Let $X_{\tilde{r}} = \{p \mid p \in X \text{ and } d(p, E) \leq \tilde{r}\}$.
4. For each vertex $p \in X_{\tilde{r}}$, assign it to its nearest neighbor in E ; for each vertex $q \in E$, let its weight be the number of vertices assigning to it.
5. Add $X \setminus X_{\tilde{r}}$ to E ; each vertex of $X \setminus X_{\tilde{r}}$ has weight 1.

Output E as the coreset.

If considering the problem in Euclidean space \mathbb{R}^D where the doubling dimension of the inliers is ρ , the running time becomes $O(2^\rho \frac{k}{\epsilon} n D)$. Inspired by Theorem 17, we can further construct coreset for k -center clustering with outliers (see Definition 3). Let $\mu \in (0, 1)$, and for simplicity we assume that $\log 2/\mu$ is an integer. If applying Definition 5 recursively, we know that each C_l is covered by $2^{\rho \log 2/\mu} = (\frac{2}{\mu})^\rho$ balls with radius $\frac{\mu}{2} r_{opt}$, and X_{opt} is covered by $(\frac{2}{\mu})^\rho k$ such balls in total. See the right figure in Figure. 2. Based on this observation, we have Algorithm 3 for constructing μ -coreset.

► **Theorem 18.** *With constant probability, Algorithm 3 outputs a μ -coreset E of k -center clustering with z outliers. The size of E is at most $2z + O((\frac{2}{\mu})^\rho k)$, and the construction time is $O((\frac{2}{\mu})^\rho kn)$.*

Remark. (1) The previous ideas based on uniform sampling [16, 23] (also our idea in Section 2.3) cannot get rid of the violation on the number of outliers; the sample sizes will become infinity if not allowing to remove more than z outliers. Our coreset in Theorem 18 works for removing z outliers exactly. Consequently, our coreset can be used for existing algorithms of k -center clustering with outliers, such as [15], to reduce their complexities. (2) Another feature is that our coreset is a natural composable coreset. If X (or the point set P) is partitioned into L parts, we can run Algorithm 3 for each part, and obtain a coreset with size $(2z + O((\frac{2}{\mu})^\rho k))L$ in total (the proof is almost identical to the proof of Theorem 18 below). So our coreset construction can potentially be applied to distributed clustering with outliers. (3) The coefficient 2 of z actually can be further reduced by modifying the value of ϵ in Step 2 of Algorithm 3 (we just set $\epsilon = 1$ for simplicity). In general, the size of E is $(1 + \epsilon)z + O(\frac{1}{\epsilon}(\frac{2}{\mu})^\rho k)$ and the construction time is $O(\frac{1}{\epsilon}(\frac{2}{\mu})^\rho kn)$ (or $O(\frac{1}{\epsilon}(\frac{2}{\mu})^\rho kn D)$ in \mathbb{R}^D).

Proof of Theorem 18. Similar to Theorem 17, we know that $|X_{\tilde{r}}| = n - 2z$ and $\tilde{r} \leq 2 \times \frac{\mu}{2} r_{opt} = \mu r_{opt}$ with constant probability in Algorithm 3. Thus, the size of E is $|X \setminus X_{\tilde{r}}| + O((\frac{2}{\mu})^\rho k) = 2z + O((\frac{2}{\mu})^\rho k)$. Moreover, it is easy to see that the running time of Algorithm 3 is $O((\frac{2}{\mu})^\rho kn)$.

Next, we show that E is a μ -coreset of X . For each vertex $q \in E$, denote by $w(q)$ the weight of q ; for the sake of convenience in our proof, we view each q as a set of $w(q)$ overlapping unit weight vertices. Thus, from the construction of E , we can see that there is a bijective mapping f between X and E , where

$$\|p - f(p)\| \leq \tilde{r} \leq \mu r_{opt}, \quad \forall p \in X. \quad (13)$$

40:12 Greedy Strategy for k -Center Clustering with Outliers

Let $H = \{c_1, c_2, \dots, c_k\}$ be any k vertices of X . Suppose that H induces k clusters $\{A_1, A_2, \dots, A_k\}$ (resp., $\{B_1, B_2, \dots, B_k\}$) with respect to the problem of k -center clustering with z outliers on E (resp., X), where each A_j (resp., B_j) has the cluster center c_j for $1 \leq j \leq k$. Let $r_E = \phi_0(E, H)$ and $r_X = \phi_0(X, H)$, respectively. Also, let r'_E (resp., r'_X) be the smallest value r , such that for any $1 \leq j \leq k$, $f(B_j) \subseteq \text{Ball}(c_j, r)$ (resp., $f^{-1}(A_j) \subseteq \text{Ball}(c_j, r)$). We need the following claim.

▷ **Claim 19.** $|r'_E - r_X| \leq \mu r_{opt}$ and $|r'_X - r_E| \leq \mu r_{opt}$.

In addition, since $\{f(B_1), \dots, f(B_k)\}$ also form k clusters for the instance E with the fixed k cluster centers of H , we know that $r'_E \geq \phi_0(E, H) = r_E$. Similarly, we have $r'_X \geq r_X$. Combining Claim 19, we have

$$r_X - \mu r_{opt} \leq \underbrace{r'_X - \mu r_{opt}}_{\text{by Claim 19}} \leq r_E \leq \underbrace{r'_E}_{\text{by Claim 19}} \leq r_X + \mu r_{opt}. \quad (14)$$

So $|r_X - r_E| \leq \mu r_{opt}$, i.e., $\phi_0(E, H) \in \phi_0(X, H) \pm \mu r_{opt} \subseteq (1 \pm \mu)\phi_0(X, H)$. Therefore E is a μ -coreset of (X, d) . ◀

4 Experiments

Our experimental results were obtained on a Windows workstation with 2.8GHz Intel(R) Core(TM) i5-840 and 8GB main memory; the algorithms were implemented in Matlab R2018a. We test our algorithms on both synthetic and real datasets. For Algorithm 2, we take two well known algorithms of k -center clustering with outliers, *Base1* of [15] and *Base2* of [33], as the baselines. For Algorithm 3, we compare our coreset construction with uniform random sampling.

To generate the synthetic datasets, we set $n = 10^5$ and $D = 10^3$, and vary the values of z and k . First, randomly generate k clusters inside a hypercube of side length 200, where each cluster is a random sample from a Gaussian distribution with variance 10; each cluster has a random number of points and we keep the total number of points to be $n - z$; we compute the minimum enclosing balls respectively for these k clusters (by using the algorithm of [6]), and randomly generate z outliers outside the balls. The maximum radius of the balls is used as r_{opt} .

We also use three real datasets. MNIST dataset [28] contains $n = 60,000$ handwritten digit images from 0 to 9, where each image is represented by a 784-dimensional vector. The 10 digits form $k = 10$ clusters. Caltech-256 dataset [29] contains 30,607 colored images with 256 categories, where each image is represented by a 4096-dimensional vector. We choose $n = 2,232$ images of 20 categories to form $k = 20$ clusters. CIFER-10 training dataset [27] contains $n = 50,000$ colored images in 10 classes as $k = 10$ clusters, where each image is represented by a 4096-dimensional vector. For each real dataset, we use the minimum enclosing ball algorithm of [6] to compute r_{opt} , and randomly generate $z = 5\%n$ outliers outside the corresponding balls.

Results and analysis. Note that we exactly exclude z outliers (rather than $(1 + \epsilon)z$ as stated in Theorem 10 and 12) in our experiments, and calculate the approximation ratio $\phi_0(X, E)/r_{opt}$ for each instance, if E is the set of returned cluster centers.

We first run our Algorithm 1 on synthetic and real datasets. For synthetic datasets, we set $k = 2-20$, and $\beta = |E|/k = 8$ via modifying the values of ϵ and η appropriately (that means we output $8k$ cluster centers); normally, we set $\eta = 0.1$ and $\epsilon \approx 0.7$. We try the instances with

$z = \{2\%n, 4\%n, 6\%n, 8\%n, 10\%n\}$, and report the average results in Figure 3 (a) and (b); the approximation ratios are within 1.3-1.4 and the running times are less than 30s. Actually, the performance is quite stable regarding different values of z in our experiments, and the standard variances of approximation ratios and running times are less than 0.03 and 0.12, respectively. We also vary the value of β from 4 to 28 with $k = 10$. Figure 3 (c) shows that the approximation ratio slightly decreases as β increases. The running times are all around 14s and do not reveal a clear increasing trend as β increases. We think the reason behind may be that we just use the simple $O(n \log n)$ sorting algorithm, rather than the linear time selection algorithm [10], for computing Q_j in practice (see Step 3(a) of Algorithm 1); thus the running time is not linearly dependent on $|E|$. The results for real datasets are shown in the full version of our paper; the approximation ratios are all below 1.3 and the running times are less than 35s even for the largest CIFER-10 dataset.

■ **Figure 3** The experimental results of Algorithm 1 on synthetic datasets.

We also test our Algorithm 2 on synthetic and real datasets. We set $\epsilon = 1$ so that to avoid to repeat running Algorithm 2 too many times (see Corollary 13), but we still exactly exclude z outliers for calculating the approximation ratio as mentioned before. Our results are shown in Table 1. The synthetic and real datasets are too large for the baseline algorithms *Base1* and *Base2*, e.g., they run too slowly or even out of memory in our workstation if n , z , and D are large (they have complexities $\Omega(n^2D)$ or $\Omega(kznD)$)³. To make a fair comparison, we run *Base1*, *Base2*, and Algorithm 2 on smaller synthetic datasets with $(n = 2000, D = 10)$ and $(n = 2000, D = 100)$; we also set $z = \{2\%n, 4\%n, 6\%n, 8\%n, 10\%n\}$ as before and report the average results. When $D = 10$, *Base1* and Algorithm 2 achieve approximation ratios < 1.5 generally (Figure 4 (a)); moreover, *Base2* and Algorithm 2 run much faster than *Base1* (Figure 4 (b)). However, when $D = 100$, *Base1* and *Base2* yield much worse approximation ratios than Algorithm 2 (Figure 4 (c) and (d)). Our experiment reveals that Algorithm 2 can achieve a more stable performance when dimensionality increases.

Finally, we compare the performances of our coresets method (Algorithm 3) and uniform random sampling in terms of reducing data sizes. Though real-world image datasets often are believed to have low intrinsic dimensions [8], it is difficult to compute them (e.g., doubling dimension) accurately. In practice, we can directly set an appropriate value for l in Step 1 of Algorithm 3 (without knowing the value of doubling dimension ρ). For example, the size of coreset is $2z + O(\left(\frac{2}{\mu}\right)^\rho k) = 2z + O(l)$ according to Theorem 18, so we keep the sizes of our coresets to be $\{15\%n, 20\%n, 25\%n\}$ via modifying the value of l in our experiments. Correspondingly, we also set the sizes of random samples to be $\{15\%n, 20\%n, 25\%n\}$. We run Algorithm 2 on the corresponding random samples and coresets, and report the results in Table 2. Running Algorithm 2 on the coresets yields approximation ratios close to

³ We are aware of several distributed algorithms for k -center clustering with outliers [12, 19, 30, 32], but we only consider the setting with single machine in this paper.

40:14 Greedy Strategy for k -Center Clustering with Outliers

■ **Figure 4** Comparison of Base1, Base2, and Algorithm 2 on smaller synthetic datasets ((a) and (b) for $D = 10$; (c) and (d) for $D = 100$).

those obtained by directly running the algorithm on the original datasets; the results also remain stably when the level reduces from 25% to 15%. More importantly, our coresets significantly reduce the running times (e.g., it only needs 15%-35% time by using 15%-level coreset). Comparing with the random samples, our coresets can achieve significantly lower approximation ratios especially for the 15% level. Note that the coreset based approach takes more time than uniform random sampling, because we count the time spent for coreset construction.

■ **Table 2** The results of Algorithm 2 on random samples, coresets, and original datasets.

		random sampling			coreset			100%

5 Future Work

Following our work, several interesting problems deserve to be studied in future. For example, can the coreset construction time of Algorithm 3 be improved, like the fast net construction method proposed by Har-Peled and Mendel [20] in doubling metrics? It is also interesting to study other problems involving outliers by using greedy strategy.

Abstract

Bidirectional compression algorithms work by substituting repeated substrings by references that, unlike in the famous LZ77-scheme, can point to either direction. We present such an algorithm that is particularly suited for an external memory implementation. We evaluate it experimentally on large data sets of size up to 128 GiB (using only 16 GiB of RAM) and show that it is significantly faster than all known LZ77 compressors, while producing a roughly similar number of factors. We also introduce an external memory decompressor for texts compressed with any uni- or bidirectional compression scheme.

1 Introduction

Text compression is a fundamental task when storing massive data sets. Most practical text compressors such as gzip, bzip2, 7zip, etc., scan a text file with a sliding window, replacing repetitive occurrences within this window. Although this approach is memory and time efficient [3, 29], two occurrences of the same substring are neglected if their distance is longer than the sliding window. More advanced solutions [12, 13, 9, 19, to mention only a few examples] drop the idea of a sliding window, thereby finding also repetitions that are far apart in the text. These so-called LZ77-algorithms have a better compression ratio in practice [8, Sect. 6]. In recent years, these algorithms have also been transformed to the *external memory* (EM) model [17, 21, 2].

In this article, we present a modification of *LZ77*, called *plcpcomp*, which is based on the bidirectional compression scheme *lcpcomp* of [6], but is better suited for an efficient external memory implementation due to its memory access patterns. We can compute this scheme by scanning the text and two auxiliary arrays stored in EM (one of them being the *permuted longest common prefix array*, hence the acronym *plcp*). We underline the performance of our algorithm with evaluations showing that it is faster than any known *LZ77* compressor for massive non-highly repetitive data sets. We also present the first external decompressor for files that are compressed with a bidirectional scheme.

1.1 Related Work

Our work is the first to join the fields of bidirectional and external memory compression.

1.1.1 Bidirectional Schemes

First considerations started with [29] who also coined this notation. [11] proved that finding the *optimal* bidirectional parsing, i.e., a bidirectional parsing with the lowest number of factors, is NP-complete. [6] were the first to present a greedy algorithm for producing a bidirectional parsing called *lcpcomp*, which performs well in practice, but comes with no theoretical performance guarantees on its size. [25] combined the techniques for *lcpcomp* [6] and the longest-first grammar compression [26] in a compression algorithm running in $\mathcal{O}(n^2)$ time, which was subsequently improved to $\mathcal{O}(n \lg n)$ time by [27]. Recently, [10] showed an upper bound of $z = \mathcal{O}(b \lg(n/b))$ and a lower bound of $z = \Omega(b \lg n)$ for some specific strings, where b and z denote the minimal number of factors in an optimal *bidirectional* parsing and in an optimal *unidirectional* parsing, respectively. This implies that bidirectional parsing can be exponentially better than unidirectional parsing. They also proposed a bidirectional parsing based on the Burrows-Wheeler transform (BWT). [22] introduced so-called *string attractors*, showed that a bidirectional scheme is a string attractor and that every string attractor can be represented with a bidirectional scheme. Last but not least, the bidirectional scheme of [28] guarantees to produce at most as many factors as *LZ77*, but has the disadvantage of a super-quadratic running time.

1.1.2 EM Compression Algorithms

Yanovsky [30] presented a compressor called *ReCoil* that is specialized on large DNA datasets. Ferragina et al. [7] gave a construction algorithm of the Burrows-Wheeler transform in EM. For *LZ77* compression, [17] devised two algorithms called *EM-LZscan* and *EM-LPF*. The former performs well on highly-repetitive data, but gets outperformed easily by *EM-LPF* on other kinds of datasets. The *LZ77* compressed files can be decompressed with an algorithm due to [2], which also works in general for all files that have been compressed by a unidirectional scheme. Finally, [21] presented an EM algorithm for computing the *LZ-End* scheme [23], a variant of *LZ77*.

1.2 Preliminaries

Model of computation. We use the commonly accepted EM model by Aggarwal and Vitter [1]. It features two memory types, namely fast internal memory (IM) which may hold up to M data words, and slow EM of unbounded size. The measure of the performance of an algorithm is the number of input and output operations (I/Os) required, where each I/O transfers a block of B consecutive words between memory levels. Reading or writing

n contiguous words from or to disk requires $\text{scan}(n) = \Theta(n/B)$ I/Os. Sorting n contiguous words requires $\text{sort}(n) = \Theta((n/B) \cdot \log_{M/B}(n/B))$ I/Os. For realistic values of n , B , and M , we stipulate that $\text{scan}(n) < \text{sort}(n) \ll n$.

Text. Let Σ denote an integer alphabet of size $\sigma = |\Sigma| = n^{O(1)}$ for a natural number n . The alphabet Σ induces the *lexicographic order* \prec on the set of strings Σ^* . Let $|T|$ denote the length of a string $T \in \Sigma^*$. We write $T[j]$ for the j -th character of T , where $1 \leq j \leq n$. Given $T \in \Sigma^*$ consists of the concatenation $T = UVW$ for $U, V, W \in \Sigma^*$, we call U , V , and W a *prefix*, a *substring*, and a *suffix* of T , respectively. Given that the substring V starts at the i -th and ends at the j -th position of T , we also write $V = T[i..j]$ and $W = T[j+1..]$. In the following, we take an element $T \in \Sigma^*$ with $|T| = n$, and call it *text*. We stipulate that T ends with a sentinel $T[n] = \$ \notin \Sigma$ that is lexicographically smaller than every character of Σ .

Text Data Structures. Let SA denote the *suffix array* [24] of T . The entry $SA[i]$ is the starting position of the i -th lexicographically smallest suffix such that $T[SA[i]..] \prec T[SA[i+1]..]$ for all integers i with $1 \leq i \leq n-1$. Let ISA of T be the inverse of SA , i.e., $ISA[SA[i]] = i$ for every i with $1 \leq i \leq n$. The *Burrows-Wheeler transform (BWT)* [4] of T is the string BWT with $BWT[i] = T[n]$ if $SA[i] = 1$ and $BWT[i] = T[SA[i]-1]$ otherwise, for every i with $1 \leq i \leq n$. The *LCP array* is an array with the property that $LCP[i]$ is the length of the longest common prefix (LCP) of $T[SA[i]..]$ and $T[SA[i-1]..]$ for $i = 2, \dots, n$. For convenience, we stipulate that $LCP[1] := 0$. The array Φ is defined as $\Phi[i] := SA[ISA[i]-1]$, and $\Phi[i] := n$ in case that $ISA[i] = 1$. The *PLCP array* $PLCP$ stores the entries of LCP in text order, i.e., $PLCP[SA[i]] = LCP[i]$. Figure 1 illustrates the introduced data structures.

Idea for Using PLCP for Compression. Given a suffix $T[i..]$ starting at text position i , $PLCP[i]$ is the length of the longest common prefix of this suffix and the suffix $T[\Phi[i]..]$, which is its lexicographical predecessor among all suffixes of T . The longest common prefix of these two suffixes $T[i..]$ and $T[\Phi[i]..]$ is $T[i..i+PLCP[i]-1]$. The longest string among all these longest common prefixes (for each i with $1 \leq i \leq n$) is one of the longest re-occurring substrings in the text. Finding this longest re-occurring substring with $PLCP$ and Φ is the core idea of our compression algorithm. This algorithm produces a bidirectional scheme, which is defined as follows.

2 Compression Scheme

A *bidirectional scheme* [29] is defined by a factorization $F_1 \cdots F_b = T$ of a text T . A factor F_x is either a *referencing* factor or a *literal* factor. A referencing factor F_x is associated with a pair (src, ℓ) such that F_x and $T[src..src+\ell-1]$ are two different but possibly overlapping occurrences of the substring F_x in T . The pair (src, ℓ) and the text position src are called

■ **Figure 3** Step-by-step execution of the $plcpcomp$ compression scheme (see Section 2) on $T = ababbabababbabbaababab\$$. We overwrite values of $PLCP$ according to Rules (\mathcal{D}) and (\mathcal{R}) . Each row $PLCP^i$ shows $PLCP$ after creating the i -th referencing factor starting at a position whose $PLCP$ entry is surrounded by a box. Changed entries according to Rules (\mathcal{D}) and (\mathcal{R}) are underlined.

reference and referred position, respectively. A factorization is *cycle-free*, i.e., references are not allowed to have cyclic dependencies. A factorization is called ξ -restricted for an integer $\xi \geq 2$ if each referencing factor F_x is at least ξ characters long (i.e., $\ell \geq \xi$).

A *unidirectional scheme* is a special case of a bidirectional scheme, with the restriction that the referred position of a referencing factor F_x must be smaller than the starting position of F_x . The most prominent example of a unidirectional scheme is the *LZ77* factorization, whose factorization is usually designed to be 2-restricted.

2.1 Coding

A bidirectional scheme codes the factors by substituting referencing factors with their associated references while keeping literal factors as strings. By doing so, the coding is a list whose x -th element is either a string (corresponding to a literal factor) or a reference representing the x -th factor ($1 \leq x \leq b$), which is referencing.

The $plcpcomp$ scheme and its predecessor, the $lcpcomp$ scheme [6], are bidirectional schemes. Both schemes are greedy, as they create a referencing factor equal to the longest re-occurring substring of the text that is not yet part of a factor. They differ in the selection of such a substring in case that there are multiple candidates with the same length. The $plcpcomp$ scheme can be computed with a rewritable $PLCP$ array and the following instructions:

1. Compute the set of *candidate positions* $\mathcal{C} := \{i \mid PLCP[i] \geq PLCP[j] \text{ for all text positions } j\}$.
2. Let dst be the leftmost position of all candidate positions \mathcal{C} . Terminate if $PLCP[dst] < \xi$.
3. Create a referencing factor by replacing $T[dst..dst + PLCP[dst] - 1]$ with the reference $(\Phi[dst], PLCP[dst])$.
4. Apply the following rules to ensure that we do not create overlapping factors (cf. Figure 2):
 - (\mathcal{D}) Decrease $PLCP[j] \leftarrow \min(PLCP[j], dst - j)$ for every $j \in [dst - PLCP[dst], dst]$.
 - (\mathcal{R}) Remove the factored positions by setting $PLCP[dst + k] \leftarrow 0$ for every $k \in [0, PLCP[dst])$.
5. Recurse with the modified $PLCP$.

Figure 4 Coding of *plcpcomp* with $\xi = 2$. The factorization described in Figure 3 computes four referencing factors, listed in the table on the right. These factors are coded by their references. The factorization with *PLCP* in Figure 3 already determines the starting position and the lengths of all referencing factors (columns “*dst*” and “length” in the table). The referred positions are obtained using Φ (column “*src*”). The figure on the left illustrates factors as boxed substrings and the references as arrows from the starting positions of referencing factors to their respective referred positions.

An application of the above instructions on our running example is given in Figure 3. The coding is visualized in Figure 4. There and in the following figures, we fix $\xi := 2$.

2.2 Comparison to *lcpcomp*

The difference to *lcpcomp* [6] is that we fix *dst* to be the *leftmost* of all candidate positions in \mathcal{C} . [6] presented an algorithm computing the *lcpcomp* scheme in $\mathcal{O}(n \lg n)$ time with a heap storing the candidate positions ranked by their *PLCP* values. We can adapt this algorithm to compute the *plcpcomp* scheme by altering the order of the heap to rank the candidate positions first by their *PLCP* values (maximal *PLCP* values first) and second (in case of equal *PLCP* values) by their values themselves (minimal text positions first).

Since *lcpcomp* is cycle-free [6, Lemma 4] regardless of the selection of $dst \in \mathcal{C}$, we conclude that *plcpcomp* is also cycle-free, i.e., the substitution of substrings by references is reversible.

3 Computing the Factorization without Random Access

In this section, we present an algorithm for computing the *plcpcomp* scheme, which linearly scans *PLCP* without changing its contents. Instead of maintaining a heap storing all text positions ranked by their *PLCP* values, we compute the factorization by scanning the text sequentially from left to right. Although the algorithm will produce the *plcpcomp* factorization, it does not compute it in the order explained previously (starting with the longest factor). Instead, it first determines a subset of those substrings that define a referencing factor according to the *plcpcomp* scheme. The starting positions of these substrings have a *PLCP* value that is relatively large compared to their neighboring positions. We call those starting positions *peaks*.

Formally, we call a text position dst a *peak* if $PLCP[dst] \geq \xi$ and one of the following conditions holds:

- $dst = 1$,
- $PLCP[dst - 1] < PLCP[dst]$,¹ or
- there is a referencing factor ending at $dst - 1$.

A peak dst is called *interesting* if there is no text position j with $dst \in (j, j + PLCP[j])$ and $PLCP[j] \geq PLCP[dst]$. An interesting peak dst is called *maximal* if there is no interesting peak j with $j \in (dst, dst + PLCP[dst])$.

¹ A subset of the so-called *irreducible PLCP* entries [20, Lemma 4] have this property.

■ **Algorithm 1** Computation of *plpcomp* factors.

```

1  $L \leftarrow \emptyset$  // Step 1a
2 for  $dst = 1$  to  $n$  do // Step 1b
3   if  $dst$  is a maximal peak then // Step 2
4     create a referencing factor replacing  $T[dst \dots dst + PLCP[dst] - 1]$  // Step 3
5     apply Rule ( $\mathcal{D}$ ) to the peaks in  $L$ 
6     while  $L$  contains maximal peaks do
7        $j \leftarrow$  rightmost maximal peak in  $L$ 
8       create referencing factor replacing  $T[j \dots j + PLCP[j] - 1]$ 
9       apply Rules ( $\mathcal{D}$ ) and ( $\mathcal{R}$ ) to the peaks in  $L$ 
10      remove those elements of  $L$  that are no longer interesting peaks
11     $dst \leftarrow dst + PLCP[dst]$ 
12  if  $dst$  is an interesting peak then
13     $L \leftarrow L \cup \{dst\}$ 

```

Given an interesting peak dst , there is no text position j with $PLCP[j] \geq PLCP[dst]$ that becomes the starting position of a referencing factor containing $T[dst]$ (such that $PLCP[dst]$ cannot be removed according to Rule (\mathcal{R})). Given a maximal peak dst , there is additionally no text position j with $PLCP[j] > PLCP[dst]$ for which we apply Rule (\mathcal{D}) on $PLCP[dst]$ after factorizing $T[j \dots j + PLCP[j] - 1]$. Informally, we can determine whether a peak is interesting by looking at the $PLCP$ values *before* this peak, whereas we need to also look *ahead* for determining whether a peak is maximal. Given that there is at least one $PLCP$ entry with a value of at least ξ , we can find a maximal peak, since the leftmost position $\min \{i \in [1 \dots n] \mid PLCP[i] \geq PLCP[j] \text{ for all } j \text{ with } 1 \leq j \leq n\}$ among all positions with the highest $PLCP$ value is a maximal peak. The following lemma states that we can always factorize the leftmost maximal peak, regardless of whether the text has even higher peaks.

► **Lemma 1.** *If the text position dst is a maximal peak, then $T[dst \dots dst + PLCP[dst] - 1]$ is a referencing factor.*

Our preliminary algorithm consists of the following steps:

1. Scan $PLCP$ for the leftmost maximal peak dst .
2. Terminate if no such peak exists.
3. Create the referencing factor $T[dst \dots dst + PLCP[dst] - 1]$.
4. Apply Rules (\mathcal{R}) and (\mathcal{D}).
5. Interpret $T[1 \dots dst - 1]$ and $T[dst + PLCP[dst] \dots n]$ as two independent strings and recurse on each of them individually.

This algorithm produces the *plpcomp* scheme, because

- $T[dst \dots dst + PLCP[dst] - 1]$ is a referencing factor for each selected leftmost maximal peak dst according to Lemma 1, and
- the part $T[1 \dots dst - 1]$ can be factorized independently from how $T[dst + PLCP[dst] \dots n]$ is factorized, and vice versa. That is because, having already $T[dst \dots dst + PLCP[dst] - 1]$ factorized, we can no longer create a factor that covers a text position in the range $[dst \dots dst + PLCP[dst] - 1]$.

Hence, we can factorize $T[1 \dots dst - 1]$ without considering the factorization of the rest of the text to produce the correct *plpcomp* scheme. Figure 5 illustrates the computation of the *plpcomp* factorization with this algorithm.

However, as the algorithm overwrites entries of $PLCP$, it is not yet satisfying. A rewritable $PLCP$ array would have to be kept in RAM, costing us $n \lg n$ bits of space if we require constant time read and write access. Instead of keeping $PLCP[1 \dots dst - 1]$ in RAM, we now

i	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22
T	a	b	a	b	b	a	b	a	b	a	b	b	a	b	b	a	a	b	a	b	a	\$
$PLCP$	4	5	4	3	4	5	5	7	6	5	4	3	2	1	2	1	3	2	1	0	0	0
$PLCP^1$	<u>1</u>	0	0	0	0	0	0	5	7	6	5	4	3	2	1	2	1	3	2	1	0	0
$PLCP^1$	1	0	0	0	0	0	<u>1</u>	0	0	0	0	0	0	0	0	2	1	3	2	1	0	0
$PLCP^2$	1	0	0	0	0	0	1	0	0	0	0	0	0	0	0	0	0	3	2	1	0	0
$PLCP^3$	1	0	0	0	0	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 5 Step-by-step execution of our *plcpcomp* algorithm on $T = \text{ababbabababbabbaababa\$}$. While the instructions of the scheme (cf. Section 2) always replace the factor starting at a position with the maximal *PLCP* value (cf. Figure 3), our algorithm described in Section 3 creates a factor at the leftmost maximal peak. Our algorithm computes the same factorization as described in the *plcpcomp* scheme, but in different order.

show that it suffices to manage only the *PLCP* values of the *interesting peaks*. For that, we enhance the search of the leftmost maximal peak by replacing the first step of the algorithm by the following instructions:

- 1a. Create an empty list of peaks L .
- 1b. Scan T from left to right until a maximal peak dst is found. While doing so, insert all visited interesting peaks into L .

Another alternation is that we apply Step 4 only to the peaks stored in L . There, we scan L from right to left while applying Rule (\mathcal{D}) and removing all elements that are no longer interesting peaks. The modified algorithm is sketched as pseudo code in Algo. 1.

► **Example 2.** Figure 6 illustrates Algo. 1 on the prefix $T[1..14] = \text{ababbabababbab}$ of our running example in three steps. The peaks at positions 1 and 2 are interesting. Since the peak at position 2 is the highest interesting peak, it is the maximal peak, which is detected after scanning $PLCP[1..6]$ (Figure 6a). In the second step (Figure 6b), the referencing factor F_1 is introduced, which starts at this maximal peak. As a consequence, Rule (\mathcal{D}) is applied to the only peak stored in L , the one at position 1. However, because the *PLCP* value 1 is below the threshold $\xi = 2$, the peak at position 1 is removed from L . Since L is then empty, we proceed with the next scan for a maximal peak starting from position 7. By definition, the peak at position 7 becomes interesting. The next maximal peak is detected at position 8 (Figure 6c). The factor F_2 (Figure 6d) is introduced, and Rule (\mathcal{D}) is applied to the peak at position 7. Its *PLCP* value drops below our threshold and thus it is removed from L . Finally, the prefix $T[1..14]$ has been processed.

In Algo. 1, we omit all other peaks that are not stored in L when applying Rules (\mathcal{D}) and (\mathcal{R}). Thus, it suffices to maintain the *PLCP* value of each peak in L in an extra list instead of maintaining a complete rewritable *PLCP* array. In the following, we prove why this omission still produces the correct factorization (Lemma 5). For that, we show that we can produce the *plcpcomp* factors contained in $T[1..dst + PLCP[dst] - 1]$ only with the *PLCP* values of the peaks stored in L (first recursive call). We start with the following property of L :

► **Lemma 3.** *The positions stored in L are in strictly ascending order with respect to their LCP values.*

Next, we examine the result of creating the referencing factor $T[dst..dst + PLCP[dst] - 1]$ starting at the maximal peak dst . After creating this factor, the *PLCP* values of peaks near dst can be decreased. However, this causes at most one new peak as can be seen by the following lemma.

■ **Figure 6** Execution of our algorithm of Section 3 computing the *plcpcomp* compression scheme on $T = \text{ababbababbabbaababa}\$$. Due to limited space, we only illustrate the processing of the prefix $T[1..14]$ in three steps (explained in Example 2). The vertical bars represent the *PLCP* array, with the corresponding values written above, in text order from left ($i = 1$) to right ($i = 14$). The shaded vertical bars represent the (current) *PLCP* value of an interesting peak. Horizontal bars represent (referencing) factors. In (b), the factor F_1 , starting at position 2, is displayed as the maximal peak being *tipped over* to the right.

► **Lemma 4.** *Applying Rules (\mathcal{D}) and (\mathcal{R}) after creating a referencing factor F_x does not cause new peaks, with the only possible exception of the position succeeding the end of F_x .*

Since Rule (\mathcal{D}) decreases at most the values of $PLCP[dst - PLCP[dst]..dst - 1]$, the highest peak dst' in $PLCP[1..dst - 1]$ is an interesting peak that is either

- in the interval $[dst - PLCP[dst]..dst - 1]$, or,
- in the case that all interesting peaks in $[dst - PLCP[dst]..dst - 1]$ are no longer interesting after decreasing their *PLCP* values, the rightmost peak preceding $dst - PLCP[dst]$ (whose *PLCP* value is equal to the *PLCP* value of the last peak removed from L in Step 4).

We can locate dst' while applying Rule (\mathcal{D}) as a result of creating the factor starting at dst . After locating dst' , we apply the following steps recursively:

1. Substitute $T[dst'..PLCP[dst'] - 1]$ with a reference, because it is the highest peak in $T[1..dst - 1]$.
2. If $dst'' := dst' + PLCP[dst']$ with $PLCP[dst''] \geq \xi$ was not a peak, then dst'' becomes an interesting peak. In this case, substitute dst' with dst'' in L to preserve the order in L . Otherwise, remove dst' from L .
3. Split L into two sub-lists:
 - one containing text positions of the range $[1..dst' - 1]$, and
 - the other containing text positions of the range $[dst' + PLCP[dst']..dst - 1]$.
4. Recurse on each of the two sub-lists, i.e., find the highest peak in each sub-list and substitute it.

This recursion is more efficient than the while-loop described in Lines 6 to 10 of Algo. 1.

► **Lemma 5.** *The algorithm emits a valid *plcpcomp* factorization of $T[1..dst + PLCP[dst] - 1]$.*

■ **Figure 7** Pointer jumping applied to references. Suppose that our example text is represented by the coding described in Figure 4. To extract the character $T[2]$, we need to resolve the reference $(12, 5)$, which has a depth of three (*bottom left* figure). In case that we split all references into references of length one, we can reduce the depth of the reference associated with $T[2]$ by pointer jumping (*right* figure). The order in which this technique is applied to the references has an impact on the resulting references. Here, we assumed that we can apply this technique *in parallel*.

After factorizing $T[1 \dots dst + PLCP[dst] - 1]$, we proceed with Algo. 1 on the remaining text $T[dst + PLCP[dst] \dots]$ to compute the factorization of the entire text. It is left to explain how this algorithm can be adapted to the EM model efficiently.

3.1 Factorization in External Memory

Having the text, $PLCP$, and Φ stored as files in EM, we can compute the *plcpcmp* scheme in three sequential scans over n tuples and one sort operation:

1. Proceed with Algo. 1 to find pairs $(dst, \ell = PLCP[dst])$ representing referencing factors $T[dst \dots dst + \ell]$ by scanning $PLCP$.
2. Sort these pairs in ascending order of their dst components (i.e., in text order).
3. Simultaneously scan this sorted list of pairs and Φ to compute triplets of the form $(dst, src = \Phi[dst], \ell)$, where the second component is the referred position of the referencing factor $T[dst \dots dst + \ell - 1]$.
4. Finally, scan simultaneously the list of references and T to replace each substring $T[dst \dots dst + \ell - 1]$ by the reference (src, ℓ) on reading the triplet (dst, src, ℓ) .

The pairs emitted during the $PLCP$ scan (Step 1) can be stored and then sorted in EM. The references computed by the second scan can be written to disk for the final scan, which computes the *plcpcmp* scheme of T sequentially. By doing so, no random access is required on the list of references.

During the $PLCP$ scan, the list L can also be maintained on disk efficiently: until a maximal peak is found, we only append peaks to L . For our experiments, we store L in RAM, as the number of elements was much lower than the upper bound $\mathcal{O}(\min(\sqrt{n \lg n}, r))$ where r is the number of BWT runs (see the full version of this paper).

Once a maximal peak dst has been found and a reference (dst, ℓ) is emitted, we scan over L sequentially (a) to apply Rules (\mathcal{D}) and (\mathcal{R}) and (b) to find a remaining maximal peak, if any, in the process. We then repeat this process until there are no more maximal peaks in L . In practice, we scan the last elements of L linearly from right to left, since only the last interesting peaks need to be updated.

4 Decompression

The task of decompressing a bidirectional scheme is to *resolve* each reference (src_i, ℓ_i) of a referencing factor $T[dst_i \dots dst_i + \ell_i - 1]$, i.e., to copy the characters from $T[src_i \dots src_i + \ell_i - 1]$ to $T[dst_i \dots dst_i + \ell_i - 1]$.

41:10 Bidirectional Text Compression in External Memory

■ **Figure 8** The dependency graph (*left*) and its EM representation (*right*) of the factorization given in Figure 4. The multi-dependent factors of length seven and five have a cyclic dependency. The EM representation of the graph described in Section 4 consists of two copies of the list of all referencing factors, sorted by their source position (*top*) as well as sorted by their destination (*bottom*).

A unidirectional scheme can be decompressed by scanning linearly over the compressed input from left to right. In that scenario, references can be resolved easily because they always refer to already decompressed parts of the text [2]. This property does not hold for a bidirectional scheme in general, as a reference can refer to a part of the text that again corresponds to a reference.

► **Definition 6 (Dependency Graph).** *Given a bidirectional factorization $F_1 \cdots F_b = T$, we model its references as a directed graph G with $V = \{v_1, \dots, v_b\}$ such that there is a 1-to-1 correlation between nodes v_i and factors F_i . We add a directed edge (v_i, v_j) from v_i to v_j with $i \neq j$ iff F_i refers to at least one character in the factor F_j . We put these edges into a set E to form a graph $G := (V, E)$ that has only literal factors as sinks. A node v_i can have more than one out-going edge if the referred substring is covered by multiple factors; in this case, we say v_i is multi-dependent and call the set of its out-going edges a multi-dependency. The dependency graph of our example from Figure 4 can be seen in Figure 8.*

Bidirectional decompressors face two challenges arising from this graph structure:

- The existence of multi-dependent nodes disallows efficient tree-based approaches.
- Long dependency chains may affect the time and space complexity of decompression.

Our compression scheme splits multi-dependencies into single dependencies and deploys the pointer jumping technique [14, Sect. 2.2] for dependency resolution. After the resolution we obtain a dependency graph in which each reference is single-dependent on a literal factor. Then the text can be trivially recovered with $\text{sort}(n)$ I/Os. The details are as follows.

Let G be the dependency graph of the factorization $T = F_1 \cdots F_b$. For now we assume that all factors are single-dependent, i.e., each node v representing a referencing factor has exactly one outgoing edge $(v, p(v))$. For all other nodes (representing literal factors) we define $p(v) := v$. Clearly, G forms a forest in which each tree is rooted in a literal factor. When applying the pointer jumping technique, we take each referencing factor and attach it to the parent of its parent (cf. Figure 7). Given that G' is the resulting graph with $p'(v) = p(p(v))$, we thereby halve the depth, i.e., $d(G') = \lceil d(G)/2 \rceil$ if $d(G) \geq 2$, where $d(G)$ denotes the maximum depth of a tree in G . Hence, after $\Theta(\lg d(G))$ iterations all indirect references are resolved and have been replaced by direct references to literal factors.

If we allow multi-dependencies, pointer jumping is only possible for single-dependent nodes. To apply pointer jumping, we split each multi-dependent reference into the smallest possible set of single-dependent references. A split is introduced ad-hoc each time it is required for a pointer jump. The details of the splitting are discussed in the full version of this paper.

We first construct a representation of the dependency graph consisting of two EM vectors called **requests** and **factors**. Intuitively, each request (child) sends a request message to the first factor it refers to (parent). Addressing is implemented indirectly in terms of

■ **Figure 9** Split-Strategy of *EM-PJ* applied to the first (*left* figure) and second (*right* figure) referencing factor of the factorization given in Figure 4. *EM-PJ* splits up references in a minimal number of sub-references on which the pointer jumping technique can be applied. The *left* figure shows such an application to the reference of the leftmost referencing factor that is split into two sub-references. The first and second sub-reference receive new referred positions based on the referred positions of the second and third referencing factors, respectively. In the *right* figure, we split up the next reference (1,7) in four sub-references, where the first and last sub-reference refer to literal factors.

text positions rather than factor indices. For each reference (src, ℓ) corresponding to a factor $F_i = T[dst..dst + \ell - 1]$, we push $\langle dst, \ell, src \rangle$ into `requests` and $\langle src, \ell, dst \rangle$ into `factors`. We omit literal factors, since the lack of a reference in `factors` for a certain text position indicates the presence of a literal factor.

Subsequently, we sort² both vectors independently, bringing the messages in `requests` and the recipients in `factors` into the same order. On the right side of Figure 8 we see a visualization of the lists (after the initial sorting) for our running example. We augment `requests` with an initially empty EM priority queue `PQSPLIT`. In the following, after processing a factor F_i , we write F_i either to a vector `result` if it refers to literal factors, or to a vector `nextRequests` otherwise: Let $\langle dst, \ell, src \rangle$ be the smallest unprocessed request of a factor F_i received via `requests` or `PQSPLIT`. If it originates from `requests`, we advance `requests`'s read pointer for the next iteration, otherwise we dequeue the top element from `PQSPLIT`. We process the read request $\langle dst, \ell, src \rangle$ depending on the following cases (cf. Figure 9):

- **Jump** The request is completely covered by parent F_j in `factors`. In this case, we substitute F_i 's reference according to F_j and push it into `nextRequests` to be processed in the next iteration.
- **Finalize** No parent (partially) overlapping with F_i is available in `factors`. Then we know that F_i points to a substring contained in literal factors. We finalize F_i by pushing it into `result`.
- **Split** A prefix of F_i is contained in the parent F_j or points to literals. Let $\ell' < \ell$ be the length of the longest such prefix. Then split F_i into a prefix F_i^P of length ℓ' and a suffix F_i^S of length $\ell - \ell'$. By construction, either case “Jump” or case “Finalize” is applicable to F_i^P , and we execute it directly. Then we push $\langle src + \ell', \ell - \ell', dst + \ell' \rangle$ representing F_i^S into `PQSPLIT` to process it later within the same iteration. Observe that F_i can be split multiple times during the same iteration.

If `nextRequests` is not empty, we sort it and recurse by processing `nextRequests` and the (unaltered) `factors` simultaneously as before. With these steps, we obtain the final result:

► **Theorem 7.** *Let $F_1 \cdots F_b = T$ be a ξ -restricted bidirectional scheme, and $d(G) < b$ be the depth of T 's dependency graph G . Then *EM-PJ* requires $\mathcal{O}(\lg(d(G)) \text{sort}(n/\xi))$ I/Os.*

² To sort tuples we always use lexicographic order, i.e., we order tuples by their first unequal elements.

■ **Table 1** Empirical entropies of our data sets. The alphabet sizes of all instances are 242 and 4 for `commoncrawl` and `dna`, respectively.

5 Practical Evaluation

Experimental Setup. Our experiments are conducted on a machine with 16 GiB of RAM³, eight Hitachi HUA72302 hard drives with 1.8 TiB, two Samsung SSD 850 SSDs with 465.8 GiB, and an Intel Xeon CPU i7-6800K. The operating system is a 64-bit version of Ubuntu Linux 16.04. We implemented *plcpcomp*⁴ in the version 1.4.99 (development snapshot) of the STXXL library [5]. We compiled the source code with the GNU g++ 7.4 compiler.

Text Collections. We conduct our experiments on two texts of different alphabet sizes and repetitiveness (cf. Table 1):

- COMMONCRAWL: A crawl of web pages with an alphabet size of 242 collected by the commoncrawl organization.
- DNA: DNA sequences with an alphabet size of 4 extracted from FASTA files.

Algorithms. We compare *plcpcomp* against *EM-LPF* [17] by Kärkkäinen et al., which is an EM algorithm computing the *LZ77* factorization by constructing the *LPF* array. In addition to the input text, it requires *SA* and *LCP*.

In early experiments with *EM-LZscan* [17], it became clear that its throughput on the text collection we use is nowhere near competitiveness with *EM-LPF* and *plcpcomp*. Therefore, it is not considered in our experiments. Semi-external *LZ77* algorithms like *SE-KKP* [17] storing the text or parts of the text in RAM have not been considered.

Data Structures. Currently, the fastest way to compute the data structures *PLCP* and Φ in EM is to compute *BWT* from *SA* with the parallel EM algorithm *pEM-BWT* by Kärkkäinen and Kempa⁵, and use it for computing *PLCP* with the parallel EM construction algorithm of [16]. We modified the source code of the latter to also produce Φ as a side product.

³ In order to avoid swapping, each experiment was conducted with a limit of 14 GiB of RAM.

⁴ Available at <https://github.com/tudocomp/tudocomp>.

⁵ https://www.cs.helsinki.fi/u/dkempa/pem_bwt.html

■ **Figure 10** Performance with different prefix lengths.

For *EM-LPF*, we additionally need to convert *PLCP* to *LCP* by a scan over *SA* and a subsequent sort step. This is currently the fastest approach for obtaining *LCP*, as other approaches building *LCP* directly from *SA* like [15] are slower.

Consequently, both contestants need (directly or indirectly) *SA*. However, it takes a considerable amount of time to construct it with EM algorithms on a single machine (e.g., with pSAScan [18]). To put the focus on the comparison between *EM-LPF* and *plcpcomp*, we do not take into account the construction of *SA* and *LCP* when measuring running times.

Measurements and Results. Our experiments measure the throughput, the maximum hard disk usage, and the number of referencing factors, for *EM-LPF* and *plcpcomp* for 2^k GiB prefixes ($4 \leq k \leq 7$) of our data sets DNA and COMMONCRAWL. We collected the median of three iterations and present the results in Figure 10. The plots show that *plcpcomp* is magnitudes faster on both data sets (cf. plots “Throughput”). The reason for this could be that the disk accesses of *EM-LPF* scale much worse than those of *plcpcomp* (cf. plots “Maximum Disk Use”). We point out that *plcpcomp* is already faster than the step for computing *LCP* from *PLCP* and *SA*. Regarding the number of factors, *plcpcomp* is on par with *LZ77* (rightmost plots), producing, relatively speaking, slightly more factors. Our decompression requires multiple sorts of factor sets depending on the maximum depth of (a tree in) the dependency graph induced by the factorization. Therefore, it is not surprising that it is a lot slower than the comparatively simple compression.

Furthermore, and for the same reason, our decompression expectedly runs orders of magnitudes slower than the external memory Lempel-Ziv decoder of [2], which is why we do not do a more detailed performance comparison here.

Decompression. We ran our decompressor implementation on the *plcpcomp* codings of our datasets. Plots of the scaling experiments are shown in Figure 11. As the decompression algorithm is superlinear, the throughput is decreasing with increasing text size. However, comparing the results for the 32GiB and 64GiB commoncrawl decompression, the throughput only decreases by 1%. The throughput between the 32GiB and 64 GiB DNA decompression differs by only 5%. The maximum external memory allocation rises linearly with increasing text size.

41:14 Bidirectional Text Compression in External Memory

■ **Figure 11** Performance of the decompression with different prefix lengths.

■ **Figure 12** Evaluation of *plpcomp* with different threshold values ξ .

In Figure 12, we measured the impact of the choice of ξ on the compressed output and the decompression algorithm of our datasets. For larger values of ξ , *plpcomp* creates less referencing factors, but the total number of factors increases (as we obtain much more literal factors). Having less referencing factors, the decompression needs less disk space.

Our decompression requires multiple sorting steps on the factor lists such as *requests* (cf. Section 4). The number of these steps depend on the maximum depth of (a tree in) the dependency graph induced by the factorization. Therefore, it is not surprising that the decompressor is magnitudes slower than the comparatively simple compression algorithm.

Furthermore, and for the same reason, our decompression (expectedly) runs slower than the external memory Lempel-Ziv decoder of [2], which is why we skip a more detailed performance comparison here.

6 Conclusions

We presented *plpcomp*, the first external memory bidirectional compression algorithm, and showed its practicality by performing experiments on very large data sets, using only very limited RAM. We also presented a decompression algorithm in external memory, which can decode the output of any bidirectional compression scheme (not only *plpcomp*). Possible future steps include relating the number of factors of *plpcomp* to the minimal number of factors in a bi- or unidirectional compression scheme, evaluating the whole compression chain by also experimenting on *codings* of the output of *plpcomp* (similar to [6]), and improving the performance of the decompression algorithm.

Abstract

In the BISECTION problem, we are given as input an edge-weighted graph G . The task is to find a partition of $V(G)$ into two parts A and B such that $||A| - |B|| \leq 1$ and the sum of the weights of the edges with one endpoint in A and the other in B is minimized. We show that the complexity of the BISECTION problem on trees, and more generally on graphs of bounded treewidth, is intimately linked to the $(\min, +)$ -CONVOLUTION problem. Here the input consists of two sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$, the task is to compute the sequence $(c[k])_{k=0}^{n-1}$, where $c[k] = \min_{i=0, \dots, k} (a[i] + b[k - i])$.

In particular, we prove that if $(\min, +)$ -CONVOLUTION can be solved in $O(\tau(n))$ time, then BISECTION of graphs of treewidth t can be solved in time $O(8^t t^{O(1)} \log n \cdot \tau(n))$, assuming a tree decomposition of width t is provided as input. Plugging in the naive $O(n^2)$ time algorithm for $(\min, +)$ -CONVOLUTION yields a $O(8^t t^{O(1)} n^2 \log n)$ time algorithm for BISECTION. This improves over the (dependence on n of the) $O(2^t n^3)$ time algorithm of Jansen et al. [SICOMP 2005] at the cost of a worse dependence on t . “Conversely”, we show that if BISECTION can be solved in time $O(\beta(n))$ on edge weighted trees, then $(\min, +)$ -CONVOLUTION can be solved in $O(\beta(n))$ time as well. Thus, obtaining a sub-quadratic algorithm for BISECTION on trees is extremely challenging, and could even be impossible. On the other hand, for *unweighted* graphs of treewidth t , by making use of a recent algorithm for BOUNDED DIFFERENCE $(\min, +)$ -CONVOLUTION of Chan and Lewenstein [STOC 2015], we obtain a sub-quadratic algorithm for BISECTION with running time $O(8^t t^{O(1)} n^{1.864} \log n)$.

1 Introduction

A *bisection* of a graph G is a partition of $V(G)$ into two parts A and B such that $||A| - |B|| \leq 1$. The *weight* of a bisection (A, B) of an edge-weighted graph G is the sum of the weights of all edges with one endpoint in A and the other in B . In the BISECTION problem the task is to find a minimum weight bisection in an edge-weighted graph G given as input. The problem can be seen as a version of MINIMUM CUT with a balance constraint on the sizes of two sides of the cut. While MINIMUM CUT is solvable in polynomial time, BISECTION is one of the classic examples of NP-complete problems [15]. BISECTION has been studied extensively from the perspective of approximation algorithms [14, 13, 18, 21], parameterized algorithms [7, 11, 22] heuristics [6, 8] and average case complexity [5].

In this paper we consider BISECTION when the input graph is required to be a tree, or more generally a graph with treewidth at most t . For trees, an $O(n^3)$ time algorithm was given by MacGregor [20] already in 1978, this was improved to a parallel algorithm running in time $O(\log^2 n \log \log n)$ on $O(n^2)$ processors by Goldberg and Miller [16]. This corresponds to a sequential algorithm running in time $O(n^2 \log^2 n \log \log n)$. For graphs of bounded treewidth Jansen et al. [17] gave an algorithm that solves BISECTION in time $O(2^t n^3)$ if a tree decomposition of width t is given as input.

The majority of natural graph problems are solvable in linear time on trees and bounded treewidth graphs (see e.g. Courcelle’s theorem [10]). Thus, it is quite natural to ask whether the dependence on n in the algorithm of Jansen et al. [17] could be improved to linear. Our first result goes “half the way” from Jansen et al.’s cubic algorithm to a linear time one, and matches (in fact slightly improves) the fastest known algorithm for BISECTION on trees¹.

► **Theorem 1.** *There is an algorithm that, given an edge-weighted graph G on n vertices together with a tree decomposition of G of width at most t , computes a minimum weight bisection of G in time $\mathcal{O}(8^t \cdot t^5 \cdot n^2 \cdot \log n)$.*

Our algorithm crucially uses the $(\min, +)$ -convolution operation. The $(\min, +)$ -convolution of two number sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$ is a sequence $(c[i])_{i=0}^{n-1}$, where $c[k] = \min_{i=0, \dots, k} (a[i] + b[k - i])$. In the $(\min, +)$ -CONVOLUTION problem the input consists of the two sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$, the task is to compute their convolution $(c[i])_{i=0}^{n-1}$. A direct application of the definition of $(\min, +)$ -convolution yields a $\mathcal{O}(n^2)$ time algorithm to compute it. The bulk of the work of our algorithm consists of making a series of $(\min, +)$ -convolution steps. In fact, the running time of our algorithm can be stated as $\mathcal{O}(8^t \cdot t \cdot \log n \cdot \tau(t^2 n))$, where $\tau(n)$ is the running time of an algorithm computing the $(\min, +)$ -convolution of two sequences of length n . Therefore, there are two natural avenues for attempting to improve the algorithm of Theorem 1 to sub-quadratic. The first approach is to design a sub-quadratic algorithm for $(\min, +)$ -convolution, the second is to design an entirely different algorithm avoiding convolution altogether.

It turns out that the first approach is quite challenging, perhaps even impossible. Indeed, in the spirit of *fine-grained complexity* [23] analysis, Cygan et al. [12] identified a number of problems that admit algorithms with running time $\mathcal{O}(n^{2-\epsilon})$ if and only if $(\min, +)$ -CONVOLUTION does. With this background they conjecture that $(\min, +)$ -CONVOLUTION does *not* admit a $\mathcal{O}(n^{2-\epsilon})$ time algorithm.

Thus, if we want to improve the algorithm of Theorem 1 to a sub-quadratic algorithm without disproving the conjecture of Cygan et al. [12], we need to avoid $(\min, +)$ -convolution altogether. However, it turns out that $(\min, +)$ -convolution is unavoidable! In particular, we prove that a sub-quadratic algorithm for BISECTION on trees implies one for $(\min, +)$ -CONVOLUTION as well.

► **Theorem 2.** *If there exists an $\epsilon > 0$ such that BISECTION on weighted trees can be solved in time $\mathcal{O}(n^{2-\epsilon})$, then there exists $\delta > 0$ such that $(\min, +)$ -CONVOLUTION can be solved in $\mathcal{O}(n^{2-\delta})$ -time.*

Theorem 2 together with Theorem 1 (or rather its re-statement in terms of convolutions), puts BISECTION on weighted trees in Cygan et al. [12]’s class of problems equivalent to $(\min, +)$ -CONVOLUTION.

¹ Note that the Goldberg and Miller’s algorithm [16] is parallel, while ours is sequential.

In light of Theorem 2, the BISECTION problem on *unweighted* graphs² becomes a natural target. Our final contribution is a sub-quadratic algorithm for BISECTION on unweighted graphs of bounded treewidth. Our algorithm also works for the case when all weights are bounded by a constant W .

► **Theorem 3.** *There is an algorithm that, given an edge-weighted graph G , where all edge weights are integers between 1 and W , together with a tree decomposition of G of width t , computes a minimum weight bisection of G in time $\mathcal{O}(8^t \cdot (tW)^{\mathcal{O}(1)} \cdot n^{1.864} \log n)$.*

The key observation behind the algorithm of Theorem 3 is that the $(\min, +)$ -convolution steps in the algorithm of Theorem 1 are applied to sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$ where $a[i]$ and $b[i]$ are both essentially equal to the minimum possible sum of weights of the edges between the two sides A and B of a partition (A, B) of $V(G)$ with $|A| = i$. Bounded treewidth graphs have many vertices of small degree, and moving one vertex of small degree from A to B or vice versa changes the number of edges between A and B by at most its degree. Thus, $a[i]$ and $a[i + 1]$ cannot be too different. This allows us to use the faster algorithm for $(\min, +)$ -CONVOLUTION of Chan and Lewenstein [9] for “bounded difference” sequences.

Organization of the paper. We start by setting up the needed notation in Section 2. Section 3 is devoted to proving our algorithmic results - namely Theorems 1 and 3. Theorem 2 is proved in Section 4.

2 Preliminaries

2.1 The $(\min, +)$ -Convolution problem

For integer n , we let $[n] := \{0, 1, \dots, n\}$. Given a vector or a sequence $A \in \mathbb{Z}^n$ and an integer $i \in [n - 1]$, we denote by A_i the i -th coordinate of A .

► **Definition 4** ($(\min, +)$ -CONVOLUTION problem). *Given two sequences $(a[i])_{i=0}^{n-1}$ and $(b[i])_{i=0}^{n-1}$, compute a third sequence $(c[i])_{i=0}^{n-1}$, where $c[k] = \min_{i=0, \dots, k} (a[i] + b[k - i])$. Equivalently, we have $c[k] = \min_{i+j=k} (a[i] + b[j])$.*

In the $(\min, +)$ -CONVOLUTION problem, we sometimes require the target sequence to be computed all the way up to $2n - 2$, i.e., $(c[i])_{i=0}^{2n-2}$. In both cases, the problem is trivially solvable in $\mathcal{O}(n^2)$ time. Recent breakthroughs have shown that computing the $(\min, +)$ -CONVOLUTION for monotone non-decreasing sequences with integer values bounded by $\mathcal{O}(n)$ can be achieved in $\mathcal{O}(n^{1.864})$ deterministic time [9]. Moreover, we can relax these requirements [4] and simply require that the sequences have bounded differences, i.e., $|a[i] - a[i + 1]|, |b[i] - b[i + 1]| \in \mathcal{O}(1)$.

2.2 Graphs and the Bisection problem

We assume that each graph G is finite, simple, and undirected. We let $V(G)$ and $E(G)$ denote the vertex set and edge set of G , respectively. The *open neighborhood* of a vertex v is denoted by $N_G(v) = \{u \mid \{u, v\} \in E(G)\}$ and the *closed neighborhood* by $N_G[v] = N_G(v) \cup \{v\}$. For a set of vertices $S \subseteq V(G)$, we define $N_G(S) = \{v \notin S \mid \{u, v\} \in E(G), u \in S\}$ and $N_G[S] = N_G(S) \cup S$. The subgraph of G induced by S is denoted by $G[S]$, where $G[S]$ has vertex set S and edge set $\{\{u, v\} \in E(G) \mid u, v \in S\}$. We let $G - S = G[V(G) \setminus S]$.

² where all weights are 1

Given a graph G and two disjoint sets $A, B \subseteq V(G)$, we denote by $E(A, B)$ the subset of edges of G with one endpoint in A and the other endpoint in B . Given an edge-weighted graph G and a weight function $w : E(G) \rightarrow \mathbb{N}$ over the edges of G , a *bisection* of G is a partition of $V(G)$ into two disjoint sets $A, B \subseteq V(G)$ such that $||A| - |B|| \leq 1$ and the *weight of bisection* (A, B) is $\sum_{e \in E(A, B)} w(e)$. Formally, the BISECTION problem is defined as follows:

► **Definition 5** (BISECTION problem). *Given an edge-weighted graph G , find a bisection (A, B) of G of minimum weight.*

2.3 Treewidth and tree decompositions

► **Definition 6.** *A tree decomposition of a graph G is a pair $(\{X_i \mid i \in I\}, T = (I, F))$, where $\{X_i \mid i \in I\}$ is a collection of subsets of $V(G)$, $T = (I, F)$ is a rooted tree such that the following conditions hold:*

- $\bigcup_{i \in I} X_i = V(G)$;
- For all edges $\{u, v\} \in E(G)$, there exists $i \in I$ with $u, v \in X_i$;
- For every vertex $v \in V(G)$, the subgraph of T induced by $\{i \in I \mid v \in X_i\}$ is connected.

The width of a tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ is $\max_{i \in I} (|X_i| - 1)$. The treewidth of a graph G , $\text{tw}(G)$, is the minimum width over all possible tree decompositions of the graph. We call the vertices of the tree T nodes and the sets X_i bags. A graph of treewidth $\mathcal{O}(1)$ is called a bounded treewidth graph.

Given a tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ of an n -vertex graph G of treewidth k , we can turn this decomposition in time in $\mathcal{O}(k^{\mathcal{O}(1)} \cdot n)$ into a *nice tree decomposition* with at most $\mathcal{O}(k|V(G)|)$ nodes, i.e., a decomposition of the same width and satisfying the following properties:

- The root bag as well as all leaf bags are empty;
- Every node of the tree decomposition is of one of four different types:
 - Leaf node: a node i with $X_i = \emptyset$ and no children;
 - Introduce node: a node i with exactly one child j such that $X_i = X_j \cup \{v\}$ for some vertex $v \in X_j$;
 - Forget node: a node i with exactly one child j such that $X_i = X_j \setminus \{v\}$ for some vertex $v \in X_j$;
 - Join node: a node i with two children j_1 and j_2 such that $X_i = X_{j_1} = X_{j_2}$.

► **Theorem 7** (Bodlaender et al. [2]). *There exists an algorithm, that given an n -vertex graph G and an integer k , in time $2^{\mathcal{O}(k)} n \log n$ either outputs that the treewidth of G is larger than k , or constructs a tree decomposition of G of width at most $3k + 4$.*

Combining Theorem 8 below with standard arguments (we refer the reader to [2] for more details), we arrive at Proposition 9, which is the form that will be required to obtain our algorithms.

► **Theorem 8** (Bodlaender and Hagerup [3]). *There is an algorithm that, given a tree decomposition of width k with $\mathcal{O}(n)$ nodes of a graph G , finds a rooted binary tree decomposition of G of width at most $3k + 2$ with depth $\mathcal{O}(\log n)$ in $\mathcal{O}(kn)$ -time.*

► **Proposition 9.** *There is an algorithm that, given an n -vertex graph G and a tree decomposition of G of width k , runs in $\mathcal{O}(kn)$ -time, and computes a nice tree decomposition of G of width $3k + 2$, height $\mathcal{O}(k \log n)$, and with $\mathcal{O}(kn)$ nodes.*

3 Algorithms for Bisection on Bounded Treewidth Graphs

We start by reviewing the $\mathcal{O}(2^{t+1} \cdot n^3)$ -time algorithm for solving the BISECTION problem on graphs of treewidth at most t by Jansen et al. [17]. The algorithm is a standard dynamic programming algorithm over a tree decomposition. Given a graph G together with its nice tree decomposition $(\{X_i | i \in I\}, T = (I, F))$ of width t the algorithm works as follows.

For each node $i \in I$, we let Y_i denote the set of all vertices in X_j , where either j is a descendant of i in T or $j = i$. The algorithm computes for each $i \in I$, an array mwp_i (which stands for minimum weight partition) containing $\mathcal{O}(2^t \cdot |Y_i|)$ entries. For each $\ell \in \{0, 1, \dots, |Y_i|\}$ and each $S \subseteq X_i$, the entry $\text{mwp}_i(\ell, S)$ is set to $\min_{S' \subseteq Y_i, |S'|=\ell, S' \cap X_i=S} (\sum_{e \in E(S', Y_i \setminus S')} w(e))$. That is, $\text{mwp}_i(\ell, S)$ is equal to the minimum possible weight of a bisection where S and $X_i \setminus S$ are in different parts of the bisection and the side including S is of cardinality exactly ℓ . When such a partition is not possible, we set $\text{mwp}_i(\ell, S)$ to ∞ .

We compute the entries of the array following the levels of the tree decomposition in a bottom-up manner as follows.

- Let i be a leaf in T . Note that $Y_i = X_i = \emptyset$. We set $\text{mwp}_i(0, \emptyset) = 0$.
- Let i be a forget node with one child j such that $X_i \subseteq X_j$. Then, for all $\ell \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, we set

$$\text{mwp}_i(\ell, S) = \min_{S' \subseteq X_j, S' \cap X_i=S} (\text{mwp}_j(\ell, S')).$$

- Let i be an introduce node with one child j such that $X_j \cup \{v\} = X_i$ and $v \notin X_j$. Then, for all $\ell \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, if $v \in S$ we set $\text{mwp}_i(\ell, S) = \text{mwp}_j(\ell - 1, S \setminus \{v\})$. Otherwise, we set

$$\text{mwp}_i(\ell, S) = \text{mwp}_j(\ell, S) + \sum_{e \in \{\{v, s\} | s \in S\}} w(e).$$

- Let i be a join node with two children j_1 and j_2 , where $X_i = X_{j_1} = X_{j_2}$. For all $\ell \in \{0, 1, \dots, |Y_i|\}$ and $S \subseteq X_i$, we set

$$\text{mwp}_i(\ell, S) = \min_{\ell_1 + \ell_2 = \ell, \ell_1, \ell_2 \geq |S|} \left(\text{mwp}_{j_1}(\ell_1, S) + \text{mwp}_{j_2}(\ell_2, S) - \sum_{e \in E(S, X_i \setminus S)} w(e) \right).$$

We omit the proof of correctness and refer the reader to [17] for more details. We focus here on the runtime analysis. Analyzing the above algorithm on the tree decomposition of width t and height $\mathcal{O}(t \log n)$, we obtain the following lemma.

► **Lemma 10.** *There is an algorithm that, given an edge-weighted graph G on n vertices and a nice tree decomposition of width t , height $\mathcal{O}(t \log n)$, and $\mathcal{O}(tn)$ nodes, computes a minimum weight bisection of G in time $\mathcal{O}(2^{t+1} \cdot t \cdot \log n \cdot \tau(t^2 n))$, where $\tau(|Y_i|)$ is the time required to compute the entries $\text{mwp}_i(\ell, S)$ for all $\ell \in [|Y_i|]$ and a fixed S in a join node.*

Proof. Let $(\{X_i | i \in I\}, T = (I, F))$ be the nice tree decomposition of G given as input. The time spent at each leaf node, introduce node, or forget node i is bounded by $\mathcal{O}(2^{t+1} \cdot |Y_i|)$. Moreover, by our assumption the time spent in each join node is $\mathcal{O}(2^{t+1} \tau(|Y_i|))$.

Now let us split the nodes of T into $r = \mathcal{O}(t \log n)$ levels L_0, \dots, L_r depending on the distance of the node from the root of T . We analyze the running time on each level separately. Clearly, the running time at level k is at most $\mathcal{O}(\sum_{i \in L_k} 2^{t+1} \tau(|Y_i|))$. Moreover, given $i, j \in L_k$ the nodes i and j cannot be descendants of each other. Therefore, from the

definition of a tree decomposition and Y_i and Y_j respectively, it follows that $Y_i \cap Y_j \subseteq X_i \cap X_j$. Hence, $\sum_{i \in L_k} |Y_i| \leq \sum_{i \in L_k} |X_i| + n \leq \sum_{i \in I} |X_i| + n \leq \mathcal{O}(t^2 n)$. Clearly $\tau(|Y_i|) = \Omega(|Y_i|)$ and it follows that $\mathcal{O}(\sum_{i \in L_k} 2^{t+1} \tau(|Y_i|)) \leq \mathcal{O}(2^{t+1} (\sum_{i \in L_k} \tau(|Y_i|))) \leq \mathcal{O}(2^{t+1} \tau(t^2 n))$. Combined with the fact that the height of the tree decomposition is $\mathcal{O}(t \log n)$, we get the claimed running time of $\mathcal{O}(2^{t+1} \cdot t \cdot \log n \cdot \tau(t^2 n))$. ◀

► **Lemma 11.** *Let i be a join node with children j_1 and j_2 , where $X_i = X_{j_1} = X_{j_2}$. There is an algorithm that, for a fixed $S \subseteq X_i$, computes all the entries $\text{mwp}_i(\ell, S)$, for all $\ell \in [|Y_i|]$, in time $\mathcal{O}(\tau(|Y_i|))$ if and only if there is an $\mathcal{O}(\tau(|Y_i|))$ time algorithm solving an instance of $(\min, +)$ -CONVOLUTION with two sequences $(a[p])_{p=0}^{|Y_i|}$ and $(b[p])_{p=0}^{|Y_i|}$, where $a[p] = \text{mwp}_{j_1}(p, S)$ for $p \in [|Y_{j_1}|]$ and $a[p] = \infty$ otherwise and $b[p] = \text{mwp}_{j_2}(p, S)$ for $p \in [|Y_{j_2}|]$ and $b[p] = \infty$ otherwise.*

Proof. Recall that

$$\text{mwp}_i(\ell, S) = \min_{\ell_1 + \ell_2 - |S| = \ell, \ell_1, \ell_2 \geq |S|} \left(\text{mwp}_{j_1}(\ell_1, S) + \text{mwp}_{j_2}(\ell_2, S) - \sum_{e \in E(S, X_i \setminus S)} w(e) \right).$$

Let $W = \sum_{e \in E(S, X_i \setminus S)} w(e)$. Note that for a fixed i and a fixed S , both $\sum_{e \in E(S, X_i \setminus S)} w(e)$ and $|S|$ are fixed. Hence,

$$\text{mwp}_i(\ell, S) = \min_{\ell_1 + \ell_2 - |S| = \ell, \ell_1, \ell_2 \geq |S|} (\text{mwp}_{j_1}(\ell_1, S) + \text{mwp}_{j_2}(\ell_2, S)) - W.$$

Let $(c[p])_{p=0}^{2|Y_i|-1}$ be the $(\min, +)$ -convolution of the sequences $(a[p])_{p=0}^{|Y_i|}$ and $(b[p])_{p=0}^{|Y_i|}$; that is $c[k] = \min_{q+r=k} (a[q] + b[r])$. Finally, we set $\text{mwp}_i(p, S) = c[p - |S|] - W$, for $p \in \{|S|, |S| + 1, \dots, |Y_i|\}$. All other entries are set to ∞ . ◀

Combining Lemmas 10 and 11 with Theorem 8 we conclude the proof of Theorem 1. We remark that if a tree decomposition is not given then we can compute it, using the algorithm of Theorem 7, at the cost of a worse dependence on t .

Proof of Theorem 1. We assume that $(\min, +)$ -CONVOLUTION can be solved in $\mathcal{O}(\tau(n))$ time. Using Proposition 9, we can compute in $\mathcal{O}(tn)$ time a nice tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ of G , such that the width of the decomposition is $3t + 2$, the height is $\mathcal{O}(t \log n)$, and the number of nodes of T is $\mathcal{O}(tn)$. Afterwards, we invoke the algorithm of Lemma 10 to compute the minimum weight bisection in time $\mathcal{O}(2^{3t+3} \cdot (3t + 2) \cdot \log n \cdot \tau((3t + 2)^2 n)) = \mathcal{O}(8^t \cdot t \cdot \log n \cdot \tau(t^2 n))$ using the $\mathcal{O}(\tau(|Y_i|))$ time algorithm to compute the $(\min, +)$ -convolution needed in the join nodes. Plugging in the naive $\mathcal{O}(n^2)$ time algorithm for $(\min, +)$ -CONVOLUTION gives $\tau(n) = \mathcal{O}(n^2)$, completing the proof. ◀

3.1 Bounded Edge Weights

We now turn our attention to the case when the maximum weight of every edge in the input graph is bounded by some constant W . We show that in this case, we can actually compute a minimum bisection of a bounded treewidth graph of size n in time $\mathcal{O}(8^t \cdot (tW)^{\mathcal{O}(1)} \cdot n^{1.864} \log n)$ or, equivalently, $\mathcal{O}(8^t \cdot (tW)^{\mathcal{O}(1)} \cdot n^{1.864+\epsilon})$, for $\epsilon > 0$.

► **Lemma 12.** *Let G be an edge-weighted graph with maximum weight of an edge W with a tree decomposition $(\{X_i \mid i \in I\}, T = (I, F))$ of width t . Then for every node $i \in I$, every $S \subseteq X_i$ and every $\ell \in \{|S|, \dots, |Y_i| - |X_i \setminus S| - 1\}$ it holds that $|\text{mwp}_i(\ell, S) - \text{mwp}_i(\ell + 1, S)| \leq (2t + 1) \cdot W$.*

Proof. It is easy to see that $\text{mwp}_i(\ell, S) = \text{mwp}_i(|Y_i| - \ell, X_i \setminus S)$. Hence, without loss of generality, we can assume that $\text{mwp}_i(\ell, S) \geq \text{mwp}_i(\ell + 1, S)$. Now let A be a set of size ℓ such that $S = A \cap X_i$ and $\text{mwp}_i(\ell, S) = \sum_{e \in E(A, \overline{A})} w(e)$. It is well-known that we can order the vertices of a graph G such that every vertex has at most $\text{tw}(G)$ neighbors earlier in the ordering [19]. Let us denote such an ordering σ and let v be the last vertex from $Y_i \setminus (A \cup X_i)$ in σ . Now $E(A \cup \{v\}, \overline{A \cup \{v\}}) = (E(A, \overline{A}) \setminus E(\{v\}, A)) \cup E(\{v\}, \overline{A \cup \{v\}})$. It follows that $\text{mwp}_i(\ell + 1, S) \leq \text{mwp}_i(\ell, S) + |E(\{v\}, \overline{A \cup \{v\}})| \cdot W$. By the choice of v , all the vertices in $\overline{A \cup \{v\}}$ are either earlier in σ than v or in X_i . Moreover, v has only at most $\text{tw}(G)$ many neighbors that are earlier in σ than v and there are at most $t + 1$ vertices in X_i , hence $|E(\{v\}, \overline{A \cup \{v\}})| \leq \text{tw}(G) + t + 1$. Since $\text{tw}(G) \leq t$, the lemma follows. ◀

Observe, that the bound of Lemma 12 is tight up to a multiplicative constant. As an example achieving difference $|\text{mwp}_i(\ell, S) - \text{mwp}_i(\ell + 1, S)| \leq (t + 1) \cdot W$ take $S = X_i$ and an instance where the edges in Y_i have all weight W and are precisely all the pairs with one endpoint in X_i and the other in $Y_i \setminus X_i$.

Lemma 12 tells us that the restriction of the sequences $(a[p])_{p=0}^{|Y_i|}$ and $(b[p])_{p=0}^{|Y_i|}$ for which we need to compute the $(\min, +)$ -CONVOLUTION in Lemma 11 to entries that are not ∞ has bounded difference. However, these two restricted sequences might not have the same length and it is not straightforward how to adapt the algorithm by Chan and Lewenstein [9]. To overcome this issue, we use a standard trick to change these sequences to monotone non-decreasing sequences with integer values bounded by $\mathcal{O}(n)$ and pad the shorter sequence by some large value. This trick is outlined by Chan and Lewenstein [9] but never formally stated, we repeat it here for completeness.

► **Theorem 13** ([9]). **MONOTONE** $(\min, +)$ -CONVOLUTION *with all entries in $\{0, \dots, nD\}$ can be solved in time $\mathcal{O}((nD)^{1.859})$ by a randomized algorithm, or in time $\mathcal{O}((nD)^{1.864})$ deterministically.*

We remark that Chan and Lewenstein [9] do not explicitly state the dependence on D . It is easy to see from their arguments that the dependence on D is at most $\mathcal{O}(D^{1.864})$, but we suspect that it is much better.

► **Lemma 14.** *Let n_1, n_2 be two integers such that $n_1 \leq n_2$ and let sequences $(a[p])_{p=0}^{n_1}$ and $(b[p])_{p=0}^{n_2}$ be two sequences with the difference bounded by a constant D and all entries in $\{0, \dots, n_2 D'\}$, for some constant D' . Then we can compute the sequence $(c[p])_{p=0}^{n_1+n_2}$ such that $c[k] = \min_{i+j=k} (a[i] + b[j])$ in time $\mathcal{O}((2n_2(D + D'))^{1.864})$.*

Proof. To compute $(c[p])_{p=0}^{n_1+n_2}$ we start by changing the sequences $(a[p])_{p=0}^{n_1}$ and $(b[p])_{p=0}^{n_2}$ to bounded monotone sequences $(a'[p])_{p=0}^{n_1}$ and $(b'[p])_{p=0}^{n_2}$ by adding $D \cdot i$ to $a'[i]$ and $b'[i]$, respectively. Note that $\min_{i+j=k} (a[i] + b[j]) = \min_{i+j=k} (a'[i] + b'[j]) - D \cdot k$. Now let $C = \max(a'[n_1], b'[n_2])$. Finally, we create sequence $(a''[p])_{p=0}^{n_2}$ by setting $a''[p] = a'[p]$ if $a'[p]$ is defined and $a''[p] = 2C + 1$ otherwise. It is easy to see that $\min_{i+j=k} (a'[i] + b'[j]) = \min_{i+j=k} (a''[i] + b'[j])$ for all $k \in \{0, \dots, n_1 + n_2\}$. Therefore, to compute the $(\min, +)$ -convolution of the sequences $(a[p])_{p=0}^{n_1}$ and $(b[p])_{p=0}^{n_2}$ it suffices to compute the $(\min, +)$ -convolution of the sequences $(a''[p])_{p=0}^{n_2}$ and $(b'[p])_{p=0}^{n_2}$, which are both monotone with integer entries between 0 and $C \leq 2(D \cdot n_2 + n_2 D') + 1$ and the proof follows due to Theorem 13. ◀

We are now in position to prove Theorem 3.

Proof of Theorem 3. Same as in the proof of Theorem 1, we start by using Proposition 9 to compute a nice tree decomposition $(\{X_i | i \in I\}, T = (I, F))$ of G , such that the width of the decomposition is $3t + 2$, the height is $\mathcal{O}(t \log n)$, and the number of nodes of T is $\mathcal{O}(tn)$.

Afterwards, we invoke the algorithm of Lemma 10 to compute the minimum weight bisection in time $\mathcal{O}(8^t \cdot t \cdot \log n \cdot \tau(t^2 n))$, where $\mathcal{O}(\tau(|Y_i|))$ is the time required to compute the entries $\text{mwp}_i(\ell, S)$ for all $\ell \in [|Y_i|]$ and a fixed S in a join node.

It remains to show that we can compute $\text{mwp}_i(\ell, S)$ for all $\ell \in [|Y_i|]$ and a fixed S in time $\mathcal{O}((tW)^{\mathcal{O}(1)} \cdot |Y_i|^{1.864})$. By Lemma 11, this is equivalent to solving an instance of $(\min, +)$ -convolution with two sequences $(a[p])_{p=0}^{|Y_i|}$ and $(b[p])_{p=0}^{|Y_i|}$, where $a[p] = \text{mwp}_{j_1}(p, S)$ for $p \in [|Y_{j_1}|]$ and $a[p] = \infty$ otherwise and $b[p] = \text{mwp}_{j_2}(p, S)$ for $p \in [|Y_{j_2}|]$ and $b[p] = \infty$ otherwise. Note that $\text{mwp}_{j_1}(\ell, S)$ ($\text{mwp}_{j_2}(\ell, S)$) is set to ∞ if $\ell < |S|$ or $\ell > |Y_{j_1}| - |X_{j_1} \setminus S|$ ($\ell > |Y_{j_2}| - |X_{j_2} \setminus S|$). Hence, from Lemma 12 it follows that if both $a[p]$ and $a[p+1]$ (respectively $b[p]$ and $b[p+1]$) are finite, then $|a[p+1] - a[p]|$ (respectively $|b[p+1] - b[p]|$) is bounded by $(2t+1) \cdot W$, where W is the maximum weight of an edge in G , and hence it is constant. To finish the proof, let $n_{j_1} = |Y_{j_1}| - |S| - |X_{j_1} \setminus S|$ and $n_{j_2} = |Y_{j_2}| - |S| - |X_{j_2} \setminus S|$ and let sequences $(a'[p])_{p=0}^{n_{j_1}}$ and $(b'[p])_{p=0}^{n_{j_2}}$ be such that $a'[p] = a[p+|S|]$ and $b'[p] = b[p+|S|]$. That is a' and b' are created from a and b by removing ∞ from the sequences. For all $k \in \{2|S|, \dots, n_{j_1} + n_{j_2} + 2|S|\}$ (that is whenever $\min_{i+j=k}(a[i] + b[j]) \neq \infty$) it holds that $\min_{i+j=k}(a[i] + b[j]) = \min_{i'+j'=k}(a'[i'] + b'[j'])$. Therefore, to compute the $(\min, +)$ -convolution of the sequences $(a[p])_0^{|Y_i|}$ and $(b[p])_0^{|Y_i|}$, it suffices to compute the sequence $(c'[p])_0^{n_{j_1} + n_{j_2}}$ such that $c'[k] = \min_{i+j=k}(a'[i] + b'[j])$. Clearly, due to Lemma 12, $(a'[p])_{p=0}^{n_{j_1}}$ and $(b'[p])_{p=0}^{n_{j_2}}$ have difference bounded by $(6t+5) \cdot W$. Moreover, let $n' = \max(n_{j_1}, n_{j_2})$, then it is easy to see that both $a[|S|]$ and $b[|S|]$ are at most $|S| \cdot n' \cdot W \leq (3t+3) \cdot n' \cdot W$ and hence the entries in $(a'[p])_{p=0}^{n_{j_1}}$ and $(b'[p])_{p=0}^{n_{j_2}}$ are all integers between 0 and $(3t+3) \cdot n' \cdot W + (6t+5) \cdot W \cdot n' = (9t+8) \cdot W \cdot n'$. Therefore, we can compute the sequence $(c'[p])_0^{n_{j_1} + n_{j_2}}$ in $\mathcal{O}(((30t+26) \cdot W \cdot n')^{1.864})$ by Lemma 14, finishing the proof. \blacktriangleleft

4 Tree Bisection is as Hard as $(\min, +)$ -Convolution

We complement Theorem 3 by showing that if the BISECTION problem can be solved in subquadratic time, i.e., in time $\mathcal{O}(n^{2-\epsilon})$ for $\epsilon > 0$, on weighted trees then the $(\min, +)$ -convolution problem can be solved in subquadratic time as well, i.e., in time $\mathcal{O}(n^{2-\delta})$ for $\delta > 0$. We follow a strategy similar to that of [1] used for proving a lower bound on the TREE SPARSITY problem.

► **Definition 15** (SUM3 problem). *Given three sequences $A, B, C \in \mathbb{Z}^n$, decide if the following statement is true: $\exists i, j : A_i + B_j + C_{i+j} \leq 0$.*

► **Theorem 16** ([1, 24]). *The $(\min, +)$ -CONVOLUTION problem can be solved in time $\mathcal{O}(n^{2-\epsilon})$, for $\epsilon > 0$, if and only if the SUM3 problem can be solved in $\mathcal{O}(n^{2-\delta})$ time, for $\delta > 0$.*

Hence, given Theorem 16, we prove the main theorem of this section by a reduction from SUM3 to the BISECTION problem on weighted trees. We start by describing the construction.

Let W be equal to 10 times the largest absolute value of an entry in A, B , and C . We create a root vertex r . Consider $A \in \mathbb{Z}^n$. We first construct a path $P_A = \{r, a_0, a_1, \dots, a_{n-1}\}$ of n vertices (excluding r) such that the weight of the i th edges is $W + A_i$, for $i = 0, 1, \dots, n-1$. Similarly, for $B \in \mathbb{Z}^n$, we construct a path $P_B = \{r, b_0, b_1, \dots, b_{n-1}\}$ of n vertices (excluding r) such that the weight of the i th edges is $W + B_i$, for $i = 0, 1, \dots, n-1$. We then create a new vertex c and a path $P_C = \{c, c_0, c_1, \dots, c_{n-1}, c_n, c_{n+1}, \dots, c_{2n-1}, r\}$ of $2n+1$ vertices such that the weight of the i th edges is $W + C_i$, for $i = 0, 1, \dots, n-1$ and the weight is nW otherwise ($i > n-1$). Finally, we attach $30n$ pendant vertices to r , $10n$ pendant vertices to

■ **Figure 1** The reduction from SUM3 (for $n = 4$) to the BISECTION problem on weighted trees.

a_{n-1} , $10n$ pendant vertices to b_{n-1} , and $10n - 1$ pendant vertices to c . The weight of each of those edges is nW . We let T denote the resulting tree (see Figure 1). Note that the total number of vertices in T is $60n + 4n = 64n$.

► **Lemma 17.** *Let $A, B, C \in \mathbb{Z}^n$ be an instance of SUM3 and let T be the corresponding instance of BISECTION. Then $\exists i, j : A_i + B_j + C_{i+j} \leq 0$ if and only if T has a bisection of weight less than or equal $3W$.*

Proof. Assume that $\exists i, j : A_i + B_j + C_{i+j} \leq 0$. We claim that T admits a bisection whose weight is at most $3W$. We pick one edge from each of the three paths P_A , P_B , and P_C . In particular, we pick the i -th edge from P_A , the j -th edge from P_B , and the k -th edge from P_C , where $k = i + j$. The total weight is therefore $3W + A_i + B_j + C_{i+j} \leq 3W$. The total number of vertices in the r -partition is $30n + i + j + 2n - k = 32n$ and the total number of vertices in the abc -partition is $30n + 2n + k - (i + j) = 32n$, as needed.

For the other direction, assume that T admits a bisection (X, Y) whose weight is at most $3W$. Notice, that from the choice of W and the construction, it follows that the weight of any at least four edges is at least $3W + \frac{6W}{10}$, and consequently $|E(X, Y)| \leq 3$. We claim that $E(X, Y)$ contains exactly three edges from T , each edge from a different path. Assume otherwise, i.e., that at least one path remains untouched. Then, the corresponding partition will contain at least $40n$ vertices which is greater than $32n$ vertices. Now, let $E(X, Y)$ contain the i -th edge from P_A , the j -th edge from P_B , and the k -th edge from P_C . It remains to show that $k = i + j$. The size of the partition containing r is $30n + i + j + 2n - k$. Since the number of vertices in T is $64n$ and both partitions must have equal size, we get $30n + i + j + 2n - k = 32n$ and therefore $i + j = k$, as needed. ◀

The construction, together with Proposition 16 and Lemma 17 conclude the proof of Theorem 2.

Abstract

Packing and covering semidefinite programs (SDPs) appear in natural relaxations of many combinatorial optimization problems as well as a number of other applications. Recently, several techniques were proposed, that utilize the particular structure of this class of problems, to obtain more efficient algorithms than those offered by general SDP solvers. For certain applications, such as those described in this paper, it may be required to deal with SDPs with *exponentially* or *infinitely* many constraints, which are accessible only via an *oracle*. In this paper, we give an efficient primal-dual algorithm to solve the problem in this case, which is an extension of a *logarithmic-potential* based algorithm of Grigoriadis, Khachiyan, Porkolab and Villavicencio (SIAM Journal of Optimization 41 (2001)) for packing/covering linear programs.

1 Introduction

1.1 Packing and Covering SDPs

We denote by \mathbb{S}^n the set of all $n \times n$ real symmetric matrices and by $\mathbb{S}_+^n \subseteq \mathbb{S}^n$ the set of all $n \times n$ positive semidefinite matrices. Consider the following pairs of *packing-covering* semidefinite programs (SDPs):

$$\begin{array}{l|l} \begin{array}{l} z_I^* = \max \quad C \bullet X \\ \text{s.t.} \quad A_i \bullet X \leq b_i, \forall i \in [m] \\ X \in \mathbb{R}^{n \times n}, X \succeq 0 \end{array} & \begin{array}{l} \text{(P-I)} \\ \\ \\ \end{array} \\ \hline \begin{array}{l} z_{II}^* = \min \quad C \bullet X \\ \text{s.t.} \quad A_i \bullet X \geq b_i, \forall i \in [m] \\ X \in \mathbb{R}^{n \times n}, X \succeq 0 \end{array} & \begin{array}{l} \text{(C-II)} \\ \\ \\ \end{array} \\ \hline \begin{array}{l} z_I^* = \min \quad b^T y \\ \text{s.t.} \quad \sum_{i=1}^m y_i A_i \succeq C \\ y \in \mathbb{R}^m, y \geq 0 \end{array} & \begin{array}{l} \text{(C-I)} \\ \\ \\ \end{array} \\ \hline \begin{array}{l} z_{II}^* = \max \quad b^T y \\ \text{s.t.} \quad \sum_{i=1}^m y_i A_i \preceq C \\ y \in \mathbb{R}^m, y \geq 0 \end{array} & \begin{array}{l} \text{(P-II)} \\ \\ \\ \end{array} \end{array}$$

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

where $C, A_1, \dots, A_m \in \mathbb{S}_+^n$ are (non-zero) positive semidefinite matrices, and $b = (b_1, \dots, b_n)^T \in \mathbb{R}_+^n$ is a nonnegative vector. In the above, $C \bullet X := \text{Tr}(CX) = \sum_{i=1}^n \sum_{j=1}^n c_{ij}x_{ij}$, and “ \succeq ” is the *Löwner order* on matrices: $A \succeq B$ if and only if $A - B$ is positive semidefinite. This type of SDPs arise in many applications, see, e.g. [19, 18] and the references therein.

We will make the following assumption throughout the paper:

(A) $b_i > 0$ and hence $b_i = 1$ for all $i \in [m]$.

It is known that, under assumption (A), *strong duality* holds for problems (P-I)-(C-I) (resp., (P-II)-(C-II)).

Let $\epsilon \in (0, 1]$ be a given constant. We say that (X, y) is an ϵ -optimal primal-dual solution for (P-I)-(C-I) if (X, y) is a primal-dual feasible pair such that

$$C \bullet X \geq (1 - \epsilon)b^T y \geq (1 - \epsilon)z_I^*. \quad (1)$$

Similarly, we say that (X, y) is an ϵ -optimal primal-dual solution for (P-II)-(C-II) if (X, y) is a primal-dual feasible pair such that

$$C \bullet X \leq (1 + \epsilon)b^T y \leq (1 + \epsilon)z_{II}^*. \quad (2)$$

Since in this paper we allow the number of constraints m in (P-I) (resp., (C-II)) to be *exponentially* (or even infinitely) large, we will assume the availability of the following *oracle*:

Max(Y) (resp., **Min**(Y)): Given $Y \in \mathbb{S}_+^n$, find $i \in \text{argmax}_{i \in [m]} A_i \bullet Y$ (resp., $i \in \text{argmin}_{i \in [m]} A_i \bullet Y$).

Note that an *approximation oracle* computing the maximum (resp., minimum) above within a factor of $(1 - \epsilon)$ (resp., $(1 + \epsilon)$) is also sufficient for our purposes.

Our objective in this paper is to develop oracle-based *primal-dual* algorithms that find ϵ -optimal solutions for (P-I)-(C-I) and (P-II)-(C-II). An interesting property of our algorithms which distinguishes them from most previously known algorithms is that they produce solutions which are *sparse*, in the following sense: A primal-dual solution (X, y) to (C-I) (resp., (P-II)) is said to be η -sparse, if the size of $\text{supp}(y) := \{i \in [m] : y_i > 0\}$ is at most η . Two applications for SDP’s with infinite/exponential number of constraints are given in Section 3.

1.2 Main Result and Related Work

Problems (P-I)-(C-I) and (P-II)-(C-II) can be solved using general SDP solvers, such as interior-point methods: for instance, the barrier method (see, e.g., [29]) can compute a solution, within an *additive* error of ϵ from the optimal, in time $O(\sqrt{nm}(n^3 + mn^2 + m^2) \log \frac{1}{\epsilon})$ (see also [1, 34]). However, due to the special nature of (P-I)-(C-I) and (P-II)-(C-II), better algorithms can be obtained. Most of the improvements are obtained by using *first order methods* [4, 6, 7, 2, 13, 19, 20, 21, 22, 28, 30, 31], or second order methods [17, 18]. In general, we can classify these algorithms according to whether they:

- (I) are *width-independent*: the running time of the algorithm depends *polynomially* on the bit length of the input; for example, in the case of (P-I)-(C-I), the running time is $\text{poly}(n, m, \mathcal{L}, \log \tau, \frac{1}{\epsilon})$, where \mathcal{L} is the maximum bit length needed to represent any number in the input; on the other hand, the running time of a width-dependent algorithm will depend polynomially on a “width parameter” ρ , which is polynomial in \mathcal{L} and τ ;
- (II) are *parallel*: the algorithm takes $\text{polylog}(n, m, \mathcal{L}, \log \tau) \cdot \text{poly}(\frac{1}{\epsilon})$ time, on a $\text{poly}(n, m, \mathcal{L}, \log \tau, \frac{1}{\epsilon})$ number of processors;

- (III) *output sparse solutions*: the algorithm outputs an η -sparse solution to (C-I) (resp., (P-II)), for $\eta = \text{poly}(n, \log m, \mathcal{L}, \log \tau, \frac{1}{\epsilon})$ (resp., $\eta = \text{poly}(n, \log m, \mathcal{L}, \frac{1}{\epsilon})$), where τ is a parameter that bounds the trace of any optimal solution X (see Section 2 for details);
- (IV) *are oracle-based*: the only access of the algorithm to the matrices A_1, \dots, A_m is via the maximization/minimization oracle, and hence the running time is independent of m .

Table 1 gives a summary¹ of the most relevant results together with their classifications, according to the four criteria described above. We note that almost all these algorithms for packing/covering SDP's are generalizations of similar algorithms for packing/covering linear programs (LPs), and most of them are essentially based on an *exponential potential function* in the form of *scalar exponentiation*, e.g., [4, 22], or *matrix exponentiation* [6, 7, 2, 21, 19]. For instance, several of these results use the scalar or matrix versions of the *multiplicative weights updates* (MWU) method (see, e.g., [5]), which are extensions of similar methods for packing/covering LPs [14, 15, 35, 32].

In [16], a different type of algorithm was given for covering LPs (indeed, more generally, for a class of concave covering inequalities) based on a *logarithmic* potential function. In this paper, we show that this approach can be extended to provide oracle-based algorithms for both versions of packing and covering SDPs:

► **Theorem 1.** *For any $\epsilon > 0$, there is a randomized algorithm that, for any given instance of (P-I)-(C-I), outputs an $O(n\mathcal{L} \log(n\tau) + \frac{n}{\epsilon^2})$ -sparse $O(\epsilon)$ -optimal primal-dual pair in time² $\tilde{O}(\frac{n^{\omega+1}\mathcal{L} \log \tau}{\epsilon^{2.5}} + \frac{n\mathcal{L}\mathcal{T} \log \tau}{\epsilon^2})$, where \mathcal{T} is the time taken by a single call to the oracle $\text{Max}(\cdot)$ and ω is the exponent of matrix multiplication.*

► **Theorem 2.** *For any $\epsilon > 0$, there is a randomized algorithm that, for any given instance of (P-II)-(C-II), outputs an $O(n\mathcal{L} \log n + \frac{n}{\epsilon^2})$ -sparse $O(\epsilon)$ -optimal primal-dual pair in time $\tilde{O}(\frac{n^{\omega+1}\mathcal{L} \log n}{\epsilon^{2.5}} + \frac{n\mathcal{L}\mathcal{T}}{\epsilon^2})$, where \mathcal{T} is the time taken by a single call to the oracle $\text{Min}(\cdot)$.*

As we can see from the table, among all the algorithms listed, the logarithmic-potential algorithm, presented in this paper, is the only one that produces sparse solutions, in the sense described above. Moreover, the only known other oracle-based algorithm (matrix Matrix MWU [7]) is *not* width-independent. It can also be shown (see [12]) that a modified version of the matrix exponential MWU algorithm [6] can yield sparse solutions for (P-II)-(C-II). However, the overall running time of this matrix MWU algorithm is larger by a factor of (roughly) $\Omega(n^{3-\omega})$ than that of the logarithmic-potential algorithm. Moreover, we were not able to extend the matrix MWU algorithm to solve (P-I)-(C-I) (in particular, it seems tricky to bound the number of iterations).

A work that is also related to ours is the sparsification of graph Laplacians [8] and positive semidefinite sums [33]. Given matrices $A_1, \dots, A_m \in \mathbb{S}_+^n$ and $\epsilon > 0$, it was shown in [33] that one can find, in $O(\frac{n}{\epsilon^2}(n^\omega + \mathcal{T}))$ time, a vector $y \in \mathbb{R}_+^m$ with support size $O(\frac{n}{\epsilon^2})$, such that $B \preceq \sum_i y_i A_i \preceq (1 + \epsilon)B$, where $B := \sum_i A_i$ and \mathcal{T} is the time taken by a single call to the minimization oracle $\text{Min}(Y)$ (for a not necessarily positive semidefinite matrix Y). An immediate corollary is that, given an ϵ -optimal solution y for (C-I) (resp., (P-I)), one can find in $O(\frac{n}{\epsilon^2}(n^\omega + \mathcal{T}))$ time an $O(\epsilon)$ -optimal solution y' with support size $O(\frac{n}{\epsilon^2})$. Interestingly, the algorithm in [33] (which is an extension for the rank-one version in [8]) uses the *barrier potential function* $\Phi'(x, F) := \text{Tr}((H - xI)^{-1})$ (resp., $\Phi'(x, H) := \text{Tr}((xI - H)^{-1})$), while in

¹ We provide rough estimates of the bounds, as some of them are not explicitly stated in the corresponding paper in terms of the parameters we consider here.

² $\tilde{O}(\cdot)$ hides polylogarithmic factors in n and $\frac{1}{\epsilon}$.

* In fact, these algorithms find sparse solutions, in the sense that the dependence of the size of the support of the dual solution on m is at most logarithmic; however, the dependence of the size of the support on the bit length \mathcal{L} is not polynomial.

our algorithms (generalizing the potential function in [16]) we use the logarithmic potential function $\Phi(x, H) = \ln x + \frac{\epsilon}{n} \ln \det(H - xI) = \ln x - \frac{\epsilon}{n} \int_x \Phi'(x, H) dx$ (resp., $\Phi(x, H) = \ln x - \frac{\epsilon}{n} \ln \det(xI - H) = \ln x - \frac{\epsilon}{n} \int_x \Phi'(x, H) dx$). Sparsification algorithms with better running times were recently obtained in [3, 24]. Since the sparse solutions produced by our algorithms may have support size slightly more (by polylogarithmic factors) than $O(\frac{n}{\epsilon^2})$, we may use, in a post-processing step, the sparsification algorithms, mentioned above, to convert the solutions obtained by Theorems 1 and 2 to ones with support size $O(\frac{n}{\epsilon^2})$, without increasing the overall asymptotic running time.

In Section 4, we give an outline of the algorithm and sketch the proof of Theorem 1; the proof of Theorem 2 is similar. To motivate our algorithms, in Section 3, we give two applications that require finding sparse solutions for a packing/covering SDP ³.

2 Reduction to Normalized Form

When $C = I = I_n$, the identity matrix in $\mathbb{R}^{n \times n}$ and $b = \mathbf{1}$, the vector of all ones in \mathbb{R}^m , we say that the packing-covering SDPs are in *normalized* form:

$$\begin{array}{l}
 z_i^* = \max \quad I \bullet X \quad \quad \quad \text{(N-P-I)} \\
 \text{s.t.} \quad A_i \bullet X \leq 1, \forall i \in [m] \\
 \quad \quad X \in \mathbb{R}^{n \times n}, X \succeq 0
 \end{array}
 \quad \left| \quad \quad \quad
 \begin{array}{l}
 z_i^* = \min \quad \mathbf{1}^T y \quad \quad \quad \text{(N-C-I)} \\
 \text{s.t.} \quad \sum_{i=1}^m y_i A_i \succeq I \\
 \quad \quad y \in \mathbb{R}^m, y \geq 0.
 \end{array}$$

³ As pointed out by an anonymous reviewer, solution-sparsity and oracle-access to the input can also be thought of as a way of reducing the *space requirement* of the algorithm, see [23].

$$\begin{array}{l}
z_{II}^* = \min \quad I \bullet X \quad (\text{N-C-II}) \\
\text{s.t.} \quad A_i \bullet X \geq 1, \forall i \in [m] \\
\quad X \in \mathbb{R}^{n \times n}, X \succeq 0
\end{array}
\left| \begin{array}{l}
z_{II}^* = \max \quad \mathbf{1}^T y \quad (\text{N-P-II}) \\
\text{s.t.} \quad \sum_{i=1}^m y_i A_i \preceq I \\
\quad y \in \mathbb{R}^m, y \geq 0.
\end{array} \right.$$

It can be shown⁴ that, at the loss of a factor of $(1 + \epsilon)$ in the objective, any pair of packing-covering SDPs of the form (P-I)-(C-I) can be brought in $O(n^3)$, increasing the oracle time only by $O(n^\omega)$, where ω is the exponent of matrix multiplication, to the normalized form (N-P-I)-(N-C-I), under the following assumption:

(B-I) There exist r matrices, say A_1, \dots, A_r , such that $\bar{A} := \sum_{i=1}^r A_i \succ 0$. In particular, $\text{Tr}(X) \leq \tau := \frac{r}{\lambda_{\min}(\bar{A})}$ for any optimal solution X for (P-I).

Similarly, one can show (see [12, 20]) that, at the loss of a factor of $(1 + \epsilon)$ in the objective, any pair of packing-covering SDPs of the form (P-II)-(C-II) can be brought in $O(n^3)$ time, increasing the oracle time only by $O(n^\omega)$, to the normalized form (N-P-II)-(N-C-II). Moreover, we may assume in this normalized form that

(B-II) $\lambda_{\min}(A_i) = \Omega\left(\frac{\epsilon}{n} \cdot \min_{i'} \lambda_{\max}(A_{i'})\right)$ for all $i \in [m]$,

where, for a positive semidefinite matrix $B \in \mathbb{S}_+^{n \times n}$, we denote by $\{\lambda_j(B) : j = 1, \dots, n\}$ the eigenvalues of B , and by $\lambda_{\min}(B)$ and $\lambda_{\max}(B)$ the minimum and maximum eigenvalues of B , respectively. With an additional $O(mn^2)$ time, we may also assume that:

(B-II') $\frac{\lambda_{\max}(A_i)}{\lambda_{\min}(A_i)} = O\left(\frac{n^2}{\epsilon^2}\right)$ for all $i \in [m]$.

Thus, from now on we focus on the normalized problems.

3 Applications

3.1 Robust Packing and Covering SDPs

Consider a packing-covering pair of the form (P-I)-(C-I) or (P-II)-(C-II). In the framework of *robust optimization* (see, e.g. [9, 10]), we assume that each constraint matrix A_i is not known exactly; instead, it is given by a convex uncertainty set $\mathcal{A}_i \subseteq \mathbb{S}_+^n$. It is required to find a (near)-optimal solution for the packing-covering pair under the *worst-case* choice $A_i \in \mathcal{A}_i$ of the constraints in each uncertainty set. A typical example of a *convex* uncertainty set is given by an *affine perturbation* around a nominal matrix $A_i^0 \in \mathbb{S}_+^n$:

$$\mathcal{A}_i = \left\{ A_i := A_i^0 + \sum_{r=1}^k \delta_r A_i^r : \delta = (\delta_1, \dots, \delta_k) \in \mathcal{D} \right\}, \quad (3)$$

where $A_i^1, \dots, A_i^k \in \mathbb{S}_+^n$, and $\mathcal{D} \subseteq \mathbb{R}_+^k$ can take, for example, one of the following forms:

- *Ellipsoidal uncertainty*: $\mathcal{D} = E(\delta_0, D) := \{\delta \in \mathbb{R}_+^k : (\delta - \delta_0)^T D^{-1} (\delta - \delta_0) \leq 1\}$, for given positive definite matrix $D \in \mathbb{S}_+^k$ and vector $\delta_0 \in \mathbb{R}_+^k$ such that $E(\delta_0, D) \subseteq \mathbb{R}_+^k$;
- *Polyhedral uncertainty*: $\mathcal{D} := \{\delta \in \mathbb{R}_+^k : D\delta \leq w\}$, for given matrix $D \in \mathbb{R}^{h \times k}$ and vector $w \in \mathbb{R}^h$.

⁴ In fact, unlike previously known reductions, the reduction we give in [12] is simpler to compute, as it is based on the *LDL-decompositions* rather than the *eigenvalue decompositions* of the input matrices.

Without loss of generality, we consider the robust version of (N-P-I)-(N-C-I), where A_i , for $i \in [m]$, belongs to a convex uncertainty set \mathcal{A}_i . Then the robust optimization problem and its dual can be written as follows:

$$\begin{array}{l|l}
 \begin{array}{l}
 z_P^* = \max \quad I \bullet X \\
 \text{s.t. } \quad A_i \bullet X \leq 1, \quad \forall A_i \in \mathcal{A}_i \quad \forall i \in [m] \\
 X \in \mathbb{R}^{n \times n}, \quad X \succeq 0
 \end{array} & \text{(R-P-I)} \\
 \hline
 \begin{array}{l}
 z_D^* = \inf \quad \sum_{i=1}^m \int_{\mathcal{A}_i} y_{A_i}^i dA_i \\
 \text{s.t. } \quad \sum_{i=1}^m \int_{\mathcal{A}_i} y_{A_i}^i A_i dA_i \succeq I \\
 y^i \text{ is a discrete measure on } \mathcal{A}_i, \quad \forall i \in [m].
 \end{array} & \text{(R-C-I)}
 \end{array}$$

As before, we assume (B-I), where $A_1, \dots, A_r \in \bigcup_{i \in [m]} \mathcal{A}_i$. We call a pair of solutions (X, y) to be ϵ -optimal for (R-P-I)-(R-C-I), if

$$z_P^* \geq I \bullet X \geq (1 - \epsilon) \sum_{i=1}^m \int_{\mathcal{A}_i} y_{A_i}^i dA_i \geq (1 - \epsilon) z_D^*.$$

Note that the number of constraints in (R-P-I) is *infinite* and hence any algorithm that solves the problem would have to be oracle-based. The Ellipsoid method is one such algorithm; a more efficient procedure is given by the following corollary of Theorem 1.

► **Theorem 3.** *For any $\epsilon > 0$, there is a randomized algorithm that outputs an $O(\epsilon)$ -optimal primal-dual pair for (R-P-I)-(R-C-I) in time $\tilde{O}\left(\frac{n^{\omega+1} \log \psi}{\epsilon^{2.5}} + \frac{nT \log \psi}{\epsilon^2}\right)$, where $\psi := \frac{r \cdot \max_{i \in [m], A_i \in \mathcal{A}_i} \lambda_{\max}(A_i)}{\lambda_{\min}(A)}$ and \mathcal{T} is the time to compute, for a given $Y \in \mathbb{S}_+^n$, a pair (i, A_i) such that*

$$(i, A_i) \in \operatorname{argmax}_{i \in [m], A_i \in \mathcal{A}_i} A_i \bullet Y. \quad (4)$$

Note that (4) amounts to solving a linear optimization problem over a convex set. Moreover, for simple uncertainty sets, such as boxes or ellipsoids, such computation can be done very efficiently.

3.2 Carr-Vempala-Type Decomposition

Consider a maximization (resp., minimization) problem over a discrete set $\mathcal{S} \subseteq \mathbb{Z}^n$ and a corresponding SDP-relaxation over $\mathcal{Q} \subseteq \mathbb{S}_+^n$:

$$\begin{array}{l|l}
 \begin{array}{l}
 z_{CO}^* = \left\{ \begin{array}{l} \max \\ \min \end{array} \right\} \quad C \bullet qq^T \\
 q \in \mathcal{S}
 \end{array} & \text{(DOP)} \\
 \hline
 \begin{array}{l}
 z_{SDP}^* = \left\{ \begin{array}{l} \max \\ \min \end{array} \right\} \quad C \bullet Q \\
 Q \in \mathcal{Q},
 \end{array} & \text{(SDP-RLX)}
 \end{array}$$

where $C \in \mathbb{S}_+^n$.

► **Definition 4.** *For $\alpha \in (0, 1]$ (resp., $\alpha \geq 1$), an α -integrality gap verifier \mathcal{A} for (SDP-RLX) is a polytime algorithm that, given any $C \in \mathbb{S}_+^n$ and any $Q \in \mathcal{Q}$ returns a $q \in \mathcal{S}$ such that $C \bullet qq^T \geq \alpha C \bullet Q$ (resp., $C \bullet qq^T \leq \alpha C \bullet Q$).*

For instance, if $\mathcal{S} = \{-1, 1\}^n$ and $\mathcal{Q} = \{X \in \mathbb{S}_+^n : X_{ii} = 1 \quad \forall i \in [n]\}$, then a $\frac{2}{\pi}$ -integrality gap verifier for the maximization version of (SDP-RLX) is known [26].

Carr and Vempala [11] gave a decomposition theorem that allows one to use an α -integrality gap verifier for a given LP-relaxation of a combinatorial maximization (resp., minimization) problem, to decompose a given fractional solution to the LP into a convex combination of integer solutions that is dominated by (resp., dominates) α times the fractional solution. Here we derive a similar result for SDP relaxations:

► **Theorem 5.** *Consider a combinatorial maximization (resp., minimization) problem (DOP) and its SDP relaxation (SDP-RLX), admitting an α -integrality gap verifier \mathcal{A} . Assume the set \mathcal{S} is full-dimensional and let $\epsilon > 0$ be a given constant. Then there is a polytime algorithm that, for any given $Q \in \mathcal{Q}$, finds a set $\mathcal{X} \subseteq \mathcal{S}$ of size $|\mathcal{X}| = O(\frac{n^3}{\epsilon^2} \log(nW))$ (resp., of size $|\mathcal{X}| = O(n \log \frac{n}{\epsilon} + \frac{n}{\epsilon^2})$), where $W := \max_{q \in \mathcal{S}, i \in [n]} |q_i|$, and a set of convex multipliers $\{\lambda_q \in \mathbb{R}_+ : q \in \mathcal{X}\}$, $\sum_{q \in \mathcal{X}} \lambda_q = 1$, such that*

$$(1 - O(\epsilon))\alpha Q \preceq \sum_{q \in \mathcal{X}} \lambda_q qq^T \quad (\text{resp.}, (1 + O(\epsilon))\alpha Q \succeq \sum_{q \in \mathcal{X}} \lambda_q qq^T). \quad (5)$$

The proof of Theorem 5 is obtained by considering the following pairs of packing and covering SDPs (of types I and II, respectively):

$z_I^* = \min \sum_{q \in \mathcal{S}} \lambda_q \quad (\text{CVX-I})$ <p>s.t. $\sum_{q \in \mathcal{S}} \lambda_q qq^T \succeq \alpha Q \quad (6)$</p> $\sum_{q \in \mathcal{S}} \lambda_q \geq 1 \quad (7)$ $\lambda \in \mathbb{R}^{\mathcal{S}}, \lambda \geq 0$		$z_I^* = \max \alpha Q \bullet Y + u \quad (\text{CVX-dual-I})$ <p>s.t. $qq^T \bullet Y + u \leq 1, \forall q \in \mathcal{S} \quad (8)$</p> $Y \in \mathbb{S}_+^n, u \geq 0.$
$z_{II}^* = \max \sum_{q \in \mathcal{S}} \lambda_q \quad (\text{CVX-II})$ <p>s.t. $\sum_{q \in \mathcal{S}} \lambda_q qq^T \preceq \alpha Q \quad (9)$</p> $\sum_{q \in \mathcal{S}} \lambda_q \leq 1 \quad (10)$ $\lambda \in \mathbb{R}^{\mathcal{S}}, \lambda \geq 0$		$z_{II}^* = \min \alpha Q \bullet Y + u \quad (\text{CVX-dual-II})$ <p>s.t. $qq^T \bullet Y + u \geq 1, \forall q \in \mathcal{S} \quad (11)$</p> $Y \in \mathbb{S}_+^n, u \geq 0.$

It can be shown, using the fact that the SDP relaxation admits an α -integrality gap verifier, that $z_I^* = z_{II}^* = 1$, and that the two primal-dual pairs can be solved in polynomial time using the Ellipsoid method. A more efficient (but approximate version) can be obtained using the algorithms of Theorems 1 and 2. Note that, once we have a set \mathcal{X} as in Theorem 5, its support can be reduced to $O(\frac{n^2}{\epsilon})$ using the sparsification techniques of [8, 33].

4 A Logarithmic Potential Algorithm for (P-I)-(C-I)

In this section we give an algorithm for finding a sparse $O(\epsilon)$ -optimal primal-dual solution for (N-P-I)-(N-C-I). Since the algorithm updates only one component of the dual solution in each iteration, it follows that the number of positive components of the dual solution when the algorithm terminates is exactly equal to the number of iterations; from this sparsity follows.

4.1 High-level Idea of the Algorithm

The idea of the algorithm is quite intuitive. It can be easily seen that problem (N-C-I) is equivalent to finding a convex combination of the A_i 's that maximizes the minimum eigenvalue, that is, $\max_{y \in \mathbb{R}_+^m: \mathbf{1}^T y = 1} \lambda_{\min}(F(y))$, where $F(y) := \sum_{i=1}^m y_i A_i$, and $\mathbf{1}$ is the m -dimensional vector of all ones. Since $\lambda_{\min}(F(y))$ is not a *smooth* function in y , it is more convenient to work with a smooth approximation of it, which is obtained by maximizing (over x) a *logarithmic potential function* $\Phi(x, F(y))$ that captures the constraints that each eigenvalue of $F(y)$ is at least x . The unique maximizer $x = \theta^*$ of $\Phi(x, F(y))$ defines a set of “weights” (these are the eigenvalues of the primal matrix X computed in line 6 of the algorithm) such that the weighted average of the $\lambda_j(F(y))$'s is a very close approximation of $\lambda_{\min}(F(y))$. Thus, to maximize this average (which is exactly $X \bullet F(y)$), we obtain a direction (line 7) along which y is modified with an appropriate step size (line 10). For numbers $x \in \mathbb{R}_+$ and $\delta \in (0, 1)$, a δ -(lower) approximation x_δ of x is a number such that $(1 - \delta)x \leq x_\delta < x$. For $i \in [m]$, $\mathbf{1}_i$ denotes the i th unit vector of dimension m .

The algorithm is shown as Algorithm 1. The main while-loop (step 4) is embedded within a sequence of scaling phases, in which each phase starts from the vector $y(t)$ computed in the previous phase and uses double the accuracy. The algorithm stops when the scaled accuracy ε_s drops below the desired accuracy $\epsilon \in (0, 1/2)$. When referring to an arbitrary iteration of the algorithm, we assume it is iteration t in phase s .

4.2 Analysis

4.2.1 High-level Idea of the Analysis

The analysis is based on a matrix generalization of the scalar arguments given in [16] (as is the case for all algorithms for SDP's, which are driven from their LP counterparts; see, e.g., [1]). Besides the technical details, the algorithm also requires estimating the minimum eigenvalue of the dual matrix $F(y(t))$, which is done using Lanczos' algorithm (see Section 4.2.4 for details).

The proof of ϵ -optimality follows easily from the stopping condition in line 4 of the algorithm, the definition of the “approximation error” ν in line 8, and the fact that $X \bullet F(y)$ is a very close approximation of $\lambda_{\min}(F(y(t)))$. The main part of the proof is to bound the number of iterations in the inner while-loop (line 4). This is done by using a *potential function argument*: we define the potential function $\Phi(t) := \Phi(\theta^*(t), F(y(t)))$ and show in Claim 23 that, in each iteration, the choice of the step size in line 9 guarantees that $\Phi(t)$ is increased substantially; on the other hand, by Claim 24, the potential difference cannot be very large, and the two claims together imply that we cannot have many iterations.

4.2.2 Some Preliminaries

Up to Claim 26, we fix a particular iteration s of the outer while-loop in the algorithm. For simplicity in the following, we will sometimes write $F := F(y(t))$, $\theta := \theta(t)$, $\theta^* := \theta^*(t)$, $X := X(t)$, $\hat{F} := A_{i(t)}$, $\tau := \tau(t + 1)$, $\nu := \nu(t + 1)$, $F' := F(y(t + 1))$, and $\theta' := \theta(t + 1)$, when the meaning is clear from the context. For $H \succ 0$ and $x \in (0, \lambda_{\min}(H))$, define the logarithmic potential function [16, 29]:

$$\Phi(x, H) = \ln x + \frac{\varepsilon_s}{n} \ln \det (H - xI). \quad (12)$$

Note that the term $\ln \det (H - xI)$ forces the value of x to stay away from the “boundary” $\lambda_{\min}(H)$, while the term $\ln x$ pushes x towards that boundary; hence, one would expect the maximizer of $\Phi(x, H)$ to be a good approximation of $\lambda_{\min}(H)$ (see Claim 8).

■ **Algorithm 1** Logarithmic-potential Algorithm for (P-I)-(C-I).

```

1  $s \leftarrow 0$ ;  $\varepsilon_0 \leftarrow \frac{1}{2}$ ;  $t \leftarrow 0$ ;  $\nu(0) \leftarrow 1$ ;  $y(0) \leftarrow \frac{1}{r} \sum_{i=1}^r \mathbf{1}_i$ 
2 while  $\varepsilon_s > \epsilon$  do
3    $\delta_s \leftarrow \frac{\varepsilon_s^3}{32n}$ 
4   while  $\nu(t) > \varepsilon_s$  do
5      $\theta(t) \leftarrow \theta^*(t)_{\delta_s}$ , where  $\theta^*(t)$  is the smallest positive number root of the
       equation  $\frac{\varepsilon_s \theta}{n} \text{Tr}(F(y(t)) - \theta I)^{-1} = 1$ 
6      $X(t) \leftarrow \frac{\varepsilon_s \theta(t)}{n} (F(y(t)) - \theta(t)I)^{-1}$  /* Set the primal solution */
7      $i(t) \leftarrow \text{argmax}_i A_i \bullet X(t)$  /* Call the maximization oracle */
8      $\nu(t+1) \leftarrow \frac{X(t) \bullet A_{i(t)} - X(t) \bullet F(y(t))}{X(t) \bullet A_{i(t)} + X(t) \bullet F(y(t))}$  /* Compute the error */
9      $\tau(t+1) \leftarrow \frac{\varepsilon_s \theta(t) \nu(t+1)}{4n(X(t) \bullet A_{i(t)} + X(t) \bullet F(y(t)))}$  /* Compute the step size */
10     $y(t+1) \leftarrow (1 - \tau(t+1))y(t) + \tau(t+1)\mathbf{1}_{i(t)}$  /* Update the dual solution */
11     $t \leftarrow t + 1$ 
12  end
13   $\varepsilon_{s+1} \leftarrow \frac{\varepsilon_s}{2}$ 
14   $s \leftarrow s + 1$ 
15 end
16  $\hat{X} \leftarrow \frac{(1-\varepsilon_{s-1})X(t-1)}{(1+\varepsilon_{s-1})^2\theta(t-1)}$ ;  $\hat{y} \leftarrow \frac{y(t-1)}{\theta(t-1)}$  /* Scale primal and dual to retain feasibility */
17 return  $(\hat{X}, \hat{y}, t)$ 

```

▷ **Claim 6.** If $F(y(t)) \succ 0$, then $\theta^*(t) = \text{argmax}_{0 < x < \lambda_{\min}(F)} \Phi(x, F(y(t)))$ and $X(t) \succ 0$.

For $x \in (0, \lambda_{\min}(F))$, let $g(x) := \frac{\varepsilon_s x}{n} \text{Tr}(F - xI)^{-1}$. The following claim shows that our choice of δ_s guarantees that $g(\theta)$ is a good approximation of $g(\theta^*) = 1$.

▷ **Claim 7.** $g(\theta(t)) \in (1 - \varepsilon_s, 1)$.

The following two claims show that $\theta(t) \approx X(t) \bullet F(y(t))$ provides a good approximation for $\lambda_{\min}(F(y(t)))$.

▷ **Claim 8.** $(1 - \varepsilon_s)\lambda_{\min}(F(y(t))) < \theta(t) < \frac{\lambda_{\min}(F(y(t)))}{1 + \varepsilon_s/n}$ and $\frac{\lambda_{\min}(F(y(t)))}{1 + \varepsilon_s} \leq \theta^*(t) \leq \frac{\lambda_{\min}(F(y(t)))}{1 + \varepsilon_s/n}$.

▷ **Claim 9.** $\theta(t) < X(t) \bullet F(y(t)) < (1 + \varepsilon_s)\theta(t)$.

Throughout the algorithm, we maintain the invariants that the (non-scaled) dual objective $\mathbf{1}^T y(t)$ is exactly 1, that the step size $\tau(t)$ and the approximation error $\nu(t)$ are between 0 and 1, and that the dual matrix $F(y(t)) = \sum_i y_i(t)A_i$ is positive definite. This is summarized in the following claims.

▷ **Claim 10.** $\mathbf{1}^T y(t) = 1$.

▷ **Claim 11.** For all iterations t , except possibly the last, $\nu(t+1), \tau(t+1) \in (0, 1)$.

▷ **Claim 12.** $F(y(t)) \succ 0$.

4.2.3 Primal Dual Feasibility and Approximate Optimality

Let $t_f + 1$ be the value of t when the algorithm terminates and $s_f + 1$ be the value of s at termination. For simplicity, we write $s = s_f$.

▷ **Claim 13.** (Primal feasibility). $\hat{X} \succ 0$ and $\max_i A_i \bullet \hat{X} \leq 1$.

Proof. The first claim is immediate from Claim 6. To see the second claim, we use the definition of $\nu(t_f)$ and the termination condition in line 4 (which is also satisfied even if $X(t_f) \bullet A_{i(t_f)} - X(t_f) \bullet F(y(t_f)) = 0$):

$$\begin{aligned} \frac{X(t_f) \bullet A_{i(t_f)} - X(t_f) \bullet F(y(t_f))}{X(t_1) \bullet A_{i(t_f)} + X(t_f) \bullet F(y(t_f))} &\leq \varepsilon_s. \\ \therefore (1 + \varepsilon_s)X(t_f) \bullet F(y(t_f)) &\geq (1 - \varepsilon_s)X(t_f) \bullet A_{i(t_f)} \\ &= (1 - \varepsilon_s) \max_i X(t_f) \bullet A_i \\ &\hspace{15em} \text{(by the definition of } i(t_f)) \\ \therefore (1 + \varepsilon_s)^2 \theta(t_f) &\geq (1 - \varepsilon_s) \max_i X(t_f) \bullet A_i. \\ &\hspace{10em} (\because X(t_f) \bullet F(y(t_f)) \leq (1 + \varepsilon_s)\theta(t_f) \text{ by Claim 9}) \end{aligned}$$

The claim follows by the definition of \hat{X} in step 16 of the algorithm. ◁

▷ **Claim 14.** (Dual feasibility). $\hat{y} \geq 0$ and $F(\hat{y}) \succ I$.

Proof. The fact that $\hat{y} \geq 0$ follows from the initialization of $y(0)$ in step 1, Claim 11, and the update of $y(t + 1)$ in step 10. For the other claim, we have

$$\lambda_{\min}(F(\hat{y})) = \frac{1}{\theta(t_f)} \lambda_{\min}(F(y(t_f))) \geq 1 + \frac{\varepsilon_s}{n}. \quad \text{(by Claim 8)}$$

◁

▷ **Claim 15.** (Approximate optimality). $I \bullet \hat{X} \geq \left(\frac{1 - \varepsilon_s}{1 + \varepsilon_s}\right)^2 \mathbf{1}^T \hat{y}$.

Proof. By Claim 7, we have $\text{Tr}(X(t_f)) \geq 1 - \varepsilon_s$, and by Claim 10, we have $\mathbf{1}^T y(t_f) = 1$. The claim follows by the definition of \hat{X} and \hat{y} in step 16. ◁

4.2.4 Running Time per Iteration

Given $F := F(y(t)) \succ 0$, we first compute an approximation $\tilde{\lambda}$ of $\lambda_{\min}(F)$ using Lanczos' algorithm with a random start [25].

► **Lemma 16** ([25]). *Let $M \in \mathbb{S}_+^n$ be a positive semidefinite matrix with N non-zeros and $\gamma \in (0, 1)$ be a given constant. Then there is a randomized algorithm that computes, with high (i.e., $1 - o(1)$) probability a unit vector $v \in \mathbb{R}^n$ such that $v^T M v \geq (1 - \gamma)\lambda_{\max}(M)$. The algorithm takes $O\left(\frac{\log n}{\sqrt{\gamma}}\right)$ iterations, each requiring $O(N)$ arithmetic operations.*

By Claim 8, we need $\tilde{\lambda}$ to lie in the range $\left[\frac{\lambda_{\min}(F)}{1 + \varepsilon_s/n}, \lambda_{\min}(F)\right]$. To obtain $\tilde{\lambda}$, we may apply the above lemma with $M := F^{-1}$ and $\gamma := \frac{\varepsilon_s}{2n}$. Then in $O\left(\sqrt{\frac{n}{\varepsilon_s}} \log n\right)$ iterations we get $\tilde{\lambda} := \frac{1 - \gamma}{v^T F^{-1} v}$ satisfying our requirement. However, we can save (roughly) a factor of \sqrt{n} in

the running time by using, instead, $M := F^{-n}$ and $\gamma := \frac{\varepsilon_s}{2}$. Let v be the vector obtained from Lemma 16, and set $\tilde{\lambda} := \left(\frac{1-\gamma}{v^T F^{-n} v}\right)^{1/n}$. Then, as $\lambda_{\max}(M) \geq v^T M v \geq (1-\gamma)\lambda_{\max}(M)$, and $\lambda_{\min}(F) = \lambda_{\max}(F^{-n})^{-1/n}$, we get

$$\frac{\lambda_{\min}(F)}{1 + \varepsilon_s/n} \leq (1-\gamma)^{1/n} \lambda_{\min}(F) \leq \tilde{\lambda} \leq \lambda_{\min}(F). \quad (13)$$

Note that we can compute F^{-n} in $O(n^\omega \log n)$, where w is the *exponent of matrix multiplication*. Thus, the overall running time for computing $\tilde{\lambda}$ is $O(n^\omega \log n + \frac{n^2 \log n}{\sqrt{\varepsilon_s}})$.

Given $\tilde{\lambda}$, we know by Claim 8 and (13) that $\theta^*(t) \in [\frac{\tilde{\lambda}}{1+\varepsilon_s}, \tilde{\lambda}]$. Then we can apply binary search to find $\theta(t) := \theta^*(t)_{\delta_s}$ as follows. Let $\theta_k = \frac{\tilde{\lambda}}{1+\varepsilon_s}(1+\delta_s)^k$, for $k = 0, 1, \dots, K := \lceil \frac{2 \ln(1+\varepsilon_s)}{\delta_s} \rceil$, and note that $\theta_L \geq \tilde{\lambda}$. Then we do binary search on the exponent $k \in \{0, 1, \dots, K\}$; each step of the search evaluates $g(\theta_k) := \frac{\varepsilon_s \theta_k}{n} \text{Tr}(F - \theta_k I)^{-1}$, and depending on whether this value is less than or at least 1, the value of k is increased or decreased, respectively. The search stops when the search interval $[\ell, u]$ has $u \leq \ell + 1$, in which case we set $\theta(t) = \theta_\ell$; the number of steps until this happens is $O(\log K) = O(\log \frac{1}{\delta_s}) = O(\log \frac{1}{\varepsilon_s})$. By the monotonicity of $g(x)$ (in the interval $[0, \lambda_{\min}(F)]$), and the property of binary search, we know that $\theta^* \in [\theta_\ell, \theta_u]$. Thus, by the stopping criterion,

$$\theta(t) = \theta_\ell \leq \theta^*(t) \leq \theta_u \leq \theta_{\ell+1} = (1 + \delta_s)\theta_\ell,$$

implying that $(1 - \delta_s)\theta^*(t) \leq \theta(t) \leq \theta^*(t)$. Since evaluating $g(\theta_\ell)$ takes $O(n^\omega)$, the overall running time for the binary search procedure is $O(n^\omega \log \frac{n}{\varepsilon_s})$, and hence the total time needed for computing $\theta(t)$ is $O(n^\omega \log \frac{n}{\varepsilon} + \frac{n^2 \log n}{\sqrt{\varepsilon}})$.

All other steps of the algorithm inside the inner while-loop can be done in $O(\mathcal{T} + n^2)$ time, where \mathcal{T} is the time taken by a single call to the oracle $\text{Max}(X(t))$ in step 7 of the algorithm. Thus, in view of Claim 26 on the number of iterations below, we obtain Theorem 1.

4.2.5 Number of Iterations

Define $B = B(t) := \frac{n}{\varepsilon_s \theta} \left(\tau X^{1/2} (\hat{F} - F) X^{1/2} - (\theta^* - \theta) X \right)$. The following (technical) claims are needed for the proofs of Claims 23 and 24 below (which are, in turn, the main claims needed for the analysis of the potential function). They can be skipped at a first reading and recalled when needed.

▷ Claim 17. $(F - \theta^* I)^{-1} = \left(\frac{\varepsilon_s \theta}{n} I - (\theta^* - \theta) X \right)^{-1} X$.

▷ Claim 18. $F' - \theta^* I = (F - \theta I)^{1/2} (I + B) (F - \theta I)^{1/2}$.

▷ Claim 19. $\max_j |\lambda_j(B)| \leq \frac{1}{2}$.

▷ Claim 20. $\theta^*(t) < \lambda_{\min}(F(y(t+1)))$.

▷ Claim 21. if $\nu > \varepsilon_s$, then $\text{Tr}(B) \geq \frac{\nu^2}{8}$.

▷ Claim 22. If $\nu > \varepsilon_s$, then $\text{Tr}(B^2) < \frac{\nu^2}{10}$.

Define the potential function $\Phi(t) := \Phi(\theta^*(t), F(y(t)))$.

The following claim states that the potential difference between two consecutive iterations of the algorithm is sufficiently large.

43:12 Oracle-Based Algorithms for Packing and Covering SDPs

▷ Claim 23. For $t, t+1$ in phase s , $\Phi(t+1) - \Phi(t) \geq \frac{\varepsilon_s \nu(t+1)^2}{40n}$.

Proof. Note that Claim 20 implies that θ^* is feasible to the problem $\max\{\Phi(\xi, F') : 0 \leq \xi \leq \lambda_{\min}(F')\}$. Thus,

$$\begin{aligned}
\Phi(t+1) &= \Phi(\theta^*(t+1), F') \geq \ln \theta^* + \frac{\varepsilon_s}{n} \ln \det(F' - \theta^* I). \\
\therefore \Phi(t+1) - \Phi(t) &\geq \frac{\varepsilon_s}{n} (\ln \det(F' - \theta^* I) - \ln \det(F - \theta^* I)) \\
&\geq \frac{\varepsilon_s}{n} (\ln \det(F' - \theta^* I) - \ln \det(F - \theta I)) && (\because \theta \leq \theta^*) \\
&= \frac{\varepsilon_s}{n} \ln \det(I + B) && (\text{by Claim 18}) \\
&= \frac{\varepsilon_s}{n} \sum_{j=1}^n \ln(1 + \lambda_j(B)) \\
&\geq \frac{\varepsilon_s}{n} \sum_{j=1}^n (\lambda_j(B) - \lambda_j(B)^2) \\
&&& (\text{by Claim 19 and } \ln(1+z) \geq z - z^2, \forall z \geq -0.5) \\
&= \frac{\varepsilon_s}{n} (\text{Tr}(B) - \text{Tr}(B^2)) \\
&> \frac{\varepsilon_s}{8n} \nu^2 - \frac{\varepsilon_s}{10n} \nu^2 && (\text{by Claims 21 and 22}) \\
&= \frac{\varepsilon_s}{40n} \nu^2.
\end{aligned}$$

◁

On the other hand, the following claim states that the overall potential difference between any iterations cannot be too large.

▷ Claim 24. For any t, t' in phase s ,

$$\Phi(t') - \Phi(t) \leq (1 + \varepsilon_s) \ln \frac{X(t) \bullet A_{i(t)}}{(1 - \varepsilon_s) X(t) \bullet F(y(t))}.$$

Proof. Write $F = F(y(t))$, $\theta^* := \theta^*(t)$, $\theta := \theta(t)$, $X := X(t)$, $F' = F(y(t'))$, $\theta'^* := \theta^*(t')$. Then

$$\begin{aligned}
\Phi(t') - \Phi(t) &= \ln \frac{\theta'^*}{\theta^*} + \frac{\varepsilon_s}{n} \ln \det [(F - \theta^* I)^{-1} (F' - \theta'^* I)] \\
&= \ln \frac{\theta'^*}{\theta^*} + \frac{\varepsilon_s}{n} \ln \det \left[\left(\frac{\varepsilon_s \theta}{n} I - (\theta^* - \theta) X \right)^{-1} X (F' - \theta'^* I) \right] && (\text{by Claim 17}) \\
&= \ln \frac{\theta'^*}{\theta^*} + \frac{\varepsilon_s}{n} \left[\ln \det \left(\frac{\varepsilon_s \theta}{n} I - (\theta^* - \theta) X \right)^{-1} + \ln \det [X (F' - \theta'^* I)] \right] \\
&\leq \ln \frac{\theta'^*}{\theta^*} + \frac{\varepsilon_s}{n} \left[\ln \left(\frac{\varepsilon_s \theta}{n} - \frac{\delta_s \theta}{1 - \delta_s} \right)^{-n} + \ln \det [X (F' - \theta'^* I)] \right] \\
&&& (\because \text{Tr}(X) \leq 1 \text{ by Claim 7 and } (1 - \delta_s)\theta^* \leq \theta)
\end{aligned}$$

$$\begin{aligned}
&\leq \ln \frac{\theta'^*}{\theta^*} + \frac{\varepsilon_s}{n} \left[\ln \left(\frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} \right)^n + \ln \det X(F' - \theta'^* I) \right] \\
&\hspace{15em} \text{(by definition of } \delta_s \text{)} \\
&= \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} + \frac{\varepsilon_s}{n} \ln [\det X(F' - \theta'^* I)] \\
&= \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} + \frac{\varepsilon_s}{n} \sum_{j=1}^n \ln \lambda_j(X(F' - \theta'^* I)) \\
&\leq \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln \left(\frac{1}{n} \sum_{j=1}^n \lambda_j(X(F' - \theta'^* I)) \right) \\
&\hspace{15em} \text{(by the concavity of } \ln(\cdot) \text{)} \\
&= \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln \left(\frac{1}{n} \text{Tr}(X(F' - \theta'^* I)) \right) \\
&\leq \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{n}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln \left(\frac{X \bullet F' - \theta'^*(1-\varepsilon_s)}{n} \right) \\
&\hspace{15em} (\because \text{Tr}(X) \geq 1 - \varepsilon_s \text{ by Claim 7)} \\
&= \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{1}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln (X \bullet F' - \theta'^*(1-\varepsilon_s)) \\
&\leq \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{1}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln \left(\max_{y \in \mathbb{R}_+^n: \mathbf{1}^T y = 1} X \bullet F(y) - \theta'^*(1-\varepsilon_s) \right) \\
&\hspace{15em} (\because \mathbf{1}^T y(t') = 1 \text{ by Claim 10)} \\
&= \ln \frac{\theta'^*}{\theta^*} + \varepsilon_s \ln \frac{1}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln (X \bullet A_{i(t)} - \theta'^*(1-\varepsilon_s)) \\
&\hspace{15em} \text{(by definition of } i(t) \text{)} \\
&\leq \max_{0 \leq \xi < X \bullet A_{i(t)}} \left\{ \ln \frac{\xi}{(1-\varepsilon_s)\theta^*} + \varepsilon_s \ln \frac{1}{(1-\varepsilon_s)\varepsilon_s\theta} + \varepsilon_s \ln (X \bullet A_{i(t)} - \xi) \right\} \\
&= (1 + \varepsilon_s) \ln \frac{X \bullet A_{i(t)}}{(1-\varepsilon_s^2)\theta} + \ln \frac{\theta}{\theta^*} \hspace{5em} (\max(\cdot) \text{ is achieved at } \xi = \frac{X \bullet A_{i(t)}}{1+\varepsilon_s}) \\
&\leq (1 + \varepsilon_s) \ln \frac{X \bullet A_{i(t)}}{(1-\varepsilon_s^2)\theta} \hspace{10em} (\because \theta \leq \theta^*) \\
&\leq (1 + \varepsilon_s) \ln \frac{X \bullet A_{i(t)}}{(1-\varepsilon_s)X \bullet F}. \hspace{10em} \text{(by Claim 9)}
\end{aligned}$$

◁

Recall by assumption (B-I) that $\bar{A} := \sum_{i=1}^r A_i \succ 0$.

▷ **Claim 25.** $\frac{X(0) \bullet A_{i(0)}}{X(0) \bullet F(y(0))} \leq \psi := \frac{r \cdot \lambda_{\max}(A_{i(0)})}{\lambda_{\min}(\bar{A})} \leq \frac{r \cdot \max_i \lambda_{\max}(A_i)}{\lambda_{\min}(\bar{A})} \leq n\tau 2\mathcal{L}$.

Proof. Let $X(0) = \sum_{j=1}^n \lambda_j u_j u_j^T$ be the spectral decomposition of $X(0)$. Then,

$$\begin{aligned}
X(0) \bullet A_{i(0)} &= \sum_{j=1}^n \lambda_j A_{i(0)} \bullet u_j u_j^T \leq \sum_{j=1}^n \lambda_j \lambda_{\max}(A_{i(0)}) = \lambda_{\max}(A_{i(0)}) \cdot \text{Tr}(X(0)) \\
X(0) \bullet F(y(0)) &= \sum_{j=1}^n \lambda_j F(y(0)) \bullet u_j u_j^T \geq \frac{1}{r} \sum_{j=1}^n \lambda_j \lambda_{\min}(\bar{A}) = \frac{1}{r} \lambda_{\min}(\bar{A}) \cdot \text{Tr}(X(0)).
\end{aligned}$$

The claim follows. ◁

Now we combine claims 23, 24 and 25 to obtain a bound on the number of iterations.

▷ Claim 26. The algorithm terminates in at most $O(n \log \psi + \frac{n}{\epsilon^2})$ iterations.

► Remark 27. If we do not insist on a sparse dual solution, then we can use the initialization $y(0) \leftarrow \frac{1}{m} \mathbf{1}$ in step 1 in Algorithm 1, and replace ψ in Claim 25, and hence in the running time in Claim 26, by m .

Abstract

The *disjoint set cover (DSC)* problem is a fundamental combinatorial optimization problem concerned with partitioning the (hyper)edges of a hypergraph into (pairwise disjoint) clusters so that the number of clusters that cover all nodes is maximized. In its *online* version, the edges arrive one-by-one and should be assigned to clusters in an irrevocable fashion without knowing the future edges. This paper investigates the *competitiveness* of online DSC algorithms. Specifically, we develop the first (randomized) online DSC algorithm that guarantees a poly-logarithmic ($O(\log^2 n)$) competitive ratio without prior knowledge of the hypergraph's minimum degree. On the negative side, we prove that the competitive ratio of any randomized online DSC algorithm must be at least $\Omega(\frac{\log n}{\log \log n})$ (even if the online algorithm does know the minimum degree in advance), thus establishing the first lower bound on the competitive ratio of randomized online DSC algorithms.

1 Introduction

1.1 Model and Problem Statement

A *hypergraph* $G = (V, E)$ consists of a set V of *nodes* and a multiset E of *hyperedges* (or simply *edges*), where each edge is a non-empty subset of V .¹ Unless stated otherwise, we denote $n = |V|$ and $m = |E|$.

The input to the *disjoint set cover (DSC)* problem is a hypergraph $G = (V, E)$ and the output is a *color* assignment $C : E \rightarrow \mathbb{Z}_{>0}$ to the edges in E . The objective is to maximize the number of colors $c \in \mathbb{Z}_{>0}$ that *cover* V , where color c is said to cover V (a.k.a. a *covering* color) if the union over all edges $e \in E$ with color $C(e) = c$ equals V . (The DSC problem

¹ The problem we address in this paper is often defined in terms of the equivalent *set system* terminology, where the nodes in V are identified with the elements of some abstract universe and the edges in E are simply referred to as sets or subsets.

should not be confused with the classic hypergraph *edge coloring* problem that also involves assigning colors to the edges. In particular, in the DSC context, it is not required that edges with the same color are disjoint.)

In the *online DSC* problem, the nodes in V are known in advance while the edges in E , assumed hereafter to be totally ordered with edges indexed as $E = \{e_1, \dots, e_m\}$, arrive sequentially in an online fashion so that edge e_t , $1 \leq t \leq m$, arrives at time t . An online DSC algorithm should decide on the color $C(e_t)$ at (or immediately after) time t , without knowing the future edges e_{t+1}, \dots, e_m , and this decision is irrevocable.

Let $\text{Alg}(G)$ be the number of covering colors obtained by (online or offline) DSC algorithm Alg when invoked on hypergraph G . Following the common practice in the realm of online computation (cf. [4]), we measure the quality of online DSC algorithms by means of *competitive analysis*. A deterministic online DSC algorithm Alg is α -*competitive* if for every n , there exists some $\beta = \beta(n) \geq 0$ such that for every n -node hypergraph G , it holds that

$$\text{Alg}(G) \geq \frac{\text{Opt}(G)}{\alpha} - \beta, \quad (1)$$

where Opt is an optimal offline algorithm. A randomized online DSC algorithm Alg is α -*competitive in expectation* if the bound in (1) holds in expectation; if this bound also holds with high probability (abbreviated *whp*), then Alg is said to be α -*competitive whp*.² We emphasize that these probabilistic statements should hold with respect to the coin tosses of Alg , making no assumptions on the input edge sequence. Notice that since DSC is a maximization problem, it follows that if Alg is α -competitive whp, then it is $O(\alpha)$ -competitive in expectation. We refer to α as the online algorithm's *competitive ratio* and say that this competitive ratio is *pure* if the bound in (1) holds with $\beta = 0$ and *impure* otherwise.

By definition, the *minimum degree* $\delta = \min_{v \in V} |\{e \in E : v \in e\}|$ of hypergraph $G = (V, E)$ serves as an obvious upper bound on $\text{Opt}(G)$. Recalling that E may exhibit edge multiplicities, we emphasize that δ (and $\text{Opt}(G)$) may become arbitrarily large with respect to n as the length m of the input edge sequence increases. To a large extent, this fact is what makes the online DSC problem interesting: if δ would have been bounded as a function of n , then one could have included it in the additive term β and trivially obtain an (impure) competitive ratio of 1.

1.2 Background and Related Work

The DSC problem is a fundamental combinatorial optimization problem with many applications in both the offline and online domains. These applications include scheduling the operation of sensors in sensor networks, allocating servers to users in file systems, and assigning users to tasks in crowd-sourcing platforms; refer to [9] for more details. The offline version of the problem is known to be NP-hard and it can be approximated to within an asymptotically tight $O(\log n)$ approximation ratio [10].

The rigorous study of the online DSC problem was initiated by Pananjady et al. [9].³ They first prove that a deterministic online DSC algorithm that does not hold a prior

² Throughout this paper, we say that event A holds whp if $\mathbb{P}(A) \geq 1 - n^{-z}$ for an arbitrarily large constant z .

³ The authors of [9] also define the DSC problem in terms of a hypergraph, however, in that paper, the role of the nodes and edges is reversed so that the nodes in V arrive in an online fashion, each reporting the edges in E to which it belongs. To avoid confusion, we discuss the results of [9] using the current paper's model that follows the common convention in the literature on online and streaming hypergraph algorithms (see, e.g., [12, 7, 8, 6]), where the hypergraph objects that arrive in an online fashion are the edges in E .

knowledge of the minimum degree δ cannot admit a pure competitive ratio better than $\Omega(n)$.⁴ Following that, Pananjady et al. focus their attention on online algorithms that know δ (or an approximation thereof) in advance and develop a deterministic purely $O(\log n)$ -competitive online DSC algorithm. They also establish an $\Omega(\sqrt{\log n})$ lower bound on the (impure) competitive ratio of any such algorithm.

The DSC problem can be viewed as a (maximization) extension of the classic (minimization) *set cover* problem, where (using our hypergraph terminology) the goal is to construct a covering edge subset of minimum size. In its online version, the hypergraph $G = (V, E)$ is known in advance, but only a subset $V' \subseteq V$ of the nodes should be covered. Those are revealed one-by-one in an online fashion and must be covered immediately upon arrival. Using the *online primal-dual* technique (see [5]), Alon et al. [1] developed a (deterministic) online algorithm for this problem with competitive ratio $O(\log n \log m)$. They also proved that this is optimal up to an $O(\log n + \log m)$ factor.

1.3 Our Contribution

Our goal in this paper is to lift the assumption that the minimum degree δ is known in advance, aiming for online DSC algorithms that do not hold any initial knowledge of that hypergraph parameter, referred to hereafter as δ -oblivious online algorithms. As a warm up, we develop a simple deterministic δ -oblivious online algorithm with linear (in n) pure competitive ratio, thus matching the $\Omega(n)$ lower bound of [9]. Nevertheless, we wish to obtain a sublinear competitiveness which means that our online algorithms must be either randomized or admit an impure competitive ratio (or both). We advocate for this compromise: randomization as well as impure competitiveness are omnipresent in the online computation literature and seem like a small price to pay for lifting the often unrealistic assumption that the online algorithm knows the parameter δ in advance, recalling that this parameter would typically increase with the length of the input sequence.

The main technical contribution of the current paper is twofold: On the positive side, we develop a randomized δ -oblivious online DSC algorithm and prove that it is purely $O(\log^2 n)$ -competitive in expectation and impurely $O(\log^2 n)$ -competitive whp. On the negative side, we prove that no randomized online DSC algorithm can have impure competitive ratio better than $\Omega(\log n / \log \log n)$ in expectation or whp. Interestingly, this result holds even for online algorithms that know δ in advance, thus improving upon the $\Omega(\sqrt{\log n})$ lower bound of [9]. A comparison between the results of [9] and those established in the current paper is presented in Table 1.

1.4 Paper's Organization

The remainder of this paper is organized as follows. Following some preliminaries in Section 2, we present our simple deterministic δ -oblivious online DSC algorithm in Section 3, where we also prove that it is $O(n)$ -competitive. Section 4 is then dedicated to our main positive result: a randomized δ -oblivious online DSC algorithm with competitive ratio $O(\log^2 n)$. The $\Omega(\log(n)/\log \log n)$ lower bound on the competitiveness of randomized online DSC algorithms is established in Section 5. Finally, Section 6 is dedicated to some open questions.

⁴ This negative result is obtained on hypergraphs whose δ parameter is proportional to n and the authors of [9] state it as an $\Omega(\delta)$ lower bound. We prefer to view it as an $\Omega(n)$ lower bound since in the current paper, all competitive ratio bounds are expressed as a function of n , and since it does not rule out the existence of a deterministic online DSC algorithm with pure competitive ratio $O(n)$ that works even for instances with $\delta \gg n$ (see Section 1.3).

2 Preliminaries

Consider some hypergraph $G = (V, E)$. Given node $v \in V$, let $E(v) = \{e \in E \mid v \in e\}$ be the set of edges that contain v and define the *degree* of v in G to be the size of this set, denoted by $d(v) = |E(v)|$. Let $\delta = \min_{v \in V} d(v)$ denote the minimum degree in G .

For $1 \leq t \leq m$, let $E_t = \{e_1, \dots, e_t\}$ be the set of edges that arrive up to (including) time t . Let $E_t(v) = E_t \cap E(v)$ and let $d_t(v) = |E_t(v)|$ be the degree of node v in the hypergraph (V, E_t) . Define $\eta_t = \min_{v \in e_t} d_t(v)$ to be the minimum degree, at time t , among the nodes included in edge e_t .

Recall that the goal in the DSC problem is to assign some color $C(e) \in \mathbb{Z}_{>0}$ to each edge $e \in E$. Color $c \in \mathbb{Z}_{>0}$ is said to *cover* node $v \in V$ if $C(e) = c$ for some edge $e \in E(v)$. Cast in this terminology, the objective of the DSC problem is to maximize the number of covering colors, that is, the colors that cover every $v \in V$ (see Section 1.1).

Given two integers $x \leq x'$, let $[x, x']$ denote the set of integers y satisfying $x \leq y \leq x'$ and let $[x] = [1, x]$. We generalize this notation to $x \in \mathbb{R}_{>1}$ by defining $[x] = \lceil x \rceil$. (The notation $[x, x']$ is reserved in the current paper only for integral x and x' .) A $\log(\cdot)$ operator with an unspecified base refers to $\log_2(\cdot)$.

Concentration Bounds

Binary random variables X_1, \dots, X_k are said to be *non-positively correlated* if the following two properties hold for any $I \subseteq [k]$:⁵

- (a) $\mathbb{P}(\bigwedge_{i \in I} X_i = 0) \leq \prod_{i \in I} \mathbb{P}(X_i = 0)$; and
- (b) $\mathbb{P}(\bigwedge_{i \in I} X_i = 1) \leq \prod_{i \in I} \mathbb{P}(X_i = 1)$.

The following theorem, referred to as *Chernoff's bounds for non-positively correlated random variables*, was proved in [11] (see also [3]).

⁵ In some literature, the term *negatively correlated* is used instead of non-positively correlated.

► **Theorem 2.1.** Let X_1, \dots, X_k be non-positively correlated binary random variables and let $0 \leq a_1, \dots, a_k \leq 1$. Let $X = \sum_{i \in [k]} a_i X_i$ and let $\mu = \mathbb{E}(X)$. Then,

- $\mathbb{P}(X \leq (1 - \delta)\mu) \leq \exp(-\delta^2\mu/2)$ for any $0 \leq \delta \leq 1$; and
- $\mathbb{P}(X \geq d) \leq 2^{-d}$ for any $d \geq 6\mu$.

Notice that independent random variables are, in particular, non-positively correlated. Indeed, by replacing the requirement that the random variables X_1, \dots, X_k are non-positively correlated by the requirement that they are independent, one obtains (two of) the classic Chernoff bounds.

3 Warmup: a Deterministic Greedy Algorithm

We begin with a simple δ -oblivious deterministic online DSC algorithm, referred to as **Greedy**, whose competitive ratio is purely $O(n)$, thus matching the $\Omega(n)$ lower bound of [9] for such algorithms. For each color $c \in \mathbb{Z}_{>0}$, the algorithm maintains the variable $U_t(c)$ defined to be the set of all nodes covered by the edges in E_t whose color is c , that is, $U_t(c) = \bigcup_{1 \leq t' \leq t: C(e_{t'})=c} e_{t'}$.

Greedy uses the $U_{t-1}(\cdot)$ variables to decide on the color assignment of edge e_t , $1 \leq t \leq m$, setting $C(e_t)$ to be the smallest color $c \in \mathbb{Z}_{>0}$ such that $e_t \not\subseteq U_{t-1}(c)$. This can be viewed as coloring e_t with the smallest color whose cover “benefits” from this assignment. The analysis of **Greedy**’s competitive ratio relies on the following two observations.

► **Observation 3.1.** If $\delta \geq 1$, then $\text{Greedy}(G) \geq 1$.

Proof. Follows immediately from the greedy nature of the algorithm that colors edge e_t with color $C(e_t) = 1$ if e_t contains a node that does not belong to any edge e_1, \dots, e_{t-1} . ◀

► **Observation 3.2.** **Greedy** colors at most n edges with color c for every $c \in \mathbb{Z}_{>0}$.

Proof. If edge e_t is assigned with color c , then $|U_t(c)| \geq |U_{t-1}(c)|$. The assertion follows since $U_t(c) \subseteq V$ for every $1 \leq t \leq m$. ◀

We are now ready to prove the following theorem.

► **Theorem 3.3.** **Greedy** is purely $O(n)$ -competitive.

Proof. If $d(v) = 0$ for some node $v \in V$, then clearly $\text{Greedy}(G) = \text{Opt}(G) = 0$, so assume hereafter that $\delta \geq 1$. We argue that $\text{Greedy}(G) \geq \lfloor \delta/n \rfloor$. Combined with Observation 3.1, this implies that

$$\text{Greedy}(G) \geq \max\{1, \delta/n - 1\} \geq \max\{1, \text{Opt}(G)/n - 1\} \geq \text{Opt}(G)/(2n),$$

thus establishing the assertion. To that end, consider some node $v \in V$ and recall that Observation 3.2 ensures that each color $c \in \mathbb{Z}_{>0}$ is assigned to at most n edges in $E(v)$. Therefore, there must exist at least $\lfloor d(v)/n \rfloor \geq \lfloor \delta/n \rfloor$ colors $c \in \mathbb{Z}_{>0}$ that cover v . Due to the greedy nature of the algorithm, we deduce that the colors $1, \dots, \lfloor \delta/n \rfloor$ cover v which establishes the assertion since this is true for every $v \in V$. ◀

4 The Main Algorithm

In this section, we present our main positive contribution: a randomized δ -oblivious online DSC algorithm, referred to as **Ob1v**. We start by providing an intuitive overview for this algorithm in Section 4.1. The algorithm itself is then presented in Section 4.2. In Section 4.3, we establish a combinatorial lemma regarding the online DSC problem in general. This lemma plays a key role in Section 4.4, where we prove that **Ob1v** is $O(\log^2 n)$ -competitive in expectation. Finally, the proof presented in Section 4.4 is extended in Section 4.5 to show that the same (asymptotic) competitive ratio bound holds also whp.

4.1 Technical Challenges and Intuition

Pananjady et al. [10] developed a randomized *offline* DSC algorithm that on hypergraph $G = (V, E)$, simply colors each edge $e \in E$ by a color $C(e)$ picked uniformly at random (abbreviated hereafter by *uar*) from the *palette* $P = [\Theta(\delta/\log n)]$. Since the degree $d(v)$ of every node $v \in V$ is at least δ , it is easy to see that each color $c \in P$ covers v whp, hence, by the union bound, c covers all V whp. Using standard arguments, one can conclude that the expected number of covering colors is at least $\Omega(|P|) = \Omega(\delta/\log n)$, which is an $O(\log n)$ -approximation as $\delta \geq \text{Opt}(G)$.

In [9], Pananjady et al. observed that the offline algorithm of [10] can be implemented as an online algorithm assuming that δ is known in advance. Their main technical contribution was then to derandomize this randomized algorithm by employing the method of conditional expectation (see, e.g., [2]), carefully adjusted to work in an online fashion.

In contrast, in the current paper we aim for a δ -oblivious online algorithm and hence, cannot use $P = [\Theta(\delta/\log n)]$ as the palette from which a color is picked for each edge $e_t \in E$. Instead, we estimate δ by the parameter $\eta_t = \min_{v \in e_t} d_t(v)$ that can be calculated at time t as it depends only on information that was already exposed to the algorithm. The combinatorial key to our algorithm is that (at least) a constant fraction of the edges e_t that contain node $v \in V$ satisfy $\eta_t \geq \Omega(d(v)/n)$. This means that we can identify (in hindsight) a sufficiently large subset of the edges $e_t \in E(v)$ for which $\Omega(\delta/n) \leq \eta_t \leq \delta$, or equivalently, $\log \eta_t \leq \log \delta \leq \log \eta_t + O(\log n)$.

We rely on this combinatorial insight for the design of **Ob1v**: Upon arrival of edge e_t , the algorithm assigns the variable r_t to be an integer picked uar from the integers in the range $[\log \eta_t, \log \eta_t + O(\log n)]$, thus ensuring that 2^{r_t} is a constant approximation of δ with probability $\Omega(1/\log n)$. The algorithm then uses 2^{r_t} to construct the palette $P_t = [\Omega(2^{r_t}/\log^2 n)]$ from which the color $C(e_t)$ of edge e_t is picked (uar), where the role of the extra $\log n$ factor in the denominator is to account for the probability that 2^{r_t} is a good estimate for δ . The rest of the analysis follows the aforementioned line of arguments, concluding that **Ob1v** is $O(\log^2 n)$ -competitive in expectation.

For whp competitiveness we have to work a little bit harder though. While we identify (in hindsight) a palette P of size $\Theta(\delta/\log^2 n)$ such that each color $c \in P$ covers V whp, the number of such colors may be too large to apply the union bound over all of them, thus we cannot simply argue that all colors in P cover V (simultaneously) whp. Instead, we show that for each node $v \in V$, the random variables that indicate the events that color $c \in P$ does not cover v are non-positively correlated. By applying the Chernoff bound for non-positively correlated random variables, we conclude that at most a $(1/(2n))$ -fraction of the colors in P do not cover v whp, hence the total number of colors in P that do not cover the whole of V is at most $|P|/2$ whp.

4.2 Algorithm's Description

Algorithm `Ob1v` works as follows. Upon arrival of edge e_t , $1 \leq t \leq m$, the algorithm calculates $\eta_t = \min_{v \in e_t} d_t(v)$ and $\ell_t = \lceil \log \eta_t \rceil$ and then assigns the variable r_t to an integer picked uar from the set $[\ell_t, \ell_t + \lceil \log(n-1) \rceil + 2]$. Following that, the color $C(e_t)$ of edge e_t is picked uar from the palette $P_t = \lceil \xi \cdot 2^{r_t} / \log^2 n \rceil$, where $\xi > 0$ is a constant whose value is determined (implicitly) later on. A pseudocode description of `Ob1v` is provided in Algorithm 1.

■ **Algorithm 1** The operation of `Ob1v` upon arrival of edge e_t , $1 \leq t \leq m$.

```

1:  $\eta_t \leftarrow \min_{v \in e_t} d_t(v)$ 
2:  $\ell_t \leftarrow \lceil \log \eta_t \rceil$ 
3: pick  $r_t$  uar from  $[\ell_t, \ell_t + \lceil \log(n-1) \rceil + 2]$ 
4:  $P_t \leftarrow \lceil \xi \cdot 2^{r_t} / \log^2 n \rceil$ 
5: color edge  $e_t$  with color  $C(e_t)$  picked uar from  $P_t$ 

```

▷ $\xi > 0$ is a constant

4.3 A Combinatorial Lemma

Fix some node $v \in V$. Edge $e_t \in E(v)$ is said to be *heavy* (for v) if

$$d_t(v) \leq 2(n-1)\eta_t;$$

otherwise, we say that it is *light* (for v).

► **Lemma 4.1.** *For every time $1 \leq T \leq m$, more than $d_T(v)/2$ of the edges in $E_T(v)$ are heavy.*

Proof. Consider the edge sequence $\sigma = (e_1, \dots, e_T)$. By the definition of η_t , edge $e_t \in E_T(v)$ is light if and only if there exists some node $u \in e_t - \{v\}$ whose degree at time t satisfies $d_t(u) < d_t(v)/(2(n-1))$. On an intuitive level, this means that the challenge in constructing an edge sequence σ that contradicts the assertion, is to increase the degree of v while keeping the degrees of the other nodes small, thus enabling the generation of many light edges with few heavy edges. We employ this intuition to make the following simplifying assumptions.

The first assumption we make for the sake of simplifying the proof is that v is contained in all edges of the sequence σ , that is, $E_T(v) = E_T$. This assumption is clearly without loss of generality since the existence of an edge e_t that does not contain v (and hence is neither heavy nor light) increases the degrees of the nodes in e_t without increasing the degree of v .

Next, notice that all singleton edges of the form $e_t = \{v\}$ are heavy. The second assumption we make for the sake of simplifying the proof is that every heavy edge e_t in σ is a singleton, i.e., $e_t = \{v\}$. To see that this assumption is without loss of generality, suppose that e_t includes additional nodes $u \neq v$ and consider the edge sequence σ' obtained from σ by removing these nodes u from e_t . Comparing σ' to σ , one observes that $d_{t'}(u)$ decreases and $d_{t'}(v)$ remains unchanged for every $t' \geq t$, thus if σ contradicts the assertion, then so does σ' .

The third assumption we make for the sake of simplifying the proof is that every light edge e_t in σ is of size $|e_t| = 2$. To see that this assumption is without loss of generality, suppose that e_t is light with $|e_t| \geq 3$ and let u be a node of minimum degree $d_t(u)$ in e_t . Consider the edge sequence σ' obtained from σ by removing from e_t any node $u' \in e_t - \{v, u\}$. Comparing σ' to σ , one observes that edge e_t remains light (due to the existence of u) while $d_{t'}(u')$ decreases and $d_{t'}(v)$ remains unchanged for every $t' \geq t$, thus if σ contradicts the assertion, then so does σ' .

The fourth assumption we make for the sake of simplifying the proof is that σ is composed of a prefix of heavy edges followed by a suffix of light edges; i.e., there exists some $1 \leq \hat{t} \leq T$ such that edge e_t is heavy if $1 \leq t \leq \hat{t}$ and light if $\hat{t} + 1 \leq t \leq T$. To see that this assumption is without loss of generality, suppose that there exists some $1 \leq t \leq T - 1$ such that edge $e_t = \{v, u\}$ is light and edge $e_{t+1} = \{v\}$ is heavy and consider the edge sequence σ' obtained from σ by swapping between e_t and e_{t+1} . By construction, this swap does not turn e_t (now arriving at time $t + 1$) into a heavy edge as $d_u(t + 1) = d_u(t)$ and $d_v(t + 1) > d_v(t)$, thus if σ contradicts the assertion, then so does σ' . Our assumption is now justified by repeating these swap operations.

So, based on the aforementioned four assumptions, the edge sequence $\sigma = (e_1, \dots, e_T)$ consists of a prefix $(e_1, \dots, e_{\hat{t}})$ of heavy edges of the form $e_t = \{v\}$ and a suffix $(e_{\hat{t}+1}, \dots, e_T)$ of light edges of the form $e_t = \{v, u\}$ for some node $u \neq v$ referred to hereafter as the *extra* node of edge e_t . The fifth and last assumption we make for the sake of simplifying the proof is that the degrees of the extra nodes are monotonically non-decreasing; that is, if u is the extra node of edge e_t , $\hat{t} + 1 \leq t \leq T - 1$, and u' is the extra node of edge e_{t+1} , then $d_t(u) \leq d_{t+1}(u')$. To see that this assumption is without loss of generality, suppose that $d_t(u) > d_{t+1}(u')$ and consider the edge sequence σ' obtained from σ by swapping between e_t and e_{t+1} . By construction, since e_t and e_{t+1} are light in σ , they are also light in σ' , thus if σ contradicts the assertion, then so does σ' . Our assumption is now justified by repeating these swap operations.

Observe that the last simplifying assumption implies that if u is the extra node of edge e_t , $\hat{t} + 1 \leq t \leq T$, and there exists some node $u' \notin \{v, u\}$ with $d_{t-1}(u') < d_{t-1}(u)$, then u' does not appear as the extra node of any edge $e_{t'}$, $t \leq t' \leq T$. This observation allows us to conclude that if u is the extra node of edge e_t , $\hat{t} + 1 \leq t \leq T$, then $d_t(u) \geq (t - \hat{t})/(n - 1)$.

We are now ready to establish the assertion by proving that $\hat{t} > T/2$. To that end, recall that by the definition of a light edge, if u is the extra node of edge e_t , $\hat{t} + 1 \leq t \leq T$, then

$$d_t(u) < \frac{d_t(v)}{2(n-1)} = \frac{t}{2(n-1)}.$$

Put together with the bound $d_t(u) \geq (t - \hat{t})/(n - 1)$, we conclude that $t/2 > t - \hat{t}$ which holds if and only if $\hat{t} > t/2$, thus completing the proof by taking $t = T$. \blacktriangleleft

► **Corollary 4.2.** *For every time $1 \leq T \leq m$, if $d_T(v) \geq z$, then*

$$\left| \left\{ e_t \in E_T(v) \mid \eta_t > \frac{z}{8(n-1)} \right\} \right| > z/4.$$

Proof. Let $e_{t(1)}, \dots, e_{t(z)}$ be the first z edges in the sequence (e_1, \dots, e_T) that contain node v , ordered so that $t(1) < \dots < t(z)$ (we know that these z edges exist as $d_T(v) \geq z$). Lemma 4.1 ensures that more than $z/2$ of the edges $e_{t(j)}$, $1 \leq j \leq z$, are heavy (for v), hence even if all edges in $\{e_{t(j)} \mid 1 \leq j \leq z/4\}$ are heavy, we still have more than $z/4$ heavy edges in $H = \{e_{t(j)} \mid z/4 < j \leq z\}$. Since $d_{t(j)}(v) = j > z/4$ for every edge $e_{t(j)} \in H$, it follows that more than $z/4$ of the edges $e_{t(j)} \in H$ satisfy $\eta_{t(j)} > z/(8(n - 1))$, thus establishing the assertion. \blacktriangleleft

4.4 Competitiveness in Expectation

We now turn to bound the competitive ratio of `Ob1v` in expectation, based on Corollary 4.2. Let $w = \lfloor \log \delta \rfloor$ and let

$$P = \lceil \xi \cdot 2^w / \log^2 n \rceil$$

be the palette from which `Ob1v` picks a color $C(e_t)$ (uar) when the random variable r_t is assigned to $r_t = w$. Given node $v \in V$, let

$$T(v) = \min \{1 \leq t \leq m \mid d_t(v) = 2^w\}$$

be the first time t at which the degree of v reaches $2^w \leq \delta$. Let

$$F(v) = \left\{ e_t \in E_{T(v)}(v) \mid \eta_t > \frac{2^w}{8(n-1)} \right\},$$

recalling that $E_{T(v)}(v)$ is the set of edges $e_t \in E(v)$ with $1 \leq t \leq T(v)$, and let

$$F^w(v) = \{e_t \in F(v) \mid r_t = w\}$$

be the (random) set of edges e_t in $F(v)$ for which `Ob1v` picks a color (uar) from the palette P .

► **Lemma 4.3.** *If $\delta \geq \Omega(\log^2 n)$, then $|F^w(v)| \geq \Omega(\delta/\log n)$ whp for every node $v \in V$.*

Proof. Consider some edge $e_t \in F(v)$ and let A_t denote the event $e_t \in F^w(v)$. By definition,

$$\frac{2^w}{8(n-1)} < \eta_t \leq d_t(v) \leq 2^w,$$

hence

$$w - (\log(n-1) + 3) < \log \eta_t \leq w.$$

Since w is an integer, it follows that

$$w - (\lceil \log(n-1) \rceil + 2) \leq \ell_t \leq w,$$

where recall that $\ell_t = \lceil \log \eta_t \rceil$. Therefore, $w \in [\ell_t, \ell_t + \lceil \log(n-1) \rceil + 2]$ and by the design of the algorithm, we conclude that r_t is assigned to w with probability $1/(\lceil \log(n-1) \rceil + 3)$ implying that $\mathbb{P}(A_t) \geq \Omega(1/\log n)$.

Corollary 4.2 guarantees that $|F(v)| > 2^w/4 \geq \Omega(\delta)$, hence

$$\mathbb{E}(|F^w(v)|) = \sum_{e_t \in F(v)} \mathbb{P}(A_t) \geq \Omega(\delta/\log n).$$

If $\delta \geq \Omega(\log^2 n)$, then $\mathbb{E}(|F^w(v)|) \geq \Omega(\log n)$, therefore, as the events A_t are independent, we can apply Theorem 2.1 to conclude that $|F^w(v)| \geq \Omega(\delta/\log n)$ whp. ◀

► **Corollary 4.4.** *Fix some color $c \in P$. If $\delta \geq \Omega(\log^2 n)$, then c covers v whp for every node $v \in V$.*

Proof. Lemma 4.3 ensures that $|F^w(v)| \geq \Omega(\delta/\log n)$ whp; condition hereafter on this event. The algorithm is designed so that each edge $e_t \in F^w(v)$ is colored $C(e_t) \leftarrow c$ with probability $1/|P| = \Omega(\log^2(n)/\delta)$. Therefore, the probability that none of the edges in $F^w(v)$ is colored c is at most

$$(1 - \Omega(\log^2(n)/\delta))^{\Omega(\delta/\log n)} \leq \exp(-\Omega(\log n)),$$

thus establishing the assertion. ◀

We are now ready to establish the desired competitive ratio bound.

44:10 Online Disjoint Set Cover Without Prior Knowledge

► **Theorem 4.5.** *Ob1v is (impurely) $O(\log^2 n)$ -competitive in expectation.*

Proof. We prove the assertion by showing that

$$\mathbb{E}(\text{Ob1v}(G)) \geq \Omega(\text{Opt}(G)/\log^2 n) - 1.$$

This bound holds trivially if $\text{Opt}(G) \leq \delta \leq O(\log^2 n)$, so assume that $\delta \geq \Omega(\log^2 n)$. Applying the union bound to the promise of Corollary 4.4, we conclude that color $c \in P$ covers all nodes in V whp and, in particular, with probability at least (say) $1/2$. Therefore, by the linearity of expectation,

$$\mathbb{E}(\text{Ob1v}(G)) \geq |P|/2 \geq \Omega(\delta/\log^2 n) \geq \Omega(\text{Opt}(G)/\log^2 n), \quad (2)$$

thus completing the proof. ◀

Recall that in Section 3, we presented the deterministic online DSC algorithm **Greedy** whose competitive ratio is purely $O(n)$. By combining it with **Ob1v**, we can turn the competitive ratio bound promised by Theorem 4.5 into a pure one. To that end, consider the online algorithm Ob1v_p that runs **Ob1v** with probability $1/2$ and **Greedy** with probability $1/2$. If $\delta = 0$, then clearly $\text{Opt}(G) = \text{Ob1v}_p(G) = 0$. If $\delta \geq \Omega(\log^2 n)$, then

$$\mathbb{E}(\text{Ob1v}_p(G)) \geq \mathbb{E}(\text{Ob1v}(G))/2 \geq \Omega(\text{Opt}(G)/\log^2 n),$$

where the last transition holds due to (2). If $1 \leq \delta \leq O(\log^2 n)$, then

$$\mathbb{E}(\text{Ob1v}_p(G)) \geq \text{Greedy}(G)/2 \geq 1/2 \geq \Omega(\text{Opt}(G)/\log^2 n),$$

where the second transition holds due to Observation 3.1. Put together, we obtain the following corollary.

► **Corollary 4.6.** *Ob1v_p is purely $O(\log^2 n)$ -competitive in expectation.*

4.5 Competitiveness with High Probability

We now turn to show that the competitive ratio bound established in Section 4.4 holds also whp (though not purely). For node $v \in V$ and color $c \in P$, define the random variable $X^v(c)$ to be an indicator for the event that color c does *not* cover v , namely, $X^v(c) = 1$ if and only if $C(e_t) \neq c$ for all edges $e_t \in E(v)$. Recall that Corollary 4.4 guarantees that if $\delta \geq \Omega(\log^2 n)$, then

$$\mathbb{E}(X^v(c)) \leq n^{-z} \quad (3)$$

for an arbitrarily large constant z .

The analysis in this section relies on proving that the random variables $X^v(\cdot)$ are non-positively correlated (Lemma 4.8), based on the following observation.

► **Observation 4.7.** *For every node $v \in V$, color subset $Q \subset P$, and color $c' \in P - Q$, we have*

- (a) $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 0 \mid X^v(c') = 0\right) \leq \mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 0\right)$; and
- (b) $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 1 \mid X^v(c') = 1\right) \leq \mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 1\right)$.

Proof. To see that property (a) holds, notice that if $X^v(c') = 0$, then at least one edge in $E(v)$ is colored c' which means that there is one less edge available for the colors in Q , hence $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 0\right)$ decreases. To see that property (b) holds, notice that if $X^v(c') = 1$, then none of the edges in P is colored c' which means that there is one less color in P to compete with the colors in Q , hence $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 1\right)$ decreases. ◀

► **Lemma 4.8.** *For every node $v \in V$, the random variables $X^v(c)$, $c \in P$, are non-positively correlated.*

Proof. Fix some $Q \subseteq P$. We prove that $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 0\right) \leq \prod_{c \in Q} \mathbb{P}(X^v(c) = 0)$; the proof that $\mathbb{P}\left(\bigwedge_{c \in Q} X^v(c) = 1\right) \leq \prod_{c \in Q} \mathbb{P}(X^v(c) = 1)$ is analogous. To that end, we let $Q = \{c_1, \dots, c_k\}$ and prove by induction on k that

$$\mathbb{P}\left(\bigwedge_{i=1}^k X^v(c_i) = 0\right) \leq \prod_{i=1}^k \mathbb{P}(X^v(c_i) = 0).$$

The case $k = 1$ holds trivially, so assume that the inequality holds for $k - 1$ and develop

$$\begin{aligned} \mathbb{P}\left(\bigwedge_{i=1}^k X^v(c_i) = 0\right) &= \mathbb{P}\left(\bigwedge_{i=1}^{k-1} X^v(c_i) = 0 \mid X^v(c_k) = 0\right) \cdot \mathbb{P}(X^v(c_k) = 0) \\ &\leq \mathbb{P}\left(\bigwedge_{i=1}^{k-1} X^v(c_i) = 0\right) \cdot \mathbb{P}(X^v(c_k) = 0) \\ &\leq \prod_{i=1}^{k-1} \mathbb{P}(X^v(c_i) = 0) \cdot \mathbb{P}(X^v(c_k) = 0) = \prod_{i=1}^k \mathbb{P}(X^v(c_i) = 0), \end{aligned}$$

where the second transition follows from Observation 4.7 and the third transition holds due to the inductive hypothesis. ◀

Assume hereafter that $\delta \geq z'n \log^3 n$ for a sufficiently large constant z' which means that $|P| \geq 2zn \log n$ for a constant z that can be made arbitrarily large. Consider some node $v \in V$ and let $X^v = \sum_{c \in P} X^v(c)$. Applying the linearity of expectation to (3), we deduce that $\mathbb{E}(X^v) \leq |P| \cdot n^{-z}$ for an arbitrarily large constant z . Lemma 4.8 allows us to apply Theorem 2.1, thus obtaining the bound

$$\mathbb{P}\left(X^v \geq \frac{|P|}{2n}\right) \leq 2^{-|P|/(2n)} \leq 2^{-2zn \log n/(2n)} = n^{-z} \tag{4}$$

for an arbitrarily large constant z . We are now ready to establish the desired competitive ratio bound.

► **Theorem 4.9.** *0blv is (impurely) $O(\log^2 n)$ -competitive whp.*

Proof. We prove the assertion by showing that

$$0\text{blv}(G) \geq \Omega(0\text{pt}(G)/\log^2 n) - O(n \log n)$$

whp. This bound holds trivially if $0\text{pt}(G) \leq \delta < z'n \log^3 n$ (recall that z' is a constant), so assume that $\delta \geq z'n \log^2 n$ which means that the bound in (4) holds for every node $v \in V$.

44:12 Online Disjoint Set Cover Without Prior Knowledge

Let X be the random variable that takes on the number of colors in P that do *not* cover V . Notice that by the definition of X^v , we know that $X \leq \sum_{v \in V} X^v$. Applying the union bound over all nodes to (4), we conclude that $X^v < |P|/(2n)$ for all nodes $v \in V$ simultaneously whp; condition hereafter on this event. We can now develop

$$X \leq \sum_{v \in V} X^v < |P|/2$$

which means that $\text{obl}_v(G) > |P|/2$. The assertion follows since $|P| \geq \Omega(\delta/\log^2 n)$. ◀

5 Lower Bound

This section is dedicated to our main negative result: there does not exist a randomized online DSC algorithm with (impure) competitive ratio better than $\Omega(\log(n)/\log \log n)$ in expectation (and thus also whp). This lower bound is derived from the following theorem by Yao's min-max principle.

► **Theorem 5.1.** *For every n_0 and δ_0 , there exist $n \geq n_0$, $\delta \geq \delta_0$, and a distribution \mathcal{D} over n -node hypergraphs with minimum degree δ such that (1) $\text{Opt}(G) = \delta$ for every hypergraph G in the support of \mathcal{D} ; and (2) $\mathbb{E}_{G \sim \mathcal{D}}(\text{Alg}(G)) \leq O\left(\delta \frac{\log \log n}{\log n}\right)$ for any deterministic online DSC algorithm Alg .*

Theorem 5.1 is established in two stages. First, in Section 5.1, we construct the promised distribution \mathcal{D} for the special case that $\delta = \Theta(\log(n)/\log \log n)$ (and $\text{Alg}(G) \leq O(1)$). Then, in Section 5.2, we show how this construction is extended for arbitrarily large values of the parameter δ .

5.1 The Basic Construction

Let $q = 2^{2^z}$ for an arbitrarily large integer z and let $r = q/(2 \log q)$ (an integer by the choice of q). Each hypergraph in the support of \mathcal{D} has 2^q nodes, $q + r$ edges, and minimum degree $\delta = r$. We present the construction of a random hypergraph $G = (V, E)$ in \mathcal{D} and then show that $\text{Opt}(G) = r$, whereas

$$\mathbb{E}_G(\text{Alg}(G)) < 3 \tag{5}$$

for any deterministic online DSC algorithm Alg , thus establishing Theorem 5.1 under the restriction that $\delta = \Theta(\log(n)/\log \log n)$.

The nodes in V are identified with the vectors in $\{0, 1\}^q$. The edges in E arrive in the form of a deterministic prefix e_1^p, \dots, e_q^p followed by a random suffix e_1^s, \dots, e_r^s . The prefix is defined by setting

$$e_i^p = \{v \in \{0, 1\}^q \mid v(i) = 1\}$$

for every $i \in [q]$. For the suffix, we pick a partition $\mathcal{S} = \{S_1, \dots, S_r\}$ of $[q]$ into r equally sized clusters (each of size $|S_\ell| = q/r = 2 \log q$) uniformly among the collection of all such partitions. The suffix is then defined by setting

$$e_\ell^s = \{v \in \{0, 1\}^q \mid v(i) = 0 \text{ for all } i \in S_\ell\}$$

for every $\ell \in [r]$. Refer to Figure 1 for an illustration of the suffix edges.

► **Lemma 5.2.** *The hypergraph G satisfies $\text{Opt}(G) = \delta = r$.*

$$e_1^s = \left\{ \begin{array}{cccccccccccccccc} \times & \times & \times & 0 & 0 & 0 & 0 & 0 & \times & \times & \times & 0 & 0 & \times & \times & 0 \end{array} \right\}$$

$$e_2^s = \left\{ \begin{array}{cccccccccccccccc} 0 & 0 & 0 & \times & \times & \times & \times & \times & 0 & 0 & 0 & \times & \times & 0 & 0 & \times \end{array} \right\}$$

Figure 1 The construction of the suffix edges for $q = 16$ assuming that the random partition $\mathcal{S} = \{S_1, S_2\}$ consists of the clusters $S_1 = \{4, 5, 6, 7, 8, 12, 13, 16\}$ and $S_2 = \{1, 2, 3, 9, 10, 11, 14, 15\}$. The \times symbol represents a 'dont-care' vector entry, i.e., it can be a 0 or a 1.

Proof. Since the zero vector $v_0 = (0, \dots, 0)$ is included in all suffix edges $e_\ell^s, \ell \in [r]$ and is not included in any prefix edge $e_i^p, i \in [q]$, it follows that $\delta \leq d(v_0) = r$. The proof is completed by showing that $\text{Opt}(G) \geq r$, recalling that $\text{Opt}(G) \leq \delta$.

Consider the color assignment $C^* : E \rightarrow [r]$ that colors each suffix edge $e_\ell^s, \ell \in [r]$, by color $C^*(e_\ell^s) = \ell$ and each prefix edge $e_i^p, i \in [q]$, by color $C^*(e_i^p) = \ell(i)$ defined to be the unique $\ell \in [r]$ that satisfies $i \in S_\ell$ (this is well defined since $\mathcal{S} = \{S_1, \dots, S_r\}$ is a partition of $[q]$). We argue that under color assignment C^* , color ℓ covers V for every $\ell \in [r]$. Indeed, if vector $v \in \{0, 1\}^q$ is not included in e_ℓ^s , then $v(i) = 1$ for some $i \in S_\ell$, hence v is included in edge e_i^p . This means that $\ell(i) = \ell$, thus $C^*(e_i^p) = \ell$. The assertion follows. \blacktriangleleft

The rest of this section is dedicated to proving that (5) holds. Fix some deterministic DSC algorithm **Alg**. We assume that **Alg** uses only (a subset of) the colors in $[q]$. To see that this assumption is without loss of generality, notice that if color $c \in \mathbb{Z}_{>0}$ is not assigned to any prefix edge $e_i^p, i \in [q]$, then it cannot cover V since the vector $(1, \dots, 1)$ is not included in any suffix edge.

So, let $C : E \rightarrow [q]$ be the color assignment returned by **Alg**. Color $c \in [q]$ is said to be *heavy*, if it is assigned to at least $q/2$ prefix edges, i.e., $|\{i \in [q] \mid C(e_i^p) = c\}| \geq q/2$; otherwise, it is said to be *light*. By definition, there exists at most 2 heavy colors, so $\text{Alg}(G)$ is bounded from above by 2 plus the number of covering light colors. The proof that (5) holds is completed by the following lemma due to the linearity of expectation as clearly, there are at most q light colors in $[q]$.

Lemma 5.3. *If color $c \in [q]$ is light, then c covers V with probability smaller than $1/q$.*

Proof. Consider some light color c and let $I = \{i \in [q] \mid C(e_i^p) = c\}$. Color c is said to be *ℓ -free*, $\ell \in [r]$, if $S_\ell \not\subseteq I$, that is, if there exists some index $j \in S_\ell$ such that the prefix edge e_j^p is not colored c . It is said to be *free* if it is ℓ -free for all $\ell \in [r]$.

We argue that if c is free, then it does not cover V even if all suffix edges are colored c . To that end, let $b_\ell, \ell \in [r]$, be some index in $S_\ell - I$ (this is well defined since c is ℓ -free) and let $B = \{b_\ell \mid \ell \in [r]\}$. Consider the vector v defined by setting $v(i) = 1$ if $i \in B$; and $v(i) = 0$ otherwise. The vector v is not included in any prefix edge $e_i^p, i \in I$, because $B \cap I = \emptyset$, hence $v(i) = 0$ for all $i \in I$. It is also not included in any suffix edge $e_\ell^s, \ell \in [q]$, because $v(b_\ell) = 1$. Therefore, if c is free, then there exists at least one vector in $\{0, 1\}^q$ that it does not cover. Refer to Figure 2 for an illustration. To complete the proof, we show that c is free with probability greater than $1 - 1/q$. Fix some $\ell \in [q]$ and recall that the cluster S_ℓ is a random subset of $[q]$ of size $q/r = 2 \log q$. For the sake of this proof, we think of S_ℓ as being formed by randomly choosing $2 \log q$ indices from $[q]$ without repetitions; denote these indices by $i_1, \dots, i_{2 \log q}$. By definition, color c is not ℓ -free if and only if $i_j \in I$ for all $1 \leq j \leq 2 \log q$.

$$\begin{aligned}
 e_2^p &= \{ \boxed{\times} \boxed{1} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \} \\
 e_4^p &= \{ \boxed{\times} \boxed{\times} \boxed{\times} \boxed{1} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \} \\
 e_7^p &= \{ \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{1} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \} \\
 e_{11}^p &= \{ \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{1} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \} \\
 e_{14}^p &= \{ \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{\times} \boxed{1} \boxed{\times} \boxed{\times} \} \\
 v &= \{ \boxed{0} \boxed{0} \boxed{1} \boxed{0} \boxed{1} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \boxed{0} \}
 \end{aligned}$$

■ **Figure 2** Building on the example depicted in Figure 1, the color c with $I = \{2, 4, 7, 11, 14\}$ is free: it is 1-free because $5 \in S_1 - I$; it is 2-free because $3 \in S_2 - I$. Therefore, the vector v is not covered by any edge in $\{e_2^p, e_4^p, e_7^p, e_{11}^p, e_{14}^p\} \cup \{e_1^s, e_2^s\}$.

We can now develop

$$\mathbb{P} \left(\bigwedge_{j=1}^{2 \log q} i_j \in I \right) = \prod_{j=1}^{2 \log q} \mathbb{P} \left(i_j \in I \mid \bigwedge_{j'=1}^{j-1} i_{j'} \in I \right) = \prod_{j=0}^{2 \log q - 1} \frac{|I| - j}{q - j} \leq (|I|/q)^{2 \log q}.$$

As c is assumed to be light, we have $|I| < q/2$, hence the probability that c is not ℓ -free is smaller than $(1/2)^{2 \log q} = 1/q^2$. By the union bound over all $\ell \in [r]$, we conclude that the probability that c is not ℓ -free for any (at least one) $\ell \in [r]$ is smaller than $r/q^2 < 1/q$, thus establishing the assertion. ◀

5.2 The Multiplied Construction

In this section, we extend the distribution \mathcal{D} presented in Section 5.1 to a distribution \mathcal{D}_k , where k is an arbitrarily large (positive) integer. Each hypergraph in the support of \mathcal{D}_k has 2^q nodes, $k(q+r)$ edges, and minimum degree $\delta_k = kr$. We present the construction of a random hypergraph $G_k = (V_k, E_k)$ in \mathcal{D}_k and then show that $\text{Opt}(G_k) = kr$, whereas

$$\mathbb{E}_{G_k} (\text{Alg}(G_k)) < 3k \tag{6}$$

for any deterministic online DSC algorithm Alg , thus completing the proof of Theorem 5.1.

Like the construction of $G = (V, E)$ presented in Section 5.1, the nodes in V_k are also identified with the vectors in $\{0, 1\}^q$. The basic idea behind the construction of the edge set E_k is to multiply the edges in E , creating k copies for each one of them. A naive attempt to do so would be to simply introduce k independent instantiations of E one after the other with the hope that the arguments used in Section 5.1 can be applied to each instantiation separately. The problem with this approach is that the prefix edges of the $(j+1)$ -st instantiation arrive after the suffix edges of the j -th instantiation, allowing the online algorithm to “color them together” optimally.

To overcome this obstacle, we design the edge sequence so that (all copies of) the prefix edges arrive before (all copies of) the suffix edges. Specifically, the edges in E_k arrive in the form of a deterministic prefix $e_{1,1}^p, \dots, e_{1,k}^p, e_{2,1}^p, \dots, e_{2,k}^p, \dots, e_{q,1}^p, \dots, e_{q,k}^p$ followed by a random suffix $e_{1,1}^s, \dots, e_{1,k}^s, e_{2,1}^s, \dots, e_{2,k}^s, \dots, e_{r,1}^s, \dots, e_{r,k}^s$, where $e_{i,1}^p, \dots, e_{i,k}^p$ and $e_{\ell,1}^s, \dots, e_{\ell,k}^s$ are k identical copies of the edges e_i^p , $i \in [q]$, and e_ℓ^s , $\ell \in [r]$, respectively, as defined in Section 5.1. We emphasize that the same (random) partition $\mathcal{S} = \{S_1, \dots, S_r\}$ is used to determine all copies of the suffix edges and that this partition is revealed to the online algorithm only after (all copies of) all prefix edges have been colored.

Since G_k is obtained from G by edge multiplicity, it follows that $\delta_k = k\delta = kr$, and by Lemma 5.2, we conclude that $\text{Opt}(G_k) = \delta_k = kr$, so it remains to show that (6) holds. To that end, we employ the same proof scheme as in Section 5.1: Fix some deterministic online DSC algorithm **Alg**. Since a color that is not assigned to any prefix edge does not cover the vector $(1, \dots, 1)$, we assume without loss of generality that **Alg** uses only (a subset of) the colors in $[kq]$. As in Section 5.1, we classify the colors in $[kq]$ according to the number of prefix edges they are assigned to, with heavy colors assigned to at least $q/2$ prefix edges and light colors assigned to less than $q/2$ prefix edges. Lemma 5.3 ensures that each light color covers $V = V_k$ with probability smaller than $1/q$, hence, since there are at most kq light colors, we conclude by the linearity of expectation that the expected gain of **Alg** from all light colors is smaller than k . The proof that (6) holds is completed by noticing that there are at most $kq/(q/2) = 2k$ heavy colors.

6 Discussion

Our investigation of the online DSC problem leaves several interesting open questions. The first one concerns the gap between our $O(\log^2 n)$ upper bound and $\Omega(\log(n)/\log \log n)$ lower bound on the competitive ratio of randomized δ -oblivious online DSC algorithms. Since our lower bound holds for online DSC algorithms that know δ in advance as well, one also wonders about the gap it leaves from the $O(\log n)$ upper bound of Pananjady et al. [9] for such algorithms.

The role of randomization in δ -oblivious online DSC algorithms is also not fully understood yet. While the lower bound of [9] states that a deterministic δ -oblivious online DSC algorithm cannot have a pure competitive ratio better than $\Omega(n)$, we still do not know if this is true also for the impure competitiveness of such online algorithms. In particular, it is not clear if the method of conditional expectation applied by Pananjady et al. [9] to derandomize their online algorithm can be applied also to our randomized online algorithm, especially since the derandomization technique of Pananjady et al. relies heavily on the knowledge of δ .

Finally, recall our assumption that the nodes of the hypergraph, and in particular their number n , are known in advance. While the simple deterministic online algorithm presented in Section 3 can be implemented to operate without this assumption, coming up with such an implementation of the randomized online algorithm of Section 4 seems to be a challenging task. More generally, it would be interesting to design online DSC algorithms that are (initially) oblivious to all “global” parameters of the input hypergraph, including both n and δ .

Abstract

We study network coordination problems, as captured by the setting of *generalized network design* (Emek et al., STOC 2018), in the face of uncertainty resulting from partial information that the network users hold regarding the actions of their peers. This uncertainty is formalized using Alon et al.'s *Bayesian ignorance* framework (TCS 2012). While the approach of Alon et al. is purely combinatorial, the current paper takes into account computational considerations: Our main technical contribution is the development of (strongly) polynomial time algorithms for local decision making in the face of Bayesian uncertainty.

1 Introduction

In real-life situations, network users are often required to coordinate actions for performance optimization. This challenging coordination task becomes even harder in the face of *uncertainty*, as users often act with partial information regarding their peers. Can users overcome their *local* views and reach a good *global* outcome? How far would this outcome be from optimal?

For a formal treatment of the aforementioned questions, we adopt the *Bayesian ignorance* framework of Alon et al. [4]. Consider N agents in a *routing* scenario, where each agent $i \in [N]$ should decide on a (u_i, v_i) -path a_i in the network with the objective of minimizing some global *cost function* that depends on the links' load. The (u_i, v_i) pair, also referred to as the *type* of agent i , is drawn from a distribution p_i . All agents know this distribution, but the actual realization (u_i, v_i) of each agent i is only known to i herself.

Our goal is to construct a *strategy* for each agent i that determines her action a_i based only on her individual type (u_i, v_i) . These strategies are computed in a “preprocessing stage” and the actual decision making happens in real-time without further communication. We measure the quality of a tuple of strategies in terms of its *Bayesian competitive ratio (BCR)* defined as the ratio of the expected cost obtained by these strategies to that of an optimal solution computed by an omnipotent algorithm (refer to Sec. 1.1.1 for the exact definition). To the best of our knowledge, this algorithmic evaluation measure has not been studied so far.

Our main technical contribution is a generic framework that yields strongly polynomial-time algorithms constructing agent strategies with low BCR for *Bayesian generalized network design (BGND)* problems – a setting that includes routing and many other network coordination problems. Our framework assumes cost functions that exhibit *diseconomy of scale (DoS)* [5, 6, 28], capturing the power consumption of devices that employ the popular *speed scaling* technique.

1.1 Model

For clarity of the exposition, we start with the special case of Bayesian routing in Sec. 1.1.1 and then present the more general BGND setting in Sec. 1.1.2. Conceptually, the new algorithmic problem of Bayesian routing that we define here is related to oblivious routing [21, 17, 35], where routing requests should be performed without any knowledge about actual network traffic. This means that the routing path chosen for a routing request may only depend on the network structure and the other parameters of the problem. Oblivious algorithms are attractive as they can be implemented very efficiently in a distributed environment as they base routing decisions only on local knowledge. As will become formally clear below, Bayesian routing has a similar flavor, but with an important additional ingredient. We will assume that the algorithm is equipped with statistical (“Bayesian”) knowledge about network traffic. Thus, in a sense, we replace internal randomization techniques, that oblivious routing usually employs, with actual data, while still being oblivious to other actual routing decisions and thus still maintaining the locality principle.¹

1.1.1 Special Case: Bayesian Routing

In the *full information* variant of the *routing* problem, we are given a (directed or undirected) graph $G = (V, E)$ and a set of N agents, where each agent $i \in [N]$ is associated with a node pair $(u_i, v_i) \in V \times V$, referred to as the (routing) *request* of agent i . This request should be satisfied by choosing some (u_i, v_i) -path in G , referred to as the (feasible) *action* of agent i , and the collection of all such paths is denoted by A_i .

¹ This is different from stochastic network design as these algorithms are not oblivious. More details are given below.

Let $A = A_1 \times \cdots \times A_N$ be the collection of all *action profiles*. The *load* on edge $e \in E$ with respect to action profile $a \in A$, denoted by l_e^a , is defined to be the number of agents whose actions include e , that is, $l_e^a = |\{i \in [N] : e \in a_i\}|$. The cost incurred by load l_e^a on edge e is determined by an (edge specific) *superadditive* cost function $F_e : \mathbb{R}_{\geq 0} \mapsto \mathbb{R}_{\geq 0}$ such that for any $l \geq 0$,

$$F_e(l) = \xi_e \cdot l^\alpha, \quad (1)$$

where $\xi_e > 0$ (a.k.a. the *speed scaling factor*) is a parameter of edge e and $\alpha > 1$ (a.k.a. the *load exponent*) is a global constant parameter. Such a superadditive cost function captures, for example, the power consumption of network devices employing the popular *speed scaling* technique [37, 25, 7, 29, 12, 3] that allows the device to adapt its power level to its actual load. In particular, for those network devices that employ the speed scaling technique, the value of α generally satisfies $1 < \alpha \leq 3$ [24, 36]. Another application of the cost function (1) with $\alpha = 2$ is to model the queuing delay of users in a TCP/IP communication networks [18]. The goal in the (full information) routing problem is to construct an action profile $a \in A$ with the objective of minimizing the total cost $C(a) = \sum_{e \in E} F_e(l_e^a)$.

1.1.1.1 Extending to Partial Information

In the current paper, we extend the full information routing problem to the *Bayesian routing* problem, where the request of agent $i \in [N]$ is not fully known to all other agents. In this problem variant, agent $i \in [N]$ is associated with a set T_i of *types* so that each type $t_i \in T_i$ specifies its own routing request $(u_i^{t_i}, v_i^{t_i}) \in V \times V$. Let $A_i^{t_i}$ be the set of all (feasible) actions for (the request of) type t_i , namely, all $(u_i^{t_i}, v_i^{t_i})$ -paths in G and let $A_i = \bigcup_{t_i \in T_i} A_i^{t_i}$.

Agent i is also associated with a *prior distribution* p_i over the types in T_i and the crux of the Bayesian routing problem is that agent i should decide on her action while knowing the realization of her own prior distribution p_i (that is, the routing request she should satisfy) but without knowing the realizations of the prior distributions of the other agents $j \neq i$. Formally, let $T = T_1 \times \cdots \times T_N$ be the collection of *type profiles* and $A = A_1 \times \cdots \times A_N$ be the collection of *action profiles*. The set of (feasible) action profiles for a type profile $t \in T$ is denoted by $A^t = A_1^{t_1} \times \cdots \times A_N^{t_N}$ and the prior distribution over the type profiles in T is denoted by p . In this paper, p is assumed to be a product distribution, i.e., the probability of type profile $t \in T$ is $p(t) = \prod_{i=1}^N p_i(t_i)$.

The goal in the Bayesian routing problem is to construct for each agent $i \in [N]$, a *strategy* $s_i : T_i \mapsto A_i$ that maps agent i 's realized type $t_i \in T_i$ to an action $a_i \in A_i^{t_i}$. We emphasize that the decision of agent i is taken irrespective of the other agents' realized types which are not (fully) known to agent i . Intuitively, a strategy s_i can be viewed as a *lookup table* constructed in the “preprocessing stage”, and queried at real-time to determine a (fixed) path for every (u_i, v_i) pair associated with i (cf. *oblivious routing* [30, 35]).

The set of strategies available for agent i is denoted by S_i and $S = S_1 \times \cdots \times S_N$ denotes the set of *strategy profiles*. For each type profile $t \in T$, the strategy profile $s \in S$ determines an action profile $a = s(t) \in A$ defined so that $a_i = s_i(t_i)$, $i \in [N]$. Using this notation, the objective in the Bayesian routing problem is to construct a strategy profile $s \in S$ that minimizes the total cost $C(s) = \mathbb{E}_{t \sim p} [\sum_{e \in E} F_e(l_e^{s(t)})]$.

1.1.1.2 Bayesian Competitive Ratio

Consider an algorithm \mathcal{A} that given a Bayesian routing instance, constructs a strategy profile s . To evaluate the performance of \mathcal{A} , we compare the total cost $C(s)$ to $\mathbb{E}_{t \sim p} [\text{OPT}(t)]$, where $\text{OPT}(t) = \min_{a \in A^t} \sum_{e \in E} F_e(l_e^a)$ is the cost of an optimal action profile for the type profile $t \in T$. This can be regarded as the expectation, over the same prior distribution p , of the

total cost incurred by an omnipotent algorithm that has a global view of the whole type profile t and enjoys unlimited computational resources. The *Bayesian competitive ratio* (BCR) of algorithm \mathcal{A} is the smallest $\beta \geq 1$ such that for every Bayesian routing instance, the strategy profile s constructed by \mathcal{A} satisfies $C(s) \leq \beta \cdot \mathbb{E}_{t \sim p}[\text{OPT}(t)]$.

Alon et al. [4] introduced the related criterion of *Bayesian ignorance* defined as $\frac{C(s^*)}{\mathbb{E}_{t \sim p}[\text{OPT}(t)]}$, where $s^* = \text{argmin}_{s \in S} C(s)$ is an optimal strategy profile for the given instance. This criterion quantifies the implication of the agents' partial knowledge regarding the global system configuration, irrespective of the computational complexity of constructing this optimal strategy profile. By definition, for any strategy profile $s \in S$, $C(s) = \mathbb{E}_{t \sim p}[\sum_{e \in E} F_e(l_e^{s(t)})] \geq \mathbb{E}_{t \sim p}[\min_{a \in A^t} \sum_{e \in E} F_e(l_e^a)]$, which implies that the Bayesian ignorance is at least 1. Notice that the BCR is equivalent to the product of the *approximation ratio* $\frac{C(s)}{C(s^*)}$ and the Bayesian ignorance, therefore it evaluates the loss caused by both algorithmic (computational complexity) considerations and the absence of the global information. The first contribution of the current paper is cast in the following theorem.

► **Theorem 1.** *For the Bayesian routing problem, there exists an algorithm whose BCR depends only on the load exponent parameter α . This algorithm is fully combinatorial and runs in strongly polynomial time.*

We emphasize that the BCR of the algorithm promised in Theorem 1 is independent of the number of agents N , the underlying graph G , the speed scaling factors ξ_e , $e \in E$, and the probability distribution p . Therefore, as α is assumed to be a constant, so is the BCR.

1.1.2 Bayesian Generalized Network Design

1.1.2.1 Generalized Network Design

The (full information) routing problem has recently been generalized by Emek et al. [15] to the wider family of *generalized network design (GND)* problems. In its full information form (the form considered in [15]), a GND instance is defined over N agents and a set E of *resources*. Each agent $i \in [N]$ is associated with an abstract (not necessarily routing) request characterized by a set $A_i \subseteq 2^E$ of (feasible) actions out of which, some action $a_i \in A_i$ should be selected. As in the routing case, the action profile $a = (a_1, \dots, a_N)$ induces a load of $l_e^a = |\{i \in [N] : e \in a_i\}|$ on each resource $e \in E$ that subsequently incurs a cost of $F_e(l_e^a)$, where $F_e : \mathbb{R}_{\geq 0} \mapsto \mathbb{R}_{\geq 0}$ is a resource specific cost function. The goal is to construct an action profile $a \in A = A_1 \times \dots \times A_N$ with the objective of minimizing the total cost $C(a) = \sum_{e \in E} F_e(l_e^a)$.

The request of agent $i \in [N]$ is said to be *succinctly represented* [15] if its corresponding action set A_i can be encoded using $\text{poly}(|E|)$ bits. Identifying the resource set E with the edge set of an underlying graph G , the routing requests defined in Sec. 1.1.1 are clearly succinctly represented since each A_i corresponds to the set of (u_i, v_i) -paths in G , hence A_i can be encoded by specifying u_i and v_i (and G). Other examples for succinctly represented requests, where the resource set E is identified with the edge set of an underlying (directed or undirected) graph $G = (V, E)$, include:

- *multi-routing* requests in directed or undirected graphs, where given a collection $D_i \subseteq V \times V$ of *terminal* pairs, the action set A_i consists of all edge subsets $F \subseteq E$ such that the subgraph (V, F) admits a (u, v) -path for every $(u, v) \in D_i$; and
- *set connectivity* (resp., *set strong connectivity*) in undirected (resp., directed) graphs, where given a set $T_i \subseteq V$ of *terminals*, the action set A_i consists of all edge subsets $F \subseteq E$ that induce on G a connected (resp., strongly connected) subgraph that spans T_i .

All requests mentioned (implicitly or explicitly) hereafter are assumed to be succinctly represented.

1.1.2.2 Bayesian GND

In the current paper, we extend the (full information) GND setting to *Bayesian GND* (BGND). This extension is analogous to the extension of full information routing to Bayesian routing as defined in Sec. 1.1.1. In particular, agent $i \in [N]$ is now associated with a set T_i of types, where each type $t_i \in T_i$ corresponds to a request whose action set is denoted by $A_i^{t_i}$, and a prior distribution p_i over the types in T_i . A strategy s_i of agent i is a function that maps the agent's realized type $t_i \in T_i$ to an action $s_i(t_i) \in A_i^{t_i}$.

Similarly to the notation introduced in Sec. 1.1.1, let $T = T_1 \times \cdots \times T_N$ be the set of type profiles. Let $A_i = \bigcup_{t_i \in T_i} A_i^{t_i}$ and let $A = A_1 \times \cdots \times A_N$ be the set of action profiles. Let S_i be the set of strategies available for agent i and let $S = S_1 \times \cdots \times S_N$ be the set of strategy profiles. Given a strategy profile $s \in S$ and a type profile $t \in T$, let $a = s(t) \in A$ be the action profile defined so that $a_i = s_i(t_i)$, $i \in [N]$. The goal in the BGND problem is to construct a strategy profile $s \in S$ with the objective of minimizing the total cost

$$C(s) = \mathbb{E}_{t \sim p} \left[\sum_{e \in E} F_e \left(l_e^{s(t)} \right) \right]. \quad (2)$$

The BCR of Algorithm \mathcal{A} is the smallest $\beta \geq 1$ such that for every BGND instance, the strategy profile $s \in S$ constructed by \mathcal{A} satisfies $C(s) \leq \beta \cdot \mathbb{E}_{t \sim p}[\text{OPT}(t)]$, where $\text{OPT}(t) = \min_{a \in A^t} \sum_{e \in E} F_e(l_e^a)$.

1.1.2.3 Generalized Cost Functions

In addition to the generalization of (full information) routing to GND, [15] also generalizes the cost functions defined in Eq. (1) to cost functions of the form

$$F_e(l) = \sum_{j \in [q]} \xi_{e,j} \cdot l^{\alpha_j}, \quad (3)$$

where q is a positive integer, $\xi_{e,j}$ is a positive real for every $e \in E$ and $j \in [q]$, and α_j is a constant real no smaller than 1 for every $j \in [q]$.² We define $\alpha_{\max} = \max_{j \in [q]} \alpha_j$ and assume hereafter that $\alpha_{\max} > 1$. As discussed in [15], this generalization of Eq. (3) is not only interesting from a theoretical perspective, but also makes the model more applicable to practical network energy saving applications. Indeed, in realistic communication networks, a link often consists of several different devices (e.g., transmitter/receiver, amplifier, adapter), all of which are operating when the link is in use. As their energy consumption can vary in terms of the load exponents and speed scaling factors [36], Eq. (3) may often provide a more accurate abstraction of the actual link's power consumption.

1.1.2.4 Action Oracles

For a BGND problem \mathcal{P} , this paper develops a framework which generates an algorithm with BCR $O(\varrho^{\alpha_{\max}})$ when provided with an *action ϱ -oracle* for \mathcal{P} . An action ϱ -oracle with parameter $\varrho \geq 1$ for BGND problem \mathcal{P} (cf. the *reply ϱ -oracles* of [15]) is a procedure that given agent $i \in [N]$, type $t_i \in T_i$, and a *weight* vector $w \in \mathbb{R}_{>0}^E$, generates an action $a_i \in A_i^{t_i}$ such that $\sum_{e \in a_i} w(e) \leq \varrho \cdot \sum_{e \in a'_i} w(e)$ for any action $a'_i \in A_i^{t_i}$. An *exact action oracle* is an action ϱ -oracle with parameter $\varrho = 1$.

² The cost functions considered in [15] have a fixed additional term, capturing the resource's *startup cost*, that makes them even more general. Due to technical difficulties, in the current paper we were not able to cope with this additional term.

Notice that the optimization problem behind the action oracle is *not* a BGND problem: It deals with a *single* type of a *single* agent and the role of the resource cost functions is now taken by the weight vector. These differences often make it possible to implement the action oracle with known (approximation) algorithms.

For example, the Bayesian routing problem, which requires paths between the given node pairs, admit an exact action oracle implemented using, e.g., Dijkstra's shortest path algorithm [14, 19]. In contrast, the BGND problem with set connectivity requests in undirected graphs (P1), the BGND problem with set strong connectivity requests in directed graphs (P2), the BGND problem with multi-routing requests in undirected graphs (P3), and the BGND problem with multi-routing requests in directed graphs (P4) do not admit exact action oracles unless $P = NP$ as these would imply exact (efficient) algorithms for the *Steiner tree*, *strongly connected Steiner subgraph*, *Steiner forest*, and *directed Steiner forest* problems, respectively. However, employing known approximation algorithms for the latter (Steiner) problems, one concludes that BGND problem (P1) admits an action ϱ -oracle for $\varrho \leq 1.39$ [9]; BGND problem (P2) admits an action ν^ϵ -oracle, where ν is the number of terminals [10]; BGND problem (P3) admits an action 2-oracle [1]; and BGND problem (P4) admits an action $k^{1/2+\epsilon}$ -oracle, where k is the number of terminal pairs [11]. This means, in particular, that BGND problems (P1) and (P3) always admit an action ϱ -oracle with a constant approximation ratio ϱ , whereas BGND problems (P2) and (P4) admit such an oracle when ν and k are fixed [1, 10, 11, 9]. The guarantees of our approximation framework are cast in the following theorem.

► **Theorem 2.** *Consider a BGND problem \mathcal{P} with an action ϱ -oracle $\mathcal{O}_{\mathcal{P}}$. When provided access to $\mathcal{O}_{\mathcal{P}}$, the framework proposed in this paper generates an algorithm $\mathcal{A}_{\mathcal{P}}$ whose BCR depends only on the load exponent parameters $\alpha_1, \dots, \alpha_q$ of Eq. (3). This framework is fully combinatorial and runs in strongly polynomial time, hence if $\mathcal{O}_{\mathcal{P}}$ can be implemented to run in strongly polynomial time, then so can $\mathcal{A}_{\mathcal{P}}$.*

Again, we emphasize that the BCR of the algorithm promised in Theorem 2 is independent of the number of agents N , the number of resources $|E|$, the speed scaling factors $\xi_{e,j}$, $j \in [q]$, $e \in E$, and the probability distribution p . Therefore, as $\alpha_1, \dots, \alpha_q$ are assumed to be constants, so is the BCR. Since the Bayesian routing problem admits an exact action oracle, Theorem 1 follows trivially from Theorem 2. Throughout the remainder of this paper, we focus on the BGND framework promised in Theorem 2.

1.2 Related Works

The technical framework that we use is inspired by [15]. Sec. 3 gives a detailed technical overview including a full comparison.

In the full information case, network design problems with superadditive cost functions as defined in Eq. (1) have been extensively studied with the motivation of improving the energy efficiency of networks [5, 6, 28]. To the best of our knowledge, none of these studies has been extended to the Bayesian case.

In the research works on oblivious routing (e.g., [17, 35, 27, 23]), the absence of global information in routing is modeled in an adversarial (non-Bayesian) manner. In particular, oblivious routing assumes that no knowledge about t_{-i} is available when determining every a_i , and the performance of the algorithm is evaluated by means of its *competitive ratio* $\max_{t \in T} \frac{\sum_{e \in E} F_e(l_e^s(t))}{\text{OPT}(t)}$. For the cost function $F_e(l) = l^\alpha$ with $\alpha > 1$, Englert and Räcke [17]

propose an $O(\log^\alpha |V|)$ -competitive oblivious routing algorithm for the scenario where the traffic requests are allowed to be partitioned into fractional flows. Shi et al. [35] prove that for such a cost function, there exists no oblivious routing algorithm with competitive ratio $O\left(|E|^{\frac{\alpha-1}{\alpha+1}}\right)$ when it is required to choose an integral path for every request.

The Bayesian approach is often used in the game theoretic literature to model the uncertainty a player experiences regarding the actions taken by the other players. Roughgarden [32] studies a *routing game* (among other things) in which the players share (equally) the cost of the edges they use and proposes a theoretical tool called *smoothness* to analyze the *price of anarchy* (PoA) of this game in a Bayesian setting, defined as $\frac{\max_{s \in S^{\text{BNE}}} C(s)}{\mathbb{E}_{t \sim p}[\text{OPT}(t)]}$, where S^{BNE} denotes the set of *Bayes-Nash equilibria*. In particular, he proves that with the cost function $F_e(l) = \xi_{e,1} \cdot l + \xi_{e,2} \cdot l^2$, the PoA is bounded by $\frac{5}{2}$. We employ the smoothness toolbox in our algorithmic construction, as further described in Sec. 5 (see also the overview in Sec. 3, as well as the detail in Sec. 6 of the full version [16]).

Alon et al. [4] investigate the Bayesian routing game with a constant cost function $F_e = \xi_e$ and prove that the Bayesian ignorance $\frac{C(s^*)}{\mathbb{E}_{t \sim p}[\text{OPT}(t)]}$ is bounded by $O(N)$ (resp., $O(\log |E|)$) in directed (resp., undirected) graphs $G = (V, E)$. They also introduce game theoretic variants of the Bayesian ignorance notion and analyze them in that game.

To deal with the inherent uncertainty of the demand in realistic networks, many research works have been conducted on *stochastic network design* [22, 13, 31], formulated as a *two-stage stochastic optimization* problem: in the first stage, each link in the network has a fixed cost and the algorithm needs to make decisions to purchase links knowing the probability distribution over the network demands; in the second stage, the network demands are realized (according to the aforementioned probability distribution) and should be satisfied, which may require purchasing additional links, this time with an inflated cost. The objective is to minimize the total cost of the two stages plus a load dependent term, in expectation.

The BGND setting considered in the current paper is different from two-stage stochastic optimization (particularly, stochastic network design) in several aspects, the most significant one is that in BGND, an agent’s strategy should dictate her “complete action” (e.g., a path for routing requests) for every possible type, obliviously of the realized types of the other agents. In particular, one cannot “update” the agents’ actions and purchase additional resources at a later stage to satisfy the realized demands. Moreover, the current paper evaluates the performance of a BGND algorithm by means of its BCR that takes into consideration computational complexity limitations as well as the lack of global information (see Sec. 1.1) whereas the literature on two-stage stochastic optimization typically evaluates algorithms using standard approximation guarantees that accounts only for computational complexity limitations.

In [20], Garg et al. investigate online combinatorial optimization problems where the requests arriving online are drawn independently and identically from a known distribution. As an example, Garg et al. [20] study the online Steiner tree problem on an undirected graph $G = (V, E)$. In this problem, at each step the algorithm receives a terminal that is drawn independently from a distribution over V , and needs to maintain a subset of edges connecting all the terminals received so far.

Our work differs from [20] in following four aspects. First, in the stochastic online optimization problem studied in [20], when each request i arrives, the previous requests $\{1, \dots, i-1\}$ have been realized, and the realization is known. By contrast, in the BGND problem, every agent i needs to be served without knowing the actual realization of the other agents. Second, the cost function studied in [20] maps each resource e to a fixed toll, which

is subadditive in the number of requests using e , while our cost function is superadditive. Third, in the BGND problem with the set connectivity requests, for each agent i , each type t_i is a set of terminals rather than a single terminal, and each action in $A_i^{t_i}$ is a Steiner tree spanning over the set of terminals corresponding to t_i . Fourth, in the BGND problem, each prior distribution p_i is over the types of agent i , while there is no distribution over the agents.

1.3 Paper Organization

The rest of this paper is organized as follows. Sec. 2 introduces some of the concepts employed in our approximation framework together with some notation and terminology. The main challenges that we had to overcome when developing this framework and some of the techniques used for that purpose are discussed in Sec. 3. Sec. 4 is dedicated to a detailed exposition of our approximation framework. Its performance is then analyzed in Sec. 5 using certain game theoretic properties.

2 Preliminaries

We follow the common convention that for an N -tuple $x = (x_1, \dots, x_N)$ and for $i \in [N]$, the notation x_{-i} denotes the $(N-1)$ -tuple $(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_N)$. Likewise, for a Cartesian product $X = X_1 \times \dots \times X_N$ and for $i \in [N]$, the notation X_{-i} denotes the Cartesian product $X_1 \times \dots \times X_{i-1} \times X_{i+1} \times \dots \times X_N$.

2.1 The BGND Game

Given an instance $\mathcal{I} = \langle N, E, \{T_i, p_i\}_{i \in [N]}, \{\xi_{e,j}\}_{e \in E, j \in [q]}, \{\alpha_j\}_{j \in [q]} \rangle$ of a BGND problem \mathcal{P} , we define a *BGND game* by associating every agent $i \in [N]$ with a strategic player who decides on the strategy s_i with the objective of minimizing her own individual cost defined as follows. Given an action profile $a \in A$ and a resource $e \in E$, the corresponding cost $F_e(l_e^a)$ is equally divided among the players $i \in [N]$ satisfying $e \in a_i$; in other words, the *cost share* of player i in resource e under action profile a , denoted by $f_{i,e}(a)$, is defined to be

$$f_{i,e}(a) = \begin{cases} 0, & e \notin a_i \\ \frac{F_e(l_e^a)}{|\{i: e \in a_i\}|} = \sum_j \xi_{e,j} (l_e^a)^{\alpha_j - 1}, & \text{otherwise} \end{cases}.$$

Informally, the individual cost of player i is the sum of her cost shares over all resources.

For a more formal treatment of the BGND game, we occasionally need to explicitly specify the type t_i of player i in the expressions involving her cost share in which case we use the notation $f_{i,e}(t_i; a)$, following the convention that $f_{i,e}(t_i; a) = f_{i,e}(a)$ if $a_i \in A_i^{t_i}$; and $f_{i,e}(t_i; a) = \infty$ otherwise. The individual cost of a player i with respect to the type t_i and a fixed action profile a is defined as $C_i(t_i; a) = \sum_{e \in E} f_{i,e}(t_i; a)$. Correspondingly, for each player $i \in [N]$ and each type $t_i \in T_i$, we define the *type-specified* expected individual cost $C_i(t_i; s) = \mathbb{E}_{t_{-i} \sim p_{-i}} [C_i(t_i; s(t_i, t_{-i}))]$. The objective function that player i wishes to minimize is her *type-averaged* expected individual cost $C_i(s) = \mathbb{E}_{t_i \sim p_i} [C_i(t_i; s)]$, irrespective of the total cost $C(s)$, often referred to as the *social cost*.

Let $f_{i,e}(a_i; s_{-i}) = \mathbb{E}_{t_{-i} \sim p_{-i}} [f_{i,e}(a_i, s_{-i}(t_{-i}))]$ be the expected cost share of player $i \in [N]$ on resource $e \in E$ with respect to action $a_i \in A_i$ and strategy profile $s_{-i} \in S_{-i}$. Fixing $a_{-i} \in A_{-i}$ (resp., $s_{-i} \in S_{-i}$), the cost share $f_{i,e}(a_i, a_{-i})$ (resp., expected cost share $f_{i,e}(a_i; s_{-i})$) of

player i on resource e is the same for every action $a_i \in A_i$ such that $e \in a_i$. Therefore, it is often convenient to ignore the specifics of action a_i and use the notations $f_{i,e}(+, a_{-i})$ and $\hat{f}_{i,e}(+; s_{-i})$ instead of $f_{i,e}(a_i, a_{-i})$ and $\hat{f}_{i,e}(a_i; s_{-i})$, respectively, given that $e \in a_i$.³

2.2 Definitions for the Algorithm Design and Analysis

The following definitions play key roles in the design and analysis of our framework.

► **Definition (Choice Function [32]).** A choice function $\sigma : T \mapsto A$ maps every type profile $t \in T$ to an action profile $a \in A^t$. The action specified by σ for player $i \in [N]$ with respect to type profile t is denoted by $\sigma_i(t)$. In particular, the choice function that maps each type profile t to an action profile that realizes $\text{OPT}(t)$ is denoted by σ^* .

► **Definition (Smoothness [32]).** Given parameters $\lambda > 0$ and $0 < \mu < 1$, a BGND game is said to be (λ, μ) -smooth if $\sum_{i \in [N]} C_i(t_i; (\sigma_i^*(t), a_{-i})) \leq \lambda \cdot \text{OPT}(t) + \mu \cdot \sum_{i \in [N]} C_i(t'_i, a)$ for every type profiles $t, t' \in T$ and action profile $a \in A^{t'}$.

► **Definition (Potential Function).** A function $\Phi : S \mapsto \mathbb{R}_{\geq 0}$ is said to be a potential function of the BGND game if $\Phi(s) - \Phi(s'_i, s_{-i}) = C_i(s) - C_i(s'_i, s_{-i})$ for every strategy profile $s \in S$, player $i \in [N]$, and strategy $s'_i \in S_i$. The potential function $\Phi(\cdot)$ is said to be K -bounded for a parameter $K \geq 1$ if $\Phi(s) \leq C(s) \leq K \cdot \Phi(s)$ for every strategy profile $s \in S$.

► **Definition ($(\underline{\eta}, \bar{\eta})$ -Estimation).** Given real parameters $\underline{\eta}, \bar{\eta} \geq 1$, a value x is said to be an $(\underline{\eta}, \bar{\eta})$ -estimation of the expected cost share $\hat{f}_{i,e}(a_i; s_{-i})$ (resp., $\hat{f}_{i,e}(+; s_{-i})$) if it satisfies $x/\underline{\eta} \leq \hat{f}_{i,e}(a_i; s_{-i}) \leq x \cdot \bar{\eta}$ (resp., $x/\underline{\eta} \leq \hat{f}_{i,e}(+; s_{-i}) \leq x \cdot \bar{\eta}$). We typically denote this estimation x by $\hat{f}_{i,e}(a_i; s_{-i})$ (resp., $\hat{f}_{i,e}(+; s_{-i})$). The BGND game is said to be poly-time $(\underline{\eta}, \bar{\eta})$ -estimable if for every player $i \in [N]$ and strategy profile $s_{-i} \in S_{-i}$, there exists an algorithm which runs in time $\text{poly}(N, q, |T_1|, \dots, |T_N|)$ and outputs an $(\underline{\eta}, \bar{\eta})$ -estimation of the expected cost share $\hat{f}_{i,e}(+; s_{-i})$. The BGND game is said to be tractable if it is poly-time $(\underline{\eta}, \bar{\eta})$ -estimable with $\bar{\eta} = \underline{\eta} = 1$.

Fix some player $i \in [N]$, type $t_i \in T_i$, and $(\underline{\eta}, \bar{\eta})$ -estimations $\hat{f}_{i,e}(s_i(t_i); s_{-i})$, $e \in E$. With respect to these variables, let $\hat{C}_i(t_i; s) = \sum_{e \in E} \hat{f}_{i,e}(s_i(t_i); s_{-i})$ and $\hat{C}_i(s) = \mathbb{E}_{t_i \sim p_i}[\hat{C}_i(t_i; s)]$. By the linearity of expectation, we know that $\hat{C}_i(t_i; s)/\underline{\eta} \leq C_i(t_i; s) \leq \hat{C}_i(t_i; s) \cdot \bar{\eta}$ and $\hat{C}_i(s)/\underline{\eta} \leq C_i(s) \leq \hat{C}_i(s) \cdot \bar{\eta}$. Consequently, we refer to $\hat{C}_i(t_i; s)$ and $\hat{C}_i(s)$ as $(\underline{\eta}, \bar{\eta})$ -estimations of $C_i(t_i; s)$ and $C_i(s)$, respectively.

► **Definition (Approximate Best Response).** For strategy profile $s \in S$ and player $i \in [N]$, strategy $s_i \in S_i$ is said to be an approximate best response (ABR) of i with approximation parameter $\chi \geq 1$ if $C_i(s_i, s_{-i}) \leq \chi \cdot C_i(s'_i, s_{-i})$ holds for any $s'_i \in S_i$. We may omit the explicit mention of the approximation parameter χ when it is clear from the context. A best response (BR) is an ABR with approximation parameter $\chi = 1$.

► **Definition (Approximate Best Response Dynamics).** An approximate best response dynamic (ABRD) is a procedure that starts from a predetermined strategy profile $s^0 \in S$ and generates a series of strategy profiles s^1, \dots, s^R such that for every $1 \leq r \leq R$, there exists some player $i \in [N]$ satisfying (1) $s_{-i}^r = s_{-i}^{r-1}$; and (2) s_i^r is an ABR of i to s_{-i}^{r-1} .

³ To avoid ambiguity concerning the definition of $f_{i,e}(+, a_{-i})$ and $\hat{f}_{i,e}(+; s_{-i})$ for resources $e \notin A_i$, we assume (in the scope of using these notations) that $A_i = E$ for all $i \in [N]$. This is without loss of generality as one can augment T_i with a virtual type \tilde{t}_i such that $A_i^{\tilde{t}_i} = \{E\}$ and $p_i(\tilde{t}_i)$ is arbitrarily small.

3 Overview of the Main Challenges and Techniques

The approximation framework presented in Sec. 4 for BGND problems is inspired by the framework designed in [15] for full information GND problems only in the conceptual sense that both algorithms employ approximate best response dynamics. In a high-level, for a certain number R of rounds that will be carefully chosen in order to achieve the approximation promise, and starting from some properly chosen initial strategy profile s^0 , for each round $1 \leq r \leq R$ the strategy profile s^r is generated from s^{r-1} in the following manner:

1. For every player $i \in [N]$ and resource $e \in E$, compute an $(\underline{\eta}, \bar{\eta})$ -estimation $\widehat{f}_{i,e}(+; s_{-i}^{r-1})$ of the expected cost share $f_{i,e}(+; s_{-i}^{r-1})$.
2. For every player $i \in [N]$, construct the strategy s'_i by mapping each type $t_i \in T_i$ to the action $a_i \in A_i^{t_i}$ computed by invoking the action ϱ -oracle with weight vector w defined by setting $w(e) = \widehat{f}_{i,e}(+; s_{-i}^{r-1})$.
3. Choose player $i \in [N]$ according to the game theoretic criterion presented in Sec. 4 regarding the estimations $\widehat{C}_i(s^{r-1})$ and $\widehat{C}_i(s'_i, s_{-i}^{r-1})$ of the type-averaged expected individual costs. Construct s^r by updating the strategy of the chosen player i to s'_i .

However, beyond the similar high-level structure, the technical construction in this paper is entirely different from [15] since the incomplete information assumption of the BGND setting exhibits new algorithmic challenges that require novel techniques. Specifically, the main challenges that our technical analysis in this paper handles are as follows.

A first obstacle here is the difficulty in computing the estimation $\widehat{f}_{i,e}(+; s_{-i}^{r-1}) = \mathbb{E}_{t_{-i} \sim p_{-i}}[f_{i,e}(+, s_{-i}(t_{-i}))]$ in step 1 since there are exponentially (in N) many possibilities for t_{-i} . Another source of difficulty in this regard is that the function $f_{i,e}(+, s_{-i}(t_{-i}))$ is nonlinear in $l_e^{s_{-i}(t_{-i})}$. One may hope that Jensen's inequality [26] can resolve this issue, however, as we explain in the technical sections, it is not enough for obtaining proper bounds on both $\underline{\eta}$ and $\bar{\eta}$. This obstacle is addressed in Sec. 5 (and Sec. 8 of the full version [16]) where we employ probabilistic tools from [8] and using Cantelli's inequality [34] to obtain the required estimation of the expression $\mathbb{E}_{t_{-i} \sim p_{-i}}[f_{i,e}(+, s_{-i}(t_{-i}))]$.

A second obstacle is that the ABRD-based approximation framework expresses its approximation guarantees in terms of smoothness parameters and bounded potential functions. However, neither the smoothness parameters nor the existence of a bounded potential function are known for the BGND game that we have defined here. We provide a new analysis for these two issues in Sec. 6 and Sec. 7 of the full version [16], respectively.

A third obstacle involves the stopping condition of the best response dynamics. A stopping condition for the full information case, via the smoothness framework, was developed by [33] (showing that if the current outcome in a best response dynamics is far from optimal there must exist a player whose best response significantly improves his own utility). For the Bayesian case, to the best of our knowledge, no such general stopping condition was known prior to the current paper. In fact, the smoothness framework for the Bayesian case which was developed in [32] did not include any results on best response dynamics. One specific technical difficulty is that Bayesian smoothness is defined in [32] w.r.t. a deviation to the optimal choice function rather than to a best response. This obstacle is resolved in Sec. 5 of the full version [16] where we provide such a stopping condition by proving that if the outcome of the current step of the ABRD in the Bayesian case is far from optimal, there must exist a player whose approximate best response must significantly improve her utility.

A fourth obstacle regards the output of the algorithm, once the ABRD terminates. Although we prove that there exists at least one strategy profile s^r , $1 \leq r \leq R$, with a sufficiently small social cost $C(s^r)$, we do not know how to find it. In particular, we wish to emphasize that we cannot simply evaluate the social cost function $C(\cdot)$ (see Eq. (2)) due

to the exponential number of type profiles. This obstacle does not exist in [15] where they can explicitly go over all steps of the full information ABRD and find the exact step whose outcome has minimal cost. To resolve this issue, we output the last strategy profile s^R generated in the ABRD and bound its loss. This is described in Sec. 5 of the full version [16].

Our technical constructions and our analysis employ various techniques from algorithmic game theory, demonstrating once again (as in [15]) the usefulness of this literature as a toolbox for algorithmic constructions that, on the face of it, have nothing to do with selfish agents. In particular, in this paper (and as assumed in the literature on oblivious routing [21, 17, 35]), we construct an algorithm that receives a correct input and outputs routing tables that the agents are going to follow without issues of selfish deviations.

4 The Algorithm

In this part, we present an algorithm, which is referred to as **Bayes-ABRD**, for a given BGND problem \mathcal{P} . The algorithm is assumed to have free access to an action ϱ -oracle for \mathcal{P} , which is denoted by $\mathcal{O}_{\mathcal{P}}$.

With an input instance $\mathcal{I} = \langle N, E, \{T_i, p_i\}_{i \in [N]}, \{\xi_{e,j}\}_{e \in E, j \in [q]}, \{\alpha_j\}_{j \in [q]} \rangle$, the first step of the algorithm is to (conceptually) construct a BGND game, and choose a tuple of parameters $(\lambda, \mu, K, \underline{\eta}, \bar{\eta})$ such that the BGND game

1. is (λ, μ) -smooth with $\varrho(\underline{\eta}\bar{\eta})^2\mu < 1$,
2. has a potential function Φ that is K -bounded,
3. is poly-time $(\underline{\eta}, \bar{\eta})$ -estimable.

The existence and exact values of the parameters in this tuple are presented in Sec. 5.

► **Lemma 3.** *For any $i \in [N]$ and any $s_{-i} \in S_{-i}$, there exists a $\text{poly}(|E|, N, q, \{|T_i|\}_{i \in [N]})$ -time procedure which generates a strategy $s_i \in S_i$ and the corresponding $(\underline{\eta}, \bar{\eta})$ -estimation $\hat{C}_i(s_i, s_{-i})$ of the individual costs such that $\hat{C}_i(s_i, s_{-i}) \leq \varrho \cdot \eta \cdot C_i(s'_i, s_{-i})$ for any $s'_i \in S_i$. This means in particular that s_i is an ABR of i to s_{-i} with approximation parameter $\varrho \cdot \underline{\eta}\bar{\eta}$.⁴*

Employing the procedure promised by Lemma 3, **Bayes-ABRD** simulates an ABRD of at most R rounds s^0, s^1, \dots for the BGND game induced by \mathcal{I} . Here R is a positive integer depending on the tuple $(\lambda, \mu, K, \underline{\eta}, \bar{\eta})$, and its exact value is also deferred to the following parts (Sec. 5). The ABRD simulated in our algorithm is done as follows.

Each player i chooses her initial strategy s_i^0 by taking each $s_i^0(t_i)$ to be the action generated by $\mathcal{O}_{\mathcal{P}}$ for type t_i with respect to the weight vector w^0 defined by setting $w^0(e) = \sum_{j \in [q]} \xi_{e,j}$, that is, as if i is playing alone. The obtained strategy s_i^0 is broadcast by player i to all the other players such that the full strategy profile s^0 is known by every player. Assuming that s^{r-1} , $1 \leq r \leq R$, was already constructed and known by all the players, s^r is obtained as follows. Every player $i \in [N]$ employs the procedure promised by Lemma 3 to generate an ABR \hat{s}_i^{r-1} to s_{-i}^{r-1} , and computes $\Delta_i^r = \hat{C}_i(s^{r-1}) - (\underline{\eta}\bar{\eta}) \cdot \hat{C}_i(\hat{s}_i^{r-1}, s_{-i}^{r-1})$. Both the strategy \hat{s}_i^{r-1} and the value Δ_i^r are broadcast to all the other players. If $\Delta_i^r \leq 0$ for all $i \in [N]$, then the ABRD stops, and every player i sets $s_i^r = s_i^{r-1}$; in this case, we say that the ABRD *converges*. Otherwise, fix $\Delta^r = \sum_{i \in [N]} \Delta_i^r$ and choose some player $i' \in [N]$ so that $\Delta_{i'}^r > 0$ and $\Delta_{i'}^r \geq \frac{1}{N}\Delta^r$ to update her strategy, setting $s^r = (\hat{s}_{i'}^{r-1}, s_{-i'}^{r-1})$ (the existence of such a player is guaranteed by the pigeonhole principle, and ties are always broken by choosing the player with the smallest index). Such an update can be performed by each

⁴ All subsequent occurrences of the term ABR (and ABRD) share the same approximation parameter $\varrho\underline{\eta}\bar{\eta}$, hence we may refrain from mentioning this parameter explicitly.

player in a distributed manner, as every player has the knowledge of the full vectors $\{s_i^r\}_{i \in [N]}$ and $\{\Delta_i^r\}_{i \in [N]}$. When the ABRD terminates (either because it has reached round $r = R$ or because it converges), **Bayes-ABRD** outputs the strategy generated in the last round.

► **Remark.** Note that **Bayes-ABRD** is designed for computing the strategy profile, not for invoking the strategies to decide the actions in real-time. All the operations of **Bayes-ABRD**, including broadcasting the strategy \hat{s}_i^{r-1} and the value Δ_i^r for every player i in every round $r \in [R]$, are carried out in a “precomputing stage” without seeing the realized type profile. The decision making that happens in real-time does not involve any further communication.

5 Analysis Sketch

Using the property of smoothness parameters, our analysis first gives the upper bound on the BCR with the tuple $(\lambda, \mu, K, \underline{\eta}, \bar{\eta})$ of parameters.⁵

► **Theorem 4.** Let $Q = \frac{2(\underline{\eta}\bar{\eta})N}{1-\varrho(\underline{\eta}\bar{\eta})^2\mu}$. If $R = \lceil Q \cdot \ln(KN^{\alpha_{\max}-1}) \rceil$, then the output s^{out} of **Bayes-ABRD** satisfies $C(s^{out}) \leq \frac{2K\varrho(\underline{\eta}\bar{\eta})^2\lambda}{1-\varrho(\underline{\eta}\bar{\eta})^2\mu} \cdot \mathbb{E}_{t \sim T}[\text{OPT}(t)]$.

Next, we consider the case where the parameters ϱ , $\underline{\eta}$ and $\bar{\eta}$ are fixed, and focus on finding proper smoothness parameters (λ, μ) such that the BGND game is (λ, μ) -smooth with $\mu < 1/[\varrho(\underline{\eta}\bar{\eta})^2]$. For any $\mu' \in (0, \frac{1}{\varrho(\underline{\eta}\bar{\eta})^2})$, define $g_{\mu'}(x) = (x+1)^{\alpha_{\max}-1} - \mu' \cdot x^{\alpha_{\max}}$ and $h(x) = \left[(\alpha_{\max}-1)(x+1)^{\alpha_{\max}-2} \right] / \left[\alpha_{\max} \cdot x^{\alpha_{\max}-1} \right]$. Define $\gamma_{z'}$ to be the unique positive root of $(x+1)^{z'-1} = x^{z'}$ for any $z' \geq 1$ [2]. Let $\mu_\alpha = h(\varrho(\underline{\eta}\bar{\eta})^2 \cdot \gamma_{\alpha_{\max}})$, and $\lambda_\alpha = g_{\mu_\alpha}(\varrho(\underline{\eta}\bar{\eta})^2 \cdot \gamma_{\alpha_{\max}})$. Then we have the following result on the smoothness.

► **Theorem 5.** The BGND game is $(\lambda_\alpha, \mu_\alpha)$ -smooth, and $\varrho(\underline{\eta}\bar{\eta})^2\mu_\alpha < 1 - 1/\alpha_{\max}$.

We then proceed to prove that the BGND game admits a potential function that is K -bounded with $K = \lceil \alpha_{\max} \rceil$.

► **Theorem 6.** For the BGND game, there exists a potential function $\Phi(s)$ that satisfies $\Phi(s) \leq C(s) \leq \lceil \alpha_{\max} \rceil \cdot \Phi(s)$ for any strategy profile s .

Now it remains to compute and analyze the $(\underline{\eta}, \bar{\eta})$ -estimation of the expected cost shares. For any $z \in (0, 1)$ and $z' \geq 1$, define $b_z = ((\beta^\circ)^2 + 1)(1 - \frac{1}{\beta^\circ})^{-z}$ with β° being the unique root of $2\beta^3 - (z+2)\beta^2 - 2 = 0$ in the interval $(1, +\infty)$, and $B_{z'}$ to be the fractional Bell number with the parameter z' [6, 28]. Our analysis utilizes the following propositions.

► **Lemma 7** ([8]). Let $\{X_1, X_2, \dots, X_k, \dots\}$ be a finite set of mutually independent random variables following the Bernoulli distribution supported on $\{0, 1\}$. Then for any $z \geq 1$, $\mathbb{E}\left[\left(\sum_k X_k\right)^z\right] \leq B_z \cdot \max\left\{\mathbb{E}\left[\sum_k X_k\right], \left(\mathbb{E}\left[\sum_k X_k\right]\right)^z\right\}$.

► **Lemma 8.** Let $\{X_1, X_2, \dots, X_k, \dots\}$ be a finite set of Bernoulli random variables that are mutually independent. For any $z' \in (0, 1)$, $\frac{1}{b_{z'}} \leq \mathbb{E}\left[\left(1 + \sum_k X_k\right)^{z'}\right] \leq \left(\mathbb{E}\left[1 + \sum_k X_k\right]\right)^{z'}$.

⁵ The proof of Theorem 4 bears similarity to the analysis in [33, 15]. Hence it is deferred to the attached full version. The main differences between that proof of Theorem [33, 15] are discussed in Sec. 3.

For each action a_i of player i and each resource e , denote the indicator of whether e is contained in a_i by $\delta(a_i, e)$. Formally,

$$\delta(a_i, e) = \begin{cases} 0 & \text{if } e \notin a_i \\ 1 & \text{otherwise} \end{cases}.$$

► **Theorem 9.** For any player i , any edge e , any action a_i , and any strategies s_{-i} , let

$$\widehat{f}_{i,e}(+; s_{-i}) = \sum_{j \in [q]} \xi_{e,j} \left[1 + \sum_{i' \neq i} \sum_{t_{i'} \in T_{i'}} p_{i'}(t_{i'}) \delta(s_{i'}(t_{i'}), e) \right]^{\alpha_j - 1}, \quad (4)$$

then $\frac{\widehat{f}_{i,e}(+; s_{-i})}{\max \left\{ 1, \max_{j: \alpha_j \in (1,2)} b_{\alpha_j - 1} \right\}} \leq f_{i,e}(+; s_{-i}) \leq \widehat{f}_{i,e}(+; s_{-i}) \cdot \left\{ 1, \max_{j: \alpha_j \geq 2} B_{\alpha_j - 1} \right\}$.

Sketch of Proof. Let a_i be an action in A_i satisfying $e \in a_i$. By definition, we have

$$\begin{aligned} f_{i,e}(+; s_{-i}) &= \mathbb{E}_{t_{-i} \sim p_{-i}} [f_{i,e}(a_i, s_{-i}(t_{-i}))] \\ &= \sum_{j \in [N]} \xi_{e,j} \cdot \mathbb{E}_{t_{-i} \sim p_{-i}} [(I_e^{a_i, s_{-i}(t_{-i})})^{\alpha_j - 1}] \\ &= \sum_{j \in [N]} \xi_{e,j} \cdot \mathbb{E}_{t_{-i} \sim p_{-i}} \left[\left(1 + \sum_{i' \in [N]: i' \neq i} \delta(s_{i'}(t_{-i}(i')), e) \right)^{\alpha_j - 1} \right] \\ &= \sum_{j \in [N]} \xi_{e,j} \mathbb{E}_{\{t_{i'} \sim p_{i'}\}_{i' \neq i}} \left[\left(1 + \sum_{i' \neq i} \delta(s_{i'}(t_{i'}), e) \right)^{\alpha_j - 1} \right]. \end{aligned}$$

The last transition holds because the prior distribution p is assumed to be a product distribution.

Now define a finite set of mutually independent Bernoulli random variables $\{X_{i',e}(s)\}_{i' \neq i}$ such that each $X_{i',e}(s)$ takes the value 1 with probability $\sum_{t_{i'}: e \in s_{i'}(t_{i'})} p_{i'}(t_{i'})$. Then it can be inductively proved that

$$\mathbb{E}_{\{t_{i'} \sim p_{i'}\}_{i' \neq i}} \left[\left(1 + \sum_{i' \neq i} \delta(s_{i'}(t_{i'}), e) \right)^{\alpha_j - 1} \right] = \mathbb{E} \left[\left(1 + \sum_{i' \neq i} X_{i',e}(s) \right)^{\alpha_j - 1} \right].$$

Recall that the constant 1 in the last expression above can also be viewed as a Bernoulli random variable which equals to 1 with probability 1. For every $\alpha_j \geq 2$, Lemma 7 gives

$$\begin{aligned} \mathbb{E} \left[\left(1 + \sum_{i' \neq i} X_{i',e}(s) \right)^{\alpha_j - 1} \right] &\leq B_{\alpha_j - 1} \cdot \max \left\{ \mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right], \left(\mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right] \right)^{\alpha_j - 1} \right\} \\ &= B_{\alpha_j - 1} \cdot \left(\mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right] \right)^{\alpha_j - 1}. \end{aligned}$$

The second line holds because $\mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right] > 1$. Similarly, it can be derived from Lemma 8 that for every $\alpha_j \in (1, 2)$,

$$\mathbb{E} \left[\left(1 + \sum_{i' \neq i} X_{i',e}(s) \right)^{\alpha_j - 1} \right] \leq \left(\mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right] \right)^{\alpha_j - 1},$$

which also trivially holds for $\alpha_j = 1$. So, $\mathbb{E} \left[\left(1 + \sum_{i' \neq i} X_{i',e}(s) \right)^{\alpha_j - 1} \right] \leq \max \left\{ 1, \max_{j: \alpha_j \geq 2} B_{\alpha_j - 1} \right\} \left(\mathbb{E} \left[1 + \sum_{i' \neq i} X_{i',e}(s) \right] \right)^{\alpha_j - 1}$, and in a similar way, it also be

inferred from Lemma 7 and Lemma 8 that $\mathbb{E}\left[\left(1 + \sum_{i' \neq i} X_{i',e}(s)\right)^{\alpha_j - 1}\right] \geq \left(\mathbb{E}\left[1 + \sum_{i' \neq i} X_{i',e}(s)\right]\right)^{\alpha_j - 1} / \max\{1, \max_{j: \alpha_j < 2} b_{\alpha_j - 1}\}$. Since $\mathbb{E}\left[1 + \sum_{i' \neq i} X_{i',e}(s)\right] = 1 + \sum_{i' \neq i} \sum_{t_{i'}} p_{i'}(t_{i'}) \delta(s_{i'}(t_{i'}), e)$, this proposition holds. \blacktriangleleft

Theorem 9 shows that for any $i \in [N]$, $e \in E$ and any s_{-i} , there exists a $(\max\{1, \max_{\alpha_j \in (1,2)} b_{\alpha_j - 1}\}, \max\{\max_{\alpha_j \geq 2} B_{\alpha_j - 1}, 1\})$ -estimation $\widehat{f}_{i,e}(+; s_{-i})$ of $f_{i,e}(+; s_{-i})$, and the following proposition indicates that such an estimation can be obtained in $\text{poly}(q, N, \{|T_i|\}_{i \in [N]})$ -time.

► **Corollary 10.** *By computing Eq. (4), the desired estimation of each expected cost share is obtained in $O(q \cdot \sum_{i \in [N]} |T_i|)$ -time.*

Plugging Theorem 5, Theorem 6, Theorem 9, and Corollary 10 into Theorem 4 proves our main result, Theorem 2.

Abstract

Catering to the incentives of people with limited rationality is a challenging research direction that requires novel paradigms to design mechanisms and approximation algorithms. Obviously strategyproof (OSP) mechanisms have recently emerged as the concept of interest to this research agenda. However, the majority of the literature in the area has either highlighted the shortcomings of OSP or focused on the “right” definition rather than on the construction of these mechanisms.

We here give the first set of *tight* results on the approximation guarantee of OSP mechanisms for scheduling related machines. By extending the well-known cycle monotonicity technique, we are able to concentrate on the algorithmic component of OSP mechanisms and provide some novel paradigms for their design.

1 Introduction

Mechanism design has been a very active research area that aims to develop algorithms that align the objectives of the designer (e.g., optimality of the solution) with the incentives of self-interested agents (e.g., maximize their own utility). One of the main obstacles to its application in real settings is the assumption of full rationality. Where theory predicts that people should not strategize, lab experiments show that they do (to their own disadvantage): this is, for example, the case for Vickrey’s renown second-price auction; proved to be strategyproof and yet bidders lie when submitting sealed bids. Interestingly, however, lies are less frequent when the very same mechanism is implemented via an ascending auction [18].

A vague explanation of this phenomenon is that, from the point of view of a bidder, the strategyproofness of an ascending price auction is *easier to grasp* than the strategyproofness of the second-price sealed bid auction [3]. The key difference is the way these auctions are *implemented*:

- In the second-price sealed-bid auction (direct-revelation implementation), each bidder submits her own bid *once* (either her true valuation or a different value). This mechanism is *strategyproof* meaning that truth-telling is a dominant strategy: *for every report of the other bidders*, the utility when truth-telling is not worse than the utility when bidding untruthfully.
- In the ascending price auction (extensive-form implementation), each bidder is repeatedly offered some price which she can accept (stay in the auction) or reject (leave the auction). In this auction, momentarily *accepting a good price* guarantees a non-negative utility, while *rejecting a good price* or *accepting a bad price* yield non-positive utility. Here good price refers to the private valuation of the bidder and, intuitively, truth-telling in this auction means accepting prices as long as they are not above the true valuation.

Intuitively speaking, in the second type of auction, it is *obvious* for a bidder to decide her strategy, because the utility for the *worst scenario* when truth-telling is at least as good as that of the *best scenario* when cheating. The recent definition of *obviously strategyproof* (OSP) mechanisms [23] formalizes this argument: ascending auctions are OSP mechanisms, while sealed-bid auctions are not. Interestingly, [23] proves that a mechanism is OSP *if and only if* truth-telling is dominant even for bidders who lack contingent reasoning skills.

As being OSP is *stronger* than being strategyproof, it is natural to ask if this has an impact on what can be done by such mechanisms. For instance, the so-called *deferred-acceptance* (DA) auctions [26] are OSP (as they essentially are ascending price auctions), but unfortunately their performance (approximation guarantee) for several optimization problems is quite poor compared to what strategyproof mechanisms can do [9]. Whether this is an inherent limitation of OSP mechanisms or just of this technique is not clear.

One of the reasons behind this open question might be the absence of a general technique for designing OSP mechanisms and the lack of an algorithmic understanding of OSP mechanisms. Specifically, it is well known that strategyproofness is equivalent to certain *monotonicity* conditions of the *algorithm* used by the mechanism for computing the solution (be it an allocation of goods or a path in a network with self-interested agents). Therefore, one can essentially focus on the algorithmic part and study questions regarding the approximation and the complexity. The same type of questions seems much more challenging for OSP mechanisms, as such characterizations are not known. Recent work in the area [5, 27, 24] aims at simplifying the notion of OSP, by looking at versions of the revelation principle for OSP mechanisms. This, for example, allows to think, without loss of generality, at deterministic (rather than randomized) extensive-form mechanisms where each agent moves sequentially (rather than concurrently).

The goal of this work is build the foundations to reason about OSP algorithmically. In particular, we advance the state of the art by providing an algorithmic characterization of OSP mechanisms. Among others, our results show why deferred acceptance auctions [26] – essentially the only known technique to design OSP mechanisms with money – do not fully capture the power of a “generic” OSP mechanism, as the latter may exploit some aspects of the implementation (i.e., extensive-form game) in a crucial way.

Our Contribution. To give an algorithmic characterization of OSP mechanisms, we extend the well known cycle-monotonicity (CMON) technique. This approach allows to abstract the truthfulness of an algorithm in terms of non-negative weight cycles on suitably defined graphs. We show that non-negative weight cycles continue to characterize OSP when the graph of

interest is carefully defined. Our main conceptual contribution is a way to accommodate the OSP constraints, which *depend on the particular extensive-form implementation* of the mechanism, in the machinery of CMON, which is designed to focus on the algorithmic output of mechanism. Interestingly, our technique shows the interplay between algorithms (which solution to return) and how this is implemented as an extensive-form game (what we call the *implementation tree*). Roughly speaking, our characterization says which algorithms can be used for *any* choice of the implementation tree. The ability to choose between different implementation trees is what gives extra power to the designer: for example, the construction of OSP mechanisms based on DA auctions [26] uses always *the same* fixed tree for all problems and instances. Though this yields a simple algorithmic condition, it can be wasteful in terms of optimality (approximation guarantee) as we show herein. In fact, for our results, we will use CMON *two ways* to characterize both algorithmic properties (having fixed an implementation tree) and implementation properties (having fixed the approximation guarantee we want to achieve).

Armed with the OSP CMON technique, we are able to give the first *tight* bounds on the approximation ratio of OSP mechanisms. In particular, we consider the problem of scheduling n related machines (for identical jobs). While the lower bound holds regardless of the size of the domain, the mechanisms that we provide are shown to be OSP only for two- and three-value domains, as we prove that these are the only cases in which non-negative two-cycles are necessary and sufficient.

We show that the optimum for machine scheduling can be implemented OSP-ly when the agents' domains have size two. We prove that given a “balanced” optimum (i.e., a greedy allocation of jobs to machines) we can always find an implementation tree for which OSP is guaranteed. The mechanism directly asks the queried agents to reveal their type; given that the domain only contains two values, this is basically a descending/ascending auction. For domains of size three, instead, we give a lower bound of \sqrt{n} and an essentially tight upper bound of $\lceil\sqrt{n}\rceil$. Interestingly, the latter is proved with two different mechanisms – one assuming more than $\lceil\sqrt{n}\rceil^2$ number of jobs and the second under the hypothesis that there are less than that. On the technical level, these results are shown by using our approach of CMON two ways. We prove that any better than \sqrt{n} -approximate OSP mechanism must have the following structure: for a number of rounds, the mechanism must (i) separate, in its implementation tree, largest and second largest value in the domain; (ii) assign nothing to agents who have maximum value in the domain. The former property restricts the family of implementation trees we can use, whilst the latter restricts the algorithmic output. Our lower bound shows that there is nothing in this intersection. Our matching upper bounds need to find *both* implementation tree and algorithm satisfying OSP and approximation guarantee.

► **Main Theorem** (informal). *The tight approximation guarantee of OSP mechanisms that can be guaranteed over all three-valued domains is \sqrt{n} . The OSP mechanisms use a descending auction (to find the $n - \lceil\sqrt{n}\rceil$ slowest machines) followed by an ascending auction (to find the fastest machine(s)).*

While the general idea of the implementation is that of a descending auction followed by an ascending auction independently of the number of jobs, we need to tailor the design of the mechanisms (namely, their ascending phase) according to the number of jobs to achieve OSP and desired approximation simultaneously. This proves two important points. On one hand, the design of OSP mechanisms is challenging yet interesting as one needs to carefully balance algorithms and their implementation. On the other hand, it proves why fixing the implementation, as in DA auctions, might be the wrong choice. It is indeed straightforward to extend and adapt our analysis in order to prove that any ascending and descending (thus including DA) auction has an approximation of n .

We remark that our mechanisms are, to the best of our knowledge, the first examples of OSP mechanisms with money that do not follow a clock or a posted price auction format (other mechanisms that do not follow these formats have been proposed only for setting without money, namely matching and voting [23, 2, 5, 27]). One of the main messages of our work is exactly that it is possible to combine ascending and descending phases for the implementation trees of algorithms with good approximation guarantees and obtain OSP mechanisms.

Related Works. The notion of OSP mechanism has been introduced recently by [23] and has received a lot of attention in the community. As mentioned above, the class of deferred-acceptance auctions [26] yields OSP mechanisms since every such auction can be implemented as a (suitable) ascending price auction. One of the main advantages of DA auctions is that the construction boils down to the problem of defining a suitable *scoring function* for the bidders [26]. [9] studied the approximability of DA auctions for several optimization problems, and showed that in some cases DA auctions must have an approximation guarantee significantly worse than the best strategyproof mechanism; [9, 19] provide a number of positive results where DA auctions are instead optimal. [15] studies also DA auction for the job scheduling problem: they design an approximate mechanism, but for a different objective function, namely the weighted completion time.

Several works have focused on understanding better the notion of OSP mechanism, and studying settings without money, namely matching and voting. In particular [2, 5, 24] mainly attempt to simplify the notion, whilst [27, 31, 14] define, among other results, stronger and weaker versions of OSP. A couple of recent papers related to ours are [12], where among other settings the authors consider OSP mechanisms with money for machine scheduling, and [21], where this problem is studied in the setting without money. In particular, the lower bound for machine scheduling in [12] is *constant* and uses a particular definition of payments, while here we prove a \sqrt{n} lower bound that follows from the CMON characterization of OSP; their upper bound instead uses monitoring, a model wherein agents pay their reported costs whenever they overbid. Monitoring is also used in [21] to prove an encouraging bound for OSP mechanisms without money and a single task; the bound (asymptotically) matches the performances of strategyproof mechanisms.

Research in algorithmic mechanism design [17, 7] has suggested to focus on “simple” mechanisms to deal with bounded rationality. For example, posted-price mechanisms received huge attention very recently and have been applied to many different settings [4, 11, 1, 10, 8]. In these mechanisms one’s own bid is immaterial for the price paid to get some goods of interest – this should immediately suggest that trying to play the mechanism is worthless no matter the cognitive abilities of the agents. However, posted price mechanisms do not fully capture the concept of simple mechanisms: e.g., ascending price auctions are not posted price mechanisms and still turn out to be “simple” to play and understand.

CMON is a widely used technique in mechanism design that dates back to [28] – a general treatment is given in [25, 16]. This method has been used quite extensively to prove strategyproofness of mechanisms in the classical setting, cf., e.g., [6, 22] and when some form of verification can be adopted, see [30, 20]. Particularly relevant for our work is the research which shows that in order to establish strategyproofness it is sufficient to study cycles of length 2 as in [29].

2 Preliminaries

A mechanism design setting is defined by a set of n *selfish agents* and a set of allowed *outcomes* \mathcal{S} . Each agent i has a *type* $t_i \in D_i$, where D_i is called the *domain* of i . The type t_i is usually assumed to be *private knowledge* of agent i . We will let $t_i(X) \in \mathbb{R}$ denote the *cost* of agent i with type t_i for the outcome $X \in \mathcal{S}$. In our application, we will assume that costs are non-negative; however, our framework and characterization hold in general no matter the sign.

A *mechanism* is a process for selecting an outcome $X \in \mathcal{S}$. To this aim, the mechanism interacts with agents. Specifically, agent i is observed to take *actions* (e.g., saying yes/no) that may depend on her presumed type $b_i \in D_i$ (e.g., saying yes could “signal” that the presumed type has some properties that b_i enjoys). We say that agent i takes *actions compatible with (or according to) b_i* to stress this. We highlight that the presumed type b_i can be different from the real type t_i .

For a mechanism \mathcal{M} , we let $\mathcal{M}(\mathbf{b})$ denote the outcome returned by the mechanism when agents take actions according to their presumed types $\mathbf{b} = (b_1, \dots, b_n)$. In our context, this outcome is given by a pair (f, \mathbf{p}) , where $f = f(\mathbf{b})$ (termed *social choice function* or, simply, algorithm) maps the actions taken by the agents according to \mathbf{b} (i.e., each agent i takes actions compatible with b_i) to a feasible solution in \mathcal{S} , and $\mathbf{p} = \mathbf{p}(\mathbf{b}) = (p_1(\mathbf{b}), \dots, p_n(\mathbf{b})) \in \mathbb{R}^n$ maps the actions taken by the agents according to \mathbf{b} to *payments* from the mechanism to the agents.

Each selfish agent i is equipped with a *utility function* $u_i: D_i \times \mathcal{S} \rightarrow \mathbb{R}$. For $t_i \in D_i$ and for an outcome $X \in \mathcal{S}$ returned by a mechanism \mathcal{M} , $u_i(t_i, X)$ is the utility that agent i has for outcome X when her type is t_i . We define utility as a quasi-linear combination of payments and costs, i.e., $u_i(t_i, \mathcal{M}(b_i, \mathbf{b}_{-i})) = p_i(b_i, \mathbf{b}_{-i}) - t_i(f(b_i, \mathbf{b}_{-i}))$.

A mechanism \mathcal{M} is *strategy-proof* if, for each i , the utility of player i is maximized by playing the extensive-form implementation of \mathcal{M} according to her true type t_i . That is, in a strategy-proof mechanism the actions taken according to the true type are dominant for each agent.

For our application, we will be focusing on *single-parameter* settings, that is, the case in which the private information of each bidder i is a single real number t_i and $t_i(X)$ can be expressed as $t_i w_i(X)$ for some publicly known function w_i . To simplify the notation, we will write $t_i f_i(\mathbf{b})$ when we want to express the cost of a single-parameter agent i of type t_i for the output of social choice function f on input the actions corresponding to a bid vector \mathbf{b} .

Obvious Strategyproofness. We now formally define the concept of obviously strategy-proof deterministic mechanisms. This concept has been introduced in [23]. However, our definition is built on the more accessible ones given by [2] and [12]. As shown in [5, 24], our definition is equivalent to Li’s.¹

Let us first formally model how a mechanism works. An *extensive-form mechanism* \mathcal{M} is defined by a directed tree $\mathcal{T} = (V, E)$, called the *implementation tree*, such that:

- Every leaf ℓ of the tree is labeled with a possible outcome $X(\ell) \in \mathcal{S}$ of the mechanism;
- Every internal vertex $u \in V$ is labeled with an agent $S(u) \in [n]$;

¹ More in detail, our definition of implementation tree is equivalent to the concept of round-table mechanism in [24]. Consequently, our definition of OSP is equivalent to the concept of SP-implementation through a round table mechanism, that is proved to be equivalent to the original definition of OSP for deterministic mechanisms. For a discussion of randomization for OSP mechanisms, we kindly refer the reader to [2, 13].

- Every edge $e = (u, v) \in E$ is labeled with a subset $T(e) \subseteq D = \times_i D_i$ of type profiles such that:
 - The subsets of profiles that label the edges outgoing from the same vertex u are disjoint, i.e., for every triple of vertices u, v, v' such that $(u, v) \in E$ and $(u, v') \in E$, we have that $T(u, v) \cap T(u, v') = \emptyset$;
 - The union of the subsets of profiles that label the edges outgoing from a non-root vertex u is equal to the subset of profiles that label the edge going in u , i.e., $\bigcup_{v: (u,v) \in E} T(u, v) = T(\phi(u), u)$, where $\phi(u)$ is the parent of u in \mathcal{T} ;
 - The union of the subsets of profiles that label the edges outgoing from the root vertex r is equal to the set of all profiles, i.e., $\bigcup_{v: (r,v) \in E} T(r, v) = D$;
 - For every u, v such that $(u, v) \in E$, where u is not the root, and for every two profiles $\mathbf{b}, \mathbf{b}' \in T(\phi(u), u)$ such that $b_i = b'_i$, $i = S(u)$, if \mathbf{b} belongs to $T(u, v)$, then \mathbf{b}' must belong to $T(u, v)$ also.

Roughly speaking, the tree represents the steps of the execution of the mechanism. As long as the current visited vertex u is not a leaf, the mechanism interacts with the agent $S(u)$. Different edges outgoing from vertex u are used for modeling the different actions that the agent $S(u)$ can take during this interaction with the mechanism. In particular, each possible action is assigned to an edge outgoing from u . As suggested above, the action that agent i takes may depend on her presumed type $b_i \in D_i$. That is, different presumed types may correspond to taking different actions, and thus to different edges. The label $T(e)$ on edge $e = (u, v)$ then lists the type profiles that enable the agent $S(u)$ to take those actions that have been assigned to e . In other words, when the agent takes the actions assigned to edge e , then the mechanism (and the other agents) can infer that the type profile must be contained in $T(e)$. The constraints on the edges' label can be then explained as follows: first we can safely assume that different actions must correspond to different type profiles (indeed, if two different actions are enabled by the same profiles we can consider them as a single action); second, we can safely assume that each action must correspond to at least one type profile that has not been excluded yet by actions taken before node u was visited (otherwise, we could have excluded this type profile earlier); third, we have that the action taken by agent $S(u)$ can only inform about her types and not about the type of the remaining agents. The execution ends when we reach a leaf ℓ of the tree. In this case, the mechanism returns the outcome that labels ℓ .

Observe that, according to the definition above, for every profile \mathbf{b} there is only one leaf $\ell = \ell(\mathbf{b})$ such that \mathbf{b} belongs to $T(\phi(\ell), \ell)$. Similarly, to each leaf ℓ there is at least a profile \mathbf{b} that belongs to $T(\phi(\ell), \ell)$. For this reason we say that $\mathcal{M}(\mathbf{b}) = X(\ell)$. Moreover, for every type profile \mathbf{b} and every node $u \in V$, we say that \mathbf{b} is *compatible* with u if $\mathbf{b} \in T(\phi(u), u)$. Finally, two profiles \mathbf{b}, \mathbf{b}' are said to *diverge* at vertex u if there are two vertices v, v' such that $(u, v) \in E$, $(u, v') \in E$ and $\mathbf{b} \in T(u, v)$, whereas $\mathbf{b}' \in T(u, v')$.

For every node u in a mechanism \mathcal{M} such that there are two profiles \mathbf{b}, \mathbf{b}' that diverge at u , we say that u is a *divergent node*, and $i = S(u)$ the corresponding *divergent agent*. For each agent i , we define the *current domain* at node u , denoted $D_i(u)$, such that $D_i(r) = D_i$ for the root r and $D_i(u) = \cup_{\mathbf{b} \in T(\phi(u), u)} b_i$. In words, this is the set of types of i that are compatible with the actions that i took during the execution of the mechanism until node u is reached. Indeed, according to the definition, at each node u in which i diverges, \mathcal{M} partitions $D_i(u)$ in k subsets, where k is the number of children of u , and where for every child v of u , $D_i(v) \subset D_i(u)$ contains the types of bidder i compatible with the action that she takes when interacting with the mechanism at node u .

We are now ready to define obvious strategyproofness. An extensive-form mechanism \mathcal{M} is *obviously strategy-proof (OSP)* if for every agent i with real type t_i , for every vertex u such that $i = S(u)$, for every $\mathbf{b}_{-i}, \mathbf{b}'_{-i}$ (with \mathbf{b}'_{-i} not necessarily different from \mathbf{b}_{-i}), and for every $b_i \in D_i$, with $b_i \neq t_i$, such that (t_i, \mathbf{b}_{-i}) and (b_i, \mathbf{b}'_{-i}) are compatible with u , but diverge at u , it holds that $u_i(t_i, \mathcal{M}(t_i, \mathbf{b}_{-i})) \geq u_i(t_i, \mathcal{M}(b_i, \mathbf{b}'_{-i}))$. Roughly speaking, an obviously strategy-proof mechanism requires that, at each time step agent i is asked to take a decision that depends on her type, the worst utility that she can get if she behaves according to her true type is at least the best utility achievable by behaving differently. We stress that our definition does not restrict the alternative behavior to be consistent with a fixed type. Indeed, as noted above, each leaf of the tree \mathcal{T}_u rooted in u corresponds to a profile $\mathbf{b} = (b_i, \mathbf{b}'_{-i})$ compatible with u : then, our definition implies that the utility of i in the leaves where she plays truthfully is at least as much as the utility in every other leaf of \mathcal{T}_u . Hence, if a mechanism is obviously strategy-proof, then it is also strategy-proof.

We say that an extensive-form mechanism is *trivial* if for every vertex $u \in V$ and for every two type profiles \mathbf{b}, \mathbf{b}' , it holds that \mathbf{b} and \mathbf{b}' do *not* diverge at u . That is, a mechanism is trivial if it never requires agents to take actions that depend on their type. If a mechanism is not trivial, then there is at least one divergent node. On the other hand, every execution of a mechanism (i.e., every path from the root to a leaf in the mechanism implementation tree) may go through at most $\sum_i (|D_i| - 1)$ divergent nodes, the upper bound being the case in which at each divergent node u , the agent $i = S(u)$ separates $D_i(u)$ in $D_i(u) \setminus \{b\}$ and $\{b\}$ for some $b \in D_i(u)$.

Machine Scheduling. Here, we are given a set of m identical jobs to execute and the n agents control related machines. That is, agent i has a job-independent processing time t_i per unit of job (equivalently, an execution speed $1/t_i$ that is independent from the actual jobs). The social choice function f must choose a possible schedule $f(\mathbf{b}) = (f_1(\mathbf{b}), \dots, f_n(\mathbf{b}))$ of jobs to the machines, where $f_i(\mathbf{b})$ denotes the job load assigned to machine i when agents take actions according to \mathbf{b} . The cost that agent i faces for the schedule $f(\mathbf{b})$ is $t_i(f(\mathbf{b})) = t_i \cdot f_i(\mathbf{b})$. We focus on social choice functions f^* minimizing the *makespan*, i.e., $f^*(\mathbf{b}) \in \arg \min_{\mathbf{x}} \max_{i=1}^n b_i(\mathbf{x})$. We say that f is ρ -approximate if it returns a solution whose cost is at most ρ times the optimum.

3 Cycle-monotonicity for OSP Mechanisms

We now show how to generalize the cycle-monotonicity technique to design OSP mechanisms.

Let us consider an extensive-form mechanism $\mathcal{M} = (f, \mathbf{p})$ with implementation tree \mathcal{T} .

► **Definition 1** (separating vertices). *A vertex u in the implementation tree \mathcal{T} is $\alpha\beta$ -separating for agent i if the following holds: Node u is labelled with i , i.e., $i = S(u)$; there are two profiles $(\alpha, \mathbf{a}_{-i})$ and (β, \mathbf{b}_{-i}) which are compatible with u but diverge at u , where $\mathbf{a}_{-i}, \mathbf{b}_{-i} \in D_{-i}(u) = \times_{j \neq i} D_j(u)$.*

Note that there might exist several $\alpha\beta$ -separating vertices for agent i as the agent may be asked to separate α from β in different paths from the root to a leaf (but only once for every such path).

The algorithmic characterization of OSP we provide herein is based on the following observation.

► **Observation 2.** *An extensive-form mechanism $\mathcal{M} = (f, \mathbf{p})$ with implementation tree \mathcal{T} is OSP if and only if for all i , for all $\alpha, \beta \in D_i$, $\alpha \neq \beta$, for all vertices u that are $\alpha\beta$ -separating for i :*

$$p_i(\beta, \mathbf{b}_{-i}) - p_i(\alpha, \mathbf{a}_{-i}) \leq \alpha(f(\beta, \mathbf{b}_{-i})) - \alpha(f(\alpha, \mathbf{a}_{-i})) \quad \text{for all } \mathbf{a}_{-i}, \mathbf{b}_{-i} \in D_{-i}(u). \quad (1)$$

We next restate these conditions in terms of suitable weighted graphs and their cycles.

► **Definition 3** (OSP-graph). *Let f be a social choice function and \mathcal{T} be an implementation tree. We define for every agent i , the OSP-graph $OSP_i^{(f,\mathcal{T})}$ as follows: There is a node for each type profile in D , and a directed edge $e = ((\alpha, \mathbf{a}_{-i}), (\beta, \mathbf{b}_{-i}))$ for every $\alpha, \beta \in D_i$, $\alpha \neq \beta$, and $\mathbf{a}_{-i}, \mathbf{b}_{-i} \in D_{-i}(u)$, where u is an $\alpha\beta$ -separating vertex of \mathcal{T} . The weight of the edge is $w(e) = \alpha(f(\beta, \mathbf{b}_{-i})) - \alpha(f(\alpha, \mathbf{a}_{-i}))$.*

► **Definition 4** (OSP CMON). *We say that the OSP cycle monotonicity (OSP CMON) property holds if, for all i , the graph $OSP_i^{(f,\mathcal{T})}$ does not have negative weight cycles. Moreover, we say that the OSP two-cycle monotonicity (OSP 2CMON) holds if the same is true when considering cycles of length two only, i.e., cycles with two edges only.*

► **Theorem 5.** *A mechanism with implementation tree \mathcal{T} is an OSP mechanism for a social function f on finite domains if and only if OSP CMON holds.*

The proof of the theorem follow standard arguments used for the classical definition of strategyproofness. For our application, it is useful to recast the OSP CMON and OSP 2CMON for the case of single-parameter agents.

► **Proposition 6.** *For single-parameter settings, OSP 2CMON is equivalent to the following condition. For every i , for any $\alpha, \beta \in D_i$ with $\alpha < \beta$, for any $\alpha\beta$ -separating node u of \mathcal{T} , with $i = S(u)$, it holds*

$$f_i(\alpha, \mathbf{a}_{-i}) \geq f_i(\beta, \mathbf{b}_{-i}) \quad \text{for all } \mathbf{a}_{-i}, \mathbf{b}_{-i} \in D_{-i}(u). \quad (2)$$

Warm-up: Using OSP CMON to Bound Approximation Guarantee. We next give a simple lower bound for the machine scheduling problem. This simple result gives a taster of the power of OSP CMON as a tool to answer algorithmic questions about OSP.

► **Proposition 7.** *For the machine scheduling problem, no OSP mechanism can be better than 2-approximate, even for two jobs and two agents with three-value domains $D_i = \{L, M, H\}$, where $L < M < H$, with $M > 3L$ and $H > 3M$.*

Proof. Assume by contradiction that there is an OSP mechanism \mathcal{M} that is better than 2-approximate, and let \mathcal{T} be its implementation tree. Since $M > 3L$ and $H > 3M$, every trivial OSP mechanism must have approximation guarantee at least 2. Hence \mathcal{M} must be non trivial. Let i be the first divergent agent of \mathcal{M} implemented with \mathcal{T} , and let u be the node where this agent diverges (such an agent exists because the mechanism is not trivial). We show that this mechanism cannot satisfy OSP 2CMON, thus a contradiction.

If i diverges at u on M and H , then consider $\mathbf{b} = (\beta, \mathbf{b}_{-i}) = (H, H)$ and $\mathbf{a} = (\alpha, \mathbf{a}_{-i}) = (M, L)$. Since the mechanism is better than 2-approximate, it must satisfy $f_i(\beta, \mathbf{b}_{-i}) = 1$ and $f_i(\alpha, \mathbf{a}_{-i}) = 0$. Note that this violates the OSP 2CMON condition (Equation 2 in Proposition 6): Since i is the first divergent agent, and u is the corresponding node, the set $D_{-i}(u)$ consists of all types in the domain of the other agent, and therefore $H, L \in D_{-i}(u)$ as required to invoke (2) with our choice $\mathbf{b}_{-i} = H$ and $\mathbf{a}_{-i} = L$. If i diverges at u on L and M , then consider $\mathbf{a} = (\alpha, \mathbf{a}_{-i}) = (L, L)$ and $\mathbf{b} = (\beta, \mathbf{b}_{-i}) = (M, H)$. Since the mechanism is better than 2-approximate, it must satisfy $f_i(\alpha, \mathbf{a}_{-i}) = 1$ and $f_i(\beta, \mathbf{b}_{-i}) = 2$. Similarly to the previous case, this violates the OSP 2CMON condition (2). ◀

Note that for this bound we require the domain to have at least three different values; we will in fact prove in Section 4 that we can design an optimal OSP mechanism for scheduling related machines when $D_i = \{L_i, H_i\}$ for every i . We will also show how to use a more involved argument to prove a substantially higher (and tight) bound of \sqrt{n} .

Two-cycles are Sufficient for Single-parameter Domains of Size at most Three. Two-cycle monotonicity is a property easier to work with than CMON. We will now observe that, for single parameter settings, these properties turns out to be equivalent if and only if $D_i = \{L_i, M_i, H_i\}$ for each i , with $L_i \leq M_i \leq H_i$.

► **Theorem 8.** *Consider a single-parameter setting where $|D_i| \leq 3$ for each agent i . A mechanism with implementation tree \mathcal{T} and social choice function f is OSP iff OSP 2CMON holds.*

We next show that this result is essentially tight in the sense that OSP 2CMON does not imply OSP CMON (and thus OSP-ness) already in four-value domains.

► **Theorem 9.** *There exists a mechanism for which OSP 2CMON holds for every agent, but there is an agent i for which the mechanism does not satisfy OSP CMON, whenever $|D_i| \geq 4$. The claim holds even for a single-item auction setting and $D_j = D$ for every $j \neq i$.*

4 Scheduling Related Machines

In this section, we show how the domain structure impacts on the performance guarantee of OSP mechanisms, for the problem of scheduling related machines. Roughly speaking, the problem is easy for *two-value* domains, while it becomes difficult already for *three-value* domains and *two* jobs.

We can prove that an OSP optimal mechanism exists for the case in which each agent's domain has size two. Specifically, we have the following theorem.

► **Theorem 10.** *For the machine scheduling problem, there exists an optimal polynomial-time OSP mechanism for any number of agents with two-value domains $D_i = \{L_i, H_i\}$.*

Lower Bound for Three-value Domain

We now show how to strengthen Proposition 7 and prove a \sqrt{n} -inapproximability result for three-value domains.

► **Theorem 11.** *For the machine scheduling problem, no OSP mechanism can be better than \sqrt{n} -approximate. This also holds for three-value domains $D_i = \{L, M, H\}$.*

For the proof, we consider $m = n = c^2$, for some $c > 1$, and a three-value domain $D_i = \{L, M, H\}$ such that $M \geq m \cdot L$ and $H \geq m\sqrt{n} \cdot M$. Observe that, in such domains, every trivial mechanism must have an approximation ratio not lower than \sqrt{n} . Consider then a non-trivial mechanism \mathcal{M} and let \mathcal{T} be its implementation tree. Let us rename the agents as follows: Agent 1 is the 1st agent that diverges in \mathcal{T} ; since the mechanism is not trivial agent 1 exists. We now call agent 2, the 2nd distinct agent that diverges in the subtree of \mathcal{T} defined by agent 1 taking an action compatible with type H ; if no agent diverges in this subtree of \mathcal{T} we simply call 2 an arbitrary agent different from 1. More generally, agent i is the i th distinct agent that diverges, if any, in the subtree of \mathcal{T} that corresponds to the case that the actions previously taken by agents are compatible with their type being H . As above, if no agent diverges in the subtree of interest, we just let i denote an arbitrary agent different from $1, 2, \dots, i - 1$. We denote with u_i the node in which i first diverges in the subtree in which all the other agents have taken actions compatible with H ; if i does not diverge (i.e., got her id arbitrarily) we denote with u_i a dummy node in which we will say that i does not diverge and i takes an action compatible with every type in D_i . We then have the following lemma.

► **Lemma 12.** Any OSP mechanism \mathcal{M} which is k -approximate, with $k < \sqrt{n}$, must satisfy:

1. For every $i \leq n - \sqrt{n} + 1$, if agent i diverges at node u_i , it must diverge on M and H .
2. For every $i \leq n - \sqrt{n}$, if agent i diverges at node u_i and takes an action compatible with her type being H , then \mathcal{M} does not assign any job to i , regardless of the actions taken by the other agents.

Proof. Let us first prove part (1). Suppose that there is $i \leq n - \sqrt{n} + 1$ such that at node u_i i diverges on L and $\{M, H\}$. Consider the type profile \mathbf{x} such that $x_i = M$, and $x_j = H$ for every $j \neq i$. Observe that \mathbf{x} is compatible with node u_i . The optimal allocation for the type profile \mathbf{x} assigns all jobs to machine i , with cost $OPT(\mathbf{x}) = mM$. Since \mathcal{M} is k -approximate, then it also assigns all jobs to machine i . Indeed, if a job is assigned to a machine $j \neq i$, then the cost of the mechanism would be at least $H \geq \sqrt{n} \cdot mM > k \cdot OPT(\mathbf{x})$, that contradicts the approximation bound.

Consider now the profile \mathbf{y} such that $y_i = L$, $y_j = H$ for every $j < i$, and $y_j = L$ for every $j > i$. Observe that also \mathbf{y} is compatible with node u_i . It is not hard to see that $OPT(\mathbf{y}) \leq \left\lceil \frac{m}{n-i+1} \right\rceil \cdot L$. Since \mathcal{M} is k -approximate, then it cannot assign all jobs to machine i . Indeed, in this case the cost of the mechanism contradicts the approximation bound, since it would be $mL \geq \sqrt{n} \left\lceil \frac{m}{n-i+1} \right\rceil L > k \cdot OPT(\mathbf{y})$, where we used that $\sqrt{n} \left\lceil \frac{m}{n-i+1} \right\rceil \leq \sqrt{n} \left\lceil \frac{m}{\sqrt{n}} \right\rceil = \sqrt{n} \left\lceil \frac{m}{\sqrt{n}} \right\rceil = \sqrt{n} \cdot \sqrt{n} = n = m$.

Hence, we have that if i takes actions compatible with M , then there exists a type profile compatible with u_i such that i receives n jobs, whereas, if i takes a different action compatible with a lower type, then there exists a type profile compatible with u_i such that i receives less than n jobs. However, this contradicts the OSP CMON property.

Let us now prove part (2). Suppose that there is $i \leq n - \sqrt{n}$ and \mathbf{x}_{-i} compatible with u_i such that if i takes an action compatible with type H , then \mathcal{M} assigns at least a job to i . According to part (1), machine i diverges at node u_i on H and M .

Consider then the profile \mathbf{y} such that $y_i = M$, $y_j = H$ for $j < i$, and $y_j = L$ for $j > i$. It is easy to see that the optimal allocation has cost $OPT(\mathbf{y}) = \left\lceil \frac{m}{n-i} \right\rceil \cdot L$. Since \mathcal{M} is k -approximate, then it does not assign any job to machine i . Otherwise, the mechanism contradicts the approximation bound since his cost would be at least $M \geq mL \geq \sqrt{n} \left\lceil \frac{m}{n-i} \right\rceil L > k \cdot OPT(\mathbf{x})$, where we used that $\sqrt{n} \left\lceil \frac{m}{n-i} \right\rceil \leq \sqrt{n} \left\lceil \frac{m}{\sqrt{n}} \right\rceil = \sqrt{n} \left\lceil \frac{m}{\sqrt{n}} \right\rceil = \sqrt{n} \cdot \sqrt{n} = n = m$.

Hence, we have that if i takes actions compatible with H , then there exists a type profile compatible with u_i such that i receives one job, whereas, if i takes a different action compatible with a lower type, then there exists a type profile compatible with u_i such that i receives zero jobs. However, this contradicts the OSP CMON property. ◀

Proof of Theorem 11. Suppose that there is an OSP k -approximate mechanism \mathcal{M} for some $k < \sqrt{n}$, thus implying that the mechanism is not trivial.

Assume first that for all $i \leq n - \sqrt{n}$ agent i diverges at u_i . Consider \mathbf{x} such that $x_i = H$ for every i . Observe that \mathbf{x} is compatible with u_i for every i . The optimal allocation consists in assigning a job to each machine, and has cost $OPT(\mathbf{x}) = H$. According to Part (2) of Lemma 12, if machines take actions compatible with \mathbf{x} , then the mechanism \mathcal{M} does not assign any job to machine i , for every $i \leq n - \sqrt{n}$. Hence, the best outcome that \mathcal{M} can return for \mathbf{x} consists in assigning \sqrt{n} jobs to each of the other \sqrt{n} machines. Therefore, the cost of \mathcal{M} is at least $\sqrt{n}H > kOPT(\mathbf{x})$, which contradicts the approximation ratio of \mathcal{M} .

Consider now the case that there is $1 < i \leq n - \sqrt{n}$ that does not diverge at u_i (since the mechanism is not trivial $i > 1$). This means that all the machines $j \geq i$ will not diverge at u_i ; let S denote this set of machines. Note that the $n - i + 1 \geq \sqrt{n} + 1$ machines in S will have

the same outcome no matter their types when the machines not in S have type H ; in other words, any profile \mathbf{x} where $x_j = H$ for $j \notin S$ is compatible with u_i . Consider \mathbf{x} such that $x_j = H$ for $j \notin S$ and $x_j = L$ otherwise. Since $H \geq n^{5/2}L$, to guarantee approximation k , the mechanism must return a solution for \mathbf{x} which keeps the machines not in S empty; then there is a $j^* \in S$ which is allocated at least $\lceil \frac{n}{\sqrt{n+1}} \rceil$ jobs. Consider now \mathbf{y} where $y_j = H$ for $j \notin S \setminus \{j^*\}$ and $y_j = L$ otherwise. The mechanism must give in output the same allocation given in output for \mathbf{x} since it cannot distinguish \mathbf{x} from \mathbf{y} . However, giving that many jobs to machine j^* contradicts the approximation guarantee on \mathbf{y} . ◀

The arguments above can be used to prove that ascending and descending auctions do not help in this setting. Specifically, they cannot return an approximation better than n .

Upper bound for Three-value Domain

We describe our mechanisms for a generic domain, as this turns out to be useful in the analysis. In what follows, the usual bold notation \mathbf{x} denotes vectors of n entries, while a “hat-bold” notation $\hat{\mathbf{x}}$ denotes vectors of $\lceil \sqrt{n} \rceil$ entries only.

A Mechanism for Many Jobs (Large m). We now introduce mechanism \mathcal{M}_{many} whose approximation ratio approaches $\lceil \sqrt{n} \rceil$, whenever $m \gg \lceil \sqrt{n} \rceil$. The mechanism consists of a descending Phase (Algorithm 1) followed by an ascending Phase (Algorithm 2). The descending phase simply queries the agents to identify (and forget about) the $n - \sqrt{n}$ slowest machines; the ascending phase instead identifies the fastest machine and then computes the optimal solution to a vector where the types of the remaining $\sqrt{n} - 1$ machines is set to the best type of the slow machines found in the descending phase.

■ **Algorithm 1** Descending Phase (for both mechanisms \mathcal{M}_{many} and \mathcal{M}_{few}).

```

1 Set  $A = [n]$ , and  $t_i = \max\{d \in D_i\}$ 
2 while  $|A| > \lceil \sqrt{n} \rceil$  do
3   Set  $p = \max_{a \in A}\{t_a\}$  and  $i = \min\{a \in A : t_a = p\}$ 
4   Ask machine  $i$  if her type is equal to  $p$ 
5   if yes then remove  $i$  from  $A$ 
6   else set  $t_i = \max\{t \in D_i : t < p\}$ 

```

► **Proposition 13.** *Mechanism \mathcal{M}_{many} is OSP for any three-value domain $D_i = \{L_i, M_i, H_i\}$.*

Proof. We prove that \mathcal{M}_{many} satisfies OSP 2CMON. The claim then follows from Theorem 8. Specifically, for each machine i , for each node u in which the mechanism makes a query to i , for each pair of type profiles \mathbf{x}, \mathbf{y} compatible with u such that i diverges at u between x_i and y_i , we need to prove that if $x_i > y_i$, then $f_i(\mathcal{M}_{many}(\mathbf{x})) \leq f_i(\mathcal{M}_{many}(\mathbf{y}))$.

Let us first consider a node u corresponding to the descending phase of the mechanism. In this case, $x_i = p$, where p is as at node u . Moreover, in all profiles compatible with u there are at least $\lceil \sqrt{n} \rceil$ machines that either have a type lower than p , or they have type p but are queried after i . However, for every \mathbf{x}_{-i} satisfying this property, we have that $f_i(\mathcal{M}_{many}(\mathbf{x})) = 0$, which implies that these two-cycles have non-negative weight.

Suppose now that node u corresponds to the ascending phase of the mechanism. In this case, $y_i = p$, where p is as at node u . Observe that for every \mathbf{y}_{-i} compatible with node u , $f_i(\mathcal{M}_{many}(\mathbf{y})) = f_i^*(y_i, \hat{\mathbf{z}}_{-i})$, where $f_i^*(y_i, \hat{\mathbf{z}}_{-i})$ is the number of jobs assigned to machine i by the optimal outcome on input profile $(y_i, \hat{\mathbf{z}}_{-i})$, $\hat{\mathbf{z}}_{-i}$ being such that $\hat{z}_j = \max_{k \in A} t_k$

for every $j \in A \setminus \{i\}$. Observe that for every \mathbf{x} compatible with u , it must be the case that $x_j \geq y_i$ for every $j \in A$. Hence, we can distinguish two cases: if $\min_j x_j = x_i$, then $f_i(\mathcal{M}_{many}(\mathbf{x})) = f_i^*(x_i, \hat{\mathbf{z}}_{-i}) \leq f_i^*(y_i, \hat{\mathbf{z}}_{-i}) = f_i(\mathcal{M}_{many}(\mathbf{y}))$; if instead $\min_j x_j = x_k$, for some $k \neq i$, then $f_i(\mathcal{M}_{many}(\mathbf{x})) = f_i^*(x_k, \hat{\mathbf{z}}_{-k}) \leq f_k^*(x_k, \hat{\mathbf{z}}_{-k}) \leq f_i^*(y_i, \hat{\mathbf{z}}_{-i}) = f_i(\mathcal{M}_{many}(\mathbf{y}))$, where we used that $\hat{\mathbf{z}}_{-k} = \hat{\mathbf{z}}_{-i}$ and the inequalities follow since: (i) in the optimal outcome the fastest machine must receive at least as many jobs as slower machines; (ii) the optimal outcome is monotone, (i.e., given the speeds of other machines, the number of jobs assigned to machine i decreases as its speeds decreases). ◀

■ **Algorithm 2** Ascending Phase (\mathcal{M}_{many}).

```

1 Set  $s_i = \min\{d \in D_i\}$ 
2 while  $|A| > 0$  do
3   Set  $p = \min_{a \in A}\{s_a\}$  and
    $i = \min\{a \in A : s_a = p\}$ 
4   Ask machine  $i$  if her type is  $p$ 
5   if yes then
6     Let  $\hat{\mathbf{z}}$  be s.t.  $\hat{z}_i = p$  and
      $\hat{z}_j = \min_{k \notin A} t_k$  for  $j \in A, j \neq i$ 
7     Let  $f^*(\hat{\mathbf{z}}) = (f_i^*(\hat{\mathbf{z}}))_{i \in A}$  be the
     optimal assignment for profile  $\hat{\mathbf{z}}$ 
8     Assign  $f_j^*(\hat{\mathbf{z}})$  jobs to each  $j \in A$ 
9     Set  $A = \emptyset$ 
10  else set  $s_i = \min\{d \in D_i : d > p\}$ 

```

■ **Algorithm 3** Ascending Phase (\mathcal{M}_{few}).

```

1 Set  $t_a = \min_i\{d \in D_i\}$  and  $C = m$ 
2 while  $|A| > 0$  do
3   Set  $q = \min_{a \in A}\{t_a\}$  and
    $i = \min\{a \in A : t_a = q\}$ 
4   Ask machine  $i$  if her type is  $q$ 
5   if yes then
6     Let  $\zeta = \lceil C/|A| \rceil$ 
7     Let  $z$  be the largest integer in
      $[\zeta, C]$  such that  $z \cdot q \leq \lceil \sqrt{n} \rceil \cdot p$ 
8     Assign  $z$  jobs to  $i$ 
9     Set  $C = C - z$ 
10    Remove  $i$  from  $A$ 
11  else set  $t_i = \min\{d \in D_i : d > p\}$ 

```

The next theorem bounds the approximation ratio of the mechanism

► **Theorem 14.** *Mechanism \mathcal{M}_{many} is $(\lceil \sqrt{n} \rceil + 1)$ -approximate for $m > \lceil \sqrt{n} \rceil^2$.*

A Mechanism for Few Jobs (Small m). We now introduce a mechanism \mathcal{M}_{few} which is OSP and $\lceil \sqrt{n} \rceil$ -approximate whenever $m \leq \lceil \sqrt{n} \rceil^2$. Like \mathcal{M}_{many} , \mathcal{M}_{few} consists of a descending phase followed by an ascending phase. The descending phase is exactly the same (Algorithm 1) with the difference that the ascending phase (Algorithm 3) does not need the information on the type of the machines that are not in A at that point.

We show next that \mathcal{M}_{few} is well defined under our assumption on m , is OSP and has approximation $\lceil \sqrt{n} \rceil$.

► **Lemma 15.** *If $m \leq \lceil \sqrt{n} \rceil^2$ then there exists a z in line 7 of Algorithm 3.*

Proof. We next show that it never occurs during the ascending phase that $\zeta \cdot q > \lceil \sqrt{n} \rceil \cdot p$. Indeed, for the first machine to reveal the type during the ascending phase, we have that $|P_0| = m \leq \lceil \sqrt{n} \rceil^2$, and, thus $\zeta \leq \lceil \sqrt{n} \rceil$. Hence, $\zeta \cdot q \leq \lceil \sqrt{n} \rceil \cdot p$ since $q \leq p$. If a set $Q \subset A$ of machines has previously revealed the type during the ascending phase, and the execution of this phase has not been stopped, then these machines received at least $m' = \lfloor |Q|m/|A| \rfloor + \min\{|Q|, m \bmod |A|\}$ jobs. Then $|P_0| = m - m' \leq (|A| - |Q|) \lceil \sqrt{n} \rceil$, and thus $\zeta \leq \lceil \sqrt{n} \rceil$, and, since $q \leq p$, $\zeta \cdot q \leq \lceil \sqrt{n} \rceil \cdot p$. ◀

► **Proposition 16.** *Mechanism \mathcal{M}_{few} is OSP for three-value domains $D_i = \{L_i, M_i, H_i\}$.*

Proof. We prove that \mathcal{M}_{many} satisfies the OSP 2CMON. The claim then follows from Theorem 8. Specifically, for each machine i , for each node u in which the mechanism makes a query to i , for each pair of type profiles \mathbf{x}, \mathbf{y} compatible with u such that x_i and y_i diverge at u , we need to prove that if $x_i > y_i$, then $f_i(\mathcal{M}_{few}(\mathbf{x})) \leq f_i(\mathcal{M}_{few}(\mathbf{y}))$.

Let us first consider a node u corresponding to the descending phase of the mechanism. In this case, $x_i = p$, where p is as at node u . Moreover, in all profiles compatible with u there are at least $\lceil \sqrt{n} \rceil$ machines that either have a type lower than p , or they have type p but they are queried after i . Hence, for every \mathbf{x}_{-i} satisfying this property, we have that $f_i(\mathcal{M}_{few}(\mathbf{x})) = 0$, that implies the claim.

Suppose now that node u corresponds to the ascending phase of the mechanism. Let $C(u)$, $A(u)$, $p(u)$ and $q(u)$ be the value of C , A , p and q at that node. Observe that for every profile compatible with u , the type of machines not in $A(u)$ is fixed, whereas for every machine in $A(u)$, the type is at least $q(u)$. Moreover, $y_i = q(u)$. Hence, $f_i(\mathcal{M}_{few}(\mathbf{y}))$ is the largest integer $z \leq C(u)$ such that $z \cdot y_i \leq \lceil \sqrt{n} \rceil \cdot p(u)$. On the other side, for every $x_i > y_i$, $f_i(\mathcal{M}_{few}(\mathbf{x}))$ is at most the largest integer $z' \leq C(u)$ such that $z' \cdot x_i \leq \lceil \sqrt{n} \rceil \cdot p(u)$. Since $x_i > y_i$, then $z' \leq z$, and the lemma follows. \blacktriangleleft

► **Proposition 17.** *Mechanism \mathcal{M}_{few} is $\lceil \sqrt{n} \rceil$ -approximate.*

5 Conclusions

We have focused on OSP mechanisms, a compelling and needed notion of incentive compatibility for bounded rationality; [23] proves that OSP is the notion that captures strategyproofness for agents who lack contingent reasoning skills. It is thus paramount to understand the limitations and the power of these mechanisms.

We have introduced a new technique to look at OSP mechanisms, and shown its power by giving tight results on the approximation for a paradigmatic problem in the area. Our contribution highlights how there are two dimensions, algorithms and their implementation, to the design of these mechanisms. The interplay between these dimensions is encapsulated by OSP CMON and plays a central role, as shown by the limitations of fixing the implementation beforehand (as in DA auctions or direct revelation mechanisms).

Furthermore, the significance of the technique can be seen by comparing the previously known lower bounds on the approximation guarantee of OSP mechanisms given in [12, 5]. These results focus on the first divergent agent only and bound the *strategyproof* payments for the identified instances in order to understand and limit the behavior of the algorithm. As a result, their bounds are small constants (2 for machine scheduling in [12] and $1 + \epsilon$, for combinatorial auctions with additive bidders in [5]).

We leave a number of open problems. A technical one is about the domain size and the difference between 2-cycles and longer ones; to what extent adding an extra type in the domain can deteriorate the approximation ratio of OSP mechanisms? A second, more conceptual question, is about dealing with multi-parameter agents. Even with the machinery of OSP CMON, it does not seem immediate to characterize the implementation trees for this kind of agents as there is not a concept of relative ordering of types. Hence, the common pattern of OSP mechanisms, where at each node of the implementation tree an extreme of the current domain is separated from the rest, cannot be adopted.

Abstract

An undirected graph G is d -degenerate if every subgraph of G has a vertex of degree at most d . By the classical theorem of Erdős and Gallai from 1959, every graph of degeneracy $d > 1$ contains a cycle of length at least $d + 1$. The proof of Erdős and Gallai is constructive and can be turned into a polynomial time algorithm constructing a cycle of length at least $d + 1$. But can we decide in polynomial time whether a graph contains a cycle of length at least $d + 2$? An easy reduction from HAMILTONIAN CYCLE provides a negative answer to this question: Deciding whether a graph has a cycle of length at least $d + 2$ is NP-complete. Surprisingly, the complexity of the problem changes drastically when the input graph is 2-connected. In this case we prove that deciding whether G contains a cycle of length at least $d + k$ can be done in time $2^{\mathcal{O}(k)}|V(G)|^{\mathcal{O}(1)}$. In other words, deciding whether a 2-connected n -vertex G contains a cycle of length at least $d + \log n$ can be done in polynomial time. Similar algorithmic results hold for long paths in graphs. We observe that deciding whether a graph has a path of length at least $d + 1$ is NP-complete. However, we prove that if graph G is connected, then deciding whether G contains a path of length at least $d + k$ can be done in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$. We complement these results by showing that the choice of degeneracy as the “above guarantee parameterization” is optimal in the following sense: For any $\varepsilon > 0$ it is NP-complete to decide whether a connected (2-connected) graph of degeneracy d has a path (cycle) of length at least $(1 + \varepsilon)d$.

1 Introduction

The classical theorem of Erdős and Gallai [11] says that

► **Theorem 1** (Erdős and Gallai [11]). *Every graph with n vertices and more than $(n - 1)\ell/2$ edges ($\ell \geq 2$) contains a cycle of length at least $\ell + 1$.*

Recall that a graph G is d -degenerate if every subgraph H of G has a vertex of degree at most d , that is, the minimum degree $\delta(H) \leq d$. Respectively, the *degeneracy* of graph G , is $\text{dg}(G) = \max\{\delta(H) \mid H \text{ is a subgraph of } G\}$. Since a graph of degeneracy d has a subgraph H with at least $d \cdot |V(H)|/2$ edges, by Theorem 1, it contains a cycle of length at least $d + 1$. Let us note that the degeneracy of a graph can be computed in polynomial time, see e.g. [28], and thus by Theorem 1, deciding whether a graph has a cycle of length at least $d + 1$ can be done in polynomial time. In this paper we revisit this classical result from the algorithmic perspective.

We define the following problem.

LONGEST CYCLE ABOVE DEGENERACY

Input: A graph G and a positive integer k .

Task: Decide whether G contains a cycle of length at least $\text{dg}(G) + k$.

Let us first sketch why LONGEST CYCLE ABOVE DEGENERACY is NP-complete for $k = 2$ even for connected graphs. We can reduce HAMILTONIAN CYCLE to LONGEST CYCLE ABOVE DEGENERACY with $k = 2$ as follows. For a connected non-complete graph G on n vertices, we construct connected graph H from G and a complete graph K_{n-1} on $n - 1$ vertices as follows. We identify one vertex of G with one vertex of K_{n-1} . Thus the obtained graph H has $|V(G)| + n - 2$ vertices and is connected; its degeneracy is $n - 2$. Then H has a cycle with $\text{dg}(H) + 2 = n$ vertices if and only if G has a Hamiltonian cycle.

Interestingly, when the input graph is 2-connected, the problem becomes fixed-parameter tractable being parameterized by k . Let us recall that a connected graph G is (vertex) 2-connected if for every $v \in V(G)$, $G - v$ is connected. Our first main result is the following theorem.

► **Theorem 2.** *On 2-connected graphs LONGEST CYCLE ABOVE DEGENERACY is solvable in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.*

Similar results can be obtained for paths. Of course, if a graph contains a cycle of length $d + 1$, it also contains a simple path on $d + 1$ vertices. Thus for every graph G of degeneracy d , deciding whether G contains a path on $\text{dg}(G) + 1$ vertices can be done in polynomial time. Again, it is easy to show that it is NP-complete to decide whether G contains a path with $d + 2$ vertices by a reduction from HAMILTONIAN PATH. The reduction is very similar to the one we sketched for LONGEST CYCLE ABOVE DEGENERACY. The only difference that this time graph H consists of a disjoint union of G and K_{n-1} . The degeneracy of H is $d = n - 2$, and H has a path with $d + 2 = n$ vertices if and only if G contains a Hamiltonian path. Note that graph H used in the reduction is not connected. However, when the input graph G is connected, the complexity of the problem changes drastically. We define

LONGEST PATH ABOVE DEGENERACY

Input: A graph G and a positive integer k .
Task: Decide whether G contains a path with at least $\text{dg}(G) + k$ vertices.

The second main contribution of our paper is the following theorem.

► **Theorem 3.** *On connected graphs* LONGEST PATH ABOVE DEGENERACY *is solvable in time* $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.

Let us remark that Theorem 2 does not imply Theorem 3, because Theorem 2 holds only for 2-connected graphs.

We also show that the parameterization lower bound $\text{dg}(G)$ that is used in Theorems 2 and 3 is tight in some sense. We prove that for any $0 < \varepsilon < 1$, it is NP-complete to decide whether a connected graph G contains a path with at least $(1 + \varepsilon)\text{dg}(G)$ vertices and it is NP-complete to decide whether a 2-connected graph G contains a cycle with at least $(1 + \varepsilon)\text{dg}(G)$ vertices.

Related work. HAMILTONIAN PATH and HAMILTONIAN CYCLE problems are among the oldest and most fundamental problems in Graph Theory. In parameterized complexity the following generalizations of these problems, LONGEST PATH and LONGEST CYCLE, were heavily studied. The LONGEST PATH problem is to decide, given an n -vertex (di)graph G and an integer k , whether G contains a path of length at least k . Similarly, the LONGEST CYCLE problem is to decide whether G contains a cycle of length at least k . There is a plethora of results about parameterized complexity (we refer to the book of Cygan et al. [9] for the introduction to the field) of LONGEST PATH and LONGEST CYCLE (see, e.g., [4, 5, 7, 6, 12, 14, 22, 23, 24, 32]) since the early work of Monien [29]. The fastest known randomized algorithm for LONGEST PATH on undirected graph is due to Björklund et al. [4] and runs in time $1.657^k \cdot n^{\mathcal{O}(1)}$. On the other hand very recently, Tsur gave the fastest known deterministic algorithm for the problem running in time $2.554^k \cdot n^{\mathcal{O}(1)}$ [31]. Respectively for LONGEST CYCLE, the current fastest randomized algorithm running in time $4^k \cdot n^{\mathcal{O}(1)}$ was given by Zehavi in [33] and the best deterministic algorithm constructed by Fomin et al. in [13] runs in time $4.884^k \cdot n^{\mathcal{O}(1)}$.

Our theorems about LONGEST PATH ABOVE DEGENERACY and LONGEST CYCLE ABOVE DEGENERACY fit into an interesting trend in parameterized complexity called “above guarantee” parameterization. The general idea of this paradigm is that the natural parameterization of, say, a maximization problem by the solution size is not satisfactory if there is a lower bound for the solution size that is sufficiently large. For example, there always exists a satisfying assignment that satisfies half of the clauses or there is always a max-cut containing at least half the edges. Thus nontrivial solutions occur only for the values of the parameter that are above the lower bound. This indicates that for such cases, it is more natural to parameterize the problem by the difference of the solution size and the bound. The first paper about above guarantee parameterization was due to Mahajan and Raman [26] who applied this approach to the MAX SAT and MAX CUT problem. This approach was successfully applied to various problems, see e.g. [1, 8, 16, 17, 18, 19, 20, 25, 27].

For LONGEST PATH, the only successful above guarantee parameterization known prior to our work was parameterization above shortest path. More precisely, let s, t be vertices of an undirected graph G . Clearly, the length of any (s, t) -path in G is lower bounded by the shortest distance, $d(s, t)$, between these vertices. Based on this observation, Bezáková et al. in [3] introduced the LONGEST DETOUR problem that asks, given a graph G , two vertices

s, t , and a positive integer k , whether G has an (s, t) -path with at least $d(s, t) + k$ vertices. They proved that for undirected graphs, this problem can be solved in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$. On the other hand, the parameterized complexity of LONGEST DETOUR on directed graphs is still open. For the variant of the problem where the question is whether G has an (s, t) -path with *exactly* $d(s, t) + k$ vertices, a randomized algorithm with running time $2.746^k \cdot n^{\mathcal{O}(1)}$ and a deterministic algorithm with running time $6.745^k \cdot n^{\mathcal{O}(1)}$ were obtained [3]. These algorithms work for both undirected and directed graphs. Parameterization above degeneracy is “orthogonal” to the parameterization above the shortest distance. There are classes of graphs, like planar graphs, that have constant degeneracy and arbitrarily large diameter. On the other hand, there are classes of graphs, like complete graphs, of constant diameter and unbounded degeneracy.

Our approach. Our algorithmic results are based on classical theorems of Dirac [10], and Erdős and Gallai [11] on the existence of “long cycle” and “long paths” and can be seen as non-trivial algorithmic extensions of these classical theorems. Let $\delta(G)$ be the minimum vertex degree of graph G .

► **Theorem 4** (Dirac [10]). *Every n -vertex 2-connected graph G with minimum vertex degree $\delta(G) \geq 2$, contains a cycle with at least $\min\{2\delta(G), n\}$ vertices.*

► **Theorem 5** (Erdős and Gallai [11]). *Every connected n -vertex graph G contains a path with at least $\min\{2\delta(G) + 1, n\}$ vertices.*

Theorem 4 is used to prove Theorem 2 and Theorem 5 is used to prove Theorem 3.

We give a high-level overview of the ideas used to prove Theorem 2. The ideas behind the proof of Theorem 3 are similar. Let G be a 2-connected graph of degeneracy d . If $d = \mathcal{O}(k)$, we can solve LONGEST CYCLE ABOVE DEGENERACY in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ by making use of one of the algorithms for LONGEST CYCLE. Assume from now that $d \geq c \cdot k$ for some constant c , which will be specified in the proof. Then we find a d -core H of G (a connected subgraph of G with the minimum vertex degree at least d). This can be done in linear time by one of the known algorithms, see e.g. [28]. If the size of H is sufficiently large, say $|V(H)| \geq d + k$, we use Theorem 4 to conclude that H contains a cycle with at least $|V(H)| \geq d + k$ vertices.

The most interesting case occurs when $|V(H)| < d + k$. Suppose that G has a cycle of length at least $d + k$. It is possible to prove that there is also a cycle of length at least $d + k$ that hits the core H . We do not know how many times and in which vertices of H this cycle enters and leaves H , but we can guess these terminal points. The interesting property of the core H is that, loosely speaking, for any “small” set of terminal points, inside H the cycle can be rerouted in such a way that it will contain all vertices of H .

A bit more formally, we prove the following structural result. We define a system of segments in G with respect to $V(H)$, which is a family of internally vertex-disjoint paths $\{P_1, \dots, P_r\}$ in G (see Figure 1). Moreover, for every $1 \leq i \leq r$, every path P_i has at least 3 vertices, its endpoints are in $V(H)$ and all internal vertices of P_i are in $V(G) \setminus V(H)$. Also the union of all the segments is a forest with every connected component being a path.

We prove that G contains a cycle of length at least $k + d$ if and only if

- either there is a path of length at least $k + d - |V(H)|$ with endpoints in $V(H)$ and all internal vertices outside H , or
- there is a system of segments with respect to $V(H)$ such that the total number of vertices outside H used by the paths of the system, is within the interval $[k + d - |V(H)|, 2 \cdot (k + d - |V(H)|)]$.

■ **Figure 1** Reducing LONGEST CYCLE ABOVE DEGENERACY to finding a system of segments P_1, \dots, P_r ; complementing the segments into a cycle is shown by dashed lines.

The proof of this structural result is built on Lemma 8, which describes the possibility of routing in graphs of large minimal degree. The crucial property is that we can complement any system of segments of bounded size by segments inside the core H to obtain a cycle that contains all the vertices of H as is shown in Figure 1.

Since $|V(H)| > d$, the problem of finding a cycle of length at least $k + d$ in G boils down to one of the following tasks. Either find a path of length $c' \cdot k$ with all internal vertices outside H , or find a system of segments with respect to $V(H)$ such that the total number of vertices used by the paths of the system is $c'' \cdot k$, here c' and c'' are the constants to be specified in the proof. In the first case, we can use one of the known algorithms to find in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ such a long path. In the second case, we can use color-coding to solve the problem.

Organization of the paper. In Section 2 we give basic definitions and state some known fundamental results. Sections 3–4 contain the proof of Theorems 3 and 2. In Section 3 we state structural results that we need for the proofs and in Section 4 we complete the proofs. In Section 5, we give the complexity lower bounds for our algorithmic results. We conclude the paper in Section 6 by stating some open problems.

2 Preliminaries

We consider only finite undirected graphs. For a graph G , we use $V(G)$ and $E(G)$ to denote its vertex set and edge set, respectively. Throughout the paper we use $n = |V(G)|$ and $m = |E(G)|$. For a graph G and a subset $U \subseteq V(G)$ of vertices, we write $G[U]$ to denote the subgraph of G induced by U . We write $G - U$ to denote the graph $G[V(G) \setminus U]$; for a single-element set $U = \{u\}$, we write $G - u$. For a vertex v , we denote by $N_G(v)$ the (*open*) *neighborhood* of v , i.e., the set of vertices that are adjacent to v in G . For a set $U \subseteq V(G)$, $N_G(U) = (\bigcup_{v \in U} N_G(v)) \setminus U$. The *degree* of a vertex v is $d_G(v) = |N_G(v)|$. The *minimum degree* of G is $\delta(G) = \min\{d_G(v) \mid v \in V(G)\}$. A d -*core* of G is an inclusion maximal induced connected subgraph H with $\delta(H) \geq d$. Every graph of degeneracy at least d contains a d -core and that can be found in linear time (see [28]). A vertex u of a connected graph G with at least two vertices is a *cut vertex* if $G - u$ is disconnected. A connected graph G is *2-connected* if it has no cut vertices. An inclusion maximal induced 2-connected subgraph of G is called a *biconnected component* or *block*. Let \mathcal{B} be the set of blocks of a connected graph G and let C be the set of cut vertices. Consider the bipartite graph $Block(G)$ with the vertex set $\mathcal{B} \cup C$, where (\mathcal{B}, C) is the bipartition, such that $B \in \mathcal{B}$ and $c \in C$ are adjacent if and only if $c \in V(B)$. The block graph of a connected graph is always a tree (see [21]).

A path in a graph is a self-avoiding walk. Thus no vertex appears in a path more than once. A cycle is a closed self-avoiding walk. For a path P with end-vertices s and t , we say that the vertices of $V(P) \setminus \{s, t\}$ are *internal*. We say that G is a *linear forest* if each component of G is a path. The *contraction* of an edge xy is the operation that removes the

vertices x and y together with the incident edges and replaces them by a vertex u_{xy} that is adjacent to the vertices of $N_G(\{x, y\})$ of the original graph. If H is obtained from G by contracting some edges, then H is a *contraction* of G .

We summarize below some known algorithmic results which will be used as subroutines by our algorithm.

► **Proposition 6.** LONGEST PATH and LONGEST CYCLE are solvable in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.

We also need the result about the variant of LONGEST PATH with fixed end-vertices. In the (s, t) -LONGEST PATH, we are given two vertices s and t of a graph G and a positive integer k . The task is to decide, whether G has an (s, t) -path with at least k vertices. Using the results of Bezáková et al. [2], we immediately obtain the following.

► **Proposition 7.** (s, t) -LONGEST PATH is solvable in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.

3 Segments and rerouting

In this section we define systems of segments and prove structural results about them. These combinatorial results are crucial for our algorithms for LONGEST PATH ABOVE DEGENERACY and LONGEST CYCLE ABOVE DEGENERACY.

The following rerouting lemma is crucial for our algorithms.

► **Lemma 8.** Let G be an n -vertex graph and k be a positive integer such that $\delta(G) \geq \max\{5k - 3, n - k\}$. Let $\{s_1, t_1\}, \dots, \{s_r, t_r\}$, $r \leq k$, be a collection of pairs of vertices of G such that (i) $s_i, t_i \notin \{s_j, t_j\}$ for all $i \neq j$, $i, j \in \{1, \dots, r\}$, and (ii) there is at least one index $i \in \{1, \dots, r\}$ such that $s_i \neq t_i$. Then there is a family of pairwise vertex-disjoint paths $\mathcal{P} = \{P_1, \dots, P_r\}$ in G such that each P_i is an (s_i, t_i) -path and $\bigcup_{i=1}^r V(P_i) = V(G)$, that is, the paths cover all vertices of G .

Proof. We prove the lemma in two steps. First we show that there exists a family \mathcal{P}' of pairwise vertex-disjoint paths connecting all pairs $\{s_i, t_i\}$. Then we show that if the paths of \mathcal{P}' do not cover all vertices of G , it is possible to enlarge a path such that the new family of paths covers more vertices.

We start by constructing a family of vertex-disjoint paths $\mathcal{P}' = \{P_1, \dots, P_r\}$ in G such that each $P_i \in \mathcal{P}'$ is an (s_i, t_i) -path. We prove that we can construct paths in such a way that each P_i has at most 3 vertices. Let $T = \bigcup_{i=1}^r \{s_i, t_i\}$ and $S = V(G) \setminus T$. Notice that $|S| \geq n - 2k \geq \delta(G) + 1 - 2k \geq 3k - 2$. We consecutively construct paths of \mathcal{P}' for $i \in \{1, \dots, r\}$. If $s_i = t_i$, then we have a trivial (s_i, t_i) -path. If s_i and t_i are adjacent, then edge $s_i t_i$ forms an (s_i, t_i) -path with 2 vertices. Assume that $s_i \neq t_i$ and $s_i t_i \notin E(G)$. The already constructed paths contain at most $r - 1 \leq k - 1$ vertices of S in total. Hence, there is a set $S' \subseteq S$ of at least $2k - 1$ vertices that are not contained in any of already constructed paths. Since $\delta(G) \geq n - k$, each vertex of G has at most $k - 1$ non-neighbors in G . By the pigeonhole principle, there is $v \in S'$ such that $s_i v, t_i v \in E(G)$. Then we can construct the path $P_i = s_i v t_i$.

We proved that there is a family $\mathcal{P}' = \{P_1, \dots, P_r\}$ of vertex-disjoint (s_i, t_i) -paths in G . Among all such families, let us select a family $\mathcal{P} = \{P_1, \dots, P_r\}$ covering the maximum number of vertices of $V(G)$. If $\bigcup_{i=1}^r V(P_i) = V(G)$, then the lemma holds. Assume that $|\bigcup_{i=1}^r V(P_i)| < |V(G)|$. Suppose $|\bigcup_{i=1}^r V(P_i)| \leq 3k - 1$. Since $s_i \neq t_i$ for some i , there is an edge uv in one of the paths. Since $n \geq \delta(G) + 1 \geq 5k - 2$, there are at least $2k - 1$ vertices uncovered by paths of \mathcal{P} . Since $\delta(G) \geq n - k$, each vertex of G has at most $k - 1$

non-neighbors in G . Thus there is $w \in V(G) \setminus (\bigcup_{i=1}^r V(P_i))$ adjacent to both u and v . But then we can extend the path containing uv by replacing uv by the path uvw . The paths of the new family cover more vertices than the paths of \mathcal{P} , which contradicts the choice of \mathcal{P} .

Suppose $|\bigcup_{i=1}^r V(P_i)| \geq 3k$. Because the paths of \mathcal{P} are vertex-disjoint, the union of edges of paths from \mathcal{P} contains a k -matching. That is, there are k edges u_1v_1, \dots, u_kv_k of G such that for every $i \in \{1, \dots, k\}$, vertices u_i, v_i are consecutive in some path from \mathcal{P} and $u_i \neq u_j, u_i \neq v_j$ for all non-equal $i, j \in \{1, \dots, k\}$. Let $w \in V(G) \setminus (\bigcup_{i=1}^r V(P_i))$. We again use the observation that w has at most $k - 1$ non-neighbors in G and, therefore, there is $j \in \{1, \dots, k\}$ such that $u_jw, v_jw \in E(G)$. Then we extend the path containing u_jv_j by replacing edge u_jv_j by the path u_jwv_j , contradicting the choice of \mathcal{P} . We conclude that the paths of \mathcal{P} cover all vertices of G . ◀

Let G be a graph and let $T \subset V(G)$ be a set of terminals. We need the following definitions.

▶ **Definition 9** (Terminal segments). *We say that a path P in G is a one-terminal T -segment if it has at least two vertices, exactly one end-vertex of P is in T and other vertices are not in T . Respectively, P is a two-terminal T -segment if it has at least three vertices, both end-vertices of P are in T and internal vertices of P are not in T .*

For every cycle C hitting H , removing the vertices of H from C turns it into a set of two-terminal T -segments for $T = V(H)$. So here is the definition.

▶ **Definition 10** (System of T -segments). *We say that a set $\{P_1, \dots, P_r\}$ of paths in G is a system of T -segments if it satisfies the following conditions.*

- (i) *For each $i \in \{1, \dots, r\}$, P_i is a two-terminal T -segment,*
- (ii) *P_1, \dots, P_r are pairwise internally vertex-disjoint, and*
- (iii) *the union of P_1, \dots, P_r is a linear forest.*

Let us remark that we do not require that the end-vertices of the paths $\{P_1, \dots, P_r\}$ cover all vertices of T . System of segments will be used for solving LONGEST CYCLE ABOVE DEGENERACY.

For LONGEST PATH ABOVE DEGENERACY we need to modify the definition of a system of T -segments to include the possibility that path can start or end in H .

▶ **Definition 11** (Extended system of T -segments). *We say that a set $\{P_1, \dots, P_r\}$ of paths in G is an extended system of T -segments if the following holds.*

- (i) *At least one and at most two paths are one-terminal T -segments and the others are two-terminal T -segments.*
- (ii) *P_1, \dots, P_r are pairwise internally vertex-disjoint and the end-vertices of each one-terminal segment that is in $V(G) \setminus T$ is pairwise distinct with the other vertices of the paths.*
- (iii) *The union of P_1, \dots, P_r is a linear forest and if $\{P_1, \dots, P_r\}$ contains two one-terminal segments, then the vertices of these segments are in distinct components of the forest.*

The following lemma will be extremely useful for the algorithm solving LONGEST PATH ABOVE DEGENERACY. Informally, it shows that if a connected graph G is of large degeneracy but has a small core H , then deciding whether G has a path of length $k + d$ can be reduced to checking whether G has an extended system of T -segments with terminal set $T = V(H)$ such that the total number of vertices used by the system is $\mathcal{O}(k)$.

► **Lemma 12.** *Let $d, k \in \mathbb{N}$. Let G be a connected graph with a d -core H such that $d \geq 5k - 3$ and $d > |V(H)| - k$. Then G has a path on $d + k$ vertices if and only if G has an extended system of T -segments $\{P_1, \dots, P_r\}$ with terminal set $T = V(H)$ such that the total number of vertices contained in the paths of the system in $V(G) \setminus V(H)$ is $p = d + k - |V(H)|$.*

Proof. We put $T = V(H)$. Suppose first that G has an extended system $\{P_1, \dots, P_r\}$ of T -segments and that the total number of vertices of the paths in the system outside T is $p = d + k - |T|$. Let s_i and t_i be the end-vertices of P_i for $i \in \{1, \dots, r\}$ and assume without loss of generality that for $1 \leq i < j \leq r$, the vertices of P_i and P_j are pairwise distinct with the possible exception $t_i = s_j$ when $i = j - 1$. We also assume without loss of generality that P_1 is a one-terminal segment and $t_1 \in T$ and if $\{P_1, \dots, P_r\}$ has two one-terminal segments, then the second such segment is P_r and $s_r \in T$. Note that because $|V(H)| > d$, we have that $p = d + k - |V(H)| < k$.

Suppose that $\{P_1, \dots, P_r\}$ contains one one-terminal segment P_1 . Let s_{r+1} be an arbitrary vertex of $T \setminus (\bigcup_{i=1}^r V(P_i))$. Notice that such a vertex exists, because $|T \cap (\bigcup_{i=1}^r V(P_i))| \leq 2p - 1 < 2k - 1$ and $|T| \geq d + 1 \geq 5k - 3$. Consider the collection of pairs of vertices $\{t_1, s_2\}, \{t_2, s_3\}, \dots, \{t_r, s_{r+1}\}$. Notice that vertices from distinct pairs are distinct and $t_r \neq s_{r+1}$. By Lemma 8, there are vertex-disjoint paths P'_1, \dots, P'_r in H that cover T such that P'_i is a (t_i, s_{i+1}) -path for $i \in \{1, \dots, r\}$. By concatenating $P_1, P'_1, P_2, \dots, P_r, P'_r$ we obtain a path in G with $|T| + p = d + k$ vertices.

Assume now that $\{P_1, \dots, P_r\}$ contains two one-terminal segments P_1 and P_r . Consider the collection of pairs of vertices $\{t_1, s_2\}, \dots, \{t_{r-1}, s_r\}$. Notice that vertices from distinct pairs are distinct and there is $i \in \{2, \dots, r\}$ such that $t_{i-1} \neq s_i$ by the condition (iii) of the definition of an extended system of segments. By Lemma 8, there are vertex-disjoint paths P'_1, \dots, P'_{r-1} in H that cover T such that P'_i is a (t_i, s_{i+1}) -path for $i \in \{1, \dots, r - 1\}$. By concatenating $P_1, P'_1, \dots, P'_{r-1}, P_r$ we obtain a path in G with $|T| + p = d + k$ vertices.

To show the implication in the opposite direction, let us assume that G has an (x, y) -path P with $d + k$ vertices. We distinguish several cases.

Case 1: $V(P) \cap T = \emptyset$. Consider a shortest path P' with one end-vertex $s \in V(P)$ and the second end-vertex $t \in T$. Notice that such a path exists, because G is connected. Denote by P_x and P_y the (s, x) and (s, y) -subpaths of P respectively. Because $d \geq 5k - 3$, $|V(P_x)| \geq k$ or $|V(P_y)| \geq k$. Assume that $|V(P_x)| \geq k$. Then the concatenation of P' and P_x is a path with at least $k + 1$ vertices and it contains a subpath P'' with the end-vertex t with $p + 1$ vertices. We have that $\{P'\}$ is an extended system of T -segments and P'' has p vertices outside T .

Case 2: $V(P) \cap T \neq \emptyset$ and $E(P) \cap E(H) = \emptyset$. Let $S = V(P) \cap T$. Since H is an induced subgraph of G and $E(P) \cap E(H) = \emptyset$, $|V(P) \setminus S| \geq (d + k)/2 - 1 \geq 3k - 5/2 > 3p - 5/2 \geq 2p - 2$. Then for every $t \in S$, either the (t, x) -subpath P_x of P contains at least p vertices outside T or the (t, y) -subpath P_y of P contains at least p vertices outside T . Assume without loss of generality that P_x contains at least p vertices outside T . Consider the minimal subpath P' of P_x ending at t such that $|V(P') \setminus T| = p$. Then the start vertex s of P' is not in T . Let $\{t_1, \dots, t_r\} = V(P') \cap T$ and assume that t_1, \dots, t_r are ordered in the same order as they occur in P' starting from s . In particular, $t_r = t$. Let $t_0 = s$. Consider the paths P_1, \dots, P_r where P_i is the (t_{i-1}, t_i) -subpath of P' for $i \in \{1, \dots, r\}$. Since $k > p$, $r \leq k$. We obtain that $\{P_1, \dots, P_r\}$ is an extended system of T -segments with p vertices outside T .

Case 3: $E(P) \cap E(H) \neq \emptyset$. Then there are distinct $s, t \in T \cap V(P)$ such that the (s, t) -subpath of P lies in H . Since P has at least p vertices outside T , there are $s', t' \in V(P) \setminus T$ such that the (s', t') -subpath P' of P is a subpath with exactly p vertices outside T with $s, t \in V(P')$. Let P_1, \dots, P_r be the family of inclusion maximal subpaths of P' containing

the vertices of $V(P') \setminus T$ such that the internal vertices of each P_i are outside T . Observe that since $s \neq t$, the union of these paths is a linear forest with at least two components. We conclude that the set $\{P_1, \dots, P_r\}$ is a required extended system of T -segments. ◀

The next lemma will be used for solving LONGEST CYCLE ABOVE DEGENERACY.

► **Lemma 13.** *Let $d, k \in \mathbb{N}$. Let G be a 2-connected graph with a d -core H such that $d \geq 5k - 3$ and $d > |V(H)| - k$. Then G has a cycle with at least $d + k$ vertices if and only if one of the following holds (where $p = d + k - |V(H)|$).*

- (i) *There are distinct $s, t \in V(H)$ and an (s, t) -path P in G with all internal vertices outside $V(H)$ such that P has at least p internal vertices.*
- (ii) *G has a system of T -segments $\{P_1, \dots, P_r\}$ with terminal set $T = V(H)$ and the total number of vertices of the paths outside $V(H)$ is at least p and at most $2p - 2$.*

Proof. We put $T = V(H)$. First, we show that if (i) or (ii) holds, then G has a cycle with at least $d + k$ vertices. Suppose that there are distinct $s, t \in T$ and an (s, t) -path P in G with all internal vertices outside T such that P has at least p internal vertices. By Lemma 8, H has a Hamiltonian (s, t) -path P' . By taking the union of P and P' we obtain a cycle with at least $|T| + p = d + k$ vertices.

Now assume that G has a system of T -segments $\{P_1, \dots, P_r\}$ and the total number of vertices of the paths outside T is at least p . Let s_i and t_i be the end-vertices of P_i for $i \in \{1, \dots, r\}$ and assume without loss of generality that for $1 \leq i < j \leq r$, the vertices of P_i and P_j are pairwise distinct with the possible exception $t_i = s_j$ when $i = j - 1$. Consider the collection of pairs of vertices $\{t_1, s_2\}, \dots, \{t_{r-1}, s_r\}, \{t_r, s_1\}$. Notice that vertices from distinct pairs are distinct and $t_r \neq s_1$. By Lemma 8, there are vertex-disjoint paths P'_1, \dots, P'_r in H that cover T such that P'_i is a (t_i, s_{i+1}) -path for $i \in \{1, \dots, r - 1\}$ and P'_r is a (t_r, s_1) -path. By taking the union of P_1, \dots, P_r and P'_1, \dots, P'_r we obtain a cycle in G with at least $|T| + p = d + k$ vertices.

To show the implication in the other direction, assume that G has a cycle C with at least $d + k$ vertices.

Case 1: $V(C) \cap T = \emptyset$. Since G is a 2-connected graph, there are pairwise distinct vertices $s, t \in T$ and $x, y \in V(C)$ and vertex-disjoint (s, x) and (y, t) -paths P_1 and P_2 such that the internal vertices of the paths are outside $T \cup V(C)$. The cycle C contains an (x, y) -path P with at least $(d + k)/2 + 1 \geq p$ vertices. The concatenation of P_1, P and P_2 is an (s, t) -path in G with at least p internal vertices and the internal vertices are outside T . Hence, (i) holds.

Case 2: $|V(C) \cap T| = 1$. Let $V(C) \cap T = \{s\}$ for some vertex s . Since G is 2-connected, there is a shortest (x, t) -path P in $G - s$ such that $x \in V(C)$ and $t \in T$. The cycle C contains an (s, x) -path P' with at least $(d + k)/2 + 1 \geq p$ vertices. The concatenation of P' and P is an (s, t) -path in G with at least p internal vertices and the internal vertices of the path are outside T . Therefore, (i) is fulfilled.

Case 3: $|V(C) \cap T| \geq 2$. Since $|V(C)| \geq d$ and $|T| < d$, we have that $V(C) \setminus T \neq \emptyset$. Then we can find pairs of distinct vertices $\{s_1, t_1\}, \dots, \{s_\ell, t_\ell\}$ of $T \cap V(C)$ and segments P_1, \dots, P_ℓ of C such that (a) P_i is an (s_i, t_i) -path for $i \in \{1, \dots, \ell\}$ with at least one internal vertex and the internal vertices of P_i are outside T , (b) for $1 \leq i < j \leq \ell$, the vertices of P_i and P_j are distinct with the possible exception $t_i = s_j$ if $i = j - 1$ and, possibly, $t_\ell = s_1$, and (c) $\bigcup_{i=1}^{\ell} V(P_i) \setminus T = V(C) \setminus T$. If there is $i \in \{1, \dots, \ell\}$ such that P_i has at least p internal vertices, then (i) is fulfilled.

47:10 Going Far From Degeneracy

Now assume that each P_i has at most $p - 1$ internal vertices; notice that $p \geq 2$ in this case. We select an inclusion minimal set of indices $I \subseteq \{1, \dots, \ell\}$ such that $|\bigcup_{i \in I} V(P_i) \setminus T| \geq p$. Notice that because each path has at most $p - 1$ internal vertices, $|\bigcup_{i \in I} V(P_i) \setminus T| \leq 2p - 2$. Let $I = \{i_1, \dots, i_r\}$ and $i_1 < \dots < i_r$. By the choice of P_{i_1}, \dots, P_{i_r} , the union of P_{i_1}, \dots, P_{i_r} is either the cycle C or a linear forest. Suppose that the union of the paths is C . Then $I = \{1, \dots, \ell\}$, $\ell \leq p$ and $|V(P) \cap T| = \ell$. Note that because $|V(H)| > d$, we have that $p = d + k - |V(H)| < k$. We obtain that C has at most $(2p - 2) + p \leq 3p - 2 < 3k - 2 < d + k$ vertices (the last inequality follows from the fact that $d \geq 5k - 3$); a contradiction. Hence, the union of the paths is a linear forest. Therefore, $\{P_{i_1}, \dots, P_{i_r}\}$ is a system of T -segments with terminal set $T = V(H)$ and the total number of vertices of the paths outside T is at least p and at most $2p - 2$, that is, (ii) is fulfilled. ◀

We have established the fact that the existence of a long (path) cycle is equivalent to the existence of an (extended) system of T -segments for some terminal set T with at most $p \leq k$ vertices from outside T . Towards designing algorithms for LONGEST PATH ABOVE DEGENERACY and LONGEST CYCLE ABOVE DEGENERACY, we define two auxiliary problems which can be solved using well known color-coding technique.

SEGMENTS WITH TERMINAL SET

Input: A graph G , $T \subset V(G)$ and a positive integers p and r .
Task: Decide whether G has a system of segments $\{P_1, \dots, P_r\}$ w.r.t. T such that the total number of internal vertices of the paths is p .

EXTENDED SEGMENTS WITH TERMINAL SET

Input: A graph G , $T \subset V(G)$ and a positive integers p and r .
Task: Decide whether G has an extended system of segments $\{P_1, \dots, P_r\}$ w.r.t. T such that the total number of vertices of the paths outside T is p .

► **Lemma 14** (*).¹ SEGMENTS WITH TERMINAL SET and EXTENDED SEGMENTS WITH TERMINAL SET are solvable in time $2^{\mathcal{O}(p)} \cdot n^{\mathcal{O}(1)}$.

4 Putting all together: Final proofs

Proof of Theorem 3. Let G be a connected graph of degeneracy at least d and let k be a positive integer. If $d \leq 5k - 4$, then we check the existence of a path with $d + k \leq 6k - 4$ vertices using Proposition 6 in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$. Assume from now that $d \geq 5k - 3$. Then we find a d -core H of G . This can be done in linear time using the results of Matula and Beck [28]. If $|V(H)| \geq d + k$, then by Theorem 5, H , and hence G , contains a path with $\min\{2d + 1, |V(H)|\} \geq d + k$ vertices. Assume that $|V(H)| < d + k$. By Lemma 12, G has a path with $d + k$ vertices if and only if G has paths P_1, \dots, P_r such that $\{P_1, \dots, P_r\}$ is an extended system of T -segments for $T = V(H)$ and the total number of vertices of the paths outside T is $p = d + k - |T|$. Since the number of vertices in every graph is more than its minimum degree, we have that $|T| > d$, and thus $p < k$. For each $r \in \{1, \dots, p\}$, we verify if such a system exists in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ by making use of Lemma 14. Thus the total running time of the algorithm is $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$.

¹ Proofs of results marked with (*) are omitted in this extended abstract.

Proof of Theorem 2. Let G be a 2-connected graph of degeneracy at least d and let $k \in \mathbb{N}$. If $d \leq 5k - 4$, then we check the existence of a cycle with at least $d + k \leq 6k - 4$ vertices using Proposition 6 in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$. Assume from now on that $d \geq 5k - 3$. Then we find a d -core H of G in linear time using the results of Matula and Beck [28].

We claim that if $|V(H)| \geq d + k$, then H contains a cycle with at least $d + k$ vertices. If H is 2-connected, then this follows from Theorem 4. Assume that H is not a 2-connected graph. By the definition of a d -core, H is connected. Observe that $|V(H)| \geq d + 1 \geq 5k - 2 \geq 3$. Hence, H has at least two blocks and at least one cut vertex. Consider the block graph $Block(H)$ of H . Recall that the vertices of $Block(H)$ are the blocks and the cut vertices of H and a cut vertex c is adjacent to a block B if and only if $c \in V(B)$. Recall also that $Block(H)$ is a tree. We select an arbitrary block R of H and declare it to be the *root* of $Block(H)$. Let $S = V(G) \setminus V(H)$. Observe that $S \neq \emptyset$, because G is 2-connected and H is not. Let F_1, \dots, F_ℓ be the components of $G[S]$. We contract the edges of each component and denote the obtained vertices by u_1, \dots, u_ℓ . Denote by G' the obtained graph. It is straightforward to verify that G' has no cut vertices, that is, G' is 2-connected. For each $i \in \{1, \dots, \ell\}$, consider u_i . This vertex has at least 2 neighbors in $V(H)$. We select a vertex $v_i \in N_{G'}(u_i)$ that is not a cut vertex of H or, if all the neighbors of u_i are cut vertices, we select v_i be a cut vertex at maximum distance from R in $Block(H)$. Then we contract $u_i v_i$. Observe that by the choice of each v_i , the graph G'' obtained from G' by contracting $u_1 v_1, \dots, u_\ell v_\ell$ is 2-connected. We have that G'' is a 2-connected graph of minimum degree at least d with at least $d + k$ vertices. By Theorem 4, G'' has a cycle with at least $\min\{2d, |V(G'')|\} \geq d + k$ vertices. Because G'' is a contraction of G , we conclude that G contains a cycle with at least $d + k$ vertices as well.

From now we can assume that $|V(H)| < d + k$. By Lemma 13, G has a cycle with $d + k$ vertices if and only if one of the following holds for $p = d + k - |T|$ where $T = V(H)$.

- (i) There are distinct $s, t \in T$ and an (s, t) -path P in G with all internal vertices outside T such that P has at least p internal vertices.
- (ii) G has a system of T -segments $\{P_1, \dots, P_r\}$ and the total number of vertices of the paths outside T is at least p and at most $2p - 2$.

Notice that $p \leq k$ (because $d - |T| \leq 0$). We verify whether (i) holds using Proposition 7. To do it, we consider all possible choices of distinct s, t . Then we construct the auxiliary graph G_{st} from G by the deletion of the vertices of $T \setminus \{s, t\}$ and the edges of $E(H)$. Then we check whether G_{st} has an (s, t) -path of length at least $p + 1$ in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ applying Proposition 7.

Assume that (i) is not fulfilled. Then it remains to check (ii). For every $r \in \{1, \dots, p\}$, we verify the existence of a system of T -segments $\{P_1, \dots, P_r\}$ in time $2^{\mathcal{O}(k)} \cdot n^{\mathcal{O}(1)}$ using Lemma 14. We return the answer *yes* if we get the answer *yes* for at least one instance of SEGMENTS WITH TERMINAL SET and we return *no* otherwise.

5 Hardness for Longest Path and Cycle above Degeneracy

In this section we complement Theorems 3 and 2 by some hardness observations.

► **Proposition 15** (\star). ² LONGEST PATH ABOVE DEGENERACY is NP-complete even if $k = 2$ and LONGEST CYCLE ABOVE DEGENERACY is NP-complete even for connected graphs and $k = 2$.

² Proposition 15 and its proof was pointed to us by Nikolay Karpov.

47:12 Going Far From Degeneracy

Recall that a graph G has a path with at least $\text{dg}(G) + 1$ vertices and if $\text{dg}(G) \geq 2$, then G has a cycle with at least $\text{dg}(G) + 1$ vertices. Moreover, such a path or cycle can be constructed in polynomial (linear) time. Hence, Proposition 15 gives tight complexity bounds. Nevertheless, the construction used to show hardness for LONGEST PATH ABOVE DEGENERACY uses a disconnected graph, and the graph constructed to show hardness for LONGEST CYCLE ABOVE DEGENERACY has a cut vertex. Hence, it is natural to consider LONGEST PATH ABOVE DEGENERACY for connected graphs and LONGEST CYCLE ABOVE DEGENERACY for 2-connected graphs. We show in Theorems 3 and 2 that these problems are FPT when parameterized by k in these cases. Here, we observe that the lower bound $\text{dg}(G)$ that is used for the parameterization is tight in the following sense.

► **Proposition 16.** *For any $0 < \varepsilon < 1$, it is NP-complete to decide whether a connected graph G contains a path with at least $(1 + \varepsilon)\text{dg}(G)$ vertices and it is NP-complete to decide whether a 2-connected graph G contains a cycle with at least $(1 + \varepsilon)\text{dg}(G)$ vertices.*

Proof. Let $0 < \varepsilon < 1$.

First, we consider the problem about a path with $(1 + \varepsilon)\text{dg}(G)$ vertices. We reduce HAMILTONIAN PATH that is well-known to be NP-complete (see [15]). Let G be a graph with $n \geq 2$ vertices. We construct the graph G' as follows.

- Construct a copy of G .
- Let $p = 2\lceil \frac{n}{\varepsilon} \rceil$ and construct p pairwise adjacent vertices u_1, \dots, u_p .
- For each $v \in V(G)$, construct an edge vu_1 .
- Let $q = \lceil (1 + \varepsilon)(p - 1) - (n + p) \rceil$. Construct vertices w_1, \dots, w_q and edges $u_1w_1, w_q u_2$ and $w_{i-1}w_i$ for $i \in \{2, \dots, q\}$.

Notice that $q = \lceil (1 + \varepsilon)(p - 1) - (n + p) \rceil = \lceil 2\varepsilon\lceil \frac{n}{\varepsilon} \rceil - n - 1 - \varepsilon \rceil \geq \lceil n - 1 - \varepsilon \rceil \geq 1$ as $n \geq 2$. Observe also that G is connected. We claim that G has a Hamiltonian path if and only if G' has a path with at least $(1 + \varepsilon)\text{dg}(G')$ vertices. Notice that $\text{dg}(G') = p - 1$ and $|V(G')| = n + p + q = \lceil (1 + \varepsilon)\text{dg}(G') \rceil$. Therefore, we have to show that G has a Hamiltonian path if and only if G' has a Hamiltonian path. Suppose that G has a Hamiltonian path P with an end-vertex v . Consider the path $Q = vu_1w_1 \dots w_q u_2u_3 \dots u_p$. Clearly, the concatenation of P and Q is a Hamiltonian path in G' . Suppose that G' has a Hamiltonian path P . Since u_1 is a cut vertex of G' , we obtain that P has a subpath that is a Hamiltonian path in G .

Consider now the problem about a cycle with at least $(1 + \varepsilon)\text{dg}(G)$ vertices. We again reduce HAMILTONIAN PATH and the reduction is almost the same. Let G be a graph with $n \geq 2$ vertices. We construct the graph G' as follows.

- Construct a copy of G .
- Let $p = 2\lceil \frac{n}{\varepsilon} \rceil$ and construct p pairwise adjacent vertices u_1, \dots, u_p .
- For each $v \in V(G)$, construct edges vu_1 and vu_2 .
- Let $q = \lceil (1 + \varepsilon)(p - 1) - (n + p) \rceil$. Construct vertices w_1, \dots, w_q and edges $u_2w_1, w_q u_3$ and $w_{i-1}w_i$ for $i \in \{2, \dots, q\}$.

As before, we have that $q \geq 1$. Notice additionally that $p \geq 3$, i.e., the vertex u_3 exists. It is straightforward to see that G' is 2-connected. We claim that G has a Hamiltonian path if and only if G' has a cycle with at least $(1 + \varepsilon)\text{dg}(G')$ vertices. We have that $\text{dg}(G') = p - 1$ and $|V(G')| = \lceil (1 + \varepsilon)\text{dg}(G') \rceil$. Hence, we have to show that G has a Hamiltonian path if and only if G' has a Hamiltonian cycle. Suppose that G has a Hamiltonian path P with end-vertices x and y . Consider the path $Q = xu_2w_1 \dots w_q u_3u_4 \dots u_p y$. Clearly, P and Q together form a Hamiltonian cycle in G' . Suppose that G' has a Hamiltonian cycle C . Since $\{u_1, u_2\}$ is a cut set of G' , we obtain that C contains a path that is a Hamiltonian path of G . ◀

6 Conclusion

We considered the lower bound $\text{dg}(G) + 1$ for the number of vertices in a longest path or cycle in a graph G . It would be interesting to consider the lower bounds given in Theorems 4 and 5. More precisely, what can be said about the parameterized complexity of the variants of LONG PATH (CYCLE) where given a (2-connected) graph G and $k \in \mathbb{N}$, the task is to check whether G has a path (cycle) with at least $2\delta(G) + k$ vertices? Are these problems FPT when parameterized by k ? It can be observed that the bound $2\delta(G)$ is “tight”. That is, for any $0 < \varepsilon < 1$, it is NP-complete to decide whether a connected (2-connected) G has a path (cycle) with at least $(2 + \varepsilon)\delta(G)$ vertices. See also [30] for related hardness results.

Abstract

The Group Activity Selection Problem (GASP) models situations where a group of agents needs to be distributed to a set of activities while taking into account preferences of the agents w.r.t. individual activities and activity sizes. The problem, along with its well-known variants sGASP and gGASP, has previously been studied in the parameterized complexity setting with various parameterizations, such as *number of agents*, *number of activities* and *solution size*. However, the complexity of the problem parameterized by the *number of types of agents*, a natural parameter proposed already in the first paper that introduced GASP, has so far remained unexplored.

In this paper we establish the complexity map for GASP, sGASP and gGASP when the number of types of agents is the parameter. Our positive results, consisting of one fixed-parameter algorithm and one XP algorithm, rely on a combination of novel Subset Sum machinery (which may be of general interest) and identifying certain *compression steps* which allow us to focus on solutions which are “acyclic”. These algorithms are complemented by matching lower bounds, which among others close a gap to a recently obtained tractability result of Gupta, Roy, Saurabh and Zehavi (2017). In this direction, the techniques used to establish W[1]-hardness of sGASP are of particular interest: as an intermediate step, we use Sidon sequences to show the W[1]-hardness of a highly restricted variant of multi-dimensional Subset Sum, which may find applications in other settings as well.

1 Introduction

In this paper we consider the GROUP ACTIVITY SELECTION PROBLEM (GASP) together with its two most prominent variants, the SIMPLE GROUP ACTIVITY SELECTION PROBLEM (sGASP), and the GROUP ACTIVITY SELECTION PROBLEM WITH GRAPH STRUCTURE (gGASP) [6, 18]. Since their introduction, these problems have received considerable attention, notably in venues dedicated to multi-agent systems and game theory [3, 4, 5, 19, 14, 15]. In GASP one is given a set of agents, a set of activities, and a set of preferences for each agent in the form of a complete transitive relation (also called the *preference list*) over the set of pairs consisting of an activity a and a number s , expressing the willingness of the agent to

participate in the activity a if it has s participants. The aim is to find a “good” assignment from agents to activities subject to certain *rationality* and *stability* conditions. Specifically, an assignment is individually rational if agents that are assigned to an activity prefer this outcome over not being assigned to any activity, and an assignment is (Nash) stable if every agent prefers its current assignment over moving to any other activity. In this way GASP captures a wide range of real-life situations such as event organization and work delegation.

sGASP is a simplified variant of GASP where the preferences of agents are expressed in terms of *approval sets* containing (activity, size) pairs instead of preference lists. In essence sGASP is GASP where each preference list has only two equivalence classes: the class of the approved (activity, size) pairs (which contains all pairs that are preferred over not being assigned to any activity), and the class of disapproved (activity, size) pairs (all possible remaining pairs). On the other hand, gGASP is a generalization of GASP where one is additionally given an undirected graph (network) on the set of all agents that can be employed to model for instance acquaintanceship or physical distance between agents. Crucially, in gGASP one only considers assignments for which the subnetwork induced by all agents assigned to some activity is connected. Note that if the network forms a complete graph, then gGASP is equivalent to the underlying GASP instance.

Related Work. sGASP, GASP, and gGASP, are known to be NP-complete even in very restricted settings [6, 18, 14, 15]. It is therefore natural to study these problems through the lens of parameterized complexity [8, 2]. Apart from parameterizing by the solution size (i.e., the number of agents assigned to any activity in a solution) [19], the perhaps most prominent parameterizations thus far have been the number of activities, the number of agents, and in the case of gGASP parameterizations tied to the structure of the network [6, 17, 18, 14, 9]. Consequently, the parameterized complexity of all three variants of GASP w.r.t. the number of activities and/or the number of agents is now almost completely understood.

Namely, computing a stable assignment for a given instance of GASP is known to be W[1]-hard and contained in XP parameterized by either the number of activities [6, 17, 15] or the number of agents [18, 15] and known to be fixed-parameter tractable parameterized by both parameters [17, 15]. Even though it has never been explicitly stated, the same results also hold for gGASP when parameterizing by the number of agents as well as when using both parameters. This is because both the XP algorithm for the number of agents as well as the fixed-parameter algorithm for both parameters essentially brute-force over every possible assignment and are hence also able to find a solution for gGASP. Moreover, the fact that gGASP generalizes GASP implies that the W[1]-hardness result for the number of agents also carries over to gGASP.

On the other hand, if we consider the number of activities as a parameter then gGASP turns out to be harder than GASP: Gupta et al. ([14]) showed that gGASP is NP-complete even when restricted to instances with a single activity. The hardness of gGASP has inspired a series of tractability results [14, 18, 17] obtained by employing additional restrictions on the structure of the network. One prominent result in this direction has been recently obtained by Gupta et al. ([14]), showing that gGASP is fixed-parameter tractable parameterized by the number of activities if the network has constant treewidth.

Already with the introduction of GASP [6] the authors argued that instead of putting restrictions on the total number of agents, which can be very large in general, it might be much more useful to consider the number of distinct types of agents. It is easy to imagine a setting with large groups of agents that share the same preferences (for instance due to inherent limitations of how preferences are collected). In contrast to the related parameter number of activity types, where it is known that sGASP remains NP-complete even for a

constant number of activity types [6], the complexity of the problems parameterized by the number of agent types (with or without restricting the number of activities) has remained wide open thus far.

Our Results. In this paper we obtain a complete classification of the complexity of GASP and its variants sGASP and gGASP when parameterized by the number of agent types (t) alone, and also when parameterized by t plus the number of activities (a). In particular, for each of the considered problems and parameterizations, we determine whether the problem is in FPT, or W[1]-hard and in XP, or paraNP-hard. One distinguishing feature of our lower- and upper-bound results is that they make heavy use of novel Subset-Sum machinery. Below, we provide a high-level summary of the individual results presented in the paper.

Result 1. sGASP is fixed-parameter tractable when parameterized by $t + a$

This is the only fixed-parameter tractability result presented in the paper, and is essentially tight: it was recently shown that sGASP is W[1]-hard when parameterized by a alone [9], and the W[1]-hardness of the problem when parameterized by t is obtained in this paper. Our first step towards obtaining the desired fixed-parameter algorithm for sGASP is to show that every YES-instance contains a solution which is *acyclic* – in particular, a solution with no cycles formed by interactions between activities and agent types (captured in terms of the *incidence graph* G of an assignment). This is proved via the identification of certain *compression steps* which can be applied on a solution in order to remove cycles.

Once we show that it suffices to focus on acyclic solutions, we branch over all acyclic incidence graphs (i.e., all acyclic edge sets of G); for each such edge set, we can reduce the problem of determining whether there exists an assignment realizing this edge set to a variant of SUBSET SUM embedded in a tree structure. The last missing piece is then to show that this problem, which we call TREE SUBSET SUM, is polynomial-time tractable; this is done via dynamic programming, whereas each step boils down to solving a simplified variant of SUBSET SUM.

Result 2. sGASP is W1-hard when parameterized by t

Our second result complements Result 1. As a crucial intermediate step towards Result 2, we obtain the W[1]-hardness of a variant of SUBSET SUM with three distinct “ingredients”:

1. **Partitioning:** items are partitioned into sets, and precisely one item must be selected from each set,
2. **Multidimensionality:** each item is a d -dimensional vector (d being the parameter) where the aim is to hit the target value for each component, and
3. **Simplicity:** each vector contains precisely one non-zero component.

We call this problem SIMPLE MULTIDIMENSIONAL PARTITIONED SUBSET SUM (SMPSS). Note that SMPSS is closely related to MULTIDIMENSIONAL SUBSET SUM (MSS), which (as one would expect) merely enhances SUBSET SUM via Ingredient 2. MSS has recently been used to establish W[1]-hardness for parameterizations of EDGE DISJOINT PATHS [13] and BOUNDED DEGREE VERTEX DELETION [12]. However, Ingredient 1 and especially Ingredient 3 are critical requirements for our reduction to work, and establishing the W[1]-hardness of SMPSS was the main challenge on the way towards the desired lower-bound result for sGASP. Since MSS has already been successfully used to obtain lower-bound results and SMPSS is a much more powerful tool in this regard, we believe that SMPSS will find applications in establishing lower bounds for other problems in the future.

Result 3. GASP is in XP when parameterized by t

This is the only XP result required for our complexity map, as it implies XP algorithms for sGASP parameterized by t and for GASP parameterized by t . We note that the techniques used to obtain Result 3 are disjoint from those used for Result 1; in particular, our first step is to reduce GASP parameterized by t to solving “XP-many” instances of sGASP parameterized by t . This is achieved by showing that once we know a “least preferred alternative” for every agent type that is active in an assignment, then the GASP instance becomes significantly easier – and, in particular, can be reduced to a (slightly modified version of) sGASP. It is interesting to note that the result provides a significant conceptual improvement over the known brute force algorithm for GASP parameterized by the number of agents which enumerates all possible assignments of agents to activities [16, Theorem 3] (see also [15]): instead of guessing an assignment for all agents, one merely needs to guess a least preferred alternative for every agent type.

The second part of our journey towards Result 3 focuses on obtaining an XP algorithm for sGASP parameterized by t . This algorithm has two components. Initially, we show that in this setting one can reduce sGASP to the problem of finding an assignment which is individually rational (i.e., without the stability condition) and satisfies some additional minor properties. To find such an assignment, we once again make use of SUBSET SUM: in particular, we develop an XP algorithm for the MPSS problem (i.e., SUBSET SUM enhanced by ingredients 1 and 2) and apply a final reduction from finding an individually rational assignment to MPSS.

Result 4. GASP is W1-hard when parameterized by $t + a$ **Result 5.** gGASP is W1-hard when parameterized by $t + a$ and the *vertex cover number* [11] of the network

The final two results are hardness reductions which represent the last pieces of the presented complexity map. Both are obtained via reductions from PARTITIONED CLIQUE (also called MULTICOLORED CLIQUE in the literature [2]), and both reductions essentially use $k + \binom{k}{2}$ activities whose sizes encode the vertices and edges forming a k -clique. The main challenge lies in the design of (a bounded number of) agent types whose preference lists ensure that the chosen vertices are indeed endpoints of the chosen edges. The reduction for gGASP then becomes even more involved, as it can only employ a limited number of connections between the agents in order to ensure that vertex cover of the network is bounded.

We note that Result 5 also followed up on previous work by Gupta, Roy, Saurabh and Zehavi [14], who showed that gGASP is fixed-parameter tractable parameterized by the number of activities if the network has constant treewidth. In this sense, our hardness result represents a substantial shift of the boundaries of (in)tractability: in addition to excluding fixed-parameter tractability when parameterizing by the number of activities and treewidth, it also rules out the use of agent types as a parameter and replaces treewidth by the more restrictive vertex cover number. An overview of our results is provided in Table 1.

2 Preliminaries

For an integer i , we let $[i] = \{1, 2, \dots, i\}$ and $[i]_0 = [i] \cup \{0\}$. We denote by \mathbb{N} the set of natural numbers, by \mathbb{N}_0 the set $\mathbb{N} \cup \{0\}$. For a set S and an integer k , we denote by S^k and 2^S the set of all k dimensional vectors over S and the set of all subsets of S , respectively.

■ **Table 1** Lower and upper bounds for sGASP, GASP, and gGASP parameterized by the number of agent types (t), with or without additionally parameterizing by the number of activities (a). In the case of gGASP, also the parameter vertex cover number (vc) of the network is considered. The numbers 1 to 5 in the upper index are used to identify results 1 to 5. Entries in bold are shown in this paper; previously known entries follow from the work of Gupta et al. [14].

	Parameter	Lower Bound	Upper Bound
sGASP	t	W[1]²	XP
GASP		W[1]	XP³
gGASP		paraNP	
sGASP	$t + a$		FPT¹
GASP		W[1]⁴	XP
gGASP		paraNP	
gGASP	$t + a + vc$	W[1]⁵	XP

We refer to the handbook by Diestel ([7]) for standard graph terminology. Due to space constraints, we also refer to the respective handbooks [8, 2] for standard terminology and basic notions in parameterized complexity. The *vertex cover number* of a graph G is the size of a minimum vertex cover of G .

2.1 Group Activity Selection

The task in the GROUP ACTIVITY SELECTION PROBLEM (GASP) is to compute a *stable assignment* π from a given set N of *agents* to a set A of *activities*, where each agent participates in at most one activity in A . The assignment π is (Nash) stable if and only if it is *individually rational* and no agent has an *NS-deviation* to any other activity (both of these stability rules are defined in the next paragraph). We use a dummy activity a_\emptyset to capture all those agents that do not participate in any activity in A and denote by A^* the set $A \cup \{a_\emptyset\}$. Thus, an assignment π is a mapping from N to A^* , and for an activity $a \in A$ we use $\pi^{-1}(a)$ to denote the set of agents assigned to a by π ; we set $|\pi^{-1}(a_\emptyset)| = 1$ if there is at least one agent assigned to a_\emptyset and 0 otherwise.

The set X of *alternatives* is defined as $X = (A \times [|N|]) \cup \{(a_\emptyset, 1)\}$. Each agent is associated with its own *preferences* defined on the set X . In the case of the standard GASP problem, an instance I is of the form $(N, A, (\succeq_n)_{n \in N})$ where each agent n is associated with a complete transitive preference relation (list) \succeq_n over the set X . An assignment π is *individually rational* if for every agent $n \in N$ it holds that if $\pi(n) = a$ and $a \neq a_\emptyset$, then $(a, |\pi^{-1}(a)|) \succeq_n (a_\emptyset, 1)$ (i.e., n weakly prefers staying in a over moving to a_\emptyset). An agent n where $\pi(n) = a$ is defined to have an *NS-deviation* to a different activity a' in A if $(a', |\pi^{-1}(a')| + 1) \succ_n (a, |\pi^{-1}(a)|)$ (i.e., n prefers moving to an activity a' over staying in a). The task in GASP is to compute a stable assignment.

gGASP is defined analogously to GASP, however where one is additionally given a set L of *links* $L \subseteq \{\{n, n'\} \mid n, n' \in N \wedge n \neq n'\}$ between the agents on the input; specifically, L can be viewed as a set of undirected edges and (N, L) as a simple undirected graph. In gGASP, the task is to find an assignment π which is not only stable but also connected; formally, for every $a \in A$ the set of agents $\pi^{-1}(a)$ induces a connected subgraph of (N, L) . Moreover, an agent $n \in N$ only has an NS-deviation to some activity $a \neq \pi(n)$ if (in addition to the conditions for NS-deviations defined above) n has an edge to at least one agent in $\pi^{-1}(a)$.

In sGASP, an instance I is of the form $(N, A, (P_n)_{n \in N})$, where each agent has an *approval set* $P_n \subseteq X \setminus \{(a_\emptyset, 1)\}$ of preferences (instead of an ordered preference list). We denote by $P_n(a)$ the set $\{i \mid (a, i) \in P_n\}$ for an activity $a \in A$. An assignment $\pi : N \rightarrow A^*$ is said to be *individually rational* if every agent $n \in N$ satisfied the following: if $\pi(n) = a$ and $a \neq a_\emptyset$, then $|\pi^{-1}(a)| \in P_n(a)$. Further, an agent $n \in N$ where $\pi(n) = a_\emptyset$, is said to have an *NS-deviation* to an activity a in A if $(|\pi^{-1}(a)| + 1) \in P_n(a)$.

We now introduce the notions and definitions required for our main parameter of interest, the “number of agent types”. We say that two agents n and n' in N have the same *agent type* if they have the same preferences. To be specific, $P_n = P_{n'}$ for sGASP and $\succeq_n = \succeq_{n'}$ for GASP and gGASP. In the case of sGASP and GASP n and n' are indistinguishable, while in gGASP n and n' can still have different links to other agents. For a subset $N' \subseteq N$, we denote by $T(N')$ the set of agent types occurring in N' . Note that this notation requires that the instance is clear from the context. If this is not the case then we denote by $T(I)$ the set $T(N)$ if N is the set of agents for the instance I of sGASP, GASP, or gGASP.

For every agent type $t \in T(I)$, we denote by N_t the subset of N containing all agents of type t ; observe that $\{N_t \mid t \in T(I)\}$ forms a partition of N . For an agent type $t \in T(I)$ we denote by P_t (sGASP) or \succeq_t (GASP) the preference list assigned to all agents of type t and we use $P_t(a)$ (for an activity $a \in A$) to denote P_t restricted to activity a , i.e., $P_t(a)$ is equal to $P_n(a)$ for any agent n of type t . For an assignment $\pi : N \rightarrow A^*$, $t \in T(I)$, and $a \in A$ we denote by $\pi_{t,a}$ the set $\{n \mid n \in N_t \wedge \pi(n) = a\}$ and by π_t the set $\bigcup_{a \in A} \pi_{t,a}$. Further, $\pi(t)$ is the set of all activities that have at least one agent of type t participating in it. We say that π is a perfect assignment for some agent type $t \in T(I)$ if $\pi(n) \neq a_\emptyset$ for every $n \in N_t$. We denote by $\text{PE}(I, \pi)$ the subset of $T(I)$ consisting of all agent types that are perfectly assigned by π , and say that π is a *perfect assignment* if $\text{PE}(I, \pi) = T(I)$.

One notion that will appear through the paper is that of *compatibility*: for a subset $Q \subseteq T(I)$, we say that π is *compatible* with Q if $\text{PE}(I, \pi) = Q$. We conclude this section with a technical lemma which provides a preprocessing procedure that will be used as a basic tool for obtaining our algorithmic results. In particular, Lemma 1 allows us to reduce the problem of computing a stable assignment for a sGASP instance compatible with Q to the problem of finding an individually rational assignment.

► **Lemma 1.** *Let $I = (N, A, (P_n)_{n \in N})$ be an instance of sGASP and $Q \subseteq T(I)$. Then in time $\mathcal{O}(|N|^2|A|)$ one can compute an instance $\gamma(I, Q) = (N, A, (P'_n)_{n \in N})$ and $A_{\neq \emptyset}(I, Q) \subseteq A$ with the following property: for every assignment $\pi : N \rightarrow A^*$ that is compatible with Q , it holds that π is stable for I if and only if π is individually rational for $\gamma(I, Q)$ and $\pi^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}(I, Q)$.*

3 Subset Sum Machinery

In this section we introduce the Subset Sum machinery required for our algorithms and lower bound results. In particular, we introduce three variants of SUBSET SUM, obtain algorithms for two of them, and provide a W[1]-hardness result for the third.

Tree Subset Sum. Here we introduce a useful generalization of SUBSET SUM, for which we obtain polynomial-time tractability under the assumption that the input is encoded in unary. Intuitively, our problem asks us to assign values to edges while meeting a simple criterion on the values of edges incident to each vertex.

TREE SUBSET SUM (TSS)

Input: A vertex-labeled undirected tree T with labeling function $\lambda : V(T) \rightarrow 2^{\mathbb{N}}$.
 Question: Is there an assignment $\alpha : E(T) \rightarrow \mathbb{N}$ such that for every $v \in V(T)$ it holds that $\sum_{e \in E(T) \wedge v \in e} \alpha(e) \in \lambda(v)$.

Let us briefly comment on the relationship of TSS with SUBSET SUM. Recall that given a set S of natural numbers and a natural number t , the SUBSET SUM problem asks whether there is a subset S' of S such that $\sum_{s \in S'} s = t$. One can easily construct a simple instance (G, λ) of TSS that is equivalent to a given instance (S, t) of SUBSET SUM as follows. G consists of a star having one leaf l_s for every $s \in S$ with $\lambda(l_s) = \{0, s\}$ and $\lambda(c) = \{t\}$ for the center vertex c of the star. Given this simple reduction from SUBSET SUM to TSS it becomes clear that TSS is much more general than SUBSET SUM. In particular, instead of a star TSS allows for the use of an arbitrary tree structure and moreover one can use arbitrary subsets of natural numbers to specify the constraints on the vertices. The above reduction in combination with the fact that SUBSET SUM is weakly NP-hard implies that TSS is also weakly NP-hard. In the remainder of this paragraph we will show that TSS (like SUBSET SUM) can be solved in polynomial-time if the input is given in unary. This will later be used to obtain Result 1 (in Section 4).

Let $I = (T, \lambda)$ be an instance of TSS. We denote by $\max(I)$ the value of the maximum number occurring in any vertex label. The main idea behind our algorithm for TSS is to apply leaf-to-root dynamic programming. In order to execute our dynamic programming procedure, we will need to solve a special case of TSS which we call PARTITIONED SUBSET SUM; this is the problem that will later arise when computing the dynamic programming tables for TSS. In the PARTITIONED SUBSET SUM problem one is given a target set R of natural numbers and ℓ source sets S_1, \dots, S_ℓ of natural numbers and the aim is to compute the set S of all natural numbers s such that there are s_1, \dots, s_ℓ , where $s_i \in S_i$ for every i with $1 \leq i \leq \ell$, satisfying $(\sum_{1 \leq i \leq \ell} s_i) + s \in R$.

► **Lemma 2.** *An instance $I = (T, \lambda)$ of TSS can be solved in time $\mathcal{O}(|V(T)|^2 \cdot \max(I)^2)$.*

Multidimensional Partitioned Subset Sum. Our second generalization of SUBSET SUM is a multi-dimensional variant of the problem that allows to separate the input set of numbers into several groups, and restricts the solution to take at most 1 vector from each group. For technical reasons, we will only search for solutions of size at most r .

MULTIDIMENSIONAL PARTITIONED SUBSET SUM (MPSS)

Input: $k \in \mathbb{N}$, $r \in \mathbb{N}_0$, and a family $\mathcal{P} = \{P_1, \dots, P_l\}$ of sets of vectors over \mathbb{N}_0^k .
 Question: Compute the set of all vectors $\bar{t} \in \{0, \dots, r\}^k$ such that there are $\bar{p}_1, \dots, \bar{p}_l$ with $\bar{p}_i \in P_i$ for every i with $1 \leq i \leq l$ such that $\sum_{1 \leq i \leq l} \bar{p}_i = \bar{t}$.

It is easy to see that SUBSET SUM is a special case of MPSS: given an instance of SUBSET SUM, we can create an equivalent instance of MPSS by setting r to a sufficiently large number and simply making each group P_i contain two vectors: the all-zero vector and the vector that is equal to the i -th number of the SUBSET SUM instance in all entries. The following algorithm is used as a subprocedure for Result 3 (in Section 6).

► **Lemma 3.** *An instance $I = (k, r, \mathcal{P})$ of MPSS can be solved in time $\mathcal{O}(|I| \cdot r^k)$.*

Simple Multidimensional Partitioned Subset Sum. Here, we are interested in a much more restrictive version of MPSS, where all vectors (apart from the target vector) are only allowed to have at most one non-zero component. Surprisingly, we show that the $W[1]$ -hardness of the previously studied MULTIDIMENSIONAL SUBSET SUM problem [13, 12] carries over to this more restrictive variant using an intricate and involved reduction. This result forms the main ingredient needed for our Result 2 (provided in Section 5). To formalize our problem, we say that a set P of vectors in \mathbb{N}_0^d is *simple* if each vector in P has at most one non-zero component and the values of the non-zero components for any two distinct vectors in P are distinct.

SIMPLE MULTIDIMENSIONAL PARTITIONED SUBSET SUM (SMPSS)	
Input:	$d \in \mathbb{N}$, $\bar{t} \in \mathbb{N}_0^d$, and a family $\mathcal{P} = \{P_1, \dots, P_l\}$ of simple sets of vectors in \mathbb{N}_0^d .
Parameter:	d .
Question:	Are there vectors $\bar{p}_1, \dots, \bar{p}_l$ with $\bar{p}_i \in P_i$ for every i with $1 \leq i \leq l$ such that $\sum_{1 \leq i \leq l} \bar{p}_i = \bar{t}$.

► **Theorem 4.** *SMPSS is strongly $W[1]$ -hard.*

Proof Sketch. We will employ a parameterized reduction from the PARTITIONED CLIQUE problem, which is well-known to be $W[1]$ -complete [20]. In PARTITIONED CLIQUE we are given an integer k along with a graph G whose vertex set V is partitioned into k given independent sets V_1, \dots, V_k , and are asked to decide whether G contains a k -clique. We denote by $E_{i,j}$ the set of edges of G that have one endpoint in V_i and one endpoint in V_j and we assume w.l.o.g. that $|V_i| = \{v_1^i, \dots, v_n^i\} = n$ and $|E_{i,j}| = m$ for every i and j with $1 \leq i < j \leq k$ (see the standard textbooks for a justification of these assumptions [2, 8]).

Given an instance (G, k) of PARTITIONED CLIQUE with partition V_1, \dots, V_k , we construct an equivalent instance $I = (d, \bar{t}, \mathcal{P})$ of SMPSS in polynomial time, where $d = k(k-1) + \binom{k}{2}$ and $|\mathcal{P}| = \binom{k}{2} + nk(2k-3)$. We will also make use of the following notation. For i and j with $1 \leq i \leq k$ and $1 \leq j < k$, we denote by $\text{indJ}(i, j)$ the j -th smallest number in $[k] \setminus \{i\}$ and we denote by $\text{indMin}(i)$ and $\text{indMax}(i)$ the numbers $\text{indJ}(i, 1)$ and $\text{indJ}(i, k-1)$, respectively.

We assign to every vertex v of G a unique number $\mathcal{S}(v)$ from a Sidon sequence \mathcal{S} of length $|V(G)|$ [10]. A *Sidon sequence* is a sequence of natural numbers such that the sum of each pair of numbers is unique; it can be shown that it is possible to construct such sequences whose maximum value is bounded by a polynomial in its length [1, 10].

To simplify the description of I , we will introduce names and notions to identify both components of vectors and sets in \mathcal{P} . Every vector in I has the following components:

- For every i and j with $1 \leq i, j \leq k$ and $i \neq j$, the *vertex component* $c_V^i(j)$. We set $\bar{t}[c_V^i(j)]$ to:
 - $n^6 + n^4$ if $j = \text{indMin}(i)$,
 - $(n-1)n^8 + n^6 + n^4 + \sum_{\ell=1}^n (\ell + \ell n^2)$ if $j > \text{indMin}(i)$ and $j < \text{indMax}(i)$, and
 - $(n-1)n^8 + n^6 + \sum_{\ell=1}^n \ell$, otherwise.
- For every i and j with $1 \leq i < j \leq k$, the *edge component* $c_E(i, j)$ with $\bar{t}[c_E(i, j)] = \sum_{v \in V_i \cup V_j} \mathcal{S}(v)$.

Note that the total number of components d is equal to $k(k-1) + \binom{k}{2}$ and that for every i with $1 \leq i \leq k$, there are $k-1$ vertex components, i.e., the components $c_V^i(\text{indJ}(i, 1)), \dots, c_V^i(\text{indJ}(i, k-1))$, which intuitively have the following tasks. The first component, i.e., the component $c_V^i(\text{indJ}(i, 1))$ identifies a vertex $v \in V_i$ that should be part of a k -clique in G . Moreover, every component $c_V^i(\text{indJ}(i, j))$ (including the first component), is also responsible for: (1) Signalling the choice of the chosen vertex $v \in V_i$ to the next component,

i.e., the component $c_V^i(\text{indJ}(i, j + 1))$ and (2) Signalling the choice of the vertex $v \in V_i$ to the component $c_E(i, j)$ that will then verify that there is an edge between the vertex chosen for V_i and the vertex chosen for V_j . This interplay between the components will be achieved through the sets of vectors in \mathcal{P} that will be defined and explained next.

■ **Table 2** An illustration of the vectors contained in the sets $P_{EV}^1(2, \ell), \dots, P_{EV}^1(4, \ell)$ and $P_V^1(2, \ell), \dots, P_V^1(3, \ell)$. For example the column for the set $P_{EV}^1(2, \ell)$ shows that the set contains two vectors, one whose only non-zero component $c_V^1(2)$ has the value $n^6 + \ell$ and a second one whose only non-zero component $c_E(1, 2)$ and has the value $\mathcal{S}(v_\ell^1)$. The last column provides the value for the target vector for the component given by the row. Finally, the value Z is equal to $(n - 1)n^8 + n^6 + \sum_{\ell=1}^n (\ell)$.

	$P_{EV}^1(2, \ell)$	$P_V^1(2, \ell)$	$P_{EV}^1(3, \ell)$	$P_V^1(3, \ell)$	$P_{EV}^1(4, \ell)$	\bar{t}
$c_V^1(2)$	$n^6 + \ell$	$n^4 - \ell$				$n^6 + n^4$
$c_V^1(3)$		$n^8 + \ell + \ell n^2$	$n^6 + \ell$	$n^4 + \ell n^2$		$Z + n^4 + \sum_{\ell=1}^n (\ell n^2)$
$c_V^1(4)$				$n^8 + \ell$	$n^6 + \ell$	Z
$c_E(1, 2)$	$\mathcal{S}(v_\ell^1)$					$\sum_{v \in V_1 \cup V_2} \mathcal{S}(v)$
$c_E(1, 3)$			$\mathcal{S}(v_\ell^1)$			$\sum_{v \in V_1 \cup V_3} \mathcal{S}(v)$
$c_E(1, 4)$					$\mathcal{S}(v_\ell^1)$	$\sum_{v \in V_1 \cup V_4} \mathcal{S}(v)$

■ **Table 3** An illustration of the vectors contained in the sets $P_{EV}^i(j, \ell)$, $P_{EV}^j(i, \ell)$, and $P_E(i, j)$ and their interplay with the components $c_V^i(j)$, $c_V^j(i)$, and $c_V(i, j)$. For the conventions used in the table please refer to Table 2. Additionally, note that the column for $P_E(i, j)$ indicates that the set contains one vector for every edge $\{v, u\} \in E_{i,j}$, whose only non-zero component $c_E(i, j)$ has the value $\mathcal{S}(v) + \mathcal{S}(u)$.

	$P_{EV}^i(j, \ell)$	$P_{EV}^j(i, \ell)$	$P_E(i, j)$	\bar{t}
$c_V^i(j)$	$n^6 + \ell$			
$c_V^j(i)$		$n^6 + \ell$		
$c_E(i, j)$	$\mathcal{S}(v_\ell^i)$	$\mathcal{S}(v_\ell^j)$	$\{\mathcal{S}(v) + \mathcal{S}(u) \mid \{v, u\} \in E_{i,j}\}$	$\sum_{v \in V_i \cup V_j} \mathcal{S}(v)$

\mathcal{P} consists of the following sets, which are illustrated in Table 2 and 3:

- For every i, j' , and ℓ with $1 \leq i \leq k$, $1 \leq j' \leq k - 2$, and $1 \leq \ell \leq n$, the *vertex set* $P_V^i(j, \ell)$, where $j = \text{indJ}(i, j')$, containing two vectors $\bar{v}_{i,j,\ell}^+$ and $\bar{v}_{i,j,\ell}^-$ defined as follows:
 - if $j' = 1$, then $\bar{v}_{i,j,\ell}^+[c_V^i(j)] = n^4 - \ell$ and $\bar{v}_{i,j,\ell}^-[c_V^i(\text{indJ}(i, j' + 1))] = n^8 + \ell + \ell n^2$ or
 - if $1 < j' < k - 2$, then $\bar{v}_{i,j,\ell}^+[c_V^i(j)] = n^4 + \ell n^2$ and $\bar{v}_{i,j,\ell}^-[c_V^i(\text{indJ}(i, j' + 1))] = n^8 + \ell + \ell n^2$ or
 - if $j' = k - 2$, then $\bar{v}_{i,j,\ell}^+[c_V^i(j)] = n^4 + \ell n^2$ and $\bar{v}_{i,j,\ell}^-[c_V^i(\text{indJ}(i, j' + 1))] = n^8 + \ell$.
 We denote by $P_V^i(j)$, $P_{V^+}^i(j)$, and $P_{V^-}^i(j)$ the sets $\bigcup_{\ell=1}^n (P_V^i(j, \ell))$, $P_V^i(j) \cap \{\bar{v}_{i,j,\ell}^+ \mid 1 \leq \ell \leq n\}$, and $P_V^i(j) \setminus P_{V^+}^i(j)$, respectively.
- For every i, j , and ℓ with $1 \leq i, j \leq k$, $i \neq j$, and $1 \leq \ell \leq n$, the *vertex incidence set* $P_{EV}^i(j, \ell)$, which contains the two vectors $\bar{a}_{i,j,\ell}^+$ and $\bar{a}_{i,j,\ell}^-$ such that $\bar{a}_{i,j,\ell}^+[c_V^i(j)] = n^6 + \ell$ and $\bar{a}_{i,j,\ell}^-[c_E(i, j)] = \mathcal{S}(v_\ell^i)$. We denote by $P_{EV}^i(j)$, $P_{EV^+}^i(j)$, and $P_{EV^-}^i(j)$ the sets $\bigcup_{\ell=1}^n (P_{EV}^i(j, \ell))$, $P_V^i(j) \cap \{\bar{a}_{i,j,\ell}^+ \mid 1 \leq \ell \leq n\}$, and $P_{EV}^i(j) \setminus P_{EV^+}^i(j)$, respectively.
- For every i, j with $1 \leq i < j \leq k$, the *edge set* $P_E(i, j)$, which for every $e = \{v, u\} \in E_{i,j}$ contains the vector \bar{e} such that $\bar{e}[c_E(i, j)] = \mathcal{S}(v) + \mathcal{S}(u)$; note that $P_E(i, j)$ is indeed a simple set, because \mathcal{S} is a Sidon sequence.

Note that altogether there are $nk(k - 2) + \binom{k}{2} + nk(k - 1) = \binom{k}{2} + nk(2k - 3)$ sets in \mathcal{P} .

Informally, the two vectors $\bar{v}_{i,j,\ell}^+$ and $\bar{v}_{i,j,\ell}^-$ in $P_V^i(j, \ell)$ represent the choice of whether or not the vertex v_ℓ^i should be included in a k -clique for G , i.e., if a solution for I chooses $v_{i,j,\ell}^+$ then v_ℓ^i should be part of a k -clique and otherwise not. The component $c_V^i(j)$, more specifically the value for $\bar{t}[c_V^i(j)]$, now ensures that a solution can choose at most one such vector in $P_{V^+}^i(j)$. Moreover, the fact that all but one of the vectors $\bar{v}_{i,j,1}^-, \dots, \bar{v}_{i,j,n}^-$ need to be chosen by a solution for I signals the choice of the vertex for V_i to the next component, i.e., either the component $c_V^i(j+1)$ if $j+1 \neq i$ or the component $c_V^i(j+2)$ if $j+1 = i$. Note that we only need $k-2$ sets $P_V^i(j)$ for every i , because we need to copy the vertex choice for V_i to only $k-1$ components. A similar idea underlies the two vectors $\bar{a}_{i,j,\ell}^+$ and $\bar{a}_{i,j,\ell}^-$ in $P_{EV}^i(j, \ell)$, i.e., again the component $c_V^i(j)$ ensures that $\bar{a}_{i,j,\ell}^+$ can be chosen for only one of the sets $P_{EV}^i(j, 1), \dots, P_{EV}^i(j, n)$ and $\bar{a}_{i,j,\ell}^-$ must be chosen for all the remaining ones. Note that the component $c_V^i(j)$ now also ensures that the choice made for the sets in $P_V^i(j)$ is the same as the choice made for the sets in $P_{EV}^i(j)$. Moreover, the choice made for the sets in $P_{EV}^i(j)$ is now propagated to the component $c_E(i, j)$ (instead of the next vertex component). Finally, the vectors in the set $P_E(i, j)$ represent the choice of the edge used in a k -clique between V_i and V_j and the component $c_E(i, j)$ ensures that only an edge, whose endpoints are the two vertices signalled by the sets $P_{EV}^i(j)$ and $P_{EV}^j(i)$ can be chosen. \blacktriangleleft

4 Result 1: Fixed-Parameter Tractability of sGASP

In this section we will establish that sGASP is FPT when parameterized by the number of agent types and the number of activities by proving Theorem 5.

► **Theorem 5.** sGASP can be solved in time $\mathcal{O}(2^{|T(N)| \cdot (1+|A|)} \cdot ((|N| + |A|)|N|)^2)$.

Let $I = (N, A, (P_n)_{n \in N})$ be a sGASP instance and let $\pi : N \rightarrow A^*$ be an assignment of agents to activities. We denote by $G_I(\pi)$ the incidence graph between $T(N)$ and A , which is defined as follows. $G_I(\pi)$ has vertices $T(N) \cup A$ and contains an edge between an agent type $t \in T(N)$ and an activity $a \in A$ if $\pi_{t,a} \neq \emptyset$. We say that π is *acyclic* if $G_I(\pi)$ is acyclic.

Our first aim towards the proof of Theorem 5 is to show that if I has a stable assignment, then it also has an acyclic stable assignment (Lemma 7). We will then show in Lemma 9 that finding a stable assignment whose incidence graph is equal to some given acyclic pattern graph can be achieved in polynomial-time via a reduction to the TSS problem (see Lemma 2). Since the number of (acyclic) pattern graphs is bounded in our parameters, we can subsequently solve sGASP by enumerating all acyclic pattern graphs and checking for each of them whether there is an acyclic solution matching the selected pattern.

A crucial notion towards showing that it is sufficient to consider only acyclic solutions is the notion of (strict) compression. We say that an assignment τ is a *compression* of π if it satisfies the following conditions:

- (C1) for every $t \in T(N)$ it holds that $|\pi_t| = |\tau_t|$,
- (C2) for every $a \in A$ it holds that $|\pi^{-1}(a)| = |\tau^{-1}(a)|$, and
- (C3) for every $a \in A$ it holds that the set of agent types τ assigns to a is a subset of the agent types π assigns to a .

Intuitively, an assignment τ is a compression of π if it maintains all the properties required to preserve stability and compatibility with a given subset $Q \subseteq T(N)$. We note that condition (C3) can be formalized as $T(\pi^{-1}(a)) \supseteq T(\tau^{-1}(a))$. The following lemma shows that every assignment that is not acyclic admits a compression.

► **Lemma 6.** Let $\pi : N \rightarrow A^*$ be an assignment for I . Then there exists an acyclic assignment π' that compresses π .

The next lemma provides the first cornerstone for our algorithm by showing that it is sufficient to consider only acyclic solutions. Intuitively, it is a consequence of Lemma 6 along with the observation that compression preserves stability and individual rationality.

► **Lemma 7.** *If I has a stable assignment, then I has an acyclic stable assignment.*

Our next step is the introduction of terminology related to the pattern graphs mentioned at the beginning of this section. Let G be a bipartite graph with bi-partition $\{T(N), A\}$. We say that G *models* an assignment $\pi : N \rightarrow A^*$ if $G_I(\pi) = G$; in this sense every such bipartite graph can be seen as a pattern (or model) for assignments. For a subset $Q \subseteq T(N)$ we say that G is *compatible* with Q if every vertex in Q and every vertex in $A_{\neq \emptyset}(I, Q)$ (recall the definition of $A_{\neq \emptyset}(I, Q)$ given in Lemma 1) has at least one neighbor in G ; note that if G is compatible with Q then any assignment π modeled by G satisfies $\tau^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}(I, Q)$. Intuitively, the graph G captures information about which types of agents are mapped to which activities (without specifying numbers), while Q captures information about which agent types are perfectly (i.e., “completely”) assigned.

Let $Q \subseteq T(N)$ and let G be a bipartite graph with bi-partition $\{T(N), A\}$ that is compatible with Q . The following simple lemma shows that, modulo compatibility requirements, finding a stable assignment for I can be reduced to finding an individually rational assignment for $\gamma(I, Q)$ (recall the definition of $\gamma(I, Q)$ given in Lemma 1).

► **Lemma 8.** *Let $Q \subseteq T(N)$ and let G be a bipartite graph with bi-partition $\{T(N), A\}$ that is compatible with Q . Then for every assignment $\pi : N \rightarrow A^*$ modeled by G and compatible with Q , π is stable for I if and only if π is individually rational for $\gamma(I, Q)$.*

The next lemma forms (along with Lemma 7) the core component for our proof.

► **Lemma 9.** *Let $Q \subseteq T(N)$ and let G be an acyclic bipartite graph with bi-partition $\{T(N), A\}$ that is compatible with Q . Then one can decide in time $\mathcal{O}((|N| + |A|)^2 |N|^2)$ whether I has a stable assignment which is modeled by G and compatible with Q .*

We now have all the ingredients needed to establish Theorem 5 (\star).

5 Result 2: Lower Bound for sGASP

In this section we complement Theorem 5 by showing that if we drop the number of activities in the parameterization, then sGASP becomes W[1]-hard. We achieve this via a parameterized reduction from SMPSS that we have shown to be strongly W[1]-hard in Theorem 4.

► **Theorem 10.** *sGASP is W[1]-hard parameterized by the number of agent types.*

6 Result 3: XP Algorithms for sGASP and GASP

In this section, we present our XP algorithm for GASP parameterized by the number of agent types. In order to obtain this result, we observe that the stability of an assignment for GASP can be decided by only considering the stability of agents that are assigned to a “minimal alternative” w.r.t. their type. We then show that once one guesses (i.e., branches over) a minimal alternative for every agent type, the problem of finding a stable assignment for GASP that is compatible with this guess can be reduced to the problem of finding a perfect and individual rational assignment for a certain instance of sGASP, where one additionally requires that certain activities are assigned to at least one agent. Our first task will hence be to obtain an XP algorithm which can find such a perfect and individually rational assignment for sGASP. To that end, we obtain Lemma 11, which allows us to find certain individually rational assignments in sGASP instances and forms a core part of our XP algorithm for GASP.

48:12 Group Activity Selection with Few Agent Types

► **Lemma 11.** *Let $I = (N, A, (P_n)_{n \in N})$ be an instance of sGASP, $Q \subseteq T(N)$, and $A_{\neq \emptyset} \subseteq A$. Then one can decide in time $\mathcal{O}(|A| \cdot (|N|)^{|T(N)|})$ whether I has an individual rational assignment π that is compatible with Q such that $\pi^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}$.*

As a secondary result, we can already obtain an XP algorithm for sGASP parameterized by the number of agent types, which may also be of independent interest, as the obtained running time is strictly better than that of the algorithm obtained for the more general GASP.

► **Theorem 12.** *An instance $I = (N, A, (P_n)_{n \in N})$ of sGASP can be solved in time $|A| \cdot |N|^{\mathcal{O}(|T(N)|)}$.*

Our next aim is to use Lemma 11 to obtain an XP algorithm for GASP. To simplify the presentation of our algorithm, we start by introducing the notion of an NS*-deviations that combines and unifies individual rationality and NS-deviations. Namely, let $I = (N, A, (\succeq_n)_{n \in N})$ be a GASP instance, $\pi : N \rightarrow A^*$ be an assignment, and $n \in N$. We say that n has an NS*-deviation to an activity $a' \in A^* \setminus \{\pi(n)\}$ if $(a', |\pi^{-1}(a')| + 1) \succ_{T(n)} (a, |\pi^{-1}(a)|)$. In order to deal with the case that $a' = a_\emptyset$, we let $(a_\emptyset, i + 1)$ stand for $(a_\emptyset, 1)$ for every i .

► **Observation 13.** An assignment π for I is stable if and only if no agent $n \in N$ has an NS*-deviation to any activity in $A^* \setminus \{\pi(n)\}$.

Let I and π be as above and let $t \in T(I)$. We denote by π_t^* the set of activities π_i if t is perfectly assigned by π and $\pi_t \cup \{a_\emptyset\}$, otherwise. We say an activity $a \in \pi_t^*$ is *minimal with respect to t* if $(a', |\pi^{-1}(a')|) \succeq_t (a, |\pi^{-1}(a)|)$ for each $a' \in \pi_t^*$ and we address the alternative $(a, |\pi^{-1}(a)|)$ as a *minimal alternative* with respect to t .

The following lemma uses Observation 13 and allows us to characterize the stability condition of an assignment in terms of minimal activities for each agent type.

► **Lemma 14.** *An assignment π for I is stable if and only if for each $t \in T(N)$ and each $a \in A^* \setminus \{a_m\}$, it holds that $(a_m, |\pi^{-1}(a_m)|) \succeq_t (a, |\pi^{-1}(a)| + 1)$, where a_m is a minimal activity w.r.t. t .*

The next theorem now employs the above lemma to construct an instance I' of sGASP together with a subset $A_{\neq \emptyset}$ of activities such that for every function $f_{\min} : T(I) \rightarrow X$ (or in other words for every guess of minimal alternatives in an assignment), it holds that I has a stable assignment such that $f_{\min}(t)$ is a minimal alternative w.r.t. t for every $t \in T(I)$ if and only if I' has a perfect and individual rational assignment π such that $\pi^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}$. For brevity, we will say that an assignment π is *compatible with f_{\min}* if and only if $f_{\min}(t)$ is a minimal alternative w.r.t. t for every $t \in T(I)$.

► **Theorem 15.** *Let $I = (N, A, (\succeq_n)_{n \in N})$ be an instance of GASP and let $f_{\min} : T(N) \rightarrow X$, which informally represents a guess of a minimal alternative for every agent type. Then one can in time $\mathcal{O}(|N|^2 |A|)$ construct an instance $I' = (N, A \cup \{a_\emptyset\}, (P_n)_{n \in N})$ of sGASP together with a subset $A_{\neq \emptyset}$ of activities such that $|T(I')| \leq 2|T(I)|$ and I has a stable assignment compatible with $f_{\min}(t)$ if and only if I' has a perfect individual rational assignment π with $\pi^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}$.*

We now have all the ingredients needed to prove the main result of this section.

► **Theorem 16.** *An instance $I = (N, A, (\succeq_n)_{n \in N})$ of GASP can be solved in time $(|A| \cdot |N|)^{\mathcal{O}(|T(I)|)}$.*

Proof Sketch. Given an instance $I = (N, A, (\succeq_n)_{n \in N})$ of GASP, the algorithm enumerates all of the at most $(|A| \cdot |N|)^{|T(I)|}$ possible functions f_{\min} and for each such function f_{\min} the algorithm uses Theorem 15 to construct the instance $I' = (N, A \cup \{a_\phi\}, (P_n)_{n \in N})$ of sGASP with $|T(I')| \leq |T(I)|$ together with the set $A_{\neq \emptyset}$ of activities in time $\mathcal{O}(|N|^2|A|)$. It then uses Lemma 11 to decide whether I' has a perfect individual rational assignment π_1 such that $\pi_1^{-1}(a) \neq \emptyset$ for every $a \in A_{\neq \emptyset}$ in time $\mathcal{O}((|A| + 1)(|N|)^{|T(I')|}) = \mathcal{O}((|A| + 1)(|N|^{2|T(I)|}))$. If this is true for at least one of the functions f_{\min} , the algorithm returns that I has a solution, otherwise the algorithm correctly returns that I has no solution. ◀

7 Results 4 and 5: Two Lower Bounds

Our next result shows that GASP is unlikely to be fixed-parameter tractable parameterized by both the number of activities (a) and the number of agent types (t).

► **Theorem 17.** *GASP is $W[1]$ -hard parameterized by $t + a$.*

Since GASP and gGASP are equivalent on complete networks the above hardness result clearly also applies to gGASP. However, to our surprise, the hardness does even hold if we additionally parameterize gGASP with the vertex cover number (vc) of the network.

► **Theorem 18.** *gGASP is $W[1]$ -hard parameterized by $t + a + vc$.*

8 Conclusion

We obtained a comprehensive picture of the parameterized complexity of Group Activity Selection problems parameterized by the number of agent types, both with and without the number of activities as an additional parameter. Our positive results suggest that using the number of agent types is a highly appealing parameter for GASP and its variants; indeed, this parameter will often be much smaller than the number of agents due to the way preference lists are collected or estimated (as also argued in initial work on GASP [6]). For instance, in the large-scale event management setting of GASP (or sGASP), one would expect that preference lists for event participants are collected via simple questionnaires – and so the number of agent types would remain fairly small regardless of the size of the event.

We believe that the techniques used to obtain the presented results, and especially the Subset Sum tools developed to this end, are of broad interest to the algorithms community. For instance, MULTIDIMENSIONAL SUBSET SUM (MSS) has been used as a starting point for $W[1]$ -hardness reductions in at least two different settings over the past year [13, 12], but the simple and partitioned variant of the problem (i.e., SMPSS) is much more restrictive and hence forms a strictly better starting point for any such reductions in the future. This is also reflected in our proof of the $W[1]$ -hardness of SMPSS, which is *significantly* more involved than the analogous result for MSS. Likewise, we expect that the developed algorithms for TREE SUBSET SUM and MULTIDIMENSIONAL PARTITIONED SUBSET SUM may find applications as subroutines for (parameterized and/or classical) algorithms in various settings.

Note that there is now an almost complete picture of the complexity of Group Activity Selection problems w.r.t. any combination of the parameters number of agents, number of activities, and number of agent types (see also Table 1). There is only one piece missing, namely, the parameterized complexity of sGASP parameterized by the number of agents, which we resolve for completeness with the following theorem.

► **Theorem 19.** *sGASP is fixed-parameter tractable parameterized by the number of agents.*

Proof. Let $I = (N, A, (P_n)_{n \in N})$ be a sGASP instance. The main idea behind the algorithm is to guess (i.e., branch over) the set M_\emptyset of agents that are assigned to a_\emptyset as well as a partition \mathcal{M} of the remaining agents, i.e., the agents in $N \setminus M_\emptyset$, and then check whether there is a stable assignment π for I such that:

(P1) $\pi^{-1}(a_\emptyset) = M_\emptyset$ and

(P2) $\{\pi^{-1}(a) \mid a \in A\} \setminus \{\emptyset\} = \mathcal{M}$, i.e., \mathcal{M} corresponds to the grouping of agents into activities by π .

Since there are at most n^n possibilities for M_\emptyset and \mathcal{M} and those can be enumerated in time $\mathcal{O}(n^n)$, it remains to show how to decide whether there is a stable assignment for I satisfying (P1) and (P2) for any given M_\emptyset and \mathcal{M} . Towards showing this, we first consider the implications for a stable assignment resulting from assigning the agents in M_\emptyset to a_\emptyset . Namely, let P'_n for every $n \in N$ be the approval set obtained from P_n after removing all alternatives (a, i) such that $i \neq 0$ and there is an agent $n_\emptyset \in M_\emptyset$ with $(a, i+1) \in P_{n_\emptyset}$. Moreover, let $A_{\neq \emptyset}$ be the set of all activities that cannot be left empty if the agents in M_\emptyset are assigned to a_\emptyset , i.e., the set of all activities such that there is an agent $n_\emptyset \in M_\emptyset$ with $(a, 1) \in P_{n_\emptyset}$. Now consider a set $M \in \mathcal{M}$, and observe that the set A_M of activities that the agents in M can be assigned to in any stable assignment satisfying (P1) and (P2) is given by: $A_M = \{a \mid |M| \in \bigcap_{n \in M} P'_n(a)'\}$. Let B be the bipartite graph having \mathcal{M} on one side and A on the other side and having an edge between a vertex $M \in \mathcal{M}$ and a vertex $a \in A$ if $a \in A_M$. We claim that I has a stable assignment satisfying (P1) and (P2) if and only if B has a matching that saturates $\mathcal{M} \cup A_{\neq \emptyset}$. Since deciding the existence of such a matching can be achieved in time $\mathcal{O}(\sqrt{|V(B)||E(B)|}) = \mathcal{O}(\sqrt{|N \cup A||N||A|})$ (see e.g. [13, Lemma 4]), establishing this claim is the last component required for the proof of the theorem.

Towards showing the forward direction, let π be a stable assignment for I satisfying (P1) and (P2). Then $O = \{(a, \phi^{-1}(a)) \mid a \in A\}$ is a matching in B that saturates $\mathcal{M} \cup A_{\neq \emptyset}$. Note that O saturates \mathcal{M} due to (P2), moreover, O saturates $A_{\neq \emptyset}$ since otherwise there would be an activity $a \in A_{\neq \emptyset}$ with $\pi^{-1}(a) = \emptyset$, which due to the definition of $A_{\neq \emptyset}$ and (P1) implies there is an agent n with $\pi(n) = a_\emptyset$ such that $1 \in P_n(a)$, contradicting our assumption that π is stable.

Towards showing the reverse direction, let O be a matching in B that saturates $\mathcal{M} \cup A$. Then the assignment π mapping all agents in M (for every $M \in \mathcal{M}$) to its partner in O and all other agents to a_\emptyset clearly already satisfies (P1) and (P2). It remains to show that it is also stable. Note that π is individually rational because of the construction of B . Moreover, assume for a contradiction that there is an agent $n \in N_\emptyset$ with $\pi(n) = a_\emptyset$ and an activity $a \in A$ such that $(a, |\pi^{-1}(a)| + 1) \in P_n$. If $|\pi^{-1}(a)| = 0$, then $a \in A_{\neq \emptyset}$ and hence $|\pi^{-1}(a)| > 0$ (because O saturates $A_{\neq \emptyset}$), a contradiction. If on the other hand $|\pi^{-1}(a)| \neq 0$, then $\{M, a\} \in O$ (for some $M \in \mathcal{M}$), but $(a, |\pi^{-1}(a)|) \notin P'_n$ and hence $\{M, a\} \notin E(B)$, also a contradiction. \blacktriangleleft

For future work, we believe that it would be interesting to see how the complexity map changes if one were to consider the number of activity types instead of the number of activities in our parameterizations.

Abstract

We consider the problem of sorting n elements in the case of *persistent* comparison errors. In this problem, each comparison between two elements can be wrong with some fixed (small) probability p , and *comparisons cannot be repeated* (Braverman and Mossel, SODA'08). Sorting perfectly in this model is impossible, and the objective is to minimize the *dislocation* of each element in the output sequence, that is, the difference between its true rank and its position. Existing lower bounds for this problem show that no algorithm can guarantee, with high probability, *maximum dislocation* and *total dislocation* better than $\Omega(\log n)$ and $\Omega(n)$, respectively, *regardless of its running time*.

In this paper, we present the first $O(n \log n)$ -time sorting algorithm that guarantees both $O(\log n)$ *maximum dislocation* and $O(n)$ *total dislocation* with high probability. This settles the time complexity of this problem and shows that comparison errors do not increase its computational difficulty: a sequence with the best possible dislocation can be obtained in $O(n \log n)$ time and, even without comparison errors, $\Omega(n \log n)$ time is necessary to guarantee such dislocation bounds.

In order to achieve this optimality result, we solve two sub-problems in the persistent error comparisons model, and the respective methods have their own merits for further application. One is how to locate a position in which to insert an element in an almost-sorted sequence having $O(\log n)$ maximum dislocation in such a way that the dislocation of the resulting sequence will still be $O(\log n)$. The other is how to simultaneously insert m elements into an almost sorted sequence of m different elements, such that the resulting sequence of $2m$ elements remains almost sorted.

1 Introduction

We study the problem of *sorting* n distinct elements under *persistent random comparison errors*, where each comparison is wrong with some fixed (small) probability p , and the errors are independent over all possible pairs of elements. There are two types of comparison errors, *persistent* and *non-persistent*. For non-persistent errors, it is possible to repeat the same comparison several times and each result is wrong with probability p independently of the others. In the 80s and 90s, non-persistent errors have received considerable attention, and it has been shown that the perfectly sorted sequence can be computed in $O(n \log n)$ time with high probability. For persistent errors the repetition of a single comparison always yields the same outcome and this makes *impossible* to consistently recover the *perfectly sorted* sequence, as we explain below. The goal is therefore that of computing an *almost sorted* sequence. This seems a challenging task as all known algorithms have rather high running time and only recently a sub-quadratic running time has been achieved (see below for details). In particular, whether an optimal $O(n \log n)$ running time is sufficient for sorting with *persistent* comparison errors is a fundamental open question.

The above persistent-errors model is a well-studied theoretical abstraction of the errors that arise in hardware architectures. Here, avoiding these errors requires involved fault-tolerant mechanisms that reduce performances and increase manufacturing costs and energy consumption. Recently, a contrasting trend of simplifying hardware architectures has emerged: errors are traded for cheaper manufacturing costs, lower energy consumption, or better performances. The study of sorting algorithms with persistent comparison errors has been also motivated in [5, 13] by experts comparing items according to their importance, by ranking in sports where comparisons correspond to matches between teams, and –more generally– by situations where one wants to aggregate noisy comparisons into a global ranking and repeating a comparison is impossible or too expensive.

A common way to measure the quality of an output sequence in terms of sortedness, is to consider the *dislocation* of an element, which is the difference between its position in the output and its position in the correctly sorted sequence. In particular, a reasonable measure is the *maximum dislocation* of any element in the sequence or the *total dislocation* of the sequence, i.e., the sum of the dislocations of all n elements.

To see why sorting with persistent errors is much more difficult than the case in which comparisons can be repeated, note that in the latter case there is a trivial $O(n \log^2 n)$ time solution to sort perfectly with high probability (simply repeat each comparison $O(\log n)$ times and take the majority of the results). Instead, in the model with persistent errors, it is impossible to sort perfectly as, for any constant p , no algorithm can achieve a maximum dislocation that is smaller than $\Omega(\log n)$ w.h.p., or total dislocation smaller than $\Omega(n)$ in expectation [10]. This problem has been extensively studied in the literature, and several algorithms have been devised with the goal of sorting *quickly* with small dislocation (see Table 1). Unfortunately, even though all the algorithms achieve the best possible maximum dislocation of $\Theta(\log n)$, they use a truly superlinear number of comparisons (specifically, $\Omega(n^c)$ with $c \geq 1.5$), and/or require significant amount of time (namely, $O(n^{3+c_p})$ where c_p is a big constant that depends on p). This naturally suggests the following question:

What is the time complexity of sorting optimally with persistent errors?

In this work, we answer this basic question by showing the following result:

*There exists an algorithm with **optimal running time** $O(n \log n)$ which achieves simultaneously **optimal maximum dislocation** $O(\log n)$ and **optimal total dislocation** $O(n)$, both with high probability.*

■ **Table 1** The existing approximate sorting algorithms and our result. The constant c_p in the exponent of the running time of [5] depends on the error probability p and it is typically quite large. We write $\Omega(f(n))$ w.h.p. (resp. exp.) to mean that no algorithm can achieve dislocation $o(f(n))$ with high probability (resp. in expectation).

Upper bounds

Running Time	Max Dislocation	Tot Dislocation	Reference
$O(n^{3+c_p})$	$O(\log n)$ w.h.p.	$O(n)$ w.h.p.	[5]
$O(n^2)$	$O(\log n)$ w.h.p.	$O(n \log n)$ w.h.p.	[13]
$O(n^2)$	$O(\log n)$ w.h.p.	$O(n)$ expected	[10]
$\tilde{O}(n^{3/2})$	$O(\log n)$ w.h.p.	$O(n)$ expected	[11]
$O(n \log n)$	$O(\log n)$ w.h.p.	$O(n)$ w.h.p.	this work

Lower bounds

Any	$\Omega(\log n)$ w.h.p.	$\Omega(n)$ expected	[10]
-----	-------------------------	----------------------	------

The dislocation guarantees of our algorithm are optimal, due to the lower bound of [10], while the existence of an algorithm achieving a maximum dislocation of $d = O(\log n)$ in time $T(n) = o(n \log n)$ would immediately imply the existence of an algorithm that sorts n elements in $T(n) + O(n \log \log n) = o(n \log n)$ time, even in the absence of comparison errors, thus contradicting the classical $\Omega(n \log n)$ lower bound for comparison-based algorithms.¹ Along the way to our result, we consider the problem of *searching with persistent errors*, defined as follows:

We are given an approximately sorted sequence S , and an additional element $x \notin S$. The goal is to compute, under persistent comparison errors, an approximate rank (position) of x which differs from the true rank of x in S by a small additive error.

For this problem, we show an algorithm that requires $O(\log n)$ time to compute, w.h.p., an approximate rank that differs from the true rank of x by at most $O(\max\{d, \log n\})$, where d is the maximum dislocation of S . For $d = \Omega(\log n)$ this allows to insert x into S without any asymptotic increase of the maximum (and total) dislocation in the resulting sequence. Notice that, if d is also in $O(n^{1-\epsilon})$ for any constant $\epsilon > 0$, this is essentially the best we can hope for, as an easy decision-tree lower bound shows that any algorithm must require $\Omega(\log n)$ time. Finally, we remark that [13] considered the variant in which the original sequence is *sorted*, and the algorithm must compute the correct rank. For this problem, they present an algorithm that runs in $O(\log n \cdot \log \log n)$ time and succeeds with probability $1 - f(p)$, with $f(p)$ vanishing as p goes to 0. As by-product of our result, we can obtain the optimal $O(\log n)$ running time with essentially the same success probability. Similarly to other prior related works, all our results apply when p is below a sufficiently small constant, e.g., $p < 1/20$ in [13]. For technical simplicity, throughout this work we assume $p < 1/32$, though the results hold for $p < 1/16$ as in [10].²

¹ Indeed, the smallest d elements of a sequence S having dislocation $d = 2^{o(\log n)}$ can be found in time $O(d \log d)$ using any $O(n \log n)$ -time sorting algorithm on the first $2d$ elements of S . Removing those elements and repeating the above procedure $O(\frac{n}{d})$ times, would allow to sort in $T(n) + O(\frac{n}{d} \cdot d \log d) = o(n \log n)$ time.

² Except for the derandomization technique of Section 5, all our results also hold for the case in which each comparison is wrong with an adversarially chosen and unknown probability in $[0, p]$.

1.1 Main Intuition and Techniques

Approximate Sorting

In order to convey the main intuitions behind our $O(n \log n)$ -time optimal-dislocation approximate sorting algorithm, we consider the following ideal scenario: we already have a perfectly sorted sequence A containing a random half of the elements in our input sequence S and we, somehow, also know the position in which each element $x \in S \setminus A$ should be inserted into A so that the resulting sequence is also sorted (i.e., the *rank* of x in A). If these positions alternate with the elements of A , then, to obtain a sorted version of S , it suffices to *merge* S and $S \setminus A$, i.e., to simultaneously insert all the elements of $S \setminus A$ into their respective positions of A . Unfortunately, we are far from this ideal scenario for several reasons: first of all, multiple elements in $S \setminus A$, say δ of them, might have the same rank in A . Since we do not know the order in which those elements should appear, this will already increase the dislocation of the merged sequence to $\Omega(\delta)$. Moreover, due to the lower bound of [10], we are not actually able to obtain a perfectly sorted version of A and we are forced to work with a permutation of A having dislocation $d = \Omega(\log n)$, implying that the natural bound on the resulting dislocation can be as large as $d \cdot \delta$. This is bad news, as one can show that $\delta = \Omega(\log n)$. However, it turns out that the number of elements in $S \setminus A$ whose positions lie in a $O(\log n)$ -wide interval of A is still $O(\log n)$, w.h.p., implying that the final dislocation of A is just $O(\log n)$.

But how do we obtain the approximately sorted sequence A in the first place? We could just recursively apply the above strategy on the (unsorted) elements of A , except that this would cause a blow-up in the resulting dislocation due to the constant hidden by the big-O notation. We therefore interleave merge steps with invocations of (a modified version of) the sorting algorithm of [10], which essentially reduces the dislocation by a constant factor, so that the increase in the worst-case dislocation will be only an *additive* constant per recursive step.

An additional complication is due to the fact that we are not able to compute the exact ranks in A of the elements in $S \setminus A$. We therefore have to deal, once again, with approximations that are computed using the other main contribution of this paper: *noisy binary search trees*, whose key ideas are described in the following.

Noisy Binary Search

As a key ingredient of our approximate sorting algorithm, we need to *merge* an almost-sorted sequence with a set of elements, without any substantial increase in the final maximum dislocation. More precisely, given a sequence S with maximum dislocation d and an element $x \notin S$, we want to compute an *approximate rank* of x in S , i.e., a position that differs by $O(\max\{d, \log n\})$ from the position that x would occupy if the elements $S \cup \{x\}$ were perfectly sorted. This same problem has been solved optimally in $O(\log n)$ time in the easier case in which errors are *not persistent* and S is already sorted [9]. The idea of [9] is to locate the correct position of x using a binary decision tree: ideally each vertex v of the tree *tests* whether x appears to belong to a certain *interval* of S and, depending on the result, one of the children of v is considered next. Since these intervals become narrower as we move from the root towards the leaves (that are in a one-to-one correspondence with positions of S) we eventually discover the correct rank of x in S . In order to cope with failures, this process is allowed to *backtrack* when inconsistent comparisons are observed, thus repeating some of the comparisons involving ancestors of v . Moreover, to obtain the correct result with high probability, a logarithmic number of consistent comparisons with a leaf are needed before the algorithm terminates.

Notice how the above process relies on the fact that it is possible to gather more information on the true relative position of x by repeating a comparison multiple times (in fact, it is trivial to design a simple $O(\log^2 n)$ -time algorithm in this error model). Unfortunately, this is no longer the case when errors are *persistent*. To overcome this problem we design a *noisy binary search tree* in which testing whether x belongs to the interval associated with a vertex v also causes the interval itself to *grow* thus ensuring that, in future tests involving v , x will always be compared with different elements. This, however, is a source of other difficulties: first, the intervals of the descendants of v also need to be suitably updated to account for the new elements in v 's interval. Moreover, since intervals are now *dynamic*, it is possible for multiple tests on the same vertex to report different results even when no comparison errors occur: this is because an interval that did not initially contain x might eventually grow into one that does. Finally, since growing intervals need to overlap, one also has to be careful in avoiding repeated comparisons arising from *unrelated* vertices (i.e., vertices that are not in ancestor–descendant relation in the tree). We overcome these problems by using two search trees that initially comprise of disjoint intervals and ensure that all the vertices exhibiting the problematic behaviours discussed above will be confined to only one of the two trees: in some sense, we guarantee that one of two search trees will behave similarly to the one of [9], where leaves now represent groups of $O(\log n)$ positions in S .

1.2 Related work

Sorting with *persistent errors* has been studied in several works, starting from [5] who presented the first algorithm achieving optimal dislocation (matching lower bounds appeared only recently in [10]) by finding a maximum-likelihood permutation of the input elements given the observed errors. The algorithm in [5] uses only $O(n \log n)$ comparisons and is able to handle any constant comparison error probability $p \in (0, \frac{1}{2})$ (later improved to $p \leq \frac{1}{2} - \Omega(\frac{\log \log n}{\log n})^{\frac{1}{6}}$ in [17]), but unfortunately its running time $O(n^{3+c_p})$ is quite large. For example, if we require the algorithm to succeed with a probability of $1 - 1/n$, the analysis in [5] yields $c_p = \frac{110525}{(1/2-p)^4}$. On the contrary, all subsequent faster algorithms [10,11,13] – see Table 1 – use a number of comparisons which is asymptotically equal to their respective running time and work for a smaller range of values of p (i.e., $p \leq \frac{1}{20}$ in [13] and $p < \frac{1}{16}$ in [10,11]).

Other works considered error models in which repeating comparisons is possible, although expensive. For example, [4] studied algorithms which use a *bounded number of rounds* for some “easier” versions of sorting (e.g., distinguishing the top k elements from the others). Note that each round consists of a set of comparison operations, where it is possible to compare the same pair of elements several times using independent comparisons like in the non-persistent model; Also, the comparisons made in each round are decided a priori, i.e., they do not depend on the results of the comparisons in this round. In each round, a fresh set of comparison results is generated, and each round consists of $\delta \cdot n$ comparisons. They evaluate the algorithm’s performance by estimating the number of “misclassified” elements and also consider a variant in which errors now correspond to missing comparison results.

In general, sorting in presence of errors seems to be computationally more difficult than the error-free counterpart. For instance, [1] provides algorithms using *subquadratic* time (and number of comparisons) when errors occur only between elements whose difference is at most some fixed threshold. Also, [8] gives a *subquadratic* time algorithm when the number k of errors is known in advance.

As mentioned above, an easier error model is the one with *non-persistent* errors, meaning that the same comparison can be *repeated* and the errors are independent, and happen with some probability $p < 1/2$. In this model it is possible to sort n elements in time $O(n \log(n/q))$, where $1 - q$ is the success probability of the algorithm [9] (see also [2,12] for the analysis of the classical Quicksort and recursive Mergesort algorithms in this error model).

More generally, computing with errors is often considered in the framework of a two-person game called *Rényi-Ulam Game*. In this game a questioner tries to identify an unknown object x from a universe U by asking yes-or-no questions to a responder, but some of the answers might be wrong. The case in which $U = \{1, \dots, n\}$, the questions are of the form “is $s > x$?”, and each answer is independently incorrect with probability $p < \frac{1}{2}$ has been considered by [9], where the authors provide a binary search algorithm that succeeds with probability $1 - \delta$ and requires $O(\log \frac{n}{\delta})$ worst-case time. In [3], the authors then showed how to find s using an optimal amount of queries up to additive polylogarithmic terms. The variant in which responder is allowed to adversarially lie up to k times has been proposed by Rényi [15] and Ulam [18], which has then been solved by Rivest et al. [16] using only $\log n + k \log \log n + O(k \log k)$ question, which is tight. Among other results, near-optimal strategies for the distributional version of the game have been devised in [7]. For more related results on the topic, we refer the interested reader to [14] for a survey and to [6] for a monograph.

1.3 Paper Organization

The rest of this work is organized as follows: in Section 2 we give some preliminary definitions; then, in Section 3, we present our noisy binary search algorithm, which will be used in Section 4 to design an optimal randomized sorting algorithm. Finally, in Section 5, we briefly argue on how our sorting algorithm can be adapted so that it does not require any external source of randomness. Due to space limitations, this manuscript only includes the core parts of the analysis of our sorting algorithm. We refer the reader to the full version of the paper for the formal analysis of other claims of Section 4, and of the results in the remaining sections. Moreover, Section 4 makes use of an improved analysis of the sorting algorithm of [10] which can also be found in the full version of the paper.

2 Preliminaries

According to our error model, elements possess a true total linear order, however this order can only be observed through noisy comparisons. In the following, given two distinct elements x and y , we will write $x \prec y$ (resp. $x \succ y$) to mean that x is smaller (resp. larger) than y according to the true order, and $x < y$ (resp. $x > y$) to mean that x appears to be smaller (resp. larger) than y according to the observed comparison result.

Given a sequence or a set of elements A and an element x (not necessarily in A), we define $\text{rank}(x, A) = |\{y \in A : y \prec x\}|$ as the *true rank* of element x in A (notice that ranks start from 0). Moreover, if A is a sequence and $x \in A$, we denote by $\text{pos}(x, A) \in [0, |A| - 1]$ the *position* of x in A (notice that positions are also indexed from 0), so that the *dislocation* of x in A is $\text{disl}(x, A) = |\text{pos}(x, A) - \text{rank}(x, A)|$, and the *maximum dislocation* of the sequence A is $\text{disl}(A) = \max_{x \in A} \text{disl}(x, A)$.

For $z \in \mathbb{R}^+$, $\ln z$ and $\log z$ refer to the natural and the binary logarithm of z , respectively.

3 Noisy Binary Search

Given a sequence $S = \langle s_0, \dots, s_{n-1} \rangle$ of n elements with maximum dislocation $d \geq \log n$, and an additional element x not in S , we want to compute in time $O(\log n)$ an *approximate rank* of x in S , that is, a position where to insert x in S while preserving a $O(d)$ upper bound on dislocation of the resulting sequence. More precisely, we want to compute index r_x such that $|r_x - \text{rank}(x, S)| = O(d)$, in presence of persistent comparison errors: Errors between x and

the elements in S happen independently with probability p , and whether the comparison between x and an element $y \in S$ is correct or erroneous does not depend on the position of y in S , nor on the actual permutation of the sorted elements induced by their order in S (i.e., we are not allowed to pick the order of the elements in S as a function of the comparison errors involving x). We do not impose any restriction on the errors of comparisons that do not involve x .

In the following, we will show an algorithm that computes such a rank r_x in time $O(\log n)$. This immediately implies that $O(\log n)$ time also suffices to insert x into S so that the resulting sequence $\langle s_0, \dots, s_{r_x-1}, x, s_{r_x}, s_{n-1} \rangle$ still has maximum dislocation $O(d)$.

► **Remark 1.** The $O(\log n)$ running time is asymptotically optimal for all $d = n^{1-\epsilon}$, for constant $\epsilon < 1$, since a $\Omega(\log n - \log d) = \Omega(\log n)$ decision-tree lower bound holds even in absence of comparison errors.

In the following, for the sake of simplicity, we let $c = 10^3$ and we assume that $n = 2cd \cdot 2^h - 1$ for some non-negative integer h . Moreover, we focus on $p \leq \frac{1}{32}$ even though this restriction can be easily removed to handle all constant $p < \frac{1}{2}$, as we argue at the end of the section.

We consider the set $\{0, \dots, n\}$ of the possible ranks of x in S and we subdivide them into $2 \cdot 2^h$ ordered groups g_0, g_1, \dots each containing cd contiguous positions, namely, group g_i contains positions $cid, \dots, c(i+1)d - 1$. Then, we further partition these $2 \cdot 2^h$ groups into two ordered sets G_0 and G_1 , where G_0 contains the groups g_i with even i ($i \equiv 0 \pmod{2}$) and G_1 the groups g_i with odd i ($i \equiv 1 \pmod{2}$). Notice that $|G_0| = |G_1| = 2^h$. In the next section, for each G_j , we shall define a *noisy binary search tree* T_j , which will be the main ingredient of our algorithm.

3.1 Constructing T_0 and T_1

Let us consider a fixed $j \in \{0, 1\}$ and define $\eta = 2 \lceil \log n \rceil$. The tree T_j comprises of a binary tree of height $h + \eta$ in which the first $h + 1$ levels (i.e., those containing vertices at depths 0 to h) are complete and the last η levels consists of 2^h paths of η vertices, each emanating from a distinct vertex on the $(h + 1)$ -th level. We index the leaves of the resulting tree from 0 to $2^h - 1$, we use $h(v)$ to denote the depth of vertex v in T_j , and we refer to the vertices v at depth $h(v) \geq h$ as *path-vertices*. Each vertex v of the tree is associated with one *interval* $I(v)$, i.e., as a set of contiguous positions, as follows: for a leaf v having index i , $I(v)$ consists of the positions in g_{2^i+j} ; for a non-leaf path-vertex v having u as its only child, we set $I(v) = I(u)$; finally, for an internal vertex v having u and w as its left and right children, respectively, we define $I(v)$ as the interval containing all the positions between $\min I(u)$ and $\max I(w)$, endpoints included.

Moreover, each vertex v of the tree has a reference to two *shared pointers* $L(v)$ and $R(v)$ to positions in $\mathbb{Z} \setminus \bigcup_{g_i \in G_j} g_i$. Intuitively, $L(v)$ (resp. $R(v)$) will always point to positions of S occupied by elements that are *smaller* (resp. *larger*) than all the elements s_i with $i \in I(v)$. For each leaf v , let $L(v)$ initially point to $\min I(v) - d - 1$ and $R(v)$ initially point to $\max I(v) + d$. A non-leaf path-vertex v shares both its pointers with the corresponding pointers of its only child, while a non-path vertex v shares its left pointer $L(v)$ with the left pointer of its left child, and its right pointer $R(v)$ with the right pointer of its right child. See Figure 1 for an example.

Notice that we sometimes allow $L(v)$ to point to negative positions and $R(v)$ to point to positions that are larger than $n - 1$. In the following we consider all the elements s_i with $i < 0$ (resp. $i \geq n$) to be copies a special $-\infty$ (resp. $+\infty$) element such that $-\infty \prec x$ and $-\infty < x$ in every observed comparison (resp. $+\infty \succ x$ and $+\infty > x$).

■ **Figure 1** An example of the noisy tree T_0 . On the left side the shared pointers $L(\cdot)$ and $R(\cdot)$ are shown. Notice how $L(r)$ (and, in general, all the $L(\cdot)$ pointers on the leftmost side of the tree) points to the special $-\infty$ element. Good (resp. bad) vertices are shown in black (resp. white). Notice that, since $i^* \in I(w)$, $T^* = T_0$ and all the depicted vertices are either good or bad.

3.2 Walking on T_j

The algorithm will perform a discrete-time random walk on each T_j . Before describing such a walk in more detail, it is useful to define the following operation:

► **Definition 2** (test operation). A test of an element x with a vertex v is performed by (i) comparing x with the elements $s_{L(v)}$ and $s_{R(v)}$, (ii) decrementing $L(v)$ by 1 and, (iii) incrementing $R(v)$ by 1. The tests succeeds if the observed comparison results are $x > s_{L(v)}$ and $x < s_{R(v)}$, otherwise the test fails.

The walk on T_j proceeds as follows. At time 0, i.e., before the first step, the *current* vertex v coincides with the root r of T_j . Then, at each time step, we *walk* from the current vertex v to the next vertex as follows:

1. We test x with all the children of v and, if *exactly one* of these tests succeeds, we *walk to the corresponding child*.
2. Otherwise, if *all the tests fail*, we *walk to the parent* of v , if it exists.

In the remaining cases we “walk” from v to itself. We also define $\tau = 240 \lceil \log n \rceil$ and we stop the walk as soon as one of the following two conditions is met:

Success: The current vertex v is a leaf of T_j . In this case we say that the walk *returns* v ;

Timeout: The τ -th time step is completed and the success condition is not met.

It turns out that at least one of the walks on T_0 and T_1 will succeed w.h.p., while the other can either succeed or timeout. If any of the walks succeeds and returns v , we output any position in the interval $I(v)$. Otherwise, we return an arbitrary position. We are then to prove the following result, whose analysis can be found in the full version of the paper:

► **Theorem 3.** Let S be a sequence of n elements having maximum dislocation at most $d \geq \log n$ and let $x \notin S$. Under our error model, an index $r_x \in [\text{rank}(x, S) - \alpha d, \text{rank}(x, S) + \alpha d]$ can be found in $O(\log n)$ time with probability at least $1 - O(n^{-6})$, where $\alpha > 1$ is an absolute constant.

To conclude this section, we remark that our assumption that $p \leq \frac{1}{32}$ can be easily relaxed to handle any constant error probability $p < \frac{1}{2}$. This can be done by modifying the test operation so that, when x is tested with a vertex v , the majority result of the

comparisons between x and the set $\{s_{L(v)}, s_{L(v)-1}, \dots, s_{L(v)-k+1}\}$ (resp. x and the set $\{s_{R(v)}, s_{R(v)+1}, \dots, s_{R(v)+k-1}\}$) of η elements is considered, where k is a constant that only depends on p . Consistently, the pointers $L(v)$ and $R(v)$ are shifted by k positions, and the group size is increased to $k \cdot c$. Notice how our description for $p \leq \frac{1}{32}$ corresponds exactly to the case $k = 1$. The only difference in the statement Theorem 3 is that α is no longer an absolute constant, but rather, it depends (only) on the value of p .

4 Optimal Sorting Algorithm

4.1 The algorithm

Here we present an optimal sorting algorithm that, given a sequence S of n elements, computes, in $O(n \log n)$ worst-case time, a permutation of S having maximum dislocation $O(\log n)$ and total dislocation $O(n)$, w.h.p. In order to avoid being distracted by roundings, we assume that n is a power of two.³ Our algorithm will make use of the noisy binary search of Section 3 and of the `WindowSort` algorithm [10]. For our purposes, we need the following *stronger* version of the original result in [10], in which the bound on the total dislocation was only given in expectation:

► **Theorem 4.** *Consider a set of n elements that are subject to random persistent comparison errors. For any dislocation d , and for any (adversarially chosen) permutation S of these elements such that $\text{disl}(S) \leq d$, `WindowSort`(S, d) requires $O(nd)$ worst-case time to compute, with probability at least $1 - \frac{1}{n^4}$, a permutation of S having maximum dislocation at most $c_p \cdot \min\{d, \log n\}$ and total dislocation at most $c_p \cdot n$, where c_p is a constant depending only on the error probability $p < \frac{1}{32}$.*

We give a brief description of `WindowSort` and prove the above theorem in Section 5 of the full version of the paper. Notice that `WindowSort` also works in a stronger error model in which S can be chosen adversarially after the comparison errors between all pairs of elements have been randomly fixed, as long as its maximum dislocation is at most d . In the remaining of this section, we assume $p \leq 1/32$ in order to be consistent with Section 3, though both the above theorem and the algorithm we are going to present will only require $p < 1/16$.⁴ Using the noisy binary search in Section 3, we now define an operation that allows us to add a linear number of elements to an almost-sorted sequence without any asymptotic increase in the resulting dislocation, as we will formally prove in the sequel. More precisely, if A and B are two disjoint subsets of S , we denote by `Merge`(A, B) the sequence obtained as follows:

- For each $x \in B$, compute an index r_x such that $|\text{rank}(s, A) - r_x| \leq \alpha d$. This can be done using the noisy binary search of Section 3, which succeeds with probability at least $1 - \frac{1}{|A|^6}$.
- Insert *simultaneously* all the elements $x \in B$ into A in their computed positions r_x , breaking ties arbitrarily. Return the resulting sequence.

Our sorting algorithm, that we call `RiffleSort` (see the pseudocode in Algorithm 1), works as follows. For $k = \frac{\log n}{2}$, we first partition S into $k + 1$ subsets T_0, T_1, \dots, T_k : Each T_i , with $1 \leq i \leq k$, contains $2^{i-1} \sqrt{n}$ elements chosen uniformly at random from $S \setminus \{T_{i+1}, T_{i+2}, \dots, T_k\}$, and $T_0 = S \setminus \{T_1, T_2, \dots, T_k\}$ contains the remaining $n - \sqrt{n} \sum_{i=1}^k 2^{i-1} = \sqrt{n}$ elements. As its

³ This assumption can be easily removed by adding dummy $+\infty$ elements to S . Since `WindowSort`, the noisy binary search of Section 3, and ultimately our algorithm will also work when p is an upper bound on the error probability, it is not necessary to simulate errors when comparisons involving dummy elements are performed.

⁴ In fact, Theorem 4 is the only reason preventing our novel sorting algorithm to work for any constant $p \in [0, \frac{1}{2})$.

■ **Algorithm 1** RiffleSort(S).

```

1  $T_0, T_1, \dots, T_k \leftarrow$  partition of  $S$  computed as explained in Section 4.1;
2  $S_0 \leftarrow$  WindowSort( $T_0, \sqrt{n}$ );
3 foreach  $i = 1, \dots, k = \frac{\log n}{2}$  do
4    $S_i \leftarrow$  Merge( $S_{i-1}, T_i$ );
5    $S_i \leftarrow$  WindowSort( $S_i, \gamma \cdot c_p \cdot \log n$ );
6 return  $S_k$ ;

```

first step, RiffleSort will approximately sort T_0 using WindowSort, and then it will alternate merge operations with calls to WindowSort. On one hand the merge operations allow us to iteratively grow the set of approximately sorted elements to ultimately include all the elements in S but, on the other hand, each operation also increases the dislocation by a constant factor. This is a problem since the rate at which the dislocation increases is faster than the rate at which new elements are inserted. The role of the sorting operations is exactly to circumvent this issue: each WindowSort call has the effect of locally rearranging the elements, so that all newly inserted elements are now closer to their intended positions, causing (an upper bound to) the resulting maximum dislocation to increase by only an additive constant. The corresponding pseudocode is shown in Algorithm 1, in which $\gamma \geq \max\{202\alpha, 909\}$ is an absolute constant (recall that α is the constant from Theorem 3).

4.2 Analysis

► **Lemma 5.** *The worst-case running time of Algorithm 1 is $O(n \log n)$.*

Proof. Clearly the random partition T_0, \dots, T_k can be computed in time $O(n \log n)$,⁵ and the first call to WindowSort requires time $O(|T_0| \cdot \sqrt{n}) = O(n)$ (see Theorem 4). We can therefore restrict our attention to the generic i -th iteration of the for loop. The call to Merge(S_{i-1}, T_i) can be performed in $O(|S_i| \log n)$ time since, for each $x \in T_i$, the required approximation of $\text{rank}(x, S_{i-1})$ can be computed in time $O(\log |S_{i-1}|)$ and $|T_i| = |S_{i-1}| \leq n$, while inserting the elements of T_i in their computed ranks requires linear time in $|S_{i-1}| + |T_i| = |S_i|$. The subsequent execution of WindowSort with $d = O(\log n)$ requires time $O(|S_i| \log n)$, where the hidden constant does not depend on i . Therefore, for a suitable constant c , the time spent in the i -th iteration is $c|S_i| \log n$ and total running time of Algorithm 1 can be upper bounded by:

$$c \sum_{i=1}^k |S_i| \log n = c\sqrt{n} \log n \cdot \sum_{i=1}^k 2^i < 2^{k+1} c\sqrt{n} \log n = 2cn \log n. \quad \blacktriangleleft$$

The following lemma, that concerns a thought experiment involving urns and randomly drawn balls, will be useful to upper bound the dislocation of the sequences returned by the Merge operations. Since it can be proved using arguments that do not depend on the details of RiffleSort, we omit its proof, which can be found in the full version of the paper.

⁵ The exact complexity depends on whether we can sample u.a.r. an integer from a range in $O(1)$ time. If this is not the case, then integers can be generated bit-by-bit using rejection, and the total number of required random bits will be $O(n)$ with probability at least $1 - n^{-2}$, as shown in the full version of this paper. To maintain a worst-case upper bound on the running time also in the unlikely event that $\Theta(n \log n)$ bits do not suffice, we can stop the algorithm and return any arbitrary permutation of S .

► **Lemma 6.** *Consider an urn containing $N = 2M$ balls, M of which are white, while the remaining M are black. Balls are iteratively drawn from the urn without replacement until the urn is empty. If N is sufficiently large and $9 \log N \leq k \leq \frac{N}{16}$ holds, the probability that any contiguous subsequence of at most $100k$ drawn balls contains k or fewer white balls is at most N^{-6} .*

We can now show that, if A and B contain randomly selected elements, the dislocation of $\text{Merge}(A, B)$ is likely to be at most a constant factor larger than the dislocation of A :

► **Lemma 7.** *Let A be a sequence containing m randomly chosen elements from S and having maximum dislocation at most d , with $\log n \leq d = o(m)$. Let B be a set of m randomly chosen elements from $S \setminus A$. Then, for a suitable constant γ , and for large enough values of m , $\text{merge}(A, B)$ has maximum dislocation at most γd with probability at least $1 - m^{-4}$.*

Proof. Let $\beta = \max\{\alpha, 9/2\}$, $S' = \text{Merge}(A, B)$, and $S^* = \langle s_0^*, s_1^*, \dots, s_{2m-1}^* \rangle$ be the sequence obtained by sorting S' according to the true order of its elements. Assume that:

- all the approximate ranks r_x , for $x \in B$, are such that $|r_x - \text{rank}(x, A)| \leq \beta d$; and
- all the contiguous subsequences of S^* containing no more than $2\beta d + 2$ elements in A have length at most $200\beta d + 200$.

We will show in the sequel that the above assumptions are likely to hold.

Pick any element $x \in S'$. We now show that our assumptions imply that the dislocation of x in S' is at most $201d$. An element $y \in B$ can affect the final dislocation of x in S' only if one of the following two (mutually exclusive) conditions holds: (i) $y \prec x$ and $r_y \geq r_x$, or (ii) $y \succ x$ and $r_y \leq r_x$. All the remaining elements in B will be placed in the correct relative order w.r.t. x in S' , and hence they do not affect the final dislocation of x . If (i) holds, we have:

$$r_x - \beta d \leq r_y - \beta d \leq \text{rank}(y, A) \leq \text{rank}(x, A) \leq r_x + \beta d,$$

while, if (ii) holds, we have:

$$r_x - \beta d \leq \text{rank}(x, A) \leq \text{rank}(y, A) \leq r_y + \beta d \leq r_x + \beta d,$$

and hence, all the elements $y \in B$ that can affect the dislocation of x in S' are contained in the set $Y = \{y \in B : r_x - \beta d \leq \text{rank}(y, A) \leq r_x + \beta d\}$.

We now upper bound the cardinality of Y . Let y^- be the $(r_x - \beta d - 1)$ -th element of A ; if no such element exists, then let $y^- = s_0^*$. Similarly, let y^+ be the $(r_x + \beta d)$ -th element of A ; if no such element exists, then let $y^+ = s_{2m-1}^*$. Due to our choice of y^- and y^+ we have that $\forall y \in Y, y^- \preceq y \preceq y^+$, implying that all the elements in Y appear in the contiguous subsequence \bar{S} of S^* having y^- and y^+ as its endpoints. Since no more than $2\beta d + 2$ elements of A belong to \bar{S} , our assumption guarantees that \bar{S} contains at most $200\beta d + 200$ elements. This implies that the dislocation of x in S' is at most $\beta d + |Y| \leq \beta d + |\bar{S}| \leq 201\beta d + 200 \leq \gamma d$, where the last inequality holds for large enough n once we choose $\gamma = 202\beta$.

To conclude the proof we need to show that our assumptions hold with probability at least $1 - |S'|^{-4}$. Regarding the first assumption, for $x \in B$, a noisy binary search returns a rank r_x such that $|r_x - \text{rank}(x, A)| \leq \alpha d \leq \beta d$ with probability at least $1 - O(\frac{1}{m^6})$. Therefore the probability that the assumption holds is at least $1 - O(\frac{1}{m^5})$.

Regarding our second assumption, notice that, since the elements in A and B are randomly selected from S , we can relate their distribution in S^* with the distribution of the drawn balls in the urn experiment of Lemma 6: the urn contains $N = 2m$ balls each corresponding to an element in $A \cup B$, a ball is white if it corresponds to one of the $M = m$ elements of A ,

49:12 Optimal Sorting with Persistent Comparison Errors

while a black ball corresponds one of the $M = m$ elements of B . If the assumption does not hold, then there exists a contiguous subsequence of S^* of at least $200\beta d + 200$ elements that contains at most $2\beta d + 2$ elements from A . By Lemma 6 with $k = 2\beta d + 2$, this happens with probability at most $(2m)^{-6}$ (for sufficiently large values of n). The claim follows by using the union bound. \blacktriangleleft

We can now use Lemma 7 and Theorem 4 together to derive an upper bound to the final dislocation of the sequence returned by Algorithm 1.

► **Lemma 8.** *The sequence returned by Algorithm 1 has maximum dislocation $O(\log n)$ and total dislocation $O(n)$ with probability at least $1 - \frac{1}{n\sqrt{n}}$.*

Proof. For $i = 1, \dots, k$, we say that the i -th iteration of Algorithm 1 is *good* if the sequence S_i computed at its end has both (i) maximum dislocation at most $c_p \log n$, and (ii) total dislocation at most $c_p |S_i|$. As a corner case, we say that iteration 0 is good if S_0 also satisfies conditions (i) and (ii) above, which happens with probability at least $1 - \frac{1}{|S_0|^4} \geq 1 - \frac{1}{n^2}$ as shown by Theorem 4.

We now focus on a generic iteration $i \geq 1$ and show that, assuming that iteration $i - 1$ is good, iteration i is also good with probability at least $1 - \frac{1}{n^2}$. Since iteration $i - 1$ was good, the sequence S_{i-1} has maximum dislocation $c_p \log n$ and hence, by Lemma 7, the sequence resulting from call to `Merge`(S_{i-1}, T_i) returns a sequence with dislocation at most $\gamma c_p \log n$ with probability at least $1 - \frac{1}{|T_i|^4} \geq 1 - \frac{1}{n^2}$. If this is indeed the case, we have that the sequence S_i returned by the subsequent call to `WindowSort` satisfies (i) and (ii) with probability at least $1 - \frac{1}{|S_{i+1}|^4} \geq 1 - \frac{1}{n^2}$ (see Theorem 4). The claim follows by using the union bound on the $k = O(\log n)$ iterations, and by noticing that the returned sequence is exactly S_k . \blacktriangleleft

We can therefore state the following result, which follows directly from Lemma 8 and Lemma 5:

► **Theorem 9.** *Consider a set of n elements that are subject to random persistent comparison errors. For any (adversarially chosen) input permutation of these elements, `RiffleSort` is a randomized algorithm that returns, in $O(n \log n)$ worst-case time, a sequence having maximum (resp. total) dislocation $O(\log n)$ (resp. $O(n)$), w.h.p.*

5 Derandomization

In Section 4 we showed how it is possible to design a *randomized* algorithm that approximately sorts a sequence S of n elements achieving simultaneously asymptotically optimal maximum dislocation, total dislocation, and running time, w.h.p.⁶ In this section we sketch how `RiffleSort` can be adapted to obtain a *deterministic* algorithm with the same asymptotic guarantees on running time, dislocation, and success probability (over the comparison errors), as long as the order of the elements in S does not depend of the comparison errors.⁷

In order to run `RiffleSort`, we need to partition the input sequence S into a collection of random sets T_0, T_1, \dots, T_k where $k = \frac{\log n}{2}$ and each T_i contains $m = \sqrt{n} \cdot 2^{i-1}$ elements that are chosen uniformly at random from the $n - \sqrt{n} \sum_{j=i+1}^k 2^{j-1} = 2m$ elements in $S \setminus \bigcup_{j=i+1}^k T_j$.

⁶ The *randomized* result also holds when each comparison c has an adversarially chosen and unknown probability of error $p_c \in [0, p]$. The deterministic result holds if $p_c \in [p_0, p]$ for some constant $p_0 > 0$.

⁷ An adversary could make the algorithm fail by first observing all comparison results among the input elements, and then choosing a suitable input permutation S . In other words, our result holds if the comparison errors do not depend on the element values nor on the positions in S of the involved elements.

Notice also that this is the only step in the algorithm that is randomized. To obtain a version of `RiffleSort` that does not require any external source of randomness, i.e., that depends only on the input sequence and on the comparison results, we will generate such a partition by exploiting the intrinsic random nature of the comparison results. As shown in the full version of the paper, with probability at least $1 - \frac{1}{n^3}$, the partition T_0, \dots, T_k can be found in $O(n)$ time using only $6n$ random bits. Moreover, with a technique similar to that of [11], it is possible to simulate “almost-fair” coin flips by xor-ing together a sufficiently large number of comparison results. Indeed, we can associate the two possible results of a comparison with the values 0 and 1, so that each comparison behaves as a Bernoulli random variable whose (unknown) parameter is either p or $1 - p$. We can then use the following fact: let c_1, \dots, c_k be $k = \Theta(\log n)$ independent Bernoulli random variables such that $P(c_i = 1) \in \{p, 1 - p\} \forall i = 1, \dots, k$, then $|\Pr(c_1 \oplus c_2 \oplus \dots \oplus c_k = 0) - \frac{1}{2}| \leq \frac{1}{n^4}$. Therefore, if we consider the set A containing the first $7k$ elements from S and we compare each element in A to all the elements in $S \setminus A$, we obtain a collection of $7k(n - 7k) \geq 6kn$ comparison results (for sufficiently large values of n) from which we can generate $6n$ almost-fair coin flips. A coupling argument shows that, with probability at least $1 - \frac{6kn}{n^4} - \frac{1}{n^3} > 1 - \frac{1}{n^2}$, all these almost-fair coin flips behave exactly as unbiased random bits, and they suffice to select a partition T_0, \dots, T_k of $S \setminus A$. It is now possible to use `RiffleSort` on $S \setminus A$ to obtain a sequence S' having maximum dislocation $d = O(\log n)$ and total dislocation $O(n)$. This requires time $O(n \log n)$ and succeeds with probability at least $1 - |S \setminus A|^{-\frac{3}{2}} > 1 - 3n^{-\frac{3}{2}}$ since $|S \setminus A| \geq \frac{n}{2}$.

What is left to do is to reinsert all the elements of A into S' without causing any asymptotic increase in the total and in the maximum dislocation. While one might be tempted to use the result of Section 1, this is not actually possible since the errors between the elements in A and the elements in S' now depend on the permutation S' . In the full version of this work we show a simple, but slower, $O(n)$ -time strategy to compute $\text{rank}(x, S')$ with an additive error of $O(\log n)$, even when S' is adversarially chosen as a function of the errors. Since A contains $O(\log n)$ elements, simultaneously reinserting them in S' affects the maximum dislocation by at most an $O(\log n)$ additive term, while their combined contribution to the total dislocation is at most $O(\log^2 n)$. We summarize the discussion of this section in the following theorem:

► **Theorem 10.** *Consider a set of n elements that are subject to random persistent comparison errors. For any input permutation of these elements that is chosen independently of the errors, there exists a deterministic algorithm that returns, in $O(n \log n)$ worst-case time, a sequence having maximum (resp. total) dislocation $O(\log n)$ (resp. $O(n)$), w.h.p.*

Abstract

We consider practical algorithms for maintaining the dominator tree and a low-high order in directed acyclic graphs (DAGs) subject to dynamic operations. Let G be a directed graph with a distinguished start vertex s . The dominator tree D of G is a tree rooted at s , such that a vertex v is an ancestor of a vertex w if and only if all paths from s to w in G include v . The dominator tree is a central tool in program optimization and code generation, and has many applications in other diverse areas including constraint programming, circuit testing, biology, and in algorithms for graph connectivity problems. A low-high order of G is a preorder of D that certifies the correctness of D , and has further applications in connectivity and path-determination problems.

We first provide a practical and carefully engineered version of a recent algorithm [ICALP 2017] for maintaining the dominator tree of a DAG through a sequence of edge deletions. The algorithm runs in $O(mn)$ total time and $O(m)$ space, where n is the number of vertices and m is the number of edges before any deletion. In addition, we present a new algorithm that maintains a low-high order of a DAG under edge deletions within the same bounds. Both results extend to the case of *reducible* graphs (a class that includes DAGs). Furthermore, we present a fully dynamic algorithm for maintaining the dominator tree of a DAG under an intermixed sequence of edge insertions and deletions. Although it does not maintain the $O(mn)$ worst-case bound of the decremental algorithm, our experiments highlight that the fully dynamic algorithm performs very well in practice. Finally, we study the practical efficiency of all our algorithms by conducting an extensive experimental study on real-world and synthetic graphs.

1 Introduction

Dynamic graph algorithms have been extensively studied for several decades, and many important results have been achieved for fundamental problems, including connectivity, minimum spanning tree, transitive closure, shortest paths (see, e.g., the survey in [13]). Typically, the goal of a dynamic graph algorithm is to update the solution of a problem, following the insertion or deletion of an edge, as quickly as possible (usually much faster than recomputing from scratch). A dynamic graph problem is said to be *fully dynamic* if it is required to process both insertions and deletions of edges, *incremental* if it requires to process edge insertions only and *decremental* if it requires to process edge deletions only. Here we consider two decremental problems in directed graphs, namely maintaining the dominator tree and a low-high order of a flow graph.

A *flow graph* $G = (V, E, s)$ is a directed graph (digraph) with a distinguished start vertex $s \in V$. A vertex v is *reachable* in G if there is a path from s to v ; v is *unreachable* if no such path exists. The *dominator relation* in G is defined for the set of reachable vertices as follows. A vertex v is a *dominator* of a vertex w (v *dominates* w) if every path from s to w contains v ; v is a *proper dominator* of w if v dominates w and $v \neq w$. The dominator relation in G can be represented by a tree rooted at s , the *dominator tree* D , such that v dominates w if and only if v is an ancestor of w in D . See Figure 1. If $w \neq s$ is reachable, we denote by $d(w)$ the parent of w in D . The dominator tree of a flow graph can be computed in linear time [2, 8, 14, 15]. The dominator tree is a central tool in program optimization and code generation [11], and it has many applications in other diverse areas including constraint programming [40], circuit testing [4], biology [1, 29], memory profiling [38], the analysis of diffusion networks [28], and in connectivity problems [17, 18, 21, 22, 24, 31, 32, 33, 34].

A *low-high order of G* [25] is a preorder of the dominator tree D such that for all reachable vertices $v \neq s$, $(d(v), v) \in E$ or there are two edges $(u, v), (w, v) \in E$, where u and w are reachable, w is not a descendant of v in D , and $u < v < w$ in low-high order. See Figure 1. Every flow graph G has a low-high order, computable in linear-time [25]. Low-high orders provide a correctness certificate for dominator trees that is straightforward to verify [46]. By augmenting an algorithm that computes the dominator tree D of a flow graph G so that it also computes a low-high order of G , one obtains a *certifying algorithm* to compute D . Low-high orders also have applications in path-determination problems [45] and in fault-tolerant network design [5, 6, 26].

In this paper we consider how to maintain the dominator tree and a low-high order of acyclic flow graphs subject to dynamic operations. We believe that acyclic graphs are not a significant restriction, since several real-world networks, such as certain types of biological networks, are acyclic [29]. Furthermore, our results extend to reducible flow graphs (defined below), a class that includes acyclic flow graphs. Reducible flow graphs are important in program optimization since one notion of a “structured” program is that its flow graph is reducible. The dynamic dominator problem arises in various applications, such as data flow analysis and compilation [10, 16]. Moreover, dynamic dominators can be used for dynamically testing various connectivity properties in digraphs, such as 2-vertex connectivity, strong bridges and strong articulation points [32].

The problem of updating the dominator relation has been studied for several decades (see, e.g., [3, 9, 10, 20, 23, 41, 42]). While for the incremental dominators problem there are simple algorithms that achieve total $O(mn)$ running time for processing a sequence of edge insertions in a flow graph with n vertices, where m is the number of edges after all insertions [3, 10, 23], the decremental version seems much harder. Cicerone et al. [10] achieved a total $O(mn)$ update bound for the decremental problem in reducible flow graphs, where

■ **Figure 1** (Top) A flow graph G and its dominator tree D . The numbers correspond to a preorder numbering of D that is a low-high order of G . (Bottom) The flow graph G' and its dominator tree D' after the deletion edge (g, d) .

m is the initial number of edges, but using $O(n^2)$ space. For general digraphs, Georgiadis et al. [20] presented an algorithm that can process a sequence of edge deletions in a flow graph in $O(mn \log n)$ total time and $O(n^2 \log n)$ space, and can answer dominance queries in constant time. For reducible flow graphs, Georgiadis et al. [20] presented an algorithm that achieves $O(mn)$ total running time using only $O(m + n)$ space. A conditional lower bound in [20] suggests that it might be hard to substantially improve the $O(mn)$ update bounds in the partial dynamic (incremental or decremental) problem of maintaining the dominator tree, even for acyclic flow graphs. As the algorithms in [20] are quite sophisticated, their implementation was a challenging task. Nevertheless, we show here that this is really worth the effort, since their efficient implementation performs very well in practice. To produce an implementation of practical value, we performed a careful engineering and choice of data structures, including a data structure for an extension of the dynamic list order maintenance problem [7, 12] and a data structure for maintaining and updating derived edges [25]. To assess the merits of our implementation in practical scenarios, we conducted a thorough experimental study.

As a second contribution, we show that we can maintain decrementally a low-high order of a reducible flow graph in $O(mn)$ total time. This implies the first decremental *certifying algorithm* [39] for computing dominators in $O(mn)$ total time in reducible flow graphs. It also immediately provides $O(mn)$ -time algorithms for the following problems:

- A data structure that maintains an acyclic flow graph G decrementally, and answers the following queries in constant time: (i) For any two query vertices v and w , find a path π_{sv} from s to v and a path π_{sw} from s to w that are maximally vertex-disjoint, i.e., such that π_{sv} and π_{sw} share only the common dominators of v and w . We can output these

- paths in $O(|\pi_{sv}| + |\pi_{sw}|)$ time. (ii) For any two query vertices v and w , find a path π_{sv} from s to v that avoids w , if such a path exists. We can output this path in $O(|\pi_{sv}|)$ time. Such a data structure (in the static case) was used by Tholey [45] in a linear-time algorithm for the 2-disjoint paths problem in a directed acyclic graph (DAG).
- A decremental version of the fault-tolerant reachability problem [5, 6] in DAGs. We maintain an acyclic flow graph $G = (V, E, s)$ through a sequence of edge deletions, so that we can answer the following query in $O(n)$ time. Given a spanning forest $F = (V, E_F)$ of G rooted at s , find a set of edges $E' \subseteq E \setminus E_F$ of minimum cardinality, such that the subgraph $G' = (V, E_F \cup E', s)$ of G has the same dominators as G .

An incremental low-high order algorithm with $O(mn)$ total update time was presented in [19]. As in the dynamic dominators problem, the decremental version seems more difficult than the incremental. To highlight this aspect, note that a single edge deletion can cause $O(n)$ changes in a given low-high order even if the dominator tree remains unaltered. See Figure 2. On the other hand, in the incremental setting, it suffices to update the low-high order only for the vertices that change parent in the dominator tree.

Our third contribution is an efficient fully dynamic algorithm for maintaining the dominator tree of a DAG under an intermixed sequence of edge insertions and deletions. We obtain this algorithm by incorporating the insertion method of [23] in our decremental algorithm. The fully dynamic algorithm does not preserve the $O(mn)$ worst case bound of the decremental algorithm because the vertex depths in the dominator tree no longer change monotonically. Despite this, however, our experimental results show that it performs very well in practice.

■ **Figure 2** An example of propagation of changes in the low-high order after the deletion of an edge. Vertices are arranged from left to right in low-high order. (a) After the deletion of (x, y) , y violates the given low-high order. (b)-(c) Moving y between z and t causes a new violation at vertex v , which in turn causes another violation at vertex u after v is placed between z and y . (d) The low-high order is finally restored when we place u between v and t .

2 Preliminaries

Let $G = (V, E, s)$ be a flow graph with start vertex s , and let D be the dominator tree of G . For any vertex $v \in V$, we let $In(v)$ denote the set of vertices that have an edge in G entering v , i.e., $In(v) = \{u \in V : (u, v) \in E\}$. An edge (x, y) of flow graph G is a *bridge* if its deletion makes y unreachable from s . Given a rooted tree T , we denote by $T(v)$ the subtree of T rooted at v (we also view $T(v)$ as the set of descendants of v). Let T be a tree rooted at s

with vertex set $V_T \subseteq V$, and let $t(v)$ denote the parent of a vertex $v \in V_T$ in T . If v is an ancestor of w , $T[v, w]$ is the path in T from v to w . In particular, $D[s, v]$ consists of the vertices that dominate v . If v is a proper ancestor of w , $T(v, w]$ is the path to w from the child of v that is an ancestor of w . Analogously, $T[v, w)$ denotes the path from v to $t(w)$. Suppose now that the vertex set V_T of T consists of the vertices reachable from s . Tree T has the *parent property* if for all $(v, w) \in E$ with v and w reachable, v is a descendant of $t(w)$ in T . If T has the parent property and has a low-high order, then $T = D$ [25]. For any vertex $v \in V$, we denote by $C(v)$ the set of children of v in D . A *preorder* of T is a total order of the vertices of T such that, for every vertex v , the descendants of v are ordered consecutively, with v first. A preorder of D is a low-high order of G , if $(d(v), v) \in E$ or there are two edges $(u, v), (w, v) \in E$ such that $u < v < w$, and w is not a descendant of v in D .

A *reducible* flow graph [30, 44] is one in which every strongly connected subgraph S has a single *entry* vertex $v \in S$ such that every path from s to a vertex in S contains v . A flow graph is reducible if and only if it becomes acyclic when every edge (v, w) such that w dominates v is deleted [44]. We refer to such an edge as a *back edge*. Deletion of such edges reduces the problem of computing dominators on a reducible flow graph to the same problem on an acyclic graph.

3 Decremental dominators

The algorithm of Georgiadis et al. [20] is based on the concept of *derived edges*. Recall that from the parent property of D , for any edge (v, w) of G , $d(w)$ is an ancestor of v in D . Let (v, w) be an edge of G , with w not an ancestor of v in D . (Such edges do not exist if G is acyclic.) Then, the *derived edge* of (v, w) is the edge (\bar{v}, w) , where $\bar{v} = v$ if $v = d(w)$, \bar{v} is the sibling of w in D that is an ancestor of v if $v \neq d(w)$. If w is an ancestor of v in D , then the derived edge of (v, w) is null. Note that a derived edge (\bar{v}, w) may not be an original edge of G . Given the dominator tree D of a flow graph $G = (V, E, s)$ and a list of edges $S \subseteq E$, we can compute the derived edges of S in $O(|V| + |S|)$ time [25].

Now consider the effect of an edge deletion on the dominator tree D . Let (x, y) be the deleted edge. We call the deletion of (x, y) *regular* if (x, y) is not a bridge of G , i.e., y remains reachable from s after the deletion. We let G' and D' denote the flow graph and its dominator tree after the update ($G' = G \setminus (x, y)$). Similarly, for any function f on V , we let f' be the function after the update. In particular, $d'(v)$ denotes the parent of v in D' . By definition, $D' \neq D$ only if x is reachable before the update. We say that a vertex v is *affected* by the update if $d'(v) \neq d(v)$, and *unaffected* otherwise. If v is affected then $d'(v)$ does not dominate v in G . Since the effect of an edge deletion is the reverse of an edge insertion, [23, Lemma 1], and [25, Lemma 4.1] imply the following:

► **Lemma 1.** *Suppose x is reachable and the deletion of edge (x, y) is regular, i.e., y does not become unreachable after the deletion. Then the following statements hold:*

- (a) *All affected vertices become descendants in D' of a child c of $d(y)$.*
- (b) *A vertex v is affected if and only if $(d(v), v)$ is not an edge of G' and all edges $(u, v) \in E \setminus (x, y)$ correspond to the same derived edge $(\bar{u}, v) = (c, v)$ of G .*
- (c) *After the deletion, each affected vertex v becomes a child of a vertex on the critical path $D'[c, d'(y)]$.*
- (d) *No vertex on $D'[c, d'(y)]$ is affected. Hence, $D'[c, d'(y)] = D[c, d'(y)]$.*

We note that statements (a) and (c) hold for arbitrary flow graphs, while (b) and (d) are true only for acyclic (and reducible) flow graphs. The algorithm of [20] applies Lemma 1 in order to locate the affected vertices in some topological order of G as follows. For each vertex

v we maintain a count $InSiblings(v)$ which corresponds to the number of distinct siblings w of v such that (w, v) is a derived edge. We also maintain the lists $DerivedOut(v)$ of the derived edges (v, u) leaving each vertex v . As we locate each affected vertex, we find its new parent in the dominator tree and update the counts $InSiblings$ for the siblings of v . The first step is to update $InSiblings(y)$. If $InSiblings(y) = 1$, then we compute the nearest common ancestor $z = d'(y)$ in D' of all vertices in $In(y)$. In this case, by Lemma 1(c), z is a descendant of a sibling c of y in D . Next, we update the $InSiblings(v)$ counts for all $v \in DerivedOut(y)$. Specifically, we decrement $InSiblings(v)$ if $v \in DerivedOut(c)$; if $InSiblings(v) = 1$ then we identify v as affected and inserted into a FIFO queue Q . Then we repeat the same process for each vertex extracted from Q . We can locate the new parent $d'(v)$ of each affected vertex v in D' as for y , i.e., by computing the nearest common ancestor in D' of all vertices in $In(v)$. This way, however, does not guarantee the desired $O(mn)$ total update time. Therefore, we locate $d'(v)$ by traversing the critical path $D[c, d'(y)]$ in top-down order, until we find a vertex u such that $In(v)$ contains a vertex that is not a descendant of u in D' . Then we have $d'(v) = d(u)$. Finally, we can compute the updated $InSiblings$ counts and $DerivedOut$ lists in a postprocessing step. The analysis in [20] is based on the fact that the affected vertices that remain reachable increase their depth in D .

3.1 Efficient implementation

Providing a practical version and an efficient implementation of the above algorithm turns out to be a very challenging task. In particular, we need to incorporate efficient solutions to the following subproblems: (i) answering ancestor-descendant queries in the dominator tree D that changes dynamically, (ii) maintaining dynamically the derived edges of G , and (iii) handling the deletion of bridges. We note that (i) and (ii) are not needed when we update D incrementally.

Ancestor-descendant queries. Throughout the execution of the deletion sequence, we need to test in $O(1)$ time the ancestor-descendant relation between pairs of vertices in D , in order to locate the new parent of each affected vertex $v \neq y$. To that end, it suffices to recompute a preorder and a postorder numbering of the vertices in D after each update, since this takes $O(n)$ time by simply performing a dfs traversal of D . Then, v is a descendant of u in D if and only if $u \leq v$ in preorder and $v \leq u$ in postorder [43]. Another option is to represent each order (preorder and postorder) with a data structure for the dynamic list order problem [7, 12]. Both methods guarantee the desired $O(mn)$ total update bound, but the use of a dynamic list order data structure gives a much faster implementation in practice.

Here, we also take advantage of the fact that for each affected vertex v we can move the entire subtree of $D(v)$ in the new location in the dynamic lists, rather than inserting the vertices in $D(v)$ one by one. Specifically, we remove the subtree $D(v)$ from its current locations in the two dynamic lists and insert them immediately after $d'(v)$ in the preorder list and immediately before the first descendant of $d'(v)$ in the postorder list. Thus, we have immediate access to the appropriate location in the preorder list, but we still need to find the corresponding location in the postorder list. In order to do this search fast, we maintain, for each $v \in D$, the list $C(v)$ of the children of v in D ordered in preorder. Then, we can find the first descendant of a vertex u in the postorder list by repeatedly following the links to the first child in preorder, until we reach a leaf.

We implemented the dynamic preorder and postorder lists by adapting the dynamic list order data structure of Bender et al. [7] that uses a two-level structure (implementing a numbering scheme) and supports insertions, deletions and order queries in constant amortized time. We extend this structure so that it can also support the following operation:

move(u, v, w): Move the items between u and v (inclusive) from their current location in the dynamic list and insert them right after w .

We implement the above operation as follows. First, we find the representative nodes (in the top-level structure) for u and v . We check if the left-representative (right-representative, respectively) has items in the second-level list that do not belong to the moved set of items; if there are such items then we split the second-level lists and create new representative items. After this step, both representative items and every other representative item between them, have only second-level items that belong to the set we want to move. Hence, we can quickly move the entire set by linking the left-representative and right-representative to their new position in the dynamic list, right after w . Finally, we check if we can merge the representatives that we move or split with their neighbours.

In our experiments, we observed that the above method was several orders of magnitude faster compared to recomputing a preorder and a postorder numbering in D .

Derived edges. Recall that after finding the affected vertices of an edge deletion, we need to compute the updated *InSiblings* counts and *DerivedOut* lists. The only types of edges that may change their corresponding derived edge are (i) edges entering affected vertices, and (ii) edges that enter a former sibling of y from a descendant of an affected vertex. Let S be the set of these edges. As mentioned above, we can compute the derived edges of S in $O(n + |S|)$ time [25], which suffices for our $O(mn)$ bound since every edge in S is adjacent to at least one vertex that changes depth in D . The method given in [25] for computing derived edges is based on bucket sorting using a preorder numbering of D . This is not suitable for our framework, since we do not maintain a preorder numbering of the vertices, but use a dynamic list order data structure instead. Here we propose a more practical method. First we note that for each edge (u, v) of type (ii), i.e., u is a descendant of an affected vertex and $d(v) = d'(v) = d(y)$, we have $\bar{u} = c$. Now let (u, v) be of type (i), i.e., v is affected so $d'(v) \in D'[c, y]$ and u is a descendant of $d'(v)$. If $u = d'(v)$ then $\bar{u} = u$, so suppose u is a proper descendant of $d'(v)$. Let w_v be the next vertex on $D'[c, y]$ following $d'(v)$ ($w_v = d'(d'(v))$), and let z_u be the nearest ancestor of u such that $d'(z_u) \in D'[c, y]$. Then, $\bar{u} = w_v$ if $d'(z_u) \neq d'(v)$, and $\bar{u} = z_u$ if $d'(z_u) = d'(v)$. Note that we have already computed w_v , for each affected vertex v , when we locate its new parent in D' . Hence, it suffices to compute z_u for all edges (u, v) where u is a proper descendant of $d'(v)$. We do that by visiting the ancestors of u until we reach z_u . First we mark all vertices on $D'[c, y]$, so we stop our search when reaching a vertex that has a marked parent. To avoid multiple visits to the same vertices, we maintain at each vertex w a label $l(w)$, initially null. After we locate z_u , we set $l(w) = z_u$ for each visited vertex w . Thus, the next search stops at a vertex w such that $d'(w)$ is marked or $l(w)$ is not null. Therefore, we can compute all the new derived edges in $O(n + |S|)$ time as desired.

Unreachable vertices. After the deletion of an edge (x, y) , some vertices may become unreachable. This happens when (x, y) is a bridge of the current flow graph. Since we deal with acyclic graphs, this means that (x, y) is the only edge entering y from a reachable vertex. Hence, we can detect easily if (x, y) is a bridge, since we have $InSiblings(y) = 0$ and $d(y) = x$. In order to achieve $O(mn)$ total running time, we can simply recompute the dominator tree from scratch after each such deletion, since the total number of bridges that can appear is at most $n - 1$. In practice, however, this causes a significant slowdown of our algorithm. A better idea is to handle the deletion of a bridge (x, y) as follows:

1. Compute the set of edges Y from vertices in $D(y)$ to vertices in $D \setminus D(y)$. Note that no edge $e \in Y$ is a bridge in $G \setminus (Y \setminus e)$, since for any vertex $v \in D \setminus D(y)$, all edges in $(w, v) \in Y$ correspond to the same derived edge (\bar{w}, v) .
2. Process each edge $e \in Y$ as a regular deletion.
3. Delete $D(y)$ from the dominator tree D' of G' , and update accordingly the data structures. Note that Steps 1 and 3 take $O(m)$ time. Also, since in Step 2 we have regular deletions, the total running time remains $O(mn)$.

4 Decremental low-high order

Now we consider how to update a low-high order of an acyclic flow graph $G = (V, E, s)$ after the deletion of an edge (x, y) . First, we show how to achieve an $O(mn)$ total update bound using a sparsification technique, similar to the one used for the incremental problem in [19]. The idea is to maintain a subgraph $H = (V, E_H)$ of G with $O(n)$ edges that has the same dominator tree as G . By Lemma 1(c), each vertex v with $(d(v), v) \notin E$ has two entering edges (u, v) and (w, v) such that $\bar{u} \neq \bar{w}$; then, it suffices to add two such edges in H .

► **Corollary 2.** *Let $H = (V, E_H)$ be subgraph of an acyclic flow graph G such that E_H contains:*

- (a) *All edges $(u, v) \in E$ such that $u = d(v)$.*
- (b) *Two edges (u, v) and (w, v) such that $\bar{u} \neq \bar{w}$ for each vertex v with $(d(v), v) \notin E$.*

Then H has the same dominator tree as G . Moreover, a low-high order of H is also a valid low-high order of G .

Note that the two edges in Corollary 2(b) exist by Lemma 1(c). Clearly $H = (V, E_H)$ has $O(n)$ edges as required. Now, we can compute a low-high order of H in $O(|E_H|) = O(n)$ time using the static algorithm of [25]. The algorithm arranges the children $C(x)$ of each non-leaf vertex x of D in a local low-high order δ_x . First, we place all vertices $v \in C(x)$ with $(x, v) \in E$ in arbitrary order in δ_x . Then, we process the remaining children of x in topological order. For each such vertex v , H contains edges (u, v) and (w, v) such that $\bar{u} \neq \bar{w}$, so \bar{u} and \bar{w} precede v in the topological order and are already located in δ_x . Hence, it suffices to insert v in any location in δ_x between \bar{u} and \bar{w} . When we have computed all the local low-high orders, we can get the complete low-high order of G by arranging each subtree $D(v)$ of D immediately after v . After the deletion of (x, y) we need to update H in order to ensure that it still satisfies Corollary 2. We can do this during the update of the derived edges, after we have located all their affected vertices and their new parents in D' . Therefore, we get the following result.

► **Theorem 3.** *We can maintain a low-high order of a reducible flow graph G with n vertices through a sequence of edge deletions in $O(mn)$ total time, where m is number of edges in G before all deletions.*

4.1 Bounded search algorithm

Here we present an algorithm that updates a low-high order much faster in practice than the above algorithm. To that end, we also need to maintain the lists $DerivedIn(v)$ of the derived edges (u, v) entering each vertex v . The algorithm is based on two ideas. First, we observe that it is easy to update the low-high order for the affected vertices. The problematic case is to update the low-high order for unaffected vertices. For the latter case, we propose a bounded search process that identifies the vertices that may need to be relocated in low-high order.

Affected vertices. The crucial observation is that the decremental dominators algorithm of Section 3 discovers the affected vertices in topological order. Thus, after we move all the affected vertices in their new locations in D' and update their incoming derived edges, we can position them in low-high order. For each affected vertex v , if $(d(v), v) \notin E$, then $DerivedIn(v)$ contains two vertices u and w such that $u < w$ in low-high order, so we can insert v between these two vertices.

Unaffected vertices. Now we deal with the more challenging case of updating the low-high order of unaffected vertices. As we already observed, a single edge deletion may cause many changes in a given low-high order, even if there are no affected vertices. (See Figure 2.) Our first step is to identify the initial set I of unaffected vertices that violate the low-high order after updating the dominator tree and the low-high order of the affected vertices. Fixing the low-high order of the vertices in I may invalidate the low-high order of other vertices that are reachable from I . So, our next step is to compute a set X ($I \subseteq X$) of vertices that may need to be relocated in low-high order due to the changes in the low-high order of I . The next lemma determines the location of the vertices in I .

► **Lemma 4.** *Let v be an unaffected vertex that violates the given low-high order after updating the dominator tree in response to an edge deletion (i.e., $v \in I$). Then $d'(v) = d(y)$.*

Proof. A vertex v may violate the low-high order only if it has an entering edge (u, v) such that u is a descendant of an affected vertex and the derived edge of (u, v) changes. From the parent property of the dominator tree we have that for all $(v, w) \in E$ with v and w reachable, v is a descendant of $d(w)$ in D . Since, by Lemma 1(c), all affected vertices become descendants of a child c of $d(y)$, the derived edge of (u, v) changes only if v is a child of $d(y)$. Since v is unaffected, $d'(v) = d(v) = d(y)$. ◀

The above lemma also helps us limit our search for candidate vertices that may need to be relocated in the low-high order in response to the update of the position of the vertices in I . Since I consists only of children of $d(y)$, we only need to search among the unaffected children of $d(y)$ that are reachable from I . As we relocate vertices in low-high order, this process may cascade. See Figure 2.

In order to bound the total running time of our algorithm by $O(mn)$, we maintain a sparse spanning subgraph $H = (V, E_H)$ of G with $O(n)$ edges that satisfies Corollary 2, together with the derived edges \overline{E}_H of E_H . We also maintain the invariant that for each vertex v such that $(d(v), v) \notin E$, the two derived edges $(u, v), (w, v) \in \overline{E}_H$ are such that $u < v < w$ in low-high order.

Our algorithm, $FixLH(y)$, computes a set of vertices $X \subseteq C'(d(y))$ that we will need to process in order to ensure that they satisfy a low-high order of G' . Initially, we set $X = I$ and execute a search from each vertex in I in order to discover vertices that may violate the given low-high order due the replacement of the vertices in I . During this search, we would like to avoid any unnecessary propagation of changes in the low-high order. To achieve this, when we process a vertex $u \in X$, we examine its outgoing derived edges in \overline{E}_H . For each such edge (u, v) we test if v satisfies the current low-high order without considering the derived edges from X . If this is not the case, then we insert v into X . This bounded search is outlined by Procedure `scan`. Note that we can only afford to check a constant number k of entries in $DerivedIn(v)$ in order to have $O(n)$ running time per deletion. (In our experiments we set $k \leq 3$.) Thus, we get the following result.

► **Lemma 5.** *Algorithm $FixLH$ correctly updates the low-high order of the children of $d(y)$ in D' in $O(n)$ time.*

Algorithm 1 FixLH(y).

```

1  $I =$  children of  $d(y)$  that violate the low-high order of  $G$  after the deletion  $/*I \subseteq \{y\}$ 
   if  $y$  is not affected; otherwise,  $I$  contains unaffected children of  $d(y)$  that
   have an entering edge from a descendant of an affected vertex */
2 initialize  $X = I$   $/*X$  will contain the unaffected children of  $d(y)$  that need to be
   relocated in low-high order */
3 foreach vertex  $u \in I$  do
4   | if  $u$  not scanned then scan( $u$ )
5 end
6 Process vertices in  $X$  in topological order to place them in low-high order using the
   edges in  $\overline{E}_H$ 

```

Procedure scan(u).

```

1 foreach derived edge  $(u, v) \in \overline{E}_H$  do
2   | if  $v \notin X$  and  $(d(v), v) \notin E$  then
3     | if  $u < v$  in low-high order then
4       | examine the first  $k = O(1)$  edges in  $DerivedIn(v)$  to find a replacement
5         | derived edge  $e = (w, v)$  with  $w \notin X$  and  $w < v$  in low-high order
6       | end
7     | else
8       | examine the first  $k = O(1)$  edges in  $DerivedIn(v)$  to find a replacement
9         | derived edge  $e = (z, v)$  with  $z \notin X$  and  $v < z$  in low-high order
10      | end
11     | if a replacement derived edge  $e$  was found then
12       | replace  $(u, v)$  with  $e$  in  $\overline{E}_H$ 
13     | end
14     | else
15       | insert  $v$  into  $X$ 
16       | scan( $v$ )
17     | end
18   | end
19 end

```

Proof. To prove the correctness of algorithm FixLH, first note that it correctly updates the low-high order of all vertices in X . Now we need to argue that the remaining vertices satisfy the updated low-high order. Observe that any vertex v that is visited during the search for X , is not inserted into X only if $(d(v), v) \in \overline{E}_H$ or if both derived edges in \overline{E}_H entering v are not in X . Clearly, the same holds for all vertices that are not visited during this process. Hence, any vertex $v \notin X$ does not violate the computed low-high order before and after relocating the vertices in X .

Now we argue that the algorithm runs in $O(n)$ time. Each vertex v may change its two entering edges in \overline{E}_H at most $O(1)$ times, since we look for replacement edges only in the first $O(1)$ edges in $DerivedIn(v)$. Thus, $DerivedIn(v)$ will be examined in lines 4 and 7 of Procedure scan a constant number of times in total for each v , so we spend constant time for

each vertex. Finally, we need to process the vertices of X in topological order. Note that the vertices may be inserted in X in arbitrary order. We can sort them topologically by computing a topological order of the subgraph of $\overline{H} = (V, \overline{E}_H)$ that is induced by the vertices of X . Since \overline{E}_H has $O(n)$ edges, this step also takes $O(n)$ time. ◀

► **Remark 6.** We also test the following, slightly more complicated, variant of Algorithm FixLH. In line 6, where we place each vertex of $u \in X$ in low-high order, we do not use only the derived edges entering u that are contained in \overline{E}_H , but also consider a constant number of derived edges entering u contained in $\overline{E} \setminus \overline{E}_H$. Let $\overline{E}(u)$ be the set of derived edges entering u that we consider in order to decide the location of u in the low-high order. Also, let $\overline{V}(u) = \{w \in V : (w, u) \in \overline{E}(u)\}$, i.e., the vertices from which the derived edges in $\overline{E}(u)$ originate. Then, we place u right after the median vertex in $\overline{V}(u)$, sorted with respect to the low-high order. By doing this placement for u , we hope that Procedure scan will have better chances for locating replacement derived edges.

4.2 Implementation issues

We extend our decremental dominators algorithm of Section 3 so that it also maintains a low-high order as described above. The following implementation issues affect the efficiency of our algorithm in practice.

Representation of a low-high order. Since a low-high order is a preorder of D , we can use the same dynamic list order data structure as in Section 3.1. This choice, however, has the serious drawback that we may need to update the data structures for both the preorder and the postorder of D much more often than in Section 3.1. For this reason, we use a separate dynamic list order data structure for the low-high order, which is updated independently of the preorder and the postorder of D .

Unreachable vertices. As in the decremental dominators algorithm of Section 3.1, we have to take special care of how the deletion of a bridge (x, y) is handled. To that end, we first tested the two methods mentioned in Section 3.1: (a) Run a static algorithm to recompute the dominator tree D and a low-high order from scratch, and (b) Process each edge $e = (u, v)$ with u a descendant of y in D and v not a descendant of y in D as a regular deletion (e cannot be a bridge) and update the low-high order after each such deletion. Then delete (x, y) , making all descendants of y in D unreachable from s .

Unlike the decremental dominators algorithm, choice (b) here is not always superior to (a) because during the sequence of regular deletions a vertex may be scanned several times when the FixLH process is executed. Hence, we also implemented the following improvement, which updates the low-high order of unaffected vertices after the sequence of regular deletions is processed. Specifically, we first update the dominator tree as in (b) but do not compute the complete low-high order after each regular deletion of an edge $e = (u, v)$. As we process each regular deletion (u, v) , we also fix the low-high order of each affected vertex. Let A^* denote the set of all affected vertices found during all regular deletions. For each edge (w, t) such that w is a descendant of an affected vertex in A^* we insert t in a list I^* . We compute a set X^* of vertices which may need their low-high to be updated by executing $scan(v)$, starting from all vertices v in I^* that have not been scanned yet. Finally, we sort X^* topologically and update the low-high order of all vertices in X^* .

All of the above three methods are executed in $O(m)$ time per bridge deletion, so they all guarantee the $O(mn)$ total running time. In our experiments, however, the last method turned out to be an order of magnitude faster than (a) and (b).

5 Empirical Analysis

We wrote our implementations in C++, using g++ v.4.6.4 with full optimization (flag `-O3`) to compile the code. We report the running times on a Dell Precision Tower 7820 CTO Base machine running Ubuntu (16.04 LTS), equipped with an Intel Xeon Gold 5118 2.3 GHz processor with 16 MB L3 cache and 192GB DDR4-2400 RAM at 2,666 MHz. We did not use any parallelization, and each algorithm ran on a single core. We report CPU times measured with the `getrusage` function.

■ **Table 1** Graph instances used in the experiments. The original graphs are taken from [35] and [37], and were converted to DAGs by including vertices and edges reachable from the start vertex and deleting depth-first search back edges. The graph categories are: source code (SC), social network (SN), peer to peer network (P2P), web graph (WG), communication network (CN), and product co-purchasing network (PN). The number of vertices n and edges m refer to the produced instances.

Table 1 shows some statistics about the graphs used in our experimental evaluation. In all test instances we select the first vertex of the graph as the start vertex. (Choosing a random start vertex produces similar results.) We produce decremental instances as follows. The number of edges that will be deleted is controlled by a parameter $p \in [0, 1]$. Let m be the initial number of edges in the graph. We create a sequence of deletions by choosing $\lfloor p \cdot m \rfloor$ edges in the original graph uniformly at random. For each graph and each choice of p , we create 10 such random instances using different seeds for the initialization of the random functions, and report the average running times. (For a given input graph, two values $p_1 < p_2$ of p , and a fixed seed, the deletion sequence for p_1 is a subsequence of the deletion sequence for p_2 .) The algorithms compute (in static mode) the dominator tree (and a low-high order for the decremental low-high order algorithms) of the original graph and then they run in decremental mode, processing the sequence of deletions. Note that during the execution of the algorithms some vertices may become unreachable, and thus some subsequent deletions may involve a disconnected portion of the graph. These deletions are detected and ignored by all algorithms. For computing dominators in static mode we use the SNCA algorithm from [27], which is a simplified variant of the classic Lengauer-Tarjan algorithm [36] that performs very well in practice. (Algorithm SNCA was generally faster than other well-known algorithms tested in [27].) As an intermediary, this algorithm computes a sparse subgraph H of the input graph G that has the same dominators as G . The indegree of each vertex in H is at most 2, so H has at most $2(n - 1)$ edges (the start vertex has zero indegree). For computing a low-high order, we augment this algorithm with the low-high order algorithm for acyclic graphs from [25]. We speedup the computation of a low-high order by using only the edges in H (instead of all the edges of G).

Dominators. We compare our efficient algorithm, *Decr* of Section 3, with two dynamized versions of *SNCA*. (We did not consider the algorithm of Cicerone et al. [10] since it requires $O(n^2)$ space, and therefore is impractical for large graphs.) The first algorithm, *DSNCA1*, first tests if the deleted edge (x, y) belongs to the sparse subgraph H . If not, then the dominator tree is not affected and the algorithm does nothing. Otherwise, it simply runs *SNCA* from scratch. The second algorithm, *DSNCA2*, also performs the same test, but if $(x, y) \in H$, then it computes the nearest common ancestor z of x and y in D and runs *SNCA* only for the subgraph of G induced by $D(z)$.

The average running times are reported in Table 3. Our experimental results show that the new algorithm *Decr* is much faster than both *DSNCA1* and *DSNCA2*. In particular, *Decr* is consistently at least two orders of magnitude faster than *DSNCA1* and *DSNCA2*. For several graphs considered in our experiments, a large fraction of the vertices tended to get disconnected from the start vertex after the deletion of about 50% of the edges, and therefore many subsequent deletions are ignored. We also observe that recomputing the dominator tree only for the subgraph induced by $D(z)$ (where z is the nearest common ancestor of x and y in D) does not provide a significant improvement in the running time of *DSNCA*, and it may even cause slowdown in some instances, due to the overhead of computing the nearest common ancestor of x and y in D .

Fully-dynamic case. We also report some experimental results for our fully dynamic algorithm, that we refer to as *Dyn*, that maintains the dominator tree of a DAG under a mixed sequence of edge insertions and deletions. We obtain this algorithm by incorporating the insertion method of [23] in our decremental algorithm. Note that, as in our decremental algorithm, we need to maintain the same data structures for the derived edges and for the dynamic preorder and postorder lists. (These data structures are not required in the incremental setting.) The fully dynamic algorithm does not preserve the $O(mn)$ worst case bound of the incremental or the decremental algorithm because the vertex depths in the dominator tree no longer change monotonically. Despite this, however, our experimental results show that it performs very well in practice.

We produce fully dynamic instances as follows. The number of edges that will be inserted and deleted are controlled by parameters $p_i \in [0, 1]$ and $p_d \in [0, 1]$, respectively. Let m be the initial number of edges in the graph. We create a sequence of insertions and deletions by choosing $m_i = \lfloor p_i \cdot m \rfloor$ random edge insertions and $m_d = \lfloor p_d \cdot m \rfloor$ random edge deletions. This means that the flow graph initially has $m' = m - m_i$ edges. For each graph and each choice of p_i, p_d , we create 10 such random instances using different seeds for the initialization of the random functions, and report the average running times. The algorithms compute (in static mode) the dominator tree of the original graph and then they run in fully-dynamic mode, processing the (intermixed) sequence of insertions and deletions. As in the decremental algorithm, we compute the dominator tree in static mode with the *SNCA* algorithm from [27]. In the fully-dynamic mode, the type of each update operation is chosen uniformly at random, so that there are m_i insertions interspersed with m_d deletions. During this simulation that produces the dynamic graph instance we keep track of the edges currently present in the graph. If the next operation is a deletion then the edge to be deleted is chosen uniformly at random from the edges in the current graph.

Here we only give some preliminary experimental results, presented in Table 2, and defer to the full version of the paper for a more comprehensive experimental study. As in the decremental setting, we observe significant speed ups with respect to *DSNCA1* and *DSNCA2*.

■ **Table 2** Average running times in seconds over 10 random intermixed update sequences of edge insertions and deletions. The suffixes in the graph names correspond to the percentage of inserted edges and deleted edges, respectively.

Low-high order. Here we examine the efficiency of our algorithm Decr-LH, using the slightly more complicated variant for placing of a vertex in low-high order, described in Remark 6. In some instances, this variant performed significantly better than the simple version, as shown in Figure 3. We compare the running time of Decr-LH with a dynamized version of SNCA that also computes a low-high order of an acyclic flow graph. This algorithm, that we refer to as DSNCA-LH, works as follows. It maintains a sparse subgraph $H = (V, E_H)$ of G such that for each $v \neq s$, $(d(v), v) \in E_H$, or E_H contains edges (u, v) and (w, v) with $u < v < w$. When we delete an edge (x, y) we test if this edge belongs to H . If not, then the dominator tree and the low-high order are not affected, so we do nothing. Otherwise, we look into the entering edges of v and try to find a replacement edge for (x, y) so that y satisfies the current low-high order. If this fails, then we compute the dominator tree and the low-high from scratch.

■ **Figure 3** Running time of two implementations of Decr-LH. The first, Decr-LH-Simple, uses the simple method for placing of a vertex in low-high order, as described in Algorithm FixLH, while the second, Decr-LH-Median, uses the method described in Remark 6.

■ **Table 3** Average running times in seconds over 10 random deletion sequences. The suffixes in the graph names correspond to the percentage of deleted edges $p = 5\%, 10\%, 20\%, 40\%$, and 80% . Running times exceeding 2.5 hours are not reported.

The corresponding average running times are reported in the last two columns of Table 3. As above, our efficient algorithm Decr-LH is much faster than DSNCA-LH. We also observe that in most instances, maintaining a low-high order with our decremental algorithm Decr-LH incurs a relatively low overhead with respect to Decr. For some instances, such as product co-purchasing networks and web graphs (Amazon0302, Amazon0601, web-BerkStan and web-Google), however, the overhead of maintaining a low-high order is significantly higher. In our experiments this was due to the fact that a low-high order may change substantially (i.e., many vertices will be inserted into set X maintained by Algorithm FixLH), even if the dominator tree remains the same. (See Figure 2.)

Abstract

In recent years several *compressed indexes* based on variants of the Burrows-Wheeler transformation have been introduced. Some of these are used to index structures far more complex than a single string, as was originally done with the FM-index [Ferragina and Manzini, J. ACM 2005]. As such, there has been an increasing effort to better understand under which conditions such an indexing scheme is possible. This has led to the introduction of Wheeler graphs [Gagie et al., Theor. Comput. Sci., 2017]. Gagie et al. showed that de Bruijn graphs, generalized compressed suffix arrays, and several other BWT related structures can be represented as Wheeler graphs, and that Wheeler graphs can be indexed in a way which is space efficient. Hence, being able to recognize whether a given graph is a Wheeler graph, or being able to approximate a given graph by a Wheeler graph, could have numerous applications in indexing. Here we resolve the open question of whether there exists an efficient algorithm for recognizing if a given graph is a Wheeler graph. We present:

- The problem of recognizing whether a given graph $G = (V, E)$ is a Wheeler graph is NP-complete for any edge label alphabet of size $\sigma \geq 2$, even when G is a DAG. This holds even on a restricted, subset of graphs called d -NFA's for $d \geq 5$. This is in contrast to recent results demonstrating the problem can be solved in polynomial time for d -NFA's where $d \leq 2$. We also show the recognition problem can be solved in linear time for $\sigma = 1$;
- There exists an $2^{e \log \sigma + O(n+e)}$ time exact algorithm where $n = |V|$ and $e = |E|$. This algorithm relies on graph isomorphism being computable in strictly sub-exponential time;
- We define an optimization variant of the problem called Wheeler Graph Violation, abbreviated WGV, where the aim is to remove the minimum number of edges in order to obtain a Wheeler graph. We show WGV is APX-hard, even when G is a DAG, implying there exists a constant $C \geq 1$ for which there is no C -approximation algorithm (unless $P = NP$). Also, conditioned on the Unique Games Conjecture, for all $C \geq 1$, it is NP-hard to find a C -approximation;
- We define the Wheeler Subgraph problem, abbreviated WS, where the aim is to find the largest subgraph which is a Wheeler Graph (the dual of the WGV). In contrast to WGV, we prove that the WS problem is in APX for $\sigma = O(1)$;

The above findings suggest that most problems under this theme are computationally difficult. However, we identify a class of graphs for which the recognition problem is polynomial time solvable, raising the open question of which parameters determine this problem's difficulty.

1 Introduction

Within the last two decades, there has been the development of Burrows Wheeler Transform (BWT) [7] based indices for compressing a diverse collection of data structures. This list includes labeled trees [31], certain classes of graphs [14, 29], and sets of multiple strings [16, 26]. This has motivated the search for a set of general conditions under which a structure can be indexed by a BWT based index, and consequently the introduction of Wheeler graphs. A Wheeler graph is a directed graph with edge labels which satisfies two simple axioms related to the ordering of its vertices. They were introduced by Gagie et al. [17] (also see [2]). Although not general enough to encompass all BWT-based structures (e.g., [18]), the authors demonstrated that Wheeler graphs offer a unified way of modeling several BWT based data structures such as representations of de Bruijn graphs [6, 10], generalized compressed suffix arrays [31], multistring BWTs [27], XBWTs [14], wavelet matrices [9], and certain types of finite automaton [1, 5, 24]. They also showed that there exists an encoding of a Wheeler graph $G = (V, E)$ which requires only $2(e + n) + e \log \sigma + \sigma \log e + o(n + e \log \sigma)$ bits where σ is the size of the edge label alphabet, $e = |E|$, and $n = |V|$. This encoding allows for the efficient traversal of multiple edges while processing characters in a string, using an algorithm similar to the backward search in the FM-index [15]. Since their introduction Wheeler graphs have been further developed using techniques such as tunneling by Alanko et al. [2]. Also, ideas closely coupled to Wheeler graphs have shown up in the recent work by Equi et al. for exact pattern matching on graphs [12, 13]. However, not all directed edge labeled graphs are Wheeler graphs, and thus not all directed edge labeled graphs can have such techniques applied to them. The authors of [17] posed the question of *how to reasonably recognize whether a given graph is a Wheeler graph*.

The question is of both theoretical and practical value, as it might be the first step before attempting to apply some compression scheme to a given graph. For example, one could use the existence of a *Wheeler subgraph* to encode a graph. To do so, you could maintain an encoding of the subgraph using the framework presented in [17] in addition to an adjacency list of the edges not included in the encoding. Depending on the size of the subgraph, such an encoding might provide a large space savings at the cost of a modest time trade-off while traversing the graph. This concept also motivates the portion of the paper where we look at *optimization versions* of this problem that seek subgraphs of the given graph which are Wheeler graphs. Unfortunately for practitioners of such a method, this problem turns out to be computationally difficult as well. As a positive result, we show that the problem of finding a maximal Wheeler subgraph admits a polynomial time algorithm which has solution size within some constant factor of optimal for constant alphabet size. We also show that the problem of recognizing Wheeler graphs is similar to that of identifying the queue number of a graph, indicating a class of graphs where the problem becomes computationally tractable.

1.1 Wheeler Graphs

The notation (u, v, k) is used for the directed edge from u to v with label k . We will assume the usual ordering on the edge labels which come from the alphabet $\{1, 2, \dots, \sigma\}$.

► **Definition 1.** *A Wheeler graph is a directed graph with edge labels where there exists an ordering π on the vertices such that for any two edges (u, v, k) and (u', v', k') :*

- (i) $k < k' \implies v <_{\pi} v'$;
- (ii) $(k = k') \wedge (u <_{\pi} u') \implies v \leq_{\pi} v'$.

In addition, vertices with in-degree zero must be placed first in the ordering.

We consider an ordering of the vertices of the graph a *proper* ordering if it satisfies the axioms of the Wheeler graph definition. See Figure 1 for an illustration. One critical property of Wheeler graphs is called *path coherence*. This property is characterized by the fact that if you start at any consecutive range of vertices under the proper ordering π , and traverse the graph following edge labels matching the characters in a string P , then when finished processing P the vertices ended on will form a consecutive range. This property is key to allowing the efficient traversal of multiple edges simultaneously, as well as achieving a compressed representation of the graph.

■ **Figure 1** An example of a Wheeler graph with $\sigma = 3$. The ordering on the edge labels is: red (solid) < blue (long-dash) < green (short-dash).

The following list of properties for a Wheeler graph can be deduced from Definition 1.

- ▶ **Property 1.** *All edges inbound to a vertex v have the same edge label.*
- ▶ **Property 2.** *In a proper ordering all vertices with same inbound edge label are ordered consecutively.*
- ▶ **Property 3.** *It is possible for a vertex to have multiple outbound edges with the same label. It is also possible for a vertex to have more than σ inbound or outbound edges.*
- ▶ **Property 4.** *We call two edges (u, v, k) and (u', v', k) with the same label a rainbow if $u < u'$ and $v' < v$. No rainbows can exist in a proper ordering (see Figure 2).*
- ▶ **Property 5.** *For $\sigma = 1$, ignoring self-loops, any proper ordering is also a topological ordering. The vertices with self-loops must be placed last in the ordering otherwise a rainbow is created.*

1.2 Problem Definitions

The first question we wish to answer is given a directed graph with edge labels, does a proper ordering π exist? We define this problem formally as the following.

▶ **Problem 1 (Wheeler Graph Recognition).** *Given a directed edge labeled graph $G = (V, E)$, answer “YES” if G is a Wheeler graph and “NO” otherwise.*

Although we do not demand it here, ideally, a solution to the above problem would also return a proper ordering.

■ **Figure 2** In a proper ordering all of the above configurations cannot occur.

Motivated by the compression of general graphs (which are not necessarily Wheeler graphs), we next define two optimization versions of Problem 1 where we seek to find Wheeler subgraphs.

► **Problem 2** (Wheeler Graph Violation (WGV)). *Given a directed edge labeled graph $G = (V, E)$ identify the smallest $E' \subseteq E$ such that $G' = (V, E \setminus E')$ is a Wheeler graph.*

We also consider the dual of this problem.

► **Problem 3** (Wheeler Subgraph (WS)). *Given a directed edge labeled graph $G = (V, E)$ identify the largest $E'' \subseteq E$ such that $G'' = (V, E'')$ is a Wheeler graph.*

1.3 Our Contribution

- In Section 2 we show that the problem of recognizing whether a given graph is a Wheeler graph is NP-complete even for an edge alphabet of size $\sigma = 2$. The result holds even when the input is a directed acyclic graph (DAG) and when the number of edges leaving a vertex with the same label is at most five. In the full version of this paper [19] we show that for $\sigma = 1$ the recognition problem can be reduced to that of determining if a DAG has queue number one which can be solved in linear time [22].
- In Section 3 we provide an exponential time algorithm which solves the recognition problem on a graph $G = (V, E)$ in time $2^{O(n+e \log \sigma)}$ where $n = |V|$ and $e = |E|$. It uses the idea of enumerating through all possible encodings (of bounded size) of Wheeler graphs, and the fact that we can test whether there exists an isomorphism between two undirected graphs in sub-exponential time. This technique also gives us exact algorithms for the optimization problems presented in this paper which run in time $2^{O(n+e \log \sigma)}$.
- Section 4 examines the optimization versions of this problem called Wheeler Graph Violation (WGV) and Wheeler Subgraph (WS). We show via a reduction of the Minimum Feedback Arc Set problem that the Wheeler Graph Violation problem is APX-hard, and assuming the Unique Games Conjecture, cannot be approximated within a constant factor. This holds even when the graph is a DAG. On the other hand, we show that the Wheeler Subgraph problem is in the complexity class APX for $\sigma = O(1)$. We do so by providing a poly-time algorithm whose solution size is $\Omega(1/\sigma)$ times the optimal value.
- Using PQ-trees and ideas similar to those used in detecting if the queue number of a DAG is one, we demonstrate a class of graphs where Wheeler graph recognition can be done in linear time (see full version [19]).

2 NP-completeness of Wheeler Graph Recognition

► **Theorem 2.** *The Wheeler Graph Recognition Problem is NP-complete for any $\sigma \geq 2$.*

We first show a simple reduction from the Betweenness problem to Wheeler Graph Recognition. Although straightforward, it requires graphs with either $O(n)$ sources or $O(n)$ edges with the same label leaving a single vertex. In Section 2.3, by expanding on the techniques used in the first reduction we show that even if these quantities are limited to at most five the recognition problem remains NP-complete.

2.1 The Betweenness Problem

The Betweenness Problem was established as NP-complete by Opatrný in 1979 [30]. Like our problem, it deals with finding a total ordering on a set of elements subject to some constraints. The input to the Betweenness problem is a list of distinct elements $T = t_1, \dots, t_n$ and a collection of $k < n^3$ ordered triples of $(t_1^1, t_2^1, t_3^1), (t_1^2, t_2^2, t_3^2), \dots, (t_1^k, t_2^k, t_3^k)$ where every element

in a triple is in T . The list T should be placed into a total ordering with the property that for each of the given triples the middle item in the triple appears somewhere between the other two items. The items of each triple are not required to be consecutive in the total ordering. The decision problem is determining if such an ordering is possible.

As an example, consider the input $T = 1, 2, 3, 4, 5, 6$ and the triples: $(5, 2, 3)$, $(1, 5, 2)$, $(4, 5, 6)$, $(4, 6, 2)$. A total ordering which satisfies the given triples is $1, 4, 5, 6, 2, 3$. An ordering which does not satisfy the given triples is $1, 2, 3, 4, 5, 6$ since it violates the triples $(5, 2, 3)$, $(1, 5, 2)$, and $(4, 6, 2)$.

2.2 Reduction from Betweenness to Wheeler Graph Recognition

■ **Figure 3** An example of the reduction with input list $1, 2, 3, 4, 5, 6$ and triples $(5, 2, 3), (1, 5, 2), (4, 5, 6)$.

Suppose we are given as input to the Betweenness Problem the list t_1, t_2, \dots, t_n and triples $(t_1^1, t_2^1, t_3^1), (t_1^2, t_2^2, t_3^2), \dots, (t_1^k, t_2^k, t_3^k)$. We construct a DAG of size $O(nk)$ as follows:

- Create a source vertex v_0 and vertices v_i^j for $1 \leq i \leq n$ and $1 \leq j \leq k$.
- For each triple (t_1^j, t_2^j, t_3^j) create a vertex for each element of the triple, we call them w_1^j, w_2^j , and w_3^j respectively.
- Create the edges $(v_0, v_i^1, 1)$ and edges $(v_i^j, v_i^{j+1}, 1)$ for $1 \leq i \leq n, 1 \leq j \leq k - 1$.
- Create the following edges:
 - $(v_i^j, w_1^j, 2)$ if $t_i = t_1^j$
 - $(v_i^j, w_2^j, 2)$ if $t_i = t_2^j$
 - $(v_i^j, w_3^j, 2)$ if $t_i = t_3^j$
 - $(v_i^j, w_2^j, 2)$ if $t_i = t_1^j$
 - $(v_i^j, w_1^j, 2)$ if $t_i = t_3^j$

► **Lemma 3.** *An instance of the Betweenness problem has an ordering satisfying all of the constraints iff the graph constructed as above is a Wheeler graph.*

Proof Sketch. The intuition is that the vertices with inbound edge label 1 represent the permutation of the elements in T . The edges labeled 1 force the permutation to be duplicated k times, once for each constraint. The vertices with the inbound edge label 2 represent the

elements in each triple. The edges with label 2 enforce that the only valid orderings of the vertices representing elements in T are orderings that satisfy the Betweenness constraints. This is enforced by having no edges labeled 2 which are crossing in the figure. The detailed proof can be found in the full version of this paper [19]. ◀

Theorem 2 follows from Lemma 3. The fact that being a Wheeler graph implies (arched) level planarity with respect to each edge label is the key to the reduction.

The Wheeler graph recognition problem can be solved in linear time for an alphabet of size one. This follows from relating the notion of queue number to Wheeler graphs, and previous results which give a linear time algorithm for finding a one-queue DAG [21, 22, 23]. This also gives an upper bound on the number of edges which can be in a Wheeler graph [11]. The proof can be found in the full version of this paper [19].

► **Theorem 4.** *The Wheeler graph recognition problem can be solved in linear time for an edge alphabet of size $\sigma = 1$.*

► **Theorem 5.** *For $\sigma = 1$, the number of edges in a Wheeler graph is $O(n)$.*

2.3 NP-completeness of Wheeler Graph Recognition on d -NFA's

Now we restrict the number of edges with the same label that can leave a single vertex. We adopt the terminology used by Alanko, Policriti and Prezza and consider the problem of recognizing whether a d -NFA is also a Wheeler graph [3]. A d -NFA is defined as follows:

► **Definition 6.** *A d -NFA G is an NFA where the number of edges with the same character leaving a vertex is at most d . We refer to the value d as the non-determinism of G .*

We emphasize that here an NFA contains a single start state, from which we assume each vertex is reachable. The results in this section are in contrast to the recent work of Alanko, Policriti and Prezza who showed that it can be recognized in polynomial time whether a 2-NFA is a Wheeler graph [3]. Their result coupled with the observation that the reduction in Section 2 requires a $n^{\Theta(1)}$ -NFA suggests an interesting question about what role non-determinism plays in the tractability of Wheeler graph recognition. To this end, we prove Theorem 7.

► **Theorem 7.** *The Wheeler Graph Recognition Problem is NP-complete for d -NFA's, $d \geq 5$.*

The strategy of the proof is to reduce the NP-complete problem 4-NAESAT to Wheeler Graph Recognition. In 4-NAESAT each clause is of length 4, and an expression is satisfiable iff there exists a truth assignment such that each clause contains both a true literal and a false literal. We start with 4-NAESAT, rather than 3-NAESAT, to obtain a 3-NAESAT instance with the special property highlighted by Lemma 8.

► **Lemma 8.** *An instance ϕ of 4-NAESAT can be reduced in poly-time to an instance ϕ' of 3-NAESAT where a variable occurring in the middle of a clause appears at most twice in ϕ' .*

Proof. Convert the 4-NAESAT instance ϕ to a 3-NAESAT instance ϕ' by converting each clause (a_k, b_k, c_k, d_k) into the clauses (a_k, w_k, b_k) and $(c_k, \overline{w_k}, d_k)$. Both clauses have a satisfying not-all-equal assignment iff it is not the case that $a_k = b_k = c_k = d_k$. We note that the variable used in the middle of the clauses, w_k , is used only twice in ϕ' . ◀

For convenience, we define a case of 3-NAESAT where each variable occurring in the middle occurs at most twice, we call this 3-NAESAT*. We next describe the construction of a one source DAG from an instance of 3-NAESAT*.

■ **Figure 4** Vertex Z_1 and Z_2 could be for clauses (x_1, x_2, x_3) , (x_2, \bar{x}_3, x_4) . Each “betweenness” constraint adds a layer. (x_4, X, \bar{x}_4) constraint shown.

Suppose we are given an instance ϕ of 3-NAESAT* with variables x_1, x_2, \dots, x_n and the clauses (a_k, b_k, c_k) where we assume a_k, b_k, c_k can represent either a Boolean variable or its negation. We create a single source DAG G based on ϕ . The first step creates a *menorah like* structure which allows for the vertices representing x_i and \bar{x}_i to swap places in G , but otherwise fixes the positions of the vertices. We begin by adding the vertices which represent our variables, $x_1, \dots, x_n, X, \bar{x}_1, \dots, \bar{x}_n$; (the role of X will become clear). Next, we add the structure to constrain their possible positions.

Add to G the vertices:

- s_1^0, \dots, s_n^0 ;
- For $1 \leq i \leq n-1, 1 \leq j \leq n-i$: s_i^j and \bar{s}_i^j ;

Add to G the red edges:

- $(s_1^0, s_2^0, 1), \dots, (s_n^0, X, 1)$;
- For $1 \leq i \leq n-1, 2 \leq j \leq n-i$: $(s_i^{j-1}, s_i^j, 1)$ and $(\bar{s}_i^{j-1}, \bar{s}_i^j, 1)$;
- For $1 \leq i \leq n-1$: $(s_i^0, s_i^1, 1)$ and $(\bar{s}_i^0, \bar{s}_i^1, 1)$;
- For $1 \leq i \leq n$: $(s_i^{n-i}, x_i, 1)$ and $(\bar{s}_i^{n-i}, \bar{x}_i, 1)$;

For clause k , denoted (a_k, b_k, c_k) , we add a vertex Z_k . Suppose the middle variable of the clause, b_k , is x_h (positive or negated), then we add the vertices z_k^j for $1 \leq j \leq n-h$, and red edges $(s_h^0, z_k^1, 1), (z_k^1, z_k^2, 1) \dots (z_k^{n-h}, Z_k, 1)$.

Now we wish add a set of *betweenness* type constraints on any proper ordering given of the vertices $\mathcal{L}^0 = \{x_1, \dots, X, \bar{x}_1, \dots, \bar{x}_n, Z_1, Z_2, \dots\}$. Given a constraint (y_1, y_2, y_3) we insist y_2 be between y_1 and y_3 in the ordering. This can be enforced by adding a layer of new vertices $\mathcal{L}^1 = \{x_1^1, \dots, X^1, \bar{x}_1^1, \dots, \bar{x}_n^1, Z_1^1, Z_2^1, \dots\}$ with red edges labeled 1 from vertices in layer \mathcal{L}^0 to their corresponding vertices in \mathcal{L}^1 . We use the same gadget that was used in Section 2. Consider adding a betweenness on the vertices y_1, y_2, y_3 in \mathcal{L}^0 . Add the vertices w_1^1, w_2^1 , and w_3^1 and the blue edges $(y_1^1, w_1^1, 2), (y_2^1, w_2^1, 2), (y_3^1, w_3^1, 2), (y_1^1, w_2^1, 2)$ and $(y_3^1, w_2^1, 2)$. Additional betweenness constraints can be similarly enforced by adding a new layer on top of \mathcal{L}^1 with a new gadget. Add the betweenness constraints (x_i, X, \bar{x}_i) for $1 \leq i \leq n$ fixing X , and betweenness constraints (a_k, Z_k, b_k) and (c_k, X, Z_k) for every clause (a_k, b_k, c_k) .

■ **Table 1** Possible relative orderings of a_k, b_k, c_k, Z_k, X subject to (a_k, Z_k, b_k) and (c_k, X, Z_k) .

Possible Orderings (a_k has variable x_j and c_k has variable x_h)		
$a_k b_k c_k$	$j < h$	$h < j$
FFT	$c_k \dots X \dots b_k, Z_k \dots a_k$	$c_k \dots X \dots b_k, Z_k \dots a_k$
FTF	$b_k, Z_k \dots X \dots c_k \dots a_k$	$b_k, Z_k \dots X \dots a_k \dots c_k$
TFF	$a_k \dots \bar{b}_k, Z_k \dots X \dots b_k \dots c_k$	$a_k \dots \bar{b}_k, Z_k \dots X \dots b_k \dots c_k$
FTT	$c_k \dots b_k \dots X \dots \bar{b}_k, Z_k \dots a_k$	$c_k \dots b_k \dots X \dots \bar{b}_k, Z_k \dots a_k$
TFT	$a_k \dots c_k \dots X \dots Z_k, b_k$	$c_k \dots a_k \dots X \dots Z_k, b_k$
TTF	$a_k \dots Z_k, b_k \dots X \dots c_k$	$a_k \dots Z_k, b_k \dots X \dots c_k$

■ **Table 2** Orderings implied by all-equal assignment are not possible while satisfying constraints.

(Not) Possible Orderings (a_k has variable x_j and c_k has variable x_h)		
$a_k b_k c_k$	$j < h$	$h < j$
TTT	$a_k \dots b_k \dots c_k \dots X$	$c_k \dots b_k \dots a_k \dots X$
FFF	$X \dots c_k \dots b_k \dots a_k$	$X \dots a_k \dots b_k \dots c_k$

Before proving the correctness of the reduction, we make the observation that because any variable occurring in the middle of a clause occurs as most **twice** in the whole expression, the maximum number of edges leaving a vertex s_i^0 is bounded by $3 + 2 = 5$. All of the other vertices have at most three edges with the same label leaving them.

► **Lemma 9.** *The leveled graph G constructed as above from an instance ϕ' of 3-NAESAT* is a Wheeler graph iff ϕ' is satisfiable.*

Proof. Given a truth assignment that satisfies the 3-NAESAT* instance ϕ' , put the vertices in \mathcal{L}^0 whose variables are assigned the value T on the left side of X in Figure 4, and the vertices whose variables are assigned F on the right side of X . For example, if $x_1 = T, x_2 = F$, the two left-most vertex on level \mathcal{L}^0 would be x_1 followed by \bar{x}_2 . Now, for clause (a_k, b_k, c_k) we have the possible not-all-equal truth assignments and relative orderings of \mathcal{L}^0 which satisfy the Wheeler graph axioms in Table 1. This shows that a Wheeler graph ordering of the vertices is possible by placing Z_k 's correctly given the truth assignment.

In the other direction, if G is a Wheeler graph then the ordering of the menorah structure is fixed with the exception of z_i^j vertices and the ordering duplicated across layers $\mathcal{L}^0, \mathcal{L}^1, \dots$. We will show the ordering given to \mathcal{L}^0 must have every clause getting a not-all-equal assignment. Suppose to the contrary that \mathcal{L}^0 was given an ordering where either a_k, b_k, c_k are all on the left(true) or the right side(false) of X . Then we have the options in Table 2.

In all cases listed in Table 2, placing Z_k between a_k and b_k violates the constraint (c_k, X, Z_k) , implying we violate a Wheeler graph constraint as well, a contradiction. Hence, if G is a Wheeler graph, a valid ordering for \mathcal{L}^0 implies a valid truth assignment for ϕ' . ◀

This leaves open the complexity of the recognition problem for 3-NFA's and 4-NFA's.

3 An Exponential Time Algorithm

We can apply the encoding introduced by Gagie et al. [17] to develop exponential time algorithms to solve all of the problems presented in this paper. The idea is to enumerate over all possible encodings of Wheeler graphs with the proper number of vertices, edges, and labels, checking whether the encoding is isomorphic with the given graph. This idea exploits

the fact that having such a space efficient encoding also implies have a limited search space of Wheeler graphs. The graph isomorphism can be checked efficiently enough to maintain the desired time complexity. The results are summarized in the following two theorems.

► **Theorem 10.** *Recognizing whether $G = (V, E)$ is a Wheeler graph can be done in time $2^{e \log \sigma + O(n+e)}$, where $n = |V|$, $e = |E|$, and σ is the size of the edge label alphabet.*

Before describing the algorithm that proves Theorem 10 we need to describe the encoding of a Wheeler graph given in [17]. A Wheeler graph can be completely specified by three bit vectors. Two bit vectors I and O both of length $e + n$ and a bit vector L of length $e \log \sigma$. We assume that the vertices of the Wheeler graph G are listed in a proper ordering $x_1 <_{\pi} x_2 <_{\pi} \dots <_{\pi} x_n$. The array I is of the form $0^{\ell_1} 1 0^{\ell_2} 1 \dots 0^{\ell_n} 1$ and O is of the form $0^{k_1} 1 0^{k_2} 1 \dots 0^{k_n} 1$. Here ℓ_i is the out-degree of x_i whereas k_i is the in-degree of x_i . The array L indicates which of the e character symbols are assigned to each edge. Specifically, the i^{th} character in L gives us the label of the edge corresponding to the i^{th} zero in O . In [17] an additional C array is added, and these arrays are equipped with additional rank and select structures to allow for efficient traversal as is done in the FM-index [15]. For our purposes, however, the arrays O , I , and L are adequate.

The outline of the algorithm is given below as Algorithm 1. It essentially enumerates all bit vectors of a given length, checks whether or not the bit vector encodes a valid Wheeler graph, and if so then checks whether the encoding matches our given graph G . Let S represent the set of all possible encodings we wish to check. Note that $|S| \leq 2^{2(e+n)+e \log \sigma}$.

■ **Algorithm 1** IdentifyWheelerGraph(G).

```

for all  $(O, I, L) \in S$  do
  if  $(O, I, L)$  defines a valid wheeler graph  $G'$  then
    convert  $G$  to undirected graph  $\alpha(G)$ 
    convert  $G'$  to undirected graph  $\alpha(G')$ 
    if  $\alpha(G)$  and  $\alpha(G')$  are isomorphic then
      return "Wheeler Graph"
    end if
  end if
end for
return "Not a Wheeler Graph"

```

The Wheeler graph corresponding to the encoding can be extracted by working from right to left reading the array I . For each zero in I , we know which symbol should be on the inbound edge going into the corresponding vertex. We only need to decide where the edge's tail was. Let k be the edge label and j be the index of the label k in L which is furthest to the right in L and yet to be used. If no such j exists we reject the encoding. When assigning the tail for an edge, take as the tail the vertex x_i where $i = \text{rank}_1(O, \text{select}_0(O, j))$. We call the graph constructed in this way G' .

We now wish to check whether G' and G are the same graphs only with a reordering of the vertices, that is, G' is the result of applying an isomorphism to G . Unlike the typical isomorphism for labeled graphs, where a bijection between the symbols on the edge alphabet is all that is required, here we wish for the adjacency and the label on the edge to be preserved in the mapping between G and G' . Specifically, we wish to know if there exists a bijective

function $f : V(G) \rightarrow V(G')$, such that if $u, v \in V(G)$ are adjacent via an edge (u, v, k) with label k in G , then $f(u)$ and $f(v)$ are also adjacent via an edge $(f(u), f(v), k)$ with label k in G' . Using ideas similar to those presented by Miller in [28], this problem can be reduced in polynomial time to checking whether two undirected graphs are isomorphic.

► **Lemma 11.** *Checking whether the direct edge labeled graph G' is edge label preserving isomorphic to G can be reduced in polynomial time to checking if two undirected graphs are isomorphic.*

Proof. See full version [19]. ◀

The final step in this algorithm is to check whether $\alpha(G)$ and $\alpha(G')$ are isomorphic. Using well established techniques this can be done in time $2^{\sqrt{n'}+O(1)}$ where n' is the number of vertices in $\alpha(G)$ [4]. The total time complexity of Algorithm 1 is the number of bit strings tested, multiplied by the time it takes to (1) validate whether the bit string encodes a Wheeler graph G' and decode it, (2) convert G and G' to undirected graphs $\alpha(G)$ and $\alpha(G')$, and (3) test whether $\alpha(G)$ and $\alpha(G')$ are isomorphic. This yields an overall time complexity of $|S|n^{O(1)}2^{\sqrt{n+2e(\sigma+1)+O(1)}}$, i.e., $2^{e \log \sigma + O(n+e)}$ for Algorithm 1.

4 Optimization Variants to Wheeler Graph Recognition

4.1 The Wheeler Graph Violation Problem is APX-hard

In this section, we show that obtaining an approximate solution to the WGV problem that comes within a constant factor of the optimal solution is NP-hard. We do this through a reduction that shows that WGV is at least as hard as solving the Minimum Feedback Arc Set problem (FAS). FAS in its original formulation is phrased in terms of a directed graph where the objective is to find the minimum number of edges which need to be removed in order to make the directed graph a DAG. A slightly different formulation proves more useful for us. Letting $F_\pi = \{(v_i, v_j) \in E \mid \pi(v_i) > \pi(v_j)\}$ we have the following:

► **Lemma 12** (Younger [32]). *Determining a minimum feedback arc set for $G = (V, E)$ is equivalent to finding an ordering π on V for which $|F_\pi|$ is minimized.*

From this, we can present the equivalent formulation of FAS.

► **Definition 13** (Minimum Feedback Arc Set (FAS)). *The input is a list $T = t_1 t_2 \dots t_n$ of n numbers and a set of k inequalities of the form $t_i < t_j$. This task is to compute an ordering π on T so that the number of inequalities violated is minimized.*

Interestingly, we could not have used FAS for proving that the Wheeler graph recognition problem is NP-complete, as FAS is fixed-parameter tractable in terms of the size of the feedback arc set [8]. Indeed, setting the size of the feedback arc-set to zero is equivalent to checking if the given graph is a DAG and the problem becomes solvable in polynomial time.

On the other hand, it has been shown that FAS is APX-hard, meaning that every problem in APX is reducible to it [25]. It also implies, assuming $\text{NP} \neq \text{P}$, that there is a constant $C \geq 1$ such that there is no polynomial time algorithm which provides a C -approximation. The reduction provided in this section implies:

► **Theorem 14.** *The WGV problem is APX-hard.*

■ **Figure 5** A bold edge in Figure 6 is actually $k + 1$ subdivided edges.

In addition, Guruswami et al. demonstrated that assuming the Unique Games Conjecture holds, and $\text{NP} \neq \text{P}$, there is no constant $C \geq 1$ such that a polynomial-time algorithm's approximate solution to FAS is always a factor C from the optimal solution. We state this as a lemma.

► **Lemma 15** (Guruswami et al. [20]). *Conditioned on the Unique Games Conjecture, for every $C \geq 1$, it is NP-hard to find a C -approximation to FAS.*

An approximation preserving reduction from FAS to WGV combined with Lemma 15 proves the other main result of this section:

► **Theorem 16.** *Conditioned on the Unique Games conjecture, for every constant $C \geq 1$, it is NP-hard to find a C -approximation to WGV.*

4.2 The Reduction of FAS to WGV

Let $T = t_1, t_2, \dots, t_n$ and inequalities $t_1^1 < t_2^1, t_1^2 < t_2^2, \dots, t_1^k < t_2^k$ be the input to FAS.

We define a heavy edge between the vertices u and v with label ℓ as $k + 1$ subdivided edges between u and v each with label ℓ . That is, a heavy edge between u and v with label ℓ consists of the edges (u, w_i, ℓ) and (w_i, v, ℓ) for $1 \leq i \leq k + 1$. See Figure 5 for an illustration. Use the following steps to create a graph (which is a DAG):

- Create a vertex v_0 and vertices v_i^j for $1 \leq i \leq n + 1$ and $1 \leq j \leq k$.
- For each inequality $t_1^j < t_2^j$ create a vertex for both t_1^j and t_2^j , labeled w_1^j and w_2^j , respectively.
- Create heavy edges $(v_0, v_i^1, 1)$ for $1 \leq i \leq n + 1$ and heavy edges $(v_i^j, v_i^{j+1}, 1)$ for $1 \leq i \leq n + 1, 1 \leq j \leq k - 1$.
- Create heavy edges $(v_0, w_1^1, 2)$, and heavy edges $(v_{n+1}^j, w_2^j, 2)$ and $(v_{n+1}^j, w_1^{j+1}, 2)$ for $1 \leq j \leq k - 1$, and heavy edge $(v_{n+1}^k, w_2^k, 2)$.
- Add the regular (not heavy) edges $(v_i^j, w_1^j, 2)$ if $t_i = t_1^j$, and $(v_i^j, w_2^j, 2)$ if $t_i = t_2^j$ for $1 \leq i \leq n, 1 \leq j \leq k$.

An example of the reduction is given in Figure 6. The intuition is that the vertices with an inbound heavy edge labeled 1 represent the permutation of the elements in T . The heavy edges labeled 1 force the permutation to be duplicated k times, once for each constraint. The vertices with the inbound edge label 2 represent the elements in each inequality. We will show that this is an approximation preserving reduction.

Let E' be a solution to WGV and $G' = (V, E \setminus E')$ and let π represent a proper ordering on the vertices of G' . Lemma 17 indicates that, other than permuting the ordering found on the vertices v_i^j for $1 \leq i \leq n$ (with the ordering duplicated for $1 \leq j \leq k$), the ordering for the vertices in Figure 6 is fixed.

■ **Figure 6** An example of the reduction from FAS to WGV where $T = 1, 2, 3, 4, 5, 6$ and the set of inequalities is $5 < 3$, $1 < 5$, and $6 < 4$.

► **Lemma 17.** *Let ϕ represent a permutation of the set $[n + 1]$. Any ordering π which provides a solution to the WGV instance is of the form*

$$v_0, v_{\phi(1)}^1, v_{\phi(2)}^1, \dots, v_{\phi(n+1)}^1, \dots, v_{\phi(1)}^k, v_{\phi(2)}^k, \dots, v_{\phi(n+1)}^k, w_1^1, w_2^1, w_1^2, w_2^2, \dots, w_1^k, w_2^k.$$

Proof. See full version [19]. ◀

Let $f(x)$ refer to the reduction described above applied to an instance x of FAS creating an instance $f(x)$ of WGV. We also refer to the solution to either of these problems as $\text{OPT}(\cdot)$, and $\text{val}(\cdot)$ as the cost function. For instance x of FAS $\text{val}(x)$ is the number of violated inequalities and for an instance $f(x)$ of WGV $\text{val}(f(x))$ it is the number of violating edges.

► **Lemma 18.** *Given an instance x of FAS, a solution (or sub-optimal solution) to the instance $f(x)$ of WGV that has $\ell \leq k$ axiom violating edges yields a solution (or sub-optimal solution) to x with ℓ violated inequalities. The converse holds as well.*

Proof. See full version [19]. ◀

► **Lemma 19.** *Given an instance x of FAS, a C -approximation to the solution $\text{OPT}(f(x))$ yields a C -approximation to the solution $\text{OPT}(x)$.*

Proof. By Lemma 18 any (sub-optimal) solution with objective value $C \cdot \text{val}(\text{OPT}(f(x)))$ to $f(x)$, gives us a (sub-optimal) solution to x with the same objective value, $C \cdot \text{val}(\text{OPT}(x))$. ◀

Theorem 14 follows from Lemma 19 and Theorem 16 follows from Lemma 19 and Lemma 15.

■ **Figure 7** Arborescences have their roots aligned in level L_0 . The relative ordering for each type of vertex can be read from top to bottom, left to right.

4.3 The Wheeler Subgraph Problem is in APX

The dual problem to WGV is the problem of finding the largest subgraph of G which is a Wheeler graph. This problem (defined in Section 1.2) is called Wheeler Subgraph problem, abbreviated WS. Unlike WGV, this problem yields a $\Theta(1)$ -approximate solution for constant σ .

We first prove the result for $\sigma = 1$. We then apply this result to get an approximation for $\sigma > 1$. The proof for $\sigma = 1$ uses a branching of a directed graph. A branching is a set of arborescence where an arborescence is a directed, rooted tree where all edges point away from the root. A branching is spanning in that every vertex in V is included exactly one arborescence in the branching.

► **Lemma 20.** *There exists a linear time $\Theta(1)$ -approximation algorithm for WS when the alphabet set size σ is one.*

Proof. Let V_0 be the set of sources in G (vertices with in-degree zero). There are two cases:

Case $|V_0| \leq n/2$: Take a branching \mathcal{F} of the input graph G such that each vertex with in-degree greater than zero is included in some non-singleton arborescence whose root is a source vertex in V_0 . Let $|\mathcal{F}|$ denote the total number of arborescences in \mathcal{F} . Since $|V_0| \leq n/2$, it follows that $|\mathcal{F}| \leq n/2$ as well.

We create a planar leveling (L_0, L_1, \dots) of \mathcal{F} by aligning all roots of the branching on level L_0 in an arbitrary order. Then set L_i to be all of the vertices which are distance i from some root in L_0 . Because these are trees, we can order the vertices in levels in such a way that the leveling is planar (and for the purpose of visualization say left to right as in Figure 7).

We claim that \mathcal{F} is a Wheeler graph and that we can obtain a proper ordering π for the vertices of \mathcal{F} from this leveling. Starting with V_0 , we order the vertices on each level from the bottom to top before proceeding right to the next level. One can check that the Wheeler graph axioms are satisfied.

The number of edges in \mathcal{F} , denoted $e(\mathcal{F})$, is equal to $n - |\mathcal{F}|$. And, since $|\mathcal{F}| \leq n/2$, we have that $e(\mathcal{F}) \geq n/2$. At the same time, by Theorem 5 the optimal number of edges, denoted $|E^*|$, is $\Theta(n)$. The ratio of the optimal solution value over the branching solution value is bounded. In particular, $|E^*|/e(\mathcal{F}) \leq \Theta(n)/(n/2) = \Theta(1)$. The construction of the branching, the planar leveling, and the extracting π can all be done in linear time.

51:14 On the Hardness and Inapproximability of Recognizing Wheeler Graphs

Case $|V_0| > n/2$: Take one outbound edge from each vertex in V_0 . We obtain a Wheeler graph with $|V_0| > n/2$ edges. This gives us a solution with an approximation ratio of $|E^*|/|V_0| < \Theta(n)/(n/2) = \Theta(1)$.

In either case, we have an approximate solution with \tilde{e} edges where $\tilde{e} \in \Theta(|E^*|)$. ◀

Next, we consider when $\sigma > 1$. Suppose $G^* = (V, E^*)$ is the optimal solution for G . Then $E^* = E_1^* \cup E_2^* \dots E_\sigma^*$ where $E_k^* = \{(u, v, k) \in E^*\}$. Let $G_k = (V, E_k)$ where $E_k = \{(u, v, k) \in E\}$ and let $G'_k = (V, E'_k)$ be the optimal solution for G_k . Then, since $|E_k^*| \leq |E'_k|$ we have

$$|E^*| = \sum_{k=1}^{\sigma} |E_k^*| \leq \sigma \cdot \max_k |E_k^*| \leq \sigma \cdot \max_k |E'_k|.$$

Applying the result for $\sigma = 1$ (Lemma 20), we can approximate $\max_k |E'_k|$ with a solution having $\tilde{e} = \alpha \cdot \max_k |E'_k|$ edges for some constant $\alpha \leq 1$. Therefore,

$$\frac{\alpha}{\sigma} |E^*| \leq \alpha \max_k |E'_k| = \tilde{e} \leq \max_k |E'_k| \leq |E^*|.$$

So the solution provides $\Omega(1/\sigma)$ -approximation for G as well.

► **Theorem 21.** *There exists a linear time $\Omega(1/\sigma)$ -approximation algorithm for WS.*

As a final result, we note that the algorithm presented in Section 3 also provides us with an exponential time solution to the two optimization problems defined in Section 4. The solution is to iterate over all possible subsets of edges in E , take the corresponding induced subgraph, and apply Algorithm 1 to identify if the induced subgraph is isomorphic to a Wheeler graph. For both the WGV and WS problems the optimal solution is the encoding with the fewest edges removed. The resulting time complexity is the same as in Theorem 10 with the addition of one e term in the exponent. We have shown the following:

► **Theorem 22.** *The WGV problem and WS problem for an input $G = (V, E)$ with $n = |V|$, $e = |E|$ and σ is the size of the edge label alphabet can be solved in time $2^{e \log \sigma + O(n+e)}$.*

Abstract

In this paper, we propose HyperFlowCutter, an algorithm for balanced hypergraph bipartitioning that is based on minimum S - T hyperedge cuts and maximum flows. It computes a sequence of bipartitions that optimize cut size and balance in the Pareto sense, being able to trade one for the other. HyperFlowCutter builds on the FlowCutter algorithm for partitioning graphs. We propose additional features, such as handling disconnected hypergraphs, novel methods for obtaining starting S, T pairs as well as an approach to refine a given partition with HyperFlowCutter. Our main contribution is ReBaHFC, a new algorithm which obtains an initial partition with the fast multilevel hypergraph partitioner PaToH and then improves it using HyperFlowCutter as a refinement algorithm. ReBaHFC is able to significantly improve the solution quality of PaToH at little additional running time. The solution quality is only marginally worse than that of the best-performing hypergraph partitioners KaHyPar and hMETIS, while being one order of magnitude faster. Thus ReBaHFC offers a new time-quality trade-off in the current spectrum of hypergraph partitioners. For the special case of perfectly balanced bipartitioning, only the much slower plain HyperFlowCutter yields slightly better solutions than ReBaHFC, while only PaToH is faster than ReBaHFC.

1 Introduction

Given a hypergraph $H = (V, E)$, a hyperedge cut $C \subset E$ is a set of hyperedges whose removal disconnects H . The *balanced hypergraph bipartitioning problem* is to find a hyperedge cut of minimum cardinality whose removal separates H into two blocks of roughly equal size – up to $(1 + \varepsilon)\frac{|V|}{2}$. Hypergraph partitioning has applications in VLSI design, database sharding, and high performance computing, in particular load balancing and reducing communication for highly parallel computations as well as accelerating sparse matrix vector multiplications. This problem is NP-hard [35] and it is hard to approximate, even for graphs [12]. Therefore, practical algorithms use heuristics. Most of them are based on the *multilevel* framework [28].

In this paper we consider a different approach based on the max-flow min-cut duality. The basic idea has already been used in the Flow-Balanced-Bipartition algorithm (FBB) of Yang and Wong [51]. So far it has not been of further consideration due to being too slow compared to multilevel algorithms and too slow to solve current instances in feasible time. More recently, FlowCutter [27] for graph bipartitioning has been introduced independently of FBB. It is designed for computing very small node separators in road networks with a rather loose balance constraint; $\varepsilon = 0.33$ is recommended for the application of accelerating shortest path computations [20]. Based on similar ideas as FBB but equipped with more engineering, it computes both unbalanced and highly balanced bipartitions of high quality on the Walshaw graph partitioning benchmark [47].

Contribution. We present HyperFlowCutter, an algorithm which computes a series of hypergraph bipartitions with increasing balance, up to perfectly balanced solutions. With HyperFlowCutter, we extend FlowCutter to hypergraphs and contribute additional features. We provide a method to handle disconnected hypergraphs, which FlowCutter and FBB cannot handle. Our main contribution is ReBaHFC, an algorithm to refine a given partition using HyperFlowCutter. It is a natural extension of the max-flow based refinement of the k -way hypergraph partitioner KaHyPar [29]. We provide a thoroughly engineered implementation as well as an extensive experimental evaluation on the benchmark set of Heuer and Schlag [30], comparing HyperFlowCutter and ReBaHFC against the state-of-the-art hypergraph partitioning tools KaHyPar [30, 29], PaToH [13] and hMETIS [31, 32].

In our experiments we use the fast algorithm PaToH to obtain initial partitions for ReBaHFC. When using the quality preset of PaToH, ReBaHFC computes solutions for $\varepsilon = 0.03$, which are only slightly worse than those of the best-performing partitioners KaHyPar and hMETIS and significantly better than those of PaToH. ReBaHFC is only marginally slower than PaToH and thus, like PaToH, it is one order of magnitude faster than KaHyPar and hMETIS, when using the quality preset, and two orders of magnitude faster, when using the default preset. Furthermore, ReBaHFC with the PaToH default preset computes better solutions than PaToH with its quality preset. Thus ReBaHFC offers new time-quality trade-offs. For the special case of perfectly balanced bipartitioning, only the much slower plain HyperFlowCutter yields marginally better solutions than ReBaHFC, while only PaToH is faster than ReBaHFC.

Outline. After discussing related work in Section 2 and presenting notation and preliminaries in Section 3, we introduce the core algorithm of HyperFlowCutter for S - T hyperedge cuts in Section 4.1. Then we show how to handle disconnected hypergraphs in Section 4.2, propose our refinement algorithm ReBaHFC in Section 4.3 and finally discuss the experimental evaluation in Section 5.

2 Related Work

For an overview of the field of hypergraph partitioning we refer to survey articles [7, 40, 5]. The most common approach among hypergraph partitioning tools is the multilevel framework. Multilevel algorithms repeatedly *contract* vertices to obtain a hierarchy of *coarser* hypergraphs while trying to preserve the cut structure. On the coarsest hypergraph an *initial partition* is computed in some way. Then the contractions are reversed step-by-step and after every uncontraction a *refinement* algorithm tries to improve the solution. Most multilevel algorithms use a variant of the Fiduccia-Mattheyses (FM) [23] or Kernighan-Lin (KL) [33] local vertex

moving heuristics. These algorithms move vertices between blocks, prioritized by cut improvement. The multilevel framework has been immensely successful because it provides a global view on the problem through local operations on the coarse levels. Furthermore, it allows a great deal of engineering and tuning, which have a drastic impact on solution quality. Even though this framework has been used since the 1990s, the implementations are still improving today. A selection of well-known multilevel hypergraph partitioners are PaToH [13] (scientific computing), hMETIS [31, 32] (VLSI design) KaHyPar [30, 29] (general purpose, n-level), Zoltan [19] (scientific computing, parallel), Zoltan-AlgD [46] (algebraic distances based coarsening, sequential), Mondriaan [49] (sparse matrices), MLPart [4] (circuit partitioning) and Parkway [48] (parallel).

Compared to graph partitioning, the performance of local vertex moving suffers from the presence of large hyperedges with vertices scattered over multiple blocks, since many moves have zero cut improvement. On coarse levels of the multilevel hierarchy, this problem is alleviated since hyperedges contain fewer vertices. A second remedy are flow-based refinement algorithms. For graphs, Sanders and Schulz [43] extract a size-constrained corridor around the cut and compute a minimum cut within this corridor. If the cut is balanced, an improved solution was found, otherwise the step is repeated with a smaller corridor. Heuer et al. [29] extend their approach to hypergraphs by using *Lawler networks* [34]. The Lawler network of a hypergraph is a flow network such that minimum S - T hyperedge cuts can be computed via max-flow.

In their Flow-Balanced-Bipartition algorithm (FBB), Yang and Wong [51] use incremental maximum flows on the Lawler network to compute ε -balanced hypergraph bipartitions. Liu and Wong [37] enhance FBB with a *most-desirable-minimum-cut* heuristic, which is inspired by the correspondence between S - T minimum cuts and closed node sets due to Picard and Queyranne [41]. It is similar to the *most-balanced-minimum-cut* heuristics used in the multilevel graph partitioning tool KaHiP [43] and KaHyPar-MF [29] as well as the *avoid-augmenting-paths* piercing heuristics of FlowCutter [27] and HyperFlowCutter. Li et al. [36] propose a push-relabel algorithm, which operates directly on the hypergraph. Furthermore they present heuristics rooted in VLSI design for choosing sets of initial seed vertices S and T as well as piercing vertices. The performance of their approach in other contexts than VLSI design remains unclear.

For perfectly balanced graph partitioning, diffusion-based methods have been successful [38]. Furthermore Sanders and Schulz [44] propose an algorithm based on detecting negative cycles, which is used on top of their evolutionary partitioner. Delling and Werneck [18] provide an efficient implementation of an optimal branch-and-bound algorithm. Additionally there are metaheuristic approaches such as PROBE [14], as well as multilevel memetic algorithms due to Benlic and Hao [9, 10, 11].

3 Preliminaries

A *hypergraph* $H = (V, E)$ consists of a set of n vertices V and a set of m hyperedges E , where a hyperedge e is a subset of the vertices V . A vertex $v \in V$ is *incident* to hyperedge $e \in E$ if $v \in e$. The vertices incident to e are called the *pins* of e . We denote the incident hyperedges of v by $I(v)$ and its degree by $\deg(v) := |I(v)|$. Furthermore let $p := \sum_{e \in E} |e|$ denote the total number of pins in H . All hypergraphs in this paper are unweighted. H can be represented as a bipartite graph $G = (V \cup E, \{(v, e) \in V \times E \mid v \in e\})$ with bipartite node set $V \cup E$ and an edge for every pin. This is also referred to as the *star expansion* of H . H is *connected* if its star expansion is connected. Let $V[E'] := \bigcup_{e' \in E'} e'$ denote the vertex set induced by the hyperedge set E' . To avoid confusion, we use the terms vertices, hyperedges and pins for hypergraphs, and we use the terms nodes and edges for graphs.

3.1 Hypergraph Partitioning

A *bipartition* of a hypergraph H is a partition (A, B) of the vertices V into two non-empty, disjoint sets (called blocks). The *cut* $\text{cut}(A, B) := \{e \in E \mid e \cap A \neq \emptyset \wedge e \cap B \neq \emptyset\}$ consists of all hyperedges with pins in both blocks. The *size* of a cut is the number of cut hyperedges $|\text{cut}(A, B)|$. Let $\varepsilon \in [0, 1)$. A bipartition (A, B) is ε -balanced if $\max(|A|, |B|) \leq \lceil (1 + \varepsilon) \frac{n}{2} \rceil$. The *balanced hypergraph bipartitioning problem* is to find an ε -balanced bipartition (A, B) which minimizes the cut. The special case $\varepsilon = 0$ is called *perfectly balanced bipartitioning*.

3.2 Maximum Flows

A flow network $\mathcal{N} = (\mathcal{V}, \mathcal{E}, S, T, c)$ is a simple symmetric directed graph $(\mathcal{V}, \mathcal{E})$ with two non-empty *terminal* node sets $S, T \subsetneq \mathcal{V}$, $S \cap T = \emptyset$, the source and target node set, as well as a capacity function $c : \mathcal{E} \mapsto \mathbb{R}_{\geq 0}$. Any node that is not a source node and not a target node is a *non-terminal* node. A flow in \mathcal{N} is a function $f : \mathcal{E} \mapsto \mathbb{R}$ subject to the *capacity constraint* $f(e) \leq c(e)$ for all edges e , *flow conservation* $\sum_{(u,v) \in \mathcal{E}} f((u,v)) = 0$ for all non-terminal nodes v and *skew symmetry* $f((u,v)) = -f((v,u))$ for all edges (u,v) . The *value* of a flow $|f| := \sum_{s \in S, (s,u) \in \mathcal{E}} f((s,u))$ is the amount of flow leaving S . The *residual capacity* $r_f(e) := c(e) - f(e)$ is the additional amount of flow that can pass through e without violating the capacity constraint. The residual network with respect to f is the directed graph $\mathcal{N}_f = (\mathcal{V}, \mathcal{E}_f)$ where $\mathcal{E}_f := \{e \in \mathcal{E} \mid r_f(e) > 0\}$. A node v is *source-reachable* if there is a path from S to v in \mathcal{N}_f , it is *target-reachable* if there is a path from v to T in \mathcal{N}_f . We denote the source-reachable and target-reachable nodes by S_r and T_r , respectively. An *augmenting path* is an S - T path in \mathcal{N}_f . The flow f is a *maximum flow* if $|f|$ is maximal of all possible flows in \mathcal{N} . This is the case iff there is no augmenting path in \mathcal{N}_f . An S - T edge cut is a set of edges whose removal disconnects S and T . The value of a maximum flow equals the weight of a minimum-weight S - T edge cut [24]. The *source-side cut* consists of the edges from S_r to $\mathcal{V} \setminus S_r$ and the *target-side cut* consists of the edges from T_r to $\mathcal{V} \setminus T_r$. The bipartition $(S_r, \mathcal{V} \setminus S_r)$ is induced by the source-side cut and $(\mathcal{V} \setminus T_r, T_r)$ is induced by the target-side cut. Note that $\mathcal{V} \setminus S_r \setminus T_r$ is not necessarily empty.

3.3 Hyperedge Cuts via Maximum Flows

Lawler [34] uses maximum flows to compute minimum S - T hyperedge cuts without balance constraints. On the star expansion, the standard construction to model node capacities as edge capacities [1] is applied to the hyperedge-nodes. A hyperedge e is expanded into an *in-node* e_i and an *out-node* e_o joined by a directed *bridge edge* (e_i, e_o) with unit capacity. For every pin $u \in e$ there are two directed *external edges* $(u, e_i), (e_o, u)$ with infinite capacity. The transformed graph is called the *Lawler network*. A minimum S - T edge cut in the Lawler network consists only of bridge edges, which directly correspond to S - T cut hyperedges in H .

Instead of using the Lawler network, we emulate max-flow algorithms directly on the hypergraph, using an approach first proposed by Pistorius and Minoux [42]. In the paper it is formulated for unit weight hyperedges and the Edmonds-Karp flow algorithm [22] but it can be easily extended to handle weighted hyperedges and emulate any flow algorithm. For every hyperedge $e \in E$, we store the pins sending and receiving flow via e . In this work, we consider only unit weight hyperedges and thus need to store only one pin $\text{flow-from}(e)$ sending flow into e , and one pin $\text{flow-to}(e)$ receiving flow from e . To keep the description simple, it relies on this assumption as well. Let u be a fixed vertex. The idea is to enumerate short paths of the form $u \rightarrow e \in I(u) \rightarrow v \in e$ that correspond to paths in the residual Lawler network. This allows us to emulate algorithms for traversing the residual Lawler network directly on

■ **Figure 1** Flow augmentation and computing S_r, T_r in Fig.1a; adding S_r to S and piercing the source-side cut in Fig.1b. S in blue, $S_r \setminus S$ in yellow, T in green, $T_r \setminus T$ in red, $V \setminus S_r, \setminus T_r$ in white.

the hypergraph, such as Breadth-First-Search or Depth-First-Search, as well as other types of local operations, e. g., the *discharge* and *push* operations in push-relabel algorithms [25]. For every hyperedge $e \in I(u)$ we do the following. If e has no flow, we enumerate all pins $v \in e$. These paths correspond to (u, e_i, e_o, v) in the Lawler network. If e has flow and $u = \text{flow-to}(e)$ we also enumerate all pins $v \in e$. However, these paths correspond to (u, e_o, e_i, v) in the Lawler network. If e has flow and $u = \text{flow-from}(e)$, there is no path in the residual Lawler network starting at u that uses e . If e has flow and $\text{flow-from}(e) \neq u \neq \text{flow-to}(e)$, we enumerate just one path $(u, e, \text{flow-from}(e))$, corresponding to $(u, e_i, \text{flow-from}(e))$ in the Lawler network. If we can push flow from the vertex $\text{flow-from}(e)$ to T , we can redirect the flow that the vertex $\text{flow-from}(e)$ sends into e , and instead route flow coming from u to $\text{flow-to}(e)$. Then u becomes the new $\text{flow-from}(e)$.

We use this approach in our implementation because it is significantly more efficient than the Lawler network in practice. In the last case we can avoid scanning all pins of e . In a preliminary experiment, computing flow directly on the hypergraph yielded a speedup of 15 over using the Lawler network, for a hypergraph with maximum hyperedge size of only 36. The speedup will be more extreme on hypergraphs with larger hyperedges.

Via the Lawler network and the above emulation approach, the notions of flow, source-reachable vertices and source-side cuts translate naturally from graphs to hypergraphs. We use the notation and terminology already known from max-flows in graphs.

4 HyperFlowCutter

In the following we outline the core HyperFlowCutter algorithm, which can only be used on connected hypergraphs. Then we discuss how to handle disconnected hypergraphs, and finally show how to improve an existing partition using HyperFlowCutter.

4.1 The Core Algorithm

The idea of the *core* HyperFlowCutter algorithm is to solve a sequence of incremental S - T max-flow min-cut problems with monotonically increasing cut size and balance, until an ε -balanced bipartition is found. They are incremental in the sense that the terminals S, T of the current flow problem are subsets of the terminals in the next flow problem, which allows us to reuse previously computed flows.

Given starting terminal sets $S_{\text{init}}, T_{\text{init}}$, we set $S := S_{\text{init}}, T := T_{\text{init}}$. First, we compute a maximum S - T flow. We terminate if the bipartition $(S_r, V \setminus S_r)$ induced by the source-side cut or $(V \setminus T_r, T_r)$ induced by the target-side cut is ε -balanced. Otherwise, we add the source-reachable vertices S_r to S , if $|S_r| \leq |T_r|$, or we add T_r to T if $|S_r| > |T_r|$. Assume

$|S_r| \leq |T_r|$ without loss of generality. Further, we add one or more vertices, called *piercing vertices*, to S . This step is called *piercing* the cut. It ensures that the next flow problem yields a different bipartition. Subsequently, we augment the previous flow to a max-flow that respects the new sources. We repeat these steps until an ε -balanced bipartition is found.

Note that after adding S_r to S , the flow is still a maximum S - T flow, even though the added vertices are now exempt from flow conservation. Using the smaller side allows it to catch up with the larger side. In particular, this ensures that ε -balance is always possible, as neither side grows beyond $\lceil n/2 \rceil$ vertices.

A hyperedge with pins in both S and T is *mixed*, all other hyperedges are *non-mixed*. We consider two options to find piercing vertices. The preferred option is to choose all pins $e \setminus S \setminus T$ of a non-mixed hyperedge e in the source-side cut. Adding multiple vertices is faster in practice. This small detail is a major difference to FBB [51] and is necessary to make the running time feasible on the used benchmark set. If the source-side cut contains only mixed hyperedges, we choose a single non-terminal vertex incident to the source-side cut. We prefer piercing vertices which are not reachable from T , as these avoid augmenting paths in the next iteration, and thus the cut size does not increase. Avoiding augmenting paths has the highest precedence, followed by choosing hyperedges over single vertices. Ties are broken randomly. If the piercing vertices are not reachable from T , we do not recompute T_r and we skip flow augmentation, but we do recompute S_r .

We experimented with other piercing methods, including trying to avoid mixed hyperedges, the distance-based piercing of FlowCutter, as well as piercing based on a machine learning technique named ensemble classification. We discuss ensemble classification again in the experimental section, although in a different context. None of these approaches yielded consistent or significant quality improvements over just avoiding augmenting paths and random tie-breaking, which is why we use only those.

Asymptotic Complexity. The asymptotic running time of Core HyperFlowCutter is $\mathcal{O}(cp)$ where c is the cut size of the ε -balanced partition and p is the number of pins in the hypergraph. Roughly speaking, the term p stems from performing up to one hypergraph traversal per flow unit. Here we use that $n \leq p, m \leq p$ holds for connected hypergraphs. Note that the running time is output-sensitive, however the factor c is rather pessimistic in practice, since the flow algorithm finds many augmenting paths in a single traversal. The original proof for FlowCutter [27] is applicable, but implementing the piercing step requires a little care. Selecting piercing vertices takes $\mathcal{O}(c)$ per iteration, and we have at most $n \leq p$ iterations. Selecting a non-mixed hyperedge for piercing takes $\mathcal{O}(c)$ time, by iterating over the cut hyperedges. Selecting single piercing vertices which avoid augmenting paths whenever possible, is slightly more involved, when restricted to $\mathcal{O}(c)$ time. For every cut hyperedge e we additionally track its pins that are not reachable from either side. This can be implemented with a linked list, from which we delete vertices once they get reachable from a side. An alternative implementation divides the memory storing the pins of e into three regions: the pins in S_r , in T_r or not reachable. Then we can check, whether e has pins that are not reachable from either side, and if so pick one. In practice, this adds significantly to the complexity of the implementation and the piercing step is never critical for running time, so our implementation simply scans all non-terminal boundary vertices.

Our implementation has $\mathcal{O}(n + m)$ memory footprint by transferring and re-engineering the implementation details from [27]. This is dominated by the $\mathcal{O}(n + m + p)$ memory for storing the hypergraph.

Isolated Vertices. We call a vertex $v \notin S \cup T$ *isolated* if every incident hyperedge $e \in I(v)$ is mixed. Figure 1c illustrates an isolated vertex. An isolated vertex cannot be reached from either S or T via hyperedges not in the cut. Mixed hyperedges remain in both the source-side cut and the target-side cut. Thus isolated vertices can be moved freely between the two blocks to increase balance. It never makes sense to permanently add them to a side, so we exclude them from the piercing step. Furthermore, this needs to be reflected when checking for ε -balance. For checking the bipartition $(S_r, V \setminus S_r)$ we assume up to $n/2 - |S_r|$ of the isolated vertices were part of S_r , analogously for T_r .

Maximum Flow Algorithm. In our implementation, we adapt Dinic maximum flow algorithm [21] to operate directly on the hypergraph, as described in Section 3.3. Dinic algorithm has two alternating phases that are repeated until a maximum flow is found: computing hop distance labels of nodes, using Breadth-First-Search, and finding augmenting paths using Depth-First-Search, such that the distance labels always increase by one along the path. We interleave the first phase of Dinic algorithm with the computation of reachable vertices, in order to avoid duplicate hypergraph traversal. This intrusive optimization is important for improving the running time of flow augmentation in practice, as the part of the running time of the flow algorithm that cannot be charged towards computing reachable vertices is dominated by the part that can be. This is not possible with push-relabel algorithms [25], which is why they were ruled out after short experimentation. We experimented with the Edmonds-Karp flow algorithm [22], modified to augment flow along multiple vertex-disjoint paths in one Breadth-First-Search by propagating vertex labels through the layers. It is slightly slower than Dinic for plain HyperFlowCutter but unfeasible for the refinement variant of HyperFlowCutter, since there are fewer vertices to route flow through and thus the amount of flow augmented per Breadth-First-Search is limited by a few bottleneck vertices.

4.2 Disconnected Hypergraphs

The HyperFlowCutter core algorithm is limited to connected hypergraphs since it computes S - T -cuts. An obvious approach for handling disconnected hypergraphs is connecting components artificially. We refrained from this because a component that intersects neither S nor T would be added to S or T in its entirety. Instead, we run the core algorithm up to $\varepsilon = 0$ on every connected component. The core algorithm computes multiple bipartitions with different balances. We systematically try all possible ways to combine the bipartitions of the components into a bipartition of H .

This can be stated as a generalization of the well-known SUBSETSUM problem. SUBSETSUM is a weakly NP-hard decision problem, which asks whether a subset of an input multiset of positive integers $A = \{a_1, \dots, a_z\}$, the *items*, sums to an input target sum W . Finding a bipartition with zero cut is equivalent to SUBSETSUM, where the items are the sizes of the components and W is the minimum size of the smaller block. We are interested in any subset summing to at least W . Let A be sorted in increasing order and let $Q(i, S)$ be a boolean variable, which is true iff a subset of the first i items sums to S . The standard pseudo-polynomial time dynamic program (DP) [15, Section 35.5] for SUBSETSUM computes solutions for all possible target sums. It fills the DP table Q by iterating through the items in increasing order and setting $Q(i, S)$ to true if $Q(i-1, S - a_i)$ or $Q(i-1, S)$ is true. For filling row i , only row $i-1$ is required, so the memory footprint is not quadratic.

We now turn to non-zero cut bipartitions by allowing to split items in different ways and associating costs with the splits. The core algorithm computes multiple bipartitions P_i on component C_i , at most one for every possible size of the smaller side. These correspond

directly to the different ways we can split items. The associated cost is the cut size. We modify the standard SUBSETSUM DP to minimize the added cuts instead of finding any subset, ensuring every component/item is split only one way in a solution, i. e., select a bipartition, and trying the smaller and larger side of the component bipartition for the smaller side of the bipartition of H . The worst case asymptotic running time of this DP is $\mathcal{O}(\sum_{i=1}^z \sum_{j=1}^{i-1} |P_i||P_j|)$.

We propose some optimizations to make the approach faster in practice. First we solve standard SUBSETSUM to check whether H has an ε -balanced bipartition with zero cut. For the *gap-filler* optimization, we find the largest $g \in \mathbb{N}$ such that for every $x \in [0, g]$ there are connected components, whose sizes sum to x . Computing g is possible in $\mathcal{O}(n)$ time. Let C_1, \dots, C_z be sorted by increasing size, which takes $\mathcal{O}(n)$ time using counting sort [15, Section 8.2]. Then $g = \sum_{j=1}^{k-1} |C_j|$ for the smallest k such that $|C_k| > 1 + \sum_{j=1}^{k-1} |C_j|$. It is never beneficial to split the components C_1, \dots, C_{k-1} . For most hypergraphs we consider in our experiments, we do not invoke the DP because, due to gap-filler, we split only the largest component. For the hypergraphs on which we do invoke the DP, its running time is negligible. Nonetheless, it is easy to construct a worst case instance, where the quadratic running time is prohibitive. For a robust algorithm, we propose to sample bipartitions from every P_i so that the worst case running time falls below some input threshold. The samples should include balanced bipartitions to guarantee that a balanced partition on H can be combined from those on $H[C_i]$.

4.3 HyperFlowCutter as a Refinement and Balancing Algorithm

Instead of partitioning from scratch, HyperFlowCutter can be used to refine an existing balanced bipartition $\pi = (V_1, V_2)$, or repair the balance of an unbalanced bipartition. We fix two blocks of vertices $V'_i \subset V_i$ such that $|V'_i| \leq \alpha \cdot n$ for a *relative block-size threshold* parameter $\alpha \in [0, 0.5]$. To obtain V'_i we run Breadth-First-Search from the boundary vertices on the side of V_i until $|V_i| - \alpha \cdot n$ vertices have been visited. The $\alpha \cdot n$ vertices not visited by the Breadth-First-Search are set as V'_i . Then we run HyperFlowCutter with $S = V'_1, T = V'_2$. We call this algorithm *ReBaHFC*. This idea is equivalent to the way KaHyPar and KaHiP extract *corridors* around the cut for their flow-based refinement. Only the semantics of the size constraint are different to our approach. However, KaHyPar and KaHiP only compute one flow. If the associated bipartition is not balanced, a smaller flow network is derived. This is repeated until the bipartition is balanced. ReBaHFC does not need to repeatedly re-scale flow networks.

In this work we only perform refinement as a post-processing step to a given partition, whereas KaHyPar and KaHiP employ flow-based refinement on the multilevel hierarchy. In a future work we hope to integrate HyperFlowCutter based refinement into KaHyPar. Using ReBaHFC could eliminate the significant overhead of repeated rescaling and improve solution quality – in particular when the minimum cut is just short of being balanced.

We use the fast multilevel partitioner PaToH [13] to obtain initial partitions. We briefly discuss properties of PaToH and differences between its presets. For coarsening, PaToH uses agglomerative clustering, based on the number of common hyperedges divided by cluster size. For initial partitioning, a portfolio of graph growing, bin packing and neighborhood expansion algorithms is used. For refinement PaToH uses a pass of FM [23] followed by a pass of KL [33], each initialized with boundary nodes.

In order to improve cut size, Walshaw [50] proposed to iterate the multilevel scheme by contracting only nodes from the same block, which maintains the cut size, thus allowing refinement on coarse levels starting from a relatively high quality partition. The existing

partition serves as initial partition on the coarsest level. One iteration is called a *V-cycle*. Contraction can be stopped at different stages. The quality preset PaToH-Q, uses 3 full *V-cycles* and 3 shorter *V-cycles* as opposed to the single *V-cycle* of the default preset PaToH-D. To accelerate partitioning, both presets temporarily discard hyperedges which have more pins than some threshold. PaToH-D sets a lower threshold than PaToH-Q.

5 Experimental Evaluation

We implemented HyperFlowCutter and ReBaHFC in C++17 and compiled our code using g++8 with flags `-O3 -mtune=native -march=native`. The source code is available on GitHub¹. Experiments are performed sequentially on a cluster of Intel Xeon E5-2670 (Sandy Bridge) nodes with two Octa-Core processors clocked at 2.6 GHz with 64 GB RAM, 20 MB L3- and 8×256 KB L2-Cache, using only one core of a node.

We use the benchmark set² of Heuer and Schlag [30], which has been used to evaluate KaHyPar. It consists of 488 hypergraphs from four sources: the ISPD98 VLSI Circuit Benchmark Suite [3] (VLSI, 18 hypergraphs), the DAC 2012 Routability-Driven Placement Benchmark Suite [39] (DAC, 10), the SuiteSparse Matrix Collection [17] (SPM, 184) and the international SAT Competition 2014 [8] (Literal, Primal, Dual, 92 hypergraphs each). The set contains 173 disconnected hypergraphs, in particular all DAC instances are disconnected. Refer to [30] for more information on how the hypergraphs were derived. Unless mentioned otherwise, experiments are performed on the full benchmark set.

In the following we describe the configuration of ReBaHFC and plain HyperFlowCutter, before comparing them to competing algorithms in Section 5.4.

5.1 General HyperFlowCutter Configuration

To improve the solution quality of HyperFlowCutter, we run it $q \in \mathbb{N}$ times with different terminal pairs and take the minimum cut. To improve running time we run them simultaneously, in an *interleaved* fashion, as already described in [27], so that the output-sensitive running time depends on the smallest found ε -balanced cut, not the largest. We always schedule the terminal pair with the currently smallest cut to progress.

Table 1 shows the average and some quantile speedups when interleaving the execution of 20 random terminal vertex pairs, instead of running them one after another; repeated for 5 random seeds. Because consecutive execution exhibits more memory locality, we also tested a hybrid strategy where the instance with the currently smallest cut is allowed to make multiple progress iterations. Interleaving outperforms consecutive execution by a factor of 3.88 on average and also consistently beats hybrid execution. This shows that saving work is more important than memory locality. These numbers stem from a preliminary experiment

■ **Figure 2** Improvement ratios $1 - \frac{\text{cut}(\text{ReBaHFC})}{\text{cut}(\text{PaToH})}$ of the two ReBaHFC variants and $\varepsilon = 0, 0.03$ compared to their initial partitions. The curves are independent from one another. Higher values are better. Ratios of zero mean ReBaHFC did not improve the initial partition. We count partitions with zero cut as an improvement ratio greater than 1, since ReBaHFC does not invoke PaToH in this case.

on a 139 hypergraph subset of the full benchmark set. The subset contains 78 sparse matrices, 17 Primal, 23 Dual, 6 Literal SAT instances, 15 VLSI and 0 DAC instances. It contains only connected hypergraphs (all DAC instances are disconnected) in order to measure the impact of interleaving, not the setup overhead for many small connected components.

5.2 ReBaHFC Configuration

We now discuss the configuration for ReBaHFC. The imbalance for the initial partition is set to the same value as the desired imbalance ε for the output partition, which proved superior to larger imbalances on initial partitions. The block-size threshold parameter α should depend on ε , so we settled on $\alpha = 0.4$ for $\varepsilon = 0.03$ and $\alpha = 0.46$ for $\varepsilon = 0$. In the TR [26] we conduct a thorough parameter study for these choices. We resize the blocks once and run HyperFlowCutter five times, interleaved as described in the previous section. This number seems to provide decent quality without increasing running time too much. We consider two variants: ReBaHFC-D, which uses PaToH with default preset and ReBaHFC-Q, which uses PaToH with quality preset.

Figure 2 shows how much ReBaHFC improves the initial partition. We run the two ReBaHFC variants for $\varepsilon = 0, 0.03$ on all hypergraphs of the benchmark set with five different random seeds and plot the ratio $1 - \frac{\text{cut}(\text{ReBaHFC})}{\text{cut}(\text{PaToH})}$ per run. Note that there is no comparison between the curves, and higher values are better for ReBaHFC. Table 2 reports how often ReBaHFC improves the initial partition, for different hypergraph classes. As expected, ReBaHFC-Q could improve fewer solutions than ReBaHFC-D since the PaToH baseline is already better. Furthermore, ReBaHFC has more opportunities for refinement with $\varepsilon = 0.03$, in particular on the DAC and VLSI instances, whereas it struggles with the Primal and Literal SAT instances for $\varepsilon = 0$. Note that other refinement algorithms do not always improve solutions either. In particular, local moving based refinement algorithms struggle with zero-gain moves in the presence of large hyperedges, and the flow-based refinement in KaHyPar can yield unbalanced solutions or reproduce the existing solution. These results show that HyperFlowCutter is a promising candidate for a refinement algorithm integrated in a multilevel partitioner, which is a direction we hope to investigate in future work.

■ **Table 2** Overview by hypergraph class, how often ReBaHFC improves the initial partition.

Algorithm	ε	all	SPM	Dual	Primal	Lit	DAC	VLSI
ReBaHFC-Q	0.00	37.3	39.8	47.4	23.9	33.0	66.0	34.4
ReBaHFC-D	0.00	49.2	58.4	59.8	27.4	41.3	58.0	47.8
ReBaHFC-Q	0.03	52.5	47.2	51.5	50.9	57.8	82.0	76.7
ReBaHFC-D	0.03	64.5	61.5	65.9	56.7	71.1	76.0	86.7

The PaToH runs in the experiments from Section 5.4 use other random seeds than those used internally in ReBaHFC. This makes sure that stand-alone PaToH can find smaller cuts than ReBaHFC.

5.3 Plain HyperFlowCutter Configuration

For the experiments on perfectly balanced partitioning we run plain HyperFlowCutter with up to $q = 100$ terminal pairs and take the minimum cut. This value was used already for FlowCutter [27]. With plain HyperFlowCutter we want to push the envelope on solution quality for $\varepsilon = 0$, regardless of running time – because, as the experiments show, ReBaHFC already provides a good time-quality trade-off. The most simple method for choosing starting terminals is to select random vertices. We unsuccessfully experimented with *pseudo-peripheral* terminals, i. e. two vertices that are intuitively far away from each other and at the boundary of the hypergraph. Instead we propose a selection method based on ensemble classification. Ensemble classification is a technique used in machine learning to build a strong classifier from multiple weak ones. We compute 10 bipartitions π_1, \dots, π_{10} with PaToH-D. Let $x \equiv y \Leftrightarrow \pi_i(x) = \pi_i(y)$ for all $i = 1, \dots, 10$ be the equivalence relation, in which two vertices are equivalent if they are in the same block for all ensemble bipartitions. An equivalence class is likely in the same block of a good bipartition and is thus suited as a terminal set. We order the equivalence classes by size in descending order and group two successive classes as one terminal pair. Generally speaking, the larger equivalence classes make for better terminal pairs. Based on experiments in the TR [26], we use 3 ensemble terminal pairs and 97 random vertex pairs. The reported running time for plain HyperFlowCutter always includes the running time for the 10 PaToH-D runs.

On 42 of the 488 hypergraphs, plain HyperFlowCutter with 100 terminal pairs exceeds the eight hour time limit. One downside of interleaving executions is that the solution is only available once all terminal pairs have been processed. Instead of interleaving all 100 executions, we run four waves of $\langle 1, 5, 14, 80 \rangle$ terminal pairs consecutively and interleave execution within waves. An improved bipartition is available after every wave, so that, even if the time limit is exceeded, a solution is available as long as the first wave has been completed. We chose wave sizes, so that completing waves four and three corresponds to 100 and 20 terminal pairs, respectively, as these values were used in [27]. The first wave consists of the first ensemble terminal pair, the second/third wave consist of 5/14 random terminal pairs and the fourth wave consists of 78 random as well as two additional ensemble terminal pairs. There are 438 hypergraphs for which the fourth wave finishes, 35 for which the third but not the fourth wave finishes, 6 for the second, 1 for the first and there are 8 hypergraphs which are partitioned with zero cut, using just the subset sum preprocessing.

■ **Figure 3** Comparison between the algorithms for $\varepsilon = 0.03$. Left: Absolute running times for every hypergraph and random seed. Right: Performance plot relating the minimum cut per algorithm and hypergraph to the overall best cut for that hypergraph. Lower values are better.

5.4 Comparing ReBaHFC and HyperFlowCutter against State-of-the-Art Hypergraph Partitioners

In this section, we compare ReBaHFC and plain HyperFlowCutter against state-of-the-art hypergraph partitioners. After discussing our comparison methodology, we present results for two settings, namely $\varepsilon = 0.03$ and $\varepsilon = 0$.

Methodology. We run each partitioner five times with different random seeds and report the minimum cut. For every run we set a time limit of eight hours. We use the *performance plots* introduced in [45] to compare algorithms on a per-hypergraph basis regarding cut size. For each algorithm and hypergraph these plots contain a *performance ratio* $1 - \text{best}/\text{algorithm}$, which relates the minimum cut found by any algorithm to the minimum cut found by this algorithm. The ratios of each algorithm are sorted in increasing order. A ratio of 0 means that this algorithm found the smallest overall cut, the number of achieved ratios of 0 is the number of hypergraphs on which this algorithm is the best. Furthermore, algorithm A dominates algorithm B if the curve of A is strictly below that of B. We use values greater than 1 to indicate that algorithms exceeded the time limit or produced unbalanced solutions. This is clearly marked in the plots. To include partitions with zero cut, we set the performance ratio to 0, if the algorithm found the zero cut partition, and 1 otherwise. The performance plots use a cube root scaled y-axis in order to reduce right skewness [16] and to give a fine-grained view on the smaller improvements. For comparing algorithms regarding running time we use a combination of a scatter plot, which shows every measured running time, and a box plot (0.25, median, 0.75 quantiles, whiskers at most extreme points within distance $1.5 \cdot \text{IQR}$ from the upper/lower quartile). The running time plots use a fifth root scaled y-axis for a fine-grained view on areas with smaller running times, which contain more data points.

Comparison for 3% imbalance. For $\varepsilon = 0.03$ we compare ReBaHFC against the state-of-the-art hypergraph partitioning tools KaHyPar-MF (the latest version of KaHyPar with flow-based refinement) and hMETIS-R (the recursive bisection variant of hMETIS), as well as PaToH-D (default preset) and PaToH-Q (quality preset). We use the library interface of PaToH. According to the hMETIS manual, hMETIS-R is preferred over hMETIS-K (direct k-way) for bipartitions, so we exclude hMETIS-K. These tools were chosen because

■ **Figure 4** Comparison between the algorithms for $\varepsilon = 0$. Left: Absolute running times for every hypergraph and random seed. Right: performance plot relating the minimum cut per algorithm and hypergraph to the overall best cut for that hypergraph. Lower values are better.

they provide the best solution quality according to [2, 30]. We chose $\varepsilon = 0.03$ as this is a commonly used value in the literature. Plain HyperFlowCutter is excluded from this part of the experiments because it is not competitive.

Figure 3 shows the running times and a performance plot on the full benchmark set for $\varepsilon = 0.03$. In addition to the running time plot, we compare algorithms by the geometric mean of their running times. We use the geometric mean in order to give instances of different sizes a comparable influence. KaHyPar-MF finds the smallest cut on 292 hypergraphs, hMETIS-R on 257, ReBaHFC-Q on 228, ReBaHFC-D on 177, PaToH-Q on 136 and PaToH-D on 75 of the 488 hypergraphs. While KaHyPar-MF is the best algorithm regarding solution quality, it is also the slowest, exceeding the time limit on 11 hypergraphs. For the instances on which ReBaHFC-Q does not find the best solution it provides solution quality similar to hMETIS-R and only marginally worse than KaHyPar-MF. In particular its solution quality compared to the best cut deteriorates less than that of hMETIS-R. With 2.23s PaToH-Q is one order of magnitude faster than KaHyPar (34.1s) and hMETIS-R (20.1s), whereas ReBaHFC-Q (2.32s) is only slightly slower than PaToH-Q. Furthermore ReBaHFC-D (0.68s) finds more of the best solutions than PaToH-Q at a running time between PaToH-D (0.5s) and PaToH-Q. Thus ReBaHFC-Q and ReBaHFC-D provide new Pareto points in the time-quality trade-off. In the TR [26], we also report performance plots for the different hypergraph classes of the benchmark set. ReBaHFC is particularly good on the DAC and SPM instances. There are hypergraphs on which ReBaHFC is faster than PaToH. These are disconnected hypergraphs, for which ReBaHFC invokes PaToH on smaller sub-hypergraphs, due to the gap-filler optimization and the SUBSETSUM preprocessing described in Section 4.2.

Comparison for perfectly balanced partitioning. Even though the setting $\varepsilon = 0$ has received no attention in hypergraph partitioning and only some attention in graph partitioning [44, 38, 14, 9, 10, 11, 18], we consider it here. Previous studies on perfectly balanced partitioning for graphs have focused on high quality solutions through running time intensive metaheuristics such as evolutionary algorithms [44, 10, 9] or tabu search [11] and even an exact branch-and-bound algorithm [18]. Therefore, we include KaHyPar-EVO [6] (the evolutionary algorithm of KaHyPar) as well as plain HyperFlowCutter in addition to the already considered algorithms. We exclude hMETIS-R from this comparison since it rejects $\varepsilon < 0.002$ for bipartitions.

We include plain HyperFlowCutter with up to 100 terminal pairs as described in Section 5.1 and denote this configuration as HFC-100. The evolutionary algorithm KaHyPar-EVO generates, manages and improves a pool of solutions until a time limit is exceeded, and outputs the minimum cut out of all generated solutions. We set the instance-wise time limit to the maximum of the running times of HFC-100 and KaHyPar-MF to evaluate whether KaHyPar-EVO can yield better solution quality when given the same running time as HFC-100. As opposed to the original paper, we configure KaHyPar-EVO to use flow-based refinement, which further improves solution quality.

KaHyPar-MF is unable to find any balanced bipartition on 4 hypergraphs, whereas KaHyPar-EVO always finds one. Furthermore, KaHyPar-MF exceeds the time limit on 7 hypergraphs and KaHyPar-EVO on an additional 17, without reporting intermediate solutions. Figure 4 shows the running times and a performance plot of all tested algorithms. HFC-100 produces the best solutions on 245 hypergraphs, followed by ReBaHFC-Q (230), ReBaHFC-D (122), PaToH-Q (121), PaToH-D (40), KaHyPar-EVO (28) and finally KaHyPar-MF (15). This shows that with exorbitant running time, HFC-100 produces high quality solutions for $\varepsilon = 0$. However the time-quality trade-off is clearly in favor of ReBaHFC-Q, especially since the solution quality of the latter is closer to the best cut for the instances on which it does not find the best cut, as opposed to HFC-100. PaToH is better than KaHyPar for $\varepsilon = 0$ because it includes a KL [33] refinement pass as opposed to KaHyPar which only uses FM [23].

6 Conclusion

In this paper we propose and evaluate HyperFlowCutter, a hypergraph bipartitioning algorithm based on maximum flow computations. It enumerates partitions with increasing balance up to perfect balance. We also propose and evaluate ReBaHFC, a refinement algorithm based on HyperFlowCutter.

In our experimental evaluation on a large set of hypergraphs, we show that while ReBaHFC is unable to beat the state-of-the-art hypergraph partitioners in terms of quality, it is still close in terms of quality and at the same time an order of magnitude faster. Thus, it offers a new trade-off between quality and running time. For the special case of perfectly balanced bipartitioning, the plain HyperFlowCutter algorithm, while being slow, computes the highest-quality solutions. In this setting, ReBaHFC not only still beats all other partitioners but is also much faster.

In future work, it would be interesting to integrate the refinement step of ReBaHFC into multilevel partitioners to see if it can further improve their solution quality.

Abstract

The area of parameterized approximation seeks to combine approximation and parameterized algorithms to obtain, e.g., $(1 + \varepsilon)$ -approximations in $f(k, \varepsilon)n^{O(1)}$ time where k is some *parameter* of the input. The goal is to overcome lower bounds from either of the areas. We obtain the following results on parameterized approximability:

- In the *maximum independent set of rectangles* problem (MISR) we are given a collection of n axis parallel rectangles in the plane. Our goal is to select a maximum-cardinality subset of pairwise non-overlapping rectangles. This problem is NP-hard and also W[1]-hard [Marx, ESA'05]. The best-known polynomial-time approximation factor is $O(\log \log n)$ [Chalermsook and Chuzhoy, SODA'09] and it admits a QPTAS [Adamaszek and Wiese, FOCS'13; Chuzhoy and Ene, FOCS'16]. Here we present a *parameterized approximation scheme* (PAS) for MISR, i.e. an algorithm that, for any given constant $\varepsilon > 0$ and integer $k > 0$, in time $f(k, \varepsilon)n^{g(\varepsilon)}$, either outputs a solution of size at least $k/(1 + \varepsilon)$, or declares that the optimum solution has size less than k .
- In the (*2-dimensional*) *geometric knapsack* problem (2DK) we are given an axis-aligned square knapsack and a collection of axis-aligned rectangles in the plane (*items*). Our goal is to translate a maximum cardinality subset of items into the knapsack so that the selected items do not overlap. In the version of 2DK with rotations (2DKR), we are allowed to rotate items by 90 degrees. Both variants are NP-hard, and the best-known polynomial-time approximation factor is $2 + \varepsilon$ [Jansen and Zhang, SODA'04]. These problems admit a QPTAS for polynomially bounded item sizes [Adamaszek and Wiese, SODA'15]. We show that both variants are W[1]-hard. Furthermore, we present a PAS for 2DKR.

For all considered problems, getting time $f(k, \varepsilon)n^{O(1)}$, rather than $f(k, \varepsilon)n^{g(\varepsilon)}$, would give FPT time $f'(k)n^{O(1)}$ exact algorithms by setting $\varepsilon = 1/(k + 1)$, contradicting W[1]-hardness. Instead, for each fixed $\varepsilon > 0$, our PASs give $(1 + \varepsilon)$ -approximate solutions in FPT time.

For both MISR and 2DKR our techniques also give rise to preprocessing algorithms that take $n^{g(\varepsilon)}$ time and return a subset of at most $k^{g(\varepsilon)}$ rectangles/items that contains a solution of size at least $k/(1 + \varepsilon)$ if a solution of size k exists. This is a special case of the recently introduced notion of a polynomial-size approximate kernelization scheme [Lokshtanov et al., STOC'17].

1 Introduction

Approximation algorithms and parameterized algorithms are two well-established ways to deal with NP-hard problems. An α -approximation for an optimization problem is a polynomial-time algorithm that computes a *feasible* solution whose cost is within a factor α (that might be a function of the input size n) of the optimal cost. In particular, a *polynomial-time approximation scheme* (PTAS) is a $(1 + \varepsilon)$ -approximation algorithm running in time $n^{g(\varepsilon)}$, where $\varepsilon > 0$ is a given constant and g is some computable function. In parameterized algorithms we identify a parameter k of the input, that we informally assume to be much smaller than n . The goal here is to solve the problem optimally in *fixed-parameter tractable* (FPT) time $f(k)n^{O(1)}$, where f is some computable function. Recently, researchers started to combine the two notions (see, e.g., the survey by Marx [34]). The idea is to design approximation algorithms that run in FPT (rather than polynomial) time, e.g., to get $(1 + \varepsilon)$ -approximate solutions in time $f(k, \varepsilon)n^{O(1)}$. In this paper we continue this line of research on parameterized approximation, and apply it to two fundamental rectangle packing problems.

1.1 Our results and techniques

Our focus is on parameterized approximation algorithms. Unfortunately, as observed by Marx [34], when the parameter k is the desired solution size, computing $(1 + \varepsilon)$ -approximate solutions in time $f(k, \varepsilon)n^{O(1)}$ implies fixed-parameter tractability. Indeed, setting $\varepsilon = 1/(k+1)$ guarantees to find an optimal solution when that value equals to $k \in \mathbb{N}$ and we get time $f(k, 1/(k+1))n^{O(1)} = f'(k)n^{O(1)}$. Since the considered problems are W[1]-hard (in part, this is established in our work), they are unlikely to be FPT and similarly unlikely to have such nice approximation schemes.

Instead, we construct algorithms (for two maximization problems) that, given $\varepsilon > 0$ and an integer k , take time $f(k, \varepsilon)n^{g(\varepsilon)}$ and either return a solution of size at least $k/(1 + \varepsilon)$ or declare that the optimum is less than k . We call such an algorithm a *parameterized approximation scheme* (PAS). Note that if we run such an algorithm for each $k' \leq k$ then we can guarantee that we compute a solution with cardinality at least $\min\{k, \text{OPT}\}/(1 + \varepsilon)$ where OPT denotes the size of the optimal solution. So intuitively, for each $\varepsilon > 0$, we have an FPT-algorithm for getting a $(1 + \varepsilon)$ -approximate solution.

In this paper we consider the following two geometric packing problems, and design PASs for them.

Maximum Independent Set of Rectangles. In the *maximum independent set of rectangles* problem (MISR) we are given a set of n axis-parallel rectangles $\mathcal{R} = \{R_1, \dots, R_n\}$ in the two-dimensional plane, where R_i is the open set of points $(x_i^{(1)}, x_i^{(2)}) \times (y_i^{(1)}, y_i^{(2)})$. A feasible solution is a subset of rectangles $\mathcal{R}' \subseteq \mathcal{R}$ such that for any two rectangles $R, R' \in \mathcal{R}'$ we have $R \cap R' = \emptyset$. Our objective is to find a feasible solution of maximum cardinality $|\mathcal{R}'|$. W.l.o.g. we assume that $x_i^{(1)}, y_i^{(1)}, x_i^{(2)}, y_i^{(2)} \in \{0, \dots, 2n - 1\}$ for each $R_i \in \mathcal{R}$ (see e.g. [1]).

MISR is very well-studied in the area of approximation algorithms. The problem is known to be NP-hard [24], and the current best polynomial-time approximation factor is $O(\log \log n)$ for the cardinality case [11] (addressed in this paper), and $O(\log n / \log \log n)$ for the natural generalization with rectangle weights [12]. The cardinality case also admits a

$(1 + \varepsilon)$ -approximation with a running time of $n^{\text{poly}(\log \log(n/\varepsilon))}$ [15] and there is a (slower) QPTAS known for the weighted case [1]. The problem is also known to be $W[1]$ -hard w.r.t. the number k of rectangles in the solution [33], and thus unlikely to be solvable in FPT time $f(k)n^{O(1)}$.

In this paper we achieve the following main result:

► **Theorem 1.** *There is a PAS for MISR with running time $k^{O(k/\varepsilon^8)}n^{O(1/\varepsilon^8)}$.*

In order to achieve the above result, we combine several ideas. Our starting point is a polynomial-time construction of a $k \times k$ grid such that each rectangle in the input contains some crossing point of this grid (or we find a solution of size k directly). By applying (in a non-trivial way) a result by Frederickson [21] on planar graphs, and losing a small factor in the approximation, we define a decomposition of our grid into a collection of disjoint *groups* of cells. Each such group defines an independent instance of the problem, consisting of the rectangles strictly contained in the considered group of cells. Furthermore, we guarantee that each group spans only a *constant number* $O_\varepsilon(1)$ of rectangles of the optimum solution. Therefore in FPT time we can guess the correct decomposition, and solve each corresponding subproblem in $n^{O_\varepsilon(1)}$ time. We remark that our approach deviates substantially from prior work, and might be useful for other related problems.

An adaptation of our construction also leads to the following $(1 + \varepsilon)$ -approximative kernelization.

► **Theorem 2.** *There is an algorithm for MISR that, given $k \in \mathbb{N}$, computes in time $n^{O(1/\varepsilon^8)}$ a subset of the input rectangles of size $k^{O(1/\varepsilon^8)}$ that contains a solution of size at least $k/(1 + \varepsilon)$, assuming that the input instance admits a solution of size at least k .*

Similarly as for a PAS, if we run the above algorithm for each $k' \leq k$ we obtain a set of size $k^{O(1/\varepsilon^8)}$ that contains a solution of size at least $\min\{k, \text{OPT}\}/(1 + \varepsilon)$. Observe that any c -approximate solution on the obtained set of rectangles is also a feasible, and $c(1 + \varepsilon)$ -approximate, solution for the original instance if $\text{OPT} \leq k$ and otherwise has size at least $k/(c(1 + \varepsilon))$. Thus, our result is a special case of a *polynomial-size approximate kernelization scheme* (PSAKS) as defined in [32].¹

2-Dimensional Geometric Knapsack. In the (*2-Dimensional*) *Geometric Knapsack* problem (2DK) we are given a square *knapsack* $[0, N] \times [0, N]$, $N \in \mathbb{N}$, and a set of n items I , where each item $i \in I$ is an open rectangle $(0, w_i) \times (0, h_i)$, $N \geq w_i, h_i \in \mathbb{N}$. The goal is to find a feasible *packing* of a subset $I' \subseteq I$ of the items of maximum cardinality $|I'|$. Such packing maps each item $i \in I'$ into a new translated rectangle $(a_i, a_i + w_i) \times (b_i, b_i + h_i)$ ², so that the translated rectangles are fully contained in the knapsack and do not overlap with each other. Here we also consider a variant of 2DK *with rotations* (2DKR) where we can rotate each input rectangle by 90 degrees.

Both 2DK and 2DKR are NP-hard [31] and admit a polynomial-time $(2 + \varepsilon)$ -approximation for any constant $\varepsilon > 0$ [28]. These problems admit a QPTAS if $N = n^{O(1)}$ [2]. Somewhat surprisingly, these problems are not known to be $W[1]$ -hard when parameterized by the output number k of items. Note that showing $W[1]$ -hardness is important in our case to motivate the search for a PAS.

¹ The definition due to Lokshtanov et al. [32] is not restricted to generating a small subset of the input and a dedicated solution lifting algorithm may be used.

² Intuitively, i is shifted by a_i to the right and by b_i to the top.

► **Theorem 3.** *2DK and 2DKR are W[1]-hard when parameterized by k .*

The result is proved by parameterized reductions from a variant of the W[1]-hard SUBSET SUM problem, where we need to determine whether a set of m positive integers contains a k -tuple of numbers with sum equal to some given value t . The difficulty for reductions to 2DK or 2DKR is of course that rectangles may be freely selected and placed (and possibly rotated) to get a feasible packing.

We complement the W[1]-hardness result by giving a PAS for the case with rotations (2DKR) and a corresponding kernelization procedure like in Theorem 2 (which also yields a PSAKS).

► **Theorem 4.** *For 2DKR there is a PAS with running time $k^{O(k/\epsilon)}n^{O(1/\epsilon^3)}$ and an algorithm that, given $k \in \mathbb{N}$, computes in time $n^{O(1/\epsilon^3)}$ a subset of the input items of size $k^{O(1/\epsilon)}$ that contains a solution of size at least $k/(1 + \epsilon)$, assuming that the input instance admits a solution of size at least k .*

The above result is based on a simple combination of the following two (non-trivial) building blocks: First, we show that, by losing a fraction ϵ of the items of a given solution of size k , it is possible to free a vertical strip of width $N/k^{O_\epsilon(1)}$ (unless the problem can be solved trivially). This is achieved by first sparsifying the solution using the above mentioned result by Frederickson [21]. If this is not sufficient we construct a *vertical chain* of relatively wide and tall rectangles that split the instance into a left and right side. Then we design a *resource augmentation* algorithm, however in an FPT sense: we can compute in FPT time a packing of cardinality k if we are allowed to use a knapsack where one side is enlarged by a factor $1 + 1/k^{O_\epsilon(1)}$. Note that in typical resource augmentation results the packing constraint is relaxed by a constant factor while here this amount is controlled by our parameter.

1.2 Related work

One of the first fruitful connections between parameterized complexity and approximability was observed independently by Bazgan [3] and Cesati and Trevisan [10]: They showed that EPTASs, i.e., $(1 + \epsilon)$ -approximation algorithms with $f(\epsilon)n^{O(1)}$ time, imply fixed-parameter tractability for the decision version. Thus, proofs for W[1]-hardness of the decision version became a strong tool for ruling out improvements of PTASs, with running time $n^{g(\epsilon)}$, to EPTASs. More recently, Boucher et al. [8] improved this approach by directly proving W[1]-hardness of obtaining a $(1 + \epsilon)$ -approximation, thus bypassing the requirement of a W[1]-hard decision version (see also [17]).

The systematic study of parameterized approximation as a field was initiated independently by three separate publications [9, 13, 19]. A very good introduction to the area including key definitions as well as a survey of earlier results that fit into the picture was given by Marx [34]. In particular, Marx also defined a so-called *standard FPT-approximation algorithm (with performance ratio c)* that, given input (x, k) will run for $f(k)|x|^{O(1)}$ time and return (say, for a maximization problem) a solution of value at least k/c if the optimum is at least k . As mentioned earlier, Marx pointed out that a standard FPT-approximation scheme that finds a solution of value at least $k/(1 + \epsilon)$ in time $f(k, \epsilon)|x|^{O(1)}$ if $\text{OPT} \geq k$ is not interesting to study: By setting $\epsilon = 1/(k + 1)$ we can decide the decision problem “ $\text{OPT} \geq k$?” in FPT time. Thus, such a scheme is not helpful if the decision problem is W[1]-hard and therefore unlikely to have an FPT-algorithm. Nevertheless, PASs can be useful in this case, as they imply standard FPT-approximation algorithms with ratio $1 + \epsilon$ for each fixed $\epsilon > 0$ despite W[1]-hardness.

■ **Figure 1** (Left) Dashed lines define the grid \mathcal{G} . (Middle) Rectangles from an optimal solution and the edges that form the graph G_1 . Note that in G_1 there is no edge representing the dotted connection since otherwise the graph would not be planar anymore. (Right) The graph G_2 , that captures the missing connections of G_1 .

A central goal of parameterized approximation is to settle the status of problems like DOMINATING SET or CLIQUE, which are hard to approximate and also parameterized intractable. Recently, Chen and Lin [14] made important progress by showing that DOMINATING SET admits no constant-factor approximation with running time $f(k)n^{O(1)}$ unless $\text{FPT} = \text{W}[1]$. Generally, for problems without exact FPT-algorithms, the goal is to find out whether one can beat inapproximability bounds by allowing FPT-time in some parameter; see e.g. [23, 4, 5, 6, 30, 29, 16, 22, 7]).

For the special case of MISR where all input objects are squares a PTAS is known [20] but there can be no EPTAS [33]. Recently, Galvez et al. [25] found polynomial-time algorithms for 2DK and 2DKR with approximation ratio smaller than 2 (also for the weighted case). For the special case that all input objects are squares there is a PTAS [27] and even an EPTAS [26].

2 A Parameterized Approximation Scheme for MISR

In this section we present a PAS and an approximate kernelization for MISR. We start by showing that there exists an almost optimal solution for the problem with some helpful structural properties (Sections 2.1 and 2.2). The results are then put together in Section 2.3.

2.1 Definition of the grid

We try to construct a non-uniform grid with k rows and k columns such that each input rectangle overlaps a corner of this grid (see Figure 1). To this end, we want to compute $k - 1$ vertical and $k - 1$ horizontal lines such that each input rectangle intersects one line from each set. There are instances in which our routine fails to construct such a grid (and in fact such a grid might not even exist). For such instances, we directly find a feasible solution with k rectangles and we are done.

► **Lemma 5.** *There is a polynomial time algorithm that either computes a set of at most $k - 1$ vertical lines \mathcal{L}_V with x -coordinates $\ell_1^V, \dots, \ell_{k-1}^V$ such that each input rectangle is crossed by one line in \mathcal{L}_V or computes a feasible solution with k rectangles. A symmetric statement holds for an algorithm computing a set of at most $k - 1$ horizontal lines \mathcal{L}_H with y -coordinates $\ell_1^H, \dots, \ell_{k-1}^H$.*

Proof. Let $\ell_0^V := 0$. Assume inductively that we defined the x -coordinates $\ell_0^V, \ell_1^V, \dots, \ell_{k'}^V$ such that $\ell_1^V, \dots, \ell_{k'}^V$ are the x -coordinates of the first k' constructed vertical lines. We define the x -coordinate of the $(k'+1)$ -th vertical line by $\ell_{k'+1}^V := \min_{R_i \in \mathcal{R}: x_i^{(1)} \geq \ell_{k'}^V} x_i^{(2)} - 1/2$. We continue with this construction until we reach an iteration k^* such that $\{R_i \in \mathcal{R} : x_i^{(1)} \geq \ell_{k^*-1}^V\} = \emptyset$. If $k^* \leq k$ then we constructed at most $k-1$ lines such that each input rectangle is intersected by one of these lines. Otherwise, assume that $k^* > k$. Then for each iteration $k' \in \{1, \dots, k\}$ we can find a rectangle $R_{i(k')} := \arg \min_{R_i \in \mathcal{R}: x_i^{(1)} \geq \ell_{k'-1}^V} x_i^{(2)}$. By construction, using the fact that all coordinates are integer, for any two such rectangles $R_{i(k')}, R_{i(k'')}$ with $k' \neq k''$ we have that $(x_{i(k')}^{(1)}, x_{i(k')}^{(2)}) \cap (x_{i(k'')}^{(1)}, x_{i(k'')}^{(2)}) = \emptyset$. Hence, $R_{i(k')}$ and $R_{i(k'')}$ are disjoint. Therefore, the rectangles $R_{i(1)}, \dots, R_{i(k)}$ are pairwise disjoint and thus form a feasible solution.

The algorithm for constructing the horizontal lines works symmetrically. \blacktriangleleft

We apply the algorithms due to Lemma 5. If one of them finds a set of k independent rectangles then we output them and we are done. Otherwise, we obtain the sets \mathcal{L}_V and \mathcal{L}_H . For convenience, we define two more vertical lines with x -coordinates $\ell_0^V := 0$ and $\ell_{|\mathcal{L}_V|+1}^V = 2n-1$, resp., and similarly two more horizontal lines with y -coordinates $\ell_0^H = 0$ and $\ell_{|\mathcal{L}_H|+1}^H = 2n-1$, resp.. We denote by \mathcal{G} the set of grid cells formed by these lines and the lines in $\mathcal{L}_V \cup \mathcal{L}_H$: for any two consecutive vertices lines (i.e., defined via x -coordinates ℓ_j^V, ℓ_{j+1}^V with $j \in \{0, \dots, |\mathcal{L}_V|\}$) and two consecutive horizontal grid lines (defined via y -coordinates $\ell_{j'}^H, \ell_{j'+1}^H$ with $j' \in \{0, \dots, |\mathcal{L}_H|\}$) we obtain a grid cell whose corners are the intersection of these respective lines. We interpret the grid cells as closed sets (i.e., two adjacent grid cells intersect on their boundary).

► Proposition 6. *Each input rectangle R_i contains a corner of a grid cell of \mathcal{G} . If a rectangle R intersects a grid cell g then it must contain a corner of g .*

2.2 Groups of rectangles

Let \mathcal{R}^* denote a solution to the given instance with $|\mathcal{R}^*| = k$. We prove that there is a special solution $\mathcal{R}' \subseteq \mathcal{R}^*$ of large cardinality that we can partition into $s \leq k$ groups $\mathcal{R}'_1 \dot{\cup} \dots \dot{\cup} \mathcal{R}'_s$ such that each group has constant size $O(1/\epsilon^8)$ and no grid cell can be intersected by rectangles from different groups. The remainder of this section is devoted to proving the following lemma.

► Lemma 7. *There is a constant $c = O(1/\epsilon^8)$ such that there exists a solution $\mathcal{R}' \subseteq \mathcal{R}^*$ with $|\mathcal{R}'| \geq (1-\epsilon)|\mathcal{R}^*|$ and a partition $\mathcal{R}' = \mathcal{R}'_1 \dot{\cup} \dots \dot{\cup} \mathcal{R}'_s$ with $s \leq k$ and $|\mathcal{R}'_j| \leq c$ for each j and such that if any two rectangles in \mathcal{R}' intersect the same grid cell $g \in \mathcal{G}$ then they are contained in the same set \mathcal{R}'_j .*

Given the solution \mathcal{R}^* we construct a planar graph $G_1 = (V_1, E_1)$. In V_1 we have one vertex v_i for each rectangle $R_i \in \mathcal{R}^*$. We connect two vertices $v_i, v_{i'}$ by an edge if and only if there is a grid cell $g \in \mathcal{G}$ such that R_i and $R_{i'}$ intersect g and

- R_i and $R_{i'}$ are crossed by the same horizontal or vertical line in $\mathcal{L}_V \cup \mathcal{L}_H$ or if
- R_i and $R_{i'}$ contain the top left and the bottom right corner of g , resp.

Note that we do not introduce an edge if R_i and $R_{i'}$ contain the bottom left and the top right corner of g , resp. (see Fig. 1): this way we preserve the planarity of the resulting graph, however we will have to deal with the missing connections in a later stage.

► Lemma 8. *The graph G_1 is planar.*

Next, we use a result by Frederickson [21] to obtain a subgraph G'_1 of G_1 in which each connected component has constant size.

► **Lemma 9.** *Let $\epsilon' > 0$. There exists a value $c' = O(1/(\epsilon')^2)$ such that the following holds: let $G = (V, E)$ be a planar graph. There exists a set of vertices $V' \subseteq V$ with $|V'| \geq (1 - \epsilon')|V|$ such that in the graph $G' := G[V']$ each connected component has at most c' vertices.*

Let G'_1 be the graph obtained when applying Lemma 9 to G_1 with $\epsilon' := \epsilon/2$ and let $c_1 = O((1/\epsilon)^2)$ be the respective value c' . Now we would like to claim that if two rectangles $R_i, R_{i'}$ intersect the same grid cell $g \in \mathcal{G}$ then $v_i, v_{i'}$ are in the same component of G'_1 . Unfortunately, this is not true. It might be that there is a grid cell $g \in \mathcal{G}$ such that R_i and $R_{i'}$ contain the bottom left corner and the top right corner of g , resp., and that v_i and $v_{i'}$ are in different components of G'_1 . We fix this in a second step. We define a graph $G_2 = (V_2, E_2)$. In V_2 we have one vertex for each connected component in G'_1 . We connect two vertices $w_i, w_{i'} \in V_2$ by an edge if and only if there are two rectangles $R_i, R_{i'}$ such that their corresponding vertices $v_i, v_{i'}$ in V_1 belong to the connected components of G'_1 represented by w_i and $w_{i'}$, resp., and there is a grid cell g whose bottom left and top right corner are contained in R_i and $R_{i'}$, resp.

► **Lemma 10.** *The graph G_2 is planar.*

Similarly as above, we apply Lemma 9 to G_2 with $\epsilon' := \frac{\epsilon}{2c_1}$ and let $c_2 = O((1/\epsilon')^2) = O(1/\epsilon^6)$ denote the corresponding value of c' . Denote by G'_2 the resulting graph. We define a group \mathcal{R}'_q for each connected component \mathcal{C}_q of V'_2 . The set \mathcal{R}'_q contains all rectangles R_i such that v_i is contained in a connected component C_j of G'_1 such that $w_j \in \mathcal{C}_q$. We define $\mathcal{R}' := \dot{\cup}_q \mathcal{R}'_q$.

► **Lemma 11.** *Let $R_i, R_{i'} \in \mathcal{R}'$ be rectangles that intersect the same grid cell $g \in \mathcal{G}$. Then there is a set \mathcal{R}'_q such that $\{R_i, R_{i'}\} \subseteq \mathcal{R}'_q$.*

Proof. Assume that in G_1 there is an edge connecting $v_i, v_{i'}$. Then the latter vertices are in the same connected component $C_{j'}$ of G'_1 and thus they are in the same group \mathcal{R}'_q . Otherwise, if there is no edge connecting $v_i, v_{i'}$ in G_1 then R_i and $R_{i'}$ contain the bottom left and top right corners of g , resp. Assume that v_i and $v_{i'}$ are contained in the connected components C_j and $C_{j'}$ of G'_1 , resp. Then $w_j, w_{j'} \in V'_2$, $\{w_j, w_{j'}\} \in E_2$ and $w_j, w_{j'}$ are in the same connected component of V'_2 . Hence, $R_i, R_{i'}$ are in the same group \mathcal{R}'_q . ◀

It remains to prove that each group \mathcal{R}'_q has constant size and that $|\mathcal{R}'| \geq (1 - \epsilon)|\mathcal{R}^*|$.

► **Lemma 12.** *There is a constant $c = O(1/\epsilon^8)$ such that for each group \mathcal{R}'_q it holds that $|\mathcal{R}'_q| \leq c$.*

Proof. For each group \mathcal{R}'_q there is a connected component \mathcal{C}_q of G'_2 such that \mathcal{R}'_q contains all rectangles R_i such that v_i is contained in a connected component C_j of G'_1 and $w_j \in \mathcal{C}_q$. Each connected component of G'_1 contains at most $c_1 = O(1/\epsilon^2)$ vertices of V'_1 and each component of G'_2 contains at most $c_2 = O(1/\epsilon^6)$ vertices of V'_2 . Hence, $|\mathcal{R}'_q| \leq c_1 \cdot c_2 =: c$ and $c = O((1/\epsilon^2)(1/\epsilon^6)) = O(1/\epsilon^8)$. ◀

► **Lemma 13.** *We have that $|\mathcal{R}'| \geq (1 - \epsilon)|\mathcal{R}^*|$.*

Proof. At most $\frac{\epsilon}{2} \cdot |V_1|$ vertices of G_1 are deleted when we construct G'_1 from G_1 . Each vertex in G'_1 belongs to one connected component C_j , represented by a vertex $w_j \in G_2$. At most $\frac{\epsilon}{2c_1} |V_2|$ vertices are deleted when we construct G'_2 from G_2 . These vertices represent at most $c_1 \cdot \frac{\epsilon}{2c_1} |V_2| \leq \frac{\epsilon}{2} |V'_1| \leq \frac{\epsilon}{2} |V_1|$ vertices in G_1 (and each vertex in G_1 represents one rectangle in \mathcal{R}^*). Therefore, $|\mathcal{R}'| \geq |\mathcal{R}^*| - \frac{\epsilon}{2} \cdot |V_1| - \frac{\epsilon}{2} \cdot |V_1| = (1 - \epsilon)|\mathcal{R}^*|$. ◀

This completes the proof of Lemma 7.

2.3 The algorithm

In our algorithm, we compute a solution that is at least as good as the solution \mathcal{R}' as given by Lemma 7. For each group \mathcal{R}'_j we define by \mathcal{G}_j the set of grid cells that are intersected by at least one rectangle from \mathcal{R}'_j . Since in \mathcal{R}' each grid cell can be intersected by rectangles of only one group, we have that $\mathcal{G}_j \cap \mathcal{G}_q = \emptyset$ if $j \neq q$. We want to guess the sets \mathcal{G}_j . The next lemma shows that the number of possibilities for one of those sets is polynomially bounded in k .

► **Lemma 14.** *Each \mathcal{G}_j belongs to a set \mathcal{G} of cardinality at most $k^{O(1/\varepsilon^8)}$ that can be computed in polynomial time.*

Proof. The cells \mathcal{G}_j intersected by \mathcal{R}'_j are the union of all cells $\mathcal{G}(R)$ with $R \in \mathcal{R}'_j$ where for each rectangle R the set $\mathcal{G}(R)$ denotes the cells intersected by R . Each set $\mathcal{G}(R)$ can be specified by indicating the 4 *corner* cells of $\mathcal{G}(R)$, i.e., top-left, top-right, bottom-left, and bottom-right corner. Hence there are at most k^4 choices for each such R . The claim follows since $|\mathcal{R}'_j| = O(1/\varepsilon^8)$. ◀

We hence achieve the main result of this section.

Proof of Theorem 1. Using Lemma 14, we can guess by exhaustive enumeration all the sets \mathcal{G}_j in time $k^{O(k/\varepsilon^8)}$. We obtain one independent problem for each value $j \in \{1, \dots, s\}$ which consists of all input rectangles that are contained in \mathcal{G}_j . For this subproblem, it suffices to compute a solution with at least $|\mathcal{R}'_j|$ rectangles. Since $|\mathcal{R}'_j| \leq c = O(1/\varepsilon^8)$ we can do this in time $n^{O(1/\varepsilon^8)}$ by complete enumeration. Thus, we solve each of the subproblems and output the union of the computed solutions. The overall running time is as in the claim. If all the computed solutions have size less than $(1 - \varepsilon)k$, this implies that the optimum solution is smaller than k . Otherwise we obtain a solution of size at least $(1 - \varepsilon)k \geq k/(1 + 2\varepsilon)$ and the claim follows by redefining ε appropriately. ◀

Essentially the same construction as above also gives an approximate kernelization algorithm as claimed in Theorem 2, see the full version of this work for details.

3 A Parameterized Approximation Scheme for 2DKR

In this section we present a PAS and an approximate kernelization for 2DKR. W.l.o.g., we assume that $k \geq \Omega(1/\varepsilon^3)$, since otherwise we can optimally solve the problem in time $n^{O(1/\varepsilon^3)}$ by exhaustive enumeration. In Section 3.1 we show that, if a solution of size k exists, there is a solution of size at least $(1 - \varepsilon)k$ in which no item intersects some horizontal strip $(0, N) \times (0, (1/k)^{O(1/\varepsilon)}N)$ at the bottom of the knapsack. In Section 3.2 we show that, if there exists a solution of size k' that does not use the mentioned strip, then we can compute in polynomial time a set of size $(k')^{O(1/\varepsilon)}$ that contains a solution of size k' (where we are allowed to use the full knapsack). Combining these two results gives Theorem 4.

3.1 Freeing a Horizontal Strip

In this section, we prove the following lemma that shows the existence of a near-optimal solution that leaves a sufficiently tall empty horizontal strip in the knapsack (assuming $k \geq \Omega(1/\varepsilon^3)$). W.l.o.g., $\varepsilon \leq 1$. Since we can rotate the items by 90 degrees, we can assume w.l.o.g. that $w_i \geq h_i$ for each item $i \in I$.

■ **Figure 2** The left figure shows the arcs of the graph G . Each item corresponds to one vertex of the graph. The right figure shows the items i_1, \dots, i_K and the deletion rectangles between them.

► **Lemma 15.** *Let $k \in \mathbb{N}$, $k = \Omega(1/\epsilon^3)$, and $\epsilon > 0$. Given an instance of 2DKR with a solution of size k , there exists a solution of size at least $(1 - \epsilon)k$ in which no packed item intersects $(0, N) \times (0, (1/k)^c N)$, for a proper constant $c = O(1/\epsilon)$.*

We classify items into large and thin items. Via a shifting argument, we get the following lemma.

► **Lemma 16.** *There is an integer $B \in \{1, \dots, \lceil 8/\epsilon \rceil\}$ such that by losing a factor of $1 + \epsilon$ in the objective we can assume that the input items are partitioned into*

- large items L such that $h_i \geq (1/k)^B N$ (and thus also $w_i \geq (1/k)^B N$) for each item $i \in L$,
- thin items T such that $h_i < (1/k)^{B+2} N$ for each item $i \in T$.

Let B be the integer due to Lemma 16 and we work with the resulting item classification. If $|T| \geq k$ then we can create a solution of size k satisfying the claim of Lemma 15 by simply stacking k thin items on top of each other: any k thin items have a total height of at most $k \cdot (1/k)^{B+2} N \leq (1/k)^2 N$. Thus, from now on assume that $|T| < k$.

Sparsifying large items. Our strategy is now to delete some of the large items and move the remaining items. This will allow us to free the area $[0, N] \times [0, (1/k)^{O(1/\epsilon)} N]$ of the knapsack. Denote by OPT' the almost optimal solution obtained by applying Lemma 16. We remove the items in $\text{OPT}'_T := \text{OPT}' \cap T$ temporarily; we will add them back later.

We construct a directed graph $G = (V, A)$ where we have one vertex $v_i \in V$ for each item $i \in \text{OPT}'_L := \text{OPT}' \cap L$. We connect two vertices $v_i, v_{i'}$ by an arc $a = (v_i, v_{i'})$ if and only if we can draw a vertical line segment of length at most $(1/k)^B N$ that connects item i with item i' without intersecting any other item such that i' lies above i , i.e., the bottom coordinate of i' is at least as large as the top coordinate of i , see Figure 2 for a sketch. We obtain the following proposition since for each edge we can draw a vertical line segment and these segments do not intersect each other.

► **Proposition 17.** *The graph G is planar.*

Next, we apply Lemma 9 to G with $\epsilon' := \epsilon$. Let $G' = (V', A')$ be the resulting graph. We remove from OPT'_L all items $i \in V \setminus V'$ and denote by OPT''_L the resulting solution. We push up all items in OPT''_L as much as possible. If now the strip $(0, N) \times (0, (1/k)^B N)$ is not intersected by any item then we can place all the items in T into the remaining space. Their total height can be at most $k \cdot (1/k)^{B+2} N \leq (1/k)^{B+1} N$ and thus we can leave a strip of height $(1/k)^B N - (1/k)^{B+1} N \geq (1/k)^{O(1/\epsilon)} N$ and width N empty. This completes the proof of Lemma 15 for this case.

Assume next that the strip $(0, N) \times (0, (1/k)^B N)$ is intersected by some item: the following lemma implies that there is a set of $c' = O(1/\epsilon^2)$ vertices whose items intuitively connect the top and the bottom edge of the knapsack.

► **Lemma 18.** *Assume that in OPT_L'' there is an item i_1 intersecting $(0, N) \times (0, (1/k)^B N)$. Then G contains a path $v_{i_1}, v_{i_2}, \dots, v_{i_K}$ with $K \leq c' = O(1/\epsilon^2)$, such that the distance between i_K and the top edge of the knapsack is less than $(1/k)^B N$.*

Proof. Let C denote all vertices v in G' such that there is a directed path from v_{i_1} to v in G' . The vertices in C are contained in the connected component C' in G' that contains v_{i_1} . Note that $|C| \leq |C'| \leq c'$. We claim that C must contain a vertex v_j whose corresponding item j is closer than $(1/k)^B N$ to the top edge of the knapsack. Otherwise, we would have been able to push up all items corresponding to vertices in C by $(1/k)^B N$ units: first we could have pushed up all items such that their corresponding vertices have no outgoing arc, then all items such that their vertices have outgoing arcs pointing at the former set of vertices, and so on. By definition of C , there must be a path connecting v_{i_1} with v_j . This path $v_{i_1}, v_{i_2}, \dots, v_{i_K} = v_j$ contains only vertices in C and hence its length is bounded by c' . The claim follows. ◀

Our goal is now to remove the items i_1, \dots, i_K due to Lemma 18 and $O(K) = O(1/\epsilon^2)$ more large items from OPT_L'' . Since we can assume that $k \geq \Omega(1/\epsilon^3)$ this will lose only a factor of $1 + O(\epsilon)$ in the objective. To this end we define $K + 1$ *deletion rectangles*, see Figure 2. We place one such rectangle R_ℓ between any two consecutive items $i_\ell, i_{\ell+1}$. The height of R_ℓ equals the vertical distance between i_ℓ and $i_{\ell+1}$ (at most $(1/k)^B N$) and the width of R_ℓ equals $(1/k)^B N$. Since $v_{i_\ell}, v_{i_{\ell+1}}$ are connected by an arc in G' , we can draw a vertical line segment connecting i_ℓ with $i_{\ell+1}$. We place R_ℓ such that it is intersected by this line segment. Note that for the horizontal position of R_ℓ there are still several possibilities and we choose one arbitrarily. Finally, we place a special deletion rectangle between the item i_K and the top edge of the knapsack and another special deletion rectangle between the item i_1 and the bottom edge of the knapsack. The heights of these rectangles equal the distance of i_1 and i_K with the bottom and top edge of the knapsack, resp. (which is at most $(1/k)^B N$), and their widths equal $(1/k)^B N$. They are placed such that they touch the bottom edge of i_1 and the top edge of i_K , resp.

► **Lemma 19.** *Each deletion rectangle can intersect at most 4 large items in its interior. Hence, there can be only $O(K) \leq O(c') = O(1/\epsilon^2)$ large items intersecting a deletion rectangle in their interior.*

Observe that the deletion rectangles and the items in $\{i_1, \dots, i_K\}$ separate the knapsack into a left and a right part with items OPT_{left}'' and OPT_{right}'' , resp. We delete all items in i_1, \dots, i_K and all items intersecting the interior of a deletion rectangle. Each deletion rectangle and each item in $\{i_1, \dots, i_K\}$ has a width of at least $(1/k)^B N$. Thus, we can move all items in OPT_{left}'' simultaneously by $(1/k)^B N$ units to the right. After this, no large item intersects the area $(0, (1/k)^B N) \times (0, N)$. We rotate the resulting solution by 90 degrees, hence getting an empty horizontal strip $(0, N) \times (0, (1/k)^B N)$. The total height of items in OPT_T' is at most $k \cdot (1/k)^{B+2} N \leq (1/k)^{B+1} N$. Therefore, the items in OPT_T' can be stacked (one on top of the other) inside a horizontal strip of height $(1/k)^{B+1} N$ that can be placed right below the rectangles in $\text{OPT}_{left}'' \cup \text{OPT}_{right}''$. This leaves an empty horizontal strip of height $(1/k)^B N - (1/k)^{B+1} N \geq (1/k)^{O(1/\epsilon)} N$ at the bottom of the knapsack. This completes the proof of Lemma 15.

3.2 FPT-algorithm with resource augmentation

We now compute a packing that contains as many items as the solution due to Lemma 15. However, it might use the space of the entire knapsack. In particular, we use the free space in the knapsack in the latter solution in order to round the sizes of the items. In the following lemma the reader may think of $k' = (1 - \epsilon)k$ and $\tilde{k} = k^{O(1/\epsilon)}$.

► **Lemma 20.** *Let $k', \tilde{k} \in \mathbb{N}$. There is an algorithm for 2DKR with a running time of $(\tilde{k}k')^{O(k')}n^{O(1)}$ that computes a solution of size k' or asserts that there is no solution of size k' fitting into a restricted knapsack $[0, N] \times [0, (1 - 1/\tilde{k})N]$. Also, in time $n^{O(1)}$ we can compute a set of size $O(\tilde{k}(k')^2)$ that contains a solution of size k' if there is such a solution that fits into the latter knapsack.*

Note that Lemma 20 yields an FPT algorithm if we are allowed to increase the size of the knapsack by a factor $1 + O(1/\tilde{k})$ where \tilde{k} is a second parameter.

In the remainder of this section, we prove Lemma 20 and we do not differentiate between large and thin items anymore. Assume that there exists a solution OPT'' of size k' that leaves the area $[0, N] \times [0, N/\tilde{k}]$ of the knapsack empty. We want to compute a solution of size k' . We use the empty space in order to round the heights of the items in the packing of OPT'' to integral multiples of $N/(k'\tilde{k})$. Note that in OPT'' an item i might be rotated. Thus, depending on this we actually want to round its height h_i or its width w_i . To this end, we define rounded heights and widths by $\hat{h}_i := \left\lceil \frac{h_i}{N/(k'\tilde{k})} \right\rceil N/(k'\tilde{k})$ and $\hat{w}_i := \left\lceil \frac{w_i}{N/(k'\tilde{k})} \right\rceil N/(k'\tilde{k})$ for each item i .

► **Lemma 21.** *There exists a feasible packing for all items in OPT'' even if for each rotated item i we increase its width w_i to \hat{w}_i and for each non-rotated item $i' \in \text{OPT}''$ we increase its height $h_{i'}$ to $\hat{h}_{i'}$.*

To visualize the packing due to Lemma 21 one might imagine a container of height \hat{h}_i and width w_i for each non-rotated item i and a container of height $h_{i'}$ and width $\hat{w}_{i'}$ for each rotated item i' . Next, we group the items according to their values \hat{h}_i and \hat{w}_i . We define $I_h^{(j)} := \{i \in I \mid \hat{h}_i = jN/(k'\tilde{k})\}$ and $I_w^{(j)} := \{i \in I \mid \hat{w}_i = jN/(k'\tilde{k})\}$ for each $j \in \{1, \dots, k'\tilde{k}\}$. The crucial observation is now that from each set $I_h^{(j)}$ it suffices to consider only the k' items with smallest width. If OPT'' uses an item from $I_h^{(j)}$ with larger width then we can replace it by one of the k' thinner items that is not contained in OPT'' . A symmetric statement holds for the sets $I_w^{(j)}$.

► **Lemma 22.** *We can assume that from each set $I_h^{(j)}$ the solution OPT'' contains only items among the k' items in $I_h^{(j)}$ with smallest width. Similarly, from each set $I_w^{(j)}$ the solution OPT'' contains only items among the k' items in $I_w^{(j)}$ with smallest height.*

We eliminate from each set $L_h^{(j)}$ and $L_w^{(j)}$ the items that are not among the k' items with smallest width and height, resp. At most $2k' \cdot k'\tilde{k} = O(\tilde{k}(k')^2)$ items remain, denote them by \bar{I} . Then, in time $(\tilde{k}k')^{O(k')}$ we can solve the remaining problem by completely enumerating over all subsets of \bar{I} with at most k' elements. For each enumerated set we check within the given time bounds whether its items can be packed into the knapsack (possibly via rotating some of them) by guessing sufficient auxiliary information. Therefore, if a solution of size k' for a knapsack of width N and height $(1 - 1/\tilde{k})N$ exists, then we will find a solution of size k' that fits into a knapsack of width and height N .

Now the proof of Theorem 4 follows by using Lemma 15 and then applying Lemma 20 with $k' = (1 - \epsilon)k$ and $\tilde{k} = k^{O(1/\epsilon)}$. The set \bar{I} is the claimed set (which intuitively forms the approximative kernel), we compute a solution of size at least $(1 - \epsilon)k \geq k/(1 + 2\epsilon)$ and we can redefine ϵ appropriately.

4 Hardness of Geometric Knapsack

We show that 2DK and 2DKR are both $W[1]$ -hard for parameter k by reducing from a variant of SUBSET SUM. Recall that in SUBSET SUM we are given m positive integers x_1, \dots, x_m as well as integers t and k , and have to determine whether some k -tuple of the numbers sums to t ; this is $W[1]$ -hard with respect to k [18]. In the variant MULTI-SUBSET SUM it is allowed to choose numbers more than once. It is easy to verify that the proof for $W[1]$ -hardness of SUBSET SUM due to Downey and Fellows [18] extends also to MULTI-SUBSET SUM. In our reduction to 2DKR we prove that rotations are not required for optimal solutions, making $W[1]$ -hardness of 2DK a free consequence.

Proof sketch for Theorem 3. We give a polynomial-time parameterized reduction from MULTI-SUBSET SUM to 2DKR with output parameter $k' = O(k^2)$; this establishes $W[1]$ -hardness of 2DKR.

Observe that, for any packing of items into the knapsack, there is an upper bound of N on the total width of items that intersect any horizontal line through the knapsack, and similarly an upper bound of N for the total height of items along any vertical line. We will let the dimensions of some items depend on numbers x_i from the input instance (x_1, \dots, x_m, t, k) of MULTI-SUBSET SUM such that, using these upper bound inequalities, a correct packing certifies that $y_1 + \dots + y_k = t$ for some k of the numbers. The key difficulty is that there is a lot of freedom in the choice of which items to pack and where in case of a no instance.

To deal with this, the items corresponding to numbers x_i from the input are all *almost* squares and their dimensions are incomparable. Concretely, an item corresponding to some number x_i has height $L + S + x_i$ and width $L + S + 2t - x_i$; we call such an item a *tile*. (The exact values of L and S are immaterial here, but $L \gg S \gg t > x_i$ holds.) Thus, when using, e.g., a tile of smaller width (i.e., smaller value of x_i) it will occupy “more height” in the packing. The knapsack is only slightly larger than a k by k grid of such tiles, implying that there is little freedom for the placement. Let us also assume for the moment, that no rotations are used.

Accordingly, we can specify k vertical lines that are guaranteed to intersect all tiles of any packing that uses k^2 tiles, by using pairwise distance $L - 1$ between them. Moreover, each line is intersecting exactly k private tiles. The same holds for a similar set of k horizontal lines. Together we get an upper bound of N for the sum of the widths (heights) along any horizontal (vertical) line. Since the numbers x_i occur negatively in widths, we effectively get lower bounds for them from the horizontal lines. When the sizes of these tiles (and the auxiliary items below) are appropriately chosen, it follows that all upper bound equalities must be tight. This in turn, due to the exact choice of N , implies that there are k numbers y_1, \dots, y_k with sum equal to t .

Unsurprisingly, using just the tiles we cannot guarantee that a packing exists when given a yes-instance. This can be fixed by adding a small number of flat/thin items that can be inserted between the tiles (see Figure 3, but note that it does not match the size ratios from this proof); these have dimension $L \times S$ or $S \times L$. Because one dimension of these items is large (namely L) they must be intersected by the above horizontal or vertical lines. Thus, they can be proved to enter the above inequalities in a uniform way, so that the proof idea goes through.

Finally, let us address the question of why we can assume that there are no rotations. This is achieved by letting the width of any tile be larger than the height of any tile, and adding a final auxiliary item of width N and small height, called the *bar*. To get the desired number of items in a solution packing, it can be ensured that the bar must be used as no

■ **Figure 3** A sketch of the packing used in Theorem 3 for a solution with $k = 3$ and $1 + 3 + 6 = 10$. Items corresponding to the same number have the same size. The figure is not to scale: The gray items should be much flatter and the clear ones should look like squares of almost identical size.

■ **Figure 4** Example showing that Lemma 15 cannot be generalized to 2DK (without rotations). The total height of the $k/2$ items on the bottom of the knapsack can be made arbitrarily small. Suppose that we wanted to free up an area of height $f(k) \cdot N$ and width N or of height N and width $f(k) \cdot N$ (for some fixed function f). If the total height of the items on the bottom is smaller than $f(k) \cdot N$ then we would have to eliminate the $k/2$ items on the bottom or the $k/2$ items on top. Thus, we would lose a factor of $2 > 1 + \varepsilon$ in the approximation ratio.

more than k^2 tiles can fit into $N \times N$ and there is a limited supply of flat/thin items. W.l.o.g., the bar is not rotated. It can then be checked that using at least one tile in its rotated form will violate one of the upper bounds for the height. This completes the proof sketch. ◀

5 Open Problems

This paper leaves several interesting open problems. A first obvious question is whether there exists a PAS also for 2DK (i.e., in the case without rotations). We remark that the algorithm from Lemma 20 can be easily adapted to the case without rotations. Unfortunately, Lemma 15 does not seem to generalize to the latter case. Indeed, there are instances in which we lose up to a factor of 2 if we require a strip of width $\Omega_{\varepsilon,k}(1) \cdot N$ to be emptied, see

Figure 4. We also note that both our PASs work for the cardinality version of the problems: an extension to the weighted case is desirable. Unlike related results in the literature (where extension to the weighted case follows relatively easily from the cardinality case), this seems to pose several technical issues.

We remark that all the problems considered in this paper might admit a PTAS in the standard sense, which would be a strict improvement on our PASs. Indeed, the existence of a QPTAS for these problems [1, 2, 15] suggests that such PTASs are likely to exist. However, finding those PTASs is a very well-known and long-standing problem in the area. We hope that our results can help to achieve this challenging goal.

Abstract

In the *Highway* problem, we are given a path with n edges (the highway), and a set of m drivers, each one characterized by a subpath and a budget. For a given assignment of edge prices (the tolls), the highway owner collects from each driver the total price of the associated path when it does not exceed drivers's budget, and zero otherwise. The goal is to choose the prices to maximize the total profit. A PTAS is known for this (strongly NP-hard) problem [Grandoni,Rothvoss-SODA'11,SICOMP'16].

In this paper we study the *limited supply* generalization of Highway, that incorporates capacity constraints. Here the input also includes a capacity $u_e \geq 0$ for each edge e ; we need to select, among drivers that can afford the required price, a subset such that the number of drivers that use each edge e is at most u_e (and we get profit only from selected drivers). To the best of our knowledge, the only approximation algorithm known for this problem is a folklore $O(\log m)$ approximation based on a reduction to the related Unsplittable Flow on a Path problem (UFP). The main result of this paper is a PTAS for limited supply highway.

As a second contribution, we study a natural generalization of the problem where each driver i demands a different amount d_i of capacity. Using known techniques, it is not hard to derive a QPTAS for this problem. Here we present a PTAS for the case that drivers have uniform budgets. Finding a PTAS for non-uniform-demand limited supply highway is left as a challenging open problem.

1 Introduction

In the *Highway* problem we are given a path graph $G = (V, E)$ with n edges (the *highway*) and a set D of m drivers. Each driver i is characterized by a subpath P_i of G , and by a budget $B_i \in \mathbb{N}^+$. We have to fix a price $p_e \geq 0$ on each edge e (the same for all drivers). Then, for each driver i , we get a profit of $p(i) := \sum_{e \in P_i} p_e$ (i.e., the total price over the edges *used* by i), provided that $p(i) \leq B_i$, and otherwise 0. Intuitively, each driver wishes to travel along subpath P_i , but it is not going to do that if the total requested price exceeds her budget. Our goal is to choose the prices to maximize the total profit from all drivers.

It is not hard to imagine applications for this problem, besides the obvious one suggested by its name. For example, highway edges might represent links of a (high-bandwidth) telecommunication network. Alternatively, one might interpret the highway as a period of time, and the edges as time slots: now drivers are clients who need a service for a given interval of time.

Highway is well studied. It was shown to be weakly NP-hard in [9] via a reduction from *Partition*, and strongly NP-hard in [20] via a reduction from *Max-2-SAT*. There is a simple $O(\log m)$ -approximation that works for much more general instances. This was improved to $O(\log n)$ in [3] using ideas in [26], and to $O(\log n / \log \log n)$ in [22]. A QPTAS for the problem was presented in [21]. Finally, a PTAS was given in [25].

In this paper we study the *Limited Supply Highway* problem (Ls-Highway), which is a natural generalization of Highway with capacity constraints. Here we are additionally given an integral capacity $u_e \in \mathbb{N}^+$ for each edge e . A solution is now given by a price $p_e \geq 0$ on each edge e plus a subset $S \subseteq D$ of drivers that satisfy the following *capacity constraint*: the total number of selected drivers that use each edge e is at most u_e , i.e. $|\{i \in S : e \in P_i\}| \leq u_e$. The profit from each driver is defined in the same way as in Highway, however now we obtain profit only from the selected drivers S . Observe that there might be drivers that can afford to pay for the considered prices and are still excluded (i.e., they cannot take the highway) due to capacity constraints. Capacity constraints make sense in some of the mentioned applications, e.g., optimal networks might have insufficient bandwidth to accommodate all candidate users and the authority handling the network could exclude some of these users (regardless of their budget). The same argument applies to a company selling a limited resource, such as computational power, over time slots. The best known approximation for Ls-Highway is, to the best of our knowledge, a folklore $O(\log m)$ approximation based on a reduction to the related *Unsplittable Flow on Path* problem (UFP). Details about this reduction are given later.

In this paper we also consider a *non-uniform demand* generalization of Ls-Highway, next denoted as NuLs-Highway, where each driver i has a demand $d_i \in \mathbb{N}$. W.l.o.g., we can assume that $d_i \leq \min_{e \in P_i} \{u_e\}$ (otherwise driver i can be discarded). Now the subset S of selected drivers has to satisfy $\sum_{i \in S: e \in P_i} d_i \leq u_e$ for each edge e . In particular, Ls-Highway is the special case of NuLs-Highway where $d_i = 1$ for all i . Essentially the same reduction to UFP as mentioned above provides a $O(\log m)$ approximation also for NuLs-Highway.

1.1 Our Results and Technique

The main result of this paper is a PTAS for Ls-Highway (see Section 2).

► **Theorem 1.** *There is a deterministic PTAS for Ls-Highway.*

Our starting point is a hierarchical decomposition of G into subpaths (called *intervals*) of different levels as introduced in [25]. The whole path G forms the (only) interval of level 0. Then G is subdivided into $\Gamma = O_\epsilon(1)$ subintervals of level 1 such that for each subinterval the sum of the prices of the edges in the optimal solution is identical. Note that this decomposition depends on the unknown optimal solution and cannot be inferred directly from the input. Recursively, each interval of level ℓ is subdivided into Γ subintervals of level $\ell + 1$ with the latter property. A driver is said to be in level ℓ if its path is contained in an interval of level ℓ but not in an interval of level $\ell + 1$. The PTAS in [25] guesses this decomposition recursively. First, it guesses the partition of G into intervals of level 1. This implies which drivers are of level 0 and – using some additional arguments – for which of them the total price of the edges of their respective paths exceeds the budget. In more detail, using some shifting arguments one ensures that essentially each driver of level 0 crosses at least $1/\epsilon$ intervals of level 1 completely (and at most two such intervals partially). Since all intervals of level 1 have the same total price in the optimal solution, up to a factor of $1 + \epsilon$ this implies the amount that each driver of level 0 would have to pay if it is contained the optimal set of drivers. Then *all* drivers of level 0 are selected whose budget is not exceeded. Afterwards, the

algorithm continues recursively in the intervals of level 1. Importantly, in order to process an interval of a level ℓ , one does not need to know which drivers of smaller levels were selected previously. Instead, each arising subproblem can be described by an interval and a level. Therefore, the number of possible subproblems is bounded by a polynomial and the whole algorithm can easily be embedded into a polynomial time dynamic program.

In Ls-Highway this situation is drastically different. When we want to process an interval of level ℓ then it is not clear that we want to select all drivers of level ℓ whose budget is not exceeded since we might want to use the available edge capacity for drivers of larger levels instead. Also, we need to know the previously selected drivers of smaller levels since they might use capacity on the edges that we then cannot use for drivers of level ℓ anymore. Unfortunately, there is an exponential number of possibilities for which drivers have been selected before and hence we would get a super-polynomial number of possible subproblems. One could use the profiling technique in [5] in order to ensure that there are only a polynomial number of possibilities for the capacity taken by drivers from *each* previous level (with a small loss in the profit). However, since the number of levels is $\Omega(\log n)$ this yields a quasi-polynomial number of combinations for the used capacity from all levels together which is still too much.

At this point our main idea comes into play. We would like that the path of each driver of each level ℓ' starts and ends at the boundary vertex of an interval of level $\ell' + 1$. Then, when we process an interval of level ℓ it would be easy to describe the total capacity taken away from drivers of smaller levels: the total number of such drivers would suffice, knowing that each of them spans the entire interval. Therefore, consider the drivers of level ℓ that start or end in the middle of an interval G' of level $\ell + 1$, let us say there are m' such drivers. For each of them we try to delete a minimal set of drivers of level $\ell + 1$ or larger such that each edge of G' is used by at least one deleted driver. If we succeed then this frees up one unit of capacity along each edge of G' for each considered driver of level ℓ , and we can use this extra space to *forget* the actual portion of G' that is spanned by this driver. In other terms, we can imagine that its path spans the entire subinterval G' . If we do not succeed to delete enough drivers using some edge e then we allocate all remaining capacity on e to the drivers of level ℓ . In other words, the remaining capacity on each edge of G' is reduced *by* m' or *to zero*. Hence, when we process an interval G' of level $\ell + 1$ in our recursion then one number in $\{0, \dots, m\}$ suffices to describe by how much the capacity on each edge in G' is reduced due to drivers from smaller levels. We perform this deletion procedure for each level and each interval. This allows us then to devise a polynomial time dynamic program that computes a solution whose profit is at least as large as the profit of the remaining drivers.

To bound the cost of the above deletion step, by losing a factor $1 + \epsilon$ in the approximation ratio the construction in [25] ensures that the path of each driver i of a level ℓ spans at least $\Omega(1/\epsilon)$ intervals of level $\ell + 1$ and hence its profit is by a factor $\Omega(1/\epsilon)$ larger than the sum of the edge prices in an interval of level $\ell + 1$. Up to constant factors, the latter is the total profit of the drivers of level at least $\ell + 1$ that we delete for i in the procedure above. Therefore, the total profit due to the deleted tasks can be charged to i , losing only a factor of $1 + O(\epsilon)$.

The non-uniform demand case

Given the above PTAS, it is natural to address the non-uniform version of the problem. In particular:

► **Question 2.** *Is there a PTAS for NuLs-Highway?*

Using the hierarchical decomposition from above and ideas from [5] it is not hard to derive a QPTAS for the problem, i.e., a $(1 + \epsilon)$ -approximation that runs in quasi-polynomial time (at least for quasi-polynomially bounded capacities). Let $U_{max} = \max_{e \in G} \{u_e\}$ be the largest capacity.

► **Theorem 3.** *For any constant $\epsilon > 0$, there is a deterministic algorithm that computes a $(1 + \epsilon)$ -approximation for NuLs-Highway in time $(n \log U_{max})^{O_\epsilon(\log U_{max} \log m)}$.*

Also, using a folklore reduction to UFP one can obtain a $O(\log m)$ -approximation for NuLs-Highway.

► **Lemma 4.** *There is a polynomial-time deterministic $O(\log m)$ -approximation for NuLs-Highway.*

We were able to design a PTAS for the interesting special case of uniform budgets (see Section 3). Suppose that each driver has a budget of B . We partition G into blocks of total price B/ϵ each and ensure via a shifting argument that the path of essentially each driver is contained in some block. We guess this partition via a dynamic program step by step. For each block, on a high level we show that there is a near-optimal solution in which only $O_\epsilon(1)$ edges within the block have a non-zero price and hence we can guess these edges and their prices in polynomial time. The problem of selecting the drivers yields an instance of UFP in which each task uses one of the latter $O_\epsilon(1)$ edges. We invoke the known PTAS [23] for this case and obtain a $(1 + \epsilon)$ -approximation overall.

► **Theorem 5.** *There is a deterministic PTAS for NuLs-Highway in the special case that the budgets of all drivers are identical.*

1.2 Other Related Work

The *tollbooth* problem is the generalization of the highway problem where G is a tree. A $O(\log n)$ approximation was developed in [20], and later improved to $O(\log n / \log \log n)$ in [22]. Cygan et al. [18] present a $O(\log \log n)$ approximation for the case of uniform budgets. The tollbooth problem is APX-hard [26].

The highway and tollbooth problems belong to the family of pricing problems with single-minded customers and unlimited supply. Here we are given a set of customers: Each customer wants to buy a subset of items (*bundle*), if its total price does not exceed her budget. In the highway terminology, each driver is a subset of edges (rather than a path). For this problem a $O(\log n + \log m)$ approximation is given in [26]. This bound was refined in [9] to $O(\log L + \log B)$, where L denotes the maximum number of items in a bundle and B the maximum number of bundles containing a given item. Chalermsook et al. [12] showed that this problem is hard to approximate within $\log^{1-\epsilon} n$ for any constant $\epsilon > 0$. A $O(L)$ approximation is given in [3]. The latter approximation factor is asymptotically the best possible for constant values of L unless $P = NP$ as recently proved by Chalermsook et al. [13].

Elbassioni et al. [19] studied the limited-supply highway and tollbooth problems, however for *non-single-minded* drivers. Limited-supply pricing problems have also been studied in their *envy-free* version [26]: the goal here is to compute a maximum-profit pricing so that each client that can afford her bundle actually gets it. Cheung and Swamy [17] provided a $O(\log U)$ approximation for envy-free limited-supply highway with uniform capacities U . Observe that our algorithm does not guarantee envy-freeness. We also remark that requiring envy-freeness can substantially decrease the optimal profit, hence studying limited-supply pricing problems without this additional constraint makes sense in many applications.

The NuLs-Highway problem has several aspects in common with the well-studied *Unsplittable Flow on a Path* problem (UFP). In this problem we are given a path graph $G = (V, E)$, with edge capacities $\{u_e\}_{e \in E}$, and a set of tasks T , where each task i is characterized by a demand d_i , a subpath P_i of G , and a weight w_i . The goal is to select a maximum weight subset S of tasks such that the total demand $\sum_{i \in S: e \in P_i} d_i$ of selected tasks using each edge e is at most u_e . The current best approximation for this problem is $5/3 + \epsilon$ [24], improving on earlier results [2, 10, 6, 27, 15, 11, 8, 4]. The problem also admits a QPTAS [5, 7]. There is also a line of research on finding LP relaxations with small integrality gap for UFP [1, 11, 14].

1.3 Preliminaries

For any positive integer q let $[q] := \{1, 2, \dots, q\}$. We are given an $\epsilon > 0$ and assume w.l.o.g. that $1/(2\epsilon)$ is integral and $\epsilon \leq 1/2$. Let (OPT, p^*) denote an optimum solution to the considered instance, with drivers OPT and prices p^* , and opt be its profit. W.l.o.g., OPT contains only drivers with strictly positive profit. Standard reductions (see e.g. [25]) imply the following.

► **Lemma 6.** *By losing a factor $1 + \epsilon$ in the approximation, we can reduce in polynomial time a given instance of Ls-Highway to an instance of the same problem with $O(m^2/\epsilon)$ edges such that: (1) Budgets are integers between 1 and $\frac{m}{\epsilon}$; (2) Optimal prices take values in $\{0, 1\}$.*

Given the above reduction, we can assume that the sum P^* of the optimal prices is known by trying all the $O(m^2/\epsilon)$ possibilities.

For each edge e let $D_e := \{i \in D : e \in P_i\}$ be the drivers whose path contains e , and, for a subpath G' , $D(G') := \{i \in D : P_i \subseteq G'\}$ be the drivers whose path is contained in G' . Given prices p and a subpath G' , we let $p(G') = \sum_{e \in G'} p_e$. Given a driver i and prices p , we let the associated profit $\text{pro}(i, p)$ be $p(P_i)$ if this quantity is at most B_i , and 0 otherwise. For a subset of drivers S , $\text{pro}(S, p) = \sum_{i \in S} \text{pro}(i, p)$ is the total profit of those drivers. In case of non-uniform demands, we define $d(S') := \sum_{i \in S'} d_i$.

2 A PTAS for Ls-Highway

In this section we present our PTAS for Ls-Highway.

2.1 Hierarchical decomposition

Consider the input instance after applying the preprocessing step from Lemma 6, with optimal solution (OPT, p^*) . We next describe how to extract an almost optimal solution $\text{OPT}' \subseteq \text{OPT}$ with a convenient structure. Here we use the same construction as in [25].

Let $\Gamma = (1/\epsilon)^{1/\epsilon}$ and $\gamma = 1/(2\epsilon)$. We add dummy edges on the right of G (w.l.o.g. having a price of 1 each in the optimal solution) such that we can assume that $P^* = \Gamma^{\ell^*}$ for some integer $\ell^* = O_\epsilon(\log m)$. Since $n \leq \frac{m^2}{\epsilon}$ we can guess in polynomial time the number of dummy edges that we need and the resulting value of P^* . Let $x \in \{1, \dots, P^*\}$ and $y \in \{1, \dots, 1/\epsilon\}$ be two parameters to be fixed later. We append $P^* \cdot ((1/\epsilon)^y - 1) - x$ additional dummy edges to the left of G and x additional dummy edges to the right of G , resp., and we assume w.l.o.g. that p^* assigns a price of 1 to each one of them. To simplify the notation, we denote by G the resulting path, by p^* the resulting pricing, and by P^* the sum of prices in p^* . Observe that now $P^* = \Gamma^{\ell^*} (1/\epsilon)^y$.

Based on p^* , we define a hierarchical decomposition of G into nested subpaths (*inervals*). The starting point is the interval G of level 0. Given an interval G' of level ℓ , we partition it into Γ subintervals G'_1, \dots, G'_Γ of level $\ell + 1$, with uniform price. Observe that intervals of level ℓ have price $P^\ell := P^*/\Gamma^\ell = \Gamma^{\ell^* - \ell}(1/\epsilon)^y$. We stop the recursion at intervals of level ℓ^* , which have constant price $(1/\epsilon)^y = O_\epsilon(1)$.

For each interval G' we denote by $\ell(G')$ its level. We say that a driver i is at level ℓ if P_i is fully contained in an interval of level ℓ but in no interval of level $\ell + 1$. For each driver i , we let $\ell(i)$ be its level and $q(i)$ be the number of intervals of level $\ell(i) + 1$ which are fully contained in P_i . Based on the above decomposition and notation, we define an approximate profit function pro^* for each driver i of level $\ell(i) < \ell^*$ as follows

$$\text{pro}^*(i) = \begin{cases} 0 & \text{if } q(i) < \gamma \text{ or } q(i) \cdot P^{\ell(i)+1} > B_i \\ q(i) \cdot P^{\ell(i)+1} & \text{otherwise.} \end{cases} \quad (1)$$

For drivers i of level ℓ^* , we use the standard definition of profit, i.e. $\text{pro}^*(i) = p^*(P_i)$ for $p^*(P_i) \leq B_i$, and $\text{pro}^*(i) = 0$ otherwise. Intuitively, pro^* counts the profit of a driver i in level ℓ only if P_i spans many subintervals of level $\ell + 1$, i.e., at least γ many. For counting the profit, we ignore the two subintervals that P_i only partially overlaps with. Since P_i gets the full profit of at least γ subintervals, the difference is only a factor of $1 + O(\epsilon)$. On the other hand, it could be that $\text{pro}^*(i) > 0$ but i 's budget is exceeded. In this case it is still true that $\text{pro}(i, p^*) \geq \text{pro}^*(i)$ if i had a budget of $\frac{\gamma+2}{\gamma}B_i \leq (1 + O(\epsilon))B_i$. Therefore, intuitively we will pretend in the sequel that all drivers have a (larger) budget of $\frac{\gamma+2}{\gamma}B_i$ and repair this by scaling all edge prices at the very end. As usual, for $S \subseteq D$, $\text{pro}^*(S) = \sum_{i \in S} \text{pro}^*(i)$. We next let $\text{OPT}' \subseteq \text{OPT}$ be the drivers $i \in \text{OPT}$ with strictly positive $\text{pro}^*(i)$ (hence of profit at least $\gamma P^{\ell(i)+1}$).

► **Lemma 7** ([25]). *There exist values of x and y such that $\text{pro}^*(\text{OPT}) = \text{pro}^*(\text{OPT}') \geq (1 - O(\epsilon))\text{opt}$.*

In the following we assume that the input graph is preprocessed according to the pair (x, y) given by Lemma 7: this is w.l.o.g. since we can try all the constantly many options. By pro^* we will denote the approximate profit function given by this choice.

2.2 A Structured Solution

At this point we introduce the most critical and novel idea in our PTAS. We extract from OPT' a large profit subset OPT'' that is even more structured. Intuitively, our goal is to limit the interaction between drivers of different levels. More formally, in OPT'' for each interval G' of some level ℓ' there exists a value m' such that on each edge e of G' the drivers of level ℓ' or larger use at most $\max\{0, u_e - m'\}$ units of capacity and the drivers of levels $\ell' - 1$ or smaller use the remaining capacity. Our algorithm will later select the drivers in the order of their levels, from small to large. Hence, in order to describe the capacity available on G' for the drivers level ℓ' or larger it suffices to know m' for which there are only $m + 1$ possibilities. This will be useful to define our algorithm as a polynomial time dynamic program.

Initially we set $\text{OPT}'' = \text{OPT}'$. Then we gradually move some drivers from OPT'' to a set of *deleted* drivers DEL. We will guarantee that the profit of deleted drivers is a small fraction of the profit of drivers that are still in OPT'' at the end of the process.

■ **Figure 1** For the red driver we delete a set of short drivers whose paths are contained in G'_j , depicted in striped red, that together completely cover G'_j . For the yellow driver we do not find such a set among the remaining drivers and delete drivers (depicted in striped yellow) that cover a maximal set of edges in G'_j . The gray drivers remain in the solution.

It is convenient to describe the construction of DEL in terms of a recursive procedure *delete*. This procedure, described in Algorithm 1, takes as input a tuple (G', ℓ', m') where G' is a subpath, $\ell' \in \{0, \dots, \ell^*\}$ is a level, and $m' \in \{0, \dots, m\}$ is some capacity. Note that w.l.o.g. we can assume that $u_e \leq m$ for each edge e . Furthermore, OPT'' and DEL are considered as global variables. We initialize $(\text{OPT}'', \text{DEL})$ to (OPT', \emptyset) , and run $\text{delete}(G, 0, 0)$.

The high-level idea behind *delete* is as follows. Intuitively, G' is some interval of level ℓ' , and m' is some uniform capacity that is *reserved* along G' to allocate drivers from previous levels whose path overlaps with G' . We remark that m' might exceed the capacity u_e available on some edge $e \in G'$, in which case drivers from level ℓ' or larger cannot use edge e (in other words, the *residual capacity* on edge e is $\max\{0, u_e - m'\}$). Consider the subdivision of G' into subintervals G'_1, \dots, G'_Γ . Let us focus on a specific G'_j , and consider the drivers of level ℓ' in $\text{OPT}'' \cap D(G')$ whose path intersects G'_j , let us denote them by $\text{OPT}''_{\ell'}(G'_j)$. Let $\text{OPT}''_{\ell', \text{part}}(G'_j)$ and $\text{OPT}''_{\ell', \text{span}}(G'_j)$ be the subset of them with $G'_j \not\subseteq P_i$ and $G'_j \subseteq P_i$, resp. In order to define the residual capacity for drivers in $D(G'_j)$ the drivers in $\text{OPT}''_{\ell', \text{span}}(G'_j)$ are not problematic: they use a uniform amount of capacity along G'_j . In order to handle the problematic drivers $\text{OPT}''_{\ell', \text{part}}(G'_j)$, the procedure *delete* removes some drivers from $\text{OPT}'' \cap D(G'_j)$ of level $\ell' + 1$ or larger. This leaves some free capacity that can be used to *ignore* the exact extent by which each $i \in \text{OPT}''_{\ell', \text{part}}(G'_j)$ overlaps with G'_j . Ideally, for each $i \in \text{OPT}''_{\ell', \text{part}}(G'_j)$, we would like to find a minimal set of drivers $\text{DEL}_i(G'_j) \subseteq \text{OPT}'' \cap D(G'_j)$ that spans G'_j , i.e., such that each edge of G'_j is used by at least one driver in $\text{DEL}_i(G'_j)$. However, there might not be enough drivers available for this in which case we rather take one such set with the largest possible span of edges of G'_j . This process is illustrated in Figure 1. After deleting all drivers in the sets $\text{DEL}_i(G'_j)$ for all $i \in \text{OPT}''_{\ell', \text{part}}(G'_j)$ we can safely set the (residual) capacity on edge e for drivers of level larger than ℓ' (whose path is contained in G'_j) to $\max\{0, u_e - m' - m_{\ell'}(G'_j)\}$ where $m_{\ell'}(G'_j) := |\text{OPT}''_{\ell'}(G'_j)|$. We then recurse in each subinterval G'_j of G' by calling $\text{delete}(G'_j, \ell' + 1, m' + m_{\ell'}(G'_j))$. We stop the recursion once we reach an interval of level ℓ^* in which case we do not delete any further drivers.

Consider OPT'' at the end of the root call $\text{delete}(G, 0, 0)$. This is obviously a feasible solution (being a subset of OPT'). Let us show that it has large profit.

► **Lemma 8.** *We have that $\text{pro}^*(\text{OPT}'') \geq (1 - O(\epsilon))\text{pro}^*(\text{OPT}')$*

Proof. Let us show that $\text{pro}^*(\text{DEL}) \leq \frac{4}{\gamma}\text{pro}^*(\text{OPT}'') = O(\epsilon)\text{pro}^*(\text{OPT}'')$. We use a charging argument. Consider an interval G' of level ℓ' and one of its subintervals G'_j . Note that, by construction, the total price over G' and G'_j is $P^{\ell'}$ and $P^{\ell'+1} = P^{\ell'}/\Gamma$, respectively. Consider

■ **Algorithm 1** Procedure to build the sets OPT'' and DEL .

```

delete( $G', \ell', m'$ )
1: if  $\ell' = \ell^*$  then
2:   halt;
3: Let  $G'_1, \dots, G'_\Gamma$  be the partition of  $G'$  into subintervals of level  $\ell + 1$ ;
4: for  $j = 1, \dots, \Gamma$  do
5:   Let  $\text{OPT}''_{\ell'}(G'_j) := \{i \in \text{OPT}'' \cap D(G') : \ell(i) = \ell', E(P_i) \cap E(G'_j) \neq \emptyset\}$ ;
6:   Let  $m_{\ell'}(G'_j) = |\text{OPT}''_{\ell'}(G'_j)|$ ;
7:   Let  $\text{OPT}''_{\ell', \text{part}}(G'_j) := \{i \in \text{OPT}''_{\ell'}(G'_j) : G'_j \not\subseteq P_i\}$ ;
8:   for every  $i \in \text{OPT}''_{\ell', \text{part}}(G'_j)$  do
9:     Let  $E_i(G'_j)$  be the edges used by  $\text{OPT}'' \cap D(G'_j)$ ;
10:    Let  $\text{DEL}_i(G'_j)$  be a minimal subset of  $\text{OPT}'' \cap D(G'_j)$  that spans  $E_i(G'_j)$ ;
11:    Set  $\text{OPT}'' \leftarrow \text{OPT}'' \setminus \text{DEL}_i(G'_j)$  and  $\text{DEL} \leftarrow \text{DEL} \cup \text{DEL}_i(G'_j)$ ;
12:   delete( $G'_j, \ell' + 1, m' + m_{\ell'}(G'_j)$ );

```

any $i \in \text{OPT}''_{\ell', \text{part}}(G'_j)$. Observe that i cannot be deleted in the next recursive calls, hence it finally belongs to OPT'' . Let us charge the loss due to the removal of $\text{DEL}_i(G'_j)$ to i .

By the minimality of $\text{DEL}_i(G'_j)$, each edge $e \in G'_j$ can be used by at most two drivers in $\text{DEL}_i(G'_j)$. It thus follows that $\text{pro}^*(\text{DEL}_i(G'_j)) \leq 2p^*(G'_j) \leq 2P^{\ell'+1}$. On the other hand, $\text{pro}^*(i) \geq \gamma P^{\ell'+1}$, hence $\text{pro}^*(\text{DEL}_i(G'_j)) \leq \frac{2}{\gamma} \text{pro}^*(i)$. Observe that each driver i in OPT'' of level ℓ' can be charged by at most two sets $\text{DEL}_i(G'_a)$ and $\text{DEL}_i(G'_b)$, associated with the (at most) two subintervals G'_a and G'_b of level $\ell' + 1$ that partially overlap with P_i (since the subintervals that are fully spanned by P_i do not charge i). It follows that

$$\text{pro}^*(\text{DEL}) = \sum_{G'_j, i} \text{pro}^*(\text{DEL}_i(G'_j)) \leq \frac{2}{\gamma} \sum_{G'_j, \ell', i \in \text{OPT}''_{\ell', \text{part}}(G'_j)} \text{pro}^*(i) \leq \frac{4}{\gamma} \text{pro}^*(\text{OPT}''). \quad \blacktriangleleft$$

One can show that, if in the recursion above a call $\text{delete}(G', \ell', m')$ arises, then in OPT'' on each edge e of G' the drivers of level ℓ' or larger use at most $\max\{0, u_e - m'\}$ units of capacity. We will use this property in our dynamic program below.

2.3 Dynamic program

We describe an algorithm that computes a solution with a profit of at least $\text{pro}^*(\text{OPT}'')$, pretending that each driver i has an increased budget of $\frac{\gamma+2}{\gamma} B_i$. Afterwards, we scale down the prices by a factor $\frac{\gamma}{\gamma+2}$ in order to respect the original budgets. Together with Lemma 8 this yields an approximation factor of $1 + O(\epsilon)$. For the sake of simplicity, in the sequel we will compute only the value of the desired solution while a straightforward extension yields an algorithm that finds the corresponding set of drivers and also the pricing for the edges.

A natural idea is to define a recursive algorithm that *guesses* the hierarchical decomposition into intervals and the values $m(G'_j)$ corresponding to OPT'' . Suppose we are given a tuple (G', ℓ', m') consisting of an interval G' , a level ℓ' , and an integer m' . The reader may imagine that in the hierarchical decomposition above G' is of level ℓ' and m' units of capacity are taken away on each edge of G' due to drivers of levels smaller than ℓ' . If $\ell' < \ell^*$ we guess the corresponding subdivision into subintervals G'_1, \dots, G'_Γ of level $\ell' + 1$ (each of them having length at least $P^{\ell'+1}$), and the associated values $m(G'_j)$, i.e., we try all possibilities for them. Via a reduction to UFP we select the drivers of level ℓ' : for each driver i with $P_i \subseteq G'$ but

$P_i \not\subseteq G'_j$ for each G'_j , we introduce a task i' with path $P_{i'} := P_i$ and demand $d_{i'} := 1$. For $q(i)$ being the number of intervals G'_j with $G'_j \subseteq P_i$ we define

$$w_{i'} := \begin{cases} 0 & \text{if } q(i) < \gamma \text{ or } q(i) \cdot P^{\ell'+1} > B_i \\ q(i) \cdot P^{\ell'+1} & \text{otherwise.} \end{cases} \quad (2)$$

Observe that to guarantee that we get a profit of $w_{i'}$ from driver i we would need that i has a budget of at least $\frac{\gamma+2}{\gamma} B_i$. This can be fixed at the end by scaling down prices by a factor $\frac{\gamma+2}{\gamma}$ (with a small profit loss). We define the edge capacities by $u'_e := \min\{m(G'_j), \max\{0, u_e - m'\}\}$ for each edge e in a subinterval G'_j . Since all drivers have unit demand this instance of UFP can be solved exactly in polynomial time (see, e.g., [16]). Then we recurse on each interval G'_j such that the corresponding subproblem consists of the tuple $(G'_j, \ell' + 1, m' + m(G'_j))$. Finally, the solution for (G', ℓ', m') is the most profitable solution obtained in this way over all of the guesses above.

If we are given a tuple (G', ℓ', m') with $\ell' = \ell^*$ (the reader may again imagine that G' is an interval of level ℓ^*) then we guess directly the optimal pricing p^* which is one of the polynomially many options to assign a total price of $(1/\epsilon)^y = O_\epsilon(1)$ to the edges of G' such that each edge gets a price in $\{0, 1\}$. Selecting the drivers yields again an instance of UFP. For each driver i with $P_i \subseteq G'$ we introduce a task i' with path $P_{i'} := P_i$, demand $d_{i'} := 1$, and weight $w_{i'} = p(B_i)$ if $p(B_i) \leq B_i$ and $w_{i'} = 0$ otherwise. Each edge e has a capacity of $u'_e := \max\{0, u_e - m'\}$. Again, since all drivers have unit demand we can solve this instance of UFP in polynomial time [16]. The solution for (G', ℓ', m') is then the most profitable solution over all guesses. We return the solution to $(G, 0, 0)$.

As it is described above, this algorithm does not have polynomial running time since in each subproblem we enumerate a polynomial number of guesses and the recursion depth is $\Omega(\log n)$. However, each recursive call is specified by a tuple (G', ℓ', m') and there are only a polynomial number of those. Hence, we can embed our algorithm into a polynomial time dynamic program, see Algorithm 2. For each cell (G', ℓ', m') denote by $DP(G', \ell', m')$ the value stored in it.

■ **Algorithm 2** Dynamic program to approximate Ls-Highway. Here G' denote a subpath of G of length at least $P^{\ell'}$, $\ell' \in \{0, \dots, \ell^*\}$ a level, and $m' \in \{0, \dots, m\}$ a capacity.

compute $DP(G', \ell', m')$

- 1: **if** $\ell' < \ell^*$ **then**
- 2: **for** all possible subdivisions of G' into subpaths G'_1, \dots, G'_Γ of length at least $P^{\ell'+1}$ **each do**
- 3: **for** all possible values $m(G'_j) \in \{0, \dots, m\}$, $j = 1, \dots, \Gamma$ **do**
- 4: construct the UFP instance I' associated with $(G', m', \{G'_j\}_j, \{m(G'_j)\}_j)$;
- 5: solve I' optimally, let $wufp(I')$ be the resulting profit

54:10 Packing Cars into Narrow Roads: PTASs for Limited Supply Highway

Let us consider the recursive partition of G that corresponds to $(G, 0, 0)$, i.e., the intervals of the partition achieving the maximum in Line 7 and recursively their subpartitions achieving the maximum in their respective subproblems. Let \mathcal{G} be the intervals in this partition. For a given $G' \in \mathcal{G}$ we let $\ell'(G')$ and $m'(G')$ denote the associated values of ℓ' and m' . Furthermore, if $\ell'(G') < \ell^*$, let $\{G'_j\}_j$ and $\{m(G'_j)\}_j$ be the corresponding values achieving the maximum in Step 7. By $\text{ALG}(G')$ we denote the UFP solution corresponding to the cell $(G', \ell'(G'), m'(G'))$ that achieves the maximum value in Step 7 or 12. Note that the solution associated with $(G, 0, 0)$ is $\text{ALG} = \cup_{G' \in \mathcal{G}} \text{ALG}(G')$. By p^{ALG} we denote the pricing induced by the values p achieving the maximum in Step 12.

► **Lemma 9.** *ALG respects the capacity constraints.*

Proof. For a given $G' \in \mathcal{G}$, let $\text{ALG}^\downarrow(G') := \cup_{G'' \in \mathcal{G}: G'' \subseteq G'} \text{ALG}(G'')$ be the union of all the UFP solutions corresponding to subintervals contained in G' (G' included). We will show by induction on decreasing values of $\ell'(G')$ that $\text{ALG}^\downarrow(G')$ is a feasible solution w.r.t. residual capacities $\max\{0, u_e - m'(G')\}$ i.e.

$$|D_e \cap \text{ALG}^\downarrow(G')| \leq \max\{0, u_e - m'(G')\}, \quad \forall e \in G'.$$

The claim then follows since $m'(G) = 0$ and $\text{ALG}^\downarrow(G) = \text{ALG}$.

For the base case $\ell'(G') = \ell^*$ this is true by the definition of the edges capacities for the case that $\ell' = \ell^*$. Suppose next the claim is true up to the value $\ell' + 1$, and consider G' with $\ell'(G') = \ell'$. Consider any edge $e \in G'_j$, for some $j \in [\Gamma]$.

$$|D_e \cap \text{ALG}^\downarrow(G'_j)| \leq \max\{0, u_e - m'(G') - m(G'_j)\}.$$

By construction and the definition of the edge capacities for the case that $\ell' < \ell^*$ we have

$$|D_e \cap \text{ALG}(G'_j)| \leq \min\{m(G'_j), \max\{0, u_e - m'(G')\}\}.$$

Thus

$$\begin{aligned} |D_e \cap \text{ALG}^\downarrow(G')| &= |D_e \cap \text{ALG}(G')| + |D_e \cap \text{ALG}^\downarrow(G'_j)| \\ &\leq \min\{m(G'_j), \max\{0, u_e - m'(G')\}\} + \max\{0, u_e - m'(G') - m(G'_j)\} \\ &\leq \max\{0, u_e - m'(G')\}, \end{aligned}$$

where the last inequality follows easily by distinguishing the cases $u_e - m'(G') \leq 0$, $0 < u_e - m'(G') \leq m(G'_j)$, and $u_e - m'(G') > m(G'_j)$. ◀

The proof of the following lemma follows by constraining the choices of the algorithm in order to mimic the construction of OPT'' . The crucial step is to show that, for a subproblem (G', ℓ', m') (corresponding to an interval G' in the hierarchical decomposition due to Section 2.1) the drivers in $\text{OPT}'' \cap D(G')$ of level ℓ' (denote them by $\text{OPT}''(G', \ell')$) define a feasible solution for the associated UFP instance whose weight is precisely $\text{pro}^*(\text{OPT}''(G', \ell'))$ by the definition of the tasks weights of these instances.

► **Lemma 10.** $DP(G, 0, 0) = \text{pro}^*(\text{ALG}) \geq \text{pro}^*(\text{OPT}'')$.

Finally, we scale down the price on each edge by a factor $\frac{\gamma+2}{\gamma} \leq 1 + O(\epsilon)$, i.e. we return the solution $(\text{ALG}, \frac{\gamma}{\gamma+2} p^{\text{ALG}})$. This way, all drivers in ALG respect the original budgets and we achieve a profit almost as large as $DP(G, 0, 0)$.

► **Lemma 11.** $\text{pro}(\text{ALG}, \frac{\gamma}{\gamma+2} p^{\text{ALG}}) \geq \frac{\gamma}{\gamma+2} DP(G, 0, 0)$.

Proof. It is sufficient to show that, after scaling prices, the budget of each driver $i \in \text{ALG}$ is not exceeded. It then follows that the profit associated with i is precisely $\frac{\gamma}{\gamma+2}$ times its weight w_i in the corresponding UFP instance. W.l.o.g. we can assume that $w_i > 0$. If the level ℓ of i is ℓ^* , the claim is trivial since $\text{pro}(i, p^{\text{ALG}}) = w_i$. In other words, the budget of i is respected even without scaling the prices. Otherwise, with the usual notation, by definition we have that $q(i) \geq \gamma$ and $q(i) \cdot P^\ell \leq B_i$. By construction the total price associated with i is

$$p^{\text{ALG}}(P_i) \leq (q(i) + 2)P^\ell \leq \frac{\gamma + 2}{\gamma} q(i)P^\ell \leq \frac{\gamma + 2}{\gamma} B_i.$$

Hence $\frac{\gamma}{\gamma+2} p^{\text{ALG}}$ does not violate the budget of i as required. \blacktriangleleft

Our algorithm runs in polynomial time since we have a polynomial number of DP-cells and the computation for each takes polynomial time. Now the proof of Theorem 1 follows immediately from Lemmas 8-11.

3 A PTAS for NuLs-Highway with Uniform Budgets

In this section we present a PTAS for NuLs-Highway when all drivers have the same budget B . It is not hard (modulo technicalities) to extend our result to the case that the ratio of largest to smallest budget is upper bounded by a given constant.

We will use the following folklore result for the highway problem (and more generally for item pricing problems), that immediately extends to Ls-Highway and NuLs-Highway.

► **Lemma 12** (Close To Budget Lemma). *Given any $\alpha \in (0, 1]$, in any optimal solution (OPT, p^*) to NuLs-Highway at least a fraction $(1 - \alpha)$ of the profit is due to drivers whose profit is at least α times their budget.*

Proof. Assume by contradiction the claim is not true, and consider the drivers $i \in S \subseteq \text{OPT}$ whose profit in p^* is less than $\alpha \cdot B_i$. Then the pricing p^*/α achieves a profit larger than OPT from S , a contradiction. \blacktriangleleft

Let us first show that a solution with a convenient structure exists. Let (OPT, p^*) be an optimal solution. Using Lemma 6 we can assume that the price of each edge is in $\{0, 1\}$ and that $B \in \{1, \dots, m/\epsilon\}$. Let P^* be the sum of the optimal prices, and h^* be the smallest integer such that $P^* \leq (h^* - 1)\frac{B}{\epsilon}$. We guess P^* and hence we then also know h^* . For a choice of $x \in \{0, \dots, \frac{1}{\epsilon}B - 1\}$ to be defined later, we append x edges to the left of the input graph G , and $y = (h^* - 1)\frac{B}{\epsilon} - P^* + \frac{1}{\epsilon}B - x$ edges to its right. W.l.o.g. we assume that each new edge has a price of 1 in (OPT, p^*) . For simplicity, we still denote by G the resulting graph, by p^* its optimal pricing, by P^* the total price of all edges and we define $h^* := P^*\epsilon/B$. Observe that $p^*(G) = h^*\frac{B}{\epsilon}$.

By $\text{OPT}' \subseteq \text{OPT}$ we denote the drivers i whose profit in p^* is at least $\epsilon \cdot B_i$. By applying Lemma 12 with $\alpha = \epsilon$ one has that $\text{pro}(\text{OPT}', p^*) \geq (1 - \epsilon)\text{opt}$. We next define a solution $(\text{APX}, p^{\text{apx}})$, with $\text{APX} \subseteq \text{OPT}'$. Subdivide G in h^* subpaths B_j (blocks) with total price exactly $\frac{B}{\epsilon}$ each. Discard all drivers $i \in \text{OPT}'$ whose path P_i contains edges in two different blocks: let APX be the remaining drivers. Subdivide each B_j into $1/\epsilon^3$ subpaths $B_{j,k}$ of optimal price exactly $\epsilon^2 B$ each (sub-blocks). In p^{apx} set the price of the rightmost edge in each sub-block to $\frac{1}{1+\epsilon} \cdot \epsilon^2 B$ and the price of any other edge to zero (note that we use fractional prices even though we assumed the optimal solution to have prices in $\{0, 1\}$).

Let us show that the profit of the new solution is large enough for a proper choice of x .

► **Lemma 13.** *There is a choice of x in the above construction such that $\text{pro}(APX, p^{apx}) \geq (1 - O(\epsilon)) \text{opt}$.*

We devise now a dynamic program that computes a solution with a profit of at least $\text{pro}(APX, p^{apx})$. Intuitively, it guesses step by step the above partition into blocks. Then for each block B it guesses its partition into subblocks, sets a price of $\frac{1}{1+\epsilon} \cdot \epsilon^2 B$ to the rightmost edge of each subblock and computes a subset of drivers from $D(B)$ maximizing the profit from the selected drivers. The problem of selecting these drivers yields special instances of UFP (one for each block) in which there are $1/\epsilon^3$ special edges (the edges with non-zero price) such that each input task uses at least one of them (all other drivers yield zero profit and can be discarded). We invoke the known PTAS for this special case [23].

Formally, first we guess the value for $x \in \{0, \dots, \frac{1}{\epsilon} B - 1\}$ due to Lemma 12. Observe that $B \leq m/\epsilon$ due to Lemma 5 and hence there are only m/ϵ^2 options for x . We start by preprocessing the instance as described before for the considered x : let N be the final number of edges, and let us label them from 1 to N from left to right. Let $G_{\ell,r}$ be the subpath of G with leftmost edge ℓ and rightmost edge r . The DP table is indexed by pairs (r, h) where r is some edge and $h \in \{1, \dots, h^*\}$. Intuitively, the value of $DP(r, h)$ is the maximum profit that is achievable by drivers whose path is contained in $G_{1,r}$ in the following way:

1. We divide $G_{1,r}$ into h blocks B_j , subdivide each block into $1/\epsilon^3$ sub-blocks, and assign the price $\frac{\epsilon^2 B}{1+\epsilon}$ to the rightmost edge of each sub-block (and 0 otherwise).
2. We select a set of drivers such that the path of each driver is fully contained in some block.

As usual, we can associate to $DP(r, h)$ a specific solution of the same profit. At the end, we output the solution in the cell $DP(N, h^*)$.

Consider a given DP-cell $DP(r, h)$. For all values ℓ with $1 \leq \ell < r$ we do the following: we partition $G_{1,r}$ into a block $G_{\ell,r}$ and a remaining part $G_{1,\ell-1}$. We consider all the possible $O(n^{1/\epsilon^3})$ ways to subdivide $G_{\ell,r}$ into sub-blocks $B_{\ell,r}^1, \dots, B_{\ell,r}^{1/\epsilon^3}$ such that none of them is empty. For any such choice, we define a UFP instance $UFP(\{B_{\ell,r}^k\}_k)$ as follows. The graph is $G_{\ell,r}$, with the corresponding edge capacities u_e , $e \in G_{\ell,r}$. For each driver i with $P_i \subseteq G_{\ell,r}$, we define a task i' with path $P_{i'} := P_i$ and demand $d_{i'} := d_i$. We define its weight $w_{i'}$ as follows: assign price $\frac{\epsilon^2 B}{1+\epsilon}$ to the rightmost edge in each sub-block; set $w_{i'}$ to the total price on the edges of $P_{i'}$ if this is at most B_i , and 0 otherwise. We discard a task i' if with $w_{i'} = 0$.

Note that in this instance of UFP each task must use one of the $1/\epsilon^3$ edges with non-zero price. We invoke the PTAS in [23, Theorem 3.3] for this special case. Let $\text{alg}(\ell, r)$ be the maximum weight of any computed UFP solution for this choice of ℓ (over all partitions $B_{\ell,r}^1, \dots, B_{\ell,r}^{1/\epsilon^3}$). Observe that this value depends only on ℓ and r . If $r - \ell + 1 < 1/\epsilon^3$ then there can be no partition in which all sub-blocks are non-empty and therefore we set $\text{alg}(\ell, r) = 0$. Given the above quantities, we define

$$DP(r, h) := \max_{1 \leq \ell < r} \{\text{alg}(\ell, r) + DP(\ell - 1, h - 1)\}$$

where we define $DP(0, h) = 0$ for all h and $DP(r, 0) = 0$ for all r . Finally, we output the solution in the DP-cell $DP(N, h^*)$.

Abstract

In a wind farm turbines convert wind energy into electrical energy. The generation of each turbine is transmitted, possibly via other turbines, to a substation that is connected to the power grid. On every possible interconnection there can be at most one of various different cable types. Each cable type comes with a cost per unit length and with a capacity. Designing a cost-minimal cable layout for a wind farm to feed all turbine production into the power grid is called the WIND FARM CABLING PROBLEM (WCP).

We consider a formulation of WCP as a flow problem on a graph where the cost of a flow on an edge is modeled by a step function originating from the cable types. Recently, we presented a proof-of-concept for a negative cycle canceling-based algorithm for WCP [14]. We extend key steps of that heuristic and build a theoretical foundation that explains how this heuristic tackles the problems arising from the special structure of WCP.

A thorough experimental evaluation identifies the best setup of the algorithm and compares it to existing methods from the literature such as MIXED-INTEGER LINEAR PROGRAMMING (MILP) and Simulated Annealing (SA). The heuristic runs in a range of half a millisecond to under two minutes on instances with up to 500 turbines. It provides solutions of similar quality compared to both competitors with running times of one hour and one day. When comparing the solution quality after a running time of two seconds, our algorithm outperforms the MILP- and SA-approaches, which allows it to be applied in interactive wind farm planning.

1 Introduction

Wind energy becomes increasingly important to help reduce effects of climate change. As of 2017, 11.6% of the total electricity demand in the European Union is covered by wind power [24]. Across the Atlantic, the state of New York aims at installing 2.4 GW of offshore wind energy capacity by 2030, which could cover the demand of 1.2 million homes [19].

In an offshore wind farm a set of turbines generate electrical energy. From offshore substations the energy is transmitted via sea cables to an onshore grid point. One of the biggest wind farms currently planned is Hornsea Project Three in the North Sea with up to 300 turbines and twelve substations [1]. To transport turbine production to the substations, a system of cables links turbines to substations (*internal cabling*) where multiple turbines may be connected in series. The designer of a wind farm has various cable types available, each of which with respective costs and thermal capacities. The latter restricts the amount of energy that can be transmitted through a cable. Planning a wind farm as a whole consists of various steps, including determining the locations for turbines and substations, laying out the connections from substations to the grid point, and designing the internal cabling. The planning process comes with a high level of complexity, which automated approaches struggle with [23]. Therefore, one might opt for decoupling the planning steps. We call the task of finding a cost-minimal internal cabling of a wind farm with given turbine and substation positions, as well as given turbine production and substation capacities, the WIND FARM CABLING PROBLEM (WCP). Since WCP is a generalization of the \mathcal{NP} -hard problem CAPACITATED MINIMUM SPANNING TREE [21], it is \mathcal{NP} -hard as well.

Due to the overall cost of a wind farm, using one day of computation time or more arguably is a reasonable way to approach WCP. Such computation times, however, are not appropriate for an interactive planning process: Imagine a wind farm planner uses a planning tool which allows altering turbine positions to explore their influence on possible cable layouts. In that case, computation times of at most several seconds are desirable.

1.1 Contribution and Outline

We extend our recent proof-of-concept, in which negative cycle canceling is applied to a formulation of WCP as a network flow problem (cf. Section 3) with a step cost function representing the cable types [14]. The idea of negative cycle canceling is to iteratively identify cycles in a graph in which the edges are associated with the costs of (or gains from) changing the flow. Normally, a cycle of negative total cost corresponds to a way to decrease the cost of a previously found flow. Due to the step cost function, however, not every negative cycle helps improve a solution to WCP. We explore this and other issues for negative cycle canceling that arise from the step cost function in the flow problem formulation for WCP. We present a modification of the Bellman-Ford algorithm [3, 9] and build a theoretical foundation that explains how the modified algorithm addresses the aforementioned issues, e. g., by being able to identify cycles that actually improve a solution. This modification works on a subgraph of the line graph (cf. page 6) of the input graph and can be implemented in the same asymptotic running time as the original Bellman-Ford algorithm.

We further extend that heuristic by identifying two key abstraction layers and applying different strategies in those layers. Using different initializations is hinted at in the section on future work in [14]. We follow this hint and design eight concrete initialization strategies. In another layer, we propose a total of eight so-called “delta strategies” that specify the order in which different values for flow changes are considered.

In [14] we compared the Negative Cycle Canceling (NCC) algorithm to a MIXED-INTEGER LINEAR PROGRAM (MILP) using the MILP solver Gurobi with one-hour running times on benchmark sets from the literature [17]. We extend this evaluation by identifying the best of our variants and by comparing its results to the results of MILP experiments after running times of two seconds, one hour, and one day on the same benchmark sets. A running time of two seconds helps identify the usefulness of the NCC algorithm to an interactive planning process. The other running times stand for non-time-critical planning. We also compare the algorithm to an approach using Simulated Annealing [17] with different running times. The results show that our heuristic is very fast since it terminates on instances with up to 500 turbines in under two minutes. At two seconds our algorithm outperforms its competitors, making it feasible for interactive wind farm planning. Even with longer running times for the MILP- and SA-approaches, our algorithm yields solutions to WCP of similar quality but in tens of seconds.

In Section 2 we review existing work on WCP and negative cycle canceling. In Section 3 we define WCP as a flow problem. We give theoretical insights on the difference to standard flow problems and present and analyze our Negative Cycle Canceling algorithm in Section 4. An extensive experimental evaluation of the algorithm is given in Section 5. We conclude with a short summary of the results and outline possible research directions (see Section 6).

2 Related Work

In one of the first works on WCP, a hierarchical decomposition of the problem was introduced [4]. The layers relate to well-known graph problems and heuristics for various settings are proposed. Since then, considerable effort has been put into solving different variants of WCP. Exact solutions can be computed using MIXED-INTEGER LINEAR PROGRAM (MILP) formulations including various degrees of technical constraints, e. g., line losses, component failures, and wind stochasticity [18]. However, sizes of wind farms that are solved to optimality in reasonable time are small. Metaheuristics such as Genetic Algorithms [25, 6] or Simulated Annealing [17] can provide good but not necessarily optimal solutions in relatively short computation times.

We applied negative cycle canceling to a suitable flow formulation for WCP [14], but there is still an extensive agenda of open questions such as investigating the effect of other cable types, a comparison to existing heuristics, and using the solution as warm start for a MILP solver. Originally, negative cycle canceling is proposed in the context of minimum cost circulations when linear cost functions are considered [16]. The algorithm for the Minimum-Cost Flow Problem based on cycle canceling with strongly polynomial running time runs in $\mathcal{O}(nm(\log n) \min\{\log(nC), m \log n\})$ time on a network with n vertices, m edges, and maximum absolute value of costs C [12]. The bound for the running time of this algorithm was later tightened to $\Theta(\min\{nm \log(nC), nm^2\})$ [22]. Negative cycle canceling has also been used for problems with non-linear cost functions. Among these are multicommodity flow problems with certain non-linear yet convex cost functions based on a queueing model [20] and the Capacity Expansion Problem for multicommodity flow networks with certain non-convex and non-smooth cost functions [7]. A classic algorithm for finding negative cycles is the Bellman-Ford algorithm [3, 9] with heuristic improvements [13, 11]. An experimental evaluation of these heuristics and other negative cycle detection algorithms is given in [5].

A step cost function similar to the one in WCP appears in a multicommodity flow problem, for which exact solutions can be obtained by a procedure based on Benders Decomposition [10]. However, this procedure is only evaluated on instances with up to 20 vertices and 37 edges and

some running times exceed 13 hours. While our approach does not guarantee to solve WCP to optimality, our evaluation shows that the solution quality is very good compared to the MILP with running times not exceeding two minutes on wind farms with up to 500 turbines.

3 Model

The model presented in this paper is based on an existing flow model for WCP [14]. We briefly recall the model. Given a wind farm, let V_T and V_S be the sets of turbines and substations, respectively. We define a vertex set V of a graph by $V = V_T \cup V_S$. For any two vertices u and v that can be connected by a cable in the wind farm, we define exactly one directed edge $e = (u, v)$, where the direction is chosen arbitrarily. We obtain a directed graph $G = (V, E)$ with $V = V_T \cup V_S$ and $E \subseteq (V \times V) \setminus (V_S \times V_S)$ such that $(u, v) \in E$ implies $(v, u) \notin E$. There are no edges between any two substations since we consider the wind farm planning step in which all positions of turbines and substations, as well as the cabling from substations to the onshore grid point have been fixed. We assume that all turbines generate one unit of electricity. Note that our algorithm can be easily generalized to handle non-uniform integral generation. Substations have a capacity $\text{cap}_{\text{sub}}: V_S \rightarrow \mathbb{N}$ representing the maximum amount of turbine production they can handle and each edge has a length given by $\text{len}: E \rightarrow \mathbb{R}_{\geq 0}$ representing the geographic distance between the endpoints of the edge.

A *flow* on G is a function $f: E \rightarrow \mathbb{R}$ and for an edge (u, v) with $f(u, v) > 0$ (resp. < 0), we say that $f(u, v)$ units of flow go from u to v (resp. $-f(u, v)$ units go from v to u). For a flow f and a vertex u we define the *net flow in u* by $f_{\text{net}}(u) = \sum_{(w,u) \in E} f(w, u) - \sum_{(u,w) \in E} f(u, w)$. A flow f is *feasible* if the conditions on flow conservation for both turbines (Equation (1)) and substations (Equation (2)) are satisfied and if there is no outflow from any substation (Equations (3) and (4)).

$$f_{\text{net}}(u) = -1 \quad \forall u \in V_T, \quad (1)$$

$$f_{\text{net}}(v) \leq \text{cap}_{\text{sub}}(v) \quad \forall v \in V_S, \quad (2)$$

$$f(u, v) \geq 0 \quad \forall (u, v) \in E : v \in V_S, \quad (3)$$

$$f(v, u) \leq 0 \quad \forall (v, u) \in E : v \in V_S. \quad (4)$$

Let $c: \mathbb{R}_{\geq 0} \rightarrow \mathbb{R}_{\geq 0} \cup \{\infty\}$ be a non-decreasing, left-continuous step function with $c(0) = 0$. This function represents the cable costs and $\sup\{x \in \mathbb{R}_{\geq 0} : c(x) < \infty\}$ is the maximum cable capacity, which we assume to be a natural number. Note that such a function is neither convex nor concave in general. The cost of a flow on a wind farm graph is then given by

$$\text{cost}(f) = \sum_{e \in E} c(|f(e)|) \cdot \text{len}(e). \quad (5)$$

The value of $c(|f(e)|)$ stands for the cost per unit length of the cheapest cable type with sufficient capacity to transmit $|f(e)|$ units of turbine production. With all that, WCP is the problem of finding a feasible flow f on a given wind farm graph that minimizes the cost. There is an analogon to the linear-cost integer flow theorem (e. g. [2, Thm. 9.10]) that guarantees an optimal flow with integral values.

► **Lemma 1.** *Suppose the cost function is discontinuous only at integers and there is a feasible flow. Then, there is a cost-minimal integral flow.*

4 Algorithm

Given a wind farm graph G we define the residual graph R of G with vertices $V(R)$ and edges $E(R)$ by $V(R) = V(G) \cup \{s\}$ and $E(R) = \{e, \bar{e} : e \in E(G)\} \cup \{(v, s), (s, v) : v \in V_S\}$ where \bar{e} is the reverse of e . The new vertex s , the *super substation*, is a virtual substation without capacity, that is connected to all substations. The edges to and from s are used to model the substation capacity constraints and to allow the production of one turbine to be reassigned to another substation.

For a given feasible flow f in G of finite cost and $\Delta \in \mathbb{N}$ we further define *residual costs*, which represent by how much the cost for the edge changes if the flow on the edge is increased by Δ (cf. Figure 1 (a) – (d) for an example). Note that for negative quantities of flow this implies that the absolute value of the flow may be reduced or even the direction of the flow on an edge may change. More formally, we define $\gamma: E(R) \rightarrow \mathbb{R}$ by $\gamma(e) = (c(|f(e) + \Delta|) - c(|f(e)|)) \cdot \text{len}(e)$ for all $e \in E(R)$ that are neither incident to s nor lead to a substation where we alias $f(\bar{e}) = -f(e)$ for all $e \in E(G)$. By this definition the residual costs are infinite if $c(|f(e) + \Delta|) = \infty$, i. e., if the maximal capacity on e is exceeded. For $u \in V_S$ and $v \in V_T$, we set $\gamma(u, v) = \infty$ whenever $f(v, u) < \Delta$ because sending $f(u, v) + \Delta$ units from u to v would otherwise imply that flow leaves a substation. On edges into s , we set $\gamma(u, s) = 0$ if and only if $f(u, s) + \Delta \leq \text{cap}_{\text{sub}}(u)$ and $\gamma(u, s) = \infty$ otherwise. On edges leaving the super substation, we set $\gamma(s, u) = 0$ if and only if $f(u, s) \geq \Delta$ and $\gamma(s, u) = \infty$ otherwise to prevent flow from leaving the substation.

In a nutshell, the Negative Cycle Canceling (NCC) algorithm (Algorithm 1) starts with an initial feasible flow and some value of Δ , computes the residual costs, and looks for a negative cycle¹. If the algorithm finds a negative cycle, it cancels the cycle, i. e., it changes the flow by adding Δ units of flow on all (residual) edges of the cycle. Note that this may decrease the actual amount of flow on edges of G . Then this procedure is repeated with the new flow and a (possibly new) value of Δ . If no negative cycle is found, a new value of Δ is chosen and new residual costs are computed. This loop is repeated until all sensible values of Δ have been considered for a single flow, which is then returned by the algorithm. This flow is of integer-value, since the initial flow is designed to only have integer values and we solely consider natural values for Δ . Without loss of generality we can restrict ourselves to integer flows according to Lemma 1, even though our algorithm does not necessarily find an optimal solution of WCP. One question we answer is to what extent the algorithm benefits from different initial flows and different orders in which the values of Δ are chosen. We present different strategies in Sections 4.3 and 4.4.

The details of the algorithm (cf. Sections 4.1 and 4.2) address problems that arise from the special structure of WCP, namely the non-linear cost function c . Firstly, in classical min-cost flow problems, when c is linear, the cost for changing flow by a certain amount is proportional to the amount of flow change (and the length of the respective edge) and does not depend on the current amount of flow on that edge. Hence, there is no need for computing residual costs for different values of Δ . Secondly, *short* cycles, i. e., cycles of two edges, may have non-zero total cost in WCP (cf. cycle uv_2u in Figure 1 (d)). Canceling such a cycle, however, does not change the flow and therefore does not improve the solution. Hence, only cycles of at least three edges (*long* cycles) are interesting to us because they do not contain both an edge

¹ A *cycle* is a sequence of consecutive edges such that the first edge starts at the same vertex where the last edge ends and such that no two edges start at the same vertex. That is, all cycles are simple. A cycle is said to be *negative* if the sum of residual costs over all edges is negative.

■ **Figure 1** Examples of flows and corresponding residual graphs. (a) shows a wind farm graph. Edges between turbines are of length 2, edges between the substation u and any turbine are of length 3. (b) depicts a cost function induced by two cable types. (c) displays a feasible flow. Dashed lines do not carry any flow. The thickness of solid lines represents the necessary cable type to carry the respective flow. (d) is the residual graph for the flow in (c) and $\Delta = 1$. The super substation is omitted for ease of presentation. There are three negative cycles: uv_2u , uv_2v_1u , and uv_3v_2u in (c). (e) shows the flow obtained by sending one unit of flow along uv_3v_2u in (c). (f) is the residual graph for (e) and $\Delta = 1$. (g) depicts the flow obtained by sending one unit of flow along uv_2v_1u in (c). (h) displays the residual graph for (g) and $\Delta = 1$.

and its reverse. Finding any negative cycle can be done in polynomial time but finding long negative cycles is \mathcal{NP} -hard for general directed graphs [15, Theorem 4 for $k = 3$]. Thirdly, the order of canceling cycles matters (Figure 1 (c) – (g)). In (d), there are two long negative cycles: uv_2v_1u and uv_3v_2u . After canceling uv_3v_2u (Figure 1 (e)), the other cycle uv_2v_1u is not negative anymore. Ultimately, Figure 1 (e) and (f) show that the non-existence of negative cycles in (all) residual graphs does not imply that the underlying flow is optimal – contrary to min-cost flow problems with linear cost functions. In other words, there are flows that represent local but not global minima.

4.1 Detecting Long Negative Cycles

We assume that the reader is familiar with the standard Bellman-Ford algorithm [3, 9], which is a common approach to finding negative cycles. We observed in preliminary experiments that it mostly reports short cycles even if long cycles exist. The reason is that negative residual costs on an edge are repeatedly used if the cost of the reverse edge is, say, zero. In that case, the negative residual cost strongly influences the distance labels on close vertices and overshadows long cycles (see cycle uv_2u in comparison to cycle uv_2v_1u in Figure 1 (d)).

One solution is to prohibit propagating the residual cost of an edge over its reverse edge. To this end, we employ the Bellman-Ford algorithm on the subgraph L of the directed line graph² of R which we obtain from the line graph by removing all edges representing U-turns, i. e., edges of the form (e, \bar{e}) for $e \in E(R)$. We define the cost of an edge (e_1, e_2) in L as $\gamma(e_2)$. At every vertex e of L we maintain a distance label $\ell(e)$ initialized as $\gamma(e)$. Thus, throughout

² The *line graph* $L(G)$ of a directed graph G shows which edges are incident to each other. It is defined by $V(L(G)) = E(G)$ and $E(L(G)) = \{((u, v), (v, w)) : (u, v), (v, w) \in E(G)\}$.

the Bellman-Ford algorithm, $\ell(e)$ represents the length of some walk³ in L starting at any vertex of L and ending at e . By construction of L , the label $\ell(e)$ also stands for some walk in R which ends at the target vertex of e and which does not traverse an edge of R directly after its reverse. Consequently, a cycle C in L corresponds to a closed walk W without U-turns of the same cost in R . In particular, W is not a short cycle, which is what we wanted. It may still occur, however, that W includes an edge and its reverse. In that case, W consists of more cycles that may be negative themselves. Therefore, we decompose the closed walk W into cycles, which, in turn, can be canceled one after another. For more details, refer to Section 4.2.

A downside of running the Bellman-Ford algorithm on the line graph is that more labels have to be stored and the running time of the algorithm is in $\mathcal{O}(|V(L)| \cdot |E(L)|)$, which is worse than the running time on R . We present how to implement an algorithm that directly works on R , that is equivalent to the Bellman-Ford algorithm on L , and that has the asymptotic running time as the original Bellman-Ford algorithm on R . When running the Bellman-Ford algorithm on L , there is one label for every vertex of L . Each of those labels gives rise to a label on an edge of R . The labels at incoming edges of $v \in V(R)$ are used to compute the labels at outgoing edges of v . Let (v, w) and (v, x) be two edges leaving v . Let us assume that (x, v) has the smallest label of all edges entering v . Then, (x, v) is used to relax (v, w) . But it cannot be used to relax (v, x) . To do so, we need the second smallest label of all edges entering v . This yields the following observation.

► **Observation 2.** *For each vertex v of R only the two smallest labels of incoming edges of v are required to correctly update the labels on outgoing edges of v .*

Consequently, throughout our modified version of the Bellman-Ford algorithm, we maintain two distance labels $\ell_1(v)$ and $\ell_2(v)$, and two parent pointers $\text{parent}_1(v)$ and $\text{parent}_2(v)$ for every $v \in V(R)$, respectively. As above, $\ell_i(v)$ with $i = 1, 2$ stands for the length of a U-turn-free walk whose first edge is arbitrary and whose last edge is $(\text{parent}_i(v), v)$. That means that the parent pointers hold the edges that have been used to build the values of the distance labels. The algorithm ensures that $\text{parent}_1(v) \neq \text{parent}_2(v)$ and $\ell_1(v) \leq \ell_2(v)$ for every $v \in V(R)$. If, during a relaxation step, several incumbent labels and a newly computed candidate label have the same value, we break ties in favor of the older labels – as in the original algorithm. With Observation 2 we show reduced bounds for the number of iterations and the overall running time compared to a straightforward implementation on L .

► **Theorem 3.** *If after $2 \cdot |V(R)|$ iterations there is an edge whose label can still be reduced, then there is a negative cycle in L .*

► **Corollary 4.** *A negative cycle in L can be computed in $\mathcal{O}(|V(R)| \cdot |E(R)|)$ time if one exists.*

4.2 Algorithm in Detail

The previously described Bellman-Ford algorithm on L is encapsulated in Algorithm 1. We first compute some initial flow (line 1) using one of eight initialization strategies presented in Section 4.3. In line 3 we compute the residual graph R using a given flow f and a given Δ and run the modified Bellman-Ford algorithm (line 4). In the repeat-loop, we consider one edge after another and check in line 7 if it can be relaxed (again) after the Bellman-Ford algorithm. In that case, we extract a walk W in R with negative costs leading to that edge

³ A *walk* is a sequence of consecutive edges. A walk is called *closed* if the start vertex of the first edge equals the target vertex of the last edge. In particular, every cycle is a closed walk.

by traversing parent pointers. However, canceling W directly may not always improve the costs of the flow as W may still contain an edge and its reverse. We decompose W into a set of simple cycles $\mathcal{C} = \{C_1, \dots, C_k\}$ in line 8 and cancel each cycle independently if it is long and has negative costs (lines 9 to 12). Note that even though W has negative costs, it may happen that only short cycles in \mathcal{C} have negative costs and all long cycles have non-negative costs. In this case we search for another negative cycle in L (line 13).

If no negative cycle in the current graph L is canceled, a new value for Δ is determined according to the *delta strategy* (cf. Section 4.4) in line 14 and new residual costs γ are computed. Line 14 also checks if every possible value for Δ has been used after the last update of f without improving the solution. If so, f is returned.

We apply two well-known speed-up techniques to the Bellman-Ford algorithm. Firstly, if one iteration does not yield any update of any label, then the computation is aborted and no negative cycle can be found in the current residual graph. Secondly, after sorting edges by start vertices, we track whether the labels at a vertex v have been updated since last considering its outgoing edges. If not, then there is no need to relax the outgoing edges.

```

Input: Graph  $G$ , costs  $c$ , edge lengths  $len$ 
Result: A feasible flow  $f$  in  $G$ 
1  $f := \text{InitializeFlow}(G, len)$ ,  $\Delta := \text{InitialDelta}$ 
2 while  $\Delta \neq \text{NULL}$  do
3    $(R, \gamma) := \text{ComputeResidualGraph}(G, c, f, \Delta)$ 
4    $\text{RunBellmanFord}(R, \gamma)$ 
5    $\text{found} := \text{false}$ 
6   foreach  $e \in E(R)$  do
7      $W := \text{FindNegativeClosedWalk}(R, e)$ 
8      $\mathcal{C} := \text{DecomposeWalkIntoCycles}(W)$ 
9     foreach  $C \in \mathcal{C}$  do
10      if  $|C| \geq 3$  and  $\gamma(C) < 0$  then
11         $f := \text{AddFlowOnCycle}(f, C, \Delta)$ 
12         $\text{found} := \text{true}$ 
13      if  $\text{found}$  then break
14    $\Delta := \text{NextDelta}(\Delta, \text{found})$ 
15 return  $f$ 

```

4.3 Initialization Strategies

Before we can start searching for and canceling negative cycles, we need some feasible initial flow. To obtain such a flow, we consider eight strategies, which all roughly work as follows. We pick a turbine u whose production has not been routed to a substation yet. We then search for a shortest path P from u to a substation v with free capacity using Dijkstra's algorithm [8]. The search only considers edges on which the production of the turbine can be routed, i. e., it ignores congested edges. We then route the production of u along P to v .

We consider two metrics to compute shortest paths. Either we use the lengths defined by len (cf. Section 3) or we assume a length of 1 for every edge. Turbine production can either be routed to a nearest or a farthest (in the sense of the respective metric) substation with

free capacity. There are two ways in which the flow is updated: The simpler variant routes only the production of u along P , i. e., the flow along P is increased by 1. The other variant greedily collects as much production from u and other turbines on P as possible without violating any capacity constraints. The resulting flows are integral since the substation capacities and the maximum cable capacity are natural numbers. If no feasible flow of finite cost is found during the initialization, the algorithm returns without a result.

This yields eight initialization strategies, which we name as follows. The base part of each name is either **BFS** if unit distances are used or **Dijkstra** (abbr. **Dijk**) if the distances given by len are used. This part is followed by a suffix specifying the target substation: **Any** (abbr. **A**) for the nearest and **Last** (abbr. **L**) for the farthest substation. An optional prefix of **Collecting** (abbr. **C**) means that the production is greedily collected along shortest paths. For example, **CollectingDijkstraLast** (abbr. **C-Dijk-L**) iterates over all turbines and for each turbine u it finds the substation v such that the shortest path given by len from u to v is longest among all substations. Along a shortest path from u to v , turbine production is collected greedily.

4.4 Delta Strategies

A delta strategy consists of two parts: an initial value for Δ and a function that returns the value of Δ for the following iteration. We discuss eight delta strategies. The simplest one starts with $\Delta = 1$ and increments Δ until a negative cycle is canceled. Then, Δ is reset to 1. We call this strategy **Inc** (as in increasing). Similarly, **Dec** (as in decreasing) starts with the largest possible value for Δ , which is twice the largest cable capacity. Then, Δ is decremented until a cycle is canceled and reset to the largest value. The third strategy **IncDec** behaves like **Inc** until a negative cycle is canceled. Then, it decrements Δ until $\Delta = 1$ and behaves like **Inc** again. To improve performance, all Δ can be skipped during incrementation up to the last value of Δ for which a negative cycle was canceled. The fourth strategy **Random** returns random natural numbers between one and the maximum possible value for Δ . Between any two cycle cancellations, no value is repeated.

For each strategy, we consider the following modification: After canceling a negative cycle, we retain the current value of Δ , recompute the residual costs with the new flow, and run the Bellman-Ford algorithm again. We repeat this, until Δ does not yield a negative cycle. In that case, Δ is changed according to the respective delta strategy. We call the strategies after the modification **StayInc**, **StayDec**, **StayIncDec**, and **StayRandom** (or **S-Inc**, **S-Dec**, **S-IncDec**, and **S-Random** for short).

5 Experimental Evaluation

In the previous sections, we introduce a heuristic with various strategies for the WCP. We first use statistical tests to evaluate these strategies and identify the best ones. Using the result we compare the best *variant* (i. e., best combination of initialization and delta strategy) with different base line algorithms for the WCP namely solving an exact MILP formulation and a Simulated Annealing algorithm [17]. In preliminary experiments a comparison of the MILP solvers Gurobi and CPLEX shows that Gurobi tends to produce better solutions. We therefore use Gurobi to solve the MILP formulation. However, getting an optimal solution takes too long in almost all instances. Thus, we restrict Gurobi to different maximum running times.

For our evaluation we use benchmark sets for wind farms from the literature [17] consisting of wind farms of different sizes and characteristics: small wind farms with exactly one substation (\mathcal{N}_1 : 10–79 turbines), wind farms with multiple substations (\mathcal{N}_2 : 20–79 turbines,

■ **Table 1** Comparison of delta strategies over all initialization strategies. An entry in row i and column j shows on how many instances strategy i produces better solutions than strategy j . Values are marked by a star if they are significant with $p < 10^{-2}$ and by two stars if $p < 10^{-4}$. The best strategy is marked in green.

\mathcal{N}_3 : 80–180 turbines, \mathcal{N}_4 : 200–499 turbines), and complete graphs (\mathcal{N}_5 : 80–180 turbines). Our code is written in C++14 and compiled with GCC 7.3.1 using the `-O3 -march=native` flags. All simulations are run on a 64-bit architecture with four 12-core CPUs of AMD clocked at 2.1 GHz with 256 GB RAM running OpenSUSE Leap 15.0. We use Gurobi 8.0.0 and all computations are run in single-threaded mode to ensure comparability of the different algorithms.

5.1 Comparing Variants of our Algorithm

In a first step, we want to determine which delta strategy works best. To this end, we randomly select 200 instances per benchmark set. We run our algorithm on each instance with every pair of delta and initialization strategy. We first observe that all variants are fast, with running times between tenths of milliseconds to 4.5 minutes on large instances in the worst case. Since all variants have similarly small running times, we base our decision which variant to choose solely on their solution qualities.

To compare the variants in terms of solution quality, we compute for each delta strategy i and instance m the mean $X_m^{(i)}$ of the solution values over all eight initialization strategies. This gives us 1000 data points per delta strategy. For delta strategies i, j we perform a Binomial Sign Test counting instances with $X_m^{(i)} < X_m^{(j)}$ and $X_m^{(j)} < X_m^{(i)}$, that means for this test we are rather interested in whether strategy i performs better than strategy j on instance m and not by how much i is better than j on m . Table 1 summarizes the results of all tests after Bonferroni-correction by 112 (the number of tests from both delta and initialization strategies). The percentage given in an entry in row i and column j states on how many instances i performs strictly better than j after averaging over all initialization strategies. Note that entries (i, j) and (j, i) need not represent 1000 instances, as two variants may return equal solution values.

In the row **IncDec**, all values are above 50%, four of which are significant at the 10^{-4} -level. The smallest value (52.7% in column **StayIncDec**) stands for 481 instances on which **IncDec** performs better than **StayIncDec**. To the contrary, there are 431 instances on which **StayIncDec** yields better solutions (cf. entry 47.3% in row **StayIncDec** and column **IncDec**). While the differences between the four delta strategies involving **Inc** and **IncDec** are not statistically significant, **IncDec** does seem to have a slight advantage over the others. Hence we consider **IncDec** as the best delta strategy.

In Figure 2 (left), for the dark green curve all instances are ordered by $X_m^{(\text{Random})}/X_m^{(\text{IncDec})}$ in ascending order. For a given value α on the abscissa, the curve shows the relative cost factor of the instance at the α -quantile in the computed order. The other curves work

■ **Figure 2** Evaluation of the NCC Algorithm using different strategies. For each strategy and for each instance, the ratio of the best solution value found by that NCC variant to the best solution value found by the reference variant (marked in red) are computed. They are shown in increasing order. The dashed lines represent the 25% and 75% quantiles of the instances. *Left:* The delta strategies are presented relative to the `IncDec` strategy. Solution values represent the average over all initialization strategies. *Right:* The initialization strategies are presented relative to the `CollectingDijkstraAny` strategy with fixed delta strategy `IncDec`.

accordingly. We see, for example, that `IncDec` works strictly better than `StayInc` on 50.9% of all instances and on 7.3% of all instances `IncDec` outperforms `Inc` by at least 0.5% in cost ratio. The minimum ratios range between 0.868 (`Random`) and 0.918 (`StayIncDec`) and the maximum ratios are between 1.069 (`StayDec`) and 1.126 (`StayIncDec`).

Next, we want to find an initialization strategy after fixing `IncDec` as the delta strategy. We pair each initialization strategy with `IncDec` on the same 1000 instances. Table 2 summarizes the results of all pairwise tests after Bonferroni-correction with factor 112. We see that initialization strategies that route turbine production to the nearest substations outperform their counterparts choosing the farthest substations. Among the former, strategies using Euclidean distances work significantly better than strategies involving BFS. In Figure 2 (right) we depict ratios of solution values compared to `CollectingDijkstraAny`. The minimum ratios are between 0.65 and 0.72 for all initialization strategies other than `DijkstraAny`, which is at 0.971. The maximum ratios range between 1.05 and 1.10 for `DijkstraAny`, `BFSLast`, and `CollectingBFSLast` and are around 1.17 for all others. We see that for the main part there is hardly any difference between collecting strategies and their non-collecting counterparts. It stands out that on roughly 40% of all instances `CollectingDijkstraAny` is better than `BFSAny` and `CollectingBFSAny` by 0.5% and better than `BFSLast` and `CollectingBFSLast` by 1%. `CollectingDijkstraAny` has a slight but not significant advantage over `DijkstraAny`. We therefore declare `CollectingDijkstraAny` paired with `IncDec` as our best variant.

Table 3 shows the running time characteristics of `CollectingDijkstraAny` paired with `IncDec`. Running times range between tenths of milliseconds to under two minutes.

■ **Table 2** Comparison of the initialization strategies when the delta strategy `IncDec` is fixed. An entry in row i and column j shows on how many instances strategy i produces better solutions than strategy j . Values are marked by a star if they are significant with $p < 10^{-2}$ and by two stars if $p < 10^{-4}$. The best strategy is marked in green.

max	215	314	3.1k	89.6k	106k

5.2 Comparing our Best Variant with Gurobi

We compare our algorithm in its best variant, i. e., `CollectingDijkstraAny` with `IncDec`, with Gurobi on a MILP formulation which uses a binary variable for each edge and cable type to model the step cost function. We randomly select 200 instances per benchmark set from the benchmark sets in [17].

In Figure 3 we plot the ratio of the best solution value found by our algorithm to Gurobi’s best solution at running times of two seconds, one hour, and one day for each benchmark set separately. As mentioned before, these running times represent both interactive and non-time-critical planning. Since our algorithm terminates in under two minutes, the comparisons in Figure 3 (middle and right) use the solution our algorithm provides at termination. While discussing the plots, we also discuss the so-called relative gaps, a standard notion from MIXED-INTEGER LINEAR PROGRAMMING. From the one-day MILP experiments we know a proven lower bound (lb) on the optimal solution value for each instance. For any instance, any maximum running time and for both the MILP and the NCC algorithm take best solution value (ub) found at the maximum running time and compute $\text{ub-lb}/\text{ub}$. This value is in the unit interval and gives information on how “bad” the solution value can be compared to the (unknown) optimal value. Note, however, that a solution might be optimal even though the gap is positive. We refer to the relative gaps as MILP *gap* and NCC *gap*, respectively.

After two seconds our algorithm outperforms Gurobi on all benchmark sets except \mathcal{N}_4 and produces better solutions on 89% of the instances across all benchmark sets. On \mathcal{N}_1 the NCC gaps are on average 14.1% with a maximum of 24.8% compared to MILP gaps of 16.9% on average and at most 43%. For \mathcal{N}_3 , the NCC gaps are on average 37.8% with a spread of only seven percentage points, compared to a mean of 34.6% and a maximum of 45.4% for the MILP gap. The values for \mathcal{N}_2 range between those for \mathcal{N}_1 and \mathcal{N}_3 . The ratios of solution values range between 0.699 and 1.019 for \mathcal{N}_1 , \mathcal{N}_2 , and \mathcal{N}_3 . On \mathcal{N}_4 , which contains the largest instances, our algorithm computes better solutions on 62% of the instances.

■ **Figure 3** Comparison of the NCC algorithm to Gurobi on 200 instances per benchmark set. The ordinate shows the ratio of objective values at various maximum running times of our algorithm to objective values of Gurobi. Running times: *Left*: two seconds, *Middle*: one hour, *Right*: one day.

However, on six instances Gurobi does not find a solution. The instances on which Gurobi is better are on average larger than the other instances in \mathcal{N}_4 . There are 16 instances on which the ratio of solution values exceeds 1.1 with a maximum of 1.223. On those very large instances, detecting negative cycles takes longer and fewer iterations are performed in two seconds. The NCC gaps spread between 31.4% and 57.4% with an average of 42.6%. The MILP gaps are even worse with a mean value of 48.2% and 18 instances above 88.5%. On the complete graphs of \mathcal{N}_5 , our algorithm produces solutions that are at least 75% cheaper than Gurobi's on all but one instance (which has a ratio of 0.420). The gaps, however, are on average at 53.2% for the NCC algorithm and at 99.2% for Gurobi. The large spread in solution values indicates that both Gurobi and our algorithm seem unable to reliably find good solutions within a maximum running time of two seconds.

Within one hour (middle plot in Figure 3) Gurobi finds better solutions than our algorithm on a majority of the instances in all benchmark sets except \mathcal{N}_4 . There our algorithm still yields better solutions in 57.5% of the instances. However, our algorithm is within 1% of Gurobi's best solution on 85.9% and within 2% on 96.8% of all instances. Only on four of 1000 instances (all in \mathcal{N}_5), the ratio exceeds 1.10 with a maximum of 1.203. That means, our algorithm is comparable to Gurobi in solution quality but much faster since it terminates in under two minutes. We make similar observations for running times of one day (right plot in Figure 3). While our algorithm is at least as good as Gurobi only on between 7% (\mathcal{N}_4) and 38.5% (\mathcal{N}_1) of the instances, it is within 1% of Gurobi's solution on 77.6% of all instances. Again, there are only four instances with a ratio worse than 1.10 with a maximum of 1.210. Our algorithm does not profit from long running times since it gets stuck in local minima. Thus, the MILP solver is the better choice if more time is available. Between running times of one hour and day, the gaps look vastly the same and there is hardly any difference between NCC gaps and MILP gaps. They range between zero and 25.0% on \mathcal{N}_1 , clot around 28% for \mathcal{N}_3 and \mathcal{N}_4 and around 34% for \mathcal{N}_5 with seven outliers to the worse by the NCC algorithm.

■ **Figure 4** Comparison of Negative Cycle Canceling algorithm to the Simulated Annealing algorithm on 200 instances per benchmark set. The ordinate represents the ratio of objective values at different maximum running times of our algorithm to objective values of the Simulated Annealing algorithm. *Left*: Running time of two seconds. *Right*: Running time of one hour.

5.3 Comparison to Metaheuristic Simulated Annealing

We compare our best algorithm variant with the best variant of a Simulated Annealing (SA) algorithm [17]. We run the SA algorithm on 200 randomly selected instances per benchmark set (independently selected from other experiments). We compare the best solutions found after two seconds and one hour (Figure 4). After two seconds, our algorithm outperforms the SA algorithm on all instances from \mathcal{N}_3 and on 74.5% and 86.5% on \mathcal{N}_1 and \mathcal{N}_2 , respectively. The minimum ratios are 0.381 for \mathcal{N}_1 and around 0.90 for \mathcal{N}_2 and \mathcal{N}_3 with one instance in \mathcal{N}_2 where the SA algorithm does not find a solution. The maximum ratio on those benchmark sets is at most 1.024. On the larger instances of \mathcal{N}_4 and \mathcal{N}_5 , our algorithm presumably cannot perform sufficient iterations, as the SA algorithm is better on 70% of those instances. Yet, the SA algorithm does not find feasible solutions on 38.5% of instances from \mathcal{N}_5 . The ratios have a wide spread: from 0.203 to 1.256 for \mathcal{N}_4 and 0.788 to 1.482 for \mathcal{N}_5 (save for the instances without a solution from the SA algorithm). After one hour, the SA algorithm provides better solutions than our algorithm on 83% and 90.5% of instances from \mathcal{N}_2 and \mathcal{N}_3 , respectively. Our algorithm, however, stays within 1% in solution quality on 77% on the benchmark sets \mathcal{N}_1 – \mathcal{N}_3 . Again, our algorithm seems to be stuck in local minima. On \mathcal{N}_4 and \mathcal{N}_5 , our algorithm performs better than the SA algorithm on 65.5% and 56.5%, respectively. Apparently, the SA algorithm needs more time to explore the solution space. The minimum ratios of solution values are as low as 0.716 for \mathcal{N}_1 and between 0.908 and 0.996 for the other benchmark sets. The maximum ratios are at most 1.055 for all benchmark sets except \mathcal{N}_5 (1.179). This supports our findings from the MILP experiments that our algorithm is competitive to other approaches to solving WCP within very short amounts of time. In view of an interactive planning process, it stands out that the SA algorithm struggles to find solutions quickly in dense graphs.

6 Conclusion

Based on recently presented ideas [14] we propose and compare numerous variants of a Negative Cycle Canceling heuristic for the WIND FARM CABLING PROBLEM. While all variants run in the order of milliseconds up to 4.5 minutes, they differ significantly in quality. We identify the best variant and use it to compare our heuristic to the MILP solver Gurobi and a Simulated Annealing algorithm from the literature. With these comparisons we are able to solve several open questions [14]. While the MILP solver Gurobi has the potential to find optimal solutions if it runs long enough, our heuristic is able to find solutions of comparable quality in only a fraction of the time. Our algorithm beats Gurobi in finding good solutions in a matter of seconds. We make similar observations when we compare ourselves with a Simulated Annealing approach.

Moving forward, one may investigate how to improve the solution quality of our heuristic. Visually comparing flows from our algorithm and other solution methods may help to identify what kind of more complex circulations improve the solution. It then remains to investigate how these circulations can be detected. Also, methods for escaping local minima such as temporarily allowing worse solutions could help to improve our algorithm. It also remains open whether one can prove any theoretical guarantees on the solution quality or the number of iterations. Along the same lines, any theoretical insights on why one delta or initialization strategy works better than another, or on the order in which cycles should be canceled could help improve the NCC algorithm.

In a broader algorithmic view, the heuristic can be easily generalized to minimum-cost flow problems with other types of cost functions provided that one searches for integral flows. It would be interesting to see how well the heuristic performs there.

Abstract

We study the traveling salesman problem (TSP) in the case when the objective function of the subtour linear programming relaxation is minimized by a *half-cycle point*: $x_e \in \{0, \frac{1}{2}, 1\}$ where the half-edges form a 2-factor and the 1-edges form a perfect matching. Such points are sufficient to resolve half-integer TSP in general and they have been conjectured to demonstrate the largest integrality gap for the subtour relaxation.

For half-cycle points, the best-known approximation guarantee is $\frac{3}{2}$ due to Christofides' famous algorithm. Proving an integrality gap of α for the subtour relaxation is equivalent to showing that αx can be written as a convex combination of tours, where x is any feasible solution for this relaxation. To beat Christofides' bound, our goal is to show that $(\frac{3}{2} - \epsilon)x$ can be written as a convex combination of tours for some positive constant ϵ . Let $y_e = \frac{3}{2} - \epsilon$ when $x_e = 1$ and $y_e = \frac{3}{4}$ when $x_e = \frac{1}{2}$. As a first step towards this goal, our main result is to show that y can be written as a convex combination of tours. In other words, we show that we can *save on 1-edges*, which has several applications. Among them, it gives an alternative algorithm for the recently studied *uniform cover* problem. Our main new technique is a procedure to glue tours over proper 3-edge cuts that are tight with respect to x , thus reducing the problem to a base case in which such cuts do not occur.

1 Introduction

In the **traveling salesman problem (TSP)** we are given a complete graph $G = (V, E)$ together with a vector $c \in \mathbb{R}_{\geq 0}^E$ of edge costs satisfying the triangle inequality: $c_{uv} + c_{vw} \geq c_{uw}$ for $u, v, w \in V$. The goal is to find a minimum cost Hamiltonian cycle of G . The following formulation is a classic linear programming relaxation for TSP [9].

$$\min \left\{ \sum_{e \in E} c_e x_e : \sum_{u \in V \setminus \{v\}} x_{vu} = 2 \text{ for } v \in V, \sum_{v \in S, u \notin S} x_{vu} \geq 2 \text{ for } \emptyset \subset S \subset V, x \in \mathbb{R}_{\geq 0}^E \right\}.$$

Let $\text{SUBTOUR}(G)$ denote the feasible region of this relaxation. We will refer to $\sum_{e \in E} c_e x_e$ as the *objective function*. A *tour* of G is a connected, spanning, Eulerian multi-subgraph of G . It is well known that due to the triangle inequality on the edge costs, a tour of G can be turned into a Hamiltonian cycle of G of no greater cost. For any $x \in \text{SUBTOUR}(G)$, the vector $\frac{3}{2}x$ can be decomposed into a convex combination of tours of G . This follows from a polyhedral analysis of Christofides' famous $\frac{3}{2}$ -approximation algorithm [7, 21, 20]. For a point $x \in \text{SUBTOUR}(G)$, define $G_x = (V, E_x = \{e \in E : x_e > 0\})$ to be the support graph of x . Let $\text{TSP}(G_x)$ be the convex hull of characteristic vectors of tours of G_x . The following conjecture is well-known and widely studied and implies a $\frac{4}{3}$ -approximation algorithm for TSP.

► **Conjecture 1** (The Four-Thirds Conjecture). *If $x \in \text{SUBTOUR}(G)$, then $\frac{4}{3}x \in \text{TSP}(G_x)$.*

However, more than four decades after the publication of Christofides' algorithm, there is still no $(\frac{3}{2} - \epsilon)$ -approximation algorithm known for TSP. For special cases, there has been some progress in the past few years. For example, in the *unweighted* case where the edge costs correspond to the shortest path metric of an unweighted graph, a series of papers improved the $\frac{3}{2}$ factor to $\frac{7}{5}$ [16, 15, 19].

One interesting special case of *weighted* TSP is when the solution $x \in \text{SUBTOUR}(G)$ that minimizes the objective function is half-integer. In the unweighted case, if a half-integer point $x \in \text{SUBTOUR}(G)$ minimizes the objective function, then there is a $\frac{4}{3}$ -approximation algorithm for TSP [15].

► **Problem 2** (Half-integer TSP). *For $x \in \text{SUBTOUR}(G) \cap \{0, \frac{1}{2}, 1\}^E$, henceforth a half-integer point, show $\alpha x \in \text{TSP}(G_x)$ for constant $\alpha \in [1, \frac{3}{2})$.*

Consider a half-integer point $x \in \text{SUBTOUR}(G) \cap \{0, \frac{1}{2}, 1\}^E$ and let $H_x = \{e \in E : x_e = \frac{1}{2}\}$ and $W_x = \{e \in E : x_e = 1\}$. Carr and Vempala showed that in Problem 2, we can assume without loss of generality a stronger condition for $x \in \text{SUBTOUR}(G)$: a *half-integer Carr-Vempala point* is a half-integer point such that the support graph G_x is a cubic graph and for every vertex $u \in V$, there is exactly one edge e incident on u with $x_e = 1$ and two edges f, g incident on u with $x_f = x_g = \frac{1}{2}$. Moreover, H_x forms a Hamilton cycle of G_x , and W_x forms a perfect matching of G_x . If for any half-integer Carr-Vempala point x we have $\alpha x \in \text{TSP}(G_x)$, then for any half-integer point y we have $\alpha y \in \text{TSP}(G_y)$ [6, 4].

We consider a generalization of a half-integer Carr-Vempala point called a *half-cycle point*, which is a half-integer point $x \in \text{SUBTOUR}(G)$ such that the graph G_x is a cubic graph and for every vertex $u \in V$, there is exactly one edge e incident on u with $x_e = 1$ and two edges f, g incident on u with $x_f = x_g = \frac{1}{2}$. This implies that H_x , the half-edges in G_x , forms a 2-factor of G (in which the minimum cycle length is three). Formally, we define a half-cycle point as follows.

► **Definition 3.** *A vector $x \in \text{SUBTOUR}(G)$ is called a half-cycle point if the support graph G_x of x is cubic and 2-edge-connected and $x_e \in \{1, \frac{1}{2}\}$ for all $e \in E_x$.*

Half-cycle points have been studied in restricted cases when all cycles in the 2-factor are triangles [2, 3] or squares [4, 11]. Schalekamp, Williamson and van Zuylen conjectured that the largest gap between $\text{SUBTOUR}(G)$ and $\text{TSP}(G_x)$ occurs for half-cycle points in which the 2-factor consists of odd-cycles [17].¹ We can restate Problem 1 as follows.

¹ Their precise conjecture is that instances of TSP that have an optimal solution $x \in \text{SUBTOUR}(G)$ that is also an optimal *fractional 2-matching* exhibit the largest integrality gap for $\text{SUBTOUR}(G)$. The extreme points of the fractional 2-matching polytope are half-cycle points in which all cycles in the 2-factor are odd [1].

► **Problem 4** (Half-integer TSP). *Let $x \in \mathbb{R}_{\geq 0}^E$ be a half-cycle point. Show $\alpha x \in \text{TSP}(G_x)$ for constant $\alpha \in [1, \frac{3}{2})$.*

We can also state Problem 4 in different way.

► **Problem 5** (Half-integer TSP). *Let $x \in \mathbb{R}_{> 0}^E$ be a half-cycle point. Define vector $y \in \mathbb{R}^{E_x}$ as follows: $y_e = \frac{3}{2} - \epsilon$ for $e \in W_x$ and $y_e = \frac{3}{4} - \delta$ for $e \in H_x$. Show there exists constants $\epsilon, \delta > 0$ such that $y \in \text{TSP}(G_x)$.*

The aforementioned polyhedral analysis of Christofides' algorithm implies the following theorem.

► **Theorem 6** ([7, 21, 20]). *Let $x \in \mathbb{R}_{\geq 0}^E$ be a half-cycle point. Define vector $y \in \mathbb{R}^{E_x}$ as follows: $y_e = \frac{3}{2}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ for $e \in H_x$. Then $y \in \text{TSP}(G_x)$.*

Our main result is the following.

► **Theorem 7**. *Let $x \in \mathbb{R}_{\geq 0}^E$ be a half-cycle point. Define vector $y \in \mathbb{R}^{E_x}$ as follows: $y_e = \frac{3}{2} - \frac{1}{20}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ for $e \in H_x$. Then $y \in \text{TSP}(G_x)$.*

While Theorem 7 is not strong enough to resolve Problem 5 (and therefore Problem 4), it does have several applications. For example, given an edge cost function c for which a half-cycle point $x \in \text{SUBTOUR}(G)$ minimizes the objective function, if the total edge costs of the 1-edges is a constant fraction of the total cost of the half-edges, then by Theorem 7, we obtain an approximation factor better than $\frac{3}{2}$.

Another application is related to the problem of *uniform covers* posed by Sebő [18]. Let x be a *cubic point* if $x \in \text{SUBTOUR}(G) \cap \{0, \frac{2}{3}\}$. Observe that G_x is cubic and 3-edge-connected.

► **Problem 8** (Uniform cover problem). *Let x be a cubic point. Show that $\alpha x \in \text{TSP}(G_x)$ for constant $\alpha \in [1, \frac{3}{2})$.*

Recently, Haddadan, Newman and Ravi gave a positive answer to Problem 8 and showed $\alpha \leq \frac{27}{19} \approx 1.421$ [13]. Previously, Boyd and Sebő had shown that $\alpha \leq \frac{9}{7} \approx 1.286$ if G_x is additionally Hamiltonian [4]. In fact, Theorem 7 gives an alternative way to answer Problem 8.

► **Lemma 9**. *Let x be a half-cycle point. Define vector $y \in \mathbb{R}^{E_x}$ as follows: $y_e = \frac{3}{2} - \epsilon$ for $e \in W_x$ and $y_e = \frac{3}{4} - \delta$ for $e \in H_x$ for constants $\epsilon, \delta \geq 0$. Suppose $y \in \text{TSP}(G_x)$. Then for any cubic point z , we have $\alpha z \in \text{TSP}(G_z)$ for $\alpha = \frac{3}{2} - \frac{\epsilon}{2} - \delta$.*

In other words, suppose that we can *save either on the 1-edges or on the half-edges*. Then we can solve the uniform cover problem. Moreover, Theorem 7 can be used to slightly improve the currently best-known factors for Problem 8. The proofs of Lemma 9 and Theorem 10 can be found in the full version [12].

► **Theorem 10**. *Let x be a cubic point. Then $\alpha x \in \text{TSP}(G_x)$ for $\alpha = 1.416$. If G_x is Hamiltonian, then $1.279x \in \text{TSP}(G_x)$.*

On a high level, our proof of Theorem 7 is based on Christofides' algorithm: We show that a half-cycle point x can be written as a convex combination of spanning subgraphs with certain properties and then we show that vector $y \in \mathbb{R}^{E_x}$, where $y_e = \frac{9}{20}$ for $e \in W_x$ and $y_e = \frac{1}{4}$ for $e \in H_x$, can be used for parity correction. Our main new tool is a procedure to glue tours over *critical cuts*. For $S \subset V$, let $\delta(S) \subset E_x$ denote the subset of edges crossing the cut $(S, V \setminus S)$.

► **Definition 11.** Let x be a half-cycle point. A proper cut² $S \subset V$ in G_x is called *critical* if $|\delta(S)| = 3$ and $\delta(S)$ contains exactly one edge e with $x_e = 1$. Moreover, for each pair of edges in $\delta(S)$, their endpoints in S (and in $V \setminus S$) are distinct.

Observe that a critical cut in G_x is a proper 3-edge cut that is *tight*: the x -values of the three edges crossing the cut sum to 2. Thus, critical cuts are difficult to handle using an approach based on Christofides' algorithm. In particular, using $(\frac{1}{2} - \epsilon)x$ would be insufficient for parity correction of a critical cut if it is crossed by an odd number of edges in the spanning subgraph.

Applying our gluing procedure, we can reduce TSP on half-cycle points to a problem (i.e., base case) where there are only two types of tight 3-edge cuts. The first type of cut is a *vertex cut*, which we show are easier to handle. In particular, the parity of vertex cuts can be addressed with a key tool used by Boyd and Sebö [4] called *rainbow v -trees* (see Theorem 17). We refer to the second type of cut as a *degenerate tight cut*, which is a cut $S \subset V$ such that $|\delta(S)| = 3$, $|S| > 3$ and $|V \setminus S| > 3$ and the two half-edges in $\delta(S)$ share an endpoint in either S or $V \setminus S$. (Observe that for every degenerate tight cut in G_x , there is a 2-edge cut in G_x .) These cuts are also easier to handle. Using this in combination with a decomposition of the 1-edges into few *induced matchings* (see Definition 18), which have some additional required properties, we can prove Theorem 7 for the base case. We discuss gluing procedures in more detail in Section 1.1.

Let us look back at Problem 2. Let x be a *quartic point* if $x \in \text{SUBTOUR}(G) \cap \{0, \frac{1}{2}\}$. Observe that G_x is 4-regular and 4-edge-connected. Yet another equivalent version of Problem 2 is as follows.

► **Problem 12** (Half-integer TSP). Let x be a quartic point. Show $\alpha x \in \text{TSP}(G_x)$ for $\alpha \in [1, \frac{3}{2}]$.

If we assume that the only 4-edge cuts of G_x are its vertex cuts and the number of vertices is even, we can answer this problem.

► **Theorem 13.** Let x be a quartic point. If G_x has an even number of vertices, and G_x does not have any proper 4-edge cuts, then $(\frac{3}{2} - \frac{1}{42})x \in \text{TSP}(G_x)$.

In the case of a quartic point, Theorem 13 could serve as the base case for if we were able to glue over proper 4-edge cuts of G_x . However, the main difference here is that the gluing arguments we presented for half-cycle points can not easily be extended to this case due to the increased complexity of the distribution of patterns. The proof of Theorem 13 can be found in the full version [12].

1.1 Gluing tours over cuts

The approach of gluing solutions over (often) 3-edge cuts and thereby reducing to an instance without such cuts has been used previously for TSP (e.g., [8]) and extensively in the case of two related problems: the **2-edge-connected multigraph problem (2EC)** and the **2-edge-connected subgraph problem (2ECSS)**. In 2EC, we want to find a minimum cost 2-edge-connected spanning multi-subgraph (henceforth, multigraph for brevity), and in 2ECSS, we want to find a minimum cost 2-edge-connected spanning subgraph (i.e., we are not allowed to double edges). Let $2\text{EC}(G_x)$ and $2\text{ECSS}(G_x)$ denote that convex hulls of characteristic vectors of 2-edge-connected multigraphs and subgraphs, respectively, of G_x . Observe that $\text{TSP}(G_x) \subseteq 2\text{EC}(G_x)$ and $2\text{ECSS}(G_x) \subseteq 2\text{EC}(G_x)$.

² A cut $S \subset V$ is *proper* if $|S| \geq 2$ and $|V \setminus S| \geq 2$.

For example, consider the problem of showing $\frac{6}{5}x \in 2\text{ECSS}(G_x)$ for a cubic point x [3]. Here, we can assume that G_x is essentially 4-edge-connected due to the following commonly used observation. Let $S \subset V$ be a subset of vertices such that $|\delta(S)| = 3$ in G_x . We construct graphs, $G_{\bar{S}}$ and G_S by contracting the sets \bar{S} and S , respectively, in G_x to a *pseudovortex*. Suppose that the graphs $G_{\bar{S}}$ and G_S contain no proper 3-edge cuts and suppose we can write αx restricted to the edge set of each graph as a convex combination of 2-edge-connected subgraphs of the respective graph. Let us consider the patterns around the pseudovortices; each vertex can be adjacent to two or three edges and therefore, there are only four possible patterns around a vertex. Moreover, since each pattern appears the same percentage of time (in the respective convex combinations) for each pseudovortex, tours with corresponding patterns can be *glued* over the 3-edge cut. (For a more formal presentation of this argument, see Lemma 3.3 in [11] or Case 2 in Section 3.1.2 in [14].) Thus, for 2ECSS, this gluing procedure is quite straightforward. Gluing has also been used for 2EC, but here it is necessary to make certain extra assumptions to control the number of patterns around a vertex, due to the fact that the distribution of possible patterns is more complex. Carr and Ravi proved that the vector $\frac{4}{3}x \in 2\text{EC}(G_x)$ for a half-integer point x [5]. To control the number of patterns so that they can use gluing, they require some strong assumptions on the multigraphs in their convex combinations: for example, no edge e with $x_e = \frac{1}{2}$ is doubled and some arbitrarily chosen edge is never used.

In contrast, it appears that no such gluing procedure has been used in approximation algorithms for TSP. Indeed, gluing proofs for 2ECSS and 2EC [5, 3, 14] can not be easily extended to TSP for several reasons: (1) As just discussed, they are used for gluing subgraphs (no doubled edges), while for multigraphs, there are often too many different patterns around a vertex. (For TSP, we must allow doubled edges.) (2) They do not necessarily preserve parity of the vertex degrees. Finally, (3) many of the results for 2ECSS and 2EC based on gluing do not result in polynomial-time algorithms.

The main technical contribution of this paper is to show that for a carefully chosen set of tours, we can design a gluing procedure over critical cuts. In particular, we can fix a critical cut $S \subset V$ in G_x and find a convex combination of tours for G_S . Then we can find a set of tours for $G_{\bar{S}}$ such that the distribution of patterns around the pseudovortex corresponding to S matches that of the pseudovortex corresponding to \bar{S} in G_S . This is done by separately matching the pattern for the spanning subgraphs and for the parity correction. In fact, while each vertex may have a different set of patterns around it, we show that the patterns around each vertex can be encapsulated by a single parameter: the fraction of times in the convex combination of spanning subgraphs that a vertex is a leaf. There can be some flexibility in this degree distribution for some arbitrarily chosen vertex, and this is what we exploit to sufficiently control the patterns around a pseudovortex to enable gluing.

1.2 Definitions, tools and notation

► **Definition 14.** Let $G = (V, E)$ be a graph. For a vertex $v \in V$, a *v-tree* of G is a subset F of E such that $|F \cap \delta(v)| = 2$ and $F \setminus \delta(v)$ induces a spanning tree of $V \setminus \{v\}$.

Denote by $v\text{-TREE}(G)$ the convex hull of incidence vectors of *v-trees* of G . The $v\text{-TREE}(G)$ is characterized by the following linear inequalities.

$$\begin{aligned} v\text{-TREE}(G) = \{x \in [0, 1] : x(\delta(v)) = 2, \\ x(E[U]) \leq |U| - 1 \text{ for all } \emptyset \subset U \subseteq V \setminus \{v\}, x(E) = |V|\}. \end{aligned}$$

► **Definition 15.** Let $G = (V, E)$ and v be a vertex of G . Let \mathcal{P} a collection of disjoint subsets of E . A \mathcal{P} -rainbow v -tree of G , is a v -tree of G such that $|T \cap P| = 1$ for $P \in \mathcal{P}$.

► **Definition 16.** Let $G = (V, E)$ and let x be a vector $(0, 1]^E$. Let \mathcal{S} denote a set of subgraphs of G (i.e., each $S \subseteq E$ for each $S \in \mathcal{S}$). If there is a probability distribution $\lambda = \{\lambda_S\}_{S \in \mathcal{S}}$ such that $x = \sum_{S \in \mathcal{S}} \lambda_S \chi^S$, then we say $\{\lambda, \mathcal{S}\}$ is a convex combination for x . If such a probability distribution exists, then we say that x can be decomposed into (or written as) a convex combination of subgraphs in \mathcal{S} .

► **Theorem 17** (Boyd, Sebö [4]). Let $x \in \text{SUBTOUR}(G)$ and \mathcal{P} be a collection of disjoint subsets of E such that $x(P) = 1$ for $P \in \mathcal{P}$. Then, x can be decomposed into a convex combination of \mathcal{P} -rainbow v -trees of G_x for any $v \in V$.

► **Definition 18.** Given a graph $G = (V, E)$, a set of edges $M \subseteq E$ forms an induced matching in G if the subgraph of G induced on the endpoints of M forms a matching (i.e., if edges e and f belong to an induced matching M , then there is no 3-edge path in G containing both e and f).

Consider a half-cycle point x . For a vertex u in G_x we denote by e_u the unique 1-edge incident on u and by $\gamma(u)$ the two vertices that are the other endpoints of the half-edges incident on v . In other words, suppose $\delta(u) = \{e_u, f, g\}$ and suppose that w_1 and w_2 are the other endpoints of f and g , respectively. Then $\gamma(u) = \{w_1, w_2\}$.

2 Saving on 1-edges for half-cycle points

Let x be a half-cycle point. In this section, we present an algorithm to write x as a convex combination of tours of G_x . Following Christofides' algorithm, we first construct a convex combination of spanning subgraphs in Section 2.1. Next, we address parity correction in Section 2.2. We combine these two steps in Section 2.3 for the base case, in which G_x contains no critical cuts. In Section 2.4, we show how to iteratively glue tours for base cases together to construct tours for general G_x .

2.1 Convex combinations of spanning subgraphs

► **Definition 19.** Let x be a half-cycle point and let v be a vertex of G_x . Suppose $M \subset W_x$ is a subset of 1-edges of G_x . Let $0 \leq \Lambda \leq \frac{1}{2}$. Let \mathcal{T} be a set of spanning connected subgraphs of G_x and let $\lambda = \{\lambda_T\}_{T \in \mathcal{T}}$ be a probability distribution such that $\{\lambda, \mathcal{T}\}$ is a convex combination for x . Then we say $P(v, M, \Lambda)$ holds for the convex combination $\{\lambda, \mathcal{T}\}$ if it has the following properties.

1. $\sum_{T \in \mathcal{T}: |\delta_T(v)|=1} \lambda_T = \sum_{T \in \mathcal{T}: |\delta_T(v)|=3} \lambda_T = \Lambda$ and $\sum_{T \in \mathcal{T}: |\delta_T(v)|=2} \lambda_T = 1 - 2\Lambda$.
2. For each edge $st \in M$, $|\delta_T(s)| = |\delta_T(t)| = 2$ for $T \in \mathcal{T}$.
3. $T \setminus \delta_T(v)$ induces a spanning subgraph on $V \setminus \{v\}$.

► **Lemma 20.** Suppose $M \subset W_x$ forms an induced matching in G_x and edge $e_v \in M$. Then there is a set of spanning connected subgraphs \mathcal{T} of G_x and a probability distribution $\lambda = \{\lambda_T\}_{T \in \mathcal{T}}$ such that $\{\lambda, \mathcal{T}\}$ is a convex combination for x for which $P(v, M, 0)$ holds.

Proof. For each $st \in M$, pair the half-edges incident on s and pair those incident on t to obtain disjoint subsets of edges \mathcal{P} and decompose x into a convex combination of \mathcal{P} -rainbow v -trees \mathcal{T} (i.e., $x = \sum_{T \in \mathcal{T}} \lambda_T \chi^T$) via Theorem 17. This is the desired convex combination since for all $T \in \mathcal{T}$, we have $|\delta_T(v)| = 2$ and $|\delta_T(u)| = 2$ for all endpoints u of edges in M . Thus, the first and second conditions are satisfied. The third condition holds by definition of v -trees. ◀

► **Lemma 21.** *Let $\gamma(v) = \{w_1, w_2\}$ and let Λ be any constant such that $0 \leq \Lambda \leq \frac{1}{2}$. If $M \subset W_x$ forms an induced matching in G_x , $e_v \notin M$ and $|M \cap \{e_{w_1}, e_{w_2}\}| \leq 1$. Then there is a set of spanning connected subgraphs \mathcal{T} of G_x and a probability distribution $\lambda = \{\lambda_T\}_{T \in \mathcal{T}}$ such that $\{\lambda, \mathcal{T}\}$ is a convex combination for x for which $P(v, M, \Lambda)$ holds.*

Proof. As in the proof of Lemma 20, for each $st \in M$, pair the half-edges incident on s and pair those incident on t to obtain a collection of disjoint subsets of edges \mathcal{P} . Apply Theorem 17 to obtain $\{\lambda, \mathcal{T}\}$ which is a convex combination for x , where \mathcal{T} is a set of \mathcal{P} -rainbow v -trees (i.e., $x = \sum_{T \in \mathcal{T}} \lambda_T \chi^T$). Notice that this convex combination clearly satisfies the second requirement in Definition 19.

Now let $\delta(v) = \{e_v, f, g\}$, where w_1 and w_2 are the other endpoints of f and g , respectively. Without loss of generality, assume $e_{w_1} \notin M$. Since $x = \sum_{T \in \mathcal{T}} \lambda_T \chi^T$, we have $e_v \in T$ for $T \in \mathcal{T}$, since $x_{e_v} = 1$. In addition, we have $|\delta_T(v)| = 2$ for all $T \in \mathcal{T}$ by the definition of v -trees. Hence, $\sum_{T \in \mathcal{T}: f \in T, g \notin T} \lambda_T = \sum_{T \in \mathcal{T}: f \notin T, g \in T} \lambda_T = x_f = \frac{1}{2}$. Without loss of generality, assume $f \in T$ and $g \notin T$ for $T \in \mathcal{T}_f$, and $f \notin T$ and $g \in T$ for $T \in \mathcal{T}_g$, where $\mathcal{T}_f \cup \mathcal{T}_g = \mathcal{T}$ and $\mathcal{T}_f \cap \mathcal{T}_g = \emptyset$.

We can also assume that there are subsets $\mathcal{T}_f^1 \subseteq \mathcal{T}_f$ and $\mathcal{T}_g^1 \subseteq \mathcal{T}_g$ such that $\sum_{T \in \mathcal{T}_f^1} \lambda_T = \Lambda$ and $\sum_{T \in \mathcal{T}_g^1} \lambda_T = \Lambda$, since $\Lambda \leq \frac{1}{2}$. For $T \in \mathcal{T}_f^1$, replace T with $T - f$. Similarly, for $T \in \mathcal{T}_g^1$, replace T with $T + f$. For all $T \in \mathcal{T} \setminus (\mathcal{T}_f^1 \cup \mathcal{T}_g^1)$, keep T as is. Observe that $T \setminus \delta_T(v)$ still induces a spanning subgraph on $V \setminus \{v\}$ since we did not remove any edge in $T \setminus \delta(v)$ from the v -tree T . We want to show that the new convex combination $\{\lambda, \mathcal{T}\}$ is the desired convex combination for x . Notice that

$$\begin{aligned} \sum_{T \in \mathcal{T}} \lambda_T \chi_f^T &= \sum_{T \in \mathcal{T}_f^1} \lambda_T \chi_f^T + \sum_{T \in \mathcal{T}_f \setminus \mathcal{T}_f^1} \lambda_T \chi_f^T + \sum_{T \in \mathcal{T}_g^1} \lambda_T \chi_f^T + \sum_{T \in \mathcal{T}_g \setminus \mathcal{T}_g^1} \lambda_T \chi_f^T \\ &= 0 + \left(\frac{1}{2} - \Lambda\right) + \Lambda + 0 = x_f. \end{aligned}$$

So $x = \sum_{T \in \mathcal{T}} \lambda_T \chi^T$. Also, $T \in \mathcal{T}$ is a connected subgraph of G_x since each $T \in \mathcal{T}_f^1$ is obtained by removing an edge incident on v , which does not disconnect it. Finally, for each vertex s with $e_s \in M$, we have $|\delta_T(s)| = 2$ for all $T \in \mathcal{T}$. To observe this, notice that the initial convex combination satisfies this property for vertex s (since the convex combination is obtained via Theorem 17). In the transformation of the convex combination we only change edges incident on w_1 and w_2 , so if $s \neq w_1, w_2$ the property clearly still holds after the transformation. If $s = w_1$ or w_2 , we only remove or add an edge incident on s if $e_s \notin M$. ◀

2.2 Tools for parity correction

Let $G = (V, E)$ be an arbitrary graph and $O \subseteq V$ where $|O|$ is even. An O -join of G is a subgraph J of G in which the set of odd-degree vertices of J are exactly O . The convex hull of characteristic vectors of O -joins of G , denoted by O -JOIN(G) can be described as follows.

$$\begin{aligned} O\text{-JOIN}(G) &= \{x \in [0, 1]^E : \\ &\quad x(\delta(S) \setminus U) - x(U) \geq 1 - |U| \text{ for } S \subseteq V, U \subseteq \delta(S), |S \cap O| + |U| \text{ odd}\}. \end{aligned}$$

► **Lemma 22.** *Let x be a half-cycle point and assume that $G_x = (V, E_x)$ has no critical cuts. Let $M \subset W_x$ be a subset of 1-edges of G_x such that each 3-edge cut in G_x contains at most one edge from M . Let $O \subseteq V$ be a subset of vertices such that $|O|$ is even and for all $e = st \in M$, neither s nor t is in O . Also for any set $S \subseteq V$ such that $|\delta(S)| = 2$, both $|S \cap O|$ and $|\delta(S) \cap M|$ are even. Define vector z as follows: $z_e = \frac{1}{2}$ if $e \in W_x$ and $e \notin M$, and $z_e = \frac{1}{4}$ otherwise. Then vector $z \in O$ -JOIN(G_x).*

The proof of Lemma 22 can be found in the full version [12].

► **Observation 1.** *Let $G = (V, E)$ be a cubic graph, and let $O \subseteq V$ be a subset of vertices such that $|O|$ is even. Let $z \in O\text{-JOIN}(G)$, and $z(\delta(u)) \leq 1$ for all $u \in V$. Then there exists a set of O -joins of G , namely \mathcal{J} , and a probability distribution $\psi = \{\psi_J\}_{J \in \mathcal{J}}$ such that $\{\psi, \mathcal{J}\}$ is a convex combination for z . Moreover, for each vertex $v \in V$, the following properties hold.*

1. *If $u \in O$, then we have $|J \cap \delta(u)| = 1$ for each $J \in \mathcal{J}$. (Notice that in this case we must have $z(\delta(u)) = 1$.)*
2. *If $u \notin O$ and $\delta(u) = \{e, f, g\}$, then we have the following (four) cases. (Notice that sum of the right hand sides is exactly 1.)*

$$\sum_{J \in \mathcal{J}: J \cap \delta(u) = \emptyset} \psi_J = 1 - \frac{z(\delta(u))}{2},$$

$$\sum_{J \in \mathcal{J}: J \cap \delta(u) = \{h, h'\}} \psi_J = \frac{z(\delta(u))}{2} - z_{h''} \quad \text{for any distinct } h, h', h'' \in \delta(u).$$

The proof of this observation follows from the fact that if $z \in O\text{-JOIN}(G)$, then it can be efficiently decomposed into a convex combination of O -joins of G [10].

2.3 Convex combinations of tours: Base case

Let x be a half-cycle point such that $G_x = (V, E_x)$ has no critical cuts. Let v be a fixed vertex in V and let $\gamma(v) = \{w_1, w_2\}$. Let $\{M_1, \dots, M_h\}$ be a partition of W_x into induced matchings such that $|M_i \cap \{e_v, e_{w_1}, e_{w_2}\}| \leq 1$ for all $i \in [h]$, $e_v \in M_1$, each 3-edge cut of G_x contains at most one edge from each M_i , and each 2-edge cut of G_x contains an even number of edges from each M_i . Let $\alpha = \frac{1}{h}$ and Λ be some constant where $0 \leq \Lambda \leq \frac{1-\alpha}{2}$.

For $i = 1$, let \mathcal{T}_1 be a set of spanning subgraphs of G_x and let $\{\theta, \mathcal{T}_1\}$ be a convex combination for x for which $P(v, M_1, 0)$ holds (by Lemma 20). For $i \in \{2, \dots, \ell\}$, let \mathcal{T}_i be a set of spanning subgraphs of G_x and let $\{\theta, \mathcal{T}_i\}$ be a convex combination for x for which $P(v, M_i, \frac{\Lambda}{1-\alpha})$ holds (by Lemma 21). Notice that $\frac{\Lambda}{1-\alpha} \leq \frac{1}{2}$ since $\Lambda \leq \frac{1-\alpha}{2}$. Let $\mathcal{T} = \cup_{i \in [h]} \mathcal{T}_i$.

We can write x as a convex combination of the spanning subgraphs in \mathcal{T} , by weighting each set \mathcal{T}_i by α . In particular, we have $x = \alpha \sum_{i=1}^h \sum_{T \in \mathcal{T}_i} \theta_T \chi^T$. For each $T \in \mathcal{T}$, let $\sigma_T = \alpha \cdot \theta_T$. Then $\{\sigma, \mathcal{T}\}$ is a convex combination for x . From Definition 19 and Lemmas 20 and 21, we observe the following.

► **Claim 23.** For each $T \in \mathcal{T}$, $T \setminus \delta(v)$ induces a connected, spanning subgraph on $V \setminus \{v\}$.

For each $i \in [h]$, define $z_e^i = \frac{1}{2}$ if $e \in W_x \setminus M_i$ and $z_e^i = \frac{1}{4}$ otherwise. For each $T \in \mathcal{T}_i$, let $O_T \subseteq V$ be the set of odd-degree vertices of T . By construction, we have $V(M_i) \cap O_T = \emptyset$. By Lemma 22, we have $z^i \in O_T\text{-JOIN}(G)$, so there exists a set of O -joins \mathcal{J}_T and a probability distribution $\psi = \{\psi_J\}_{J \in \mathcal{J}_T}$ such that $\{\psi, \mathcal{J}_T\}$ is a convex combination for z^i . This implies that $x + z^i$ can be written as a convex combination of tours of G_x . We denote this set of tours by \mathcal{F}_i and we let $\mathcal{F} = \cup_{i \in [h]} \mathcal{F}_i$. We claim that $\sum_{i=1}^h \alpha(x + z^i)$ can be written as a convex combination of tours of G_x in \mathcal{F} using the probability distribution $\phi = \{\phi_F\}_{F \in \mathcal{F}}$, constructed as follows: For a tour F that is the union of $T \in \mathcal{T}$ and $J \in \mathcal{J}_T$, set $\phi_F = \sigma_T \cdot \psi_J$.

► **Claim 24.** Let x be a half-cycle point such that $G_x = (V, E_x)$ contains no critical cuts. Define vector $y \in \mathbb{R}^E$ as $y_e = \frac{3}{2} - \frac{\alpha}{4}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ for $e \in H_x$. Then $\{\phi, \mathcal{F}\}$ is a convex combination for y .

Proof. We need to show that $y = \sum_{i=1}^h \alpha(x + z^i)$. First, let e be a 1-edge of G_x and M_j be the induced matching that contains e . Then, $x_e = 1$, $z_e^i = \frac{1}{2}$ for $i \in [h] \setminus \{j\}$ and $z_e^j = \frac{1}{4}$. Hence,

$$\sum_{i=1}^h \alpha(x_e + z_e^i) = \sum_{\ell=1}^h \alpha \cdot \frac{3}{2} - \alpha \cdot \frac{1}{4} = \frac{3}{2} - \frac{\alpha}{4}.$$

For a half-edge e of G_x , we have $x_e = \frac{1}{2}$ and $z_e^i = \frac{1}{4}$ for $i \in [h]$, so $\sum_{i=1}^h \alpha(x_e + z_e^i) = \frac{3}{4}$. \triangleleft

Now we prove some additional useful properties of the convex combination $\{\phi, \mathcal{F}\}$. For a vertex u such that $\delta(u) = \{e_u, f, g\}$ (i.e., where e_u is a 1-edge and f and g are half-edges), let \mathbb{P}_u denote the following set of patterns of edges such that u has even degree and the 1-edge e_u is included at least once.

$$\mathbb{P}_u = \{\{2e_u\}, \{e_u, f\}, \{e_u, g\}, \{2e_u, 2f\}, \{2e_u, 2g\}, \{2e_u, f, g\}, \{e_u, 2f, g\}, \{e_u, f, 2g\}\}.$$

Let $\mathbb{P} = \cup_{u \in V} \mathbb{P}_u$. For $0 \leq \alpha, \rho \leq 1$, define the function $\zeta_{\alpha, \rho} : \mathbb{P} \rightarrow [0, 1]$ as follows.

$$\zeta_{\alpha, \rho}(p_u) = \begin{cases} \frac{2-\alpha}{8} & \text{for } p_u = \{2e_u, f, g\}; \\ \frac{\rho}{2} & \text{for } p_u = \{2e_u\}; \\ \frac{\alpha+4\rho}{16} & \text{for } p_u \in \{\{e_u, 2f, g\}, \{e_u, f, 2g\}\}; \\ \frac{4+\alpha-4\rho}{16} & \text{for } p_u \in \{\{e_u, f\}, \{e_u, g\}\}; \\ \frac{2-\alpha-4\rho}{16} & \text{for } p_u \in \{\{2e_u, 2f\}, \{2e_u, 2g\}\}. \end{cases}$$

\triangleright **Claim 25.** The convex combination $\{\phi, \mathcal{F}\}$, has the following properties.

(i) For each vertex $u \in V$ there is a some constant η_u where $0 \leq \eta_u \leq \frac{1-\alpha}{2}$ and

$$\sum_{F \in \mathcal{F}: F \cap \delta(u) = p_u} \phi_F = \zeta_{\alpha, \eta_u}(p_u) \text{ for } p_u \in \mathbb{P}_u.$$

(ii) $\eta_v = \Lambda$.

The proof of Claim 25 can be found in the full version [12].

\blacktriangleright **Lemma 26.** Let x be a half-cycle point, and assume $G_x = (V, E_x)$ does not have any critical cuts. Let r be a vertex in V and let $\gamma(r) = \{w_1, w_2\}$. The set of 1-edges in G_x , W_x , can be partitioned into five induced matchings $\{M_1, \dots, M_5\}$ such that for $i \in \{1, \dots, 5\}$, the following properties hold.

(i) $M_i \cap \{e_r, e_{w_1}, e_{w_2}\} \leq 1$,

(ii) For $S \subseteq V$ such that $|\delta(S)| = 3$, $|\delta(S) \cap M_i| \leq 1$.

(iii) For $S \subseteq V$ such that $|\delta(S)| = 2$, $|\delta(S) \cap M_i|$ is even.

The proof of Lemma 26, which can be found in the full version, uses induction (i.e., gluing solutions for base cases) and the proof of the base case is an application of Brooks' theorem on a slight modification of the line graph of G_x [12].

Let $\gamma_v = \{w_1, w_2\}$. By Lemma 26, there are $\{M_1, \dots, M_5\}$ that partition W_x into induced matchings such that $|M_i \cap \{e_v, e_{w_1}, e_{w_2}\}| \leq 1$ for all $i \in [5]$, and each induced matching intersects a 3-edge-cut at most once and a 2-edge cut an even number of times. The following Lemma follows from Claim 25 by setting $\alpha = \frac{1}{5}$.

\blacktriangleright **Lemma 27.** Let x be a half-cycle point such that $G_x = (V, E_x)$ contains no critical cuts. Fix any vertex in $v \in V$ and Λ with $0 \leq \Lambda \leq \frac{2}{5}$. Define $y \in \mathbb{R}^E$ as $y_e = \frac{3}{2} - \frac{1}{20}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ if $e \in H_x$. Then there is a set of tours of G_x denoted by \mathcal{F} and a probability distribution $\phi = \{\phi_F\}_{F \in \mathcal{F}}$ such that $\{\phi, \mathcal{F}\}$ is a convex combination for y . Moreover, this convex combination has the following properties.

(i) For each vertex $u \in V$, there is a some constant η_u where $0 \leq \eta_u \leq \frac{2}{5}$ and

$$\sum_{F \in \mathcal{F}: F \cap \delta(u) = p_u} \phi_F = \zeta_{\frac{1}{5}, \eta_u}(p_u) \text{ for } p_u \in \mathcal{P}_u.$$

(ii) $\eta_v = \Lambda$.

(iii) $F \setminus \delta_F(v)$ induces a connected multigraph on $V \setminus \{v\}$ for each $F \in \mathcal{F}$.

2.4 Convex combinations of tours: Gluing over critical cuts

► **Theorem 7.** Let $x \in \mathbb{R}_{\geq 0}^E$ be a half-cycle point. Define vector $y \in \mathbb{R}^E$ as follows: $y_e = \frac{3}{2} - \frac{1}{20}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ for $e \in H_x$. Then $y \in \text{TSP}(G_x)$.

For a graph $G = (V, E)$ and nonempty subset of vertices $S \subset V$, contract the component induced on $\bar{S} = V \setminus S$ into a vertex and call this vertex $v_{\bar{S}}$. We define the graph G_S to be the graph induced on vertex set $S \cup v_{\bar{S}}$. The graph $G_{\bar{S}}$ is analogously defined on the vertex set $\bar{S} \cup v_S$.

► **Lemma 28.** Consider a graph $G = (V, E)$ and nonempty $S \subset V$ such that $\delta(S)$ is a minimum cardinality cut in $G = (V, E)$. Let F_S be a tour in G_S and let $F_{\bar{S}}$ be a tour in $G_{\bar{S}}$ such that $\chi_e^{F_S} = \chi_e^{F_{\bar{S}}}$ for $e \in \delta(S)$. Moreover, assume that $F_S \setminus \delta(v_{\bar{S}})$ induces a connected multigraph on S . Then the multiset of edges F defined as $\chi_e^F = \chi_e^{F_S}$ for $e \in E(G_S)$ and $\chi_e^F = \chi_e^{F_{\bar{S}}}$ for $e \in E(G_{\bar{S}})$ is a tour of G .

Proof. It is clear that F induces an Eulerian multigraph on G , but we need to ensure that F is connected. For example, the tour induced on $F_S \setminus \delta(v_{\bar{S}})$ might not be connected. However, since the subgraph of F_S induced on the vertex set S is connected, the tour F is connected: each vertex in \bar{S} is connected to some vertex in S . ◀

► **Lemma 29.** Let x be a half-cycle point such that $G_x = (V, E_x)$. Define $y \in \mathbb{R}^E$ as $y_e = \frac{3}{2} - \frac{1}{20}$ for $e \in W_x$ and $y_e = \frac{3}{4}$ if $e \in H_x$. Then there is a set of tours of G_x denoted by \mathcal{F} and a probability distribution $\phi = \{\phi_F\}_{F \in \mathcal{F}}$ such that $\{\phi, \mathcal{F}\}$ is a convex combination for y . Moreover, this convex combination has the following property.

For each vertex $u \in V$, there is a some constant η_u where $0 \leq \eta_u \leq \frac{2}{5}$ and

$$\sum_{F \in \mathcal{F}: F \cap \delta(u) = p_u} \phi_F = \zeta_{\frac{1}{5}, \eta_u}(p_u) \text{ for } p_u \in \mathcal{P}_u.$$

Proof. If G_x does not contain a critical cut, we apply Lemma 27. Otherwise, set $G := G_x$ and conduct the following procedure: Find a cut $S_1 \subset V(G)$ such that $G_1 = G_{S_1}$ contains no critical cuts. Then set $G := G_{\bar{S}_1}$ and find a cut $S_2 \subset V(G)$ such that $G_2 = G_{S_2}$ contains no critical cuts, etc.

At the end of this procedure, we have a series of graphs $\{G_1, \dots, G_k\}$ such that for each $j \in [k]$, G_j is the support graph of a half-cycle point and contains no critical cuts. Therefore, each G_j is a base case and we can find a convex combination of tours applying the procedure described in Section 2.3.

We glue the tours together in reverse order according to their index beginning with G_k and G_{k-1} . The graph G_{k-1} corresponds to G_S for some vertex set S of G , where G is the graph at the beginning of iteration $k-1$ of the above procedure. Note that $G_{\bar{S}}$ equals G_k and it has no critical cuts. Therefore, after invoking Lemma 27 to find a convex combination of tours for $G_{\bar{S}}$, we invoke Lemma 27 on G_S with $v = v_{\bar{S}}$ and $\Lambda = \eta_{v_{\bar{S}}}$ based on the convex combination of tours returned for $G_{\bar{S}}$. Now in the tours returned, the patterns on vertex $v_{\bar{S}}$ match those of v_S in the convex combination of tours previously found for $G_{\bar{S}}$.

After having glued together the tours from G_{k-1} and G_k in this manner, we glue the resulting tours with those in G_{k-2} , etc., until we have found a convex combination of tours for G_x . ◀

3 Discussion

In this paper, we presented an algorithm to save on 1-edges for a half-cycle point. To fully resolve half-integer TSP, we need to be able to save on half-edges. Towards this goal, we proposed a “base case” when there is no proper minimum cut (Theorem 13). It is not clear how to combine this with a gluing approach similar to the one for half-cycle points described in Section 2. Thus, we close with the following open problem.

► **Problem 30.** *Let x be a half-cycle point. vector $y \in \mathbb{R}^{E_x}$ as follows: $y_e = \frac{3}{2}$ for $e \in W_x$ and $y_e = \frac{3}{4} - \delta$ for $e \in H_x$. Show there exists a constant $\delta > 0$ such that $y \in \text{TSP}(G_x)$.*

Abstract

We consider the task of measuring time with probabilistic threshold gates implemented by bio-inspired spiking neurons. In the model of *spiking neural networks*, network evolves in discrete rounds, where in each round, neurons fire in pulses in response to a sufficiently high membrane potential. This potential is induced by spikes from neighboring neurons that fired in the previous round, which can have either an excitatory or inhibitory effect.

Discovering the underlying mechanisms by which the brain perceives the duration of time is one of the largest open enigmas in computational neuro-science. To gain a better algorithmic understanding onto these processes, we introduce the *neural timer* problem. In this problem, one is given a time parameter t , an input neuron x , and an output neuron y . It is then required to design a minimum sized neural network (measured by the number of auxiliary neurons) in which every spike from x in a given round i , makes the output y fire for the subsequent t consecutive rounds.

We first consider a deterministic implementation of a neural timer and show that $\Theta(\log t)$ (deterministic) threshold gates are both sufficient and necessary. This raised the question of whether randomness can be leveraged to reduce the number of neurons. We answer this question in the affirmative by considering neural timers with spiking neurons where the neuron y is required to fire for t consecutive rounds with probability at least $1 - \delta$, and should stop firing after at most $2t$ rounds with probability $1 - \delta$ for some input parameter $\delta \in (0, 1)$. Our key result is a construction of a neural timer with $O(\log \log 1/\delta)$ spiking neurons. Interestingly, this construction uses only *one* spiking neuron, while the remaining neurons can be deterministic threshold gates. We complement this construction with a matching lower bound of $\Omega(\min\{\log \log 1/\delta, \log t\})$ neurons. This provides the first separation between deterministic and randomized constructions in the setting of spiking neural networks.

Finally, we demonstrate the usefulness of compressed counting networks for *synchronizing* neural networks. In the spirit of distributed synchronizers [Awerbuch-Peleg, FOCS'90], we provide a general transformation (or simulation) that can take any synchronized network solution and simulate it in an asynchronous setting (where edges have arbitrary response latencies) while incurring a small overhead w.r.t the number of neurons and computation time.

1 Introduction

Understanding the mechanisms by which brain experiences time is one of the major research objectives in neuroscience [26, 2, 9]. Humans measure time using a global clock based on standardized units of minutes, days and years. In contrast, the brain perceives time using specialized neural clocks that define their own time units. Living organisms have various other implementations of biological clocks, a notable example is the circadian clock that gets synchronized with the rhythms of a day.

In this paper we consider the algorithmic aspects of measuring *time* in a simple yet biologically plausible model of *stochastic spiking neural networks* (SNN) [23, 24], in which neurons fire in discrete pulses, in response to a sufficiently high membrane potential. This model is believed to capture the spiking behavior observed in real neural networks, and has recently received quite a lot of attention in the algorithmic community [18, 19, 20, 17, 15, 28, 6]. In contrast to the common approach in computational neuroscience and machine learning, the focus here is not on general computation ability or broad learning tasks, but rather on specific algorithmic implementation and analysis.

The SNN network is represented by a directed weighted graph $G = (V, A, W)$, with a special set of neurons $X \subset V$ called *inputs* that have no incoming edges, and a subset of *output* neurons¹ $Y \subset V$. The neurons in the network can be either deterministic threshold gates or probabilistic threshold gates. As observed in biological networks, and departing from many artificial network models, neurons are either strictly inhibitory (all outgoing edge weights are negative) or excitatory (all outgoing edge weights are positive). The network evolves in discrete, synchronous *rounds* as a Markov chain, where the firing probability of every neuron in round τ depends on the firing status of its neighbors in the preceding round $\tau - 1$. For probabilistic threshold gates this firing is modeled using a standard sigmoid function. Observe that an SNN network is in fact, a *distributed network*, every neuron responds to the firing spikes of its *neighbors*, while having no global information on the entire network.

Remark. In the setting of SNN, unlike classical distributed algorithms (e.g., LOCAL or CONGEST), the algorithm is fully specified by the *structure* of the network. That is, for a given network, its dynamic is fully determined by the model. Hence, the key complexity measure here is the size of the network measured by the number of auxiliary neurons². For certain problems, we also care for the tradeoff between the size and the computation time.

1.1 Measuring Time with Spiking Neural Networks

We consider the algorithmic challenges of measuring time using networks of threshold gates and probabilistic threshold gates. We introduce the *neural timer* problem defined as follows:

Given an input neuron x , an output neuron y , and a time parameter t , it is required to design a small neural network such that any firing of x in a given round invokes the firing of y for exactly the next t rounds.

In other words, it is required to design a succinct timer, activated by the firing of its input neuron, that alerts when exactly t rounds have passed.

¹ In contrast to the definition of *circuits*, we do allow output neurons to have outgoing edges and self loops. The requirement will be that the value of the output neurons converges over time to the desired solution.

² I.e., neurons that are not the input or the output neurons.

A trivial solution with t auxiliary neurons can be obtained by taking a directed chain of length t (Fig. 1): the head of the chain has an incoming edge from the input x , the output y has incoming edges from the input x , and all the other t neurons on the chain. All these neurons are simple *OR*-gates, they fire in round τ if at least one of their incoming neighbors fired in round $\tau - 1$. Starting with the firing of x in round 0, in each round i , exactly one neuron, namely the i^{th} neuron on the chain fires, which makes y keep on firing for exactly t rounds until the chain fades out. In this basic solution, the network spends one neuron that counts +1 and dies. It is noteworthy that the neurons in our model are very simple, they do not have any memory, and thus cannot keep track of the firing history. They can only base their firing decisions on the firing of their neighbors in the *previous* round.

With such a minimal model of computation, it is therefore intriguing to ask how to beat this linear dependency (of network size) in the time parameter t . Can we count to ten using only two (memory-less) neurons? We answer this question in the affirmative, and show that even with just simple deterministic threshold gates, we can measure time up to t rounds using only $O(\log t)$ neurons. It is easy to see that this bound is tight when using deterministic neurons (even when allowing some approximation). The reason is that $o(\log t)$ neurons encode strictly less than t distinct configurations, thus in a sequence of t rounds, there must be a configuration that re-occurs, hence locking the system into a state in which y fires forever.

► **Theorem 1 (Deterministic Timers).** *For every input time parameter $t \in \mathbb{N}_{>0}$, (1) there exists a deterministic neural timer network \mathcal{N} with $O(\log t)$ deterministic threshold gates, (2) any deterministic neural timer requires $\Omega(\log t)$ neurons.*

This timer can be easily adapted to the related problem of *counting*, where the network should output the number of spikes (by the input x) within a time window of t rounds.

Does Randomness Help in Time Estimation? Neural computation in general, and neural spike responses in particular, are inherently stochastic [16]. One of our broader scope agenda is to understand the power and limitations of randomness in neural networks. Does neural computation become *easier* or *harder* due to the stochastic behavior of the neurons?

We define a randomized version of the neural timer problem that allows some slackness both in the approximation of the time, as well as allowing a small error probability. For a given error probability $\delta \in (0, 1)$, the output y should fire for at least t rounds, and must stop firing after at most $2t$ rounds³ with probability at least $1 - \delta$. It turns out that this randomized variant leads to a considerably improved solution for $\delta = 2^{-O(t)}$:

► **Theorem 2 (Upper Bound for Randomized Timers).** *For every time parameter $t \in \mathbb{N}_{>0}$, and error probability $\delta \in (0, 1)$, there exists a probabilistic neural timer network \mathcal{N} with $O(\min\{\log \log 1/\delta, \log t\})$ deterministic threshold gates plus additional random spiking neuron.*

Our starting point is a simple network with $O(\log 1/\delta)$ neurons, each firing independently with probability $1 - 1/t$. The key observation for improving the size bound into $O(\log \log 1/\delta)$ is to use the *time axis*: we will use a *single* neuron to generate random samples over time, rather than having *many* random neurons generating these samples in a *single* round. The deterministic neural counter network with time parameter of $O(\log 1/\delta)$ is used as a building block in order to gather the firing statistics of a single spiking neuron. In light of the $\Omega(\log t)$

³ Taking $2t$ is arbitrary here, and any other constant would work as well.

lower bound for deterministic networks, we get the first separation between deterministic and randomized solutions for error probability $\delta = \omega(1/2^t)$. This shows that randomness can help, but up to a limit: Once the allowed error probability is exponentially small in t , the deterministic solution is the best possible. Perhaps surprisingly, we show that this behavior is tight:

► **Theorem 3 (Lower Bound for Randomized Timers).** *Any SNN network for the neural timer problem with time parameter t , and error $\delta \in (0, 1)$ must use $\Omega(\min\{\log \log 1/\delta, \log t\})$ neurons.*

Neural Counters. Spiking neurons are believed to encode information via their firing rates. This underlies the *rate coding* scheme [1, 30, 11] in which the spike-count of the neuron in a given span of time is interpreted as a *letter* in a larger alphabet. In a network of memory-less spiking neurons, it is not so clear how to implement this rate dependent behavior. How can a neuron convey a complicated message over time if its neighboring neurons remember only its recent spike? This challenge is formalized by the following neural counter problem: Given an input neuron x , a time parameter t , and $\Theta(\log t)$ output neurons represented by a vector \bar{y} , it is required to design a neural network such that the output vector \bar{y} holds the binary representation of the number of times that x fired in a sequence of t rounds. As we already mentioned this problem is very much related to the neural timer problem and can be solved using $O(\log t)$ neurons. Can we do better?

The problem of maintaining a *counter* using a small amount of space has received a lot of attention in the *dynamic streaming* community. The well-known Morris algorithm [27, 10] maintains an approximate counter for t counts using only $\log \log t$ bits. The high-level idea of this algorithm is to increase the counter with probability of $1/2^{C'}$ where C' is the current read of the counter. The counter then holds the exponent of the number of counts. By following ideas of [10], carefully adapted to the neural setting, we show:

► **Theorem 4 (Approximate Counting).** *For every time parameter t , and $\delta \in (0, 1)$, there exists a randomized construction of approximate counting network using $O(\log \log t + \log(1/\delta))$ deterministic threshold gates plus an additional single random spiking neuron, that computes an $O(1)$ (multiplicative) approximation for the number of input spikes in t rounds with probability $1 - \delta$.*

We note that unlike the deterministic construction of timers that could be easily adopted to the problem of neural counting, our optimized randomized timers with $O(\log \log 1/\delta)$ neurons cannot be adopted into an approximate counter network. We therefore solve the latter by adopting Morris algorithm to the neural setting.

Broader Scope: Lessons From Dynamic Streaming Algorithms. We believe that approximate counting problem provides just one indication for the potential relation between succinct neural networks and dynamic streaming algorithms. In both settings, the goal is to gather statistics (e.g., over time) using a small amount of space. In the setting of neural network there are additional difficulties that do not show up in the streaming setting. E.g., it is also required to obtain fast *update time*, as illustrated in our solution to the approximate counting problem.

1.2 Neural Synchronizers

The standard model of spiking neural networks assumes that all edges (synapses) in the network have a uniform response latency. That is, the electrical signal is passed from the presynaptic neuron to the postsynaptic neuron within a fixed time unit which we call a

round. However, in real biological networks, the response latency of synapses can vary considerably depending on the biological properties of the synapse, as well as on the distance between the neighboring neurons. This results in an asynchronous setting in which different edges have distinct response time. We formalize a simple model of spiking neurons in the asynchronous setting, in which the given neural network also specifies a *response latency* function $\ell : A \rightarrow \mathbb{R}_{\geq 1}$ that determines the number of rounds it takes for the signal to propagate over the edge. Inspired by the synchronizers of Awerbuch and Peleg [4], and using the above mentioned compressed timer and counter modules, we present a general simulation methodology (a.k.a synchronizers) that takes a network $\mathcal{N}_{\text{sync}}$ that solves the problem in the synchronized setting, and transform it into an “analogous” network $\mathcal{N}_{\text{async}}$ that solves the same problem in the asynchronous setting.

The basic building blocks of this transformation is the neural time component adapted to the asynchronous setting. The cost of the transformation is measured by the overhead in the number of neurons and in the computation time. Using our neural timers leads to a small overhead in the number of neurons.

► **Theorem 5** (Synchronizer, Informal). *There exists a synchronizer that given a network $\mathcal{N}_{\text{sync}}$ with n neurons and maximum response latency⁴ L , constructs a network $\mathcal{N}_{\text{async}}$ that has an “analogous” execution in the asynchronous setting with a total number of $O(n + L \log L)$ neurons and a time overhead of $O(L^3)$.*

We note that although the construction is inspired by the work of Awerbuch and Peleg [4], due to the large differences between these models, the precise formulation and implementation of our synchronizers are quite different. The most notable difference between the distributed and neural setting is the issue of memory: in the distributed setting, nodes can aggregate the incoming messages and respond when all required messages have arrived. In strike contrast, our neurons can only respond (by either firing or not firing) to signals arrived in the *previous* round, and all signals from previous rounds cannot be locally stored. For this reason and unlike [4], we must assume a bound on the largest edge latency. In particular, in the full version we show that the size overhead of the transformed network $\mathcal{N}_{\text{async}}$ must depend, at least logarithmically, on the value of the largest latency L .

► **Observation 1.** *The size overhead of any synchronization scheme is $\Omega(\log L)$.*

This provably illustrates the difference in the overhead of synchronization between general distributed networks and neural networks. We leave the problem of tightening this lower bound (or upper bound) as an interesting open problem.

Additional Related Work. To the best of our knowledge, there are two main previous theoretical work on asynchronous neural networks. Maass [22] considered a quite elaborated model for deterministic neural networks with *arbitrary* response *functions* for the edges, along with latencies that can be chosen by the network designer. Within this generalized framework, he presented a coarse description of a synchronization scheme that consists of various time modules (e.g., initiation and delay modules). Our work complements the scheme of [22] in the simplified SNN model by providing a rigorous implementation and analysis for size and time overhead. Khun et al. [14] analyzed the synchronous and asynchronous behavior under the stochastic neural network model of DeVille and Peskin [7]. Their model and framework is quite different from ours, and does not aim at building synchronizers.

⁴ I.e., L correspond to the *length* of the longest round.

Turning to the setting of logical circuits, there is a long line of work on the asynchronous setting under various model assumptions [3, 12, 29, 5, 25] that do not quite fit the memory-less setting of spiking neurons.

Comparison with Concurrent Work [31]. Independently to our work, Wang and Lynch proposed a similar construction for the neural counter problem. Their work restricts attention to deterministic threshold gates and do not consider the neural timer problem and synchronizers which constitute the main contribution of our paper. We note that our approximate counter solution with $O(\log \log t + \log(1/\delta))$ neurons resolves the open problem stated in [31].

1.3 Preliminaries

We start by defining our model along with useful notation.

A Neuron. A *deterministic* neuron u is modeled by a *deterministic* threshold gate. Letting $b(u)$ to be the threshold value of u . Then it outputs 1 if the weighted sum of its incoming neighbors exceeds $b(u)$. A *spiking neuron* is modeled by a probabilistic threshold gate that fires with a sigmoidal probability $p(x) = \frac{1}{1+e^{-x}}$ where x is the difference between the weighted incoming sum of u and its threshold $b(u)$.

Neural Network Definition. A *Neural Network* (NN) $\mathcal{N} = \langle X, Z, Y, w, b \rangle$ consists of n input neurons $X = \{x_1, \dots, x_n\}$, m output neurons $Y = \{y_1, \dots, y_m\}$, and ℓ auxiliary neurons $Z = \{z_1, \dots, z_\ell\}$. In a *deterministic* neural network (DNN) all neurons are deterministic threshold gates. In spiking neural network (SNN), the neurons can be either deterministic threshold gates or probabilistic threshold gates. The directed weighted synaptic connections between $V = X \cup Z \cup Y$ are described by the weight function $w : V \times V \rightarrow \mathbb{R}$. A weight $w(u, v) = 0$ indicates that a connection is not present between neurons u and v . Finally, for any neuron v , $b(v) \in \mathbb{R}_{\geq 0}$ is the threshold value (activation bias). The weight function defining the synapses is restricted in two ways. The in-degree of every input neuron x_i is zero, i.e., $w(u, x) = 0$ for all $u \in V$ and $x \in X$. Additionally, each neuron is either inhibitory or excitatory: if v is inhibitory, then $w(v, u) \leq 0$ for every u , and if v is excitatory, then $w(v, u) \geq 0$ for every u .

Network Dynamics. The network evolves in discrete, synchronous rounds as a Markov chain. The firing probability of every neuron in round τ depends on the firing status of its neighbors in round $\tau - 1$, via a standard sigmoid function, with details given below. For each neuron u , and each round $\tau \geq 0$, let $u^\tau = 1$ if u fires (i.e., generates a spike) in round τ . Let u^0 denote the initial firing state of the neuron. The firing state of each input neuron x_j in each round is the input to the network. For each non-input neuron u and every round $\tau \geq 1$, let $pot(u, \tau)$ denote the membrane potential at round τ and $p(u, \tau)$ denote the firing probability ($\Pr[u^\tau = 1]$), calculated as:

$$pot(u, \tau) = \sum_{v \in V} w_{v,u} \cdot v^{\tau-1} - b(u) \text{ and } p(u, \tau) = \frac{1}{1 + e^{-\frac{pot(u, \tau)}{\lambda}}} \quad (1)$$

where $\lambda > 0$ is a *temperature parameter* which determines the steepness of the sigmoid. Clearly, λ does not affect the computational power of the network (due to scaling of edge weights and thresholds), thus we set $\lambda = 1$. In *deterministic* neural networks (DNN), each neuron u is a deterministic threshold gate that fires in round τ iff $pot(u, \tau) \geq 0$.

■ **Figure 1** Illustration of timer networks with time parameter t . Left: The naïve timer with $\Theta(t)$ neurons. Mid: deterministic timer with $\Theta(\log t)$ neurons. Right: randomized timer with $O(\log \log 1/\delta)$ neurons, using the DetTimer modules with parameter $t' = \log 1/\delta$.

Network States (Configurations). Given a network \mathcal{N} (either a DNN or SNN) with N neurons, the configuration (or *state*) of the network in time τ denoted as s_τ can be described as an N -length binary vector indicating which neuron fired in round τ .

The Memoryless Property. The neural networks have a memoryless property, in the sense that each state depends only on the state of the previous round. In a DNN network, the state $s_{\tau-1}$ fully determines s_τ . In an SNN network, for every fixed state s^* it holds $\Pr[s_\tau = s^* \mid s_1, \dots, s_{\tau-1}] = \Pr[s_\tau = s^* \mid s_{\tau-1}]$. Moreover for any $\tau, \tau', r > 0$, it holds that $\Pr[s_{\tau+r} = s^* \mid s_\tau] = \Pr[s_{\tau'+r} = s^* \mid s_{\tau'}]$.

Hard-Wired Inputs. We consider neural networks that *solve* a given parametrized problem (e.g., neural timer with time parameter t). The parameter to the problem can be either hard-wired in the network or alternatively be given as part of the input layer to the network. In most of our constructions, the time parameter is hard-wired. In some cases, we also show constructions with soft-wiring.

2 Deterministic Constructions of Neural Timer Networks

As a warm-up, we start by considering deterministic neural timers.

► **Definition 6** (Det. Neural Timer Network). *Given time parameter t , a deterministic neural timer network \mathcal{DT} is a network of threshold gates, with an input neuron x , an output neuron y , and additional auxiliary neurons. The network satisfies that in every round τ , $y^\tau = 1$ iff there exists a round $\tau > \tau' \geq \tau - t$ such that $x^{\tau'} = 1$.*

Lower Bound (Pf. of Thm. 1(2)). For a given neural timer network \mathcal{N} with N auxiliary neurons, recall that the *state* of the network in round τ is described by an N -length vector indicating the firing neurons in that round. Assume towards contradiction that there exists a neural timer with $N \leq \log t - 1$ auxiliary neurons. Since there are at most 2^N different states, by the pigeonhole principle, there must be at least two rounds $\tau, \tau' \leq t - 1$ in which the state of the network is identical, i.e., where $s_\tau = s_{\tau'} = s^*$ for some $s^* \in \{0, 1\}^N$. By the correctness of the network, the output neuron y fires in all rounds $\tau'' \in [\tau + 1, \tau' + 1]$. By the memoryless property, we get that $s_{\tau''} = s^*$ for $\tau'' = \tau + i \cdot (\tau' - \tau)$ for every $i \in \mathbb{N}_{\geq 0}$.

Thus y continues firing forever, in contradiction that it stops firing after t rounds. Note that this lower bound holds even if y is allowed to stop firing in any finite time window.

A Matching Upper Bound (Pf. Thm. 1(1)). For ease of explanation, we will sketch here the description of the network assuming that it is applied only once (i.e., the input x fires once within a window of t rounds). Taking care of the general case requires slight adaptations⁵, see the full version for complete details.

At the high-level, the network consists of $k = \Theta(\log t)$ layers A_1, \dots, A_k each containing two excitatory neurons $a_{i,1}, a_{i,2}$ denoted as *counting* neurons, and one inhibitory neuron d_i . Each layer A_i gets its input from layer A_{i-1} for every $i \geq 2$, and A_1 gets its input from x . The role of each layer A_i is to count *two* firing events of the neuron $a_{i-1,2} \in A_{i-1}$. Thus the neuron $a_{\log t, 2}$ counts $2^{\log t}$ rounds.

Because our network has an update time of $\log t$ rounds (i.e., number of rounds to update the timer), for a given time parameter t , the construction is based on the parameter \hat{t} where $\hat{t} + \log \hat{t} = t$. We assume that \hat{t} is a power of 2, the general case can also be solved with $O(\log t)$ neurons, the analysis is deferred to the full version.

- The first layer A_1 consists of two neurons $a_{1,1}, a_{1,2}$. The first neuron $a_{1,1}$ has positive incoming edges from x and $a_{1,2}$ with weights $w(x, a_{1,1}) = 3$, $w(a_{1,2}, a_{1,1}) = 1$, and threshold $b(a_{1,1}) = 1$. The second neuron $a_{1,2}$ has an incoming edge from $a_{1,1}$ with weight $w(a_{1,1}, a_{1,2}) = 1$ and threshold $b(a_{1,2}) = 1$. Because we have a loop going from $a_{1,1}$ to $a_{1,2}$ and back, once x fired $a_{1,2}$ will fire every two rounds.
- For every $i = 2 \dots \log \hat{t}$, the i^{th} layer A_i contains 3 neurons, two *counting* neurons $a_{i,1}, a_{i,2}$ and a reset neuron d_i . The first neuron $a_{i,1}$ has positive incoming edges from $a_{i-1,2}$, and a self loop with weight $w(a_{i-1,2}, a_{i,1}) = w(a_{i,1}, a_{i,1}) = 1$, a negative incoming edge from d_i with weight $w(d_i, a_{i,1}) = -1$, and threshold $b(a_{i,1}) = 1$. The second counting neuron $a_{i,2}$ has incoming edges from $a_{i-1,2}$ and $a_{i,1}$ with weight $w(a_{i-1,2}, a_{i,2}) = w(a_{i,1}, a_{i,2}) = 1$, and threshold $b(a_{i,2}) = 2$. The reset neuron d_i is an inhibitor copy of $a_{i-1,2}$ and therefore also has incoming edges from $a_{i-1,2}$ and $a_{i,1}$ with weight $w(a_{i-1,2}, d_i) = w(a_{i,1}, d_i) = 1$ and threshold $b(d_i) = 2$. As a result, $a_{i,1}$ starts firing after $a_{i-1,2}$ fires once, and $a_{i,2}$ fires after $a_{i-1,2}$ fires twice. Then the neuron d_i inhibits $a_{i,1}$ and the layer is ready for a new count.
- The output neuron y has a positive incoming edge from x as well as a self-loop with weights $w(x, y) = 2$, $w(y, y) = 1$. In addition, it has a negative incoming edge from the last counting neuron $a_{\log \hat{t}, 2}$ with weight $w(a_{\log \hat{t}, 2}, y) = -1$ and threshold $b(y) = 1$. Hence, after x fires the output y continues to fire as long as $a_{\log \hat{t}, 2}$ did not fire.
- The last counting neuron $a_{\log \hat{t}, 2}$ also have negative outgoing edges to all counting neurons (neurons of the form $a_{i,j}$) with weight $w(a_{\log \hat{t}, 2}, a_{i,j}) = -2$. As a result, after the timer counts t rounds it is reset.

Timer with Time Parameter. In the full version we show a slight modified variant of neural timer denoted by DetTimer^* which also receives as input an additional set of $\log t$ neurons that encode the desired duration of the timer. This modified variant is used in our improved randomized constructions.

⁵ I.e., whenever x fires again in a window of t rounds, one should reset the timer and start counting t rounds from that point on.

Neural Counters. We also show a modification of the timer into a counter network DetCounter that instead of counting the number of rounds, counts the number of input spikes in a time interval of t rounds. For complete details we defer the reader to the full version.

► **Lemma 7.** *Given time parameter t , there exists a deterministic neural counter network which has an input neuron x , a collection of $\log t$ output neurons represented by a vector \bar{y} , and $O(\log t)$ additional auxiliary neurons. In a time window of t rounds, for every round τ , if x fired r_τ times in the last τ rounds, the output \bar{y} encodes r_τ by round $\tau + \log r_\tau + 1$.*

This extra-additive factor of $\log r_\tau$ is due to the update time of the counter. In addition, in the full version we revisit the neural counter problem and provide an *approximate* randomized solution with $O(\log \log t + \log(1/\delta))$ many neurons where δ is the error parameter. This construction is based on the well-known Morris algorithm (using the analysis of [10]) for approximate counting in the streaming model.

3 Randomized Constructions of Neural Timer Networks

We now turn to consider randomized implementations. The input to the construction is a time parameter t and an error probability $\delta \in (0, 1)$, that are hard-wired into the network.

► **Definition 8** (Rand. Neural Timer Network). *A randomized neural timer \mathcal{RT} for parameters $t \in \mathbb{N}_{>0}$ and $\delta \in (0, 1)$, satisfies the following for a time window of $\text{poly}(t)$ rounds.*

- *For every fixed firing event of x in round τ , with probability $1 - \delta$, y fires in each of the following t rounds.*
- *$y^{\tau'} = 0$ for every round τ' such that $\tau' - \text{Last}(\tau') \geq 2t$ with probability $1 - \delta$, where $\text{Last}(\tau') = \max\{i \leq \tau' \mid x^i = 1\}$ is the last round τ in which x fired up to round τ' .*

Note that in our definition, we have a success guarantee of $1 - \delta$ for any fixed firing event of x , on the event that y fires for t many rounds after this firing. In contrast, with probability of $1 - \delta$ over the entire span of $\text{poly}(t)$ rounds, y does not fire in cases where the last firing of x was $2t$ rounds apart. We start by showing a simple construction with $O(\log 1/\delta)$ neurons.

3.1 Warm Up: Randomized Timer with $O(\log 1/\delta)$ Neurons

The network BasicRandTimer(t, δ) contains a collection of $\ell = \Theta(\log 1/\delta)$ spiking neurons $A = \{a_1, \dots, a_\ell\}$ that can be viewed as a *time-estimator population*. Each of these neurons have a positive self loop, a positive incoming edge from the input neuron x , and a positive outgoing edge to the output neuron y . See Figure 2 for an illustration. Whereas these a_i neurons are probabilistic spiking neurons⁶, the output y is simply a threshold gate. We next explain the underlying intuition. Assume that the input x fired in round 0. It is then required for the output neuron y to fire for at least t rounds $1, \dots, t$, and stop firing after at most $2t$ rounds with probability $1 - \delta$. By having every neuron a_i firing (independently) w.p $(1 - 1/t)$ in each round given that it fired in the previous round⁷, we get that a_i fires for t consecutive rounds with probability $(1 - 1/t)^t = 1/e$. On the other hand, it fires for $2t$ consecutive rounds with probability $(1 - 1/t)^{2t} = 1/e^2$. Since we have $\Theta(\log 1/\delta)$ many neurons, by a simple application of Chernoff bound, the output neuron y (which simply counts the number of firing neurons in A) can distinguish between round t and round $2t$ with probability $1 - \delta$, see the full version for the complete proof.

⁶ A neuron that fires with a probability specified in Eq. (1)

⁷ A neuron a_i that stops firing in a given round, drops out and would not fire again with good probability.

■ **Figure 2** Illustration of the $\text{BasicRandTimer}(t, \delta)$ network. Each neuron a_i fires with probability $1 - 1/t$ in round τ given that it fired in the previous round $\tau - 1$, and therefore fires for t consecutive rounds with constant probability. The output y fires if at least $1/(2e)$ fraction of the a_i neurons fired in the previous round.

3.2 Improved Construction with $O(\log \log 1/\delta)$ Neurons

We next describe an optimal randomized timer RandImprovedTimer with an exponentially improved number of auxiliary neurons. This construction also enjoys the fact that it requires a *single* spiking neuron, while the remaining neurons can be deterministic threshold gates. Due to the tightness of Chernoff bound, one cannot really hope to estimate time with probability $1 - \delta$ using $o(\log(1/\delta))$ samples. Our key idea here is to generate the same number of samples by re-sampling one particular neuron over several rounds. Intuitively, we are going to show that for our purposes having $\ell = \log(1/\delta)$ neurons a_1, \dots, a_ℓ firing with probability $1 - 1/t$ in a *given* round is *equivalent* to having a *single* neuron a^* firing with probability $1 - 1/t$ (independently) in a sequence of ℓ rounds.

Specifically, observe that the distinction between round t and $2t$ in the BasicRandTimer network is based only on the *number* of spiking neurons in a given round. In addition, the distribution on the number of times a^* fires in a span of ℓ rounds is equivalent to the distribution on the number of firing neurons a_1, \dots, a_ℓ in a given round. For this reason, every phase of RandImprovedTimer simulates a single round of BasicRandTimer . To count the number of firing events in ℓ rounds, we use the deterministic neural counter module with $\log \ell = O(\log \log 1/\delta)$ neurons.

We now further formalize this intuition. The network RandImprovedTimer simulates each round of BasicRandTimer using a phase of $\ell' = \Theta(\log 1/\delta)$ rounds⁸, but with only $O(\log \log 1/\delta)$ neurons. In the BasicRandTimer network each of the neurons a_i fires (independently) in each round w.p $1 - 1/t$. Once it stops firing in a given round, it basically drops out and would not fire again with good probability. Formally, consider an execution of the BasicRandTimer and let n_i be the number of neurons in A that fired in round i . In round $i + 1$ of this execution, we have n_i many neurons each firing w.p $1 - 1/t$ (while the remaining neurons in A fire with a very small probability). In the corresponding $i + 1$ phase of the network RandImprovedTimer , the chief neuron a^* fires w.p $1 - 1/t'$ where $t' = \frac{t}{\ell'}$ for $n'_i \leq \ell$ consecutive rounds⁹ where n'_i is the number of rounds in which a^* fired in phase i .

The dynamics of the network RandImprovedTimer is based on discrete phases. Each phase has a fixed number of $\ell' = O(\ell)$ rounds, but has a possibly different number of *active rounds*, namely, rounds in which a^* attempts firing. Specifically, a phase i has an active part of n'_i rounds where n'_i is the number of rounds in which a^* fired in phase $i - 1$. In the remaining $\ell' - n'_i$ rounds of that phase, a^* is idle. To implement this behavior, the network should keep

⁸ Due to tactical reasons each phase consists of $\ell' = \ell + \log \ell$ rounds instead of ℓ .

⁹ Note that because each phase takes $\ell' = \Theta(\log 1/\delta)$ rounds, we will need to count $t' = \frac{t}{\ell'}$ many phases. Thus a^* fires with probability $1 - 1/t'$ rather than w.p $1 - 1/t$.

track of the number of rounds in which a^* fires in each phase, and supply it as an input to the next phase (as it determines the length of the active part of that phase). For that purpose we will use the deterministic modules of neural timers and counters. The module `DetCounter` with time parameter $\Theta(\log 1/\delta)$ is responsible for counting the number of rounds that a^* fires in a given phase i . The output of this module at the end of the phase is the input to a `DetTimer*` module¹⁰ in the beginning of phase $i + 1$. In addition, we also need a *phase timer* module `DetTimer` with time parameter $\Theta(\log 1/\delta)$ that “announces” the end of a phase and the beginning of a new one. Similarly to the network `BasicRandTimer`, the output neuron y fires as long as a^* fires for at least $(1/2e)$ fraction of the rounds in each phase (in an analogous manner as in the `BasicRandTimer` construction). See Fig. 1 for an illustration of the network. Note that since we only use deterministic modules with time parameter $\Theta(\log 1/\delta)$, the total number of neurons (which are all threshold gates) will be bounded by $O(\log \log 1/\delta)$. See the full version for the complete proof of Thm. 2.

Remark. We note that the fact that one can get a randomized upper bound of $O(\log \log 1/\delta)$ neurons has to do with the fact that our spiking neurons can be set to fire with probability $1 - 1/t$. Therefore the value of t is hard-wired in the network. We also note that in a more restrictive setting where neurons are simple fair coins that fire with probability half in each round, the size complexity might be dependent in t .

3.3 A Matching Lower Bound

We now turn to provide a proof sketch for Thm. 2. The full proof can be found in the full version. Assume towards contradiction that there exists a randomized neural timer \mathcal{N} for a given time parameter t with $N = o(\log \log 1/\delta)$ neurons that succeeds with probability at least $1 - \delta$. This implies that there exists some constant $c \geq 2$ such that y stops firing after $(c - 1) \cdot t$ rounds w.p $1 - \delta$. Since we have N many neurons, the number of distinct states (or configurations) is bounded by $S = 2^N = o(\log 1/\delta)$. In particular, we will adjust the constant in the number of neurons N such that $S \leq \frac{\log 1/\delta}{\log \log 1/\delta}$. Since $t > \log(1/\delta)$ ¹¹, in every execution of \mathcal{N} for at least t rounds, there must be a state that occurs at least *twice* during the execution. Moreover, the sequence of t rounds consists of at least $2S$ disjoint intervals each of length $t/3S$. We therefore get that in every execution of the network, there must be a state that occurs at least twice for some rounds t', t'' such that $t'' - t' > t/3S$. In other words, we have the guarantee that there is always some state that reoccurs after a sufficiently large number of rounds. Since there are at most S configurations, we conclude that there must be one particular configuration s^* for which the probability to reoccur (after at least $t/(3S)$ rounds) is at least $1/S = \Omega(1/\log(1/\delta))$.

Let Π be the family of all $(c \cdot t)$ -length executions of \mathcal{N} . We now restrict attention to all those executions in which s^* reoccurs within the first t rounds, with spacing of $\Omega(t/\log(1/\delta))$ rounds between its appearances¹². We call the subset $\Pi^* \subseteq \Pi$ of those executions *special*. In addition, an execution in Π is *good* if y fires in *each* of the first t rounds, otherwise it is *bad*.

We next claim that the probability of an execution to be both special and good is at least $p^* = \Omega(1/\log(1/\delta) - \delta)$. First, by the definition of Π^* , the probability of an execution to be special is at least $1/S = \Omega(1/\log(1/\delta))$. In addition, by the success guarantee of \mathcal{N} , y fires in the first t rounds w.p. at least $1 - \delta$. Thus by the union bound, we get that the probability of a special and good execution is $1/S - \delta$. This allows us to also conclude that given that s^*

¹⁰ Here we use the variant of `DetTimer` in which the time is encoded in the input layer of the network.

¹¹ The lower bound is meaningful only when $\delta = 2^{-O(t)}$.

¹² We do allow s^* to appear several times within this interval.

appears in some round $t' < t - t/3S$, with probability of at least p^* the following happens: (1) s^* reoccurs in some round t'' such that $t'' - t \in [t/3S, t]$ and (2) y fires during the entire interval $[t', t'']$. We now use this argument to conclude that w.p. at least δ , the output y fires for at least $c \cdot t$ rounds, which will lead to a contradiction. To see this claim, note that w.p. at least $1/S$ there is a round $t' < t - t/3S$ in which s^* appears. With probability at least p^* there is a round $t'' > t + t/3S$ in which s^* appears again and y fires in each of the rounds in $[t', t'']$. A time window of $c \cdot t$ rounds contains at most $3c \cdot S$ intervals of length $t/3S$. Thus by the memory-less property, we get that the probability s^* reoccurs every $[t/3S, t]$ rounds and that y fires after ct rounds is at least $1/S \cdot (p^*)^{3c \cdot S} > \delta$, contradiction as y fires after $c \cdot t$ rounds w.p at most δ .

4 Applications to Synchronizers

The Asynchronous Setting. In this setting, the neural network $\mathcal{N} = \langle X, Z, Y, w, b \rangle$ also specifies a response latency function $\ell : A \rightarrow \mathbb{N}_{>0}$. For ease of notation, we normalize all latency values such that $\min_{e \in A} \ell(e) = 1$ and denote the maximum response latency by $L = \max_{e \in A} \ell(e)$. Supported by biological evidence [13], we assume that self-loop edges (a.k.a. autapses) have the minimal latency in the network, that $\ell((u, u)) = 1$ for self-edges (u, u) . This assumption is crucial in our design¹³. Indeed the exceptional short latency of self-loop edges has been shown to play a critical role in biological network synchronization [21, 8]. The dynamics proceeds in synchronous rounds and phases. The length of a round corresponds to the minimum edge latency, this is why we normalize the latency values so that $\min_{e \in A} \ell(e) = 1$. If neuron u fires in round τ , its endpoint v receives u 's signal in round $\tau + \ell(e)$. Formally, a neuron u fires in round τ with probability $p(u, \tau)$:

$$pot(u, \tau) = \sum_{v \in X \cup Z \cup Y} w_{v,u} \cdot v^{\tau - \ell(u,v)} - b(u) \text{ and } p(u, \tau) = \frac{1}{1 + e^{-\frac{pot(u,\tau)}{\lambda}}} \quad (2)$$

Synchronizer. A synchronizer ν is an algorithm that gets as input a network $\mathcal{N}_{\text{sync}}$ and outputs a network $\mathcal{N}_{\text{async}} = \nu(\mathcal{N}_{\text{sync}})$ such that $V(\mathcal{N}_{\text{sync}}) \subseteq V(\mathcal{N}_{\text{async}})$ where $V(\mathcal{N})$ denotes the neurons of a network \mathcal{N} . The network $\mathcal{N}_{\text{async}}$ works in the asynchronous setting and should have *similar execution* to $\mathcal{N}_{\text{sync}}$ in the sense that for every neuron $v \in V(\mathcal{N}_{\text{sync}})$, the firing pattern of v in the asynchronous network should be similar to the one in the synchronous network. The output network $\mathcal{N}_{\text{async}}$ simulates each round of the network $\mathcal{N}_{\text{sync}}$ as a *phase*.

► **Definition 9 (Pulse Generator and Phases).** A pulse generator is a module that fires to declare the end of each phase. Denote by $t(v, p)$ the (global) round in which neuron v receives the p^{th} spike from the pulse generator. We say that v is in phase p during all rounds $\tau \in [t(v, p - 1), t(v, p)]$.

► **Definition 10 (Similar Execution (Deterministic Networks)).** The synchronous execution Π_{sync} of a deterministic network $\mathcal{N}_{\text{sync}}$ is specified by a list of states $\Pi_{\text{sync}} = \{\sigma_1, \dots, \}$ where each σ_i is a binary vector describing the firing status of the neurons in round i . The asynchronous execution of network $\mathcal{N}_{\text{async}}$ denoted by Π_{async} is defined analogously only when applying the asynchronous dynamics (of Eq. (2)). The execution Π_{async} is divided into phases of fixed length. The networks $\mathcal{N}_{\text{sync}}$ and $\mathcal{N}_{\text{async}}$ have a similar execution if $V(\mathcal{N}_{\text{sync}}) \subseteq V(\mathcal{N}_{\text{async}})$, and in addition, a neuron $v \in V(\mathcal{N}_{\text{sync}})$ fires in round p in the execution Π_{sync} iff v fires during phase p in Π_{async} .

¹³In a follow-up work, we actually show that this assumption is necessary for the existence of synchronizers even when $L = 2$.

For simplicity of explanation, we assume that the network $\mathcal{N}_{\text{sync}}$ is deterministic. However, our scheme can easily capture randomized networks as well (i.e., by fixing the random bits in the synchronized simulation and feeding it to the async. one). See the full version for more details.

The Challenge. Consider a network of a threshold gate z with two incoming inputs: an excitatory neuron x , and an inhibitory neuron y . The weights are set such that z computes $X \wedge \bar{Y}$ thus it fires in round τ if x fired in round $\tau - 1$ and y did not fire. Implementing an $X \wedge \bar{Y}$ gate in the asynchronous setting is quite tricky. In the case where both x and y fire in round τ , in the synchronous network, z should not fire in round $\tau + 1$. However, in the asynchronous setting, if $\ell(x, z) < \ell(y, z)$, then z will mistakenly fire in round $\tau + \ell(x, z)$. This illustrates the need of enforcing a *delay* in the asynchronous simulation: the neurons should attempt firing only after receiving *all* their inputs from the previous phase. We handle this by introducing a pulse-generator module, that announces when it is safe to attempt firing.

To illustrate another source of challenge, consider the asynchronous implementation of an AND-gate $X \wedge Y$. If both x and y fire in round τ , then z fires in round $\tau + 1$ in the synchronous setting. However, if the latencies of the edges $\ell(x, z)$ and $\ell(y, z)$ are distinct, z receives the spike from x and y in *different* rounds, thus preventing the firing of z . Recall, that z has no memory, and thus its firing decision is based only on the potential level in the previous round. To overcome this hurdle, in the transformed network, each neuron in the original synchronous network is augmented with 3 copy-neurons, some of which have self-loops. Since self-loops have latency 1, once a neuron with a self-loop fires, it fires in the next round as well. This will make sure that the firing states of x and y are kept on being presented to z for sufficiently many rounds, which guarantees the existence of a round where both spikes arrive.

While solving one problem, introducing self-loops into the system brings along other troubles. Clearly, we would not want the neurons to fire forever, and at some point, those neurons should get inhibition to allow the beginning of a new phase. This calls for a delicate *reset* mechanism that cleans up the old firing states at the end of each phase, only after their values have already being used. Our final solution consists of global synchronization modules (e.g., pulse-generator, reset modules) that are inter-connected to a modified version of the synchronous network. Before explaining those constructions, we start by providing a modified neural timer $\text{DetTimer}_{\text{async}}$ adapted to asynchronous setting. This timer will be the basic building block in our global synchronization infrastructures.

Asynchronous Analog of DetTimer. A basic building block in our construction is a variant of DetTimer to the asynchronous setting. Observe that the DetTimer implementation of Sec. 2 might fail miserably in the asynchronous setting, e.g., when the edges $(a_{i-1,2}, a_{i,2})$ have latency 2 for every $i \geq 2$, and the remaining edges have latency 1, the timer will stop counting after $\Theta(\log t)$ rounds, rather than after t rounds. In the full version we show:

► **Lemma 11.** *[Neural Timer in the Asynchronous Setting] For a given time parameter t , there exists a deterministic network $\text{DetTimer}_{\text{async}}$ with $O(L \cdot \log t)$ neurons, satisfying that in the asynchronous setting with maximum latency L , the output neuron fires at least $\Theta(t)$ rounds, and at most $\Theta(L \cdot t)$ rounds after each firing of the input neuron.*

Description of the Synchronizer. The construction has two parts: a global infrastructure, that can be used to synchronize many networks¹⁴, and an adaptation of the given network $\mathcal{N}_{\text{sync}}$ into a network $\mathcal{N}_{\text{async}}$. The global infrastructure consists of the following modules:

- A *pulse generator* PG implemented by $\text{DetTimer}_{\text{async}}$ with time parameter $\Theta(L^3)$.
- A *reset* module R_1 implemented by a directed chain of $\Theta(L)$ neurons¹⁵ with input from the output neuron of the PG module.
- A *delay* module D implemented by $\text{DetTimer}_{\text{async}}$ with time parameter $\Theta(L^2)$ and input from the output of of the PG module.
- Another *reset* module R_2 implemented by a chain of $\Theta(L)$ neurons with input from D .

The heart of the construction is the pulse-generator that fires once within a fixed number of $\ell \in [\Theta(L^3), \Theta(L^4)]$ rounds, and invokes a cascade of activities at the end of each phase. When its output neuron g fires, it activates the reset and the delay modules, R_1 and D . The second reset module R_2 will be activated by the delay module D . Both reset modules R_1 and R_2 are implemented by chains of length L , with the last neuron on these chains being an *inhibitor* neuron. The role of the reset modules is to *erase* the firing states of some neurons (in $\mathcal{N}_{\text{async}}$) from the previous phase, hence their output neuron is an inhibitor. The timing of this clean-up is very delicate, and therefore the reset modules are separated by a delay module that prevents a premature operation. The total number of neurons in these global modules is $O(L \cdot \log L)$. We next consider the specific modifications to the synchronous network $\mathcal{N}_{\text{sync}}$ (see Fig. 3).

Modifications to the Network $\mathcal{N}_{\text{sync}}$. The input layer and output layer in $\mathcal{N}_{\text{async}}$ are *exactly* as in $\mathcal{N}_{\text{sync}}$. We will now focus on the set of *auxiliary* neurons V in $\mathcal{N}_{\text{sync}}$. In the network $\mathcal{N}_{\text{async}}$, each $v \in V$ is augmented by three additional neurons $v_{\text{in}}, v_{\text{delay}}$ and v_{out} . The incoming (resp., outgoing) neighbors to v_{in} (resp., v_{out}) are the out-copies (resp., in-copies) of all incoming (resp., outgoing) neighboring neurons of v . The neurons $v_{\text{in}}, v, v_{\text{delay}}$ and v_{out} are connected by a directed chain (in this order). Both v_{delay} and v_{out} have self-loops.

In case where the original network $\mathcal{N}_{\text{sync}}$ contains spiking neurons, the neuron v_{in} will be given the exact same firing function as v in Π_{sync} . That is, in phase p , v_{in} will be given the random coins¹⁶ used by v in round p in Π_{sync} . The other neurons v, v_{delay} and v_{out} are deterministic threshold gates. The role of the *out-copy* v_{out} is to *keep on presenting* the firing status of v from the previous phase $p - 1$ throughout the rounds of phase p . This is achieved through their self-loops. The role of the *in-copy* v_{in} is to simulate the firing behavior of v in phase p . We will make sure that v_{in} fires in phase p only if v fires in round p in Π_{sync} . For this reason, we set the incoming edge weights of v_{in} as well as its bias to be exactly the same as that of v in $\mathcal{N}_{\text{sync}}$. The neuron v is an AND gate of its in-copy v_{in} and the PG output g . Thus, we will make sure that v fires at the *end* of phase p only if v_{in} fires in this phase as well. The role of the delay copy v_{delay} is to delay the update of v_{out} to the up-to-date firing state of v (in phase p). Since both neurons v_{delay} and v_{out} have self-loops, at the end of each phase, we need to carefully reset their values (through inhibition). This is the role of the reset modules R_1 and R_2 . Specifically, the reset module R_1 operated by the pulse-generator inhibits v_{out} . The second reset module R_2 inhibits the delay neuron v_{delay} only after we can be certain that its value has already being “copied” to v_{out} . Finally, we describe the connections of the neuron v_{out} . The neuron v_{out} has an incoming edge from the reset module R_1 with a

¹⁴ It is indeed believed that the neural brain has centers of synchronization.

¹⁵ Each neuron in the chain has an incoming edge from its preceding neuron with weight 1 and threshold 1.

¹⁶ I.e., the random coins that are used to simulate the firing decision of v .

■ **Figure 3** Illustration of the synchronizer modules. Left: global modules implemented by neural timers. Right: a neuron $v \in N_{\text{sync}}$ augmented by three additional neurons that interact with the global modules.

super-large weight. This makes sure that when the reset module is activated, v_{out} will be inhibited shortly after. In addition, it has a self-loop also of large weight (yet smaller than the inhibition edge) that makes sure that if v_{out} fires in a given round, and the reset module R_1 is not active, v_{out} also fires in the next round. Lastly, if v_{out} did not fire in the previous round, then it fires when receiving the spikes from *both* the delay module and from the delay copy v_{delay} . This will make sure that the firing state of v_{delay} will be copied to v_{out} only after the output of the delay module D fires. The complete analysis is given in the full version.

5 Open Problems

In this paper we introduce the problems of neural timer and neural counter in order to shed light into the way that neurons measure time in real biological neural networks. We believe that these timer and counting modules should be useful for many other computational tasks. The key application considered in this paper is for asynchronous computation. For that purpose we introduce a simplified asynchronous model. It would be interesting to delve into this setting and tighten the overhead in the number of neurons and computation time. Finally, exploring the connections between succinct neural networks and dynamic streaming algorithms is yet another promising research direction. The approximate counting problem already provides a positive indication for a potential relation between these models.

Triconnected Planar Graphs of Maximum Degree Five are Subhamiltonian*

Michael Hoffmann

Abstract

We show that every triconnected planar graph of maximum degree five is subhamiltonian planar. A graph is subhamiltonian planar if it is a subgraph of a Hamiltonian planar graph or, equivalently, if it admits a 2-page book embedding. In fact, our result is stronger because we only require vertices of a separating triangle to have degree at most five, all other vertices may have arbitrary degree. This degree bound is tight: We describe a family of triconnected planar graphs that are not subhamiltonian planar and where every vertex of a separating triangle has degree at most six. Our results improve earlier work by Heath and by Bauernöppel and, independently, Bekos, Gronemann, and Raftopoulou, who showed that planar graphs of maximum degree three and four, respectively, are subhamiltonian planar. The proof is constructive and yields a quadratic time algorithm to obtain a subhamiltonian plane cycle for a given graph.

As one of our main tools, which might be of independent interest, we devise an algorithm that, in a given 3-connected plane graph satisfying the above degree bounds, collapses each maximal separating triangle into a single edge such that the resulting graph is biconnected, contains no separating triangle, and no separation pair whose vertices are adjacent.

We thank the organizers and participants for the stimulating atmosphere and, in particular, Oswin Aichholzer, Bahareh Banyassady, Philipp Kindermann, Irina Kostitsyna, and Fabian Lipp for initial discussions about the problem.

1 Introduction

The structure of spanning a.k.a. Hamiltonian paths and cycles in graphs has been a fruitful subject of intense research over many decades, both from a combinatorial and from an algorithmic point of view. For general graphs, sufficient conditions for the existence of a Hamiltonian cycle typically involve rather strong assumptions on the degree, such as in

* Due to space constraints, some proofs in this extended abstract are only sketched or omitted entirely.

Dirac's Theorem [9] (minimum degree $\geq n/2$), Ore's Theorem [16] (degree sum of every nonadjacent vertex pair $\geq n$), or Asratian and Khachatrian's Theorem [1] ($\deg(u) + \deg(w) = |N(u) + N(v) + N(w)|$, for every induced path uvw). Planar graphs provide a lot more structure so that by a famous theorem of Tutte, 4-connectivity suffices to guarantee the existence of a Hamiltonian cycle [19], which can be computed in linear time [7]. In contrast, deciding Hamiltonicity is NP-complete for 3-connected cubic planar graphs [11]. Finally, *maximal* planar graphs of degree at most six are Hamiltonian [10]. We observe that both vertex degree and connectivity are crucial parameters concerning Hamiltonicity.

Hamiltonian cycles are also of interest in the context of graph embeddings. Specifically, in a *book embedding*, all vertices are embedded on a line called *spine*, and every edge is embedded in a halfplane, called *page*, bounded by the spine. No two edges (on the same page) cross. If k pages are used, then the corresponding embedding is a k -page book embedding. Note that a k -page book embedding with $k \leq 2$ is plane. Bernhart and Kainen [4] characterized those graphs that can be embedded on k pages, for $k \leq 2$. For $k = 2$ these are the subhamiltonian planar¹ graphs, that is, subgraphs of Hamiltonian planar graphs, cf. Figure 1a. Hence not all planar graphs can be embedded on two pages; in fact, it is NP-complete to decide whether a given planar graph is subhamiltonian [20], even if all vertices have degree at most seven [2]. However, no planar graph is too far away from being subhamiltonian: Subdividing at most $n/2$ of the up to $3n - 6$ edges of a planar graph on n vertices yields a subhamiltonian planar graph [6].

■ **Figure 1** (a) A nonhamiltonian graph with a subhamiltonian cycle and a corresponding two-page book embedding. (b) A subhamiltonian cycle using e_1 and e_2 in a wheel with at least four spokes.

Despite a plethora of results concerned with Hamiltonian cycles in planar graphs and book embeddings, several fundamental questions are still open. Let us give just two prominent examples to illustrate this point. For once, there is Barnette's Conjecture: "Every 3-connected cubic bipartite planar graph is Hamiltonian." And then there is the question if every planar graph can be embedded on three pages. Yannakakis showed, improving a series of earlier results, that four pages are sufficient for every planar graph [22]. However, a corresponding lower bound is still elusive, in spite of initial claims [21].

In this paper, we investigate what upper bound on the vertex degree guarantees that a planar graph is subhamiltonian planar. Heath [14] showed that maximum degree three suffices. Later, Bauernöppel [2] and, independently, Bekos et al. [3] showed that every planar graph of degree at most four is subhamiltonian planar. On the negative side, Bauernöppel [2] described planar graphs of vertex degree at most seven that are not subhamiltonian (these graphs are biconnected but not 3-connected). In a preprint, Guan and Yang [12] show that planar graphs of maximum degree five can be embedded on three pages. Our goal is to further relax the degree bound so as to (ultimately) determine what is the largest k so that every

¹ We prefer the term "subhamiltonian planar" over just "subhamiltonian" because the former is more descriptive as a shortcut for "subgraph of a Hamiltonian planar graph".

planar graph of degree at most k is subhamiltonian planar. Specifically, we are interested in the case where the given graph is 3-connected and hence the combinatorial embedding is unique. Along these lines, we make a natural next step by considering the case of maximum degree five. In fact, we prove a much stronger statement where the degree restriction applies to vertices of separating 3-cycles only.

► **Theorem 1.** *Let G be a 3-connected simple planar graph on n vertices where every vertex of a separating 3-cycle has degree at most five. Then G is subhamiltonian planar. Moreover, a subhamiltonian plane cycle for G can be computed in $O(n^2)$ time.*

► **Corollary 2.** *Every 3-connected simple planar graph with maximum vertex degree five can be embedded on two pages, and such an embedding can be computed in quadratic time.*

We also show that the degree bound in Theorem 1 is tight.

► **Theorem 3.** *There exists a family of 3-connected simple planar graphs that are not subhamiltonian planar and where every vertex of a separating 3-cycle has degree at most six.*

Organization. We begin by introducing some terminology in Section 2. In Section 3, we study three special cases for which Theorem 1 is easily proven. In Section 4, we proceed with a high-level overview of the proof of Theorem 1, which is then developed in some more detail in Sections 5–7. We conclude with an example to illustrate Theorem 3 in Section 8.

2 Notation

All graphs in this paper are undirected. We denote by $V(G)$ the vertex set and by $E(G)$ the edge set of a graph G . For a set of edges $E \subseteq E(G)$ we use $V(E)$ to denote the set of vertices that are incident to at least one edge in E . For a face f of G we denote by ∂f the closed walk in G that traverses the vertices and edges on the boundary of f in anticlockwise direction. If G is biconnected, then ∂f is a cycle, for every face f of G . A *Hamiltonian* cycle for a graph is a simple cycle through all vertices and a graph is *Hamiltonian* if it contains a Hamiltonian cycle. An *augmentation* of a graph $G = (V, E)$ is a supergraph $A = (V, E')$ with $E' \supseteq E$. If G is a plane graph, then a *plane augmentation* H of G is an augmentation that respects the embedding of G , that is, if Γ denotes the embedding of G and Γ' denotes the embedding of H , then $\Gamma'|_G = \Gamma$. A *subhamiltonian cycle* for a graph G is a Hamiltonian cycle in some augmentation of G .

We distinguish between separating 3-cycles as a notion for both abstract and embedded graphs and separating triangles in embedded graphs. A *separating 3-cycle* is a 3-cycle whose removal disconnects the graph. A *separating triangle* is a 3-cycle C of an embedded graph G such that both the interior and the exterior region bounded by C contain some vertex of G .

For a cycle C in a plane graph G denote by G_C^+ the plane subgraph of G that contains all vertices and edges on C and exterior to C . Similarly denote by G_C^- the plane subgraph of G that contains all vertices and edges on C and interior to C . The *inside* of C refers to the interior of the bounded region enclosed by C . So a vertex of G *inside of* C is a vertex of $G_C^- \setminus C$. Analogously a vertex *outside of* C is a vertex of $G_C^+ \setminus C$. A separating triangle T is called *trivial* if $G_T^- \simeq K_4$ and *nontrivial*, otherwise.

Our algorithm uses a decomposition of the graph into its triconnected components, which can be efficiently maintained via the SPQR-tree data structure [13, 15]. We use the terminology by Gutwenger and Mutzel [13].

3 Three simple cases

It suffices to prove Theorem 1 for an arbitrary plane embedding of the given graph, which we assume to be represented as a doubly-connected edge list (DCEL) [8]. In fact, by 3-connectivity, the combinatorial plane embedding is unique up to the choice of the outer face, and there is no difference between separating 3-cycles and separating triangles. So let G be an embedded 3-connected simple planar graph (with a fixed outer face) where every vertex incident to a separating triangle has degree at most five. By combining known results, it is easy to deal with the case that G has no separating triangle:

► **Theorem 4.** *If an embedded simple planar graph $\mathcal{G} = (V, E)$ does not contain any separating triangle, then for any two distinct edges $e_1, e_2 \in E$ there is a plane augmentation \mathcal{H} of \mathcal{G} that contains a Hamiltonian cycle C using e_1 and e_2 . Moreover, the cycle C can be computed in $O(n^2)$ time, where n is the number of vertices in \mathcal{G} . If both e_1 and e_2 are on the outer face of \mathcal{G} , then C can be computed in linear time.*

Proof Sketch. Augment \mathcal{G} using an algorithm by Biedl, Kant, and Kaufmann [5] to obtain, if possible, a 4-connected planar graph, which contains the desired Hamiltonian cycle due to a theorem of Sanders [17, Corollary 2]. If such an augmentation is impossible, then the graph can be augmented to a wheel, in which the desired cycle is easily found; see Figure 1b.

Algorithmically, the bottleneck is Sanders' theorem. While the original formulation is purely existential, a recently developed algorithmic version by Schmid and Schmidt [18] allows to compute such a cycle in quadratic time. For the special case where both e_1 and e_2 are on the outer face, we can use the linear time algorithm by Chiba and Nishizeki [7]. ◀

In order to be able to argue inductively, we prove a stronger statement than necessary, namely a version of Theorem 1 where, similar to the statement in Theorem 4, two edges of the desired subhamiltonian cycle may be prescribed:

► **Theorem 5.** *Let $\mathcal{G} = (V, E)$ be an embedded 3-connected simple planar graph on n vertices with outer face T_o , where every vertex that is incident to a separating triangle has degree at most five. Further, let $F \subset E$ be a set of at most two edges so that*

(P1) *all edges in F are edges of T_o ;*

(P2) *if T_o is not a triangle, then $F = \emptyset$;*

(P3) *if $F \neq \emptyset$, then no vertex of T_o is incident to a separating triangle of \mathcal{G} ; and*

(P4) *if $F \neq \emptyset$, then either at least one vertex of T_o has degree three in \mathcal{G} , or all vertices of T_o have degree four in \mathcal{G} .*

Then there is a plane augmentation of \mathcal{G} that contains a Hamiltonian cycle C that uses all edges from F . Moreover, the cycle C can be computed in $O(n^2)$ time.

The proof, sketched in Sections 5–7, is carried out by induction on the number of vertices. In this context, one can easily show that:

► **Lemma 6.** *Suppose that the statement of Theorem 5 holds for all graphs with at most $n - 1$ vertices, where $n \geq 6$. Then it also holds for every graph on n vertices that contains at least one nontrivial separating triangle.*

Proof Sketch. Let T be a nontrivial separating triangle in \mathcal{G} . Replace the interior of T with a single vertex d and inductively find a subhamiltonian cycle C in the resulting smaller graph. Then, inductively obtain a subhamiltonian cycle C' for \mathcal{G}_T^- . For this second inductive call, we make use of the ability to prescribe edges, depending on how C visits d , in order to ensure that the cycles C and C' may be glued together to obtain a subhamiltonian cycle for \mathcal{G} . ◀

The degree restriction basically enforces that the separating triangles of G are pairwise vertex-disjoint. However, there are some exceptional configurations where two separating triangles share an edge. Our next goal is to classify these configurations precisely.

A *double kite* is a subgraph $U \simeq K_4$ of an embedded graph \mathcal{G} so that exactly two of the four triangles of U are separating in \mathcal{G} . The two separating triangles are said to *define* the double kite. Note that \mathcal{G} may contain multiple double kites, see Figure 2a. We refer \mathcal{G} itself as a *trivial double kite* if it is 3-connected, contains a double kite, and has precisely 6 vertices.

► **Lemma 7.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let T_1, T_2 be two distinct separating triangles of \mathcal{G} such that every vertex incident to T_1 has degree at most five. Then if T_1 and T_2 share a vertex, the triangles T_1 and T_2 define a double kite.*

► **Observation 8.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let T_1, T_2 be two distinct trivial separating triangles of \mathcal{G} such that all vertices incident to T_1 or T_2 have degree at most five. Then if T_1 and T_2 share a vertex, the graph \mathcal{G} is a trivial double kite.*

For a trivial double kite G , the statement of Theorem 5 is easily verified. Hence, from now on we may assume that the separating triangles of G are trivial and pairwise vertex-disjoint.

4 Proof overview

To prove Theorem 5 we proceed in three steps.

In the first step (Section 5), we destroy all separating triangles using edge collapses. An edge $e = ab$ of a separating triangle $T = abc$ is *collapsed* by contracting (the three edges of) the triangle that is spanned by the endpoints of e and the single vertex d inside T into a new vertex x and merging the two edges ac and bc to a new edge cx ; see Figure 2b. Observe that an edge collapse can be performed in constant time in a DCEL.

■ **Figure 2** (a) A graph with three double kites. (b) Collapsing the edge $e = ab$.

A collapse operation may create multiple edges if a and b have a common neighbor $z \notin \{c, d\}$. However, we will assert that an edge ab is collapsed only if the triangle abz is not separating, i.e., one of its sides is empty. In particular, if T is not part of a double kite, we may collapse any of its edges by Lemma 7. Our assertion ensures that whenever an edge collapse creates multiple edges, we may merge them into a singleton edge without losing information about the embedding. Hence, we may assume that the graph resulting from an edge collapse is always simple. Moreover, note that the collapse operation does not increase the degree of any vertex. In particular, the degree of c decreases by two. The degree of the new vertex x is at most five. Hence, collapsing an edge in G results in a graph that satisfies the degree constraints, unless the collapse creates a new separating triangle.

We describe a procedure to find a set $K \subset E$ of edges such that the graph G' obtained by simultaneously collapsing all edges of K does not contain any separating triangle.

In the second step (Section 6), we augment G' by *stellating* every face, that is, for each nontriangular face f of G' we insert a new vertex v_f into f and we add an edge between v_f and each vertex on the boundary of f . By choosing the set K suitably, we ensure that the graph G'' resulting from these stellations does not contain any separating triangle. Thus, using Theorem 4 we obtain a subhamiltonian cycle C'' for G'' .

Finally, in the third step (Section 7), we iteratively revert the edge collapses. Due to the stellated faces, we have some control over the possible ways that C'' visits the vertex pairs in G'' that result from collapsing a triangle of G . We will show that a series of local rerouting steps suffices to transform C'' into a subhamiltonian cycle for G .

5 Collapsing edges

Recall that G is an embedded 3-connected simple planar graph in which every separating triangle is trivial and all vertices incident to a separating triangle have degree at most five. Moreover, G is not a trivial double kite. Let S denote the set of separating triangles of G , which are pairwise vertex-disjoint by Observation 8. We want to find a set $K \subset E$ of edges so that (1) every edge in K is incident to a triangle in S ; (2) every triangle in S is incident to exactly one edge from K ; and (3) the graph obtained by simultaneously collapsing the edges of K does not contain any separating triangle.

Obviously, there exists a set \hat{K} of edges that satisfies (1) and (2). Suppose that (3) does not hold for \hat{K} , that is, the graph \hat{G} obtained from G by collapsing the edges in \hat{K} contains a separating triangle T . By (2) we know that T is not a triangle in G , but T corresponds to a separating k -cycle in G , for $k \geq 4$. By (1), (2), and since the triangles in S are pairwise vertex-disjoint, at most every other edge of a cycle in G is in \hat{K} and, therefore, we have $k \leq 6$. In other words, every separating triangle in \hat{G} corresponds to a separating k -cycle in G where $k \in \{4, 5, 6\}$ and exactly $k - 3$ edges are in \hat{K} . Moreover, for any such separating k -cycle in G , both the interior and the exterior must contain at least one vertex that is not the interior vertex of a triangle from S because by (2) every interior vertex of a triangle from S disappears in some collapse.

Inspired by these observations, we call a cycle C of an embedded graph *hyperseparating* if both the interior and the exterior contain at least one vertex that is not the interior vertex of a trivial separating triangle. We define an *inhibitor* to be a hyperseparating k -cycle I , where $k \in \{4, 5, 6\}$, for which at least $k - 3$ edges are incident to a trivial separating triangle, for an illustration refer to Figure 3d. We refer to these at least $k - 3$ edges as *constrained*. An edge e of an embedded graph is *constrained* if there exists an inhibitor I so that e is a constrained edge of I and *unconstrained*, otherwise. An inhibitor of length $k \in \{4, 5, 6\}$ is also called a *k-inhibitor*.

Note that a set \hat{K} of edges that satisfies (1) and (2) also satisfies (3) if for every inhibitor of length k in G , no more than $k - 4$ of its constrained edges are in \hat{K} . Next we study the:

5.1 Structure of inhibitors

First, let us observe that 4-inhibitors of G are chordless.

► **Observation 9.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let $T = abc$ be a trivial separating triangle of \mathcal{G} with inner vertex d such that all vertices incident to T have degree at most five. Further, let $abxy$ be a 4-inhibitor constraining ab . Then $\{x, y\} \cap \{c, d\} = \emptyset$.*

► **Lemma 10.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let $T = abc$ be a trivial separating triangle of \mathcal{G} with inner vertex d such that all vertices incident to T have degree at most five. Suppose that ab is constrained by a 4-inhibitor $I_{ab} = abxy$. Then I_{ab} is chordless, unless ab is incident to two separating triangles that define a double kite.*

Proof. Assume without loss of generality that by is a chord of I_{ab} . By Observation 9, $x, y \notin \{c, d\}$ and, so, the degree of b is saturated; see Figure 3a. We claim that by is on the side of I_{ab} that contains c and d . To see this, assume the contrary. Since I_{ab} is separating, there is some vertex z on the side of I_{ab} that does not contain c, d . The chord by splits this side of I_{ab} into two triangles, one of which contains z , see Figure 3b and 3c. However, by 3-connectivity, this implies that b has a neighbor in this triangle, in contradiction to the degree bound of b . So the claim holds, that is, by is indeed on the side of I_{ab} that contains c, d . Then aby is a triangle that separates x from c, d , see Figure 3d. By Lemma 7, the triangles abc and aby define a double kite. ◀

■ **Figure 3** A 4-inhibitor $I_{ab} = abxy$ that constrains the edge ab of the separating triangle abc .

A necessary requirement for the existence of a set K of edges to collapse is that our graph does not contain a separating triangle for which every edge is constrained by a 4-inhibitor. We show that this requirement is met, except for some specific special cases.

► **Lemma 11.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let \mathcal{I} be a set of 4-inhibitors of \mathcal{G} . Further, let T be a trivial separating triangle of \mathcal{G} such that all vertices incident to T have degree at most five. Finally, assume that \mathcal{G} contains no separating triangle that together with T defines a double kite.*

Then either (1) T is incident to at least one edge that is not constrained by a 4-inhibitor of \mathcal{I} ; or (2) \mathcal{G} contains a subgraph \mathcal{G}' that is isomorphic to one of the graphs $\mathcal{G}_1, \mathcal{G}_2$ depicted in Figure 4 such that each thick (colored) edge of \mathcal{G}' is incident to some 4-inhibitor of \mathcal{I} .

■ **Figure 4** If all three edges of a separating triangle in the graph \mathcal{G} are constrained by a 4-inhibitor, there is a subgraph \mathcal{G}' isomorphic to \mathcal{G}_1 or \mathcal{G}_2 . The gray parts in (a) represent arbitrary subgraphs.

Proof Sketch. Assume that each edge of $T = abc$ is constrained by a 4-inhibitor of \mathcal{I} , and that \mathcal{G} contains no subgraph \mathcal{G}' as in the claim. We denote the inhibitors of \mathcal{I} constraining ab , bc , and ac by $I_{ab} = abxy$, $I_{bc} = bcst$, and $I_{ac} = acvw$, respectively. By Lemma 10, we have $c, d \notin I_{ab}$, $a, d \notin I_{bc}$, and $b, d \notin I_{ac}$, where d denotes the inner vertex of T . By 3-connectivity and since I_{ab} is separating, we may assume w.l.o.g. that b has a neighbor z which is located on the side of I_{ab} that does not contain c ; see Figure 4c. Due to the degree bound of b , we have $t \in \{x, z\}$.

First, assume that $t = z$. By planarity, s belongs to I_{ab} ; and by Lemma 10 applied to I_{bc} we have $s = y$ and, thus, $I_{bc} = bcyz$. We study the third inhibitor $I_{ac} = acvw$. We have $v \neq y$, as otherwise ay would be a chord of I_{ac} , contradicting Lemma 10. The triangle acy is nonseparating by Lemma 7 and the assumption that T does not define a double kite. Thus, v is located on the side of I_{bc} that does not contain a and, hence, by planarity, v or w has to belong to I_{bc} . Since $c \in I_{ac} \cap I_{bc}$, Lemma 10 implies that the only other vertex of I_{ac} in this intersection is z . As z and c are located on distinct sides of I_{ab} , the vertex v must belong to I_{ab} and, thus, $v = x$ and $I_{ac} = acxz$. Altogether, this establishes that \mathcal{G} contains a subgraph $\mathcal{G}' \simeq \mathcal{G}_2$ as in the statement, which yields the desired contradiction.

It remains to consider the case that $t = x$. Using similar arguments as in the previous paragraph, we obtain a contradiction to the assumption that \mathcal{G} does not contain a subgraph $\mathcal{G}'' \simeq \mathcal{G}_1$ as in the statement. \blacktriangleleft

Similar to the proof of Lemma 6, we can deal with the special case that there is a separating triangle in S such that each of its edges is constrained using the inductive framework of the proof of Theorem 5. So assume from now on that G does not contain a subgraph isomorphic to \mathcal{G}_1 or \mathcal{G}_2 as in Lemma 11. Our plan is to use Lemma 11 to identify an unconstrained edge, which is then collapsed. This procedure is then iterated until no separating triangle is left. The edges collapsed during this process form the desired set K .

Due to the degree bound, it is easy to determine in quadratic time the set of *ineligible* edges, that is, edges of separating triangles that are constrained by 4-inhibitors. Whenever an edge collapses, we check all separating triangles in the constant size neighborhood in order to update the set of ineligible edges in constant time. These edges are never considered for inclusion into the set \mathcal{K} of edges to collapse.

An edge collapse is *3-connectivity preserving* if the graph resulting from the collapse is 3-connected. As long as there is an eligible edge whose collapse preserves 3-connectivity, we collapse it. In order to test whether this is the case for an edge ab of a separating triangle $T = abc$, it suffices to determine and check all pairs of distinct faces f_a and f_b of \mathcal{G}_T^+ incident to a and b , respectively, and a vertex $v \neq c$ such that $v \in \partial f_a \cap \partial f_b$. This test can be performed in linear time, given that there is only a constant number of choices for f_a and f_b . Observe that negative test results are robust under 3-connectivity preserving collapses; whereas, in general, positive results are not. Hence, it suffices to consider every eligible edge at most once, and so the time spent on these tests is quadratic overall.

However, in general an edge collapse may reduce the connectivity of the graph. In this case, we plan to recurse on the triconnected components of the graph. To make such a recursion work in the context of our overall proof strategy, we must take special care concerning the vertices of separation pairs. Specifically, as we will discuss in the following section, we should never create a separation pair whose vertices are adjacent.

5.2 Avoiding adjacent separation pairs

Recall that we plan to stellate each face of the graph G' that is obtained by simultaneously collapsing all edges in K , and that we need to ensure that the resulting graph G'' does not contain any separating triangle. Consider a face f of G' and assume that its stellation creates a separating triangle $s = av_f$ where v_f is the new vertex inserted into f . Note that the vertices a and b are incident to f . Therefore, the edge $ab \in E(G')$ is a chord of ∂f and, moreover, a, b is a separation pair of G' .

In order to avoid this situation, it suffices to choose the set K subject to the following additional constraint: (4) the graph obtained by simultaneously collapsing the edges of K does not create an *adjacent* separation pair, i.e., a separation pair a, b where a and b are adjacent. Inspired by this observation, we devise a strengthened version (Lemma 13) of Lemma 11. For its proof, we require the following observation:

► **Observation 12.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let $T = abc$ be a trivial separating triangle of \mathcal{G} with inner vertex d . Further, assume that collapsing ab results in a graph \mathcal{G}' that is 2-connected but not 3-connected; and let p, q be a separation pair of \mathcal{G}' . Then we may assume that p is the new vertex that is created by the collapse of ab and that $q \notin \{c, d\}$.*

► **Lemma 13.** *Let \mathcal{G} be an embedded 3-connected simple planar graph and let \mathcal{I} be a set of 4-inhibitors of \mathcal{G} . Further, let $T = abc$ be a trivial separating triangle of \mathcal{G} with inner vertex d such that all vertices incident to T have degree at most five. Finally, assume that \mathcal{G} contains no separating triangle that together with T defines a double kite.*

Then either (1) T is incident to at least one edge e such that (i) e is not constrained by a 4-inhibitor of \mathcal{I} ; and (ii) collapsing e does not create an adjacent separation pair; or (2) \mathcal{G} contains a subgraph \mathcal{G}' that isomorphic to one of the graphs $\mathcal{G}_1, \mathcal{G}_2$ depicted in Figure 4 such that each thick (colored) edge of \mathcal{G}' is incident to some 4-inhibitor of \mathcal{I} .

5.3 Choosing the set of edges to collapse

We are now prepared to discuss how the desired edge set K is obtained.

► **Theorem 14.** *Let \mathcal{H} be an embedded 3-connected simple planar graph on n vertices where every vertex incident to a separating triangle has degree at most five and where every separating triangle is trivial. Further, let \mathcal{S} denote the set of separating triangles in \mathcal{H} . Assume that \mathcal{H} is not a trivial double kite and that \mathcal{H} contains no subgraph isomorphic to \mathcal{G}_1 or \mathcal{G}_2 . Then we can compute in $O(n^2)$ time a set $\mathcal{K} \subset E(\mathcal{H})$ of edges so that:*

- (I1) every edge in \mathcal{K} is incident to a triangle in \mathcal{S} ;
- (I2) every triangle in \mathcal{S} is incident to exactly one edge from \mathcal{K} ;
- (I3) \mathcal{H} contains no k -inhibitor I such that \mathcal{K} contains $k - 3$ or more edges of I ; and
- (I4) the graph \mathcal{H}'' obtained by simultaneously collapsing the edges of \mathcal{K} is biconnected and does not contain an adjacent separation pair.

Proof Sketch. The proof is by induction on the number $|\mathcal{S}|$ of separating triangles. Let e be an edge of \mathcal{H} that satisfies Property (1) of Lemma 13. Let \mathcal{H}' be the embedded simple planar graph obtained by collapsing e in \mathcal{H} . We show that \mathcal{H}' is not a trivial double kite or contains a subgraph isomorphic to \mathcal{G}_2 . We also show that e can always be chosen such that \mathcal{H}' contains no \mathcal{G}_1 . If \mathcal{H}' is 3-connected, we inductively obtain an edge set \mathcal{K}' that satisfies the Properties (I1)–(I4) and, hence, $\mathcal{K} = \mathcal{K}' \cup \{e\}$ satisfies these properties for \mathcal{H} .

It remains to deal with the case that for every edge e that satisfies Property (1) of Lemma 13, collapsing e results in a graph \mathcal{H}' that is biconnected, but not 3-connected. In this case, we recurse on the triconnected components of \mathcal{H}' . In particular, from the fact that \mathcal{H}' contains no adjacent separation pair, we may derive that each separating triangle of \mathcal{H}' appears, with all its real edges, in some rigid triconnected component R of \mathcal{H}' , which is a simple 3-connected planar graph. The graph R may contain separating triangles that do not belong to \mathcal{S} , namely the separating triangles that are incident to virtual edges. Keeping in mind that virtual edges correspond to separation pairs of \mathcal{H}' , and that \mathcal{H}' contains no adjacent separation pairs, virtual edges of R may be thought of as paths (in \mathcal{H}') of length at least two. As a consequence, we may ignore such *virtual* separating triangles. Similarly,

regarding Property (I3), when picking the next edge to collapse in R , we do not need to worry about 4-inhibitors that have virtual edges. Formally, this is realized by proving a generalized version of the theorem, in which each edge of \mathcal{H} is labeled as either real or virtual and in which the Properties (I1)–(I4) are relaxed accordingly.

The relaxed versions of Property (I1) and (I2) are easy to achieve. Regarding Property (I4), the main challenge is to ensure that the separation pairs already present in \mathcal{H}' do not become adjacent when performing further edge collapses. Let p, q be a separation pair of \mathcal{H}' . By Observation 12, we may assume that p is the vertex created by collapsing e . Since the *real* separating triangles of \mathcal{H}' are pairwise vertex-disjoint, we conclude that in order for p and q to become adjacent, there must exist a path psq in \mathcal{H}' , where sq is incident to a triangle T of \mathcal{S} . Let R be the rigid triconnected component of \mathcal{H}' that contains T . We compute an edge set \mathcal{K}_R for R that satisfies Properties (I1)–(I4). We show that if sq is constrained by a 4-inhibitor in \mathcal{H} , we may simply obtain \mathcal{K}_R by induction as the Properties (I1)–(I4) of \mathcal{K}_R already suffice to guarantee that p, q do not become adjacent. If sq is not constrained by a 4-inhibitor, there are choices of \mathcal{K}_R for which p, q become adjacent even though Properties (I1)–(I4) hold for \mathcal{K}_R . We show that this is only possible in a very constrained special case, where

- either R has constant size (in this case we select \mathcal{K}_R explicitly, rather than inductively);
- or we can apply a strategy ϱ to replace e with a new edge $\varrho(e)$, so that ϱ is acyclic, that is, $\varrho^i(e) \neq e$, for all $i \in \mathbb{N}$.

Finally, we show that Property (I4) implies Property (I3). To maintain the triconnected components, we use a decremental data structure by Holm et al. [15, Theorem 11] that allows to dynamically maintain an SPQR-tree under a sequence of edge contractions or deletions in $O(n \log^2 n)$ total time. Note that an edge collapse can be implemented using edge contractions and deletions. The runtime of our algorithm is dominated by the replacement strategy ϱ . We show that a single replacement step can be performed in constant time. After at most a linear number of replacements, we obtain an edge that can safely be collapsed. Hence, as the number of collapses is linear, the overall complexity is quadratic. ◀

6 Stellation

Let $K \subset E(G)$ be a set of edges to collapse as described in Theorem 14, and let G' denote the graph that results from simultaneously collapsing the edges from K in G . Then by Property (I3) of Theorem 14 the graph G' does not contain any separating triangle. Let G'' denote the graph that results from stellating all faces in G' , that is, for every nontriangular face f of G' we insert a new vertex v_f into f and we add an edge between v_f and each vertex on ∂f . As discussed in Section 5.2, the following lemma is an easy consequence of Property (I4).

► **Lemma 15.** *The graph G'' does not contain any separating triangle.*

Therefore, we can apply Theorem 4 to G'' to obtain a Hamiltonian cycle C'' for G'' . It remains to address the case that one or two edges of the outer face T_\circ of G are prescribed.

► **Observation 16.** *If any edge of T_\circ is prescribed, then T_\circ is also the outer face of G'' .*

Proof. By Property (P3) we know that T_\circ is also the outer face of G' . By Property (P2) we know that T_\circ a triangle and, therefore, it is not subdivided when going from G' to G'' . ◀

By Observation 16 we can pass any possibly prescribed edge of T_\circ to Theorem 4 so that the obtained Hamiltonian cycle C'' for G'' passes through the(se) prescribed edge(s).

7 Reconstructing Collapses

As a final step to prove Theorem 1, it remains to undo the edge collapses, that is, to go back from the modified graph G'' to the original graph G . Our algorithm maintains a subhamiltonian plane cycle in the current graph, starting with a subhamiltonian plane cycle in G'' . Then the separating triangles of G are processed in a certain order, which is incrementally computed as part of the algorithm. At every step of the algorithm we handle one separating triangle and include its vertices into the current working cycle. For some steps we may choose this separating triangle freely among the remaining ones, while in other steps that choice might be dictated by the previous step.

During the whole reconstruction process, we modify the current cycle in specific ways only. In particular, we only modify edges of the cycle that are incident to a separating triangle of G (including vertices that result from the collapse of an edge in K). By Observation 16 and (P3) this assertion suffices to ensure that prescribed edges on the outer face of G (if any) are part of the cycle that is constructed. Our algorithm proceeds in up to three phases.

Phase 1. First, we reconstruct *some* collapsed triangles, while maintaining a subhamiltonian plane cycle in the current graph. We consider only triangles that are visited by the current working cycle in a specific way so that after reconstructing them the cycle can easily be extended to visit all vertices of and in the interior of those triangles; see Figure 5 for examples, where the solid orange segments depict edges of the current cycle.

■ **Figure 5** Examples of two easy reconstructions in Phase 1 (where uv was collapsed to \bar{u}).

At the end of the first phase, we move on to the graph G , that is, we reconstruct all remaining triangles at once. The previously Hamiltonian cycle then becomes a nonspanning cycle in a plane augmentation of G that visits all vertices of G but a pair of vertices from each of the *remaining* triangles (that have not been reconstructed during the first phase already). We can classify these remaining triangles – up to symmetry – into five different types according to how they interact with the current cycle. This classification is illustrated in Figure 6(a)–(e), where the dotted orange segments depict three different options for an edge of the current cycle, and the red crosses mark vertices that are not part of a remaining separating triangle.

■ **Figure 6** The six types of remaining triangles during Phase 2 of the reconstruction.

Phase 2 and 3. During the second phase we then maintain this classification: although a triangle may change its type, it always remains one of these five types. As in the first phase, we process the triangles one by one. Processing a triangle amounts to extending the current cycle to visit the two missing vertices. At the end of Phase 2 we either have a subhamiltonian plane cycle for G (and are done), or we are in a situation where *all* remaining triangles to be handled are of a very specific type with respect to the current cycle, which is illustrated in Figure 6f; the vertices labeled with a red exclamation mark are also part of a remaining separating triangle. Note that this type is a specialization of the more general type depicted in Figure 6c. The remaining triangles – if any – are then processed during a third phase, at the end of which we obtain the desired subhamiltonian plane cycle for G .

Remarks. The complexity of the reconstruction algorithm is linear overall. To illustrate the challenges for this reconstruction process and why it is important to control the interaction of the remaining triangles with the cycle under construction, consider the examples shown in Figure 7. If the cycle was to visit a remaining triangle in one of the ways depicted, then there is no way to locally modify the cycle to visit the missing vertices. Note that due to the stellation, these two configurations are avoided in the beginning of Phase 1.

8 Conclusions

The graph G_3 whose construction is depicted in Figure 8 is a member of the infinity family described in Theorem 3, which shows that our degree restriction in Theorem 1 is necessary in general. The most prominent open question is whether all planar graphs of degree ≤ 6 are subhamiltonian.

■ **Figure 7** Two types of remaining triangles to avoid: There is no easy way to extend the cycle.

■ **Figure 8** The construction of G_3 , a 3-connected planar graph that is not subhamiltonian and where every vertex of a separating triangle has degree at most six. We start from the Cartesian product $C_4 \square P_3$, where we pick three pairwise nonadjacent faces (shaded in (a)). Then we plant a rectangular prism on each picked face, obtaining the frame F_3 (b). Finally, to obtain G_3 we add a new vertex in every face of F_3 and connect it to three vertices on the boundary (c). The separating triangles of G_3 are shaded red; their vertices have degree six. The red vertices form an independent set, and no edge between any two red vertices can be added while maintaining planarity. As there are 25 red vertices and 24 black vertices, no plane augmentation of G_3 is Hamiltonian.

Abstract

Data structures for efficient sampling from a set of weighted items are an important building block of many applications. However, few parallel solutions are known. We close many of these gaps both for shared-memory and distributed-memory machines. We give efficient, fast, and practicable algorithms for sampling single items, k items with/without replacement, permutations, subsets, and reservoirs. We also give improved sequential algorithms for alias table construction and for sampling with replacement. Experiments on shared-memory parallel machines with up to 158 threads show near linear speedups both for construction and queries.

1 Introduction

Weighted random sampling asks for sampling items (elements) from a set such that the probability of sampling item i is proportional to a given weight w_i . Several variants of this fundamental computational task appear in a wide range of applications in statistics and computer science, *e.g.*, for computer simulations, data analysis, database systems, and online ad auctions (see, *e.g.*, Motwani et al. [26], Olken et al. [28]). Continually growing data volumes (“Big Data”) imply that the input sets and even the sample itself can become large. Since actually processing the sample is often fast, sampling algorithms can easily become a performance bottleneck. Due to the hardware developments of the last years, this means that we need *parallel algorithms* for weighted sampling. This includes *shared-memory* algorithms that exploit current multi-core processors, and *distributed algorithms* that split the work across multiple machines without incurring too much overhead for communication.

However, there has been surprisingly little work on parallel weighted sampling. This paper closes many of these gaps. Table 1 summarizes our results on the following widely used variants of the weighted sampling problem. We process the input set $A = 1..n$ on p processing elements (PEs) where $i..j$ is a shorthand for $\{i, \dots, j\}$. Item i has weight w_i and $W := \sum_{i=1}^n w_i$. Define $u := \log U$ where $U := w_{\max}/w_{\min} := \max_i w_i / \min_i w_i$.

WRS-1: Weighted sampling of *one item* from a categorical (or multinoulli) distribution (equivalent to WRS-R and WRS-N for $k = 1$).

WRS-R: Sample k items from A *with replacement*, *i.e.*, the samples are independent and for each sample X , $\mathbf{P}[X = i] = w_i/W$. Let $s = |S| \leq k$ denote the number of *different* items in the sample S . Note that we may have $s \ll k$ for skewed input distributions.

WRS-N: Sample k pairwise unequal items $s_1 \neq \dots \neq s_k$ *without replacement* such that $\mathbf{P}[s_l = i] = w_i/(W - w_{s_1} - \dots - w_{s_{l-1}})$.

WRP: Permute the elements with the same process as for WRS-N using $k = n$.

WRS-S: Sample a *subset* $S \subseteq A$ where $\mathbf{P}[i \in S] = w_i \leq 1$.

WRS-B: *Batched reservoir sampling.* Repeatedly solve WRS-N when batches of new items arrive. Only the current sample and batch may be stored. Let b denote the batch size.

When applicable, our algorithms build a data structure once which is later used to support fast sampling queries. Most of the algorithms have linear work and variants with logarithmic (or even constant) latency. Neither competitive parallel algorithms nor more efficient sequential algorithms are known. The distributed algorithms are refinements of the shared-memory algorithms with the goal to reduce communication costs compared to a direct distributed implementation of the shared-memory algorithms. As a consequence, each PE mostly works on its local data (the owner-computes approach). Communication – if at all – is only performed to coordinate the PEs and is sublinear in the local work except for extreme corner cases. The owner-computes approach introduces the complication that differences in local work introduce additional parameters into the analysis that characterize the local work in different situations (*e.g.*, the last line of Table 1). The summary in Table 1 therefore covers the case when items are randomly assigned to PEs. This simplifies the exposition and is actually an approach that one can sometimes take in practice.

Outline

First, in Section 2, we review the models of computation used in this paper as well as known techniques we are building on. We discuss additional related work in Section 3. In Section 4, we consider Problem WRS-1. We first give an improved sequential algorithm for constructing

■ **Table 1** Result overview (expected and asymptotic). Distributed results assume random distribution of inputs. Input size n , output size s , sample size k , startup latency of point-to-point communication α , time for communicating one machine word β , log-weight ratio $u = \log U = \log w_{\max}/w_{\min}$, mini-batches of b items per PE. The complexity of sorting n integers with keys from $0..x$ is $\text{isort}_x(n)$ (isort^* = parallel, isort^1 = sequential).

Problem	Shared Memory					Distributed		
	§	Preprocessing		Query		§	Preprocessing	Query
		Work	Span	Work	Span		Time	Time
WRS-1	4.2	n	$\log n$	1	1	4.3	$\frac{n}{p} + \alpha \log p$	α

alias tables – the most widely used data structure for Problem WRS-1 that allows sampling in constant time. Then we parallelize that algorithm for shared and distributed memory. We also present parallel construction for a more space efficient variant.

Sampling k items with replacement (Problem WRS-R) seems to be trivially parallelizable with an alias table. However this does not lead to a communication-efficient distributed algorithm and we can generally do better for skewed input distributions where the number of *distinct* output elements s can be much smaller than k . Section 5 develops such an algorithm which is interesting both as a parallel and a sequential algorithm.

Section 6 employs the algorithm for Problem WRS-R to solve Problem WRS-N. The main difficulty here is to estimate the right number of samples with replacement to obtain a sufficient number of distinct samples. Then an algorithm for WRS-N without preprocessing is used to reduce the “weighted oversample” to the desired exact output size.

It is well known that the weighted permutation Problem WRP can be reduced to sorting (see Section 2.3). We show in Section 7 that this is actually possible with linear work by appropriately defining the (random) sorting keys so that we can use integer sorting with a small number of different keys. Since previous linear-time algorithms are fairly complicated [20], this may also be interesting for a sequential algorithm. Indeed, a similar approach might also work for other problems where sorting can be a bottleneck, *e.g.*, smoothed analysis of approximate weighting matching [24].

For subset sampling (Problem WRS-S), we parallelize the approach of Bringmann et al. [6] in Section 8. Once more, the preprocessing requires integer sorting. However, only $\mathcal{O}(\log n)$ different keys are needed so that linear work sorting works with logarithmic latency even deterministically on a CREW PRAM.

In Section 9, we adapt the sequential streaming algorithm of Efrimidis et al. [12] to a distributed setting where items are processed in small batches. This can be done in a communication efficient way using our previous work on distributed priority queues [16].

Section 10 gives a detailed experimental evaluation of our algorithms for WRS-1 and WRS-R. Section 11 summarizes the results and discusses possible future directions.

2 Preliminaries

2.1 Models of Computation

We strive to describe our parallel algorithms in a model-agnostic way, *i.e.*, we largely describe them in terms of standard operations such as prefix sums for which efficient parallel algorithms are known on various models of computation. We analyze the algorithms for two simple models of computation. In each case p denotes the number of processing elements (PEs). Most of our algorithms achieve polylogarithmic running time for a sufficiently large number of PEs. This is a classical goal in parallel algorithm theory and we believe that it is now becoming practically important with the advent of massively parallel (“exascale”) computing and fine-grained parallelism in GPGPU.

For shared-memory algorithms we use the CREW PRAM model (concurrent read exclusive write parallel random access machine) [18]. We will use the concepts of total *work* and *span* of a computation to analyze these algorithms. The span of a computation is the time needed by a parallel algorithm with an unbounded number of PEs.

For distributed-memory computations we use point-to-point communication between PEs where exchanging a message of length ℓ takes time $\alpha + \ell\beta$. We assume $1 \leq \beta \leq \alpha$. We will use that *prefix sums* and (*all-reductions*) can be computed in time $\mathcal{O}(\beta\ell + \alpha \log p)$ for vectors of size ℓ . The *all-gather* operation collects a value from each PE and delivers all values to

all PEs. It can be implemented to run in time $\mathcal{O}(\beta p + \alpha \log p)$ [19]. We will particularly strive to obtain *communication-efficient algorithms* [35] where total communication cost is sublinear in the local computations. Some of our algorithms are even *communication free*.

We need one basic toolbox operation where the concrete machine model has some impact on the complexity. Sorting n items with integer keys from $1..K$ can be done with linear work in many relevant cases. Sequentially, this is possible if K is polynomial in n (radix sort). Radix sort can be parallelized even on a distributed-memory machine with linear work and span n^ε for any constant $\varepsilon > 0$. Logarithmic span is possible for $K = \mathcal{O}(\log^c n)$ for any constant c , even on an EREW PRAM [30, Lemma 3.1]. For a CRCW PRAM, expected linear work and logarithmic span can be achieved when $K = \mathcal{O}(n \log^c n)$ [30] (the paper gives the constraint $K = \mathcal{O}(n)$) but the generalization is obvious and important for us in Section 7). Resorting to comparison based algorithms, we get work $\mathcal{O}(n \log n)$ and $\mathcal{O}(\log n)$ span on an EREW PRAM [8].

2.2 Bucket-Based Sampling

The basic idea behind several solutions of Problem WRS-1 is to build a table of $m = \Theta(n)$ buckets where each bucket represents a total weight of W/m . Sampling then selects a random bucket uniformly at random and uses the information stored in the bucket to determine the actual item. If item weights differ only by a constant factor, we can simply store one item per bucket and use rejection sampling to obtain constant expected query time (see, e.g., Devroye [9], Olken et al. [28]).

Deterministic sampling with only a single memory probe is possible using Walker's alias table method [38], and its improved construction due to Vose [37]. An alias table consists of $m := n$ buckets where bucket $b[i]$ represents some part w'_i of the weight of item i . The remaining weight of the heavier items is distributed to the remaining capacity of the buckets such that each bucket only represents one other item (the *alias* a_i). Algorithm 1 gives high-level pseudocode for the approach proposed by Vose. The items are first classified into light and heavy items. Then the heavy items are distributed over light items until their residual weight drops below W/n . They are then treated in the same way as light items.

To sample an item, pick a bucket index r uniformly at random, toss a biased coin that comes up heads with probability $w'_r n/W$, and return r for heads, or $b[r].a$ for tails.

■ **Algorithm 1** Classical construction of alias tables similar to Vose's approach [37].

```

Procedure voseAliasTable( $\langle w_1, \dots, w_n \rangle$ ,  $b$  : Array of  $w$  :  $\mathbb{R} \times a$  :  $\mathbb{N}$ )
   $W := \sum_i w_i$  -- total weight
   $h := \{i \in 1..n : w_i > W/n\}$  : Stack -- heavy items
   $\ell := \{i \in 1..n : w_i \leq W/n\}$  : Stack -- light items
  for  $i := 1$  to  $n$  do  $b[i].w := w_i$  -- init buckets with weights
  while  $h \neq \emptyset$  do -- consume heavy items
     $j := h.\text{pop}$  -- get a heavy item
    while  $b[j].w > W/n$  do -- still heavy
       $i := \ell.\text{pop}$  -- get a light item
       $b[i].a := j$  -- Fill bucket  $b[i]$  with a ...
       $b[j].w := (b[j].w + b[i].w) - W/n$  -- ... piece of item  $j$ .
     $\ell.\text{push}(j)$  -- Bucket  $j$  is light now.

```

2.3 Weighted Sampling using Exponential Variates

It is well known that an unweighted sample without replacement of size k out of n items $1..n$ can be obtained by associating with each item a uniform variate $v_i := \mathbf{rand}()$, and selecting the k with the smallest associated variates. This method can be generalized to generate a *weighted* sample without replacement by raising uniform variates to the power $1/w_i$ and selecting the k items with the *largest* associated values [11, 12, 10]. Equivalently, one can generate exponential random variates $v_i := -\ln(\mathbf{rand}())/w_i$ and select the k items with the *smallest* associated v_i [2] (“*exponential clocks method*”), which is numerically more stable.

2.4 Divide-and-Conquer Sampling

Uniform sampling with and without replacement can be done using a divide-and-conquer algorithm [34]. To sample k out of n items uniformly and with replacement, split the set into two subsets with n' (left) and $n - n'$ (right) items, respectively. Then the number of items k' to be sampled from the left has a binomial distribution (k trials with success probability n'/n). We can generate k' accordingly and then recursively sample k' items from the left and $k - k'$ items from the right. This can be used for a communication-free parallel sampling algorithm. We have a tree with p leaves. Each leaf represents a subproblem of size about $n/p - 1$ for each PE. Each PE descends this tree to the leaf assigned to it (time $\mathcal{O}(\log p)$) and then generates the resulting number of samples (time $\mathcal{O}(k/p + \log p)$ with high probability). Different PEs have to draw the same random variates for the same interior node of the tree. This can be achieved by seeding a pseudo-random number generator with an ID of this node.

3 Related Work

3.1 Sampling one Item (Problem WRS–1)

Extensive work has been done on generating discrete random variates from a fixed distribution [38, 37, 21, 9, 6]. All these approaches use preprocessing to construct a data structure that subsequently supports very fast (constant time) sampling of a single item. Bringmann et al. [5] explain how to achieve expected time r using only $\mathcal{O}(n/r)$ bits of space beyond the input distribution itself. There are also dynamic versions that allow efficient weight updates. Some (rather complicated ones) allow that even in constant expected time [15, 22].

3.2 Sampling Without Replacement (Problems WRS–N and WRP)

The exponential clocks method of Section 2.3 is an $\mathcal{O}(n)$ algorithm for sampling without replacement. This approach also lends itself towards use in streaming settings (*reservoir sampling*) and can be combined with a skip value distribution to reduce the number of required random variates from $\mathcal{O}(n)$ to $\mathcal{O}(k \log \frac{n}{k})$ [12]. A related algorithm for WRS–N with given inclusion probabilities instead of relative weights is described by Chao [7].

More efficient algorithms for WRS–N repeatedly sample an item and remove it from the distribution using a dynamic data structure [40, 28, 15, 22]. With the most efficient such algorithms [15, 22] we achieve time $\mathcal{O}(k)$, albeit at the price of an inherently sequential and rather complicated algorithm that might have considerable hidden constant factors.

It is also possible to combine techniques for sampling *with* replacement with a rejection method. However, the performance of these methods depends heavily on U , the ratio between the largest and smallest weight in the input, as the rejection probability rises steeply once the heaviest items are removed. Lang [20] gives an analysis and experimental evaluation of such methods for the case of $k = n$ (*cf.* “Permutation” below). A recent practical evaluation of approaches that lend themselves towards efficient implementation is due to Müller [27].

3.3 Parallel Sampling

There is surprisingly little work on parallel sampling. Even uniform unweighted sampling had many loose ends until recently [34]. Parallel uniformly random permutations are covered in [14, 33]. Efraimidis and Spirakis note that WRS-N can be solved in parallel with span $\mathcal{O}(\log n)$ and work $\mathcal{O}(n \log n)$ [11]. They also note that solving the selection problem suffices if the output need not be sorted. The optimal dynamic data structure for WRS-1 [22] admits a parallel bulk update in the (somewhat exotic) combining-CRCW-PRAM model. However, this does not help with Problem WRS-N since batch sizes are one.

4 Alias Table Construction (Problem WRS-1)

4.1 Improved Sequential Alias Tables

Before discussing parallel alias table construction, we discuss a simpler, faster and more space efficient sequential algorithm that is a better basis for parallelization. Previous algorithms need auxiliary arrays/queues of size $\Theta(n)$ in order to decide in which order the buckets are filled. Vose [37] mentions that this can be avoided but does not give a concrete algorithm. We now describe an algorithm with this property.

The idea of the algorithm is that two indices i and j sweep the input array with respect to light and heavy items, respectively. The loop invariant is that the weight of items corresponding to light (heavy) items preceding i (j) has already been distributed over some buckets and that their corresponding buckets have already been constructed. Variable w stores the weight of the part of item j that has not yet been assigned to buckets. Each iteration of the main loop advances one of the indices and initializes one bucket. When the residual weight w exceeds W/n , item j is used to fill bucket i , the residual weight w is reduced by $W/n - w_i$, and index i is advanced to the next light item. Otherwise, the remaining weight of heavy item j fits into bucket j and the remaining capacity of bucket j is filled with the next heavy item. Algorithm 2 gives pseudocode that emphasizes the high degree of symmetry between these two cases.

■ **Algorithm 2** A sweeping algorithm for building alias tables.

```

Procedure sweepingAliasTable( $\langle w_1, \dots, w_n \rangle$ ,  $b$  : Array of  $w : \mathbb{R} \times a : \mathbb{N}$ )
   $W := \sum_i w_i$  -- total weight
   $i := \min \{k > 0 : w_k \leq W/n\}$  -- first light item
   $j := \min \{k > 0 : w_k > W/n\}$  -- first heavy item
   $w := w_j$  -- residual weight of current heavy item
  while  $j \leq n$  do
    if  $w > W/n$  then -- Pack a light bucket.
       $b[i].w := w_i$  -- Item  $i$  completely fits here.
       $b[i].a := j$  -- Item  $j$  fills the remainder of bucket  $i$ .
       $w := (w + w_i) - W/n$  -- Update residual weight of item  $j$ .
       $i := \min \{k > i : w_k \leq W/n\}$  -- next light item, assume  $w_{n+2} = 0$ 
    else -- Pack a heavy bucket.
       $b[j].w := w$  -- Now item  $j$  completely fits here.
       $b[j].a := j' := \min \{k > j : w_k > W/n\}$  -- next heavy item, assume  $w_{n+1} = \infty$ 
       $w := (w + w_{j'}) - W/n$  -- Find residual weight of item  $j'$ .
       $j := j'$ 

```

4.2 Parallel Alias Tables

The basic idea behind our *splitting based algorithm* is to identify subsets L and H of light ($w_i \leq W/n$) and heavy ($w_i > W/n$) items such that they can be allocated precisely within their respective buckets, *i.e.*, $w(H \cup L) := \sum_{i \in H \cup L} w_i = (|H| + |L|) \cdot W/n$. By splitting the items into such pairs of subsets, we can perform alias table construction for these subsets in parallel. Since the above balance condition cannot always be achieved, we allow to “steal” a piece of a further heavy item, *i.e.*, this item can be used to fill buckets in several subproblems. Such a split item will only be used as an alias except in the last subproblem where it is used. Thus, the computed data structure is still an alias table.

We first explain how to split n items into two subsets of size n' and $n - n'$. Similar to Vose’s algorithm, we first compute arrays ℓ and h containing the indices of the light and heavy items, respectively. We then determine indices i and j such that $i + j = n'$, $\sigma := \sum_{x \leq i} w_{\ell[x]} + \sum_{x \leq j} w_{h[x]} \leq n'W/n$ and $\sigma + w_{h[j+1]} > n'W/n$; see Figure 1 for an example. These values can be determined by binary search over the value of j . By precomputing prefix sums of the weights of the items in ℓ and h , each iteration of the binary search takes constant time. The resulting subproblem then consists of the light items $L := \{\ell[1], \dots, \ell[i]\}$, the heavy items $H := \{h[1], \dots, h[j]\}$ and a fraction of size $n'W/n - \sigma$ of item $h[j + 1]$.

To split the input into p independent subproblems of near-equal size, we perform the above two-way-split for the values $n'_k = \lceil nk/p \rceil$ for $k \in 1..p - 1$. PE k is then responsible for filling a set of buckets corresponding to sets of light and heavy items, each represented by a range of indices into ℓ and h . A piece of a further heavy item may be used to make the calculation work out. Note that a subproblem might contain an empty set of light or heavy items and that a single heavy item j may be assigned partially to multiple subproblems, but only the last PE using a heavy item will fill its bucket.

Algorithm 3 gives detailed pseudocode. It uses function `split` to compute $p - 1$ different splits in parallel. The result triple (i, j, s) of `split` specifies that buckets $\ell[1] \dots \ell[i]$ as well as $h[1] \dots h[j]$ shall be filled using the left subproblem. Moreover, total weight s of item $h[j + 1]$ is *not used* on the left side, *i.e.*, spilled over to the right side.

This splitting information is then used to make p parallel calls to procedure `pack` – giving each PE the task to fill up to $\lceil n/p \rceil$ buckets. `Pack` has input parameters specifying ranges of heavy and light items it should use. The parameter `spill` determines how much weight of item $h[j - 1]$ can be used for that. `Pack` works similar to the sweeping algorithm from Algorithm 2. If the residual weight of item $h[j - 1]$ drops below W/n , this item is actually also packed in this call. The body of the main loop is dominated by one if-then-else case distinction. When the residual weight of the current heavy item falls below W/n , its bucket is filled using the next heavy item. Otherwise, its weight is used to fill the current light item.

► **Theorem 1.** *We can construct an alias table with work $\Theta(n)$ and span $\Theta(\log n)$ on a CREW PRAM.*

■ **Figure 1** Parallel alias tables: splitting $n = 13$ items into two parts of size $n' = 7$ and $n - n' = 6$.

■ **Algorithm 3** Pseudocode for parallel splitting based alias table construction (PSA).

```

Procedure psaAliasTable( $\langle w_1, \dots, w_n \rangle$ ,  $b$  : Array of  $w : \mathbb{R} \times a : \mathbb{N}$ )
   $W := \sum_i w_i$  -- total weight
   $h := \{i \in 1..n : w_i > W/n\}$  : Array -- parallel traversal finds heavy items and
   $\ell := \{i \in 1..n : w_i \leq W/n\}$  : Array -- and light items
  for  $k := 1$  to  $p - 1$  dopar  $(i_k, j_k, \text{spill}_k) := \text{split}(\lceil nk/p \rceil)$  -- split into  $p$  pieces
   $(i_0, j_0, \text{spill}_0) := (0, 0, 0)$ ;  $(i_p, j_p) := (n, n)$  -- cover corner cases
  for  $k := 1$  to  $p$  dopar  $\text{pack}(i_{k-1} + 1, i_k, j_{k-1} + 1, j_k, \text{spill}_{k-1})$ 

Function split( $n'$ ) :  $\mathbb{N} \times \mathbb{N} \times \mathbb{R}$ 
   $a := 1$ ;  $b := \min(n', |h|)$  --  $a..b$  is search range for  $j$ 
  loop -- binary search
     $j := \lfloor (a + b)/2 \rfloor$  -- bisect search range
     $i := n' - j$  -- Establish the invariant  $i + j = n'$ .
     $\sigma := \sum_{x \leq i} w_{\ell[x]} + \sum_{x \leq j} w_{h[x]}$  -- work to the left; use precomputed prefix sums
    if  $\sigma \leq n'W/n$  and  $\sigma + w_{h[j+1]} > n'W/n$  then return  $(i, j, w_{h[j+1]} + \sigma - n'W/n)$ 
    if  $\sigma \leq n'W/n$  then  $b := j - 1$  else  $a := j + 1$  -- narrow search range

  (* pack buckets  $b[\ell[\underline{i}]], \dots, b[\ell[\bar{i}]]$  and buckets  $b[h[\underline{j}]], \dots, b[h[\bar{j}]]$ . *)
  (* Use up to weight spill from item  $h[\underline{j} - 1]$ . *)
  Procedure pack( $\underline{i}, \bar{i}, \underline{j}, \bar{j}, \text{spill}$ )
     $i := \underline{i}$  --  $\ell[i]$  is the current light item.
     $j := \underline{j} - 1$  --  $h[j]$  is the current heavy item.
     $w := \text{spill}$  -- part of current heavy item still to be placed
    if  $\text{spill} = 0$  then  $j++$ ;  $w := w_{h[j]}$ 
    loop
      if  $w \leq W/n$  then -- pack a heavy bucket
        if  $j > \bar{j}$  then return
         $b[h[j]].w := w$ 
         $b[h[j]].a := h[j + 1]$ 
         $w := (w + w_{h[j+1]}) - W/n$ 
         $j++$ 
      else -- pack a light bucket
        if  $i > \bar{i}$  then return
         $b[\ell[i]].w := w_{\ell[i]}$ 
         $b[\ell[i]].a := h[j]$ 
         $w := (w + w_{\ell[i]}) - W/n$ 
         $i++$ 

```

Proof. The algorithm requires linear work and logarithmic span for identifying light and heavy items and for computing prefix sums [4] over them. Splitting works in logarithmic time. Then each PE needs time $\mathcal{O}(n/p)$ to fill the buckets assigned to its subproblem. ◀

4.3 Distributed Alias Table Construction

The parallel algorithm described in Section 4.2 can also be adapted to a distributed-memory machine. However, this requires information about all items to be communicated. Hence, more communication efficient algorithms are important for large n . To remedy this problem, we will now view sampling as a 2-level process implementing the owner-computes approach underlying many distributed algorithms.

Let E_i denote the set of items allocated to PE i . For each PE i , we create a *meta-item* of weight $W_i := \sum_{j \in E_i} w_j$. Sampling now amounts to sampling a meta-item and then delegating the task to sample an actual item from E_i to PE i . The local data structures can be built independently on each PE.¹ In addition, we need to build a data structure for sampling a meta-item. There are several variants in this respect with different trade-offs:

► **Theorem 2.** *Assuming that $\mathcal{O}(n/p)$ elements are allocated to each PE, we can sample a single item in time $\mathcal{O}(\alpha)$ after preprocessing a 2-level alias table, which can be done in time $\mathcal{O}(n/p)$ plus the following communication overhead*

$$\beta p + \alpha \log p \text{ with replicated preprocessing} \tag{1}$$

$$\alpha \log^2 p \text{ expected time using the algorithm from Section 4.2} \tag{2}$$

$$\alpha \log p \text{ with only expected time bounds for the query} \tag{3}$$

Proof. Building the local alias tables takes time $\mathcal{O}(\max_i |E_i|) = \mathcal{O}(n/p)$ sequentially. For Equation (1), we can perform an all-gather operation on the meta-items and compute the data structure for the meta-items in a replicated way.

For Equation (2) and Equation (3), we can compute an alias table for the meta-items using a parallel algorithm. Sampling then needs an additional indirection. First, a meta-bucket j is computed. Then a request is sent to PE j which identifies the subset E_i from which the item should be selected and delegates that task of sampling from E_i to PE i .² Equation (2) then follows by using the shared-memory algorithm from Section 4.2. It can be implemented to run in expected time $\mathcal{O}(\alpha \log^2 p)$ on a distributed-memory machine using PRAM emulation [31].

At the price of getting only expected query time, we can also achieve logarithmic latency (Equation (3)) by using the rejection sampling algorithm from Section 4.4. The preprocessing there requires only prefix sums that can directly be implemented on distributed memory: We have to assign p meta-items to $2p$ meta-buckets (two on each PE). Suppose PE i computes the prefix sum $k = \sum_{j < i} \lceil W_j/W \rceil$. It then sends item i to PE $j = \lfloor k/2 \rfloor$. PE j then initiates a broadcast of item i to PEs $j.. \lfloor (j + \lfloor W_i/W \rfloor - 1)/2 \rfloor$. All of this is possible in time $\mathcal{O}(\alpha \log p)$. ◀

4.3.1 Redistributing Items

As discussed so far, *constructing* distributed-memory 2-level alias tables is communication efficient. However, when large items are predominantly allocated on few PEs, *sampling* many items can lead to an overload on PEs with large W_i . We can remedy this problem by moving large items to different PEs or even by splitting them between multiple PEs. This redistribution can be done in the same way we construct alias tables. This implies a trade-off between redistribution cost (part of preprocessing) and load balance during sampling.

We now look at the case where an adversary can choose an arbitrarily skewed distribution of item sizes but where the items are randomly allocated to PEs (or that we actively randomize the allocation implying $\mathcal{O}(n/p)$ additional communication volume).

¹ Possibly using a shared-memory parallel algorithm locally.

² If we ensure that meta-items have similar size (see Section 4.3.1) then we can arrange the meta-items in such a way that $i = j$ most of the time.

► **Theorem 3.** *If items are randomly distributed over the PEs initially, it suffices to redistribute $\mathcal{O}(\log p)$ items from each PE such that afterwards each PE has total weight $\mathcal{O}(W/p)$ in expectation and $\mathcal{O}(n/p + \log p)$ (pieces of) items. This redistribution takes expected time $\mathcal{O}(\alpha \log^2 p)$ when supporting deterministic queries (Theorem 2-(2)) and expected time $\mathcal{O}(\alpha \log p)$ using rejection sampling (Theorem 2-(3)).*

Proof. Let us distinguish between *heavy* items that are larger than $cW/(p \log p)$ for an appropriate constant c and the remaining *light* items. The expected maximum weight allocated to a PE based on light items is $\mathcal{O}(W/p)$ [32].

There can be at most $p \log(p)/c$ heavy items. By standard balls into bins arguments, only $\mathcal{O}(\log p)$ heavy items can initially be allocated to any PE with high probability. We use the algorithm from Theorem 2-(2) to distribute the heavy items to p meta-buckets of remaining capacity $\max(0, W/p - S_i)$ where S_i is the total weight of the light items allocated to PE i . Using the bound from Equation (2) would result in a time bound of $\mathcal{O}(\log^3 p)$ since we have a factor $\mathcal{O}(\log p)$ more items. However, the only place where we need a full-fledged PRAM emulation is for doing the binary search which takes only $\mathcal{O}(\log p)$ steps on the PRAM and time $\mathcal{O}(\alpha \log^2 p)$ when emulated on distributed memory.

For the faster variant with rejection sampling, we use prefix sums to distribute the largest $N := \mathcal{O}(p \log p)$ items such that each PE gets an even share of it. For this, we build groups of $N/p = \mathcal{O}(\log p)$ items that we distribute in an analogous fashion to the proof in Theorem 2-(3) – a prefix sum, followed by forwarding a group followed by a segmented broadcast. The asymptotic complexity does not change since even messages of size $\mathcal{O}(\log p)$ can be broadcast in time $\mathcal{O}(\alpha \log p)$, *e.g.*, using pipelining. Finally, each PE unpacks the group it received and extracts the parts that it has to represent in the meta-table. ◀

4.4 Compressed Data Structures for WRS–1

Bringmann and Larsen [5] give a construction similar to alias tables that allows expected query time $\mathcal{O}(r)$ using $2n/r + o(n)$ bits of additional space. We describe the variant for $r = 1$ in some more detail. We assign $\lceil w_i/W \rceil$ buckets to each item, *i.e.*, $\leq 2n$ in total. Item i is assigned to buckets $\sum_{j < i} \lceil w_j/W \rceil .. \sum_{j \leq i} \lceil w_j/W \rceil - 1$. A query samples a bucket j uniformly at random. Suppose bucket j is assigned to item i . If $j \in \sum_{j < i} \lceil w_j/W \rceil .. \sum_{j \leq i} \lceil w_j/W \rceil - 2$, item i is returned. If $j = \sum_{j \leq i} \lceil w_k/W \rceil - 1$, item i is returned with probability $\lceil w_i/W \rceil - \lfloor w_i/W \rfloor$. Otherwise, bucket j is rejected and the query starts over. Since the overall success probability is $\geq 1/2$, the expected query time is constant.

The central observation for compression is that it suffices to store one bit for each bucket that indicates whether a new item starts at bucket $b[i]$. When querying bucket j , the item stored in it can be determined by counting the number of 1-bits up to position j . This *rank*-operation can be supported in constant time using an additional data structure with $o(n)$ bits. Further reduction in space is possible by representing r items together as one entry in b .

Both constructing the bit vector and constructing the rank data structure is easy to parallelize using prefix sums (for adding scaled weights and counting bits, respectively) and embarrassingly parallel computations. Shun [36] even gives a bit parallel algorithm needing only $\mathcal{O}(n/\log n)$ work for computing the rank data structure. We get the following result:

► **Theorem 4.** *Bringmann and Larsen’s $n/r + o(n)$ bit data structure can be built using $\mathcal{O}(n)$ work and $\mathcal{O}(\log n)$ span allowing queries in expected time $\mathcal{O}(r)$.*

5 Output Sensitive Sampling With Replacement (Problem WRS–R)

The algorithm of Section 4.2 easily generalizes to sampling k items with replacement by simply executing k queries. Since the precomputed data structures are immutable, these queries can be run in parallel. We obtain optimal span $\mathcal{O}(1)$ and work $\mathcal{O}(k)$.

► **Corollary 5.** *After a suitable alias table data structure has been computed, we can sample k items with replacement with work $\mathcal{O}(k)$ and span $\mathcal{O}(1)$.*

Yet if the weights are skewed this may not be optimal since large items will be sampled multiple times. Here, we describe an *output sensitive* algorithm that outputs only different items in the sample together with how often they were sampled, *i.e.*, a set S of pairs (i, k_i) indicating that item i was sampled k_i times. The work will be proportional to the output size s up to a small additive term.

Note that outputting multiplicities may be important for appropriately processing the samples. For example, let X denote a random variable where item i is sampled with probability w_i/W and suppose we want a truthful estimator for the expectation of $f(X)$ for some function f . Then $\sum_{(i,k_i) \in S} k_i f(i)/k$ is such an estimator.

We will combine and adapt three previously used techniques for related problems: the bucket tables from Section 2.2, the divide-and-conquer technique from Section 2.4 [34], and the subset sampling algorithm of Bringmann et al. [6].

We approximately sort the items into $u = \lceil \log U \rceil$ groups of items whose weights differ by at most a factor of two – weight w_i is mapped to group $\lceil \log(w_i/w_{\min}) \rceil$.

To help determine the number of samples to be drawn from each group, we build a complete binary tree with one *nonempty* group at each leaf. Interior nodes store the total weight of items in groups assigned to their subtrees. This *divide-and-conquer tree* (*DC-tree*) allows us to generalize the technique from Section 2.4 to weighted items. Suppose we want to sample k elements from a subtree rooted at an interior node whose left subtree has total weight L and whose right subtree has total weight R . Then the number of items k' to be sampled from the left has a binomial distribution (k trials with success probability $L/(L+R)$). We can generate k' accordingly and then recursively sample k' items from the left subtree and $k - k'$ items from the right subtree. A recursive algorithm can thus split the number of items to be sampled at the root into numbers of items sampled at each group. When a subtree receives no samples, the recursion can be stopped. Since the distribution of weights to groups can be highly skewed, this stopping rule will be important in the analysis.

For each group G , we integrate bucket tables and DC-tree as follows. For the bucket table we can use a very simple variant that stores n_G items with weights from the interval $[a, 2a)$ in n_G buckets of capacity $2a$. Sampling one element then uses a rejection method that repeats the sampling attempt when the random variate leads to an empty part of a bucket.³

We also build a DC-tree for each group. A simple linear mapping of items into the bucket table allows us to associate a range of relevant buckets b_T with each subtree T of the DC-tree.

For sampling m items from a group G , we use the DC-tree to decide which subtree has to contribute how many samples. When this number decreases to 1 for a subtree T , we sample this element directly and in constant expected time from the buckets in the range b_T .

Figure 2 gives an example. We obtain the following complexities:

³ If desired, we can also avoid rejection sampling by mapping the items without gaps into up to $2n_G$ buckets of size a . This way there are at most two items in each bucket. Note that this is still different from alias tables because we need to map ranges of consecutive items to ranges of buckets. This is not possible for alias tables.

■ **Figure 2** Output-sensitive sampling: assignment of multiplicities with $k = 36$.

► **Theorem 6.** *Preprocessing for Problem WRS-R can be done in the time and span needed for integer sorting n elements with $u = \lceil \log U \rceil = \lceil \log(w_{\max}/w_{\min}) \rceil$ different keys⁴ plus linear work and logarithmic span (on a CREW PRAM) for building the actual data structure. Using this data structure, sampling a multiset S with k items and s different items can be done with span $\mathcal{O}(\log n)$ and expected work $\mathcal{O}(s + \log n)$ on a CREW PRAM.*

Proof. Besides sorting the items into groups, we have to build binary trees of total size $\mathcal{O}(n)$. This can be done with logarithmic span and linear work using a simple bottom-up reduction. The bucket-tables which have total size n can be constructed as in Section 4.2.

The span of a query is essentially the depth of the trees, $\log u + \log n \leq 2 \log n$.

Bounding the work for a query is more complicated since, in the worst case, the algorithm can traverse paths of logarithmic length in the DC-trees for just a constant number of samples taken at its leaves. However, this is unlikely to happen and we show that in expectation the overhead is a constant factor plus an additive logarithmic term. We are thus allowed to charge a constant amount of work to each different item in the output and can afford a leftover logarithmic term.

We first consider the top-most DC-tree T that divides samples between groups. Tree T is naturally split into a *heavy* range of groups that contain some items which are sampled with probability at least $1/2$ and a remaining range of *light* groups in which all items are sampled with probability at most $1/2$. Assuming the heavy groups are to the left, consider the path P in T leading to the first light group. Subtrees branching from P to the left are complete subtrees that lead to heavy groups only. Since all leaves represent non-empty groups, we can charge the cost for traversing the left trees to the elements in the groups at the leaves – in expectation, at least half of these groups contain elements that are actually sampled.

Then follow at most $2 \log n$ light groups that have a probability $\geq 1/n$ to yield at least one sample. These middle groups fit into subtrees of T of logarithmic total size and hence cause logarithmic work for traversing them.

The expected work for the remaining very light groups can be bounded by their number ($\leq u \leq n$) times the length of the path in T leading to them ($\leq \log u \leq \log n$) times the probability that they yield at least one sample ($\leq 1/n$). The product ($\leq n \log(n)/n = \log n$) is another logarithmic term.

Finally, Lemma 7 shows that the work for traversing DC-trees within a group is linear in the output size from each group. Summing this over all groups yields the desired bound. ◀

⁴ Section 2.1 discusses the cost of this operation on different models of computation.

► **Lemma 7.** *Consider a DC-tree plus bucket array for sampling with replacement of k out of n items where weights are in the range $[a, 2a)$. Then the expected work for sampling is $\mathcal{O}(s)$ where s is the number of different sampled items.*

Proof. If $k \geq n$, $\Omega(n)$ items are sampled in expectation at a total cost of $\mathcal{O}(n)$. So assume $k < n$ from now on. The first $\log k + \mathcal{O}(1)$ levels of T may be traversed completely, contributing a total cost of $\mathcal{O}(k)$.

For the lower levels, we count the number Y of visited nodes from which at least 2 items are sampled. This is proportional to the total number of visited nodes since nodes from which only one item is sampled contribute only constant expected cost (for directly sampling from the array) and since there are at most $2Y$ such nodes.

Let X denote the number of items sampled at a node at level ℓ of tree T . An interior node at level ℓ represents $2^{L-\ell}$ leaves with total weight $W_\ell \leq 2a2^{L-\ell}$ where $L = \lceil \log n \rceil$. X has a binomial distribution with k trials and success probability

$$\rho = \frac{W_\ell}{W} \leq \frac{2a2^{L-\ell}}{a2^{L-1}} = 4 \cdot 2^{-\ell} .$$

Hence,

$$\mathbf{P}[X \geq 2] = 1 - \mathbf{P}[X = 0] - \mathbf{P}[X = 1] = 1 - (1-p)^k - kp(1-p)^{k-1} \approx (k\rho)^2/2$$

where the “ \approx ” holds for $k\rho \ll 1$ and was obtained by series development in the variable $k\rho$.

The expected cost at level $\ell > \log k + \mathcal{O}(1)$ is thus estimated as

$$2^\ell \mathbf{P}[X \geq 2] \approx 2^\ell (k\rho)^2/2 \leq 2^\ell (k \cdot 4 \cdot 2^{-\ell})^2/2 = 8k^2 2^{-\ell} .$$

At level $\ell = \lceil \log k \rceil + 3 + i$ we thus get expected cost $\leq k2^{-i}$. Summing this over i yields total cost $Y = \mathcal{O}(k)$. ◀

5.1 Distributed Case

The batched character of sampling with replacement makes this setting even more adequate for a distributed implementation using the owner-computes approach. Each PE builds the data structure described above for its local items. Furthermore, we build a top-level DC-tree that distributes the samples between the PEs, *i.e.*, with one leaf for each PE. We will see below that this can be done using a bottom-up reduction over the total item weights on each PE, *i.e.*, no PRAM emulation or replication is needed. Each PE only needs to store the partial sums appearing on the path in the reduction tree leading to its leaf. Sampling itself can then proceed without communication – each PE simply descends its path in the top-level DC-tree analogous to the uniform case [34]. Afterwards, each PE knows how many samples to take from its local items. Note that we assume k to be known on all PEs and that communication for computing results from the sample is not considered here.

► **Theorem 8.** *Sampling k out of n items with replacement (Problem WRS-R) can be done in a communication-free way with processing overhead $\mathcal{O}(\log p)$ in addition to the time needed for taking the local sample. Building and distributing the DC-tree for distributing the samples is possible in time $\mathcal{O}(\alpha \log p)$.*

Proof. It remains to explain how the reduction can be done in such a way that it can be used as a DC-tree during a query and such that each PE knows the path in the reduction tree leading to its leaf. First assume that $p = 2^d$ is a power of two. Then we can use

the well known hypercube algorithm for all-reduce (e.g., [19]). In iteration $i \in 1..d$ of this algorithm, a PE knows the sum for its local $i - 1$ dimensional subcube and receives the sum for the neighboring subcube along dimension i to compute the sum for its local i dimensional subcube. For building the DC-tree, each PE simply records all these values.

For general values of p , we first build the DC tree for $d = \lfloor \log p \rfloor$. Then, each PE i with $i < 2^d$ and $j = i + 2^d < p$ receives the aggregate local item weight from PE j and then sends its path to PE j . ◀

Similar to Section 4.3, it depends on the assignment of the items to the PEs whether this approach is load balanced for the local computations. Before, we needed a balanced distribution of both number of items and item weights. Now the situation is better because items may be sampled multiple times but require work only once. On the other hand, we do not want to split heavy items between multiple PEs since this would increase the amount of work needed to process the sample. It would also undermine the idea of communication-free sampling if we had to collect samples of the same item assigned to different PEs. Below, we once more analyze the situation for items with arbitrary weight that are allocated to the PEs randomly.

► **Theorem 9.** *Consider an arbitrary set of item sizes and let $u = \log(\max_i w_i / \min_i w_i)$. If items are randomly assigned to the PEs initially, then preprocessing takes expected time $\mathcal{O}(\text{isort}_u^1(n/p) + \alpha \log p)$ where $\text{isort}_u^1(x)$ denotes the time for sequential integer sorting of x elements using keys from the range $0..u$.⁵ Using this data structure, sampling a multiset S with k items and s different items can be done in expected time $\mathcal{O}(s/p + \log p)$.*

Proof. For preprocessing, standard Chernoff bound arguments tell us that $\mathcal{O}(n/p + \log p)$ items will be assigned to a PE with high probability. Since sorting is now a local operation, we only need an efficient sequential algorithm for approximately sorting integers. The term $\alpha \log p$ is for the global DC-tree as in Theorem 8.

A sampling operation will sample s items. Since their allocation is independent of the choice of the sampled items, we can once more use Chernoff bounds to conclude that only $\mathcal{O}(s/p + \log p)$ of them are allocated to any PE with high probability. ◀

6 Sampling k Items Without Replacement (Problem WRS-N)

We can construct an algorithm for sampling without replacement based on the output-sensitive algorithm for sampling *with* replacement of Section 5. Presume we know an $\ell > k$ so that a sample of size ℓ with replacement contains at least k and no more than $\mathcal{O}(k)$ unique items. Then we can obtain a sample with $k' \geq k$ different items using the algorithm of Section 5, discard the multiplicities, and downsample to size k using the exponential clocks method (see Section 2.3).

To find the right value for ℓ , we derive an estimation of the number of unique samples as a function of ℓ . The basis of this estimation is to assume that sufficiently heavy items are sampled once and lighter items are sampled with probability proportional to their weight. We precompute the data needed for the estimation for each group and then perform a binary search over the groups. More concretely, when the currently considered group stores elements with weights in the range $[a, 2a)$, we try the value $\ell = \lceil 1/(2a) \rceil$. We (over)estimate the resulting number of unique samples as

$$|\{i : w_i \geq a\}| + \ell \cdot \frac{\sum \{w_i : w_i < a\}}{W} .$$

⁵ Note that this will be linear in all practically relevant situations.

In the full paper we show that this is a good estimate and how to use it to drive the binary search.

7 Permutation (Problem WRP)

As already explained in Section 2.3, weighted permutation can be reduced to sorting random variates of the form $-\ln(r)/w_i$ where r is a uniform random variate. The nice thing is that a lot is known about parallel sorting. The downside is that sorting may need superlinear work in the worst case. However, since we are sorting *random* numbers, we may still get linear expected work. This is well known when sorting uniform random variates; *e.g.*, [25, Theorem 5.9]. The idea is to map the random variates in linear time to a small number of buckets such that the occupancy of a bucket is bounded by a binomial distribution with constant expectation. Then the buckets can be sorted using a comparison based algorithm without getting more than linear work in total.

In the full paper, we explain how to achieve the same for the highly skewed distribution needed for WRP by applying radix sort and the monotonous transformation function $f(r, w_i) := n \ln(-\ln(r)nw_{\max}/w_i)$.

8 Subset Sampling (Problem WRS-S)

Subset sampling is a generalization of Bernoulli Sampling to the weighted case. The unweighted case can be solved in expected time linear in the output size by computing the geometrically distributed distances between elements in the sample [1]. The naïve algorithm for the weighted problem, which consists of throwing a biased coin for each item, requires $\mathcal{O}(n)$ time. Bringmann et al. [6] show that this is optimal if only a single subset is desired, and present a sequential algorithm that is also optimal for multiple queries.

The difference between WRS-S on the one hand and WRS-1/WRS-R on the other hand is that we do not have a fixed sample size but rather treat the item weights as independent inclusion probabilities in the sample (this requires $w_i \leq 1$ for all i). Hence, different algorithms are required. Observe that the expected sample size is $W \leq n$. Then our goal is to devise a parallel preprocessing algorithm with work $\mathcal{O}(n)$ which subsequently permits sampling with work $\mathcal{O}(1 + W)$.

In the full paper we parallelize the approach of Bringmann et al. [6]. Similar to our algorithm for sorting with replacement, this algorithm is based on grouping items into sets with similar weight. In each group, one can use ordinary Bernoulli sampling in connection with rejection sampling. Load balanced division between PEs can be done with a prefix sum calculation over the weights in each group.

9 Sampling with a Reservoir

In the full paper, we adapt the streaming algorithm of Efrimidis et al. [12] to a distributed mini-batch streaming model, where PEs process variable-size batches of items one at a time. The PEs' memory is too small to store previous batches, only the current mini-batch is available in memory. This is a generalization of the traditional data stream model and widely used in practice, *e.g.*, in Apache Spark Streaming [41], where it is called *discretized streams*. The basic idea is to keep the reservoir in a distributed priority queue [16].

10 Experiments

We now report experiments on alias tables (Problem WRS-1, Section 4) and the closely related problem of sampling with replacement (Problem WRS-R, Section 5).

Experimental Setup. We use machines with Intel and AMD processors in our experiments. The Intel machine has four Xeon Gold 6138 CPUs (4×20 cores, 160 hyper-threads, of which we use up to 158 to minimize the influence of system tasks on our measurements) and 768 GiB of DDR4-2666 main memory. The AMD machine is a single-socket system with a 32-core AMD EPYC 7551P CPU (64 hyper-threads, of which we use up to 62) and 256 GiB of DDR4-2666 RAM. While single-socket, this machine also has non-uniform memory access (NUMA), as the CPU consists of four dies internally. Both machines run Ubuntu 18.04. All implementations are in C++ and compiled with GNU g++ 8.2.0 (flags `-O3 -fno`).

Our measurements do not include time spent on memory allocation and mapping.

Implementation Details. We implemented alias table construction using our parallel splitting algorithm (PSA, Section 4.2) and output-sensitive sampling with replacement (OS, Section 5), as well as a shared-memory version of the distributed algorithm (2vl, Section 4.3, Theorem 2-(1)). The 2vl algorithm can either use Vose’s method (2vl-classic, Algorithm 1) or our sweeping algorithm of Section 4.1 (2vl-sweep, Algorithm 2) as base case. For OS, we use an additional optimization that aborts the tree descent and uses the base case bucket table when fewer than 128 samples are to be drawn from at least half as many items. The resulting elements are then deduplicated using a hash table to ensure that each element occurs only once in the output. A variant without this deduplication is called OS-ND and may be interesting if items *may* be returned multiple times. We also implemented sequential versions of both alias table construction methods. Both of the machines used require some degree of Non-Uniform Memory Access (NUMA) awareness in memory-bound applications like ours. Thus, in our parallel implementations, all large arrays are distributed over the available NUMA nodes, and threads are pinned to NUMA nodes to maintain data locality. All pseudorandom numbers are generated with 64-bit Mersenne Twisters [23], using the Intel Math Kernel Library (MKL) [17] on the Intel machine and dSFMT⁶ on the AMD machine. All of our implementations are publicly available under the GNU General Public License (version 3) at <https://github.com/lorenzhs/wrs>.

Compared to the descriptions in Sections 2.2 and 4.2, we performed a minor modification to construction of the tables to improve query performance. In the alias table, we store tuples $(w_i, A = [i, a_i])$ of a weight w_i , item i and alias a_i . This allows for an optimization at query time, where we return $A[\text{rand}() \cdot W/n \geq w_i]$, saving a conditional branch. When indices are 32-bit integers and weights are 64-bit doubles, this does not use additional space since the record size is padded to 128 bits anyway.

Sequential Performance. Surprisingly, many common existing implementations of alias tables (*e.g.*, `gsl_rand_discrete_preproc` in the GNU Scientific Library (GSL) [13] or `sample` in the R project for statistical computing [29]) use a struct-of-arrays memory layout for the alias table data structure. By using the array-of-structs paradigm instead, we can greatly improve memory locality, incurring one instead of up to two cache misses per query. Combined with branchless selection inside the buckets and a faster random number generator,

⁶ <http://www.math.sci.hiroshima-u.ac.jp/~m-mat/MT/SFMT/>, version 2.2.3

our query is more than three times as fast as that of GSL version 2.5 (measured for $n = 10^8$). At the same time, alias table construction using our implementation of Vose’s method is 30 % faster than GSL. Other popular statistics packages, such as NumPy (version 1.5.1, function `np.choice`) or Octave (Statistics package version 1.4.0, function `randsample`) employ algorithms with superlinear query time. We therefore use our own implementation of Vose’s algorithm as the baseline in our evaluation.

Among our sequential implementations, construction with Vose’s method is slightly faster than our sweeping algorithm. On the Intel machine, it is 8 % faster, while on the AMD machine, the gap is 3 %. However, since all of our measurements exclude the time for memory allocations, this is not the full picture. If we include memory allocation, our method is around 5 % faster than Vose’s on both machines. This is because it requires no additional space, compared to $\mathcal{O}(n)$ auxiliary space for Vose’s method.

The optimization described above to make queries branchless lowers query time substantially, namely by 22 % on the Intel machine and 27 % on the AMD machine, again for $n = 10^8$. Storing the item indices at construction time comes at no measurable extra cost.

10.1 Construction

Speedups compared to an optimized sequential implementation of Vose’s alias table construction algorithm are shown in Figure 3 (strong scaling with $n = 10^8$ and weak scaling with $n/p = 10^7$ uniform random variates). Speedups do not increase further once the machine’s memory bandwidth is saturated, limiting the speedup that can be achieved with techniques that require multiple passes over the data (PSA, 2lvl-classic). In contrast, 2lvl-sweep can be constructed almost independently by the PEs and requires much fewer accesses to memory. Sequentially, there is little difference between our sweeping algorithm and Vose’s method. However, our algorithm scales much better to high thread counts because it reduces the memory traffic and since hyper-threading (HT) helps to hide the overhead of branch mispredictions. This is especially visible on the AMD machine (Figure 3b), where 2lvl-sweep achieves more than twice the speedup of 2lvl-classic, 34 compared to 16. The lack of scaling for 2lvl-classic and 2lvl-sweep when going from 32 to 40 cores on the Intel machine (Figure 3a) coincides with a large frequency reduction in the CPUs at this point [39]. Preprocessing for OS introduces some overhead but is not much slower than 2lvl.

In the weak scaling experiments (Figures 3c and 3d), we again see clearly how 2lvl-classic and PSA are limited by memory bandwidth. Using more than two threads per available memory channel (4×6 for the Intel machine, 8 for the AMD machine) yields nearly no additional benefit for these algorithms. Meanwhile, 2lvl-sweep and OS are not limited by the available memory bandwidth, but rather latency of memory accesses. As a result, they scale well even to the highest thread counts.

10.2 Queries

We performed strong and weak scaling experiments for queries (Figure 4) as well as throughput measurements for different sample sizes (Figure 5). Besides uniform random variates, we use random permutations of the weights $\{1^{-s}, 2^{-s}, \dots, n^{-s}\}$ for a parameter s to obtain more skewed “power-law” distributions.

Scaling. First, consider the scaling experiments of Figure 4. These experiments were conducted on the Intel machine, as its highly non-uniform memory access characteristics highlight the differences between the algorithms. All speedups are given relative to sampling

■ **Figure 3** Strong (top) and weak (bottom) scaling evaluation of parallel alias table construction techniques. Strong scaling with input size $n = 10^8$, weak scaling with $n/p = 10^7$. Speedups are measured relative to our optimized implementation of Vose’s method (Algorithm 1, Section 2.2).

sequentially from an alias table. The strong scaling experiments (Figures 4a and 4b) deliberately use a small sample size to show scaling to low per-thread sample counts ($\approx 64\,000$ for 158 threads). We can see that all algorithms have good scaling behavior. Hyper-threading (marked “HT” in the plots) yields additional speedups, as it helps to hide memory latency. This already shows that sampling is bound by random access latency to memory. Sampling from PSA and 2vl is done completely independently by all threads, with no interaction apart from reading from the same shared data structures. Because the Intel machine has four NUMA zones, most queries have to access another NUMA node’s memory. This limits the speedups achievable using PSA and 2vl.

On the other hand, OS and OS-ND have a shared top-level sample assignment stage, after which threads only access local memory. This benefits scaling, especially on NUMA machines. As a result, OS-ND achieves the best speedups, despite this benchmark producing very few samples with multiplicity greater than one (Figure 4a, sample size is 1% of input size). On the other hand, deduplication in the base case of OS has significant overhead, making it roughly 25% slower than sampling from an alias table for such inputs, even sequentially.

■ **Figure 4** Query strong and weak scaling for $n = 10^9$ input elements. Sample size for strong scaling $s = 10^7$, per-thread sample size for weak scaling $s/p = 10^6$. All speedups relative to sequential alias tables. Intel machine.

The weak scaling experiments of Figures 4c and 4d show even better speedups because many more samples are drawn here than in our strong scaling experiment, reducing overheads. Sampling from a classical alias table (PSA) achieves a speedup of 40 here, again limited by memory accesses rather than computation. Meanwhile, the output-sensitive methods (OS, OS-ND) reap the benefits of accessing only local memory.

Throughput. Figure 5 shows the query throughput of the different approaches. We can see that 2lvl suffers a significant slowdown compared to PSA on all inputs since an additional query for a meta-item is needed (this is also clearly visible in Figure 4). This slowdown is much more pronounced on the Intel machine (60%) than on the AMD machine (30%) because inter-NUMA-node memory access latency on the quad-socket Intel machine is much higher than on the single-socket AMD machine. Nonetheless, throughput is limited by the latency of random accesses to memory for the (bottom) tables for both approaches and on both machines.

(a) Intel machine (158 threads). Note the logarithmic y axes for the bottom plots.(b) AMD machine (62 threads). Note the logarithmic y axes for the bottom plots.

■ **Figure 5** Query throughput of the different methods for $n = 10^9$, using all available cores. Top left: uniform inputs, top right: power law with $s = 0.5$, bottom left: power law $s = 1$, bottom right: power law $s = 2$. Dashed lines on the right y axis belong to the same-colored solid lines on the left y axis and show fraction of output size over sample size for output-sensitive algorithms.

(a) Intel machine (158 threads). Note the logarithmic y axes for the bottom plots.

(b) AMD machine (62 threads). Note the logarithmic y axes for the bottom plots.

Figure 6 Time per unique output item for the different methods for $n = 10^9$ using all available cores on the Intel (top) and AMD (bottom) machines. Top left: uniform inputs, top right: power law with $s = 0.5$, bottom left: power law $s = 1$, bottom right: power law $s = 2$. Dashed lines on the right y axis belong to the same-colored solid lines on the left y axis and show fraction of output size over sample size for output-sensitive algorithms.

As long as the sample contains few duplicates (*cf.* the dashed lines with scale on the right y axis, which belong to the solid lines of the same color and marker shape), the cost of base case deduplication in OS cancels out the gains of increased memory locality. On the AMD machine, where memory access locality is less important, this results in higher throughput for 2vl than for OS for small sample sizes when inputs are not too skewed. As expected, when there are many duplicates, the output sensitive algorithms (OS and OS-ND) scale very well. Omitting base case deduplication (OS-ND) doubles throughput for uniform inputs and does no harm for skewed inputs, making OS-ND the consistently fastest algorithm. In comparison, adding sequential deduplication to normal alias tables using a fast hash table (Google’s `dense_hash_map`) takes 5.4 times longer for uniform inputs ($n = 10^8, 10^7$ samples) compared to simply storing samples in an array without deduplication.

Lastly, we observe that 2vl and PSA throughput levels off after $10^{7.5}$ samples on the AMD machine, whereas it keeps increasing slightly on the Intel machine.

Time per Item. Figure 6 shows the time per unique item in the sample. We can see that the 2vl and PSA approaches work well as long as few items have multiplicity larger than one. In these cases, what OS gains from having higher locality of memory accesses is lost in base case deduplication – especially on the AMD machine. Because it may emit items repeatedly, OS-ND does not suffer from this and is the fastest algorithm. The same is true for the power law inputs with $s = 0.5$ and $s = 1$ (observe that as in Figure 5, the y axes for the lower two plots are logarithmic). For power law inputs with $s = 2$, the running time of OS and OS-ND is nearly constant regardless of sample size. This is because the number of unique items is very low for this input (measured in the low thousands), and thus what little time is spent on sampling is dominated by thread synchronization and scheduling overhead. This overhead is particularly problematic with the 158 threads on the Intel machine (Figure 6a), where it amounts to several milliseconds, ten times as much as on the AMD machine (Figure 6b). Further, observe that the leveling off of 2vl and PSA throughput on the AMD machine causes unfavorable time per item for large samples.

11 Conclusions and Future Work

We have presented parallel algorithms for a wide spectrum of weighted sampling problems running on a variety of machine models. The algorithms are at the same time efficient in theory and sufficiently simple to be practically useful.

Future work can address the trade-off between parallel alias tables and (distributed) 2-level alias tables (fast queries versus fast scalable construction). We can also consider support of additional machine models such as GPUs as well as MapReduce or of other big data tools like Thrill [3] or Spark [42]. For example, the solution to WRS-1 based on Theorem 2-(3) could be implemented on top of Thrill using its prefix sum primitive. It might also be possible to transfer some of the distributed data structures. For example, the variant of Theorem 2-(1) could be supported by emulating the behavior of $p = \sqrt{n}$ PEs. Storing the \sqrt{n} second-level tables as elementary objects in the big data tool ensures load balancing and fault tolerance; a replicated meta-table of size \sqrt{n} can be used to assign samples to groups.

Abstract

We present priority queues in the external memory model with block size B and main memory size M that support on N elements, operation UPDATE (a combination of operations INSERT and DECREASEKEY) in $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os and operations EXTRACTMIN and DELETE in $O\left(\lceil \frac{M^\varepsilon}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os, for any real $\varepsilon \in (0, 1)$, using $O\left(\frac{N}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ blocks. Previous I/O-efficient priority queues either support these operations in $O\left(\frac{1}{B} \log_2 \frac{N}{B}\right)$ amortized I/Os [Kumar and Schwabe, SPDP '96] or support only operations INSERT, DELETE and EXTRACTMIN in optimal $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os, however without supporting DECREASEKEY [Fadel et al., TCS '99].

We also present buffered repository trees that support on a multi-set of N elements, operation INSERT in $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ I/Os and operation EXTRACT on K extracted elements in $O\left(M^\varepsilon \log_{\frac{M}{B}} \frac{N}{B} + K/B\right)$ amortized I/Os, using $O\left(\frac{N}{B}\right)$ blocks. Previous results achieve $O\left(\frac{1}{B} \log_2 \frac{N}{B}\right)$ I/Os and $O\left(\log_2 \frac{N}{B} + \frac{K}{B}\right)$ I/Os, respectively [Buchsbaum et al., SODA '00].

Our results imply improved $O\left(\frac{E}{B} \log_{\frac{M}{B}} \frac{E}{B}\right)$ I/Os for single-source shortest paths, depth-first search and breadth-first search algorithms on massive directed dense graphs (V, E) with $E = \Omega(V^{1+\varepsilon})$, $\varepsilon > 0$ and $V = \Omega(M)$, which is equal to the I/O-optimal bound for sorting E values in external memory.

1 Introduction

Priority queues are fundamental data structures with numerous applications across computer science, most prominently in the design of efficient graph algorithms. They support the following operations on a set of N stored *elements* of the type $(key, priority)$, where “key” serves as an identifier and “priority” is a value from a total order:

- INSERT(element e): Insert element e to the priority queue.
- DELETE(key k): Remove all elements with key k from the priority queue.
- element $e = \text{EXTRACTMIN}()$: Remove and return the element e in the priority queue with the smallest priority.
- DECREASEKEY(element (k, p)): Given that an element with key k and priority p' is stored in the priority queue, if priority $p < p'$, replace the element’s priority p' with p .

Operation UPDATE(element (k, p)) is a combination of operations INSERT and DECREASEKEY, such that if the priority queue does not contain any element with key k , INSERT((k, p)) is executed, otherwise DECREASEKEY((k, p)) is executed.

We study the problem of designing priority queues that support all these operations in external memory. In the *external memory model* (also known as the *I/O model*) [1] the amount of input data is assumed to be much larger than the main memory size M . Thus, the data is stored in an external memory device (i.e. disk) that is divided into consecutive blocks of size B elements. Time complexity is measured in terms of *I/O operations* (or *I/Os*), namely block transfers from external to main memory and vice versa, while computation in main memory is considered to be free. Space complexity is measured in the number of blocks occupied by the input data in external memory. Algorithms and data structures in this model are considered *cache-aware*, since they are parameterized in terms of M and B . In contrast, *cache-oblivious* algorithms and data structures [11] are oblivious to both these values, which allows them to be efficient along all levels of a memory hierarchy. I/O-optimally scanning and sorting x consecutive elements in an array are commonly denoted to take $\text{Scan}(x) = O\left(\frac{x}{B}\right)$ I/Os and $\text{Sort}(x) = O\left(\frac{x}{B} \log \frac{M}{B} \frac{x}{B}\right)$ I/Os, respectively [1, 11].

Priority queues are a basic component in several fundamental graph algorithms, including:

- The *single-source shortest paths (SSSP)* algorithm on directed graphs with positively weighted edges, which computes the minimum edge-weight paths from a given source node to all other nodes in the graph.
- The *depth-first search (DFS)* and *breadth-first search (BFS)* algorithms on directed unweighted graphs, which number all nodes of the graph according to a depth-first or a breadth-first exploration traversal starting from a given source node, respectively.

Another necessary component for these algorithms are I/O-efficient *buffered repository trees (BRTs)* [6, 2, 7]. They are used by external memory graph algorithms in order to confirm that a given node has already been visited by the algorithm. This avoids expensive random-access I/Os incurred by internal memory methods. In particular, BRTs support the following operations on a stored multi-set of N (key, value) elements, where “key” serves as an identifier and “value” is from a total order:

- INSERT(element e): Insert element e to the BRT.
- element $e_i = \text{EXTRACT}(\text{key } k)$: Remove and return all K elements e_i (for $i \in [1, K]$) in the BRT with key k .

1.1 Previous work

Designing efficient external memory priority queues able to support operation DECREASEKEY (or at least operation UPDATE) has been a long-standing open problem [14, 10, 16, 9, 7, 13]. I/O-efficient adaptations of the standard heap data structure [10] or other sorting-based approaches [16], despite achieving optimal base- (M/B) logarithmic amortized I/O-complexity, fail to support operation DECREASEKEY. (Nevertheless, we use these priority queues as subroutines in our structure.) Adaptations of the tournament tree data structure support all operations, albeit in not so efficient base-2 logarithmic amortized I/Os [14, 7]. Indeed, in the recent work of Eenberg, Larsen and Yu [9] it is shown that for a sequence of N operations, any external-memory priority queue supporting DECREASEKEY must spend $\max\{\text{INSERT}, \text{DELETE}, \text{EXTRACTMIN}, \text{DECREASEKEY}\} = \Omega\left(\frac{1}{B} \log_{\log N} B\right)$ amortized I/Os. Randomized priority queues with matching complexity were recently presented by Jiang and Larsen [13].

The BRTs introduced by Buchsbaum et al. [6, Lemma 2.1] and their cache-oblivious counterparts [2] support INSERT in $O\left(\frac{1}{B} \log_2 N\right)$ amortized I/Os and EXTRACT on K extracted elements in $O(\log_2 N + K/B)$ amortized I/Os on a multi-set of N stored elements.

1.2 Our contributions

We present I/O-efficient priority queues that support on N stored elements, operation UPDATE in optimal $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os and operations EXTRACTMIN and DELETE in $O\left(\lceil \frac{M^\varepsilon}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil \log_{\frac{M}{B}} \frac{N}{B}\right)$, for any real $\varepsilon \in (0, 1)$. Our priority queues are the first to support operation UPDATE (and thus DECREASEKEY) in a cache-aware setting in optimal I/Os, while also I/O-optimally supporting operation INSERT. These bounds improve upon previous priority queues supporting DECREASEKEY [14], albeit at the expense of suboptimal I/O-efficiency for EXTRACTMIN and DELETE (respecting the lower bound of [9] for $M = \Omega(B \log_2 N)$). See Table 1 for a comparison with previous cache-aware and cache-oblivious I/O-efficient priority queues.

We also present I/O-efficient BRTs that support on a multi-set of N elements, operation INSERT in $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os and operation EXTRACT on K extracted elements in $O\left(M^\varepsilon \log_{\frac{M}{B}} \frac{N}{B} + K/B\right)$ amortized I/Os. Previous cache-aware bounds were $O\left(\frac{1}{B} \log_2 \frac{N}{B}\right)$ and $O\left(\log_2 \frac{N}{B} + \frac{K}{B}\right)$, respectively [6]. Combined with our priority queues, for external memory SSSP, DFS and BFS algorithms on graphs with V nodes and E directed edges, we achieve $O\left(V \frac{M^{\frac{\alpha}{1+\alpha}}}{B} \log_{\frac{M}{B}}^2 \frac{E}{B} + V \log_{\frac{M}{B}} \frac{E}{B} + \frac{E}{B} \log_{\frac{M}{B}} \frac{E}{B}\right)$ I/Os. This compares to previous

$O\left(\left(V + \frac{E}{B}\right) \log_2 E\right)$ I/Os for directed SSSP [14, 15, 7] and $O\left(\left(V + \frac{E}{B}\right) \log_2 \frac{V}{B} + \frac{E}{B} \log_{\frac{M}{B}} \frac{E}{B}\right)$ I/Os for directed DFS and BFS [6, 2]. Our bounds are I/O-optimal for dense graphs with $E = \Omega(V^{1+\epsilon})$ and $V = \Omega(M)$.

1.3 Our approach

The main component of our priority queues is the *x-treap*, a recursive structure inspired by similar cache-oblivious *x-box* [4] and cache-aware hashing data structures [12] that solve the dynamic dictionary problem in external memory (respectively, under predecessor and membership queries on a dynamic set of keys). To solve the priority queue problem, we adapt this recursive scheme to also handle priorities, inspired by the cache-oblivious priority queues of Brodal et al. [5] that support UPDATE, yet in suboptimal I/Os. Here we discuss informally these ideas, the rationale for combining them, and a back-of-the-envelope intuitive, but incomplete analysis. It is hoped that this will provide the intuition to more easily follow the full details in the sequel.

The idea behind the cache-oblivious priority queues of Brodal et al. [5] is simple. The structure has a logarithmic number of levels, where level i has two arrays, or buffers, of size roughly 2^i . These buffers are called the *front* and *rear* buffers. They contain key-priority pairs or a key-delete message (described later). The idea is that the front buffers are sorted, with everything in the i -th front buffer having smaller priorities than everything in the $(i + 1)$ -th front buffer. The items in the rear buffers do not have this rigorous ordering, but instead must be larger than the items in the rear buffer at the smaller levels. When an UPDATE operation occurs, the key-priority pair gets placed in the first rear buffer; when an EXTRACTMIN operation occurs, the key-priority pair with the smallest priority is removed from the first front buffer. Every time a level- i buffer gets too full or empty relative to its target size of 2^i , this is fixed by moving things up or down as needed, and moving things from the rear to front buffer if that respects the ordering of items in the front buffer. This resolution of problems is done efficiently using a scan of the affected and neighbouring levels. Thus, looking in a simplified manner at the lifetime of an UPDATED item, it will be inserted in the smallest rear buffer, be pushed down to larger rear buffers as they overflow, be moved from a rear buffer to a front buffer once it has gone down to a level where its priority is compatible with those in the corresponding front buffer, then moves up from the front buffer to smaller front buffers as they underflow, and is finally removed from the smallest front buffer during an EXTRACTMIN. Thus, during its lifetime, it could be moved from one level to another a total of $O\left(\log_2 \frac{N}{B}\right)$ times at an I/O-cost of $O\left(\frac{1}{B}\right)$ per level, for a total cost of $O\left(\frac{1}{B} \log_2 \frac{N}{B}\right)$ I/Os. One detail is that when an item moves from a rear to a front buffer, we want to make sure that no items in larger levels with the same key and larger priority are ever removed. This is done through special delete messages, which stay in the rear buffers and percolate down, removing any key-priority pairs with the given key that they encounter in their buffer or the corresponding front buffer.

The problem with this approach is that the base-2 logarithm seems unavoidable, with the simple idea of a geometrically increasing buffer size. So here instead we use the more complicated recursion introduced with the cache-oblivious *x-box* [4] structure and also used in the cache-aware hashing data structures [12]. In its simplest form, used for a dictionary, an *x-box* has three buffers: top, middle and bottom (respectively of approximate size x , $x^{1.5}$ and x^2), as well as \sqrt{x} recursive *upper-level* \sqrt{x} -boxes (ordered logically between the top and middle buffers) and x recursive *lower-level* \sqrt{x} -boxes (ordered logically between the middle and bottom buffers). Data in each buffer is sorted, and all keys in a given recursive buffer are

smaller than all keys in subsequent recursive buffers in the same level (upper or lower). There is no enforced order among keys in different buffers or in a recursive upper- or lower-level \sqrt{x} -box. The key feature of this construction is that the top/middle/bottom buffers have the same size as the neighbouring recursive buffers: the top buffer has size x , the top buffers of the upper-level recursive \sqrt{x} -boxes have total size x ; the middle buffer, sum of the bottom buffers of the upper-level, and sum of the top buffers of the lower-level recursive structures all have size $x^{1.5}$; the sum of the bottom buffers of the lower-level recursive structures and the bottom buffer both have size x^2 . Therefore, when for example a top buffer overflows, it can be fixed by moving excess items to the top buffers of the top recursive substructures. In a simplified view with only insertions, as buffers overflow, an item over its lifetime will percolate from the top buffer to the upper-level substructures, to the middle buffer, to the lower-level substructures, and to the bottom buffer, with each overflow handled only using scans. Assuming a base case of size M , there will be $O(\log_M N)$ times that an item will move from one buffer to another and an equal number of times that an item will pass through a base case. One major advantage of this recursive approach, is that an item will pass through a small base case not just once at the structure's top, as before, but many times.

We combine these ideas to form the x -treap, described at a high level as follows: Everywhere an x -box has a buffer, we replace it with front and rear buffers storing key-priority pairs. The order used by x -box is imposed on the keys, not the priorities. The order imposed on priorities in the Brodal et al. structure are carried over and imposed on the priorities in different levels of the x -treap; this is aided by the fact that the buffers in the x -treap form a DAG, thus the buffers where items with a given key can appear, form a natural total order. Hence, this forms a treap-like arrangement where we use the keys for order in one dimension and priorities for order in the other. We use a separate trivial base case structure which is invoked at a size smaller than the memory size; it stores items in no particular order and thus supports fast insertion of items when a neighbouring buffer adds them ($O(\frac{1}{B})$), but slow ($O(M^\epsilon)$ amortized) removal of items with small priorities to fix the underflow of a front buffer above. Thus, again considering the typical hypothetical lifetime of an item, it will be inserted at the top in the rear buffer, percolate down $O(\log_{\frac{M}{B}} \frac{N}{B})$ levels and base cases at a cost of $O(\frac{1}{B})$ amortized each, move over to a front buffer, then percolate up $O(\log_{\frac{M}{B}} \frac{N}{B})$ levels at a cost of $O(\frac{M^\epsilon}{B})$ amortized each. Thus, the total amortized cost for an item that is eventually removed by an EXTRACTMIN is $O(\frac{M^\epsilon}{B} \log_{\frac{M}{B}} \frac{N}{B})$.

However, we want the amortized cost for an item that is inserted via UPDATE to be much faster than this, i.e. $O(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B})$. This requires additional observations and tricks. The first is that, unlike Brodal et al., we do not use delete-type messages that percolate down to eliminate items with larger than minimum priority in order to prevent their removal from EXTRACTMIN. Instead, we adopt a much simpler approach, and use a hash table to keep track of all keys that have been removed by an EXTRACTMIN, and when an EXTRACTMIN returns a key that has been seen before, it is discarded and EXTRACTMIN is repeated. The second trick is to simply ensure that each buffer has at most one item with each key (and removes key-priority pairs other than the one with the minimum priority among those with the same key in the buffer). This has the effect that if there are a total of u updates performed on a key before it is removed by an EXTRACTMIN, the total cost will involve up to $O(u \log_{\frac{M}{B}} \frac{N}{B})$ percolations down at a cost of $O(\frac{1}{B})$, but only $O(\log_{\frac{M}{B}}^2 \frac{N}{B})$ percolations up at a cost of $O(\frac{M^\epsilon}{B})$ amortized each. After the EXTRACTMIN, some items may still remain in the structure and will be discarded when removed by EXTRACTMIN however, due to the no-duplicates-per-level property there will only be $O(\log_{\frac{M}{B}} N)$ such items (called *ghosts*) which

will incur a cost of at most $O\left(\lceil \frac{M^\epsilon}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil\right)$ amortized each, where the ceiling accounts for accessing the hash table. Thus the total amortized cost for the lifetime of the u UPDATES and one EXTRACTMIN involving a single key is $O\left(\frac{u}{B} \log_{\frac{M}{B}} \frac{N}{B} + \lceil \frac{M^\epsilon}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil \log_{\frac{M}{B}} \frac{N}{B}\right)$. This cost can be apportioned in the amortized sense by having the EXTRACTMIN cost $O\left(\lceil \frac{M^\epsilon}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized and the updates cost $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized each, assuming that the treap finishes in an empty state and no item can be UPDATED after it has been EXTRACTMIN'd.

The details that implement these rough ideas consume the rest of the paper. One complication that eludes the above discussion is that items don't just percolate down and then up; they could move up and down repeatedly and this can be handled through an appropriate potential function. The various layers of complexity needed for the x -treap recursion combined with the front/rear buffer idea, various types of over/underflows of buffers, a special base case, having the middle and bottom buffers be of size $x^{1+\frac{\alpha}{2}}$ and $x^{1+\alpha}$ for a suitable parameter α rather than $x^{1.5}$ and x^2 as described above, and a duplicate-catching hash table, result in a complex structure with an involved potential analysis, but that follows naturally from the above high-level description.

2 x -Treap

Given real parameter $\alpha \in (0, 1]$ and *key range* $[k_{\min}, k_{\max}) \subseteq \mathbb{R}$, an x -treap D stores a set of at most $2(D.x)^{1+\alpha}$ *elements* $(*, k, p)$ associated with a *key* $k \in [D.k_{\min}, D.k_{\max})$ and a *priority* p from a totally ordered set. D represents a set $D.rep$ of pairs (key, priority), such that a particular key k contained in D is represented to have the smallest priority p of any element with key k stored in D , unless an element with key k and a smaller priority has been removed from the structure. In particular, we call the key and priority *represented*, when the pair (key, priority) $\in D.rep$. A *representative* element contains a represented key and its represented priority. More formally, we define:

$$D.rep := \bigcup_{\{k|(k,p) \in D\}} \left\{ \left(k, \min_p (k, p) \in D \right) \right\}$$

The proposed representation scheme works under the assumption that a key that is not represented by the structure anymore, cannot become represented again. In other words, a key returned by operation EXTRACTMIN cannot be INSERTED to the structure again.

The following *interface operations* are supported (See full version for their correctness):

- BATCHED-INSERT(D, e_1, e_2, \dots, e_b): For constant $c \in (0, \frac{1}{3}]$, insert $b \leq c \cdot D.x$ elements e_1, e_2, \dots, e_b to D , given they are key-sorted with keys $e_i.k \in [D.k_{\min}, D.k_{\max})$, $i \in [1, b]$. BATCHED-INSERT adds the pairs $(e_i.k, e_i.p)$ to $D.rep$ with key $e_i.k$ that is not contained in D already. BATCHED-INSERT decreases the priority of a represented key $e_i.k$ to $e_i.p$, if its represented priority is larger than $e_i.p$ before the operation. More formally, let X_{new} contain the inserted pairs $(e_i.k, e_i.p)$ with $e_i.k \notin D.rep$. Let X_{old} contain the pairs in $D.rep$ with an inserted key, but with larger priority than the inserted one, and let X_{dec} contain these inserted pairs. After BATCHED-INSERT, a new x -treap D' is created where $D'.rep = D.rep \cup X_{new} \cup X_{dec} \setminus X_{old}$.
- BATCHED-EXTRACTMIN(D): For constant $c \in (0, \frac{1}{4}]$, remove and return the at most $c \cdot D.x$ elements (k, p) with the smallest priorities in D . BATCHED-EXTRACTMIN removes the pairs X_{\min} from $D.rep$ with the at most $c \cdot D.x$ smallest priorities. Let X_{key} contain the pairs in D with keys in X_{\min} . After BATCHED-EXTRACTMIN, a new x -treap D' is created where $D'.rep = D.rep \setminus X_{\min} \setminus X_{key}$.

■ **Figure 1** Overview of an x -treap D on “key” \times “partial order” space. Black/white dots represent elements in the front/rear buffers, respectively. All buffers are resolved. Buffer sizes and maximum number of subtrees in a level are shown on the right-hand side.

► **Theorem 1.** *An x -treap D supports BATCHED-EXTRACTMIN in $O\left(M^{\frac{\alpha}{1+\alpha}} \frac{1+\alpha}{B} \log_M D.x\right)$ amortized I/Os per element and BATCHED-INSERT in $O\left(\frac{1+\alpha}{B} \log_M D.x\right)$ amortized I/Os per element, using $O\left(\frac{(D.x)^{1+\alpha}}{B} \log_M D.x\right)$ blocks, for any real $\alpha \in (0, 1]$.*

The structure is recursive. The base case is described separately in Subsection 2.3. The base case structure is used when $D.x \leq c' M^{\frac{1}{1+\alpha}}$ (for an appropriately chosen constant $c' > 0$). Thus assuming $D.x > c' M^{\frac{1}{1+\alpha}}$, we define an x -treap to contain three *buffers* (which are arrays that store elements) and many \sqrt{x} -treaps (called *subtreaps*). Specifically, the *top*, *middle* and *bottom* buffers have *sizes* $D.x$, $(D.x)^{1+\frac{\alpha}{2}}$ and $(D.x)^{1+\alpha}$, respectively. Each buffer is divided in the middle into a *front* and a *rear buffer*. The subtrees are divided into the *upper* and the *lower level* that contain at most $\frac{1}{4} (D.x)^{\frac{1}{2}}$ and $\frac{1}{4} (D.x)^{\frac{1+\alpha}{2}}$ subtrees, respectively. Let $|b|$ denote the *size* of a buffer b . We define the *capacity* of an x -treap D to be the maximum number of elements it can contain, which is $D.x + \frac{5}{4} (D.x)^{1+\frac{\alpha}{2}} + \frac{5}{4} (D.x)^{1+\alpha} < 2 (D.x)^{1+\alpha}$.

We define a partial order (\preceq) using the terminology “above/below” among the buffers of an x -treap and all of the buffers in recursive subtrees or base case structures. In this order we have top buffer \preceq upper level recursive subtrees \preceq middle buffer \preceq lower level recursive subtrees \preceq bottom buffer.

Along with all buffers of D , we also store several additional pieces of bookkeeping information: a counter with the total number of elements stored in D and an index indicating which subtree is stored in which space in memory.

2.1 Invariants

An x -treap D maintains the following invariants with respect to every one of its top/middle/bottom buffers b . The invariants hold after the execution of each interface operation, but may be violated during the execution. They allow changes to D that do not change $D.rep$.

1. The front and rear buffers of b store elements sorted by key and left-justified.
2. The front buffer’s elements’ priorities are smaller than the rear buffer’s elements’ priorities.

3. The front buffer's elements' priorities are smaller than all elements' priorities in buffers below b in D .
4. For a top or middle buffer b with key range $[b.k_{\min}, b.k_{\max})$, the r upper or lower subtrees $D_i, i \in \{1, r\}$, respectively, have distinct key ranges $[D_i.k_{\min}, D_i.k_{\max})$, such that $b.k_{\min} = D_1.k_{\min} < D_1.k_{\max} = D_2.k_{\min} < \dots < D_r.k_{\max} = b.k_{\max}$.
5. If the middle or bottom buffer b is not empty, then at least one upper or lower subtree is not empty, respectively.

2.2 Auxiliary operations

The operations BATCHED-INSERT and BATCHED-EXTRACTMIN make use of the following *auxiliary operations* (See full version for their implementation and correctness):

- Operation RESOLVE(D, b). We say that a buffer b is *resolved*, when the front and rear buffers contain elements with pairs (key,priority) (k, p) , such that k is a represented key, and when the front buffer contains those elements with smallest priorities in the buffer. To resolve b , operation RESOLVE assigns to the elements with represented keys, the key's minimum priority stored in b . Also, it removes any elements with non-represented keys from b . RESOLVE restores Invariant 2 in b , when it is temporarily violated by other (interface or auxiliary) operations that call it.
- Operation INITIALIZE(D, e_1, e_2, \dots, e_b) distributes to a new x -treap D , $\frac{1}{4}(D.x) \leq b \leq \frac{1}{2}(D.x)^{1+\alpha}$ elements $e_i, i \in [1, b]$ from a temporary array (divided in the middle into a front and a rear array, respecting Invariants 1 and 2).
- Operation FLUSH-UP(D) ensures that the front top buffer of D contains at least $\frac{1}{4}D.x$ elements (unless all buffers of D contains less elements altogether, in which case FLUSH-UP moves them all to the top front buffer of D). By Invariants 2 and 3, these are the elements in D with smallest priority.
- Operation FLUSH-DOWN(D) is called by BATCHED-INSERT on an x -treap D whose bottom buffer contains between $\frac{1}{2}(D.x)^{1+\alpha}$ and $(D.x)^{1+\alpha}$ elements. It moves to a new temporary array, at least $\frac{1}{6}(D.x)^{1+\alpha}$ and at most $\frac{2}{3}(D.x)^{1+\alpha}$ elements from the bottom buffer of D . It ensures that the largest priority elements are removed from D .
- Operation SPLIT(D) is called by BATCHED-INSERT on an x -treap D that contains between $\frac{1}{2}(D.x)^{1+\alpha}$ and $(D.x)^{1+\alpha}$ elements. It moves to a new temporary (front and rear) array, the at most $\frac{1}{3}(D.x)^{1+\alpha}$ elements with largest keys in D .

2.3 Base case

The x -treap is a recursive structure. When the x -treap stores few enough elements so that it can be stored in internal memory, we use simple arrays to support the interface operations and operation FLUSH-UP.

► **Lemma 2.** *An $O\left(M^{\frac{1}{1+\alpha}}\right)$ -treap fits in internal memory and supports operation BATCHED-INSERT in $O(1/B)$ amortized I/Os per element and operations BATCHED-EXTRACTMIN and FLUSH-UP in $\text{Scan}\left(M^{\frac{\alpha}{1+\alpha}}\right)$ amortized I/Os per element.*

Proof. For a universal positive constant c_0 and a constant parameter $c' < c_0^{\frac{1}{\alpha}+1}$, we allocate an array of size $\left(c' \left(M^{\frac{1}{1+\alpha}}\right)\right)^{\frac{\alpha}{1+\alpha}} \leq c_0 M$ and divide it in the middle into a front and a rear buffer that store elements and maintain only Invariants 1 and 2. To implement BATCHED-INSERT on at most $\frac{c'}{2}M^{\frac{1}{1+\alpha}}$ elements, we simply add them to the rear buffer and

update the counter. This costs $O\left(\frac{M^{\frac{1}{1+\alpha}}}{B}/\frac{1}{2}M^{\frac{1}{1+\alpha}}\right) = O\left(\frac{1}{B}\right)$ I/Os amortized per added element, since we only scan the part of the rear buffer where the elements are being added to. To implement BATCHED-EXTRACTMIN on at most $\frac{c'}{2}M^{\frac{1}{1+\alpha}}$ extracted elements, we RESOLVE the array (as implemented for Theorem 1), remove and return all elements in the front buffer, and update the counter. By Lemma 5 (proven later in Subsection 2.5) this costs $O\left(\frac{M}{B}/\frac{1}{2}M^{\frac{1}{1+\alpha}}\right) = O\left(\frac{M^{\frac{\alpha}{1+\alpha}}}{B}\right)$ I/Os amortized per extracted element. FLUSH-UP is implemented like BATCHED-EXTRACTMIN with the difference that the returned elements are not removed from the array. ◀

2.4 Interface operations

(See full version for the correctness of the interface operations.)

2.4.1 Inserting elements to an x -treap

Interface operation BATCHED-INSERT on an x -treap D is implemented by means of the recursive subroutine BATCHED-INSERT($D, e_1, \dots, e_{c \cdot |b|}, b$) that also takes as argument a top or middle buffer b of D and inserts $c \cdot |b|$ elements $e_1, \dots, e_{c \cdot |b|}$ (contained in a temporary array) inside and below b in D , for constant $c \in (0, \frac{1}{3}]$. For a bottom buffer b , a non-recursive subroutine BATCHED-INSERT(D, b) simply executes Step 1 below and discards the temporary array. BATCHED-INSERT($D, e_1, \dots, e_{c \cdot |b|}, b$) is implemented as following:

1. If $D.x > c' M^{\frac{1}{1+\alpha}} + c|b|$:
 - 1.1. 2-way merge into the temporary array, the elements in the temporary array and in the rear buffer of b (by simultaneous scans in increasing key-order). RESOLVE b considering the temporary array as the rear buffer of b .
 - 1.2. Implicitly partition the front buffer of b and the temporary array by the key ranges of the subtrees immediately below b . Consider the subtrees in increasing key-order by reading the index of D . For every key range (associated with subtree D') that contains at least $\frac{1}{3}(D.x)^{\frac{1}{2}}$ elements in either the front buffer of b or the temporary array: While the key range in the front buffer of b and in the temporary array contains at most $\frac{2}{3}(D.x)^{\frac{1}{2}}$ elements, do:
 - 1.2.1. Find the $\left(\frac{2}{3}(D.x)^{\frac{1}{2}}\right)$ -th smallest priority within the key range in the front buffer of b and in the temporary array (by an external memory order-statistics algorithm [3]) and move the elements in the key range with larger priority to a new auxiliary array (by simultaneous scans in increasing key-order).
 - 1.2.2. If the counter of D' plus the auxiliary array's size does not exceed the capacity of D' : BATCHED-INSERT the elements in the auxiliary array to the top buffer of D' . Discard the auxiliary array.
 - 1.2.3. Else, if there are fewer than the maximum allowed number of subtrees in the level immediately below b : SPLIT D' . Let k be the smallest key in the array returned by SPLIT (determined by a constant number of random accesses to the leftmost elements in the returned front/rear array). Move the elements in the auxiliary array with key smaller than k to a new temporary array (by a scan), BATCHED-INSERT these elements to D' and discard this temporary array. 2-way merge the remaining elements in the auxiliary array into the returned rear array and discard the auxiliary array. INITIALIZE a new subtree with the elements in the returned array. Discard the returned array.

1.2.4. Else, FLUSH-DOWN all subtrees immediately below b , which writes them to many returned arrays. 2-way merge into a new temporary array, all elements in b and in all returned arrays (by simultaneous scans in increasing key-order). (When the scan on a subtree's temporary array is over, determine the subtree with the key-next elements in the level by reading the index of D .) BATCHED-INSERT the elements in the new temporary array to the buffer b' immediately below b . Discard the new temporary array and all returned arrays.

1.3. Discard the temporary array and update the counter of D .

1.4. Else if $D.x \leq c'M^{\frac{1}{1+\alpha}} + c|b|$: BATCHED-INSERT the elements to the base case structure.

2.4.2 Extracting minimum-priority elements from an x -treap

Interface operation BATCHED-EXTRACTMIN on an x -treap D is implemented as following:

1. If $D.x > c'M^{\frac{1}{1+\alpha}}$:
 - 1.1 If the front top buffer contains less than $\frac{1}{4}D.x$ elements: FLUSH-UP the top buffer.
 - 1.2 Remove and return all the elements $(e_i.k, e_i.p)$ from the front top buffer.
 - 1.3 Update the counter of D .
2. Else if $D.x \leq c'M^{\frac{1}{1+\alpha}}$: BATCHED-EXTRACTMIN the base case structure.

2.5 Analysis

(See full version for the proofs of Lemmata 3, 4, 5, 6 and 7, respectively.)

► **Lemma 3.** *An x -treap D has $O\left(\log_{\frac{M}{B}} D.x\right)$ levels and occupies $O\left((D.x)^{1+\alpha} \log_{\frac{M}{B}} D.x\right)$ blocks of space.*

► **Lemma 4.** *By the tall-cache assumption, scanning the buffers of an x -treap D and randomly accessing $O\left((D.x)^{\frac{1+\alpha}{2}}\right)$ subtrees takes $\text{Scan}\left((D.x)^{1+\alpha}\right)$ I/Os, for any real $\alpha \in (0, 1]$.*

A buffer b_i at level $i \leq h = O\left(\log_{\frac{M}{B}} D.x\right)$ with current number of elements in the front and rear buffers b_f, b_r , respectively, has potential $\Phi(b_i) = \Phi_f(b_i) + \Phi_r(b_i)$, such that (for constants $\varepsilon := \frac{\alpha}{1+\alpha}$ and $c_0 \geq 1$):

$$\begin{aligned} \blacksquare \quad \Phi_f(b_i) &= \begin{cases} 0, & \text{if } \frac{1}{4}|b_i| \leq b_f \leq \frac{1}{3}|b_i|, \\ \frac{c_0}{B} M^\varepsilon \cdot \left(\frac{|b_i|}{4} - b_f\right) \cdot (h - i), & \text{if } b_f < \frac{1}{4}|b_i|, \\ \frac{c_0}{B} \cdot \left(b_f - \frac{|b_i|}{3}\right) \cdot (h - i), & \text{if } b_f > \frac{1}{3}|b_i|, \end{cases} \\ \blacksquare \quad \Phi_r(b_i) &= \begin{cases} 2\frac{c_0}{B} \cdot \left(b_r - \frac{|b_i|}{2}\right) \cdot (h - i), & \text{if } b_r > 0. \end{cases} \end{aligned}$$

In general, a particular element will be added to a rear buffer and will be moved down the levels of the structure over rear buffers by operation FLUSH-DOWN. A RESOLVE operation will move the element from the rear to the front buffer, if it is a representative element. From this point, it will be moved up the levels over front buffers by operation FLUSH-UP. If it is not representative, it will either get discarded by RESOLVE (when there is an element with the same key and with smaller priority in the same buffer) or it will keep going down the structure. Since RESOLVE leaves only one element per key at the level it operates, $O\left(\log_{\frac{M}{B}} D.x\right)$ elements with the same key (i.e. at most one per level) will remain in the structure after the extraction of the representative element for this key.

The M^ε -factor accounts for the extra cost of FLUSH-UP and BATCHED-EXTRACTMIN, the $(h - i)$ -factor allows for moving elements up or down a level by FLUSH-UP and FLUSH-DOWN and the 2-factor accounts for moving elements from the rear to the front buffer.

► **Lemma 5.** RESOLVE on a buffer b_i takes $\text{Scan}(|b_i|) + O(1)$ amortized I/Os.

► **Lemma 6.** BATCHED-INSERT on an x -treap D takes $O\left(\frac{1+\alpha}{B} \log_{\frac{M}{B}} D.x\right)$ amortized I/Os per element, for any real $\alpha \in (0, 1]$.

► **Lemma 7.** BATCHED-EXTRACTMIN on an x -treap D takes $O\left(M^{\frac{\alpha}{1+\alpha}} \frac{1+\alpha}{B} \log_{\frac{M}{B}} D.x\right)$ amortized I/Os per element, for any real $\alpha \in (0, 1]$.

3 Priority queues

Priority queues support operations UPDATE and EXTRACTMIN that are defined similarly to BATCHED-INSERT and BATCHED-EXTRACTMIN, respectively, but on a *single* element.

To support these operations, we compose a priority queue out of its batched counterpart in Theorem 1. The data structure on N elements consists of $1 + \log_{1+\alpha} \log_2 N$ x -treaps of doubly increasing size with parameter α being set the same in all of them. Specifically, for $i \in \{0, \log_{1+\alpha} \log_2 N\}$, the i -th x -treap D_i has $D_i.x = 2^{(1+\alpha)^i}$. We store all keys returned by EXTRACTMIN in a hash table X [12, 8].

For $i \in \{0, \log_{1+\alpha} \log_2 N - 1\}$, we define the top buffer of D_i to be “below” the bottom buffer of D_{i-1} and the bottom buffer of D_i to be “above” the top buffer of D_{i+1} . We define the set of represented pairs (key, priority) $rep = \bigcup_{i=0}^{\log_{1+\alpha} \log_2 N} D_i.rep \setminus \{(k, p) \mid k \in X\}$ and call *represented* the keys and priorities in rep . We maintain the invariant that the maximum represented priority in $D_i.rep$ is smaller than the smallest represented priority below it.

To implement UPDATE on a pair (key, priority) $\in rep$, we BATCHED-INSERT the corresponding element to D_0 . D_0 handles single-element batches, since for $i = 0 \Rightarrow x = \Theta(1)$. When D_i reaches capacity (i.e. contains $(D_i.x)^{1+\alpha}$ elements), we call FLUSH-DOWN on it, BATCHED-INSERT the elements in the returned temporary array to D_{i+1} and discard the array. This process terminates at the first x -treap that can accommodate these elements without reaching capacity.

To implement EXTRACTMIN, we call BATCHED-EXTRACTMIN to the first x -treap D_i with a positive counter, add the extracted elements to the (empty) bottom front buffer of D_{i-1} and repeat this process on D_{i-1} , until D_0 returns at least one element. If the returned key does not belong to X , we insert it. Else, we discard the element and repeat EXTRACTMIN.

To implement DELETE of a key, we add the key to X .

(See full version for the proof of Theorem 8.)

► **Theorem 8.** There exist priority queues on N elements that support operation UPDATE in $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ amortized I/Os per element, operations EXTRACTMIN and DELETE in amortized $O\left(\lceil \frac{M^{1+\alpha}}{B} \log_{\frac{M}{B}} \frac{N}{B} \rceil \log_{\frac{M}{B}} \frac{N}{B}\right)$ I/Os per element, using $O\left(\frac{N}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ blocks, for any real $\alpha \in (0, 1]$.

4 Buffered repository trees

A *buffered repository tree (BRT)* [6, 2, 7] stores a multi-set of at most N elements, each associated with a *key* in the range $[1 \dots k_{\max}]$. It supports the operations INSERT and EXTRACT that, respectively, insert a new element to the structure and remove and report all

elements in the structure with a given key. To implement a BRT, we make use of the x -box [4]. Given positive real $\alpha \leq 1$ and key range $[k_{\min}, k_{\max}] \subseteq \mathfrak{R}$, an x -box D stores a set of at most $\frac{1}{2}(D.x)^{1+\alpha}$ elements associated with a key $k \in [D.k_{\min}, D.k_{\max}]$. An x -box supports the following operations:

- **BATCHED-INSERT**(D, e_1, e_2, \dots, e_b): For constant $c \in (0, \frac{1}{2}]$, insert $b \leq c \cdot D.x$ elements e_1, e_2, \dots, e_b to D , given they are key-sorted with keys $e_i.k \in [D.k_{\min}, D.k_{\max}]$, $i \in [1, b]$.
- **SEARCH**(D, κ): Return pointers to all elements in D with key κ , given they exist in D and $\kappa \in [D.k_{\min}, D.k_{\max}]$.

To implement operation **EXTRACT**(D, κ) that extracts all elements with key κ from an x -box D , we **SEARCH**(D, κ) and remove from D all returned pointed elements.

The BRT on N elements consists of $1 + \log_{1+\alpha} \log_2 N$ x -boxes of doubly increasing size with parameter α being set the same in all of them. We obtain the stated bounds by modifying the proof of the x -box [4, Theorem 5.1] to account for Lemmata 9 and 10.

► **Lemma 9.** For $D.x = \Omega\left(M^{\frac{1}{1+\alpha}}\right)$, an x -box supports operation **BATCHED-INSERT** in amortized $O\left(\frac{1+\alpha}{B} \log_{\frac{M}{B}} \frac{D.x}{B}\right)$ I/Os and operation **EXTRACT** on K extracted elements in amortized $O\left((1+\alpha) \log_{\frac{M}{B}} \frac{D.x}{B} + \frac{K}{B}\right)$ I/Os, using $O\left(\frac{(D.x)^{1+\alpha}}{B}\right)$ blocks of space.

Proof. Regarding **BATCHED-INSERT** on a cache-aware x -box, we obtain $O\left(\frac{1+\alpha}{B} \log_{\frac{M}{B}} \frac{D.x}{B}\right)$ amortized I/Os by modifying the proof of **BATCHED-INSERT** [4, Theorem 4.1] according the proof of Lemma 6. Specifically, every element is charged $O(1/B)$ amortized I/Os, instead of $O\left(1/B^{\frac{1}{1+\alpha}}\right)$, and the recursion stops when $D.x = O\left(M^{\frac{1}{1+\alpha}}\right)$, instead of $D.x = O\left(B^{\frac{1}{1+\alpha}}\right)$.

Regarding **SEARCHING** for the first occurrence of a key in a cache-aware x -box, we obtain $O\left(\log_{\frac{M}{B}} \frac{D.x}{B}\right)$ amortized I/Os by modifying the proof of **SEARCH** [4, Lemma 4.1], such that the recursion stops when $D.x = O\left(M^{\frac{1}{1+\alpha}}\right)$, instead of $D.x = O\left(B^{\frac{1}{1+\alpha}}\right)$. To **EXTRACT** all K occurrences of the searched key, we access them by scanning the x -box and by following fractional cascading pointers, which incurs an extra $O(K/B)$ I/Os. ◀

► **Lemma 10.** An $O\left(M^{\frac{1}{1+\alpha}}\right)$ -box fits in internal memory and supports operations **BATCHED-INSERT** in $O(1/B)$ amortized I/Os per element and operation **EXTRACT** on K extracted elements in $\text{Scan}\left(M^{\frac{\alpha}{1+\alpha}}\right)$ amortized I/Os per element.

Proof. We allocate an array of size $O(M)$ and implement **BATCHED-INSERT** by simply appending the inserted element to the array and **EXTRACT** by scanning the array and removing and returning all occurrences of the searched key. ◀

► **Theorem 11.** There exist buffered priority trees on a multi-set of N elements and of K extracted elements that support operations **INSERT** and **EXTRACT** in amortized $O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right)$ and $O\left(\frac{M^{\frac{\alpha}{1+\alpha}}}{B} \log_{\frac{M}{B}} \frac{N}{B} + \frac{K}{B}\right)$ I/Os per element, using $O\left(\frac{N}{B}\right)$ blocks, for any real $\alpha \in (0, 1]$.

5 Graph algorithms

► **Theorem 12.** Single source shortest paths on a directed graph with V nodes and E edges can be computed in $O\left(V \frac{M^{\frac{1+\alpha}{1+\alpha}}}{B} \log_{\frac{M}{B}}^2 \frac{E}{B} + V \log_{\frac{M}{B}} \frac{E}{B} + \frac{E}{B} \log_{\frac{M}{B}} \frac{E}{B}\right)$ I/Os, for any real $\alpha \in (0, 1]$.

Proof. The algorithm of Vitter [15] (described in detail in [7, Lemma 4.1] for the cache-oblivious model) makes use of a priority queue that supports the UPDATE operation and of a BRT on $O(E)$ elements. Specifically, it makes V calls to EXTRACTMIN and E calls to UPDATE on the priority queue and V calls to EXTRACT and E calls to INSERT on the BRT. Hence, we obtain the stated bounds, by using Theorems 8 and 11. ◀

▶ **Theorem 13.** *Depth-first search and breadth-first search numbers can be assigned to a directed graph with V nodes and E edges in $O\left(V \frac{M^{1+\alpha}}{B} \log^2 \frac{E}{M} + V \log \frac{E}{M} + \frac{E}{B} \log \frac{E}{M}\right)$ I/Os, for any real $\alpha \in (0, 1]$.*

Proof. The algorithm of Buchsbaum et al. [6] makes use of a priority queue and of a BRT on $O(E)$ elements. Specifically, it makes $2V$ calls to EXTRACTMIN and E calls to INSERT on the priority queue and $2V$ calls to EXTRACT and E calls to INSERT on the BRT [6, Theorem 3.1]. Hence, we obtain the stated bounds, by using Theorems 8 and 11. ◀

Abstract

Motivated by adjacency in perfect matching polytopes, we study the shortest reconfiguration problem of perfect matchings via alternating cycles. Namely, we want to find a shortest sequence of perfect matchings which transforms one given perfect matching to another given perfect matching such that the symmetric difference of each pair of consecutive perfect matchings is a single cycle. The problem is equivalent to the combinatorial shortest path problem in perfect matching polytopes. We prove that the problem is NP-hard even when a given graph is planar or bipartite, but it can be solved in polynomial time when the graph is outerplanar.

■ **Figure 1** Two sequences of perfect matchings between M and N under the alternating cycle model. The sequence $\langle M, M_1, M_2, N \rangle$ following the yellow alternating cycles is shortest even though it touches the edge in $M \cap N$ twice. On the other hand, $\langle M, M'_1, M'_2, M'_3, N \rangle$ following the pink alternating cycles is not shortest although it touches only the edges in $M \Delta N$.

1 Introduction

Combinatorial reconfiguration is a fundamental research subject that sheds light on solution spaces of combinatorial (search) problems, and connects various concepts such as optimization, counting, enumeration, and sampling. In its general form, combinatorial reconfiguration is concerned with properties of the configuration space of a combinatorial problem. The configuration space of a combinatorial problem is often represented as a graph, but its size is usually exponential in the instance size. Thus, algorithmic problems on combinatorial reconfiguration are not trivial, and require novel tools for resolution. For recent surveys, see [11, 7].

Two basic questions have been encountered in the study of combinatorial reconfiguration. The first question asks the existence of a path between two given solutions in the configuration space, namely the *reachability* of the two solutions. The second question asks the shortest length of a path between two given solutions, if it exists. The second question is usually referred to as a *shortest reconfiguration problem*.

In this paper, we focus on reconfiguration problems of matchings, namely sets of independent edges. There are several ways of defining the configuration space for matchings, and some of them have already been studied in the literature [8, 9, 6, 3, 2]. We will explain them in Section 1.1.

We study yet another configuration space for matchings, which we call the *alternating path/cycle* model. The model is motivated by adjacency in matching polytopes, which we will see soon. In the model, we are given an undirected and unweighted graph G , and also an integer $k \geq 0$. The vertex set of the configuration space consists of the matchings in G of size at least k . Two matchings M and N in G are adjacent in the configuration space if and only if their symmetric difference $M \Delta N := (M \cup N) \setminus (M \cap N)$ is a single path or cycle. In particular, we are interested in the case where $k = |V(G)|/2$, namely the reconfiguration of *perfect matchings*. In that case, the model is simplified to the *alternating cycle* model since $M \Delta N$ cannot have a path. See Figure 1 as an example.

The reachability of two perfect matchings is trivial under the alternating cycle model: the answer is always yes. This is because the symmetric difference of two perfect matchings always consists of vertex-disjoint cycles. Therefore, we focus on the shortest perfect matching reconfiguration under the alternating cycle model.

1.1 Related Work¹

Other Configuration Spaces for Matchings

As mentioned, reconfiguration problems of matchings have already been studied under different models [8, 9, 6, 3, 2]. These models chose more elementary changes as the adjacency on the configuration space. Then, the situation changes drastically under such models: even the reachability of two matchings is not guaranteed.

Matching reconfiguration was initiated by the work of Ito et al. [8]. They proposed the *token addition/removal* model of reconfiguration, in which we are also given an integer $k \geq 0$, and the vertex set of the configuration space consists of the matchings of size at least k .² Two matchings M and N are adjacent if and only if they differ in only one edge. Ito et al. [8] proved that the reachability of two given matchings can be checked in polynomial time.

Another model of reconfiguration is *token jumping*, introduced by Kamiński et al. [9]. In the token jumping model, we are also given an integer $k \geq 0$, and the vertex set of the configuration space consists of the matchings of size exactly k . Two matchings M and N are adjacent if and only if they differ in only two edges. Kamiński et al. [9, Theorem 1] proved that the token jumping model is equivalent to the token addition/removal model when two given matchings have the same size. Thus, using the result by Ito et al. [8], the reachability can be checked in polynomial time also under the token jumping model [9, Corollary 2].

On the other hand, the shortest matching reconfiguration is known to be hard. Gupta et al. [6] and Bousquet et al. [3] independently proved that the problem is NP-hard under the token jumping model. Then, the problem is also NP-hard under the token addition/removal model, because the shortest lengths are preserved under the two models [9, Theorem 1].

Recently, Bonamy et al. [2] studied the reachability of two perfect matchings under a model close to ours, namely the alternating cycle model *restricted to length four*. In the model, two perfect matchings M and N are adjacent if and only if their symmetric difference $M \triangle N$ is a cycle of length four. Then, the answer to the reachability is not always yes, and Bonamy et al. [2] proved that the reachability problem is PSPACE-complete under this restricted model.

Relation to Matching Polytopes

Our alternating cycle model (without any restriction of cycle length) for the perfect matching reconfiguration is natural when we see the connection with the simplex methods for linear optimization, or combinatorial shortest paths of the graphs of convex polytopes.

In the combinatorial shortest path problem of a convex polytope, we are given a convex polytope P , explicitly or implicitly, and two vertices v, w of P . Then, we want to find a shortest sequence u_0, u_1, \dots, u_t of vertices of P such that $u_0 = v, u_t = w$ and $\overline{u_i u_{i+1}}$ forms an edge of P for every $i = 0, 1, \dots, t - 1$. Often, we are only interested in the length of such a shortest sequence, and we are also interested in the maximum shortest path length among all pairs of vertices, which is known as the combinatorial diameter of the polytope P . The combinatorial diameter of a polytope has attracted much attention in the optimization community from the motivation of better understanding of simplex methods. Simplex methods for linear optimization start at a vertex of the feasible region, follow edges, and arrive at an optimal vertex. Therefore, the combinatorial diameter dictates the best-case

¹ Further related work can be found in the full version.

² Precisely, their model is defined in a slightly different way, but it is essentially the same as this definition.

behavior of such methods. The famous Hirsch conjecture states that every d -dimensional convex polytope with n facets has the combinatorial diameter at most $n - d$. This has been disproved by Santos [14], and the current best upper bound of $(n - d)^{\log_2 O(d/\log d)}$ for the combinatorial diameter was given by Sukegawa [15]. On the other hand, for the 0/1-polytopes (i.e., polytopes in which the coordinates of all vertices belong to $\{0, 1\}$), the Hirsch conjecture holds [10].

The shortest perfect matching reconfiguration under the alternating cycle model can be seen as the combinatorial shortest path problem of a perfect matching polytope. The *perfect matching polytope* of a graph G is defined as follows. The polytope lives in $\mathbb{R}^{E(G)}$, namely each coordinate corresponds to an edge of G . Each vertex v of the polytope corresponds to a perfect matching M of G as $v_e = 1$ if $e \in M$ and $v_e = 0$ if $e \notin M$. The polytope is defined as the convex hull of those vertices. It is known that two vertices u, v of the perfect matching polytope form an edge if and only if the corresponding perfect matchings M, N have the property that $M \triangle N$ contains only one cycle [4]. This means that the graph of the perfect matching polytope is exactly the configuration space for perfect matchings under the alternating cycle model.

1.2 Our Contribution

To the best of the authors' knowledge, known results under different models do not have direct relations to our alternating cycle model, because their configuration spaces are different. In this paper, we thus investigate the polynomial-time solvability of the shortest perfect matching reconfiguration under the alternating cycle model. The results of our paper are two-fold.

1. The shortest perfect matching reconfiguration under the alternating cycle model can be solved in polynomial time if the input graph is outerplanar.
2. The shortest perfect matching reconfiguration under the alternating cycle model is NP-hard even when the input graph is planar or bipartite.

Since outerplanar graphs form a natural and fundamental subclass of planar graphs, our results exhibit a tractability border among planar graphs.

The hardness result for bipartite graphs implies that the computation of a combinatorial shortest path in a convex polytope is NP-hard even when an inequality description is explicitly given. This is because a polynomial-size inequality description of the perfect matching polytope can be explicitly written down from a given bipartite graph.

We point out that the hardness results have been independently obtained by Aichholzer et al. [1]. Indeed, they proved the hardness for planar bipartite graphs (i.e., an input graph is planar *and* bipartite).

Technical Key Points

Compared to recent algorithmic developments on reachability problems, only a few polynomial-time solvable cases are known for shortest reconfiguration problems. We now explain two technical key points, especially for algorithmic results on shortest reconfiguration problems.

The first point is the symmetric difference of two given solutions. Under several known models (not only for matchings) that employ elementary changes as the adjacency on the configuration space, the symmetric difference gives a (good) lower bound on the shortest reconfiguration. This is because any reconfiguration sequence (i.e., a path in the configuration space) between two given solutions must touch all elements in their symmetric difference at least once. For example, in Figure 1, the symmetric difference of two perfect matchings M and N consists of 16 edges and hence it gives the lower bound of $16/4 = 4$ under

the alternating cycle model restricted to length 4 [2]. In such a case, if we can find a reconfiguration sequence touching only the elements in the symmetric difference (e.g., the sequence $\langle M, M'_1, M'_2, M'_3, N \rangle$ in Figure 1), then it is automatically the shortest under that model. However, this useful property does not hold under our alternating cycle model, because the length of an alternating cycle for reconfiguration is not fixed.

The second point is the characterization of *unhappy moves* that touch elements contained commonly in two given solutions. For example, the shortest reconfiguration sequence $\langle M, M_1, M_2, N \rangle$ in Figure 1 has an unhappy move, since it touches the edge in $M \cap N$ twice. In general, analyzing a shortest reconfiguration becomes much more difficult if such unhappy moves are required. A well-known example is the (generalized) 15-puzzle [13] in which the reachability can be determined in polynomial time, while the shortest reconfiguration is NP-hard. As illustrated in Figure 1, the shortest perfect matching reconfiguration requires unhappy moves even for outerplanar graphs, and hence we need to characterize the unhappy moves to develop a polynomial-time algorithm.

2 Problem Definition

In this paper, a graph always refers to an undirected graph that might have parallel edges and does not have loops. For a graph G , we denote by $V(G)$ and $E(G)$ the vertex set and edge set of G , respectively. An edge subset $M \subseteq E$ is called a *matching* in G if no two edges in M share the end vertices. A matching M is *perfect* if $|M| = |V(G)|/2$.

A graph is *planar* if it can be drawn on the plane without edge crossing. Such a drawing is called a *plane* drawing of the planar graph. A *face* of a plane drawing is a maximal region of the plane that contains no point used in the drawing. There is a unique unbounded face, which is called the *outer face*. A planar graph is *outerplanar* if it has an *outerplane* drawing, i.e., a plane drawing in which all vertices are incident to the outer face.

For a matching M in a graph G , a cycle C in G is called *M -alternating* if edges in M and $E(G) \setminus M$ alternate in C . We identify a cycle with its edge set to simplify the notation. We say that two perfect matchings M and N are *reachable* (under the alternating cycle model) if there exists a sequence $\langle M_0, M_1, \dots, M_t \rangle$ of perfect matchings in G such that

- (i) $M_0 = M$ and $M_t = N$; and
- (ii) $M_i = M_{i-1} \triangle C_i$ for some M_{i-1} -alternating cycle C_i for each $i = 1, \dots, t$.

Such a sequence is called a *reconfiguration sequence* between M and N , and its *length* is defined as t .

For two perfect matchings M and N , the subgraph $M \triangle N$ consists of disjoint M -alternating cycles C_1, \dots, C_t . Thus it is clear that M and N are always reachable for any two perfect matchings M and N by setting $M_i = M_{i-1} \triangle C_i$ for $i = 1, \dots, t$. In this paper, we are interested in finding a *shortest* reconfiguration sequence of perfect matchings. That is, the problem is defined as follows:

SHORTEST PERFECT MATCHING RECONFIGURATION

Input: A graph G and two perfect matchings M and N in G

Find: A shortest reconfiguration sequence between M and N .

We denote by a tuple $I = (G, M, N)$ an instance of SHORTEST PERFECT MATCHING RECONFIGURATION. Also, we denote by $\text{OPT}(I)$ the length of a shortest reconfiguration sequence of an instance I . We note that it may happen that $\text{OPT}(I)$ is much shorter than the number of disjoint M -alternating cycles in $M \triangle N$ (see Figure 1).

3 Polynomial-Time Algorithm for Outerplanar Graphs

In this section, we prove that there exists a polynomial-time algorithm for SHORTEST PERFECT MATCHING RECONFIGURATION on an outerplanar graph, as follows.

► **Theorem 1.** SHORTEST PERFECT MATCHING RECONFIGURATION *on outerplanar graphs* G can be solved in $O(|V(G)|^5)$ time.

We give such an algorithm in this section. Let $I = (G, M, N)$ be an instance of the problem such that $G = (V, E)$ is an outerplanar graph. We first observe that it suffices to consider the case when G is 2-connected.

► **Lemma 2** (*³). *Let $I = (G, M, N)$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION, and G_1, \dots, G_p be the 2-connected components of G . Furthermore, for every $i = 1, \dots, p$, let $I_i = (G_i, M \cap E(G_i), N \cap E(G_i))$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION. Then, $\text{OPT}(I) = \sum_{i=1}^p \text{OPT}(I_i)$.*

Since the 2-connected components of a graph can be found in linear time, the reduction to 2-connected outerplanar graphs can be done in linear time, too.

We fix an outerplane drawing of a given 2-connected outerplanar graph G , and identify G with the drawing for the sake of convenience. We denote by C_{out} the outer face boundary. Then C_{out} is a simple cycle since G is 2-connected. We denote the set of the *inner edges* of G by $E_{\text{in}} = E \setminus C_{\text{out}}$. In other words, E_{in} is the set of chords of C_{out} .

3.1 Technical Highlight

As mentioned in Introduction, there are two technical key points to develop a polynomial-time algorithm for SHORTEST PERFECT MATCHING RECONFIGURATION: a lower bound on the length of a shortest reconfiguration sequence, and the characterization of unhappy moves. We here explain our ideas roughly, and will give detailed descriptions in the next subsections.

Since G is planar, we can define its “dual-like” graph G^* . Then, G^* forms a tree since G is outerplanar and 2-connected. (The definition of G^* will be given in Section 3.2, and an example is given in Figure 2.) We make a correspondence between an edge in G^* and a set of edges in G . Then, we will define the length $\ell(e^*)$ of each edge e^* in G^* so that it represents the “gap” between M and N when we are restricted to the edges in the corresponding set of e^* . It is important to notice that any cycle C in G corresponds to a subtree of G^* , and vice versa. Indeed, we focus on a cut C^* of G^* clipping the subtree from G^* , that is, the set of edges in G^* leaving the subtree. If we apply an M -alternating cycle C to a perfect matching M of G , then it changes lengths $\ell(e^*)$ of the edges e^* in the corresponding cut C^* .

For our algorithm, we need a (good) lower bound for the length of a shortest reconfiguration sequence between two given perfect matchings M and N . Recall that $|M \triangle N|$ does not give a good lower bound under the alternating cycle model. This is because we can take a cycle of an arbitrary (non-fixed) length, and hence $|M \triangle N|$ can decrease drastically by only a single alternating cycle. Furthermore, no matter how we define the length $\ell(e^*)$ of each edge e^* in G^* , the total length of *all* edges in G^* does not give a good lower bound. This is because a cycle C of non-fixed length in G may correspond to a cut C^* having many edges in G^* , and hence it can change the total length drastically. Our key idea is to focus on the total length of each *path* in G^* , that is, we take the *diameter* of G^* (with respect to length ℓ)

³ The symbol (*) means that the proof is postponed to the full version.

as a lower bound. Then, because G^* is a tree, any path in G^* can contain at most two edges from the corresponding cut C^* . Therefore, regardless of the cycle length, the diameter of G^* can be changed by only these two edges. By carefully setting the length $\ell(e^*)$ as in (1), we will prove that the diameter of G^* is not only a lower bound, but indeed gives the shortest length under the assumption that $E_{\text{in}} \cap M \cap N$ is empty. Therefore, the real difficulty arises when $E_{\text{in}} \cap M \cap N$ is not empty.

In the latter case, we will characterize the unhappy moves. Assume that we know the set $F \subseteq E_{\text{in}} \cap M \cap N$ of chords that are *not* touched in a shortest reconfiguration sequence between M and N ; in other words, *all* chords in $(E_{\text{in}} \cap M \cap N) \setminus F$ must be touched for unhappy moves in that sequence. Then, we subdivide a given outerplanar graph G into subgraphs $G_1, \dots, G_{|F|+1}$ along the chords in F . Notice that each edge in F appears on the outer face boundaries in two of these subgraphs. Furthermore, each chord e in these subgraphs satisfies $e \in (E_{\text{in}} \cap M \cap N) \setminus F$ if $e \in M \cap N$. Therefore, *all* chords in these subgraphs are touched for unhappy moves as long as they are in $M \cap N$. Under this assumption, we will prove that the diameter of G_i^* gives the shortest length of a reconfiguration sequence between $M \cap E(G_i)$ and $N \cap E(G_i)$. Thus, we can solve the problem in polynomial time if we know F which yields a shortest reconfiguration sequence between M and N . Finally, to find such a set F of chords, we construct a polynomial-time algorithm which employs a dynamic programming method along the tree G^* .

3.2 Preliminaries: Constructing a Dual Graph

Let $I = (G, M, N)$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION such that G is a 2-connected outerplanar graph. Since G is planar, we can define the *dual* of G . In fact, we here construct a graph G^* obtained from the dual by applying a slight modification as follows. The construction is illustrated in Figure 2. Let V^* be the set of faces (without the outer face) of G . For a face $v^* \in V^*$, let $E_{v^*} \subseteq E(G)$ be the set of edges around v^* . We denote the set of faces touching the outer face by U^* , i.e., $U^* = \{v^* \in V^* \mid E_{v^*} \cap C_{\text{out}} \neq \emptyset\}$. We make a copy of U^* , denoted by \tilde{U}^* . We set the vertex set of G^* to be $V^* \cup \tilde{U}^*$. For v^*, w^* in V^* , an edge v^*w^* in G^* exists if and only if the faces v^* and w^* share an edge in E_{in} , i.e., $|E_{v^*} \cap E_{w^*}| = 1$. Also G^* has an edge between u^* and \tilde{u}^* for every $u^* \in U^*$, where $\tilde{u}^* \in \tilde{U}^*$ is the copy of u^* . Thus the edge set of G^* is given by

$$E(G^*) = \{v^*w^* \mid v^*, w^* \in V^*, |E_{v^*} \cap E_{w^*}| = 1\} \cup \{u^*\tilde{u}^* \mid u^* \in U^*\}.$$

The first part is denoted by E_{in}^* , and the second part is denoted by \tilde{E}^* . We observe that G^* is a tree, since G is 2-connected and outerplanar. A face of G that touches only one face (other than the outer face) is called a *leaf* in $G^* - \tilde{U}^*$. We note that there is a one-to-one correspondence between edges in E_{in} of G and E_{in}^* of G^* . For an edge subset $F \subseteq E_{\text{in}}$, F^* denotes the corresponding edge subset in G^* , that is, $F^* = \{e^* \in E_{\text{in}}^* \mid e \in F\}$. Conversely, for an edge subset $F^* \subseteq E(G^*)$, F denotes the corresponding edge subset in E_{in} , that is, $F = \{e \in E_{\text{in}} \mid e^* \in F^* \cap E_{\text{in}}^*\}$. We extend this correspondence to \tilde{E}^* , that is, $u^*\tilde{u}^* \in \tilde{E}^*$ corresponds to the edge set $E_{u^*} \cap C_{\text{out}}$ for $u^* \in U^*$, and vice versa.

It follows from the duality that there is a relationship between a cut in G^* and a cycle in G . Suppose that we are given a cycle C ($\neq C_{\text{out}}$) in G . Then, since G is outerplanar, the cycle C surrounds a set X^* of faces such that X^* does not have the outer face. The set X^* induces a connected graph (subtree) in G^* , and the set of edges leaving from X^* yields a cut $C^* = \{e^* = v^*w^* \mid v^* \in X^*, w^* \in V(G^*) \setminus X^*\}$. Conversely, let $X^* \subseteq V^*$ be a vertex subset of G^* such that the subgraph induced by X^* is connected. Then the set of edges leaving from X^* yields a cut C^* in G^* , which corresponds to a cycle in G .

■ **Figure 2** The construction of G^* and the length function ℓ . In (c), the edge lengths are depicted by different styles: thick solid lines represent edges of length two, thin solid lines represent edges of length one, and dotted lines represent edges of length zero.

We classify faces in U^* into two groups. For a face u^* in U^* , the edge set $E_{u^*} \cap C_{\text{out}}$ forms a family \mathcal{P}_{u^*} of disjoint paths. Since M and N are perfect matchings, each path P in \mathcal{P}_{u^*} is both M -alternating and N -alternating. In addition, P satisfies either

- (i) $E(P) \subseteq M \triangle N$, or
- (ii) $(M \triangle N) \cap E(P) = \emptyset$.

Furthermore, we observe that either (i) holds for *every* path P in \mathcal{P}_{u^*} , or (ii) holds for *every* path P in \mathcal{P}_{u^*} . Indeed, since $M \triangle N$ consists of disjoint cycles, if some path P in \mathcal{P}_{u^*} satisfies (i), then P is included in a cycle C in $M \triangle N$ that separates u^* from the outer face. Since the other paths in \mathcal{P}_{u^*} touch the outer face, they are on C . Thus every path satisfies (i), which shows the observation. We divide U^* into two groups U_1^* and U_2^* where each face in U_1^* satisfies (i) for every path, while each face in U_2^* satisfies (ii) for every path.

For an edge e^* in $E(G^*)$, we define the length $\ell(e^*)$ to be

$$\ell(e^*) = \begin{cases} |M \cap \{e\}| + |N \cap \{e\}| & \text{if } e^* \in E_{\text{in}}^*; \\ 1 & \text{if } e^* = u^* \tilde{u}^* \in \tilde{E}^* \text{ such that } u^* \in U_1^*; \\ 0 & \text{if } e^* = u^* \tilde{u}^* \in \tilde{E}^* \text{ such that } u^* \in U_2^*. \end{cases} \quad (1)$$

See Figure 2 for an example. Let $\ell(u^*, v^*)$ be the length of the (unique) path from u^* to v^* in G^* . We define the *gap* between M and N in the graph G as the diameter of G^* , that is, we define $\text{gap}(I) = \max\{\ell(u^*, v^*) \mid u^*, v^* \in V(G^*)\}$. This value is simply denoted by $\text{gap}(M, N)$ if G is clear from the context.

3.3 Characterization for the Disjoint Case

Let $I = (G, M, N)$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION such that G is a 2-connected outerplanar graph. In this subsection, we show that if $E_{\text{in}} \cap M \cap N$ is empty, we can characterize the optimal value with $\text{gap}(I)$, which leads to a simple polynomial-time algorithm for this case. We note that if $E_{\text{in}} \cap M \cap N$ is empty, then no edge in E_{in} belongs to both M and N , and hence $\ell(e^*)$ can only take 0 or 1.

► **Lemma 3** (*). *It holds that $\text{gap}(M, N)$ is even.*

A main theorem of this subsection is to give a characterization of the optimal value with $\text{gap}(M, N)$.

► **Theorem 4.** *Let $I = (G, M, N)$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION such that G is a 2-connected outerplanar graph. If $E_{\text{in}} \cap M \cap N$ is empty, then it holds that $\text{OPT}(I) = \text{gap}(M, N)/2$.*

■ **Figure 3** Decomposition of the outerplanar graph in Figure 2. The edges in E'_{in} are shown with bold lines.

Proof. To show the theorem, we first prove the following claim.

▷ **Claim 5 (*)**. For any M -alternating cycle C , it holds that $\text{gap}(M, N) \leq \text{gap}(M \triangle C, N) + 2$.

Consider a shortest reconfiguration sequence $\langle M_0, M_1, \dots, M_t \rangle$ from $M_0 = M$ to $M_t = N$. Then, $t = \text{OPT}(I)$. For each $i = 1, \dots, t$, it then holds that $\text{gap}(M_{i-1}, N) \leq \text{gap}(M_i, N) + 2$. By repeatedly applying the above inequalities, we obtain

$$\text{gap}(M, N) = \text{gap}(M_0, N) \leq \text{gap}(M_t, N) + 2t = 2t = 2\text{OPT}(I)$$

since $\text{gap}(M_t, N) = 0$. Hence it holds that $\text{OPT}(I) \geq \text{gap}(M, N)/2$.

It remains to show that $\text{OPT}(I) \leq \text{gap}(M, N)/2$. We prove the following claim.

▷ **Claim 6 (*)**. There exists an M -alternating cycle C such that $\text{gap}(M, N) = \text{gap}(M \triangle C, N) + 2$.

For a perfect matching M_{i-1} in G , it follows from Claim 6 that there exists an M_{i-1} -alternating cycle C_i such that $\text{gap}(M_{i-1}, N) = \text{gap}(M_{i-1} \triangle C_i, N) + 2$. Define $M_i = M_{i-1} \triangle C_i$, and repeat finding an alternating cycle satisfying the above equation. The repetition ends when $\text{gap}(M_i, N) = 0$, which means that $M_i = N$. The number of repetitions is equal to $\text{gap}(M, N)/2$, and therefore, we have $\text{OPT}(I) \leq \text{gap}(M, N)/2$. Thus the proof is complete. ◀

3.4 General Case

Let $I = (G, M, N)$ be an instance of SHORTEST PERFECT MATCHING RECONFIGURATION such that G is a 2-connected outerplanar graph. Define $E'_{\text{in}} = E_{\text{in}} \cap M \cap N$. In this subsection, we deal with the general case, that is, E'_{in} is not necessarily empty. Then, there is a case when changing an edge in E'_{in} reduces the number of reconfiguration steps as in Figure 1. We call such a move an *unhappy move*. The key idea of our algorithm is to detect a set of edges necessary for unhappy moves.

Since G is outerplanar and 2-connected, any $F \subseteq E'_{\text{in}}$ divides the inner region of C_{out} into $|F| + 1$ parts $R_1, \dots, R_{|F|+1}$. For each $i = 1, \dots, |F| + 1$, let G_i be the subgraph of G consisting of all the vertices and the edges in R_i and its boundary. Thus, each edge $e \in F$ appears on the outer face boundaries in two of these subgraphs. See Figure 3. Let $\mathcal{G}_F = \{G_1, \dots, G_{|F|+1}\}$. Note that each graph in \mathcal{G}_F is outerplanar and 2-connected. For each $H \in \mathcal{G}_F$, let $I_H = (H, M \cap E(H), N \cap E(H))$. We now show the following theorem.

► **Theorem 7.** $\text{OPT}(I) = \frac{1}{2} \min_{F \subseteq E'_{\text{in}}} \sum_{H \in \mathcal{G}_F} \text{gap}(I_H)$.

61:10 Shortest Reconfiguration of Perfect Matchings via Alternating Cycles

Proof. Let $\langle M_0, M_1, \dots, M_t \rangle$ be a shortest reconfiguration sequence from $M_0 = M$ to $M_t = N$. We denote by C_i the M_{i-1} -alternating cycle with $M_i = M_{i-1} \Delta C_i$. Define $F_{\text{opt}} = \{e \in E'_{\text{in}} \mid e \notin C_i, \forall i\}$, which is the set of edges in E'_{in} that are not touched in the shortest reconfiguration sequence. Then C_i is contained in some $H \in \mathcal{G}_{F_{\text{opt}}}$, and can be used to obtain a reconfiguration sequence from $M \cap E(H)$ to $N \cap E(H)$ in H . Therefore, we have

$$\text{OPT}(I) = \sum_{H \in \mathcal{G}_{F_{\text{opt}}}} \text{OPT}(I_H). \quad (2)$$

We can also see that

$$\text{OPT}(I) \leq \sum_{H \in \mathcal{G}_F} \text{OPT}(I_H) \quad (3)$$

for any $F \subseteq E'_{\text{in}}$.

To evaluate $\text{OPT}(I_H)$ for $H \in \mathcal{G}_F$, we slightly modify the instance I_H by replacing every inner edge of H contained in $M \cap N$ by two parallel edges each in M and N , respectively. The obtained graph is denoted by H' , and the corresponding instance is denoted by $I_{H'}$. Since a reconfiguration sequence for $I_{H'}$ can be converted to one for I_H , it holds that $\text{OPT}(I_H) \leq \text{OPT}(I_{H'})$, and hence

$$\text{OPT}(I) \leq \sum_{H \in \mathcal{G}_F} \text{OPT}(I_H) \leq \sum_{H \in \mathcal{G}_F} \text{OPT}(I_{H'}) \quad (4)$$

holds for any $F \subseteq E'_{\text{in}}$ by (3). Moreover, by the definition of F_{opt} , there exists an index i such that $e \in C_i$ for any $e \in E'_{\text{in}} \setminus F_{\text{opt}}$. Therefore, for $H \in \mathcal{G}_{F_{\text{opt}}}$, the shortest reconfiguration sequence for I_H can be converted to a reconfiguration sequence for $I_{H'}$. Thus, $\text{OPT}(I_H) \geq \text{OPT}(I_{H'})$ holds for $H \in \mathcal{G}_{F_{\text{opt}}}$, and hence

$$\text{OPT}(I) = \sum_{H \in \mathcal{G}_{F_{\text{opt}}}} \text{OPT}(I_H) \geq \sum_{H \in \mathcal{G}_{F_{\text{opt}}}} \text{OPT}(I_{H'}) \quad (5)$$

by (2). By (4) and (5), we obtain

$$\text{OPT}(I) = \min_{F \subseteq E'_{\text{in}}} \sum_{H \in \mathcal{G}_F} \text{OPT}(I_{H'}), \quad (6)$$

and F_{opt} is a minimizer of the right-hand side.

By (6) and Theorem 4, we obtain

$$\text{OPT}(I) = \frac{1}{2} \min_{F \subseteq E'_{\text{in}}} \sum_{H \in \mathcal{G}_F} \text{gap}(I_{H'}), \quad (7)$$

because each $I_{H'}$ satisfies the condition in Theorem 4. Since $(H')^*$ is obtained from H^* by subdividing some edges of length two into two edges of length one, the diameter of $(H')^*$ is equal to that of H^* , that is, $\text{gap}(I_{H'}) = \text{gap}(I_H)$. Therefore, we obtain the theorem by (7). ◀

As an example, we apply this theorem to the instance in Figure 2. See Figure 3(c). If F consists of only the right thick edge in Figure 2(c), then \mathcal{G}_F consists two graphs G_1 and G_2 such that $\text{gap}(I_{G_1}) = 6$ and $\text{gap}(I_{G_2}) = 2$. Since we can check that such F attains the minimum in the right-hand side of Theorem 7, we obtain $\text{OPT}(I) = 4$ by Theorem 7.

In order to compute the value in Theorem 7 efficiently, we reduce the problem to MIN-SUM DIAMETER DECOMPOSITION, whose definition will be given later.

For $F \subseteq E'_{\text{in}}$, let F^* be the edge subset of E_{in}^* corresponding to F , and let $\mathcal{G}_F = \{G_1, \dots, G_{|F|+1}\}$. Then, $G^* - F^*$ consists of $|F| + 1$ components $T_1, T_2, \dots, T_{|F|+1}$ such that T_i coincides with G_i^* (except for the difference of edges of length zero) for $i = 1, \dots, |F| + 1$. In particular, for each i , we have $\text{gap}(I_{G_i}) = \max\{\ell(u^*, v^*) \mid u^*, v^* \in V(T_i)\}$, where ℓ is the length function on $E(G^*)$ defined by the instance $I = (G, M, N)$. We call $\max\{\ell(u^*, v^*) \mid u^*, v^* \in V(T_i)\}$ the *diameter* of T_i , which is denoted by $\text{diam}_\ell(T_i)$. Then, Theorem 7 shows that

$$\text{OPT}(I) = \frac{1}{2} \min_{F \subseteq E'_{\text{in}}} \sum_{i=1}^{|F|+1} \text{diam}_\ell(T_i). \quad (8)$$

Therefore, we can compute $\text{OPT}(I)$ by solving the following problem in which $T = G^*$ and $E_0 = (E'_{\text{in}})^*$.

MIN-SUM DIAMETER DECOMPOSITION

Input: A tree T , an edge subset $E_0 \subseteq E(T)$, and a length function $\ell : E(T) \rightarrow \mathbb{Z}_{\geq 0}$

Find: An edge set $F \subseteq E_0$ that minimizes $\sum_{T'} \text{diam}_\ell(T')$, where the sum is taken over all the components T' of $T - F$.

In the subsequent subsection, we show that MIN-SUM DIAMETER DECOMPOSITION can be solved in time polynomial in $|V(T)|$ and $L := \sum_{e \in E(T)} \ell(e)$.

► **Theorem 8.** MIN-SUM DIAMETER DECOMPOSITION can be solved in $O(|V(T)|L^4)$ time, where $L := \sum_{e \in E(T)} \ell(e)$.

Since (8) shows that SHORTEST PERFECT MATCHING RECONFIGURATION on outerplanar graphs is reduced to MIN-SUM DIAMETER DECOMPOSITION in which $L = O(|V(T)|)$, we obtain Theorem 1.

3.5 Algorithm for Min-Sum Diameter Decomposition

The remaining task is to show Theorem 8, that is, to give an algorithm for MIN-SUM DIAMETER DECOMPOSITION that runs in $O(|V(T)|L^4)$ time. For this purpose, we adopt a dynamic programming approach.

We choose an arbitrary vertex r of a given tree T , and regard T as a rooted tree with the root r . For each vertex v of T , we denote by T_v the subtree of T which is rooted at v and is induced by all descendants of v in T . (See Figure 4(a).) Thus, $T = T_r$ for the root r . Let w_1, w_2, \dots, w_q be the children of v , ordered arbitrarily. For each $j \in \{1, 2, \dots, q\}$, we denote by T_v^j the subtree of T induced by $\{v\} \cup V(T_{w_1}) \cup V(T_{w_2}) \cup \dots \cup V(T_{w_j})$. For example, in Figure 4(b), the subtree T_v^j is surrounded by a thick dotted rectangle. For notational convenience, we denote by T_v^0 the tree consisting of a single vertex v . Then, $T_v = T_v^0$ for each leaf v of T . Our algorithm computes and extends partial solutions for subtrees T_v^j from the leaves to the root r of T by keeping the information required for computing (the sum of) diameters of a partial solution.

We now define partial solutions for subtrees. For a subtree T_v^j and an edge subset $F' \subseteq E_0 \cap E(T_v^j)$, the *frontier* for F' is the component (subtree) in $T_v^j - F'$ that contains the root v of T_v^j . We sometimes call it the *v-frontier* for F' to emphasize the root v . For three integers $x, y, z \in \{0, 1, \dots, L\}$, the edge subset F' is called an (x, y, z) -separator of T_v^j if the following three conditions hold. (See also Figure 4(c).)

■ **Figure 4** (a) Subtree T_v in the whole tree T , (b) subtree T_v^j in T_v , and (c) an (x, y, z) -separator of T_v^j .

- $x = \max\{\ell(v, u) \mid u \in V(T_{F'})\}$, where $T_{F'}$ is the v -frontier for F' . That is, the longest path from v to a vertex in $T_{F'}$ is of length x .
 - $y = \text{diam}_\ell(T_{F'})$, that is, y denotes the diameter of the v -frontier $T_{F'}$ for F' .
 - $z = \sum_{T'} \text{diam}_\ell(T')$, where the sum is taken over all the components T' of $(T - F') \setminus T_{F'}$.
- Note that $x \leq y$ always holds for an (x, y, z) -separator of T_v^j . We then define the following function: for a subtree T_v^j and two integers $x, y \in \{0, 1, \dots, L\}$, we let

$$f(T_v^j; x, y) = \min \{z \mid T_v^j \text{ has an } (x, y, z)\text{-separator}\}.$$

Note that $f(T_v^j; x, y)$ is defined as $+\infty$ if T_v^j does not have an (x, y, z) -separator for any $z \in \{0, 1, \dots, L\}$. Then, the optimal objective value to MIN-SUM DIAMETER DECOMPOSITION can be computed as $\min\{y + f(T; x, y) \mid x, y \in \{0, 1, \dots, L\}\}$.

For a given tree T , our algorithm computes $f(T_v^j; x, y)$ for all possible triplets (T_v^j, x, y) from the leaves to the root r of T . The algorithm runs in $O(|V(T)|L^4)$ time in total. (The details are explained in the full version.) Note that we can easily modify the algorithm so that we obtain not only the optimal value but also an optimal solution. This completes the proof of Theorem 8.

We note here that the algorithm can be modified so that the running time is bounded by a polynomial in $|V(T)|$ by replacing the domain $\{0, 1, \dots, L\}$ of x and y with $D := \{\ell(u, v) \mid u, v \in V(T)\}$. This modification is valid, because $f(T_v^j; x, y) = +\infty$ unless $x, y \in D$. Since $|D| = O(|V(T)|^2)$, the modified algorithm runs in $O(|V(T)||D|^4) = O(|V(T)|^9)$ time. Note that, although this bound is polynomial only in $|V(T)|$, it is worse than $O(|V(T)|L^4)$ when $L = O(|V(T)|)$.

4 NP-Hardness for Planar Graphs and Bipartite Graphs

In this section, we prove that SHORTEST PERFECT MATCHING RECONFIGURATION is NP-hard even when the input graph is planar or bipartite.

► **Theorem 9.** SHORTEST PERFECT MATCHING RECONFIGURATION is NP-hard even for planar graphs of maximum degree three.

We reduce the HAMILTONIAN CYCLE problem, which is known to be NP-complete even when a given graph is 3-regular and planar [5].

HAMILTONIAN CYCLE

Input: A 3-regular planar graph $H = (V, E)$

Question: Decide whether H has a Hamiltonian cycle, i.e., a cycle that goes through all the vertices exactly once.

Proof. Let H be a 3-regular planar graph, which is an instance of HAMILTONIAN CYCLE. For each vertex $v \in V(H)$, we define a 8-vertex graph D_v (see also the top right in Figure 5):

$$\begin{aligned} V(D_v) &= \{v_1, v_2, v_3, v_4, v_5, v_6, v_7, v_8\}, \\ E(D_v) &= \{v_1v_2, v_2v_3, v_3v_4, v_4v_1, v_4v_5, v_5v_7, v_3v_6, v_6v_8\}. \end{aligned}$$

We construct an instance $I = (G, M, N)$ of our problem as follows. (See Figure 5 as an example.) We subdivide each edge $e = uv$ in H twice, and the obtained vertices are denoted by u_e and v_e , where u_e is closer to u . Then, for each vertex $v \in V(H)$, we replace v with the graph D_v , and connect v_7 to $v_{e_v^{(1)}}$ and $v_{e_v^{(2)}}$, v_8 to $v_{e_v^{(2)}}$ and $v_{e_v^{(3)}}$, where $e_v^{(1)}, e_v^{(2)}, e_v^{(3)}$ are edges incident to v and the order follows the plane drawing of H . Let $E_v = \{v_7v_{e_v^{(1)}}, v_7v_{e_v^{(2)}}, v_8v_{e_v^{(2)}}, v_8v_{e_v^{(3)}}\}$. The resulting graph is denoted by G , i.e., G is defined as follows:

$$\begin{aligned} V(G) &= \bigcup_{v \in V(H)} V(D_v) \cup \bigcup_{e=uv \in E(H)} \{u_e, v_e\}, \\ E(G) &= \left(\bigcup_{v \in V(H)} E(D_v) \cup E_v \right) \cup \{u_e v_e \mid e \in E(H)\}. \end{aligned}$$

It follows that G is a planar graph of maximum degree three. Furthermore, we define initial and target perfect matchings M and N in G , respectively, to be

$$\begin{aligned} M &= \{v_1v_2, v_3v_4, v_5v_7, v_6v_8 \mid v \in V(H)\} \cup \{u_e v_e \mid e \in E(H)\}, \\ N &= \{v_1v_4, v_2v_3, v_5v_7, v_6v_8 \mid v \in V(H)\} \cup \{u_e v_e \mid e \in E(H)\}. \end{aligned}$$

This completes the construction of our corresponding instance $I = (G, M, N)$. The construction can be done in polynomial time.

We then give the following claim.

▷ **Claim 10 (*).** H has a Hamiltonian cycle if and only if $\text{OPT}(I) = 2$.

This completes the proof of Theorem 9. ◀

The hardness for bipartite graphs of maximum degree three can be obtained with a similar proof; the reduction uses the DIRECTED HAMILTONIAN CYCLE problem which is NP-complete even when input directed graphs have the maximum in-degree two and the maximum out-degree two [12]. The details are deferred to the full version.

► **Theorem 11 (*).** SHORTEST PERFECT MATCHING RECONFIGURATION is NP-hard even for bipartite graphs of maximum degree three.

The proofs actually show that SHORTEST PERFECT MATCHING RECONFIGURATION is NP-hard to approximate within a factor of less than $3/2$.

■ **Figure 5** Reduction for planar graphs of maximum degree three. Top left: a yes instance H of HAMILTONIAN CYCLE with a green Hamiltonian cycle. Top right: the constructed fragment D_v . Bottom left: The initial perfect matching M (red). Bottom middle: The target perfect matching N (blue). Bottom right: The perfect matching obtained as $M \Delta C$, where C corresponds to the Hamiltonian cycle of H .

5 Conclusion

In this paper, we studied the shortest reconfiguration problem of perfect matchings under the alternating cycle model, which is equivalent to the combinatorial shortest path problem on perfect matching polytopes. We prove that the problem can be solved in polynomial time for outerplanar graphs, but it is NP-hard, and even APX-hard for planar graphs and bipartite graphs.

Several questions remain unsolved. For polynomial-time solvability, our algorithm runs only for outerplanar graphs, and it looks difficult to extend the algorithm to other graph classes. A next step would be to try k -outerplanar graphs for fixed $k \geq 2$.

One way to tackle NP-hard cases is approximation. We only know the NP-hardness of approximating within a factor of less than $3/2$. We believe the existence of a polynomial-time constant-factor approximation. Note that we do not obtain a constant-factor approximation by flipping alternating cycles in the symmetric difference of two given perfect matchings one by one.

This paper was mainly concerned with reconfiguration of perfect matchings. Alternatively, we may consider reconfiguration of maximum matchings, or maximum-weight matchings. In those cases, we need to adopt the alternating path/cycle model. Then, the question is related to the combinatorial shortest path problem on faces of matching polytopes. Note that the perfect matching polytope is also a face of the matching polytope. Therefore, the study on maximum-weight matchings will be a generalization of this paper.

To the best of the authors' knowledge, the combinatorial shortest path problem of 0/1-polytopes has not been well investigated while the adjacency in 0/1-polytopes has been extensively studied in the literature. This paper opens up a new perspective for the study of combinatorial and computational aspects of polytopes, and connects them with the study of combinatorial reconfiguration.

Closing the Gap for Pseudo-Polynomial Strip Packing

Abstract

Two-dimensional packing problems are a fundamental class of optimization problems and Strip Packing is one of the most natural and famous among them. Indeed it can be defined in just one sentence: Given a set of rectangular axis parallel items and a strip with bounded width and infinite height, the objective is to find a packing of the items into the strip minimizing the packing height. We speak of pseudo-polynomial Strip Packing if we consider algorithms with pseudo-polynomial running time with respect to the width of the strip. It is known that there is no pseudo-polynomial time algorithm for Strip Packing with a ratio better than $5/4$ unless $P = NP$. The best algorithm so far has a ratio of $4/3 + \varepsilon$. In this paper, we close the gap between inapproximability result and currently known algorithms by presenting an algorithm with approximation ratio $5/4 + \varepsilon$. The algorithm relies on a new structural result which is the main accomplishment of this paper. It states that each optimal solution can be transformed with bounded loss in the objective such that it has one of a polynomial number of different forms thus making the problem tractable by standard techniques, i.e., dynamic programming. To show the conceptual strength of the approach, we extend our result to other problems as well, e.g., Strip Packing with 90 degree rotations and Contiguous Moldable Task Scheduling, and present algorithms with approximation ratio $5/4 + \varepsilon$ for these problems as well.

1 Introduction

Two-dimensional packing problems typically have quite natural formulations and arise in a wide variety of contexts (see e.g. [8]). A characteristic challenge in this kind of problem is the space efficient placement of rectangles in a given area. Despite their simple description, they are usually quite hard and require sophisticated algorithmic techniques in order to reliably and efficiently find good solutions. Indeed, the study of algorithms for fundamental two-dimensional packing problems, like, e.g., Strip Packing, 2D-Knapsack, 2D-Bin Packing, or Unsplittable Flow on a Path, can be traced back to 1980 when Baker et al. [4] and Coffman et al [9] studied the first algorithms for two-dimensional packing problems. Furthermore, new results for these problems are regularly presented on top level conferences like FOCS, STOC and SODA up to today (see, e.g., [2, 5, 10, 13, 14, 18, 33, 27]). As all of these packing problems are NP-hard, they are typically studied in the context of approximation algorithms.

■ **Figure 1** The upper and lower bounds for pseudo-polynomial approximations achieved so far.

We say an approximation algorithm A has an (absolute) approximation ratio α (or call it α -approximation) if for each instance I of the problem it holds that $A(I) \leq \alpha \text{OPT}(I)$, where $\text{OPT}(I)$ is the optimal value of the corresponding objective function.

Although there is a huge range of work related to improving the absolute approximation ratio of algorithms for Strip Packing [3, 4, 6, 9, 12, 16, 22, 24, 28, 29, 30, 31] and there have been breakthroughs for 2D-Knapsack [10] and Unsplittable Flow on a Path [14], these problems are still not understood well. In the context of Strip Packing, for instance, there is a huge gap between the best known lower and upper bound of $3/2$ and $5/3 + \varepsilon$ [15], respectively. Similar, for 2D-Knapsack and Unsplittable Flow on a Path, $(1 + \varepsilon)$ -approximation schemes might be possible while the best algorithms known so far have absolute approximation ratios of $17/9 + \varepsilon$ [10] and $5/3 + \varepsilon$ [14] respectively. Closing these gaps between lower and upper bounds poses a fascinating challenge.

To close these gaps, it is essential that the corresponding problem and the structure of optimal or at least good solutions, in particular, are understood well. Hence, it can be helpful to look at the problem from different angles and consider other goals regarding the approximation or the running time. One example, where this approach has already been particularly effective, is the consideration of asymptotic approximation ratios, where we allow an extra additive term, i.e., an algorithm A has an *asymptotic* approximation ratio of α if there exists a constant c such that $A(I) \leq \alpha \text{OPT} + c$ for each instance I . While there has been extensive work on algorithms with asymptotic approximation ratios [3, 9, 12, 24, 31, 6, 22] the algorithm by Kenyon and Rémila [24] is particularly prominent. It has an asymptotic approximation ratio of $(1 + \varepsilon)\text{OPT} + \mathcal{O}(h_{\max}/\varepsilon^2)$ for each $\varepsilon > 0$ where h_{\max} is the largest occurring item height. Due to its small running time (which is a polynomial in the number of jobs as well as $1/\varepsilon$) and its relatively small additive term, the techniques used in this algorithm have become the standard to handle items which have a small height compared to the value of the objective function in most of the later developed algorithms for Strip Packing and other 2-dimensional packing problems. On the other hand, for the 2-dimensional geometric Knapsack problem, the consideration of other running times (as e.g. in [2] where the considered algorithm has a pseudo- and quasi-polynomial running time, which allows the size of the Knapsack and terms of the form $2^{\log(n)^{\mathcal{O}(1)}}$ to appear as factors in the running time) have brought new insights, which ultimately led to an algorithm for this problem (presented in [10]) that has the currently best approximation ratio of $\frac{17}{9} + \varepsilon$.

In this spirit, algorithms with pseudo-polynomial running time, which allow the widths of the strip or the size of the smallest or largest item to appear in the running time with a polynomial dependence, have been considered for the Strip Packing problem to provide a better understanding of its hardness, see Figure 1 for an overview. The so far best pseudo-polynomial time algorithm has an approximation ratio of $4/3 + \varepsilon$ [11, 21] while there is a lower bound of $5/4$ (see [17]) on the approximation ratio for this kind of algorithms unless $\text{P} = \text{NP}$.

Results

Before we summarize the results presented in this paper, we define the Strip Packing problem formally. We have to pack a set \mathcal{I} of n rectangular items into a given strip with width $W \in \mathbb{N}$ and infinite height. Each item $i \in \mathcal{I}$ has a width $w(i) \in \mathbb{N}_{\leq W}$ and a height $h(i) \in \mathbb{N}$. The area of an item $i \in \mathcal{I}$ is defined as $a(i) := h(i) \cdot w(i)$ and the area of a set of items $\mathcal{I}' \subseteq \mathcal{I}$ is defined as $a(\mathcal{I}') := \sum_{i \in \mathcal{I}'} a(i)$. A packing of the items is given by a mapping $\rho : \mathcal{I} \rightarrow \mathbb{N}_{\leq W} \times \mathbb{N}, i \mapsto (x_i, y_i)$ which assigns the lower left corner of an item $i \in \mathcal{I}$ to a position $\rho(i) = (x_i, y_i)$ in the strip. An inner point of $i \in \mathcal{I}$ (with respect to a packing ρ) is a point from the set $\text{inn}(i) := \{(x, y) \in \mathbb{R} \times \mathbb{R} \mid x_i < x < x_i + w(i), y_i < y < y_i + h(i)\}$. We say two items $i, j \in \mathcal{I}$ overlap if they share an inner point (i.e., $\text{inn}(i) \cap \text{inn}(j) \neq \emptyset$). A packing is feasible if no two items overlap and if $x_i + w(i) \leq W$ for all $i \in \mathcal{I}$. The objective of the Strip Packing problem is to find a feasible packing ρ with minimal height $h(\rho) := \max\{y_i + h(i) \mid i \in \mathcal{I}, \rho(i) = (x_i, y_i)\}$. Given an instance I of the Strip Packing problem, we denote this minimal packing height with $\text{OPT}(I)$ and dismiss the I if the instance is clear from the context.

Analyzing the structure of solutions is a valuable tool in the development of algorithms, and this holds for approximation as well as exact algorithms. By analyzing the structure of optimal solutions and finding properties that all optimal solutions share, we aim to dramatically reduce the search space of solutions in size and gain other structural insights enabling the application of well-understood algorithmic techniques like dynamic or integer programming. This general approach is widely used in the context of two-dimensional packing problems, and there are many success stories in other areas of combinatorial optimization as well. One such example is the problem of Scheduling on Identical Machines where it lead to an approximation scheme [19] whose running time (nearly) matches the lower bound [7]. In this paper, we present an analysis of the structure of optimal solutions that consist of rectangular objects placed inside a rectangular packing area, that is restricted on one side. The structural result developed from this consideration (see Lemma 3) is particularly valuable in the design of algorithms for the Strip Packing problem as we can find a pseudo-polynomial time algorithm that matches the lower bound of $5/4$ except for a negligibly small ε .

► **Theorem 1.** *There is a pseudo-polynomial algorithm for Strip Packing which finds a $(5/4 + \varepsilon)$ -approximation in $\mathcal{O}(n \log(n)) \cdot W^{\mathcal{O}_\varepsilon(1)}$ operations, where \mathcal{O}_ε dismisses all factors solely dependent on $1/\varepsilon$.*

Moreover, since we consider optimal solutions with the above described properties, this result also comes in handy for the development of algorithms for the problem Contiguous Moldable Task Scheduling, which is a generalization of Strip Packing where each rectangular item can take on a bounded number of different shapes. However, when adapting the algorithm to this problem, we get a running time where $\mathcal{O}_\varepsilon(1)$ also does appear in the exponent of the number of items n , see Theorem 2. More formally in this problem, we are given a set \mathcal{J} of n jobs and m identical machines. Each job $j \in \mathcal{J}$ can be scheduled on different numbers of machines given by $M_j \subseteq \{1, \dots, m\}$. Depending on the number of machines $i \in M_j$, each job $j \in \mathcal{J}$ has a specific processing time $p_j(i) \in \mathbb{N}$. A schedule S is given by three functions: $\sigma : \mathcal{J} \rightarrow \mathbb{N}$ which maps each job $j \in \mathcal{J}$ to a starting time $\sigma(j)$; $\rho : \mathcal{J} \rightarrow \{1, \dots, m\}$ which maps each job $j \in \mathcal{J}$ to the number of processors $\rho(j) \in M_j$ it is processed on; and $\varphi : \mathcal{J} \rightarrow \{1, \dots, m\}$ which maps each job $j \in \mathcal{J}$ to the first machine it is processed on. The job $j \in \mathcal{J}$ will use the machines $\varphi(j)$ to $\varphi(j) + \rho(j) - 1$ contiguously. A schedule $S = (\sigma, \rho, \varphi)$ is feasible if each machine processes at most one job at a time and its makespan is defined by $\max_{j \in \mathcal{J}} \sigma(j) + p_j(\rho(j))$. The objective is to find a feasible schedule, which minimizes the makespan. This problem and prominent variants where the jobs do not need to occupy contiguous machines have been widely studied, see e.g. [32, 25, 26, 23, 20].

62:4 Closing the Gap for Pseudo-Polynomial Strip Packing

This problem is a generalization of Strip Packing as it contains this problem (and Strip Packing with rotations) as a special case: We define the number of machines m as the width of the strip W and for each item $i \in \mathcal{I}$ we introduce one job i with $M_i := \{w(i)\}$ and processing time $p_i(w(i)) = h(i)$ (or introduce one job i with $M_i := \{w(i), h(i)\}$ and processing times $p_i(w(i)) = h(i)$ and $p_i(h(i)) = w(i)$ respectively). Therefore, we cannot hope for a pseudo-polynomial algorithm with a ratio better than $5/4$ unless $P = NP$. We adapt the structure and algorithmic result to find an algorithm with an approximation ratio, which almost matches this bound.

► **Theorem 2.** *There is a pseudo-polynomial algorithm for the Contiguous Moldable Parallel Tasks Scheduling problem which finds a $(5/4 + \varepsilon)$ -approximation in $(nm)^{\mathcal{O}_\varepsilon(1)}$ operations.*

Remark that for the case where for at least one job $j \in \mathcal{J}$ we have that $|M_j| \in \Omega(m)$ the running time of this algorithm is polynomial in the input size. Furthermore, we can hope that in realistic instances the number of machines is bounded by a function in the number of jobs n . If this is the case, the mentioned algorithm is a polynomial time algorithm as well, which further motivates the consideration of pseudo-polynomial time algorithms. As the Contiguous Moldable Parallel Tasks Scheduling contains the Strip Packing with Rotations as a special case, this theorem implies a $(5/4 + \varepsilon)$ -approximation with running time $(nW)^{\mathcal{O}_\varepsilon(1)}$ for this problem as well.

Methodology

We follow the general approach mentioned above. More precisely, we analyze optimal solutions and how they can be transformed carefully into well-structured solutions without too much loss in the objective. Knowing that such a transformation is always attainable, the algorithm will iterate the potential structures of the transformed optimal packings and fill the items inside this structure using dynamic and linear programming. The same basic scheme has been used for this and other packing problems before, e.g. [2, 27, 11, 21]. However, finding a suitable transformation to a well structured solution provides a challenge that depends on the problem itself (i.e. a structural result from other packing problems might not be applicable for Strip Packing) and our approach significantly differs from previous ones.

In the approaches seen before, i.e., in [27], [11] and [21], there arises a natural set of critical items, e.g., all items with height larger than $1/3 \text{ OPT}$ in [11] and [21]. The characteristic of this set is that the aspired approximation ratio is exceeded if we place one of these items on top of the optimal packing area. The transformation strategy used in these previous approaches is heavily dependent on the fact that there can be at most two critical items on top of each other. This allows placing all critical items in the optimal packing area while discarding some noncritical items, which are placed on top of the optimal packing later (see Figure 2a). If three critical items can be put on top of each other (which will be the case as soon as a critical item can have a height smaller than $\text{OPT}/3$) the described transformation will not work. To find an algorithm with ratio $4/3 - \varepsilon$, we need to overcome this major obstacle.

To construct a $(5/4 + \varepsilon)$ -approximation, we introduce a new technique, in the following called **shifting and reordering**. In contrast to the previous results, our structural result does not guarantee that all critical items are packed inside the optimal packing area. Instead, we shift and reorder the items of an optimal packing such that the critical items with height larger than $1/4 \text{ OPT}$ are aligned into three shelves using the area $W \times (5/4 + \varepsilon) \text{ OPT}$ (see Figure 2b).

■ **Figure 2** A comparison of old and new strategies in the simplified case. Dark gray rectangles represent the critical items, while the light gray area represents the other items, which can be sliced vertically during the reordering. The hatched area represents an area where we can place the items that are sliced by the reordering.

A challenge which arises using this new strategy is the fact that by the newly introduced shifting and reordering technique a constant number of the other (non-critical) items will be sliced vertically and thus have to be discarded temporarily from the packing. Although this set of discarded items also appears in previous approaches, their handling differs significantly. Since the shifting strategy extends the occupied packing area by the factor $(5/4 + \varepsilon)$ with respect to its height, these discarded items cannot be placed on top of the packing as done in previous approaches, see Figure 2. Instead, the discarded items have to be placed carefully into gaps generated by the shifting and reordering step. By a careful analysis of the rearrangement, we prove that each possible structure of a rearranged optimal packing provides suitable gaps to place these items.

In Section 3, we present the central idea to find the improved structural result – the shifting and reordering technique. However, to highlight the basic steps, a simplified problem is considered. In this simplified case just the critical items have to be placed integrally while all other items are allowed to be partitioned into vertical slices, which do not have to be placed contiguously.

In general (when the non critical items cannot be placed as non contiguous vertical slices) the slicing of some items will cause problems when trying to place them inside gaps generated by the new strategy, because these gaps might be thin. Hence, we cannot slice items that are too wide in some sense. Nevertheless, we may slice certain narrow items further called sliceable. To overcome this obstacle, we use a lemma from [21], which states the possibility to partition each slightly stretched packing into $\mathcal{O}_\varepsilon(1)$ rectangular areas (without removing any item). This partition provides the property that each critical item is contained in (or intersected by) area(s) exclusively containing critical and sliceable items. Up to three critical items can overlap each of the vertical borders of these areas and these overlapping items may not be shifted horizontally or vertically by our new technique. In the full version, we extend the strategy presented in Section 3 to these areas although it becomes much more involved.

Combining our new techniques to place critical items on three shelves, find suitable gaps for discarded non-critical items and handle the exclusive slicing of narrow items together enables us to prove the structural result from Lemma 3 and in Section 2, we provide a more detailed road-map of its proof. As mentioned above, the algorithm iterates all possible structures defined by the structure result and tries to place all items into this structure using linear and dynamic programming until a suitable structure is found.

The structural result applies to all optimal solutions with the property that they consist of rectangular objects placed into a rectangle that is extendable on one side. Optimal solutions of the three considered problems, i.e., Strip Packing, Strip Packing with rotations and Contiguous Moldable Task Scheduling, all have this property. Thanks to this fact, we were able to obtain algorithms which find $5/4 + \varepsilon$ approximations for each of the three problems by carefully adapting the underlying dynamic program.

2 Structural Result

In this section, we introduce the *Structural Lemma*, which presents the fundamental insight to achieve the approximation ratio $(5/4 + \varepsilon)$. Roughly speaking, the lemma states that each optimal solution can be transformed such that it has a simple structure, see Lemma 3. Due to space limitations, we cannot present the proof here and we refer to the full version. Nevertheless, we provide a high-level overview on the steps of the proof, which consists of the following two basic steps. First the given instance and a corresponding optimal solution is simplified by rounding the sizes of the items (widths and heights) as well as partitioning the set of items into parts, that can be handled almost independently. Afterward, the items in the optimal packing are reordered such that they provide the properties demanded by the lemma.

Given an optimal packing with height OPT for an instance I , we first perform some simplification steps. First, we partition the set of items by defining

- $\mathcal{L} := \{i \in \mathcal{I} \mid h(i) > \delta\text{OPT}, w(i) \geq \delta W\}$ as the set of large items,
- $\mathcal{T} := \{i \in \mathcal{I} \mid h(i) \geq (1/4 + \varepsilon)\text{OPT}, w(i) < \delta W\}$ as the set of tall items,
- $\mathcal{V} := \{i \in \mathcal{I} \mid \delta\text{OPT} \leq h(i) < (1/4 + \varepsilon)\text{OPT}, w(i) \leq \mu W\}$ as the set of vertical items,
- $\mathcal{M}_V := \{i \in \mathcal{I} \mid \varepsilon\text{OPT} \leq h(i) < (1/4 + \varepsilon)\text{OPT}, \mu W < w(i) \leq \delta W\}$ as the set of vertical medium items,
- $\mathcal{H} := \{i \in \mathcal{I} \mid h(i) \leq \mu\text{OPT}, \delta W \leq w(i)\}$ as the set of horizontal items,
- $\mathcal{S} := \{i \in \mathcal{I} \mid h(i) \leq \mu\text{OPT}, w(i) \leq \mu W\}$ as the set of small items and
- $\mathcal{M} := \{i \in \mathcal{I} \mid h(i) < \varepsilon\text{OPT}, \mu W < w(i) \leq \delta W\} \cup \{i \in \mathcal{I} \mid \mu\text{OPT} < h(i) \leq \delta\text{OPT}\} = \mathcal{I} \setminus (\mathcal{L} \cup \mathcal{T} \cup \mathcal{V} \cup \mathcal{M}_V \cup \mathcal{H} \cup \mathcal{S})$ as the set of medium sized items,

where we chose δ and μ such that the total area of the items $\mathcal{M}_V \cup \mathcal{M}$ is small, resulting in $|\mathcal{M}_V|$ to be in $\mathcal{O}(1/(\varepsilon\delta^2))$. Afterward the heights of the items with height larger than δOPT are rounded such that there are at most $\mathcal{O}(1/(\varepsilon\delta))$ sizes and such that their y -coordinates are positioned on multiples of $\varepsilon\delta\text{OPT}$.

In the next step, we discard the items $\mathcal{S} \cup \mathcal{M}$ from the packing since they can be placed later on, using the NFDH algorithm from [9]. By an adaption of a lemma in [21], we were able to show that the residual packing can be partitioned into $\mathcal{O}_\varepsilon(1)$ rectangular subareas, called boxes, that contain exactly one item from the set $\mathcal{L} \cup \mathcal{M}_V$, only items from the set \mathcal{H} , or only items from the set $\mathcal{T} \cup \mathcal{V}$. Furthermore, horizontal items are allowed to overlap horizontal box borders, while vertical and tall items are allowed to overlap vertical box borders. Note that in this partitioning step no item is removed from the packing or changes its position.

Remark that in [21] the items in \mathcal{M}_V were handled the same as the medium sized items \mathcal{M} , i.e., they were simply placed on the top of the packing. However, this is not possible in our case since these items can have a height of up to $(1/4 + \varepsilon)\text{OPT}$ and we need the extra height of $(1/4 + \varepsilon)\text{OPT}$ to apply the shifting and reordering. Consequently, we have to think of a new strategy to handle them. Since their number is bounded by $\mathcal{O}_\varepsilon(1)$, it is possible to handle them as if they were large. This different handling of vertical medium items \mathcal{M}_V is, regarding previous algorithms, one of the novelties of this result.

Next, we consider the mentioned partition of the optimal solution into rectangular axis-parallel boxes. The items in $\mathcal{L} \cup \mathcal{M}_V$ and the boxes containing horizontal items need no more attention since for each item in $\mathcal{L} \cup \mathcal{M}_V$ we can guess its position in pseudo-polynomial time and by extending the packing by a factor of $\mathcal{O}(\varepsilon)$ the horizontal items can be placed inside the boxes using a configuration LP building upon the techniques presented in [24].

We innovate the reordering of the items inside the boxes for vertical and tall items $\mathcal{T} \cup \mathcal{V}$ using the new *shifting and reordering* technique (see Section 3). Using this technique, we extend all the boxes with height larger than $\text{OPT}/2$ by only $\text{OPT}/4$, shift and reorder the items inside, and partition their area such that each subarea contains either only tall items of the same height, only vertical items, or no item. Note that the boxes can be overlapped by up to three tall items on each side (left or right). When reordering the items inside the boxes, we cannot move these overlapping items. We refer to the full version for the proof of this alteration with overlapping items.

During this reordering step, we slice vertical items vertically. This slicing needs to be fixed since in the aspired Structural Lemma 3 all the items are positioned integral. We prove that by using a configuration LP to place the vertical items, we end up with only $\mathcal{O}_\varepsilon(1)$ items, that have to be placed fractionally. We place these items inside $\mathcal{O}_\varepsilon(1)$ containers of width μW and height $\text{OPT}/4$. An arising challenge is the placement of these containers inside the already extended packing. Other than in the previous attempts (see [27], [11], or [21]), it is not possible to place these extra boxes on top of the packing. By a careful analysis of the area added due to the shifting step, we manage to find a placement of these items inside the rearranged packing. All these considerations together are enough to prove the following structural result:

► **Lemma 3 (Structural Lemma).** *By extending the packing height to $(5/4 + 5\varepsilon)\text{OPT}$ each rounded optimal packing can be rearranged and partitioned into $\mathcal{O}(1/(\delta^3\varepsilon^5))$ boxes with the following properties:*

- *There are $|\mathcal{L}| + |\mathcal{M}_V| = \mathcal{O}(1/(\delta^2\varepsilon))$ boxes $\mathcal{B}_\mathcal{L}$ each containing exactly one item from the set $\mathcal{L} \cup \mathcal{M}_V$ and all items from this set are contained in these boxes.*
- *There are at most $\mathcal{O}(1/(\delta^2\varepsilon))$ boxes $\mathcal{B}_\mathcal{H}$ containing all horizontal items \mathcal{H} with $\mathcal{B}_\mathcal{H} \cap \mathcal{B}_\mathcal{L} = \emptyset$. The horizontal items can overlap horizontal box borders, but never vertical box borders.*
- *There are at most $\mathcal{O}(1/(\delta^2\varepsilon^5))$ boxes $\mathcal{B}_\mathcal{T}$ containing tall items, such that each tall item t is contained in a box with rounded height $h(t)$.*
- *There are at most $\mathcal{O}(1/(\delta^3\varepsilon^5))$ boxes $\mathcal{B}_\mathcal{V}$ containing vertical items, such that each vertical item v is contained in a box with rounded height $h(v)$.*
- *There are at most $\mathcal{O}(1/(\delta^2\varepsilon^5))$ boxes $\mathcal{B}_\mathcal{S}$ for small items, such that the total area of these boxes combined with the total free area inside the horizontal boxes is at least as large as the total area of the small items.*
- *The lower and top border of each box is positioned at a multiple of $\varepsilon\delta\text{OPT}$.*

3 Introducing the Shifting and Reordering Technique

To demonstrate the central new idea which leads to the improved structural result – the shifting and reordering technique – we consider the following simplified case. We have to pack items with a tall height integrally, while we are allowed to slice all other items vertically. We can assume that the packing, which we consider here, is the packing inside a box for \mathcal{T} and \mathcal{V} for the case that no tall item overlaps the box borders. Remember, in the general case, there can be such items and hence the reordering gets a little bit more complicated as in this simplified case. We will demonstrate that, in this simplified scenario, it is possible to rearrange the items such that there are a constant number of rectangular subareas, which contain only tall items with the same height.

■ **Figure 3** States of the item rearrangement. Dark rectangles represent tall items while light gray areas might contain non-tall sliced items.

Let a packing with height H be given. We define tall items as the items which have a height larger than $\frac{1}{4}H$. Further, assume that there is an arithmetic grid with $N + 1$ horizontal grid lines with distance H/N such that each tall item starts and ends at the grid lines. For now, we can think of this grid as the integral grid with $H + 1$ grid lines. Later, we can reduce the grid lines by rounding the heights of the items. We are interested in a fractional packing of the non-tall items. Therefore, we replace each non-tall item i by exactly $w(i)$ items with height $h(i)$ and width 1. This step is called slicing. We define a box as a rectangular subarea of the packing area.

► **Lemma 4.** *By adding at most $\frac{1}{4}H$ to the packing height and slicing non-tall items, we can rearrange the items such that we generate at most $\frac{3}{2}N$ containers which contain tall items with the same height only, and at most $\frac{9}{4}N + 1$ container for sliced items.*

Proof. In this proof, we will present a rearrangement strategy which provides the desired properties. This strategy consists of two shifting steps and one reordering step. In the shifting steps, we shift items in the vertical direction, while in the reordering step we change the item positions horizontally. In the first shifting step, we ensure that tall items intersecting the horizontal lines $\frac{1}{4}H$ or $\frac{3}{4}H$ will touch the bottom or the top of the packing area, respectively. In the second shift, we ensure that tall items not intersecting these lines have a common upper border as well. Last, we reorder the items such that tall items with the same height are positioned next to each other if they have a common upper or lower border.

Step 1: First Shift. Note that there is no tall item completely below $\frac{1}{4}H$ or completely above $\frac{3}{4}H$ since each tall item has a height larger than $\frac{1}{4}H$. We shift each tall item t intersecting the horizontal line $\frac{1}{4}H$ down, such that its bottom border touches the bottom of the strip. The sliced items below t are shifted up exactly $h(t)$, such that they are now positioned above t . In the same way, we shift each tall item intersecting the horizontal line at $\frac{3}{4}H$ but not the horizontal line at $\frac{1}{4}H$ such that its upper border is positioned at H and shift the sliced items down accordingly, see Figure 3b.

Step 2: Introducing Pseudo Items. At this point, we introduce a set of containers for the sliced items, which we call pseudo items, see Figure 3b. We draw vertical lines at each left or right border of a tall item and erase these lines on any tall item. Each area between two

consecutive lines which is bounded on top and bottom by a tall item or the packing area and contains sliced items represents a new item called pseudo item. Note that no sliced item is intersecting any box border since they are positioned on integral widths only. Furthermore, when we shift a pseudo item, we shift all sliced items included in this container as well.

When constructing the pseudo items, we consider one special case. Consider a tall item t with height larger than $\frac{3}{4}H$. There can be no tall item positioned above or below t , and t was shifted down. For these items, we introduce one pseudo item of height H and width $w(t)$ containing t and all sliced items above. Note that each pseudo item has a height, which is a multiple of H/N . Furthermore, note that each tall or pseudo item touching the top or the bottom border of the packing area has a height larger than $\frac{1}{4}H$.

Step 3: Second Shift. Next, we do a second shifting step consisting of three sub-steps. First, we shift each tall or pseudo item intersected by the horizontal line at $\frac{3}{4}H$ but not the horizontal line at $\frac{1}{4}H$ exactly $\frac{1}{4}H$ upwards. Second, we shift each pseudo item positioned between the horizontal lines at $\frac{1}{2}H$ and $\frac{3}{4}H$, such that their lower border is positioned at the horizontal line $\frac{3}{4}H$. Last, we shift each tall or pseudo item intersected by the horizontal line at $\frac{1}{2}H$ but not the horizontal line at $\frac{1}{4}H$ or $\frac{3}{4}H$ such that its upper border is positioned at the horizontal line $\frac{3}{4}H$. After this shifting, no item overlaps another item since we have shifted the items intersecting the line at $\frac{3}{4}H$ exactly $\frac{1}{4}H$, while each item below is shifted at most $\frac{1}{4}H$.

Step 4: Fusing Pseudo Items. After the second shift, we will fuse and shift some pseudo items. We want to establish the property that each tall and pseudo item has one border (upper or lower), which touches one of the horizontal lines at 0 , $\frac{3}{4}H$, or $\frac{5}{4}H$. At the moment there can be some pseudo items between the horizontal lines $\frac{1}{4}H$ and $\frac{1}{2}H$, which do not touch one of the three lines. In the following, we study the three cases where those pseudo items can occur. These items do only exist if there is a tall item touching the bottom of the packing and another tall item above this item with a lower border at or below $\frac{1}{2}H$ before the second shifting step. Consider two consecutive vertical lines we had drawn to generate the pseudo items. If a tall item overlaps the vertical strip between these lines, its right and left borders either lie on the strips borders or outside of the strip.

Case 1: In the first considered case there are three tall items, t_1 , t_2 , and t_3 from bottom to top, which overlap the strip. In this scenario t_1 must have its lower border at 0 , t_2 its upper border at $\frac{3}{4}H$, and t_3 its upper border at $\frac{5}{4}H$. As a consequence, there are at most two pseudo items: One is positioned between t_1 and t_2 , and the other between t_2 and t_3 . We will stack them, such that the lower border of the stack is positioned at $\frac{3}{4}H$ and prove that this is possible without overlapping t_3 . The total height of both pseudo items is $H - h(t_1) - h(t_2) - h(t_3)$. The total area not occupied by tall items is $H - h(t_1) - h(t_2) - h(t_3) + \frac{1}{4}H$ since we have added $\frac{1}{4}H$ to the packing height. The distance between t_1 and t_2 is at most $\frac{1}{4}H$ since t_1 's lower border is at 0 and t_2 's upper border is at $\frac{3}{4}H$ and both have a height larger than $\frac{1}{4}H$. Therefore, the distance between t_2 and t_3 is at least $H - h(t_1) - h(t_2) - h(t_3)$, see Figure 3c at the items marked with 1.

Case 2: Now consider the case where there is one tall item t_1 touching the bottom, and one tall item t_2 with height at least $\frac{1}{2}H$ touching $\frac{5}{4}H$. Obviously, t_2 has a height of at most $\frac{3}{4}H$. Furthermore, there is at most one pseudo item, and it has to be positioned between $\frac{1}{4}H$ and $\frac{1}{2}H$. We shift this pseudo item up until its bottom touches $\frac{1}{2}H$, see Figure 3c

62:10 Closing the Gap for Pseudo-Polynomial Strip Packing

at the item marked with 2. This is possible without constructing any overlap, because the distance between t_1 and the horizontal line $1/2H$ is less than $1/4H$ and, therefore, the distance between the line $1/2H$ and the lower border of the tall item is larger than the height of the pseudo item.

After this step, we consider each tall item t with height larger than $1/2H$ touching $5/4H$. We generate a new pseudo item with width $w(t)$ and height $3/4H$, with upper border at $5/4H$ and lower border at $1/2H$, containing all pseudo items below t touching $1/2H$ with their lower border.

Case 3: In the last case we consider, there are two tall items t_1 and t_2 and two pseudo items; one of the items t_1 and t_2 touches the top of the packing or the bottom, while the other ends at $3/4H$. Hence, the distance between the tall items has to be smaller than $1/4H$. Furthermore, one of the pseudo items has to touch the top or the bottom of the packing while the other is positioned between t_1 and t_2 . Since the distance between t_1 and t_2 is less than $1/4H$, one of the distances between the packing border and the lower border of t_1 or the upper border of t_2 is at least $H - h(t_1) - h(t_2)$. Therefore, we can fuse both pseudo items by shifting the one between t_1 and t_2 such that it is positioned above or below the other one, see Figure 3c at the items marked with 3.

► **Observation 1.** *After the shifting and fusing, each tall or pseudo item touches one of the horizontal lines at 0, $3/4H$ or $5/4H$.*

Step 5: Reordering the Items. In the last part of the rearrangement, we reorder the items horizontally to place pseudo and tall items with the same height next to each other. In this reordering step, we create five areas each reserved for certain items. To do so, we take vertical slices of the packing and move them to the left or the right in the strip. A vertical slice is an area of the packing with width one and height of the considered packing area, i.e. $5/4H$ in this case. While rearranging these slices, it will never happen that two items overlap. However, it can happen, that some of the tall items are placed fractionally afterward. This will be fixed in later steps.

Area 1: First, we will extract all vertical slices containing (pseudo) items with height H . Then, shifting all the remaining vertical slices to the left as much as possible, we create one box for pseudo items of height H at the right, see Figure 3d at Area 1. In this area, we sort the pseudo items such that the pseudo items containing tall items with the same height are placed next to each other. In this step, we did not place any tall item fractionally.

Area 2: Afterward, we take each vertical slice containing a (pseudo) item with height at least $1/2H$ touching the horizontal line at $5/4H$. Remember, there might be pseudo items containing a tall item t with a height between $1/2H$ and $3/4H$. We shift these slices to the left of the packing and sort them in descending order of the tall items height $h(t)$, see Figure 3d at Area 2. Afterward, we sort the pseudo items below these tall items, which are touching $1/2H$ with their bottom in ascending order of their heights, which is possible without generating any overlapping. In this step, it can happen that we slice tall items which touch the bottom of the strip. We will fix this slicing in one of the following steps, when we consider Area 5.

Area 3: Next, we look at vertical slices containing (pseudo) items t with height at least $1/2H$ touching the bottom of the strip. We shift them to the right until they touch the Area 1 and sort these slices in ascending order of the heights $h(t)$, see Figure 3d at Area 3.

Note that there are no pseudo or tall items that have their upper border positioned at $\frac{3}{4}H$ in these slices. In this step, it can happen that we slice tall items touching the top of the packing. This will be fixed in the next step.

Area 4: Look at the area above $\frac{3}{4}H$ and left of Area 2 but right of Area 1, see Figure 3d at Area 4. In this area no item overlaps the horizontal line $\frac{3}{4}H$. Therefore, we have a rectangular area where each item either touches its bottom or its top and no item is intersected by the area's borders. In [27] it was shown that, in this case, we can sort the items touching the line $\frac{3}{4}H$ in ascending order of their height and the items touching $\frac{5}{4}H$ in descending order of heights and no item will overlap another item. Now all items with the same height are placed next to each other, and thus we fixed the slicing of tall items.

Area 5: In the last step, we will reorder the remaining items. Namely the items touching the bottom of the strip left of Area 3 and the items touching the horizontal line at $\frac{3}{4}H$ with their top between Area 2 and Area 3. The items touching the bottom are sorted in descending order of their height and the items touching the horizontal line at $\frac{3}{4}H$ are sorted in ascending order regarding their heights.

▷ **Claim.** After the reordering of Area 5 no item overlaps another.

Proof. First, note that the items touching $\frac{5}{4}H$ have a height of at most $\frac{3}{4}H$. Therefore, no item touching the bottom having height at most $\frac{1}{2}H$ can overlap with these items. Furthermore, note that before the reordering no item was overlapping another. Let us assume there are two items b and t , which overlap at a point (x, y) after this reordering. Then all items left of x touching $\frac{3}{4}H$ have their lower border below y , while all items touching the bottom left of x have their upper border above y . Therefore, at every point left and right of (x, y) in the Area 5 there is an item overlapping it. Hence, the total width of items overlapping the horizontal line y is larger than the width of the Area 5. Therefore in the original ordering, there would have been items overlapping each other already since we did not add any items – a contradiction. As a consequence in this new ordering, no two items overlap, which concludes the proof of the claim. ◁

Analyzing the Number of Constructed Boxes. In the last part of this proof, we analyze how many boxes we have created for tall and sliced items.

▷ **Claim.** After the described reordering there are at most $\frac{3}{2}N$ boxes for tall items all containing items of only one height.

Proof. Each tall item with height at least $\frac{3}{4}H$ touches the bottom and we create at most one box in Area 1 for each height. Therefore, we create at most $N/4$ boxes for these items. Each tall item that has a height between $\frac{1}{2}H$ and $\frac{3}{4}H$ touches either the bottom or the horizontal line $\frac{5}{4}H$. On each of these lines, we create at most one box for items with the same height. Therefore, we create at most $2N/4$ boxes for these items. Last, each tall item with height larger than $\frac{1}{4}H$ but smaller than $\frac{1}{2}H$ either touches the bottom of the packing, the horizontal line $\frac{3}{4}H$ or the horizontal line $\frac{5}{4}H$. At each of these lines, we create at most one box for each height. Therefore, we create at most $3N/4$ of these boxes. In total, we create at most $\frac{3}{2}N$ boxes for tall items. ◁

▷ **Claim 5.** After the described reordering there are at most $\frac{9}{4}N + 1$ boxes containing sliced items.

62:12 Closing the Gap for Pseudo-Polynomial Strip Packing

Proof. Let us consider the number of boxes for sliced items. Each pseudo item's height is a multiple of H/N . Therefore, we have at most N different sizes for pseudo items. There are at most 4 boxes for each height less than $1/4H$. One is touching H with its top border in Area 1, one is touching $3/4H$ with its bottom border in Area 4, one is touching $3/4H$ with its top border in Area 5, and one is touching $1/2H$ with its bottom border in Area 2. Furthermore, there are at most 3 boxes for each size between $1/4H$ and $1/2H$. One is touching $5/4H$ with its top border in Area 4, one is touching $3/4H$ with its top border in Area 5, and one is touching 0 with its bottom border in Area 5. Additionally, there are at most 2 boxes for each pseudo item size larger than $1/2H$. One is touching $5/4H$ with its top border in Area 2, the other is touching 0 with its bottom border in Area 3. Last there is only one pseudo item with height larger than $3/4H$ in Area 1. It has height H . Since the grid is arithmetically defined, we have at most $N/4$ sizes with height at most $1/4H$, $N/4$ sizes between $1/4H$ and $1/2H$ and at most $1/4N$ sizes between $1/2H$ and $3/4H$. Therefore, we create at most $4 \cdot 1/4N + 3 \cdot 1/4N + 2 \cdot 1/4N + 1 = \frac{9}{4}N + 1$ boxes for sliced items. \triangleleft

Since the number of boxes for tall and sliced items is as small as claimed, this concludes the proof of the Lemma 4. \blacktriangleleft

In this section, we have proven that in this simplified case it is possible to reorder the items such that they have a nice structure. Nevertheless, when considering the mentioned partition into rectangular subareas (called boxes) from [21] we encounter some obstacles. In each box B containing tall and vertical items there can be up to three tall items overlapping its left and right border. Especially critical to apply the above described shifting and reordering technique are the items overlapping the box at the height $h(B) - H/4$, because these items cannot be moved. The reason why we cannot move these objects is the impossibility of judging their intertwining with other objects within the respective other box(es) in which they are contained. Therefore, since the reordering technique requires them to be shifted up, a first step is to discard these items from the respective boxes by partitioning them into smaller boxes at the left and right borders of these items. However, we cannot get rid of the items overlapping the box below this horizontal line of $h(B) - H/4$, and handling these items without moving them becomes quite technical. A detailed analysis how to reorder the items inside a box if tall items overlap the borders can be found in the full version of this paper.

Abstract

Solving the NP-hard Maximum Cut or Binary Quadratic Optimization Problem to optimality is important in many applications including Physics, Chemistry, Neuroscience, and Circuit Layout. The leading approaches based on linear/semidefinite programming require the separation of so-called odd-cycle inequalities for solving relaxations within their associated branch-and-cut frameworks. In their groundbreaking work, F. Barahona and A.R. Mahjoub have given an informal description of a polynomial-time separation procedure for the odd-cycle inequalities. Since then, the odd-cycle separation problem has broadly been considered solved. However, as we reveal, a straightforward implementation is likely to generate inequalities that are not facet-defining and have further undesired properties. Here, we present a more detailed analysis, along with enhancements to overcome the associated issues efficiently. In a corresponding experimental study, it turns out that these are worthwhile, and may speed up the solution process significantly.

1 Introduction

There are various applications that require solving the Maximum Cut (henceforth MaxCut) problem to optimality, and this has been achieved in the literature by specialized branch-and-cut algorithms that are based on certain relaxations of MaxCut. A prominent example is the determination of ground states in Ising Spin Glasses [1, 3, 4]. Other applications occur in, e.g., Chemistry, Neuroscience, and Circuit Layout. Also, the generic Binary Quadratic Optimization problem (BQP) has a direct transformation to MaxCut, see, e.g. [1], such that enhanced branch-and-cut algorithms for MaxCut directly lead to enhanced branch-and-cut algorithms for the BQP.

A key element to be carried out repeatedly in the course of such branch-and-cut algorithms is the separation of *odd-cycle inequalities* associated with the *cut polytope* as defined in Section 2. In their groundbreaking work, F. Barahona and A.R. Mahjoub [2] have shown that, under certain conditions, the odd-cycle inequalities induce maximal faces (facets) of the cut polytope – which is desirable for their application within a branch-and-cut algorithm. Moreover, they have given an informal description of a polynomial-time separation

procedure for these inequalities. Since then, this “algorithmic frame” has been used in many computational studies, but we are not aware of any accounts on the details of the respective implementations or experimental evaluations.

As we show in this paper, however, the odd-cycle inequalities derived using a “straightforward” implementation of this frame are frequently *not* facet-inducing – for two reasons that are both inherent to the algorithm. At the same time, it is, to the best of our knowledge, the only polynomial-time one proposed so far. Along with a more detailed analysis of odd-cycle separation, we thus provide extensions to overcome these shortcomings efficiently by extending the original algorithm. Finally, we present an experimental study showing the practical impact of these enhancements using established benchmark instances for MaxCut and the BQP. It turns out that the additional effort invested is typically more than compensated, i.e., has a positive effect on the solution process.

The outline of this paper is as follows: In Section 2, we define the separation problem for odd-cycle inequalities in the context of solving MaxCut by branch-and-cut, present the outline of the polynomial time separation algorithm given in [2], and point out the shortcomings of a naïve implementation. In Section 3, we analyze the problem formally and present various strategies to enhance the separation procedure. These are experimentally evaluated in Section 4.

2 The Maximum Cut Problem and Odd-Cycle Inequalities

Let $G = (V, E)$ be a simple undirected graph, i.e., there are no loops and no parallel edges. For $k > 1$, a *walk* in G is a set of edges $W = \{\{v_0, v_1\}, \{v_1, v_2\}, \dots, \{v_{k-1}, v_k\}\} \subseteq E$. If, in addition, the vertices $v_0, v_1, \dots, v_k \in V$ are pairwise different, W is called a *path*. Provided that W is a walk and $\{v_0, v_k\} \in E$, we call $W \cup \{v_0, v_k\}$ a *closed walk*. If P is a path, and $\{v_0, v_k\} \in E$, then $C = P \cup \{v_0, v_k\}$ is called a (*simple*) *cycle*. We will also refer to a closed walk that is not a simple cycle as a *non-simple cycle*.

For $W \subseteq V$, let $\delta(W) := \{e = \{u, v\} \in E \mid u \in W, v \in V \setminus W\}$. The edge subsets $\delta(W)$ for any $W \subseteq V$ are the *cuts* of G . They correspond to bipartitions of the vertex set V into W and $V \setminus W$. Given weights w_e for $e \in E$, the maximum cut problem, formulated as an integer linear programming problem, reads:

$$\max \sum_{e \in E} w_e x_e \quad (1)$$

$$\sum_{e \in Q} x_e - \sum_{e \in C \setminus Q} x_e \leq |Q| - 1 \quad \text{for all } Q \subseteq C \subseteq E, C \text{ cycle and } |Q| \text{ odd} \quad (2)$$

$$0 \leq x_e \leq 1 \quad \text{for all } e \in E \quad (3)$$

$$x_e \in \mathbb{Z} \quad \text{for all } e \in E \quad (4)$$

Any solution \hat{x} of (2)–(4) corresponds to a cut $\hat{F} = \{e \in E \mid \hat{x}_e = 1\}$ and vice versa. The necessary and sufficient condition for this to hold is that \hat{F} intersects with every cycle in G in an even number of edges which is enforced by the *odd-cycle inequalities* (2) while the trivial constraints (3) give lower and upper bounds. Consequently, any optimum solution x^* of (2)–(4) gives rise to an optimum cut $F^* = \{e \in E \mid x_e^* = 1\}$ with maximum total weight. We refer to \hat{x} and x^* as the characteristic vectors of \hat{F} and F^* , respectively. Also, we will call a cycle associated with an odd-cycle inequality “odd cycle” although $|C|$ may be even, and refer to it as a pair (C, Q) if its unique determination matters.

The *cut polytope* is the convex hull of the feasible solutions to the maximum cut problem associated with $G = (V, E)$:

$$P_{\text{CUT}}(G) = \text{conv}\{x \in \mathbb{R}^E \mid x \text{ satisfies (2)–(4)}\}$$

At the core of any linear programming based branch-and-cut algorithm, a sequence of linear programming relaxations of (1)–(3) is solved by a *cutting plane algorithm*: The first relaxation just consists of (1) and (3). Then it is the task of an *odd-cycle separation algorithm* to decide if the optimum solution \hat{x} of the current relaxation satisfies all odd-cycle constraints (2). If so, the linear programming relaxation (1)–(3) is solved to optimality and its objective function value is used as an upper bound in a branch-and-bound scheme. If not, the separation algorithm must provide at least one odd-cycle inequality that is violated by \hat{x} . The produced inequalities are then added to strengthen the current relaxation, this new relaxation is solved to optimality, and the process is iterated until the separation algorithm decides that the solution of the current linear program satisfies all odd-cycle constraints.

In branch-and-cut, it is preferred that the separated inequalities define facets of the polytope associated with the problem, so here, we would prefer odd-cycle inequalities that define facets of the cut polytope $P_{\text{CUT}}(G)$. Barahona and Mahjoub [2] have given a proof that an odd-cycle inequality defines a facet of $P_{\text{CUT}}(G)$ if and only if its associated cycle C is *chordless*, i.e., if there is no edge in $E \setminus C$ that connects two vertices of C .

2.1 Polynomial-Time Separation of Odd-Cycle Inequalities

We describe the polynomial time algorithm of Barahona and Mahjoub [2]. For this purpose, we rewrite the odd-cycle inequalities (2) associated with a graph $G = (V, E)$ as follows:

$$\sum_{e \in Q} (1 - x_e) + \sum_{e \in C \setminus Q} x_e \geq 1 \quad \text{for all } Q \subseteq C \subseteq E, C \text{ cycle and } |Q| \text{ odd} \quad (5)$$

Our task is to solve the separation problem for $\hat{x} \in [0, 1]^E$. Let $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$ be two copies of G , and denote with $u_1 \in V_1$ the representative of $u \in V$ in G_1 and with $u_2 \in V_2$ the one in G_2 . Based on these copies, define a new weighted graph $G_S = (V_S, E_S)$ with $V_S = V_1 \cup V_2$, $E_S = E_1 \cup E_2 \cup E_3$. The additional edge set $E_3 \subseteq V_1 \times V_2$ consists of the edges $\{u_1, v_2\}$ and $\{v_1, u_2\}$ for each $\{u, v\} \in E$. The edges $\{u_1, v_1\} \in E_1$ receive weights $\omega(\{u_1, v_1\}) = \hat{x}_{\{u, v\}}$, the edges $\{u_2, v_2\} \in E_2$ also receive weights $\omega(\{u_2, v_2\}) = \hat{x}_{\{u, v\}}$, and the edges $\{u_1, v_2\}, \{v_1, u_2\} \in E_3$ receive “inverted” weights $\omega(\{u_1, v_2\}) = \omega(\{v_1, u_2\}) = 1 - \hat{x}_{\{u, v\}}$. To ease notation, we will frequently write $\omega(F) := \sum_{e \in F} \omega(e)$ for any edge set $F \subseteq E_S$ or $F \subseteq E$. Moreover, we will also write $V_S(F)$ or $V(F)$ to denote the vertex set $\{v \in V_S \mid \exists \{v, w\} \in F\}$ or $\{v \in V \mid \exists \{v, w\} \in F\}$, respectively.

The fundamental property of the construction described is that, for any $u \in V$, any path $P_u \subseteq E_S$ from u_1 to u_2 in G_S corresponds to a closed walk C in the original graph G containing u . Moreover, it inevitably involves an odd number of edges from the set E_3 that, as the associated ω -weights indicate, define the subset $Q \subseteq C$.

Thus, each such path P_u corresponds to an odd closed walk (C, Q) in G that may however have vertex as well as edge repetitions, i.e., C is not necessarily a simple cycle. Fig. 1 shows a small example where two different paths of equal length (w.r.t. ω as well as the total number of edges) in G_S lead to either a simple or non-simple cycle in G .

Now, the central idea of the algorithm is to compute, for each $u \in V$, an ω -shortest path P_u from u_1 to u_2 in G_S .

If then $\omega(P_u) \geq 1$ for every $u \in V$, then there is no odd closed walk (C, Q) that violates

$$\sum_{e \in Q} (1 - x_e) + \sum_{e \in C \setminus Q} x_e \geq 1 \quad \text{for all } Q \subseteq C \subseteq E, C \text{ closed walk and } |Q| \text{ odd} \quad (6)$$

and, therefore, no simple cycle C that violates (5).

Otherwise, if $\omega(P_u) < 1$ for some $u \in V$, then P_u corresponds to an odd closed walk (C, Q) that violates (6). However, only if (C, Q) is “accidentally” simple, we have found a violated inequality of type (5).

This does not affect the correctness of the approach: Even when using (C, Q) “as is” in the cutting plane algorithm, i.e., when possibly adding an inequality of type (6) rather than one of type (5) to the linear program, the final result satisfies all the latter and thus solves the relaxation (1)–(3) of MaxCut. However, while inequalities (6) are valid for $P_{\text{CUT}}(G)$, they are not facet-inducing. And even if a cycle (C, Q) derived from an ω -shortest path in G_S is simple, it is very likely to have chords as we show in Sect. 3.3. So in summary, when using the described approach, the likelihood to generate cutting planes that do *not* correspond to facets of $P_{\text{CUT}}(G)$ is high. Fortunately, we can efficiently construct from P_u a simple odd cycle (C, Q) that violates (5), and even one that is chordless, as we shall see in Sect. 3.2 and 3.3, respectively.

■ **Figure 1** Left: An example graph G whose edges are annotated with an (integral) linear program solution. Middle: The corresponding separation graph G_S (only zero-weight edges are shown). The dashed edges correspond to a shortest u_1 - u_2 -path that induces a non-simple odd closed walk in G (edge $\{v, w\}$ is used twice, see the left of the two cycles depicted on the right). If the subpath within the right copy of G is replaced by the dotted one, the induced cycle is simple (but not chordless).

3 Non-Simple and Non-Chordless Simple Odd Cycles

To the best of our knowledge, the possible non-simplicity of odd closed walks derived with the common procedure, as well as the possible presence of chords, has attracted almost no further consideration in the literature before. However, as we will see, it matters not only in theory but also in practice.

Besides the preserved correctness of the separation algorithm already discussed, another possible reason why non-simplicity has been ignored may be the existence of an easy proof that any odd closed walk (C, Q) contains at least one simple cycle (C', Q') with $C' \subseteq C$, $Q' \subseteq Q$, and with $|Q'|$ odd:

If (C, Q) is non-simple, then either there is at least one edge $e = \{u, v\} \in E$ that occurs $k > 1$ times on C . Or, each edge $e \in E$ occurs at most once on C , but there is a vertex $v \in V$ whose degree w.r.t. the edges of C is $d_C(v) := |\{w \in V : \{v, w\} \in C\}| > 2$ (cf. Fig. 2). Since we assumed before that no edge is contained twice in C , $d_C(v)$ must then be even¹.

¹ The present case of odd closed walks induced by simple paths P in G_S with weight $\omega(P) < 1$ implies $k \leq 2$ since any combination of an E_3 -instance with an E_1 - or E_2 -instance of the same edge $e \in E$ leads to an ω -weight of at least one. Moreover, the simplicity of P_u implies $d_C(v) \leq 4$ for all $v \in V$.

■ **Figure 2** Multiple cycles comprising an edge $\{u, v\} \in E$ or a single vertex $v \in V$.

In the first case, let C_1^e, \dots, C_k^e be the corresponding closed walks that result from starting a path in v – each time using a different edge that is not e – and continuing the path until v is reached again first using e . In the second case, let $C_1^v, \dots, C_{\frac{d_C(v)}{2}}^v$ be the respective closed walks that result from starting a path in v using each time a different edge, and ending when v is first reached again.

We refer to the associated subsets of Q as $Q_i^e := C_i^e \cap Q, i \in \{1, \dots, k\}$, and $Q_i^v := C_i^v \cap Q, i \in \{1, \dots, \frac{d_C(v)}{2}\}$, respectively. Since Q is odd, there is at least one $i^* \in \{1, \dots, k\}$ ($i^* \in \{1, \dots, \frac{d_C(v)}{2}\}$) such that $|Q_{i^*}^e| \leq |Q|$ ($|Q_{i^*}^v| \leq |Q|$) is odd as well. Now either $(C_{i^*}^e, Q_{i^*}^e)$ ($(C_{i^*}^v, Q_{i^*}^v)$) is simple in which case we are done. Or, we find an edge $f \in C_{i^*}^e, f \neq e$, that occurs more than once on $C_{i^*}^e$ (a vertex $w \neq v$ in $C_{i^*}^e$ such that $d_{C_{i^*}^e}(w) > 2$) and have thus reduced the extraction of a simple cycle to a strictly smaller non-simple one. Thus, since any simple cycle has length at least three, the according recursion must terminate after finitely many steps with a cycle that is simple.

It however remains open how to *extract* a (chordless) simple odd closed walk from a non-simple one *efficiently*. This will be addressed in Sect. 3.2 and Sect. 3.3 after clarifying in Sect. 3.1 which kinds of non-simplicity can occur from the method described in Sect. 2.1.

3.1 Cases of Non-Simplicity

The landscape of different cases and their implications concerning the facet-defining property of the associated odd-cycle inequalities is depicted in Fig. 3.

■ **Figure 3** Categorization of odd closed walks.

Let P_u be an ω -shortest path from u_1 to u_2 in G_S , and let (C, Q) be its induced odd closed walk in G . We may assume w.l.o.g. (and enforce in an implementation) that P_u does not enter u_1 and that it does not leave u_2 which implies that $d_C(u) = 2$.

Now if (C, Q) is non-simple, there must be at least one vertex v with $d_C(v) > 2$, i.e., $v \neq u$. The simplicity of P_u then implies that it must traverse v_1 as well as v_2 . Denote the corresponding subpath, that itself defines an odd closed walk, with P_v . It is *fully nested* within P_u , i.e., $P_v \subsetneq P_u$. Moreover, since the number of E_3 -edges in P_u as well as in P_v is odd, the number of E_3 -edges in $P_u \setminus P_v$ must be even. Hence, while its induced edge set in G is still a closed walk, it is not an odd one.

Of course, an odd closed walk (C, Q) induced by an ω -shortest path P_u in G_S may have not only one but several vertices $v \in V$ with $d_C(v) > 2$. If all the associated subpaths of P_u are fully nested, the previous arguments imply that only the innermost one of them induces a simple odd cycle. Otherwise, any two strict subpaths of P_u , say P_v and P_w , may either occur *subsequently*, i.e., $P_v \cap P_w = \emptyset$, or *crossing*, i.e., either w_1 or w_2 occurs in P_v but not both. Fig. 4 displays the respective vertex sequences using the notation v_s and v_e (for “start” and “end”) since, for any $v \in V$, $v \neq u$, v_2 may be visited by P_u before v_1 is visited and vice versa.

■ **Figure 4** Left: Schematic depiction of (from top to bottom) two fully nested, subsequent, and crossing subpaths P_v and P_w of P_u . Right: The corresponding interpretations in the original graph (from left to right).

In the subsequent case, both P_v and P_w correspond to odd closed walks since they both comprise an odd-cardinality subset of E_3 -edges (but neither $P_u \setminus P_v$ nor $P_u \setminus P_w$ does). In the crossing case, P_v and P_w both correspond to odd closed walks as well. However, if the subpaths from v_s to w_s and from v_e to w_e refer to the same edge set in G , then both odd closed walks associated to P_v and P_w are equivalent (and thus lead to the same inequality).

3.2 Handling Non-Simple and Chorded Simple Odd Cycles

There are basically three ways to deal with non-simplicity.

3.2.1 The “Take-As-Is” Strategy

Since the potential non-simplicity of a closed odd walk (C, Q) does not affect the validity of the associated inequality, one may consider to simply *use it as a cutting plane as is*.

3.2.2 The “Throw-Away” Strategy

Another strategy is to *discard* non-simple closed odd walks, i.e., to generate an inequality only if a closed odd walk computed is “accidentally” simple.

However, to still preserve an *exact* separation algorithm, it must then be sure that *at least one* simple cycle is still identified if a violated odd-cycle inequality exists. Moreover, as already discussed in Sect. 2.1, any vertex $u \in V$ may have several ω -shortest paths P_u some of which may induce non-simple cycles, and that may even all have the same number of edges. So “throwing away” any such P_u containing a subpath P_v by “trusting” that a simple cycle will be identified when computing an ω -shortest v_1 - v_2 -path may fail in general.

Fortunately, the desired guarantee can nevertheless be established if we strive for (ω, ℓ) -shortest paths instead, where $\ell(v) \in \mathbb{Z}$ denotes the number of edges used in a (currently) shortest path to each vertex $v \in V_S$. In this context, a u_1 - v -path P in G_S involving edge $\{v, w\} \in E_S$ is (ω, ℓ) -shorter than the best previous one, if either “classically” $\text{dist}(u) + \omega(u, v) < \text{dist}(v)$, or if $\text{dist}(u) + \omega(u, v) = \text{dist}(v)$ and $\ell(u) + 1 < \ell(v)$. With these extensions, the original separation algorithm will identify at least one violated odd-cycle inequality if any exists, as we will now show.

► **Theorem 1.** *Let $P_u \subseteq E_S$ be an ω -shortest path from u_1 to u_2 in G_S with weight $\omega(P_u) < 1$ and of edge length $\ell(P_u)$. Then there exists a vertex $w \in V$ such that each (ω, ℓ) -shortest path P_w in G_S satisfies $\omega(P_w) \leq \omega(P_u)$, $|P_w| \leq |P_u|$, and whose induced odd closed walk (C, Q) in G is simple.*

Proof. If the odd closed walk induced by P_u is itself simple, the statement follows by choosing $P_w = P_u$. So suppose this is not the case. Then there exists a strict subpath P_v of P_u . Now either P_v is simple, in which case we may choose $P_w = P_v$. Otherwise, we recurse on the path P_v that clearly satisfies $|P_v| \leq |P_u| - 2$. Since the number of edges of the paths considered thus decreases strictly monotonically, and since any shortest path in G_S has a positive length, this process will eventually terminate at some simple path P_w , $w \in V_S$, as otherwise, there would exist a path of the same ω -weight which is shorter w.r.t. ℓ – a contradiction. ◀

3.2.3 The “Extraction” Strategy

A final strategy to deal with non-simple odd closed walks is to extract the simple odd cycles contained in it. This is motivated by several advantages, e.g.:

- If a shortest inner subpath $P_v \subseteq P_u$ corresponding to a simple cycle in G is found, the shortest path computation w.r.t. v may be omitted (accepting a possible loss of a different inequality corresponding to another shortest v_1 - v_2 -path).
- A single pass of P_u might allow to extract *several* simple cycles from one non-simple one.
- Information found during the extraction might be used to avoid the addition of duplicate inequalities (cf. the case of crossing subpaths at the end of Sect. 3.1).

Moreover, as expressed in the following observation, it is possible to implement simple cycle extractions requiring only a number of operations that is proportional to the length of the closed walk (which can be no more than $2|V|$). So since a *single pass* of the closed walk is inevitably required to even generate an inequality from it or find out whether it is simple, the respective enhancement does not increase the asymptotic running time, and does not even require the (ω, ℓ) -extension from Sect. 3.2.2 (which is nevertheless worthwhile) in order to provide a safe *exact* separation procedure.

► **Observation 2.** *Let P_u be an ω -shortest path from u_1 to u_2 in G_S with weight $\omega(P_u) < 1$, and whose induced odd closed walk (C, Q) in G is not simple. Traverse P_u starting from u_1 (or, walking backwards, from u_2) and let $v \in W$ be the first vertex such that v_1 and v_2 were both visited on this traversal. Then the cycle in G corresponding to the path P_v is simple.*

An inequality derived based on Observation 2 (i.e., on a first *fully nested* subpath P_v of P_u that does not contain any further fully nested subpaths itself) neither needs to be the only one that can be extracted from P_u (cf. Sect. 3.1), nor needs to be maximally violated among these.

Fortunately, subsequent and crossing simple cycles may as well be easily recognized algorithmically by only maintaining the positions of the start and end vertices of the *last* subpath identified as to correspond to a simple cycle. Suppose that P_v was the last such subpath on a traversal of P_u , i.e., the positions of v_s and v_e are known. Assume further that the traversal then arrives at some vertex, say w_e , whose other copy, w_s , has already been visited. If $w_s \prec v_s$, then P_v is fully nested within P_w , and thus P_w need not be considered. Otherwise, either $w_s \prec v_e$ in which case P_v and P_w cross, or $v_e \prec w_s$ in which case P_w is subsequent to P_v (cf. Fig. 4). In any case, we can safely update the two maintained positions to those of w_s and w_e . We will then classify later paths correctly since a later path crossing P_v must inevitably either also cross P_w or contain P_w fully nested.

Additionally, a constant-time check to eliminate some unwanted duplicate inequalities in the case of crossing paths P_v and P_w is right at hand from the final statement in Sect. 3.1. If v_e is the immediate predecessor of w_e on P_u , then the same is likely true (sure if computing (ω, ℓ) -shortest paths) for v_s and w_s . This means that $\{v, w\}$ is a chord (being part of the odd closed walk w.r.t. P_u), and the odd-cycle inequalities according to P_v and P_w are equivalent.

3.2.4 Further Engineering of the Extraction Strategy

A further opportunity to improve the practical performance of the separation procedure is to exploit the symmetry of the graph G_S : Suppose that, while computing a shortest u_1 - u_2 -path in G_S , we process a vertex v_2 (v_1) such that the distances $\text{dist}(v_1)$ and $\text{dist}(v_2)$ are both known. If $\text{dist}(v_1) + \text{dist}(v_2) \geq 1$, then v_2 (v_1) cannot lie on any u_1 - u_2 -path that induces a violated odd-cycle inequality and thus need not be considered for the update of other distances.

3.3 Chorded Simple Odd Cycles

Finally, as we now know how to extract simple odd cycles, it is natural to strive for chordless ones, i.e. facet-defining inequalities. However, we will show in this subsection, why we will not always find these when searching for *maximally violated* inequalities (as we do when computing ω - or (ω, ℓ) -shortest paths).

For this purpose, let (C, Q) be a simple cycle, and suppose that, for some $\hat{x} \in [0, 1]^E$, the associated odd-cycle inequality is violated, i.e. $\sum_{e \in Q} (1 - \hat{x}_e) + \sum_{e \in C \setminus Q} \hat{x}_e < 1$.

Suppose further that C has a chord c , i.e., there exist vertices $u, v \in V$ such that $c = \{u, v\} \in E \setminus C$. Partitioning C into the corresponding two $\{u, v\}$ -paths P_1 and P_2 partitions Q into Q_1 and Q_2 , and inevitably renders either $|Q_1|$ odd and $|Q_2|$ even or vice versa (cf. Fig. 5).

■ **Figure 5** Left: A cycle C with an odd-cardinality edge subset Q (thicker), assumed to have a chord $c = \{u, v\}$. Right: Splitting C into two chordless odd cycles C_1 and C_2 , declaring c once as “odd” and once as “even”.

Assume w.l.o.g. that $|Q_1|$ is even. The cycles $C_1 = P_1 \cup \{c\}$, with c “marked as odd”, and $C_2 = P_2 \cup \{c\}$, with c “marked as even”, correspond to the two odd-cycle inequalities

$$\sum_{e \in Q_1} (1 - x_e) + (1 - x_c) + \sum_{e \in P_1 \setminus Q_1} x_e \geq 1 \tag{7}$$

$$\sum_{e \in Q_2} (1 - x_e) + x_c + \sum_{e \in P_2 \setminus Q_2} x_e \geq 1 \tag{8}$$

whose sum gives the original one above assumed to be violated. This implies that at least one of (7) and (8) needs to be violated as well.

Let $\gamma_1 := 1 - \sum_{e \in Q_1} (1 - \hat{x}_e) - (1 - \hat{x}_c) - \sum_{e \in P_1 \setminus Q_1} \hat{x}_e$ and $\gamma_2 := 1 - \sum_{e \in Q_2} (1 - \hat{x}_e) - \hat{x}_c - \sum_{e \in P_2 \setminus Q_2} \hat{x}_e$ denote the violations of (7) and (8), respectively. Then $\gamma := \gamma_1 + \gamma_2$ is the violation of the original inequality. Therefore, one of (7) or (8) can only be found if the other is not violated at all.

It remains to clarify whether we can *efficiently* extract chordless cycles from a simple but not chordless one. This turns out to be the case when restricting to *one* chordless cycle whose associated inequality is violated. In this case, we may use any chord to (conceptually) split the initial cycle (C, Q) into two cycles, and proceed with these in the same fashion if necessary. This can be implemented in a way such that no chord is used for a split more than once, and the adjacency list of each vertex $v \in V(C)$ is traversed at most once (by continuing at the list position of a possible previous visit of the vertex, cf. Fig. 6). Assuming the presence of the respective data structures, and the use of bucket sort to order the adjacency lists appropriately, an asymptotic running time of $\mathcal{O}(|E|)$ can be achieved.

■ **Figure 6** Decomposition of a simple cycle with chords to retrieve *one* chordless cycle. After numbering the vertices consecutively and sorting adjacency lists descendingly w.r.t. this numbering, the decomposition can be carried out in a greedy fashion. If, e.g., the inequality associated to the first chordless cycle depicted on the right turns out not to be violated, it can be neglected by backtracking to vertex 2 and continuing with the next edge of its adjacency list. Even if further subdecompositions take place, the process will never consider any edge more than twice. In particular, no enumerative consideration of chords used as split edges is required – e.g., the chordless cycles related to the chord $\{5, 8\}$ crossing the cycles considered before can be neglected.

4 Experiments

Our experimental study shall particularly address the following two questions:

- Does the “quality” of odd-cycle cutting planes matter, i.e., to what extent is the process of solving the linear programming relaxations of maximum cut and binary quadratic optimization problems affected by the exclusive separation of odd-cycle inequalities that correspond to simple or even chordless simple cycles?
- Is it worthwhile to invest time for the extraction of (chordless) simple cycles (and to save some shortest path computations) rather than to simply employ or discard non-simple cycles?

To this end, we implemented an odd-cycle separation algorithm supporting the “take-as-is”-strategy, the “throw-away”-strategy, the extraction of simple cycles, an improved extraction exploiting the symmetry of the separation graph as described in Sect. 3.2.4, and finally the extraction of one chordless cycle from each simple one. In each of these variants, (ω, ℓ) -shortest paths are computed for each $v \in V$ in general. The three mentioned extraction variants however omit the shortest path computation w.r.t. a vertex $v \in V$ if a simple cycle based on a shortest subpath P_v has been identified before.

Based on this implementation, we solved the linear programming relaxations of several instances from the “binary quadratic and max cut library” [5] by iteratively calling the linear program solver Gurobi² in version 8, and our separation algorithm. In case of the MaxCut instances, the initial linear program defined only lower and upper bounds of the variables. In case of BQP instances, we started with all inequalities that correspond to the respective standard linearization. Moreover, after solving a linear program, previously added inequalities not being satisfied at equality, were removed.

For presentation, we selected those instances where *at least one cut was required to solve the relaxation* and the *total time needed for this was at most one hour and at least half a second*.

4.1 Odd Cycle Separation Quality

The first two experiments relate to the first question mentioned in the beginning of this section. As a first quality indicator, we consider *the total number of inequalities added* while solving the relaxation and when using the different strategies. Since however, a smaller number of cuts might result in an increase of the required number of linear programs to solve, and there is a natural decrease in the number of generated cuts *per iteration* of the extraction and “take-as-is”-strategies compared to the “throw-away”-strategy, we complement this evaluation with another one that considers *the total relaxation solution time*.

In both experiments, the “take-as-is”-strategy serves as the basis (100% level in the figures), and the symmetry-aware version of the extraction strategy is omitted from the presentation, as it generates the same inequalities as the one without symmetry-awareness. Moreover, to reduce side-effects, duplicate inequalities found during any of the variants are not counted and eliminated before passing the cuts to the linear program.

■ **Figure 7** Relative total number of inequalities added (MaxCut instances).

² <http://www.gurobi.com/>

■ **Figure 8** Relative total number of inequalities added (BQP instances).

■ **Figure 9** Relative total relaxation solution time (MaxCut instances).

Figs. 7 and 8 show a clear trend of decrease of the total number of inequalities added when restricting to simple or even only chordless simple cycles. Indeed the quality of a cut appears to have a significant impact, as the extraction of the facet-defining chordless simple cycles clearly performs best on average across the instances considered. Moreover, in Figs. 9 and 10, one can see that, in most of the cases, the additional effort to extract simple or one chordless simple cycle does not lead to an increase but a noticeable decrease of the total relaxation solution time. This means in particular that the advantage of requiring fewer cuts is a true one, i.e., not negatively compensated by a significant increase of the number of linear programs required to solve the relaxation.

4.2 Odd Cycle Separation Time

The total relaxation solution time considered in the last experiment is affected by several aspects. In particular, the different runs per instance did not correspond to the same series of linear programs, as different cuts lead to different solutions. To address the second

63:12 Odd-Cycle Separation for MaxCut and the BQP

■ Figure 10 Relative total relaxation solution time (BQP instances).

■ Figure 11 Relative accumulated separation times (MaxCut instances).

■ Figure 12 Relative accumulated separation times (BQP instances).

question mentioned at the beginning of this section, i.e., in order to show that simple and even chordless simple cycle extraction truly come at negligible cost – we now create equal preconditions for all separation strategies as follows: After solving a linear program, the separator is called four times, once with each of the different strategies. After that, *one* cutting plane set (the inequalities generated in the “extract-simple”-run) is added to the linear program and the procedure is iterated.

In this experiment, we thus consider the *accumulated time spent in the separation procedure* over all linear programs solved in order to solve the respective relaxation, with the presentation restricted to those instances where this was *at least half a second*. As another difference to the previous experiment, here, duplicate inequalities are not avoided in general. In case of the extraction strategies, they are however avoided in the way described in Sect. 3.2.3.

The results are shown in Figs. 11 and 12, as well as the percentage of time spent in separation w.r.t. the total time to solve the relaxation in the fastest of the four cases (denoted “% LP-relaxation”). As before, the “take-as-is”-strategy (100% level) serves as the basis for comparisons. Across almost all the instances considered, the extraction of simple cycles results in a quicker separation compared to the “take-as-is”- and the “throw-away”-strategy. Not surprisingly, the latter two perform very similarly, as both require a single pass of each identified odd closed walk. Exploiting symmetries usually gives another measurable speedup. This may of course as well be applied to the chordless extraction variant which has anyway not been implemented as efficiently as indicated in Sect. 3.3.

Abstract

Let $S \subset \mathbb{R}^2$ be a set of n sites, where each $s \in S$ has an associated radius $r_s > 0$. The *disk graph* $D(S)$ is the undirected graph with vertex set S and an undirected edge between two sites $s, t \in S$ if and only if $|st| \leq r_s + r_t$, i.e., if the disks with centers s and t and respective radii r_s and r_t intersect. Disk graphs are used to model sensor networks. Similarly, the *transmission graph* $T(S)$ is the directed graph with vertex set S and a directed edge from a site s to a site t if and only if $|st| \leq r_s$, i.e., if t lies in the disk with center s and radius r_s .

We provide algorithms for detecting (directed) triangles and, more generally, computing the length of a shortest cycle (the *girth*) in $D(S)$ and in $T(S)$. These problems are notoriously hard in general, but better solutions exist for special graph classes such as planar graphs. We obtain similarly efficient results for disk graphs and for transmission graphs. More precisely, we show that a shortest (Euclidean) triangle in $D(S)$ and in $T(S)$ can be found in $O(n \log n)$ expected time, and that the (weighted) girth of $D(S)$ can be found in $O(n \log n)$ expected time. For this, we develop new tools for batched range searching that may be of independent interest.

1 Introduction

Given a graph G with n vertices and m edges, does G contain a *triangle* (a cycle with three vertices)? This is one of the most basic algorithmic questions in graph theory, and many other problems reduce to it [12, 21]. The best known algorithms use fast matrix multiplication and run in either $O(n^\omega)$ time or in $O(m^{2\omega/(\omega+1)})$ time, where $\omega < 2.37287$ is the matrix multiplication exponent [1, 10, 12]. Despite decades of research, the best available “combinatorial” algorithm¹ needs $O(n^3 \text{polyloglog}(n)/\log^4 n)$ time [22], only slightly better than checking all vertex triples. This lack of progress can be explained by a connection to Boolean matrix multiplication (BMM): if there is a truly subcubic combinatorial algorithm for finding triangles, there is also a truly subcubic combinatorial algorithm for BMM [21]. Itai and Rodeh [12] reduced computing the *girth* (the length of a shortest cycle) of an unweighted undirected graph to triangle detection. For integer edge weights, Roditty and V. Williams [19] gave an equivalence between finding a minimum weight cycle (the weighted girth) and finding a minimum weight triangle.

For the special case of *planar* graphs, significantly better algorithms are known. Itai and Rodeh [12] and, independently, Papadimitriou and Yannakakis [17] showed that a triangle can be found in $O(n)$ time, if it exists. Chang and Lu [7] presented an $O(n)$ time algorithm for computing the girth. The weighted girth can be found in $O(n \log \log n)$ time both in an undirected and in a directed planar graph [15, 16].

In computational geometry, there are two noteworthy graph classes that generalize planar graphs: *disk graphs* and *transmission graphs*. We are given a set S of n planar point *sites*. Each $s \in S$ has an *associated radius* $r_s > 0$ and an *associated disk* D_s with center s and radius r_s . The *disk graph* $D(S)$ is the undirected graph on S where two sites $s, t \in S$ are adjacent if and only if D_s and D_t intersect, i.e., $|st| \leq r_s + r_t$, where $|\cdot|$ is the Euclidean distance. In a *weighted disk graph*, the edges are weighted according to the Euclidean distance between their endpoints. The *transmission graph* $T(S)$ is the directed graph on S where there is an edge from s to t if and only if t lies in D_s , i.e., $|st| \leq r_s$. Again, there is a weighted variant. Both graph classes have received a lot of attention, as they give simple and natural theoretical models for geometric sensor networks (see, e.g., [13, 14]).

Motivated by the vastly better algorithms for planar graphs, we investigate triangle detection and girth computation in disk graphs and transmission graphs. We will see that in a disk graph, a triangle can be found in $O(n \log n)$ time, using a simple geometric observation to relate disk graphs and planar graphs. By a reduction from ε -CLOSENESS [18], this is optimal in the algebraic decision tree model, a contrast to planar graphs, where $O(n)$ time is possible. Our method generalizes to finding a shortest triangle in a weighted disk graph in $O(n \log n)$ expected time. Moreover, we can compute the unweighted and weighted girth in a disk graph in $O(n \log n)$ time, with a deterministic algorithm for the unweighted case and a randomized algorithm for the weighted case. The latter result requires a method to find a shortest cycle that contains a given vertex. Finally, we provide an algorithm to detect a directed triangle in a transmission graph in $O(n \log n)$ expected time. For this, we study the geometric properties of such triangles in more detail, and we develop several new techniques for batched range searching that might be of independent interest, using linearized quadtrees and three-dimensional polytopes to test for containment in the union of planar disks. As before, this algorithm extends to the weighted version. We will assume *general position*, meaning that all edge lengths (and more generally shortest path distances) are pairwise

¹ An algorithm is “combinatorial” if it does not need algebraic manipulations to achieve its goal.

distinct, that no site lies on a disk boundary, and that all radii are pairwise distinct. Due to space reasons, some proofs in this extended abstract are only sketched. The complete proofs can be found in the full version of this paper.

2 Finding a (Shortest) Triangle in a Disk Graph

We would like to decide if a given disk graph contains a triangle. If so, we would also like to find a triangle of minimum Euclidean perimeter.

2.1 The Unweighted Case

The following property of disk graphs, due to Evans et al. [9], is the key to our algorithm. For a proof refer to the full version.

► **Lemma 2.1.** *Let $D(S)$ be a disk graph that is not plane, i.e., the embedding that represents each edge by a line segment between its endpoints has two segments that cross in their relative interiors. Then, there are three sites whose associated disks intersect in a common point.*

If $D(S)$ is not plane, it contains a triangle by Lemma 2.1. If $D(S)$ is plane, we can construct it explicitly and then search for a triangle in $O(n)$ time [12, 17]. To check whether $D(S)$ is plane, we begin an explicit construction of $D(S)$ and abort if we discover too many edges.

► **Theorem 2.2.** *Let $D(S)$ be a disk graph on n sites. We can find a triangle in $D(S)$ in $O(n \log n)$ worst-case time, if it exists.*

Proof (Sketch). We compute the edges of $D(S)$, using a sweepline approach. If at some point we find more than $3n - 6$ edges, we stop and proceed with the partial graph (which is not plane). If there are at most $3n - 6$ edges, we check for edge crossings, again by a plane sweep. If there is a crossing, we report the resulting triangle in $O(1)$ time. If not, $D(S)$ is plane and we determine if it contains a triangle in $O(n)$ time [12, 17]. ◀

2.2 The Weighted Case

Suppose the edges in $D(S)$ are weighted by their Euclidean lengths. We would like to find a triangle of minimum perimeter, i.e., of minimum total edge length. For this, we solve the decision problem: given $W > 0$, does $D(S)$ contain a triangle with perimeter at most W ? Once a decision algorithm is available, the optimization problem can be solved with Chan’s randomized geometric optimization framework [5].

To decide if $D(S)$ contains a triangle with perimeter at most W , we use a grid with diameter $W/3$. We look for triangles whose vertices lie in a single grid cell, using the algorithm from Section 2.1. If no cell contains such a triangle, then $D(S)$ will be sparse and we will need to check only $O(n)$ further triples. Details follow.

Set $\ell = W/(3\sqrt{2})$. Let G_1 be the grid whose cells are pairwise disjoint, axis-parallel squares with side length ℓ , aligned so that the origin $(0, 0)$ is a vertex of G_1 . The cells of G_1 have diameter $\sqrt{2} \cdot \ell = W/3$, so any triangle whose vertices lie in a single cell has perimeter at most W . We make three additional copies G_2, G_3, G_4 of G_1 , and we shift them by $\ell/2$ in the x -direction, in the y -direction, and in both the x - and y -directions, respectively. In other words, G_2 has $(\ell/2, 0)$ as a vertex, G_3 has $(0, \ell/2)$ as a vertex, and G_4 has $(\ell/2, \ell/2)$ as a vertex, see Figure 1. This ensures that if all edges in a triangle are “short”, the triangle lies in a single grid cell.

■ **Figure 1** The four shifted grids, with a cell from each grid shown in red, orange, green, and blue, respectively. Every square with side length at most $\ell/2$ is wholly contained in a single grid cell.

► **Lemma 2.3.** *Let Δ be a triangle formed by three vertices $a, b, c \in \mathbb{R}^2$ such that each edge of Δ has length at most $\ell/2$. There is a cell $\sigma \in \bigcup_{i=1}^4 G_i$ with $a, b, c \in \sigma$.*

Proof. We can enclose Δ with a square of side length $\ell/2$. This square must be completely contained in a cell of one of the four grids, see Figure 1. ◀

We go through all nonempty grid cells $\sigma \in \bigcup_{i=1}^4 G_i$, and we search for a triangle in the disk graph $D(S \cap \sigma)$ induced by the sites in σ , with Theorem 2.2. Since each site lies in $O(1)$ grid cells, and since we can compute the grid cells for a given site in $O(1)$ time (using the floor function), the total running time is $O(n \log n)$. If a triangle is found, we return YES, since the cells have diameter $W/3$ and thus such a triangle has perimeter at most W . If no triangle is found, Lemma 2.3 implies that any triangle in $D(S)$ has one side of length more than $\ell/2$ and hence at least one vertex with associated radius at least $\ell/4$. We call a site $s \in S$ large if $r_s > \ell/4$. A simple volume argument bounds the number of large sites in a grid cell.

► **Lemma 2.4.** *Let $\sigma \in \bigcup_{i=1}^4 G_i$ be a nonempty grid cell, and suppose that $D(S \cap \sigma)$ does not contain a triangle. Then σ contains at most 18 large sites.*

Proof. Suppose σ contains at least 19 large sites. We cover σ with 3×3 congruent squares of side length $\ell/3$. Then, at least one square τ contains at least $\lceil 19/9 \rceil = 3$ large sites. The associated radius of a large site is more than $\ell/4$ and each square has diameter $(\sqrt{2}/3)\ell < \ell/2$, so the large sites in τ form a triangle in $D(S \cap \sigma)$, a contradiction. ◀

Let $\sigma \in G_i, i \in \{1, \dots, 4\}$, be a grid cell. The neighborhood $N(\sigma)$ of σ is the 5×5 block of cells in G_i centered at σ . Since the diameter of a grid cell is $W/3$, any two sites $u, v \in S$ that form a triangle of perimeter at most W with a site $s \in S \cap \sigma$ must be in $N(\sigma)$. Let $S_\ell \subseteq S$ denote the large sites. At this stage, we know that any triangle in $D(S)$ has at least one vertex in S_ℓ . By Lemma 2.4, for any $\sigma \in \bigcup_{i=1}^4 G_i$, we have $|\bigcup_{\tau \in N(\sigma)} \tau \cap S_\ell| = O(1)$. Thus, to detect a triangle of perimeter at most W with at least two large vertices, we proceed as follows: for each non-empty cell $\sigma \in G_i$, iterate over all large sites s in σ , over all large sites t in $N(\sigma)$, and over all (not necessary large) sites u in $N(\sigma)$. Check whether stu is a triangle of perimeter at most W . If so, return YES. Since the sites in each grid cell are examined $O(1)$ times for $O(1)$ pairs of large sites, the total time is $O(n)$.

It remains to detect triangles of perimeter at most W with exactly one large vertex. We iterate over all grid cells $\sigma \in \bigcup_{i=1}^4 G_i$, and we compute $D(S \cap \sigma)$. Since $D(S \cap \sigma)$ contains no triangle, Lemma 2.1 shows that $D(S \cap \sigma)$ is plane, has $O(|S \cap \sigma|)$ edges and can be

constructed in time $O(|S \cap \sigma| \log |S \cap \sigma|)$. For every edge $st \in D(S \cap \sigma)$ with both endpoints in $S \setminus S_\ell$, we iterate over all large sites u in $N(\sigma)$ and we test whether stu makes a triangle in $D(S)$ with perimeter at most W . If so, we return YES. By Lemma 2.4, this takes $O(|S \cap \sigma|)$ time, so the total running time is $O(n \log n)$. If there is a triangle of perimeter at most W with exactly one vertex in S_ℓ , the edge with both endpoints in $S \setminus S_\ell$ has length at most $\ell/2$ and thus must lie in a single grid cell $\sigma \in \bigcup_{i=1}^4 G_i$. To summarize:

► **Lemma 2.5.** *Let $D(S)$ be a disk graph on n sites, and let $W > 0$. We can decide in $O(n \log n)$ worst-case time whether $D(S)$ contains a triangle of perimeter at most W .*

Now, Chan's framework [5] gives a randomized optimization algorithm with no additional overhead. The details can be found in the full version.

► **Theorem 2.6.** *Let $D(S)$ be a weighted disk graph on n sites. We can compute a shortest triangle in $D(S)$ in $O(n \log n)$ expected time, if one exists.*

3 Computing the Girth of a Disk Graph

We extend the results from Section 2 to the girth. The unweighted case is easy: if $D(S)$ is not plane, the girth is 3, by Lemma 2.1. If $D(S)$ is plane, we use the algorithm for planar graphs [7]. The weighted case is harder. If $D(S)$ is plane, we use the algorithm for planar graphs [15]. If not, Theorem 2.6 gives a shortest triangle Δ in $D(S)$. However, there could be cycles with at least four edges that are shorter than Δ . To address this, we use Δ to split $D(S)$ into sparse pieces where a shortest cycle can be found efficiently.

3.1 The Unweighted Case

Chang and Lu [7, Theorem 1.1] showed how to find the girth of an unweighted planar graph with n vertices in $O(n)$ time. Hence, we obtain a simple extension of Theorem 2.2.

► **Theorem 3.1.** *Let $D(S)$ be a disk graph for a set S of n sites. We can compute the unweighted girth of $D(S)$ in $O(n \log n)$ worst-case time.*

Proof. We proceed as in Theorem 2.2. If $D(S)$ is not plane, the girth is 3. If $D(S)$ is plane, we apply the algorithm of Chang and Lu [7, Theorem 1.1] to an explicit representation of $D(S)$. ◀

3.2 The Weighted Case

We describe how to find the shortest cycle through a given vertex in a weighted graph with certain properties. This is then used to compute the weighted girth of a disk graph.

Let G be a graph with nonnegative edge weights so that all shortest paths and cycles in G have pairwise distinct lengths and so that for all edges uv , the shortest path from u to v is the edge uv . We present a deterministic algorithm that, given G and a vertex s , computes the shortest cycle in G containing s , if it exists. A simple randomized algorithm can also be found in Yuster [23, Section 2]. The next lemma states a structural property of the shortest cycle through s . It resembles Lemma 1 of Roditty and V. Williams [19] that deals with an overall shortest cycle in G .² For details on the proof see the full version.

² Even though this seems to be a simple fact, we could not locate a previous reference for this.

► **Lemma 3.2.** *The shortest cycle in G that contains s consists of two paths in the shortest path tree of s , and one additional edge.*

► **Theorem 3.3.** *Let $G = (V, E)$ be a weighted graph with n vertices and m edges that has the properties given at the beginning of this section. Let $s \in V$. We can compute the shortest cycle in G that contains s in $O(n \log n + m)$ time, if it exists.*

Proof (Sketch). We find the shortest path tree T for s , and we identify the edges that close a cycle in T containing s . We check all candidate cycles to find the shortest. Correctness follows from Lemma 3.2. The running time for finding the shortest path tree dominates the rest of the algorithm. ◀

Let $D(S)$ be a weighted disk graph on n sites. A careful combination of the tools developed so far gives an algorithm for the weighted girth of $D(S)$.

► **Theorem 3.4.** *Given a weighted disk graph $D(S)$ on n sites, we can compute the weighted girth of $D(S)$ in $O(n \log n)$ expected time.*

Proof (Sketch). We find the shortest triangle in $D(S)$ in $O(n \log n)$ expected time, if it exists (Theorem 2.6). If $D(S)$ has no triangle, it is plane by Lemma 2.1, and we construct $D(S)$ in $O(n \log n)$ time. We find the girth of $D(S)$ using the algorithm of Łącki and Sankowski [15, Section 5], in $O(n \log \log n)$ time. If $D(S)$ has a triangle, let W be the perimeter of the shortest triangle in $D(S)$. Then, W is an upper bound for the girth of $D(S)$. We set $\ell = W/(3\sqrt{2})$, and we call a site $s \in S$ *large*, if $r_s \geq \ell/4$, and we write $S_\ell \subseteq S$ for the set of large sites. Let G be the grid with side length ℓ and the origin $(0, 0)$ as a vertex.

We must check whether $D(S)$ contains a cycle with more than three vertices and length less than W . By our choice of ℓ , the graph $D(S \setminus S_\ell)$ induced by $S \setminus S_\ell$ is plane. Thus, we can find a cycle in $D(S \setminus S_\ell)$ with the algorithm of Łącki and Sankowski [15, Section 5], in $O(n \log \log n)$ time. It remains to test cycles with at least one large site. The choice of ℓ implies that each cycle of length at most W is contained in a grid neighborhood of constant size. Since there are $O(1)$ large sites in each neighborhood, the induced graph in each neighborhood has linear size. We check the remaining cycles by applying Theorem 3.3 to all large sites in each neighborhood. ◀

4 Finding a Triangle in a Transmission Graph

Given a transmission graph $T(S)$ on n sites, we want to decide if $T(S)$ contains a directed triangle. We first describe an inefficient algorithm for this problem, and then we will explain how to implement it in $O(n \log n)$ expected time.

The algorithm iterates over each directed edge $e = st$ with $r_t \geq r_s$, and it performs two tests: first, for each directed edge tu with $r_u \geq r_t/2$, it checks if us is an edge in $T(S)$, i.e., if $s \in D_u$. If so, the algorithm reports the triangle stu . Second, the algorithm tests if there is a site u such that $r_u \in [r_s, r_t/2)$ and such that us is an edge in $T(S)$, i.e., such that $s \in D_u$. If such a u exists, it reports the triangle stu . If both tests fail for each edge e , the algorithm reports that $T(S)$ contains no triangle. The next lemma shows that the algorithm is correct.

► **Lemma 4.1.** *A triple stu reported by the algorithm is a triangle in $T(S)$. Furthermore, if $T(S)$ contains a triangle, the algorithm will find one.*

(a) We do not need to check $u \in D_t$.

(b) Three disks with radius at least $r/4$ in the same grid cell form a clique.

Proof (Sketch). It is easy to see that the algorithm finds a triangle if one exists. The algorithm is also sound: a triple reported by the first test is a triangle by construction, and for the second test, Figure 2a shows that $u \in D_t$, so tu is an edge of $T(S)$. ◀

There are several challenges for making the algorithm efficient. First of all, there might be many edges st with $r_t \geq r_s$. However, the following lemma shows that if there are $\omega(n)$ such edges, the transmission graph $T(S)$ must contain a triangle.

► **Lemma 4.2.** *There is an absolute constant α so that for any $r > 0$, if there is an $r \times r$ square σ that contains more than α sites $s \in S$ with $r_s \geq r/4$, then $T(S)$ has a directed triangle.*

Proof. We cover σ with a 6×6 grid of side length $r/6$; see Figure 2b. There are 36 grid cells. For every $s \in S \cap \sigma$ with $r_s \geq r/4$, the disk D_s completely covers the grid cell containing s . If σ contains more than $\alpha = 72$ sites s with $r_s \geq r/4$, then one grid cell contains at least three such sites. These sites form a directed triangle in $T(S)$. ◀

Thus, to implement the algorithm, we must solve two range searching problems.

(R1) EITHER determine that for every site $s \in S$, there are at most α outgoing edges st with $r_t \geq r_s/2$ and report all these edges; OR find a square σ of side length $r > 0$ that contains more than α sites $s \in S$ with $r_s \geq r/4$.

(R2) Given $O(n)$ query triples (s, r_1, r_2) with $s \in S$ and $0 < r_1 < r_2$, find a site $u \in S$ such that there is a query triple (s, r_1, r_2) with $u \neq s$, $r_u \in [r_1, r_2)$, and $s \in D_u$; or report that no such site exists.

The query (R1) indeed always has a valid outcome: suppose there is a site $s \in S$ with more than α outgoing edges st with $r_t \geq r_s/2$. Then, all the endpoints t lie in D_s , so the square σ centered at s with side length $r = 2r_s$ contains more than α sites with associated radius at least $r/4$. The next theorem shows that we can detect a triangle in $T(S)$ with linear overhead in addition to the time needed for answering (R1) and (R2). The proof is in the full version.

► **Theorem 4.3.** *If (R1) and (R2) can be solved in time $R(n)$ for input size n , we can find a directed triangle in a transmission graph $T(S)$ on n sites in time $R(n) + O(n)$, if it exists.*

In the next section, we will implement (R1) and (R2) in $O(n \log n)$ expected time.

► **Theorem 4.4.** *Let $T(S)$ be a transmission graph on n sites. We can find a directed triangle in $T(S)$ in expected time $O(n \log n)$, if it exists.*

■ **Figure 3** Example is for a query of type (R1), assuming that $r_{s_3} < r_{s_7}/2 \leq r_{s_4}$.

5 Batched Range Searching

The range queries must handle subsets of sites whose associated radii lie in certain intervals: a query s in (R1) concerns sites $t \in S$ such that $r_t \geq r_s/2$; and a query (s, r_1, r_2) in (R2) concerns sites t such that $r_t \in [r_1, r_2)$. Using a standard approach [2, 20], we subdivide each such *query interval* into $O(\log n)$ pieces from a set of *canonical intervals*. For this, we build a balanced binary tree B whose leaves are the sites of S , sorted by increasing associated radius. For each vertex $v \in B$, let the *canonical interval* \mathcal{I}_v be the sorted list of sites in the subtree rooted at v . There are $O(n)$ canonical intervals.

Next, we define *canonical paths* and *canonical nodes*. For a radius $r > 0$, the (proper) *predecessor* of r is the site $s \in S$ with the largest radius $r_s \leq r$ ($r_s < r$). The (proper) *successor* of r is defined analogously. For a query s in (R1), we consider the path π in B from the root to the leaf with the proper predecessor t of $r_s/2$. If t does not exist (i.e., if $r_t \geq r_s/2$, for all $t \in S$), we let π be the left spine of B . We call π the *canonical path* for s . The *canonical nodes* for s are the right children of the nodes in π that are not in π themselves, plus possibly the last node of π , if $r_t \geq r_s/2$, for all $t \in S$, see Figure 3.

For a query (s, r_1, r_2) in (R2), we consider the path π_1 in B from the root to the leaf with the proper predecessor t_1 of r_1 and the path π_2 in B from the root to the leaf for the successor t_2 of r_2 . Again, if t_1 does not exist, we take π_1 as the left spine of B , and if t_2 does not exist, we take π_2 as the right spine of B . Then, π_1 and π_2 are the *canonical paths* for (s, r_1, r_2) . The *canonical nodes* for (s, r_1, r_2) are defined as follows: for each vertex v in $\pi_1 \setminus \pi_2$, we take the right child of v if it is not in π_1 , and for each v in $\pi_2 \setminus \pi_1$, we take the left child of v if it is not in π_1 . Furthermore, we take the last node of π_1 if t_1 does not exist, and the last node of π_2 if t_2 does not exist. A standard argument bounds the number and total size of the canonical intervals, see the full version for the proof.

► **Lemma 5.1.** *The total size of the canonical intervals is $O(n \log n)$. The tree B and the canonical intervals can be built in $O(n \log n)$ time. For any query q in (R1) or (R2), there are $O(\log n)$ canonical nodes, and they can be found in $O(\log n)$ time. The canonical intervals for the canonical nodes of q constitute a partition of the query interval for q .*

5.1 Queries of Type (R1)

We build a compressed quadtree on S , and we perform the range searches the compressed quadtree. It is possible to compute a compressed quadtree for each canonical interval without logarithmic overhead. Since Lemma 4.2 gives us plenty of freedom in choosing the squares

■ **Figure 4** Z-Order. On the very right we have $\sigma \leq_Z \tau \leq_Z \tilde{\sigma}$.

for our range queries, we take squares from the grid that underlies the quadtree. This allows us to reduce the range searching problem to predecessor search in a linear list, a task that can be accomplished by one top-down traversal of B . Details follow.

Hierarchical grids, Z-order, compressed quadtrees. We translate and scale S (and the associated radii), so that S lies in the interior of the unit square $U = [0, 1]^2$ and so that all radii are at most $\sqrt{2}$. We define a sequence of hierarchical grids that subdivide U . The grid G_0 consists of the single cell U . The grid G_i , $i \geq 1$, consists of the 2^{2i} square cells with side length 2^{-i} and pairwise disjoint interiors that cover U . The hierarchical grids induce an infinite four-regular tree \mathcal{T} : the vertices are the cells of $\mathcal{G} = \bigcup_{i=0}^{\infty} G_i$. The unit square U is the root, and for $i = 1, \dots$, a cell σ in G_i is the child of the cell in G_{i-1} that contains it. We make no explicit distinction between a vertex of \mathcal{T} and its corresponding cell.

The *Z-order* \leq_Z is a total order on the cells of \mathcal{G} ; see [4] for more details. Let $\sigma, \tau \in \mathcal{G}$. If $\sigma \subseteq \tau$, then $\sigma \leq_Z \tau$; and if $\tau \subseteq \sigma$, then $\tau \leq_Z \sigma$. If σ and τ are unrelated in \mathcal{T} , let ρ be the lowest common ancestor of σ and τ in \mathcal{T} , and let σ' and τ' be the children of ρ with $\sigma \subseteq \sigma'$ and $\tau \subseteq \tau'$. We set $\sigma \leq_Z \tau$ if σ' is before τ' in the order shown in Figure 4; and $\tau \leq_Z \sigma$, otherwise. The next lemma shows that given $\sigma, \tau \in \mathcal{G}$, we can decide if $\sigma \leq_Z \tau$ in constant time.

► **Lemma 5.2** (Chapter 2 in Har-Peled [11]). *Suppose the floor function and the first differing bit in the binary representations of two given real numbers can be computed in $O(1)$ time. Then, we can decide in $O(1)$ time for two given cells $\sigma, \tau \in \mathcal{G}$ whether $\sigma \leq_Z \tau$ or $\tau \leq_Z \sigma$.*

For a site $s \in S$, let σ_s be the largest cell in \mathcal{G} that contains only s . The *quadtree* for S is the smallest connected subtree of \mathcal{T} that contains the root U and all cells σ_s , for $s \in S$. The *compressed quadtree* \mathcal{C} for S is obtained from the quadtree by contracting any maximal path of vertices with only one child into a single edge. Vertices that were at the top of such a path are now called *compressed vertices*. The compressed quadtree for S has $O(n)$ vertices, and it can be constructed in $O(n \log n)$ time (see, e.g., [3, Appendix A] and [11]).

The *linearized compressed quadtree* \mathcal{L} for S is the sorted sequence of cells obtained by listing the nodes of \mathcal{C} according to a postorder traversal, where the children of a node $\sigma \in \mathcal{C}$ are visited according to the Z-order from Figure 4. The cells in \mathcal{L} appear in increasing Z-order, and range searching for a given cell $\sigma \in \mathcal{G}$ reduces to a simple predecessor search in \mathcal{L} , as is made explicit in the following lemma.

► **Lemma 5.3.** *Let σ be a cell of \mathcal{G} , and let \mathcal{L} be the linearized compressed quadtree on S . Let $\tau = \max_Z\{\rho \in \mathcal{L} \mid \rho \leq_Z \sigma\}$ be the Z-predecessor of σ in \mathcal{L} ($\tau = \emptyset$, if the predecessor does not exist). Then, if $\sigma \cap \tau = \emptyset$, then also $\sigma \cap S = \emptyset$, and if $\sigma \cap \tau \neq \emptyset$, then $\sigma \cap S = \tau \cap S$.*

Proof. Let \mathcal{C} be the compressed quadtree on S , and let $\mathcal{C}_\sigma = \{\tau \in \mathcal{C} \mid \tau \subseteq \sigma\}$ be the cells in \mathcal{C} that are contained in σ . If \mathcal{C}_σ is non-empty, then \mathcal{C}_σ is a connected subtree of \mathcal{C} . Let τ be the root of this subtree. Then, $\tau = \max_Z\{\rho \in \mathcal{C}_\sigma\}$, and $\tau \leq_Z \sigma$. Furthermore, all other cells

■ **Figure 5** The neighborhood of a site has constant size.

in $\mathcal{C} \setminus \mathcal{C}_\sigma$ are either smaller than all cells in \mathcal{C}_σ or larger than σ . Thus, τ is the Z -predecessor of σ in \mathcal{L} , and $\sigma \cap S = \tau \cap S \neq \emptyset$. Otherwise, if $\mathcal{C}_\sigma = \emptyset$, the Z -predecessor of σ in \mathcal{L} either does not exist or is disjoint from σ . Thus, in this case, we have $\emptyset = \sigma \cap \tau = \sigma \cap S$. ◀

The search algorithm. For a site $s \in S$, we define the *neighborhood* $N(s)$ of s as all cells in \mathcal{G} with side length $2^{\lceil \log_2 r_s \rceil}$ that intersect D_s . The neighborhood will be used to approximate D_s for the range search in the quadtrees.

► **Lemma 5.4.** *There is a constant β such that $|N(s)| \leq \beta$ for all $s \in S$.*

Proof. We have $r_s/2 < 2^{\lceil \log_2 r_s \rceil}$, and a 5×5 grid with cells of side length $r_s/2$ covers D_s , no matter where s lies; see Figure 5. Thus, the lemma holds with $\beta = 25$. ◀

We now show that a linearized compressed quadtree for each canonical interval can be found without logarithmic overhead.

► **Lemma 5.5.** *We can compute for each $v \in B$ the linearized quadtree \mathcal{L}_v for the sites in \mathcal{I}_v in $O(n \log n)$ time.*

Proof (Sketch). We traverse B and build the compressed quadtree \mathcal{C}_v for \mathcal{I}_v , for each $v \in B$. For the root, this takes $O(n \log n)$ time. The compressed quadtree \mathcal{C}_w for a child w of a node v can be found by traversing \mathcal{C}_v in $O(|\mathcal{C}_v|)$ time. Then, we compute the linearized trees \mathcal{L}_v by a postorder traversal of each \mathcal{C}_v . ◀

Using the linearized compressed quadtrees, the range searching problem can be solved by a batched predecessor search, using a single traversal of B .

► **Lemma 5.6.** *The range searching problem (R1) can be solved in $O(n \log n)$ time.*

Proof (Sketch). We apply Lemma 5.5 to find the linearized quadtrees for B . Let $\mathcal{Q}' = \bigcup_{s \in S} \{(\sigma, s) \mid \sigma \in N(s)\}$. We call \mathcal{Q}' the set of *split queries*. They approximate the disks D_s by cells from the hierarchical grid. By Lemma 5.4, $|\mathcal{Q}'| = O(n)$. We now want to perform range queries for all the cells in the split queries. For this, we first sort the elements of \mathcal{Q}' in the Z -order of their first components, in $O(n \log n)$ time. Now we store all split queries (σ, s) with all nodes $v \in B$ such that v is a canonical node of s . This can be done by one traversal over B . We call the resulting lists \mathcal{Q}''_v , for $v \in B$.

We iterate over all $v \in B$, and we merge the lists \mathcal{Q}'_v with the lists \mathcal{L}_v , in Z -order. This takes $O(\sum_{v \in B} |\mathcal{L}_v| + |\mathcal{Q}'_v|) = O(n \log n)$ time. By Lemma 5.3, we obtain for each $(\sigma, s) \in \mathcal{Q}''_v$ a cell $\tau_v^{\sigma, s}$. If $\sigma \cap \tau_v^{\sigma, s} \neq \emptyset$, we know that $\sigma \cap \mathcal{I}_v = \tau_v^{\sigma, s} \cap \mathcal{I}_v$. Since these sites are all from \mathcal{I}_v they all have radius at least $r_s/2$. We can find all these sites in $O(k)$ time, where k is the output size. If $k > \alpha$, we stop and report σ as a square with many sites of large radius.³

Otherwise, we use the sites in σ to accumulate the sites for the query disk D_s . This we can do by considering all canonical nodes of s and for each cell σ iterate over the sites contained in σ . In each such cell there are at most α sites. For each site $t \in \sigma$ we can check if $t \in D_s$. If we find a query disk D_s with more than α sites of large radius, we stop and report its enclosing square with many sites of large radius.⁴ Otherwise, for each $s \in S$, we have found the at most α sites of radius at least $r_s/2$ in D_s . The whole algorithm takes $O(n \log n)$ time. ◀

5.2 Queries of Type (R2)

We use the tree structure of the canonical intervals (i) to construct quickly the search structures for each canonical interval; and (ii) to solve all queries for a canonical interval in one batch. We exploit the connection between planar disks and three-dimensional polytopes. Let $U = \{(x, y, z) \mid x^2 + y^2 = z\}$ be the three-dimensional unit paraboloid. For a site $s \in S$, the lifted site \hat{s} is the vertical projection of s onto U . Each disk D_s is transformed into an upper halfspace \widehat{D}_s , so that the projection of $\widehat{D}_s \cap U$ onto the xy -plane is the set $\mathbb{R}^2 \setminus D_s$;⁵ see Figure 6. The union of a set of disks in \mathbb{R}^2 corresponds to the intersection of the lifted upper halfspaces in \mathbb{R}^3 .

▶ **Lemma 5.7.** *The range searching problem (R2) can be solved in $O(n \log n)$ expected time.*

Proof (Sketch). For each $v \in B$, we construct the intersection \mathcal{E}_v of the \widehat{D}_s , $s \in \mathcal{I}_v$. We can find all the polyhedra \mathcal{E}_v , for $v \in B$, in overall $O(n \log n)$ time, by a single traversal of B . This traversal goes bottom up and uses that we can find the intersection of two convex polyhedra in $O(n)$ time [6]. For batched query processing, we need for each $v \in B$ the convex hull of the lifted query sites that have v as a canonical node. These convex hulls can be computed top-down by splitting the current convex hulls in each node in $O(n \log n)$ overall time, using linear time per node [8]. We call these hulls \widehat{Q}_v .

To answer all queries, we use the polyhedra \widehat{Q}_v and \mathcal{E}_v . For each node $v \in B$, we compute the lifted sites in \widehat{Q}_v that are not inside of \mathcal{E}_v . These sites correspond to the vertices of \widehat{Q}_v that are not vertices of $\widehat{Q}_v \cap \mathcal{E}_v$. These intersections can be found in overall $O(n \log n)$ time, again by using the fact that we can intersect two polyhedra in $O(n)$ time. If for any such intersection $\widehat{Q}_v \cap \mathcal{E}_v$, there is a lifted site $\hat{s} \in \widehat{Q}_v$ that is not a vertex of $\widehat{Q}_v \cap \mathcal{E}_v$, we report s as the result of the range search. Otherwise, we report our range search to be unsuccessful. ◀

6 Finding the Shortest Triangle in a Transmission Graph

We extend Theorem 4.4 to find the shortest triangle in $T(S)$. As in Section 2.2, we solve the decision problem: given $W > 0$, does $T(S)$ have a directed triangle of perimeter at most W ? We set $\ell = W/\sqrt{27}$, and call a site $s \in S$ *large* if $r_s > \ell$. We let $S_\ell \subseteq S$ be the set of all large sites.

³ Note that here the radii are $\geq r_s/2$ inside of the cells σ . This might be larger than the value $2^{\lceil \log_2 r_s \rceil} / 4$ needed by (R1). But still, if there are more than α sites in σ , we still have a triangle in a square. Otherwise we will later determine that each disk contains few sites of radius at least $r_s/2$.

⁴ $r = 2r_s$ is the side length of the enclosing square, the radii are at least $r/4$ as desired.

⁵ This halfspace is bounded by the plane $z = 2x_s x - x_s^2 + 2y_s y - y_s^2 + r_s^2$, where $s = (x_s, y_s)$.

■ **Figure 6** Lifting disks and points. For \hat{D} only the bounding plane is shown.

► **Lemma 6.1.** *We can find a triangle in $T(S \setminus S_\ell)$ of perimeter at most W in $O(n \log n)$ time, if it exists.*

Proof. Any triangle in $T(S \setminus S_\ell)$ has perimeter at most W : consider a directed triangle stu in $T(S \setminus S_\ell)$ with $r_s \geq \max\{r_t, r_u\}$. Then we have $t, u \in D_s$, so the triangle stu lies in D_s . Elementary calculus shows that a triangle of maximum perimeter in D_s must be equilateral with its vertices on ∂D_s , so any triangle contained in D_s has perimeter at most $3 \cdot \sqrt{3} \cdot r_s \leq \sqrt{27} \cdot \ell = W$. We can find a triangle in T' in $O(n \log n)$ time by Theorem 4.4. ◀

It remains to check for triangles of perimeter at most W with at least one large vertex. Some such triangles have to be considered individually, while the others can be handled efficiently in batch mode. The following lemma shows that we may assume that there are few edges from $S \setminus S_\ell$ to S_ℓ .

► **Lemma 6.2.** *If $T(S)$ does not have a triangle of perimeter at most W , every site in S_ℓ has at most six incoming edges from $S \setminus S_\ell$. Furthermore, in $O(n \log n)$ time, we can either find a triangle of perimeter at most W in $T(S)$ or determine for each site in S_ℓ all incoming edges from $S \setminus S_\ell$.*

Proof (Sketch). By a suitable variant of (R1), we either find a triangle of perimeter at most W , or we restrict the overall number of edges from $S \setminus S_\ell$ to S_ℓ to $O(n)$ in $O(n \log n)$ time. To bound the indegree of the large sites, we observe that if a large site has 7 incoming edges from $S \setminus S_\ell$, then there is a triangle in $T(S)$ of perimeter at most W . ◀

Next, we want to limit the number of relevant edges between large sites. For this, we subdivide the plane with a grid G of side length $\ell/\sqrt{2}$. Then, we have the following:

► **Lemma 6.3.** *A triangle contained in a cell $\sigma \in G$ has perimeter at most W . If there is no triangle in σ , then σ contains $O(1)$ large sites. We can check for such triangles in $O(n \log n)$ overall expected time.*

Proof. The maximum perimeter of a triangle contained in σ is $(1 + \sqrt{2})\ell < W$. Furthermore, if there are at least three large sites in σ , these large sites form a triangle, since the disk of a large site covers σ . By applying Theorem 4.4 to the induced subgraph in each cell of G , we can find such a triangle in $O(n \log n)$ total expected time. ◀

We define the neighborhood $N(\sigma)$ of a cell $\sigma \in G$ as the 5×5 block of cells centered at σ . Let t be a site and σ the cell containing t , then the neighborhood $N(t)$ of t are all sites contained in $N(\sigma)$. Since the side length of a grid cell is $W/3\sqrt{6}$, each triangle of perimeter at most W is completely contained in the neighborhood of some cell.

► **Lemma 6.4.** *We can check the remaining triangles in $O(n)$ overall time.*

Proof. Consider a remaining triangle sut with $r_t \geq \max\{r_u, r_s\}$. Then, $t \in S_\ell$, and s, t, u all lie in $N(t)$. By Lemma 6.3, there are $O(1)$ large candidates for u in $N(t)$, and by Lemma 6.2, there are $O(1)$ small candidates for u . Having fixed a t and a possible candidate u , we iterate over all $s \in N(t)$ and check if s, u , and t form a triangle with weight at most W . Every site s is contained in $O(1)$ grid neighborhoods, and since there are $O(1)$ candidate pairs in each grid neighborhood, s participates in $O(1)$ explicit checks. The result follows. ◀

The following theorem summarizes the considerations in this section.

► **Theorem 6.5.** *It takes $O(n \log n)$ expected time to find the shortest triangle in a transmission graph.*

Proof. We already saw that there is an $O(n \log n)$ time decision algorithm for the problem. As in Theorem 2.6, the result follows from an application of Chan's randomized optimization technique [5]. ◀

7 Conclusion

Once again, disk graphs and transmission graphs prove to be a simple yet powerful graph model where difficult algorithmic problems admit faster solutions. It would be interesting to find a *deterministic* $O(n \log n)$ time algorithm for finding a shortest triangle in a disk graph. Currently, we are working on extending our results to the girth problem in transmission graphs; can we find an equally simple and efficient algorithm as for disk graphs?

Abstract

We give new partially-dynamic algorithms for the all-pairs shortest paths problem in weighted directed graphs. Most importantly, we give a new *deterministic* incremental algorithm for the problem that handles updates in $\tilde{O}(mn^{4/3} \log W/\epsilon)$ total time (where the edge weights are from $[1, W]$) and explicitly maintains a $(1 + \epsilon)$ -approximate distance matrix. For a fixed $\epsilon > 0$, this is the first deterministic partially dynamic algorithm for all-pairs shortest paths in directed graphs, whose update time is $o(n^2)$ regardless of the number of edges. Furthermore, we also show how to improve the state-of-the-art partially dynamic *randomized* algorithms for all-pairs shortest paths [Baswana et al. STOC'02, Bernstein STOC'13] from Monte Carlo randomized to Las Vegas randomized without increasing the running time bounds (with respect to the $\tilde{O}(\cdot)$ notation).

Our results are obtained by giving new algorithms for the problem of dynamically maintaining *hubs*, that is a set of $\tilde{O}(n/d)$ vertices which hit a shortest path between each pair of vertices, provided it has hop-length $\Omega(d)$. We give new subquadratic deterministic and Las Vegas algorithms for maintenance of hubs under either edge insertions or deletions.

1 Introduction

The sampling scheme of Ullman and Yannakakis [27] is a fundamental tool in designing dynamic algorithms for maintaining shortest path distances. Roughly speaking, the main idea is that if each vertex of the graph is sampled independently with probability $\Omega(\frac{d \ln n}{n})$, then with high probability¹ the set of the sampled vertices has the following property. If the shortest path between some vertices u and v contains more than d edges, then this shortest path contains a sampled vertex². We call each set having this property a set of *hubs*³ of that graph.

¹ We say that a probabilistic statement holds *with high (low) probability*, abbreviated w.h.p., if it holds with probability at least $1 - n^{-\beta}$ (at most $n^{-\beta}$, resp.), where β is a constant that can be fixed arbitrarily.

² For simplicity, in the introduction we assume that the shortest paths are unique.

³ Zwick [29] uses the name *bridging set* for an analogous concept. Some works also use the term *hitting set*, but hitting set is a more general notion, which in our paper is used in multiple different contexts.

The fact that one can easily obtain a set of hubs by random sampling is particularly useful for dynamic graph algorithms, since, by tuning constants in the sampling probability, one can assure that the set of hubs remains valid at each step (with high probability), while the graph is undergoing edge insertions and deletions, assuming the total number of updates is polynomial. This property has been successfully exploited to give a number of dynamic graph algorithms, e.g. [2, 4, 5, 9, 12, 11, 13, 20, 21, 22]. At the same time, the sampling approach also suffers from two drawbacks. First, it yields Monte Carlo algorithms, which with some nonzero probability can return incorrect answers. Second, it relies on the *oblivious adversary* assumption, that is, it requires that the updates to the graph are independent of the randomness used for sampling hubs. This becomes a substantial issue for problems where the answer to a query is not unique, e.g., for maintaining $(1 + \epsilon)$ -approximate distances or maintaining the shortest paths themselves (i.e. not just their lengths). In a typical case, the choice of the specific answer to a query depends on the randomness used for vertex sampling, which in turn means that in each answer to a query the data structure is revealing its randomness. Hence, if the following updates to the data structure depend on the specific values returned by the previous queries, the oblivious adversary assumption is not met.

In this paper we attempt to address both these issues. We study the dynamic maintenance of *reliable* hubs, that is we show how to maintain hubs using an algorithm that does not err, even with small probability. In addition, in the incremental setting we give an algorithm that maintains hubs deterministically. While the algorithms are relatively straightforward for unweighted graphs, making them also work in the weighted setting is a major challenge, which we manage to overcome. We then show how to take advantage of our results on reliable hubs to obtain improved algorithms for the problem of maintaining all-pairs shortest paths in directed graphs. In particular, we give a faster deterministic incremental algorithm and show how to improve the state-of-the-art decremental algorithms from Monte Carlo to Las Vegas.

1.1 Our Contribution

We study the problem of maintaining *reliable* hub sets in the partially dynamic setting. For the description, let us first assume the case when the graph is unweighted. Our first observation is that one can deterministically maintain the set of hubs H_d under edge insertions in $\tilde{O}(nmd)$ total time. To that end, we observe that after an edge uw is inserted, we may ensure the set of hubs H_d is valid by extending it with both u and w . This increases the size of H_d , and hence we have to periodically discard all the hubs and recompute them from scratch.

The deterministic computation of hubs has been studied before. For unweighted digraphs, King [19] showed how to compute a hub set H_d of size $\tilde{O}\left(\frac{n}{d}\right)$ in $\tilde{O}(n^2)$ time. The algorithm, given shortest path trees up to depth d from all vertices $v \in V$, computes a *blocker-set* [19] of these trees. (A blocker-set S of a rooted tree is a set such that, for each path from the root to a leaf of length d , that path contains a vertex of S distinct from the root.) Hence, if we work on unweighted graphs, in order to keep the set H_d valid and relatively small, we can maintain shortest path trees up to depth d from all vertices using the Even-Shiloach algorithm [10] in $O(nmd)$ total time, and recompute H_d using King's algorithm every $\tilde{O}\left(\frac{n}{d}\right)$ insertions. The total time needed for maintaining the hubs is therefore $\tilde{O}(nmd)$.

Furthermore, we also show how to maintain reliable hubs in a decremental setting. Suppose our goal is to compute a set of hubs that is guaranteed to be valid, which clearly is not the case for the sampled hubs of [27]. We show that if shortest path trees up to depth d are maintained using *dynamic tree* data structures [24, 25], one can recompute a certainly-valid set H_d in $\tilde{O}\left(\frac{n^2}{d}\right)$ time using a Las Vegas algorithm. To this end observe

that one can deterministically *verify* if a set $B \subseteq V$ is a blocker-set of n shortest path trees up to depth d in $\tilde{O}(n \cdot |B|)$ time. Therefore, a hub set H_d can be found by combining the approaches of [27] and [19]: we may sample candidate hub sets of size $\tilde{O}(\frac{n}{d})$ until a blocker-set of the trees is found. The number of trials is clearly constant with high probability.

We further extend this idea and show that the information whether B is a blocker-set of a collection of n shortest path trees up to depth d can be maintained subject to the changes to these trees with only polylogarithmic overhead. Consequently, we can detect when the sampled hub set H_d (for any d) ceases to be a valid hub set in $\tilde{O}(nmd)$ total time. The algorithm may make one-sided error (i.e., say that H_d is no longer a valid hub set when it is actually still good), but the probability of an error is low if we assume that the update sequence does not depend on our random bits. Subsequently we show how to extend this idea to improve the total update time to $\tilde{O}(nm)$. Assume we are given a valid d -hub set H_d . We prove that in order to verify whether H_{6d} is a valid $6d$ -hub set, it suffices to check whether it hits sufficiently long paths between the elements of H_d . We use this observation to maintain a family of reliable hub sets $H_1, H_6, \dots, H_{6^i}, \dots, H_{6^k}$ (where $6^k \leq n$) under edge deletions (or under edge insertions) in $\tilde{O}(nm)$ total time. Using that, we immediately improve the state-of-the-art decremental APSP algorithms of Baswana et al. [4] (for the exact unweighted case) and Bernstein [5] (for the $(1 + \epsilon)$ -approximate case) from Monte Carlo to Las Vegas (but still assuming an oblivious adversary) by only adding a polylogarithmic factor to the total update time bound.

Generalization to weighted digraphs. Adapting the reliable hub sets maintenance (for both described approaches: the incremental one and sample/verify) to *weighted* digraphs turns out to be far from trivial. This is much different from the sampling approach of Ullman and Yannakakis [27], which works regardless of whether the input graph is weighted or not. The primary difficulty is maintaining all shortest paths consisting of up to d edges. While in the unweighted case the length of a path is equal to the number of edges on this path, this is no longer true in the weighted case.

To bypass this problem we first relax our definition of hubs. For each $u, v \in V$ we require that some $(1 + \epsilon)$ -approximate shortest $u \rightarrow v$ path contains a hub on each subpath consisting of at least $d + 1$ edges. Next, we show that running King's blocker-set algorithm on a set of $(1 + \epsilon)$ -approximate shortest path trees up to depth⁴ d from all vertices of the graph yields a hub set that hits paths approximating the true shortest paths within a factor of $(1 + \epsilon)^{\Theta(\log n)}$. Note that a collection of such trees can be maintained in $\tilde{O}(nmd \log W/\epsilon)$ total time subject to edge insertions, using Bernstein's h -SSSP algorithm [5] with $h = d$.

The $\Theta(\log n)$ exponent in the approximation ratio comes from the following difference between the weighted and unweighted case. In a $(1 + \epsilon)$ -approximate shortest path tree up to depth d , the length of a $u \rightarrow v$ path is no more than $(1 + \epsilon)$ -times the length of the shortest $u \rightarrow v$ path in G that uses at most d edges. However, the $u \rightarrow v$ path in the tree might consist of any number of edges, in particular very few. Pessimistically, all these trees have depth $o(d)$ and their blocker-set is empty, as there is no path of hop-length $\Omega(d)$ that we need to hit. Note that this is an inherent problem, as the fact that we can find a small blocker-set in the unweighted case relies on the property that we want it to hit paths of $\Omega(d)$ edges.

⁴ In such a tree (see Definition 23), which is a subgraph of G , for all $v \in V$, the path from the source s to v has length not exceeding $(1 + \epsilon)$ times the length of a shortest out of $s \rightarrow v$ paths in G that use no more than d edges; however the tree path itself can have arbitrary number of edges.

Luckily, a deeper analysis shows that our algorithm can still approximate the length of a $s \rightarrow v$ path. Roughly speaking, we split the $s \rightarrow v$ path P into two subpaths of $d/2$ edges. If each of these two subpaths are approximated in the h -SSSP data structures by paths of less than $d/4$ edges, we replace the P by the concatenation of the two approximate paths from the h -SSSP data structures. This way, we get a path that can be longer by a factor of $(1 + \epsilon)$, but whose hop-length is twice smaller. By repeating this process $O(\log n)$ times we obtain a path of constant hop-length whose length is at most $(1 + \epsilon)^{\Theta(\log n)}$ larger than the length of P . The overall approximation ratio is reduced to $(1 + \epsilon)$ by scaling ϵ by a factor of $\Theta(\log n)$.

Deterministic incremental all-pairs shortest paths. We now show how to apply our results on reliable hubs to obtain an improved algorithm for incremental all-pairs shortest paths problem in weighted digraphs. We give a deterministic incremental algorithm maintaining all-pairs $(1 + \epsilon)$ -approximate distance estimates in $\tilde{O}(mn^{4/3} \log W/\epsilon)$ total time.

Let us now give a brief overview of our algorithm in the unweighted case. First, we maintain the set of hubs H_d under edge insertions as described above in $\tilde{O}(nmd)$ total time. Second, since the set H_d changes and each vertex of the graph may eventually end up in H_d , we cannot afford maintaining shortest path trees from all the hubs (which is done in most algorithms that use hubs). Instead, we use the folklore $\tilde{O}(n^3/\epsilon)$ total time incremental $(1 + \epsilon)$ -approximate APSP algorithm [5, 19] to compute distances between the hubs. Specifically, we run it on a graph whose vertex set is H_d and whose edges represent shortest paths between hubs of hop-lengths at most d . These shortest paths are taken from the shortest path trees up to depth d from all $v \in V$ that are required for the hub set maintenance. We reinitialize the algorithm each time the set H_d is recomputed. This allows us to maintain approximate pairwise distances between the hubs at all times in $\tilde{O}\left(m(n/d)^2/\epsilon\right)$ total time.

Finally, we show how to run a dynamic algorithm on top of a *changing* set of hubs by adapting the shortcut edges technique of Bernstein [5]. Roughly speaking, the final estimates are maintained using $(1 + \epsilon)$ -approximate shortest path trees [5] up to depth $O(d)$ from all vertices v on graph G augmented with shortcuts from v to H_d and from H_d to v . This poses some technical difficulties as the set of shortcuts is undergoing both insertions (when a hub is added) and deletions (when the entire set of hubs is recomputed from scratch). However, one can note that in the incremental setting the shortcuts that no longer approximate the distances between their endpoints do not break the approximation guarantee of our algorithm. Eventually, we use shortcuts between all pairs of vertices of G but only some of them are guaranteed (and sufficient) to be up to date at any time. The total time cost of maintaining this component is $\tilde{O}(nmd/\epsilon)$. Setting $d = \tilde{O}(n^{1/3})$ gives the best update time.

It is natural to wonder if this approach could be made to work in the decremental setting. There are two major obstacles. First, it is unclear whether one can deterministically maintain a valid set of hubs under deletions so that only $O(1)$ vertices (in amortized sense) are added to the hub set after each edge deletion. Note that in extreme cases, after a single edge deletion the set of hubs may have to be extended with polynomially many new vertices. Second, all algorithms using the above approach of introducing shortcuts from and to hubs also maintain a decremental shortest path data structure on a graph consisting of the edges of the original graph and shortcut edges representing distances between the hubs. If hubs were to be added, the graph maintained by the data structure would undergo both insertions (of shortcuts) and deletions (of edges of the original graph) which would make this a much harder, fully dynamic problem. Some earlier works dealt with a similar issue by ignoring some “inconvenient” edge insertions [14] or showing that the insertions are well-behaved [6]. However, these approaches crucially depended on the graph being undirected.

1.2 Related Work

The dynamic graph problems on digraphs are considerably harder than their counterparts on undirected graphs. An extreme example is the dynamic reachability problem, that is, transitive closure on directed graphs, and connectivity on undirected graphs. While there exist algorithms for undirected graphs with polylogarithmic query and update times [17, 28, 26, 16, 18], in the case of directed graphs the best known algorithm with polylogarithmic query time has an update time of $O(n^2)$ [23, 7, 20]. In addition, a combinatorial algorithm with an update time of $O(n^{2-\epsilon})$ is ruled out under Boolean matrix multiplication conjecture [1].

In 2003, in a breakthrough result Demetrescu and Italiano gave a fully dynamic, exact and deterministic algorithm for APSP in weighted directed graphs [8]. The algorithm handles updates in $\tilde{O}(n^2)$ amortized time and maintains the distance matrix explicitly. The bound of $O(n^2)$ is a natural barrier as a single edge insertion or deletion may change up to $\Omega(n^2)$ entries in the distance matrix. For dynamic APSP in digraphs there exists faster algorithms with polylogarithmic query time, all of which work in incremental or decremental setting:

- Ausiello et al. [3] gave a deterministic incremental algorithm for exact distances in unweighted digraphs that handles updates in $\tilde{O}(n^3)$ total time.
- Baswana et al. [4] solved the same problem in the decremental setting with a Monte Carlo algorithm with $\tilde{O}(n^3)$ total update time.
- Bernstein [5] gave a Monte Carlo algorithm for $(1 + \epsilon)$ -approximate distances in weighted graphs (with weights in $[1, W]$) with $\tilde{O}(nm \log W/\epsilon)$ total update time. The algorithm works both in the incremental and decremental setting.
- Finally, deterministic partially-dynamic (both incremental and decremental) algorithms for APSP in directed graphs with $\tilde{O}(n^3 \log W/\epsilon)$ total update time can be obtained by combining the results of [19] and [5].

The algorithms of Baswana et al. [4] and Bernstein [5] both use sampled hubs and thus require the *oblivious adversary* assumption. We highlight that in the class of deterministic algorithms, the best known results have total update time $\tilde{O}(n^3)$ [3, 5], even if we only consider sparse unweighted graphs in incremental or decremental setting and allow $(1 + \epsilon)$ approximation. In the incremental setting, for not very dense graphs, when $m = O(n^{5/3-\epsilon})$, our algorithm improves this bound to $\tilde{O}(mn^{4/3})$.

Organization of the paper. In Section 2 we fix notation, review some of the existing tools that we use and give a formal definition of hubs. Section 3 describes the hub set maintenance for incremental unweighted digraphs and our $(1 + \epsilon)$ -approximate incremental algorithm for sparse graphs. In Section 4 we show a faster Las Vegas algorithm for computing reliable hubs and further extend it to maintain reliable hub sets in the partially dynamic setting. There we also sketch how to use it in order to improve the state-of-the-art decremental APSP algorithms from Monte Carlo to Las Vegas randomized. Finally, in Section 5 we sketch how to adapt the hub set maintenance algorithms of Sections 3 and 4, so that they work on weighted graphs. Due to limited space, many proofs and details can only be found in the full version of this paper.

2 Preliminaries

In this paper we deal with *directed* graphs. We write $uv \in E(G)$ when referring to edges of G and use $w_G(uv)$ to denote the weight of uv . If G is unweighted, then $w_G(e) = 1$ for each $e \in E$. For weighted graphs, $w_G(e)$ can be any real number from the interval $[1, W]$. For simplicity, in this paper we assume that W is an input parameter given beforehand. If $uv \notin E$, we assume

$w_G(uv) = \infty$. We define the union $G \cup H$ to be the graph $(V(G) \cup V(H), E(G) \cup E(H))$ with weights $w_{G \cup H}(uv) = \min(w_G(uv), w_H(uv))$ for each $uv \in E(G \cup H)$. For an edge $e = uv$, we write $G + e$ to denote $(V(G) \cup \{u, v\}, E(G) \cup \{e\})$. The *reverse graph* G^R is defined as $(V(G), \{xy : yx \in E(G)\})$ and $w_{G^R}(xy) = w_G(yx)$.

A sequence of edges $P = e_1 \dots e_k$, where $k \geq 1$ and $e_i = u_i v_i \in E(G)$, is called a $u \rightarrow v$ path in G if $u = u_1$, $v_k = v$ and $v_{i-1} = u_i$ for each $i = 2, \dots, k$. We sometimes view a path P in G as a subgraph of G with vertices $\{u_1, \dots, u_k, v\}$ and edges $\{e_1, \dots, e_k\}$ and write $P \subseteq G$. The *hop-length* $|P|$ is defined as $|P| = k$. The *length* of the path $\ell(P)$ is defined as $\ell(P) = \sum_{i=1}^k w_G(e_i)$. If G is unweighted, then we clearly have $|P| = \ell(P)$. For convenience, we sometimes consider a single edge uv a path of hop-length 1. It is also useful to define a length-0 $u \rightarrow u$ path to be the graph $(\{u\}, \emptyset)$. If P_1 is a $u \rightarrow v$ path and P_2 is a $v \rightarrow w$ path, we denote by $P_1 \cdot P_2$ (or simply $P_1 P_2$) a path $P_1 \cup P_2$ obtained by concatenating P_1 with P_2 .

A digraph T is called an *out-tree over V rooted in r* if $v \in V(T) \subseteq V$, $|E(T)| = |V(T)| - 1$ and for all $v \in V(T)$ there is a unique path $T[v]$ from r to v . The depth $\text{dep}_T(v)$ of a vertex $v \in V(T)$ is defined as $|T[v]|$. The depth of T is defined as $\max_{v \in V(T)} \{\text{dep}_T(v)\}$. Each non-root vertex of an out-tree has exactly one incoming edge. For $v \in V(T) \setminus \{r\}$ we call the other endpoint of the incoming edge of v the *parent* v and write $\text{par}_T(v)$ when referring to it.

The *distance* $\delta_G(u, v)$ between the vertices $u, v \in V(G)$ is the length of the shortest $u \rightarrow v$ path in G , or ∞ , if no $u \rightarrow v$ path exists in G . We define $\delta_G^k(u, v)$ to be the length of the shortest path from u to v among paths of at most k edges. Formally, $\delta_G^k(u, v) = \min\{\ell(P) : u \rightarrow v = P \subseteq G \text{ and } |P| \leq k\}$. We sometimes omit the subscript G and write $w(uv)$, $\delta(u, v)$, $\delta^k(u, v)$ etc. instead of $w_G(u, v)$, $\delta_G(u, v)$, $\delta_G^k(u, v)$, etc., respectively.

We say that a graph G is *incremental*, if it only undergoes edge insertions and edge weight decreases. Similarly, we say that G is *decremental* if it undergoes only edge deletions and edge weight increases. We say that G is *partially dynamic* if it is either incremental or decremental. For a dynamic graph G we denote by n the maximum value of $|V|$ and by m the maximum value of $|E|$ throughout the whole sequence of updates.

We denote by Δ the total number of updates a dynamic graph G is subject to. If G is unweighted, then clearly $\Delta \leq m$ and in fact we assume $\Delta = m$, which allows us to simplify the analyses. For weighted digraphs, on the other hand, since the total number of weight increases/decreases that an edge is subject to is unlimited, Δ may be much larger than m . As a result, it has to be taken into account when analyzing the efficiency of our algorithms.

We call a partially-dynamic $(1 + \epsilon)$ -approximate APSP problem on weighted graphs *restricted* if the edge weights of G are of the form $(1 + \epsilon)^i$ for $i \in [0, \lceil \log_{1+\epsilon} W \rceil] \cap \mathbb{N}$ at all times and additionally each update is required to actually change the edge set or change the weight of some existing edge. Consequently, observe that in the restricted problem we have $\Delta \leq m \cdot (\lceil \log_{1+\epsilon} W \rceil + 2)$. In the following we concentrate on the restricted problem. This is without much loss of generality – we provide a reduction in the full version of the paper.

Partially-dynamic single-source shortest path trees.

► **Definition 1.** Let $G = (V, E)$ be an unweighted digraph and let $s \in V$. Let $d > 0$ be an integer. We call an out-tree $T \subseteq G$ rooted in s a *shortest path tree from s up to depth d* if: (a) for any $v \in V$, $v \in V(T)$ iff $\delta_G(s, v) \leq d$, and (b) for any $v \in V(T)$, $\delta_T(s, v) = \delta_G(s, v)$.

► **Theorem 2 (Even-Shiloach tree [10, 15]).** Let $G = (V, E)$ be an unweighted graph subject to partially dynamic edge updates. Let $s \in V$ and let $d \geq 1$ be an integer. Then, a shortest path tree from s up to depth d can be explicitly maintained⁵ in $O(md)$ total time.

⁵ By this we mean that the algorithm outputs all changes to the edge set of the maintained tree.

► **Theorem 3** (*h*-SSSP [5]). Let $G = (V, E)$ be a weighted digraph. Let $s \in V$ and let $h \geq 1$ be an integer. There exists a partially dynamic algorithm explicitly maintaining $(1 + \epsilon)$ -approximate distance estimates $\delta'(s, v)$ satisfying $\delta_G(s, v) \leq \delta'(s, v) \leq (1 + \epsilon)\delta_G^h(s, v)$ for all $v \in V$. The total update time of the algorithm $O(mh \log n \log(nW)/\epsilon + \Delta)$.

Hubs and how to compute them.

► **Definition 4.** Let $G = (V, E)$ be a directed graph. Let $B \subseteq V$ and let $d > 0$ be an integer. We say that a path P in G is (B, d) -covered if it can be expressed as $P = P_1 \dots P_k$, where $P_i = u_i \rightarrow v_i$, $|P_i| \leq d$ for each $i = 1, \dots, k$, and $u_i \in B$ for each $i = 2, \dots, k$.

We now define a blocker set, slightly modifying a definition by King [19].

► **Definition 5.** Let V be a vertex set and let d be a positive integer. Let $B \subseteq V$ and let T be a rooted tree over V of depth no more than d . We call B a (T, d) -blocker set if for each $v \in V(T)$ such that $\text{dep}_T(v) = d$, either v or one of its ancestors in T belongs to B .

Let \mathcal{T} be a collection of rooted trees over V of depth no more than d . We call B a (\mathcal{T}, d) -blocker set if B is a (T, d) -blocker set for each $T \in \mathcal{T}$.

► **Lemma 6.** Let V be a vertex set of size n . Let d be a positive integer. Let \mathcal{T} be a collection of rooted trees over V of depth at most d . Then, a (\mathcal{T}, d) -blocker set of size $O(\frac{n}{d} \log n)$ can be computed deterministically in $O(n \cdot (|\mathcal{T}| + n) \log n)$ time.

► **Definition 7.** Let $G = (V, E)$ be a directed graph and let $d > 0$ be an integer. A set $H_d \subseteq V$ is called a d -hub set of G if for every $u, v \in V$ such that $\delta_G(u, v) < \infty$, there exists some shortest $u \rightarrow v$ path that is (H_d, d) -covered.

► **Lemma 8.** Let $G = (V, E)$ be a directed unweighted graph and let $d > 0$ be an integer. Suppose we are given a collection $\mathcal{T} = \{T_v : v \in V\}$ of shortest path trees up to depth d from all vertices of G . Let B be a (\mathcal{T}, d) -blocker set. Then B is a $2d$ -hub set of G .

Deterministic incremental algorithm for dense graphs.

► **Theorem 9** ([19]+[5]). There exist an incremental algorithm maintaining all-pairs $(1 + \epsilon)$ -approximate distance estimates of a digraph in $\tilde{O}(n^3 \log(W)/\epsilon) + O(\Delta)$ total time.

As mentioned before, the above theorem basically follows by combining the partially dynamic transitive closure algorithm of King [19] with Bernstein's *h*-SSSP algorithm (Theorem 3) for $h = 2$.

3 Deterministic Incremental Algorithm for Sparse Graphs

In this section we present our deterministic incremental algorithm with $\tilde{O}(mn^{4/3}/\epsilon)$ total update time. We first observe that whenever an edge xy is added, the set of hubs may be “fixed” by extending it with both x and y .

► **Lemma 10.** Let $G = (V, E)$ be a directed unweighted graph. Let H_d be a d -hub set of G . Let $x, y \in V$ be such that $xy \notin E$. Then $H'_d = H_d \cup \{x, y\}$ is a d -hub set of $G' = G + xy$.

Let $d > 1$ be an even integer and let $\epsilon_1, 0 < \epsilon_1 < \epsilon$ be a real number, both to be set later. Our data structure consists of several components. Each subsequent component builds upon the previously defined components only.

Exact shortest paths between nearby vertices. The data structure maintains two collections $\mathcal{T}^{\text{from}} = \{T_v^{\text{from}} : v \in V\}$ and $\mathcal{T}^{\text{to}} = \{T_v^{\text{to}} : v \in V\}$ of shortest path trees up to depth $\frac{d}{2}$ in G and G^{R} , resp. By Theorem 2, each tree of $\mathcal{T}^{\text{from}} \cup \mathcal{T}^{\text{to}}$ can be maintained under edge insertions in $O(md)$ total time. The total time spent in this component is hence $O(nmd)$.

The hubs. A d -hub set H_d of both G and G^{R} such that $|H_d| = O(\frac{n}{d} \log n)$ is maintained at all times, as follows. Initially, H_d is computed in $O(n^2 \log n)$ time using Lemma 6 and the trees of $\mathcal{T}^{\text{from}} \cup \mathcal{T}^{\text{to}}$ (see Lemma 8). Next, the data structure operates in phases. Each phase spans $f = \Theta(\frac{n}{d} \log n)$ consecutive edge insertions. When an edge xy is inserted, its endpoints are inserted into H_d . By Lemma 10, this guarantees that H_d remains a d -hub set of both G and G^{R} after the edge insertion. Once f edges are inserted in the current phase, the phase ends and the hub set H_d is recomputed from scratch, again using Lemma 6. Observe that the size of $|H_d|$ may at most triple within each phase.

The total time spent on maintaining the set H_d is clearly $O(\frac{m}{f} \cdot n^2 \log n) = O(nmd)$.

Approximate shortest paths between the hubs. In each phase, we maintain a *weighted* graph $A = (H_d, E_A)$, where $E_A = \{uv : u, v \in H_d, \delta_{G^{\text{R}}}(u, v) \leq d\}$ and $w_A(uv) = \delta_{T_u^{\text{to}}}(u, v) = \delta_{G^{\text{R}}}(u, v) \leq d$. Observe that during each phase, the graph A is in fact incremental. We can thus maintain $(1 + \epsilon_1)$ -approximate distance estimates $\delta'_A(u, v)$ for all $u, v \in H_d$ in $\tilde{O}(|H_d|^3/\epsilon_1) = \tilde{O}((\frac{n}{d})^3/\epsilon_1)$ total time per phase, using a data structure \mathcal{D}_A of Theorem 9.⁶

Summing over all phases, the total time spent on maintaining the $(1 + \epsilon')$ -approximate distances estimates of the graph A is $\tilde{O}(m(\frac{n}{d})^2/\epsilon_1)$.

► **Lemma 11.** For any $u, v \in H_d$, $\delta_{G^{\text{R}}}(u, v) = \delta_A(u, v)$.

By the above lemma, for each $u, v \in H_d$ we actually have $\delta'_A(u, v) \leq (1 + \epsilon_1)\delta_{G^{\text{R}}}(u, v)$.

Shortcuts to hubs. For each $u \in V$, let S_u be a graph on V with exactly n edges $\{uv : v \in V\}$ satisfying $w_{S_u}(u, v) \geq \delta_{G^{\text{R}}}(u, v)$ for all $v \in V$, and additionally $w_{S_u}(u, v) \leq (1 + \epsilon_1)\delta_{G^{\text{R}}}(u, v)$ if u, v both currently belong to H_d . The edges between vertices of H_d are the only ones that our algorithm needs to compute approximate distances. For other edges we only need to make sure they will not cause the algorithm to underestimate the distances.

Observe that the graphs S_u can be maintained using the previously defined components as follows. First, they are initialized so that their edges are all infinite-weight. Whenever the data structure \mathcal{D}_A changes (or initializes) some of its estimates $\delta'_A(u, v) \leq (1 + \epsilon_1)\delta_{G^{\text{R}}}(u, v)$, we perform $w_{S_u}(u, v) := \min(w_{S_u}(u, v), \delta'_A(u, v))$. This guarantees that the invariants posed on S_u are always satisfied and S_u is incremental. The total number of updates to all graphs S_u is equal to the number of estimate updates made by \mathcal{D}_A and thus can be neglected.

For $u \in V$, we set up a h -SSSP data structure \mathcal{D}_u of Theorem 3 for the graph $G^{\text{R}} \cup S_u$ with source vertex u and $h = d + 1$. Hence, \mathcal{D}_u maintains distance estimates $\delta'(u, v)$ such that $\delta'(u, v) \leq (1 + \epsilon')\delta_{G^{\text{R}} \cup S_u}^{d+1}(u, v)$. As the graph $G^{\text{R}} \cup S_u$ is incremental and has $O(m)$ edges, the total time that \mathcal{D}_u needs to operate is $\tilde{O}(md/\epsilon_1) + O(\Delta_u)$, where Δ_u is the total number of updates to $G^{\text{R}} \cup S_u$. Summing the update times for all data structures \mathcal{D}_u , we obtain

⁶ Technically speaking, the total update time of the data structure of Theorem 9 is $\tilde{O}(n^3/\epsilon') + O(\Delta)$. However, all updates to \mathcal{D}_A arise when some previous component updates its explicitly maintained estimates, so the Δ term is asymptotically no more than the total update time of the previously defined components and can be charged to those. In the following, we omit Δ terms like this without warnings.

$\tilde{O}(nmd/\epsilon_1) + O(\sum_{v \in V} \Delta_u)$ total time. Note that $\sum_{u \in V} \Delta_u$ equals nm plus the number of updates to the graphs S_u , which can be charged to the operating cost of data structure \mathcal{D}_A , as argued before. We conclude that the total update time of all \mathcal{D}_u is $\tilde{O}(nmd/\epsilon_1)$.

Observe that a shortest $u \rightarrow v$ path in G^R , where $u \in H_d$ and $v \in V$ is approximated by a path in $G^R \cup S_u$ consisting of at most $d+1$ edges. The first edge belongs to S_u and “jumps” to some hub. The latter (at most d) edges belong to G^R . This is formalized as follows.

► **Lemma 12.** *Let $u \in H_d$ and $v \in V$. Then $\delta_{G^R \cup S_u}^{d+1}(u, v) \leq (1 + \epsilon_1)\delta_{G^R}(u, v)$.*

By the above lemma, we conclude that for $u \in H_d, v \in V$, the estimate $\delta'(u, v)$ produced by the data structure \mathcal{D}_v satisfies $\delta'(u, v) \leq (1 + \epsilon_1)\delta_{G^R \cup S_u}^{d+1}(u, v) \leq (1 + \epsilon_1)^2\delta_{G^R}(u, v)$.

All-pairs approximate shortest paths. We maintain another set of shortcut graphs R_u , for $u \in V$. Again R_u has exactly n edges $\{uv : v \in V\}$ whose weights satisfy $w_{R_u}(uv) \geq \delta_G(u, v)$ for all v and $w_{R_u}(uv) \leq (1 + \epsilon_1)^2\delta_G(u, v)$ if $v \in H_d$. Each graph R_u is maintained using the previously defined data structures \mathcal{D}_v . Initially all weights of R_u are infinite. Whenever some \mathcal{D}_v changes the estimate $\delta'(v, u)$, we set $w_{R_u}(uv) := \min(w_{R_u}(uv), \delta'(v, u))$. Since for $v \in H_d$ we have $\delta'(v, u) \leq (1 + \epsilon_1)^2\delta_{G^R}(v, u)$, equivalently, $\delta'(v, u) \leq (1 + \epsilon_1)^2\delta_G(u, v)$ and we obtain $w_{R_u}(uv) \leq (1 + \epsilon_1)^2\delta_G(u, v)$. Therefore, the graphs R_u are all incremental and the total number of changes they are subject to is no more than the total number of estimate changes made by the data structures $\mathcal{D}_v, v \in V$. Thus, we may neglect the cost of actually performing these changes.

Finally, for each $u \in V$ we set up a h -SSSP data structure \mathcal{D}'_u of Theorem 3 on graph $G \cup R_u$ with source u and $h = d+1$, maintaining $(1 + \epsilon_1)$ -approximate estimates of the values $\delta_{G \cup R_u}^{d+1}(u, \cdot)$. Similarly as was the case for the data structures \mathcal{D}_u of the previous component, as the graphs $G \cup R_u$ are incremental, the total operating time of the h -SSSP instances running on the graphs $G \cup R_u$ is $\tilde{O}(nmd/\epsilon_1)$.

► **Lemma 13.** *Let $u, v \in V$. Then $\delta_{G \cup R_u}^{d+1}(u, v) \leq (1 + \epsilon_1)^2\delta_G(u, v)$.*

By the above lemma, the the distance estimates $\delta''(u, v)$ maintained by the data structure \mathcal{D}'_u , approximate the corresponding distances $\delta_G(u, v)$ within a factor of $(1 + \epsilon_1)^3$.

► **Theorem 14.** *Let G be a directed unweighted graph. There exists a deterministic incremental algorithm maintaining $(1 + \epsilon)$ -approximate distance estimates between all pairs of vertices of G in $\tilde{O}(mn^{4/3}/\epsilon)$ total time.*

4 Partially-Dynamic Verification of a Sampled Hub Set

In this section we show how to maintain the information whether a sampled set remains a hub set of an unweighted digraph G subject to partially dynamic updates. For simplicity, assume that G is decremental (the incremental case, being somewhat easier, can be handled similarly). We start by showing how a reliable hub set can be found if we are given shortest path trees up to depth d from all vertices of G , stored in dynamic tree data structures.

► **Lemma 15** ([27, 29]). *Let V be a vertex set of size n and let $d > 0$ be an integer. Let \mathcal{T} be a collection of rooted trees of depth no more than d , whose vertex sets are subsets of V .*

Let $c > 1$ be some constant. Let B be a random subset of V of size $\min(\lceil c \frac{n}{d} \ln n \rceil, n)$. Then, B is a (\mathcal{T}, d) -blocker set with probability at least $\max(0, 1 - |\mathcal{T}|/n^{c-1})$.

The following data structure is an easy application of the data structure of Tarjan [25].

► **Lemma 16.** *Let V be some set of n vertices. Let F be a forest of (initially single-vertex) rooted out-trees over V such that the vertex sets of the individual trees of F form a partition of V . For $v \in V$, let $T_v \in F$ denote the unique tree of F containing v .*

There exists a data structure for dynamically maintaining F (initially consisting of n 1-vertex trees) and supporting the following operations in $O(\log n)$ time each:

1. **parent**(v): *if v is not the root of T_v , return its parent. Otherwise return **nil**.*
2. **link**(u, v): *assuming $T_u \neq T_v$ and that u is the root of T_u , make u a child of v in T_v .*
3. **cut**(v): *assuming v is not the root of T_v , split T_v into two trees by removing the edge between v and its parent.*
4. **depth**(v): *return the depth of the tree T_v .*

► **Lemma 17.** *Let V be a vertex set, $n = |V|$, and let $d > 0$ be integral. Let \mathcal{T} be a collection of rooted trees over V of depth no more than d , where $|\mathcal{T}| = O(\text{poly } n)$. Suppose each $T \in \mathcal{T}$ is given as a separate data structure of Lemma 16 and for each $T \in \mathcal{T}$, $\text{root}(T)$ is known.*

Then, there exists a Las Vegas randomized algorithm computing a (\mathcal{T}, d) -blocker set B of size $O(\frac{n}{d} \log n)$ in $O(|\mathcal{T}| \cdot \frac{n}{d} \cdot \log^2 n)$ time with high probability.

Proof. Let $|\mathcal{T}| = O(n^\alpha)$ for some $\alpha > 0$. The algorithm is to simply repeatedly pick random subsets B of V of size $\min(\lceil (\alpha + 2) \frac{n}{d} \ln n \rceil, n)$ until B succeeds in being a (\mathcal{T}, d) -blocker set. By Lemma 15, for a random B , the probability that this is not the case is at most $\frac{1}{n}$. Hence, the probability that we fail finding a (\mathcal{T}, d) -blocker set after $k = O(1)$ trials is at most $1/n^k$.

We thus only need to show how to verify whether a set B is actually a (\mathcal{T}, d) -blocker set in $O(|\mathcal{T}| \cdot |B| \log n)$ time. Recall that for a single $T \in \mathcal{T}$, if the depth of T is no more than d , then B is a (T, d) -blocker set if the tree T' obtained from T by removing all subtrees rooted in vertices of B , has depth less than d . Consequently, to verify whether B is a (T, d) -blocker set, we take advantage of the fact that T is stored in a data structure of Lemma 16.

We first check whether $r = \text{root}(T) \in B$. If this is the case, B is a (T, d) -blocker set in a trivial way. Otherwise, for each $b \in B$, we store $p_b = \text{parent}(b)$ and perform **cut**(b). Afterwards, one can see that B is a (T, d) -blocker set if and only if $\text{depth}(r) < d$. Finally, we revert all the performed **cut** operations by running **link**(b, p_b) for all $b \in B$.

Clearly, the time needed to verify whether B is a (T, d) -blocker set for any $T \in \mathcal{T}$, is $O(|B| \log n)$. Hence, one can check whether B is a (\mathcal{T}, d) -blocker set in $O(|\mathcal{T}| \cdot |B| \log n)$ time. ◀

Now we move on to the problem of detecting when a sampled set ceases to be a valid hub set of G . In fact, our algorithm will solve a bit more general problem (which is anyway needed for applications, as we will see later), as follows.

Let $|V| = n = a_0 > a_1 > \dots > a_q = 1$ be some sequence of integers such that $a_i \mid a_{i-1}$. For each $i = 0, \dots, q$, let A_i be a random a_i -subset (a subset of size a_i) of V . By Lemmas 8 and 15, each A_i is in fact an $\Theta((n/a_i) \ln n)$ -hub set of G with high probability.

We would like to detect when some A_i ceases to be an $\Theta((n/a_i) \ln n)$ -hub set of G while G undergoes edge deletions. Using this terminology, both state-of-the-art Monte-Carlo randomized algorithms for decremental exact shortest paths [4] and partially-dynamic $(1 + \epsilon)$ -approximate shortest paths [5] (for unweighted digraphs) use randomness only for constructing hub sets A_0, \dots, A_q (they use $a_i = 2^{q-i}$, but in fact any $a_i = c^{q-i}$, where c is a positive integer, would be sufficient for these algorithms to work), valid simultaneously for all versions of the input graph with high probability (the sets A_i satisfy this, as we will later show).

Without loss of generality, we can assume that given the sets A_0, \dots, A_q , the algorithms of [4, 5] proceed deterministically. Suppose we develop an efficient partially dynamic algorithm \mathcal{A} verifying whether each A_i remains a $\Theta((n/a_i) \ln n)$ -hub set of G (i.e., \mathcal{A} is supposed to

detect that some A_i ceases to be a $\Theta((n/a_i) \ln n)$ -hub set immediately after this happens) and producing *false negatives* with low probability (the algorithm is guaranteed to be correct if it says that all A_i have the desired property but might be wrong saying that some A_i is no longer a hub set). Then, we could use \mathcal{A} to convert the algorithms of [4, 5] into *Las Vegas* algorithms by drawing new sets A_0, \dots, A_q and restarting the respective algorithms whenever \mathcal{A} detects (possibly incorrectly) that any of these sets ceases to be a hub set. As this does not happen w.h.p., with high probability the overall asymptotic running time remains unchanged. The remainder of this section is devoted to describing such an algorithm \mathcal{A} .

► **Lemma 18.** *Let $d > 0$ be an integer. Let F be a forest of out-trees of depth no more than d over V . Denote by T_v the unique tree of F containing $v \in V$. Let $B \subseteq V$ be fixed.*

There exists a data structure with update time $O(\log n)$, maintaining the information whether B is a (F, d) -blocker set, subject to updates to F of the following types:

- *cut the subtree rooted in v out of T_v where $v \in V$ and v is not the root of T_v ,*
- *make the tree T_r a child of $v \in T_v$ where $r \in V$ is the root of T_r and $v \notin T_r$,*

The following lemma says that in order to test whether a given set of vertices is a $6d$ -hub set it suffices to test the hub set property for paths starting in vertices of a d -hub set.

► **Lemma 19.** *Let $G = (V, E)$ be a directed unweighted graph. Let H_d be a d -hub set of G . Suppose we are given two collections $\mathcal{T}^{\text{from}} = \{T_v^{\text{from}} : v \in H_d\}$, $\mathcal{T}^{\text{to}} = \{T_v^{\text{to}} : v \in H_d\}$ of shortest path trees up to depth d from all vertices of H_d in G and G^{R} , respectively.*

Let B be a $(\mathcal{T}^{\text{from}} \cup \mathcal{T}^{\text{to}}, d)$ -blocker set. Then B is a $6d$ -hub set of G .

Observe that by Lemma 15, there exists an integral constant $z > 0$, such that for any fixed collection of trees \mathcal{T} of depth no more than $z \cdot \frac{n}{a_i} \lceil \ln n \rceil$, where $|\mathcal{T}| = O(n^3)$, A_i is a $(\mathcal{T}, z \cdot \frac{n}{a_i} \lceil \ln n \rceil)$ -blocker set with high probability. For $i = 0, \dots, q$, set $d_i = z \cdot \frac{n}{a_{i+1}} \lceil \ln n \rceil$ where $a_{q+1} = 1$. Suppose G undergoes partially dynamic updates. For each $i = 1, \dots, q$, and $v \in V$ let $T_{i,v}^{\text{from}}$ ($T_{i,v}^{\text{to}}$) denote the shortest path tree that the algorithm of Theorem 2 would maintain for $d = d_{i-1}$ and source v in G (in G^{R} , respectively). Note that how the trees $T_{i,v}^{\text{from}}$ and $T_{i,v}^{\text{to}}$ evolve depends only on the sequence of updates to G (which, by the oblivious adversary assumption, does not depend on sets A_0, \dots, A_q in any way) and the details of the deterministic algorithm of Theorem 2. Since only $O(mn) = O(n^3)$ different trees appear in $\{T_{i,v}^{\text{from}} : v \in V\} \cup \{T_{i,v}^{\text{to}} : v \in V\}$ throughout all updates, A_i remains a $(\{T_{i,v}^{\text{from}} : v \in V\} \cup \{T_{i,v}^{\text{to}} : v \in V\}, d_{i-1})$ -blocker set throughout the whole sequence of updates with high probability, by Lemma 15.

Let $\mathcal{T}_i^{\text{from}} = \{T_{i,v}^{\text{from}} : v \in A_{i-1}\}$ and $\mathcal{T}_i^{\text{to}} = \{T_{i,v}^{\text{to}} : v \in A_{i-1}\}$, i.e., $\mathcal{T}_i^{\text{from}}$ ($\mathcal{T}_i^{\text{to}}$) contains only trees with roots from a subset $A_{i-1} \subseteq V$. However A_i being a blocker set of such a collection of trees will turn out sufficient for our needs. Clearly, since we have $\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}} \subseteq \{T_{i,v}^{\text{from}} : v \in V\} \cup \{T_{i,v}^{\text{to}} : v \in V\}$, by the above claim, A_i in fact remains a $(\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}}, d_{i-1})$ -blocker set throughout the whole sequence of updates with high probability.

Now, let $q = \lceil \log_6 n \rceil$ and for $i = 1, \dots, q$ set $a_i = 6^{q-i}$. To verify whether each A_i remains a d_i -hub set subject to partially dynamic updates to G , we proceed as follows. We deterministically maintain the trees $\bigcup_{i=1}^q (\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}})$ subject to partially dynamic updates to G using Theorem 2. The total number of changes these trees are subject to throughout the whole sequence of updates is $O(\sum_{i=1}^q a_{i-1} \cdot m \cdot d_{i-1}) = O(\sum_{i=1}^q a_{i-1} \cdot m \cdot \frac{n}{a_i} \ln n) = O(nm \log n \cdot \sum_{i=1}^q \frac{a_{i-1}}{a_i}) = \tilde{O}(nm)$.

We additionally store each tree $T_{i,v}^{\text{from}}$ (and $T_{i,v}^{\text{to}}$), for $v \in A_{i-1}$, in a data structure of Lemma 18 with $B = A_i$. Whenever the data structure of Theorem 2 updates some tree, the update is repeated in the corresponding data structure of Lemma 18. Consequently, the total time needed to maintain these additional data structures is $\tilde{O}(nm \cdot \sum_{i=1}^q \frac{a_{i-1}}{a_i}) = \tilde{O}(nm)$.

After each update we can detect whether each A_i is still a $(\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}}, d_{i-1})$ -blocker set in $O(\sum_i^q |A_{i-1}| \log n) = \tilde{O}(n)$ time by querying the relevant data structures of Lemma 18⁷ storing $\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}}$. By Lemma 19, a simple inductive argument shows that if this is the case, each A_i is a d_i -hub set of both G and G^R . Hence, verifying all A_1, \dots, A_q while G evolves takes $\tilde{O}(mn)$ total time. The algorithm terminates when it turns out that some A_i is no longer a $(\mathcal{T}_i^{\text{from}} \cup \mathcal{T}_i^{\text{to}}, d_{i-1})$ -blocker set. However, recall that this happens only with low probability, regardless of whether A_i actually ceases to be a d_i hub set or not. We have proved the following.

► **Theorem 20.** *Let G be an unweighted digraph. Let $q = \lceil \log_6 n \rceil$. For $i = 0, \dots, q$, let A_i be a random 6^{q-i} -subset of V . One can maintain the information whether each A_i is a $\Theta(6^i \ln n)$ -hub set of G , subject edge deletions issued to G , in $\tilde{O}(nm)$ total time.*

The algorithm might produce false negatives with low probability.

By plugging in the hubs of Theorem 20 into the algorithms of [4, 5], we obtain the following.

► **Corollary 21.** *Let G be an unweighted digraph. There exists a Las Vegas randomized decremental algorithm maintaining exact distance between all pairs of vertices of G with $\tilde{O}(n^3)$ total update time w.h.p. It assumes an adversary oblivious to the random bits used.*

► **Corollary 22.** *Let G be an unweighted digraph. There exists a Las Vegas randomized decremental algorithm maintaining $(1 + \epsilon)$ -approximate distance estimates between all pairs of vertices of G in $\tilde{O}(nm/\epsilon)$ total time w.h.p. The algorithm assumes an oblivious adversary.*

5 Approximate Shortest Paths for Weighted Graphs

In this section we give key definitions used to generalize the reliable hub maintenance algorithms to weighted graphs, at the cost of $(1 + \epsilon)$ -approximation. Then, we state the main theorem (Theorem 26) relating blocker sets in $(1 + \epsilon)$ -approximate shortest path trees to the approximate hub sets. Finally, we explain briefly how to incorporate these tools into our improved dynamic APSP algorithms in order to generalize them to weighted graphs.

► **Definition 23.** *Let $G = (V, E)$ be a weighted digraph and let $s \in V$ be a source vertex. Let d be a positive integer. An out-tree $T \subseteq G$ is called a $(1 + \epsilon)$ -approximate shortest path tree from s up to depth d , if T is rooted at s and for any $v \in V$ such that $\delta_G^d(s, v) < \infty$, we have $v \in V(T)$ and $\delta_T(s, v) \leq (1 + \epsilon)\delta_G^d(s, v)$.*

► **Definition 24.** *Let $G = (V, E)$ be directed and let $d > 0$ be an integer. A set $H_d^\epsilon \subseteq V$ is called an $(1 + \epsilon)$ -approximate d -hub set of G if for every $u, v \in V$ such that $\delta_G(u, v) < \infty$, there exists a path $P = u \rightarrow v$ in G such that $\ell(P) \leq (1 + \epsilon)\delta_G(u, v)$ and P is (H_d^ϵ, d) -covered.*

We also extend the definition of a (T, d) -blocker set to trees of depth more than d .

► **Definition 25.** *Let V be a vertex set and let $d > 0$ be an integer. Let T be a rooted tree over V . Define T^d to be the set of all maximal subtrees of T of depth no more than d , rooted in non-leaf vertices $x \in V(T)$ satisfying $d \mid \text{dep}_T(x)$.*

⁷ The Even-Shiloach algorithm (Theorem 2), apart from maintaining distance labels for all $v \in V$, moves around entire subtrees of the maintained tree T . Hence, in order to ensure that some set B remains a blocker-set of T , it is not sufficient to simply check whether $B \cap V(T[v])$ whenever the Even-Shiloach algorithm changes the distance label of v to d (and, consequently, use a data structure much simpler than that given in Lemma 18).

Then, B is a (T, d) -blocker set if and only if it is a (T^d, d) -blocker set (in terms of Definition 5). Let \mathcal{T} be a collection of rooted trees over V . We call B a (\mathcal{T}, d) -blocker set if and only if B is a (T, d) -blocker for each $T \in \mathcal{T}$.

► **Theorem 26.** Let $G = (V, E)$ be a directed graph and let $d < n$ be an even integer. Let $\mathcal{T}^{\text{from}} = \{T_v^{\text{from}} : v \in V\}$ ($\mathcal{T}^{\text{to}} = \{T_v^{\text{to}} : v \in V\}$) be a collection of $(1 + \epsilon)$ -approximate shortest path trees up to depth $3d$ from all vertices in G (in G^{R} , resp.).

Let $B \subseteq V$ be a $(\mathcal{T}^{\text{from}} \cup \mathcal{T}^{\text{to}}, \frac{d}{2})$ -blocker set. Then B is a $(1 + \epsilon)^p$ -approximate $2dp$ -hub set of G , where $p = \lceil \log_2 n \rceil + 1$.

Recall that our reliable hubs maintenance algorithms for unweighted graphs essentially maintained some shortest path trees up to depth d and either computed their blocker sets using King’s algorithm, or dynamically verified whether the sampled hub sets remain blocker sets of the shortest path trees.

We first replace all shortest path trees up to depth d with $(1 + \epsilon)$ -approximate shortest path trees up to depth d . We use the following extension of Bernstein’s h -SSSP algorithm.

► **Lemma 27.** The h -SSSP algorithm of Theorem 3 can be extended so that it maintains a $(1 + \epsilon)$ -approximate shortest path tree up to depth h from s within the same time bound.

By Theorem 26, by finding blocker sets of approximate shortest path trees (as in Definition 25), we can compute/verify $(1 + \epsilon')^{\Theta(\log n)}$ -approximate $\Theta(d \log n)$ -hub sets as before.

Given appropriate hub sets, all that both our deterministic incremental $(1 + \epsilon)$ -approximate APSP algorithm, and Bernstein’s randomized $(1 + \epsilon)$ -approximate partially dynamic APSP algorithm do, is essentially set up and maintain a “circuit” (i.e., a collection of data structures whose outputs constitute the inputs of other structures) of h -SSSP data structures from the hubs with different parameters h and appropriately set ϵ' . In order to make these algorithms work with our reliable approximate hub sets, we basically need to play with the parameters: increase all h ’s by a polylogarithmic factor, and decrease ϵ' by a polylogarithmic factor.

Abstract

In this paper we give an $\tilde{O}((nm)^{2/3} \log C)$ time algorithm for computing min-cost flow (or min-cost circulation) in unit capacity planar multigraphs where edge costs are integers bounded by C . For planar multigraphs, this improves upon the best known algorithms for general graphs: the $\tilde{O}(m^{10/7} \log C)$ time algorithm of Cohen et al. [SODA 2017], the $O(m^{3/2} \log(nC))$ time algorithm of Gabow and Tarjan [SIAM J. Comput. 1989] and the $\tilde{O}(\sqrt{nm} \log C)$ time algorithm of Lee and Sidford [FOCS 2014]. In particular, our result constitutes the first known fully combinatorial algorithm that breaks the $\Omega(m^{3/2})$ time barrier for min-cost flow problem in planar graphs.

To obtain our result we first give a very simple successive shortest paths based scaling algorithm for unit-capacity min-cost flow problem that does not explicitly operate on dual variables. This algorithm also runs in $\tilde{O}(m^{3/2} \log C)$ time for general graphs, and, to the best of our knowledge, it has not been described before. We subsequently show how to implement this algorithm faster on planar graphs using well-established tools: r -divisions and efficient algorithms for computing (shortest) paths in so-called dense distance graphs.

1 Introduction

The min-cost flow is the core combinatorial optimization problem that now has been studied for over 60 years, starting with the work of Ford and Fulkerson [14]. Classical combinatorial algorithms for this problem have been developed in the 80s. Goldberg and Tarjan [18] showed an $\tilde{O}(nm \log C)$ time weakly-polynomial algorithm for the case when edge costs are integral, and where C is the maximum edge cost. Orlin [31] showed the best-known strongly polynomial time algorithm running in $\tilde{O}(m^2)$ time. Faster weakly-polynomial algorithms have been developed in this century using interior-point methods: Daitch and Spielman [8] gave an $\tilde{O}(m^{3/2} \log(U + C))$ algorithm, and later Lee and Sidford [28] obtained an $\tilde{O}(\sqrt{nm} \log(U + C))$ algorithm, where U is the maximum (integral) edge capacity.

Much attention has been devoted to the unit-capacity case of the min-cost flow problem. Gabow and Tarjan [15] gave a $O(m^{3/2} \log(nC))$ time algorithm. Lee and Sidford [28] matched this bound up to polylogarithmic factors for $m = \tilde{O}(n)$, and improved upon it for larger densities, even though their algorithm solves the case of arbitrary integral capacities. Gabow and Tarjan's result remained the best known bound for more than 28 years – the problem

witnessed an important progress only very recently. In 2017 an algorithm that breaks the $\Omega(m^{3/2})$ time barrier for min-cost flow problem was given by Cohen et al. [7]. This algorithm runs in $\tilde{O}(m^{10/7} \log C)$ time and is also based on interior-point methods.

It is worth noting that currently the algorithms of [7, 28] constitute the most efficient solutions for the entire range of possible densities (up to polylogarithmic factors) and are also the best-known algorithms for important special cases, e.g., planar graphs or minor-free graphs. Both of these solutions are based on interior point methods and do not shed light on the combinatorial structure of the problem.

In this paper we study the unit-capacity min-cost flow in planar multigraphs. We improve upon [7, 28] by giving the first known $\tilde{O}((mn)^{2/3} \log C) = \tilde{O}(m^{4/3} \log C)$ time algorithm for computing min-cost s, t -flow and min-cost circulation in planar multigraphs.¹ Our algorithm is fully combinatorial and uses the scaling approach of Goldberg and Tarjan [18]. At each scale it implements the classical shortest augmenting path approach similar to the one known from the well-known Hopcroft-Karp algorithm for maximum bipartite matching [19].

Related work. Due to immense number of works on flows and min-cost flows we will not review all of them. Instead we concentrate only on the ones that are relevant to the sparse and planar graph case, as that is the regime where our results are of importance. As already noted above the fastest algorithms for min-cost flows in planar multigraphs are implied by the algorithms for general case. This, however, is not the case for maximum flow problem. Here, the fastest algorithms are based on planar graph duality and reduce the problem to shortest path computations. The undirected s, t -flow problem can be solved in $O(n \log \log n)$ time [22], whereas the directed s, t -flow problem can be solved in $O(n \log n)$ time [3, 11]. Even for the case with multiple source and sinks, a nearly-linear time algorithm is known [4].

These results naturally raise as an open question whether similar nearly-linear bounds could be possible for min-cost flow. Until very recently there has been no progress towards answering this open question. Partial progress was made by devising $\tilde{O}(n^{4/3} \log C)$ time [1] and $\tilde{O}(n^{6/5} \log C)$ time [27] algorithms for min-cost perfect matchings in bipartite planar graphs. Lahn and Raghvendra also give an $\tilde{O}(n^{7/5} \log C)$ time minimum cost perfect matching algorithm for minor-free graphs. These algorithms can be seen as specialized versions of the Gabow-Tarjan's algorithm for the assignment problem [15].

Gabow and Tarjan [15] reduced min-cost flow problem to so-called min-cost perfect degree-constrained subgraph problem on a bipartite multigraph, which they solved by extending their algorithm for minimum cost perfect matching. Hence it seems plausible that the recent algorithm of Lahn and Raghvendra [27] can be extended to solve min-cost flow, since their algorithm builds upon the Gabow-Tarjan algorithm. The reduction presented by Gabow and Tarjan *is not* planarity preserving, though. Nevertheless, min-cost perfect matching problem can be reduced to min-cost flow problem in an efficient and planarity preserving way [29]. The opposite reduction can be done in planarity preserving way as recently shown [33]. However, this reduction is not efficient and produces a graph of quadratic size. Hence, we cannot really take advantage of it.

Overview and comparison to [1, 27]. We concentrate on the *min-cost circulation* problem, which is basically the min-cost flow problem with all vertex demands equal to 0. It is well-known [17] that the min-cost s, t -flow problem can be solved by first computing some s, t -flow

¹ It is known that simple planar graphs have $O(n)$ edges. However, multiple parallel edges (with possibly different costs) are useful in the unit-capacity min-cost flow problem, as they allow us to encode larger edge capacities. Therefore, in this paper we work with planar multigraphs.

f of requested value (e.g., the maximum value), and then finding a min-cost circulation on the residual network G_f . This reduction is clearly planarity-preserving. Since an s, t -flow of any given value (in particular, the maximum value) can be found in a planar graph in nearly-linear time (see [11]), this reduction works in nearly-linear time as well.

Our min-cost circulation algorithm resembles the recent works on minimum cost planar perfect matching [1, 27], in the sense that we simulate some already-good scaling algorithm for general graphs, but implement it more efficiently using the known and well-established tools from the area of planar graph algorithms. However, instead of simulating an existing unit-capacity min-cost flow algorithm, e.g., [15, 17], we use a very simple successive-shortest paths based algorithm that, to the best of our knowledge, has not been described before.

Our algorithm builds upon the cost-scaling framework of Goldberg and Tarjan [18], similarly as the recent simple unit-capacity min-cost flow algorithms of Goldberg et al. [17]. In this framework, a notion of ϵ -optimality of a flow is used. A flow f is ϵ -optimal with respect to a price function p if for any edge $uv = e \in E(G_f)$ we have $c(e) - p(u) + p(v) \geq -\epsilon$.

Roughly speaking, the parameter ϵ measures the quality of a circulation: any circulation is trivially C -optimal wrt. p , whereas any $\frac{1}{n}$ -feasible (wrt. p) circulation is guaranteed to be optimal. The general scheme is to start with a C -optimal circulation, run $O(\log(nC))$ scales that improve the quality of a circulation by a factor of 2, and this way obtain the optimal solution.

We show that a single scale can be solved by repeatedly sending flow along a cheapest $s \rightarrow t$ path in a certain graph G_f'' with a single source s and a single sink t , that approximates the residual graph G_f . Moreover, if we send flow simultaneously along a maximal set of cheapest $s \rightarrow t$ paths at once, like in [12, 19], we finish after $O(\sqrt{m})$ augmentations. However, as opposed to [12, 19], our graph G_f'' is weighted and might have negative edges. We overcome this difficulty as in the classical successive shortest path approach for min-cost flow, by using distances from the previous flow augmentation as a feasible price function that can speed-up next shortest path computation. Our algorithm also retains a nice property² of the Even-Tarjan algorithm that the total length (in terms of the number of edges) of all the used augmenting paths is $O(m \log m)$.

The crucial difference between our per-scale procedure and those of [15, 17] is that we do not “adjust” dual variables $p(v)$ at all while the procedure runs: we only use them to compute G_f'' , and recompute them from scratch in nearly-linear time when the procedure finishes. In particular, the recent results of [1, 27] are quite complicated since, in order to simulate the Gabow-Tarjan algorithm [15], they impose and maintain additional invariants about the duals.

The only bottlenecks of our per-scale procedure are (1) shortest paths computation, (2) picking a maximal set of edge-disjoint $s \rightarrow t$ paths in an unweighted graph³.

We implement these on a planar network using standard methods. Let $r \in [1, n]$ be some parameter. We construct a *dense distance graph* H_f'' (e.g., [13, 16]) built upon an r -division (e.g., [26]) of G_f'' . The graph H_f'' is a compressed representation of the distances in G_f'' with $O(n/\sqrt{r})$ vertices and $O(m)$ edges. Moreover, it can be updated in $\tilde{O}(r)$ time per edge used by the flow. Hence, the total time spent on updating H_f'' is $\tilde{O}(mr)$. As we show, running our per-scale procedure on H_f'' is sufficient to simulate it on G_f'' . Computing distances in a dense distance graph requires $\tilde{O}(n/\sqrt{r})$ time [13, 16]. To complete the construction, we show how

² Gabow-Tarjan algorithm for min-cost bipartite matching has a similar property, which was instrumental for obtaining the recent results on minimum-cost planar bipartite matching [1, 27].

³ This is sometimes called *the blocking flow* problem and can be solved for unit capacities in linear time.

to find a maximal set of edge-disjoint paths in $\tilde{O}(n/\sqrt{r})$ amortized time. To this end, we also exploit the properties of reachability in a dense distance graph, used previously in dynamic reachability algorithms for planar digraphs [21, 24]. This way, we obtain $\tilde{O}(\sqrt{mn}/\sqrt{r} + mr)$ running time per scale. This is minimized roughly when $r = n^{2/3}/m^{1/3}$.

Recall that Lahn and Raghvendra [27] obtained a polynomially better (than ours) bound of $\tilde{O}(n^{6/5} \log C)$, but only for planar min-cost perfect matching problem. To achieve that, they use an additional idea due to Asathulla et al. [1]. Namely, they observe that by introducing vertex weights, one can make augmenting paths avoid edges incident to boundary vertices, thus making the total number of pieces “affected” by augmenting paths truly-sublinear in n . It is not clear how to apply this idea to the min-cost flow problem without making additional assumptions about the structure of the instance, like bounded-degree (then, there are only $O(n/\sqrt{r})$ edges incident to boundary vertices of an r -division), or bounded vertex capacities (so that only $O(1)$ units of flow can go through each vertex; this is satisfied in the perfect matching case). This phenomenon seems not very surprising once we recall that such assumptions lead to better bounds even for general graphs: the best known combinatorial algorithms for min-cost perfect matching run in $O(n^{1/2}m \log(nC))$ time, whereas for min-cost flow in $O(m^{3/2} \log(nC))$ time [15, 17].

Organization of the paper. In Section 2 we introduce the notation and describe the scaling framework of [18]. Next, in Section 3, we describe the per-scale procedure of unit-capacity min-cost flow for general graphs. Finally, in Section 4 we give our algorithm for planar graphs. Due to limited space, some of the missing proofs can only be found in the full version of the paper.

2 Preliminaries

Let $G_0 = (V, E_0)$ be the input directed multigraph. Let $n = |V|$ and $m = |E_0|$. Define $G = (V, E)$ to be a multigraph such that $E = E_0 \cup E_0^R$, $E_0 \cap E_0^R = \emptyset$, where E_0^R is the set of *reverse edges*. For any $uv = e \in E$, there is an edge $e^R \in E$ such that $e^R = vu$ and $(e^R)^R = e$. We have $e \in E_0$ iff $e^R \in E_0^R$.

Let $u : E_0 \rightarrow \mathbb{R}_+$ be a *capacity function*. A *flow* is a function $f : E \rightarrow \mathbb{R}$ such that for any $e \in E$ $f(e) = -f(e^R)$ and for each $e \in E_0$, $0 \leq f(e) \leq u(e)$. These conditions imply that for $e \in E_0$, $-u(e) \leq f(e^R) \leq 0$. We extend the function u to E by setting $u(e^R) = 0$ for all $e \in E_0$. Then, for all edges $e \in E$ we have $-u(e^R) \leq f(e) \leq u(e)$. The *unit capacity* function satisfies $u(e) = 1$ for all $e \in E_0$.

The *excess* $\text{exc}_f(v)$ of a vertex $v \in V$ is defined as $\sum_{uv=e \in E} f(e)$. Due to anti-symmetry of f , $\text{exc}_f(v)$ is equal to the amount of flow going into v by the edges of E_0 minus the amount of flow going out of v by the edges of E_0 . The vertex $v \in V$ is called an *excess* vertex if $\text{exc}_f(v) > 0$ and *deficit* if $\text{exc}_f(v) < 0$. Let X be the set of excess vertices of G and let D be the set of deficit vertices. Define the *total excess* Ψ_f as the sum of excesses of the excess vertices, i.e., $\Psi_f = \sum_{v \in X} \text{exc}_f(v) = \sum_{v \in D} -\text{exc}_f(v)$.

A flow f is called a *circulation* if there are no excess vertices, or equivalently, $\Psi_f = 0$.

Let $c : E_0 \rightarrow \mathbb{Z}$ be the input *cost* function. We extend c to E by setting $c(e^R) = -c(e)$ for all $e \in E_0$. The *cost* $c(f)$ of a flow f is defined as $\frac{1}{2} \sum_{e \in E} f(e)c(e) = \sum_{e \in E_0} f(e)c(e)$.

To *send a unit of flow* through $e \in E$ means to increase $f(e)$ by 1 and simultaneously decrease $f(e^R)$ by 1. By sending a unit of flow through e we increase the cost of flow by $c(e)$. To *send a unit of flow through a path* P means to send a unit of flow through each edge of P . In this case we also say that we *augment flow* f *along path* P .

The *residual network* G_f of f is defined as (V, E_f) , where $E_f = \{e \in E : f(e) < u(e)\}$.

Price functions and distances. We call any function $p : V \rightarrow \mathbb{R}$ a *price function* on G . The *reduced cost* of an edge $uv = e \in E$ wrt. p is defined as $c_p(e) := c(e) - p(u) + p(v)$. We call p a *feasible price function* of G if each edge $e \in E$ has nonnegative reduced cost wrt. p .

It is known that G has no negative-cost cycles (negative cycles, in short) if and only if some feasible price function p for G exists. If G has no negative cycles, distances in G (where we interpret c as a *length* function) are well-defined. For $u, v \in V$, we denote by $\delta_G(u, v)$ the distance between u and v , or, in other words, the length of a shortest $u \rightarrow v$ path in G .

► **Fact 1.** *Suppose G has no negative cycles. Let $t \in V$ be reachable in G from all vertices $v \in V$. Then the distance to function $\delta_{G,t}(v) := \delta_G(v, t)$ is a feasible price function of G .*

For $A, B \subseteq V(G)$ we sometimes write $\delta_G(A, B)$ to denote $\min\{\delta_G(u, v) : u \in A, v \in B\}$.

Planar graph toolbox. An r -*division* of a simple undirected plane graph G is a collection of $O(n/r)$ edge-induced subgraphs of G , called *pieces*, whose union is G and such that each piece P has $O(r)$ vertices and $O(\sqrt{r})$ *boundary vertices*. The boundary vertices ∂P of a piece P are the vertices of P shared with some other piece.

An r -*division with few holes* has an additional property that for each piece P , (1) P is connected, (2) there exist $O(1)$ faces of P whose union of vertex sets contains ∂P .

Let G_1, \dots, G_λ be some collection of plane graphs, where each G_i has a distinguished boundary set ∂G_i lying on $O(1)$ faces of G_i . A *distance clique* $DC(G_i)$ of G_i is defined as a complete digraph on ∂G_i such that the cost of the edge uv in $DC(G_i)$ is equal to $\delta_{G_i}(u, v)$.

► **Theorem 2** (MSSP [6, 25]). *Suppose a feasible price function on G_i is given. Then the distance clique $DC(G_i)$ can be computed in $O((|V(G_i)| + |E(G_i)| + |\partial G_i|^2) \log |V(G_i)|)$ time.*

The graph $DDG = DC(G_1) \cup \dots \cup DC(G_\lambda)$ is called a *dense distance graph*⁴.

► **Theorem 3** (FR-Dijkstra [13, 16]). *Given a feasible price function of DDG , single-source shortest paths in DDG can be computed in $O\left(\sum_{i=1}^\lambda |\partial G_i| \frac{\log^2 n}{\log^2 \log n}\right)$ time, where $n = |V(DDG)|$.*

Scaling framework for minimum-cost circulation. The following fact characterizes minimum circulations.

► **Fact 4** ([32]). *Let f be a circulation. Then $c(f)$ is minimum iff G_f has no negative cycles.*

It follows that a circulation f is minimum if there exists a feasible price function of G_f .

► **Definition 5** ([2, 18, 34]). *A flow f is ϵ -optimal wrt. price function p if for any $uv = e \in E_f$, $c(e) - p(u) + p(v) \geq -\epsilon$.*

The above notion of ϵ -optimality allows us, in a sense, to measure the optimality of a circulation: the smaller ϵ , the closer to the optimum a circulation f is. Moreover, if we deal with integral costs, $\frac{1}{n+1}$ -optimality is equivalent to optimality.

► **Lemma 6** ([2, 18]). *Suppose the cost function has integral values. Let circulation f be $\frac{1}{n+1}$ -optimal wrt. some price function p . Then f is a minimum cost circulation.*

⁴ Dense distance graphs have been defined differently multiple times in the literature. We use the definition of [16, 30] that captures all the known use cases (see [16] for discussion).

Proof. Suppose f is not minimum-cost. By Fact 4, f is not minimum-cost iff G_f contains a simple negative cycle C . Note that the cost of C is the same with respect to the cost functions c and c_p , as the prices cancel out. Therefore $\sum_{e \in C} c_p(e) \geq -\frac{n}{n+1} > -1$. But the cost of this cycle is integral and hence is at least 0, a contradiction. \blacktriangleleft

Let $C = \max_{e \in E_0} \{|c(e)|\}$. Suppose we have a procedure $\text{REFINE}(G, f_0, p_0, \epsilon)$ that, given a circulation f_0 in G that is 2ϵ -optimal wrt. p_0 , computes a pair (f', p') such that f' is a circulation in G , and it is ϵ -optimal wrt. p' . We use the general *scaling* framework, due to Goldberg and Tarjan [18], as given in Algorithm 1. By Lemma 6, it computes a min-cost circulation in G in $O(\log(nC))$ iterations. Therefore, if we implement REFINE to run in $T(n, m)$ time, we can compute a minimum cost circulation in G in $O(T(n, m) \log(nC))$ time.

3 Refinement via Successive Approximate Shortest Paths

In this section we introduce our implementation of $\text{REFINE}(G, f_0, p_0, \epsilon)$. For simplicity, we start by setting $c(e) := c(e) - p_0(u) + p_0(v)$. After we are done, i.e., we have a circulation f' that is ϵ -optimal wrt. p' , (assuming costs reduced with p_0), we will return $(f', p' + p_0)$ instead. Therefore, we now have $c(e) \geq -2\epsilon$ for all $e \in E_{f_0}$.

Let f_1 be the flow initially obtained from f_0 by sending a unit of flow through each edge $e \in E_{f_0}$ such that $c(e) < 0$. Note that f_1 is ϵ -optimal, but it need not be a circulation.

We denote by f the *current flow* which we will gradually change into a circulation. Recall that X is the set of excess vertices of G and D is the set of deficit vertices (with respect to the current flow f). Recall a well-known method of finding the min-cost circulation exactly [5, 20, 23]: repeatedly send flow through shortest $X \rightarrow D$ paths in G_f . The sets X and D would only shrink in time. However, doing this on G_f exactly would be too costly. Instead, we will gradually convert f into a circulation, by sending flow from vertices of X to vertices of D but only using approximately (in a sense) shortest paths.

Let $\text{round}(y, z)$ denote the smallest integer multiple of z that is greater than y .

For any $e \in E$, set $c'(e) = \text{round}(c(e) + \epsilon/2, \epsilon/2)$. We define G'_f to be the “approximate” graph G_f with the costs given by c' instead of c .

For convenience, let us also define an extended version G''_f of G'_f to be G'_f with two additional vertices s (a super-excess-vertex) and t (a super-deficit-vertex) added. Let $M = \sum_{e \in E} |c'(e)| + \epsilon$. We also add to G''_f the following auxiliary edges:

1. an edge vt for all $v \in V$, we set $c'(vt) = 0$ if $v \in D$ and $c'(vt) = M$ otherwise,
2. an edge sx with $c'(sx) = 0$ for all $x \in X$.

Clearly, $\delta_{G''_f}(s, t) = \delta_{G'_f}(X, D)$ and every vertex in G''_f can reach t .

Our algorithm can be summarized very briefly, as follows. Start with $f = f_1$. While $X \neq \emptyset$, send a unit of flow along any shortest path P from X to D in G'_f (equivalently: from s to t in G''_f). Once finished, return f and $\delta_{G''_f,t}$ as the price function. The correctness of this approach follows from the following two facts that we discuss later on:

1. G'_f is negative-cycle free at all times,
2. after the algorithm finishes, f is a circulation in G that is ϵ -optimal wrt. $\delta_{G''_f,t}$.

If implemented naively, the algorithm would need $O(m)$ negative-weight shortest paths computations to finish. If we used Bellman-Ford method for computing shortest paths, the algorithm would run in $O(nm^2)$ time. To speed it up, we apply two optimizations.

First, as in the successive shortest paths algorithm for general graphs [10, 35], we observe that the distances $\delta_{G''_f,t}$ computed before sending flow through a found shortest $s \rightarrow t$ path constitute a feasible price function of G''_f after augmenting the flow. This allows us to replace Bellman-Ford algorithm with Dijkstra's algorithm and reduce the time to $O(m^2 + nm \log n)$. Next, instead of augmenting the flow along a single shortest $X \rightarrow D$ path, we send flow through a maximal set of edge-disjoint shortest $X \rightarrow D$ paths, as in Hopcroft-Karp algorithm for maximum bipartite matching [19]. Such a set can be easily found in $O(m)$ time when the distances to t in G''_f are known. This way, we finish after only $O(\sqrt{m})$ phases of shortest path computation and flow augmentation. The pseudocode is given in Algorithm 2.

■ **Algorithm 2** Refinement via successive shortest paths.

Require: f_0 is a circulation in G 2ϵ -feasible wrt. p_0

Require: $\text{DISTANCETO}(H, t, p)$ computes the vector of distances (i.e., $\delta_{G,t}$) from all $v \in V(H)$ to $t \in V(H)$, where p is a feasible price function of H .

Require: $\text{SENDFLOW}(f, E^*)$ returns a flow f' such that $f'(e)$ equals $f(e) + 1$ if $e \in E^*$, $f(e) - 1$ if $e^R \in E^*$, and $f(e)$ otherwise.

Output: (f, p) , where f is a circulation in G ϵ -feasible wrt. p

```

3.1 Analysis

Below we state some key properties of our refinement method. The proofs are can be found in the full version of the paper.

► **Lemma 7.** *Suppose G''_f has no negative cycles. Then f is ϵ -optimal wrt. $\delta_{G''_f,t}$.*

Proof. Recall that G_f and G'_f have the same sets of edges, only different costs. Let $uv = e \in G_f$. Set $p := \delta_{G''_f,t}$. By Fact 1, $c'(e) - p(u) + p(v) \geq 0$. Note that $c(e) \geq c'(e) - \epsilon$. Hence, $c(e) - p(u) + p(v) \geq c'(e) - p(u) + p(v) - \epsilon \geq -\epsilon$. ◀

► **Lemma 8.** *If $X \neq \emptyset$, then there exists a path from X to D in G_f .*

Before we proceed further, we need to introduce more notation. Let Δ denote the length of the shortest $X \rightarrow D$ path in G'_f (Δ changes in time along with f).

Let $q = \Psi_{f_1}$. Clearly, $q \leq m$. For $i = 1, \dots, q$, denote by f_{i+1} the flow (with total excess $q - i$) obtained from f_i by sending a unit of flow through an arbitrarily chosen shortest $X \rightarrow D$ path P_i of G'_{f_i} .

For $i = 1, \dots, q$, let Δ_i be the value Δ when $f = f_i$. We set $\Delta_{q+1} = \infty$.

► **Lemma 9.** *Let $p_i^* : V \cup \{s, t\} \rightarrow \{k \cdot \epsilon/2 : k \in \mathbb{Z}\}$ be defined as $p_i^* = \delta_{G'_{f_i}, t}$. Then:*

1. G'_{f_i} has no cycles of non-positive cost,
2. for any $e \in P_i$, the reduced cost of e^R wrt. p_i^* is positive,
3. p_i^* is a feasible price function of both G'_{f_i} and $G''_{f_{i+1}}$,
4. $0 < \Delta_i \leq \Delta_{i+1}$.

By Lemmas 8 and 9, our general algorithm computes a circulation f_{q+1} such that p_q^* is a feasible price function of $G'_{f_{q+1}}$. Since f_{q+1} has no negative cycles, by Lemma 7, f_{q+1} is ϵ -optimal wrt. $\delta_{G'_{f_{q+1}}, t}$. We conclude that the algorithm is correct.

The following lemma is the key to the running time analysis.

► **Lemma 10.** *If $X \neq \emptyset$ (equivalently, if $\Delta < \infty$), then $\Psi_f \cdot \Delta \leq 6\epsilon m$.*

3.2 Efficient Implementation

As mentioned before, we could use Lemma 9 directly: start with flow f_1 and $p_0^* \equiv 0$. Then, repeatedly compute a shortest $X \rightarrow D$ path P_i along with the values p_i^* using Dijkstra's algorithm on G'_f (with the help of price function p_{i-1}^* to make the edge costs non-negative), and send flow through P_i to obtain f_{i+1} . However, we can also proceed as in Hopcroft-Karp algorithm and augment along many shortest $X \rightarrow D$ paths of cost Δ at once. We use the following lemma.

► **Lemma 11.** *Let p be a feasible price function of G'_f . Suppose there is no $s \rightarrow t$ path in G'_f consisting of edges with reduced (wrt. p) cost 0. Then $\Delta = \delta_{G'_f}(X, D) > p(s) - p(t)$.*

Suppose we run the simple-minded algorithm. Assume that at some point $f = f_i$, and we have p_i^* computed. Any $s \rightarrow t$ path in G''_{f_i} with reduced (wrt. p_i^*) cost 0 corresponds to some shortest $X \rightarrow D$ path (of length Δ_i) in G'_f . Additionally, we have $p_i^*(s) = 0$ and $p_i^*(t) = \Delta_i$.

Let Q_0, \dots, Q_k be some maximal set of edge-disjoint $s \rightarrow t$ paths in G''_{f_i} with reduced cost 0. By Lemma 9, we could in principle choose $P_i = Q_0, P_{i+1} = Q_1, \dots, P_{i+k} = Q_k$ and this would not violate the rule that we repeatedly choose shortest $X \rightarrow D$ paths.

Moreover, p_i^* is a feasible price function of $G''_{f_{i+1}}$ for any choice of $P_i = Q_j, j = 0, \dots, k$. Hence, the reduced cost wrt. p_i^* of any $e^R \in Q_j$, is non-negative. Therefore, in fact p_i^* is a feasible price function of all $G''_{f_{i+1}}, G''_{f_{i+2}}, \dots, G''_{f_{i+k+1}}$. On the other hand, since for all $e \in P_i \cup \dots \cup P_{i+k}$, the reduced cost (wrt. p_i^*) of e^R is positive, and the set Q_0, \dots, Q_k was maximal, we conclude that there is no $s \rightarrow t$ path in $G''_{f_{i+k+1}}$ consisting only of edges with reduced cost (wrt. p_i^*) 0. But $p_i^*(s) - p_i^*(t) = \Delta_i$, so by Lemma 11 we have $\Delta_{i+k+1} > \Delta_i$.

Since we can choose a maximal set Q_0, \dots, Q_k using a DFS-style procedure in $O(m)$ time (for details, see Section 4.3, where we take a closer look at it to implement it faster in the planar case), we can actually move from f_i to f_{i+k+1} and simultaneously increase Δ in $O(m)$ time. Since p_i^* is a feasible price function of $G''_{f_{i+k+1}}$, the new price function p_{i+k+1}^* can be computed, again, using Dijkstra's algorithm. The total running time of this algorithm is $O(m + n \log n)$ times the number of times Δ increases.

► **Lemma 12.** *The value Δ changes $O(\sqrt{m})$ times.*

Proof. By Lemma 9, Δ can only increase, and if it does, it increases by at least $\epsilon/2$. After it increases $2\sqrt{m}$ times, $\Delta \geq \epsilon\sqrt{m}$. But then, by Lemma 10, Ψ_f is no more than $6\sqrt{m}$. As each change of Δ is accompanied with some decrease of Ψ_f , Δ can change $O(\sqrt{m})$ times more. ◀

► **Theorem 13.** *REFINE as implemented in Algorithm 2 runs in $O((m + n \log n)\sqrt{m})$.*

We can in fact improve the running time to $O(m\sqrt{m})$ by taking advantage of so-called Dial's implementation of Dijkstra's algorithm [9]. The details are deferred to the full version.

3.3 Bounding the Total Length of Augmenting Paths

► **Fact 14.** *For every $e \in E$ we have $c'(e) + c'(e^R) > \epsilon$.*

Proof. We have $c'(e) > c(e) + \epsilon/2$. Hence, $c'(e) + c'(e^R) > c(e) + \epsilon/2 + c(e^R) + \epsilon/2 = \epsilon$. ◀

There is a subtle reason why we set $c'(e)$ to be $\text{round}(c(e) + \epsilon/2, \epsilon/2)$ instead of $\text{round}(c(e), \epsilon)$. Namely, this allows us to obtain the following bound.

► **Lemma 15.** *For any $i = 1, \dots, q$ we have $c'(f_{i+1}) - c'(f_i) < \Delta_i - \frac{1}{2}|P_i| \cdot \epsilon$.*

Proof. We have

$$c'(f_{i+1}) - c'(f_i) = \frac{1}{2} \sum_{e \in E} (f_{i+1}(e) - f_i(e))c'(e) = \frac{1}{2} \sum_{e \in P_i} (c'(e) - c'(e^R)).$$

By Fact 14, $-c'(e^R) < c'(e) - \epsilon$ for all $e \in E$. Hence

$$c'(f_{i+1}) - c'(f_i) < \sum_{e \in P_i} c'(e) - \frac{1}{2}|P_i| \cdot \epsilon = \Delta_i - \frac{1}{2}|P_i| \cdot \epsilon. \quad \blacktriangleleft$$

► **Lemma 16.** *Let f^* be any flow. Then $c(f_0) - c(f^*) \leq 2\epsilon m$.*

Proof. We have

$$c(f_0) - c(f^*) = \frac{1}{2} \sum_{e \in E} (f_0(e) - f^*(e))c(e).$$

If $f_0(e) > f^*(e)$, then $e^R \in E_{f_0}$ and hence $c(e^R) \geq -2\epsilon$, and thus $c(e) \leq 2\epsilon$. Otherwise, if $f_0(e) < f^*(e)$ then $e \in E_{f_0}$ and $c(e) \geq -2\epsilon$.

In both cases $(f_0(e) - f^*(e))c(e) \leq 2\epsilon$. Therefore, since $|E| = 2m$, $c(f_0) - c(f^*) \leq 2\epsilon m$. ◀

► **Lemma 17.** *Let f^* be any flow. Then $|c'(f^*) - c(f^*)| \leq \epsilon m$.*

Proof. Recall that we had $0 < c'(e) - c(e) \leq \epsilon$. Hence $|f^*(e)(c'(e) - c(e))| \leq \epsilon$ and:

$$|c'(f^*) - c(f^*)| = \frac{1}{2} \left| \sum_{e \in E} f^*(e)(c'(e) - c(e)) \right| \leq \frac{1}{2} \sum_{e \in E} |f^*(e)(c'(e) - c(e))| \leq \frac{1}{2} \sum_{e \in E} \epsilon = \epsilon m. \quad \blacktriangleleft$$

The inequalities from Lemmas 15, 16 and 17 combined give us the following important property of the set of paths we augment along.

► **Lemma 18.** *The total number of edges on all the paths we send flow through is $O(m \log m)$.*

Proof. By Lemma 16 and the fact that $c(f_1) \leq c(f_0)$, we have:

$$c(f_1) - c(f_{q+1}) \leq c(f_0) - c(f_{q+1}) \leq 2\epsilon m.$$

On the other hand, by Lemma 17 and Lemma 15, we obtain:

$$\begin{aligned} c(f_1) - c(f_{q+1}) &\geq (c'(f_1) - \epsilon m) + (-c'(f_{q+1}) - \epsilon m) = c'(f_1) - c'(f_{q+1}) - 2\epsilon m \\ &= \sum_{i=1}^q (c'(f_i) - c'(f_{i+1})) - 2\epsilon m \geq \sum_{i=1}^q \left(\frac{1}{2}|P_i| \cdot \epsilon - \Delta_i\right) - 2\epsilon m. \end{aligned}$$

By combining the two inequalities and applying Lemma 10, we get:

$$\sum_{i=1}^q \frac{1}{2}|P_i| \leq 4m + \sum_{i=1}^q \frac{\Delta_i}{\epsilon} \leq 4m + \sum_{i=1}^q \frac{6m}{\Psi_{f_i}} = 4m + \sum_{i=1}^q \frac{6m}{q-i+1} = O(m \log m). \quad \blacktriangleleft$$

4 Unit-Capacity Min-Cost Circulation in Planar Graphs

In this section we show that the refinement algorithm per scale from Section 3 can be simulated on a planar digraph more efficiently. Specifically, we prove the following theorem.

► **Theorem 19.** *REFINE can be implemented on a planar graph in $\tilde{O}((nm)^{2/3})$ time.*

Let $r \in [1, n]$ be a parameter. Suppose we are given an r -division with few holes $\mathcal{P}_1, \dots, \mathcal{P}_\lambda$ of G such that for any i we have $\lambda = O(n/r)$, $|V(\mathcal{P}_i)| = O(r)$, $|\partial\mathcal{P}_i| = O(\sqrt{r})$, $\partial\mathcal{P}_i$ lies on $O(1)$ faces of \mathcal{P}_i , and the pieces are edge-disjoint. We set $\partial G = \bigcup_{i=1}^\lambda \partial\mathcal{P}_i$. Clearly, $|\partial G| = O(n/\sqrt{r})$.

In the full version we show that we can reduce our instance to the case when the above assumptions are satisfied in nearly-linear time.

Since m might be $\omega(n)$, we cannot really guarantee that $|E(\mathcal{P}_i)| = O(r)$. This will not be a problem though, since, as we will see, for all the computations involving the edges of \mathcal{P}_i (e.g., computing shortest paths in \mathcal{P}_i , or sending a unit of flow through a path of \mathcal{P}_i) of all edges $uv = e \in E(\mathcal{P}_i)$ we will only care about an edge $e \in E(\mathcal{P}_i) \cap G_f$ with minimal cost $c'(e)$. Therefore, since \mathcal{P}_i is planar, at any time only $O(r)$ edges of \mathcal{P}_i will be needed.

Recall that the per-scale algorithm for general graphs (Algorithm 2) performed $O(\sqrt{m})$ phases, each consisting of two steps: a shortest path computation (to compute the price function p^* from Lemma 9), followed by the computation of a maximal set of edge-disjoint augmenting paths of reduced (wrt. p^*) cost 0. We will show how to implement both steps in $\tilde{O}(n/\sqrt{r})$ amortized time, at the additional total data structure maintenance cost (over all phases) of $\tilde{O}(mr)$. Since there are $O(\sqrt{m})$ steps, this will yield $\tilde{O}(nm)^{2/3}$ time by appropriately setting r .

We can maintain the flow f explicitly, since it undergoes only $O(m \log n)$ edge updates (by Lemma 18). However, we will not compute the entire price function p^* at all times explicitly, as this is too costly. Instead, we will only compute p^* limited to the subset $\partial G \cup \{s, t\}$.

For each \mathcal{P}_i , define $\mathcal{P}'_{f,i} = G'_f \cap \mathcal{P}_i$. We also define $\mathcal{P}''_{f,i}$ to be $\mathcal{P}'_{f,i}$ with vertices $\{s, t\}$ added, and those edges sv, vt of G''_f that satisfy $v \in V(\mathcal{P}_i) \setminus \partial\mathcal{P}_i$. This way, $\mathcal{P}''_{f,i} \subseteq G''_f$ and $E(\mathcal{P}''_{f,i}) \cap E(\mathcal{P}''_{f,j}) = \emptyset$ for $i \neq j$. The costs of edges $e \in E(\mathcal{P}''_{f,i})$ are the same as in G''_f , i.e., $c'(e)$. Besides, for each i we will store a “local” price function p_i that is feasible only for $\mathcal{P}''_{f,i}$.

After the algorithm finishes, we will know how the circulation looks like precisely. However, the general scaling algorithm requires us to also output price function p such that f is an ϵ -optimal circulation wrt. p . f is ϵ -optimal wrt. p^* in the end, but we will only have it computed for the vertices $\partial G \cup \{s, t\}$. Therefore, we extend it to all remaining vertices of G .

► **Lemma 20.** *Suppose we are given the values of p^* on $\partial\mathcal{P}_i$ and a price function p_i feasible for $\mathcal{P}_{f,i}''$. Then we can compute the values $p^*(u)$ for all $v \in V(\mathcal{P}_{f,i}'')$ in $O(r \log r)$ time.*

Hence, in order to extend p^* to all vertices of G once the final circulation is found, we apply Lemma 20 to all pieces. This takes $O(\frac{n}{r} \cdot r \log r) = O(n \log n)$ time.

4.1 Dijkstra Step

Let us start with an implementation of the Dijkstra step computing the new price function p^* . First, for each piece \mathcal{P}_i we define the compressed version $H_{f,i}''$ of $\mathcal{P}_{f,i}''$ as follows. Let $V(H_{f,i}'') = \partial\mathcal{P}_i \cup \{s, t\}$. The set of edges of $H_{f,i}''$ is formed by:

- a distance clique $\text{DC}(\mathcal{P}_{f,i}'')$ between vertices $\partial\mathcal{P}_i$ in $\mathcal{P}_{f,i}''$,
- for each $v \in \partial\mathcal{P}_i$, an edge sv of cost $\delta_{\mathcal{P}_{f,i}''}(s, v)$ if this distance is finite,
- for each $v \in \partial\mathcal{P}_i$, an edge vt of cost $\delta_{\mathcal{P}_{f,i}''}(v, t)$ if this distance is finite,
- an edge st of cost $\delta_{\mathcal{P}_{f,i}''}(s, t)$ if this distance is finite.

Recall that we store a price function p_i of $\mathcal{P}_{f,i}''$. Therefore, by Theorem 2, $\text{DC}(\mathcal{P}_{f,i}'')$ can be computed in $O(r \log r)$ time. All needed distances $\delta_{\mathcal{P}_{f,i}''}(s, v)$ and $\delta_{\mathcal{P}_{f,i}''}(v, t)$ can be computed in $O(r \log r)$ time using Dijkstra's algorithm (again, with the help of price function p_i).

Now define H_f'' to be $\bigcup_{i=1}^{\lambda} H_{f,i}''$ with edges sv and vt of G_f'' that satisfy $v \in \partial G$ added.

► **Fact 21.** *For any $u, v \in V(H_f'')$, $\delta_{H_f''}(u, v) = \delta_{G_f''}(u, v)$.*

Observe that H_f'' is a dense distance graph in terms of the definition of Section 2: it consists of $O(n/r)$ distance cliques $\text{DC}(\mathcal{P}_{f,i}'')$ with $O(\sqrt{r})$ vertices each, and $O(n/\sqrt{r})$ additional edges which also can be interpreted as 2-vertex distance cliques.

Hence, given a feasible price function on H_f'' , we can compute distances to t in H_f'' on it using Theorem 3 in $O\left(n/\sqrt{r} \cdot \frac{\log^2 n}{\log^2 \log n}\right)$ time. Since $V(H_f'') = \partial G \cup \{s, t\}$, the price function p^* we have is indeed sufficient. The computed distances to t form the new price function p^* on $\partial G \cup \{s, t\}$ as in the algorithm for general graphs (see Algorithm 2).

4.2 Sending Flow Through a Path

In the general case updating the flow after an augmenting path has been found was trivial. However, as we operate on a compressed graph, the update procedure has to be more involved.

Generally speaking, we will repeatedly find some shortest $s \rightarrow t$ path $Q = e_1 \dots e_k$ in H_f'' , translate it to a shortest $s \rightarrow t$ path \mathcal{P} in G_f'' and send flow through it. It is easy to see by the definition of H_f'' that Q can be translated to a shortest $s \rightarrow t$ path in G_f'' and vice versa. Each edge e_j can be translated to either some subpath inside a single graph $\mathcal{P}_{f,i}''$, or an edge of G_f'' of the form sv or vt , where $v \in \partial G$. This can be done in $O(r \log n)$ time by running Dijkstra's algorithm on $\mathcal{P}_{f,i}''$ with price function p_i . We will guarantee that path P obtained by concatenating the translations of individual edges e_j contains no repeated edges of G_f'' .

We now show how to update each $H_{f,i}''$ after sending flow through the found path P . Note that we only need to update $H_{f,i}''$ if $E(P) \cap E(\mathcal{P}_{f,i}'') \neq \emptyset$. In such case we call \mathcal{P}_i an *affected piece*. Observe that some piece can be affected at most $O(m \log m)$ times since the total number of edges on all shortest augmenting paths P in the entire algorithm, regardless of their choice, is $O(m \log m)$ (see Lemma 18).

To rebuild $H_{f,i}''$ to take into account the flow augmentation we will need a feasible price function on $\mathcal{P}_{f,i}''$ after the augmentation. However, we cannot be sure that what we have, i.e., p_i , will remain a good price function of $\mathcal{P}_{f,i}''$ after the augmentation. By Lemma 9, luckily, we know that p^* is a feasible price function after the augmentation for the whole

graph G_f'' . In particular, p^* (before the augmentation) limited to $V(\mathcal{P}_{f,i}'')$ is a feasible price function of $\mathcal{P}_{f,i}''$ after the augmentation. Hence, we can compute new p_i equal to p^* using Lemma 20 in $O(r \log r)$ time. Given a feasible price function p_i on $\mathcal{P}_{f,i}''$ after f is augmented, we can recompute $H_{f,i}''$ in $O(r \log r)$ time as discussed in Section 4.1. We conclude that the total time needed to update the graph H_f'' subject to flow augmentations is $O(mr \log r \log m) = O(mr \log n \log m)$.

4.3 A Path Removal Algorithm

In this section we consider an abstract “path removal” problem, that generalizes the problem of finding a maximal set of edge-disjoint $s \rightarrow t$ paths. We will use it to reduce the problem of finding such a set of paths on a subgraph of G_f'' consisting of edges with reduced cost 0 wrt. p^* to the problem of finding such a set of paths on the zero-reduced cost subgraph of H_f'' .

Suppose we have some directed acyclic graph H with a fixed source s and sink t , that additionally undergoes some limited adversarial changes. We are asked to efficiently support a number of *rounds*, until t ceases to be reachable from s . Each round goes as follows.

1. We first find either any $s \rightarrow t$ path P , or detect that no $s \rightarrow t$ path exists.
2. Let $E^+ \subseteq V \times V$, and $P \subseteq E^- \subseteq E(H)$ be some adversarial sets of edges. Let $H' = (V, E')$, where $E' = E(H) \setminus E^- \cup E^+$. Assume that for any $v \in V(H)$, if v cannot reach t in H , then v cannot reach t in H' either. Then the adversarial change is to remove E^- from E and add E^+ to E , i.e., set $E(H) = E'$.

Let $\bar{n} = |V(H)|$ and let \bar{m} be the number of edges ever seen by the algorithm, i.e., the sum of $|E(H)|$ and all $|E^+|$. We will show an algorithm that finds all the paths P in $O(\bar{n} + \bar{m})$ total time. Let us also denote by $\bar{\ell}$ the sum of lengths of all returned paths P . Clearly, $\bar{\ell} \leq \bar{m}$.

A procedure handling the phase 1 of each round, i.e., finding a $s \rightarrow t$ path or detecting that there is none, is given in Algorithm 3. The second phase of each round simply modifies the representation of the graph H accordingly. Throughout all rounds, we store a set W of vertices w of H for which we have detected that there is no more $w \rightarrow t$ path in H . Initially, $W = \emptyset$. Each edge $e \in E(H)$ can be *scanned* or *unscanned*. Once e is scanned, it remains scanned forever. The adversarial edges E^+ that are inserted to $E(H)$ are initially unscanned. The following lemmas establishing the correctness and efficiency of the crucial parts of Algorithm 3 are all proved in the full version.

■ **Algorithm 3** Path-finding procedure. Returns a $s \rightarrow t$ path in H or detects there is none.

```

1: procedure FINDPATH( $H$ )
2:    $Q :=$  an empty path with a single endpoint  $s$                                 ▷  $Q$  is an  $s \rightarrow s$  path
3:   while  $s \notin W$  and the other endpoint  $y$  of  $Q$  is not equal to  $t$  do          ▷  $Q$  is an  $s \rightarrow y$  path
4:     if there exists an unscanned edge  $yv = e \in E(H)$  such that  $v \notin W$  then
5:       mark  $e$  scanned
6:        $Q := Qe$ 
7:     else
8:        $W := W \cup \{y\}$ 
9:       remove the last edge of  $Q$  unless  $Q$  is empty
10:  if  $Q = \emptyset$  then
11:    report  $t$  not reachable from  $s$  and stop
12:  else
13:    return  $Q$  and  $Q := 0$ .

```

► **Lemma 22.** *Algorithm 3 correctly finds an $s \rightarrow t$ path in H or detects there is none.*

► **Lemma 23.** *The total number of times line 9 is executed, through all rounds, is $O(\bar{n})$.*

► **Lemma 24.** *Line 6 of Algorithm 3 is executed $O(\bar{n} + \bar{\ell})$ times through all rounds.*

► **Lemma 25.** *The total time used by Algorithm 3, through all rounds, is $O(\bar{n} + \bar{m})$.*

4.4 Finding a Maximal Set of Shortest Augmenting Paths

Recall that for a general graph, after computing the price function p^* we found a maximal set of edge-disjoint $s \rightarrow t$ paths in the graph Z_f'' , defined as a subgraph of G_f'' consisting of edges with reduced cost 0 (wrt. p^*). To accomplish that, we could in fact use the path removal algorithm from Section 4.3 run on Z_f'' : until there was an $s \rightarrow t$ path in Z_f'' , we would find such a path P , remove edges of P (i.e., set $E^- = P$ and $E^+ = \emptyset$), and repeat. Since in this case we never add edges, the assumption that t cannot become reachable from any v due to updating Z_f'' is met.

Let Y_f'' be the subgraph of the graph H_f'' from Section 4.1 consisting of edges with reduced (wrt. p^*) cost 0. Since all edges of H_f'' correspond to shortest paths in G_f'' , all edges of Y_f'' correspond to paths in G_f'' with reduced cost 0. Because Z_f'' is acyclic by Lemma 9, Y_f'' is acyclic as well. Moreover, for any two edges $e_1, e_2 \in E(Y_f'')$, if there is a path going through both e_1 and e_2 in Y_f'' , then the paths represented by e_1 and e_2 are edge-disjoint in Z_f'' (as otherwise Z_f'' would have a cycle). Therefore, any path Q in Y_f'' translates to a simple path in $Z_f'' \subseteq G_f''$.

We will now explain why running Algorithm 3 on Y_f'' can be used to find a maximal set of edge-disjoint $s \rightarrow t$ paths. Indeed, by Fact 21, Y_f'' contains an $s \rightarrow t$ path iff Z_f'' does. Since Y_f'' is just a compressed version of Z_f'' , and Z_f'' undergoes edge deletions only (since we only remove the found paths), the updates to Y_f'' cannot make some t reachable from some new vertex $v \in V(Y_f'')$. Technically speaking, we should think of Y_f'' as undergoing both edge insertions and deletions: whenever some path $Q \subseteq Y_f''$ is found, we include Q in E^- and send the flow through a path corresponding to Q in G_f'' , as described in Section 4.2. But then for all affected pieces \mathcal{P}_i , $H_{f,i}''$ is recomputed and thus some of the edges of Q might be reinserted to Y_f'' again. These edges should be seen as forming the set E^+ , whereas the old edges of the recomputed graphs $H_{f,i}''$ belong to E^- . In terms of the notation of Section 4.3, when running Algorithm 3 on Y_f'' , we have $\bar{n} = O(n/\sqrt{r})$. The sum of values $\bar{\ell}$ from Section 4.3 over all phases of the algorithm is, by Lemma 18, $O(m \log m)$. Similarly, again by Lemma 18, the sum of the values \bar{m} from Section 4.3 over all phases, is $O(m^{3/2} + mr^2 \log m)$ (since each time E^+ might be as large as r^2 times the number of affected pieces).

Recall that there are $O(\sqrt{m})$ phases, and the total time needed to maintain the graph H_f'' subject to flow augmentations is $O(mr \log r \log m)$ (see Section 4.2). For each phase, running a Dijkstra step to compute p^* using FR-Dijkstra, followed by running Algorithm 3 directly until there are no $s \rightarrow t$ paths in Y_f'' would lead to $O\left(\sqrt{m} \left(\frac{n}{\sqrt{r}} \frac{\log^2 n}{\log^2 \log n}\right) + m^{3/2} + mr^2 \log m\right)$ total time, i.e., would not yield any improvement over the general algorithm. However, we can do better by implementing Algorithm 3 on Y_f'' more efficiently.

► **Lemma 26** ([21, 24]). *Let Z be the subgraph of $\mathcal{P}'_{f,i}$ consisting of edges with reduced cost 0 with respect to some feasible price function p . There exists $O(\sqrt{r})$ pairs of subsets $(A_{i,1}, B_{i,1}), (A_{i,2}, B_{i,2}), \dots$ of $\partial\mathcal{P}_i$ such that for each $v \in \partial\mathcal{P}_i$:*

- *The number of sets $A_{i,j}$ ($B_{i,j}$) such that $v \in A_{i,j}$ ($v \in B_{i,j}$, resp.) is $O(\log r)$.*
- *Each $B_{i,j}$ is totally ordered according to some order $\prec_{i,j}$.*

- For any j such that $v \in A_{i,j}$, there exist $l_{i,v,j}, r_{i,v,j} \in B_{i,j}$ such that the subset $R_{i,v}$ of $\partial\mathcal{P}_i$ reachable from v in Z can be expressed as $\bigcup_{j:v \in A_{i,j}} \{w \in B_{i,j} : l_{i,v,j} \preceq_{i,j} w \preceq_{i,j} r_{i,v,j}\}$. The sets $A_{i,j}$, $B_{i,j}$ and the vertices $l_{i,v,j}, r_{i,v,j}$ for all v, j can be computed in $O(\sqrt{r} \log r)$ time based on the distance clique between $\partial\mathcal{P}_i$ in $\mathcal{P}'_{f,i}$ and the values of p^* on $\partial\mathcal{P}_i$.

Recall that in Section 4.3, to bound the total running time, it was enough to bound the total time spent on executing lines 4, 6 and 9. We will show that using Lemma 26, in terms of the notation from Section 4.3, we can make the total time spent on executing line 4 only $\tilde{O}(\bar{n} + \bar{\ell})$ instead of $O(\bar{m})$, at the cost of increasing the total time of executing line 9 to $\tilde{O}(\bar{n})$.

Specifically, at the beginning of each phase we compute the data from Lemma 26 for all pieces \mathcal{P}_i . Since for all i we have the distance cliques $\text{DC}(\mathcal{P}''_{f,i})$ computed, this takes $O(\frac{n}{r} \cdot \sqrt{r} \log r) = O(n/\sqrt{r} \log n)$ time. We will also recompute the information of Lemma 26 for an affected piece \mathcal{P}_i after $H''_{f,i}$ is recomputed. As the total number of times some piece is affected is $O(m \log m)$, this takes $O(m\sqrt{r} \log r \log m)$ time through all phases.

Whenever the data of Lemma 26 is computed for some piece \mathcal{P}_i , for each pair $(A_{i,j}, B_{i,j})$ we store $B_{i,j} \cap W$ in a dynamic predecessor/successor data structure $D_{i,j}$, sorted by $\prec_{i,j}$. For each $v \in \partial\mathcal{P}_i$ and j such that $v \in A_{i,j}$ we store a vertex $next_{i,v,j}$ initially equal to $l_{i,v,j}$. It is easy to see that these auxiliary data structures can be constructed in time linear in their size, i.e., $O(\sqrt{r} \log r)$ time. Hence, the total cost of computing them is $O(\sqrt{mn}/\sqrt{r} \log n + m\sqrt{r} \log r \log m) = O\left(\sqrt{m}\left(\frac{n}{\sqrt{r}} \frac{\log^2 n}{\log^2 \log n}\right) + mr \log n \log m\right)$.

Now, to implement line 9, when y is inserted into W we go through all pieces \mathcal{P}_i such that $y \in \partial\mathcal{P}_i$ and all $B_{i,j}$ such that $y \in B_{i,j}$. For each such (i, j) , we remove y from $D_{i,j}$ in $O(\log \log n)$ time. Recall that the sum of numbers of such pairs (i, j) over all $v \in \partial G$ is $O(\sum_{i=1}^{\lambda} |\partial\mathcal{P}_i| \log r) = O(n/\sqrt{r} \log n)$. Hence, by Lemma 23 the total time spent on executing line 9 in a single phase is $O(n/\sqrt{r} \log n \log \log n)$.

Finally, we implement line 4 as follows. The unscanned edges of Y_f'' that are not between boundary vertices are handled in a simple-minded way as in Lemma 25. There are only $O(n/\sqrt{r})$ of those, so we can neglect them. In order to be able to efficiently find some unscanned edge yv such that $y, v \in \partial G$ and $v \notin W$, we keep for any $v \in \partial G$ a set U_v of pieces \mathcal{P}_i such that $v \in \partial\mathcal{P}_i$ and there may still be some unscanned edges from v to $w \in \partial\mathcal{P}_i$ in $H''_{f,i}$. Similarly, for each $\mathcal{P}_i \in U_v$ we maintain a set $U_{v,i}$ of data structures $D_{i,j}$ such that $next_{i,v,j} \neq \mathbf{nil}$. Whenever the data of Lemma 26 is computed for \mathcal{P}_i , \mathcal{P}_i is inserted back to U_v for all $v \in \partial\mathcal{P}_i$, and the sets $U_{v,i}$ are recomputed with no additional asymptotic overhead. To find an unscanned edge yv , for each $\mathcal{P}_i \in U_y$ we proceed as follows. We attempt to find an unscanned edge yv in \mathcal{P}_i . If we succeed or U_y is empty, we stop. Otherwise we remove \mathcal{P}_i from U_y and repeat, i.e., try another $\mathcal{P}_j \in U_y$, unless U_y is empty. To find an unscanned edge yv from a piece \mathcal{P}_i , we similarly try to find an unscanned edge yv in subsequent data structures $D_{i,j} \in U_{v,i}$, and remove the data structures for which we fail from $U_{v,i}$. For a single data structure $D_{i,j}$, we maintain an invariant that an edge yw , $w \in D_{i,j}$ has been scanned iff $w \prec_{i,j} next_{i,v,j}$. Hence, to find the next unscanned edge, we first find $x \in D_{i,j}$ such that $next_{i,v,j} \preceq_{i,j} x$ and x is smallest possible. This can be done in $O(\log \log n)$ time since $D_{i,j}$ is a dynamic successor data structure. If x does not exist or $r_{i,v,j} \prec x$, then, by Lemma 26, there are no more unscanned edges yw such that $w \in D_{i,j}$, and thus we remove $D_{i,j}$ from $U_{v,i}$. Otherwise, we return an edge yx and set $next_{i,v,j}$ to be the successor of x in $D_{i,j}$ (or possibly $next_{i,v,j} := \mathbf{nil}$ if none exists), again in $O(\log \log n)$ time.

Observe that all “failed” attempts to find an edge yv , where $v \in \partial G$ can be charged to an insertion of some \mathcal{P}_i to U_y or to an insertion of some $D_{i,j}$ to $U_{v,i}$. The total number of such insertions is again $O\left(\sqrt{m} \frac{n}{\sqrt{r}} \log n + m\sqrt{r} \log r \log m\right)$. A successful at-

tempt, on the other hand, costs $O(\log \log n)$ worst-case time. Since line 4 is executed $O(\sqrt{mn}/\sqrt{r} + m \log n)$ times through all phases, the total time spent on executing line 4 is again $O\left(\sqrt{m}\left(\frac{n}{\sqrt{r}} \frac{\log^2 n}{\log n}\right) + mr \log n \log m\right)$. By setting $r = \frac{n^{2/3}}{m^{1/3}} \cdot \left(\frac{\log n}{\log m \cdot \log^2 \log n}\right)^{2/3}$ we obtain the main result of this paper.

► **Theorem 27.** *The min-cost circulation in a planar multigraph can be found in $O\left((nm)^{2/3} \cdot \frac{\log^{5/3} n \log^{1/3} m}{\log^{4/3} \log n} \cdot \log(nC)\right)$ time.*

Abstract

Due to its many applications, *curve simplification* is a long-studied problem in computational geometry and adjacent disciplines, such as graphics, geographical information science, etc. Given a polygonal curve P with n vertices, the goal is to find another polygonal curve P' with a smaller number of vertices such that P' is sufficiently similar to P . Quality guarantees of a simplification are usually given in a *local* sense, bounding the distance between a shortcut and its corresponding section of the curve. In this work we aim to provide a systematic overview of curve simplification problems under *global* distance measures that bound the distance between P and P' . We consider six different curve distance measures: three variants of the *Hausdorff* distance and three variants of the *Fréchet* distance. And we study different restrictions on the choice of vertices for P' . We provide polynomial-time algorithms for some variants of the global curve simplification problem, and show NP-hardness for other variants. Through this systematic study we observe, for the first time, some surprising patterns, and suggest directions for future research in this important area.

■ **Figure 1** For a target distance δ , the red curve (middle) is a global simplification of the input curve (left), but it is not a local simplification, since the first shortcut does not closely represent its corresponding curve section (right). The example works for both Hausdorff and Fréchet distance.

sufficiently similar to P . Classical algorithms for this problem famously include a simple recursive scheme by Douglas and Peucker [16], and a more involved dynamic programming approach by Imai and Iri [21]; both are frequently implemented and cited. Since then, numerous further results on curve simplification, often in specific settings or under additional constraints, have been obtained [1, 2, 6, 11, 12, 14, 8, 18, 20].

Despite its popularity, the Douglas-Peucker algorithm comes with no provable quality guarantees. The method by Imai and Iri, though slower, was introduced as an alternative which does supply guarantees: it finds an optimal shortest path in a graph in which potential shortcuts are marked as either *valid* or *invalid*, based on their distance to the corresponding sections of the input curve. However, Agarwal et al. [2] note that the Imai-Iri algorithm does not actually globally optimize any distance measure between the original curve P and the simplification P' . This work initiated a more formal study of curve simplification; van Kreveld et al. [24] systematically show that both Douglas-Peucker and Imai-Iri may indeed produce far-from-optimal results.

This raises a question of what it means for a simplification to be optimal. We may view it as a dual-optimization problem: we wish to minimize the number of vertices of P' given a constraint on its similarity to P . This depends on the distance measure used; popular curve distance measures include the *Hausdorff* and *Fréchet* distances (variants and formal definitions are discussed in Section 2.1). However, the difference in interpretation between Agarwal et al. and Imai and Iri lies not so much in the choice of distance measure, but rather what exactly it is applied to. In fact, the Imai-Iri algorithm is optimal in a *local* sense: it outputs a subsequence of the vertices of P such that the Hausdorff distance between each shortcut and *its corresponding section of the input* is bounded: each shortcut approximates the section of P between the vertices of the shortcut.

In this work, we underline this difference by using the term *global* simplification when a bound on a distance measure must be satisfied between P and P' (formal definition in Section 2.3), and *local* simplification when a bound on a distance measure must be satisfied between each edge of P' and its corresponding section of P . Clearly, a local simplification is also a global simplification, but the reverse is not necessarily true, see Figure 1. Both local and global simplifications have their merits: one can imagine situations where it is important that each segment of a simplified curve is a good representation of the curve section it replaces, but in other applications (e.g., visualization) it is really the similarity of the overall result to the original that matters. Most existing work on curve simplification falls in the *local* category. In this work, we focus on *global* curve simplification.

1.1 Existing Work on Global Curve Simplification

Surprisingly, only a few results on simplification under global distance measures are known [2, 7, 10, 24]; consequently, what makes the problem difficult is not well understood.

Agarwal et al. [2] first consider the idea of global simplification. They introduce what they call a *weak simplification*: a model in which the vertices of the simplification are not restricted to be a subset of the input vertices, but can lie anywhere in the ambient space.¹ Interestingly, they compare this to a *local* simplification where vertices are restricted to be a subset of the input. We may interpret a combination of two of their results (Theorem 1.2 and Theorem 4.1) as an approximation algorithm for global curve simplification with unrestricted vertices under the Fréchet distance: for a given curve P and threshold δ one can compute, in $O(n \log n)$ time, a simplification P' which has at most the number of vertices of an optimal simplification with threshold $\delta/8$.

Bereg et al. [7] first explicitly consider global simplification in the setting where vertices are restricted to be a subsequence of input vertices, but using the *discrete Fréchet distance*: a variant of the Fréchet distance which only measures distances between vertices (refer to Section 2.1). They show how to compute an optimal simplification where vertices are restricted to be a subsequence in $O(n^2)$ time, and they give an $O(n \log n)$ time algorithm for the setting where vertices may be placed freely.

Van Kreveld et al. [24] consider the same (global distance, but vertices should be a subsequence) setting, but for the continuous Fréchet and Hausdorff distances. They give polynomial-time algorithms for the Fréchet distance and directed Hausdorff distance (from simplification curve to input curve), but they show the problem is NP-hard for the directed Hausdorff distance in the opposite direction and for the undirected Hausdorff distance. Recently, Bringmann and Chaudhury [10] improved their result for the Fréchet distance to $O(n^3)$, and also give a conditional cubic lower bound.

Finally, we mention there is earlier work which does not explicitly study simplification under global distance measures, but contains results that may be reinterpreted as such. Guibas et al. [19] provide algorithms for computing minimum-link paths that stab a sequence of regions in order. One of the variants, presented in Theorems 10 and 14 of [19], computes what may be seen as an optimal simplification under the Fréchet distance with no vertex restrictions, i.e., the same setting that was studied by Agarwal et al., in $O(n^2 \log^2 n)$ time.

2 Classification

We aim to provide a systematic overview of curve simplification problems under global distance measures. To this end, we have collected known results and arranged them in a table (Table 1), and provide several new results to complement these (refer to Section 2.4). This allows us for the first time to observe some surprising patterns, and it suggests directions for future research in this important area. We first discuss the dimensions of the table.

2.1 Distance Measures

For our study, we consider six different curve distance measures: three variants of the *Hausdorff* distance and three variants of the *Fréchet* distance. These are among the most popular curve distance measures in the algorithms literature. The Hausdorff distance captures the maximum distance from a point on one curve to a point on the other curve. The variants of the Hausdorff distance we consider are the directed Hausdorff distance from the input to the output, the directed Hausdorff distance from the output to the input, and the undirected

¹ We choose not to adopt the terms *weak* and *strong* in this context because we will also distinguish an intermediate model, and to avoid confusion with the *weak Fréchet* distance; refer to Section 2.2.

Figure 2 Globally simplified curves under Fréchet distance (left) and Hausdorff distance (right). The vertex-restricted case (in red) requires 5 vertices for Fréchet distance and 8 vertices for the Hausdorff distance. The curve-restricted case (in blue) requires 4 vertices for Fréchet distance and 6 vertices for the Hausdorff distance. The non-restricted case (in green) requires only 3 vertices for Fréchet distance and only 5 vertices for the Hausdorff distance. The δ -neighborhoods for the original curves are shown in yellow.

(or bidirectional) Hausdorff distance. The Fréchet distance captures the maximum distance between a pair of points traveling along the two curves simultaneously. We now formally define all six distance measures.

Let $P = \langle p_1, p_2, \dots, p_n \rangle$ be the input polygonal curve. We treat P as a continuous map $P : [1, n] \rightarrow \mathbb{R}^d$, where $P(i) = p_i$ for integer i , and the i -th edge is linearly parametrized as $P(i + \lambda) = (1 - \lambda)p_i + \lambda p_{i+1}$. We write $P[s, t]$ for the subcurve between $P(s)$ and $P(t)$ and denote the *shortcut*, i.e., the straight line connecting them, by $\langle P(s)P(t) \rangle$.

The *Fréchet distance* between two polygonal curves P and Q , with n and m vertices, respectively, is $F(P, Q) = \inf_{(\sigma, \theta)} \max_t \|P(\sigma(t)) - Q(\theta(t))\|$, where σ and θ are continuous non-decreasing functions from $[0, 1]$ to $[1, n]$ and $[1, m]$, respectively. If σ and θ are continuous but not necessarily monotone, the resulting infimum is called the *weak Fréchet distance*. Finally, the *discrete Fréchet distance* is a variant where σ and θ are discrete functions from $\{1, \dots, k\}$ to $\{1, \dots, n\}$ and $\{1, \dots, m\}$ with the property that $|\sigma(i) - \sigma(i + 1)| \leq 1$.

The *directed Hausdorff distance* between two polygonal curves (or more generally, compact sets) P and Q is defined as $\vec{H}(P, Q) = \max_{p \in P} \min_{q \in Q} \|p - q\|$. The *undirected Hausdorff distance* is then simply the maximum over the two directions: $H(P, Q) = \max\{\vec{H}(P, Q), \vec{H}(Q, P)\}$.

2.2 Vertex Restrictions

Once we have fixed the distance measure and agreed that we wish to apply it globally, one important design decision still remains to be made. Traditional curve simplification algorithms consider the (polygonal) input curve P to be a sequence of points, and produce

■ **Table 1** Known and new results (in blue) for the GCS problem under global distance measures.

Distance	Vertex-restricted (\mathcal{V})	Curve-restricted (\mathcal{C})	Non-restricted (\mathcal{N})
$\overleftarrow{\mathbf{H}}(P, \delta)$	strongly NP-hard [24]	weakly NP-hard (Thm 5)	?
$\overrightarrow{\mathbf{H}}(P, \delta)$	$O(n^4)$ [24] $O(n^3 \log n)$ (Thm 3)	weakly NP-hard (Thm 5)	poly(n) [23]
$\mathbf{H}(P, \delta)$	strongly NP-hard [24]	strongly NP-hard (Cor 14)	strongly NP-hard (Thm 13)
$\mathbf{F}(P, \delta)$	$O(mn^5)$ [24] $O(n^3)$ [22] $O(n^3)$ [10]	$O(n)$ in \mathbb{R}^1 (Thm 7) weakly NP-hard in \mathbb{R}^2 (Thm 5)	$O(n^2 \log^2 n)$ in \mathbb{R}^2 [19] $O(n \log n)$ (1, 8)-approx [2] $O^*(n^2 \log n \log \log n)$ (2, $1 + \varepsilon$)-approx (Thm 11)
$\mathbf{dF}(P, \delta)$	$O(n^2)$ [7]	$O(n^3)$ (Thm 6)	$O(n \log n)$ [7]
$\mathbf{wF}(P, \delta)$	$O(n^3)$ (Thm 2)	weakly NP-hard (Thm 5)	(2, $1 + \varepsilon$)-approx (Cor 12)

as output P' a subsequence of this sequence. However, if we measure the distance globally, there may be no strong reason to restrict the family of acceptable output curves so much: the distance measure already ensures the similarity between input and output curves, so perhaps we may allow a more free choice of vertex placement. Indeed, several results under this more relaxed viewpoint exist, as discussed in Section 1.1. Here, we choose to investigate three increasing levels of freedom: (1) *vertex-restricted* (\mathcal{V}), where vertices of P' have to be a subsequence of vertices of P ; (2) *curve-restricted* (\mathcal{C}), where vertices of P' can lie anywhere on P but have to respect the order along P ; and (3) *non-restricted* (\mathcal{N}), where vertices of P' can be anywhere in the ambient space. Figure 2 illustrates the difference between the three models. The third category does not make sense for local curve simplification, but is very natural for global curve simplification. Observe that when the vertices of a simplified curve have more freedom, the optimal simplified curve never has more, but may have fewer, vertices.

2.3 Global Curve Simplification Overview

We are now ready to formally define a class of global curve simplification problems. When $D(\cdot, \cdot)$ denotes a distance measure between curves (e.g., the *Hausdorff* or *Fréchet* distance), the *global curve simplification* (GCS) problem asks what is the smallest number k such that there exists a curve P' with at most k vertices, chosen either as a subsequence of the vertices of P (variant \mathcal{V}), as a sequence of points on the edges of P in the correct order along P (variant \mathcal{C}), or chosen anywhere in \mathbb{R}^d (variant \mathcal{N}) and such that $D(P, P') \leq \delta$, for a given threshold δ . In all cases, we require that P and P' start at the same point and end at the same point.

Table 1 summarizes results for the different variants of the GCS problem obtained by instantiating D with the Hausdorff or Fréchet distance measures and by applying a vertex restriction R . Here $R \in \{\mathcal{V}, \mathcal{C}, \mathcal{N}\}$, and D is either the undirected Hausdorff distance \mathbf{H} , the directed Hausdorff distance $\overleftarrow{\mathbf{H}}(P, \delta)$ from P to P' , the directed Hausdorff distance $\overrightarrow{\mathbf{H}}(P, \delta)$ from P' to P , the Fréchet distance \mathbf{F} , the discrete Fréchet distance \mathbf{dF} , or the weak Fréchet distance \mathbf{wF} . Throughout the paper we use $D_R(P, \delta)$ to denote a curve P' that is the optimal R -restricted simplification of P with $D(P, P') \leq \delta$.

Since GCS is a dual-optimization problem, we call an algorithm an (α, β) -approximation if it computes a solution with distance at most $\beta\delta$ and uses at most α times more shortcuts than the optimal solution for distance δ .

2.4 New Results

In order to provide a thorough understanding of the different variants of the GCS problem we provide several new results. In some cases these are straightforward adaptations of known results, in other cases they require deeper ideas. Additional lemmas, theorems, and proofs are available in the full version of this paper [22]. We give polynomial time algorithms for finding $wF_{\mathcal{V}}(P, \delta)$, the vertex-restricted GCS under the weak Fréchet distance (Section 3, Theorem 2), and $wF_{\mathcal{V}}(P, \delta)$, the vertex-restricted GCS under the strong Fréchet distance (see [22]). In Section 4 we consider the vertex-restricted problem under the directed Hausdorff distance from P' to P (that is, to find $\vec{H}_{\mathcal{V}}(P, \delta)$), originally considered by van Kreveld et al. [24], and we provide an algorithm with an improved runtime of $O(n^3 \log n)$ (Theorem 3). In Section 5 we prove that solving the curve-restricted GCS is NP-hard for almost all distance measures considered in this paper except for the discrete Fréchet distance (Theorem 6) and strong Fréchet distance in \mathbb{R}^1 (Theorem 7) for which we present polynomial time algorithms. To the best of our knowledge, these are the first results in the curve-restricted setting under global distance measures. Finally, in Section 8, we give a $(2, 1 + \varepsilon)$ -approximation algorithm for $F_{\mathcal{N}}(P, \delta)$, the non-restricted GCS under the Fréchet distance, which runs in $O^*(n^2 \log n \log \log n)$ time, where O^* hides factors polynomial in $1/\varepsilon$ (Theorem 11). The same result also holds for $wF_{\mathcal{N}}(P, \delta)$ (Corollary 12). In Section 9 we show that the non-restricted GCS problem becomes NP-hard when we consider the Hausdorff distance (Theorem 13).

2.5 Discussion

With both the existing work and our new results in place, we now have a good overview of the complexity of the different variants of the GCS problem, see Table 1.

Observe that the curve-restricted variants seem to generally be harder than both the vertex-restricted and the non-restricted variants. That means that, on the one hand, broadening the search space from the vertex-restricted to the curve-restricted case makes the problem harder. But on the other hand it does not give unrestricted freedom of choice, which in turn enables the development of efficient algorithms for the unrestricted case.

Another interesting pattern can be observed for the Hausdorff distance measures. The direction of the Hausdorff distance makes a significant difference in whether the corresponding GCS problem is NP-hard or polynomially solvable. The GCS problem for the undirected Hausdorff distance is at least as hard as for the directed Hausdorff distance from the input curve to the simplification.

Drawing upon the above observations we make the following conjecture:

► **Conjecture 1.** *The curve-restricted and non-restricted GCS problems for $\overleftarrow{H}(P, \delta)$ are strongly NP-hard.*

3 Freespace-Based Algorithms for Fréchet Simplification

We use the free space diagram between P and its shortcut graph G to solve the vertex-restricted GCS problem under the weak and strong Fréchet distances in $O(n^3)$ time and space. This is related to *map-matching* [4, 9], however in our case we need to compute *shortest* paths in the free space that correspond to *simple* paths in G . While map-matching for closed simple paths is NP-complete [25], we exploit the DAG property of G to develop efficient algorithms. The proof for the strong Fréchet distance can be found in [22].

■ **Figure 3** A free space diagram $FSD_\delta(P, G)$ with strips and spines.

3.1 Shortcut DAG and Free Space Diagram

Let $G = (V, E)$ be the *shortcut DAG* of P , where $V = \{1, \dots, n\}$ and $E = \{(u, v) \mid 1 \leq u < v \leq n\}$. Each $v \in V$ is embedded at p_v and each edge $e = (u, v) \in E$ as a straight line shortcut is linearly parameterized as $e(t) = (1 - t)p_u + tp_v$ for $t \in [0, 1]$. We consider the parameter space of G to be $E \times [0, 1]$.

Now, let $\delta > 0$, and consider the joint parameter space $[1, n] \times E \times [0, 1]$ of P and G . Any $(s, e, t) \in [1, n] \times E \times [0, 1]$ is called *free* if $\|P(s) - e(t)\| \leq \delta$, and the union of all free points is referred to as the *free space*. For brevity, we write $(s, e(t))$ instead of (s, e, t) , and if $e(t) = v \in V$ we write (s, v) . The *free space diagram* $FSD_\delta(P, G)$ consists of all points in $[1, n] \times E \times [0, 1]$ together with an annotation for each point whether it is free or not. In the special case that the graph is a polygonal curve Q with m vertices, then $FSD_\delta(P, Q)$ consists of $(n - 1) \times (m - 1)$ cells in the domain $[1, n] \times [1, m]$. A monotone path from $(1, 1)$ to (n, m) that lies entirely within the free space corresponds to a pair of monotone reparameterizations (σ, θ) that witness $F(P, Q) \leq \delta$. Such a *reachable path* can be computed using dynamic programming in $O(mn)$ time [5]. If one drops the monotonicity requirement for the path, one obtains a witness for $wF(P, Q) \leq \delta$.

The free space diagram $FSD_\delta(P, G)$ consists of one *cell* for each edge in P and each edge in G . The free space in such a cell is convex. The boundary of a cell comprises four line segments that each contain at most one *free space interval*. $FSD_\delta(P, G)$ is composed of spines and strips. For any $v \in V$ and $e \in E$ we call $SP(v) = [1, n] \times v$ a *spine* and $ST(e) = [1, n] \times e \times [0, 1]$ a *strip*. We denote the free space within spines and strips as $SP_\delta(v) = \{(s, v) \mid 1 \leq s \leq n, \|P(s) - p_v\| \leq \delta\}$ and $ST_\delta(e) = \{(s, e(t)) \mid 1 \leq s \leq n, 0 \leq t \leq 1, \|P(s) - e(t)\| \leq \delta\}$. For $(u, v) \in E$, both spines centered at the vertices of the edge are subsets of the strip: $SP(u), SP(v) \subseteq ST(u, v)$, and $SP(u)$ is a subset of all strips with respect to edges incident on u . See Figure 3 for an illustration.

3.2 Weak Fréchet Distance $wF_V(P, \delta)$ in Polynomial Time

Let $P' = wF_V(P, \delta)$ and let $n' = \#P'$ be the number of vertices in P' . Then P' is a path in G , and P' visits an increasing subsequence of vertices in P (or V). From the fact that $wF(P, P') \leq \delta$ we know that there is a path $\mathcal{P} = (\sigma, \theta)$ from $(1, 1)$ to (n, n') in $FSD_\delta(P, P')$ that lies entirely within free space. And since $FSD_\delta(P, P')$ is a subset of $FSD_\delta(P, G)$, the path $\mathcal{P} = (\sigma, \theta)$ is also a path in $FSD_\delta(P, G)$. Here, σ is a reparameterization of P , and θ is a reparameterization of P' , and P' is simple. We call (s, d) in $FSD_\delta(P, G)$ *weakly reachable* if

there exists a path $\mathcal{P} = (\sigma, \theta)$ from $(1, 1)$ to (s, d) in $\text{FSD}_\delta(P, G)$ that lies in free space such that θ is a reparameterization of a simple path from p_1 to some point on an edge in G . We denote the number of vertices on this simple path by $\#\mathcal{P}$, and we call \mathcal{P} *weakly reachable*. We define the cost function $\phi : [1, n] \times V \rightarrow \mathbb{N}$ as $\phi(z, v) = \min_{\mathcal{P}} \#\mathcal{P}$, where the minimum ranges over all weakly reachable paths to (z, v) in the free space diagram. If no such path exists then $\phi(z, v) = \infty$. Note that all points in a free space interval (on the boundary of a free space cell) have the same ϕ -value.

► **Observation 1.** *There is a weakly reachable path \mathcal{P} in $\text{FSD}_\delta(P, G)$ from $(1, 1)$ to (n, n) with $\#\mathcal{P} = \#\text{wF}_V(P, \delta)$ if and only if $\phi(n, n) = \#\text{wF}_V(P, \delta)$.*

Since ϕ is the length of a shortest path, it seems as if one could compute it by simply using a breadth-first propagation. However, one has to be careful because a weakly reachable path \mathcal{P} is only allowed to backtrack *along the path in G that it has already traversed*. We therefore carefully combine two breadth-first propagations to compute the ϕ values for all $I \in \mathcal{I}$, where \mathcal{I} is the set of all (non-empty) free space intervals on all spines $\text{SP}(v)$ for all $v \in V$. For the primary breadth-first propagation, we initialize a queue Q by enqueueing the interval $I \subseteq \text{SP}_\delta(1)$ that contains $(1, 1)$. Once an interval has been enqueueued it is considered *visited*, and it can never become unvisited again. Then we repeatedly extract the next interval I from Q . Assume $I \subseteq \text{SP}_\delta(u)$. For each v from $u + 1$ to n we consider $\text{ST}(u, v)$ and we compute all unvisited intervals $J \subseteq \text{SP}_\delta(u) \cup \text{SP}_\delta(v)$ that are reachable from I with a path in $\text{ST}_\delta(u, v)$. These J can be reached using one more vertex, therefore we set $\phi(J) = \phi(I) + 1$, we insert J into Q , and we store the predecessor $\pi(J) = I$. For each $J \in \text{SP}_\delta(u)$ we then launch a secondary breadth-first traversal to propagate $\phi(J)$ to all unvisited intervals $J' \in \mathcal{I}$ that are reachable from J within the free space of $\text{FSD}_\delta(P, G(\pi(J)))$. Here, $G(\pi(J))$ denotes the projection of the predecessor DAG rooted at $\pi(J)$ onto G , i.e., each interval I in the predecessor DAG is projected to u if $I \subseteq \text{SP}_\delta(u)$. This allows \mathcal{P} to backtrack along the path in G that it has already traversed, *without* increasing ϕ . This secondary breadth-first traversal uses a separate queue Q' , and sets $\phi(J') = \phi(J)$ and $\pi(J') = J$. When this secondary traversal is finished, Q' is prepended to Q , and then the primary breadth-first propagation continues. Once Q is empty, i.e., all intervals have been visited, $\phi(I) = \#\text{wF}_V(P, \delta)$, where $I \subseteq \text{SP}_\delta(n)$ is the interval that contains (n, n) . Backtracking a path \mathcal{P} from n to 1 in the predecessor DAG rooted at $\pi(I)$, and projecting \mathcal{P} onto G , yields the simplified curve P' . This algorithm visits each interval in \mathcal{I} once using nested breadth-first traversals. Since there are $O(n^3)$ free space intervals this takes $O(n^3)$ time and space.

► **Theorem 2.** *Given a polygonal curve P with n vertices and $\delta > 0$, an optimal solution to the vertex-restricted GCS problem under the weak Fréchet distance can be computed in $O(n^3)$ time and space.*

4 Vertex-Restricted GCS under Directed Hausdorff from P' to P

In this section we revisit the GCS problem for $\vec{H}_V(P, \delta)$ considered by Kreveld et al. [24]. We improve on the running time of their $O(n^4)$ time algorithm. First we thicken the input curve P by width δ . This induces a polygon \mathcal{P} with $h = O(n^2)$ holes. Now all we need is to decide whether each shortcut $\langle p_i p_j \rangle$ for all $1 \leq i < j \leq n$ lies entirely within \mathcal{P} or not. To this end, we preprocess \mathcal{P} into a data structure such that for any straight line query ray ρ originating from a point inside \mathcal{P} one can efficiently compute the first point on the boundary of \mathcal{P} hit by ρ . We use the data structure proposed by [13] of size $O(N)$ which can be constructed in time $O(N\sqrt{h} + h^{3/2} \log h + N \log N)$ and which answers queries in

■ **Figure 4** Sketch of the template curve.

■ **Figure 5** Pinhole gadgets π for $F_C(P, \delta)$ (left) and $\overline{H}_C(P, \delta)$ (right). The pinhole is shown in red.

$O(\sqrt{h} \log N)$ time. We have $\Theta(n^2)$ shortcuts $\langle p_i p_j \rangle$ to process and need to examine whether each shortcut lies inside \mathcal{P} or not. If a shortcut lies inside \mathcal{P} then we include it in the edge set of the shortcut graph proposed by Imai and Iri [20]. Otherwise we eliminate the shortcut. We originate a ray at p_i and compute the first point x on the boundary of \mathcal{P} hit by the ray in $O(\sqrt{h} \log N)$ time. If $\|p_i - x\| \geq \|p_i - p_j\|$ then the shortcut lies inside \mathcal{P} , otherwise it does not. Once the edge set of the shortcut graph is constructed, we compute the shortest path in it. As a result we have the following theorem:

► **Theorem 3.** *Given a polygonal curve P with n vertices and $\delta > 0$, an optimal solution to the curve-restricted GCS problem for $\overline{H}_V(P, \delta)$ can be computed in $O(n^3 \log n)$ time using $O(n^2)$ space.*

5 NP-Hardness of Several Curve-Restricted Variants

In this section we construct a template that we use to prove NP-hardness of the curve-restricted GCS problems for most of the distance measures discussed in this paper. The template takes inspiration from the NP-hardness proofs of minimum-link path problems [23]. We believe that this template can be adapted to show hardness of other similar problems.

The template reduces from the SUBSET SUM problem. Given a set of m integers $A = \{a_1, a_2, \dots, a_m\}$ and an integer M , we will construct an instance of the curve-restricted GCS problem such that there exists a subset $B \subset A$ with the total sum of its integers equal to M if and only if there exists a simplified polygonal curve with at most $2m + 1$ vertices.

The input curve P we construct has a zig-zag pattern. It has m *split gadgets* at every other bend of the pattern, $m + 1$ *enumeration gadgets* at the other bends, and $2m$ *pinhole gadgets* halfway through each zig-zag segment (refer to Figure 4).

The construction forces any optimal simplification P' to follow a zig-zag pattern with a vertex on each split and enumeration gadget and no other vertices. The pinhole gadget is named as such because any segment of P' that goes through it is forced to pass through a specific point, called the *pinhole*. This limits the placements of P' 's vertices. The choice of where to place the vertex on each split gadget then corresponds to the choice of including or excluding a given integer in the subset B and the x -coordinate of the vertex on each enumeration gadget encodes the sum of integers in B up to that point. We ensure that the endpoint of P is reachable with at most $2m + 1$ vertices only if B sums to exactly M .

The split and enumeration gadgets always have the same shape, but the shape of the pinhole gadget depends on the distance measure. Pinhole gadgets must be chosen so that the following properties hold:

1. Any segment of P' starting before a pinhole gadget and ending after the pinhole gadget must pass through the pinhole gadget's *pinhole*.
2. It must be impossible to have a segment of P' traverse multiple pinhole gadgets at once.
3. Any segment of P' where the starting vertex u is on a split or enumeration gadget, the segment goes through a pinhole, and the ending vertex v is on the next enumeration or split gadget, must have distance $\leq \delta$ to $P[u, v]$.
4. P must be polynomial in size. Specifically, only a polynomial number of polyline segments can be used and all vertices must have rational coordinates.

In Figure 5 we show pinhole gadgets for Fréchet distance and directed Hausdorff distance directed from P' to P . The gadget for Fréchet distance also works for weak Fréchet distance, undirected Hausdorff distance and directed Hausdorff distance in the other direction. For these latter three distance measures, we note that the pinhole gadget here does not force P' to go through the pinhole but to pass close enough by it instead. This results in there being reachable intervals on the split and enumeration gadgets rather than reachable points. This leads to an expanded version of the first property:

1. The endpoint of any segment of P' starting before a pinhole gadget and ending after the pinhole gadget must have distance less than $\frac{0.5}{2m}$ to the endpoint of the segment with the same starting point that passes exactly through the pinhole and ends on the same segment of P .

If this property holds (as it does for the gadget in Figure 5 (left) under weak Fréchet and Hausdorff distance) the reachable intervals on the gadgets are so small they never overlap, so the reduction still holds. This leads to the following theorems:

► **Theorem 4.** *Given a curve distance measure, if there exists a pinhole gadget that can be inserted in the described template such that the listed properties hold, the curve-restricted GCS problem for that distance measure is NP-hard.*

► **Theorem 5.** *The GCS problem for $\overleftarrow{H}_C(P, \delta)$, $\overrightarrow{H}_C(P, \delta)$, $H_C(P, \delta)$, $F_C(P, \delta)$, $wF_C(P, \delta)$ is NP-hard.*

Theorem 4 implies this template may be used to prove curve-restricted simplification under other distance measures NP-hard as well in the future. Since the template reduces from SUBSET SUM it proves the above problems weakly to be NP-hard. For undirected Hausdorff distance, we also prove strong NP-hardness in Corollary 14.

6 Curve-Restricted GCS under Discrete Fréchet Distance

Next we present an $O(n^3)$ -time algorithm for the GCS problem for $dF_C(P, \delta)$. Observe that, given an input curve P , there is only a discrete set of candidate points we need to consider for vertices of the output curve. Let \mathcal{A} be the arrangement of n disks of radius δ centered on the vertices of P , and let $C = \langle c_1, \dots, c_m \rangle$, with $m \in O(n^2)$, be the sequence of intersections between P and \mathcal{A} , in order along P . Observe that under the discrete Fréchet distance, if there exists a curve-restricted simplification $P' = \langle q_1, \dots, q_k \rangle$ of P , then there exists a subsequence of C of length k which is a simplification of P .

Although the approach of Bereg et al. [7] to compute the minimal vertex-restricted simplification of \mathcal{A} does not apply in our case, we can design a dynamic programming algorithm in a similar fashion. Define $K(i, j)$ to be the minimum value k such that there exists a subsequence $\langle c_1, \dots, c_j \rangle$ of length k that has discrete Fréchet distance at most δ to the sequence $\langle p_1, \dots, p_i \rangle$. We will design a dynamic program to calculate all nm values

■ **Figure 6** The time-stamped traversals made by the man m and the dog d . The red lines indicate the dog's jumps.

$K(i, j)$. Specifically, if p_{i-1} and c_j are within distance δ , then

$$K(i, j) = \min \left(K(i-1, j), \min_{1 \leq j' < j} (K(i-1, j') + 1) \right),$$

and $K(i, j) = \infty$ otherwise. This definition immediately gives an $O(n^4)$ algorithm to compute $K(n, m)$. We can improve on this by maintaining a second table with prefix minima $M(i, j) = \min_{1 \leq j' \leq j} K(i, j')$, which can be calculated in constant time per table entry and overall saves a linear factor. The full proof of the following theorem can be found in [22].

► **Theorem 6.** *Given a polygonal curve P with n vertices and $\delta > 0$, an optimal solution to the $\text{dF}_C(P, \delta)$ can be computed in $O(n^3)$ time and $O(n^2)$ space.*

7 GCS Fréchet Distance in One Dimension

In this section we provide a greedy algorithm for the curve-restricted GCS problem in \mathbb{R}^1 under the Fréchet distance. We describe our algorithm using the man-dog terminology that is often used in the literature on Fréchet distance: Initially a man and his dog start at p_1 . The man walks along P until his distance to the dog exceeds δ . Now if there is a turn between the man and the dog, the dog marks its current position and jumps over the turn and stays at distance exactly δ away from the man. If there is no turn in between, the dog just follows the man at distance exactly δ and stops when the man arrives at the next turn or the end. Once they both end the walk at p_n we report the positions marked by the dog as P' . See Figure 6. More details are given in [22].

► **Theorem 7.** *Given a polygonal curve P in \mathbb{R}^1 with n vertices and $\delta > 0$, an optimal solution to the curve-restricted GCS problem under the Fréchet distance can be computed in linear time.*

8 Approximation of Non-Restricted GCS under Fréchet Distance

In this section we present an approximation algorithm for the non-restricted GCS problem that discretizes the feasible space for the vertices of the simplified curve. The idea is to compute a polynomial number of shortcuts in the discretized space, and (approximately) validate for each shortcut whether it is within Fréchet distance δ to a subcurve of P . For every subcurve of P we incrementally add the valid shortcuts to the edge set of a graph G until all the shortcuts have been processed. Once G is built, we compute the shortest path in G and

■ **Algorithm 1** Non-restricted GCS problem for the Fréchet distance.

```

1 forall  $i \in \{1, \dots, n\}$  do Compute  $\mathcal{C}_i(\delta, (\varepsilon\delta/(4\sqrt{d}))$  and  $\mathcal{G}_i$ ;
2  $E \leftarrow \emptyset$ ,  $V \leftarrow \emptyset$ ,  $\mathcal{C}_1 \leftarrow p_1 \cup \mathcal{C}_1$ ,  $\mathcal{C}_n \leftarrow p_n \cup \mathcal{C}_n$ ;
3 forall  $\mathcal{C}_i$  and  $\mathcal{C}_j$ , with  $1 \leq i \leq j \leq n$  do
4   forall  $c_1 \in \mathcal{C}_i$  and  $c_2 \in \mathcal{C}_j$  do
5     if VALIDATE( $\langle c_1 c_2 \rangle, P[i, j]$ ) = true then  $E \leftarrow E \cup \langle c_1 c_2 \rangle$ ,  $V \leftarrow V \cup \{c_1, c_2\}$ ;
6 return the shortest path between  $p_1$  and  $p_n$  in  $G = (V, E)$ .
```

return P' . To speed up the validation for each shortcut, we use a data structure to decide whether the Fréchet distance between a shortcut and a subcurve of P is at most δ . For a better understanding of our algorithm, we introduce some notation. Consider a ball $B(o, r)$ of radius $r > 0$ centered at $o \in \mathbb{R}^d$. Let $\text{Prt}(\mathbb{R}^d, l)$ be a *partitioning* of \mathbb{R}^d into a set of disjoint cells (hypercubes) of side length l that is induced by axis parallel hyperplanes placed consecutively at distance l . For any $1 \leq i \leq n$ we call $\mathcal{C}_i = \mathcal{C}_i(r, l) = \{c \in \text{Prt}(\mathbb{R}^d, l) \mid c \cap B(p_i, r) \neq \emptyset\}$ a *discretization* of $B(p_i, r)$. Let \mathcal{G}_i be the set of *corners* of all cells in \mathcal{C}_i .

As we can see, Algorithm 1 is a straightforward computation of valid shortcuts and shortest path in the graph G . The **VALIDATE** procedure takes a shortcut $\langle c_1 c_2 \rangle$ and a subcurve $P[i, j]$ as arguments and decides (approximately) if $F(\langle c_1 c_2 \rangle, P[i, j]) \leq \delta$. In particular, it returns *true* if $F(\langle c_1 c_2 \rangle, P[i, j]) \leq (1 + \varepsilon/2)\delta$ and *false* if $F(\langle c_1 c_2 \rangle, P[i, j]) > (1 + \varepsilon)\delta$. We implement the **VALIDATE** procedure (line 5) using the data structure in [17]. Let $\#P'$ denote the number of vertices of the polygonal curve P' . The following lemmas imply Theorem 11. More details and proofs are provided in [22].

► **Lemma 8.** *The shortest path P'_{alg} returned by Algorithm 1 exists and $F(P, P'_{\text{alg}}) \leq (1 + \varepsilon)\delta$.*

► **Lemma 9.** *Let $P' = F_{\mathcal{N}}(P, \delta)$ and let P'_{alg} be the curve returned by Algorithm 1. Then $\#P'_{\text{alg}} \leq 2(\#P' - 1)$.*

► **Lemma 10.** *Algorithm 1 runs in $O(\varepsilon^{-d} n \log n (\log^2(1/\varepsilon) \log n + \varepsilon^{-(d+2)} n \log \log n))$ time and uses $O((\varepsilon^{-d} \log^2(1/\varepsilon))n)$ space.*

► **Theorem 11.** *Let P be a polygonal curve with n vertices in \mathbb{R}^d , $\delta > 0$, and $P' = F_{\mathcal{N}}(P, \delta)$. For any $0 < \varepsilon \leq 1$, one can compute in $O^*(n^2 \log n \log \log n)$ time and $O^*(n)$ space a non-restricted simplification P^* of P such that $\#P^* \leq 2(\#P' - 1)$ and $F(P, P^*) \leq (1 + \varepsilon)\delta$. Here, O^* hides factors polynomial in $1/\varepsilon$.*

► **Corollary 12.** *Theorem 11 also holds for the non-restricted GCS under the weak Fréchet distance.*

9 Strong NP-Hardness for Non-Restricted GCS under Undirected Hausdorff Distance

Van Kreveld et al. [24] showed that the vertex-restricted GCS problem is NP-hard for undirected Hausdorff distance by a reduction from Hamiltonian cycle in segment intersection graphs. Their proof can be extended to the curve-restricted and non-restricted case; however, because of the increased freedom in vertex placement we must take care when exact embedding the segment graph: e.g., segments that intersect at arbitrarily small angles could potentially cause coordinates with unbounded bit complexity. For this reason, we here reduce from a

more restricted class of graphs: *orthogonal* segment intersections graphs. Czyzowicz et al. [15] show that Hamiltonian cycle remains NP-complete in 2-connected cubic bipartite planar graphs, and Akiyama et al. [3] prove that every bipartite planar graph has a representation as an intersection graph of orthogonal line segments. Hence, Hamiltonian cycle in orthogonal segment intersection graphs is NP-complete.

We sketch the adapted proof; the full proof can be found in [22]. Let S be a set of n horizontal or vertical line segments in the plane with integer-coordinate endpoints such that $\bigcup S$ forms one connected component. Furthermore, assume that all intersections of segments in S are proper, that is no endpoints of segments in S coincide. Let the input polygonal curve P consist of the subsegments of S , and let P cover all the segments of S (possibly multiple times). That is, the vertices of P are chosen from the set of endpoints and the intersection points of segments in S , and the union of all the links of P equals to the union of the segments in S . Set $\delta = \frac{1}{8}$, and let $D \subset \mathbb{R}^2$ be the Minkowski sum of S and a closed ball of radius δ . A simplification P' with Hausdorff distance at most δ to P must visit the δ -disks around all endpoints of S , while staying inside D . A Hamiltonian path in the intersection graph of S corresponds to a simplification P' with $3n - 1$ vertices. Indeed, since no two δ -disks around the endpoints of the segments in S are visible to each other within D (unless they are endpoints of the same segment), an optimal solution visits the two endpoints of each segment consecutively and has one extra bend to switch to the next segment. This results in three links of P' per segment, except for the first and the last segment to be covered, for which only two links each are needed.

► **Theorem 13.** *The non-restricted GCS problem under undirected Hausdorff distance is strongly NP-hard.*

Since a solution to the reduction never benefits from placing vertices not on P , we also immediately obtain an improvement over Theorem 5 for the case of $H_C(P, \delta)$.

► **Corollary 14.** *The curve-restricted GCS problem under undirected Hausdorff distance is strongly NP-hard.*

Abstract

In the beautifully simple-to-state problem of trace reconstruction, the goal is to reconstruct an unknown binary string x given random “traces” of x where each trace is generated by deleting each coordinate of x independently with probability $p < 1$. The problem is well studied both when the unknown string is arbitrary and when it is chosen uniformly at random. For both settings, there is still an exponential gap between upper and lower sample complexity bounds and our understanding of the problem is still surprisingly limited. In this paper, we consider natural parameterizations and generalizations of this problem in an effort to attain a deeper and more comprehensive understanding. Perhaps our most surprising results are:

1. We prove that $\exp(O(n^{1/4}\sqrt{\log n}))$ traces suffice for reconstructing arbitrary matrices. In the matrix version of the problem, each row and column of an unknown $\sqrt{n} \times \sqrt{n}$ matrix is deleted independently with probability p . Our results contrasts with the best known results for sequence reconstruction where the best known upper bound is $\exp(O(n^{1/3}))$.
2. An optimal result for random matrix reconstruction: we show that $\Theta(\log n)$ traces are necessary and sufficient. This is in contrast to the problem for random sequences where there is a super-logarithmic lower bound and the best known upper bound is $\exp(O(\log^{1/3} n))$.
3. We show that $\exp(O(k^{1/3} \log^{2/3} n))$ traces suffice to reconstruct k -sparse strings, providing an improvement over the best known sequence reconstruction results when $k = o(n/\log^2 n)$.
4. We show that $\text{poly}(n)$ traces suffice if x is k -sparse and we additionally have a “separation” promise, specifically that the indices of 1’s in x all differ by $\Omega(k \log n)$.

1 Introduction

In the trace reconstruction problem, first proposed by Batu et al. [4], the goal is to reconstruct an unknown string $x \in \{0, 1\}^n$ given a set of random subsequences of x . Each subsequence, or “trace”, is generated by passing x through the *deletion channel* in which each entry of x is deleted independently with probability p . The locations of the deletions are not known; if they were, the channel would be an *erasure channel*. The central question is to find how many traces are required to exactly reconstruct x with high probability.

This intriguing problem has attracted significant attention from a large number of researchers [4, 8, 10, 11, 15, 17, 18, 21, 24, 26–28]. In a recent breakthrough, De et al. [11] and Nazarov and Peres [26] independently showed that $\exp(O((n/q)^{1/3}))$ traces suffice where $q = 1 - p$. This bound is achieved by a *mean-based* algorithm, which means that the only information used is the fraction of traces that have a 1 in each position. While $\exp(O((n/q)^{1/3}))$ is known to be optimal amongst mean-based algorithms, the best algorithm-independent lower bound is the much weaker $\Omega(n^{5/4}/\log n)$ [16].

Many variants of the problem have also been considered including: (1) larger alphabets and (2) an average case analysis where x is drawn uniformly from $\{0, 1\}^n$. Larger alphabets are only easier than the binary case, since we can encode the alphabet in binary, e.g., by mapping a single character to 1 and the rest to 0 and repeating for all characters. In the average case analysis, the state-of-the-art result is that $\exp(O(\log^{1/3}(n)))$ traces suffice¹, whereas $\Omega(\log^{9/4} n / \sqrt{\log \log n})$ traces are necessary [15–17]. Very recently, and concurrent with our work, other variants have been studied including a) where the bits of x are associated with nodes of a tree whose topology determines the distribution of traces generated [10] and b) where x is a codeword from a code with $o(n)$ redundancy [8].

In order to develop a deeper understanding of this intriguing problem, we consider fine-grained parameterization and structured generalizations of trace reconstruction. We prove several new results for these variations that shed new light on the problem. Moreover, in studying these settings, we refine existing tools and introduce new techniques that we believe may be helpful in closing the gaps in the fully general problem.

1.1 Our Results

Parametrizations. We begin by considering parameterizations of the trace reconstruction problem. Given the important role that sparsity plays in other reconstruction problems (see, e.g., Gilbert and Indyk [13]), we first study the recovery of sparse strings. Here we prove the following result.

► **Theorem 1.** *If x has at most k non-zeros, $\exp(O((k/q)^{1/3} \log^{2/3} n))$ traces suffice to recover x exactly, with high probability, where $q = 1 - p = \Omega(k^{-1/2} \log^{1/2} n)$ is the retention probability.*

As some points of comparison, note that there is a trivial $\exp(O(k/q + \log n))$ upper bound, which our result improves on with a polynomially better dependence on k/q in the exponent. The best known results for the general case is $\exp(O((n/q)^{1/3}))$ [11, 26] and our result is a strict improvement when $k = o(n/\log^2 n)$. Note that since we have no restrictions on k in the statement, improving upon $\exp(O((k/q)^{1/3}))$ would imply an improved bound in the general setting.

¹ p is assumed to be constant in that work.

Somewhat surprisingly, our actual result is considerably stronger (See Corollary 7 for a precise statement). We also obtain $\exp(O((k/q)^{1/3} \log^{2/3} n))$ sample complexity in an asymmetric deletion channel, where each 0 is deleted with probability exponentially close to 1, but each 1 is deleted with probability $p = 1 - q$. With such a channel, all but a vanishingly small fraction of the traces contain only 1s, yet we are still able to exactly identify the location of every 0. Since we can accommodate $k = \Theta(n)$ this result also applies to the general case with an asymmetric channel, yielding improvements over De et al. [11] and Nazarov and Peres [26].

We elaborate more on our techniques in the next section, but the result is obtained by establishing a connection between trace reconstruction and learning binomial mixtures. There is a large body of work devoted to learning mixtures [1, 2, 5, 7, 9, 12, 14, 19, 20, 25] where it is common to assume that the mixture components are well-separated. In our context, separation corresponds to a promise that each pair of 1s in the original string is separated by a 0-run of a certain length. Our second result concerns strings with a separation promise.

► **Theorem 2.** *If x has at most k 1s and each 1 is separated by 0-run of length $\Omega(k \log n)$, then, with $p = 1/2$, $\text{poly}(n)$ traces suffice to recover x with high probability.*

Note that reconstruction with $\text{poly}(n)$ traces is straightforward if every 1 is separated by a 0-run of length $\Omega(\sqrt{n \log n})$; the basic idea is that we can identify which 1s in a collection of traces correspond to the same 1 in the original sequence and then we can use the indices of these 1s in their respective traces to infer the index of the 1 in the original string. However, reducing to $\Omega(k \log n)$ separation is rather involved and is perhaps the most technically challenging result in this paper.

Here as well, we actually obtain a slightly stronger result. Instead of parameterizing by the sparsity and the separation, we instead parameterize by the number of runs, and the run lengths, where a run is a contiguous sequence of the same character. We require that each 0-run has length $\Omega(r \log n)$, where r is the total number of runs. Note that this parameterization yields a stronger result since r is at most $2k + 1$ if the string is k sparse, but it can be much smaller, for example if the 1-runs are very long. On the other hand, the best lower bound, which is $\Omega(n^{5/4}/\log n)$ [16], considers strings with $\Omega(n)$ runs and run length $O(1)$.

As our last parametrization, we consider a sparse testing problem. We specifically consider testing whether the true string is x or y , with the promise that the Hamming distance between x and y , $\Delta(x, y)$, is at most $2k$. This question is naturally related to sparse reconstruction, since the difference sequence $x - y \in \{-1, 0, 1\}^n$ is $2k$ sparse, although of course neither string may be sparse on its own. Here we obtain the following result.

► **Theorem 3.** *For any pair $x, y \in \{0, 1\}^n$ with $\Delta(x, y) \leq 2k$, $\exp(O(k \log n))$ traces suffice to distinguish between x and y with high probability.*

Generalizations. Turning to generalizations, we consider a natural multivariate version of the trace reconstruction problem, which we call *matrix reconstruction*. Here we receive matrix traces of an unknown binary matrix $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$, where each matrix trace is obtained by deleting each row and each column with probability p , independently. Here the deletion channel is much more structured, as there are only $2\sqrt{n}$ random bits, rather than n in the sequence case. Our results show that we can exploit this structure to obtain improved sample complexity guarantees.

In the worst case, we prove the following theorem.

► **Theorem 4.** *For the matrix deletion channel with deletion probability p ,*

$$\exp(O(n^{1/4}\sqrt{p\log n/q}))$$

traces suffice to recover an arbitrary matrix $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$.

While no existing results are directly comparable, it is possible to obtain $\exp(O(n^{1/3} \log n))$ sample complexity via a combinatorial result due to Kós et al. [22]. This agrees with the results from the sequence case, but is obtained using very different techniques. Additionally, our proof is constructive, and the algorithm is actually mean-based, so the only information it requires are estimates of the probabilities that each received entry is 1. As we mentioned, for the sequence case, both Nazarov and Peres [26] and De et al. [11] prove a $\exp(\Omega(n^{1/3}))$ lower bound for mean-based algorithms. Thus, our result provides a strict separation between matrix and sequence reconstruction, at least from the perspective of mean-based approaches.

Lastly, we consider the random matrix case, where every entry of X is drawn iid from $\text{Ber}(1/2)$. Here we show that $O(\log n)$ traces are sufficient.

► **Theorem 5.** *For any constant deletion probability $p < 1$, $O(\log n)$ traces suffice to reconstruct a random $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$ with high probability over the randomness in X and the channel.*

This result is optimal, since with $o(\log n)$ traces, there is reasonable probability that a row/column will be deleted from all traces, at which point recovering this row/column is impossible. The result should be contrasted with the analogous results in the sequence case. For sequences, the best results for random strings is $\exp(O(\log^{1/3} n))$ [17] and $\Omega(\log^{9/4} n / \sqrt{\log \log n})$ [16]. In light of the lower bound for sequences, it is surprising that matrix reconstruction admits $O(\log n)$ sample complexity.

1.2 Our Techniques

To prove our results, we introduce several new techniques in addition to refining and extending many existing ideas in prior trace reconstruction results.

Theorem 1 is proved via a reduction from trace reconstruction to learning the parameters of a mixture of binomial distributions. Surprisingly, this natural connection does not seem to have been observed in the earlier literature. We then use a generalization of a complex-analytic approach introduced by De et al. [11] and Nazarov and Peres [26] to prove a bound on the sample complexity of learning a binomial mixture. This generalization is to move beyond the analysis of Littlewood polynomials, i.e., polynomials with $\{-1, 0, 1\}$ coefficients, to the case where coefficients have bounded precision. The generalization is not difficult. This is our simplest result to prove but we consider the final result to be revealing as it shows that sparsity plays a more important role than length in the complexity of trace reconstruction.

Our most technically involved result is Theorem 2. This is proved via an algorithm that constructs a hierarchical clustering of the individual 1s in all received traces according to their corresponding position in the original string. This clustering step requires a careful recursion, where in each step we ensure no false negatives (two 1s from the same origin are always clustered together) but we have many false positives, which we successively reduce. At the bottom of the recursion, we can identify a large fraction 1s from each 1 in the original string. However, as the recursion eliminates many of the 1s, simply averaging the positions of the surviving fraction leads to a biased estimate. To resolve this, we introduce a de-biasing step which eliminates even more 1s, but ensures the survivors are unbiased, so that we can accurately estimate the location of each 1 in the original string. The initial recursion has $L = \log \log n$ levels, which is critical since the debiasing step involves conditioning on the presence of 2^L 1s in a trace, which only happens with probability $2^{-2^L} = 1/n$.

Theorem 3 leverages combinatorial arguments about k -decks (the multiset of subsequences of a string) due to Krasikov and Roditty [23]. The result demonstrates the utility of these combinatorial tools in trace reconstruction. As further evidence for the utility of combinatorial tools, the connection to k -decks was also used by Ban et al. [3] in independent concurrent work on the deletion channel.

For Theorem 4, we return to the complex-analytic approach and extend the Littlewood polynomial argument to multivariate polynomials. Since the unknown matrices are $\sqrt{n} \times \sqrt{n}$, we can use a natural bivariate polynomial of degree $O(\sqrt{n})$, which yields the improvement. However, the result of Borwein and Erdélyi [6] used in previous work on trace reconstruction applies only to univariate polynomials. Our key technical result is a generalization of their result to accommodate bivariate Littlewood polynomials, which we then use to demonstrate separation.

For Theorem 5, using an averaging argument and exploiting randomness in the original matrix, we construct a statistical test to determine if two rows (or columns) from two different traces correspond to the same row (column) in the original string. We show that this test succeeds with overwhelming probability, which lets us align the rows and columns in all traces. Once aligned, we know which rows/columns were deleted from each trace, so we can simply read off the original matrix X .

Notation. Throughout, n is the length of the binary string being reconstructed, n_0 is the number of 0s, k is the number of 1s, i.e., the *sparsity* or *weight*. For matrices n is the total number of entries, and we focus on square $\sqrt{n} \times \sqrt{n}$ matrices. For most of our results, we assume that n, n_0, k are known since, if not, they can easily be estimated using a polynomial number of traces. Let p denote the deletion probability when the 1s and 0s are deleted with the same probability. We also study a channel where the 1s and 0s are deleted with different probabilities; in this case, p_0 is the deletion probability of a 0 and p_1 is the deletion probability of a 1. We refer to the corresponding channel as the (p_0, p_1) -Deletion Channel or the asymmetric deletion channel. It will also be convenient to define $q = 1 - p, q_0 = 1 - p_0$ and $q_1 = 1 - p_1$ as the corresponding retention probabilities. Throughout, m denotes the number of traces.

2 Sparsity and Learning Binomial Mixtures

We begin with the sparse trace reconstruction problem, where we assume that the unknown string x has at most k 1s. Our analysis for this setting is based on a simple reduction from trace reconstruction to learning a mixture of binomial distributions, followed by a new sample complexity guarantee for the latter problem. This approach yields two new results: first, we obtain an $\exp(O((k/q_1)^{1/3} \log^{2/3} n))$ sample complexity bound for sparse trace reconstruction, and second, we show that this guarantee applies even if the deletion probability for 0s is exponentially close to 1.

To establish our results, we introduce a slightly more challenging channel which we refer to as the *Austere Deletion Channel*. The bulk of the proof analyzes this channel, and we obtain results for the (p_0, p_1) channel via a simple reduction.

► **Theorem 6** (Austere Deletion Channel Reconstruction). *In the Austere Deletion Channel, all but exactly one 0 are deleted (the choice of which 0 to retain is made uniformly at random) and each 1 is deleted with probability p_1 . For such a channel,*

$$m = \exp(O((k/q_1)^{1/3} \log^{2/3} n))$$

traces suffice for sparse trace reconstruction where $q_1 = 1 - p_1$, provided $q_1 = \Omega(\sqrt{k^{-1} \log n})$.

68:6 Trace Reconstruction: Generalized and Parameterized

We will prove this result shortly, but we first derive our main result for this section as a simple corollary.

► **Corollary 7** (Deletion Channel Reconstruction). *For the (p_0, p_1) -deletion channel,*

$$m = q_0^{-1} \exp(O((k/q_1)^{1/3} \log^{2/3} n))$$

traces suffice for sparse trace reconstruction where $q_0 = 1 - p_0$ and $q_1 = 1 - p_1 = \Omega(\sqrt{k^{-1} \log n})$.

Proof. This follows from Theorem 6. By focusing on just a single 0, it is clear that the probability that a trace from the (p_0, p_1) -deletion channel contains at least one 0 is at least q_0 . If among the retained 0s we keep one at random and remove the rest, we generate a sample from the austere deletion channel. Thus, with m samples from the (p_0, p_1) deletion channel, we obtain at least $m q_0$ samples from the austere channel and the result follows. Note that Theorem 1 is a special case where $p_0 = p_1 = p$. ◀

Remarks. First, note that the case where q_1 is constant (a typical setting for the problem) and $k = o(\log n)$ is not covered by the corollary. However, in this case a simpler approach applies to argue that $\text{poly}(n)$ traces suffice: with probability $q_1^k \geq 1/\text{poly}(n)$ no 1s are deleted in the generation of the trace and given $\text{poly}(n)$ such traces, we can infer the original position of each 1 based on the average position of each 1 in each trace. Second, note that the weak dependence on q_0 ensures that as long as $q_0 = 1/\exp(O((k/q_1)^{1/3} \log^{2/3} n))$, we still have the $\exp(O((k/q_1)^{1/3} \log^{2/3} n))$ bound. Thus, our result shows that sparse trace reconstruction is possible even when zeros are retained with exponentially small probability.

Reduction to Learning Binomial Mixtures. We prove Theorem 6 via a reduction to learning binomial mixtures. Given a string x of length n , let r_i be the number of ones before the i^{th} zero in x . For example, if $x = 1001100$ then $r_1 = 1, r_2 = 1, r_3 = 3, r_4 = 3$. Note that the multi-set $\{r_1, r_2, \dots\}$ uniquely determines x , that each $r_i \leq k$, and that the multi-set has size n_0 . The reduction from trace reconstruction to learning binomial mixtures is appealingly simple:

1. Given traces t_1, \dots, t_m from the austere channel, let s_i be the number of leading ones in t_i .
2. Observe that each s_i is generated by a uniform² mixture of $\text{Bin}(r_1, q_1), \dots, \text{Bin}(r_{n_0}, q_1)$ where $q_1 = 1 - p_1$. Hence, learning r_1, r_2, \dots, r_{n_0} from s_1, s_2, \dots, s_m allows us to reconstruct x .

To obtain Theorem 6, we establish the following new guarantee for learning binomial mixtures.

► **Theorem 8** (Learning Binomial Mixtures). *Let \mathcal{M} be a mixture of $d = \text{poly}(n)$ binomials:*

Draw sample from $\text{Bin}(a_i, q)$ with probability α_i

where $0 \leq a_1, \dots, a_d \leq a$ are distinct integers, the values α_i have $\text{poly}(n)$ precision, and $q = \Omega(\sqrt{a^{-1} \log n})$. Then $\exp(O((a/q)^{1/3} \log^{2/3} n))$ samples suffice to learn the parameters exactly with high probability.

² Note that since the r_i are not necessarily distinct some of the binomial distributions are the same.

Proof. Let \mathcal{M}' be a mixture where the samples are drawn from $\sum_{i=1}^d \beta_i \text{Bin}(b_i, q)$, where $0 \leq b_1, \dots, b_d \leq a$ are distinct and the probabilities $\beta_i \in \{0, \gamma, 2\gamma, \dots, 1\}$ where $1/\gamma = \text{poly}(n)$. Consider the variational distance $\sum_i |A_i - B_i|$ between \mathcal{M} and \mathcal{M}' where

$$A_i = \Pr[\text{sample from } \mathcal{M} \text{ is } i] = \sum_{j=1}^d \alpha_j \binom{a_j}{i} q^i (1-q)^{a_j-i}$$

$$B_i = \Pr[\text{sample from } \mathcal{M}' \text{ is } i] = \sum_{j=1}^d \beta_j \binom{b_j}{i} q^i (1-q)^{b_j-i}.$$

We will show that the variational distance between \mathcal{M} and \mathcal{M}' is at least

$$\epsilon = \exp(-O((a/q)^{1/3}(\log 1/\gamma)^{2/3})).$$

Since there are at most $((a+1) \cdot (1/\gamma+1))^d$ possible choices for the parameters of \mathcal{M}' , standard union bound arguments show that

$$O(\log(((a+1) \cdot (1/\gamma+1))^d / \epsilon^2)) = \exp(O((a/q)^{1/3}(\log 1/\gamma)^{2/3}))$$

samples are sufficient to distinguish \mathcal{M} from all other mixtures.

To prove the total variation bound, observe that by applying the binomial formula, for any complex number w , we have

$$\begin{aligned} \sum_{i \geq 0} (A_i - B_i) w^i &= \sum_{i \geq 0} w^i \left(\sum_{j \geq 0} \alpha_j \binom{a_j}{i} q^i (1-q)^{a_j-i} - \sum_{j \geq 0} \beta_j \binom{b_j}{i} q^i (1-q)^{b_j-i} \right) \\ &= \sum_{j \geq 0} (\alpha_j z^{a_j} - \beta_j z^{b_j}) \end{aligned}$$

where $z = qw + (1-q)$. Let $G(z) = \sum_{j \geq 0} (\alpha_j z^{a_j} - \beta_j z^{b_j})$ and apply the triangle inequality to obtain:

$$\sum_{i \geq 0} |A_i - B_i| |w^i| \geq |G(z)|.$$

Note that $G(z)$ is a non-zero degree d polynomial with coefficients in the set

$$\{-1, \dots, -2\gamma, -\gamma, 0, \gamma, 2\gamma, \dots, 1\}.$$

We would like to find a z such that $G(z)$ has large modulus but $|w^i|$ is small, since this will yield a total variation lower bound. We proceed along similar lines to Nazarov and Peres [26] and De et al. [11]. It follows from Corollary 3.2 in Borwein and Erdélyi [6] that there exists $z \in \{e^{i\theta} : -\pi/L \leq \theta \leq \pi/L\}$ such that

$$|G(z)| \geq \gamma \exp(-c_1 L \log(1/\gamma))$$

for some constant $c_1 > 0$. For such a value of z , Nazarov and Peres [26] show that

$$|w| \leq \exp(c_2/(qL)^2)$$

for some constant $c_2 > 0$. Therefore,

$$\sum_{i \geq 0} |A_i - B_i| \exp(ic_2/(qL)^2) \geq \sum_{i \geq 0} |A_i - B_i| |w^i| \geq |G(z)| \geq \gamma \exp(-c_1 L \log(1/\gamma))$$

68:8 Trace Reconstruction: Generalized and Parameterized

For $i > \tau = 6qa$, by an application of the Chernoff bound, $A_i, B_i \leq 2^{-i}$, so we obtain

$$\underbrace{\sum_{i>\tau} 2^{-i} \exp(ic_2/(qL)^2)}_{=T_\tau} + \sum_{i=0}^{\tau} |A_i - B_i| \exp(\tau c_2/(qL)^2) \geq \gamma \exp(-c_1 L \log(1/\gamma)) .$$

$$\sum_{i=0}^{\tau} |A_i - B_i| \geq \frac{\exp(-c_1 L \log(1/\gamma))}{\exp(\tau c_2/(qL)^2)} - \frac{T_\tau}{\exp(\tau c_2/(qL)^2)} \geq \frac{\gamma \exp(-c_1 L \log(1/\gamma))}{\exp(\tau c_2/(qL)^2)} - O(2^{-\tau}) \quad (1)$$

where the second equality follows from the assumption that $c_2/(qL^2) \leq (\ln 2)/2$ (which we will ensure when we set L) since,

$$\frac{T_\tau}{\exp(\tau c_2/(qL)^2)} = \frac{O(1) \cdot 2^{-\tau} \exp(\tau c_2/(qL)^2)}{\exp(\tau c_2/(qL)^2)} = O(2^{-\tau}) .$$

Set

$$L = c \sqrt[3]{\tau/(q^2 \log(1/\gamma))} = c \sqrt[3]{6a/(q \log(1/\gamma))}$$

for some sufficiently large constant c . This ensures that the first term of Eqn. 1 is

$$\exp(-O((a/q)^{1/3} \log^{2/3}(1/\gamma))).$$

Note that

$$\frac{c_2}{qL^2} < \frac{c_2}{qc^2(a/(q \log(1/\gamma)))^{2/3}} \leq \frac{c_2}{c^2} \cdot \left(\frac{\log(1/\gamma)}{aq^{1/2}}\right)^{2/3} \leq \frac{c_2}{c^2} \cdot \left(\frac{\log(1/\gamma)}{aq^2}\right)^{2/3}$$

and so by the assumption that $q = \Omega(\sqrt{\log(1/\gamma)/a})$ we may set the constant c large enough such that $c_2/(qL^2) \leq (\ln 2)/2$ as required. The second term of Eqn. 1 is a lower order term given the assumption from the assumption on q and thus we obtain the required lower bound on the total variation distance. ◀

Theorem 6 now follows from Theorem 8, since in the reduction, we have $d = O(n)$ binomials, one per 0 in x , α_i is a multiple of $1/n_0$ and importantly, we have $a = k$. The key is that we have a polynomial with degree $a = k$ rather than a degree n polynomial as in the previous analysis.

Remark. If all α_i are equal, Theorem 8 can be improved to $\text{poly}(n) \cdot \exp(O((a/p)^{1/3}))$ by using a more refined bound from Borwein and Erdélyi [6] in our proof. This follows by observing that if $\alpha_i = \beta_i = 1/d$, then $\sum_{j \geq 0} (\alpha_j z^{aj} - \beta_j z^{sj})$ is a multiple of a Littlewood polynomial and we may use the stronger bound $|G(z)| \geq \exp(-c_1 L)/d$, see Borwein and Erdélyi [6]. We can also show that the exponential dependence on $a^{1/3}$ in Theorem 8 is necessary.

► **Theorem 9 (Binomial Mixtures Lower Bound).** *There exists subsets*

$$\{a_1, \dots, a_k\} \neq \{b_1, \dots, b_k\} \subset \{0, \dots, a\}$$

such that if $\mathcal{M} = \sum_{i=1}^k \text{Bin}(a_i, 1/2)/k$ and $\mathcal{M}' = \sum_{i=1}^k \text{Bin}(b_i, 1/2)/k$, then $\|\mathcal{M} - \mathcal{M}'\|_{TV} = \exp(-\Omega(a^{1/3}))$. Thus, $\exp(\Omega(a^{1/3}))$ samples are required to distinguish \mathcal{M} from \mathcal{M}' .

Proof. Previous work [11, 26] shows the existence of two strings $x, y \in \{0, 1\}^n$ such that $\sum_i |t_i^x - t_i^y| = \exp(-\Omega(n^{1/3}))$ where t_i^z is the expected value of the i th element (indexed at 0) of a string formed applying the $(1/2, 1/2)$ -deletion channel to the string z . We may assume $\sum_{i \in [n]} x_i = \sum_{i \in [n]} y_i \equiv k$ since otherwise

$$\sum_i |t_i^x - t_i^y| \geq \left| \sum_i t_i^x - \sum_i t_i^y \right| = \left| \sum_{i \in [n]} x_i/2 - \sum_{i \in [n]} y_i/2 \right| \geq 1/2$$

which would contradict the assumption $\sum_i |t_i^x - t_i^y| \neq \exp(-\Omega(n^{1/3}))$.

Consider $\mathcal{M} = \sum_{i=1}^k \text{Bin}(a_i, 1/2)/k$ and $\mathcal{M}' = \sum_{i=1}^k \text{Bin}(b_i, 1/2)/k$, where a_i (b_i) is the number of coordinates preceding the i th 1 in x (y). Note that

$$t_i^x = \sum_{r=1}^k \binom{a_r}{i} / 2^{a_r+1} \quad \text{and} \quad t_i^y = \sum_{r=1}^k \binom{b_r}{i} / 2^{b_r+1},$$

and so

$$\begin{aligned} \|\mathcal{M} - \mathcal{M}'\|_{TV} &= \sum_i |\Pr[\mathcal{M} = i] - \Pr[\mathcal{M}' = i]| \\ &= \sum_i \frac{1}{k} \left| \sum_{r=1}^k \binom{a_r}{i} / 2^{a_r} - \sum_{r=1}^k \binom{b_r}{i} / 2^{b_r} \right| \\ &= \frac{2}{k} \sum_i |t_i^x - t_i^y| = \exp(-\Omega(n^{1/3})), \end{aligned}$$

which proves the result. ◀

3 Well-Separated Sequences

We now prove Theorem 2, showing that $\text{poly}(n)$ traces suffice for reconstruction of a k -sparse string when there are $\Omega(k \log n)$ 0s between each consecutive 1. We call such sequences of 0s the *0-runs* of the string. We also refer to the length of the shortest 0-run as the *gap* g of the string x .

► **Theorem** (Restatement of Theorem 2). *Let x be a k -sparse string of length n and gap at least $ck \log(n)$ for a large enough c . Then $\text{poly}(n)$ traces from the $(1/2, 1/2)$ -Deletion Channel suffice to recover x with high probability.*

In Section 3.1, we present the basic ideas and technical challenges in proving the theorem. We also describe the algorithm in detail and explain how to set the parameters. Full details are presented in Section 3.3. In Section 3.2, we strengthen Theorem 2 to show that $\text{poly}(n)$ traces suffice under the weaker assumption that each 0-run has length $\tilde{\Omega}(r)$ where r is the total number of runs (0-runs + 1-runs). Observe that this is a weaker assumption, since $r \leq 2k + 1$ always, but r can be much less than k .

3.1 A Recursive Hierarchical Clustering Algorithm and Its Analysis: Overview

Let $\{p_u\}_{u=1}^k$ denote the positions (index of the coordinate from the left) of the k 1s in the original string x . Let \mathcal{N} denote the multi-set of all positions of all received 1s and call $N = |\mathcal{N}|$. We will construct a graph G on N vertices where every vertex is associated with a

received 1. We decorate each vertex v with a number $z_v \in \mathcal{N}$, which is the position of the associated received 1. Each vertex v also has an *unknown* label $y_v \in \{1, \dots, k\}$ denoting the corresponding 1 in the *original* string.

At a high level, our approach uses the observed values $\{z_v\}_{v \in V}$ to recover the unknown labels $\{y_v\}_{v \in V}$. Once this “alignment” has been performed, the original string can be recovered easily, since the average of $\{z_v \mathbf{1}\{y_v = u\}\}_{v \in V}$ is an unbiased estimator for $p_u/2$.

A starting observation. Our first observation is a simple fact about binomial concentration, which we will use to define the edge set in G : by the Chernoff bound, with high probability, for every vertex v , if $y_v = u$ then we must have $|z_v - p_u/2| \leq c\sqrt{n \log n}$ for some constant c . Defining the edges in G to be $\{(v, w) : |z_v - z_w| \leq 2c\sqrt{n \log n}\}$ then guarantees that all vertices with $y_v = u$ are connected. This immediately yields an algorithm for the much stronger gap condition $g \geq 4c\sqrt{n \log n}$, since with such separation, no two vertices v, w with $y_v \neq y_w$ will have an edge. Therefore, the connected components reveal the labeling so that $\text{poly}(n)$ traces suffice with $g = \Omega(\sqrt{n \log n})$.

Intuitively, we have constructed a clustering of the received 1s that corresponds to the underlying labeling. To tolerate a weaker gap condition, we proceed recursively, in effect constructing a *hierarchical clustering*. However there are many subtleties that must be resolved.

The first recursion. To proceed, let us consider the weaker gap condition of $g \geq \tilde{\Omega}(k^{1/2}n^{1/4})$. In this regime, G still maintains a *consistency* property that for each u all vertices with $y_v = u$ are in the same connected component, but now a connected component may have vertices with different labels, so that each connected component C identifies a contiguous set $U \subset \{1, \dots, k\}$ of the original 1s. Moreover, due to the sparsity assumption, C must have length, defined as $\max_{v \in C} z_v - \min_{v \in C} z_v$, at most $O(k\sqrt{n \log n})$. Therefore if we can correctly identify every trace that contains the left-most and right-most 1 in U , we can recurse and are left to solve a subproblem of length $O(k\sqrt{n \log n})$. Appealing to our starting observation, this can be done with a gap of $g \geq \tilde{\Omega}(k^{1/2}n^{1/4})$.

The challenge for this step is in identifying every trace that contains the left-most and right-most 1 in U , which we call u_L and u_R respectively. This is important for ensuring a “clean” recursion, meaning that the traces used in the subproblem are generated by passing exactly the same substring through the deletion channel. To solve this problem we use a device that we call a *Length Filter*. For every trace, consider the subtrace that starts with the first received 1 in U and ends with the last received 1 in U (this subtrace can be identified using G). If the trace contains u_L, u_R then the length of this subtrace is $2 + \text{Bin}(L - 2, 1/2)$ where L is the distance between u_L, u_R in the original string. On the other hand, if the subtrace does not contain both end points, then the length is $2 + \text{Bin}(L' - 2, 1/2)$ where $L' \leq L - g$. Since we know that $L \leq \tilde{O}(k\sqrt{n})$ and we are operating with gap condition $g = \tilde{\Omega}(k^{1/2}n^{1/4}) = \tilde{\Omega}(\sqrt{L})$, binomial concentration implies that with high probability we can *exactly* identify the subtraces containing u_L and u_R .

Further recursion. The difficulty in applying a second recursive step is that when $g = o(k^{1/2}n^{1/4})$ the length filter cannot isolate the subtraces that contain the leftmost and rightmost 1s for a block U , so we cannot guarantee a clean recursion. However, substrings that pass through the filter are only missing a short prefix/suffix which upper bounds any error in the indices of the received 1s. We ensure consistency at subsequent levels by incorporating this error into a more cautious definition of the edge set (in fact the additional error is the same order as the binomial deviation at the next level, so it has negligible effect). In this

way, we can continue the recursion until we have isolated each 1 from the original string. The $\Omega(k \log n)$ lower bound on run length arises since the gap at level t of the recursion, g_t , is related to the gap at level $t-1$ via $g_t = \sqrt{k \log n} \cdot g_{t-1}$ with $g_1 = \sqrt{n \log n}$, and this recursion asymptotes at $\Omega(k \log n)$.

The last technical challenge is that, while we can isolate each original 1, the error in our length filter introduces some bias into the recursion, so simply averaging the z_v values of the clustered vertices does not accurately estimate the original position. However, since we have isolated each 1 into pure clusters, for any connected component corresponding to a block of 1s, we can identify *all* traces that contain the first and last 1 in the block. Applying this idea recursively from the bottom up allows us to debias the recursion and accurately estimate all positions.

The algorithm in detail: recursive hierarchical clustering. We now describe the recursive process in more detail. Let us define the thresholds:

$$\tau_1 = \tilde{O}(n^{1/2}), \tau_2 = \tilde{O}(k^{1/2} n^{1/4}), \tau_3 = \tilde{O}(k^{3/4} n^{1/8}), \dots, \tau_D = \tilde{O}(k^{1-1/2^D} n^{1/2^D}),$$

which will be used in the length filter and in the definitions of the edge set. Observe that with $D = \log \log n$, we have $\tau_D = \tilde{O}(k)$. Let $\tilde{x}_1, \dots, \tilde{x}_m$ denote the $m = \text{poly}(n)$ traces. We will construct a sequence of graphs G_1, G_2, \dots, G_D on the vertex sets $V_1 \supset V_2, \dots, \supset V_D$, where each vertex v corresponds to a received 1 in some trace $t_v \in [m]$ and is decorated with its position z_v and the unknown label y_v . The d^{th} round of the algorithm is specified as follows with $z_v^{(1)} = z_v$ and V_1 as the set of all received 1s.

1. Define G_d with edge set $E_d = \{(v, w) : v, w \in V_d \text{ and } |z_v^{(d)} - z_w^{(d)}| \leq \tau_d\}$.
2. Extract $k_d \leq k$ connected components $C_1^{(d)}, \dots, C_{k_d}^{(d)}$ from G_d .
3. For each connected component $C_i^{(d)}$, extract substraces $\{\tilde{x}_j^{(d,i)}\}_{j=1}^m$ where $\tilde{x}_j^{(d,i)}$ is the substring of \tilde{x}_j starting with the first 1 in C_i and ending with the last 1 in C_i . Formally, with $\ell = \min\{z_v : v \in C_i, t_v = j\}$ and $r = \max\{z_v : v \in C_i, t_v = j\}$, we define $\tilde{x}_j^{(d,i)} = \tilde{x}_j[\ell, \dots, r]$.
4. Length Filter: Define $L^{(d,i)} = \max_j \text{len}(\tilde{x}_j^{(d,i)})$. If

$$\text{len}(\tilde{x}_j^{(d,i)}) \leq L^{(d,i)} - \Omega(\sqrt{L^{(d,i)} \log(L^{(d,i)})}),$$

delete all vertices $v \in C_i$ with $t_v = j$. Let V_{d+1} be all surviving vertices.

5. For $v \in V_{d+1}$, define $z_v^{(d+1)} = z_v - \min_{v' \in C_i, t_v = t_{v'}} z_{v'}$.

We analyze the procedure via sequence of lemmas. The first one establishes a basic consistency property: that two 1s originating from the same source 1 are always clustered together.

► **Lemma 10 (Consistency).** *At level d let $V_{d,u} = \{v \in V_d, y_v = u\}$ for each $u \in [k]$. Then with high probability, for each d and u there exists some component $C_i^{(d)}$ at level d such that $V_{d,u} \subset C_i^{(d)}$.*

The next lemma provides a length upper bound on any component, which is important for the recursion. At a high level since we are using a threshold τ_d at level d and the string is k -sparse, no connected component can span more than $k\tau_d$ positions.

► **Lemma 11 (Length Bound).** *For every component $C_i^{(d)}$ at level d , we have $L^{(d,i)} \leq 2k\tau_d$. Moreover if U is a contiguous subsequence of $\{1, \dots, k\}$ with $\bigcup_{u \in U} V_{d,u} \subset C_i^{(d)}$, then $\min_{u \in U} p_u - \max_{u \in U} p_u \leq 2k\tau_d$.*

Finally we characterize the length filter.

► **Lemma 12 (Length Filter).** *For a component $C_i^{(d)}$ at level d , let U be the maximal contiguous subsequence of $\{1, \dots, k\}$ such that $\bigcup_{u \in U} V_{d,u} \subset C_i^{(d)}$. Define $u_L = \arg \min_{u \in U} p_u$ and $u_R = \arg \max_{u \in U} p_u$. Then for any $v \in C_i^{(d)}$, if u_L and u_R are present in t_v , then v survives to round $d + 1$, that is $v \in V_{d+1}$. Moreover, for any $v \in V_{d+1}$, let $p_{\min}(v, U)$ denote the original position of the first 1 from U that is also in the trace t_v . Then we have $p_{\min}(v, u) - p_{u_L} \leq \tilde{O}(\sqrt{k\tau_d})$.*

The lemmas are all interconnected and proved formally in Section 3.3. It is important that the error incurred by the length filter is $\sqrt{k\tau_d} = \tau_{d+1}$ which is exactly the binomial deviation at level $d + 1$. Thus the threshold used to construct G_{d+1} accounts for both the length filter error and the binomial deviation. This property, established in Lemma 12, is critical in the proof of Lemma 10.

For the hierarchical clustering, observe that after $D = \log \log n$ iterations, we have $\tau_D = \tilde{O}(k)$. With gap condition $g = \tilde{\Omega}(k)$ and applying Lemma 10, this means that the connected components at level D each correspond to exactly one 1 in the original string. Moreover since the length filter preserves every trace containing the left-most and right-most 1 in the component, the probability that a subtrace passes through the length filter is at least $1/4$. Hence, after $\log \log n$ levels, the expected number of surviving traces in each cluster is $m/4^{\log \log n} = m/(\log^2 n)$. Thus for each original 1 $u \in \{1, \dots, k\}$, our recursion identifies at least $m/(\log^2 n)$ vertices $v \in V_1$ such that $t_v = u$.

Removing Bias. The last step in the algorithm is to overcome bias introduced by the length filter. The de-biasing process works upward from the bottom of the recursion. Since we have isolated the vertices corresponding to each 1 in the original string, for a component $C_i^{(D-1)}$ at level $D - 1$, we can identify all subtraces that survived to this level that contain the first and last 1 of the corresponding block $U_i^{(D-1)} \subset [k]$. Thus, we can eliminate all subtraces that erroneously passed this length filter.

Working upwards, consider a component $C_i^{(d)}$ that corresponds to a block $U_i^{(d)} \subset [k]$ of 1s in the original string. Since we have performed further clustering, we have effectively partitioned $U_i^{(d)}$ into sub-blocks $U_1^{(d+1)}, \dots, U_s^{(d+1)}$. We would like to identify exactly the subtraces that survived to level d that contain the first and last 1 of $U_i^{(d)}$, but unfortunately this is not possible due to a weak gap condition. However, by induction, we *can exactly* identify all subtraces that survive to level d that contain the first and last 1 of the first and last sub-block of $U_i^{(d)}$, namely $U_1^{(d+1)}$ and $U_s^{(d+1)}$. Thus we can de-bias the length filter at level d by filtering based on a more stringent event, namely the presence of 2^{D-d} nodes. In total to de-bias all length filters above a particular component, we require the presence of $\sum_{d=1}^D 2^{D-d} = O(2^D) = O(\log n)$ nodes, which happens with probability $\Omega(1/n)$. Thus we can debias with only a polynomial overhead in sample complexity. See Figure 1 for an illustration.

3.2 Strengthening to a Parameterization by Runs

We next parameterized the problem by the number of runs, $r = 1 + |\{i \in [n-1] : x_i \neq x_{i+1}\}|$, in the string x being reconstructed. We will argue that if every 0-run has length $\tilde{\Omega}(r)$ then $\text{poly}(n)$ traces suffice. The proof is via a reduction to the k -sparse case in the previous sections.

Let $x' \in \{0, 1\}^{<n}$ be the string formed by replacing every run of 1s in x by a single 1. We first argue that we can reconstruct x' with high probability using $\text{poly}(n)$ traces generated by applying the $(1/2, 1/2)$ -Deletion Channel to x . We will prove this result for

the case $r = \Omega(\log n)$ since otherwise $\text{poly}(n)$ traces is sufficient even with no gap promise.³ Observe that with $m = \text{poly}(n)$ traces, if every 0-run in x has length at least $c \log n$ for some sufficiently large constant $c > 0$, then a bit in every 0-run of x appears in every trace with high probability. Conditioned on this event, no two 1's that originally appeared in different runs of x are adjacent in any trace. Next replace each run of 1s in each trace with a single 1. The end result is that we generate traces that are generated as if we had deleted each 0 in x' with probability $1/2$ and each 1 in x' with probability $1 - 1/2^t \geq 1/2$ where t is the length of the run that the 1 belonged to in x . This channel is not equivalent to the $(1/2, 1/2)$ -Deletion channel, but our analysis for the sparse case continues to hold even if the deletion probability of each 1 is different. Thus we can apply Theorem 2 to recover x' , and the sparsity of x' is at most r . Since the algorithm identifies corresponding 1s in x' in the different traces, we can then estimate the length of the 1-runs in x that were collapsed to each single 1 of x' by looking at the lengths of the corresponding 1-runs in the traces of x before they were collapsed.

► **Theorem 13.** *For the $(1/2, 1/2)$ -Deletion Channel, $\text{poly}(n)$ traces suffice if the lengths of the 0-runs are $\tilde{\Omega}(r)$ where r is the number of runs in x .*

3.3 Sparsity with Gap: Technical Details

This section contains missing details from Section 3. Recall that we have a string $x \in \{0, 1\}^n$ that is k -sparse. We further assume that each 1 in x is separated by a run of g 0s, and we refer to g as the *gap*. Recall that we define $\{p_u\}_{u=1}^k$ as the position of the k 1s in original string, where $p_1 < p_2 < \dots, p_k$. As further notation we refer to the collection of $m = \text{poly}(n)$ traces as $\mathcal{T} = \{\tilde{x}_j\}_{j=1}^m$.

The first level

As a warm up, we show an algorithm called `FindPositions`, that uses $\text{poly}(n)$ traces to reconstruct x exactly with high probability when the gap $g = \Omega(\sqrt{n \log n})$. The algorithm returns the values $\{p_u\}_{u=1}^k$ and crucially uses a *binomial mean estimator*. Given s samples X_1, X_2, \dots, X_s from a binomial distribution $\text{Bin}(n, \frac{1}{2})$ this estimator returns an estimate of n , $\hat{n} = \text{round}\left(\frac{2}{s} \sum_{i=1}^s X_i\right)$, where the round function simply rounds the argument to the nearest integer. From the Hoeffding bound, it is clear that

$$\begin{aligned} \Pr(\hat{n} \neq n) &= \Pr(|\hat{n} - n| \geq 0.5n) = \Pr\left(\left|\frac{1}{s} \sum_{i=1}^s X_i - \frac{n}{2}\right| \geq \frac{1}{4}\right) \\ &\leq 2 \exp\left(-\frac{s}{8n^2}\right) \leq 2 \exp(-n^\epsilon), \end{aligned}$$

as long as $s = 8n^{2+\epsilon}$ for any $\epsilon > 0$.

The algorithm `FindPositions` is displayed in Algorithm 1. Our first result of this section guarantees that with $g = \Omega(\sqrt{n \log n})$ Algorithm 1 recovers x exactly with $\text{poly}(n)$ traces.

► **Theorem 14.** *Algorithm 1 (`FindPositions`) successfully returns the string x from m traces with probability at least $1 - 3n^{-2}$ as long as $m \geq \Omega(n^2 \log n)$ and the gap $g \geq 4\sqrt{2n \log(nm^3)} = \Theta(\sqrt{n \log n})$.*

³ Specifically, if $r = O(\log n)$, with probability at least $1/2^r = 1/\text{poly}(n)$ a trace also has r runs. Given $\text{poly}(n)$ traces with r runs we can estimate each run length because we know the i^{th} run in each such trace corresponds to the i^{th} run in the original string.

68:14 Trace Reconstruction: Generalized and Parameterized

■ Algorithm 1 FindPositions.

Initialize: length of x : n , m traces \mathcal{T} , gap $g > 4\sqrt{2n \log(mn^3)}$.

For each received 1, create a vertex v decorated with tuple (z_v, t_v) where $z_v \in [n]$ is the position of the received 1 and $t_v \in [m]$ is the index of the trace.

Create graph $G = (V, E)$ using vertex set above, and with edges:

$$E = \left\{ (v, w) : |z_v - z_w| \leq \sqrt{2n \log(mn^3)} \right\}$$

Find connected components $C_1, \dots, C_{k'}$ in G (If $k' \neq k$ report failure).

For each connected component C_i , use the binomial mean estimator on $\{z_v\}_{v \in C_i}$ to estimate \hat{p}_i .

Return $\{\hat{p}_i\}_{i=1}^{k'}$.

Proof. First, let us associate with each vertex v an unknown label $y_v \in [k]$ describing the correspondence between this received 1 and a 1 in the original string. The first observation is that if $y_v = u$ then $z_v \sim \text{Bin}(p_u, \frac{1}{2})$ and we always have $p_u \leq n$. Thus, by Hoeffding's inequality and a union bound, we have

$$\Pr[\exists v \in V : |z_v - p_u/2| > \tau] \leq |V| \exp(-2\tau^2/n) \leq \exp(\log(mk) - 2\tau^2/n)$$

And so with $\tau = \sqrt{n \log(mkn^2)}/2$, with probability $1 - n^{-2}$ all z_v values concentrate appropriately.

This event immediately implies that G is *consistent* in the sense that if $y_v = y_{v'}$ then $(v, v') \in E$. Further the gap condition implies the converse property, which we call *purity*: if $y_v \neq y_{v'}$ then $(v, v') \notin E$. Formally, if $y_v \neq y_{v'}$ then

$$\begin{aligned} g/2 &\leq |p_{y_v}/2 - p_{y_{v'}}/2| \\ &\leq |z_v - p_{y_v}/2| + |z_{v'} - p_{y_{v'}}/2| \\ &\leq \sqrt{2n \log(mkn^2)} + |z_v - z_{v'}| \end{aligned}$$

which implies that $|z_v - z_{v'}| \geq g/2 - \sqrt{2n \log(mkn^2)} > \sqrt{2n \log(mn^3)}$. Hence $(v, v') \notin E$.

The above two properties reveal that each connected component can be identified with a single 1 $u \in [k]$ and the component contains exactly the received 1s corresponding to that original one (formally $C_u = \{v : y_v = u\}$). From here we simply use the binomial estimator on each component. First observe that, by a Chernoff bound, with probability $1 - k \exp(-m/36)$, each 1 from the original string appears in at least a 1/3-fraction of the traces, so that $|C_u| \geq m/3$. Then apply the guarantee for the binomial mean estimator along with another union bound over the k positions. Overall the failure probability is

$$n^{-2} + k \exp(-m/36) + 2k \exp\left(\frac{-m}{24n^2}\right)$$

which is at most $3n^{-2}$ with $m \geq 24n^2 \log(2kn^2)$. With this choice, we can tolerate $g = O(\sqrt{n \log n})$. ◀

The recursion

We now use the algorithm **FindPositions** in a recursive manner to estimate the parameters p_1, \dots, p_k even when the gap g is much less than $\sqrt{n \log n}$. Define a series of threshold parameters, to be used in the d^{th} level of recursion:

Algorithm 2 Algorithm RecurGap.

Initialize: Traces $\mathcal{T} = \{\tilde{x}_j\}_{j=1}^m$, gap lower bound $g \geq ck \log^2(n)$.

For each received 1, create vertex v decorated with (z_v, t_v) where $z_v \in [n]$ is the position of the received 1 and $t_v \in [m]$ is the index of the trace.

Set $z_v^{(1)} = z_v, V_1 = V$

for $d = 1, \dots, D$: **do**

 Create graph G_d with vertices V_d and with edges

$$E_1 = \left\{ (v, w) \in V_d : |z_v^{(d)} - z_w^{(d)}| \leq \tau_d/4 \right\}$$

 Extract connected components $C_1^{(d)}, \dots, C_{k_d}^{(d)}$ of G_d .

 For each connected component $C_i^{(d)}$, extract subtraces $\{\tilde{x}_j^{(d,i)}\}_{j=1}^m$ where $\tilde{x}_j^{(d,i)} = \tilde{x}_j[\ell, r]$ and $\ell = \min\{z_v : v \in C_i^{(d)}, t_v = j\}$ and $r = \max\{z_v : v \in C_i^{(d)}, t_v = j\}$.

 Define $L^{(d,i)} = \max_j \text{len}(\tilde{x}_j^{(d,i)})$. If

$$\text{len}(\tilde{x}_j^{(d,i)}) \leq L^{(d,i)} - \sqrt{2L^{(d,i)} \log(kmn)},$$

 delete all vertices $v \in C_i^{(d)}$ with $t_v = j$. Let V_{d+1} be all surviving vertices.

 For $v \in C_i^{(d)} \cap V_{d+1}$, define $z_v^{(d+1)} = z_v - \min\{z_{v'} : v' \in C_i^{(d)}, t_{v'} = t_v\}$.

end for

$$\tau_1 = 4\sqrt{2n \log(mnk)};$$

$$\tau_d = 80\sqrt{k\tau_{d-1} \log(mnk)}, \quad d = 2, \dots, D$$

where the total number of levels is D . Note that, $\tau_d \leq 80^2 \cdot 4\sqrt{2} \cdot k^{1-\frac{1}{2^{d-1}}} n^{\frac{1}{2^d}} \log^{1-1/2^d}(nmk)$. In particular, if $D = O(\log \log n)$ then we have $\tau_D = O(k \log(n))$.

Recall that V is the vertex set for the graph used above, where each vertex corresponds to a received 1 and is associated with an unknown original one y_v . Our main theorem of this section is the following.

► **Theorem 15.** *Assume $g \geq 2\tau_D$ for some $D \leq \log \log(n)$. Then except with probability $1 - 1/n$, Algorithm 2 (RecurGap) with D levels of recursion returns sets $S_1, \dots, S_k \subset V$ such that*

1. *For all $u \in [k]$, $S_u \subset \{v \in V : y_v = u\}$.*
2. *$|S_u| \geq m/\log^5(n)$.*

The theorem follows from the three lemmas stated earlier. Here we re-state the lemmas in detail and provide the proofs.

► **Lemma 16 (Consistency).** *At level d let $V_{d,u} = \{v \in V_d, y_v = u\}$ for each $u \in [k]$. Then with probability $1 - 1/n^2$, for each d and u there exists some component $C_i^{(d)}$ at level d such that $V_{d,u} \subset C_i^{(d)}$.*

► **Lemma 17 (Length Bound).** *At level d , the following holds with probability at least $1 - 1/n^2$: For every component $C_i^{(d)}$ at level d , we have $L^{(d,i)} \leq 2k\tau_d$. Moreover if U is a contiguous subsequence of $\{1, \dots, k\}$ with $\bigcup_{u \in U} V_{d,u} \subset C_i^{(d)}$, then $\min_{u \in U} p_u - \max_{u \in U} p_u \leq 4k\tau_d$.*

► **Lemma 18** (Length Filter). *Assume $m \geq n$. At level d , the following holds with probability at least $1 - 1/n^2$: For a component $C_i^{(d)}$ at level d , let U be the maximal contiguous subsequence of $\{1, \dots, k\}$ such that $\bigcup_{u \in U} V_{d,u} \subset C_i^{(d)}$. Define $u_L = \arg \min_{u \in U} p_u$ and $u_R = \arg \max_{u \in U} p_u$. Then for any $v \in C_i^{(d)}$, if u_L and u_R are present in t_v , then v survives to round $d + 1$, that is $v \in V_{d+1}$. Moreover, for any $v \in V_{d+1}$, let $p_{\min}(v, U)$ denote the original position of the first 1 from U that is also in the trace t_v . Then we have $p_{\min}(v, u) - p_{u_L} \leq 8\sqrt{k\tau_d \log(nmk)}$.*

The proofs of the lemmas are all-intertwined. In the induction step we will assume that all lemmas hold at the previous level of the recursion. Throughout we repeatedly take union bound over all m traces and all up-to- k components, and set the failure probability for each event to be $1/n^2$. In applications of Hoeffding's inequality, this produces a $2 \log(nmk)$ term inside the square root.

Proof of Lemma 17. We proceed by induction. For the base case, by Hoeffding's inequality, we know that for all $v \in V_1$ we have

$$|z_v - p_{y_v}/2| \leq \sqrt{n \log(mkn)} = \tau_1/8$$

except with probability n^{-2} . This means that the position corresponding to a single original 1 u can span at most $\tau_1/4$ positions. If two such regions are merged into a single connected component, then the distance between the regions is at most τ_1 , by construction. Since there are most k such regions, the total length is at most $(k-1)\tau_1 + k\tau_1/4 \leq 2k\tau_1$. The second claim follows from the concentration statement.

For the induction step, assume that the connected components at level $d-1$ have length at most $2k\tau_{d-1}$. Fix a connected component $C_i^{(d-1)}$ and let $u_{i,1}^{(d-1)}$ denote the left-most original 1 present in $C_i^{(d-1)}$ ($u_{i,1}^{(d-1)} = \min\{y_v : v \in C_i^{(d-1)}\}$). By another application of Hoeffding's inequality and using the error guarantee in Lemma 18, we have that

$$\begin{aligned} & |z_v^{(d-1)} - (p_{y_v} - p_{u_{i,1}^{(d-1)}})/2| \\ & \leq |z_v^{(d-1)} - (p_{y_v} - p_{\min}(v, U_i^{(d-1)}))/2| + |p_{\min}(v, U_i^{(d-1)}) - p_{u_{i,1}^{(d-1)}}|/2 \\ & \leq \sqrt{2k\tau_{d-1} \log(mkn)} + 8\sqrt{k\tau_{d-1} \log(mkn)} \leq \tau_d/8 \end{aligned}$$

except with probability n^{-2} . From here, the same argument as in the base case yields the claim. ◀

Proof of Lemma 18. We have two conditions to verify. Fix a component $C_i^{(d)}$ at level d with maximal contiguous subsequence $U \subset [k]$ and recall the definitions $u_L = \arg \min_{u \in U} p_u$ and $u_R = \arg \max_{u \in U} p_u$. By another concentration bound, we know that

$$\forall j : \text{len}(\tilde{x}_j^{(d,i)}) \leq (p_{u_R} - p_{u_L})/2 + \sqrt{(p_{u_R} - p_{u_L}) \log(mnk)}$$

with probability $1 - n^{-2}$. This reveals that:

$$L^{(d,i)} \leq (p_{u_R} - p_{u_L})/2 + \sqrt{(p_{u_R} - p_{u_L}) \log(mnk)}$$

Moreover, for any trace j that contains u_R, u_L the tail bound is two-sided:

$$\forall j \text{ s.t. } u_L, u_R \in \tilde{x}_j^{(d,i)} : \left| \text{len}(\tilde{x}_j^{(d,i)}) - (p_{u_R} - p_{u_L})/2 \right| \leq \sqrt{(p_{u_R} - p_{u_L}) \log(mnk)}.$$

Note that we also have $L^{(d,i)} \geq (p_{u_R} - p_{u_L})/2$ with overwhelming probability as:

$$\begin{aligned} & \Pr[\forall j : \text{len}(\tilde{x}_j^{(d,i)}) \leq (p_{u_R} - p_{u_L})/2] \\ & \leq \prod_{j=1}^m \Pr[\text{len}(\tilde{x}_j^{(d,i)}) \leq (p_{u_R} - p_{u_L})/2 \mid u_R, u_L] \cdot \Pr[u_R, u_L] \\ & \leq \left(\frac{1}{2} \cdot \frac{1}{4}\right)^m = 2^{-3m} \end{aligned}$$

Here we are using the symmetry of the binomial distribution. Thus, with $m \geq n$, the failure probability here is $\exp(-\Omega(n))$, which is negligible.

Using the upper bound on $L^{(d,i)}$ reveals that $\tilde{x}_j^{(d,i)}$ survives, since

$$\begin{aligned} \text{len}(\tilde{x}_j^{(d,i)}) & \geq (p_{u_R} - p_{u_L})/2 - \sqrt{(p_{u_R} - p_{u_L}) \log(mnk)} \\ & \geq L^{(d,i)} - 2\sqrt{(p_{u_R} - p_{u_L}) \log(mnk)} \geq L^{(d,i)} - 2\sqrt{2L^{(d,i)} \log(mnk)}. \end{aligned}$$

For the second condition, assume that some trace j survives but does not contain u_L . Let $u_{\min} = \arg \min\{y_v : v \in C_i^{(d)}, t_v = j\}$ denote the first original $\mathbf{1}$ in this trace that belongs to $C_i^{(d)}$'s block (By definition $p_{u_{\min}} = p_{\min}(v, U)$ for each $v : t_v = j$). Then we know that

$$\begin{aligned} \text{len}(\tilde{x}_j^{(d,i)}) & \leq (p_{u_R} - p_{u_{\min}})/2 + \sqrt{(p_{u_R} - p_{u_{\min}}) \log(nmk)} \\ & \leq (p_{u_R} - p_{u_{\min}})/2 + \sqrt{2L^{(d,i)} \log(nmk)} \end{aligned}$$

but since $\tilde{x}_j^{(d,i)}$ passed through the length filter, we also have a lower bound on its length, and so we get that

$$p_{u_{\min}} - p_{u_L} \leq 4\sqrt{2L^{(d,i)} \log(nmk)} \leq 8\sqrt{k\tau_d \log(nmk)}$$

where the last inequality follows from Lemma 17. ◀

Proof of Lemma 16. The proof here follows the discussion in the previous subsection. Fix a component $C_i^{(d-1)}$ with corresponding block $U_i^{(d-1)} \subset [k]$ at level $d-1$ and assume that all three lemmas apply for all previous levels. For a subtrace $x_j^{(d-1,i)}$ in this component observe and recall the definition $u_{i,1}^{(d-1)} = \min\{y_v : v \in C_i^{(d-1)}\}$ and $p_{\min}(v, U_i^{(d-1)})$, which is the position of the first $\mathbf{1}$ in $U_i^{(d-1)}$ that appears in trace $t_v = j$. Since the length of the subtrace is at most $2k\tau_{d-1}$ by Lemma 17 we get that

$$\begin{aligned} & |z_v^{(d-1)} - (p_{t_v} - p_{u_{i,1}^{(d-1)}})/2| \\ & \leq |z_v^{(d-1)} - (p_{t_v} - p_{\min}(v, U_i^{(d-1)}))/2| + |p_{\min}(v, U_i^{(d-1)}) - p_{u_{i,1}^{(d-1)}}|/2 \\ & \leq \sqrt{2k\tau_{d-1} \log(mnk)} + 8\sqrt{k\tau_{d-1} \log(mkn)} = \tau_d/8. \end{aligned} \tag{2}$$

Here the last inequality uses Hoeffding's bound along with Lemma 18 at level $d-1$. This implies that the clustering at level d is consistent. ◀

Proof of Theorem 15. First take a union bound over $D \leq \log \log n$ applications of the three lemmas, so that the total failure probability is $cD/n^2 \leq 1/n$. From now, assume that the events in the three lemmas all hold for all levels. In particular, this implies that the components $C_i^{(D)}$ are consistent. We must verify that the clusters are pure and then track how many vertices remain.

■ **Figure 1** De-biasing of traces. The figure displays the regions of the original string x that correspond to each connected component found in the algorithm. The end-points of each component correspond to 1s in the original string. To de-bias the length filter for component $C_1^{(1)}$ at level 1, we identify and retain only the traces that contain *all* of the 1s colored red above. Then, to de-bias the length filter at $C_2^{(2)}$ at level 2, we identify and retain only the traces that contain *all* of the green 1s.

For the first claim, let us revisit the proof of Lemma 16. If two vertices, say v, v' , in a component at level $D - 1$ corresponded to different 1s, say u, u' then by the gap condition, we know that $|p_u - p_{u'}| \geq g$. On the other hand, we know that (2) holds, and we will use this to prove that no edge appears between these vertices. We have that

$$|z_v - z_{v'}| \geq \tau_D/8 + \tau_D/8 + |p_{t_v} - p_{t_{v'}}|/2 \geq \tau_D/4 + g/2,$$

and so, if $g/2 \geq \tau_D$, then the two vertices will not share an edge. The argument applies for all pairs and hence the clusters at level D are pure, which establishes the first claim in the Theorem 15.

For the second claim, note that by Lemma 18, for every component at every level, if a trace contains the two endpoints of that component, then it will survive the filter. Hence, in every filtering step we expect to retain 1/4 of the subtraces passing through, and, by a Chernoff bound, we will retain 1/5 of the subtraces except with $\exp(-\Omega(n))$, provided $m \geq n$. Since we perform $D = \log \log n$ levels, we retain $m/5^{\log \log n} = m/\log^5(n)$ traces in each cluster with high probability. ◀

Removing Bias: The reverse recursion

Now that we have isolated the vertices into pure clusters, we need to work our way up through the recursion to remove biases introduced by the hierarchical clustering. For any component $C_i^{(D-1)}$ corresponding to block $U_i^{(D-1)} \subset [k]$ at level $D - 1$, since the components at level D are pure, we can identify exactly the subtraces that contain the first and last 1 in the block. We throw away all other traces, which de-bias the length filter at level $D - 1$.

Unfortunately for a component $C_i^{(d-1)}$ corresponding to a block $U_i^{(d-1)}$ at level $d - 1$, we cannot identify exactly the subtraces that contain the exactly the first and last 1 in the block. However, we know that $C_i^{(d-1)}$ is further refined into sub-components $\{C_{i'}^{(d)}\}$ at level d , and by induction we can identify all the traces that contain the left-most and right-most 1 in the left-most and right-most sub-components. We identify all such traces and eliminate the rest to debias the length filter at level $d - 1$. See Figure 1 for an illustration.

To debias this length filter, we filter based on the presence of two 1s at level $d - 1$ (just the end points), and two further 1s at level d (the inner endpoints of the first and last sub-components), four further 1s at $d + 1$, and so on. So, just to debias the length filter at level $d - 1$ we require $2^{D-(d-1)}$ 1s to be present. Since we must debias all length filters above a particular component, we require the presence of $\sum_{d=1}^{D-1} 2^{D-d} \leq 2^D \leq \log_2(n)$ 1s. The probability of all $\log_2(n)$ of these 1s appearing is $1/n$ and by Chernoff bound, with high probability at least $m/2n$ of our traces will contain all of these 1s.

For any $1, u$, in the original string, let S denote the subset of $\log_2(n)$ 1s, whose presence we require to debias the length filters above the pure component containing u . After the debiasing step, the remaining vertices in the component containing u have z_v values distributed as

$$z_v \sim \text{Bin}(p_u - 1 - |S_L|, 1/2) + (|S_L| + 1)$$

where $|S_L|$ is the number of 1s in $|S|$ that appear before u in the sequence, and the final 1 is due to the presence of u . Using the binomial mean estimator, we can therefore estimate p_u with probability $1 - 1/n$, provided $m/n \geq n^2 \log(n)$. Thus, $\text{poly}(n)$ traces suffice to recover all p_u values, provided that $g > \tau_D$ and $D = \log_2 \log_2 n$. This proves Theorem 2.

4 Reconstructing Arbitrary Matrices

Recall that in the matrix reconstruction problem, we are given samples of a matrix $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$ passed through a *matrix deletion channel*, which deletes each row and each column independently with probability $p = 1 - q$. In this section we prove Theorem 4.

► **Theorem** (Restatement of Theorem 4). *For matrix reconstruction, $\exp(O(n^{1/4} \sqrt{p \log n}/q))$ traces suffice to recover an arbitrary matrix $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$, where p is the deletion probability and $q = 1 - p$.*

The bulk of the proof involves designing a procedure to test between two matrices X and Y . This test is based on identifying a particular received entry where the traces must differ significantly, and to show this, we analyze a certain bivariate Littlewood polynomial, which is the bulk of the proof. Equipped with this test, we can apply a union bound and simply search over all pairs of matrices to recover the string.

For a matrix $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$, let \tilde{X} denote a matrix trace. Let us denote the $(i, j)^{\text{th}}$ entry of the matrix as $X_{i,j}$, $i, j = 0, 1, \dots, \sqrt{n} - 1$, an indexing protocol we adhere to for every matrix. For two complex numbers $w_1, w_2 \in \mathbb{C}$, observe that

$$\begin{aligned} \mathbb{E} \left[\sum_{i,j=0}^{\sqrt{n}-1} \tilde{X}_{i,j} w_1^i w_2^j \right] &= q^2 \sum_{i,j} w_1^i w_2^j \sum_{k_i \geq i, k_j \geq j} X_{k_i, k_j} \binom{k_i}{i} \binom{k_j}{j} p^{k_i-i} q^i p^{k_j-j} q^j \\ &= q^2 \sum_{k_1, k_2=0}^{\sqrt{n}-1} X_{k_1, k_2} (qw_1 + p)^{k_1} (qw_2 + p)^{k_2} \end{aligned}$$

Thus, for two matrices X, Y , we have

$$\begin{aligned} \frac{1}{q^2} \mathbb{E} \left[\sum_{i,j=0}^{\sqrt{n}-1} (\tilde{X}_{i,j} - \tilde{Y}_{i,j}) w_1^i w_2^j \right] &= \sum_{k_1, k_2=0}^{\sqrt{n}-1} (X_{k_1, k_2} - Y_{k_1, k_2}) (qw_1 + p)^{k_1} (qw_2 + p)^{k_2} \\ &\triangleq A(z_1, z_2) \end{aligned}$$

where we are rebinding $z_1 = qw_1 + p$ and $z_2 = qw_2 + p$. Observe that $A(z_1, z_2)$ is a *bivariate Littlewood polynomial*; all coefficients are in $\{-1, 0, 1\}$, and the degree is \sqrt{n} . For such polynomials, we have the following estimate, which extends a result due of Borwein and Erdélyi [6] for univariate polynomials.

► **Lemma 19.** *Let $f(z_1, z_2)$ be non-zero degree n Littlewood polynomial. Then,*

$$|f(z_1^*, z_2^*)| \geq \exp(-C_1 L^2 \log n)$$

for some $z_1^* = \exp(i\theta_1), z_2^* = \exp(i\theta_2)$ where $|\theta_1|, |\theta_2| \leq \pi/L$, and C_1 is a universal constant.

Proof. Fix $L > 0$ and define the polynomial

$$F(z_1, z_2) = \prod_{1 \leq a \leq L, 1 \leq b \leq L} f(z_1 e^{\pi i a/L}, z_2 e^{\pi i b/L}).$$

We first show that there exists z_1^*, z_2^* on the unit disk such that $F(z_1^*, z_2^*) \geq 1$. This follows from an iterated application of the maximum modulus principle. First factorize $F(z_1, z_2) = z_2^k G(z_1, z_2)$ where k is chosen such that $G(z_1, z_2)$ has no common factors of z_2 . Since F has non-zero coefficients, this implies that $G(z_1, 0)$ is a non-zero univariate polynomial. Further factorize $G(z_1, 0) = z_1^\ell H(z_1)$ so that terms in H have no common factors of z_1 . H is also a Littlewood polynomial and moreover it has non-zero leading term, so that $|H(0)| \geq 1$. Thus by the maximum modulus principle:

$$|F(z_1^*, z_2^*)| = |G(z_1^*, z_2^*)| \geq |G(z_1^*, 0)| \geq |H(z_1^*)| \geq |H(0)| \geq 1.$$

Now, for any $a, b \in \{1, \dots, L\}$ we have

$$1 \leq |F(z_1^*, z_2^*)| \leq |f((z_1^*)^{\pi i a/L}, (z_2^*)^{\pi i b/L})| \cdot n^{(L-1)},$$

where we are using the fact that $|f(z_1, z_2)| \leq n$. This proves the lemma, since we may choose a such that $(z_1^*)^{\pi i a/L} = \exp(i\theta)$ for $|\theta| \leq \pi/L$. \blacktriangleleft

Let $\gamma_L = \{e^{i\theta} : |\theta| \leq \pi/L\}$ denote the arc specified in Lemma 19. For any $z_1 \in \gamma_L$, Nazarov and Peres [26] provide the following estimate for the modulus of $w_1 = (z_1 - p)/q$:

$$\forall z \in \gamma_L : |(z - p)/q| \leq \exp(C_2 p/(Lq)^2).$$

Using these two estimates, we may sandwich $|A(z_1, z_2)|$ by

$$\exp(-C_1 L^2 \log n) \leq \max_{z_1, z_2 \in \gamma_L} |A(z_1, z_2)| \leq \frac{\exp(C' p \sqrt{n}/(Lq)^2)}{q^2} \sum_{ij} |\mathbb{E}[\tilde{X}_{ij} - \tilde{Y}_{ij}]|.$$

This implies that there exists some coordinate (i, j) such that

$$|\mathbb{E}[\tilde{X}_{ij} - \tilde{Y}_{ij}]| \geq \frac{q^2}{n} \exp\left(-C_1 L^2 \log n - \frac{C' p \sqrt{n}}{L^2 q^2}\right) \geq \frac{q^2}{n} \exp\left(-C \frac{n^{1/4} \sqrt{p \log n}}{q}\right),$$

where the second inequality follows by optimizing for L .

The remainder of the proof follows the argument of [26]: Since we have witnessed significant separation between the traces received from X and those received from Y , we can test between these cases with $\exp(O(n^{1/4} \sqrt{\log n}))$ samples (via a simple Chernoff bound). Since we do not know which of the 2^n traces is the truth, we actually test between all pairs, where the test has no guarantee if neither matrix is the truth. However, via a union bound, the true matrix will beat every other in these tests and this only introduces a poly(n) factor in the sample complexity.

5 Reconstructing Random Matrices

In this section, we prove Theorem 5: $O(\log n)$ traces suffice to reconstruct a random $\sqrt{n} \times \sqrt{n}$ matrix with high probability for any constant deletion probability $p < 1$. This is optimal since $\Omega(\log n)$ traces are necessary to just ensure that every bit appears in a least one trace.

Our result is proved in two steps. We first design an oracle that allows us to identify when two rows (or two columns) in different matrix traces correspond to the same row (resp. column) of the original matrix. We then use this oracle to identify which rows and columns of the original matrix have been deleted to generate each trace. This allows us to identify the original position of each bit in each trace. Hence, as long as each bit is preserved in at least one trace (and $O(\log n)$ traces is sufficient to ensure this with high probability), we can reconstruct the entire original matrix.

Oracle for Identifying Corresponding Rows/Columns. We will first design an oracle that given two strings t and t' distinguishes, for any constant $q > 0$, with high probability between the cases:

Case 1: t and t' are traces generated by the deletion channel with preservation probability q from the same random string $x \in_R \{0, 1\}^{\sqrt{n}}$

Case 2: t and t' are traces generated by the deletion channel with preservation probability q from independent random strings $x, y \in_R \{0, 1\}^{\sqrt{n}}$

If t and t' are two rows (or two columns) from two different matrix traces, then this test determines whether t and t' correspond to the same or different row (resp. column) of the original matrix. In Section 5.1, we show how to perform this test with failure probability at most $1/n^{10}$. In fact, the failure probability can be made exponentially small but a polynomially small failure probability will be sufficient for our purposes.

Using the Oracle for Reconstruction. Given $m = \Theta(\log n)$ traces we can ensure that every bit of X appears in at least one of the matrix traces with high probability. We then use this oracle to associate each row in each trace with the rows in other traces that are subsequences of the same original row. This requires at most $\binom{m\sqrt{n}}{2} \leq (m\sqrt{n})^2$ applications of the oracle and so, by the union bound, this can be performed with failure probability at most $(m\sqrt{n})^2/n^{10} \leq 1/n^8$ where the inequality applies for sufficiently large n .

After using the oracle to identify corresponding rows amongst the different traces we group all the rows of the traces into \sqrt{n} groups $G_1, \dots, G_{\sqrt{n}}$ where the expected size of each group is mq . We next infer which group corresponds to the i^{th} row of X for each $i \in [\sqrt{n}]$. Let f be the bijection between groups and $[\sqrt{n}]$ that we are trying to learn, i.e., $f(j) = i$ if the j^{th} group corresponds to the i^{th} row of X . It suffices to determine whether $f(j) < f(j')$ or $f(j) > f(j')$ for each pair $j \neq j'$. If there exists a matrix trace \tilde{X} that includes a row in G_j and a row in $G_{j'}$, then we can infer the relative ordering of $f(j)$ and $f(j')$ based on whether the row from G_j appears higher or lower in \tilde{X} than the row in $G_{j'}$. The probability there exists such a trace is $1 - (1 - q^2)^m \geq 1 - 1/\text{poly}(n)$ and we can learn the bijection f with high probability.

We also perform an analogous process with columns. After both rows and columns have been processed, we know exactly which rows and columns were deleted to form each trace, which reveals the original position of each received bit in each trace. Given that every bit of X appeared in at least some trace, this suffices to reconstruct X , proving Theorem 5.

► **Theorem** (Restatement of Theorem 5). *For any constant deletion probability $p < 1$, $O(\log n)$ traces are sufficient to reconstruct a random $X \in \{0, 1\}^{\sqrt{n} \times \sqrt{n}}$.*

5.1 Oracle: Testing whether two traces come from same random string

Define $S_i = \{2wi + j : j = 0, \dots, w - 1\}$ to be a contiguous subsets of size

$$w = 100n^{1/4} \sqrt{1/q \cdot \log n}.$$

Note that there are size w gaps between each S_i and S_{i+1} , i.e., w elements that are both larger than S_i and smaller than S_{i+1} . This will later help us argue that the bits in positions S_i and S_{i+1} in different traces are independent. Given a traces t, t' , define the three quantities: $X_i = \sum_{j \in S_i} t_j$, $Y_i = \sum_{j \in S_i} t'_j$ and $Z_i = (X_i - Y_i)^2$. We will show that by considering Z_0, Z_1, Z_2, \dots we can determine whether t and t' are traces of the same original string or traces of two different random strings.

68:22 Trace Reconstruction: Generalized and Parameterized

The basic idea is that if t and t' are generated by the same string, many of the bits summed to construct X_i and the bits summed to construct Y_i will correspond to the same bits of the original string; hence Z_i will be smaller than it would be if t and t' were generated from two independent random strings. To make this precise, we need to introduce some additional notation.

► **Definition 20.** For $A \subset \{0, 1, 2, \dots\}$, let $R_t(A)$ be the indices of the bits in the transmitted string that landed in positions A in trace t . Similarly define $R_{t'}(A)$. For example, if bits in position 0 and 2 were deleted during the transmission of t then $R_t(\{0, 1, 2\}) = \{1, 3, 4\}$.

The next lemma quantifies the overlap between $R_t(S_i)$ and $R_{t'}(S_i)$.

► **Lemma 21 (Deletion Patterns).** With high probability over the randomness of the deletion channel,

$$\forall i, |R_t(S_i) \cap R_{t'}(S_i)| \geq qw/2 \quad \text{and} \quad \forall i \neq j, |R_t(S_i) \cap R_{t'}(S_j)| = 0.$$

Note that conditioned on the second property, each Z_i is independent.

Proof. First note that by the Chernoff bound, for each $j \in [\sqrt{n}]$, the j^{th} bit of the original sequence appears in position $qj \pm r$ where $r = 5n^{1/4}\sqrt{q \log n}$ with high probability. The second part of the lemma follows since $r = wq/20 < w/20$ and therefore, with high probability, any bit in the original string will not appear in S_α in one trace and S_β in another for $\alpha \neq \beta$ because there was a size w gap between S_α and S_β .

For the first part of the lemma, for each S_i , define

$$S'_i = \{2wi/q + r/q, 2wi/q + r + 1, \dots, (2wi + w - 1)/q - r/q\}.$$

By the Chernoff Bound, with high probability the $w/q - 2r/q > 0.9w/q$ bits in S'_i positions in the original string arrive in positions S_i in the trace. Also with high probability, $0.9q^2|S'_i|$ of the bits in S'_i are transmitted in the generation of both t and t' . Hence, $|R_t(S_i) \cap R_{t'}(S_i)| \geq 0.9w/q \cdot 0.9q^2 > qw/2$ as required. ◀

We are now ready to argue that the values Z_0, Z_1, \dots are sufficient to determine whether or not t and t' are generated from the same random string.

► **Theorem 22.** Let $z_j = \sum_{i=0}^{g-1} Z_{jg+i}$ for $g = 96/q^2$ and $D = \text{median}(z_0, z_1, z_2, \dots, z_{\Theta(\log n)})$.
Case 1: If t and t' are generated from the same string, then $\Pr[D < (1 - q/4)gw/2] \geq 1 - 1/n^{10}$.

Case 2: If t and t' are generated from different strings, then $\Pr[D \geq (1 - q/4)gw/2] \geq 1 - 1/n^{10}$.

Proof. Throughout the proof we condition on the equations in Lemma 21 being satisfied. Note that this event is a function of the randomness of the deletion channel rather than the randomness of the strings being transmitted over the deletion channel.

First, suppose t and t' are generated from different strings. Then Z_i has the same distribution as the variable C in Lemma 23 when r is set to w . Hence, $\mathbb{E}[z_j] = gw/2$ and $\text{var}(z_j) \leq gw^2/2$. Therefore,

$$\Pr[z_j < (1 - q/4)gw/2] \leq \Pr[|z_j - \mathbb{E}[z_j]| \geq (q/4)gw/2] \leq \frac{\text{var}(z_j)}{\mathbb{E}[z_j]^2 \cdot q^2/16} \leq \frac{2}{qq^2/16} = 1/3.$$

Therefore, by the Chernoff bound, $D \geq (1 - q/4)gw/2$ with probability at least $1 - 1/n^{10}$.

Now, suppose t and t' are generated from the same string. Then, Z_i has the same distribution as C in Lemma 23 for some $r \leq w - qw/2$. Hence, $\mathbb{E}[z_j] = gr/2$ and $\text{var}(z_j) \leq gr^2/2$. Therefore,

$$\Pr[z_j \geq (1 - q/4)gw/2] \leq \Pr[|z_j - \mathbb{E}[z_j]| \geq (q/4)gw/2] \leq \frac{\text{var}(z_j)}{\mathbb{E}[z_j]^2 \cdot q^2/16} \leq \frac{2}{gq^2/16} = 1/3.$$

Therefore, by the Chernoff bound, $D < (1 - q/4)gw/2$ with probability at least $1 - 1/n^{10}$. ◀

► **Lemma 23.** *Let $A \sim \text{Bin}(h, 1/2)$ and $B \sim \text{Bin}(h, 1/2)$ be independent and $C = (A - B)^2$. Then,*

$$\mathbb{E}[C] = h/2 \quad \text{and} \quad \text{var}[C] \leq m^2/2.$$

Proof. The result follows by direct calculation:

$$\mathbb{E}[(A - B)^2] = \mathbb{E}[A^2] + \mathbb{E}[B^2] - 2\mathbb{E}[A]\mathbb{E}[B] = m(m + 1)/2 - m^2/2 = m/2$$

and

$$\text{var}((A - B)^2) = \mathbb{E}[(A - B)^4] - (m/2)^2 = m/2 + 6\binom{m}{2}/4 - m^2/4 = (2m - 1)m/4.$$

◀

6 Bounded Hamming Distance

In this section, we turn to the sparse testing problem. We show that is possible to distinguish between two strings x and y with Hamming distance $\Delta(x, y) < 2k$, given $\exp(O(k \log n))$ traces. This question is naturally related to sparse reconstruction, since the difference string $x - y \in \{-1, 0, 1\}^n$ is at most $2k$ sparse, but distinguishing two strings from traces is also at the core of our analysis in Section 2, as well as the analysis of Nazarov and Peres [26] and De et al. [11]. In particular given a testing routine, reconstruction simply requires applying the union bound.

In the binary symmetric channel (where each bit is flipped independently with some probability), distinguishing between two strings is easier if the Hamming distance is larger, since the two strings are farther apart. However, it is unclear if this intuition carries over to the deletion channel. In particular, the number of traces required for testing is unlikely to even be monotonic in the Hamming distance; if the Hamming distance is odd, then x and y have different Hamming weight, and we can estimate the Hamming weight using just $O(n)$ traces.

Our analysis uses a combinatorial result about k -decks due to Krasikov and Roditty [23], along with an approach first used in McGregor et al. [24].

► **Theorem 24** (Krasikov and Roditty [23]). *The k -deck of a string is the multi-set of length k subsequences. No two strings x, y of length n have the same k -deck if $\Delta(x, y) < 2k$.*

► **Theorem 25.** *The k -deck of a binary string can be determined exactly with $\exp(O(k \log n))$ traces from the symmetric deletion channel assuming $p \leq 1 - k/n$.*

Proof. We argue that sampling $\exp(O(k \log n))$ length k -subsequence of a string is sufficient to reconstruct the k -deck with high probability. The result then follows because if $p \leq 1 - k/n$, then with constant probability a trace generated by the deletion channel has length at least k and hence we can take a random k subsequence of such a trace as a random k subsequence from x .

Let f_u be the number of times that $u \in \{0, 1\}^k$ appears as a subsequence of x . Then, let X_u be the number of times u is generated if we sample $r = 3n^k \log n^k$ subsequences of length k uniformly at random. $\mathbb{E}[X_i] = rf_u/\binom{n}{k}$ and by an application of the Chernoff bound.

$$\Pr \left[|X_u \binom{n}{k} / r - f_u| \geq 1 \right] = \Pr \left[|X_u - \mathbb{E}[X]| \geq r / \binom{n}{k} \right] \leq \exp \left(-\frac{f_u^2 \cdot r f_u}{3 \binom{n}{k}} \right) \leq 1/n^k$$

where the last line follows given $f_u \geq 1$ (if $f_u = 0$ the bound is trivially true) and $r = 3n^k \log n^k$. Hence, by taking the union bound over all 2^k sequences u , it follows that we can determine the frequency of all length k subsequences with high probability. ◀

Theorem 3 follows directly from Theorem 24 and Theorem 25.

► **Theorem** (Restatement of Theorem 3). *For all $x, y \in \{0, 1\}^n$ such that $\Delta(x, y) < 2k$,*

$$m = \exp(O(k \log n))$$

traces are sufficient to be distinguished between x and y .

As noted earlier, if $\Delta(x, y)$ is odd then $\text{poly}(n)$ traces suffice. Also, regardless of the Hamming distance, if the location of the first and second positions (say i and j) where x and y differs by at least $\Omega(\sqrt{n \log n})$ then it is easy to show that expected weight of the length $i/2$ prefix of the traces differs by $\Omega(1/\text{poly}(n))$ and hence we can distinguish x and y with $\text{poly}(n)$ traces.

Abstract

We study a variant of the *generalized assignment problem* (GAP) with group constraints. An instance of **Group GAP** is a set I of items, partitioned into L groups, and a set of m uniform (unit-sized) bins. Each item $i \in I$ has a size $s_i > 0$, and a profit $p_{i,j} \geq 0$ if packed in bin j . A group of items is *satisfied* if all of its items are packed. The goal is to find a feasible packing of a subset of the items in the bins such that the total profit from satisfied groups is maximized. We point to central applications of **Group GAP** in Video-on-Demand services, mobile Device-to-Device network caching and base station cooperation in 5G networks.

Our main result is a $\frac{1}{6}$ -approximation algorithm for **Group GAP** instances where the total size of each group is at most $\frac{m}{2}$. At the heart of our algorithm lies an interesting derivation of a submodular function from the classic LP formulation of **GAP**, which facilitates the construction of a high profit solution utilizing at most half the total bin capacity, while the other half is *reserved* for later use. In particular, we give an algorithm for submodular maximization subject to a knapsack constraint, which finds a solution of profit at least $\frac{1}{3}$ of the optimum, using at most half the knapsack capacity, under mild restrictions on element sizes. Our novel approach of submodular optimization subject to a knapsack *with reserved capacity* constraint may find applications in solving other group assignment problems.

1 Introduction

With the rapid adoption of cloud computing, wireless networks, and other modern platforms, resource allocation problems of various flavors have regained importance. One classic example is the *generalized assignment problem* (GAP). We are given a set of n items and m bins, $[m] = \{1, 2, \dots, m\}$. Each item $i \in [n]$ has a size $s_{i,j} > 0$ and a profit $p_{i,j} \geq 0$ when packed into bin $j \in [m]$. The goal is to feasibly pack in the bins a subset of the items of maximum total profit. GAP has been widely studied, with applications ranging from grouping and loading in manufacturing systems to land use optimization in regional planning (see, e.g., [2, 10]). In discrete optimization, GAP has received considerable attention also as a special case of the *separable assignment* problem and *submodular maximization* (see, e.g., [23, 14, 4, 5]). We consider a variant of GAP with group constraints. An instance of **Group GAP** consists of a set $I = \{1, 2, \dots, n\}$ of n items and m uniform (unit-sized) bins $M = \{1, \dots, m\}$. Each item $i \in I$ has a size $s_i > 0$ and a profit $p_{i,j} \geq 0$ when assigned to bin $j \in [m]$. The items in I are partitioned into $L \geq 1$ groups, $\mathcal{G} = \{G_1, \dots, G_L\}$. Given an assignment of items to bins, we say that a group is *satisfied* if all of its items are assigned. The goal is to find a feasible assignment of a subset of the items to bins such that the total profit from satisfied groups is maximized. Formally, a feasible assignment is a tuple (U_1, \dots, U_m) , such that $U_j \cap U_k = \emptyset$ for all $1 \leq j < k \leq m$, $U_j \subseteq I$ and $\sum_{i \in U_j} s_i \leq 1$, for all $1 \leq j \leq m$. Let $I(U) = \cup_j U_j$. Then, $G_\ell \in \mathcal{G}$ is satisfied if $G_\ell \subseteq I(U)$. Let $\mathcal{G}_s = \{G_{\ell_1}, \dots, G_{\ell_t}\}$ be the set of satisfied groups and $I(\mathcal{G}_s) = \cup_{G_\ell \in \mathcal{G}_s} G_\ell$. Then we seek an assignment (U_1, \dots, U_m) for which $\sum_{j=1}^m \sum_{i \in U_j \cap I(\mathcal{G}_s)} p_{i,j}$ is maximized.

The following scenario suggests a natural application for **Group GAP**. Consider a Video-on-Demand (VoD) service where each video is given as a collection of segments. The system has a set of m servers of uniform capacity distributed over multiple locations. To obtain revenue from a video the system must store all of its segments (possibly on different servers). The revenue from a specific video also depends on the servers which store the segments. This is due to the content delivery costs resulting from the distance between the servers and the predicted location of the video audience. The objective of the VoD service provider is to select a subset of segments and an allocation of these segments to servers so as to maximize the total revenue. In [16] we describe central applications of **Group GAP** in mobile Device-to-Device network caching and in base station cooperation in 5G networks.

1.1 Prior Work

We note that a **Group GAP** instance in which each group consists of a *single* item yields an instance of classic GAP where each item takes a single size across the bins, and all the bins have identical capacities. GAP is known to be APX-hard already in this case, even if there are only two possible item sizes, and each item can take one of two possible profits [8]. Thus, most of the previous research focused on obtaining efficient approximate solutions.¹ Fleischer et al. [14] obtained a $(1 - e^{-1})$ -approximation for GAP, as a special case of the *separable assignment problem*. Feige and Vondrák [12] obtained the current best known ratio of $1 - e^{-1} + \varepsilon$, for some absolute constant $\varepsilon > 0$.

¹ Given an algorithm \mathcal{A} , let $\mathcal{A}(I)$, $OPT(I)$ denote the profit of the solution output by \mathcal{A} and by an optimal solution for a problem instance I , respectively. For $\rho \in (0, 1]$, we say that \mathcal{A} is a ρ -approximation algorithm if, for any instance I , $\frac{\mathcal{A}(I)}{OPT(I)} \geq \rho$.

Chen and Zhang [9] studied the problem of *group packing of items into multiple knapsacks* (GMKP), a special case of Group GAP where the profit of each item is the same across the bins. Let $\text{GMKP}(\delta)$ be the restriction of GMPK to instances in which the total size of items in each group is at most δm (that is, a factor δ of the total capacity of all bins). For $\delta > \frac{2}{3}$, the paper [9] rules out the existence of a constant factor approximation for $\text{GMKP}(\delta)$, unless $\text{P} = \text{NP}$. For $\frac{1}{3} < \delta \leq \frac{2}{3}$, the authors show that there is no $(\frac{1}{2} + \varepsilon)$ -approximation for $\text{GMKP}(\delta)$, unless $\text{P} = \text{NP}$, and derive a nearly matching $(\frac{1}{2} - \varepsilon)$ -approximation, for any $\varepsilon > 0$. The paper presents also approximation algorithms and hardness results for other special cases of GMPK.

There has been earlier work also on variants of Group GAP with the added constraint that in any feasible assignment there is at most one item from G_ℓ in bin j , for any $1 \leq \ell \leq L$, $j \in [m]$. Adany et al. [1] considered this problem, called *all-or-nothing* GAP (AGAP). They presented a $(\frac{1}{19} - \varepsilon)$ -approximation algorithm for general instances, and a $(\frac{1}{3} - \varepsilon)$ -approximation for the special case where the profit of an item is identical across the bins, called the *group packing* (GP) problem. Sarpatwar et al. [20] consider a more general setting for AGAP, where each group of items is associated with a time window in which it can be packed. The paper shows that this variant of the problem, called χ -AGAP, admits an $\Omega(1)$ -approximation, assuming the time windows are large enough relative to group sizes. Specifically, for a group G_ℓ having a time window of m slots ($= m$ bins), it is assumed that $s(G_\ell) \leq \frac{m}{20}$.

1.1.1 Submodular Maximization

Given a finite set Ω , a function $f : 2^\Omega \rightarrow \mathbb{R}$ is *submodular* if for every $S, T \subseteq \Omega$ we have

$$f(S) + f(T) \geq f(S \cup T) + f(S \cap T).$$

An equivalent definition of submodularity refers to its diminishing returns: for any $T \subseteq S \subseteq \Omega$, and $u \in \Omega \setminus S$,

$$f(S \cup \{u\}) - f(S) \leq f(T \cup \{u\}) - f(T).$$

A set function f is *monotone* if for every $S \subseteq T \subseteq \Omega$ it holds that $f(S) \leq f(T)$. Submodular functions arise naturally in a wide variety of optimization problems, ranging from coverage problems and graph cut problems to welfare problems (see [6] for a survey on submodular functions). Submodular optimization under various constraints has been widely studied in the past four decades (see, e.g., [22, 7, 13] and [6] and the references therein).

The problem of maximizing a monotone submodular function subject to a knapsack constraint is defined as follows. We are given an oracle to a monotone, non-negative submodular function $f : 2^\Omega \rightarrow \mathbb{R}_{\geq 0}$. Each element $i \in \Omega$ is associated with a size $s_i \geq 0$. We are also given a capacity $B > 0$. The objective is to find a subset $S \subseteq \Omega$ such that $\sum_{i \in S} s_i \leq B$ and $f(S)$ is maximized. The best known result is a $(1 - e^{-1})$ -approximation algorithm due to Sviridenko [22]. The ratio of $(1 - e^{-1})$ cannot be improved even when f is a coverage function and element sizes are uniform, unless $\text{P} = \text{NP}$ [11]. A matching lower bound of $(1 - e^{-1})$ is known also for the oracle model with no complexity assumption [19].

1.2 Contribution and Techniques

Our main result is a $\frac{1}{6}$ -approximation algorithm for Group GAP instances where the total size of each group is at most $\frac{m}{2}$. We note that when group sizes can be arbitrary in $(0, m]$, Group GAP cannot be approximated within any bounded ratio, even if item profits are identical

across the bins, and $m = 2$, unless $P = NP$. Indeed, in this case, deciding whether a single group of items of total size 2 and total profit 1 can be packed in the bins yields an instance of PARTITION, which is NP-complete [15]. Furthermore, even if group sizes are restricted to be no greater than δm , for some $\delta > \frac{2}{3}$, then Group GAP still cannot be approximated within a constant factor, as it generalizes $\text{GMKP}(\delta)$, for which the paper [9] shows hardness of approximation. Similarly, as we consider in this paper a generalization of $\text{GMKP}(\frac{1}{2})$, it follows from [9] that our problem cannot be approximated within ratio better than $\frac{1}{2}$.

In solving Group GAP we combine the framework of Adany et al. [1] with the rounding technique of Shmoys and Tardos [21]. The framework of [1] uses submodular maximization to select a collection of groups for the solution. It then finds a feasible assignment for the selected groups.

At the heart of our algorithm lies an interesting derivation of a submodular function from the classic LP formulation of GAP, which facilitates the construction of a high profit solution utilizing at most half the total bin capacity. In particular, we give an algorithm for submodular maximization subject to a knapsack constraint, which finds a solution occupying at most half the knapsack capacity, while the other half is *reserved* for later use.² We show that this algorithm achieves an approximation ratio of $\frac{1}{3}$ relative to an optimal solution that may use the whole knapsack capacity. We note that this ratio is tight. Indeed, it is easy to construct an instance for which the best solution with half the knapsack capacity has only $\frac{1}{3}$ the profit of the optimal solution with full knapsack capacity. We also note that a naive application of the algorithm of Sviridenko [22] with half the knapsack capacity will only guarantee a $\frac{1-e^{-1}}{3} \approx \frac{1}{4.7}$ -approximation.

To obtain an integral solution, given a fractional assignment of the selected groups, we apply the rounding technique of Shmoys and Tardos [21], followed by a filling phase. We show that if the total size of the items in the selected groups is at most $\frac{m}{2}$, the rounding procedure yields a *feasible* assignment of the selected groups, whose profit is at least half the value of the submodular function. Our novel approach of submodular optimization subject to a knapsack *with reserved capacity* constraint may find applications in solving other group assignment problems.

2 Approximation Algorithm

In this section we present an approximation algorithm for Group GAP. We first introduce several definitions and tools that will be used as building blocks of our algorithm.

2.1 Basic Definitions and Tools

2.1.1 The Submodular Relaxation

For simplicity, we assume that all the numbers are rational. For a subset of elements $I' \subseteq I$, let $s(I') = \sum_{i \in I'} s_i$ be the total size of the elements in I' . We assume throughout the discussion that every $G_\ell \in \mathcal{G}$ satisfies $s(G_\ell) \leq \frac{m}{2}$. We define below a function $\phi : 2^I \rightarrow \mathbb{R}_{\geq 0}$. Let $x_{i,j} \in \{0,1\}$ be an indicator for the assignment of item i to bin j , for $1 \leq i \leq n$, $1 \leq j \leq m$. The following is a linear program associated with a subset $S \subseteq I$, in which $x_{i,j} \geq 0$ for all i, j .

² We assume throughout the discussion that the size of each element is at most half the knapsack capacity.

$$\begin{aligned}
LP(S): \text{ maximize } & \sum_{i \in I, j \in M} x_{i,j} \cdot p_{i,j} \\
\text{subject to: } & \sum_{j \in M} x_{i,j} \leq 1 \quad \forall i \in I \tag{1} \\
& \sum_{i \in I} x_{i,j} \cdot s_i \leq 1 \quad \forall j \in M \tag{2} \\
& x_{i,j} = 0 \quad \forall i \in I \setminus S, j \in M \\
& x_{i,j} \geq 0 \quad \forall i \in I, j \in M
\end{aligned}$$

Note that, by the above constraints, all solutions for the LP have the same dimension, regardless of the size of S . We define $\phi(S)$ as the optimal value of $LP(S)$.

We denote the profit of a solution x for the linear program by $p \cdot x = \sum_{i \in I, j \in M} x_{i,j} \cdot p_{i,j}$. In Section 3 we prove the next result.

► **Theorem 1.** *The function ϕ is submodular.*

We note that ϕ is also monotone and non-negative. We use ϕ to define the *group function* $\psi : 2^{\mathcal{G}} \rightarrow \mathbb{R}_{\geq 0}$. For any $G^* \subseteq \mathcal{G}$ let $I(G^*) = \bigcup_{G_\ell \in G^*} G_\ell$ and $\psi(G^*) = \phi(I(G^*))$. As ϕ is submodular, monotone and non-negative, it is easy to see that ψ is submodular, monotone and non-negative as well. We optimize ψ subject to a knapsack (budget) constraint, using the next general result.

► **Theorem 2** (Submodular optimization with reserved capacity). *Let $\Omega = \{1, \dots, n\}$ be a ground set, and $m \geq 0$ a knapsack capacity. Each $i \in \Omega$ is associated with non-negative size $s_i \leq \frac{m}{2}$. Let $f : 2^\Omega \rightarrow \mathbb{R}_{\geq 0}$ be a non-negative monotone submodular function, and $OPT = \max\{f(S) \mid S \subseteq \Omega, \sum_{i \in S} s_i \leq m\}$. Then Algorithm 2 (in Section 4) finds in polynomial time³ a subset $S \subseteq \Omega$ satisfying $f(S) \geq \frac{OPT}{3}$ and $\sum_{i \in S} s_i \leq \frac{m}{2}$.*

The proof of Theorem 2 is given in Section 4.

2.1.2 Solution Types

Our algorithm uses a few types of intermediate solutions for **Group GAP**, as defined below. Given $G^* \subseteq \mathcal{G}$, we say that a solution x for $LP(I(G^*))$ is a *fractional solution*. Let $U = (U_1, \dots, U_m)$ be an assignment of elements to bins, where U_j is the set of elements assigned to bin j . Then $I(U) = \bigcup_{j=1}^m U_j$ is the subset of elements packed in the bins. We say that U is *feasible* if for each bin $1 \leq j \leq m$ we have $s(U_j) \leq 1$. We say that U is *almost feasible* if for each bin $1 \leq j \leq m$ there is an element u_j^* such that $s(U_j \setminus \{u_j^*\}) \leq 1$. We also define the profit of an assignment as $p(U) = \sum_{1 \leq j \leq m} \sum_{i \in U_j} p_{i,j}$.

Our algorithm first obtains a fractional solution, which is then converted to an almost feasible solution. Finally, the algorithm converts this solution to a feasible one. We now state the results used in these conversion steps.

³ The explicit representation of a submodular function might be exponential in the size of its ground set. Thus, it is standard practice to assume that the function is accessed via a value oracle. Then the number of operations and oracle calls is polynomial in the size of Ω and the maximum length of the representation of $f(S)$.

► **Theorem 3.** *Given $G^* \subseteq \mathcal{G}$, such that $s(I(G^*)) \leq m$, and a fractional solution x for $LP(I(G^*))$, it is possible to construct in polynomial time an almost feasible assignment U such that $p(U) \geq p \cdot x$, and $I(U) = I(G^*)$.*

The theorem easily follows by applying a rounding technique of [21] to a fractional solution in which every element in $I(G^*)$ is fully assigned (fractionally, in multiple bins). We note that such a solution always exists, since $s(I(G^*)) \leq m$. We give the proof in the full version of the paper [16]. To convert an almost feasible solution to a feasible one we use the following result (we give the proof in Section 5).

► **Theorem 4.** *Let $U = (U_1, \dots, U_m)$ be an almost feasible assignment such that $s(I(U)) \leq \frac{m}{2}$, then U can be converted in polynomial time to a feasible assignment U' , with $I(U') = I(U)$ and $p(U') \geq \frac{1}{2}p(U)$.*

2.2 The Algorithm

Our approximation algorithm for Group GAP follows easily from the tools presented in Section 2.1. Initially, we solve the problem of maximizing a submodular function subject to a knapsack with reserved capacity constraint for the set function ψ . Then we solve the linear program and convert the solution to a feasible assignment. We give the pseudocode in Algorithm 1.

■ Algorithm 1 Group GAP Algorithm.

-
- 1: Solve the submodular optimization problem: $\max_{\{S \subseteq \mathcal{G}, \sum_{G_\ell \in S} s(G_\ell) \leq m/2\}} \psi(S)$ using Algorithm 2. Let S^* be the solution found.
 - 2: Find a (fractional) solution x for $LP(I(S^*))$ that realizes $\psi(S^*)$.
 - 3: Use Theorem 3 to convert x to an almost feasible assignment U with $I(U) = I(S^*)$.
 - 4: Use Theorem 4 to convert U into a feasible solution; return this solution.
-

► **Theorem 5.** *Algorithm 1 is a polynomial time $\frac{1}{6}$ -approximation algorithm for Group GAP when the total size of a single group is bounded by $\frac{m}{2}$; that is, $\forall G_\ell \in \mathcal{G} : \sum_{i \in G_\ell} s_i \leq \frac{m}{2}$.*

Proof. It is easy to see that the algorithm runs in polynomial time. By Theorem 2, we have that $\psi(S^*) \geq \text{OPT}/3$, where OPT is the value of the optimal solution for the original instance.

By Theorems 3 and 4, we are guaranteed to find in Steps 3–4 a feasible assignment U of all elements in $I(S^*)$, such that $p(U) \geq \frac{1}{2}\psi(S^*) \geq \frac{1}{6}\text{OPT}$. ◀

3 Submodularity

In this section we show that the function ϕ is submodular. Our proof builds on the useful relation of our problem to maximum weight bipartite matching. Let $G = (A \cup B, E)$ be a bipartite (edge) weighted graph, where $|B| \geq |A|$. Assume that the graph is complete (by adding zero weight edges if needed). For $e \in E$, let $W(e)$ be the weight of edge e , and for $F \subseteq E$, let $W(F) = \sum_{e \in F} W(e)$ be the total weight of edges in F . For $S \subseteq A$, define $h(S)$ to be the value of the maximum weight matching in $G[S \cup B]$, the graph induced by $S \cup B$. We call h the *partial maximum weight matching function*. The next result was shown by Bar-Noy and Rabanca [3].

► **Theorem 6.** *If the edge weights are non-negative then the function h is (monotone) submodular.*

We give a simpler proof in the full version of the paper [16]. We are now ready to prove our main result.

Proof of Theorem 1. We first note that since all numbers are rational, for some $N \in \mathbb{Z}^+$, we can write $s_i = \frac{\hat{s}_i}{N}$, where $\hat{s}_i \in \mathbb{Z}^+$ for all $i \in I$.⁴

Now, set the capacity of each bin $1 \leq j \leq m$ to be $b_j = N$, and let $0 \leq y_{i,j} \leq \hat{s}_i$ indicate the size of item i assigned to bin j . For a subset of items $S \subseteq I$, we now write the following linear program.

$$M(S): \text{ maximize } \sum_{i \in I} \frac{1}{\hat{s}_i} \sum_{j \in M} y_{i,j} \cdot p_{i,j}$$

$$\text{ subject to: } \sum_{j \in M} y_{i,j} \leq \hat{s}_i \quad \forall i \in I \quad (3)$$

$$\sum_{i \in I} y_{i,j} \leq N \quad \forall j \in M \quad (4)$$

$$y_{i,j} = 0 \quad \forall i \in I \setminus S, j \in M$$

$$y_{i,j} \geq 0 \quad \forall i \in I, j \in M$$

Indeed, Constraint (3) ensures that the total size assigned for item i over the bins is upper bounded by \hat{s}_i , and Constraint (4) guarantees that the capacity constraint is satisfied for all the bins $j \in M$. Given a subset of elements $S \subseteq I$, let $\eta(S)$ be the value of an optimal solution for $M(S)$.

Now, observe that any feasible solution for $LP(S)$ induces a feasible solution for $M(S)$ of the same value, by setting $y_{i,j} = x_{i,j} \cdot \hat{s}_i$ for all $i \in I$ and $j \in M$. Similarly, a feasible solution for $M(S)$ induces a feasible solution for $LP(S)$ of the same value. Hence, $\phi(S) = \eta(S)$ for all $S \subseteq I$.

By the above discussion, to prove the theorem it suffices to show that η is submodular. Given our Group GAP instance, we construct the following bipartite graph G . For each item $i \in I$, we define \hat{s}_i vertices, $V_i = \{v_{i,1}, \dots, v_{i,\hat{s}_i}\}$. For each bin $j \in M$, we define N vertices $U_j = \{u_{j,1}, \dots, u_{j,N}\}$. For any $i \in [n]$ and $j \in [m]$, there are edges $(v_{i,s}, u_{j,r})$ of weight $p_{i,j}/\hat{s}_i$, for all $1 \leq s \leq \hat{s}_i$, $1 \leq r \leq N$. Let $V_I = \cup_{i \in I} V_i$, $U_M = \cup_{j \in M} U_j$, and let E be the set of edges. Consider the bipartite graph $G = (V_I \cup U_M, E)$. W.l.o.g we may assume that $|U_M| \geq |V_I|$; otherwise, we can add new bins $j = m+1, m+2, \dots$ with corresponding sets of vertices $U_j = \{u_{j,1}, \dots, u_{j,N}\}$ and zero weight edges $(v_{i,s}, u_{j,r})$ for all $i \in [n]$, $1 \leq s \leq \hat{s}_i$, $1 \leq r \leq N$.

We note that, given a subset of items $S \subseteq I$, $M(S)$ is the linear programming relaxation of the problem of finding a maximum weight matching in the subgraph $G[V_S \cup U_M]$, where $V_S \subseteq V_I$ is the subset of vertices in G that corresponds to S . Using standard techniques (see, e.g., [17]), it can be shown that $M(S)$ has an optimal integral solution. Hence, $\eta(S) = h(V_S)$, where $h : 2^{V_I} \rightarrow \mathbb{R}_{\geq 0}$ is a partial maximum weight matching function in G . By Theorem 6, h is (monotone) submodular. Hence, η is also (monotone) submodular. ◀

⁴ Note that N , which may be arbitrarily large, is used just for the proof. Our algorithm does not rely on obtaining a solution (or an explicit formulation) for $M(S)$.

4 Submodular Optimization with Reserved Capacity

In this section we prove Theorem 2. We start with some definitions and notation. Assume we are given a ground set $\Omega = \{1, \dots, n\}$ and capacity $m > 0$, where each element $i \in \Omega$ is associated with a non-negative size $s_i \leq \frac{m}{2}$. For $S \subseteq \Omega$, let $s(S) = \sum_{i \in S} s_i$. Also, for $S, T \subseteq \Omega$ let $f_S(T) = f(S \cup T) - f(S)$. We use throughout this section basic properties of monotone submodular functions (see, e.g., [6]).

Algorithm 2 SUBMODULAROPT.

Input: A monotone submodular function $f : 2^\Omega \rightarrow \mathbb{R}_{\geq 0}$, sizes $s_i \geq 0$ for all $i \in \Omega$, and capacity $m > 0$.

Output: A subset of elements $R \subseteq \Omega$ such that $s(R) \leq \frac{m}{2}$.

```

1: procedure GREEDY( $g, m'$ )
2:   Set  $S = \emptyset, E = \Omega$ .
3:   while  $E \setminus S \neq \emptyset$  do
4:     Find  $i = \arg \max_{i \in E \setminus S} \frac{g_S(\{i\})}{s_i}$ 
5:     if  $s(S) + s_i \leq m'$  then set  $S = S \cup \{i\}$ .
6:     end if
7:     Set  $E = E \setminus \{i\}$ .
8:   end while
9:   Return  $S$ 
10: end procedure
11: Set  $R = \emptyset$ 
12: for every set  $S_e \subseteq \Omega, |S_e| \leq 6$  do
13:   for every set  $B \subseteq S_e, s(B) \leq m/2$  do
14:      $T = \text{GREEDY}(f_{S_e}, m/2 - s(B))$ 
15:     if  $f(B \cup T) \geq f(R)$  then Set  $R = B \cup T$ .
16:   end if
17: end for
18: end for
19: Return  $R$ 

```

In the following we give an outline of an algorithm for maximizing a monotone submodular function f subject to a knapsack *with reserved capacity* constraint. Specifically, assuming that the knapsack capacity is m for some $m > 0$, the algorithm solves the problem $\max_{\{S \subseteq \Omega: s(S) \leq \frac{m}{2}\}} f(S)$. The algorithm, SUBMODULAROPT, initially guesses the set of at most six items of highest profits in some optimal solution (for the problem with knapsack capacity m), and a subset of these profitable items, whose total size is at most $m/2$. Then the algorithm calls a procedure which applies the Greedy approach as in [22] to find the remaining items in the solution. We give a pseudocode of SUBMODULAROPT in Algorithm 2. It is important to note that while the algorithm produces a solution of size at most $m/2$, the analysis compares this solution against an optimal solution of size at most m .

The next lemma, which plays a key role in our analysis, follows from the technique presented in [22].

► **Lemma 7.** *Given the knapsack capacity $m > 0$, let $0 < m' \leq m^* \leq m$. Let $S^* \subseteq \Omega$ be a non-empty subset of elements, such that $s(S^*) \leq m^*$. Also, let $g : 2^\Omega \rightarrow \mathbb{R}$ be a monotone submodular function satisfying $g(\emptyset) = 0$, and let $S = \text{GREEDY}(g, m')$. Then, there is an element $i^* \in S^*$ such that $g(S) + g(\{i^*\}) \geq (1 - e^{-m'/m^*})g(S^*)$.*

In the full version of the paper [16] we prove a more general result (see Lemma 12 therein). Lemma 7 is obtained by setting $T = \emptyset$ in Lemma 12 in [16].

Lemma 7 was applied in [22] in the special case where $m' = m^*$. It was applied in conjunction with a guessing phase, used to ensure that the three most profitable elements in an optimal solution are selected by the algorithm, thus bounding the value of $g(\{i^*\})$.

Several difficulties arise while attempting to apply a similar approach to the problem with *reserved* capacity. The first one is that the most profitable elements in *any* optimal solution may already exceed the reduced capacity, and therefore cannot be added to the solution. Another difficulty is that even if these elements do fit in the smaller knapsack, one can easily come up with a scenario in which it is better not to include them in the solution.

To overcome these difficulties we use the following main observation. Given P_k , the set of $k = 6$ most profitable elements in an optimal solution⁵, and a partition of this set into two subsets B_1, B_2 , each of size at most $m/2$ (if such a partition exists), adding elements to either B_1 or B_2 using the greedy procedure leads to a solution of value at least one third of the value of an optimal solution. This observation comes into play in Case 2.2 in the proof of Theorem 2. The next technical lemma is used to prove this observation (we give the proof below).

► **Lemma 8.** *For $k = 6$, $p_A, p_B, S_A, S_B \geq 0$ such that $p_A + p_B \leq 1$ and $S_A + S_B \leq 1$, define*

$$h(p_A, p_B, S_A, S_B) = p_A + (1 - p_A - p_B) \left(1 - e^{-\frac{\frac{1}{2} - S_A}{1 - S_A - S_B}} \right) - \frac{p_A + p_B}{k}.$$

Then for p_1, p_2, S_1, S_2 such that $0 \leq p_1, p_2 \leq \frac{1}{3}$ and $0 \leq S_1, S_2 \leq \frac{1}{2}$ it holds that

$$\max(h(p_1, p_2, S_1, S_2), h(p_2, p_1, S_2, S_1)) \geq \frac{1}{3}.$$

Another main tool used in the proof of Theorem 2 is a simple partitioning procedure. It shows that P_k can either be partitioned into two sets as required in the above observation, or we reach a simple corner case (Case 2.1 in the proof) in which at least one third of the optimal value can be easily attained. For the latter case, we use the following result, due to [18].

► **Lemma 9.** *Let $g : 2^\Omega \rightarrow \mathbb{R}$ be a non-negative and monotone submodular function. Let $OPT = \max\{g(S) \mid S \subseteq \Omega, \sum_{i \in S} s_i \leq m\}$, and $S^* = \text{GREEDY}(g, m)$. Then either $g(S^*) \geq (1 - e^{-1/2})OPT$, or there is an element $i \in \Omega$ such that $g(\{i\}) \geq (1 - e^{-1/2})OPT$ and $s_i \leq m$.*

Proof of Theorem 2. (Submodular optimization with reserved capacity). It is easy to see that the running time of the algorithm is polynomial. Let $S \subseteq \Omega$, $s(S) \leq m$, $f(S) = OPT$, and $k = 6$.

Case 1: We first handle the case where $|S| < k$. We prove that in this case the algorithm finds a set R such that $f(R) \geq OPT/3$. Start with $A_1 = \emptyset$, iterate over the elements of S and add them to A_1 , as long as $s(A_1) \leq m/2$. If $S \neq A_1$, let $j \in S \setminus A_1$, and set $A_2 = \{j\}$ and $A_3 = S \setminus (A_1 \cup A_2)$. Clearly, $s(A_2) \leq m/2$, and since $s(A_1 \cup A_2) > m/2$ and $s(S) \leq m$, we have that $s(A_3) \leq m/2$. If $S = A_1$ set $A_2 = A_3 = \emptyset$.

⁵ The value $k = 6$ is derived from Lemma 8. It may be possible to obtain the same approximation ratio using smaller values of k , leading to a more efficient algorithm.

69:10 Generalized Assignment via Submodular Optimization

By the submodularity of f , we have $f(S) \leq f(A_1) + f(A_2) + f(A_3)$. Hence, for some $r \in \{1, 2, 3\}$, $f(A_r) \geq f(S)/3 = \text{OPT}/3$. We also have that $|A_r| \leq 5$; therefore, at some iteration of the algorithm $S_e = B = A_r$, and following this iteration $f(R) \geq \text{OPT}/3$.

Case 2: Assume now that $|S| \geq k$. Let $S = \{i_1, i_2, \dots, i_\ell\}$ such that the elements are ordered by their marginal profits: $i_j = \arg \max_{j \leq r \leq \ell} f_{\{i_1, \dots, i_{j-1}\}}(\{i_r\})$. Set $P_k = \{i_1, i_2, \dots, i_k\}$. Consider the following process. Start with $B_1 = \emptyset$ and $B_2 = \emptyset$. Iterate over the elements $i \in P_k$ in decreasing order by size. For each element i , let $t = \arg \min_{j=1,2} s(B_j)$. If $s(B_t) + s_i \leq m/2$ then $B_t = B_t \cup \{i\}$; otherwise, Stop. We now distinguish between two sub-cases for the termination of the process.

Case 2.1: Suppose that the process terminates due to an element i which cannot be added to any of the sets. Let B_1 and B_2 be the sets in this iteration. Also, set $B_3 = \{i\}$, $U = B_1 \cup B_2 \cup B_3$, and $L = S \setminus U$. W.l.o.g assume that $s(B_1) \geq s(B_2)$. As the process terminated, we have that $s(B_3) + s(B_2) = s_i + s(B_2) > m/2$. The sets B_1, B_2, B_3 and L form a partition of S , and $s(S) \leq m$. We conclude that $s(B_1) + s(L) \leq m/2$. Hence, $s(B_2) + s(L) \leq m/2$, and $s(B_3) + s(L) \leq m/2$ as well (it is easy to see that $s(B_3) \leq s(B_1)$). By the submodularity of f , $f(U) \leq f(B_1) + f(B_2) + f(B_3)$; thus, there is $j \in \{1, 2, 3\}$ such that $f(B_j) \geq f(U)/3$. As none of the sets B_1, B_2, B_3 is empty, we have that $|B_j| \leq |P_k| - 2 = 4$.

Let $T = \text{GREEDY}(f_U, m/2 - s(B_j))$. By Lemma 9, either

$$f_U(T) \geq (1 - e^{-1/2})f_U(L) \geq f_U(L)/3,$$

or there is $i \in L$ such that

$$f_U(\{i\}) \geq (1 - e^{-1/2})f_U(L) \geq f_U(L)/3.$$

In the former case, we can consider the iteration in which $S_e = U, B = B_j$. In this iteration, we have

$$f(B \cup T) \geq f(B_j) + f_U(T) \geq \frac{1}{3}(f(U) + f_U(L)) = \frac{1}{3}\text{OPT}.$$

In the latter case, we can consider the iteration where $S_e = B = B_j \cup \{i\}$, and in which

$$f(B \cup T) \geq f(B) \geq f(B_j) + f_{B_j}(\{i\}) \geq f(B_j) + f_U(\{i\}) \geq \frac{1}{3}\text{OPT}.$$

Case 2.2: The process terminated with B_1, B_2 satisfying $B_1 \cup B_2 = P_k$, and $s(B_1), s(B_2) \leq m/2$.

Let $p_1 = f(B_1)/\text{OPT}$, $p_2 = (f(P_k) - f(B_1))/\text{OPT}$, $S_1 = s(B_1)$, $S_2 = s(B_2)$ and $L = S \setminus P_k$. If $p_1 \geq \frac{1}{3}$ (or $p_2 \geq \frac{1}{3}$) we have that in the iteration where $S_e = P_k$ and $B = B_1$ (or $B = B_2$) the algorithm finds a solution of value at least $\text{OPT}/3$, and the theorem holds. Thus, we may assume that $p_1, p_2 \leq \frac{1}{3}$.

For $j = 1, 2$, let $T_j = \text{GREEDY}(f_{P_k}, m/2 - S_j)$. Using Lemma 7 with $S^* = L$, we have that there is $i_j \in L$ for which

$$f_{P_k}(T_j) + f_{P_k}(\{i_j\}) \geq (1 - e^{-\frac{\frac{1}{2}-S_j}{1-S_1-S_2}})f_{P_k}(L).$$

By the selection of elements in P_k , we have $f_{P_k}(\{i_j\}) \leq \frac{1}{k}f(P_k)$. Thus,

$$f_{B_j}(T_j) \geq f_{P_k}(T_j) \geq (1 - e^{-\frac{\frac{1}{2}-S_j}{1-S_1-S_2}})f_{P_k}(L) - \frac{1}{k}f(P_k).$$

Hence, in the iteration where $S_e = P_k, B = B_j$, we obtain a solution satisfying

$$\begin{aligned} f(S_e \cup T) &= f(B_j \cup T_j) \geq f(B_j) + (1 - e^{-\frac{\frac{1}{2}-S_j}{1-S_1-S_2}})f_{P_k}(L) - \frac{1}{k}f(P_k) \\ &\geq \text{OPT} \left(p_j + (1 - p_1 + p_2)(1 - e^{-\frac{\frac{1}{2}-S_j}{1-S_1-S_2}}) - \frac{p_1 + p_2}{k} \right). \end{aligned}$$

By Lemma 8, in one of these iterations we obtain a solution of value at least $\text{OPT}/3$, implying the statement of the theorem. \blacktriangleleft

Proof of Lemma 8. Let p_1, p_2, S_1, S_2 be values that satisfy the conditions in the lemma.

Denote $p = p_1 + p_2, d = p_1 - p_2$ and $r = e^{-\frac{\frac{1}{2}-S_1}{1-S_1-S_2}}$. It is easy to see that $e^{-\frac{\frac{1}{2}-S_2}{1-S_1-S_2}} = e^{-1}r^{-1}$. Define $V_1 = h(p_1, p_2, S_1, S_2)$ and $V_2 = h(p_2, p_1, S_2, S_1)$. By the definition of h and above definitions we get

$$V_1 = \frac{p+d}{2} + (1-p)(1-r) - \frac{p}{k}$$

and

$$V_2 = \frac{p-d}{2} + (1-p)(1 - e^{-1}r^{-1}) - \frac{p}{k}$$

Let $g_1(x) = \frac{p+d}{2} + (1-p)(1-x) - \frac{p}{k}$ and $g_2(x) = \frac{p-d}{2} + (1-p)(1 - e^{-1}x^{-1}) - \frac{p}{k}$. Clearly, $V_1 = g_1(r)$ and $V_2 = g_2(r)$. It is also easy to see that g_1 is decreasing and g_2 is increasing (for $x > 0$).

\triangleright **Claim 10.** It holds that $g_1(x^*) = g_2(x^*)$ where $x^* = \frac{d + \sqrt{d^2 + 4e^{-1}(1-p)^2}}{2(1-p)}$.

Proof. By rearranging terms we have $g_1(x) = g_2(x)$ if and only if $d = (1-p)(x - e^{-1}x^{-1})$, which holds for $x > 0$ if and only if $0 = (1-p)x^2 - dx - e^{-1}(1-p)$. The latter is a quadratic equation and $x^* > 0$ is a root. \triangleleft

If $r \geq x^*$, since g_2 is increasing, we have $V_2 = g_2(r) \geq g_2(x^*) = g_1(x^*)$, and if $r \leq x^*$, as g_1 is decreasing, we have $V_1 = g_1(r) \geq g_1(x^*)$. Therefore $\max(V_1, V_2) \geq g_1(x^*)$. By rearranging terms and substituting $k = 6$ we have

$$g_1(x^*) = 1 - \frac{p}{2} - \frac{\sqrt{d^2 + 4e^{-1}(1-p)^2}}{2} - \frac{p}{6} = 1 - \frac{2p}{3} - \frac{\sqrt{d^2 + 4e^{-1}(1-p)^2}}{2}$$

Our goal is to show that for $0 \leq p \leq \frac{2}{3}$, we have $1 - \frac{2p}{3} - \frac{1}{2} \cdot \sqrt{d^2 + 4e^{-1}(1-p)^2} \geq \frac{1}{3}$, or $\frac{2}{3}(1-p) - \frac{1}{2} \cdot \sqrt{d^2 + 4e^{-1}(1-p)^2} \geq 0$. By rearranging terms this is equivalent to showing

$$\frac{2}{3} \geq \sqrt{\frac{d^2}{4(1-p)^2} + e^{-1}}.$$

Consider two cases:

Case 1: $0 \leq p \leq \frac{1}{3}$. Since $|d| \leq p$ we have

$$\sqrt{\frac{d^2}{4(1-p)^2} + e^{-1}} \leq \sqrt{\frac{p^2}{4(1-p)^2} + e^{-1}} \leq \sqrt{\frac{1}{16} + e^{-1}} \leq \frac{2}{3}.$$

The last inequality follows since the function $\frac{x}{1-x}$ is increasing in the interval $[0, \frac{1}{3}]$.

69:12 Generalized Assignment via Submodular Optimization

Case 2: $\frac{1}{3} \leq p \leq \frac{2}{3}$, as $\frac{p+d}{2}, \frac{p-d}{2} \leq \frac{1}{3}$, we have that $|d| \leq \frac{2}{3} - p$. Therefore,

$$\sqrt{\frac{d^2}{4(1-p)^2} + e^{-1}} \leq \sqrt{\frac{(2/3-p)^2}{4(1-p)^2} + e^{-1}} \leq \sqrt{\frac{1}{16} + e^{-1}} \leq \frac{2}{3}.$$

The last inequality follows since the function $\frac{2/3-x}{1-x}$ is decreasing in the interval $[\frac{1}{3}, \frac{2}{3}]$.

In both cases we get $g_1(x^*) \geq \frac{1}{3}$, and as $\max(V_1, V_2) \geq g_1(x^*)$, the lemma follows. \blacktriangleleft

5 Filling Phase

In this section we prove Theorem 4. Define the size of bin j in assignment U as $s_j^U = \sum_{i \in U_j} s_i$. We first divide the bins and items into types. We say that a bin j is *full* if $s_j^U > 1$, *semi-full* if $\frac{1}{2} \leq s_j^U \leq 1$, and *semi-vacant* if $s_j^U < \frac{1}{2}$. An item $i \in I(U)$ is *big* if $s_i > \frac{1}{2}$; otherwise, i is *small*. Clearly, there are no big items in semi-vacant bins.

Informally, we use in the proof several types of resolution steps. Each step takes as input a full bin and possibly one or two semi-vacant bins, and reassigns some of the items into the bins while evicting others. These resolution steps ensure that the new assignment has at least half the profit of the original assignment, the assignment to any bin remains feasible, and only small items are evicted.

We apply the resolution steps repeatedly, but once a bin participated in a resolution step it may not participate in another one. We then prove that as long as there are full bins, one of the steps can be applied. Hence, by applying the resolution steps, we have a new assignment in which all bins are feasible, and the total profit is at least half the profit of the original assignment. To handle the evicted items, we note that as $s(I(U)) \leq m/2$ and all the evicted items are small, it is possible to assign the evicted items to bins without violating the capacity constraints.

Proof of Theorem 4. For any bin $1 \leq j \leq m$ and $A \subseteq I$, let $p_j(A) = \sum_{i \in A} p_{i,j}$ be the total profit gained from packing A into j . The first step is to resolve the violation of the capacity constraint in each full bin. We do that using four types of resolution steps. Each step takes a full bin and possibly one or two semi-vacant bins, modifies their contents and adds some small elements to a set V of *evicted* elements, that will be handled later. Throughout the discussion, we consider for a full bin j a partition of the elements in U_j into two feasible subsets, given by $\{A_j, B_j\}$. We use the following resolution steps.

1. Consider a full bin j such that U_j has no big elements. If $p_j(A_j) > p_j(B_j)$ then set $U'_j = A_j$ and evict B_j ($V := V \cup B_j$); otherwise, set $U'_j = B_j$ and evict A_j , ($V := V \cup A_j$). In both cases U'_j is feasible and $p_j(U'_j) \geq \frac{1}{2} \cdot p_j(U_j)$.
2. Now, suppose we have a full bin j such that U_j has a single big element, and a semi-vacant bin ℓ . Let $\{A^*, B^*\} = \{A_j, B_j\}$, such that the big element is in A^* . If $p_j(A^*) + p_\ell(U_\ell) > p_j(B^*)$, set $U'_j = A^*$, $U'_\ell = U_\ell$ and evict the elements in B^* ($V := V \cup B^*$). We note that in this case $p_j(U'_j) + p_\ell(U'_\ell) = p_j(A^*) + p_\ell(U_\ell)$. Otherwise, set $U'_j = B^*$ and $U'_\ell = A^*$, and evict all the elements in U_ℓ , ($V := V \cup U_\ell$). In this case we have $p_j(U'_j) + p_\ell(U'_\ell) \geq p_j(B^*)$. Therefore, in both cases have $p_j(U'_j) + p_\ell(U'_\ell) \geq \frac{1}{2} \cdot (p_j(U_j) + p_\ell(U_\ell))$.
3. Consider a full bin j such that U_j has two big elements, and a semi-vacant bin ℓ , such that one of the big elements has space in bin ℓ ; that is, there is a big element $i^* \in U_j$ such that $s_{i^*} + s_\ell^U \leq 1$.

Let $\{A^*, B^*\} = \{A_j, B_j\}$ such that $i^* \in A^*$. We note that there cannot be any other big element in A^* other than i^* .

If $p_j(B^*) + p_\ell(U_\ell) > p_j(A^*)$ set $U'_j = B^*$ and $U'_\ell = U_\ell \cup \{i^*\}$ (note that $s_\ell^{U'_\ell} \leq 1$). Also, evict all elements in $A^* \setminus \{i^*\}$. In this case we have $p_j(U'_j) + p_\ell(U'_\ell) \geq p_j(B^*) + p_\ell(U_\ell)$.

Otherwise, we set $U'_j = A^*$ and $U'_\ell = B^*$, and evict U_ℓ ($V := V \cup U_\ell$). In this case we have $p_j(U'_j) + p_\ell(U'_\ell) \geq p_j(A^*)$.

Thus, in both cases $p_j(U'_j) + p_\ell(U'_\ell) \geq \frac{1}{2} \cdot (p_j(U_j) + p_\ell(U_\ell))$.

4. Finally, consider a full bin j , such that U_j has two big elements, and two semi-vacant bins ℓ_1 and ℓ_2 . Recall A_j, B_j is a partition of the elements in U_j into two feasible subsets. If $p_j(A_j) + p_{\ell_1}(U_{\ell_1}) > p_j(B_j) + p_{\ell_2}(U_{\ell_2})$, set $U'_j = A_j$, $U'_{\ell_1} = U_{\ell_1}$ and $U'_{\ell_2} = B_j$, and evict U_{ℓ_2} . Thus, we have

$$p_j(U'_j) + p_{\ell_1}(U'_{\ell_1}) + p_{\ell_2}(U'_{\ell_2}) \geq p_j(A_j) + p_{\ell_1}(U_{\ell_1}).$$

Otherwise, set $U'_j = B_j$, $U'_{\ell_1} = A_j$ and $U'_{\ell_2} = U_{\ell_2}$ and evict U_{ℓ_1} . Here

$$p_j(U'_j) + p_{\ell_1}(U'_{\ell_1}) + p_{\ell_2}(U'_{\ell_2}) \geq p_j(B_j) + p_{\ell_2}(U_{\ell_2}).$$

And finally, we always have

$$p_j(U'_j) + p_{\ell_1}(U'_{\ell_1}) + p_{\ell_2}(U'_{\ell_2}) \geq \frac{1}{2} \cdot (p_j(U_j) + p_{\ell_1}(U_{\ell_1}) + p_{\ell_2}(U_{\ell_2})).$$

Each time we execute a step we mark the bins used in this step as *resolved*, and we do not consider them in the next steps. We first use Steps 1, 2, and 3, until none of them can be applied.

Consider the average size of the unresolved bins. When we start, there are m bins of average size no greater than half. Each of Steps 1, 2, and 3 reduces the size of the unresolved bins by at least one (as a full bin is removed) and reduces the number of bins by at most two. Therefore, the average size of the unresolved bins remains no more than half. Also, marking all the semi-full bins as resolved will preserve the property.

Let a be the number of unresolved full bins and c be the number of unresolved semi-vacant bins. Due to the average size of bins, we have $a \leq \frac{a+c}{2}$, therefore $a \leq c$. Hence, if we have a full bin, there must be a semi-vacant bin as well. As we used Steps 1, 2, and 3 to exhaustion, every full bin must have two big elements (no bin in U contains more than two big elements), and none of these big elements can fit into one of the semi-vacant bins.

Denote the minimal size of a semi-vacant unresolved bin by r . Then each of the full bins has two big elements of size greater than $1 - r$. Hence, we have $c \cdot r + 2a \cdot (1 - r) < \frac{a+c}{2}$, which leads to $2a(1 - r) - \frac{a}{2} < c(\frac{1}{2} - r)$, and

$$c > a \cdot \frac{2 - 2r - \frac{1}{2}}{\frac{1}{2} - r} = a \cdot \frac{3 - 4r}{1 - 2r} = a \cdot \left(\frac{2 - 4r}{1 - 2r} + \frac{1}{1 - 2r} \right) = a \cdot \left(2 + \frac{1}{1 - 2r} \right) > 2a,$$

implying that we can now run Step 4, until there are no more unresolved full bins.

We use the resolution steps to eliminate all the full bins. Every time we run such a step over a set of bins we lose at most half the profit of the bins participating in the step. As the total size of items in the assignment is bounded by $m/2$, we are guaranteed that it is possible to assign all the evicted elements to some bins. Thus, we are able to resolve the capacity overflow while losing at most half of the profit. ◀

6 Discussion and Future Work

In this paper we presented a $\frac{1}{6}$ -approximation algorithm for Group GAP, using a mild assumption on the size of each group. A key component in our result is an algorithm for submodular maximization subject to a knapsack constraint, which finds a solution occupying at most half the knapsack capacity, while the other half is *reserved* for later use. Our results leave several avenues for future work.

As mentioned above, Group GAP with no assumption on group sizes cannot be approximated within any constant factor. Yet, the maximum group size that still allows to obtain a constant ratio can be anywhere in $[\frac{m}{2}, \frac{2}{3}m]$. Thus, a natural question is: “Can our results be applied to instances with larger group sizes?” We note that the ratio stated in Theorem 5 may not hold already for instances in which group sizes can be at most $\frac{m}{2}(1 + \varepsilon)$, for some $\varepsilon > 0$. Indeed, for such instances, it may be the case that no set of groups of total size at most $m/2$ is “good” relative to the optimum. The existence of an algorithm that yields a constant ratio for such instances remains open.

While our result for submodular optimization with reserved capacity (Theorem 2) gives an optimal approximation ratio for the studied subclass of instances, we believe the result can be extended to other subclasses. In particular, we conjecture that for instances where each item has size at most $\delta > 0$, the approximation ratio approaches $1 - e^{-\frac{1}{2}}$ as $\delta \rightarrow 0$. Such result would immediately imply an improved approximation ratio for instances of Group GAP in which the total size of each group is bounded by δm . We defer this line of work to the full version of the paper.

Lastly, we introduced in the paper the novel approach of submodular optimization subject to a knapsack with reserved capacity constraint. We applied the approach along with a framework similar to the one developed in [1]. It would be interesting to investigate whether the approach can be used to improve the approximation ratio obtained in [1] for *all-or-nothing* GAP.

Abstract

We study the problem of designing a dictionary data structure that is *resilient* to memory corruptions. Our error model is a variation of the faulty RAM model in which, except for constant amount of definitely *reliable* memory, each memory word is randomly *unreliable* with a probability $p < \frac{1}{2}$, and the locations of the unreliable words are unknown to the algorithm. An adversary observes the whole memory and can, at any time, arbitrarily *corrupt* (i.e., modify) the contents of one or more *unreliable* words.

Our dictionary has capacity n , stores $N < n$ keys in the optimal $O(N)$ amount of space, supports insertions and deletions in $O(\log n)$ amortized time, and allows to search for a key in $O(\log n)$ worst-case time. With a *global* probability of at least $1 - \frac{1}{n}$, all possible search operations are guaranteed to return the correct answer w.r.t. the set of uncorrupted keys.

The closest related results are the ones of Finocchi et al. [13] and Brodal et al. [6] on the faulty RAM model, in which all but $O(1)$ memory is unreliable. There, if an upper bound δ on the number of corruptions is known in advance, all dictionary operations can be implemented in $\Theta(\log n + \delta)$ amortized time, thus trading resiliency for speed as soon as $\delta = \omega(\log n)$.

Our construction does not need to know the value of δ in advance and remains *fast* and *effective* even when up to a constant fraction of the available memory is corrupted. Our techniques can be immediately extended to implement other data types (e.g., associative containers and priority queues), which can then be used as a building block in the design of other resilient algorithms. For example, we are able to solve the *resilient sorting* problem in our model using $O(n \log n)$ time.

1 Introduction

Computing platforms sometimes exhibit temporary or permanent memory failures and they can be expected to become more frequent due to the challenge of providing high amounts of energy on an ever smaller scale, while simultaneously increasing the operation frequency. Most algorithms completely malfunction even if a single memory error occurs. For example, one may consider the *Mergesort* algorithm, where a constant fraction of elements can be placed out of order following a single corruption. Classical approaches to deal with these

faults involve data replication or the use of error-correcting code (ECC) memory, and typically require more computational resources (i.e., space and/or time) or dedicated hardware. This gave rise to a line of research focusing on the design of fast and compact algorithms and data structures that are *resilient* to memory faults, i.e., that provide provable guarantees on their output even when some memory words become corrupted.

A widely used model to capture this kind of corruption is the faulty RAM model [14], in which an algorithm has access to only a constant amount of *reliable* memory, while all the other words are *unreliable*. An adversary is then allowed to corrupt (i.e., change the value of) up to δ unreliable words,¹ and the algorithms' performances are evaluated as a function of δ . We consider a variation of the above model in which, in addition to the $O(1)$ reliable memory, each of the remaining words is unreliable with a certain probability $p < \frac{1}{2}$ but the algorithm is unaware of which of these locations are reliable. While both settings are theoretical abstractions of the more complex error patterns that can happen in the real-world, it is not hard to come up with examples that closely resemble our error model. For example, when a DRAM module is faulty, its contents are no longer reliable and read and write operations might produce corrupted values. To complicate things further, even though the faulty locations might be contiguous, processors map physical addresses to hardware locations using complex (and often undocumented) mapping functions.² This increases memory access parallelism but has the side effect of distributing the unreliable locations over the whole address space.

We focus on the problem of designing a resilient data structure implementing the *dictionary* abstract data type, that is, we want to maintain a set of up to n keys under insertion and deletions so that we can answer membership queries. While it is easy to adapt any classical (non-resilient) data structure to our model with a multiplicative blow up of $\Theta(\log n)$ in the time and space complexities, one might wonder whether provably good guarantees w.r.t. the number of corruptions can be achieved using the asymptotically optimal $O(n)$ amount of space. In the rest of this paper we show that the answer is indeed affirmative.

Our model

Our model of computation is a random access machine [1] in which each word of memory is either *reliable* or *unreliable*. The memory itself is split into two regions:

- A *safe* region of $O(1)$ words (representing, e.g., processor registers) that are always *reliable*.
- A region containing all of the remaining words (representing, e.g., the main memory). Each of these words is independently *reliable* with probability $1 - p$ and *unreliable* with probability p , for some constant $p < \frac{1}{2}$.

Unreliable words can be affected by *corruption* phenomena, i.e., their contents can unexpectedly change. Except for the $O(1)$ words in the safe memory region, an algorithm is unaware of which memory locations are unreliable and is unable to detect whether the value stored in an unreliable location has been corrupted. Following [14], we adopt a worst case approach to corruptions: a computationally-unbounded adversary knows the algorithm that is being executed, can observe the contents of the whole memory, and can distinguish reliable from unreliable words. The adversary can, at any point during the execution of the algorithm, *simultaneously* corrupt the values stored in one or more *unreliable* words.

¹ This implicitly adopts a worst-case approach, so that all positive results also hold in the easier case of random, non-malicious corruptions.

² Finding techniques to reliably discover the mapping functions is an area of active research. Proposed methods use thermal and timing data to correlate physical addresses to memory locations [19, 18, 24].

Our results and techniques

We design a *resilient dictionary* that stores up to n keys using the optimal amount of space, supports insertions, deletions, and membership queries (in the following **insert**, **delete**, and **search**) in $O(\log n)$ amortized time and guarantees *with high probability* (w.h.p.) that, regardless of the number δ of corruptions, all **search** operations work reliably on all uncorrupted keys. More precisely, the **search** operation behaves as follows: if the searched key k belongs to the dictionary and is uncorrupted, then the **search** operation correctly returns **yes**. If k does not belong to the dictionary and no corrupted key equals k , the returned answer is guaranteed to be **no**. In the remaining cases the answer might be either **yes** or **no**.

As a comparison, the closest related results are the ones of Brodal et al. [6] and Finocchi et al. [13] on the faulty RAM model. There the authors show how, given δ , it is possible to build a dictionary that is resilient to up to δ word corruptions, uses $O(n)$ space, and whose **insert**, **delete**, and **search** operations require $O(\log n + \delta)$ amortized time, which is tight.³

Crucially, the task of selecting a good upper bound δ on the number of corruptions at design time can turn out to be problematic: if δ is too small then the resulting dictionary can abruptly fail when the $(\delta + 1)$ -th corruption occurs while, if $\delta = \omega(\log n)$, one is forced to trade-off resiliency for speed as the additive term of δ now becomes dominant in the time complexity.

Notice that, in our setting, the *expected* number of unreliable locations is $pn = \Theta(n)$, implying that the *actual* number of unreliable locations is $\Theta(n)$, except for an exponentially vanishing probability. Since δ can be as large $\Theta(n)$ (think, e.g., of our faulty DRAM-example), a direct instantiation of the results of [6] and [13] yields the same bounds of the trivial dictionary that uses $O(n)$ space and time per operation (just store all the keys in an unsorted array). Nevertheless, one might wish for a dictionary that remains resilient w.r.t. a constant fraction of key corruptions and whose operations do not bear the exorbitant cost of $O(n)$ time per operation. Our results shows that this is indeed possible: when the unreliable locations are random fraction of the available memory, it is possible handle *any (unknown) number* δ of corruptions with the same asymptotic guarantees obtained by the existing fault-tolerant dictionaries in the faulty RAM model when $\delta = O(\log n)$.

From a high-level point of view, [13] *buffers* the dictionary keys into groups of size $\Theta(\delta)$, and organizes the resulting groups into a pointer-based AVL tree. A core subroutine then consists of **locating** the group responsible for a given key in $O(\log n + \delta)$ time. Since the corruption of any auxiliary information associated with a group might lead the search astray, the corresponding variables are replicated $\Theta(\delta)$ times. A first difficulty to overcome in our model is that of removing the dependency from δ . We do so by using a different locate procedure that is based on a suitable walk over the tree vertices. The behavior of the walk is guided by the observed memory contents, yet we prove that there is an absolute probability of at least $1 - \frac{1}{n}$ that no possible walk can be misled by the adversary, even when all the unreliable memory locations are corrupted. Another difficulty is intrinsic in pointer-based structures: if the address stored in a pointer cannot be reliably recovered, the whole pointed object becomes inaccessible. The natural way to deal with this problem involves reading multiple copies of the pointer. However, since reading only $o(\log n)$ copies would still allow the adversary to corrupt the pointer with a probability larger than $\frac{1}{n}$, this would lead to a

³ The dictionary of [13] is randomized and the above bounds hold in expectation, while the one of [6] is deterministic. The dictionary of [13] can be made deterministic by slightly worsening the δ additive term in the amortized complexity to $\delta^{1+\epsilon}$, for a constant $\epsilon > 0$ of choice.

slowdown of $\Omega(\log n)$. We avoid this problem altogether by using a *dynamic* binary search tree (BST) that is *nearly balanced*, i.e., whose height is at most an *additive constant* larger than the optimal one [7]. This tree is then embedded into a *static* and *pointer-free* complete BST. We are now left with one final technical obstacle: since rebalancing such a dynamic tree following an update operation is more expensive w.r.t. its AVL counterpart, we need to employ a more elaborate 2-level buffering scheme. Namely, we group keys into $O(\frac{n}{\log n})$ *pages* of capacity $O(\log n)$ which are in turn arranged into sorted *folders* consisting of $O(\log n)$ pages (i.e., $O(\log^2 n)$ keys) each.

We remark that the high probability bound on the correctness of our dictionary does not depend on the number of operations performed. In other words, there is a *global* probability of at least $1 - \frac{1}{n}$ that the operations in any (arbitrarily long) sequence of **inserts**, **deletes**, and **searches**, are *all* jointly correct. The following Theorem summarizes our result:

► **Theorem 1.** *A resilient dictionary with capacity n can be constructed in $O(1)$ worst-case time. Search, and update operations (i.e., **insert** and **delete**) require $O(\log n)$ worst-case and $O(\log n)$ amortized time, respectively. The space required is $O(N)$, where N is the number of elements currently stored in the dictionary. All operations performed during the lifetime of the dictionary are (jointly) correct with probability at least $1 - \frac{1}{n}$.*

Although our focus is on the dictionary abstract data type, our techniques immediately extended to other data types (e.g., associative containers and priority queues), as we discuss in Section 6.

Other related results

Apart from the already mentioned results of [13] and [6], several other algorithms and models to deal with faulty computations have been proposed, with considerable attention paid to the problems of sorting and searching. In the faulty RAM model, the *resilient sorting* problem asks to output a permutation of an input set of n elements such that the set of uncorrupted elements forms a sorted subsequence, while the *resilient searching* problem asks to locate an uncorrupted key k in such a sorted sequence, if it exists. Roughly speaking, when δ corruptions happen, one can resiliently sort and search at the cost of an additional *additive* term in the time complexity that depends only on δ . More specifically, one can search in $\Theta(\log n + \delta)$ time [6, 14] and sort in $O(n \log n + \delta^2)$ time which can be improved to $O(n + \delta^2)$ when elements are polynomially-bounded integers [12]. Moreover, for $\delta = \omega(\sqrt{n \log n})$, all resilient sorting algorithms must require $\omega(n \log n)$ time in the general case [14].

Another popular model dealing with faults considers the elements as opaque objects possessing an unknown linear order that needs to be discovered or approximated through *pairwise noisy comparisons*, i.e., comparisons that can sometimes be incorrect. If comparison errors happen randomly and resampling is allowed (i.e., a comparison can be repeated multiple times and the results are independent) then one can sort and search, w.h.p., in the optimal $O(n \log n)$ and $O(\log n)$ time, respectively [11]. If resampling is not allowed then one cannot reliably reconstruct the correct linear order. Nevertheless, it is possible to compute a permutation in which each element is misplaced by at most $O(\log n)$ positions, which is asymptotically optimal. Several solutions have been designed for this problem [5, 25, 20, 15, 16, 17] culminating in an optimal $O(n \log n)$ time algorithm. If errors are adversarial then $\Omega(n \log n + \delta n)$ comparisons are needed, and this is tight [3, 21, 22]. Adversarial errors in searching are studied in the context of Rényi-Ulam Games, in which a questioner needs to guess an element from a domain by asking comparison questions to a lying responder. An extensive collection of results exists, depending on the considered domain and on the constraints on the responder's lies. We refer the interested reader to [23] and [9] for a survey and a monograph.

In [2] the authors define the *fault-tolerance* of a data structure as the maximum ratio between the amount of data lost as a consequence of a number δ of corruptions and δ . They provide implementations of linked lists, stacks, and binary search trees with a fault-tolerance of $O(\log \delta)$ or $O(1)$, depending on the specific construction used, while losing only constant *multiplicative* factors in the time and space requirements. We remark that in [2], unlike both our dictionary and the ones in [13, 6], uncorrupted keys can also be lost until the whole data structure is reconstructed. If $\Theta(\delta)$ words of safe memory are available then, instead of the multiplicative overhead of [2], one can pay only an *additive* overhead of $\tilde{O}(\delta)$ in the time and space complexities, and the data structure can be reconstructed in linear time [8]. Similarly to [13] and [6], and differently from our dictionary, both [2] and [8] require the value of δ to be known in advance.

2 Preliminaries

For simplicity we assume that the capacity n of our dictionary is a sufficiently large power of 2, so that $\log n$ is a sufficiently large integer and we do not have to deal with rounding. We also assume, w.l.o.g., that $p \leq \frac{1}{1024}$.⁴ A concept of *resilient variable* similar to the one used in [13] will also be useful in the sequel. For our purposes, a resilient variable x consists of $20 \log n + 1$ consecutive copies x_1, x_2, \dots of a classical variable. A resilient variable can be written (i.e., assigned to) in $O(\log n)$ time and constant space by simply writing the intended value to each x_i . We can then read the value stored in x either resiliently or non-resiliently: a non-resilient read amounts to returning the (possibly corrupted) value of a single x_i ; a resilient read returns the majority value among those stored in all the copies $x_1, \dots, x_{20 \log n + 1}$, or fails if no majority value exists. Notice that, if at least $10 \log n + 1$ copies are uncorrupted, the majority value coincides with the one previously stored in x and can be computed in $O(\log n)$ time using a constant number of words in safe memory (see, e.g., the Boyer-Moore majority vote algorithm [4]). An easy Chernoff-bound argument shows that this is indeed the case for *all possible read operations that can be performed*, w.h.p, as the following Lemma states (a formal proof will appear in the full version of the paper).

► **Lemma 2.** *Suppose that the number of words used to store replicated variables is $O(n)$. With probability at least $1 - n^{-2}$, all resilient read operations return the previously stored value.*

In the following we assume that all resilient read operations succeed as we will eventually union bound the success probability of the other operations in our dictionary with that of Lemma 2. Finally, we use $-\infty$ (resp. $+\infty$) to denote a key smaller than (resp. the largest among) all valid keys that can be inserted in our dictionary, and \perp as a placeholder for some invalid key value.

The paper is organized in a bottom-up fashion: Section 3 describes *pages*, which are groups of $O(\log n)$ keys; In Section 4 we further group pages into sorted *folders* and show how to *quickly* locate pages, while Section 5 uses pages and folders to build our dictionary. In Section 6 we summarize our results and provide some concluding remarks.

⁴ For any constant $\epsilon > 0$ and $p \in (\frac{1}{1024}, \frac{1}{2} - \epsilon]$, we can simulate the required error probability by storing $\lceil 30\epsilon^{-2} \rceil$ copies of each word, with a strategy similar to the one described in the rest of this section.

3 Pages

Each page v is associated with a contiguous interval $I(v) = (L_v, R_v]$ of keys and will be responsible for storing a set $K(v)$ of $O(\log n)$ keys, where all *uncorrupted* keys in $K(v)$ will belong to $I(v)$. A page π is implemented as contiguous array $A(\pi)$ of capacity $6 \log n$ and three replicated variables storing: the endpoints L_π and R_π of $I(\pi)$, and the *size* $|K(\pi)|$ of π . The keys in $K(\pi)$ are stored in the first $|K(\pi)|$ positions of $A(\pi)$ in an arbitrary order. If $|K(\pi)| = 0$ (resp. $|K(\pi)| = 6 \log n$) we say that π is empty (resp. full).

Pages will support five basic operations, namely **search**, **insert**, **delete**, **split**, and **merge**, as detailed in the following.

Search. Given $k \in I(v)$, the **search** operation determines whether $k \in K(\pi)$. We simply resiliently read the variable $|K(v)|$ and compare k with the first $|K(v)|$ elements of $A(\pi)$. If any (resp. no) element compares equal to k we report that k belongs to (resp. does not belong to) π . Clearly, this requires $O(\log n)$ worst-case time.

Insert. The **insert** operation adds a key $k \in I(\pi)$ to $K(\pi)$ and is only legal if π is not full. We first **search** for k and, if $k \in K(\pi)$, we are immediately done. Otherwise we write k in the $|K(\pi)|$ -th position of the array storing the set $K(v)$, where $|K(\pi)|$ is read resiliently. The time required is $O(\log n)$ in the worst-case.

Delete. The **delete** operation removes a key k from $K(\pi)$. If $k \notin K(\pi)$, then π is unaltered. The operation requires $O(\log n)$ time: after a resilient read of $|K(v)|$, we perform linear search on $A(\pi)$ and, if k is found in some position i , we swap the i -th and the $|K(v)|$ -th element of $A(\pi)$ and decrement $|K(v)|$ by 1 (which requires a replicated write operation). Due to corruptions, $A(\pi)$ might contain multiple occurrences of k , in which case exactly one of them is removed.

Split. The **split** operation destroys π and returns (the addresses of) two newly created pages π_1, π_2 such that: (i) $I(\pi_1) \cap I(\pi_2)$ is the empty interval; (ii) $I(\pi_1) \cup I(\pi_2) = I(\pi)$; (iii) $|K(\pi_1)| = \lfloor |K(\pi)|/2 \rfloor$ and $|K(\pi_2)| = \lceil |K(\pi)|/2 \rceil$; (iv) $K(\pi_1) \cup K(\pi_2) = K(\pi)$.

The difficulty of the **split** operation lies in computing a key $x \in [L_\pi, R_\pi]$ that allows to split $I(v)$ into two sub-intervals $I(\pi_1) = (L_\pi, x]$ and $I(\pi_2) = (x, R_\pi]$ while preserving the bounds on the sizes of π_1 and π_2 . We create a new page π_1 and we populate $A(\pi_1)$ by repeating the following iterative procedure $\lfloor |K(\pi)|/2 \rfloor$ times: in iteration i we search for the smallest key $k_i \in K(v)$, we remove k_i from $K(\pi)$ (in a way similar to our implementation of the **delete** operation), and we add it into the i -th position of $A(\pi_1)$. Finally, we rename π as π_2 , we choose $x = \min\{R_\pi, \max\{L_\pi, k_1, k_2, \dots, \}\}$, and we set $I(\pi_1)$ and $I(\pi_2)$ accordingly. It is easy to see that the split operation requires $O(\log^2 n)$ time in the worst case. The following lemma, whose proof is deferred to the full version of the paper, shows the uncorrupted keys are correctly partitioned among π_1 and π_2 .

► **Lemma 3.** *Let k be an uncorrupted key belonging to π before the **split** operation. If $k \leq x$ (resp. $k > x$) then k belongs to $K(\pi_1)$ (resp. $K(\pi_2)$) after the **split** operation.*

Merge. The **merge** operation can be thought of as the opposite of the **split** operation. It requires two pages π_1 and π_2 as inputs such that (i) $I(\pi_1) \cap I(\pi_2)$ is the empty interval, (ii) $I(\pi_1) \cup I(\pi_2)$ is a contiguous interval, and (iii) $|K(\pi_1)| + |K(\pi_2)| \leq 6 \log n$; and produces the following effects: it adds all keys in $K(\pi_2)$ to $K(\pi_1)$, updates $I(\pi_1)$ to $I(\pi_1) \cup I(\pi_2)$, and destroys π_2 . Notice that the order of π_1 and π_2 determines which of the two pages is destroyed.

Pages π_1 and π_2 are merged as follows: first we resiliently read $|K(\pi_1)|$ and $|K(\pi_2)|$, and append the $|K(\pi_2)|$ keys in π_2 in positions $|K(\pi_1)| + 1, \dots, |K(\pi_1)| + |K(\pi_2)|$ of $A(\pi_1)$. We then update $|K(\pi_1)|$ to $|K(\pi_1)| + |K(\pi_2)|$ and $I(\pi_1)$ to $(\min\{L_{\pi_1}, L_{\pi_2}\}, \max\{R_{\pi_1}, R_{\pi_2}\})$ where $L_{\pi_1}, L_{\pi_2}, R_{\pi_1}, R_{\pi_2}$ are also read resiliently. One can easily check that the overall time complexity of a merge operation is $O(\log n)$ in the worst case.

4 Folders

Folders are *sorted* arrays of capacity $6 \log n$ in which elements are *pages* having pairwise disjoint intervals. Each folder F additionally stores two replicated variables holding the number $|F|$ of pages currently in the array, and the overall number $|K(F)|$ of keys stored in (the pages of) F . With a slight abuse of notation we say that $\pi \in F$ if π is one of the pages of F . We denote by $K(F)$ the union of all sets $K(\pi)$ for $\pi \in F$. A folder F will always contain at least one page and, similarly to pages, it is (implicitly) associated with an interval $I(F) = (L_F, R_F]$. When F is first created it consists of a single *innate* empty page π with $I(\pi) = I(F)$. In general, each $\pi \in F$ is responsible for a certain sub-interval of $I(F)$ (formally, the intervals $I(\pi)$ are pairwise disjoint and satisfy $\cup_{\pi \in F} I(\pi) = I(F)$). Moreover, all pages except the first one will always contain at least $\log n + 1$ keys, and hence we immediately have that $|K(F)| \geq (|F| - 1) \cdot (\log n + 1)$ and that a folder can always accommodate at least $(6 \log n - 1)(\log n + 1) > 6 \log^2 n$ keys. In fact, we guarantee that F will always contain at most $6 \log^2 n$ keys. Quite naturally, we say that a folder F is *empty* if it contains no keys, and *full* if it contains exactly $6 \log^2 n$ keys. If F is not empty, then its first page will also be non-empty.

The pages in the array of F are sorted w.r.t. the order relation \prec implicitly defined by the order of their intervals, i.e., we say that two pages π_1, π_2 are such that $\pi_1 \prec \pi_2$ iff $I(\pi_1)$ precedes $I(\pi_2)$ ($\pi_1 \preceq \pi_2$, $\pi_1 \succ \pi_2$, and $\pi_1 \succeq \pi_2$ are defined accordingly). As a consequence, there is no need to explicitly store $I(F)$ since its left and right endpoints coincide with those of the first and last page in F , respectively.

We now discuss the operations supported by folders, most of which are similar to the ones for pages, on which they rely.

Locate and Search. Given a key $k \in I(F)$, the **locate** operation returns the unique page $\pi \in F$ such that $k \in I(\pi)$. Once the **locate** operation is available, one can easily **search** for a key $k \in I(F)$ by first **locating** the page π such that $k \in I(\pi)$ and then **searching** for k in π .

Notice that the **locate** operation can be easily implemented in $O(\log^2 n)$ worst case time, w.h.p., by binary searching for the page π while reading all the replicated variables resiliently. We now show that it is possible to reduce the time complexity to $O(\log n)$ by using a technique similar to the one of [11], where an element in a sorted array A is located through a random walk over the contiguous sub-intervals induced by the elements in A . Such a random walk will observe inconsistent results *independently at random* and is allowed to backtrack when this happens. Moreover, to guarantee a *high probability* of success, $\Omega(\log |A|)$ consistent observations are required before an element is returned. However, the analysis of [11] is not immediately suitable for our case due to two main obstacles, namely: (i) we want the high probability bound on the success probability to hold *jointly* for all **locate** operations performed during the lifetime of our dictionary, and (ii) since the adversary has complete control over the unreliable memory locations and a complete knowledge of the memory state, he can cause the inconsistent results to become correlated (e.g., by steering

■ **Figure 1** (a) An example tree T used by our random walk to implement the `locate` operation. (b) An example graph G having maximum out-degree $\Delta = 4$. Preferential edges are drawn with solid lines. A traversable path of type 2 and length 9 is highlighted in bold.

the walk towards corrupted memory locations). We overcome these obstacles by relating all the problematic realizations of all possible random walks to a collection of paths in a suitable graph. We then show that, with high probability, no possible set of memory corruptions can cause any such path to become viable.

The locate algorithm. We start by considering an almost-complete binary tree⁵ T in which the i -th leaf π_i corresponds to the i -th page of F , and an internal node v represents the (contiguous) interval $I(v) = (L_v, R_v]$ obtained by the union of all intervals $I(\pi)$ where π is a leaf of the subtree T_v of T rooted at v . Then, we augment such a tree by appending, to each π_i , a path P_{π_i} consisting of $20 \log n - d(\pi_i)$ copies of π_i itself, where $d(\pi_i) \in \{\lfloor \log 6n \rfloor, \lceil \log 6n \rceil\}$ is the depth of vertex π_i in T . See Figure 1 (a) for an example.

It is important to remark that T does not need to be explicitly constructed since each vertex $v \in V(T)$ can be represented by a triple of integers (i, j, h) , where i (resp. j) is the index, in the array of pages, of the smallest (resp. largest) leaf (i.e., page) in T_v , and h is the depth of v in T .

We now perform a discrete-time *walk* on T as follows: initially the current vertex v of the walk coincides with the root r of T and, at the generic i -th step, we *walk* from v to one of its neighbors. More precisely, if $I(v)$ is obtained by the union of all the intervals $I(\pi)$ for $\pi^- \preceq \pi \preceq \pi^+$ we read the i -th copy ℓ (resp. r) of the replicated variable L_{π^-} (resp. R_{π^+}), we check whether $\ell < k \leq r$ and, if that is *not* the case, we *walk* from v to the parent of v in T (in the special case $v = r$ we “walk” from v to itself). Otherwise, if v has only one child u in T , we walk from v to u . Finally, if v has two children u_1 and u_2 in T where $I(u_1)$ precedes $I(u_2)$ and is obtained by the union of all the intervals $I(\pi)$ for $\pi_1^- \preceq \pi \preceq \pi_1^+$, we compare k with the i -th copy x of $R_{\pi_1^+}$. If $k \leq x$ we walk to u_1 , otherwise we walk to u_2 .

We continue the walk for $20 \log n$ steps so that we are guaranteed that all v , except possibly for the one reached after the last step, have at least one child. If the vertex v reached at the end of the walk belongs to a path P_π , we return π . We say that the `locate` operation *fails* if either the v does not belong to any path P_π , or if $k \notin I(\pi)$.

⁵ A binary tree of height h is almost-complete if it is complete up to the $(h - 1)$ -th level. Moreover, we also assume that all the leaves on the h -th level are left-justified.

Analysis. Let us consider the following related problem. We are given a directed acyclic graph G having maximum out-degree at most $\Delta \geq 2$, a vertex $s \in V(G)$, and a probability $\rho \leq \frac{1}{32(\Delta-1)}$. Moreover, each non-sink vertex $v \in V(G)$ has exactly one *preferential* outgoing edge $(v, v^*) \in E(G)$ and we define E^* as the set of all preferential edges. The vertices of G are independently colored either red or blue with probability at most ρ and at least $1 - \rho$, respectively. Finally, we say that a path $P = \langle v_0, v_1, \dots, v_k \rangle$ in G is *traversable* if, for every $v_i \in P$ with $i = 0, \dots, k-1$, we have that v_i is red, or (v_i, v_{i+1}) is preferential, or both. See Figure 1 (b) for an example. We are now ready to state the following:

► **Lemma 4.** *Let ℓ be a multiple of 4. The probability that G contains a traversable path P of length ℓ from s such that $|E(P) \cap E^*| \geq \frac{\ell}{4}$ is at most $2^{-\frac{\ell}{4}+1}$.*

Proof. We will count the number of possible paths of length ℓ from s by grouping them according to the number of non-preferential edges they use. More precisely, we say that the *type* of a path $P = \langle s = v_0, v_1, \dots, v_\ell \rangle$ in G is κ if $|\{v_i^* \neq v_{i+1} : i \in \{0, \dots, \ell-1\}\}| = \kappa$, where (v_i, v_i^*) is the unique preferential edge outgoing from v_i . Notice that each path of type κ can be described by a set of κ pairs: $\{(\tau_1, a_1), \dots, (\tau_\kappa, a_\kappa)\}$ where (τ_i, a_i) signifies that when the path reaches v_{τ_i} , it continues towards the a_i -th non-preferential outgoing edge from v_{τ_i} (according to some fixed arbitrary order of the edges). This immediately implies that there are at most $\binom{\ell}{\kappa} (\Delta-1)^\kappa$ paths of type κ . Moreover, for any such path to be traversable, it must happen that all the vertices v_i with $i \in \{\tau_1, \dots, \tau_\kappa\}$ are red (while the remaining vertices can be either blue or red). This happens with probability at most ρ^κ , and hence the probability that there exists at least one traversable path of type κ is at most $\binom{\ell}{\kappa} (\Delta-1)^\kappa \rho^\kappa$. By summing over all $\kappa \in [\ell/4, \ell]$ we obtain:

$$\sum_{\kappa=\ell/4}^{\ell} \binom{\ell}{\kappa} (\Delta-1)^\kappa \rho^\kappa \leq \left(\sum_{\kappa=\ell/4}^{\ell} \binom{\ell}{\kappa} \right) \cdot \left(\sum_{\kappa=\ell/4}^{\infty} (\Delta-1)^\kappa \rho^\kappa \right) \leq \frac{2^\ell (\Delta-1)^{\frac{\ell}{4}} \rho^{\frac{\ell}{4}}}{1 - (\Delta-1)\rho} < 2^{-\frac{\ell}{4}+1}. \quad \blacktriangleleft$$

► **Lemma 5.** *With probability at least $1 - n^{-3}$ no `locate` operation on folders fails.*

Proof. We relate our random walk on T to the traversable paths in a suitable graph G . Let t be the unique leaf of T such that the key k to locate belongs to the corresponding page π and direct each edge of T towards t . We define G as the graph whose vertex set consists of $\ell + 1$ copies $u^{(1)}, u^{(2)}, \dots$ of each vertex $u \in V(T)$ and whose edge set contains, for all $i = 1, \dots, \ell$, the edge $(r^{(i)}, r^{(i+1)})$ and all the edges $(u^{(i)}, v^{(i+1)})$ where (u, v) is a directed edge in T . We color a vertex $u^{(i)}$ of G red if the i -th copy of at least one of the (at most 3) replicated variables accessed when a step of the random walk is performed from vertex $u^{(i)}$ is in an unreliable memory location (notice that these replicated variables correspond to the page associated with u and, possibly, with a child of u in T). For each non-sink vertex $u^{(i)}$ of G we let (u, v) be the unique (directed) edge outgoing from u in T and we choose the edge from $u^{(i)}$ to $v^{(i+1)}$ as the preferential edge from $u^{(i)}$ in G .

The graph G has maximum out-degree 3 and hence, once we choose $\Delta = 3$, $s = r$, $\rho = \frac{1}{128} > 3p$, and $\ell = 20 \log n$, we can invoke Lemma 4 to conclude that all the traversable paths from s in G of length $20 \log n$ use less than $5 \log n$ non-preferential edges with probability at least $1 - 2n^{-5}$. Since any sequence of vertices $\langle r = v_1, v_2, \dots, v_{\ell+1} \rangle$ corresponding to a realization of our random walk induces a traversable path $P = \langle s = v_1^{(1)}, v_2^{(2)}, \dots, v_{\ell+1}^{(\ell+1)} \rangle$ in G we know that, with the aforementioned probability, all possible random walks on T will use at least $15 \log n$ edges directed towards t . Each such edge decreases the distance in T from the current vertex of the walk to t by at least 1, while any other edge increases such a distance by at most 1. Since the distance $d_T(r, t)$ from r to t in T is $20 \log n$ by

70:10 Resilient Dictionaries for Randomly Unreliable Memory

construction, we conclude that the final vertex v of the walk must satisfy $d_T(v, t) \leq 10 \log n$ or, in other words, v lies on P_π and the `locate` operation is successful. The claim follows by noticing that, once the locations of the unreliable words are fixed, at most $O(n \log^2 n)$ distinct (colored) graphs G can exist, namely those corresponding to the $O(\log n)$ possible different sizes of T , to the $O(\log n)$ different positions of the sought leaf t in T , and to the $O(n)$ memory locations at which a folder can be stored. ◀

Insert. The `insert` operation adds a key $k \in I(F)$ into $K(F)$, and it is only legal when F is not full. We first `locate` the page π responsible for k and we say that the insert operation *targets* π . Then, if π is not full, we simply `insert` k into π , we update $|K(F)|$, and we are done. Otherwise, we say that the insert operation is *expensive*. Let i be the position of π in the array of pages. We move all pages in positions $i + 1, \dots, |F|$ one position to the right (so that the page originally in position j is now in position $j + 1$), and increment $|F|$ by 1.⁶ Every read and write operation on the replicated variables of the moved pages is performed resiliently, i.e., a replicated variable is moved by first resiliently reading its value x from the old memory location and then resiliently writing x to the new memory location. We now `split` π into two pages π_1 and π_2 containing $3 \log n$ keys each, and we store them in positions i and $i + 1$, respectively. Finally, we `insert` k into the unique page $\pi' \in \{\pi_1, \pi_2\}$ such that $k \in I(\pi')$, and we update $|K(F)|$.

Overall, an `insert` operation requires $O(\log n)$ worst-case time if it is not expensive and $O(\log^2 n)$ worst-case time otherwise.

Delete. The `delete` operation removes a key k from $K(T)$ if $k \in K(T)$. If $k \notin K(T)$ the operation does nothing. We first `locate` the page π responsible for k and we say that the delete operation *targets* π . We now try to `delete` k from π and, if k was not found in $K(\pi)$ we are already done. If k is found, then we decrement $|K(F)|$ by 1 and proceed differently depending on the size and on the position of π in the pages array of F . Whenever, after the deletion, any of the following conditions is true, no further work is necessary: (D1) $|K(\pi)| > \log n$; or (D2) π is the only page of F ; or (D3) π is the first page of F and is non-empty. Otherwise, we say that the delete operation is *expensive* and we distinguish two cases. If (i) π is the first page of F , (ii) F has at least 2 pages, and (iii) π is empty, we let π' be the second page in F and we delete π from F as follows: We set the left endpoint of $I(\pi')$ to the left endpoint of $I(\pi)$ (effectively updating $I(\pi')$ to $I(\pi) \cup I(\pi')$), and we shift every page of F other than π one position to its left, thus overwriting and destroying π . Finally, we decrement the value of $|F|$ by 1.

The complementary case is the one in which $|K(\pi)| \leq \log n$ and π is not the first page of F , which implies that $|K(\pi)| = \log n$. We let π' be the page preceding π in F and we further distinguish two sub-cases depending on the value of $|K(\pi')|$:

- If $|K(\pi')| \leq 4 \log n$, we `merge` π' and π . Since this operation destroys π , we shift all pages $\pi'' \in F$ such that $\pi'' \succ \pi$ by one position to their left, and we decrement $|F|$ by 1. Notice that π' now contains at most $4 \log n + \log n = 5 \log n$ keys.
- If $|K(\pi')| > 4 \log n$ we first `split` π' (destroying it) into π_1 and π_2 . We then `merge` π_2 and π (destroying π). We store π_1 in place of π' and π_2 in place of π . Notice that π_1 now contains at least $2 \log n$ and at most $3 \log n$ keys, while π_2 contains at least $2 \log n + \log n = 3 \log n$ and at most $3 \log n + \log n = 4 \log n$ keys.

⁶ Notice that, before the `insert` operation, we necessarily had $|F| < 6 \log n$ as otherwise $|K(F)|$ is at least $(6 \log n - 1)(\log n + 1)$, which violates our invariant on the number of keys stored in F .

Similarly to the **insert** operation, when pages are moved in the array of F , all their resilient variables are read and written resiliently. Overall, the required worst-case time is $O(\log n)$ if the operation is not expensive, and $O(\log^2 n)$ otherwise.

Split. If $|K(F)| \geq 12 \log n$, the **split** operation destroys F and returns two new folders F_1 and F_2 that together contain the same set of keys of F and such that: $I(F) = I(F_1) \cup I(F_2)$, $I(F_1) \cap I(F_2) = \emptyset$, and $|K(F)|/2 \leq |K(F_1)| < |K(F)|/2 + 6 \log n$ (implying $|K(F)|/2 - 6 \log n < |K(F_2)| \leq |K(F)|/2$), and all the uncorrupted keys $k \in K(\pi)$ belong to the unique folder $F' \in \{F_1, F_2\}$ such that $k \in I(F')$.

To implement the operation, we look for the first page π such that $\sum_{\pi' \preceq \pi} |K(\pi')| \geq |K(F)|/2$. We then construct the folders F_1 and F_2 , where T_1 contains all the pages $\pi' \preceq \pi$, and T_2 contains all the pages $\pi' \succ \pi$. Notice that the condition $|K(F)| \geq 12 \log n$ ensures that F_2 will always contain at least one page from F . All involved variables are read and written resiliently.

Overall, the **split** operation can be performed in $O(\log^2 n)$ time in the worst-case.

Merge. The **merge** operation takes two non-empty folders F_1 and F_2 such that $|F_1| + |F_2| \leq 6 \log^2 n$, $I(F_1)$ precedes $I(F_2)$, and $I(F_1) \cup I(F_2)$ is a contiguous interval, and returns a new folder F containing the keys in $K(F_1) \cup K(F_2)$ and such that $I(F) = I(F_1) \cup I(F_2)$. The operation destroys F_1 and F_2 .

We first handle some corner cases that only happen if F_1 contains a single page π . If this is the case and $|K(\pi)| \leq 2 \log n$ also holds, then we let π' be the first page of F_2 and proceed as follows:

- If $|K(\pi)| + |K(\pi')| \leq 5 \log n$, **merge** π' and π (destroying π), and return F_2 (where $I(F_2)$ and $|K(F_2)|$ are suitably updated);
- Otherwise, if $|K(\pi')| \geq 4 \log n$, we **split** π' into π_1 and π_2 , we merge π_1 and π (so that π is destroyed), and we return a new folder consisting of π_1 , π_2 and all pages other than π' in F_2 . Both π_1 and π_2 contain between $2 \log n$ and $5 \log n$ keys.
- In the remaining case, we have that $5 \log n < |K(\pi)| + |K(\pi')| < 6 \log n$. We, first **merge** π and π' , then we split π into π_1 and π_2 , each containing more than $2 \log n$ and at most $3 \log n$ keys. We return the folder consisting of π_1 , π_2 and all pages other than π' in F_2 .

We now suppose that we are not in any of the above cases, and preprocess F_1 and F_2 to ensure that the leftmost page π' of F_2 will always contain at least $2 \log n$ keys. If that is not already the case, we let π be the last page of F_1 and modify F_1 and F_2 as follows:

- If $|K(\pi)| + |K(\pi')| \leq 5 \log n$ we **merge** π' and π . We decrement $|F_1|$ to account for the destroyed page π (this might cause F_1 to temporarily become empty).
- If $|K(\pi)| \geq 4 \log n$ we first split π into π_1 and π_2 and then **merge** π_2 and π' . We store π_1 and π_2 in place of the, now destroyed, pages π and π' in F_1 and F_2 , respectively.
- Otherwise we must have $5 \log n < |K(\pi)| + |K(\pi')| < 6 \log n$. We first **merge** π and π' , then we **split** π into π_1 and π_2 . We store π_1 and π_2 in place of π and π' in F_1 and F_2 , respectively.

The rest of the operation is now straightforward: we simply create a new folder F by concatenating all pages in F_1 with those in F_2 and set $|F| = |F_1| + |F_2|$, $|K(F)| = |K(F_1)| + |K(F_2)|$, and $I(F) = I(F_1) \cup I(F_2)$. We remark that the involved pages are simply moved from their previous folder to the new folder F , rather than being destroyed and recreated anew. Overall, the merge operation requires $O(\log^2 n)$ time in the worst-case.

Amortized analysis

The following lemma, whose proof is omitted, summarizes the time complexities of the folder's operations and shows that the $O(\log^2 n)$ time needed by the expensive `insertions` and `deletions` can be amortized over $\Omega(\log n)$ non-expensive operations.

► **Lemma 6.** *An empty folder can be constructed in $O(\log n)$ worst-case time. Each search operation can be performed in $O(\log n)$ worst-case time. Merge and split operations requires $O(\log^2 n)$ worst-case time. Each insert or delete operation requires $O(\log n)$ amortized time.*

5 Our dictionary

We store the dictionary keys into $\eta = O(\frac{n}{\log^2 n})$ folders, such that (i) each folder contains at most $6 \log^2 n$ keys and (ii) all but at most one folder contain at least $\log^2 n + 1$ keys. These folders are logically organized into a dynamic *nearly-balanced* binary search tree T , in which each vertex v_F is associated with a folder F and consists of three resilient variables, namely: and a pointer containing the address of folder F , and two variables L_{v_F} and R_{v_F} defining an interval $I(v_F) = (L_{v_F}, R_{v_F}]$ where L_{v_F} (resp. R_{v_F}) is the leftmost (resp. rightmost) endpoint among of all the intervals of the folders associated with the descendants of v_F in T (including v_F itself). The intervals of the stored folders will be pairwise disjoint and will cover the whole range $(-\infty, +\infty]$. An empty dictionary consists of a single empty folder F with $I(F) = (-\infty, +\infty]$.

As shown in [7], an embedding of a *dynamic* binary search tree with $N \geq 1$ vertices into a *static* complete binary tree of height $H(N) = \lceil \log(2N + 1) \rceil - 1$ can be maintained under insertion and deletion of vertices in $O(\log^2 N)$ amortized time per operation, assuming that vertices can be accessed and copied in constant time.⁷ For the sake of completeness we briefly sketch the construction of [7]. Let $\rho(u)$ be the ratio between the number of vertices of the subtrees rooted at u in the dynamic and in the static trees, respectively. The root r will always satisfy $\frac{1}{8} \leq \rho(r) \leq \frac{1}{2}$. This is initially true when the dynamic tree consists of single vertex since $H(1) = 1$ and $\rho(r) = \frac{1}{2^{H(1)+1}-1} = \frac{1}{3}$. Whenever an insertion or deletion needs to be performed, we first check whether it will causes the value of $H(N)$ to change and, if this is the case, the operation is handled by rebuilding the updated dynamic tree in a perfectly balanced fashion. The remaining updates are as follows: insertions are performed as in an ordinary binary search tree except when they cause the height of the newly inserted vertex u to exceed $H(N)$. In this case the subtree rooted at the lowest ancestor v of u such that $\frac{1}{8} - \frac{d(v)}{16 \cdot H(N)} \leq \rho(v) \leq \frac{1}{2} + \frac{d(v)}{2 \cdot H(N)}$ is rebuilt to be perfectly-balanced (recall that $d(v)$ is the depth of vertex v). When a vertex u needs to be deleted, it is first pushed down the dynamic tree by iteratively swapping it with either its predecessor or its successor until it becomes a leaf. Then, u is deleted and the subtree rooted on the lowest vertex v that was ancestor of u and that satisfies $\frac{1}{8} - \frac{d(v)}{16 \cdot H(N)} \leq \rho(v) \leq \frac{1}{2} + \frac{d(v)}{2 \cdot H(N)}$ is rebuilt. The current number of vertices of the dynamic tree is explicitly stored (which allows to compute $\rho(r)$ in constant time) while no additional information needs to be maintained for the values $\rho(v)$ for $v \neq r$ as the complexity needed to compute them (e.g., with a DFS visit of the subtree rooted in v) is subsumed by that of the rebalancing step.

⁷ We restated the result of [7] using the standard definitions of depth and height employed in this paper. We also fixed the parameters τ_1 , γ_1 , and γ_H of [7] to $\frac{1}{2}$, $\frac{1}{8}$, and $\frac{1}{16}$ respectively.

■ **Figure 2** On the left: an example of static tree \bar{T} of height $H(\eta) = 3$ onto which is embedded the dynamic tree T consisting of the $\eta = 6$ white vertices. The label of each vertex $v \in V(T)$ is the interval $I(v)$. On the right: the folder F pointed by the root of T . In this example F contains 3 pages π_1, π_2, π_3 . Three possible intervals for the pages in F are: $I(\pi_1) = (20, 33]$, $I(\pi_2) = (33, 41]$, and $I(\pi_3) = (41, 50]$. Key 83 in π_2 is corrupted and is highlighted in red.

Since, in our case, the number of nodes η in T can be at most $1 + \lfloor \frac{n}{\log^2 n} \rfloor$, we have that $H(\eta) \leq \log(2\eta + 1) \leq 2 + \log \frac{n}{\log^2 n}$. We therefore embed T into a static tree \bar{T} which, in turn, is implicitly stored in a positional array of $2^{H(\eta)+1} - 1 \leq 8 \frac{n}{\log^2 n}$ elements. In this way, given the address of any node of \bar{T} , we can compute the addresses of its left child, right child, and parent in constant time. Overall, the space required to store \bar{T} is at most $8 \frac{n}{\log^2 n} \cdot O(\log n) = O(\frac{n}{\log n})$. Since the resilient variables of a vertex $v \in V(T)$ can be read and written in $O(\log n)$ time, we are able to insert and delete vertices from \bar{T} in $O(\log^2 \eta) \cdot O(\log n) = O(\log^3 n)$ amortized time.⁸ We distinguish the vertices v that belong in our static tree \bar{T} but not in our *logical tree* T by setting their intervals $I(v)$ to the bogus range $(\perp, \perp]$ and their pointers to some arbitrary address (see Figure 2 for an example). Notice that, when a subtree is rebalanced, the intervals of the affected nodes also need to be recomputed. The same applies to the ancestors of a deleted or newly inserted vertex. In both cases the required time complexity is $O(\log n)$ per vertex and, since the tree is nearly balanced, it is subsumed by the amortized cost of the operation. We store η , the number of keys currently in the dictionary, and the address of the array representing \bar{T} as global variables in safe memory.

Implementing the dictionary operations

Using a technique similar to the one described in Section 4 to locate a page in a folder, we are able to `locate` the folder F responsible for a given key k in our tree T (along with the corresponding node v_F).

► **Lemma 7.** *With probability at least $1 - n^{-3}$ no `locate` operation on the dictionary fails.*

Once the `locate` operation is available, the `search` operation can be easily implemented by first `locating` the (unique) folder F in T such that $k \in I(F)$ and `searching` for k in F . Moreover, we also use the `locate` operation to implement the `insert` and `delete` operations of our dictionary, together with a suitable strategy for splitting and merging the folders of

⁸ Here the amortization is performed over all insertion and deletion of vertices in \bar{T} . In the sequel we will derive an amortized bound w.r.t. insertions and deletions of keys in our dictionary.

T when they become full or contain less than $1 + \log^2 n$ keys. Due to space limitations, a formal description of these operation and the proof of the above lemma are deferred to the full version of this paper.

Space complexity

Our dictionary as described so far achieves all the bounds of Theorem 1 except for the one regarding its space complexity, which would be $O(\log^2 n + N)$ instead of the promised $O(N)$, where N is the number of keys in the dictionary. The missing range $N = o(\log^2 n)$ can be handled by lazily building the first page and the first folder of our dictionary, and by employing a suitable halving/doubling strategy [10] to ensure that their size is always linear in the number of keys stored therein. A complete proof of Theorem 1 will appear in the full version of the paper.

6 Conclusions

We presented a resilient dictionary that is able to operate correctly on all uncorrupted keys, uses the optimal amount of space, and whose operations require $O(\log n)$ amortized time. All operations are deterministic, i.e., their execution is completely determined by their input and by the observed memory contents. The same construction can also be used if satellite data is attached to the keys, in which case the `search` operation returns either the data associated with a given uncorrupted key k or that of a key that equals k following a corruption. Moreover, one can easily implement other commonly used operation on BSTs, e.g., we can report all the N stored keys in $O(N)$ worst-case time, find the predecessors or successors in $O(\log n)$ worst-case time, support range queries in $O(\log n + t)$ time where t is the size of the output, and find (resp. extract) the minimum/maximum element in $O(\log n)$ worst-case (resp. amortized) time.

Our data structure can aid in the design of other resilient algorithms and, sometimes, can even be used as a drop-in replacement of corresponding non fault-tolerant implementations. For example, when our dictionary is augmented with the `find-min` operation described above, it can substitute the heap in the classical heapsort algorithm, which then immediately solves the resilient sorting problem in our error model using $O(n \log n)$ worst-case time.

Finally, we observe that our approach can be combined with a constant replication scheme to ensure that, for any constant $c \geq 1$ of choice, at most δ/c keys are lost when δ words are corrupted. In addition, if we slightly worsen the construction time to $O(\log n)$, the time required to report the N stored keys to $O(N + \log n)$, and the the space requirements to $O(N + \log n)$, then our results also hold even when no definitely reliable memory words exist, except for $O(1)$ *temporary* registers that can only be used to hold intermediate computation results (i.e., whose contents are invalidated at the beginning/end of each dictionary operation).

Abstract

We study spectral approaches for the MAX-2-LIN(k) problem, in which we are given a system of m linear equations of the form $x_i - x_j \equiv c_{ij} \pmod k$, and required to find an assignment to the n variables $\{x_i\}$ that maximises the total number of satisfied equations.

We consider Hermitian Laplacians related to this problem, and prove a Cheeger inequality that relates the smallest eigenvalue of a Hermitian Laplacian to the maximum number of satisfied equations of a MAX-2-LIN(k) instance \mathcal{I} . We develop an $\tilde{O}(kn^2)$ time algorithm that, for any $(1 - \varepsilon)$ -satisfiable instance, produces an assignment satisfying a $(1 - O(k)\sqrt{\varepsilon})$ -fraction of equations. We also present a subquadratic-time algorithm that, when the graph associated with \mathcal{I} is an expander, produces an assignment satisfying a $(1 - O(k^2)\varepsilon)$ -fraction of the equations. Our Cheeger inequality and first algorithm can be seen as generalisations of the Cheeger inequality and algorithm for MAX-CUT developed by Trevisan.

1 Introduction

In the MAX-2-LIN(k) problem, we are given a system of m linear equations of the form $u_i - v_i \equiv c_i \pmod k$, where $u_i, v_i \in \{x_1, \dots, x_n\}$ and each equation has weight b_i . The objective is to find an assignment to the variables x_i that maximises the total weight of satisfied equations. As an important case of Unique Games [8, 15], the MAX-2-LIN(k) problem has been extensively studied in theoretical computer science. This problem is known to be NP-hard to approximate within a ratio of $11/12 + \delta$ for any constant $\delta > 0$ [9, 13], and it is conjectured to be hard to distinguish between MAX-2-LIN(k) instances for which a $(1 - \varepsilon)$ -fraction of equations can be satisfied versus instances for which only an ε -fraction can

be satisfied [16]. On the algorithmic side, there has been a number of LP and SDP-based algorithms proposed for the MAX-2-LIN(k) problem (e.g., [6, 12, 15, 26]), and the case of $k = 2$, which corresponds to the classical MAX-CUT problem for undirected graphs [10, 14], has been widely studied over the past fifty years.

In this paper we investigate efficient spectral algorithms for MAX-2-LIN(k). For any MAX-2-LIN(k) instance \mathcal{I} with n variables, we express \mathcal{I} by a Hermitian Laplacian matrix $L_{\mathcal{I}} \in \mathbb{C}^{n \times n}$, and analyse the spectral properties of $L_{\mathcal{I}}$. In comparison to the well-known Laplacian matrix for undirected graphs [7], complex-valued entries in $L_{\mathcal{I}}$ are able to express directed edges in the graph associated with \mathcal{I} , and at the same time ensure that all the eigenvalues of $L_{\mathcal{I}}$ are real-valued. We demonstrate the power of our Hermitian Laplacian matrices by relating the maximum number of satisfied equations of \mathcal{I} to the spectral properties of $L_{\mathcal{I}}$. In particular, we develop a Cheeger inequality that relates partial assignments of \mathcal{I} to $\lambda_1(L_{\mathcal{I}})$, the smallest eigenvalue of $L_{\mathcal{I}}$. Based on a recursive application of the algorithm behind our Cheeger inequality, as well as a spectral sparsification procedure for MAX-2-LIN(k) instances, we present an approximation algorithm for MAX-2-LIN(k) that runs in $\tilde{O}(k \cdot n^2)$ time¹. To the best of our knowledge, this is the first purely spectral polynomial-time algorithm for the MAX-2-LIN(k) problem with approximation guarantees that matches SDP-based ones for constant values of k . The formal statement of our result is as follows:

► **Theorem 1.** *There is an $\tilde{O}(k \cdot n^2)$ -time algorithm such that, for any given MAX-2-LIN(k) instance \mathcal{I} with optimum $1 - \varepsilon$, the algorithm returns an assignment ϕ satisfying at least a $(1 - O(k)\sqrt{\varepsilon})$ -fraction of the equations².*

Our result can be viewed as a generalisation of the MAX-CUT algorithm by Trevisan [27], who derived a Cheeger inequality that relates the value of the maximum cut to the smallest eigenvalue of an undirected graph's adjacency matrix. The proof of Trevisan's Cheeger inequality, however, is based on constructing sweep sets in \mathbb{R} , while in our setting constructing sweep sets in \mathbb{C} is needed, as the underlying graph defined by $L_{\mathcal{I}}$ is directed and eigenvectors of $L_{\mathcal{I}}$ are in \mathbb{C}^n . The other difference between our result and the one in [27] is that the goal of the MAX-CUT problem is to find a *bipartition* of the vertex set, while for the MAX-2-LIN(k) problem we need to use an eigenvector to find k vertex-disjoint subsets, which corresponds to subsets of variables assigned to the same value.

Our approach also shares some similarities with the one by Goemans and Williamson [11], who presented a 0.793733-approximation algorithm for MAX-2-LIN(3) based on Complex Semidefinite Programming. The objective function of their SDP relaxation is, in fact, exactly the quadratic form of our Hermitian Laplacian matrix $L_{\mathcal{I}}$, although this matrix was not explicitly defined in their paper. In addition, their rounding scheme divides the complex unit ball into k regions according to the angle with a random vector, which is part of our rounding scheme as well. Therefore, if one views Trevisan's work [27] as a spectral analogue to the celebrated SDP-based algorithm for MAX-CUT by Goemans and Williamson [10], our result can be seen as a spectral analogue to the Goemans and Williamson's algorithm for MAX-2-LIN(k).

We further prove that, when the undirected graph associated with a MAX-2-LIN(k) instance is an expander, the approximation ratio from Theorem 1 can be improved. Our result is formally stated as follows:

¹ The notation $\tilde{O}(\cdot)$ suppresses poly-logarithmic factors in n , m , and k .

² An instance \mathcal{I} has optimum $1 - \varepsilon$, if the maximum fraction of the total weights of satisfied equations is $1 - \varepsilon$.

► **Theorem 2.** *Let \mathcal{I} be an instance of MAX-2-LIN(k) on a d -regular graph with n vertices and suppose its optimum is $1 - \varepsilon$. There is an $\tilde{O}\left(nd + \frac{n^{1.5}}{k\sqrt{\varepsilon}}\right)$ -time algorithm that returns an assignment $\phi : V \rightarrow [k]$ satisfying at least a*

$$1 - O(k^2) \cdot \frac{\varepsilon}{\lambda_2^3(\mathcal{L}_{\mathcal{U}})} \quad (1)$$

fraction of equations in \mathcal{I} , where $\lambda_2(\mathcal{L}_{\mathcal{U}})$ is the second smallest eigenvalue of the normalised Laplacian matrix of the underlying undirected graph \mathcal{U} .

Our technique is similar to the one by Kolla [18], which was used to show that solving the MAX-2-LIN(k) problem on expander graphs is easier. In [18], a MAX-2-LIN(k) instance is represented by the label-extended graph, and the algorithm is based on an exhaustive search in a subspace spanned by eigenvectors associated with eigenvalues close to 0. When the underlying graph of the MAX-2-LIN(k) instance has good expansion, this subspace is of dimension k . Therefore, the exhaustive search runs in time $O(2^k + \text{poly}(n \cdot k))$, which is polynomial-time when $k = O(\log n)$. Comparing with the work in [18], we show that, when the underlying graph has good expansion, the eigenvector associated with the smallest eigenvalue $\lambda_1(\mathcal{L}_{\mathcal{I}})$ of the Hermitian Laplacians suffices to give a good approximation. We notice that Arora et al. [4] already showed that, for expander graphs, it is possible to satisfy a $1 - O(\varepsilon \log(1/\varepsilon))$ fraction of equations in polynomial time without any dependency on k . Their algorithm is based on an SDP relaxation.

1.1 Other related work

There are many research results for the MAX-2-LIN(k) problem (e.g., [6, 12, 15, 26]), and we briefly discuss the ones most closely related to our work. For the MAX-2-LIN(k) problem and Unique Games, spectral techniques are often employed to analyse the Laplacian matrix of the Label-Extended graph (see, e.g., the aforementioned [18]), which has a strong connection with our Hermitian Laplacian: the latter can be seen as one of the blocks that arise in a particular block-diagonalisation of the former. Arora et al. [3], instead, use spectral techniques to obtain a particular decomposition of the constraint graph of a Unique Games instance, and exploit this decomposition to design an $\exp((kn)^{O(\varepsilon)}) \text{poly}(n)$ -time algorithm for Unique Games. Regarding polynomial-time algorithms, Charikar et al. [6] propose an SDP-based algorithm for Unique Games that satisfies a $1 - O(\sqrt{\varepsilon} \log k)$ fraction of constraints, which is nearly optimal assuming the Unique Games Conjecture [16]. We remark that canonical SDP programs for Unique Games can be solved in nearly-linear time [25].

Our result also relates to the research on spectral methods for synchronisation problems. For example, the adjacency matrix corresponding to our Hermitian Laplacian is considered by Singer [23] in relation to an angular synchronisation problem. The relation between the eigenvectors of such matrix and the MAX-2-LIN(k) problem is also mentioned but without offering formal approximation guarantees. Bandeira et al. [5] prove a Cheeger-type inequality that relates the spectra of an operator, the graph connection Laplacian, to “how well” an instance of the $O(d)$ -synchronisation problem can be solved. Their results, however, are not directly comparable to ours: even though our Hermitian Laplacian can also be seen as a graph connection Laplacian for an $SO(2)$ -synchronisation problem, our goal is to assign the n vertices to at most k elements of $SO(2)$, while the goal of Bandeira et al. is to assign each vertex to a possibly different element of $O(d)$.

2 Hermitian Matrices for MAX-2-LIN(k)

We can write an instance of MAX-2-LIN(k) by $\mathcal{I} = (G, k)$, where $G = (V, E, b, c)$ denotes a directed graph with an edge weight function $b : E \rightarrow \mathbb{R}^+$ and an edge color function $c : E \rightarrow [k]$, where $[k] \stackrel{\text{def}}{=} \{0, 1, \dots, k-1\}$. More precisely, every equation $u_i - v_i \equiv c_i \pmod k$ with weight b_i corresponds to a directed edge (u_i, v_i) with weight $b(u_i, v_i) = b_{u_i v_i} = b_i$ and color $c(u_i, v_i) = c_{u_i v_i} = c_i$. In the rest of this paper, we will assume that G is weakly connected, and write $u \rightsquigarrow v$ if there is a directed edge from u to v . The conjugate transpose of any vector $x \in \mathbb{C}^n$ is denoted by x^* .

We define the Hermitian adjacency matrix $A_{\mathcal{I}} \in \mathbb{C}^{n \times n}$ for instance \mathcal{I} by

$$(A_{\mathcal{I}})_{uv} \stackrel{\text{def}}{=} \begin{cases} b_{uv} \omega_k^{c_{uv}} & u \rightsquigarrow v, \\ b_{vu} \overline{\omega_k}^{c_{vu}} & v \rightsquigarrow u, \\ 0 & \text{otherwise,} \end{cases}$$

where $\omega_k = \exp\left(\frac{2\pi i}{k}\right)$ is the complex k -th root of unity, and $\overline{\omega_k} = \exp\left(-\frac{2\pi i}{k}\right)$ is its conjugate. We define the degree-diagonal matrix $D_{\mathcal{I}}$ by $(D_{\mathcal{I}})_{uu} = d_u$ where d_u is the weighted degree given by $d_u \stackrel{\text{def}}{=} \sum_{u \rightsquigarrow v} b_{uv} + \sum_{v \rightsquigarrow u} b_{vu}$. The Hermitian Laplacian matrix is then defined by $L_{\mathcal{I}} = D_{\mathcal{I}} - A_{\mathcal{I}}$, and the corresponding normalised Laplacian matrix by $\mathcal{L}_{\mathcal{I}} = D_{\mathcal{I}}^{-1/2} L_{\mathcal{I}} D_{\mathcal{I}}^{-1/2} = I - D_{\mathcal{I}}^{-1/2} A_{\mathcal{I}} D_{\mathcal{I}}^{-1/2}$. The eigenvalues of any matrix A are expressed by $\lambda_1(A) \leq \dots \leq \lambda_n(A)$. The quadratic forms of $L_{\mathcal{I}}$ can be related to the corresponding instance of MAX-2-LIN(k) by the following lemma.

► **Lemma 3.** *For any vector $x \in \mathbb{C}^n$, we have $x^* L_{\mathcal{I}} x = \sum_{u \rightsquigarrow v} b_{uv} \|x_u - \omega_k^{c_{uv}} x_v\|^2$ and*

$$x^* L_{\mathcal{I}} x = 2 \sum_{u \in V} d_u \|x_u\|^2 - \sum_{u \rightsquigarrow v} b_{uv} \|x_u + \omega_k^{c_{uv}} x_v\|^2.$$

The lemma below presents a qualitative relationship between the eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$ and an assignment of \mathcal{I} .

► **Lemma 4.** *All eigenvalues of $\mathcal{L}_{\mathcal{I}}$ are in the range $[0, 2]$. Moreover, $\lambda_1(\mathcal{L}_{\mathcal{I}}) = 0$ if and only if there exists an assignment satisfying all equations in \mathcal{I} .*

3 A Cheeger inequality for $\lambda_1(\mathcal{L}_{\mathcal{I}})$ and MAX-2-LIN(k)

The discrete Cheeger inequality [1] shows that, for any undirected graph G , the conductance h_G of $G = (V, E)$ can be approximated by the second smallest eigenvalue of G 's normalised Laplacian matrix \mathcal{L}_G , i.e.,

$$\frac{\lambda_2(\mathcal{L}_G)}{2} \leq h_G \leq \sqrt{2 \cdot \lambda_2(\mathcal{L}_G)}. \quad (2)$$

Moreover, the proof of the second inequality above is constructive, and indicates that a subset $S \subset V$ with conductance at most $\sqrt{2 \cdot \lambda_2(\mathcal{L}_G)}$ can be found by using the second bottom eigenvector of \mathcal{L}_G to embed vertices on the real line. As one of the most fundamental results in spectral graph theory, the Cheeger inequality has found applications in the study of a wide range of optimisation problems, e.g., graph partitioning [20], max-cut [27], and many practical problems like image segmentation [22] and web search [17].

In this section, we develop connections between $\lambda_1(\mathcal{L}_{\mathcal{I}})$ and MAX-2-LIN(k) by proving a Cheeger-type inequality. Let $\phi : \{x_1, \dots, x_n\} \rightarrow [k] \cup \{\perp\}$ be an arbitrary *partial assignment* of an instance \mathcal{I} , where $\phi(x_i) = \perp$ means that the assignment of x_i has not been decided.

These variables' assignments will be determined through some recursive construction, which will be elaborated in Section 5. We remark that this framework of recursively computing a partial assignment was first introduced by Trevisan [27], and our theorem can be viewed as a generalisation of the one in [27], which corresponds to the $k = 2$ case of ours.

To relate quadratic forms of \mathcal{L}_G with the objective function of the MAX-2-LIN(k) problem, we introduce a *penalty* function as follows:

► **Definition 5.** *Given a partial assignment $\phi : \{x_1, \dots, x_n\} \rightarrow [k] \cup \{\perp\}$ and a directed edge (u, v) , the penalty of (u, v) with respect to ϕ is defined by*

$$p_{uv}^\phi(\mathcal{I}) \stackrel{\text{def}}{=} \begin{cases} 0 & \phi(u) \neq \perp, \phi(v) \neq \perp, \phi(u) - \phi(v) \equiv c_{uv} \pmod{k} \\ 1 & \phi(u) \neq \perp, \phi(v) \neq \perp, \phi(u) - \phi(v) \not\equiv c_{uv} \pmod{k} \\ 0 & \phi(u) = \phi(v) = \perp \\ 1 - \frac{1}{k} & \text{exactly one of } \phi(u), \phi(v) \text{ is } \perp. \end{cases} \quad (3)$$

For simplicity, we write p_{uv}^ϕ when the underlying instance \mathcal{I} is clear from the context.

The values of p_{uv}^ϕ from Definition 5 are chosen according to the following facts: (1) If both u and v 's values are assigned, then their penalty is 1 if the equation $\phi(u) - \phi(v) \equiv c_{uv} \pmod{k}$ associated with (u, v) is unsatisfied, and 0 otherwise; (2) If both u and v 's values are \perp , then their penalty is temporally set to 0. Their penalty will be computed when u and v 's assignment are determined during a later recursive stage. (3) If exactly one of u, v is assigned, p_{uv}^ϕ is set to $1 - 1/k$, since a random assignment to the other variable makes the edge (u, v) satisfied with probability $1/k$, hence p_{uv}^ϕ is set to $1 - 1/k$.

Without loss of generality, we only consider ϕ for which $\phi(u) \neq \perp$ for at least one vertex u , and define the penalty of assignment ϕ by

$$p^\phi \stackrel{\text{def}}{=} \frac{2 \sum_{u \rightsquigarrow v} b_{uv} p_{uv}^\phi}{\text{Vol}(\phi)}, \quad (4)$$

where $\text{Vol}(\phi) \stackrel{\text{def}}{=} \sum_{\phi(u) \neq \perp} d_u$. Notice that the p_{uv}^ϕ 's value is multiplied by b_{uv} in accordance with the objective of MAX-2-LIN(k) that maximises the total weight of satisfied assignments. Also, we multiply p_{uv}^ϕ by 2 in the numerator since edges with at least one assigned endpoint are counted at most twice in $\text{Vol}(\phi)$. Notice that, as long as G is weakly connected, $p^\phi = 0$ if and only if all edges are satisfied by ϕ and, in general, the smaller the value of p^ϕ , the more edges are satisfied by ϕ . With this in mind, we define the *imperfectness* $p(\mathcal{I})$ of \mathcal{I} to quantify how close \mathcal{I} is to an instance where all equations can be satisfied by a single assignment.

► **Definition 6.** *Given any MAX-2-LIN(k) instance $\mathcal{I} = (G, k)$, the imperfectness of \mathcal{I} is defined by $p(\mathcal{I}) \stackrel{\text{def}}{=} \min_{\phi \in ([k] \cup \{\perp\})^V \setminus \{\perp\}^V} p^\phi$.*

The main result of this section is a Cheeger-type inequality that relates $p(\mathcal{I})$ and $\lambda_1(\mathcal{L}_\mathcal{I})$, which is summarised in Theorem 7. Note that, since $\sin(x) \geq (2/\pi) \cdot x$ for $x \in [0, \pi/2]$, the factor before $\sqrt{2\lambda_1}$ in the theorem statement is at most $(2 + k/4)$ for $k \geq 2$.

► **Theorem 7.** *Let λ_1 be the smallest eigenvalue of $\mathcal{L}_\mathcal{I}$. It holds that*

$$\frac{\lambda_1}{2} \leq p(\mathcal{I}) \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \sqrt{2\lambda_1}. \quad (5)$$

Moreover, given the eigenvector associated with λ_1 , there is an $O(m + n \log n)$ -time algorithm that returns a partial assignment ϕ such that

$$\frac{\lambda_1}{2} \leq p^\phi \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \sqrt{2\lambda_1}. \quad (6)$$

■ **Figure 1** Illustration of the proof for Theorem 7 for the case of $k = 3$. The gray circle is obtained by sweeping $t \in [0, 1]$, and the red arrow represents a random angle $\eta \in [0, 2\pi/k)$. A partial assignment is determined by the values of η and t .

Proof Sketch of Theorem 7. We present an overview of the proof here, and a complete proof of the theorem can be found in the full version of the paper. The easy direction of (5), i.e., $\lambda_1/2 \leq p(\mathcal{I})$, follows from the Courant-Fischer characterisation of eigenvalues and that the eigenvector problem is a relaxation of $\text{MAX-2-LIN}(k)$. Hence, we will mainly sketch the techniques used to prove the other direction of (5). We assume that $z \in \mathbb{C}^n$ is the vector such that

$$\frac{z^* L_{\mathcal{I}} z}{z^* D_{\mathcal{I}} z} = \lambda_1,$$

and prove the existence of an assignment ϕ based on z satisfying

$$p^\phi \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)}\right) \sqrt{2\lambda_1} = \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)}\right) \sqrt{2 \cdot \frac{z^* L_{\mathcal{I}} z}{z^* D_{\mathcal{I}} z}}.$$

We first scale each coordinate of z such that $\max_{u \in V} \|z_u\|^2 = 1$. In this way z can be seen as an embedding of the vertices to the complex unit ball. For any real numbers $t \geq 0$ and $\eta \in [0, \frac{2\pi}{k})$, we define k sets of vertices indexed by $j \in [k]$ as follows:

$$S_{t,\eta}^{(j)} = \left\{ u \mid \|z_u\| \geq t \text{ and } \theta(z_u, e^{i\eta}) \in \left[j \cdot \frac{2\pi}{k}, (j+1) \cdot \frac{2\pi}{k} \right) \right\}.$$

Here, we use $\theta(a, b) \in [-\pi, \pi)$ to represent the angle from $b \in \mathbb{C}$ to $a \in \mathbb{C}$, i.e., $\frac{a}{\|a\|} = \frac{b}{\|b\|} \exp(i\theta(a, b))$. We then define an assignment $\phi_{t,\eta}$ where $\phi_{t,\eta}(u) = j$ if there is $j \in [k]$ such that $u \in S_{t,\eta}^{(j)}$, and $\phi_{t,\eta}(u) = \perp$ otherwise. By definition, the k vertex sets correspond to the vectors in the k regions of the unit ball after each vector is rotated by η radians counterclockwise. The role of t is to only consider the coordinates z_u with $\|z_u\| \geq t$. This is illustrated in Figure 1.

Now we assume $t \in [0, 1]$ is chosen such that t^2 follows from a uniform distribution over $[0, 1]$, and η is chosen uniformly at random from $[0, 2\pi/k)$. Further calculations show that

$$\mathbb{E}_{t,\eta} [\text{Vol}(\phi_{t,\eta})] = \sum_{u \in V} d_u \cdot \mathbb{P} [\|z_u\| \geq t] = \sum_{u \in V} d_u \|z_u\|^2 = z^* D_{\mathcal{I}} z,$$

and

$$\mathbb{E}_{t,\eta} \left[2 \sum_{u \rightsquigarrow v} b_{uv} p_{uv}^\phi \right] \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \cdot \sqrt{z^* L_{\mathcal{I}} z} \cdot \sqrt{2 z^* D_{\mathcal{I}} z}.$$

Hence, it holds that

$$\frac{\mathbb{E}_{t,\eta} [2 \sum_{u \rightsquigarrow v} b_{uv} p_{uv}^\phi]}{\mathbb{E}_{t,\eta} [\text{Vol}(\phi_{t,\eta})]} \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \cdot \sqrt{2 \cdot \frac{z^* L_{\mathcal{I}} z}{z^* D_{\mathcal{I}} z}}.$$

This implies by linearity of expectation that

$$\mathbb{E}_{t,\eta} \left[2 \sum_{u \rightsquigarrow v} b_{uv} p_{uv}^\phi - \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \cdot \text{Vol}(\phi_{t,\eta}) \cdot \sqrt{2 \cdot \frac{z^* L_{\mathcal{I}} z}{z^* D_{\mathcal{I}} z}} \right] \leq 0,$$

and existence of an assignment ϕ satisfying (6).

Now we turn to the runtime needed to find such a vertex set. Notice that we need to find t and η such that $\phi_{t,\eta}$ satisfies (6). Therefore, we construct two sequences of *sweep sets*: the first is based on t , and the second is based on η . For constructing the sweep sets based on t , the algorithm increases t from 0 to 1, and updates the corresponding conditional expectation looking only at the edges incident with u whenever t exceeds $\|z_u\|$. Notice that each edge (u, v) will be updated at most twice, i.e., the step when t reaches $\|z_u\|$ and the step when t reaches $\|z_v\|$, and the total runtime needed to update $\text{Vol}(\phi_{t,\eta})$ is $O(m)$. Hence, the total runtime for constructing the sweep sets based on t is $O(m)$. The runtime analysis for constructing the sweep sets based on η is similar: the algorithm increases η from 0 to $2\pi/k$, and updates the penalties p_{uv}^ϕ of the edges (u, v) only if the assignment of u or v changes. Since every edge will be updated at most twice, the runtime for constructing the sweep sets based on η is $O(m)$ as well. Hence, the total runtime of the algorithm is $O(m + n \log n)$. ◀

► **Remark 8.** We remark that the factors $\lambda_1/2$ and $\sqrt{\lambda_1}$ in Theorem 7 are both tight within constant factors. The tightness can be derived directly from Section 5 of [27], since when $k = 2$, our inequality is the same as the one in [27] up to constant factors.

We also remark that the factor of k in Theorem 7 is necessary, which is shown by the following instance: the linear system has nk variables where every variable belongs to one of k sets S_0, \dots, S_{k-1} with $|S_i| = n$ for any $0 \leq i \leq k-1$. Now, for any i , we add n equations of the form $x_u - x_v = 1 \pmod k$ with $x_u \in S_i$, $x_v \in S_j$, and $j = i + 1 \pmod k$, and n equations of the form $x_u - x_v = 1 \pmod k$ with $x_u \in S_i$, $x_v \in S_j$, and $j = i + 2 \pmod k$. This instance is constructed such that the underlying graph is regular, and every assignment could only satisfy at most half of the equations, implying that the imperfectness is $p(\mathcal{I}) = \Omega(1)$. However, mapping each variable in S_i to the root of unity ω_k^i , it's easy to see that $\lambda_i(\mathcal{L}_{\mathcal{I}}) = O(1/k)$. Hence Theorem 7 is tight with respect to k .

Finally, we compare the proof techniques of Theorem 7 with other Cheeger-type inequalities in the literature: first of all, most of the Cheeger-type inequalities (e.g., [1, 19, 20, 27]) consider the case where every eigenvector is in \mathbb{R}^n and are only applicable for undirected graphs, while for our problem the graph G associated with \mathcal{I} is directed and eigenvectors of

$A_{\mathcal{I}}$ are in \mathbb{C}^n . Therefore, constructing sweep sets in \mathbb{C} is needed, which is more involved than proving similar Cheeger-type inequalities (e.g., [1, 27]). Secondly, by dividing the complex unit ball into k regions, we are able to show that a partial assignment corresponding to k disjoint subsets can be found using a single eigenvector. This is quite different from the techniques used for finding k vertex-disjoint subsets of low conductance in an undirected graph, where k eigenvectors are usually needed (e.g. [19, 20, 21]).

We also remark that, while sweeping through values of t is needed to obtain *any* guarantee on the penalty of the partial assignment computed, we could in principle just choose a random angle η : in this way, however, the partial assignment returned would satisfy (6) only in expectation.

4 Sparsification for MAX-2-LIN(k)

We have seen in Section 3 that, given any vector in \mathbb{C}^n whose quadratic form with $L_{\mathcal{I}}$ is close to $\lambda_1(L_{\mathcal{I}})$, we can compute a partial assignment of \mathcal{I} with bounded approximation guarantee. In Section 5 we will show that a total assignment can be found by recursively applying this procedure on variables for which an assignment has not yet been fixed. In particular, we will show that every iteration takes a time nearly-linear in the number of equations of our instance, which can be quadratic in the number of variables. To speed-up each iteration and obtain a time per iteration that is nearly-linear in the number of variables, we need to sparsify our input instance \mathcal{I} .

In this section we show that the construction of spectral sparsifiers by effective resistance sampling introduced in [24] can be generalised to sparsify MAX-2-LIN(k) instances. In particular, given an instance \mathcal{I} of MAX-2-LIN(k) with n variables and m equations, we can find in nearly-linear time a sparsified instance \mathcal{J} with about $nk \log(nk)$ equations such that for any partial assignment $\phi : V \rightarrow [k]$, the number of unsatisfied equations in \mathcal{J} is preserved within a constant factor. This means that we can apply our algorithm for MAX-2-LIN(k) to a sparsified instance \mathcal{J} , and any dependency on m in our runtime can be replaced by $nk \log(nk)$. We remark that we could simply apply uniform sampling to obtain a sparsified instance. However, this would in the end result in an additive error in the fraction of unsatisfied equations, much like in the case of the original Trevisan's result for MAX-CUT [27]. With our construction, instead, we only lose a small multiplicative error.

To construct a sparsified instance \mathcal{J} , we introduce label-extended graphs and their Laplacian matrices to characterise the original MAX-2-LIN(k) instance. Let $P \in \mathbb{R}^{k \times k}$ be the permutation matrix where $P_{ij} = 1$ if $i \equiv j + 1 \pmod k$, and $P_{ij} = 0$ otherwise. We define the adjacency matrix $\tilde{A}_{\mathcal{I}} \in (\mathbb{R}^{k \times k})^{n \times n}$ for the label-extended graph of instance \mathcal{I} , where each entry of $\tilde{A}_{\mathcal{I}}$ is a matrix in $\mathbb{R}^{k \times k}$ given by

$$(\tilde{A}_{\mathcal{I}})_{uv} \stackrel{\text{def}}{=} \begin{cases} b_{uv} P^{c_{uv}} & u \rightsquigarrow v, \\ b_{vu} (P^{\top})^{c_{vu}} & v \rightsquigarrow u, \\ 0 & \text{otherwise.} \end{cases} \quad (7)$$

We then define the degree-diagonal matrix $\tilde{D}_{\mathcal{I}} \in (\mathbb{R}^{k \times k})^{n \times n}$ by $(\tilde{D}_{\mathcal{I}})_{uu} = d_u \cdot I_{k \times k}$, where $I_{k \times k}$ is the $k \times k$ identity matrix, and define the Laplacian matrix by $\tilde{L}_{\mathcal{I}} = \tilde{D}_{\mathcal{I}} - \tilde{A}_{\mathcal{I}}$. Notice that the Hermitian Laplacian $\mathcal{L}_{\mathcal{I}}$ is a *compression* of $\tilde{L}_{\mathcal{I}}$, i.e., there exists an orthogonal projection U such that $U^* \tilde{L}_{\mathcal{I}} U = \mathcal{L}_{\mathcal{I}}$.

For any assignment $\phi : V \rightarrow [k]$, we construct an indicator vector $\tilde{x}_{\mathcal{I}} \in (\mathbb{R}^k)^n$ by $(\tilde{x}_{\mathcal{I}})_u = e_{\phi(u)}$, where $e_j \in \mathbb{R}^k$ is the j -th standard basis vector. Then, it is easy to show that the total weight of unsatisfied equations for ϕ is $(1/2) \cdot \tilde{x}_{\mathcal{I}}^\top \tilde{L}_{\mathcal{I}} \tilde{x}_{\mathcal{I}}$.³

We show that, for every unsatisfiable instance \mathcal{I} , there is a sparsified MAX-2-LIN(k) instance \mathcal{J} such that the quadratic forms between $\tilde{L}_{\mathcal{I}}$ and $\tilde{L}_{\mathcal{J}}$ are approximately preserved. This implies that, when looking at the same assignment, the total weights of unsatisfied equations in \mathcal{I} and \mathcal{J} are approximately preserved. Notice that we can decide whether there is an assignment satisfying all the equations in \mathcal{I} by fixing the assignment of an arbitrary vertex and determining assignments for other vertices accordingly, and therefore we only need to consider the case when \mathcal{I} is unsatisfiable. The main result of the section is as follows:

► **Theorem 9.** *There is an algorithm that, given an unsatisfiable instance \mathcal{I} of MAX-2-LIN(k) with n variables and m equations and parameter $0 < \delta < 1$, returns in $\tilde{O}(mk)$ time an instance \mathcal{J} with the same set of variables and $O((1/\delta^2) \cdot nk \log(nk))$ equations. Furthermore, with high probability it holds for any vector $x \in (\mathbb{R}^k)^n$ that $(1-\delta)x^\top \tilde{L}_{\mathcal{I}} x \leq x^\top \tilde{L}_{\mathcal{J}} x \leq (1+\delta)x^\top \tilde{L}_{\mathcal{I}} x$.*

5 Algorithm for MAX-2-LIN(k)

Theorem 9 tells us that, given an instance \mathcal{I}^* , we can find a sparse instance \mathcal{I} so that the quadratic forms of the corresponding Laplacians $\mathcal{L}_{\mathcal{I}^*}$ and $\mathcal{L}_{\mathcal{I}}$ are approximately the same. Therefore throughout this section we assume that the input instance \mathcal{I} for MAX-2-LIN(k) with n variables has $m = \tilde{O}((1/\delta^2) \cdot nk)$ equations for some parameter $\delta > 0$. Recall that Theorem 7 shows that, for any MAX-2-LIN(k) instance \mathcal{I} , given an eigenvector for the smallest eigenvalue $\lambda_1(\mathcal{L}_{\mathcal{I}})$, we can obtain a partial assignment ϕ satisfying

$$p^\phi \leq \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)}\right) \sqrt{2\lambda_1}. \quad (8)$$

Now we show that, by a repeated application of Theorem 7 on the subset of the equations of \mathcal{I} for which both variables are unassigned, we can obtain a full assignment of \mathcal{I} . Our algorithm closely follows the one by Trevisan [27] and is described in Algorithm 1.

To achieve the guarantees of (8), however, we would need to compute the eigenvector corresponding to $\lambda_1(\mathcal{L}_{\mathcal{I}})$ *exactly*. To obtain a nearly-linear time algorithm, instead, we relax this requirement and compute a vector z that well-approximates this eigenvector. In particular, the following lemma shows that, for any δ , we can compute a vector $z \in \mathbb{C}^n$ satisfying (9) in nearly-linear time.

► **Lemma 10.** *For any given error parameter δ , there is an $\tilde{O}((1/\delta^3) \cdot kn)$ time algorithm that returns $z \in \mathbb{C}^n$ satisfying (9).*

To analyse Algorithm 1, we introduce some notation. Let t be the number of recursive executions of Algorithm 1. For any $1 \leq j \leq t+1$, let \mathcal{I}_j be the instance of MAX-2-LIN(k) in the j -th execution. We indicate with $\rho_j m$ the number of equations in \mathcal{I}_j , where $0 \leq \rho_j \leq 1$. Notice that $\mathcal{I}_1 = \mathcal{I}$ and $\mathcal{I}_{t+1} = \emptyset$. We assume that the maximum number of equations in \mathcal{I}_j that can be satisfied by an assignment is $(1 - \varepsilon_j)\rho_j m$, with $\varepsilon = \varepsilon_1$. Also notice that it holds for any $1 \leq j \leq t$ that $\varepsilon_j \rho_j m \leq \varepsilon m$, which implies $\varepsilon_j \leq \varepsilon/\rho_j$. The next theorem presents the performance of our algorithm, whose informal version is Theorem 1.

³ We remark that, if we use the Hermitian Laplacian matrices $L_{\mathcal{I}}$ directly instead, this relation only holds up to an $O(k)$ factor. That is why we sparsify the matrix $\tilde{L}_{\mathcal{I}}$ instead.

■ **Algorithm 1** RECURSIVECONSTRUCT(\mathcal{I}, δ).

1: Compute vector $z \in \mathbb{C}^n$ satisfying

$$\frac{z^* L_{\mathcal{I}} z}{z^* D_{\mathcal{I}} z} \leq (1 + 2\delta) \lambda_1(\mathcal{L}_{\mathcal{I}}); \quad (9)$$

2: Apply the algorithm from Theorem 7 to compute $\phi : V \rightarrow [k] \cup \{\perp\}$ such that

$$p^\phi \leq (1 + \delta) \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) \sqrt{2\lambda_1}; \quad (10)$$

3: **if** $2p^\phi \geq (1 - 1/k) \text{Vol}(\phi)$ **then**

4: return random full assignment $\phi' : V \rightarrow [k]$;

5: ▷ the case where the current assignment is worse than a random assignment

6: **else if** ϕ is a full assignment (i.e. $\phi(V) \subseteq [k]$) **then**

7: return ϕ ;

8: ▷ The recursion terminates if every variable's assignment is determined

9: **else**

10: $\mathcal{I}' \leftarrow$ set of equations from \mathcal{I} in which both variables' assignments are not determined;

11: **if** $\mathcal{I}' = \emptyset$ **then**

12: set $\phi(u)$ to be an arbitrary assignment if $\phi(u) = \perp$ for any u ;

13: return ϕ ;

14: **else**

15: $\phi_1 \leftarrow$ RECURSIVECONSTRUCT(\mathcal{I}', δ);

16: return $\phi \cup \phi_1$;

► **Theorem 11.** *Given an instance \mathcal{I} of MAX-2-LIN(k) whose optimum is $1 - \varepsilon$ and a parameter $\delta > 0$, the algorithm RECURSIVECONSTRUCT(\mathcal{I}, δ) returns in $\tilde{O}((1/\delta^3) \cdot kn^2)$ time an assignment ϕ satisfying at least $1 - 8\nu\sqrt{\varepsilon}$ fraction of the equations, where*

$$\nu \stackrel{\text{def}}{=} (1 + \delta) \left(2 - \frac{2}{k} + \frac{1}{2 \sin(\pi/k)} \right) = O(k).$$

The following corollary which states how much our algorithm beats a random assignment follows from Theorem 1.

► **Corollary 12.** *Given a MAX-2-LIN(k) instance \mathcal{I} whose optimum is ξ and a constant $\delta > 0$, Algorithm 1 returns in $\tilde{O}((1/\delta^3) \cdot n^2 k)$ time an assignment ϕ satisfying at least $(1/k + \tau)\xi$ fraction of the equations, where $\tau = \Omega(\frac{1}{k^3})$.*

6 Algorithm for MAX-2-LIN(k) on expanders

In this section we further develop techniques for analysing Hermitian Laplacian matrices by presenting a subquadratic-time approximation algorithm for the MAX-2-LIN(k) problem on expander graphs. Our proof technique is inspired by Kolla's algorithm [18]. However, in contrast to the algorithm in [18], we use the Hermitian Laplacian to represent a MAX-2-LIN(k) instance and show that, when the underlying graph has good expansion, a good approximate solution is encoded in the eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$. We assume that G is a d -regular graph, and hence $\mathcal{I} = (G, k)$ is a MAX-2-LIN(k) instance with n variables and $nd/2$

equations whose optimum is $1 - \varepsilon$. One can view \mathcal{I} as an instance generated by modifying ε fraction of the constraints (i.e., edges) from a completely satisfiable instance $\widehat{\mathcal{I}} = (\widehat{G}, k)$. Hence, a satisfiable assignment $\psi : V \rightarrow [k]$ for $\widehat{\mathcal{I}}$ will satisfy at least a $(1 - \varepsilon)$ -fraction of equations in \mathcal{I} .

Now we discuss the techniques used to prove Theorem 2. Let $y_\psi \in \mathbb{C}^n$ be the normalised “indicator vector” of ψ , i.e., $(y_\psi)_u = \frac{1}{\sqrt{n}} \omega_k^{\psi(u)}$. Then it holds that

$$(y_\psi)^* \mathcal{L}_{\widehat{\mathcal{I}}} y_\psi = \frac{1}{d} \sum_{u \rightsquigarrow v} b_{uv} \|(y_\psi)_u - \omega_k^{c_{uv}} (y_\psi)_v\|^2 = 0.$$

Hence y_ψ is an eigenvector associated with $\lambda_1(\mathcal{L}_{\widehat{\mathcal{I}}}) = 0$. We denote by \mathcal{U} the underlying undirected graph of G , and denote by $\mathcal{L}_{\mathcal{U}}$ the normalised Laplacian of \mathcal{U} . Note that since \mathcal{U} is undirected, $\mathcal{L}_{\mathcal{U}}$ only contains real-valued entries. We first show that the eigenvalues of $\mathcal{L}_{\widehat{\mathcal{I}}}$, the normalised Laplacian of the completely satisfiable instance, and of $\mathcal{L}_{\mathcal{U}}$, the normalised Laplacian of the underlining undirected graph \mathcal{U} , coincide. Since $\mathcal{L}_{\mathcal{U}}$ is the Laplacian matrix of an expander graph, this implies that there is a gap between $\lambda_1(\mathcal{L}_{\widehat{\mathcal{I}}})$ and $\lambda_2(\mathcal{L}_{\widehat{\mathcal{I}}})$.

► **Lemma 13.** *It holds for all $1 \leq i \leq n$ that $\lambda_i(\mathcal{L}_{\widehat{\mathcal{I}}}) = \lambda_i(\mathcal{L}_{\mathcal{U}})$.*

Next we bound the perturbation of the bottom eigenspace of $\mathcal{L}_{\widehat{\mathcal{I}}}$ when the latter is turned into $\mathcal{L}_{\mathcal{I}}$. In particular, Lemma 14 below proves that this perturbation does not affect too much to the vectors that have norm spreads out uniformly over all their coordinates.

► **Lemma 14.** *Let $f \in \mathbb{C}^n$ be a vector such that $\|f_u\| = \frac{1}{\sqrt{n}}$ for all $u \in V$. It holds that*

$$\left\| (\mathcal{L}_{\mathcal{I}} - \mathcal{L}_{\widehat{\mathcal{I}}}) f \right\| \leq 2\sqrt{\varepsilon}. \tag{11}$$

Based on Lemma 14, we prove that the change from $\mathcal{L}_{\widehat{\mathcal{I}}}$ to $\mathcal{L}_{\mathcal{I}}$ doesn't have too much influence on the eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$. For simplicity, let $\lambda_2 = \lambda_2(\mathcal{L}_{\widehat{\mathcal{I}}}) = \lambda_2(\mathcal{L}_{\mathcal{U}})$.

► **Lemma 15.** *Let $f_1 \in \mathbb{C}^n$ be a unit eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$. Then we have $\left\| (\mathcal{L}_{\mathcal{I}} - \mathcal{L}_{\widehat{\mathcal{I}}}) f_1 \right\| \leq 20\sqrt{\varepsilon/\lambda_2}$.*

We then prove the following lemma which shows that the eigenvector f_1 corresponding to $\lambda_1(\mathcal{L}_{\mathcal{I}})$ is close to y_ψ , the indicator vector of the optimal assignment ψ .

► **Lemma 16.** *Let $f_1 \in \mathbb{C}^n$ be a unit eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$. Then, there exist $\alpha, \beta \in \mathbb{C}$ and a unit vector $y_\perp \in \mathbb{C}^n$ orthogonal to y_ψ (i.e. $(y_\perp)^* y_\psi = 0$) such that $f_1 = \alpha y_\psi + \beta y_\perp$ and $\|\beta\| \leq 30\sqrt{\varepsilon/\lambda_2^3}$.*

Based on Lemma 16, f_1 is close to the indicator vector of an optimal assignment rotated by some angle. In particular, we have that

$$\left\| f_1 - \frac{\alpha}{\|\alpha\|} y_\psi \right\| = \sqrt{(1 - \|\alpha\|)^2 + \|\beta\|^2} \leq \sqrt{1 - \|\alpha\|^2 + \|\beta\|^2} = \sqrt{2} \|\beta\| \leq 30\sqrt{\frac{2\varepsilon}{\lambda_2^3}}, \tag{12}$$

where $\frac{\alpha}{\|\alpha\|} y_\psi$ is the vector that encodes the information of an assignment that satisfies all the equations in $\widehat{\mathcal{I}}$ and at least $1 - \varepsilon$ fraction of equations in \mathcal{I} . Therefore, our goal is to recover $\frac{\alpha}{\|\alpha\|} y_\psi$ from f_1 .

71:12 Hermitian Laplacians and a Cheeger Inequality for the Max-2-Lin Problem

Proof of Theorem 2. Let ψ be the optimal assignment of \mathcal{I} satisfying $1 - \varepsilon$ fraction of equations, which is also a completely satisfying assignment of $\widehat{\mathcal{I}}$. Let f_1 be a unit eigenvector associated with $\lambda_1(\mathcal{L}_{\mathcal{I}})$. By Lemma 16, there exists $\alpha, \beta \in \mathbb{C}$ such that $f_1 = \alpha y_\psi + \beta y_\perp$ where $\|\beta\| \leq 30\sqrt{\varepsilon/\lambda_2^3}$. Our goal is to find a vector $z_\phi \in \mathbb{C}^n$, which equals the indicator vector of ϕ rotated by some angle and satisfies

$$\|f_1 - z_\phi\| \leq \left\| f_1 - \frac{\alpha}{\|\alpha\|} y_\psi \right\| \leq 30\sqrt{\frac{2\varepsilon}{\lambda_2^3}}, \quad (13)$$

where the last inequality follows by (12). The assignment ϕ corresponding to such a z_ϕ will give us that the fraction of unsatisfied equations by ϕ is

$$\begin{aligned} p^\phi(\mathcal{I}) &\leq 10k^2 z_\phi^* \mathcal{L}_{\mathcal{I}} z_\phi \\ &= 10k^2 (z_\phi - f_1 + f_1)^* \mathcal{L}_{\mathcal{I}} (z_\phi - f_1 + f_1) \\ &\leq k^2 ((z_\phi - f_1)^* \mathcal{L}_{\mathcal{I}} (z_\phi - f_1) + f_1^* \mathcal{L}_{\mathcal{I}} f_1 + 2\|(z_\phi - f_1)^* \mathcal{L}_{\mathcal{I}} f_1\|) \\ &\leq 10k^2 \left(2\|z_\phi - f_1\|^2 + \lambda_1(\mathcal{L}_{\mathcal{I}}) + 2\|z_\phi - f_1\| \sqrt{\lambda_1(\mathcal{L}_{\mathcal{I}})} \right) \\ &\leq 10k^2 \left(2 \cdot 900 \cdot \frac{2\varepsilon}{\lambda_2^3} + 2\varepsilon + 2 \cdot 30 \cdot \sqrt{\frac{2\varepsilon}{\lambda_2^3}} \cdot \sqrt{2\varepsilon} \right) \\ &\leq 100000k^2 \cdot \frac{\varepsilon}{\lambda_2^3}, \end{aligned}$$

where the factor $10k^2$ above follows from the fact that $\|1 - \omega_k^j\|^2$ is at least $1/(10k^2)$ for $j = 1, \dots, k-1$.

To find such vector z_ϕ satisfying (13), we define $\phi_\eta(u) = \arg \min_{j \in [k]} \|(f_1)_u - e^{\eta i} \omega_k^j\|$. Notice that, since $\frac{\alpha}{\|\alpha\|}$ is equal to $e^{\eta i}$ for some $\eta \in [0, 2\pi)$, by defining $(z_{\phi_\eta})_u = e^{\eta i} \omega_k^{\phi_\eta(u)}$ the solution to the following optimisation problem $\min_{\eta \in [0, 2\pi)} \|z_{\phi_\eta} - f_1\|$ gives us a vector that satisfies (13). To solve this optimisation problem, we notice that it suffices to consider η in the range $[0, 2\pi/k)$. Therefore, we simply enumerate all η 's over the following discrete set:

$$\left\{ \frac{t\sqrt{\varepsilon}}{\sqrt{n}} \mid t = 0, 1, \dots, \left\lceil \frac{2\pi\sqrt{n}}{k\sqrt{\varepsilon}} \right\rceil \right\}.$$

By enumerating this set, we can find an assignment ϕ and an η such that

$$\|f_1 - z_{\phi_\eta}\| \leq \left\| f_1 - \frac{\alpha}{\|\alpha\|} y_\psi \right\| + O(\sqrt{\varepsilon}),$$

which is enough to get our desired approximation. Since the size of this set is $O\left(\frac{\sqrt{n}}{k\sqrt{\varepsilon}}\right)$, the total running time is $O\left(\frac{n^{1.5}}{k\sqrt{\varepsilon}}\right)$ plus the running time needed to compute f_1 . \blacktriangleleft

7 Concluding remarks

Our work leaves several open questions for further research: while the factor of k in our Cheeger inequality (Theorem 7) is needed, it would be interesting to see if it's possible to construct a different Laplacian for which a similar Cheeger inequality holds with a smaller dependency on k . For example, instead of embedding vertices in \mathbb{C} and mapping assignments to roots of unity, one could consider embedding vertices in higher dimensions using the

bottom k eigenvectors of the Laplacian of the label extended graph, and see if a relation between the imperfectness ratio of Definition 6 and the k -th smallest eigenvalue of this Laplacian still holds.

Finally, we observe that several cut problems in directed graphs can be formulated as special cases of MAX-2-LIN(k) (see, e.g., [2, 11]). Because of this, we believe the Hermitian Laplacians studied in our paper will have further applications in the development of fast algorithms for combinatorial problems on directed graphs, and might have further connections to Unique Games.

Abstract

The celebrated Erdős-Pósa theorem states that every undirected graph that does not admit a family of k vertex-disjoint cycles contains a feedback vertex set (a set of vertices hitting all cycles in the graph) of size $\mathcal{O}(k \log k)$. After being known for long as Younger's conjecture, a similar statement for directed graphs has been proven in 1996 by Reed, Robertson, Seymour, and Thomas. However, in their proof, the dependency of the size of the feedback vertex set on the size of vertex-disjoint cycle packing is not elementary.

We show that if we compare the size of a minimum feedback vertex set in a directed graph with *quarter-integral* cycle packing number, we obtain a polynomial bound. More precisely, we show that if in a directed graph G there is no family of k cycles such that every vertex of G is in at most *four* of the cycles, then there exists a feedback vertex set in G of size $\mathcal{O}(k^4)$. On the way there we prove a more general result about quarter-integral packing of subgraphs of high directed treewidth: for every pair of positive integers a and b , if a directed graph G has directed treewidth $\Omega(a^6 b^8 \log^2(ab))$, then one can find in G a family of a subgraphs, each of directed treewidth at least b , such that every vertex of G is in at most four subgraphs.

1 Introduction

The theory of graph minors, developed over the span of over 20 years by Robertson and Seymour, had a tremendous impact on the area of graph algorithms. Arguably, one of the cornerstone contributions is the notion of *treewidth* [19] and the deep understanding of obstacles to small treewidth, primarily in the form of the *excluded grid theorem* [5, 20, 21].

Very tight relations of treewidth and the size of the largest grid as a minor in sparse graph classes, such as planar graphs or graphs excluding a fixed graph as a minor, led to the rich and fruitful theory of bidimensionality [10]. In general graphs, fine understanding of the existence of well-behaved highly-connected structures (not necessarily grids) in graphs of high treewidth has been crucial to the development of efficient approximation algorithms for the DISJOINT PATHS problem [9].

In undirected graphs, one of the first theorems that gave some well-behaved structure in a graph that is in some sense highly connected is the famous Erdős-Pósa theorem [11] linking the feedback vertex set number of a graph (the minimum number of vertices one needs to delete to obtain an acyclic graph) and the cycle packing number (the maximum possible size of a family of vertex-disjoint cycles in a graph). The Erdős-Pósa theorem states that a graph that does not contain a family of k vertex-disjoint cycles has feedback vertex set number bounded by $\mathcal{O}(k \log k)$.

A similar statement for directed graphs, asserting that a directed graph without a family of k vertex-disjoint cycles has feedback vertex set number at most $f(k)$, has been long known as the Younger's conjecture until finally proven by Reed, Robertson, Seymour, and Thomas in 1996 [17]. However, the function f obtained in [17] is not elementary; in particular, the proof relies on the Ramsey theorem for $\Theta(k)$ -regular hypergraphs. This is in contrast with the (tight) $\Theta(k \log k)$ bound in undirected graphs.

Our main result is that if one compares the feedback vertex set number of a directed graph to the *quarter-integral* cycle packing number (i.e., the maximum size of a family of cycles in G such that every vertex lies on at most four cycles), one obtains a polynomial bound.

► **Theorem 1.** *If a directed graph G does not contain a family of k cycles such that every vertex in G is contained in at most four cycles, then there exists a feedback vertex set in G of size $\mathcal{O}(k^4)$.*

We remark that if one relaxes the condition even further to a *fractional cycle packing*,¹ Seymour [22] proved that a graph without a fractional cycle packing of size at least k admits a feedback vertex set of size $\mathcal{O}(k \log k \log \log k)$.

Directed treewidth is a directed analog of the successful notion of treewidth, introduced in [13, 16]. An analog of the excluded grid theorem for directed graphs has been conjectured by Johnson, Robertson, Seymour, and Thomas [13] in 2001 and finally proven by Kawarabayashi and Kreutzer in 2015 [15]. Similarly as in the case of the directed Erdős-Pósa property, the relation between the directed treewidth of a graph and a largest directed grid as a minor in [15] is not elementary.

For a directed graph G , let $\text{fvs}(G)$, $\text{dtw}(G)$, and $\text{cp}(G)$ denote the feedback vertex set number, directed treewidth, and the cycle packing number of G , respectively. The following lemma is a restatement of the result of Amiri, Kawarabayashi, Kreutzer, and Wollan [1, Lemma 4.2]:

¹ A *fractional cycle packing* assigns to every cycle C in G a non-negative real weight $w(C)$ such that for every $v \in V(G)$ the total weight of all cycles containing v is at most 1. The *size* of a fractional cycle packing w is the total weight of all cycles in the packing.

► **Lemma 2** ([1, Lemma 4.2]). *Let G be a directed graph with $\text{dtw}(G) \leq w$. For each strongly connected directed graph H , the graph G has either k disjoint copies of H as a topological minor, or contains a set T of at most $k \cdot (w + 1)$ vertices such that H is not a topological minor of $G - T$.*

Note that the authors of [1] prove Lemma 2 for topological and butterfly minors, but the previous restatement is sufficient for our purposes. By taking H as the directed 2-cycle it is easy to derive the following bound:

► **Lemma 3.** *For a directed graph G it holds that $\text{fvs}(G) \leq (\text{dtw}(G) + 1) \text{cp}(G)$.*

In the light of Lemma 3 and since a directed grid minor of size k contains k vertex-disjoint cycles, the directed grid theorem of Kawarabayashi and Kreutzer [15] is a generalization of the directed Erdős-Pósa property due to Reed, Robertson, Seymour, and Thomas [17].

Theorem 1 is a direct corollary of Lemma 3 and the following statement that we prove.

► **Theorem 4.** *If a directed graph G does not contain a family of k cycles such that every vertex in G is contained in at most four cycles, then $\text{dtw}(G) = \mathcal{O}(k^3)$.*

Furthermore, if one asks not for a cycle packing, but a packing of subgraphs of large directed treewidth, we prove the following packing result.

► **Theorem 5.** *There exists an absolute constant c with the following property. For every pair of positive integers a and b , and every directed graph G of directed treewidth at least $c \cdot a^6 \cdot b^8 \cdot \log^2(ab)$, there are directed graphs G_1, G_2, \dots, G_a with the following properties:*

1. *each G_i is a subgraph of G ,*
2. *each vertex of G belongs to at most four graphs G_i , and*
3. *each graph G_i has directed treewidth at least b .*

Note that by setting $b = 2$ in Theorem 5, one obtains Theorem 4 with a slightly weaker bound of $\mathcal{O}(k^6 \log^2 k)$ and, consequently, Theorem 1 with a weaker bound of $\mathcal{O}(k^7 \log^2 k)$.

Theorem 5 should be compared to its undirected analog of Chekuri and Chuzhoy [4] that asserts that in an undirected graph G of treewidth at least $c \min(ab^2, a^3b)$ one can find a vertex-disjoint subgraphs of treewidth at least b . While we still obtain a polynomial bound, we can only prove the existence of a quarter-integral (as opposed to integral, i.e., vertex-disjoint) packing of subgraphs of high directed treewidth.

In the DISJOINT PATHS problem, given a graph G and a set of terminal pairs $(s_i, t_i)_{i=1}^k$, we ask to find an as large as possible collection of vertex-disjoint paths such that every path in the collection connects some s_i with t_i . Let OPT be the number of paths in the optimum solution; we say that a family \mathcal{P} is a *congestion- c polylogarithmic approximation* if every path in \mathcal{P} connects a distinct pair (s_i, t_i) , each vertex of $V(G)$ is contained in at most c paths of \mathcal{P} , and $|\mathcal{P}| \geq \text{OPT}/\text{polylog}(\text{OPT})$. The successful line of research of approximation algorithms for the DISJOINT PATHS problem in undirected graphs leading in particular to a congestion-2 polylogarithmic approximation algorithm of Chuzhoy and Li [9] for the edge-disjoint version, would not be possible without a fine understanding of well-behaved well-connected structures in a graph of high treewidth. Of central importance to such *routing* algorithms is the notion of a *crossbar*: a crossbar of order k and congestion c is a subgraph C of G with an *interface* $I \subseteq V(C)$ of size k such that for every matching M on I , one can connect the endpoints of the matching edges with paths in C such that every vertex is in at most c paths. Most of the known approximation algorithms for DISJOINT PATHS find a crossbar (C, I) with a large set of disjoint paths between I and the set of terminals s_i and t_i . While one usually does not control how the paths connect the terminals s_i and t_i to interface vertices of I , the ability of the crossbar to connect *any* given matching on the interface leads to a solution.

To obtain a polylogarithmic approximation algorithm, one needs the order of the crossbar to be comparable to the number of terminal pairs, which – by well-known tools such as *well-linked decompositions* [8] – is of the order of treewidth of the graph. At the same time, we usually allow constant congestion (every vertex can appear in a constant number of paths of the solution, instead of just one). Thus, the milestone graph-theoretic result used in approximation algorithms for DISJOINT PATHS is the existence of a congestion-2 crossbar of order k in a graph of treewidth $\Omega(k \text{polylog}(k))$.

While the existence of similar results for the general DISJOINT PATHS problem in directed graphs is implausible [2], Chekuri, and Ene proposed to study the case of *symmetric demands* where one asks for a path from s_i to t_i and a path from t_i to s_i for a terminal pair (s_i, t_i) . First, they provided an analog of the well-linked decomposition for this case [6], and then with Pilipczuk [7] showed an existence of an analog of a crossbar and a resulting approximation algorithm for DISJOINT PATHS with symmetric demands in planar directed graphs. Later, this result has been lifted to arbitrary proper minor-closed graph classes [3]. However, the general case remains widely open.

As discussed above, for applications in approximation algorithms for DISJOINT PATHS, it is absolutely essential to squeeze as much as possible from the bound linking directed treewidth of a graph with the order of the crossbar, while the final congestion is of secondary importance (but we would like it to be a small constant). We think of Theorem 5 as a step in this direction: sacrificing integral packings for quarter-integral ones, we obtain much stronger bounds than the non-elementary bounds of [17]. Furthermore, such a step seems necessary, as it is hard to imagine a crossbar of order k that would not contain a constant-congestion (i.e., every vertex used in a constant number of cycles) packing of $\Omega(k)$ directed cycles.

On the technical side, the proof of Theorem 5 borrows a number of technical tools from the recent work of Hatzel, Kawarabayashi, and Kreuzer that proved polynomial bounds for the directed grid minor theorem in planar graphs [12]. We follow their general approach to obtain a directed treewidth sparsifier [12, Section 5] and modify it in a number of places for our goal. The main novelty comes in different handling of the case when two linkages intersect a lot. Here we introduce a new partitioning tool (see Section 3) which we use in the crucial moment where we separate subgraphs G_i from each other.

Organization. After brief preliminaries in Section 2, we prove Theorem 5 in Sections 3–5: Section 3 introduces the new partitioning tool, Section 4 handles the most complicated “dense case” in the analysis, while Section 5 wraps up the argument. Discussions on the the adaptation of the arguments of Section 5 to obtain the improved bound of Theorem 4 and some argumentation from Section 4 that directly follows the arguments of [12] can be found in the full version of the paper.

2 Preliminaries

Let $G = (V(G), E(G))$ be a directed graph and let A, B be subsets of $V(G)$ with $|A| = |B|$. A *linkage* from A to B in G is a set \mathcal{L} of $|A|$ pairwise vertex-disjoint paths in G , each with a starting vertex in A and ending vertex in B . The *order* of \mathcal{L} is $|\mathcal{L}| = |A|$. For $X, Y \subseteq V(G)$ and a linkage \mathcal{L} from X to Y , we denote $A(\mathcal{L}) := X$ and $B(\mathcal{L}) := Y$. For a path or a walk P , by $\text{start}(P)$ and $\text{end}(P)$ we denote the starting and ending vertex of P , respectively.

Let \mathcal{L} and \mathcal{K} be linkages. The *intersection graph* of \mathcal{L} and \mathcal{K} , denoted by $I(\mathcal{L}, \mathcal{K})$, is the bipartite graph with the vertex set $\mathcal{L} \cup \mathcal{K}$ and an edge between a vertex in \mathcal{L} and a vertex in \mathcal{K} if the corresponding paths share at least one vertex.

A vertex set $W \subseteq V(G)$ is *well-linked* if for all subsets $A, B \subseteq W$ with $|A| = |B|$ there is a linkage \mathcal{L} of order $|A|$ from A to B in $G \setminus (W \setminus (A \cup B))$.

Let \mathcal{P} be a family of walks in G and let c be a positive integer. We say that \mathcal{P} is of *congestion* c if for every $v \in V(G)$, the total number of times the walks in \mathcal{P} visit v is at most c ; here, if a walk $W \in \mathcal{P}$ visits v multiple times, we count each visit separately. A family of paths \mathcal{P} is a *half-integral* (*quarter-integral*) if it is of congestion 2 (resp. 4).

We call two linkages \mathcal{L} and $\mathcal{L}^{\text{back}}$ *dual* to each other if $A(\mathcal{L}) = B(\mathcal{L}^{\text{back}})$ and $A(\mathcal{L}^{\text{back}}) = B(\mathcal{L})$. For two dual linkages \mathcal{L} and $\mathcal{L}^{\text{back}}$ in a graph G , we define an auxiliary directed graph $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ as follows. We take $V(\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})) = \mathcal{L}$ and for every path $P \in \mathcal{L}^{\text{back}}$ that starts in a vertex $\text{start}(P) = \text{end}(L)$ for some $L \in \mathcal{L}$ and ends in a vertex $\text{end}(P) = \text{start}(L')$ for some $L' \in \mathcal{L}$, we put an arc (L, L') to $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$. Note that it may happen that $L = L'$. When the backlinkage $\mathcal{L}^{\text{back}}$ is clear from the context, we abbreviate $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ to $\text{Aux}(\mathcal{L})$. Observe that in $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ every node is of in- and out-degree exactly one and thus this graph is a disjoint union of directed cycles.

With every arc (L, L') of $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ we can associate the walk from $\text{start}(L)$ to $\text{start}(L')$ that first goes along L and then follows the path $P \in \mathcal{L}^{\text{back}}$ that gives rise to the arc (L, L') . Consequently, with every collection of pairwise disjoint paths and cycles in $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ there is an associated collection of walks (closed walks for cycles) in G that is of congestion 2 as it originated from two linkages. Note that the same construction works if \mathcal{L} and $\mathcal{L}^{\text{back}}$ are half-integral linkages, and then the walks in G corresponding to a family of paths and cycles in $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ would be of congestion 4.

Furthermore, with a pair of dual linkages \mathcal{L} and $\mathcal{L}^{\text{back}}$ we can associate a *backlinkage-induced order* $\mathcal{L} = \{L_1, L_2, \dots, L_{|\mathcal{L}|}\}$ as follows. If C_1, C_2, \dots, C_r are the cycles of the graph $\text{Aux}(\mathcal{L}, \mathcal{L}^{\text{back}})$ in an arbitrary order, then $L_1, L_2, \dots, L_{|C_1|}$ are the vertices of C_1 in the order of their appearance on C_1 , and $L_{|C_1|+1}, \dots, L_{|C_1|+|C_2|}$ are the vertices of C_2 in the order of their appearance on C_2 , etc. That is, we order the elements of \mathcal{L} first according to the cycle of $\text{Aux}(\mathcal{L})$ they lie on, and then, within one cycle, according to the order around this cycle.

We will also need the following operation on a pair of dual linkages \mathcal{L} and $\mathcal{L}^{\text{back}}$. Let $\mathcal{P} \subseteq \mathcal{L}$ be a sublinkage. For every $P \in \mathcal{P}$, construct a walk $Q(P)$ as follows. Start from the path $Q_0 \in \mathcal{L}^{\text{back}}$ with $\text{start}(Q_0) = \text{end}(P)$ and set $Q(P) = Q_0$. Given $Q_i \in \mathcal{L}^{\text{back}}$ for $i \geq 0$, proceed as follows. Let $P_{i+1} \in \mathcal{L}$ be the path with $\text{end}(Q_i) = \text{start}(P_{i+1})$. If $P_{i+1} \in \mathcal{P}$, then stop. Otherwise, define $Q_{i+1} \in \mathcal{L}^{\text{back}}$ to be the path with $\text{end}(P_{i+1}) = \text{start}(Q_{i+1})$. Append P_{i+1} and Q_{i+1} at the end of $Q(P)$ and repeat. Finally, we shortcut $Q(P)$ to a path $Q'(P)$ with the same endpoints. In this manner, $\mathcal{Q} := \{Q'(P) \mid P \in \mathcal{P}\}$ is a half-integral linkage with $A(\mathcal{P}) = B(\mathcal{Q})$ and $A(\mathcal{Q}) = B(\mathcal{P})$. We call \mathcal{Q} the *backlinkage induced by \mathcal{P} on $(\mathcal{L}, \mathcal{L}^{\text{back}})$* . Furthermore, we can perform the same construction if \mathcal{L} and $\mathcal{L}^{\text{back}}$ are half-integral linkages, obtaining a quarter-integral linkage \mathcal{Q} .

We say that G is d -degenerate if and only if every subgraph of G contains a vertex of degree at most d .

In this paper we do not need the exact definition of directed treewidth. Instead, we rely on the following two results.

► **Lemma 6** ([16]). *Every directed graph G of directed treewidth k contains a well-linked set of size $\Omega(k)$.*

► **Lemma 7** ([14, 15]). *There is an absolute constant c' with the following property. Let $\alpha, \beta \geq 1$ be integers and let G be a digraph of $\text{dtw}(G) \geq c' \cdot \alpha^2 \beta^2$. Then there exists a set of α vertex-disjoint paths P_1, \dots, P_α and sets $A_i, B_i \subseteq V(P_i)$, where A_i appears before B_i on P_i , both $|A_i|, |B_i| = \beta$, and $\bigcup_{i=1}^\alpha A_i \cup B_i$ is well-linked.*

We also need the following two auxiliary results. Note that a coloring in Lemma 8 can be arbitrary and is not necessarily proper.

► **Lemma 8** ([18, Lemma 4.3]). *Let $r \geq 2$, d be a real, and H be an r -colored graph with color classes V_1, \dots, V_r , such that for every i it holds that $|V_i| \geq 4e(r-1)d$ and for every $i \neq j$ the graph $H[V_i \cup V_j]$ is d -degenerate. Then there exists an independent set $\{x_1, \dots, x_r\}$ such that $x_i \in V_i$ for every $i \in [r]$.*

► **Lemma 9** ([12, Lemma 5.5]). *Let G be a digraph and P_1, \dots, P_k be disjoint paths such that each P_i consists of two subpaths A_i and B_i , where A_i precedes B_i . Furthermore, let $\{L_{i,j} : i, j \in [k], i \neq j\}$ be a set of pairwise disjoint paths, such that $L_{i,j}$ starts in B_i and ends in A_j . Then*

$$\text{dtw}\left(\bigcup_i P_i \cup \bigcup_{i \neq j} L_{i,j}\right) \geq \frac{k}{8}.$$

3 Partitioning Lemma

In this section, we develop a main technical tool that we use in the proof of Theorem 5. Intuitively, in a subcase of the proof, we will have a bipartite graph of large minimum degree which we partition into subgraphs induced by pairs of vertex sets (U_i, W_i) . These subgraphs will define the G_i from the statement of Theorem 5. To obtain a lower bound on the directed treewidth of G_i , we need that the parts (U_i, W_i) each induce a subgraph of large average degree. This will be achieved using the following lemma.

► **Lemma 10.** *Let $h \geq 0$ and n be integers, d be a positive real such that $d \cdot 4^{h+1} - 1 > 2$, and let G be a bipartite graph with bipartition classes $X = \{x_1, x_2, \dots, x_a\}$ and $Y = \{y_1, y_2, \dots, y_b\}$, such that $a + b \leq n$ and $|E(G)| \geq (d \cdot 4^{h+1} - 1) \cdot n$. Then in $[a]$ we can find $k := 2^h$ pairwise disjoint sets I_1, I_2, \dots, I_k , and in $[b]$ we can find k pairwise disjoint sets J_1, J_2, \dots, J_k , such that:*

1. for every $i \in [k]$ the set I_i is a segment of $[a]$ and the set J_i is a segment of $[b]$,
2. for every $i \in [k]$, the number of edges between $\{x_i : i \in I_i\}$ and $\{y_i : i \in J_i\}$ is at least $d \cdot n$.

Proof. For $I \subseteq [a]$ and $J \subseteq [b]$, let $e(I, J)$ we denote the number of edges $x_i y_j$ of G , such that $i \in I$ and $j \in J$. Observe that $|E(G)| > 2n$.

We prove the lemma by induction on h . Note that for $h = 0$ the claim is trivially satisfied by taking $I_1 = X$ and $J_1 = Y$, as $d \cdot 4^{h+1} - 1 > 2$ and $h \geq 0$ implies $d \cdot 4^{h+1} - 1 \geq d$. So now assume that $h \geq 1$ and the claim holds for $h - 1$. Let $s \in [a]$ be the minimum integer, for which $\sum_{i=1}^s \deg x_i \geq |E(G)|/2$, and let $t \in [b]$ be the minimum integer, for which $\sum_{i=1}^t \deg y_i \geq |E(G)|/2$. We observe that $d \cdot 4^{h+1} - 1 > 2$ implies that $1 < s < a$ and $1 < t < b$. Define $X^1 := \{1, 2, \dots, s-1\}$ and $X^2 := \{s+1, \dots, a\}$, and $Y^1 := \{1, 2, \dots, t-1\}$ and $Y^2 := \{t+1, \dots, b\}$.

We aim to show that the number of edges joining X^1 and Y^1 is roughly the same as the number of edges joining X^2 and Y^2 , and the number of edges joining X^1 and Y^2 is roughly the same as the number of edges joining X^2 and Y^1 . Since $\deg x_s \leq b < n$ and $\deg y_t \leq a < n$, by the choice of s and t we obtain the following set of inequalities.

$$\begin{aligned}
 e(X, Y)/2 - \deg x_s &\leq e(X^1, Y) \leq e(X, Y)/2 \\
 e(X, Y)/2 - \deg x_s &\leq e(X^2, Y) \leq e(X, Y)/2 \\
 e(X, Y)/2 - \deg y_t &\leq e(X, Y^1) \leq e(X, Y)/2 \\
 e(X, Y)/2 - \deg y_t &\leq e(X, Y^2) \leq e(X, Y)/2.
 \end{aligned} \tag{1}$$

Observe that

$$\begin{aligned}
 e(X^1, Y^1) + e(X^1, Y^2) &\leq e(X^1, Y) = e(X^1, Y^1) + e(X^1, Y^2) + e(X^1, \{t\}) \\
 &\leq e(X^1, Y^1) + e(X^1, Y^2) + \deg y_t
 \end{aligned}$$

(and analogously for each of the remaining inequalities in (1)). Thus we obtain:

$$\begin{aligned}
 e(X, Y)/2 - n &\leq e(X^1, Y^1) + e(X^1, Y^2) \leq e(X, Y)/2 \\
 e(X, Y)/2 - n &\leq e(X^2, Y^1) + e(X^2, Y^2) \leq e(X, Y)/2 \\
 e(X, Y)/2 - n &\leq e(X^1, Y^2) + e(X^2, Y^1) \leq e(X, Y)/2 \\
 e(X, Y)/2 - n &\leq e(X^1, Y^2) + e(X^2, Y^2) \leq e(X, Y)/2.
 \end{aligned} \tag{2}$$

By subtracting appropriate pairs of inequalities in (2), we obtain the following bounds.

$$\begin{aligned}
 -n &\leq e(X^1, Y^1) - e(X^2, Y^2) \leq n \\
 -n &\leq e(X^1, Y^2) - e(X^2, Y^1) \leq n
 \end{aligned} \tag{3}$$

Recall that

$$\begin{aligned}
 e(X, Y) &= e(X^1, Y^1) + e(X^1, Y^2) + e(X^2, Y^1) + e(X^2, Y^2) + \deg x_s + \deg y_t \\
 &\leq e(X^1, Y^1) + e(X^1, Y^2) + e(X^2, Y^1) + e(X^2, Y^2) + n.
 \end{aligned}$$

Thus, by the pigeonhole principle, at least one of the following holds:

$$\begin{aligned}
 e(X^1, Y^1) + e(X^2, Y^2) &\geq e(X, Y)/2 - n/2 \\
 e(X^1, Y^2) + e(X^2, Y^1) &\geq e(X, Y)/2 - n/2.
 \end{aligned} \tag{4}$$

Suppose that the first case holds. Define $G^1 = G[X^1 \cup Y^1]$ and $G^2 = G[X^2 \cup Y^2]$. Combining (3) and (4), we obtain that

$$\begin{aligned}
 |E(G^1)| = e(X^1, Y^1) &\geq e(X, Y)/4 - 3n/4 \geq (d \cdot 4^{h+1} - 1)n/4 - 3n/4 = (d \cdot 4^h - 1)n \\
 |E(G^2)| = e(X^2, Y^2) &\geq e(X, Y)/4 - 3n/4 \geq (d \cdot 4^h - 1)n.
 \end{aligned} \tag{5}$$

We observe that graphs G^1, G^2 satisfy the inductive assumption (for $h - 1$), so in the vertex set of G^1 we can find two families of $k/2$ pairwise corresponding segments $I_1^1, I_2^1, \dots, I_{k/2}^1$ and $J_1^1, J_2^1, \dots, J_{k/2}^1$, and in the vertex set of G^2 we can find two families of $k/2$ pairwise corresponding segments $I_1^2, I_2^2, \dots, I_{k/2}^2$ and $J_1^2, J_2^2, \dots, J_{k/2}^2$. We obtain the desired subsegments of X and Y by setting:

$$I_i = \begin{cases} I_i^1 & \text{if } i \leq k/2, \\ I_{i-k/2}^2 & \text{if } i > k/2, \end{cases} \quad J_i = \begin{cases} J_i^1 & \text{if } i \leq k/2, \\ J_{i-k/2}^2 & \text{if } i > k/2. \end{cases}$$

If the second case in (4) holds, we take $G^1 = G[X^1, Y^2]$ and $G^2 = G[X^2, Y^1]$, and the rest of the proof is analogous. \blacktriangleleft

72:8 Packing Directed Circuits Quarter-Integrally

The following statement brings the technical statement of Lemma 10 into a more easily applicable form.

► **Lemma 11.** *Let $k, r \geq 1$ be two integers and let G be a bipartite graph with bipartition classes $X = \{x_1, x_2, \dots, x_a\}$ and $Y = \{y_1, y_2, \dots, y_b\}$ and minimum degree at least $1200 \cdot r \cdot k$. Then there are k sets U_1, U_2, \dots, U_k , and k sets W_1, W_2, \dots, W_k , such that:*

1. *for each $i \in [k]$ the set U_i is a segment of $[a]$ and the set W_i is a segment of $[b]$,*
2. *for each distinct $i, j \in [k]$ we have $U_i \cap U_j = \emptyset$ and $W_i \cap W_j = \emptyset$,*
3. *for every $i \in [k]$, the average degree of the graph $G[U_i \cup W_i]$ is at least r .*

Proof. Let h be the minimum integer, such that $k' := 2^h \geq 3k$; note that $k' < 6k$. Also, define $d = 2r/k$ and $n = a + b$. We have

$$d \cdot 4^{h+1} - 1 = 4d(k')^2 - 1 \geq \frac{8r}{k} \cdot (3k)^2 - 1 = 72 \cdot r \cdot k - 1 > 2.$$

Observe that the number of edges in G is at least

$$n \cdot r \cdot 600k > (16r/k \cdot (6k)^2)n > (4d(k')^2)n > (d \cdot 4^{h+1} - 1)n.$$

Thus G satisfies the assumptions of Lemma 10 for h , n , and d . Let $I_1, I_2, \dots, I_{k'}$ be the disjoint segments in X , and $J_1, J_2, \dots, J_{k'}$ be the disjoint segments in Y , whose existence is guaranteed by Lemma 10.

A segment I_i (J_i , resp.) is called *large* if $|I_i| \geq 3n/k'$ ($|J_i| \geq 3n/k'$, resp.). A pair (I_i, J_i) is *large* if at least one of I_i, J_i is large, otherwise the pair is *small*. Note that there are at most $n/(3n/k') = k'/3$ large segments I_i and at most $k'/3$ large segments J_i , so the number of large pairs is at most $2k'/3$. Thus the number of small pairs is at least $k'/3 \geq k$. We obtain the segments (U_i, W_i) by taking the first k small pairs (I_i, J_i) . Clearly these segments satisfy conditions 1. and 2. of the lemma.

Now take any $i \in [k]$ and let us compute the average degree of the graph $G_i := G[U_i, W_i]$. By Lemma 10, $|E(G_i)| \geq d \cdot n$. On the other hand, since (U_i, W_i) is a small pair, we have that $|V(G_i)| = |U_i \cup W_i| < 6n/k'$. Thus we obtain that the average degree of G_i is

$$\frac{|E(G_i)|}{|V(G_i)|} > \frac{d \cdot n}{6n/k'} = \frac{dk'}{6} \geq d \frac{3k}{6} = \frac{2r}{k} \cdot \frac{k}{2} = r.$$

This completes the proof. ◀

4 The Dense Case

In this section, we prove Theorem 5 roughly in the case when there are two linkages \mathcal{L} and \mathcal{K} such that their set $A(\mathcal{L}) \cup A(\mathcal{K}) \cup B(\mathcal{L}) \cup B(\mathcal{K})$ of endpoints is well linked and such that the paths in \mathcal{L} and \mathcal{K} intersect a lot. The formal statement proved in this section is as follows.

► **Lemma 12.** *Let $a, b \in \mathbb{N}^+$. Let D be a directed graph and \mathcal{L} and \mathcal{K} be two linkages in D such that $A(\mathcal{L}) \cup B(\mathcal{L}) \cup A(\mathcal{K}) \cup B(\mathcal{K})$ is well-linked in D . Suppose that the intersection graph $I(\mathcal{L}, \mathcal{K})$ has degeneracy more than $384000 \cdot a \cdot b \cdot \log_2(|\mathcal{L}|/b)$. Then there are directed graphs D_1, D_2, \dots, D_a with the following properties:*

- (i) *each D_i is a subgraph of D ,*
- (ii) *each vertex of D belongs to at most four graphs D_i , and*
- (iii) *each graph D_i has directed treewidth at least b .*

Proof Outline. The basic idea of the proof of Lemma 12 is as follows. We first fix a pair of linkages $\mathcal{L}^{\text{back}}$ and $\mathcal{K}^{\text{back}}$ which are dual to \mathcal{L} and \mathcal{K} , respectively. (This is possible because of well-linkedness of the endpoints.) The subgraphs D_i that we construct will subpartition the vertex set of each of the four linkages $\mathcal{L}, \mathcal{L}^{\text{back}}, \mathcal{K}, \mathcal{K}^{\text{back}}$ and hence each vertex of G is in at most four subgraphs D_i . To construct the desired subgraphs D_i , we consider the backlinkage-induced order $\Pi_{\mathcal{L}}$ on \mathcal{L} and $\Pi_{\mathcal{K}}$ on \mathcal{K} . Using these orderings of the paths of \mathcal{L} and \mathcal{K} , we can apply the partitioning lemma (Lemma 11) to the intersection graph of \mathcal{L} and \mathcal{K} , obtaining a subpartition I_1, \dots, I_k of \mathcal{L} and a subpartition J_1, \dots, J_k of \mathcal{K} . These subpartitions have the nice property that each intersection graph $I(I_i, J_i)$ induced by a pair I_i, J_i contains many edges (representing intersections between the corresponding paths) and that only a constant number of cycles of $\text{Aux}(\mathcal{L})$ and $\text{Aux}(\mathcal{K})$ cross I_i or J_i . By closing each of these crossing cycles by introducing an artificial new path, we obtain a pair of dual linkages I_i, I'_i , and a pair of dual of linkages J_i, J'_i . Using then Lemma 13 below, we will obtain a lower bound on the directed treewidth of the graph induced by $I_i \cup J_i \cup I'_i \cup J'_i$, which constitute our desired subgraph D_i .

Treewidth Lower Bound. For technical reasons, we will have to work with half-integral linkages. The intersection graph for a pair of half-integral linkages is defined in the same way as for ordinary linkages.

► **Lemma 13.** *Let $k, d \in \mathbb{N}^+$ and $\mathcal{P}, \mathcal{P}^{\text{back}}, \mathcal{Q}, \mathcal{Q}^{\text{back}}$ be four half-integral linkages in a directed graph such that \mathcal{P} and $\mathcal{P}^{\text{back}}$ are dual to each other and \mathcal{Q} and $\mathcal{Q}^{\text{back}}$ are dual to each other. Let the intersection graph $I(\mathcal{P}, \mathcal{Q})$ have minimum degree at least d where $d \geq 8k \log_{\frac{4}{3}} \left(\frac{|\mathcal{P}|}{24k} \right) + 24k + 4$. Then the graph $\bigcup (\mathcal{P} \cup \mathcal{P}^{\text{back}} \cup \mathcal{Q} \cup \mathcal{Q}^{\text{back}})$ has directed treewidth at least k .*

The proof of Lemma 13 is inspired by the proof of Lemma 5.4 in [12]. We could use Lemma 5.4 here as well, but its proof, unfortunately, contains errors. Nevertheless, we derive an incomparable bound which is much better for our use since the lower bound claimed in Lemma 5.4 [12] is k^2 . Also, we adapt the constants in the lemma for half-integral linkages. We postpone the proof of Lemma 13 to the full version of the paper.

Main Proof of the Dense Case. We are now ready to prove the main lemma of this section.

Proof of Lemma 12. Let $d = 384\,000 \cdot a \cdot b \cdot \log_2(|\mathcal{L}|/b)$. Since $I(\mathcal{L}, \mathcal{K})$ is not d -degenerate, it contains an induced subgraph I' of minimum degree larger than d . Redefine \mathcal{L} and \mathcal{K} to be the sublinkages of \mathcal{L} and \mathcal{K} contained in this subgraph I' , that is, $\mathcal{L} := \mathcal{L} \cap V(I')$ and $\mathcal{K} := \mathcal{K} \cap V(I')$. Note that $|\mathcal{L}| > d$, $|\mathcal{K}| > d$, the size of \mathcal{L} only decreases, and that $A(\mathcal{L}) \cup B(\mathcal{L}) \cup A(\mathcal{K}) \cup B(\mathcal{K})$ remains well-linked.

Let $\mathcal{L}^{\text{back}}$ be a linkage in D from $B(\mathcal{L})$ to $A(\mathcal{L})$ and let $\mathcal{K}^{\text{back}}$ be a linkage in D from $B(\mathcal{K})$ to $A(\mathcal{K})$. Note that $\mathcal{L}^{\text{back}}$ and $\mathcal{K}^{\text{back}}$ exist because $A(\mathcal{L}) \cup B(\mathcal{L}) \cup A(\mathcal{K}) \cup B(\mathcal{K})$ is well linked.

We focus on $\text{Aux}(\mathcal{L})$ and $\text{Aux}(\mathcal{K})$. Take backlinkage-induced orderings $(L_1, \dots, L_{|\mathcal{L}|})$ of \mathcal{L} and $(K_1, \dots, K_{|\mathcal{K}|})$ of \mathcal{K} . Apply Lemma 11 with $k = a$, $r = 320b \log_2(|\mathcal{L}|/b)$, $G = I(\mathcal{L}, \mathcal{K})$, $X = \{L_1, \dots, L_{|\mathcal{L}|}\}$, and $Y = \{K_1, \dots, K_{|\mathcal{K}|}\}$, obtaining a sets U_1, \dots, U_a and a sets W_1, \dots, W_a with the corresponding properties. To see that Lemma 11 is applicable, observe that $I(\mathcal{L}, \mathcal{K})$ has minimum degree at least $384\,000 \cdot a \cdot b \log_2(|\mathcal{L}|/b) = 1200 \cdot 320b \log_2(|\mathcal{L}|/b) \cdot a = 1200 \cdot r \cdot k$. Observe for later on that, for each $i \in [a]$, the intersection graph $I(U_i, W_i)$ of the two linkages U_i and W_i has average degree at least $320b \log_2(|\mathcal{L}|/b)$ by property 3 of Lemma 11.

72:10 Packing Directed Circuits Quarter-Integrally

Now define, for each $i \in [a]$, a graph D_i as follows. Initially, take the union of all paths in U_i and W_i . Then, for each edge (L, L') of $\text{Aux}(\mathcal{L})$ such that $L, L' \in U_i$, add to D_i the unique path $P \in \mathcal{L}^{\text{back}}$ that connects L and L' , that is, $\text{end}(L) = \text{start}(P)$ and $\text{end}(P) = \text{start}(L')$. Similarly, for each edge (K, K') of $\text{Aux}(\mathcal{K})$ such that $K, K' \in W_i$, add to D_i the unique path $Q \in \mathcal{K}^{\text{back}}$ with $\text{end}(K) = \text{start}(Q)$ and $\text{end}(Q) = \text{start}(K')$. In formulas:

$$U'_i := \{P \in \mathcal{L}^{\text{back}} \mid \exists(L, L') \in E(\text{Aux}(\mathcal{L})):$$

$$L, L' \in U_i \wedge \text{end}(L) = \text{start}(P) \wedge \text{end}(P) = \text{start}(L')\}$$

and

$$W'_i := \{Q \in \mathcal{K}^{\text{back}} \mid \exists(K, K') \in E(\text{Aux}(\mathcal{K})):$$

$$K, K' \in W_i \wedge \text{end}(K) = \text{start}(Q) \wedge \text{end}(Q) = \text{start}(K')\}.$$

We set

$$D_i := \bigcup(U_i \cup W_i \cup U'_i \cup W'_i).$$

We claim that D_i satisfies the required properties. Clearly, D_i is a subgraph of D , giving property (i). To see property (ii), consider a linkage $\mathcal{P} \in \{\mathcal{L}, \mathcal{L}^{\text{back}}, \mathcal{K}, \mathcal{K}^{\text{back}}\}$. We claim that no two subgraphs D_i, D_j contain the same path of \mathcal{P} . This claim follows indeed from property 2. of Lemma 11, stating that $U_i \cap U_j = \emptyset$ and $W_i \cap W_j = \emptyset$ and inspecting the definition of D_i and D_j . Thus, $\{V(D_i) \mid i \in [a]\}$ is a partition of a subset of the vertex set $V(\mathcal{P})$ of the paths in \mathcal{P} . Thus, each vertex $v \in V(D)$ occurs in at most four subgraphs D_i , showing property (ii).

It remains to show property (iii), the lower bound on the directed treewidth of D_i . We aim to modify D_i , increasing the directed treewidth by at most a constant, to obtain a graph $D_i^{(2)}$ which is the union of two pairs of dual half-integral linkages such that two linkages contained in distinct pairs intersect a lot. Then we can apply Lemma 13, giving a lower bound on the directed treewidth of $D_i^{(2)}$ which then implies a lower bound on the directed treewidth of D_i .

We first modify D_i to obtain a graph $D_i^{(1)}$ which is the union of two pairs of dual linkages. Recall the orderings $\vec{\mathcal{L}} := (L_1, \dots, L_{|\mathcal{L}|})$ and $\vec{\mathcal{K}} := (K_1, \dots, K_{|\mathcal{K}|})$ on \mathcal{L} and \mathcal{K} , respectively, which we have defined above. By property 1. of Lemma 11, U_i is a segment of $\vec{\mathcal{L}}$ and W_i is a segment of $\vec{\mathcal{K}}$. Hence, by the way we have defined $\vec{\mathcal{L}}$, there are at most two cycles C in $\text{Aux}(\mathcal{L})$ which are not contained in U_i or disjoint with U_i , that is $V(C) \setminus U_i \neq \emptyset$ and $V(C) \cap U_i \neq \emptyset$. Call such a cycle *broken*. Similarly, there are at most two cycles C in $\text{Aux}(\mathcal{K})$ such that $V(C) \setminus W_i \neq \emptyset$ and $V(C) \cap W_i \neq \emptyset$. Call such a cycle *broken* as well. For each broken cycle C , do the following operation on D_i to obtain $D_i^{(1)}$. If C is in $\text{Aux}(\mathcal{L})$, let L_{out}^C be the vertex of outdegree zero in the subgraph $\text{Aux}(\mathcal{L})[V(C) \cap U_i]$ and let L_{in}^C be the vertex of indegree zero. Add the directed edge $(\text{end}(L_{\text{out}}^C), \text{start}(L_{\text{in}}^C))$ to D_i . Proceed analogously if C is in $\text{Aux}(\mathcal{K})$: Let K_{out}^C be the vertex of outdegree zero in the subgraph $\text{Aux}(\mathcal{K})[V(C) \cap W_i]$ and let K_{in}^C be the vertex of indegree zero, and add the directed edge $(\text{end}(K_{\text{out}}^C), \text{start}(K_{\text{in}}^C))$ to D_i . In this way, we add at most four edges to D_i , obtaining $D_i^{(1)}$. Note that adding an edge increases the directed treewidth by at most one², and hence $\text{dtw}(D_i^{(1)}) \leq \text{dtw}(D_i) + 4$.

² In the corresponding robber-cop game (see [13]), we can always guard the new edge with an additional cop.

We claim that $D_i^{(1)}$ is the union of two pairs of dual linkages. To see this, note first that U_i and W_i are linkages in $D_i^{(1)}$. Now consider

$$U_i^b := U_i' \cup \{(\text{end}(L_{\text{out}}^C), \text{start}(L_{\text{in}}^C)) \mid C \text{ a broken cycle in } \text{Aux}(\mathcal{L})\}$$

and

$$W_i^b := W_i' \cup \{(\text{end}(K_{\text{out}}^C), \text{start}(K_{\text{in}}^C)) \mid C \text{ a broken cycle in } \text{Aux}(\mathcal{K})\},$$

wherein $L_{\text{in}}^C, L_{\text{out}}^C, K_{\text{in}}^C$, and K_{out}^C are defined as above. Clearly, $D_i^{(1)} = \bigcup(U_i \cup W_i \cup U_i^b \cup W_i^b)$. Moreover, both U_i^b and W_i^b are linkages because U_i' and W_i' are linkages and because $L_{\text{in}}^C, L_{\text{out}}^C, K_{\text{in}}^C$, and K_{out}^C have indegree or outdegree zero in $\text{Aux}(\mathcal{L})[V(C)]$ or $\text{Aux}(\mathcal{K})[V(C)]$, respectively. Finally, by definition, U_i and U_i^b are dual to each other and W_i and W_i^b are dual to each other. Thus, $D_i^{(1)}$ is the union of two pairs of dual linkages, as claimed.

In order to apply Lemma 13, we need a pair of linkages whose intersection graph has a large minimum degree. So far, the linkages which define $D_i^{(1)}$ guarantee only large average degree (via property 3. of Lemma 11). We now derive a subgraph $D_i^{(2)}$ of $D_i^{(1)}$ such that $D_i^{(2)}$ is the union of two pairs of dual half-integral linkages $(\mathcal{P}, \mathcal{P}^{\text{back}}), (\mathcal{Q}, \mathcal{Q}^{\text{back}})$ and $I(\mathcal{P}, \mathcal{Q})$ has large minimum degree. To achieve this, recall that the intersection graph $I(U_i, W_i)$ of the two linkages U_i, W_i in $D_i^{(1)}$ has average degree at least $320b \log_2(|\mathcal{L}|/b)$. Hence, there is a subgraph I' of $I(U_i, W_i)$ with minimum degree at least $320b \log_2(|\mathcal{L}|/b)$. Let $\mathcal{P} \subseteq U_i$ be the sublinkage of U_i contained in I' , that is $\mathcal{P} = U_i \cap V(I')$. Similarly, let $\mathcal{Q} = W_i \cap V(I')$.

We define $\mathcal{P}^{\text{back}}$ to be the backlinkage induced by \mathcal{P} on (U_i, U_i^b) and $\mathcal{Q}^{\text{back}}$ to be the backlinkage induced by \mathcal{Q} on (W_i, W_i^b) . Note that $\mathcal{P}^{\text{back}}$ and $\mathcal{Q}^{\text{back}}$ are half-integral and dual to \mathcal{P} and \mathcal{Q} , respectively.

Take now the subgraph $D_i^{(2)}$ to be the union $\bigcup(\mathcal{P} \cup \mathcal{P}^{\text{back}} \cup \mathcal{Q} \cup \mathcal{Q}^{\text{back}})$. Then apply Lemma 13 to $\mathcal{P}, \mathcal{P}^{\text{back}}, \mathcal{Q}, \mathcal{Q}^{\text{back}}$ with $k = b + 4$ and $d = 320b \log_2(|\mathcal{L}|/b)$. To see that the preconditions of Lemma 13 are satisfied, first recall that the intersection graph $I(\mathcal{P}, \mathcal{Q})$ has minimum degree at least $320b \log_2(|\mathcal{L}|/b)$. Furthermore,

$$\begin{aligned} d &= 320b \log_2 \frac{|\mathcal{L}|}{b} \geq 200b \log_2 \frac{|\mathcal{L}|}{b} + 120b + 4 \geq \frac{5 \cdot 40b}{2} \log_2 \frac{|\mathcal{L}|}{b} + 120b + 4 \geq \\ &\frac{8 \cdot 5b}{\log_2(4/3)} \log_2 \frac{|\mathcal{L}|}{b} + 24(5b) + 4 \geq 8 \cdot (b + 4) \log_{4/3} \frac{|\mathcal{L}|}{24(b + 4)} + 24(b + 4) + 4 = \\ &8k \log_{4/3} \frac{|\mathcal{L}|}{24k} + 24k + 4, \end{aligned}$$

and thus indeed the preconditions of Lemma 13 are satisfied. Thus, the directed treewidth of $D_i^{(2)}$ is at least $b + 4$. Since $D_i^{(2)}$ is a subgraph of $D_i^{(1)}$ and $\text{dtw}(D_i) \geq \text{dtw}(D_i^{(1)}) - 4$, we have $\text{dtw}(D_i) \geq b$, as required. \blacktriangleleft

5 Wrapping up the Proof of Theorem 5

Proof of Theorem 5. Let G be a directed graph of $\text{dtw}(G) \geq c \cdot a^6 b^8 \log^2(ab)$, where c is a large constant, whose value will follow from the reasoning below. First, we invoke Lemma 7 with $\beta = 2^{37} a^2 b^3 \log(ab)$ and $\alpha = 8ab$ (here we assume that c is sufficiently large so that the assumption is satisfied). We obtain a set of vertex-disjoint paths P_1, \dots, P_{8ab} and sets $A_i, B_i \subseteq V(P_i)$, where A_i appears before B_i on P_i , and $|A_i| = |B_i| = 2^{37} a^2 b^3 \log(ab)$, and the set $\bigcup_{i=1}^{8ab} A_i \cup B_i$ is well-linked. Denote by $\mathcal{L}_{i,j}$ a linkage from B_i to A_j .

72:12 Packing Directed Circuits Quarter-Integrally

We split the $8ab$ paths P_i into a segments, each consisting of $8b$ paths. Formally, for every $\iota \in [a]$ we define $I_\iota = \{j \mid 8(\iota - 1)b < j \leq 8\iota b\}$.

Now we set $r = 64ab^2$ and create an auxiliary r -colored graph H , whose vertices will be paths of appropriately chosen linkages $\mathcal{L}_{i,j}$. More specifically, for every $\iota \in [a]$, and every $i, j \in I_\iota$, we introduce a vertex for every path in $\mathcal{L}_{i,j}$ and color it (i, j) . Two vertices of H are adjacent if and only if their corresponding paths share a vertex in G . Note that for two linkages $\mathcal{L}_{i,j}$ and $\mathcal{L}_{i',j'}$, the graph $H[\mathcal{L}_{i,j} \cup \mathcal{L}_{i',j'}]$ is precisely the intersection graph $I(\mathcal{L}_{i,j}, \mathcal{L}_{i',j'})$.

We set $d := 2^{27}ab \log(ab)$ and consider two cases:

- (i) for all i, j, i', j' the graph $I(\mathcal{L}_{i,j}, \mathcal{L}_{i',j'})$ is d -degenerate.
- (ii) there exist i, j, i', j' , for which the graph $I(\mathcal{L}_{i,j}, \mathcal{L}_{i',j'})$ is not d -degenerate.

An intuition behind case (i) is that for each subgraph of H there is always a path (in G) such that it shares a vertex with at most d paths from all used linkages back.

Case (i) We use Lemma 8 on H . Graph H has $64ab^2$ color classes such that for each $(i, j) \neq (i', j')$ the graph $H[\mathcal{L}_{i,j} \cup \mathcal{L}_{i',j'}]$ is d -degenerate. Note that $|\mathcal{L}_{i,j}| = 2^{37}a^2b^3 \log(ab) \geq 4e(r-1)d$ is sufficiently large to satisfy the last assumption of the lemma. We are given an independent set x_1, \dots, x_{64ab^2} that represents pairwise disjoint paths $L_{i,j}$ from B_i to A_j for all $i, j \in I_\iota$. We also recall that A_i and B_i lie on P_i and all P_i 's are pairwise disjoint.

Let G_ι consist of all paths P_i for $i \in I_\iota$ and $L_{i,j}$ for $i, j \in I_\iota$. By Lemma 9 for $k = 8b$ we obtain $\text{dtw}(G_\iota) \geq b$ while each vertex is in at most 2 such subgraphs. Indeed, each vertex can appear only once on some P_i and once on some $L_{i,j}$.

Case (ii) The claim follows from Lemma 12. Since $|\mathcal{L}| = 2^{37}a^2b^3 \log(ab)$ then $d = 2^{27}ab \log(ab) > 2^{19}ab \log(2^{37}a^2b^2 \log(ab))$. ◀

6 Conclusions

We have shown that if one relaxes the disjointness constraint to quarter-integral packing (i.e., every vertex used at most four times), then the Erdős-Pósa property in directed graphs admits a polynomial bound between the cycle packing number and the feedback vertex set number. A natural question would be to decrease the dependency further, even at the cost of higher congestion (but still a constant). More precisely, we pose the following question: Does there exist a constant c and a polynomial p such that for every integer k if a directed graph G does not contain a family of k cycles such that every vertex of G is in at most c of the cycles, then the directed treewidth of G is at most $kp(\log k)$?

One of the sources of polynomial blow-up in the proof of Theorem 5 is the quadratic blow-up in Lemma 7. Lemma 7 is a direct corollary of another result of [14] that asserts that a directed graph G of directed treewidth $\Omega(k^2)$ contains a path P and a set $A \subseteq V(P)$ that is well-linked and of size k . Is this quadratic blow-up necessary? Can we improve it, even at the cost of some constant congestion in the path P (i.e., allow P to visit every vertex a constant number of times)? We remark that the essence of the improvement from $\mathcal{O}(k^6 \log^2 k)$ (obtained by setting $b = 2$ in Theorem 5) to $\mathcal{O}(k^3)$ asserted by Theorem 4 is to avoid the usage of Lemma 7 and to replace it with a simple well-linkedness trick. However, this trick fails in the general setting of Theorem 5.

Abstract

In the Equal-Subset-Sum problem, we are given a set S of n integers and the problem is to decide if there exist two disjoint nonempty subsets $A, B \subseteq S$, whose elements sum up to the same value. The problem is NP-complete. The state-of-the-art algorithm runs in $\mathcal{O}^*(3^{n/2}) \leq \mathcal{O}^*(1.7321^n)$ time and is based on the *meet-in-the-middle* technique. In this paper, we improve upon this algorithm and give $\mathcal{O}^*(1.7088^n)$ worst case Monte Carlo algorithm. This answers a question suggested by Woeginger in his inspirational survey.

Additionally, we analyse the polynomial space algorithm for Equal-Subset-Sum. A naive polynomial space algorithm for Equal-Subset-Sum runs in $\mathcal{O}^*(3^n)$ time. With read-only access to the exponentially many random bits, we show a randomized algorithm running in $\mathcal{O}^*(2.6817^n)$ time and polynomial space.

1 Introduction

In the Subset-Sum problem, we are given as input a set S of n integers a_1, \dots, a_n and a target t . The task is to decide if there exists a subset of S , such that a total sum of the numbers in this subset is equal to t . This can be formulated in the following form:

$$\sum_{i=1}^n x_i a_i = t$$

and the task is to find $x_i \in \{0, 1\}$. Subset-Sum is one of the fundamental NP-complete problems. Study on the exact complexity of Subset-Sum led to the discovery of one of the most fundamental algorithmic tool: *meet-in-the-middle*. [24] used this technique to give a $\mathcal{O}^*(2^{n/2})$ algorithm for Subset-Sum in the following way: First, rewrite the Subset-Sum equation:

$$\sum_{i=1}^{\lfloor n/2 \rfloor} x_i a_i = t - \sum_{i=\lfloor n/2 \rfloor + 1}^n x_i a_i.$$

Then enumerate all $\mathcal{O}(2^{n/2})$ possible values of the left side $L(x_1, \dots, x_{\lfloor n/2 \rfloor})$ and $\mathcal{O}(2^{n/2})$ possible values of the right side $R(x_{\lfloor n/2 \rfloor + 1}, \dots, x_n)$. After that, it remains to look for the value that occurs in both L and R , i.e., *meeting* the tables L and R . One can do that efficiently by sorting (see [24] for details). To summarize, meet-in-the-middle technique is based on rewriting the formula as an equation between two functions and efficiently seeking any value that occurs in both of their images.

Later, [39] observed that space usage of meet-in-the-middle can be improved to $\mathcal{O}^*(2^{n/4})$ by using space-efficient algorithm for 4-SUM. However, the time complexity remains unchallenged and one of the most prominent open problem in the area of exact algorithms is to improve upon *meet-in-the-middle* for Subset-Sum:

► **Open Question 1.** *Can Subset-Sum be solved in $\mathcal{O}^*(2^{(0.5-\delta)n})$ time for some constant $\delta > 0$?*

In this paper, we consider the Equal-Subset-Sum problem. We are given a set S of n integers and the task is to decide if there exist two disjoint nonempty subsets $A, B \subseteq S$, whose elements sum up to the same value. Similarly to Subset-Sum, this problem is NP-complete [45]. In the inspirational survey, [44] noticed Equal-Subset-Sum can be solved by using meet-in-the-middle and asked if it can be improved: ¹

► **Open Question 2** (cf., [43],[44]). *Can we improve upon the meet-in-the-middle algorithm for Equal-Subset-Sum?*

The folklore meet-in-the-middle algorithm for Equal-Subset-Sum (that we will present in the next paragraph) works in $\mathcal{O}^*(3^{n/2})$ time.

Folklore algorithm for Equal-Subset-Sum

First, we arbitrarily partition S into $S_1 = \{a_1, \dots, a_{\lfloor n/2 \rfloor}\}$ and $S_2 = \{a_{\lfloor n/2 \rfloor + 1}, \dots, a_n\}$. Recall that in Equal-Subset-Sum we seek two subsets $A, B \subseteq S$, such that $A \cap B = \emptyset$ and $\Sigma(A) = \Sigma(B)$. We can write the solution as 4 subsets: $A_1 = A \cap S_1$, $A_2 = A \cap S_2$, $B_1 = B \cap S_1$

¹ [43, 44] noticed that 4-SUM gives $\mathcal{O}^*(2^n)$ algorithm, but it actually gives a $\mathcal{O}^*(3^{n/2})$ algorithm, see [35, Appendix C].

and $B_2 = B \cap S_2$, such that: $\Sigma(A_1) + \Sigma(A_2) = \Sigma(B_1) + \Sigma(B_2)$. In particular, it means that: $\Sigma(A_1) - \Sigma(B_1) = \Sigma(B_2) - \Sigma(A_2)$. So, the problem reduces to finding two vectors $x \in \{-1, 0, 1\}^{\lfloor n/2 \rfloor}$ and $y \in \{-1, 0, 1\}^{\lceil n/2 \rceil}$, such that:

$$\sum_{i=1}^{\lfloor n/2 \rfloor} x_i a_i = \sum_{i=1}^{\lceil n/2 \rceil} y_i a_{i+\lfloor n/2 \rfloor}.$$

We can do this in $\mathcal{O}^*(3^{n/2})$ time as follows. First, enumerate and store all $3^{\lfloor n/2 \rfloor}$ possible values of the left side of the equation and all $3^{\lceil n/2 \rceil}$ possible values of the right side of the equation. Then look for a value that occurs in both tables (collision) in time $\mathcal{O}^*(3^{n/2})$ by sorting the values. The total running time is therefore $\mathcal{O}^*(3^{n/2})$. Analogously to Subset-Sum, one can improve the space usage of the above algorithm to $\mathcal{O}^*(3^{n/4})$ (see [35, Appendix C]).

A common pattern seems unavoidable in algorithms for Subset-Sum and Equal-Subset-Sum: we have to go through all possible values of the left and the right side of the equation. This enumeration dominates the time used to solve the problem. So, it was conceivable that perhaps no improvement for Equal-Subset-Sum could be obtained unless we improve an algorithm for Subset-Sum first [43, 44].

1.1 Our Contribution

While the meet-in-the-middle algorithm remains unchallenged for Subset-Sum, we show that, surprisingly, we can improve the algorithm for Equal-Subset-Sum. The main result of this paper is the following theorem.

► **Theorem 1.1.** *Equal-Subset-Sum can be solved in $\mathcal{O}^*(1.7088^n)$ time with high probability.*

This positively answers Open Question 2. To prove this result we observe that the worst case for the meet-in-the-middle algorithm is that of a balanced solution, i.e., when $|A| = |B| = |S \setminus (A \cup B)| \approx n/3$. We propose a substantially different algorithm, that runs in $\mathcal{O}^*(2^{2/3n})$ time for that case. The crucial insight of the new approach is the fact that when $|A| \approx |B| \approx n/3$, then there is an abundance of pairs $X, Y \subseteq S$, $X \neq Y$ with $\Sigma(X) = \Sigma(Y)$. We use the *representation technique* to exploit this. Interestingly, that technique was initially developed to solve the average case Subset-Sum [9, 25].

Our second result is an improved algorithm for Equal-Subset-Sum running in polynomial space. The naive algorithm in polynomial space works in $\mathcal{O}^*(3^n)$ time by enumerating all possible disjoint pairs of subsets of S . This algorithm is analogous to the $\mathcal{O}^*(2^n)$ polynomial space algorithm for Subset-Sum. Recently, [6] proposed a $\mathcal{O}^*(2^{0.86n})$ algorithm for Subset-Sum on the machine that has access to the exponential number of random bits. We show that a similar idea can be used for Equal-Subset-Sum.

► **Theorem 1.2.** *There exists a Monte Carlo algorithm which solves Equal-Subset-Sum in polynomial space and time $\mathcal{O}^*(2.6817^n)$. The algorithm assumes random read-only access to exponentially many random bits.*

This result is interesting for two reasons. First, [6] require nontrivial results in information theory. Our algorithm is relatively simple and does not need such techniques. Second, the approach of [6] developed for Subset-Sum has a barrier, i.e., significantly new ideas must be introduced to get an algorithm running faster than $\mathcal{O}^*(2^{0.75n})$. In our case, this corresponds to the algorithm running in $\mathcal{O}^*(2^{1.5n}) \leq \mathcal{O}^*(2.8285^n)$ time and polynomial space (for elaboration see Section 4). We show that relatively simple observations about Equal-Subset-Sum enable us to give a slightly faster algorithm in polynomial space.

1.2 Related Work

The Equal-Subset-Sum was introduced by [45] who showed that the problem is NP-complete. This reduction automatically excludes $2^{o(n)}$ algorithms for Equal-Subset-Sum assuming ETH (see [35, Appendix B]), hence for this problem we aspire to optimize the constant in the exponent. The best known constant comes from the meet-in-the-middle algorithm. [44] asked if this algorithm for Equal-Subset-Sum can be improved.

Exact algorithms for Subset-Sum

[36] proved that in the exact setting Knapsack and Subset-Sum problems are equivalent.

[39] showed that the meet-in-the-middle algorithm admits a time-space tradeoff, i.e., $\mathcal{T}\mathcal{S}^2 \leq \mathcal{O}^*(2^n)$, where \mathcal{T} is the running time of the algorithm and $\mathcal{S} \leq \mathcal{O}^*(2^{n/2})$ is the space of an algorithm. This tradeoff was improved by [2] for almost all tradeoff parameters.

[3] considered Subset-Sum parametrized by the maximum bin size β and obtained algorithm running in time $\mathcal{O}^*(2^{0.3399n}\beta^4)$. Subsequently, [4] showed that one can get a faster algorithm for Subset-Sum than meet-in-the-middle if $\beta \leq 2^{(0.5-\varepsilon)n}$ or $\beta \geq 2^{0.661n}$. In this paper, we use the hash function that is based on their ideas. Moreover, the ideas in [3, 4] were used in the recent breakthrough polynomial space algorithm [6] running in $\mathcal{O}^*(2^{0.86n})$ time.

From the pseudopolynomial algorithms perspective Knapsack and Subset-Sum admit $\mathcal{O}(nt)$ algorithm, where t is a value of a target. Recently, for Subset-Sum the pseudopolynomial algorithm was improved to run in deterministic $\tilde{\mathcal{O}}(\sqrt{nt})$ time by [29] and randomized $\tilde{\mathcal{O}}(n+t)$ time by [11] (and simplified, see [27, 30]). However, these algorithms have a drawback of running in pseudopolynomial space $\mathcal{O}^*(t)$. Surprisingly, [32] presented an algorithm running in time $\tilde{\mathcal{O}}(n^3t)$ and space $\tilde{\mathcal{O}}(n^2)$ which was later improved to $\tilde{\mathcal{O}}(nt)$ time and $\tilde{\mathcal{O}}(n \log t)$ space assuming the Extended Riemann Hypothesis [11].

From a lower bounds perspective, no algorithm working in $\tilde{\mathcal{O}}(\text{poly}(n)t^{0.99})$ exists for Subset-Sum assuming SETH or SetCover conjecture [18, 1].

Approximation

[45] presented the approximation algorithm for Equal-Subset-Sum with the worst case ratio of 1.324. [7] considered a different formulation of approximation for Equal-Subset-Sum and showed an FPTAS for it.

Cryptography and the average case complexity

In 1978 Knapsack problems were introduced into cryptography by [34]. They introduced a Knapsack based public key cryptosystem. Subsequently, their scheme was broken by using lattice reduction [40]. After that, many knapsack cryptosystems were broken with low-density attacks [31, 17].

More recently, [26] introduced a cryptographic scheme that is provably as secure as Subset-Sum. They proposed a function $f(\vec{a}, S) = \vec{a}, \sum_{i \in S} a_i \pmod{2^{l(n)}}$, i.e., the function which concatenates \vec{a} with the sum of the a_i 's for $i \in S$. Function f is a mapping of an n bit string S to an $l(n)$ bit string and \vec{a} are a fixed parameter. Our algorithms can be thought of as an attempt to find a collision of such a function in the worst case.

However, in the average case more efficient algorithms are known. [42] showed that when solving problems involving sums of elements from lists, one can obtain faster algorithms when there are many possible solutions. In the breakthrough paper, [25] gave $\mathcal{O}^*(2^{0.337n})$

algorithm for an average case Subset-Sum. It was subsequently improved by [9] who gave an algorithm running in $\mathcal{O}^*(2^{0.291n})$. These papers introduced a *representation* technique that is a crucial ingredient in our proofs.

Total search problems

The *Number Balancing* problem is: given n real numbers $a_1, \dots, a_n \in [0, 1]$, find two disjoint subsets $I, J \subseteq [n]$, such that the difference $|\sum_{i \in I} a_i - \sum_{j \in J} a_j|$ is minimized. The pigeonhole principle and the Chebyshev's inequality guarantee that there exists a solution with difference at most $\mathcal{O}(\frac{\sqrt{n}}{2^n})$. [28] showed that in polynomial time one can produce a solution with difference at most $n^{-\Theta(\log n)}$, but since then no further improvement is known.

[37] considered the problem *Equal Sums*: given n positive integers such that their total sum is less than $2^n - 1$, find two subsets with the same sum. By the pigeonhole principle the solution always exists, hence the decision version of this problem is obviously in P. However the hard part is to actually find a solution. Equal Sums is in class PPP but it remains open to show that it is PPP-complete. Recently, this question gained some momentum. [23] showed that Number Balancing is as hard as *Minkowski*. [5] showed the reduction from Equal Sums to Minkowski and conjectured that Minkowski is complete for the class PPP. Very recently, [41] identified the first natural problem complete for PPP.

In [35, Appendix E] we show that our techniques can also be used to solve Number Balancing for integers in $\mathcal{O}^*(1.7088^n)$ time.

Combinatorial Number Theory

If $\Sigma(S) < 2^n - 1$, then by the pigeonhole principle the answer to the decision version of Equal-Subset-Sum on S is always YES. In 1931 Paul Erdős was interested in the smallest maximum value of S , such that the answer to Equal-Subset-Sum on S is NO, i.e., he considered the function:

$$f(n) = \min\{\max\{|S|\} \mid \text{all subsets of } S \text{ are distinct, } |S| = n, S \subseteq \mathbb{N}\}$$

and showed $f(n) > 2^n / (10\sqrt{n})$ [19]. The first nontrivial upper bound on f was $f(n) \leq 2^{n-2}$ (for sufficiently large n) [16]. Subsequently, [33] proved that $f(n) \leq 0.2246 \cdot 2^n$ and [10] showed $f(n) \leq 0.22002 \cdot 2^n$. [20] offered 500 dollars for proof or disproof of conjecture that $f(n) \geq c2^n$ for some constant c .

Other Variants

Equal-Subset-Sum has some connections to the study of the structure of DNA molecules [15, 14, 12]. [13] considered k -Equal-Subset-Sum, in which we need to find k disjoint subsets of a given set with the same sum. They obtained several algorithms that depend on certain restrictions of the sets (e.g., small cardinality of a solution). In the following work, [14] considered other variants of Equal-Subset-Sum and proved their NP-hardness.

2 Preliminaries

Throughout the paper we use the \mathcal{O}^* notation to hide factors polynomial in the input size and the $\tilde{\mathcal{O}}$ notation to hide factors logarithmic in the input size. We also use $[n]$ to denote the set $\{1, \dots, n\}$. If $S = \{a_1, \dots, a_n\}$ is a set of integers and $X \subseteq \{1, \dots, n\}$, then $\Sigma_S(X) := \sum_{i \in X} a_i$. Also, we use $\Sigma(S) = \sum_{s \in S} s$ to denote the sum of the elements of the set. We use the binomial coefficient notation for sets, i.e., for a set S the symbol $\binom{S}{k} = \{X \subseteq S \mid |X| = k\}$ is the set of all subsets of the set S of size exactly k .

We may assume that the input to Equal-Subset-Sum has the following properties:

- the input set $S = \{a_1, \dots, a_n\}$ consists of positive integers,
- $\sum_{i=1}^n a_i < 2^{\tau n}$ for a constant $\tau < 10$,
- integer n is a multiple of 12.

These are standard assumptions for Subset-Sum (e.g., [3, 22]). For completeness, in [35, Appendix A] we prove how to apply reductions to Equal-Subset-Sum to ensure these properties.

We need the following theorem concerning the density of prime numbers [21, p. 371, Eq. (22.19.3)].

► **Lemma 2.1.** *For a large enough integer b , there exist at least $2^b/b$ prime numbers in the interval $[2^b, 2^{b+1}]$.*

The binary entropy function is $h(\alpha) = -\alpha \log_2 \alpha - (1 - \alpha) \log_2 (1 - \alpha)$ for $\alpha \in (0, 1)$ and $h(0) = h(1) = 0$. For all integers $n \geq 1$ and $\alpha \in [0, 1]$ such that σn is an integer, we have the following upper bound on the binomial coefficient [38]: $\binom{n}{\alpha n} \leq 2^{h(\alpha)n}$. We also need a standard bound on binary entropy function $h(x) \leq 2\sqrt{x(1-x)}$.

Throughout this paper all logarithms are base 2.

3 Faster Exponential Space Algorithm

In this section, we improve upon the meet-in-the-middle algorithm for Equal-Subset-Sum.

► **Theorem 3.1.** *Equal-Subset-Sum can be solved in $\mathcal{O}^*(1.7088^n)$ time with high probability.*

Theorem 3.1 is proved by using two different algorithms for Equal-Subset-Sum. To bound the trade-off between these algorithms we introduce the concept of a *minimum solution*.

► **Definition 3.2 (Minimum Solution).** *For a set S of positive integers we say that a solution $A, B \subseteq S$ is a minimum solution if its size $|A| + |B|$ is smallest possible.*

We now assume that the size of the minimum solution has even size for simplicity of presentation. The algorithm and analysis for the case of odd-sized minimum solution is similar, but somewhat more messy due to all the floors and ceilings one needs to take care of.

In Section 3.1 we prove that the meet-in-the-middle approach for Equal-Subset-Sum already gives algorithm running in time $\mathcal{O}^*((3 - \varepsilon)^{n/2})$ if the minimum solution A, B is *unbalanced*, i.e., $||A \cup B| - \frac{2n}{3}| > \varepsilon' n$ for some $\varepsilon' > 0$ depending on ε . Subsequently, in Section 3.2 we propose an algorithm for *balanced* instances, i.e., when the size of a minimum solution is close to $2/3$. In particular, we show how to detect sets A, B with $\Sigma(A) = \Sigma(B)$ and $|A| \approx |B| \approx \frac{n}{3}$, with an $\mathcal{O}^*(2^{\frac{2}{3}n})$ time algorithm. By bounding trade-off between the algorithms from Section 3.1 and Section 3.2 we prove Theorem 3.1 and bound the running time numerically.

3.1 Equal-Subset-Sum for unbalanced solutions via meet-in-the-middle

► **Theorem 3.3.** *If S is a set of n integers with a minimum solution of size ℓ , then Equal-Subset-Sum with input S can be solved in $\mathcal{O}^*\left(\binom{n/2}{\ell/2} 2^{\ell/2}\right)$ time with high probability.*

Algorithm 1 UNBALANCEDEQUALSUBSETSUM(S, ℓ).

- 1: Randomly split S into two disjoint $S_1, S_2 \subseteq S$, such that $|S_1| = |S_2| = n/2$
 - 2: Enumerate $C_1 = \{\Sigma(A_1) - \Sigma(B_1) \mid A_1, B_1 \subseteq S_1, A_1 \cap B_1 = \emptyset, |A_1| + |B_1| = \ell/2\}$
 - 3: Enumerate $C_2 = \{\Sigma(A_2) - \Sigma(B_2) \mid A_2, B_2 \subseteq S_2, A_2 \cap B_2 = \emptyset, |A_2| + |B_2| = \ell/2\}$
 - 4: **if** $\exists x_1 \in C_1, x_2 \in C_2$ such that $x_1 + x_2 = 0$ **then**
 - 5: Let $A_1, B_1 \subseteq S_1$ be such that $x_1 = \Sigma(A_1) - \Sigma(B_1)$
 - 6: Let $A_2, B_2 \subseteq S_2$ be such that $x_2 = \Sigma(A_2) - \Sigma(B_2)$
 - 7: **return** $(A_1 \cup A_2, B_1 \cup B_2)$
 - 8: **end if**
 - 9: **return** NO
-

Proof of Theorem 3.3. Algorithm 1 uses the meet-in-the-middle approach restricted to solutions of size ℓ . We will show that this algorithm solves *Equal – Subset – Sum* in the claimed running time.

The algorithm starts by randomly partitioning the set S into two equally sized sets S_1, S_2 . Let A, B be a fixed minimum solution of size $|A \cup B| = \ell$. We will later show that with $\Omega(1/\text{poly}(n))$ probability $|(A \cup B) \cap S_1| = |(A \cup B) \cap S_2| = \ell/2$. We assume this is indeed the case and proceed with meet-in-the-middle. For S_1 we will list all A_1, B_1 that could possibly be equal to $S_1 \cap A$ and $S_1 \cap B$, i.e. disjoint and with total size $\ell/2$. We compute $x = \Sigma(A_1) - \Sigma(B_1)$ and store all these in C_1 . We proceed analogously for S_2 .

We then look for $x_1 \in C_1$ and $x_2 \in C_2$ such that $x_1 + x_2 = 0$. If we find it then we identify the sets A_1 and B_1 that correspond to x_1 and sets A_2 and B_2 that correspond to x_2 (the easiest way to do that is to store with each element of C_1 and C_2 the corresponding pair of sets when generating them). Finally we return $(A_1 \cup A_2, B_1 \cup B_2)$.

Probability of a good split. We now lower-bound the probability of S_1 and S_2 splitting $A \cup B$ in half. There are $\binom{n}{n/2}$ possible equally sized partitions. Among these there are $\binom{\ell}{\ell/2} \binom{n-\ell}{(n-\ell)/2}$ partitions that split $A \cup B$ in half. The probability that a random partition splits A and B in half is:

$$\frac{\binom{\ell}{\ell/2} \binom{n-\ell}{(n-\ell)/2}}{\binom{n}{n/2}} \geq \frac{2^\ell 2^{n-\ell}}{(n+1)^2 2^n} = \frac{1}{(n+1)^2}$$

because $\frac{2^n}{n+1} \leq \binom{n}{n/2} \leq 2^n$.

Running time. To enumerate C_1 and C_2 we need $\mathcal{O}^*(\binom{n/2}{\ell/2} 2^{\ell/2})$ time, because first we guess set $S_1 \cap (A \cup B)$ of size $\ell/2$ and then split between A and B in at most $2^{\ell/2}$ ways. We then check the existence of $x_1 \in C_1$ and $x_2 \in C_2$ such that $x_1 + x_2 = 0$ in $\mathcal{O}^*((|C_1| + |C_2|) \log(|C_1| + |C_2|))$ time by sorting.

We can amplify the probability of a *good split* to $\mathcal{O}(1)$ by repeating the whole algorithm polynomially many times.

Correctness. With probability $\Omega(1/\text{poly}(n))$ we divide the $A \cup B$ equally between S_1 and S_2 . If that happens the set C_1 contains x_1 such that $x_1 = \Sigma(A \cap S_1) - \Sigma(B \cap S_1)$ and the set C_2 contains x_2 that $x_2 = \Sigma(A \cap S_2) - \Sigma(B \cap S_2)$. Note that $x_1 + x_2 = \Sigma(A \cap S_1) + \Sigma(A \cap S_2) - \Sigma(B \cap S_1) - \Sigma(B \cap S_2) = \Sigma(A) - \Sigma(B)$ which is 0, since A, B is a solution. Therefore Algorithm 1 finds a solution of size ℓ (but of course, it could be different from A, B). ◀

3.2 Equal-Subset-Sum for balanced solutions

► **Theorem 3.4.** *Given a set S of n integers with a minimum solution size $\ell \in (\frac{1}{2}n, (1 - \varepsilon)n]$ for some constant $\varepsilon > 0$, Equal-Subset-Sum can be solved in time $\mathcal{O}^*(2^\ell)$ w.h.p.*

We use Algorithm 2 to prove Theorem 3.4. In this algorithm, we first pick a random prime p in the range $[2^{n-\ell}, 2^{n-\ell+1}]$, as well as an integer t chosen uniformly at random from $[1, 2^{n-\ell}]$. We then compute the set $C = \{X \subseteq S \mid \Sigma(X) \equiv_p t\}$. In the analysis, we argue that with $\Omega(1/\text{poly}(n))$ probability C contains two different subsets X, Y of S with $\Sigma(X) = \Sigma(Y)$. To identify such pair it is enough to sort the set $|C|$ in time $\mathcal{O}(|C| \log |C|)$, and then scan it. We return $X \setminus Y$ and $Y \setminus X$ to guarantee that the returned sets are disjoint.

■ **Algorithm 2** BALANCEDEQUALSUBSETSUM(a_1, \dots, a_n, ℓ).

-
- 1: Pick a random prime p in $[2^{n-\ell}, 2^{n-\ell+1}]$
 - 2: Pick a random number t in $[1, 2^{n-\ell}]$
 - 3: Let $C = \{X \subseteq S \mid \Sigma(X) \equiv_p t\}$ be the set of candidates ▷ C contains two sets with equal sum with probability $\Omega(1/\text{poly}(n))$.
 - 4: Enumerate and store all elements of C ▷ In time $\mathcal{O}^*(|C| + 2^{n/2})$
 - 5: Find $X, Y \in C$, such that $\Sigma(X) = \Sigma(Y)$ ▷ In time $\mathcal{O}^*(|C|)$
 - 6: **return** $(X \setminus Y, Y \setminus X)$
-

We now analyse the correctness of Algorithm 2. Later, we will give a bound on the running time and conclude the proof Theorem 3.4. First, observe the following:

► **Lemma 3.5.** *Let S be a set of n positive integers with minimum solution size of ℓ . Let*

$$\Psi = \{\Sigma(X) \mid X \subseteq S \text{ and } \exists Y \subseteq S \text{ such that } X \neq Y \text{ and } \Sigma(X) = \Sigma(Y)\}. \quad (1)$$

If $\ell > \frac{n}{2}$, then $|\Psi| \geq 2^{n-\ell}$ (note that all elements in Ψ are different).

■ **Figure 1** Scheme presents the set S of positive integers and two disjoint subsets $A, B \subseteq S$. The point is that if $\Sigma(A) = \Sigma(B)$ then for any subset $X \subseteq S \setminus (A \cup B)$ we have a guarantee that $\Sigma(A \cup X) = \Sigma(B \cup X)$.

Proof. Let $A, B \subseteq S$ be a fixed minimum solution to S . We know that $\ell = |A \cup B|$, $\Sigma(A) = \Sigma(B)$ and $A \cap B = \emptyset$. With this in hand we construct set Ψ of $2^{n-\ell}$ pairs of different $X, Y \subseteq S$ with $\Sigma(X) = \Sigma(Y)$.

Consider set $Z = S \setminus (A \cup B)$. By the bound on the size of A and B we know that $|Z| = n - \ell$. Now we construct our candidate pairs as follows: take any subset $Z' \subseteq Z$ and note that $X \cup Z'$ and $Y \cup Z'$ satisfy $\Sigma(X \cup Z') = \Sigma(Y \cup Z')$. There are $2^{|Z|}$ possible subsets of set Z and the claim follows.

Now we will prove that if $\ell > \frac{n}{2}$ then all subsets of Z have a different sum. Assume for a contradiction that there exist $Z_1, Z_2 \subseteq Z$, such that $\Sigma(Z_1) = \Sigma(Z_2)$ and $Z_1 \neq Z_2$. Then $Z_1 \setminus Z_2$ and $Z_2 \setminus Z_1$ would give a solution smaller than A, B , because $|Z| < \ell$. This contradicts the assumption about the minimality of A, B . It follows that if $\ell > \frac{1}{2}n$ then all constructed pairs have a different sum. ◀

Now, we consider the hashing function $h_{t,p}(x) = x + t \pmod p$. We prove that if the set Ψ (see Equation 1) is sufficiently large, then for a random choice of t , at least one element of set Ψ is in the congruence class t .

► **Lemma 3.6.** *Let S be the set of n positive integers bounded by $2^{\mathcal{O}(n)}$ with minimum solution of size ℓ and $\ell > \frac{n}{2}$. For a random prime $p \in [2^{n-\ell}, 2^{n-\ell+1}]$ and a random $t \in [1, 2^{n-\ell}]$ let $C_{t,p} = \{X \subseteq S \mid \Sigma(X) \equiv_p t\}$. Then,*

$$\mathbb{P}_{t,p} \left[\exists X, Y \in C_{t,p} \mid \Sigma(X) = \Sigma(Y), X \neq Y \right] \geq \Omega(1/n^2).$$

Proof. Let Ψ be the set defined in (1). So $\Psi \subseteq \{1, \dots, 2^{\mathcal{O}(n)}\}$, and $|\Psi| \geq 2^{n-\ell}$. It is sufficient to bound the probability, that there exists an element $a \in \Psi$ such $a \equiv_p t$. Let $a_1, a_2 \in \Psi$ be two distinct elements.

$$\mathbb{P}_p [a_1 \equiv_p a_2] = \mathbb{P}_p [p \text{ divides } |a_1 - a_2|] \leq \mathcal{O}(n(n - \ell)/2^{n-\ell}).$$

This is because $|a_1 - a_2|$ can only have $\mathcal{O}(n)$ prime divisors, and we are sampling p from the set of at least $2^{n-\ell}/(n - \ell)$ primes by Lemma 2.1. Let k be the number of pairs $a_1, a_2 \in \Psi$ such that $a_1 \equiv_p a_2$. We have $\mathbb{E}[k] \leq \mathcal{O}(|\Psi| + (|\Psi|n)^2/2^{n-\ell})$. We know that $|\Psi| \geq 2^{n-\ell}$, so $\frac{|\Psi|^2}{2^{n-\ell}} \geq |\Psi|$ which means that $\mathbb{E}[k] \leq \mathcal{O}((|\Psi|n)^2/2^{n-\ell})$. Hence, by Markov's inequality k is at most $\mathcal{O}((|\Psi|n)^2/2^{n-\ell})$ with at least constant probability. If this does indeed happen, then

$$|\{a \pmod p \mid a \in \Psi\}| \geq \frac{|\Psi|^2}{k} \geq \Omega\left(\frac{|\Psi|^2}{(|\Psi|n)^2/2^{n-\ell}}\right) \geq \Omega(2^{n-\ell}/n^2),$$

and the probability that t chosen uniformly at random from $[1, 2^{n-\ell}]$ will be among one of the elements of set $\{a \pmod p \mid a \in \Psi\}$ is $|\{a \pmod p \mid a \in \Psi\}|/2^{n-\ell} \geq \Omega(1/n^2)$. ◀

Proof of correctness of Algorithm 2. By Lemma 3.6, after choosing a random prime p and random number $t \in [1, 2^{n-\ell}]$ the set $C = \{X \subseteq S \mid \Sigma(X) \equiv_p t\}$ contains at least two subsets $X, Y \subseteq S$, such that $\Sigma(X) = \Sigma(Y)$ with probability $\Omega(1/\text{poly}(n))$. Algorithm 2 computes the set C and finds $X', Y' \subseteq S$, such that $\Sigma(X') = \Sigma(Y')$. Then it returns the solution $X' \setminus Y', Y' \setminus X'$. ◀

Now we focus on bounding the running time of Algorithm 2. We start by bounding the size of the candidate set C .

▷ **Claim 3.7.** Let S be the set of n non-negative integers bounded by $2^{\mathcal{O}(n)}$ with a minimum solution of size ℓ such that $\ell \leq (1 - \varepsilon)n$ for some constant $\varepsilon > 0$ (think of $\varepsilon = 1/100$). For a random prime $p \in [2^{n-\ell}, 2^{n-\ell+1}]$ and a random number $t \in [1, 2^{n-\ell}]$ let $C_{t,p} = \{X \subseteq S \mid \Sigma(X) \equiv_p t\}$. Then

$$\mathbb{E}[|C_{t,p}|] \leq \mathcal{O}^*(2^\ell)$$

Proof. By the linearity of expectations:

$$\mathbb{E}[|C_{t,p}|] = \sum_{X \subseteq S} \mathbb{P}_{t,p} [p \text{ divides } \Sigma(X) - t]$$

73:10 Equal-Subset-Sum Faster Than the Meet-in-the-Middle

For the remaining part of the proof we focus on showing $\mathbb{P}_{t,p}[p \text{ divides } \Sigma(X) - t] \leq \mathcal{O}^*(2^{\ell-n})$ for a fixed $X \subseteq S$. It automatically finishes the proof, because there are 2^n possible subsets X .

We split the terms into two cases. If $\Sigma(X) = t$, then p divides $\Sigma(X) - t$ with probability 1. However, for a fixed $X \subseteq S$, the probability that $\Sigma(X) = t$ is $\mathcal{O}(\frac{1}{2^{n-\ell}})$ because t is a random number from $[1, 2^{n-\ell}]$ and $p \geq 2^{n-\ell}$.

On the other hand, if $\Sigma(X) \neq t$, then by the assumption, the set S consists of non-negative integers bounded by $2^{\tau n}$ for some constant $\tau > 0$. In particular, $|\Sigma(X) - t| \leq 2^{\tau n}$. This means that $|\Sigma(X) - t|$ has at most $\frac{\tau n}{n-\ell} \leq \frac{\tau}{\varepsilon} = \mathcal{O}(1)$ prime factors of size at least $2^{n-\ell}$. Any prime number p that divides $\Sigma(X) - t$ must therefore be one of these numbers. By Lemma 2.1 there are at least $2^{n-\ell}/(n-\ell)$ prime numbers in range $[2^{n-\ell}, 2^{n-\ell+1}]$. Hence, for a fixed $X \subseteq S$ the probability that p divides $\Sigma(X) - t$ is bounded by $\mathcal{O}(n2^{\ell-n})$. ◀

► **Lemma 3.8.** *The set $C_{t,p}$ can be enumerated in time $\mathcal{O}^*(\max\{|C_{t,p}|, 2^{n/2}\})$.*

The proof of the above lemma is based on [39] algorithm for Subset-Sum. For a full proof of Lemma 3.8 see, e.g., Section 3.2 of [9]. Observe, that for our purposes the running time is dominated by $\mathcal{O}^*(|C_{t,p}|)$.

Proof of the running time of Algorithm 2. To enumerate the set $C_{t,p}$ we need $\mathcal{O}^*(|C| + 2^{n/2})$ time (see Lemma 3.8). To find two subsets $X, Y \in C$, such that $\Sigma(X) = \Sigma(Y)$ we need $\mathcal{O}^*(|C| \log |C|)$ time: we sort C and scan it.

The prime number p is at most $2^{n-\ell+1}$ and the expected size of C is $\mathcal{O}^*(2^\ell)$. Because we assumed that $\ell > \frac{n}{2}$ the expected running time is $\mathcal{O}^*(2^\ell)$ (we can terminate algorithm when it exceeds $\mathcal{O}^*(2^\ell)$ to Monte Carlo guarantees). The probability of success is $\Omega(1/\text{poly}(n))$. We can amplify it with polynomial overhead to any constant by repetition. ◀

This concludes the proof of Theorem 3.4.

3.3 Trade-off for Equal-Subset-Sum

In this section, we will proof the Theorem 3.1 by combining Theorem 3.4 and Theorem 3.3.

Proof of Theorem 3.1. Both Theorem 3.4 and Theorem 3.3 solve Equal-Subset-Sum. Hence, we can focus on bounding the running time. By the trade-off between Theorem 3.4 (which works for $\ell \in (\frac{n}{2}, (1-\varepsilon)n)$) and Theorem 3.3 the running time is:

$$\mathcal{O}^* \left(\max_{\ell \in [1, n/2] \cup [(1-\varepsilon)n, n]} \left\{ \binom{n/2}{\ell/2} 2^{\ell/2} \right\} + \max_{\ell \in (n/2, (1-\varepsilon)n)} \left\{ \min \left\{ \binom{n/2}{\ell/2} 2^{\ell/2}, 2^\ell \right\} \right\} \right)$$

For simplicity of analysis we bounded the sums by the maximum (note that \mathcal{O}^* notation hides polynomial factors). When $\ell \leq n/2$, the running time is maximized for $\ell = n/2$, because (let $\ell = \alpha n$):

$$\mathcal{O}^* \left(\binom{n/2}{\ell/2} 2^{\ell/2} \right) = \mathcal{O}^* \left(2^{\frac{n}{2}(h(\alpha) + \alpha)} \right)$$

and the entropy function $h(x)$ is increasing in range $[0, 0.5)$. For $\ell = \frac{n}{2}$ the running time is $\mathcal{O}^*(2^{0.75n}) \leq \mathcal{O}^*(1.682^n)$. Similarly, we get a running time superior to the claimed one when $\ell \in [(1-\varepsilon)n, n]$. Note that $h(x) \leq 2\sqrt{x(1-x)}$, which means that the running time is bounded by $\mathcal{O}^*(2^{\frac{n}{2}(h(1-\varepsilon) + (1-\varepsilon))}) \leq \mathcal{O}^*(2^{\frac{n}{2}(1+2\sqrt{\varepsilon})})$ which is smaller than our running time for a sufficiently small constant ε .

Finally, when $\ell \in [n/2, (1 - \varepsilon)n]$ we upper bound the running time by the:

$$\mathcal{O}^* \left(\max_{\ell \in [n/2, (1-\varepsilon)n]} \left\{ \min \left\{ 2^{\frac{n}{2}(h(\alpha)+\alpha)}, 2^{\alpha n} \right\} \right\} \right).$$

The above expression is maximized when $h(\alpha) = \alpha$. By numeric calculations $\alpha < 0.77291$, which gives the final running time $\mathcal{O}^*(2^{\alpha n}) \leq \mathcal{O}^*(1.7088^n)$. ◀

4 Polynomial Space Algorithm

The naive algorithm for Equal-Subset-Sum in polynomial space works in $\mathcal{O}^*(3^n)$ time. We are given a set S . We guess a set $A \subseteq S$ and then guess a set $B \subseteq S \setminus A$. Finally, we check if $\Sigma(A) = \Sigma(B)$. The running time is:

$$\mathcal{O}^* \left(\binom{|S|}{|A|} \binom{|S| - |A|}{|B|} \right) \leq \mathcal{O}^*(3^n).$$

Known techniques for Subset-Sum allow us to get an algorithm running in $\mathcal{O}^*(2^{1.5n})$ and polynomial space.

► **Theorem 4.1.** *There exists a Monte Carlo algorithm which solves Equal-Subset-Sum in polynomial space and $\mathcal{O}^*(2^{1.5n}) \leq \mathcal{O}^*(2.8285^n)$ time. The algorithm assumes random read-only access to exponentially many random bits.*

A crucial ingredient of Theorem 4.1 is a nontrivial result for the *Element Distinctness* problem [6, 8]. In this problem, one is given read-only access to the elements of a list $x \in [m]^n$ and the task is to find two different elements of the same value. The problem can be naively solved in $\mathcal{O}(n^2)$ time and $\mathcal{O}(1)$ space by brute force. Also by sorting, we can solve Element Distinctness in $\tilde{\mathcal{O}}(n)$ time and $\tilde{\mathcal{O}}(n)$ space. [8] showed that the problem can be solved in $\tilde{\mathcal{O}}(n^{3/2})$ randomized time and $\tilde{\mathcal{O}}(1)$ space. The algorithm assumes access to a random hash function $f : [m] \rightarrow [n]$.

Proof of Theorem 4.1. We can guarantee random access to the list $L = 2^S$ of all subsets of the set $S = \{a_1, \dots, a_n\}$ on the fly. Namely, for a pointer $x \in \{0, 1\}^n$ we can return an element of the list L that corresponds to x in $\mathcal{O}^*(1)$ time by choosing elements a_i for which $x_i = 1$. More precisely:

$$L(x_1, \dots, x_n) = \{a_i \mid i \in [n], x_i = 1\}.$$

Now to decide Equal-Subset-Sum on set S we execute the Element Distinctness algorithm on the list L of sums of subsets. The list has size 2^n , hence the algorithm runs in $\mathcal{O}^*(2^{1.5n})$ time. Element Distinctness uses only polylogarithmic space in the size of the input, hence our algorithm uses polynomial space. ◀

Quite unexpectedly we can still improve upon this algorithm.

4.1 Improved Polynomial Space Algorithm

In this section, we show an improved algorithm.

► **Theorem 4.2.** *There exists a Monte Carlo algorithm which solves Equal-Subset-Sum in polynomial space and time $\mathcal{O}^*(2.6817^n)$. The algorithm assumes random read-only access to exponentially many random bits.*

73:12 Equal-Subset-Sum Faster Than the Meet-in-the-Middle

Similarly to the exponential space algorithm for Equal-Subset-Sum, we will combine two algorithms. We start with a generalization of Theorem 4.1 parametrized by the size of the solution.

► **Lemma 4.3.** *Let S be a set of n positive integers, $A, B \subseteq S$ be the solution to Equal-Subset-Sum (denote $a = |A|$ and $b = |B|$). There exists a Monte Carlo algorithm which solves Equal-Subset-Sum in polynomial space and time*

$$\mathcal{O}^* \left(\left(\binom{n}{a} + \binom{n}{b} \right)^{1.5} \right).$$

The algorithm assumes random read-only access to exponentially many random bits.

Proof. The proof is just a repetition of the proof of Theorem 4.1 for a fixed sizes of solutions. Our list L will consist of all subsets $\binom{S}{a}$ and $\binom{S}{b}$. Then we run Element Distinctness algorithm, find any sets $A, B \in L$ such that $\Sigma(A) = \Sigma(B)$ and return $A \setminus B, B \setminus A$ to make them disjoint.

The running time follows because Element Distinctness runs in time $\tilde{\mathcal{O}}(n^{1.5})$ and $\text{polylog}(n)$ space. ◀

Note that the runtime of Lemma 4.3 is maximized when $|A| = |B| = n/2$. The next algorithm gives improvement in that case.

► **Lemma 4.4.** *Let S be a set of n positive integers, $A, B \subseteq S$ be the solution to Equal-Subset-Sum (denote $a = |A|$ and $b = |B|$). There exists a Monte Carlo algorithm which solves Equal-Subset-Sum in polynomial space and time*

$$\mathcal{O}^* \left(\min \left\{ \binom{n}{a} 2^{0.75(n-a)}, \binom{n}{b} 2^{0.75(n-b)} \right\} \right).$$

The algorithm assumes random read-only access to exponentially many random bits.

Proof of Lemma 4.4. Without loss of generality, we focus on the case $a \leq b$. First we guess a solution set $A \subseteq S$. We answer YES if we find set $B \subseteq S \setminus A$ such that $\Sigma(A) = \Sigma(B)$ or find two disjoint subsets with equal sum in $S \setminus A$. We show that we can do it in $\mathcal{O}^*(2^{0.75(|S \setminus A|)})$ time and polynomial space which finishes the proof.

First, we arbitrarily partition set $S \setminus A$ into two equally sized sets S_1 and S_2 . Then we create a list $L_1 = [\Sigma(X) \mid X \subseteq S_1]$ and list $L_2 = [\Sigma(A) - \Sigma(X) \mid X \subseteq S_2]$. We do not construct them explicitly because it would take exponential space. Instead we provide a read-only access to them (with the counter technique). We run Element Distinctness on concatenation of L_1 and L_2 . If element distinctness found $x \in L_1$ and $y \in L_2$ such that $x = y$, then we backtrack and look for $X \subseteq S_1$, such that $\Sigma(X) = x$ and $Y \subseteq S_2$, such that $\Sigma(Y) = \Sigma(A) - y$ and return $(A, X \cup Y)$ which is a good solution, because $\Sigma(Y) + \Sigma(X) = \Sigma(A)$.

In the remaining case, i.e. when Element Distinctness finds a duplicate only in one of the lists then, we get a feasible solution as well. Namely, assume that Element Distinctness finds $x, y \in L_1$ such that $x = y$ (the case when $x, y \in L_2$ is analogous). Then we backtrack and look for two corresponding sets $X, Y \subseteq L_1$ such that $X \neq Y$ and $\Sigma(X) = \Sigma(Y) = x$. Finally we return $(X \setminus Y, Y \setminus X)$.

For the running time, note that the size of the list $|L_1| = |L_2| = 2^{0.5|S \setminus A|}$. Hence Element Distinctness runs in time $\mathcal{O}^*((|L_1| + |L_2|)^{1.5}) = \mathcal{O}^*(2^{0.75(n-a)})$. The backtracking takes time $\mathcal{O}^*(|L_1| + |L_2|)$ and polynomial space because we scan through all subsets of S_1 and all subsets of S_2 and look for a set with sum equal to the known value. ◀

Proof of Theorem 4.2. By trade-off between Lemma 4.4 and Lemma 4.3 we get the following running time:

$$\mathcal{O}^* \left(\max_{1 \leq a, b \leq n} \left\{ \min \left\{ \left(\binom{n}{a} + \binom{n}{b} \right)^{1.5}, \binom{n}{a} 2^{0.75(n-a)}, \binom{n}{b} 2^{0.75(n-b)} \right\} \right\} \right)$$

By symmetry this expression is maximized when $a = b$. Now we will write the exponents by using entropy function (let $a = \alpha n$):

$$\mathcal{O}^* \left(\max_{\alpha \in [0,1]} \left\{ \min \left\{ 2^{1.5h(\alpha)n}, 2^{(h(\alpha)+0.75(1-\alpha))n} \right\} \right\} \right)$$

The expression is maximized when $1.5h(\alpha) = h(\alpha) + 0.75(1 - \alpha)$, By numerical computations $\alpha < 0.36751$, which means that the running time is $\mathcal{O}^*(2^{1.42312n}) \leq \mathcal{O}^*(2.6817^n)$. ◀

5 Conclusion and Open Problems

In this paper, we break two natural barriers for Equal-Subset-Sum: we propose an improvement upon the meet-in-the-middle algorithm and upon the polynomial space algorithm. Our techniques have additional applications in the problem of finding collision of hash function in cryptography and the number balancing problem (see [35, Appendix E]).

We believe that our algorithms can potentially be improved with more involved techniques. However, getting close to the running time of Subset-Sum seems ambitious. In [35, Appendix B] we show that a faster algorithm than $\mathcal{O}^*(1.1893^n)$ for Equal-Subset-Sum would yield a faster than $\mathcal{O}^*(2^{n/2})$ algorithm for Subset-Sum. It is quite far from our bound $\mathcal{O}^*(1.7088^n)$. The main open problem is therefore to close the gap between upper and lower bounds for Equal-Subset-Sum.

Abstract

Consider collections \mathcal{A} and \mathcal{B} of red and blue sets, respectively. Bichromatic Closest Pair is the problem of finding a pair from $\mathcal{A} \times \mathcal{B}$ that has similarity higher than a given threshold according to some similarity measure. Our focus here is the classic Jaccard similarity $|\mathbf{a} \cap \mathbf{b}|/|\mathbf{a} \cup \mathbf{b}|$ for $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$.

We consider the approximate version of the problem where we are given thresholds $j_1 > j_2$ and wish to return a pair from $\mathcal{A} \times \mathcal{B}$ that has Jaccard similarity higher than j_2 if there exists a pair in $\mathcal{A} \times \mathcal{B}$ with Jaccard similarity at least j_1 . The classic locality sensitive hashing (LSH) algorithm of Indyk and Motwani (STOC '98), instantiated with the MinHash LSH function of Broder et al., solves this problem in $\tilde{O}(n^{2-\delta})$ time if $j_1 \geq j_2^{1-\delta}$. In particular, for $\delta = \Omega(1)$, the approximation ratio $j_1/j_2 = 1/j_2^\delta$ increases polynomially in $1/j_2$.

In this paper we give a corresponding hardness result. Assuming the Orthogonal Vectors Conjecture (OVC), we show that there cannot be a general solution that solves the Bichromatic Closest Pair problem in $O(n^{2-\Omega(1)})$ time for $j_1/j_2 = 1/j_2^{\epsilon(1)}$. Specifically, assuming OVC, we prove that for any $\delta > 0$ there exists an $\epsilon > 0$ such that Bichromatic Closest Pair with Jaccard similarity requires time $\Omega(n^{2-\delta})$ for any choice of thresholds $j_2 < j_1 < 1 - \delta$, that satisfy $j_1 \leq j_2^{1-\epsilon}$.

1 Introduction

Twitter is a well-known social network, in which a user can connect to other users by *following* them [5]. Users can read and write messages called *tweets* of up to 280 characters. An important service that Twitter provides is helping users discover other users that they might

like to follow, by making suggestions. This service is called the *You might also want to follow*-service and is better known as the WTF (Who To Follow) recommender system [6]. In order to suggest connections that the user might like, they should be similar to the user's existing connections. As an example, if a user is already connected to Cristiano Ronaldo, Twitter might suggest Lionel Messi as a new connection, since the connection to Ronaldo hints that the user likes famous soccer players. Hence, we need a way to decide if a connection is similar to an existing connection. We might for instance suggest a new connection if the tweets are similar to the tweets of an existing connection or if the connection has a lot of the same followers as an existing connection.

The main challenge is to find similar connections when the number of user accounts increases drastically and the task is particularly difficult when the similarity does not need to be significant, i.e., when we look for connections that have only little in common with existing ones, while they may still be of interest to the particular user [5]. This leads us to the notion of *similarity search*, which concerns the general problem of searching for similar objects in a collections of objects. Often we consider these objects as sets representing some concept or entity. An object could for example be a document that is represented by a set of words. Hence, we talk about *set similarity search*.

There are several versions of the problem addressing different situations. In this paper we consider a batched version of set similarity search, namely the Bichromatic Closest Pair which can be informally described as follows:

Suppose we are given collections \mathcal{A} and \mathcal{B} , each of n sets from a universe of size $O(\log n)$. We refer to the sets in \mathcal{A} as *red* and the sets in \mathcal{B} as *blue*. Bichromatic Closest Pair is the problem of finding the pair consisting of a red and a blue set that is closest with respect to some distance or similarity measure. We will concern ourselves with Jaccard similarity, which is defined for a pair of sets $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ as

$$J(\mathbf{a}, \mathbf{b}) = \frac{|\mathbf{a} \cap \mathbf{b}|}{|\mathbf{a} \cup \mathbf{b}|} = \frac{|\mathbf{a} \cap \mathbf{b}|}{|\mathbf{a}| + |\mathbf{b}| - |\mathbf{a} \cap \mathbf{b}|}. \quad (1)$$

In particular, we consider the following *decision version* of Bichromatic Closest Pair with Jaccard similarity: decide whether there exists a pair $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ such that $J(\mathbf{a}, \mathbf{b}) \geq j_1$ or if all pairs $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$, has $J(\mathbf{a}, \mathbf{b}) < j_2$ for given thresholds j_1 and j_2 .

It is well-known that we can solve Bichromatic Closest Pair with Jaccard similarity for thresholds satisfying $j_1 \geq j_2^{1-\delta}$ in time $O(n^{2-\delta})$ (see Section 1.1). In particular, for $\delta = \Omega(1)$, the approximation ratio $j_1/j_2 = 1/j_2^\delta$ increases polynomially in $1/j_2$. In this paper, we will present a corresponding hardness result. The hardness is conditioned on one of the most well-known and widely believed hypotheses, namely the Orthogonal Vectors Conjecture [11].

► **Conjecture 1** (Orthogonal Vectors Conjecture (OVC)). *For every $\delta > 0$ there exists $c = c(\delta)$ such that given two collections $\mathcal{A}, \mathcal{B} \subset \{0, 1\}^m$ of cardinality n , where $m = c \log n$, deciding if there is a pair $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ such that $\mathbf{a} \cdot \mathbf{b} = 0$ requires time $\Omega(n^{2-\delta})$.*

Assuming OVC, we show that there cannot be a general solution that solves the Bichromatic Closest Pair problem with Jaccard similarity in $O(n^{2-\Omega(1)})$ time for $j_1/j_2 = 1/j_2^{o(1)}$. More specifically, we show

► **Theorem 2.** *Assuming the Orthogonal Vectors Conjecture (OVC), the following holds: for any $\delta > 0$, there exists an $\varepsilon > 0$ such that for any given $j_2 < j_1 < 1 - \delta$ satisfying $j_1 \leq j_2^{1-\varepsilon}$, solving Bichromatic Closest Pair with Jaccard similarity for n red and n blue sets for sets from a universe of size $\ln(n)/j_2^{O(\log 1/j_1)}$ for thresholds j_1 and j_2 requires time $\Omega(n^{2-\delta})$.*

The dependence of ε on δ is unspecified because the function $c(\delta)$ in OVC is not specified, see discussion in Appendix B in the full version on ArXiv [8, App. B].

1.1 Techniques and Related Work

Similarity search can be performed in several ways – a popular technique is Locality Sensitive Hashing (LSH) [7] which attempts to collect similar items in buckets in order to reduce the number of sets needed to check similarity against. We can for example use Broder’s MinHash [1] with locality sensitive hashing to solve Bichromatic Closest Pair with Jaccard similarity in time $\tilde{O}(n^{2-\varepsilon})$ when $j_1 \geq j_2^{1-\varepsilon}$ for any ε . This is done by ensuring that the collision probability for pairs with similarity j_2 is $1/n$ and the collision probability for pairs with similarity j_1 is $1/n^{1-\varepsilon}$. Hashing $n^{1-\varepsilon}$ times means that we find a pair with similarity j_1 if one exists. The ChosenPath method presented in [4] also uses the LSH framework to solve Bichromatic Closest Pair with Braun-Blanquet similarity in time $\tilde{O}(n^{2-\varepsilon})$ for thresholds $j_1 \geq j_2^{1-\varepsilon}$.

The proof of Theorem 2 will be based on a result by Rubinfeld [9]: Assuming the Orthogonal Vectors Conjecture, a $(1 + \varepsilon)$ -approximation to Bichromatic Closest Pair with Hamming, Edit or Euclidean distance requires time $\Omega(n^{2-\delta})$. The required approximation factor $1 + \varepsilon$ depends on δ , and tends to 1 as δ tends to zero. We translate this into an equivalent conditional lower bound for Jaccard similarity for certain constants j_1 and j_2 .

In order to handle smaller subconstant values of j_1 and j_2 we use a technique that we call squaring, which allows us to increase the gap in similarities between pairs with high Jaccard similarity and pairs with low Jaccard similarity by computing the cartesian product of a binary vector with itself. A similar technique is used in [10] by Valiant. His technique is called *tensoring* and is used to amplify the gap between small and large inner products of vectors. We also see a similar technique in the LSH framework with MinHash, where we use concatenation of hash values (which are sampled set elements) to amplify the difference in collision probability, and hence in the Jaccard similarity.

Combining two simple reductions with the above squaring we show that for any δ , we can always find ε such that Bichromatic Closest Pair with Jaccard similarity cannot be solved in time $O(n^{2-\delta})$ for any pair $j_1, j_2 < 1 - \delta$ when $j_1 \leq j_2^{1-\varepsilon}$. Contrast this with the above LSH upper bound of $\tilde{O}(n^{2-\delta})$ for $j_1 \geq j_2^{1-\delta}$. We also know that there are parts of the parameter space where $j_1 = j_2^{1-\delta}$ that can be solved in $\tilde{O}(n^{2-\delta-\Omega(1)})$ time, see the discussion in [4]. While LSH with MinHash is not the fastest possible algorithm in terms of the exponent achieved, it has been unclear how far from optimal it might be.

Other related work

Very recently, Chen and Williams [3] showed that assuming the OVC we cannot additively approximate our Bichromatic Closest Pair problem with Jaccard similarity. It might be possible to use Chen and Williams as a base for showing our main theorem, but this would require reductions quite different from the ones presented in this paper.

An earlier result of Chen [2] shows that it is not possible (under OVC) to compute a $(d/\log n)^{o(1)}$ -approximation to Maximum Inner Product (Max-IP) with two sets of n vectors from $\{0, 1\}^d$ in time $O(n^{2-\Omega(1)})$.

2 Preliminaries

2.1 Notation

We will occasionally consider a set, \mathbf{x} , from a finite universe $U = \{u_1, \dots, u_{|U|}\}$ as a vector \mathbf{v} of dimension $|U|$ such that $v_i = [u_i \in \mathbf{x}]$, in Iverson notation. We call this vector the *characteristic vector for \mathbf{x}* . Hence, we refer to the set of indexes and the universe interchangeably. We denote the Hamming weight of a binary vector \mathbf{v} by $|\mathbf{v}|$. In the following, we will not only index vectors with integers, but also with vectors of integers. Hence, we will consider vectors of dimension d^2 with entries v_{ij} , for $i = (i_1, \dots, i_d)$ and $j = (j_1, \dots, j_d)$.

2.2 Bichromatic Closest Pair

Recall Jaccard similarity as is defined in (1). We define Bichromatic Closest Pair with Jaccard similarity for thresholds t_1 and t_2 as follows: Let U be a universe of size $O(\log n)$. Given collections \mathcal{A} and \mathcal{B} , each of n sets from U , and thresholds $t_2 < t_1 < 1$, we will consider the problem of finding a pair of sets $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ with $J(\mathbf{a}, \mathbf{b}) \geq t_2$ if there exists a pair $(\mathbf{a}^*, \mathbf{b}^*) \in \mathcal{A} \times \mathcal{B}$ with $J(\mathbf{a}^*, \mathbf{b}^*) \geq t_1$. If all pairs have $J(\mathbf{a}, \mathbf{b}) < t_2$, we must not return any pair of sets.

2.3 Useful instances of Bichromatic Closest Pair

The following lemma corresponds to Theorem 4.1 in [9] and will form the basis of our results. It includes the important properties of the instances constructed in the proof the theorem, which we will use actively to prove our own Theorem 2.

► **Lemma 3.** *Assume OVC. Given $\delta > 0$, there exist $\varepsilon > 0$ and values h_1, h_2 where $h_2 = (1 + \varepsilon)h_1$ such that Bichromatic Closest Pair with Hamming distance for thresholds h_1 and h_2 requires time $\Omega(n^{2-\delta})$ for instances with n red and n blue sets from a universe of size $O(\log n)$. There are instances that require this time with the following properties, where we let $T = O(\frac{1}{\varepsilon})$ and $m = O(\log n)$:*

- All red sets have size Tm and all blue sets have size m .
- The thresholds h_1 and h_2 are $m(T - 1)$ and mT , respectively.
- All sets in the instance come from a universe of size $2Tm$.

In particular, the lemma states that we cannot compute a $(1 + \varepsilon)$ -approximation to Bichromatic Closest Pair with Hamming distance in truly subquadratic time. We will extend this result in a few steps, using the properties of the hard instances, to achieve Theorem 2.

2.4 Hardness of Bichromatic Closest Pair with Jaccard similarity

In order to prove Theorem 2, we need the following lemma, which extends Lemma 3 in the natural way to Jaccard similarity.

► **Lemma 4.** *Assuming OVC, we have the following: For any $\delta > 0$ there exist j_1, j_2 with $j_1 = 2 \cdot j_2$ such that Bichromatic Closest Pair with Jaccard similarity with thresholds j_1 and j_2 requires time $\Omega(n^{2-\delta})$.*

Proof. We use instances as described in Lemma 3. First, note that

$$J(\mathbf{a}, \mathbf{b}) = \frac{|\mathbf{a} \cap \mathbf{b}|}{|\mathbf{a} \cup \mathbf{b}|} = \frac{\frac{|\mathbf{a}| + |\mathbf{b}| - d_H(\mathbf{a}, \mathbf{b})}{2}}{|\mathbf{a}| + |\mathbf{b}| - \frac{|\mathbf{a}| + |\mathbf{b}| - d_H(\mathbf{a}, \mathbf{b})}{2}} = \frac{|\mathbf{a}| + |\mathbf{b}| - d_H(\mathbf{a}, \mathbf{b})}{|\mathbf{a}| + |\mathbf{b}| + d_H(\mathbf{a}, \mathbf{b})}$$

which implies that letting

$$j_1 = \frac{Tm + m - m(T - 1)}{Tm + m + m(T - 1)} = \frac{1}{T} \quad \text{and} \quad j_2 = \frac{Tm + m - Tm}{Tm + m + Tm} = \frac{1}{2T + 1},$$

we cannot solve Bichromatic Closest Pair with Jaccard similarity in time $O(n^{2-\delta})$. Since $T = O(\frac{1}{\varepsilon})$, as mentioned in Lemma 3, we get a lower bound for the approximation factor:

$$\frac{\frac{1}{T}}{\frac{1}{2T+1}} = \frac{2T+1}{T} = 2 + \frac{1}{T} = 2 + \Omega(\varepsilon).$$

In particular, we achieve hardness of a 2-approximation. ◀

3 Overview of reductions used

We prove Theorem 2 by combining several reductions into one. So let $(\mathcal{A}, \mathcal{B})$ be any instance of Bichromatic Closest Pair with Jaccard similarity as described in Lemma 3. We give a brief introduction to each of these reductions – note that all reductions are self-reductions. We give the details of the proof and the use of each reduction in Section 5. Further details can be found in Appendix B in the full version on ArXiv [8, App. B].

- **Adding common elements to sets:** Adding common elements to all sets in collections \mathcal{A} and \mathcal{B} increases the Jaccard similarity between any pair of red and blue sets.
- **Adding different elements to sets:** Adding elements to all sets in \mathcal{A} decreases the Jaccard similarity between any pair of red and blue sets.
- **Squaring:** Consider all sets by their characteristic vector. We define squaring as follows: given vector $\mathbf{a} = (a_1, \dots, a_d)$ the squared vector has entries

$$a'_{ij} = a_i \cdot a_j \quad \text{for } i, j \in \{1, \dots, d\}.$$

The resulting vector \mathbf{a}' , which is the characteristic vector for $\mathbf{a} \times \mathbf{a}$, has dimension d^2 as described in Section 2.1. Vector \mathbf{a}' can equivalently be considered as a set from a universe of size d^2 . We will use this reduction iteratively to reduce the Jaccard similarity between any pair of vectors in the instance of Bichromatic Closest Pair.

- **Sampling:** We will use sampling to reduce the size of the universe after each step of squaring. Hence, we consider squaring and sampling as a single reduction which first squares the vectors and then samples from the resulting vectors. We will use the squaring-and-sampling reduction iteratively.

4 The squaring-and-sampling reduction – details

In the proof of Theorem 2 we will take any instance of Bichromatic Closest Pair with Jaccard similarity with the properties described in Lemma 3 and use the squaring reduction described in Section 3 to decrease the Jaccard similarity of every pair of sets in the instance. We will argue that a solution for the new instance also provides a solution for the original instance. When squaring all sets, the Jaccard similarity between any pair of sets will decrease, so we need to capture this change in the thresholds, such that a solution for the new instance implies a solution for the initial instance. When squaring the sets in \mathcal{A} and \mathcal{B} , the size of the sets will be squared and it is easy to see that so will the size of the intersection. Hence, the Jaccard similarity of a pair (\mathbf{a}, \mathbf{b}) after squaring i times, $(\mathbf{a}_i, \mathbf{b}_i)$ is

$$J(\mathbf{a}_i, \mathbf{b}_i) = \frac{|\mathbf{a} \cap \mathbf{b}|^{2^i}}{|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i} - |\mathbf{a} \cap \mathbf{b}|^{2^i}}. \quad (2)$$

In order to keep down the size of the universe, we need to sample after each step of squaring. This might incur a small error in the Jaccard similarity. The next few sections will bound this error. From this point, we will denote the squaring-and-sampling reduction by f . Hence, applying the reduction f to a set, \mathbf{v} , i times will yield a set $\mathbf{f}(\mathbf{v}, \mathbf{i})$.

4.1 Subsampling

We bound the error incurred in each of $|\mathbf{a} \cap \mathbf{b}|$, $|\mathbf{a}|$ and $|\mathbf{b}|$ and combine these with a union bound to get a bound on the error in the Jaccard similarity. We shall see that when sampling sufficiently many elements from the universe the sets are taken from, we get that with high probability a solution for the constructed instance will provide a valid solution for the original instance.

74:6 Hardness of Bichromatic Closest Pair with Jaccard Similarity

The following lemmas will help us show that sampling after squaring will not distort the similarity of the resulting vectors too much.

► **Lemma 5.** *Let $0 < m' < m < 1$ and let \mathbf{p} be a set from a universe of size s^2 for an integer s . Assume that $(m' \cdot s)^2 \leq |\mathbf{p}| \leq (m \cdot s)^2$. Sample s' elements from the universe uniformly at random, \mathbf{z} , thus generating sample set $\mathbf{p} \cap \mathbf{z}$. We have*

$$(1 - \gamma) \cdot m'^2 \cdot s' \leq |\mathbf{p} \cap \mathbf{z}| \leq (1 + \gamma) \cdot m^2 \cdot s'$$

with probability at least $1 - 2n^{-10}$ when sampling $s' \geq \frac{30 \ln(n)}{\gamma^2 m'^2}$ elements.

Proof. The result is an immediate consequence of the Chernoff bound: when we sample $s' \geq \frac{30 \ln(n)}{\gamma^2 m'^2}$ elements, we have with probability at least $1 - n^{-10}$ that

$$(1 - \gamma) (m' \cdot s)^2 \cdot \frac{s'}{s^2} \leq |\mathbf{p} \cap \mathbf{z}|.$$

A similar result gives the upper bound on $|\mathbf{p} \cap \mathbf{z}|$ for $s' \geq \frac{30 \ln(n)}{\gamma^2 m^2}$. As $m' \leq m$, we maximize s' by $\frac{30 \ln(n)}{\gamma^2 m'^2}$ and thus ensure both bounds with probability at least $1 - 2n^{-10}$ using a union bound. ◀

We are generally going to use γ as the same fixed parameter (to be determined later) every time we invoke the sampling of Lemma 5.

Lemma 5 will be used to show that sampling after squaring will not distort the Jaccard similarity of a pair of vectors too much, and hence we get the benefits of squaring without the exploding vector dimensions. We start by bounding the resulting sizes for each of $|\mathbf{a}|$, $|\mathbf{b}|$ and $|\mathbf{a} \cap \mathbf{b}|$ for any choice of $\mathbf{a}, \mathbf{b} \in \mathcal{A} \times \mathcal{B}$ from squaring and sampling i times.

► **Lemma 6.** *Let \mathbf{v} be a set from a universe of size d or the intersection of such two sets. Let $\mathbf{f}(\mathbf{v}, \mathbf{i})$ denote the resulting set after running i iterations of the squaring-and-sampling reduction on set \mathbf{v} for $i \geq 1$. We have*

$$(1 - \gamma)^{2^i} \frac{|\mathbf{v}|^{2^i}}{d^{2^i}} s_i \leq |\mathbf{f}(\mathbf{v}, \mathbf{i})| \leq (1 + \gamma)^{2^i} \frac{|\mathbf{v}|^{2^i}}{d^{2^i}} s_i$$

with probability at least $1 - 2in^{-10}$ where $s_i \geq \frac{30 \ln(n)d^{2^i}}{\gamma^2(1-\gamma)^{2^i-2}|\mathbf{v}|^{2^i}}$.

Proof. Let \mathbf{v} be as described. We show the lemma by induction on i . Clearly, when squaring the vector \mathbf{v} once, i.e., for $i = 1$, the resulting vector has Hamming weight $|\mathbf{v}|^2$ and dimension d^2 . Hence, by Lemma 5 we have

$$(1 - \gamma) \frac{|\mathbf{v}|^2}{d^2} \cdot s_1 \leq |\mathbf{f}(\mathbf{v}, \mathbf{1})| \leq (1 + \gamma) \frac{|\mathbf{v}|^2}{d^2} \cdot s_1$$

with probability at least $1 - 2n^{-10}$ for our choice of s_1 . Assume now that after $i - 1$ iterations the following bounds hold:

$$(1 - \gamma)^{2^{i-1}-1} \frac{|\mathbf{v}|^{2^{i-1}}}{d^{2^{i-1}}} s_{i-1} \leq |\mathbf{f}(\mathbf{v}, \mathbf{i} - \mathbf{1})| \leq (1 + \gamma)^{2^{i-1}-1} \frac{|\mathbf{v}|^{2^{i-1}}}{d^{2^{i-1}}} s_{i-1}. \quad (3)$$

Then Lemma 5 gives that after i iterations of the squaring-and-sampling reduction, we have

$$(1 - \gamma)^{2^i-1} \frac{|\mathbf{v}|^{2^i} s_{i-1}^2}{d^{2^i}} \cdot \frac{s_i}{s_{i-1}^2} \leq |\mathbf{f}(\mathbf{v}, \mathbf{i})| \leq (1 + \gamma)^{2^i-1} \frac{|\mathbf{v}|^{2^i} s_{i-1}^2}{d^{2^i}} \cdot \frac{s_i}{s_{i-1}^2}$$

with probability at least $1 - 2n^{-10}$ for $s_i \geq \frac{30 \ln(n)d^{2^i}}{\gamma^2(1-\gamma)^{2^i-2}|\mathbf{v}|^{2^i}}$. This particularly means that

$$(1 - \gamma)^{2^i} \frac{|\mathbf{v}|^{2^i}}{d^{2^i}} \cdot s_i \leq |\mathbf{f}(\mathbf{v}, \mathbf{i})| \leq (1 + \gamma)^{2^i} \frac{|\mathbf{v}|^{2^i}}{d^{2^i}} \cdot s_i.$$

Now, to ensure these bounds, we assumed that $|\mathbf{f}(\mathbf{v}, \mathbf{i} - \mathbf{1})|$ satisfies certain bounds (see (3)). So in order to ensure that $\mathbf{f}(\mathbf{v}, \mathbf{i})$ satisfies the given bounds, we need $\mathbf{f}(\mathbf{v}, \mathbf{j})$ to satisfy similar bounds for every $1 \leq j \leq i$. By a union bound, we see that $|\mathbf{f}(\mathbf{v}, \mathbf{j})|$ satisfies both upper and lower bounds for all $1 \leq j \leq i$ (simultaneously) with probability at least $1 - 2in^{-10}$ when sampling $s_j \geq \frac{30 \ln(n)d^{2^j}}{\gamma^2(1-\gamma)^{2^j-2}|\mathbf{v}|^{2^j}}$ at step j . Hence, $|\mathbf{f}(\mathbf{v}, \mathbf{i})|$ satisfies the given bound with probability at least $1 - 2in^{-10}$. ◀

The next section will use Lemma 6 to bound the Jaccard similarity after i iterations of the squaring/sampling reduction.

4.2 Combining the bounds

For a given pair of vectors \mathbf{a} and \mathbf{b} , Lemma 6 gives upper and lower bounds on the Jaccard similarity $J = J(\mathbf{f}(\mathbf{a}, \mathbf{i}), \mathbf{f}(\mathbf{b}, \mathbf{i}))$. We claim that with probability at least $1 - 6in^{-10}$:

$$\begin{aligned} J &\geq \frac{(1 - \gamma)^{2^i-1} \frac{|\mathbf{a} \cap \mathbf{b}|^{2^i}}{d^{2^i}} s_i}{(1 + \gamma)^{2^i-1} \frac{|\mathbf{a}|^{2^i}}{d^{2^i}} s_i + (1 + \gamma)^{2^i-1} \frac{|\mathbf{b}|^{2^i}}{d^{2^i}} s_i - (1 - \gamma)^{2^i-1} \frac{|\mathbf{a} \cap \mathbf{b}|^{2^i}}{d^{2^i}} s_i} \\ &\geq \frac{(1 - \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 + \gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i}) - (1 - \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}} \\ J &\leq \frac{(1 + \gamma)^{2^i-1} \frac{|\mathbf{a} \cap \mathbf{b}|^{2^i}}{d^{2^i}} s_i}{(1 - \gamma)^{2^i-1} \frac{|\mathbf{a}|^{2^i}}{d^{2^i}} s_i + (1 - \gamma)^{2^i-1} \frac{|\mathbf{b}|^{2^i}}{d^{2^i}} s_i - (1 + \gamma)^{2^i-1} \frac{|\mathbf{a} \cap \mathbf{b}|^{2^i}}{d^{2^i}} s_i} \\ &\leq \frac{(1 + \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 - \gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i}) - (1 + \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}. \end{aligned}$$

This is easily seen by taking a union bound over the probabilities that each of $|\mathbf{a}|$, $|\mathbf{b}|$ and $|\mathbf{a} \cap \mathbf{b}|$ violate either the upper or the lower bound. Next, we claim that these bounds imply:

$$\begin{aligned} J &\geq \frac{(1 - \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 + 4\gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i} - |\mathbf{a} \cap \mathbf{b}|^{2^i})} \geq \frac{(1 - \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 + \gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i}) - (1 - \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}} \\ J &\leq \frac{(1 + \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 - \gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i}) - (1 + \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}} \leq \frac{(1 + \gamma)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{(1 - 4\gamma)^{2^i} (|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i} - |\mathbf{a} \cap \mathbf{b}|^{2^i})}. \end{aligned}$$

The argument can be found in Appendix A in the full version on ArXiv [8, App. A]. In particular, we have argued for the following lemma. We ignore the sample size for now and discuss it in Section 4.3.

► **Lemma 7.** *Let \mathcal{A} and \mathcal{B} be an instance of Bichromatic Closest Pair with Jaccard similarity. After applying the Squaring and Sampling mapping, f , i times as previously described to each set in \mathcal{A} and \mathcal{B} , we have for all n^2 pairs $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ in the instance that:*

$$\frac{\left(\frac{1-\gamma}{1+4\gamma}\right)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i} - |\mathbf{a} \cap \mathbf{b}|^{2^i}} \leq J(\mathbf{f}(\mathbf{a}, \mathbf{i}), \mathbf{f}(\mathbf{b}, \mathbf{i})) \leq \frac{\left(\frac{1+\gamma}{1-4\gamma}\right)^{2^i} |\mathbf{a} \cap \mathbf{b}|^{2^i}}{|\mathbf{a}|^{2^i} + |\mathbf{b}|^{2^i} - |\mathbf{a} \cap \mathbf{b}|^{2^i}}$$

with probability at least $1 - 6in^{-8}$.

Hence, with high probability none of the Jaccard similarities diverge too much from (2) due to sampling. This was exactly what we wanted, as this allows us to reduce the dimension by sampling.

4.3 Summing up

Recall that in our setting we reduce from instances where the set sizes of all red and blue sets are fixed. We now describe thresholds such that solving the instances constructed by the reduction f cannot be done in truly subquadratic time.

► **Lemma 8.** *Let \mathcal{A} and \mathcal{B} be two collections of n sets from a universe of dimension d , where all sets in \mathcal{A} have size y and all sets in \mathcal{B} have size z . Assume that $(\mathcal{A}, \mathcal{B})$ is taken from a family of instances of Bichromatic Closest Pair with Jaccard similarity, which require time $\Omega(n^{2-\delta})$ for thresholds $t_1 = \frac{x_1}{y+z-x_1}$ and $t_2 = \frac{x_2}{y+z-x_2}$. The reduction which applies f i times to each set in $\mathbf{s} \in \mathcal{A} \cup \mathcal{B}$ for $i \geq 1$ constructs an instance of Bichromatic Closest Pair with Jaccard similarity, which requires time $\Omega(n^{2-\delta})$ time for thresholds*

$$t'_1 = \left(\frac{1-\gamma}{1+4\gamma}\right)^{2^i} \frac{x_1^{2^i}}{y^{2^i} + z^{2^i} - x_1^{2^i}}, \quad \text{and} \quad t'_2 = \left(\frac{1+\gamma}{1-4\gamma}\right)^{2^i} \frac{x_2^{2^i}}{y^{2^i} + z^{2^i} - x_2^{2^i}}.$$

whose solution provides a valid solution to the original instance with high probability when sampling $s_j > \frac{30 \ln(n) d^{2^j}}{\gamma^2 (1-\gamma)^{2^j-2} x_2^{2^j}}$ at each step $1 \leq j \leq i$.

Proof. Lemma 7 ensures that with high probability a solution to the constructed instance provides a valid solution to the original instance, since no pair of sets is likely to have Jaccard similarities that deviate beyond the chosen thresholds.

In Lemma 7 we skipped the discussion of the sample size at each iteration – we will argue for it now. From Lemma 6, it is easily seen that we maximize the needed sample size for all of $|\mathbf{a}|$, $|\mathbf{b}|$ or $|\mathbf{a} \cap \mathbf{b}|$ for any choice of \mathbf{a} and \mathbf{b} in iteration i by

$$s_i > \frac{30 \ln(n) d^{2^i}}{\gamma^2 (1-\gamma)^{2^i-2} \min_{(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}} \{|\mathbf{a} \cap \mathbf{b}|\}^{2^i}}.$$

Hence, sampling s_i elements from the universe will ensure that each of the upper and lower bounds for either $|\mathbf{a}|$, $|\mathbf{b}|$ or $|\mathbf{a} \cap \mathbf{b}|$ will fail with probability at most n^{-10} in that iteration. As $\min_{(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}} \{|\mathbf{a} \cap \mathbf{b}|\}$ is unknown, we instead use x_2 , which was the intersection size for a pair with Jaccard similarity j_2 . Such a pair need not exist, but as the set sizes are fixed, x_2 can be easily computed.

We have left to argue that the pairs with intersection smaller than x_2 also satisfy the bounds in Lemma 7 with high probability. The main observation is that they only need to satisfy the upper bound, as the resulting Jaccard similarities need only to stay below the lower threshold, t'_2 – the Jaccard similarities can become arbitrarily small without affecting the result.

By bounding the size of each term as we did in Lemma 6 using the chosen s_i , we see that the error probabilities are still at most n^{-10} for each of $|\mathbf{a}|$, $|\mathbf{b}|$ and $|\mathbf{a} \cap \mathbf{b}|$ for any choice of $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$. ◀

5 Main Result

We are now ready to prove Theorem 2. We first give some intuition behind the proof and state a few lemmas to ease the proof. For convenience we restate Theorem 2.

► **Theorem 9.** *Assuming the Orthogonal Vectors Conjecture (OVC), the following holds: for any $\delta > 0$, there exists an $\varepsilon > 0$ such that for any given $j_2 < j_1 < 1 - \delta$ satisfying $j_1 \leq j_2^{1-\varepsilon}$, solving Bichromatic Closest Pair with Jaccard similarity for n red and n blue sets for sets from a universe of size $\ln(n)/j_2^{O(\log(1/j_1))}$ for thresholds j_1 and j_2 requires time $\Omega(n^{2-\delta})$.*

5.1 Intuition

The proof of Theorem 2 reduces instances of Bichromatic Closest Pair as described in Section 2.3 by composing three reductions, that together construct instances of Bichromatic Closest Pair with Jaccard similarity, which requires time $\Omega(n^{2-\delta})$ for the given thresholds j_1 and j_2 and some ε . A short description of each of the reductions can be found in Section 3. Below, we give three lemmas showing that these reductions preserve hardness.

The first lemma states that adding common elements to all sets in the instance will preserve hardness. This reduction increases the Jaccard similarity of all pairs of red and blue sets, and by choice of the number of added elements, we ensure that pairs of sets that initially had Jaccard similarity higher than the *lower* threshold will get Jaccard similarity greater than $1 - \delta$. Hence, we get hardness for thresholds that are greater than $1 - \delta$. From this point we can decrease the thresholds using two other reductions to achieve the given thresholds, that by assumption are less than $1 - \delta$.

The second lemma states that the squaring-and-sampling reduction, discussed in detail in Section 4, preserves hardness. The squaring-and-sampling reduction allows us to decrease the thresholds, so they come close to j_1 and j_2 . Finally, the third lemma states that the reduction, which adds elements to only red sets will still preserve hardness. This reduction ensures that we can decrease the Jaccard similarity further. We will use it in such a way, that we effectively multiply the upper bound by a well-chosen α that ensures that the upper threshold is j_1 after this reduction. The proof ends by picking an ε , such that j_2 is strictly greater than the current lower threshold, and thus preserves hardness for the thresholds j_1 and j_2 .

5.2 Supporting Lemmas

In the following, assume that \mathcal{A} and \mathcal{B} are collections of n red and n blue sets from a universe U , respectively.

► **Lemma 9.** *Let $0 < \delta \leq 1$ be given and let $(\mathcal{A}, \mathcal{B})$ be any instance of Bichromatic Closest Pair with Jaccard similarity as described in Lemma 3. Define $\ell := \max_{\mathbf{q} \in \mathcal{A} \cup \mathcal{B}} \{|\mathbf{q}|\} \cdot (1/\delta - 1)$ and $\mathbf{x} := \{x_1, \dots, x_\ell\}$ such that $\mathbf{x} \cap (\mathcal{A} \cup \mathcal{B}) = \emptyset$, and further define the mapping $g : \mathcal{A} \cup \mathcal{B} \rightarrow \mathcal{A}' \cup \mathcal{B}'$ by $g(\mathbf{v}) = \mathbf{v} \cup \mathbf{x}$ where $\mathcal{A}' = \mathcal{A} \cup \mathbf{x}$ and equivalently $\mathcal{B}' = \mathcal{B} \cup \mathbf{x}$. The reduction that applies g to every element of \mathcal{A} and \mathcal{B} generates an instance $(\mathcal{A}', \mathcal{B}')$ of Bichromatic Closest Pair with Jaccard similarity that requires time $\Omega(n^{2-\delta})$ for some thresholds $t'_1, t'_2 \geq 1 - \delta$.*

Proof. First, note that if $\mathbf{v} \in \mathcal{A}$, then $g(\mathbf{v}) \in \mathcal{A}'$ and similarly if $\mathbf{v} \in \mathcal{B}$ then $g(\mathbf{v}) \in \mathcal{B}'$. We recall that instances of Bichromatic Closest Pair as described in Lemma 3 are constructed such that all red sets have the same size and all blue sets have the same size. We also have $\max_{\mathbf{q} \in \mathcal{A} \cup \mathcal{B}} \{|\mathbf{q}|\} = |\mathbf{a}|$, for any $\mathbf{a} \in \mathcal{A}$, since the sets in \mathcal{A} were larger than the sets in \mathcal{B} . It is easy to see that hardness is preserved under the reduction.

74:10 Hardness of Bichromatic Closest Pair with Jaccard Similarity

We finally argue that the resulting thresholds are larger than $1 - \delta$: Let (\mathbf{a}, \mathbf{b}) be any pair from $\mathcal{A} \times \mathcal{B}$ which has Jaccard similarity at least t_2 and let $\mathbf{a}' = g(\mathbf{a})$ and $\mathbf{b}' = g(\mathbf{b})$. We argue that any such pair satisfies $|\mathbf{a} \cap \mathbf{b}| \geq \frac{|\mathbf{b}|}{2}$: Note that with these particular instances of Bichromatic Closest Pair and from the proof of Lemma 4, we have

$$J(\mathbf{a}, \mathbf{b}) = \frac{|\mathbf{a} \cap \mathbf{b}|}{|\mathbf{a} \cup \mathbf{b}|} = \frac{|\mathbf{a} \cap \mathbf{b}|}{Tm + m - |\mathbf{a} \cap \mathbf{b}|} \geq t_2 = \frac{t_1}{2} = \frac{1/T}{2}.$$

Since $|\mathbf{b}| = m \geq |\mathbf{a} \cap \mathbf{b}|$, this implies

$$|\mathbf{a} \cap \mathbf{b}| \geq \frac{m}{2} + \frac{m}{2T} - \frac{|\mathbf{a} \cap \mathbf{b}|}{2T} \Rightarrow |\mathbf{a} \cap \mathbf{b}| \geq m/2 = |\mathbf{b}|/2.$$

We will consider the Jaccard similarity of \mathbf{a}' and \mathbf{b}' :

$$\begin{aligned} J(\mathbf{a}', \mathbf{b}') &= \frac{|\mathbf{a} \cap \mathbf{b}| + |\mathbf{a}|(1/\delta - 1)}{(|\mathbf{a}| + |\mathbf{a}|(1/\delta - 1)) + (|\mathbf{b}| + |\mathbf{a}|(1/\delta - 1)) - (|\mathbf{a} \cap \mathbf{b}| + |\mathbf{a}|(1/\delta - 1))} \\ &= \frac{|\mathbf{a} \cap \mathbf{b}| + |\mathbf{a}|(1/\delta - 1)}{|\mathbf{a}|/\delta + |\mathbf{b}| - |\mathbf{a} \cap \mathbf{b}|}. \end{aligned}$$

By assumption $|\mathbf{a} \cap \mathbf{b}| \geq \frac{|\mathbf{b}|}{2}$, so:

$$\begin{aligned} \frac{|\mathbf{a} \cap \mathbf{b}| + |\mathbf{a}|(1/\delta - 1)}{|\mathbf{a}|/\delta + |\mathbf{b}| - |\mathbf{a} \cap \mathbf{b}|} &\geq \frac{|\mathbf{b}|/2 + |\mathbf{a}|(1/\delta - 1)}{|\mathbf{a}|/\delta + |\mathbf{b}|/2} \geq 1 - \delta \\ \Leftrightarrow \frac{|\mathbf{b}|}{2} + |\mathbf{a}|(1/\delta - 1) &\geq |\mathbf{a}|(1/\delta - 1) + \frac{|\mathbf{b}|}{2} - \frac{|\mathbf{b}|\delta}{2} \end{aligned}$$

which is always satisfied. Hence, $J(\mathbf{a}', \mathbf{b}') \geq 1 - \delta$ for any choice of $\delta > 0$, and so, we construct an instance where every pair with Jaccard similarity higher than t_2 will have Jaccard similarity higher than $1 - \delta$. Thus, there are thresholds that are greater than $1 - \delta$, that make the constructed instance hard. \blacktriangleleft

► **Lemma 10.** *Let $0 < \delta \leq 1$ be given and consider any instance of Bichromatic Closest Pair with Jaccard similarity, $(\mathcal{A}, \mathcal{B})$, from a family of instances which require time $\Omega(n^{2-\delta})$ for thresholds t_1 and t_2 . Using the reduction f defined in Section 4 on each $\mathbf{v} \in \mathcal{A} \cup \mathcal{B}$ for i iterations where $i \geq 1$, we construct a valid instance of Bichromatic Closest Pair with Jaccard similarity with high probability, which requires time $\Omega(n^{2-\delta})$ for thresholds that are decreasing functions of i .*

Proof. The lemma follows immediately from Lemma 8. \blacktriangleleft

► **Lemma 11.** *Let $0 < \delta \leq 1$ be given and consider any instance of Bichromatic Closest Pair with Jaccard similarity, $(\mathcal{A}, \mathcal{B})$, from a family of instances which require time $\Omega(n^{2-\delta})$ for thresholds t_1 and t_2 . Define $\ell := \max_{\mathbf{q} \in \mathcal{A} \cup \mathcal{B}} \{|\mathbf{q}|\} \cdot (1/\alpha - 1)$ and $\mathbf{y} := \{y_1, \dots, y_\ell\}$ such that $\mathbf{y} \cap (\mathcal{A} \cup \mathcal{B}) = \emptyset$. Define mapping $h : \mathcal{A} \rightarrow \mathcal{A}'$ where $\mathcal{A}' = \mathcal{A} \cup \mathcal{Y}$ by $h(\mathbf{a}) = \mathbf{a} \cup \mathbf{y}$. The reduction that applies h to every element of \mathcal{A} generates an instance $(\mathcal{A}', \mathcal{B})$ of Bichromatic Closest Pair with Jaccard similarity that requires time $\Omega(n^{2-\delta})$ for some thresholds t'_1, t'_2 .*

Proof. Clearly, hardness is preserved under the reduction that simply adds new elements to all red sets. In particular this reduction decreases the thresholds by decreasing the similarity between red and blue pairs. \blacktriangleleft

5.3 Proof outline for Theorem 2

Proof. For simplicity and readability we leave out most of the calculations – details can be found in Appendix B in the full version on ArXiv [8, App. B].

Let $\delta > 0$ be given and let j_1, j_2 be given such that $j_2 < j_1 < 1 - \delta$. Take any instance of Bichromatic Closest Pair with Jaccard similarity satisfying the properties described in Lemma 3. Recall from this lemma that $T = O\left(\frac{1}{\varepsilon}\right)$.

Apply the reductions from first Lemma 9 to achieve an instance, which requires time $\Omega(n^{2-\delta})$ for thresholds greater than $1 - \delta$. We wish to reduce to an instance that is hard for smaller thresholds j_1 and j_2 . The reduction from Lemma 10 is used to decrease the thresholds, where we pick the largest i , such that the resulting upper threshold t_1 is no smaller than j_1 , i.e., $t_1 \geq j_1$. This reduction decreases the thresholds until the upper threshold is only slightly greater than j_1 . Now, let $\alpha = \frac{j_1}{t_1}$ and apply the reduction from Lemma 11 to ensure that the resulting upper threshold is now equal to j_1 . This eventually gives an instance of Bichromatic Closest Pair with Jaccard similarity, which cannot be solved in time $O(n^{2-\delta})$ for thresholds

$$t'_1 = \alpha \left(\frac{1-\gamma}{1+4\gamma} \right)^{2^i} \left(\frac{\delta}{T} + 1 - \delta \right)^{2^i}$$

$$t'_2 = \left(\frac{1+\gamma}{1-4\gamma} \right)^{2^i} \frac{\left(\frac{\delta}{2T} + 1 - \delta \right)^{2^i}}{\frac{1}{\alpha} + \left(\frac{\delta}{T} + 1 - \delta \right)^{2^i} - \left(\frac{\delta}{2T} + 1 - \delta \right)^{2^i}}$$

where we observe that by construction $t'_1 = \alpha \cdot t_1 = j_1$. We refer to Appendix B in the full version on ArXiv for the calculations [8, App. B]. So we have constructed an instance which is hard for thresholds j_1 and t'_2 .

Set $t_2^* = \left(\frac{1+\gamma}{1-4\gamma} \right)^{2^i} \left(\frac{\delta}{2T} + 1 - \delta \right)^{2^i}$. Then $t'_2 < \alpha t_2^*$ and so the hardness for $t'_1 = j_1$ and t'_2 implies hardness for $t'_1 = j_1$ and αt_2^* . We show that there is an ε that only depends on δ such that $\alpha t_2^* < j_2$. Then the hardness for $t'_1 = j_1$ and αt_2^* implies hardness for the given j_1 and j_2 .

Note that we have chosen $\alpha \geq t_1$, since otherwise i could not be maximal. So we have:

$$\frac{\log(j_1)}{\log(\alpha t_2^*)} = \frac{\log(\alpha t_1)}{\log(\alpha t_2^*)} \leq \frac{\log(t_1^2)}{\log\left(t_1 \cdot \left(\frac{1+\gamma}{1-4\gamma}\right)^{2^i} \cdot \left(\frac{\delta}{2T} + 1 - \delta\right)^{2^i}\right)}$$

$$= \frac{2^i \cdot \log\left(\left(\frac{1-\gamma}{1+4\gamma}\right)^2 \cdot (\delta/T + 1 - \delta)^2\right)}{2^i \cdot \log\left(\left(\frac{1-\gamma}{1+4\gamma}\right) \cdot (\delta/T + 1 - \delta) \left(\frac{1+\gamma}{1-4\gamma}\right) \cdot \left(\frac{\delta}{2T} + 1 - \delta\right)\right)}.$$

We need to show that this expression is bounded by $1 - \varepsilon$ for some ε that depends on δ , but not on j_1 and j_2 . Observe that the factors 2^i cancel out and we may pick γ small enough that it can essentially be ignored. We show in Appendix B in the full version on ArXiv [8, App. B] that we can use any $\gamma < \min\left\{\frac{1}{2^{i+1}}, \frac{\delta}{20T}\right\}$. Then for given δ , there exists an ε such that the expression is bounded by $1 - \varepsilon$, since T can be considered a constant for a fixed δ . Recall that T was defined in Lemma 3. By the assumption $j_1 \leq j_2^{1-\varepsilon}$ we then have $\alpha t_2^* < j_2$. Then the hardness of t'_1 and αt_2^* where $t'_1 = j_1$ and $\alpha t_2^* < j_2$, implies the desired hardness for the given j_1 and j_2 .

We finally argue about the size of the universe of the instance constructed by the compositions of reductions described. In the following, d is the size of the universe of the initial instance of Bichromatic Closest Pair with Jaccard instance. In the proof of Lemma 8, we argued that we could use x_2 , which was the size of the intersection for a pair with Jaccard similarity j_2 , in the sample size s_i , which means that

$$\begin{aligned} s_i &\geq \frac{30 \ln(n) d^{2^i}}{\gamma^2 (1 - \gamma)^{2^i} x_2^{2^i}} = \frac{30 \ln(n) d^{2^i}}{\gamma^2 (1 - \gamma)^{2^i} (j_2 (|a| + |b| - x_2))^{2^i}} \\ &= \frac{30 \ln(n)}{\gamma^2 (1 - \gamma)^{2^i} j_2^{2^i}} \cdot \left(\frac{\delta + 1}{1 + \frac{\delta}{2T}} \right)^{2^i}. \end{aligned}$$

Again, the calculations can be found in Appendix B in the full version on ArXiv [8, App. B]. Hence, the sets constructed by the composition of reductions come from a universe whose size is bounded by

$$|U| \leq s_i + s_i(1/\alpha - 1) = \frac{s_i}{\alpha} \leq \frac{30 \ln(n)}{\gamma^2 j_2^{2^i}} \left(\frac{\delta + 1}{(\frac{\delta}{2T} + 1 - \delta)(\frac{\delta}{2T} + 1)} \right)^{2^i} \left(\frac{1 + 4\gamma}{(1 - \gamma)^2} \right)^{2^i}$$

By Assumption $t_1'^2 < j_1 \leq t_1'$, which implies that $2^i = O\left(\frac{\log j_1}{\log c}\right) = O\left(\log \frac{1}{j_1}\right)$ for constant $c < 1$. Hence, we conclude that the size of the universe is $\ln(n)/j_2^{O(\log 1/j_1)}$. This finishes the proof of Theorem 2. ◀

6 Final Comments

On a final note, we remark that one can obtain a result similar to Theorem 2 for Braun-Blanquet similarity. Recall that we define Braun-Blanquet similarity for a pair of sets $(\mathbf{a}, \mathbf{b}) \in \mathcal{A} \times \mathcal{B}$ as

$$BB(\mathbf{a}, \mathbf{b}) = \frac{|\mathbf{a} \cap \mathbf{b}|}{\max\{|\mathbf{a}|, |\mathbf{b}|\}} \in [0, 1]$$

In fact, the proof is slightly simpler than the one given in Section 5.3 and the calculations are somewhat nicer. The proof ideas, i.e., the choice and order of reductions, are exactly the same and should be easy to carry out by following the structure of the proof of Theorem 2.

The main open problem we leave is whether existing upper bounds are near-optimal when ε is an arbitrary constant between 0 and 1. Our techniques only work when ε is sufficiently small.

Compact Oblivious Routing

Abstract

Oblivious routing is an attractive paradigm for large distributed systems in which centralized control and frequent reconfigurations are infeasible or undesired (e.g., costly). Over the last almost 20 years, much progress has been made in devising oblivious routing schemes that guarantee close to optimal load and also algorithms for constructing such schemes efficiently have been designed. However, a common drawback of existing oblivious routing schemes is that they are not compact: they require large routing tables (of polynomial size), which does not scale.

This paper presents the first oblivious routing scheme which guarantees close to optimal load and is compact at the same time – requiring routing tables of *polylogarithmic* size. Our algorithm maintains the polylogarithmic competitive ratio of existing algorithms, and is hence particularly well-suited for emerging large-scale networks.

1 Introduction

1.1 Motivation

With the increasing scale and dynamics of large networked systems, observing and reacting to changes in the workload and reconfiguring the routing accordingly becomes more and more difficult. Not only does a larger network and more dynamic workload require more fine-grained monitoring and control (which both introduce overheads), also the process of re-routing traffic itself (see e.g. [15]) can lead to temporary performance degradation and transient inconsistencies.

Oblivious routing provides an attractive alternative which avoids these reconfiguration overheads while being *competitive*, i.e., while guaranteeing route allocations which are almost as good as adaptive solutions. It is hence not surprising that oblivious routing has received much attention over the last two decades. Indeed, today, we have a good understanding of fast (i.e., polynomial-time constructable) and “competitive” oblivious routing algorithms (achieving a polylogarithmic approximation of the load, which is optimal).

However, while oblivious routing seems to be the perfect paradigm for emerging large networked systems, there is a fly in the ointment. Oblivious routing algorithms that aim to minimize congestion require large routing tables: namely *polynomial* in the network size. This is problematic, as fast memory in routers is expensive, not only in terms of monetary costs but also in terms of power consumption.

The goal of this paper is to design oblivious routing schemes which only require small routing tables (which are *compact*), and that at the same time still guarantee a close-to-optimal load.

1.2 The Problem in a Nutshell

The network is given as an undirected graph $G = (V, E)$ with n vertices. The edges E are weighted by a capacity function $\text{cap} : V \times V \rightarrow \mathbb{R}_0^+$; if $\{x, y\} \in E$, the function returns 0, otherwise a positive value.

The *oblivious routing problem* is to set up a unit flow for each source-target pair $(s, t) \in V \times V$ that determines how demand between s and t is routed in the network G . This unit flow is pre-specified without knowing the actual demands. When a demand vector \vec{d} is given that specifies for each pair of vertices the amount of traffic to be sent, the demand-vector is routed by simply scaling the unit flow between a pair (s, t) by the corresponding demand d_{st} between the two vertices. This means that traffic is routed along *pre-computed paths* and that no path-selection is done dynamically.

The congestion $C_{\text{obl}}(G, \vec{d})$ resulting from a given oblivious routing scheme, is then compared to the optimal possible congestion $C_{\text{opt}}(G, \vec{d})$ that can be obtained for demand vector \vec{d} in G . The *competitive ratio* of the oblivious routing scheme is defined as

$$\max_{\vec{d}} \frac{C_{\text{obl}}(G, \vec{d})}{C_{\text{opt}}(G, \vec{d})}$$

In this paper, we are interested in designing packet forwarding rules that allow the packets to follow a flow of an oblivious routing scheme with a good competitive ratio. Apart from the competitiveness of the underlying oblivious routing scheme one goal is to encode the forwarding rules *compactly* with small space requirement. In particular we require that for a vertex v the space requirement is only $O(\deg(v) \text{polylog}(n))$, where $\deg(v)$ is the degree of the vertex. In other words, this means we roughly require a polylogarithmic number of rules *per network link*. It seems unavoidable to let the memory requirement of a vertex depend on its degree as otherwise the routing scheme might not be able to efficiently utilize all network links.

In addition to the competitive ratio, the runtime, and the table size, we are also interested in the required vertex labels (i.e., their size) and the required packet header size.

1.3 Our Contributions

This paper presents the first *compact* oblivious routing scheme. Our approach builds upon an oblivious path selection scheme based on classic decomposition trees, which is then adapted to improve scalability, and in particular, to ensure small routing tables and message headers, while preserving polynomial runtime (for constructing the routing tables) and a polylogarithmic competitive ratio.

We present two different implementations of our approach and our results come in two different flavors accordingly (more detailed theorems will follow):

► **Theorem 1.** *There exist oblivious routing strategies that achieve a polylogarithmic competitive ratio w.r.t. the congestion and require routing tables of polylogarithmic size for*

1. *networks with arbitrary edge capacities which have a decomposition tree of bounded degree, and for*
2. *arbitrary networks with uniform edge capacities.*

Our algorithms only require small (polylogarithmic) header sizes and vertex labels. The routing tables can be constructed in polynomial time.

Networks for which there are decomposition trees of small degree include for example (constant-degree) grids. The exact requirements that a decomposition tree has to fulfill will be given later.

2 Algorithm and Analysis

This section describes an oblivious path selection scheme for general undirected networks that obtains close to optimal congestion and can be implemented with routing tables and routing headers of small size. In a nutshell, our algorithm leverages a path selection scheme for general networks that guarantees a good competitive ratio w.r.t. congestion, and then adapts it so that it can be implemented with small space requirements. We discuss the two phases of this algorithm in turn.

2.1 Oblivious Path Selection Scheme

There exist essentially two path selection schemes that could be used as a basis for our approach. First, there is the original result by Räcke [32] who showed that oblivious routing with a polylogarithmic competitive ratio is possible in general networks, using a *hierarchical path selection scheme* (cf. Section 2.1) that guarantees a competitive ratio of $O(\log^3 n)$. Second, there is a path selection scheme with an improved competitive ratio of $O(\log n)$ [33]. The latter scheme can be roughly viewed as a convex combination of spanning trees.¹ A path between a vertex s and a vertex t is chosen by sampling a random spanning tree and then choosing the path between s and t in this tree.

In this paper, we will build upon the original result [32] which we call the *hierarchical path selection scheme*. The challenge with implementing the path selection mechanism in [33] space-efficiently is that the number of spanning trees is quite large (polynomial in n). It seems difficult to avoid that a vertex in the graph has to store some information for every tree, which yields routing tables of polynomial size. The approach in [32] is based on a single tree which hence avoids the problem of [33].

The hierarchical path selection scheme is based on a hierarchical decomposition of the graph $G = (V, E)$. The vertex set V is recursively partitioned into smaller and smaller pieces until all pieces contain just single vertices of G . We will refer to the pieces/subsets arising during this partitioning process as *clusters*.

To such a recursive partitioning corresponds a decomposition tree $T = (V_T, E_T)$. A vertex x in this tree corresponds to cluster $V_x \subseteq V$ and there is an edge between a parent node p and a child node c if the cluster V_c arises from partitioning V_p . The root r of T corresponds to the subset $V_r = V$ and the leaf vertices correspond to singleton sets $\{v\}, v \in V$.

In order to simplify the notation and description we assume that all leaf vertices in T have the same distance to the root (this could e.g., be achieved by introducing dummy partitioning steps in which a set is partitioned into itself). We use h to denote the height of the tree. Let for a vertex $v \in V$, $a_\ell(v)$ denote the ancestor of $\{v\}$ on level ℓ of the tree, where the level of a vertex is its distance from the root. Here we use $\{v\}$ as a shorthand for “the leaf node that corresponds to cluster $\{v\}$ ”. The ℓ -weight of v is the weight of all edges incident to v that leave the cluster $V_{a_\ell(v)}$. Formally $w_\ell(v) := \sum_{e=\{v,x\}:x \notin V_{a_\ell(v)}} \text{cap}(e)$. We extend this definition to subsets of V by setting $w_\ell(U) := \sum_{u \in U} w_\ell(u)$ for every subset $U \subseteq V$.

We also introduce for every cluster S in the decomposition tree a weight function $w_S : S \mapsto \mathbb{R}_0^+$ and a weight function $\text{out}_S : S \mapsto \mathbb{R}_0^+$. For a level ℓ -cluster S we define $w_S := w_{\ell+1}|_S$ and $\text{out}_S := w_\ell|_S$, i.e., we define it as the restriction of $w_{\ell+1}$ and w_ℓ , respectively, to the vertex set of cluster S . Note that out_S counts edges that connect vertices of S to vertices outside of S while w_S also counts edges that connect different sub-clusters of S . We refer to w_S as the *cluster-weight* of S and to out_S as the *border-weight* of S .

¹ This is not entirely correct as the trees are not proper spanning trees but the difference is not important for the above discussion.

Using this weight definition, we define a *concurrent multicommodity flow problem* (CMCF-problem) for every cluster S in the decomposition tree. For every (ordered) pair (u, v) there is a demand of $w_S(u)w_S(v)/w_S(S)$. Informally speaking, this means that every vertex injects a total flow that is equal to its w_S -weight and distributes this flow to the other vertices in S , proportionally to the w_S -weight of these vertices. We will use the decomposition tree T in [32] with the following properties:

- the height of T is $O(\log n)$, and
- for every cluster S in the decomposition tree, the CMCF-problem for S can be solved with congestion at most $C = O(\log^2 n)$ inside S .

Now suppose that we are given a decomposition tree with these properties. The path selection in [32] is then performed as follows. Suppose that we want to choose a path between vertices s and t in G . Let x_s and x_t denote the leaf vertices in T that correspond to singleton clusters $\{s\}$ and $\{t\}$, respectively. Let $x_s = x_1, x_2, \dots, x_k = x_t$ denote the vertices in the tree on the path from x_s to x_t . We first choose a random vertex v_i from each cluster V_{x_i} according to the cluster-weight, i.e., the probability that v is chosen is $w_{V_{x_i}}(v)/w_{V_{x_i}}(V_{x_i})$. Note that $v_1 = s$ and $v_k = t$ as the corresponding clusters just contain a single vertex. It remains to select a path that connects the chosen vertices.

Suppose we want to connect two consecutive vertices v_p and v_c , where V_{x_p} is the parent cluster of V_{x_c} . We choose an intermediate vertex α inside V_{x_c} according to the border-weight of V_{x_c} , i.e., the probability that v is chosen is $\text{out}_{V_{x_c}}(v)/\text{out}_{V_{x_c}}(V_{x_c})$. We then consider the solution to the CMCF-flow problems for V_{x_c} and V_{x_p} . The first solution contains a flow $f(c, \alpha)$ between v_{x_c} and α , and the second contains a flow $f(p, \alpha)$ between v_{x_p} and α . We sample a random path from each flow. Concatenating these two paths, gives a flow between v_c and v_p . For the following analysis we call the sub-path between x_c and α the *lower sub-path* and the path between α and x_p the *upper sub-path*.

Concatenating all vertices v_i in the above manner gives a path between x_s and x_t . In the following we analyze the expected load generated on an edge due to this path selection scheme under the condition that an optimal algorithm can route the demand with congestion C_{opt} . For completeness and as we will need to modify this proof later, we repeat the following observations from [32].

► **Lemma 2.** *The expected load on an edge is at most $O(h \cdot C \cdot C_{\text{opt}})$.*

Proof. Fix an edge e for which both end-points are contained in some cluster S . Let S_1, \dots, S_r denote the child-clusters of S . We first analyze the total demand that we have to route between a pair of vertices $(a, b) \in S \times S$ due to an upper sub-path where a is chosen as the intermediate vertex α and b is chosen as a random vertex from the parent cluster S . Assume $a \in S_i$ for some child cluster S_i . Then the probability that we choose a as α is $\Pr[a \text{ is chosen}] = \text{out}_{S_i}(a)/\text{out}_{S_i}(S_i)$. The probability that we choose b as the random end-point in S is $\Pr[b \text{ is chosen}] = w_S(b)/w_S(S)$. Note that any message for which we route between the child cluster S_i and the parent cluster S has to leave or enter the cluster S_i . Therefore the total demand for these messages can be at most $C_{\text{opt}} \cdot \text{out}_{S_i}(S_i)$, as otherwise an optimum congestion of C_{opt} would not be possible. Hence, the expected demand for pair a and b is only

$$\begin{aligned} \text{out}_{S_i}(S_i)C_{\text{opt}} \cdot \Pr[a \text{ is chosen}] \cdot \Pr[b \text{ is chosen}] &= \text{out}_{S_i}(S_i)C_{\text{opt}} \cdot \frac{\text{out}_{S_i}(a)}{\text{out}_{S_i}(S_i)} \cdot \frac{w_S(b)}{w_S(S)} \\ &= \frac{w_S(a) \cdot w_S(b)}{w_S(S)} \cdot C_{\text{opt}}, \end{aligned} \quad (1)$$

where we used the fact that $\text{out}_{S_i}(a) = w_S(a)$, which holds since S_i is a direct child-cluster of S .

Now we analyze the demand that is induced for a pair $(a, b) \in S \times S$ due to the lower part of a message between S and its parent cluster. We assume that a is chosen as the intermediate vertex α and b is chosen as a random node in the child-cluster S . The probability that a is chosen as intermediate vertex is $\Pr[a \text{ is chosen}] = \text{out}_S(a)/\text{out}_S(S)$ and the probability that b is chosen is $\Pr[b \text{ is chosen}] = w_S(b)/w_S(S)$. Every such message has either to leave or enter cluster S . Hence, the total demand for these messages induced on pair (a, b) is at most

$$\begin{aligned} \text{out}_S(S)C_{\text{opt}} \cdot \Pr[a \text{ is chosen}] \cdot \Pr[b \text{ is chosen}] &= \text{out}_S(S)C_{\text{opt}} \cdot \frac{\text{out}_S(a)}{\text{out}_S(S)} \cdot \frac{w_S(b)}{w_S(S)} \\ &\leq \frac{w_S(a) \cdot w_S(b)}{w_S(S)} \cdot C_{\text{opt}} \quad , \end{aligned} \quad (2)$$

where we used the fact that $\text{out}_S(a) \leq w_S(a)$.

Combining Equation 1 and Equation 2 gives that the messages involving cluster S induce a demand of only $2w_S(a) \cdot w_S(b)/w_S(S) \cdot C_{\text{opt}}$ between vertices a and b from S . Since we route this demand according to the multicommodity flow solution of the CMCF-problem for cluster S , the resulting load is at most $2C \cdot C_{\text{opt}}$ on any edge *inside* cluster S , while edges not in S have a load of zero. Summing the load induced by messages for all clusters and exploiting the fact that an edge is at most contained in h different clusters, gives a maximum load of $2hC \cdot C_{\text{opt}}$, i.e., a competitive ratio of $2hC$. ◀

Harrelson, Hildrum and Rao [21] present a decomposition tree in which the congestion for the CMCF-problem of clusters is not uniformly bounded by C but it is guaranteed that along a root-to-leaf path the congestion values of the respective flow problems sum up to at most $O(\log^2 n \log \log n)$. Then the expected load in Lemma 2 becomes $O(\log^2 n \log \log n \cdot C_{\text{opt}})$. In addition the construction of this decomposition tree is polynomial time.

In the following description we base our oblivious routing scheme on the results in [32] as it slightly simplifies the write-up. For the theorems we also present the improved version obtained by plugging in the decomposition tree from Harrelson et al.

2.2 Implementation A: Decomposition Trees with Small Degree

We now present a space efficient implementation of the above path selection scheme. In the following, we will assume that the maximum degree of the decomposition tree T is small.

The basic building block for our implementation is a method that given a random starting point $v \in S$ chosen according to the cluster-weight of S (i.e., the probability of choosing v is $w_S(v)/w_S(S)$), routes to a random node $v_i \in S_i$ chosen according to the border weight of S_i . Here S_i is either a child-cluster of S (in case we want to communicate downwards in the tree) or $S_i = S$ (in case we want to communicate upwards). In the following we use $S_i, i \in \{1, \dots, r\}$ to denote the child-clusters of S and $S_0 = S$ to denote S itself. Let $G[S]$ denote the sub-graph induced by vertices in S .

For every $i \in \{0, \dots, r\}$ we compute a single commodity flow f_i in $G[S]$ as follows. We add a super-source s and connect it to every vertex $v \in S$ with an edge of capacity $w_S(v) \cdot \text{out}_{S_i}(S_i)$ and a super-target t to which every vertex in $v \in S$ connects with capacity $\text{out}_{S_i}(v) \cdot w_S(S)$. Note that all source edges together have the same capacity as the target edges.

We now compute a flow f_i between s_i and t_i that saturates all edges from s_i and to t_i . We can find such flows f_i (for all i) such that the *combined* congestion for these flows (on edges in S ; edges from s_i 's and to t_i 's have congestion 1) is only $w_S(S) \cdot C$. To see this observe that in the CMCF-solution for cluster S the commodity (v_i, v) with $v_i \in S_i$ and $v \in S$ ships a flow of $\text{out}_{S_i}(v_i)w_S(v)/w_S(S)$ between v_i and v . By “merging” the flows of all

commodities $(v_i, v) \in S_i \times S$ into a single commodity we obtain the desired flow (up to a $w_S(S)$ -factor). Merging the commodities does not increase the congestion and, hence, the congestion is only $w_S(S) \cdot C$.

The flows f_i that we constructed so far may have fractional values that are difficult to store exactly. Therefore we slightly change the flows so that we can store them efficiently. For this we first scale every flow and the capacity of every edge up by a factor of r . Let f'_i and $\text{cap}'(e)$ denote the scaled flows and capacities. Then every edge e makes a *capacity reservation* for every flow f_i . Suppose the (scaled) flow sends $f'_i(e)$ along edge e ; then the edge e reserves a capacity of $\lceil f'_i(e) \rceil$ for the i -th flow. Note that the total capacity reservation is at most $\sum_i \lceil f'_i(e) \rceil \leq \sum_i f'_i(e) + r \leq w_S(S) \cdot C \text{cap}'(e) + r \leq 2w_S(S) \cdot C \text{cap}'(e)$, because the scaled capacity of an edge is at least r .

Now we resolve every flow problem separately with the restriction that the flow should stay within its capacity reservation. This is clearly possible and since the capacity reservations and the demands are all integral we now have an *integral* flow f'_i . Undoing the scaling gives us flows f_i that can (concurrently) be routed with congestion at most $2w_S(S) \cdot C$, and where flow values are a multiple of $1/r$.

We now store the flows f_i in a distributed manner at the vertices of S , as follows. Fix $v \in S$. For every edge we store how much flow enters or leaves v . In order to route from the cluster-distribution of S to the border-distribution for S_i , $i \in \{0, \dots, r\}$, we choose random outgoing links (where a link is taken with probability proportional to the outgoing flow) until the chosen link is the super-target t . When we want to route from the border-distribution of S_i to the cluster-distribution of S , we take random incoming links (where a link is chosen with probability proportional to the incoming flow), until the chosen link corresponds to the super-source s . The proof of the following claim is analogous to Lemma 2.

▷ **Claim 3.** The expected load of an edge due to the path selection scheme is only $O(h \cdot C \cdot C_{\text{opt}})$.

Proof. Suppose that the optimum congestion is C_{opt} . The total traffic that the scheme has to route between the cluster-distribution of S and the border-distribution of S_i is only $\text{out}_{S_i}(S_i) \cdot C_{\text{opt}}$. We route this traffic according to flow f_i of value $\text{out}_{S_i}(S_i)w_S(S)$. Hence, the maximum load of an edge in $G[S]$ (according to original capacity) is $C \cdot C_{\text{opt}}$.

Since an edge is contained in h different clusters the claim follows. ◁

▷ **Claim 4.** The path selection scheme can be implemented with routing tables of size $O(\deg(v) \deg(T)(\log m + \log W))$, labels of length $O(h \log(\deg(T)))$, and header length $O(h \log(\deg(T)))$.

Proof. Suppose that the capacities of the graph are integers in the range $\{1, \dots, W\}$. A flow value $f_i(e)$ along an edge is at most $w_S(S) \cdot W \cdot C$ (note that we assume that C is integral). Edges from s and to t have a capacity of $w_S(v) \text{out}_{S_i}(S_i)$ and $w_S(S) \text{out}_{S_i}(v)$, respectively. Using the fact that $w_S(S)$ and $\text{out}_{S_i}(S_i)$ are at most mW , and $d, C \leq m$ we get that a number describing the flow value along an edge can be encoded with

$$\log_2(m^2 W^2 r) = O(\log(m) + \log(W) + \log(r))$$

many bits (since flow values are a multiple of $1/r$). Hence, a node v has to store only $O(\deg(v) \deg(T)(\log m + \log W))$ many bits, where we used that $r \leq m$.

For the routing scheme we relabel the vertices. We number the children of a vertex in the tree and encode a leaf vertex by its path from the root. This generates labels of $O(h \log(\deg(T)))$ bits. The routing algorithm now only needs to have the label of the source vertex and the target vertex and a marker that marks where in the tree the routing currently is. ◁

In summary, we obtain the following theorem.

► **Theorem 5** (Decomposition Trees of Small Degree). *For decomposition trees of degree $\deg(T)$ one can construct an oblivious routing strategy that requires routing tables of size $O(\deg(v) \deg(T)(\log(m) + \log(W)))$, labels of length $O(h \log(\deg(T)))$, and header sizes of $O(h \log(\deg(T)))$. Depending on the decomposition tree used, we obtain two different competitive ratios:*

- *Using the decomposition tree from [32] the scheme guarantees a competitive ratio of $O(hC) = O(\log^3(n))$ w.r.t. congestion.*
- *Using the decomposition tree from [21] the scheme can be constructed in polynomial time and guarantees a competitive ratio of $O(\log^2(n) \log \log(n))$.*

2.3 Implementation B: Uniform Capacities

In this section we present a different implementation of the hierarchical routing scheme, for scenarios where the decomposition trees can be of arbitrary degree but where network capacities are uniform. Again the basic building block is to route from a node chosen according to the cluster-distribution of some cluster S to the border distribution of S_i where either $S_i = S$ or S_i is a child-cluster of S .

Assume that every edge in the graph G has capacity 1. We round the outgoing capacity $\text{out}_{S_i}(S_i)$ of a child-cluster S_i , $i \geq 0$ to the next larger power of 2 and denote the rounded value with $\|S_i\|$. We also re-order the children w.r.t. this value, i.e., S_1 is the child-cluster with smallest $\|S_i\|$ -value. Since there are at most m possible values for $\text{out}_{S_i}(S_i)$, there are only $\log m$ possible values for $\|S_i\|$. There are only $\binom{r + \log m}{\log m}$ possibilities to choose the $\|S_i\|$ -values of the r children of cluster S . Hence, we can store these with $O(\log(m) \cdot \log(r))$ many bits. In addition we store the value of $\|S_0\|$, which requires $O(\log \log m)$ bits, and the value of $w_S(S)$ which requires $O(\log m)$ bits.

In order to design the routing scheme for an individual cluster, we embed a hypercube of dimension $d := \lceil \log_2(\sum_{i \geq 0} \|S_i\|) \rceil$. We first order the hypercube nodes in an arbitrary way and then reserve a range of $\|S_i\|$ consecutive hypercube nodes for every $i \geq 0$ (the i -th range). Note that we store the (rounded) size of all children and that it is straightforward to compute the ranges assigned for any i from this information.

Then we map the hypercube nodes to nodes of S . First we map hypercube nodes in the i -th range to nodes with $\text{out}_{S_i}(v) > 0$ such that each node receives at least $\text{out}_{S_i}(v)$ and at most $2 \text{out}_{S_i}(v)$ hypercube nodes. Hypercube nodes that remain unmapped after this step (i.e., nodes that do not fall within any range) are mapped arbitrarily subject to the constraint that a cluster node v does not receive more than $8w_S(v)$ hypercube nodes. This can easily be done as the number of hypercube nodes (2^d) is at most $2 \sum_i \|S_i\| \leq 4 \sum_i \sum_{v \in S_i} \text{out}_{S_i}(v) = 4(w_S(S) + \text{out}_S(S)) \leq 8w_S(S)$.

► **Observation 6.** *There are at most $8w_S(v)$ hypercube nodes mapped to any graph node.*

For the embedding we set up a concurrent multicommodity flow problem as follows. For every edge $\{x, y\}$ of the hypercube that is mapped to endpoints $\{v_x, v_y\}$, we introduce a demand of 1 between v_x and v_y in both directions. Then every node sends and receives a total traffic of at most $8d \cdot w_S(v)$. By adding fake traffic we can turn this instance into a balanced multicommodity flow instance in which every vertex sends and receives a traffic of exactly $8d \cdot w_S(v)$.

We can solve this multicommodity flow instance with congestion at most $16dC$ inside the cluster S by using Valiant's trick [38, 25] of sending to random intermediate destinations and using the fact that each flow can send a traffic of $w_S(v)$ to random destinations with congestion C .

2.3.1 Using the Hypercube

How do we exploit the embedded hypercube? If during the routing scheme we are required to send a message from a cluster node v_p to a cluster node $v_c \in S_i$ we proceed as follows. Instead of choosing an intermediate node α according to probability distribution $\text{out}_{S_i}(v)/\text{out}_{S_i}(S_i)$ we choose a random hypercube node from the i -th range. Then we route a message inside the hypercube to this node. For this we let the message start at a random hypercube node from the nodes that are mapped to v_p .

Note that this means that the probability that the message is sent to node α lies between $\text{out}_{S_i}(\alpha)/\|S_i\|$ and $2\text{out}_{S_i}(\alpha)/\|S_i\|$ as the hypercube nodes in the i -th range are not mapped completely uniformly.

For the second part of the message we proceed analogously in the hypercube of S_i . We let the message start at a random hypercube node mapped to α and choose a random hypercube node as its target.

Again due to the non-uniform mapping, the target distribution on S_i (i.e., $w_{S_i}(v)/w_{S_i}(S_i)$) is not reached exactly, but deviations by a constant factor might occur. This only influences the congestion of a single step by a constant factor, but it could be problematic if we used this approach along a path in the tree: in each step the distribution would change by a constant factor.

Therefore, we add an additional step that fixes the distribution over S_i . We embed an additional hypercube H_S for every cluster S with dimension $\lceil \log_2(w_S(S)) \rceil$. The mapping is done such that each cluster-vertex $v \in S$ receives exactly $w_S(v)$ hypercube nodes among the first $w_S(S)$ nodes from H_S (the remaining nodes are distributed uniformly). Since every node in the cluster S stores the value of $w_S(S)$, we can route from a node $v \in S$ to a random node chosen according to distribution $w_S(v)/w_S(S)$, by just selecting a random hypercube node from the first $w_S(S)$ nodes.

2.3.2 Analysis

We showed that the congestion for sub-messages that involve cluster S is small. There are two types of such messages:

1. messages that start at an intermediate node (distributed according to the border weight of S_i for some $i \geq 0$) and are sent to a random node $v \in S$ distributed according to the cluster-weight of S ; and
2. messages that start at a random node $v \in S$ and are sent to some intermediate node.

It was shown that the total traffic that is sent between a pair v_i and v , where v is distributed according to the cluster weight of S and v_i is distributed according to the border weight of S_i , is only $\text{out}_{S_i}(v_i)w_S(v)/w_S(S) \cdot C_{\text{opt}}$.

In our new scheme this changes slightly. For messages of the second type the source is distributed as before but the target may have a slightly different distribution (as we choose a random hypercube node in the i -th range). For messages of the first type already the source may have a slightly different distribution (as we choose a random hypercube node from some range in the hypercube for a child- or parent-cluster). Also the target distribution is slightly skewed as we choose a random hypercube node as the target.

But since the distributions are only changed by a constant factor this difference does not really influence our analysis. We still have the property that the traffic between v_i and v_S is $\Theta(\text{out}_{S_i}(v_i)w_S(v)/w_S(S) \cdot C_{\text{opt}})$.

The second difference is that the traffic is not sent according to the CMCF-problem for cluster S but it is instead sent along the hypercube. Note that due to the embedding of the hypercube, a cluster node $v \in S_i$ has $\Theta(\text{out}_{S_i}(v)) = \Theta(w_S(v))$ hypercube nodes in the i -th

range mapped to it (i.e., hypercube nodes are balanced perfectly up to constant factors). Hence the demand between v_i and v will be split among $\Theta(\text{out}_{S_i}(v_i)w_S(v))$ pairs in the cube. Therefore the demand for every pair in the cube is only $\Theta(C_{\text{opt}}/w_S(S)) = \Theta(C_{\text{opt}}/2^d)$. This means that at most a traffic of $O(C_{\text{opt}})$ starts and ends at every vertex and routing this traffic using Valiant's trick gives a congestion of $O(dC_{\text{opt}})$ in the hypercube. Since we embedded the hypercube with congestion $O(dC)$, the congestion of a graph edge will be $O(d^2C \cdot C_{\text{opt}})$ (as each hypercube node has degree d), which gives rise to the following lemma.

► **Lemma 7.** *Implementation B guarantees a maximum expected load of $O(hd^2C \cdot C_{\text{opt}})$.*

Proof. The lemma follows by applying the previous argument for each level of the tree.

It remains to bound the edge-load induced by the re-randomization steps. The total traffic that is sent to a cluster S in the tree is at most $(\sum_i \text{out}(S_i)) \cdot C_{\text{opt}} = \Theta(w_S(S) \cdot C_{\text{opt}})$. For each such message we require a re-randomization, because in our current scheme, it is only distributed approximately according to the cluster-weight of S .

However by design each vertex receives exactly a $w_S(v)/w_S(S)$ -fraction of the re-randomization messages, and a $\Theta(w_S(v)/w_S(S))$ -fraction of messages start at v , since the messages are approximately distributed according to cluster-weight. Sending these messages along the hypercube introduces congestion $\Theta(d \cdot C_{\text{opt}})$ in the cube and $\Theta(d^2C \cdot C_{\text{opt}})$ due to the embedding. ◀

► **Lemma 8.** *Implementation B requires space $O(hC \log(m) \log \log(m) \deg(v))$ bits at every vertex and a label and header length of $O(h \log(\deg(T)))$.*

Proof. We will use the following helper lemma:

► **Lemma 9.** *Let X_1, \dots, X_n denote a set of negatively correlated random variables taking values in the range $[0, 1]$. Let X denote their sum and let $\mu \leq E[X]$ denote a lower bound on the expectation of X . Then for any $\delta \geq 1$*

$$\Pr[X \geq (1 + \delta)\mu] \leq e^{-\delta\mu/3} .$$

A vertex $v \in S$ has to store the approximate size $\|S_i\|$ of the child-clusters of S . Summing this over all levels gives $O(h \log(m) \cdot \log(r))$ bits. In addition one has to encode the embedding of the hypercubes. The congestion of the solution to the concurrent multicommodity flow problem for embedding a hypercube is $O(dC)$. This fractional solution will encode a flow for every hypercube edge. Using a standard randomized rounding approach, we can route the flows to paths with a congestion of $O(dC + \log(m)) = O(dC)$. This is done as follows. For every pair $\{x, y\}$ we take the unit flow and first decompose this unit flow into flow-paths. Then we choose for every pair one of the flow-paths at random (proportional to its weight). Let $X_i(e)$ denote the random variable that describes whether the flow path for the i -th pair includes edge e . By design the above process guarantees $E[X_i(e)] = f_i(e)$, where $f_i(e)$ is the flow for pair i that goes through edge e . The total load on edge e is $\sum_i X_i(e)$. This is a sum of negatively correlated random variables with expectation $\mu = O(dC)$. Using Lemma 9 with $\delta = 3 \ln(m)/\mu$ gives that with constant probability, no edge exceeds load $O(dC + \log(m))$.

Therefore only $O(\deg(v)dC)$ paths traverse a vertex v (recall that $C \geq \log(m)$). For every path, we need to store the outgoing edge and the id of the paths on this edge. This requires $(\log_2(\deg(v)) + \log_2(dC))$ bits for every path and $O(d \deg(v)C \log(d \deg(v)C))$ bits in total. Multiplying with the height and using $d = \Theta(\log(m))$ gives $O(hC \log(m)(\log(\deg(v)) + \log \log(m) \deg(v))) = O(hC \log^2(m) \cdot \deg(v))$ bits.

75:10 Compact Oblivious Routing

The header- and label-length is analogous to Implementation A. We just use the root-to-leaf path in the tree as a label and a header consists of the source-label, the target-label, and a marker. ◀

In summary we derived the following result:

► **Theorem 10** (Compact Oblivious Routing for Uniform Capacities). *For arbitrary networks of uniform capacities, there exists an oblivious routing strategy which requires label and header length of $O(h \log(\deg(T)))$, and which comes in two flavors, depending on the decomposition tree used:*

- *Using the decomposition tree from [32] the scheme requires $O(hC \log^2(m) \deg(v)) = O(\log^5(n) \deg(v))$ bits at every vertex and guarantees a competitive ratio of $O(hC \log^2(n)) = O(\log^5(n))$ w.r.t. congestion.*
- *Using the decomposition tree from [21] the scheme requires $O(\log^2 m \log^2(n) \log \log n) \deg(v) = O(\log^4 n \log \log n) \deg(v)$ bits at every vertex and guarantees a competitive ratio of $O(\log^4(n) \log \log(n))$ w.r.t. congestion. The oblivious routing scheme can be constructed in polynomial time.*

3 Related Work

The drawbacks of *adaptive routing* have been discussed intensively in the literature, see e.g., [34] for a survey. In particular, adaptive routing schemes need global information about the routing problem in order to calculate the best paths, and even if it were possible to collect such information sufficiently fast, it can still take much time to compute a (near-)optimal solution to that problem (large linear programs may have to be solved).

One of the first and well-known results on *oblivious routing* is due to Borodin and Hopcroft [8] who showed that competitive oblivious routing algorithms require randomization, as deterministic algorithms come with high lower bounds: given an unweighted network with n nodes and maximum degree Δ , there exists a (permutation) routing instance such that the congestion induced by a given deterministic oblivious routing scheme is at least $\Omega(\sqrt{n}/\Delta^{3/2})$. This result was improved by Kakkamanis et al. [22] to a lower bound of $\Omega(\sqrt{n}/\Delta)$.

For randomized algorithms Valiant and Brebner [38] showed how to obtain a polylogarithmic competitive ratio for the hypercube by routing to random intermediate destinations. Räcke [32] presented the first oblivious routing scheme with a polylogarithmic competitive ratio of $O(\log^3 n)$ in general networks. The paper by Räcke was also the first to propose designing oblivious routing schemes based on cut-based *hierarchical decompositions*. However, Räcke's result is non-constructive in the sense that only an exponential time algorithm was given to construct the hierarchy. This approach has subsequently been used to obtain approximate solutions for a variety of cut-related problems that seem very hard on general graphs but that are efficiently solvable on trees, see e.g. [2, 3, 5, 10, 14, 23, 26, 33]. Polynomial-time algorithms for constructing the hierarchical decomposition were given by Bienkowski et al. [7] and Harrelson et al. [21]. However, none of these results provide an (asymptotically) optimal competitive ratio.

Azar et al. [4] gave a polynomial time algorithm that for a given graph computes the optimal oblivious routing via a linear programming approach, i.e., without using a hierarchical decomposition.

An optimal competitive ratio of $O(\log n)$ (which matches a known lower bound from grids [6, 30]) was first presented by Räcke [33]. Instead of considering a single tree to approximate the cut-structure of a graph G , [33] proposes to use a convex combination

of decomposition trees. The paper relies on multiplicative weight updates and the proof technique is similar to the technique used by Charikar et al. [9] for finding a probabilistic embedding of a metric into a small number of dominating tree metrics.

More recently, inspired by the ideas on cut matching games introduced by Khandekar, Rao, and Vazirani [24], Räcke et al. [35] presented a *fast* construction algorithm for hierarchical tree decompositions, i.e., for a single tree: given an undirected graph $G = (V, E, c)$ with edge capacities, a single tree $T = (V_T, E_T, c_T)$ can be computed whose leaf nodes correspond to nodes in G and which approximates the cut-structure of G up to a factor of $O(\log^4 n)$ (i.e., the faster runtime comes at the price of a worse approximation guarantee). In particular, the authors present almost linear-time cut-based hierarchical decompositions, by establishing a connection between approximation of max flow and oblivious routing. This overcomes the major drawback of earlier algorithms such as [21] and even [29] which required high running times for constructing the decomposition tree (or the distribution over decomposition trees). The bound has been improved further by Peng in [31].

Previous results on *compact routing* focus on routing strategies that aim to minimize the *path length* instead of the congestion (see e.g. [13, 27, 39]). There are two variants: *labeled* (the designer is free to name the nodes according to the topology and the edge weights of the graph) and *name-independent* (name determined by an adversary). The research community has derived many interesting results on compact shortest path routing on special graphs, e.g., characterizing hypercubes, trees, scale-free networks, and planar graphs [17, 18, 19, 28, 37]. A well-known recent result on compact routing in the name-independent model on *general graphs* is by Abraham et al. [1].

However, it is also known that it is impossible to implement shortest path routing with routing tables whose size in all network topologies grows slower than linear with the increase of the network size [16, 20]. As a resort, compact routing research studies algorithms to decrease routing table sizes at the price of letting packets to be routed along suboptimal paths. In this context, suboptimal means that the forwarding paths are allowed to be longer than the shortest ones, but the length increase is bounded by a constant stretch factor. A particularly interesting result is by Thorup et al. [37] who presented compact routing schemes for general weighted undirected networks, ensuring small routing tables, small headers and low stretch. The approach relies on an interesting shortest path routing scheme for trees of arbitrary degree and diameter that assigns each vertex of an n -node tree a label of logarithmic size. Given the label of a source node and the label of a destination it is possible to compute, in constant time, the port number of the edge from the source that heads in the direction of the destination. An interesting recent work by Retvari et al. [36] generalizes compact routing to arbitrary routing policies that favor a broader set of path attributes beyond path length. Using routing algebras, the authors identify the algebraic requirements for a routing policy to be realizable with sublinear size routing tables.

There also exist interesting works focusing on *scalable* oblivious traffic engineering, e.g., for confluent (per-destination) routing schemes [11, 12]. However, we are not aware of any results on compact oblivious routing which provides polylogarithmic approximation ratios along both dimensions, table size and congestion.

4 Conclusion

Given the fast growth of communication networks (e.g., due the advent of novel paradigms such as Internet-of-Things), the high costs of network equipment (e.g., fast memory is expensive and power hungry), as well as the increasing miniaturization of communication-

enabled devices, we in this paper initiated the study of oblivious routing schemes which only require small routing tables. In particular, we presented the first *compact* oblivious routing scheme, requiring polylogarithmic tables only (as well as polylogarithmic packet headers and vertex labels).

We believe that our work opens an interesting avenue for future research. In particular, while our algorithms provide poly-logarithmic routing tables and competitive ratios, it may be possible to further improve these results by logarithmic factors. Furthermore, it would be interesting to generalize our results to non-uniform network capacities, as well as to explore whether our results can be improved for special network topologies arising in practice.

Abstract

We consider the minimization of edge-crossings in geometric drawings of graphs $G = (V, E)$, i.e., in drawings where each edge is depicted as a line segment. The respective decision problem is \mathcal{NP} -hard [5]. Crossing-minimization, in general, is a popular theoretical research topic; see Vrt'o [26]. In contrast to theory and the topological setting, the geometric setting did not receive a lot of attention in practice. Prior work [21] is limited to the crossing-minimization in geometric graphs with less than 200 edges. The described heuristics base on the primitive operation of moving a single vertex v to its *crossing-minimal position*, i.e., the position in \mathbb{R}^2 that minimizes the number of crossings on edges incident to v .

In this paper, we introduce a technique to speed-up the computation by a factor of 20. This is necessary but not sufficient to cope with graphs with a few thousand edges. In order to handle larger graphs, we drop the condition that each vertex v has to be moved to its crossing-minimal position and compute a position that is only optimal with respect to a small random subset of the edges. In our theoretical contribution, we consider drawings that contain for each edge $uv \in E$ and each position $p \in \mathbb{R}^2$ for v $o(|E|)$ crossings. In this case, we prove that with a random subset of the edges of size $\Theta(k \log k)$ the *co-crossing* number of a degree- k vertex v , i.e., the number of edge pairs $uv \in E, e \in E$ that do *not* cross, can be approximated by an arbitrary but fixed factor δ with high probability. In our experimental evaluation, we show that the randomized approach reduces the number of crossings in graphs with up to 13 000 edges considerably. The evaluation suggests that depending on the degree-distribution different strategies result in the fewest number of crossings.

1 Introduction

The minimization of crossings in geometric drawings of graphs is a fundamental graph drawing problem. In general the problem is \mathcal{NP} -hard [5, 13] and has been studied from numerous theoretical perspectives; see Vrt'o [26]. Until recently only the topological setting, where edges are drawn as topological curves, has been considered in practice [6, 8, 14]. In our previous paper [21] we describe geometric heuristics that compute straight-line drawings of graphs with significantly fewer crossings compared to common energy-based layouts. One of the heuristics is the *vertex-movement approach* that iteratively moves a single vertex v

to its *crossing-minimal position*, i.e., a position p^* so that crossings of edges incident to v are minimized. Unfortunately, the worst-case running time to compute this position is super-quadratic in the size of the graph as the following theorem states.

► **Theorem 1** (Radermacher et al. [21]). *The crossing-minimal position of a degree- k vertex v with respect to a straight-line drawing Γ of a graph $G = (V, E)$ can be computed in $O((kn + m)^2 \log(kn + m))$ time, where $n = |V|, m = |E|$.*

This is not only a theoretical upper bound on the running time but is also a limitation that has been observed in practice. The implementation we used previously requires considerable time to compute drawings with few crossings. For this reason we were only able to evaluate our approach on graphs with at most 200 edges. For example, on a class of graphs that have 64 vertices and 196 edges our implementation already required on average about 35 seconds to compute a drawing with few crossings.

Energy-based methods are common and well engineered tools to draw graphs [16]. For example, the aim of *Stress Majorization* (or simply STRESS) is to compute a drawing such that the Euclidean distance of each two vertices corresponds to their graph-theoretical distance [12]. The algorithm has been engineered to handle graphs with up to 10^6 vertices and $3 \cdot 10^6$ edges [19]. Kobourov [16] claimed that STRESS tends to minimize the number of crossings. In our previous experimental evaluation [21] we demonstrated that the statement is not true for a varied set of graph classes.

Fabila-Monroy and López [11] introduced a randomized algorithm to compute a drawing of K_n with a small number of crossings. Many best known upper bounds on the rectilinear crossing number of K_n , for $44 \leq k \leq 99$, are due to this approach [1]. The algorithm iteratively updates a set P of n points, by replacing a random point $p \in P$ by a random point q that is close to p , if q improves the number of crossings. Since the number of crossings of K_n is in $\Theta(n^4)$, the bottleneck of their approach is the running time for counting the number of crossings induced by P . A similar randomized approach has been used to maximize the smallest crossing angle in a straight-line drawing [3, 10]. The approach iteratively moves vertices to the best position within a random point set.

Contribution. The main contribution of this paper is to engineer the *vertex-movement approach* for the minimization of crossings in geometric drawings described in [21] to be applicable on graphs with a few thousands vertices and edges.

1. In Section 3 we introduce so-called *bloated duals of line arrangements*, a combinatorial technique to construct a dual representation of general line arrangements. In our application this results in an overall speed-up of about a factor of 20 in comparison to the recent implementation. This speed-up is necessary but not sufficient to handle graphs with a few thousands vertices and edges.
2. In Section 4 we demonstrate that taking a small random subset of the edges is sufficient to compute drawings with few crossings. Moreover, in Section 4.1 we prove that under certain conditions the randomized approach is an approximation of the co-crossing number of a vertex, with high probability.
3. Based on the insights of the evaluation in Section 4.2, we introduce a weighted sampling approach. A comparison to a restrictive approach of sampling points suggests that the degree-distribution of the graph is a good indicator to decide which approach results in fewer crossings.
4. Overall, our experimental evaluation shows that we are now able to handle graphs with 12 000 edges, which are 60 times more than the graphs that have been considered in the evaluation in [21].

■ **Figure 1** The black, blue and red segments show the arrangement $\mathcal{A}(\Gamma, v)$ of the black drawing Γ . The blue and red region show the complement of the visibility regions of u_1 and u_2 , respectively, and the edge e . The green region is crossing minimal.

2 Preliminaries

We repeat some notation from [21]. Let Γ be a straight-line drawing of a $G = (V, E)$. Denote by $N(v) \subseteq V$ the set of neighbors of v and by $E(v) \subseteq E$ the set of edges incident to v . For a vertex $v \in V$, denote by $\Gamma[v \mapsto p]$ the drawing that is obtained from Γ by moving the vertex v to the point p . We denote the number of crossings in a drawing Γ by $\text{cr}(\Gamma)$, the number of crossings on edges incident to v by $\text{cr}(\Gamma, v)$, and we refer with $\text{cr}(\Gamma, e, f)$ to the number of crossings on two edges e and f in Γ , i.e., $\text{cr}(\Gamma, e, f) \in \{0, 1\}$ if $e \neq f$. For a point u and a segment e , denote by $\mathcal{VR}(u, e)$ the *visibility region of u and e* , i.e., the set of points $p \in \mathbb{R}^2$ such that the segment up and e do not intersect. Moreover, let $\mathcal{BD}(u, e)$ be the boundary of $\mathcal{VR}(u, e)$. Let $\mathcal{A}(\Gamma, v)$ be the arrangement over all boundaries $\mathcal{BD}(u, e)$ for each neighbor $u \in N(v)$ of v and each edge $e \in E \setminus E(u)$; see Figure 1. The arrangement has the property that two points p and q in a common cell of $\mathcal{A}(\Gamma, v)$ induce the same number of crossings for v , i.e., $\text{cr}(\Gamma[v \mapsto p], v) = \text{cr}(\Gamma[v \mapsto q], v)$ [21]. Thus, the computation of a crossing minimal position p^* reduces to finding a *crossing-minimal region f^** in $\mathcal{A}(\Gamma, v)$.

For our experiments, we used two different compute servers. Both systems ran with an openSUSE Leap 15.0 operating system. All algorithms were compiled with `g++` version 7.3.1 with optimization mode `-O3`. System 1 was used for running time experiments, i.e., for the experiments evaluated in Section 3.1 and in Section 4.2. System 2 is used for the experiments evaluated in Section 4.3.

System 1 Intel Xeon(tm) E5-1630v3 processor clocked at 3.7 GHz, 128 GB RAM.

System 2 Two Intel Xeon(tm) E5-2670 CPU processors clocked at 2.6 GHz, 64 GB RAM.

3 Efficient Implementation of the Crossing-Minimal Position

The vertex-movement approach iteratively moves a single vertex to its crossing-minimal position. The running time of the overall algorithm crucially depends on an efficient computation of this operation. Therefore the aim of this section is to provide an efficient implementation of the crossing-minimal position of a vertex. Our previous implementation [21] heavily relies on CGAL [24], which follows an exact computations paradigm and uses exact number types to, e.g., represent coordinates and intermediate results. This helps to ensure correctness but considerably increases the running time of the algorithms. We introduce an approach to compute the crossing-minimal position that drastically reduces the usage of exact computations.

Computing a crossing-minimal position of a vertex v is equivalent to computing a crossing-minimal region f^* in the arrangement $\mathcal{A}(\Gamma, v)$. The region f^* of a vertex v can be computed by a breadth-first search in the dual graph $\mathcal{A}(\Gamma, v)^*$. Thus, the time-consuming steps to

■ **Figure 2** (a) Bloated dual \mathcal{A}^+ (blue) of an arrangement \mathcal{A} (black). Inserting edges dual to a segment s (b) and within a face (c).

compute f^* are to construct the arrangement $\mathcal{A}(\Gamma, v)$ and then to build the dual $\mathcal{A}(\Gamma, v)^*$. Instead of computing the dual $\mathcal{A}(\Gamma, v)^*$ we construct a so-called *bloated dual* $\mathcal{A}(\Gamma, v)^+$. The advantage of this approach is that it suffices to compute the set of intersecting segments in $\mathcal{A}(\Gamma, v)$ to construct $\mathcal{A}(\Gamma, v)^+$ and it is not necessary to compute the arrangement $\mathcal{A}(\Gamma, v)$ itself, i.e., the exact coordinates of each intersection.

Let S be a set of line segments and let \mathcal{A} be the arrangement of S . A *bloated dual* of \mathcal{A} is a graph \mathcal{A}^+ that has the following properties (compare Figure 2a):

- (i) each edge e incident to a face f corresponds to a vertex v_e^f in \mathcal{A}^+ ,
- (ii) if two distinct segments $s, s' \in S$ of f have a common intersection on the boundary of f , then $v_s^f v_{s'}^f \in E(\mathcal{A}^+)$, and
- (iii) for two distinct faces f, g sharing a common segment s , there is an edge $v_s^f v_s^g \in E(\mathcal{A}^+)$.

Note that given a crossing-minimal face and $v_{s_0}^f$, the geometric representation of f has to be computed in order to compute a crossing-minimal position $p \in f$. Further a vertex $v_{s_0}^f$ belongs to a cycle $v_{s_0}^f, v_{s_1}^f, \dots, v_{s_k}^f$. Then, the geometric representation of the boundary of f can be computed by intersecting the segments s_i and s_{i+1} , where we set $k+1=0$. In the following, we will show that it is sufficient to know the order in which the segments in S intersect to construct the bloated dual. Thus, exact number types only have to be used to determine the order of two segments whose intersections with a third segment s have a small distance on s .

We construct the bloated dual of \mathcal{A} in two steps. First, we insert all vertices v_s^f, v_s^g and the corresponding edge $v_s^f v_s^g$. In the second step, we insert the remaining edges $v_s^f v_{s'}^f$ within a face f . For a compact description we assume that no intersection point of two segments is an endpoint of a segment. We define the *source* of s and *target* of s to be the lexicographically smallest and largest point on s , respectively. We direct each segment s from its source to its target.

Let p_1, p_2, \dots, p_l be the intersection points on a segment s in lexicographical order. These intersection points correspond to a set of left faces $f_1^L, f_2^L, \dots, f_{l+1}^L$ and to a set of right faces $f_1^R, f_2^R, \dots, f_{l+1}^R$, such that f_i^L and f_i^R share parts of their boundary; see Figure 2b. Thus, we can associate a set of vertices $v_i^L, v_i^R, 2 \leq i \leq l+1$, with s , and add the edges $v_i^L v_i^R$ to \mathcal{A}^+ . Note that only the order and not the actual coordinates of the points p_1, \dots, p_l has to be known to insert the edges. Thus, given the set of segments that intersect s , an exact number type is only necessary to determine the order of two segments s_i and s_j whose intersection points p_i and p_j on s have a small distance.

We now add the remaining edges within a face f . Let $S' = \{s_1, \dots, s_k\} \subseteq S$ be the set of segments that intersect s in p_i ; see Figure 2c. The two segments $s^L, s^R \in S'$ that lie on the boundary of f_i^L and f_i^R can be determined as follows. To find the segment s^L , we

■ **Figure 3** Comparing the running time of two approaches (orange PRECISE, blue BD) to compute the crossing minimal region. Each point corresponds to a graph G . The x -axis shows the number of edges of G . The y -axis depicts the running time in seconds to compute the crossing minimal regions for all vertices of G .

distinguish two cases. First, assume that there exists a segment $s' \in S'$ whose source is left of s . Observe that if there is a segment s'' whose target is left of s , the segment s'' cannot be the segment s^L . Thus, we assume without loss of generality that all sources of segments in S'_s are left of s . Then a segment $s' \in S'$ is the segment s^L if and only if the segment s' and each segment $s'' \in S' \setminus \{s'\}$ form a right turn. Now consider the case that there is no segment whose source is left of s . Then a segment s' is s^L if and only if the segment s' and each segment $s'' \in S' \setminus \{s'\}$ form a left turn. The segment s^R can be determined analogously.

Implementation Details. We give some implementation details which allow us to efficiently implement the construction of the bloated dual. We use the index of a vertex to decide whether it is left or right of s , i.e., vertices with an odd index are left of s and vertices with an even index are right of s . The fact that each vertex of \mathcal{A}^+ has degree at most 3 allows us to represent \mathcal{A}^+ as a single array B of size $3n$, where n is the number of vertices of \mathcal{A}^+ . The vertices incident to a vertex v_i occupy the cells $B[3i]$, $B[3i+1]$ and $B[3i+2]$. Moreover, each pair of segments in S can be handled independently to construct the bloated dual. This enables a parallelization over the segments in S .

3.1 Evaluation of the Running Time

In this section, we compare the running time of the two approaches to compute the crossing-minimal region of a vertex. We refer with PRECISE to the approach that uses CGAL to compute the crossing minimal region and with BD to the approach based on the bloated dual. In order to compute all intersecting segments, we use a naive implementation of a sweep-line algorithm [4]. In this approach all segments within a specific interval are pairwise checked for an intersection. This has the advantage that the computation is independent of the coordinates of the intersection.

The experimental setup is as follows. Given a drawing Γ of a graph G , we are interested in the running time of moving all vertices of a graph to their crossing-minimal positions. Therefore, we measure the running time of computing the crossing-minimal regions of all vertices. In order to guarantee the comparability of the two approaches, we use the same vertex order and only compute the crossing-minimal region but do not update the positions of the vertices. We use the same set of benchmark graphs used in [21]: NORTH¹, ROME¹, graphs

¹ <http://graphdrawing.org/data.html>

■ **Figure 4** The x -axis shows the vertex-degree and the y -axis the number of intersecting edges in the arrangement $\mathcal{A}(\Gamma, v)$. The y -axis is in log-scale.

that have COMMUNITY structure, and TRIANGULATIONS on 64 vertices with an additional 10 random edges. For each graph class, 100 graphs were selected uniformly at random. We use the implementation of STRESS [12] provided by OGDF [7] (snapshot 2017-07-23) to compute an initial layout of the graphs.

The plots in Figure 3 shows the results of the experiments. Each point in the plot corresponds to the running time of computing all crossing-minimal region of a single graph. The plot shows that the BD implementation is considerably faster than the PRECISE implementation. For each graph class, we achieve on average a speed-up of at least 20. The minimum speed-up on the NORTH graphs is 8. For each graph class, the speed-up is at least 18 for at least 75 out of 100 instances.

4 Random Sampling

The worst-case running time of computing the crossing-minimal region of a vertex v is super-quadratic in the size of the graph, see Theorem 1. Figure 4 shows the number of intersecting segment in the arrangement $\mathcal{A}(\Gamma, v)$ compared to the vertex-degree of v , for vertices of three selected graphs with at most 2 133 edges, compare Table 1. For these graphs the arrangement already contains up to 440 685 519 intersecting segments. Indeed, we were not able to compute the number of intersections for all vertices of the graph c.metabolic, since the algorithm ran out of memory first. Due to the high number of intersections in graphs with a high number of edges or a large maximum vertex-degree, it is for these graphs infeasible to compute a crossing-minimal position of a vertex. This motivates the following question: Is a small subgraph of G sufficient to considerably reduce the number of crossings in a given drawing?

To address this question, we follow the *vertex-movement approach*. Let Γ_0 be a drawing of G and let v_1, v_2, \dots, v_n be an ordered set of the vertices V of G . For each vertex v_i we obtain a new drawing Γ_i from the drawing Γ_{i-1} by moving v_i to a new position p_i^* . To compute the new position we consider a *primal* sampling approach, i.e., a sampling of points in the solution space \mathbb{R}^2 , and a *dual* sampling approach, i.e., a sampling of edges that induce constraints to the solution space.

More formally, we consider the following approach to compute a new position of a single vertex v_i . Let $S_i \subset E$ be a uniform random subset of the edges of G and let $V(S_i) \subset V$ be the vertices that are incident to an edge in S_i . The graph $G|_{S_i} = (V(S_i) \cup N(v_i) \cup \{v_i\}, S_i \cup E(v_i))$ induces a drawing $\Gamma|_{S_i}$ in Γ_{i-1} . Let R_i be the crossing-minimal region of v_i with respect to the drawing $\Gamma|_{S_i}$. Recall that for $S_i = E$ the region R_i has the property that $\text{cr}(\Gamma|_{S_i}[v_i \mapsto$

$p], v_i) = \text{cr}(\Gamma|_{S_i}[v_i \mapsto q], v_i)$ for any two points $p, q \in R_i$, compare Section 2. If S_i is a strict subset of E , then R_i does not necessarily have this property anymore. For this reason, let $P_i \subset R_i$ be a set of uniform random points and let $p_i^* \in P_i \cup \{p_i'\}$ be the point that minimizes $\text{cr}(\Gamma[v \mapsto p_i^*], v_i)$, where p_i' is the position of v_i in Γ_{i-1} .

This remainder of this section is organized as follows. First, we analyze the dual sampling from a theoretical perspective (Section 4.1), followed by an experimental evaluation that compares the primal to the dual sampling (Section 4.2). Finally, based on the insights from this evaluation, we introduce in Section 4.3 a *weighted* sampling approach that is less restrictive than the dual sampling.

4.1 Approximating the Co-Crossing Number of a Vertex

In this section we study the dual sampling approach, i.e., the sampling of edges, with tools introduced in the context of the theory of VC-dimension. A thorough introduction into the theory of VC-dimension can be found in Matoušek's *Lectures on Discrete Geometry* [18]. For a fixed vertex v , a drawing Γ is ε -well behaved if for each point $p \in \mathbb{R}^2$ and each vertex $u \in N(v)$, the edge uv crosses at most $(1 - \varepsilon)|E|$ edges in the drawing $\Gamma[v \mapsto p]$. The *co-crossing number* $\text{co-cr}(\Gamma, v)$ of a vertex v is the number of edge pairs $e \in E$ and $uv \in E$ that do not cross. We show that given an ε -well-behaved drawing Γ of a graph $G = (V, E)$ and a degree- k vertex v , a random sample $S \subset E$ of size $\Theta(k \log k)$ enables us to compute a position q^* whose co-crossing number is a $(1 - \delta)$ -approximation of the co-crossing number of a vertex v . Note that we are not able to guarantee that a large co-crossing number of a vertex v implies a small crossing number of v . On the other hand, the co-crossing number is of interest for a variety of (sparse) graph. For example, drawings that contain many triangles are ε -well-behaved, since every line intersects at most two segments of a triangle.

A *set system* is a tuple (X, \mathcal{F}) with a base set X and $\mathcal{F} \subseteq 2^X$. In the following, we assume X to be finite. For some parameters $\varepsilon, \delta \in (0, 1]$, a set $S \subseteq X$ is a *relative (ε, δ) -approximation* for the set system (X, \mathcal{F}) if for each $R \in \mathcal{F}$ the following inequality holds.

$$\left| \frac{|S \cap R|}{|S|} - \frac{|R|}{|X|} \right| \leq \delta \max\left\{ \frac{|R|}{|X|}, \varepsilon \right\} \quad (1)$$

The proof of the following proposition and of proofs of statements that are marked with (\star) can be found in the appendix of the full version.

► **Proposition 2** (\star) . For $\varepsilon, \delta \in (0, 1]$, let S be an (ε, δ) -approximation of the set system (X, \mathcal{F}) . If every $R \in \mathcal{F}$ has size at least $\varepsilon|X|$ then Equation (1) can be rewritten as follows:

$$(1 - \delta)|R| \leq |X| \frac{|S \cap R|}{|S|} \leq (1 + \delta)|R|.$$

Let $\mathcal{F}|_A = \{R \cap A \mid R \in \mathcal{F}\}$ be the restriction of \mathcal{F} to a set $A \subseteq X$. A set $A \subseteq X$ is *shattered* by \mathcal{F} if every subset of A can be obtained by an intersection of A with a set $R \in \mathcal{F}$, i.e., $\mathcal{F}|_A = 2^A$. The *VC-dimension* of a set system (X, \mathcal{F}) is the size of the largest subset $A \subseteq X$ such that A is shattered by \mathcal{F} [25].

► **Theorem 3** (Har-Peled and Sharir [15], Li et al. [17]). Let (X, \mathcal{F}) be a finite set system with VC-dimension d , and let $\delta, \varepsilon, \gamma \in (0, 1]$. A uniform random sample $S \subseteq X$ of size

$$\Theta\left(\frac{d \cdot \log \varepsilon^{-1} + \log \gamma^{-1}}{\varepsilon \delta^2}\right)$$

is a relative (ε, δ) -approximation for (X, \mathcal{F}) with probability $(1 - \gamma)$.

For a vertex $u \in N(v)$, let $\overline{\mathbb{E}_{uv}(\Gamma)} = \{e \in E \mid \text{cr}(\Gamma, e, uv) = 0\}$ denote the set of edges that are not crossed by the edge uv in Γ . Then we have $\text{co-cr}(\Gamma, v) = \sum_{u \in N(v)} |\overline{\mathbb{E}_{uv}(\Gamma)}|$. Moreover, let $\overline{\mathbb{E}_{uv}(p)} = \overline{\mathbb{E}_{uv}(\Gamma[v \mapsto p])}$. Then the set $\overline{\mathcal{F}_{uv}} = \bigcup_{p \in \mathbb{R}^2} \{\overline{\mathbb{E}_{uv}(p)}\}$ contains for each drawing $\Gamma[v \mapsto p]$ the set of edges that are not crossed by the edges uv , i.e., $\overline{\mathbb{E}_{uv}(p)}$. In particular $(E, \overline{\mathcal{F}_{uv}})$ is a set system and we will prove that it has bounded VC-dimension. This allows us to approximate the number of edges that are not crossed by the edge uv . We facilitate this to approximate the co-crossing number of a vertex for ε -well behaved drawings.

► **Lemma 4.** *The VC-dimension of the set system $(E, \overline{\mathcal{F}_{uv}})$ is at most 8.*

Proof. Recall that that vertex u has a fixed position. Let $\mathcal{BD}(u, e)$ be the boundary of the visibility region of u and the edge $e \in E$. Let \mathcal{A} denote the arrangement of all boundaries $\mathcal{BD}(u, e), e \in E$. Let F be the set of faces in \mathcal{A} . Note that by Lemma 3.1 in [21] for every two points $p, q \in f$ the sets E_p and E_q of edges that have a non-empty intersection with the edge uv when v is moved to p and q , respectively, coincide. Hence, the set $E_f \subseteq E$ of edges that cross the edge uv , in the drawing obtained from Γ where v is moved to an arbitrary position in f , is well defined. Thus, the number of faces $|F|$ is an upper bound for $|\overline{\mathcal{F}_{uv}|_A}$ for every $A \subseteq E$. Note that there may be subsets of E that are represented by more than one face. Moreover, observe that the visibility region $\mathcal{VR}(u, e)$ is the intersection of three half-planes. Let l_e^1, l_e^2, l_e^3 be the supporting lines of these half-planes and let \mathcal{A}' be the arrangement of lines $l_e^i, e \in E$. Hence, the number of faces in the arrangement \mathcal{A}' of $3m$ lines is an upper bound for $|F|$, with $m = |E|$. The number of faces $|F'|$ of \mathcal{A}' is bounded by $f(m) := 3m(3m - 1)/2 + 1$ [20]. Thus, it is not possible to shatter a set $A \subseteq E$ if the number of faces $|F'|$ is smaller than the number of subsets of A . The largest number for which the equality $2^m \leq f(m)$ holds is between 8 and 9. Since 2^m grows faster than $f(m)$, the largest set that can possibly be shattered has size at most 8. ◀

Due to Proposition 2 and Theorem 3 a relative (ε, δ) -approximation S_u of $(E, \overline{\mathcal{F}_{uv}})$ allows us to approximate the number of edges that are not crossed by the edge uv . In the following we show that we can approximate the co-crossing number of a vertex v in any drawing $\Gamma[v \mapsto p]$ if we are given a relative (ε, δ) -approximation S_u for each vertex u that is adjacent to v . The number $|\overline{\mathbb{E}_{uv}(p)} \cap S_u|/|S_u|$ corresponds to the relative number of edges in S_u that are not crossed by the edge uv . Hence, the function $\lambda(p) = |E| \sum_{u \in U} |\overline{\mathbb{E}_{uv}(p)} \cap S_u|/|S_u|$ can be seen as an estimation of $\text{co-cr}(p) = \text{co-cr}(\Gamma[v \mapsto p], v)$.

► **Lemma 5** (\star). *Let $\varepsilon, \delta \in (0, 1]$ be two parameters and let Γ be an ε -well behaved drawing of G . For every $u \in N(v)$, let S_u be a relative (ε, δ) -approximation of the set system $(E, \overline{\mathcal{F}_{uv}})$. Then $(1 - \delta) \text{co-cr}(p) \leq \lambda(p) \leq (1 + \delta) \text{co-cr}(p)$ holds for all $p \in \mathbb{R}^2$.*

Assume that $\varepsilon, \delta, \gamma \in (0, 1)$ are constants. Lemma 5 shows that k independent samples S_u of constant size approximate the co-crossing number of v . By slightly increasing the number of samples, we can use a single set S for all neighbors u . This reduces the running time from $O(k^3 \log k)$ to $O(k^2 \log^3 k)$.

► **Lemma 6** (\star). *Let v be a degree- k vertex and let $\varepsilon, \delta, \gamma \in (0, 1]$ with $\gamma \leq 1/k$. A uniformly random sample $S \subseteq E$ of size $\Theta((\log \varepsilon^{-1} + \log \gamma^{-1})/(\varepsilon \delta^2))$ is a relative (ε, δ) -approximation of the set system $(E, \overline{\mathcal{F}_{uv}})$ with probability $1 - k\gamma$, for each $uv \in E$.*

With Lemma 5 and Lemma 6 at hand, we have all the necessary tools to prove the main theorem.

► **Theorem 7.** *Let $\varepsilon, \delta, \gamma \in (0, 1]$ be three constants and let $G = (V, E)$ be a graph with a ε -well behaved drawing Γ and let $v \in V$ be a degree- k vertex. Let p^* be the position that maximizes $\text{co-cr}(\Gamma[v \mapsto p^*], v)$. A $(1 - \delta)$ -approximation of $\text{co-cr}(\Gamma[v \mapsto p^*])$ can be computed in $O(k^2 \log^3 k)$ time with probability $1 - \gamma$.*

Proof. Let $\gamma' = \gamma \cdot k^{-1}$ and $\delta' = \delta/2$. Let $S \subseteq E$ be a uniformly random sample of size $\Theta((\log \varepsilon^{-1} + \log \gamma'^{-1})/(\varepsilon \delta'^2))$. According to Lemma 6, for each $uv \in E$, the sample S is a (ε, δ') -approximation of the $(E, \overline{\mathcal{F}}_{uv})$ with probability $1 - k\gamma' = 1 - \gamma$.

According to Lemma 5 the expected number of crossing-free edges $\lambda(p)$ is a $(1 - \delta)$ -approximation of $\text{co-cr}(p)$, i.e., $(1 + \delta') \text{co-cr}(q) \geq \lambda(q) \geq (1 - \delta') \text{co-cr}(q)$. Let p^* be the position that maximizes $\text{co-cr}(p)$ and let q^* be the position that maximizes $\lambda(q)$. Hence, we have $\lambda(q^*) \geq \lambda(p^*)$. Observe that over $\delta' > 0$ the inequality $(1 - \delta')/(1 + \delta') \geq 1 - 2\delta'$ holds. We use this to prove that $\text{co-cr}(q^*) \geq (1 - 2\delta') \text{co-cr}(p^*)$.

$$\text{co-cr}(q^*) \geq \frac{1}{(1 + \delta')} \lambda(q^*) \geq \frac{1}{(1 + \delta')} \lambda(p^*) \geq \frac{1 - \delta'}{1 + \delta'} \text{co-cr}(p^*) \geq (1 - 2\delta') \text{co-cr}(p^*)$$

Plugging in the value $\delta/2$ for δ' yields that $\text{co-cr}(q^*)$ is a δ -approximation of $\text{co-cr}(p^*)$. Since the three parameters $\varepsilon, \delta, \gamma$ are constants, the size of the sample S is in $\Theta(\log k)$. Recall that the running time to compute the crossing-minimal position of v in a drawing Γ is $O((kn + m)^2 \log(kn + m))$ (Theorem 1). Thus the position q^* can be computed in $O(k \log k + \log k)^2 \log(k \log k + \log k)$ time, since $m = |S| \in \Theta(\log k)$ and $n \leq 2m$. The following estimation concludes the proof.

$$O(k^2 \log^2 k \log(k \log k)) = O(k^2 \log^2 k \log(k^2)) = O(k^2 \log^3 k) \quad \blacktriangleleft$$

Note that the previous techniques can be used to design a δ -approximation algorithm for the crossing number of a vertex. But this requires drawings of graphs where at least $\varepsilon|E|$ edges, i.e., $\Omega(|E|)$, are crossed. This restriction is not too surprising, since sampling the set of edges can result in an arbitrarily bad approximation for a vertex whose crossing-minimal position induces no crossings.

4.2 Experimental Evaluation

In this section we complement the theoretical analyses of the random sampling of edges with an experimental evaluation. We first introduce our benchmark instances, followed by a description of a preprocessing step to reduce trivial cases and a set of configurations that we evaluate.

Benchmark Instances. We evaluate our algorithm on graphs from three different sources.

DIMACS The graphs from this classes are selected from the 10th DIMACS Implementation Challenge - Graph Partitioning and Graph Clustering [2].

Sparse MC Inspired by the selection of benchmark graphs in [19], we selected a few arbitrary graphs from the Suite Sparse Matrix Collection (formerly known as the Florida Sparse Matrix Collection) [9].

k -regular For each $k = 3, 6, 9$ we computed 25 random k -regular graphs on 1000 vertices following the model of Steger and Wormald [23].

Preprocessing. Some of the benchmark graphs contain multiple connected components. Moreover, we observed that the STRESS layout introduces crossings with edges that are incident to a degree-1 vertex. In both cases, these crossings can be removed. Therefore, we

reduce the benchmark instances so that they do not contain these trivial cases as follows. First, we evaluate only the connected component G_C of each graph G that has the highest number of vertices. Further, we iteratively remove all vertices of degree 1 from G_C .

The vertex-movement approach takes an initial drawing of a graph as input. Note that the experimental results in [21] showed that drawings obtained with STRESS have the smallest number of crossings compared to other energy-based methods implemented in OGDF. In order to avoid side effects, we first computed a random drawing for each graph G_C where each coordinate is chosen uniformly at random on a grid of size $m \times m$. Afterwards we applied the STRESS method implemented in OGDF [7] (snapshot 2017-07-23) to this drawing.

Configurations. The previously described approach moves the vertices in a certain order. We use the order proposed in [21], i.e, in descending order with respect to the function $\text{cr}(\Gamma_0, v_i)^2, v_i \in V$, where Γ_0 is the initial drawing. The computation of the new position p_i^* of a vertex v_i depends on three parameters $(|S_i|, |P_i|, K)$. The parameter K is a threshold on the degree k_i of v_i , since we observed in our preliminary experiments, that in case that k_i is large, 128 GB of memory are not sufficient to compute the crossing-minimal region. Note that in case that $|S_i|$ is constant the running time to compute R_i is $O((k_i \cdot n')^2 \log n') = O(k_i^2)$, where $n' = |V(S)| \in O(|S|)$. We handle vertices of degree larger than K , as follows. Let $N_1 \cup \dots \cup N_l$ be a partition of the neighborhood $N(v)$ of v with $l = \lfloor |N(v)|/K \rfloor$. Further, let u_1, u_2, \dots, u_k be a random order of $N(v)$, then N_j contains the vertices u_a with $j \leq a \leq j+K$. For each j , we compute a random sample S_i^j and a crossing-minimal position q_j^* of vertex v with neighborhood N_j with respect to S_i^j . The new position p_i^* of v_i is the position that minimizes $\text{cr}(\Gamma[v_i \mapsto q_j^*], v_i)$.

We select the same parameters for each vertex and thus denote the triple by $(|S|, |P|, K)$. We expect that with an increasing number $|S|$ the number of crossings decreases. The sample size $|S| = 512$, was the largest number of samples such that we are able to compute a final drawing of our benchmark instances in reasonable time. As a baseline we sample 1000 points in the plane. Thus, we evaluate the following two configuration, $\mathcal{S}_{512} = (512, 1, 100)$ and $\mathcal{S}_0 = (0, 1000, \infty)$. Finally, we restrict the movement of a single vertex to be within an axis-aligned square that is twice the size of the smallest axis-aligned squares that entirely contains Γ_0 .

Evaluation. Table 1 lists statistics for the DIMACS and the SPARSE MC graphs. In particular the number of crossings of the initial drawing (STRESS) and the drawing obtained by the \mathcal{S}_{512} and \mathcal{S}_0 configurations. Furthermore, we report the running times for the two configurations. Since we use an external library (OGDF) to compute the initial drawing, the reported times do not include the time to compute the initial drawing. Note that STRESS required at most 0.9 min to complete on the DIMACS graph and 2.3 min on the SPARSE MC graphs. Since the size of the arrangement $\mathcal{A}(\Gamma, v)$ depends on the degree of v , the overall running time varies with the number of vertices and the average degree. Compare, e.g., c.metabolic to c.neural, or mk9-b2 to bcsstk08. Moreover, the commanche graph shows that the running time of \mathcal{S}_0 is not necessarily smaller than the running time of \mathcal{S}_{512} . For each point $p \in P$ the number of crossings of edges incident to v in $\Gamma[v \mapsto p]$ have to be counted. Since the commanche graph contains over 11 000 edges, the \mathcal{S}_{512} configuration with $|P| = 1$ is faster than the \mathcal{S}_0 configuration, which has to count the number of crossings for 1 000 points.

Now consider the number of crossings in the initial drawing (STRESS) and in the drawing obtained by the \mathcal{S}_{512} configuration. Since we move a vertex only if it decreases its number of crossings, it is expected that the number of crossings decreases on all graphs. For most

graphs, the \mathcal{S}_{512} configuration decreases the number of crossings by over 30%. In case of the ch7-6-b1 and the netscience graph the number of crossings are even decreased by over 60%. Exceptions are the bcsstk08, power and commanche graphs with 24%, 10% and 1.4% respectively. Comparing the number crossings obtained by \mathcal{S}_{512} to the configuration \mathcal{S}_0 , \mathcal{S}_0 results in fewer crossings only on two graphs (power, commanche).

Observe that the power, 11138_bus, ch7-6-b1 and commanche graphs all have an average vertex-degree of roughly 3.0. The comparison of the number of crossing obtained by \mathcal{S}_{512} and \mathcal{S}_0 is not conclusive, since \mathcal{S}_0 yields fewer crossings on the power and commanche graphs and \mathcal{S}_{512} on the remaining two. In order to be able to further study the effect of the (average) vertex degree we evaluate the number of crossings of k -regular graphs. We use the plots

■ **Figure 5** Number of crossings of the k -regular graphs.

in Figure 5 for the evaluation. Each point (x_G, y_G) corresponds to a k -regular graph G . The color encodes the vertex-degree. Let Γ_A and Γ_B be two drawings of G obtained by an algorithm A and B , respectively. The x -value x_G corresponds to the number of crossings in Γ_A in thousands, i.e., $\text{cr}(\Gamma_A)/1000$. The y -value y_G is the quotient $\text{cr}(\Gamma_B)/\text{cr}(\Gamma_A)$. The titles of the plots are in the form (A, B) and encode the compared algorithms. For example in Figure 5a algorithm A is STRESS and B is \mathcal{S}_0 . For example, the STRESS drawings of the 3-regular graphs have on average 12 487 crossings. Drawings obtained by \mathcal{S}_0 have on average 17% less crossings, i.e., 10 402. On the other hand, \mathcal{S}_{512} decreases the number of crossings on average by 20%. For $k = 6, 9$, \mathcal{S}_0 and \mathcal{S}_{512} both reduce the number of crossings by 25%. In particular, Figure 5c shows that for $k = 6, 9$ it is unclear, whether \mathcal{S}_{512} or \mathcal{S}_0 computes drawings with fewer crossings.

4.3 Weighted Sampling

For some graphs, the previous section gives first indications that sampling a set of edges yields a small number of crossings compared to a pure sampling of points in the plane. In particular Figure 5c indicates that the edge-sampling approach does not always have a clear advantage over sampling points in the plane. One reason for this might be that sampling within the set of points P_i in the region R_i is too restrictive. Observe that the region R_i is only crossing-minimal with respect to the sample S and does not necessarily contain the crossing-minimal position p_i^* of the vertex v_i with respect to all edges E . On the other hand, sampling the set of points P_i in \mathbb{R}^2 does not use the structure of the graph at all. This motivates the following *weighted* approach of sampling points in \mathbb{R}^2 .

For a set $S \subset E$, let cr_j be the number of crossings of the vertex v_i with respect to $\Gamma|_S$, when v_i is moved to a cell c_j of the arrangement $\mathcal{A}(\Gamma|_S, v_i)$. Let M be the maximum of all cr_j . We select a cell c_j with the probability $2^{M-\text{cr}_j} / \sum_k 2^{M-\text{cr}_k}$. Within a given cell, we draw a point uniformly at random. Note that in case that there are exactly n cells such that cell c_j induces j crossings, the probability that the cell c_0 is drawn converges to $1/2$ for $n \rightarrow \infty$.

Benchmark Instances, Preprocessing & Methodology. We use the same benchmark set and the same preprocessing steps as described in Section 4. In order to obtain more reliable results, we perform 10 independent iterations for each configuration on the DIMACS and SPARSE MC graphs. Since the k -regular graphs are uniform randomly computed, they are already representative for their class. Therefore, we perform only single runs on these graphs.

Configuration. We compare the following three configurations. \mathcal{R}_0 refers to the uniform random sampling of points in \mathbb{R}^2 with the parameters $(|S|, |P|, K) = (0, 1000, \infty)$, \mathcal{R}_{512} to the restricted sampling in R_i with the parameters, $(512, 1000, 100)$, and \mathcal{W}_{512} to the weighted sampling in \mathbb{R}^2 with the parameters $(512, 1000, 100)$. The configurations are selected such that \mathcal{R}_0 and \mathcal{R}_{512} differ only in a single parameter, i.e., in the number of sampled edges. The only difference between \mathcal{R}_{512} and \mathcal{W}_{512} is the sampling strategy. Note that the parameters of \mathcal{R}_0 and \mathcal{S}_0 coincide, but not the parameters of \mathcal{S}_{512} and \mathcal{R}_{512} .

Evaluation. Since we executed 10 independent runs of the algorithm on each graph, Table 2 lists the mean and standard deviation of the computed number of crossings for each graph. For each graph, we marked the cell with the lowest number of crossings in green and the largest number in blue. For each graph, we used the Mann-Witney-U test [22] to check the null hypothesis that the crossing numbers belong to the same distribution. The test indicates

that we can reject the null hypothesis at a significance level of $\alpha = 0.01$, for all graphs with the exception of football, ch7-6-b1 and bcsstk08. First, observe that the \mathcal{R}_0 configuration never computes a drawing with fewer crossings than \mathcal{R}_{512} . Including the football, ch7-6-b1 and the bcsstk08 graphs, 11 of the drawings with the fewest crossing were obtained from the \mathcal{R}_{512} configurations. Only 7 correspond to the \mathcal{W}_{512} configuration. Table 1 shows that these graphs have an average vertex-degree of at most 11. Moreover, the degree-distributions of these graphs follow the power-law (compare full version). On the other hand, a few of the 8 graph where \mathcal{R}_{512} outperforms \mathcal{W}_{512} also have a small average vertex-degree.

We use Figure 6 to compare the effect of the vertex-degree on the number of crossings. The plot follows the same convention as the plots in Figure 5. Observe that for each k , the \mathcal{W}_{512} configuration computes drawings with fewer crossings than \mathcal{R}_{512} . The improvement decreases with an increasing k . The same observation can be made for the comparison of \mathcal{W}_{512} to \mathcal{R}_0 but not for the comparison for \mathcal{R}_{512} to \mathcal{R}_0 , which indicates that sampling the set of points P_i within the region R_i is indeed too restrictive, at least on our k -regular graphs.

Overall our experimental evaluation shows that even with a naive uniform random sampling of a set of points in the plane the number of crossings in drawings of STRESS can be reduced considerably. Using a random sample of a subset of the edges helps to compute drawings with even less crossings. The mean-vertex degree and the degree-distributions are good indicators for whether the restrictive or the weighted sampling of the point set P_i results in a drawing with the smallest number of crossings.

■ **Figure 6** Comparison of the number of crossing of the k -regular graphs computed by \mathcal{W}_{512} and \mathcal{R}_{512} .

5 Conclusion

In our previous work we showed that the primitive operation of moving a single vertex to its crossing-minimal position significantly reduces the number of crossings compared to drawings obtained by STRESS. In this paper we introduced the concept of *bloated dual of line arrangements*, a combinatorial technique to compute a dual representation of line arrangements. In our applications of computing drawings with a small number of crossings, this technique resulted in a speed-up of factor of 20. This improvement was necessary to adapt the approach for graphs with a large number of vertices and edges. On the other hand, since the worst-case running time is super-quadratic, this improvement is not sufficient to cope with large graphs. In Section 4 we showed that random sampling is a promising technique to minimize crossings in geometric drawings. In Section 4.1 we proved that a random subset of edges of size $\Theta(k \log k)$ approximates the co-crossing number of a vertex v with a high probability. Further, we evaluated three different strategies to sample a set of points in the plane in order to compute a new position for the vertex v_i . First, the evaluation confirms that the number of crossings compared to STRESS can be reduced considerably. Furthermore, sampling a small subset of the edges is sufficient to reduce the number of crossings compared to a naive sampling of points the plane. Our evaluation suggests that weighted sampling is a promising approach to reduce the number of crossings in graphs with a low average vertex degree. Otherwise, the evaluation indicates that restricted sampling results in fewer crossings.

The running time of the vertex-movement approach in combination with the sampling of the edges mostly depends on the number of vertices. Since a single movement of a vertex is not optimal anymore, two vertices can be moved independently. Thus, future research should be concerned with the question whether a parallelization over the vertex set is able to further reduce the running time while preserving the small number of crossings. Moreover, we ask whether it is sufficient to move a small subset of the vertices to considerably reduce the number of crossings.

An Approximate Kernel for Connected Feedback Vertex Set

M. S. Ramanujan 

University of Warwick, UK

https://warwick.ac.uk/fac/sci/dcs/people/ramanujan_sridharan/

R.Maadapuzhi-Sridharan@warwick.ac.uk

Abstract

The FEEDBACK VERTEX SET problem is a fundamental computational problem which has been the subject of intensive study in various domains of algorithmics. In this problem, one is given an undirected graph G and an integer k as input. The objective is to determine whether at most k vertices can be deleted from G such that the resulting graph is acyclic. The study of preprocessing algorithms for this problem has a long and rich history, culminating in the quadratic kernelization of Thomasse [SODA 2010].

However, it is known that when the solution is required to induce a *connected* subgraph (such a set is called a connected feedback vertex set), a polynomial kernelization is unlikely to exist and the problem is NP-hard to approximate below a factor of 2 (assuming the Unique Games Conjecture).

In this paper, we show that if one is interested in only preserving *approximate* solutions (even of quality arbitrarily close to the optimum), then there is a drastic improvement in our ability to preprocess this problem. Specifically, we prove that for every fixed $0 < \varepsilon < 1$, graph G , and $k \in \mathbb{N}$, the following holds.

There is a polynomial time computable graph G' of size $k^{\mathcal{O}(1)}$ such that for every $c \geq 1$, any c -approximate connected feedback vertex set of G' of size at most k is a $c \cdot (1 + \varepsilon)$ -approximate connected feedback vertex set of G .

Our result adds to the set of approximate kernelization algorithms introduced by Lokshtanov et al. [STOC 2017]. As a consequence of our main result, we show that CONNECTED FEEDBACK VERTEX SET can be approximated within a factor $\min\{\text{OPT}^{\mathcal{O}(1)}, n^{1-\delta}\}$ in polynomial time for some $\delta > 0$.

1 Introduction

Polynomial time preprocessing is one of the widely used methods to tackle NP-hardness in practice, and the area of *kernelization* has been extremely successful in laying down a mathematical framework for the design and rigorous analysis of preprocessing algorithms for decision problems. The central notion in kernelization is that of a *kernelization algorithm*, which is a preprocessing algorithm that runs in polynomial time and transforms a “large” instance of a decision problem into a significantly smaller, but equivalent instance (called a *kernel*). Over the last decade, the area of kernelization has seen the development of a wide range of tools to design preprocessing algorithms, as well as a rich theory of lower bounds based on assumptions from complexity theory [2, 6, 3, 15, 5, 9, 18, 7, 17]. We refer the reader to the survey articles by Kratsch [19] or Lokshtanov et al. [20] for relatively recent developments, or the textbooks [4, 8], for an introduction to the field.

An “efficient preprocessing algorithm” in this setting is referred to as a *polynomial kernelization* and is simply a kernelization whose output has size bounded polynomially in a parameter of the input. The central classification task in the area is to classify any problem as one which has a polynomial kernel, or as one that does not.

One fundamental class of problems for which polynomial kernels have been ruled out under certain complexity theoretic hypotheses, is the class of “subgraph hitting” problems *with a connectivity constraint*. It is well-known that placing connectivity constraints on certain subgraph hitting problems can have a dramatic effect on their amenability to preprocessing. A case in point is the classic VERTEX COVER problem. This problem is known to admit a kernelization whose output has $\mathcal{O}(k)$ vertices [4]. However, the CONNECTED VERTEX COVER problem is amongst the earliest problems shown to exclude a polynomial kernel [7] (under a complexity theoretic hypothesis) and this lower bound immediately rules out the possibility of such a kernelization for numerous well-studied generalizations of it. Consequently, obtaining a finer understanding of the impact of connectivity constraints on the limits of preprocessing is an important objective in furthering the study of preprocessing techniques. This is even more relevant when one intends to run approximation algorithms or heuristics on the preprocessed instance.

Unfortunately, the existing notion of kernels, having been built around decision problems, does not combine well with approximation algorithms and heuristics. In particular, in order for kernels to be useful, one is required to solve the preprocessed instance *exactly*. However, this may not always be possible and the existing theory of kernelization says nothing about the inference of useful information from a good *approximate* solution for the preprocessed instance. In order to facilitate the rigorous analysis of preprocessing algorithms in conjunction with approximation algorithms, Lokshtanov et al. [22] introduced the notion of α -*approximate kernels*. Informally speaking, an α -approximate kernelization is a polynomial-time algorithm that, given an instance (I, k) of a *parameterized problem*, outputs an instance (I', k') such that $|I'| + k' \leq g(k)$ for some computable function g and any c -approximate solution to the instance (I', k') can be turned in polynomial time into a $(c \cdot \alpha)$ -approximate solution to the original instance (I, k) .

As earlier, the notion of “efficiency” in this context is captured by the function g being polynomially bounded, in which case we call this algorithm, an α -*approximate polynomial kernelization*. We refer the reader to Section 2 for a formal definition of all terms related to (approximate) kernelization.

In their work, Lokshtanov et al. considered several problems which are known to exclude polynomial kernels and presented an α -approximate polynomial kernelization for these problems for *every* fixed $\alpha > 1$. This implies that allowing for an arbitrarily small amount of error while preprocessing can drastically improve the extent to which the input instance can be reduced, even when dealing with problems for which polynomial kernels have been ruled out under the existing theory of lower bounds. In particular, they showed that the CONNECTED VERTEX COVER problem admits an α -approximate polynomial kernelization for every $\alpha > 1$. Their result provided a promising starting point towards obtaining a refined understanding of the role played by connectivity constraints in relation to preprocessing for covering problems on graphs.

In this paper, we consider one of the most natural generalizations of CONNECTED VERTEX COVER, the CONNECTED FEEDBACK VERTEX SET (CFVS) problem defined as follows. In this problem, the input is a graph G and integer k (the parameter). The goal is to decide whether or not there is a set $S \subseteq V(G)$ of size at most k such that $G[S]$ is connected and $G - S$ is acyclic? The set S is called a connected feedback vertex set of G .

Misra et al. [23] were the first to study the CFVS problem from the point of view of parameterized complexity and obtained a single-exponential fixed-parameter algorithm, that is, an algorithm running in time $2^{\mathcal{O}(k)}n^{\mathcal{O}(1)}$, where n is the number of vertices in the input. They also observed that a straightforward reduction from CONNECTED VERTEX COVER implies that CFVS is also unlikely to admit a polynomial kernelization under standard complexity theoretic hypotheses. This raises the natural question of the existence of approximate kernelizations for this problem and the tradeoffs between preprocessing speed, output size and loss in the quality of the preserved solution.

Our results

A formal definition of α -approximate kernels can be found in Section 2.

► **Theorem 1.** *For every fixed $0 < \varepsilon < 1$, CONNECTED FEEDBACK VERTEX SET has a $(1 + \varepsilon)$ -approximate kernelization of polynomial size.*

Note that the exponent in the size of our kernelization depends on ε .

The proof techniques we use in order to prove Theorem 1 also lead to a polynomial time approximation for this problem (Theorem 3) via the following *parameterized* approximation.

► **Theorem 2.** *There is an algorithm that given a graph G and $k \in \mathbb{N}$, runs in polynomial time and either correctly concludes that G has no connected feedback vertex set of size at most k or returns a connected feedback vertex set of G of size $k^{\mathcal{O}(1)}$.*

As a direct consequence of Theorem 2, we obtain the following result.

► **Theorem 3.** *There is a $0 < \delta < 1$ such that CONNECTED FVS can be approximated within a factor $\min\{\text{OPT}^{\mathcal{O}(1)}, n^{1-\delta}\}$ in polynomial time.*

Proof. By iteratively invoking Theorem 2 for $k = 1, \dots, n$, one can find the least k for which the algorithm *does not* return a negative answer and returns a connected feedback vertex set of the input graph of size at most k^c for some fixed $c > 0$. Since $\text{OPT} \geq k$, it follows that the returned solution has size at most OPT^c . Moreover, this algorithm always returns a solution whose size is bounded by n . The theorem follows from fact that the approximation ratio guaranteed by this algorithm is at most $\min\{\text{OPT}^{c-1}, \frac{n}{\text{OPT}}\} \leq n^{1-\frac{1}{c}}$. ◀

Our approximation result complements the classic result of Yannakakis [25] who showed that it is NP-hard to approximate within a factor- $\mathcal{O}(n^{1-\delta})$ (for any $\delta > 0$) the minimum number of vertices to delete from a graph such that the *resulting graph* is connected and has a property Π which is hereditary, non-trivial, “interesting” on connected graphs, and is determined by the blocks of the graph. In particular, this result holds if $\Pi = \text{acyclicity}$.

Related work on connected hitting set problems. Grigoriev and Sitters [16] studied the design of approximation algorithms for the CONNECTED FEEDBACK VERTEX SET problem on planar graphs and obtained a Polynomial Time Approximation Scheme (PTAS), building upon the result of Escoffier et al. [13] for CONNECTED VERTEX COVER. Eiben et al. [11] obtained an approximate kernelization for the CONNECTED \mathcal{H} -HITTING SET problem where \mathcal{H} is a fixed set of graphs and the solution is a minimum set of vertices which induces a connected subgraph and hits all copies of graphs in \mathcal{H} , in G . Recently, Eiben et al. [12] obtained approximate kernelizations for the CONNECTED DOMINATING SET problem on various sparse graph classes.

2 Preliminaries

A set $S \subseteq V(G)$ such that $G - S$ is a forest is called a *feedback vertex set* of G . For a path P , we denote by $V_{\text{int}}(P)$ the set of internal vertices of the path P . Similarly, we denote by $V_{\text{end}}(P)$ the set of endpoints of P . Two paths P_1 and P_2 are said to be *internally vertex disjoint* if $V_{\text{int}}(P_1) \cap V_{\text{int}}(P_2) = \emptyset$. For a graph G , we denote by $\mathcal{CC}(G)$ the set of connected components of G . For ease of presentation, we will abuse notation and interchangeably refer to $X \subseteq V(G)$ both as a vertex set and as a connected component of G if clear from the context.

► **Definition 4.** *Let G be a graph and $x, y \in V(G)$. Let \mathcal{P} be a set of internally vertex-disjoint x - y paths in G . Then, we call \mathcal{P} an x - y flow. The value of this flow is $|\mathcal{P}|$.*

Recall that Menger's theorem states that for distinct *non-adjacent* vertices x and y , the size of the smallest x - y separator is precisely the value of the maximum x - y flow in G .

Parameterized problems and (approximate) kernels. A parameterized problem Π is a subset of $\Gamma^* \times \mathbb{N}$ for some finite alphabet Γ . An instance of a parameterized problem consists of a pair (x, k) , where k is called the parameter. We assume that k is *given in unary* and hence $k \leq |x|$.

► **Definition 5 (Kernelization).** *Let $\Pi \subseteq \Gamma^* \times \mathbb{N}$ be a parameterized problem and g be a computable function. We say that Π admits a kernel of size g if there exists an algorithm referred to as a kernelization (or a kernel) that, given $(x, k) \in \Gamma^* \times \mathbb{N}$, outputs in time polynomial in $|x| + k$, a pair $(x', k') \in \Gamma^* \times \mathbb{N}$ such that (a) $(x, k) \in \Pi$ if and only if $(x', k') \in \Pi$, and (b) $\max\{|x'|, k'\} \leq g(k)$. If $g(k) = k^{\mathcal{O}(1)}$ then we say that Π admits a polynomial kernel.*

► **Definition 6 ([22]).** *A parameterized optimization (minimization or maximization) problem is a computable function $\Pi : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\pm\infty\}$.*

The *instances* of a parameterized optimization problem Π are pairs $(I, k) \in \Sigma^* \times \mathbb{N}$, and a *solution* to (I, k) is simply a string $s \in \Sigma^*$, such that $|s| \leq |I| + k$. The *value* of the solution s is $\Pi(I, k, s)$.

Since we only deal with a minimization problem in this work, we state some of the definitions only in terms of minimization problems when the definition for maximization problems is analogous. The parameterized optimization version of CONNECTED FEEDBACK VERTEX SET is a minimization problem with the optimization function $\text{CFVS} : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\infty\}$ defined as follows.

$$\text{CFVS}(G, k, S) = \begin{cases} \infty & \text{if } S \text{ is not a connected feedback vertex set of } G, \\ \min\{|S|, k + 1\} & \text{otherwise.} \end{cases}$$

► **Definition 7 ([22]).** *For a parameterized minimization problem Π , the optimum value of an instance $(I, k) \in \Sigma^* \times \mathbb{N}$ is $\text{OPT}_{\Pi}(I, k) = \min_{\substack{s \in \Sigma^* \\ |s| \leq |I| + k}} \Pi(I, k, s)$.*

Consequently, in the case of CONNECTED FEEDBACK VERTEX SET, we define

$$\text{OPT}(G, k) = \min_{S \subseteq V(G)} \text{CFVS}(G, k, S).$$

► **Remark 8** (Restricting our interest to solutions of size at most k). A reader encountering this particular definition of parameterized optimization problems for the first time might find the choice of $k + 1$ as a threshold a bit counter-intuitive because when one combines it with the natural notion of approximate solutions in the most intuitive way, the size of the solution would appear to always exceed $k + 1$, thus being normalized by this explicit threshold.

However, this definition is in fact equivalent (upto constant factors) to the more seemingly natural definition and in addition allows us to define the problem we are tackling independently of the (approximation factor of) algorithms for the problem. An additional point which we encourage the reader to keep in mind is the following. We consider k as a threshold; for solutions of size at most k we care about what their size is, while all solutions of size larger than k are *equally bad* in our eyes, and are consequently assigned value $k + 1$. We point the interested reader to Section 2.1, [22] and Section 3.2, [21] for an in-depth discussion of these definitions and their motivations.

We now recall the other relevant definitions from [22] regarding *approximate kernels*.

► **Definition 9** ([22]). Let $\alpha \geq 1$ be a real number and Π be a parameterized minimization problem. An α -approximate polynomial time preprocessing algorithm \mathcal{A} for Π is a pair of polynomial-time algorithms. The first one is called the reduction algorithm, and computes a map $\mathcal{R}_{\mathcal{A}} : \Sigma^* \times \mathbb{N} \rightarrow \Sigma^* \times \mathbb{N}$. Given as input an instance (I, k) of Π the reduction algorithm outputs another instance $(I', k') = \mathcal{R}_{\mathcal{A}}(I, k)$.

The second algorithm is called the solution lifting algorithm. This algorithm takes as input an instance $(I, k) \in \Sigma^* \times \mathbb{N}$ of Π , the output instance (I', k') of the reduction algorithm, and a solution s' to the instance (I', k') . The solution lifting algorithm works in time polynomial in $|I|, k, |I'|, k'$ and s' , and outputs a solution s to (I, k) such that $\frac{\Pi(I, k, s)}{\text{OPT}(I, k)} \leq \alpha \cdot \frac{\Pi(I', k', s')}{\text{OPT}(I', k')}$.

The size of a polynomial time preprocessing algorithm \mathcal{A} is a function $\text{size}_{\mathcal{A}} : \mathbb{N} \rightarrow \mathbb{N}$ defined as $\text{size}_{\mathcal{A}}(k) = \sup\{|I'| + k' : (I', k') = \mathcal{R}_{\mathcal{A}}(I, k), I \in \Sigma^*\}$.

► **Definition 10** ([22], α -approximate kernelization). An α -approximate kernelization (or α -approximate kernel) for a parameterized optimization problem Π , and real $\alpha \geq 1$, is an α -approximate polynomial time preprocessing algorithm \mathcal{A} for Π such that $\text{size}_{\mathcal{A}}$ is upper bounded by a computable function $g : \mathbb{N} \rightarrow \mathbb{N}$. We say that \mathcal{A} is an α -approximate polynomial kernelization if g is a polynomial function.

► **Definition 11** ([22]). A polynomial size approximate kernelization scheme (PSAKS) for a parameterized optimization problem Π is a family of α -approximate polynomial kernelization algorithms, with one such algorithm for every $\alpha > 1$.

Least Common Ancestor-Closure of sets in trees. For a rooted tree T and vertex set $M \subseteq V(T)$ the least common ancestor-closure (*LCA-closure*) $\text{LCA-closure}(M)$ is obtained by the following process. Initially, set $M' = M$. Then, as long as there are vertices x and y in M' whose least common ancestor w is not in M' , add w to M' . When the process terminates, output M' as the LCA-closure of M . The following folklore lemma summarizes the properties of LCA-closures which we will use in this paper.

► **Lemma 12.** Let T be a rooted tree, $M \subseteq V(T)$ and $M' = \text{LCA-closure}(M)$. Then $|M'| \leq 2|M|$ and for every connected component C of $T - M'$, $|N(C)| \leq 2$. Moreover, the number of connected components of $T - M'$ which have exactly 2 neighbors in M' is at most $|M'| - 1$.

► **Observation 2.1.** Let T be a rooted tree and T' a subtree of T with a unique neighbor in $V(T) \setminus V(T')$. If $M \subseteq V(T) \setminus V(T')$, then $\text{LCA-closure}(M)$ is disjoint from $V(T')$.

3 Overview of our Techniques

This section is devoted to an overview of the proof techniques we use to obtain our results. Fix $0 < \varepsilon < 1$ and let (G, k) be the input. Our initial objective is to identify a partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ of $V(G)$, where $|\mathcal{B}| = k^{\mathcal{O}(1)}$, $G - \mathcal{B}$ is acyclic and there are no edges between \mathcal{A} and \mathcal{C} . In other words, \mathcal{B} separates \mathcal{A} and \mathcal{C} . Moreover, we will be able to prove that the vertices in \mathcal{C} only play the role of “connectors” and removing them from a connected feedback vertex set S of G may disconnect $G[S]$, but will still leave a subset of S which hits all cycles in G . On the other hand, the interaction of vertices in \mathcal{A} with the solution S could be much more complex. However, the number of connected components of $G[\mathcal{A}]$ will be shown to be $k^{\mathcal{O}(1)}$ and these can be shown to have a highly structured neighborhood in \mathcal{B} . For instance, we will be able to ensure (after a small modification to G) that the neighborhood of any connected component of $G[\mathcal{A}]$ can be partitioned into 2 sets T and J such that T is part of *every* feedback vertex set of G and $|J| = 2$. For every such component, the sets T and J can be efficiently computed from \mathcal{A} .

Once we have this partition in hand, we focus on each connected component of $G[\mathcal{A}]$ separately and from each component we identify a set of $k^{\mathcal{O}(f(1/\varepsilon))}$ vertices which, together with \mathcal{B} and a $k^{\mathcal{O}(f(1/\varepsilon))}$ sized subset of \mathcal{C} cover a $(1 + \varepsilon)$ -approximate solution. Finally, the remaining vertices are discarded by either deleting or contracting edges as appropriate. We note that the high level approach of trying to identify “hitters” and “connectors” among the vertices is quite natural and has been used in other work [22, 11, 12]. However, the structure is much more complex in our case due to the highly non-local nature of the forbidden structures (cycles) and the fact that there is no clear way of completely separating the two tasks of hitting cycles and connectivity. In fact, the main difficulty arises from the need to detect and control subsets of vertices which are critical with respect to both objectives simultaneously.

We now proceed to a slightly more detailed overview of the steps in our algorithm. Let δ be a positive constant such that $(1 + \delta)^3 \leq 1 + \varepsilon$. We also fix a constant $\rho = 2^{\mathcal{O}(1/\delta)^2}$ satisfying certain appropriate inequalities. As mentioned, our PSAKS for CONNECTED FEEDBACK VERTEX SET has two main parts: a structural decomposition and a reduction using marking rules.

3.1 Structural Decomposition

The first part of our PSAKS is the decomposition given by Lemma 13 below (also see Figure 1). To get the required partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ we set $\mathcal{B} = H \cup X \cup Z$ where H, X, Z are as defined in the statement of Lemma 13. We then set \mathcal{C} to be the set of vertices in connected components of $G - (H \cup X \cup Z)$ which are adjacent to at most one vertex of Z and \mathcal{A} to be the rest of the vertices in $G - (H \cup X \cup Z)$.

► **Lemma 13.** *There is a polynomial-time algorithm that given a pair (G, k) , either correctly concludes that G has no connected feedback vertex set of size at most k or outputs pairwise vertex disjoint subsets $H, X, Z \subseteq V(G)$ satisfying the following properties.*

1. $|H| \leq (1 + \frac{\delta}{2})k$, $|X| = \mathcal{O}(k)$, $|Z| = \mathcal{O}(k^6)$.
2. $H \cup X$ is a feedback vertex set of G and if G has a connected feedback vertex set S of size at most k , then there is one of size at most $(1 + \frac{\delta}{2})|S|$ that contains H .
3. Every connected component of the graph $\widetilde{G}_Z = G - (H \cup X \cup Z)$ is adjacent to at most 2 vertices of Z and there are $\mathcal{O}(k^6)$ connected components in \widetilde{G}_Z which are adjacent to exactly 2 vertices of Z .

4. No vertex of X has a neighbor in a connected component of \widetilde{G}_Z which is adjacent to 2 vertices of Z and moreover, every vertex in any such component is adjacent to vertices in $\mathcal{O}(1/\delta)$ connected components of $G[H]$.
5. For every connected component D in the graph \widetilde{G}_Z with at most 1 neighbor in Z and for every minimal feedback vertex set S of $G - H$ of size at most $2k$, $|N(D) \setminus (H \cup S)| \leq 1$.

Proof. (Sketch for the construction of H, X, Z). We only sketch the construction of these sets here.

Step 1: This step is inspired by Fomin et al. [14]. However, since we need to handle connectivity constraints, we need to enhance the output of this step further with several problem specific features. Let $H = \{v_1, \dots, v_r\}$ be a maximal set such that for every $i \in [r]$, there is a v_i -flower of order $2k + 1$ ($2k + 1$ cycles which are pairwise disjoint except for intersecting at v_i) in $G - H_{i-1}$, where $H_i = \{v_1, \dots, v_i\}$ and $H_0 = \emptyset$. It is known that there is a polynomial time algorithm that, given G, v, ℓ (assuming v is not incident on a self-loop) either outputs a v -flower of order ℓ or a set $X \subseteq V(G) \setminus \{v\}$ of $\mathcal{O}(\ell)$ vertices intersecting every cycle containing v [24]. Hence H can be computed in polynomial time. Furthermore, it can be observed that every vertex in H is part of every feedback vertex set of size at most $2k$. Therefore, if $|H| > k$, then we may correctly conclude that G has no feedback vertex set of size at most k .

Let Q be a feedback vertex set of G computed using the 2-approximation algorithm of Bafna et al. [1]. If $|Q| > 2k$, then we may correctly conclude that G has no feedback vertex set of size at most k . Otherwise, $H \subseteq Q$ and we define $X = Q \setminus H$. Due to the maximality of H , it follows that for every $x \in X$, there is a set P_x which is disjoint from x , has size $\mathcal{O}(k)$ and intersects every cycle containing x in $G - H$.

For every pair $x, y \in X$ such that there is no x - y flow of value $2k + 3$ in the graph $G_{xy} = G - (H \cup (X \setminus \{x, y\}))$, we denote by Z_{xy} an arbitrarily chosen minimum x - y separator in the graph G'_{xy} , where $G'_{xy} = G_{xy}$ if $(x, y) \notin E(G)$ and $G'_{xy} = G_{xy} - (x, y)$ otherwise. By Menger's Theorem, for every such pair x, y , the size of the set Z_{xy} is at most $2k + 2$. We define $J = (\bigcup_{x \in X} P_x \cup \bigcup_{x, y \in X} Z_{xy}) \setminus (X \cup H)$, where for every pair $x, y \in X$ such that there is an x - y flow of value at least $2k + 3$ in the graph $G_{xy} = G - (H \cup (X \setminus \{x, y\}))$, Z_{xy} is defined to be \emptyset . We now define $Y = \text{LCA-closure}(J)$ with the LCA-closure taken in the graph $G - (H \cup X)$ where each tree is arbitrarily rooted. Since $|H| \leq k$ and $|X| \leq 2k$, it follows that $|J| = \mathcal{O}(k^3)$ and Lemma 12 implies that $|Y| = |\text{LCA-closure}(J)| = \mathcal{O}(k^3)$, every connected component of the graph $G - (H \cup X \cup Y)$ is adjacent to at most 2 vertices of Y and there are $\mathcal{O}(|Y|)$ of these components which are adjacent to exactly 2 vertices of Y .

Step 2: Since Step 1 guarantees that there are no cycles in $G - (H \cup Y \cup (X \setminus \{x\}))$ for any $x \in X$ we conclude that no vertex of X can have 2 neighbors in any connected component of $\widetilde{G}_Y = G - (H \cup X \cup Y)$. Let \mathcal{R} denote the set of all connected components of \widetilde{G}_Y which have no neighbors in Y , let \mathcal{Q} denote the set of all connected components of \widetilde{G}_Y which have exactly 1 neighbor in Y , and let \mathcal{W} denote the set of all connected components of \widetilde{G}_Y which have exactly 2 neighbors in Y .

For every $x \in X$ and $y \in Y$, we define the set \mathcal{J}_{xy} as the set of components of \widetilde{G}_Y which are adjacent to x and whose neighborhood in Y is exactly $\{y\}$. We say that the set $\mathcal{J}_{x,y}$ is *rich* if $|\mathcal{J}_{xy}| \geq 2k + 3$ and *poor* otherwise. We call a connected component in \mathcal{Q} *poor* if it appears in *at least one* poor set and *rich* otherwise. Let $\mathcal{Q}_{\text{poor}}$ denote the set of poor components in \mathcal{Q} . By definition, the size of the set $\mathcal{Q}_{\text{poor}}$ is bounded by $|X| \cdot |Y| \cdot (2k + 2) = \mathcal{O}(k^5)$. Let P_1 denote the neighborhood of X in the set of components

■ **Figure 1** An illustration of the decomposition guaranteed by Lemma 13. The (blue) circles below the set $(H \cup Z \cup X)$ represent components of $G - (H \cup Z \cup X)$ with 2 neighbors in Z . Note that there are no edges between X and such a component.

in $\mathcal{Q}_{\text{poor}}$. Since every vertex of X has at most 1 neighbor in each of these components, the size of P_1 is at most $|X| \cdot |\mathcal{Q}_{\text{poor}}| = \mathcal{O}(k^6)$. Let P_2 denote the neighborhood of X in the set of components of G_Y with exactly 2 neighbors in Y . Since there are only $\mathcal{O}(k^3)$ such components (from Step 1), the size of P_2 is $\mathcal{O}(k^4)$.

Finally, we define $Z = \text{LCA-closure}(Y \cup P_1 \cup P_2)$ where the LCA-closure is taken in the graph $G - (H \cup X)$ with an arbitrary rooting of each tree. From Lemma 12, it follows that $|Z| = \mathcal{O}(k^6)$, every connected component of the graph $\widetilde{G}_Z = G - (H \cup X \cup Z)$ is adjacent to at most 2 vertices of Z and there are $\mathcal{O}(k^6)$ connected components in the graph \widetilde{G}_Z which are adjacent to exactly 2 vertices of Z . Moreover, we will be able to argue using flow arguments and the definition of rich/poor components that (i) no vertex of X has a neighbor in a connected component of \widetilde{G}_Z which is adjacent to 2 vertices of Z and (ii) for every connected component D in the graph \widetilde{G}_Z with at most 1 neighbor in Z and for any minimal feedback vertex set S of $G - H$ of size at most $2k$, S contains all but at most one vertex of $N(D) \setminus H$.

Step 3: We will finally augment the set H by adding some more vertices. Specifically, we will grow the set H by “buying a cheap set of vertices” as follows. As long as there is a vertex v which is adjacent to at least $\lceil \frac{2}{\delta} \rceil + 1$ connected components of $G[H]$ and contained in a connected component of \widetilde{G}_Z adjacent to 2 vertices of Z , we set $H := H \cup \{v\}$. When this process terminates, it must be the case that every vertex which is in a connected component of \widetilde{G}_Z adjacent to 2 vertices of Z , has at most $\lceil \frac{2}{\delta} \rceil$ neighboring components of $G[H]$. A simple counting argument based on the fact that we repeatedly decrease the number of connected components in $G[H]$ shows that the blow-up in the size of H is at most a $\delta/2$ fraction of the original value of $|H|$. ◀

We call a component D of \widetilde{G}_Z a **Type 0** component if $|N(D) \cap Z| = 0$, a **Type 1** component if $|N(D) \cap Z| = 1$ and a **Type 2** component if $|N(D) \cap Z| = 2$. Lemma 13 (5) implies that the Type 0 and Type 1 components (which comprise the set \mathcal{C}) only play the role of connectors and Lemma 13 (3) guarantees that the number of Type 2 components (which comprise the set \mathcal{A}) is $\mathcal{O}(k^6)$.

3.2 Marking Rules and Reduction Strategy via Steiner Trees

Once the partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ is computed, the second part of the PSAKS relies on an extension of the following result of Du et al. [10] to a special case of the Group Steiner Tree problem where at most one group can have size greater than 1.

► **Proposition 14** ([10]). *For every $p \geq 1$, graph G , $R \subseteq V(G)$, cost function $w : E(G) \rightarrow \mathbb{N} \cup \{0\}$ and R -Steiner tree T , there is a p -restricted R -Steiner tree in G of cost at most $(1 + \frac{1}{\lfloor \log_2 p \rfloor}) \cdot w(T)$.*

In the above proposition, an R -Steiner tree is a subtree of G containing R and a p -restricted R -Steiner tree is a connected subgraph of G containing R and whose edge set can be written as the union of the edge sets of Steiner trees for some subsets of R of size at most p where these subsets appear as the leaves of the respective Steiner trees. In a similar spirit to Proposition 14, we show that for every $p \geq 1$, graph G , $R \subseteq V(G)$, cost function $w : E(G) \rightarrow \mathbb{N} \cup \{0\}$ and R -Steiner tree T intersecting a set \mathcal{Z} of arbitrary size disjoint from R , there is a $2p + 1$ -restricted R -Steiner tree in G of cost at most $(1 + \frac{1}{\lfloor \log_2 p \rfloor}) \cdot w(T)$ which also intersects \mathcal{Z} . We believe that this extension and close variants thereof are likely to have future applications in dealing with connectivity constraints. We design a set of marking rules that achieve the following.

► **Lemma 15.** *There is an algorithm that, given G , k and the partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$, runs in time $k^{\mathcal{O}(\rho)} n^{\mathcal{O}(1)}$ and marks a set $\mathcal{A}' \subseteq \mathcal{A}$ of $k^{\mathcal{O}(\rho)}$ vertices such that for any S which is a connected feedback vertex set of G of size at most k , there is a connected feedback vertex set of G of size at most $(1 + \delta)^2 |S|$ whose intersection with \mathcal{A} is contained in \mathcal{A}' .*

The main technical difficulty in the above lemma lies in identifying and marking vertices such that for any subset of $S \cap \mathcal{A}$ which may be performing the dual job of “hit” and “connect”, the set \mathcal{A}' of marked vertices contains a subset which would do the same job with only a small increase in size. Moreover, since we deal with each connected component of $G[\mathcal{A}]$ separately, we cannot simply use Proposition 14 or its extension we propose. This is where the upper bound on the degree of vertices of \mathcal{A} into the set H will be crucial (Lemma 13 (4)).

Using Lemma 15, we will show that there is a way to reduce the graph $G[\mathcal{A}]$ by deleting or contracting all but $k^{\mathcal{O}(\rho)}$ of the rest of the edges so that the only unbounded set following this step is the set \mathcal{C} . As we know that the vertices in \mathcal{C} only perform the job of “connectors” and are not necessary to hit cycles in G , we will mark the optimal Steiner tree (if it is small enough) in G for every choice of a sufficiently small subset of $\mathcal{A}' \cup \mathcal{B}$ as the set of terminals and use Proposition 14 to prove the following.

► **Lemma 16.** *There is an algorithm that, given G , k and the partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$, runs in time $k^{\mathcal{O}(\rho^2)} n^{\mathcal{O}(1)}$ and marks a set $\mathcal{C}' \subseteq \mathcal{C}$ of $k^{\mathcal{O}(\rho^2)}$ vertices such that for any S which is a connected feedback vertex set of G of size at most k , there is a connected feedback vertex set of G of size at most $(1 + \delta)^3 |S|$ whose intersection with \mathcal{C} is contained in \mathcal{C}' .*

Finally, we show that we can delete the unmarked vertices in \mathcal{C} after marking an additional $k^{\mathcal{O}(1)}$ new vertices and edges simply to remember the cycles passing through \mathcal{C} . Since we chose δ such that $(1 + \delta)^3 \leq 1 + \varepsilon$, we will have obtained the required graph. Specifically, we prove the following lemma.

► **Lemma 17.** *There is an algorithm that given G , k and the outputs of Lemma 13, Lemma 15 and Lemma 16 runs in time $k^{\mathcal{O}(\rho^2)} n^{\mathcal{O}(1)}$ and either correctly concludes that G has no connected feedback vertex set of size at most k or returns a graph G' such that:*

1. $|V(G')| = k^{\mathcal{O}(\rho^2)}$.
2. Every minimal connected feedback vertex set of G' of size at most $(1 + \varepsilon)k$ is contained in $V(G') \cap V(G)$ and is also a connected feedback vertex set of G .
3. For every S which is a minimal connected feedback vertex set of G of size at most k , G' has a connected feedback vertex set of size at most $(1 + \varepsilon)|S|$.

We summarize the steps of our algorithm below.

1. (Lemma 13) In polynomial time, identify a partition $(\mathcal{A}, \mathcal{B}, \mathcal{C})$ of $V(G)$ such that:
 - $|\mathcal{B}| = k^{\mathcal{O}(1)}$, $G - \mathcal{B}$ is acyclic, and \mathcal{B} separates \mathcal{A} and \mathcal{C} .
 - For every connected feedback vertex set S of G , $G - (S \setminus \mathcal{C})$ is acyclic.
 - Every connected component of $G[\mathcal{A}]$ has exactly 2 neighbors in \mathcal{B} and there are $k^{\mathcal{O}(1)}$ connected components in $G[\mathcal{A}]$.
2. (Lemma 15 + Lemma 16) In time $k^{f(1/\varepsilon)}n^{\mathcal{O}(1)}$, mark sets $\mathcal{A}' \subseteq \mathcal{A}$ and $\mathcal{C}' \subseteq \mathcal{C}$ of $k^{\mathcal{O}(f(1/\varepsilon))}$ vertices such that for any S which is a connected feedback vertex set of G of size at most k , there is a connected feedback vertex set of G of size at most $(1 + \varepsilon)|S|$ whose intersection with \mathcal{A} (\mathcal{C}) is contained in \mathcal{A}' (\mathcal{C}').
3. (Lemma 17) In time $k^{f(1/\varepsilon)}n^{\mathcal{O}(1)}$, compute a graph G' with $k^{\mathcal{O}(f(1/\varepsilon))}$ vertices where:
 - Every minimal connected feedback vertex set of G' of size $\leq (1 + \varepsilon)k$ is contained in $V(G') \cap V(G)$ and is also a connected feedback vertex set of G .
 - For every S which is a minimal connected feedback vertex set of G of size at most k , G' has a connected feedback vertex set of size at most $(1 + \varepsilon)|S|$.

3.3 The PSAKS and Factor-OPT ^{$\mathcal{O}(1)$} Approximation

We are now ready to prove Theorem 1 by translating Lemma 17 into a PSAKS for CONNECTED FEEDBACK VERTEX SET under the framework from [22]. Recall the definition of the parameterized optimization version of CONNECTED FEEDBACK VERTEX SET has the optimization function $\text{CFVS} : \Sigma^* \times \mathbb{N} \times \Sigma^* \rightarrow \mathbb{R} \cup \{\infty\}$ defined as follows.

$$\text{CFVS}(G, k, S) = \begin{cases} \infty & \text{if } S \text{ is not a connected feedback vertex set of } G \\ \min\{|S|, k + 1\} & \text{otherwise} \end{cases}$$

We define $\text{OPT}(G, k) = \min_{S \subseteq V(G)} \text{CFVS}(G, k, S)$. We point out that ∞ can be replaced in our setting with a sufficiently large value depending on $|V(G)|$ while serving the same purpose and avoiding potentially undefined operations.

► **Theorem 1.** *For every fixed $0 < \varepsilon < 1$, CONNECTED FEEDBACK VERTEX SET has a $(1 + \varepsilon)$ -approximate kernelization of polynomial size.*

Proof. We begin by describing the reduction algorithm. If G is a forest, then return $(G', 0)$ where G' is the empty graph. Henceforth we ignore this corner case and assume that G contains a cycle. Given G, k and ε , we execute the algorithm of Lemma 17. If this algorithm concludes that G does not contain a connected feedback vertex set of size at most k , then we return the instance (G', k) where G' is a connected graph with $k + 1$ vertex disjoint cycles and having $\mathcal{O}(k)$ vertices. Clearly such a graph exists. For instance, take the disjoint union of $k + 1$ triangles and connect them in the form of a path by selecting exactly one vertex from each triangle. Otherwise, suppose that this algorithm returns a graph G' . Then the reduction algorithm returns the instance (G', k') where $k' = (1 + \varepsilon)k$. At this point, we may assume that G is connected and so $V(G)$ is a connected feedback vertex set of G . If G' has multiple connected components containing cycles, then it cannot have a connected feedback

vertex set of *any* size, implying (by Lemma 17 (3)) that G cannot have a connected feedback vertex set of size at most k . Therefore we fall back into the previous case and so we may assume going forward that G' is also connected (if there are multiple components but only one contains cycles, then discard the rest) and so $V(G')$ is a connected feedback vertex set of G' . The polynomial bound on the size of the output instance and the time required to obtain G' follow from Lemma 17.

We now describe the solution lifting algorithm as follows. Let S' be the given solution for (G', k') . If S' is not a connected feedback vertex set of G' , then the algorithm outputs \emptyset as the solution for (G, k) . If S' is a connected feedback vertex set of G' and $|S'| > k'$, then the algorithm outputs $V(G)$ as the solution for (G, k) . Finally, if S' is a connected feedback vertex set of G' and $|S'| \leq k'$, then the algorithm returns S' as the solution for (G, k) . We denote by S the output of the solution lifting algorithm. Clearly, the solution lifting algorithm runs in polynomial time.

We now prove that this reduction algorithm and the solution lifting algorithm together constitute a $(1 + \varepsilon)$ -approximate kernelization for CONNECTED FEEDBACK VERTEX SET. We show that if $\text{CFVS}(G', k', S') \leq c \cdot \text{OPT}(G', k')$, then $\text{CFVS}(G, k, S) \leq (1 + \varepsilon)c \cdot \text{OPT}(G, k)$. In the case where we concluded that G has no connected feedback vertex set of size at most k and returned (G', k) , notice that $\text{CFVS}(G', k, S') = \text{CFVS}(G, k, S)$ and $\text{OPT}(G, k) = \text{OPT}(G', k) = k + 1$. Hence, we are left with the following cases which arise when the invocation to Lemma 17 returned a graph G' . We will use the fact that $\text{OPT}(G', k') \leq (1 + \varepsilon)\text{OPT}(G, k)$.

Case 1: S' is a connected feedback vertex set of G' and $|S'| > k'$. In this case, $S = V(G)$.

We now consider two subcases: G has a connected feedback vertex set of size at most k or it does not. If G has no connected feedback vertex set of size at most k , it follows that $\text{OPT}(G, k) = \text{CFVS}(G, k, V(G)) = k + 1$. This is because G is connected and so $V(G)$ is a connected feedback vertex set. Therefore,

$$\frac{\text{CFVS}(G, k, V(G))}{\text{OPT}(G, k)} = 1 \leq (1 + \varepsilon) \cdot \frac{\text{CFVS}(G', k', S')}{\text{OPT}(G', k')}. \quad (1)$$

Hence, we may assume that G has a connected feedback vertex set of size at most k . That is, $\text{OPT}(G, k) \leq k$. But this implies the following.

$$\frac{\text{CFVS}(G, k, V(G))}{\text{OPT}(G, k)} = \frac{k + 1}{\text{OPT}(G, k)} \leq (1 + \varepsilon) \cdot \frac{k' + 1}{\text{OPT}(G', k')} = (1 + \varepsilon) \frac{\text{CFVS}(G', k', S')}{\text{OPT}(G', k')}. \quad (2)$$

Case 2: S' is a connected feedback vertex set of G' and $|S'| \leq k'$. In this case, $\text{OPT}(G', k') \leq k'$. We consider two subcases: $|S'| \leq k$ or $k + 1 \leq |S'| \leq k'$. In the former subcase we have the following.

$$\frac{\text{CFVS}(G, k, S)}{\text{OPT}(G, k)} = \frac{\text{CFVS}(G, k, S')}{\text{OPT}(G, k)} = \frac{\text{CFVS}(G', k', S')}{\text{OPT}(G, k)} \leq (1 + \varepsilon) \frac{\text{CFVS}(G', k', S')}{\text{OPT}(G', k')}. \quad (3)$$

And if $k + 1 \leq |S'| \leq k'$, then we have the following.

$$\begin{aligned} \frac{\text{CFVS}(G, k, S)}{\text{OPT}(G, k)} &= \frac{\text{CFVS}(G, k, S')}{\text{OPT}(G, k)} = \frac{k + 1}{\text{OPT}(G, k)} \leq (1 + \varepsilon) \frac{k + 1}{\text{OPT}(G', k')} \\ &\leq (1 + \varepsilon) \frac{\text{CFVS}(G', k', S')}{\text{OPT}(G', k')}. \end{aligned} \quad (4)$$

Case 3: S' is not a connected feedback vertex set of G' . Then, the set returned by the solution lifting algorithm, \emptyset , is also not a connected feedback vertex set of G and so, $\text{CFVS}(G', k', S') = \text{CFVS}(G, k, \emptyset)$. As a result, the required inequality follows and this completes the proof of the theorem. ◀

Lemma 17 also implies the following $\text{OPT}^{\mathcal{O}(1)}$ -approximation for CONNECTED FEEDBACK VERTEX SET.

► **Lemma 18.** *There is a polynomial time algorithm that given G, k , either correctly concludes that G has no connected feedback vertex set of size at most k or returns a connected feedback vertex set of G of size $k^{\mathcal{O}(1)}$.*

Proof. Given G, k , we set ε to be an arbitrary constant between 0 and 1, say $\frac{1}{2}$. We then invoke Lemma 17 to either correctly conclude that G has no connected feedback vertex set of size at most k or compute the graph G' guaranteed by the lemma. In the former case we return the same. Otherwise, we check for each connected component of $G[V(G') \cap V(G)]$ whether it is a connected feedback vertex set of G . If such a component exists, then we return the vertex set of this component and otherwise we conclude that G has no connected feedback vertex set of size at most k . The correctness follows from the fact that if G contains at least one connected feedback vertex set of size at most k then at least one connected component of $G[V(G') \cap V(G)]$ is guaranteed to contain a connected feedback vertex set of G according to Lemma 17 and such a connected component by itself must also be a connected feedback vertex set of G . This completes the proof of the lemma. ◀

4 Conclusions and Open Problems

Our result on approximate kernelization for CONNECTED FEEDBACK VERTEX SET provides another useful data point in improving our understanding of the extent to which (approximate) preprocessing can be performed in the presence of connectivity constraints. Moreover, we believe that our techniques could have further applications in the design of approximate kernels for covering problems with connectivity constraints. Finally, this line of investigation offers several interesting opportunities for further research.

For instance, is there a *space efficient* PSAKS for CONNECTED FEEDBACK VERTEX SET? In a space efficient PSAKS, we require the size of the output to be bounded by $f(\frac{1}{\varepsilon}) \cdot k^c$, where f is a computable function and c is a constant independent of the error parameter ε . Essentially, a PSAKS is an apt analogue of a PTAS in the approximate kernelization world and an Efficient PSAKS is a natural analogue of an Efficient PTAS in this setting. We end by pointing out that the existence of a space efficient PSAKS is open even in the case of the CONNECTED VERTEX COVER problem.

Abstract

We study rumor spreading in graphs, specifically multicommodity multicast problem under the wireless model: given source-destination pairs in the graph, one needs to find the fastest schedule to transfer information from each source to the corresponding destination. Under the wireless model, nodes can transmit to any subset of their neighbors in synchronous time steps, as long as they either transmit or receive from at most one transmitter during the same time step. We improve approximation ratio for this problem from $\tilde{O}(n^{\frac{2}{3}})$ to $\tilde{O}(n^{\frac{1}{2}+\epsilon})$ on n -node graphs. We also design an algorithm that satisfies p given demand pairs in $O(\text{OPT} + p)$ steps, where OPT is the length of an optimal schedule, by reducing it to the well-studied packet routing problem. In the case where underlying graph is an n -node tree, we improve the previously best-known approximation ratio of $O(\frac{\log n}{\log \log n})$ to 3. One consequence of our proof is a simple constructive rule for optimal broadcasting in a tree under a widely studied telephone model.

1 Introduction

1.1 Motivation and Formulation

Rumor spreading problems have been popular for decades motivated by applications ranging from increasing throughput in synchronizing networks [3], keeping object copies in distributed databases synchronized [11], to recreational mathematics [4]. Common objectives in rumor spreading involve the total number of messages, the total number of transmissions (especially when message sizes are bounded in transmissions) and the completion time. In this paper, we study the minimum completion time objective for the multicast version of the problem where a set of source terminals wish to send their messages to their respective subsets of sinks.

The requirements for rumor spreading problem range from sending a single message from a single source to all nodes (broadcast), a subset of nodes (multicast) or a more generalized multicommodity version of multicast that we study. The rules for message transmission that have been widely studied are synchronous and range from the telephone model [5], the radio model [1] and the recently introduced wireless [6] model that shares the features of the first two. We mainly study the wireless model in this paper.

Multicommodity Multicast Problem. Given a communication graph G and demand pairs of vertices $(s_1, t_1), \dots, (s_p, t_p)$, where each source s_i has a unique piece of information (message or packet), the problem is to find a schedule that transfers the message from every source s_i to its corresponding destination t_i in a minimum number of steps. The rules under which the information is allowed to be sent in each step depend on the model.

Wireless Model. During each step, every node v in G is allowed to pick some of the vertices adjacent to v and send all information v has accumulated to those nodes at once (so there is no bound on message size). Nodes cannot receive from more than one source, nor can they send and receive during the same time step.

1.2 Related Work

The type of models that have been studied could be differentiated by the demand requirements and the rules under which information is spread. We highlight three different models relevant to our study, which roughly correspond to spanning, Steiner and generalized Steiner connectivity requirements studied in network design.

1. In the **Broadcast** problem, there is a single source (root) that must send its information to *all* nodes in the system.
2. In the more general **Multicast** problem, the root only needs its information to reach a *subset* of nodes in the system.
3. In the even more general **Multicommodity Multicast** problem, we are given source-destination pairs, and *every* source must transmit its message to the corresponding destination node.

We describe various models that define the rules of synchronous information transmission in rounds.

1. In the **Telephone model**, during one time step, every node with information is allowed to send it to *only one* of the adjacent nodes (neighbours) in the graph.
2. In the **Radio model**, a set of transmitting nodes send out information and only the other nodes that have unique transmitting neighbors can receive the information from that neighbor¹.
3. In the **Wireless model**, during one time step, every node with information is allowed to send it to *any* subset of neighbours.

In all models, nodes cannot receive from more than one source, nor can they send and receive during the same time step. The key difference between the radio and wireless models is that in the wireless model, receivers have tunable apparatus that allows them to listen in one exactly one of the neighbors that may be transmitting, whereas in the radio model, a node with two neighbors transmitting cannot receive any information due to interference. The most widely studied versions do not restrict the number of messages sent between a pair of nodes in each step, but capacitated versions are possible.

1.2.1 Telephone model

For the *broadcast/multicast* problems under the telephone model Ravi [10] showed a poly-logarithmic approximation in general graphs, by relating it to spanning/Steiner trees that simultaneously have small max degree and diameter (the so-called *poise* of the graph).

¹ We do not discuss this model further in this paper.

For this *broadcast/multicast* problem under the telephone model Elkin and Kortsarz [2] gave the best known $O(\frac{\log k}{\log \log k})$ -approximation factor, where k is the number of terminals the information should be delivered to.

► **Theorem 1** (Multicast approximation [2]). *Given graph G , root r and k target sinks, there is a poly-time algorithm TELEPHONEMULTICAST that finds a schedule that sends information from the root to all sinks in the telephone model and has approximation ratio $O(\frac{\log k}{\log \log k})$.*

The very general *multicommodity multicast* under telephone model was studied as well, where the best approximating ratio $\tilde{O}(2\sqrt{\log k})$ was achieved by Nikzad and Ravi [9]. Note that this ratio is super-polylogarithmic but sub polynomial in k , the number of terminals. No better approximations are known and part of the difficulty stems from the inability to relate this objective directly to graph parameters since the solution can in general be disconnected. This problem was also studied for special classes of graphs. First, it is known that if G is a tree, then a polynomial time algorithm to find optimal schedule for telephone broadcast can be derived through dynamic programming. Recently Iglesias, Rajaraman, Ravi and Sundaram [7] have shown a $O(\frac{\log^3 k \log n}{\log \log n})$ -approximation for multicommodity multicast for planar graphs.

1.2.2 Wireless model

Given that there are no restrictions on the number of neighbors receiving a transmission, for both the *broadcast and multicast* problems, optimal schedules under wireless model can be found in polynomial time using a simple *Breadth-First Search* (BFS) algorithm.

For the *multicommodity multicast* problem the best known approximate ratio was given by Iglesias, Rajaraman, Ravi and Sundaram [6], who also introduced the wireless model. They also showed an $O(\frac{\log n}{\log \log n})$ -approximation when the underlying graph is an n -node tree, as well as $\tilde{O}(n^{\frac{2}{3}})$ -approximation for general n -node graphs. There were two main ideas used in their paper: (i) If there are many sources that want to send to the same sink, we can satisfy them quickly using approximation algorithm for multicast under the telephone model; (ii) If there are many short disjoint path from sources to their respective destinations, we can satisfy them in parallel, otherwise we can reduce the number of sources considerably.

1.3 Packet routing problem

Another widely studied problem related to our work is so-called *store-and-forward packet routing problem*, where given packets at different source nodes, one needs to find a synchronous schedule of transporting them to given destinations, with the only restriction that no two packets can traverse the same edge at the same time step.

The main difference between store-and-forward packet routing and multicommodity multicast under wireless model is that the capacity restriction is put on the edge, not on the node. This means that a node can do the following: (i) receive several packets at the same time; (ii) send several packets as long as they use different edges; (iii) send and receive at the same time. What is not allowed in this model is to accumulate several packets and send them along one edge altogether, in contrast with the wireless model which can do that.

The analysis of packet routing problem involves a trade-off between the “dilation” parameter d (maximum path length) and the “congestion” criterion c (maximum number of paths using any edge). Note, that both c and d are lower bounds on the length of the optimal schedule for packet routing. Srinivasan and Teo [12] showed a polynomial time algorithm to find a schedule of length $O(c + d)$, which achieves a constant approximation. We reduce wireless multicommodity multicast problem to a packet routing problem to derive one of our results.

When the paths for the packets are given, Leighton, Maggs and Rao [8] initiated a long line of work that showed the existence and efficient construction of schedules of length $O(c + d)$, which was used extensively in the work cited above on finding such near optimal routes when the paths are not specified in advance.

1.4 Our Contributions

In this paper we focus on *multicommodity multicast* problem under the *wireless model*.

- We show that for any given constant $\varepsilon > 0$, there is a polynomial time $\tilde{O}(n^{\frac{1}{2}+\varepsilon})$ -approximation algorithm that, given an arbitrary graph G and pairs of source-destination nodes (s_i, t_i) , finds a schedule to transfer information from source s_i to destination t_i for all i (Theorem 2). This algorithm generalizes the ideas of Iglesias et al. [6] and applies them recursively.
- We design a polynomial time algorithm that, given an arbitrary graph G and p pairs of source-destination nodes (s_i, t_i) , finds a schedule of length $O(\text{OPT} + p)$ to transfer information from source s_i to destination t_i for all i , where OPT is the length of the optimal one (Theorem 10). To prove this result, we reduce our problem to an instance of packet routing in an appropriately defined auxiliary digraph.
- We show that there is a polynomial time 3-approximation algorithm that, given a tree T and pairs of source-destination nodes (s_i, t_i) , finds a schedule to transfer information from source s_i to destination t_i for all i (Theorem 16). This result decomposes the schedule into sending messages up the tree followed by a phase that sends it down the tree.
- We give a **simple** optimal schedule for the broadcast in the tree under telephone model (Theorem 23). This is not a new result but a conceptual improvement over the previous strategies that all rely on dynamic programming by providing a simple explicit rule for choosing the transmitting pairs.

The widely studied telephone and relatively new wireless models are related to each other in the following way. Even though spreading information from one source to several sinks under wireless model can be done efficiently using BFS, collecting information from several sources into one sink is equivalent under both models. This follows from the fact that while collecting to one sink every piece of information travels on a straight path. This observation implies that the *gossip problem*, where every node in the graph has to sent its message to all other nodes, is equivalent under both models, up to a constant factor. More precisely, the optimal schedule for the gossip problem under the wireless model is no longer than twice the optimal broadcast schedule under the telephone model, which can be used to sweep all information to a fixed root and spread it back in a BFS tree to all nodes. In the other direction, the optimal schedule for the gossip problem under the wireless model is at least as long as the optimal broadcast schedule under the telephone model since both models are required to collect information from all the nodes to a root under the same constraints.

The multicommodity multicast problem is a generalization of both multicast and gossip problems, so combines the difficulty of both. Finding approximation algorithms for this problem under wireless model includes difficulties for multicommodity multicast under telephone model. As mentioned earlier, the best-known approximation ratio of $\tilde{O}(2\sqrt{\log n})$ [9] for multicommodity multicast under telephone model is sub polynomial in n , whereas the best-known ratio for this problem under the wireless model is $\tilde{O}(n^{\frac{2}{3}})$ [6]. Thus, the very general multicommodity multicast problem under the wireless model appears to be quite hard to approximate. Our work significantly improve this ratio down to roughly $O(\sqrt{n})$.

2 General graphs

In this section, we study general multicommodity-multicast problem in arbitrary graphs. The best known approximation ratio so far is $\tilde{O}(n^{\frac{2}{3}})$ [6]. We improve this bound to roughly $\tilde{O}(\sqrt{n})$.

► **Theorem 2.** *Algorithm 3 is a polynomial algorithm that, given any $\varepsilon > 0$ and arbitrary graph with demand pairs, can find a multicommodity-multicast schedule in the wireless model with approximation ratio $O(n^{\frac{1}{2}+\varepsilon})$.*

In the sequel, we assume that we are given the length L of the optimal rumor spreading schedule. Note that there is always a wireless multicast schedule of linear length in a connected graph by using any spanning tree, and traversing an Euler tour of the tree twice and using the edges in the traversal in order. Thus, we can guess the length L at the very beginning in the range $[1, 4(n-1)]$.

2.1 Algorithm

Our algorithm exploits two main observations that were introduced by Iglesias, Rajaraman, Ravi and Sundaram [6].

2.1.1 Idea 1

The first key idea is the following. If there are numerous sources that want to send to the same sink, we can satisfy **all demands** that originate in those sources. Algorithm 1 shows how this can be done. The analysis of the algorithm is summarized in Lemma 3.

► **Lemma 3** (Big in-demand [6]). *Given a vertex t that is a sink in demand pairs $(s_1, t), \dots, (s_d, t)$, Algorithm 1 satisfies **all demands** from nodes s_1, \dots, s_d in $\tilde{O}(L)$ steps.*

Note that we are not only satisfying d demand pairs, but potentially up to $d \cdot n$ demands, because every s_i could be a source of up to n demand pairs.

■ **Algorithm 1** Algorithm for satisfying all demands in the “demand-neighbourhood” of a given vertex.

procedure INDEMAND(G, S, t)

Input: graph G , source nodes $S = \{s_1, \dots, s_d\}$ with the same sink t .

Run TELEPHONEMULTICAST(G, t, S) to get schedule TM that spreads information from t to all nodes in S under telephone model.

Reverse schedule TM and run it on G to collect all information from s_1, \dots, s_d in t .

Run BFS(t) to spread information from t to all sinks that correspond to sources in S .

end procedure

2.1.2 Idea 2

The key observation here is the following. If we can find a lot of disjoint source-destination paths, we can satisfy all of them **in parallel**, and hence in at most the length of the longest path. We will try to greedily find as many paths of length at most L as possible from given sources to corresponding destinations. Algorithm 2 summarizes this procedure.

■ **Algorithm 2** Algorithm for finding disjoint paths between sources and destinations.

procedure DISJOINTPATH(G, D, L)

Input: graph G , demand pairs $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ and the length of the optimal algorithm L .

$P = \emptyset$

while there is a demand pair $(s, t) \in D$ such that the distance between s and t is at most L **do**

 Add shortest path from s to t to P .

 Delete all vertices in this path from G .

end while

Return P .

end procedure

2.1.3 Our idea

Iglesias, Rajaraman, Ravi and Sundaram [6] used both ideas and balanced parameters in them to achieve $\tilde{O}(n^{\frac{2}{3}})$ -approximation. We will combine and generalize these ideas in a different way.

Idea 2.1.1 is useful when there is a vertex with high in-demand. More precisely, it allows us to reduce the number of distinct sources while there are a lot of demand pairs.

Idea 2.1.2 instead shows how we can either satisfy a lot of demand pairs in parallel or significantly reduce the number of distinct sources.

Our contribution comes from generalizing both ideas and combining them alternatively. We use the first idea to reduce the number of demand pairs, then we use the second idea to reduce the number of distinct sources. Now, given smaller number of sources we exploit the first idea again to reduce the number of demand pairs even further, etc. Algorithm 4 corresponds to the first idea of reducing the number of demand pairs given the number of distinct sources, whereas Algorithm 5 corresponds to the second idea of reducing the number of distinct sources given fixed number of demand pairs. These two algorithms call each other recursively. If we keep doing this infinitely long, we will achieve $\tilde{O}(\sqrt{n})$ -approximation, so the main Algorithm 3 stops when it gets ε -close to it.

The analysis of the algorithm is presented in the main Lemma 7. The key idea in the analysis is that the first observation can improve the performance of the second one, and vice versa. So we alternatively apply each observation to improve the previous one.

2.2 Correctness and Complexity

▷ **Claim 4.** Algorithm 3 satisfies all given demands in the graph under wireless model rules.

First, note that the length L of the optimal schedule is at most $4(n - 1)$, where n is the number of vertices, so one of the runs of $S(G, D, k, L)$ will use the correct guess of L and hence will satisfy all demands as long as Algorithm 4 works properly.

▷ **Claim 5.** Algorithms 4 and 5 satisfies all given demands in the graph under wireless model rules.

Proof. First, note that algorithms 4 and 5 call each other alternatively, but every second time, the parameter k (which keeps track of the number of iterations) decreases by 1, so it will eventually reach 0. Also, note that every time any of these algorithms modify the set of demand pairs D , they correctly satisfy or split demands. After k reaches 0, Algorithm 4 just runs BFS from every source node, which clearly satisfies all demands. ◁

■ **Algorithm 3** Algorithm for rumor spreading in the general graph.

```

procedure GENERALMM( $G, D, \varepsilon$ )
  Input: unweighted graph  $G$ , demand pairs  $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$  and precision  $\varepsilon > 0$ .

  Take integer  $k = \lceil \frac{1}{4\varepsilon} \rceil$ .
  for  $L = 1, 2, \dots, 4(n-1)$  do           ▷ guess for the length of the optimal schedule
    if  $S(G, D, k, L)$  produces a shorter schedule then
      Save  $S(G, D, k, L)$  as current answer in BestSchedule.
    end if
  end for
  Return BestSchedule.
end procedure

```

■ **Algorithm 4** Algorithm for general graphs based on the number of sources.

```

procedure  $S(G, D, k, L)$ 
  Input: graph  $G$ , demand pairs  $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ , iteration number  $k$  and the length of the optimal schedule  $L$ .

  if  $k = 0$  then                               ▷ condition to exit the recursion
    for every distinct source  $s$  do
      Run BFS( $s$ ).                               ▷ to satisfy all demands in  $D$  that start in  $s$ 
    end for
    Exit.
  end if

  Compute  $s$  to be the number of vertices in the graph that are sources in at least one demand pair in  $D$ .
  Take  $\alpha = \frac{1+k \log_s n}{2k+1}$ .
  while there is a vertex  $t$  with at least  $s^{1-\alpha}$  demands going into it do
    Compute  $S_t$  to be those vertices that needs to send information to  $t$ . So  $S_t = \{s \mid (s, t) \in D\}$ .
    Run INDEMAND( $G, S_t, t$ ) to satisfy all demands that originate in  $S_t$ .
    Delete all demands that originate in  $S_t$  from  $D$ .
  end while
  Run  $P(G, D, k-1, L)$ .
end procedure

```

▷ **Claim 6.** Algorithm 3 runs in polynomial time($n, \frac{1}{\varepsilon}$).

Proof. First, note that Algorithm 1 runs in polynomial time, because TELEPHONEMULTICAST as well as BFS run in polynomial time. Since we can find shortest path between any two nodes in a graph in polynomial time, Greedy Algorithm 2 runs in polynomial time as well since we decrease the number of vertices in the graph at each iteration.

Then, Algorithm 3 runs Algorithm 4 $4(n-1)$ times, so it is polynomial time as long as Algorithm 4 is.

Algorithms 4 and 5 call each other alternatively, at most $k = \lceil \frac{1}{4\varepsilon} \rceil = O(\frac{1}{\varepsilon})$ times each. So it is enough to show that both of these algorithms each run in polynomial time.

■ **Algorithm 5** Algorithm for general graph based on the number of demand pairs.

procedure P(G, D, k, L)

Input: graph G , demand pairs $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ and iteration number k and the length of the optimal algorithm L .

Take $\beta = \frac{1+k \log_p n}{2k+2}$.

while the number of disjoint paths $d = |\text{DISJOINTPATH}(G, D, L)|$ is at least $p^{1-\beta}$ **do**

Satisfy all d demands in parallel following paths in $\text{DisjointPath}(G, D, L)$.

Delete all those demands from D .

end while

Denote $\text{DISJOINTPATH}(G, D, L)$ to be the disjoint paths for demand pairs $\{(s_1, t_1), \dots, (s_d, t_d)\}$.

Let a new graph G' be G with added complete binary tree with leaves t_1, \dots, t_d and root r .

Compute S to be all vertices in G that are sources in at least one demand pair in D .

$\text{TM} = \text{TELEPHONEMULTICAST}(G, r, S)$. \triangleright TM spreads information from the root r to all sources in D under telephone model

Reverse schedule TM and run it on G . \triangleright It will collect all information from sources in D into t_1, \dots, t_d

$D_{\text{new}} = \emptyset$

for $(s, t) \in D$ **do**

Find t_i among t_1, \dots, t_d that has information from source s .

Add demand pair (t_i, t) into D_{new} .

end for

Run $S(G, D_{\text{new}}, k, L)$.

end procedure

Algorithms 4 runs Algorithm 1 at most $\frac{s}{s^{1-\alpha}} = s^\alpha$ times. Given that $\alpha = \frac{1+k \log_s n}{2k+1}$ we have that $s^\alpha = \sqrt[2k+1]{sn^k} \leq \sqrt[2k+1]{n^{k+1}} \leq n$. As we have already noted, Algorithm 1 also runs in poly-time, so overall 4 is poly-time in terms of n and $\frac{1}{\varepsilon}$.

Algorithms 5 runs Algorithm 2 at most $\frac{p}{p^{1-\beta}} = p^\beta$ times. Given that $\beta = \frac{1+k \log_p n}{2k+2}$ we have that $p^\beta = \sqrt[2k+2]{pn^k} \leq \sqrt[2k+2]{n^{k+1}} \leq n$. As we have already noted, Algorithm 2 also runs in poly-time. So overall Algorithm 4 is polynomial time in terms of n and $\frac{1}{\varepsilon}$. \triangleleft

2.3 Analysis

First, assume that for the given graph and demand pairs the optimal schedule takes L time steps. The main Theorem 2 will follow from the following key lemma:

► **Lemma 7.** *For every $k \in \mathbb{N}_0$ the following holds:*

(S_k) *If the number of distinct sources is s , then there is a $\tilde{O}(\sqrt[2k+1]{sn^k})$ -approximation schedule.*

(P_k) *If the total number of demand pairs is p , then there is a $\tilde{O}(\sqrt[2k+2]{pn^k})$ -approximation schedule.*

Note that $s \leq n$, so for every $k \in \mathbb{N}_0$ from S_k we can have $\tilde{O}(\sqrt[2k+1]{sn^k}) = \tilde{O}(n^{\frac{k+1}{2k+1}})$ approximation schedule. As $k \rightarrow \infty$, $\frac{k+1}{2k+1} \rightarrow \frac{1}{2}$, and hence we can find a schedule that has approximation ratio $O(n^{\frac{1}{2}+\varepsilon})$ for any positive ε . Thus, Lemma 7 implies the main Theorem 2.

To prove the main lemma, we use an important observation that handles aggregated messages with a few sinks.

► **Lemma 8.** *If there is only one sink in multicommodity multicast under wireless model, then there is an $O(\frac{\log p}{\log \log p})$ -approximation algorithm for satisfying all demands, where p is the number of sources.*

Proof. The proof is based on the fact that collecting information from several sources to one sink t under wireless model is equivalent to multicasting information from t to those sources under telephone model (in reverse).

Note that because we are collecting information at one node, every piece of information travels on the path (the node never sends information to several neighbours at the same time) and so every step of the schedule is a matching - in other words, we have never used the power of wireless model over telephone model. Hence, collecting information at one node under wireless model is equivalent to collecting under telephone model, which is further equivalent to multicast under telephone model by reversing the schedule.

Using the known approximation result for multicasting under the telephone model given in Theorem 1, we can find a multicast schedule of length at most $O(L \cdot \frac{\log p}{\log \log p})$. Reversing it leads to a schedule that collects all information into t in time $O(L \cdot \frac{\log p}{\log \log p})$. ◀

We can now prove our initial lemma about satisfying all the demands of sources corresponding to a single sink.

Proof of the Lemma 3. We will produce a schedule that will satisfy all demands from nodes s_1, \dots, s_d in $\tilde{O}(L)$ steps. It will go in two stages:

1. Collect all information from s_1, \dots, s_d in t using Lemma 8.
2. Send it all together from t to all sinks of s_1, \dots, s_d using BFS.

Note that the second step could be done in $O(L)$ by BFS from t , because the distance from t to any sink of s_i is at most the distance from t to s_i plus the distance from s_i to sink, which is at most $L + L = 2L$. ◀

Proof of key Lemma 7. We prove this by induction on k . Moreover, the structure will be as follows.

1. $S_k \Rightarrow P_k$ for every $k \geq 0$.
2. $P_k \Rightarrow S_{k+1}$ for every $k \geq 0$.

Base case. It is enough to prove base case S_0 , in other words that it is possible to satisfy all demands with approximation ratio $O(s)$. Note that if we fix an arbitrary source v , we can satisfy all its demands in $O(L)$ steps by BFS starting at v (exploiting the power of wireless model where we can send to several neighbours at the same time). By repeating this over the s sources, it is possible to satisfy all demands in $O(L \cdot s)$ steps.

Induction step. Fix an arbitrary $k \geq 0$.

1. We want to prove that $S_k \Rightarrow P_k$.

To recall, this means that: if there is a $\tilde{O}(\sqrt[2^{k+1}]{sn^k})$ approximation schedule for s sources, then there is a $\tilde{O}(\sqrt[2^{k+2}]{pn^k})$ approximation schedule for p demand pairs.

Assume that we are given p demand pairs.

Forming greedy paths: Start with an arbitrary source and try to find a path of length at most L to one of its destinations. If found, delete all vertices in this path from the graph and repeat. This corresponds to Algorithm 2.

After this stage we have some maximal number d of disjoint paths $(s_1, t_1), \dots, (s_d, t_d)$. Note that because they are disjoint we can satisfy all of them in parallel in L steps. Let $\beta \in [0, 1]$ be a constant we will set afterwards. The idea of Algorithm 5 is the following.

- a. If the number of greedy paths d is at least $p^{1-\beta}$, then satisfy those demands in parallel and repeat.
- b. If the number of greedy paths d is less than $p^{1-\beta}$, we will reroute/collect all information at t_1, \dots, t_d using Lemma 9 and finish everything in one shot by applying S_k to it.

We cannot repeat the first case more than $\frac{p}{p^{1-\beta}} = p^\beta$ times, and so the total number of rounds in the schedule is at most $\tilde{O}(L \cdot p^\beta)$.

In the second case, there are $d \leq p^{1-\beta}$ sources now, so by applying S_k we get that we can send all information in $\tilde{O}(L \cdot {}^{2k+1}\sqrt{p^{1-\beta}n^k})$. Combining the two cases gives approximation ratio $\tilde{O}(p^\beta + {}^{2k+1}\sqrt{p^{1-\beta}n^k})$. Minimizing this leads to $\beta = \frac{1+k \log_p n}{2k+2}$ and approximation ratio $\tilde{O}({}^{2k+2}\sqrt{pn^k})$, which is exactly what we wanted.

Technical note: we need to ensure that $\beta \in [0, 1]$. Clearly $\beta \geq 0$. Now, $k = 0$ leads to $\beta = \frac{1}{2}$, giving a \sqrt{p} approximation ratio. For $k \geq 1$ we have that $p \geq n \Rightarrow \beta \leq 1$, but in the case $p < n$ the approximation ratio \sqrt{p} is better than $\tilde{O}({}^{2k+2}\sqrt{pn^k})$ for any k .

The only thing left is to prove the following lemma.

► **Lemma 9** ([6]). *If there are d greedy paths $(s_1, t_1), \dots, (s_d, t_d)$, we can collect all information at one of the t_1, \dots, t_d in $\tilde{O}(L)$ time.*

Figure 1 gives an example illustration of the Lemma 8.

■ **Figure 1** Collecting information from all sources into t_1, \dots, t_k .

Proof. For the simplicity of the argument (and to use results about broadcast time, which is the same as collecting information at one node), we will add to our graph a dummy complete binary tree with leaves t_1, \dots, t_d and root r and our goal will be to collect all information at r in $\tilde{O}(L)$ time. Obviously, if we can do this, then we also will be able to collect all information at one of the t_1, \dots, t_d in the same amount of time.

Consider an arbitrary source s and pick a fixed sink t for it (only one). Consider the path between $s \rightarrow t$ in the optimal schedule. This path has length at most L and hence it should intersect with path $s_i \rightarrow t_i$ for some i (otherwise we can find one more disjoint path of length at most L). This means that if we run the optimal schedule, then nodes on the greedy paths will contain information from all sources. Hence if we run it for L more steps by transmitting information only along greedy paths, information from all

sources will eventually be at one of t_1, \dots, t_d . The dummy binary tree has depth at most $\log d \leq \log n$, so if we run the schedule for $2 \log n$ more rounds (two parallel rounds per level), the root r will contain all the information.

This means that it is possible to collect all information in r in at most $2L + 2 \log n$ steps. Using Lemma 8 we can find schedule that collects all information into r in at most $O((2L + 2 \log n) \frac{\log n}{\log \log n}) = \tilde{O}(L)$ steps. ◀

2. We want to prove that $P_k \Rightarrow S_{k+1}$.

Here we will exploit Lemma 3. Note that we are not just satisfying d demand pairs, but potentially up to $d \cdot n$ demands, because every source s_i could be in up to n demand pairs. Also, by the base case we know that this could be done in $O(dL)$ steps, but this lemma gives a much better bound.

Now, assume that we have s sources, and let $\alpha \in [0, 1]$ be number that we will define afterwards. The main idea of Algorithm 4 is the following.

- a. **If there is a vertex with at least $s^{1-\alpha}$ demands** going into it, then satisfy those demands by Lemma 3 and repeat.
- b. **If every vertex has less than $s^{1-\alpha}$ demands** going into it, then the total number p of demand pairs is small and we will finish in one shot by applying P_k .

In the first case we can satisfy all demands in $\tilde{O}(L)$ steps by the lemma, and also we will repeat this at most $\frac{s}{s^{1-\alpha}} = s^\alpha$ times, so the total number of steps is $\tilde{O}(L \cdot s^\alpha)$.

In the second case, if every vertex has less than $s^{1-\alpha}$ demands going into it, then the total number of demands is $p \leq s^{1-\alpha}n$. Applying P_k gives that we can find a schedule to satisfy all demands in $\tilde{O}(L \cdot \sqrt[2k+2]{s^{1-\alpha}n^{k+1}})$.

Combining the two yields to approximation ratio $\tilde{O}(s^\alpha + \sqrt[2k+2]{s^{1-\alpha}n^{k+1}})$. By minimizing this we get $\alpha = \frac{1+(k+1)\log_s n}{2k+3}$ for the call to $S(G, D, k+1, L)$ and corresponding approximation ratio $\tilde{O}(\sqrt[2k+3]{sn^{k+1}})$, which is what we wanted.

Technical note: we need to ensure that $\alpha \in [0, 1]$. Clearly $\alpha \geq 0$. Note that $\alpha \leq 1$ if and only if $s \geq \sqrt{n}$, but in the case $s < \sqrt{n}$ the approximation ratio $O(s)$ in the base case is better than $\tilde{O}(\sqrt[2k+3]{sn^{k+1}})$ for any k . ◀

3 Reduction to packet routing

In this section we draw a connection between multicommodity multicast problem and extensively studied store-and-forward packet routing problem. We further derive an algorithm that satisfies all demands in $O(\text{OPT} + \text{number of demand pair})$ for multicommodity multicast under wireless model using approximation results from packet routing problem. Note that if the number of given demand pairs is small or the optimal schedule is long, this gives a better approximation result compared to the one we have shown in Section 2.

► **Theorem 10.** *There is a polynomial time algorithm that finds a schedule of length $O(L+p)$ for multicommodity multicast problem with p demand pairs under wireless model.*

3.1 Packet routing problem

We are going to relate wireless multicommodity multicast and packet routing problem.

► **Definition 11** (Store-and-forward packet routing problem). *Given an arbitrary (directed) graph G and source-sink pairs of vertices $(s_1, t_1), \dots, (s_p, t_p)$, where each source s_i has a unique packet, the problem is to find a schedule that transfers packets from every source s_i to every destination t_i in a minimum amount of steps, so that no two packets can traverse the same edge at the same unit of time.*

Note that under wireless model we are allowed to send several pieces of information at once along one edge, which is not the case for packet routing problem. On the other hand, packet routing problem has no other restrictions. This implies that a node can: (i) receive several packets at the same time (ii) send several packets as long as they use different edges (iii) send and receive at the same time.

The analysis of packet routing problem involves a trade-off between the “dilation” parameter d (maximum path length) and the “congestion” criterion c (maximum number of paths using any edge). Note that both c and d are lower bounds on the length of the optimal schedule for packet routing. Since the paths for the packets are not specified a priori, note that the problem also first involves finding such paths minimizing the sum of the dilation and congestion and then constructing an actual (offline centralized) schedule that completes in about this many rounds. Srinivasan and Teo [12] do just that and show how to construct a schedule of length $O(c + d)$, which achieves constant approximation.

► **Theorem 12** ([12]). *There is a polynomial time algorithm that finds a schedule for store-and-forward packet routing problem and gives a constant approximation.*

3.2 Reduction from wireless to packet routing

We prove Theorem 10 by reducing multicommodity multicast under the wireless model to packet routing problem and using Theorem 12. There are two superior properties in the packet routing problem: (i) a node can receive from several sources per time step; (ii) a node can send and receive at the same time step.

First, we will show how to eliminate (i). The number of incoming messages is a lower bound under wireless model (because a node can receive only from one source), whereas it is not the case in packet routing problem. Given an instance for wireless multicommodity multicast, we are going to modify it to create another instance for packet routing and use its schedule to design a fast wireless schedule that satisfies given demand pairs. Formally speaking, given an arbitrary undirected graph G we construct *directed* graph G' in the following way. For every node $v \in G$ we create two nodes v_{in} and v_{out} in G' and put a directed edge $v_{in} \rightarrow v_{out}$. Also, for every edge $(u, v) \in G$ we put directed edges $u_{out} \rightarrow v_{in}$ and $v_{out} \rightarrow u_{in}$ in G' . Then, every demand pair (s, t) in G correspond to demand pair (s_{in}, t_{out}) in G' . We split every original vertex into “only receiving” and “only sending” part. In this way the inbound restriction of v in G is translated into congestion restriction of edge $v_{in} \rightarrow v_{out}$ in G' .

We still need to address the second difference (ii) between packet routing and wireless. But for now we relax this condition and show how to transform wireless multicommodity multicast to packet routing allowing nodes to send and receive at the same time under wireless model.

► **Definition 13.** *The **Upgraded Wireless model** is the relaxation of the wireless model in which a node is allowed to send and receive information at the same time.*

► **Lemma 14** (Packet to information routing). *Given a schedule for packet routing problem on the graph G' , it is possible to transform it in polynomial time to a schedule of the same length on the graph G under the upgraded wireless model.*

Proof. First, given a packet routing schedule R on G' we modify R to schedule R' such that the following is true: (i) R' sends information through the same path as R (ii) R' finishes in the same amount of steps as R (iii) the graph G' does not contain any nodes that receive from more than one source at any time step. Then we show how given R' one can simply construct an upgraded wireless schedule of the same length on G .

Let's fix an arbitrary time step in R . Every node that sends to several destinations, or sends and receives at the same time can still do so under upgraded wireless model. The only issue is that a node cannot receive from several sources. Note that v_{out} can receive only from v_{in} , so we will show how to alter the schedule R so that every node v_{in} receives a packet from at most one neighbor. The main idea is that instead of accumulating packets at 'receiving' vertices v_{in} , we will accumulate information at 'sending' vertices u_{out} . More precisely, if vertex u_{out} sends packet p_i to v_{in} at some point t in time in R , then the new schedule R' does the following: vertex u_{out} will hold packet p_i and send it to v_{in} *right before* the time step when v_{in} sends p_i to v_{out} in R . So we send information only when needed, otherwise hold it in the previous node.

Note that in R' there is no vertex that receives from more than one node at a time. Moreover, the time at which every packet arrives to any vertex v_{out} under R is the same as in R' . This follows from the fact that whenever some vertex v_{out} needs a packet p_i from v_{in} , vertex v_{in} would have already collected packet p_i by construction of R' .

We are left to show that packet routing R' on graph G' could be transformed into upgraded wireless schedule W of the same length on graph G . Every time vertex u_{out} sends a packet p_i to v_{in} , let W send information i from u to v . Indeed, W has the same number of steps as R' and satisfies all demands, because it just mirrors packet schedule of R' . Moreover, W is a valid upgraded wireless schedule, since in R' every node receives from at most one node at every time step. ◀

► **Lemma 15.** *Given a schedule under upgraded wireless model it is possible to transform it in polynomial time to a schedule under wireless model, which has at most 3 times as many steps.*

Proof. Fix a time step and let S to be the directed graph of information flow of the given schedule under upgraded wireless model at this specific time step. So there is a directed edge $u \rightarrow v$ in S if and only if node u sends information to node v during this time step. We will show how to send all information that S does using wireless model in three time steps.

Note that the in-degree of every node in S is at most 1, because under upgraded wireless model a node still cannot receive from more than one source per time step. Each connected component in any directed graph with in-degree bounded by 1 has a simple characterization. It is a directed cycle with outbound trees hanging from it. More precisely, it is a union of the cycle $v_1 \rightarrow v_2 \rightarrow \dots \rightarrow v_k \rightarrow v_1$ with several trees each rooted at one of v_i 's, where every edge in a tree is directed out from the root. Note that it is enough to show how to transfer information in one connected component of schedule S using the wireless model and then run this in parallel across different connected components.

Deleting an edge $v_k \rightarrow v_1$ from the cycle (any other edge works as well) leads us to a tree rooted at v_1 , where every edge is directed out from the root. We show how to send all information along the edges in such a tree. We apply the following trick: let the *level* of the vertex be its distance to the root of the tree. Now, call the vertex *even* if its level is even and *odd* if its level is odd. First, all odd nodes that need to send information will do so (and so even ones will be able to receive). Then, all even nodes will be allowed to send information (and so odd ones will receive). In this way every node is either receiving or sending information. Finally, we send information along the deleted edge $v_k \rightarrow v_1$ from the cycle. Hence instead of sending all information in one time step, we did it in three. This blows up the total number of time steps by a factor of 3. ◀

► **Remark.** The result in Lemma 15 is sharp, for instance when underlying demand graph S is a directed cycle on 3 vertices. Under thre upgraded wireless model information could be sent in 1 step, whereas under the usual wireless model it requires 3 steps.

We are going to combine these results to prove Theorem 10. Given multicommodity multicast problem under wireless model on graph G with p demand pairs, we construct graph G' as described. Also, for every demand pair (s_i, t_i) in G we create a separate packet that originates at s_i and needs to be delivered to t_i . Note that even if there is one piece of information that originates at source s and needs to be sent to different sinks t_1, \dots, t_k , we create *different* packets p_1, \dots, p_k for each of these demands. If we consider optimal wireless schedule of length L on G and trace the path of every packet p_i , then the length of every such path is at most L , and on every edge the number of paths that uses that edge is at most p (because there are p paths in total). Hence, dilation $d \leq L$ and congestion $c \leq p$. We do not know the optimal wireless schedule, but both c and d are lower bound on the length of optimal packet routing schedule, and hence $\frac{c+d}{2}$ is also a lower bound. Theorem 12 gives a constant-approximation schedule for packet routing, and hence this schedule satisfy all demands in $O(c + d) = O(L + p)$ time steps. Then we exploit Lemma 14 and Lemma 15 to transform it into a $O(L + p)$ schedule for multicommodity multicast problem under the wireless model, which proves Theorem 10.

4 Rumor spreading in trees

In this section we present a simple polynomial algorithm TREE that gives a constant approximation for wireless rumor spreading in trees, which improves the best known $O(\frac{\log n}{\log \log n})$ -approximation ratio for n -node trees.

► **Theorem 16.** *Algorithm TREE runs in polynomial time and gives 3-approximation for multicommodity multicast problem in a tree under wireless model.*

The algorithm consists of two parts. We use the same idea as Iglesias, Rajaraman, Ravi and Sundaram [6], by rooting the tree and splitting rumor spreading into sending all information *up the tree* to ancestors, and then sending it *down the tree* to descendants.

4.1 Algorithm

■ **Algorithm 6** Algorithm for rumor spreading in the tree.

```

procedure TREE( $T, D$ )
  Input: Tree  $T$  and demand pairs  $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ .
  Pick an arbitrary vertex  $r$  and root the tree  $T$  at  $r$ .
   $D_{up} := \emptyset$ 
   $D_{down} := \emptyset$ 
  for  $(s, t) \in D$  do
    Find the least common ancestor  $lca(s, t)$  of  $s$  and  $t$ .
    Add demand pair  $(s, lca(s, t))$  to  $D_{up}$ .
    Add demand pair  $(lca(s, t), t)$  to  $D_{down}$ .
  end for
  Run TreeUp( $T, D_{up}$ ).
  Run TreeDown( $T, D_{down}$ ).
end procedure

```

In order to send information *up* the tree, algorithm TREEUP uses a greedy approach to send information that should go the furthest first. This strategy satisfies all demand pairs in at most $2 \cdot \text{OPT}$ time steps, where OPT is the length of the optimal schedule. Lemma 19 provides an analysis of the algorithm.

■ **Algorithm 7** Algorithm for rumor spreading, when all demands go up the tree.

```

procedure TREEUP( $T, D$ )
  Input: Rooted tree  $T$  and demand pairs  $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ , where  $t_i$  is an
  ancestor of  $s_i$  in the tree, for every  $i$ .
   $D_{clean} := \emptyset$  ▷ This will contain a subset of demand pairs  $D$  with non-repeating sources.
  for every vertex  $s \in G$  that is a source in  $D$  do
    Among all demand pairs in  $D$  with source  $s$  consider the one, which has the longest
    distance between  $s$  and corresponding sink in the tree.
    Add this pair in  $D_{clean}$ .
  end for
  Set the depth of every node  $v$ ,  $d(v)$  to be the length of the path from  $v$  to the root  $r$ .
  Set current number of steps  $i := 0$ .
  while not all demands in  $D_{clean}$  are satisfied do
    for  $v \in G$  do
      if  $d(v)$  has same parity as  $i$  then
        Find child  $u$  of  $v$  with the piece of information that at the current state
        needs to travel the longest distance up in the tree to its sink.
        Send all information  $u$  has up to  $v$ .
      end if
    end for
     $i = i + 1$ 
  end while
end procedure

```

The algorithm TREEDOWN sends information *down* the tree very fast, using two observations. First, it exploits the fact that under wireless model information could be sent to several neighbours simultaneously. Second, we note that any two nodes in a tree have disjoint set of children. We show that this strategy shows satisfies all demands in at most $\text{OPT}+1$ steps. Lemma 20 gives this analysis of algorithm TREEDOWN 8.

■ **Algorithm 8** Algorithm for rumor spreading, when all demands go down the tree.

```

procedure TREEDOWN( $T, D$ )
  Input: Rooted tree  $T$  and demand pairs  $D = \{(s_1, t_1), \dots, (s_p, t_p)\}$ , where  $t_i$  is a
  descendant of  $s_i$  in the tree, for every  $i$ .
  Set the depth of every node  $v$ ,  $d(v)$  to be the length of the path from  $v$  to the root  $r$ .
  Set current number of steps  $i := 0$ .
  while not all demands are satisfied do
    for  $v \in G$  do
      if  $d(v)$  has same parity as  $i$  then
        send all information  $v$  has to all its children in the tree.
      end if
    end for
     $i = i + 1$ 
  end while
end procedure

```

Combining these two algorithms, we get the overall algorithm TREE for wireless multicommodity multicast in the tree.

4.2 Correctness and Complexity

▷ **Claim 17.** Algorithm TREE 6 satisfies all given demands in the tree under wireless model rules.

Proof. First, it is clear that if we first send information from source s to $lca(s, t)$ for every demand pair (s, t) , and then from $lca(s, t)$ to t for all (s, t) , then we would have sent information from every s to corresponding t .

Now, we need to show that algorithms TREEUP 7 and TREEDOWN 8 correctly send information up and down the tree respectively. First, let's show that both algorithms obey wireless rules. Note that in both algorithms only nodes with the same parity of depth can send information, and so node with opposite parity of depth will receive information, hence there is no vertex that is trying to send and receive information at the same time.

Next, we show that none of the nodes is trying to receive information from more than one vertex. Every vertex v in algorithm TREEUP 7 receives from only one of its children (if any). For algorithm TREEDOWN 8, observe that nodes with even (or odd) depth are pairwise not connected, and so sets of their children are disjoint.

Finally, note that both algorithms will run until all demands are satisfied. Since at every step at least one piece of information becomes closer to the destination, it should satisfy all demands in finite number of steps. ◁

▷ **Claim 18.** Algorithm TREE runs in polynomial time.

Proof. It is enough to show that both algorithm TREEUP 7 and algorithm TREEDOWN 8 run in polynomial time. Note that since at every step at least one piece of information becomes closer to the destination, the number of while loops is at most (number of demand pairs) · (maximum distance in the tree), which is polynomial in the number of vertices in the tree. In algorithm TREEUP 7 at each iteration of the while loop, we also need to loop through all children of v and find the one that needs to send information the furthest. This could be done in poly-time as well, because the number of children, pieces of information and diameter of the tree are all polynomial in n . ◁

We show that algorithm TREE outputs a rumor spreading schedule that is at most 3 times longer than the optimal one. Let us denote the length of the optimal schedule to be L .

It is enough to analyze approximation ratios of both algorithm TREEUP and algorithm TREEDOWN. We show that the first one gives a 2-approximation and the second one is almost optimal.

► **Lemma 19.** *Algorithm TREEUP 7 produces the schedule that satisfies all demands in at most $2L$ steps.*

► **Lemma 20** ([6]). *Algorithm TREEDOWN 8 produces the schedule that satisfies all demands in at most $L + 1$ steps.*

These two lemmas clearly imply that algorithm TREE 6 has approximation ratio 3.

Proof of Lemma 19. Note that for every source s , all of its sinks could only be the vertices along the path from s to the root. Observe that for each $s - t$ pair the path from s to t is unique and hence we can also define a distance from s to t .

If s has to send to several sinks, we can leave only the furthest sink and remove others - because the tree path from s to the furthest sink also passes through closer sinks. So now we assume that every source has exactly one sink, which corresponds to the new set of demand pairs D_{clear} .

First, let us assume that the vertex is allowed to send and receive at the same time, but still is not allowed to receive from more than one source. Under this assumption, algorithm TREEUP 7 (after removing the line “If $d(v)$ has same parity as i ”) achieves the optimal spreading time! Figure 2 illustrates the execution of this modified version of algorithm TREEUP 7.

■ **Figure 2** Illustration of precursor to algorithm TREE 6.

Recall that the algorithm is the following: if node v contains some information, it will try to send it up. So if no other vertices are trying to send information to the parent of v , then v is allowed to send information and it is obviously *the best possible move*.

► **Definition 21** (The best/optimal move). *Given a multicommodity-multicast problem, the move is called optimal if there exists a subsequent sequence of moves that will achieve optimal rumor spreading time.*

Now, imagine that at the specific point in time there are several nodes v_1, \dots, v_k who want to send to their common parent t .

► **Definition 22** (The priority of the vertex). *Given a vertex v that has information from sources s_1, \dots, s_k , define the priority of v at this particular state of the system to be the maximum distance from v to all sinks t_1, \dots, t_k that correspond to sources s_1, \dots, s_k .*

The rule will be that vertices with larger priorities always send first. More precisely, if there are several nodes v_1, \dots, v_k who want to send information to their common parent t at this point in time, then pick the vertex v_i with the largest priority and allow it to propagate information to t (we will break any ties arbitrarily).

We argue that this is an optimal move. Consider the optimal algorithm and the first moment in time when the state is different from the state in our greedy algorithm. We will show that optimal algorithm could be modified, so that it still finishes rumor spreading in the same number of steps, but also does the same move as our greedy algorithm.

Assume at this state vertices v_1, \dots, v_k want to send to their parent t . One of the vertices v_i should be allowed to send info to t since one more piece of information will move closer to the sink this way. Consider what the optimal algorithm will do. Say it allows vertex v_j to send information to its parent. If $v_i = v_j$, then we are done (meaning our current move is optimal). If not, then consider a different algorithm, where we swap v_i in place of v_j , and move this step where v_j sends information to its parent to the next time when v_i is scheduled to do so in the optimal algorithm. We claim that this modified algorithm is still optimal.

To see this, consider the optimal algorithm again. Both vertices v_i and v_j have common path to the top (except the very first edge to their parent, which we will ignore). Moreover, because the priority of v_i is at least the priority of v_j , then the demand from v_j is a subpath of the demand for v_i (remember we associate demand with both the source-sink pair and the path between them). Because v_j goes first and takes the same route as v_i , but v_i goes further, we have that at some point during the optimal schedule the current information from vertices v_i and v_j will be at the same vertex (somewhere along the demand path). Hence at the end of the optimal schedule both sinks that correspond to v_i and v_j will contain the current information from both v_i, v_j . And so if we swap v_i and v_j in our algorithm, after the same number of time steps as in the optimal schedule again, both sinks that correspond to v_i, v_j will contain current information from both v_i, v_j . Hence our modified algorithm is optimal as well.

To sum up, this proves that our greedy algorithm which allows vertices with higher priority to send first is optimal.

To finish the proof we need to get rid of the assumption that a node can send and receive information at the same time. For this, we use the following idea: let the *level* of the vertex be its distance to the root of the tree. Now, call the vertex *even* if its level is even and *odd* if its level is odd. We will alternate between even/odd levels to send/receive. First, all odd nodes that need to send information will do so (and so even ones will be able to receive). Then, all even nodes will be allowed to send information (and so odd ones will receive). This is then repeated. In this way every node is either receiving or sending information at every step. Clearly, we have increased the number of time step by at most factor 2. Therefore our algorithm will finish in at most $2L$ steps. ◀

Proof of Lemma 20. First, note that the distance between any source and sink is at most L , because in the optimal schedule all distances are at most L . But we cannot start greedily send information down, because a vertex cannot both send and receive information at the same time.

Hence we will use the same idea again - vertices with even/odd levels will alternate to send/receive. Note that our algorithm TREEDOWN 8 does the following: first, all even nodes that need to send information will do so (and so odd ones will be able to receive). Then, all odd nodes will be allowed to send information (and so even ones will receive). This is repeated as before.

Consider a fixed source. If it is even, then it will start sending information down right away, if it is odd, there will be a delay of one step. But after the vertex started sending information, there will be no delays! For example, if the vertex is even, then it sends information to the odd one, and at the next iteration all odd vertices are allowed to send information. Hence, it will take at most $L + 1$ steps to deliver all information. ◀

4.3 Optimal Telephone Broadcast in a Tree

► **Corollary 23** (Optimal broadcast in the tree under telephone model). *There is a **simple** optimal schedule for broadcasting in the tree from any root under telephone model.*

Note that it is well-known that the optimal schedule for broadcast in the tree under telephone model can be found in polynomial time. For instance, one can find such a schedule using dynamic programming. But this approach only gives an implicit algorithm to find such a schedule. We will present a very **simple explicit optimal schedule** algorithm TREEBROADCAST 9.

■ **Algorithm 9** Algorithm for optimal broadcast in the tree under telephone model.

```

procedure TREEBROADCAST( $T$ )
  Input: rooted tree  $T$ .

  OptimalSchedule =  $\emptyset$ 
  while  $T$  is not empty do
    Matching =  $\emptyset$ 
    for every vertex  $v \in T$  do
      If  $v$  is not connected to any leaf, then continue to another  $v$ .
      Among all children of  $v$ , pick an arbitrary leaf  $u$ .
      Add edge  $u \rightarrow v$  to Matching.
    end for
    Add Matching to OptimalSchedule.
    Delete Matching from  $T$  and any isolated vertices.
  end while

  Return reversed OptimalSchedule
end procedure

```

▷ **Claim 24.** Algorithm TREEBROADCAST 9 outputs the optimal broadcast schedule in the tree.

Proof. Every broadcast schedule that sends information from the root to all nodes is equivalent to a schedule that sends information from the root to all leaves. This is further equivalent to a schedule that collects information from all leaves to the root - by reversing the direction of information flow and hence the schedule. We will present such a schedule.

Assume we are given that each leaf has a unique piece of information that it wants to transmit to the root. The schedule is very simple: every leaf that has some information (one or several pieces collected from other nodes) tries to send it to its parent. After the leaf successfully propagates the information up, we delete this vertex from the tree. If there are several leaves who try to send to the same parent, then choose one arbitrarily.

This is an optimal move because in each conflict when several leaves are trying to send to the parent, the priority of each of these conflicting leaves is the same (since their distance to the root is the same), so the argument is exactly the same as in the analysis of Algorithm TREEUP.

The only additional point here is that we do not allow for non-leaf vertices to send information, even though they might have some information available. This is because if there is an internal node v , such that in its subtree there are leaves with information that they haven't sent up to v yet, there is no need in an optimal scheme for v to try to send available information up, since it can wait until the very last information in its subtree will reach v . More formally, the priority of the node v is less than the priority of a leaf in a subtree of v , and hence we should give a priority to the leaf (by the same argument as in that of Algorithm TREEUP). This rule makes sure that there is no vertex that is trying to send and receive information and the same time. ◁

5 Conclusion

We have studied well-known rumor spreading problem under the wireless model. We designed approximation algorithms for the most general multicommodity multicast set-up that improve approximation ratios both for general graphs and when the underlying graph is a tree. For

general graphs we improve approximation ratio for this problem from $\tilde{O}(n^{\frac{2}{3}})$ to $\tilde{O}(n^{\frac{1}{2}+\epsilon})$ on n -node graphs. We also design an algorithm that satisfies p demand pairs in $O(\text{OPT} + p)$ steps, by reducing it to the well-studied packet routing problem. When underlying graph is an n -node tree, we improved approximation ratio from $O(\frac{\log n}{\log \log n})$ to a constant 3-approximation. A consequence of our algorithm is the simple constructive rule for optimal broadcasting in a tree under a widely studied telephone model.

Abstract

Laman graphs are the minimally rigid graphs in the plane. We present two algorithms for recognizing planar Laman graphs. A simple algorithm with running time $O(n^{3/2})$ and a more complicated algorithm with running time $O(n \log^3 n)$ based on involved planar network flow algorithms. Both improve upon the previously fastest algorithm for general graphs by Gabow and Westermann [*Algorithmica*, 7(5-6):465–497, 1992] with running time $O(n\sqrt{n \log n})$.

To solve this problem we introduce two algorithms (with the running times stated above) that check whether for a directed planar graph G , disjoint sets $S, T \subseteq V(G)$, and a fixed k the following connectivity condition holds: for each vertex $s \in S$ there are k directed paths from s to T pairwise having only vertex s in common. This variant of connectivity seems interesting on its own.

1 Introduction

Let $G = (V, E)$ be a graph with n vertices. The graph G is called a *Laman graph* if it has $2n - 3$ edges and every subset $V' \subseteq V$, with $|V'| \geq 2$, induces a subgraph with no more than $2|V'| - 3$ edges. A *bar-joint framework* is a physical structure made from fixed-length bars that are linked by universal joints (allowing 360° rotations) at their endpoints. A bar-joint framework is *flexible* if it has a continuous motion other than a global rotation or translation. A nonflexible framework is called *rigid*. Moreover it is called *minimally rigid*, if it is rigid, but it becomes flexible after removing any bar. For detailed definitions we refer to Jordán [21]. Interestingly, in 2d a bar-joint framework (in a generic configuration) is minimally rigid, if and only if its underlying graph is a Laman graph. In other words, almost every embedding of a Laman graph will be rigid. For nongeneric configurations Laman graphs can yield a flexible framework though (see Figure 1).

Various characterizations of Laman graphs are known [17, 25, 26]. The class of *plane* Laman graphs provides even more structure [9, 16, 23]. Of particular interest for our result is the following geometric characterization: A geometric graph is a *pointed pseudotriangulation* (PPT) if each inner face contains exactly three angles less than π , called *small*, and every vertex is incident to an angle larger than π , called *big* [31]. Streinu [33] proved that the underlying graph of a pointed pseudotriangulation is a Laman graph. Moreover, Haas et al. [16] showed that every planar Laman graph has an embedding as a pointed pseudotriangulation. Pointed

■ **Figure 1** A flexible drawing of a Laman graph (a), and a rigid drawing of the same graph (b).

pseudotriangulations have many applications as a geometric data structure. Maybe most prominently, they are used as a tool to show that every polygonal linkage can unfold in 2d without intersections [6, 33]. More applications come from problems in ray shooting, motion planning and polygon guarding. We refer the interested reader to the survey of Rote, Santos, and Streinu [31].

Haas et al. [16] also give an algorithm that computes a PPT realization for a Laman graph in time $O(n^{3/2})$. We could turn their algorithm into a recognition algorithm by checking whether the derived realization is a PPT. If the original graph is not a Laman graph, then the construction either fails at some intermediate step or some parts of the drawing collapse. To check whether it collapsed requires computations with exponentially large numbers. So it depends on the model of computation if the overall algorithm runs in $O(n^{3/2})$ time. We present combinatorial algorithms for recognizing planar Laman avoiding these subtleties.

Checking the Laman condition for general graphs can be done in polynomial time. The fastest (but very complicated) algorithm is due to Gabow and Westermann [13] and needs $O(n\sqrt{n\log n})$ time. Their algorithm is based on a characterization by means of matroid sums (see also [7] for a time analysis specifically for Laman graphs). There is also a very easy so-called pebble-game algorithm that runs in $O(n^2)$ time [3, 20] (a brief survey of further algorithmic aspects is given in the introduction of [26]).

1.1 Our contribution

Our recognition algorithms for planar Laman graphs rely on the theory of combinatorial pseudotriangulations developed by Haas et al. [16] which will be described in detail in Section 4. The crucial step in the algorithm is to check the following connectivity condition for a certain auxiliary directed planar graph. Consider a positive integer k , a directed graph G , and disjoint sets $S, T \subseteq V(G)$. We call S k -connected to T if for each vertex $s \in S$ there are k directed paths from s to T pairwise having only vertex s in common.

A naive approach to check this condition can be implemented in $O(|S|m)$ time and is described in Section 1.2. We present two algorithms checking this condition for planar directed graphs that are faster for large sets S . In Section 2 we present a simple algorithm that checks this connectivity condition for planar directed graphs provided that each vertex is either in S or T . This gives the following theorem.

► **Theorem 1.** *For each fixed $k \geq 1$ there is an algorithm deciding for a directed planar graph G and a partition $V(G) = S \cup T$ whether S is k -connected to T in $O(n^{3/2})$ time.*

We show how to combine this algorithm with simple algorithms of Haas et al. [16] to check the Laman property for a plane graph in time $O(n^{3/2})$ in Section 4.

If all vertices in T are incident to a common face then we obtain a much faster algorithm for the connectivity check. We then even could drop the condition that each vertex is either in S or T . It is based on latest planar network flow algorithms and presented in Section 3.

► **Theorem 2.** *For each fixed $k \geq 1$ there is an algorithm deciding for a directed planar graph G and disjoint sets $S, T \subseteq V(G)$ whether S is k -connected to T in $O(n \log^3 n)$ time, provided that all vertices in T are incident to a common face in G .*

It turns out that this condition is satisfied when checking for the Laman property. This leads to a fast algorithm for recognizing planar Laman graphs which we describe in Section 4.

► **Theorem 3.** *There is an algorithm deciding for each planar graph whether it is a Laman graph in $O(n \log^3 n)$ time.*

1.2 Related work on connectivity in directed graphs

Here we discuss how the algorithms from Theorems 1 and 2 relate to known algorithms. We briefly recall the basic definitions and results on connectivity of directed graphs first. Note that we consider only unweighted graphs. For two vertices s and t in a directed graph let $\kappa(s, t)$ and $\lambda(s, t)$ denote the largest number of internally vertex disjoint respectively edge disjoint directed paths from s to t . It is well known that $\lambda(s, t)$ is equal to the value of a maximum s - t flow and hence to the size of a minimum s - t cut. A directed graph is strongly connected if for each vertex there is a directed path to each other vertex. A directed graph with at least k vertices is called k -vertex connected (k -edge connected) if the removal of any $k - 1$ vertices (edges) yields a strongly connected directed graph. Let $\kappa(G)$ ($\lambda(G)$) denote the largest k such that G is k -vertex connected (k -edge connected). By means of Menger's theorem we have that $\kappa(G) = \min_{s \neq t} \kappa(s, t)$ and $\lambda(G) = \min_{s \neq t} \lambda(s, t)$ [2].

For general directed graphs $\kappa(s, t)$ and $\lambda(s, t)$ can be computed with time in $O(nm)$ [30]. Checking whether $\kappa(s, t) \geq k$ or whether $\lambda(s, t) \geq k$ for some fixed k can be done by k steps of the Ford–Fulkerson algorithm and hence in $O(m)$ time (see [2, p. 205]). In both cases the computation of vertex connectivity can be easily reduced to the edge connectivity [10]. Further the values of $\kappa(G)$ and $\lambda(G)$ can be computed with algorithms due to Gabow with time in $O(m(n + \min(\kappa(G)^{5/2}, \kappa(G)n^{3/4})))$ [12] and time in $O(\lambda(G)m \log(n^2/m))$ [11] respectively. Checking whether $\kappa(G) \geq 2$ and whether $\lambda(G) \geq 2$ can be done with time in $O(n + m)$ [14, 19]. For larger fixed k the fastest algorithms checking $\kappa(G) \geq k$ and $\lambda(G) \geq k$ are based on Gabow's algorithms above with times in $O(m(n + \min(k^{5/2}, kn^{3/4})))$ and $O(km \log(n^2/m))$ respectively.

For planar directed graphs $\kappa(s, t)$ and $\lambda(s, t)$ can be computed in linear time [8, 22] (and $O(n \log n)$ in the weighted case). Further $\lambda(G)$ can be calculated with time in $O(n \log \log n)$ [28]. We are not aware of algorithms computing $\kappa(G)$ specifically for planar directed graphs.

A naive approach to check whether a set S is k -connected to T (the notion considered in this paper) works as follows. First introduce a new vertex t and all arcs xt , $x \in T$, and then check whether $\kappa(s, t) \geq k$ for each $s \in S$. This leads to an $O(|S|m)$ time algorithm for general directed graphs and constant k . For planar directed graphs our algorithm from Theorem 1 is faster than this approach in case $|S| \in \omega(\sqrt{n})$ and $V(G) = S \cup T$. For planar directed graphs where the vertices in T can be embedded incident to a common face our algorithm from Theorem 2 is faster already for $|S| \in \omega(\log^3 n)$.

Further questions related to connectivity of (planar) directed graphs include the all-pairs reachability [15, 18], all pairs minimum cuts [4].

■ **Figure 2** If S is k -connected to $T \cup T'$ and T' is k -connected to T , then S is k -connected to T (a). This statement applied where $T' = A$ is a separator (b).

2 Checking directed k -connectivity

In this section we prove the statement of Theorem 1. We first give some structural results. The following statement is similar to Menger’s theorem. We provide a proof for completeness.

► **Lemma 4.** *Let $k \geq 0$, G be a directed (not necessarily planar) graph, and $S, T \subseteq V(G)$ be disjoint with $|T| \geq k$. Then S is k -connected to T if and only if for each $s \in S$ and $A \subseteq V(G) \setminus \{s\}$ with $|A| = k - 1$ there is a directed path from s to T not using the vertices in A .*

Proof. Clearly, if S is k -connected to T then for each $s \in S$ and $A \subseteq V(G) \setminus \{s\}$ with $|A| = k - 1$ there is a directed path from s to T not using the vertices in A . We deduce the reverse statement from Menger’s theorem. Obtain a directed graph G' by adding a new vertex z and edges tz for each $t \in T$. Then S is k -connected to T in G if and only if for each $s \in S$ there are k internally vertex disjoint directed paths joining s and z in G' . Suppose that for each $s \in S$ and $A \subseteq V(G) \setminus \{s\}$ with $|A| = k - 1$ there is a directed path from s to T in G not using the vertices in A . Then, under the same assumptions, there is a directed path from s to z in G' not using the vertices in A . So by Menger’s theorem there are k internally vertex disjoint directed paths joining s and z in G' . In particular S is k -connected to T in G . ◀

The following observation is crucial for using separators recursively. An illustration is given in Figure 2.

► **Lemma 5.** *Let G be a directed graph and let $S, T, T' \subseteq V(G)$ be disjoint. If S is k -connected to $T \cup T'$ and T' is k -connected to T , then S is k -connected to T .*

Proof. Let $s \in S$ and fix a set $A \subseteq V(G) \setminus \{s\}$ of size $k - 1$. We shall find a directed path from s to T not using vertices from A . There is a directed path from s to some vertex $u \in T \cup T'$ not using vertices from A since S is k -connected to $T \cup T'$. If $u \in T$ we are done. If $u \in T'$, then there is a directed path from u to T not using vertices from A since T' is k -connected to T . In each case there is a directed path from s to T not using vertices from A . So S is k -connected to T by Lemma 4. ◀

For a single vertex we can decide in linear time whether it is k -connected to T by means of Ford–Fulkerson’s algorithm (similar to the naive approach from Section 1.2). An st -connector in a directed graph G is a set of edge disjoint directed paths from vertex s to vertex t . Given an st -connector \mathcal{P} the residual graph $G_{\mathcal{P}}$ is obtained by reversing all arcs of paths in \mathcal{P} . It is well known that \mathcal{P} is a largest st -connector in G if and only if there is no directed path from s to t in $G_{\mathcal{P}}$ [2].

► **Lemma 6.** *For each $k \in \mathbb{N}$ there is an algorithm deciding for any directed (not necessarily planar) graph G , $s \in V(G)$, and $T \subseteq V(G)$ whether s is k -connected to T in $O(k(|V(G)| + |E(G)|))$ time.*

Proof. We apply the following standard modification due to Ford and Fulkerson [10]. Split each $v \in V(G)$ into two vertices v_i and v_o and replace each arc uv by an arc $u_o v_i$. Further add all arcs $v_i v_o$, $v \in V(G)$. Finally add a new vertex z and the arcs $t_o z$, $t \in T$. Let G' denote the resulting directed graph. Then s is k -connected to T in G if and only if there is an $s_o z$ -connector of size k in G' .

The algorithm iteratively builds an $s_o z$ -connector \mathcal{P} in G' in at most k steps. In each step a directed path P from s_o to z is searched in the residual graph $G'_\mathcal{P}$. If no such path exists, then the set \mathcal{P} is a largest $s_o z$ -connector in G' . Otherwise, in G' the symmetric difference of the set of arcs from paths in \mathcal{P} and the set of arcs from P (which might not be a path in G') forms an $s_o z$ -connector of size $|\mathcal{P}| + 1$ in G' .

Clearly the algorithm decides whether there is an $s_o z$ -connector of size k in G' and hence whether s is k -connected to T in G . The construction of G' in the beginning and in each step the construction of the residual graph as well as the search can be implemented in $O(n + m)$ time. Since there are at most k steps the overall time is $O(k(n + m))$. ◀

We call $A \subseteq V(G)$ a *separator* if removing A splits G into two (not necessarily connected) subgraphs G_1 and G_2 , such that $|V(G_1)|, |V(G_2)| \leq \frac{2}{3}|V(G)|$. For every planar graph G a separator with size in $O(\sqrt{n})$ can be found in linear time [27].

Proof of Theorem 1. The algorithm works recursively as follows. Let A denote a separator of G of size $O(\sqrt{n})$. Use Lemma 6 to check for each $a \in A \cap S$ whether a is k -connected to T in G . Let G_1 and G_2 denote the two subgraphs of G separated by A (each including A). For $i = 1, 2$ let $S_i = (S \cap V(G_i)) \setminus A$ and let $T_i = (T \cap V(G_i)) \cup A$. Apply the algorithm recursively to check whether S_i is k -connected to T_i in G_i , for $i = 1, 2$.

Recall that $V(G) = S \cup T$. The algorithm indeed checks whether S is k -connected to T in G since either it finds some vertex in $A \cap S$ that is not k -connected to T in G , or it is sufficient to check whether $S \setminus A$ is k -connected to $A \cup T$ by Lemma 5. Then it is sufficient to check G_1 and G_2 separately. See Figure 2(b) for an illustration

The separator can be found in linear time. Then the algorithm from Lemma 6 is called $O(\sqrt{n})$ times for each vertex in the separator, each call with linear time (since k is constant and $|E(G)|$ is linear in n). So the total time for each step of the recursion and hence for the whole algorithm is $O(n^{3/2})$. ◀

3 A faster algorithm for checking directed k -connectivity

In this section we prove Theorem 2. First we use a construction similar to one of Kaplan and Nussbaum [22] transforming the problem into a question about network flow. Consider a directed graph H and distinct $s, t \in V(H)$. Kaplan and Nussbaum construct a directed planar graph $H_{s,t}$ obtained from H by replacing each $v \in V(H) \setminus \{s, t\}$ by a cycle C_v with vertices v_1, \dots, v_d , where d is the degree of v in H , such that arcs incident to v are replaced by arcs of (flow) capacity 1 not sharing endpoints while keeping their orientation and the cyclic order around v . The edges of the cycle C_v are oriented in both directions and receive (flow) capacity $1/2$. See Figure 3.

► **Lemma 7** ([22]). *There are k internally vertex disjoint s - t -paths in H if and only if in $H_{s,t}$ the maximum s - t -flow has value at least k .*

■ **Figure 3** A directed planar graph H (a), the modification $H_{s,t}$ of Kaplan and Nussbaum (b), and the modification \vec{G} used in the algorithm for Theorem 2 (c). The modification of Kaplan and Nussbaum does not include the original vertices inside of the new cycles. We need this since all the original vertices except a fixed source are targets in our algorithm.

Since we need to calculate s - t -flows for several distinct targets t at the same time we need a modification independent of t .

► **Lemma 8.** Consider $k \geq 1$, a directed planar graph G and disjoint sets $S, T \subseteq V(G)$ where all vertices of T are incident to a common face. Then a directed planar graph \vec{G} with $|V(\vec{G})| \leq 7|V(G)|$ can be computed in linear time together with some $s \in V(\vec{G})$ and $T' \subseteq V(\vec{G})$ such that S is k -connected to T in G if and only if in \vec{G} for each $t \in T'$ the value of a maximum s - t -flow is at least k .

Proof. We consider an embedding of G where all vertices of T are incident to the outer face. Let H denote the directed planar graph obtained by reversing the direction of each arc in G and by adding a new vertex s in the outer face of G connected by arcs sv to all vertices $v \in T$. Further let $T' = S$. Then S is k -connected to T in G if and only if in H there are k internally vertex disjoint s - t -paths for each $t \in T'$ (note that we reversed the direction of all the edges).

We obtain a directed planar graph \vec{G} by splitting each vertex in $V(H) \setminus \{s\}$ into a cycle as follows. Replace each arc e in H , directed from $u \neq s$ to v , by arcs $u_e v_e$ and $v_e v$, where u_e, v_e are new vertices (and distinct for all e). Replace each arc e in H , directed from s to v , by arcs sv_e , and $v_e v$, where v_e is a new vertex. Further for each vertex v in H connect the new vertices v_e by a cycle C_v in the cyclic order of the arcs e around v , where the edges are directed in both directions. Finally a (flow) capacity function is defined where all arcs on cycles C_v receive capacity $1/2$ and all other arcs capacity 1. See Figure 3.

This construction corresponds to the graph $H_{s,t}$ constructed by Kaplan and Nussbaum, except that there is not a specific target t and, additionally the original vertices from H are kept inside of the cycles together with their incoming arcs. In particular \vec{G} is planar and $V(G) \subseteq V(H) \subseteq V(\vec{G})$. Consider some $t \in T' = S$. Note that each s - t -flow in \vec{G} does not use vertices from $V(H) \setminus \{s, t\}$, since these vertices do not have outgoing arcs in \vec{G} . Hence for each $t \in T'$ any s - t -flow in \vec{G} corresponds to an s - t -flow in $H_{s,t}$ (by contracting t and C_t to a single vertex). By Lemma 7 there are k internally vertex disjoint s - t -paths in H if and only if in \vec{G} the value of a maximum s - t -flow is at least k .

Clearly \vec{G} can be constructed in linear time and $|V(\vec{G})| \leq |V(G)| + 2|E(G)| + 1 \leq 7|V(G)|$. This shows that \vec{G} together with s and the set $T' = S$ satisfies the desired conditions. ◀

■ **Figure 4** A CPPT with big angles are marked by solid circles that is not stretchable (a) and the derived directed graph \vec{G} where the highlighted vertices do not have 3 disjoint paths to the outer face (b).

Proof of Theorem 2. First construct a planar directed graph \vec{G} with some $s \in V(\vec{G})$ and $T' \subseteq V(\vec{G})$ with the algorithm from Lemma 8. Then apply an algorithm due to Łącki et al. [24] to \vec{G} , which computes for the source s the maximum flow value to each other vertex in \vec{G} in $O(n \log^3 n)$ time. By Lemma 8 S is k -connected to T in G if and only if in \vec{G} for each $t \in T'$ the value of a maximum s - t -flow is at least k . ◀

4 Recognizing Planar Laman Graphs

Since any Laman graph is 2-connected and 2-connectivity can be checked in linear time, see, e.g., [32], we consider only 2-connected graphs in this section. Further we assume that the graph is given with some plane embedding. As mentioned in the introduction our recognition algorithms are based on the theory due to Haas et al. [16] which they developed in order to show that exactly the planar Laman graphs can be realized as pointed pseudotriangulations. They transfer the concept of PPTs to graphs given with a plane (combinatorial) embedding. A *combinatorial pointed pseudotriangulation* (CPPT) is a plane graph with $2n - 3$ edges and with an assignment of the labels “small”/“big” to the angles satisfying the properties of a PPT. That is, only big angles are incident to the outer face, each inner face contains exactly three small angles and each vertex is incident to exactly one big angle. A CPPT is called *stretchable* if there is a PPT realization (that is, a drawing) of its underlying graph respecting the given labels of the angles and the embedding. Not every CPPT can be stretched to a PPT, see Figure 4(a) for an example. But Haas et al. show that every plane Laman graph admits a CPPT assignment and each CPPT whose underlying graph is Laman is stretchable. This shows that every Laman graph has a realization as a pointed pseudotriangulation. Note that the nonstretchable CPPT in Figure 4(a) contains K_4 as a subgraph which has $6 > 2 \cdot 4 - 3$ edges and hence is not a Laman graph.

This already outlines how our algorithms check whether a given plane graph G is Laman:

Step 1: Check whether G admits a CPPT assignment and compute one if it exists.

Step 2: Check whether the CPPT from Step 1 is stretchable.

The first step can be reduced to searching for a (generalized) matching in the following planar bipartite graph. The vertex-face incidence graph of a plane graph $G = (V, E)$ with face set F is a planar bipartite graph $H = (V \cup F, E')$ where $(v, f) \in E'$ if and only if $v \in V$

is incident to $f \in F$ in G . Note that for each face each vertex appears at most once along its boundary since we assume that G is 2-connected. A plane graph G admits a CPPT assignment if and only if its vertex-face incidence graph has a subgraph A where each interior face of G has degree 3 in A , the outer face of G has degree 0 in A , and each vertex of G has degree in A equal to its degree in G minus 1. This means that the edges of A correspond to small angles in the CPPT assignment. See Figure 5 for an illustration. Haas et al. provide a simple algorithm with running time $O(n^{3/2})$ checking whether such a subgraph A exists, that is, the algorithm computes a CPPT assignment for a given plane graph if any exists. Note that this algorithm does not compute a drawing and hence does not face the numerical issues mentioned in the introduction.

■ **Figure 5** A plane graph G with a CPPT assignment with big angles marked with a solid circle (a), the vertex-face incident graph of G where vertices corresponding to faces in G are marked with a solid square and the subgraph A corresponding to the CPPT is highlighted in gray (b), the flow network H' constructed from G in the proof of Lemma 9 (some capacities are omitted for better readability) (c).

In order to implement the first step with running time in $O(n \log^3 n)$ we use an algorithm by Borradaile et al. [5] computing a maximum flow between multiple sources and sinks.

► **Lemma 9.** *There is an algorithm computing a CPPT assignment for any planar graph G if any exists in $O(n \log^3 n)$ time.*

Proof. Consider the planar directed graph H' whose vertex set consists of two vertices u_1 and u_2 for each $u \in V(G)$ and two vertices f_1, f_2 for each face of G . For each $u \in V(G)$ add an arc $u_1 u_2$ with capacity 1, for each interior face f of G add an arc from $f_1 f_2$ with capacity equal to the number of vertices incident to f minus 3, and for the outer face f of G add an arc $f_1 f_2$ with capacity equal to the number of vertices incident to f . Finally for each vertex u and face f add an arc $f_2 u_1$ with capacity 1 if u is incident to f . Then there is a 1-1-correspondence between CPPT assignments of G and integer flows in H' with sources in $\{f_1 \mid f \text{ face in } G\}$, sinks in $\{u_2 \mid u \in V(G)\}$, and value $|V(G)|$. Note that the size of H' is linear in the size of G and can be constructed in linear time. In particular the algorithm of Borradaile et al. [5] (which computes an integer flow) can be used to compute a maximum flow in $O(n \log^3 n)$ time. If this flow has value $|V(G)|$ we computed a CPPT assignment if any exists, otherwise there is no CPPT assignment. ◀

For the second step, that is, checking whether a given CPPT is stretchable, we use the following characterization of stretchability by Haas et al. Recall that a set $S \subseteq V(G)$ is 3-connected to a set $T \subseteq V(G) \setminus S$ if for each vertex $s \in S$ there are three vertex disjoint directed paths from s to distinct vertices in T . Figures 4 and 6 give illustrations of the following result.

► **Lemma 10** ([16]). *For a CPPT G a directed plane graph \vec{G} , with $V(\vec{G}) = V(G)$, can be computed in linear time such that G is stretchable if and only if the set of interior vertices of \vec{G} is 3-connected to the set of boundary vertices of \vec{G} .*

■ **Figure 6** (a) The derived directed graph \vec{G} from the CPPT in Figure 5(c). (b) The stretched pointed pseudotriangulation.

In fact any directed graph \vec{G} satisfying the following conditions is suitable in the previous lemma (see [16, Lemma 16] and note that G is a CPPT): (i) \vec{G} contains the underlying graph of G and has a planar embedding that respects the embedding of G , (ii) the vertices on the outer face have no outgoing edges, and (iii) every interior vertex v has three outgoing edges where two of them are the extreme edges in G (these are the edges incident to the big angle) and one is an edge to a vertex in the boundary of the face of G containing the big angle at v .

We give a computation of such a graph \vec{G} similar to the one of Hass et al. [16] for completeness. First for each vertex v the two extreme edges incident to its big angle are oriented from v to the respective neighbors (it might happen that some edges are oriented in both directions). Next, we triangulate the underlying graph of G as follows. Consider an inner face of G . If the face contains no big angles, we are done. Otherwise let a , b , and c be the vertices corresponding to the three small angles and let X_{ab} , X_{bc} , and X_{ac} denote the vertices between a and b , between b and c , and between a and c , respectively. Assume that $X_{a,b} \neq \emptyset$. Let x and y denote the vertices in $X_{a,b}$ adjacent to a respectively b (it might happen that $x = y$). Then we add directed diagonals from each vertex in $X_{a,b}$ to c , from each vertex in $X_{a,c}$ to x , and from each vertex in $X_{b,c}$ to y . See Figure 7 for an illustration. We do this for all faces and the obtained triangulation satisfies the conditions (i) – (iii) stated above. Finally we remove all undirected edges. This construction can be implemented in linear time by traversing the boundary of each face once.

■ **Figure 7** (a) An inner face in a CPPT with big angles marked with a solid circle. (b) The directed diagonals added to that face to obtain a directed graph satisfying the assumption of Lemma 10.

Now we are ready to describe how to check whether a given plane graph G is Laman. Note that a graph that admits a CPPT assignment has exactly $2n - e$ edges [16]. The simpler algorithm uses the algorithms of Haas et al. [16] to find a CPPT assignment and the directed plane graph \vec{G} from Lemma 10, and then the algorithm from Theorem 1 to decide whether the set of interior vertices of \vec{G} is 3-connected to the set of boundary vertices. Note that each vertex in \vec{G} is either an inner vertex or on the boundary. This decides whether G is a plane Laman graph by Theorem 1 and Lemma 10 and has running time $O(n^{3/2})$. The faster algorithm works as follows.

Proof of Theorem 3. First, search for a CPPT assignment of G using the algorithm from Lemma 9. If there is no such assignment then G is not Laman. Otherwise G is Laman if and only if the CPPT computed in the first step is stretchable. To check this we compute the auxiliary directed plane graph \vec{G} from Lemma 10 such that the CPPT is stretchable if and only if the set of interior vertices of \vec{G} is 3-connected to the set of boundary vertices of \vec{G} . Note that the boundary vertices of \vec{G} are clearly incident to a common face. Hence we can check the connectivity property using the algorithm from Theorem 2. This algorithm decides whether G is a plane Laman graph by Theorem 2 and Lemma 10 and has running time $O(n \log^3 n)$. ◀

5 Conclusions and further directions

An obvious direction for future research is to search for faster or simpler algorithms recognizing (planar) Laman graphs.

Our algorithms do not provide any certificate for their correctness. This could be a Henneberg sequence [17] or a decomposition into two acyclic subgraphs [7]. We do not know how to compute either of these faster than using the algorithm of Gabow and Westermann [13].

Further our strategy heavily depends on planarity. Thus it seems unlikely that we can extend our approach to nonplanar Laman graphs. Instead it seems interesting to extend our strategies to more general pseudotriangulations. Orden et al. [29] show a characterization of general pseudotriangulations that extends the one for PPTs described in Section 4. Again there is a notion of combinatorial pseudotriangulations (CPT) which are stretchable if and only if certain combinatorial conditions hold. Besides a connectivity condition similar to the one for CPPTs there is an additional condition on sizes of subgraphs. In particular, a CPT might not be stretchable although the underlying graph is realizable as a pseudotriangulation. We do not know how to identify the stretchable CPTs.

Instead of asking if a graph has a representation as a (pointed) pseudotriangulation one can also ask for other representations such as straight-line triangle representations [1]. For this problem no polynomial time algorithm is known, although the problem shares many similarities with the Laman graph recognition problem.

Finally it is of independent interest to see if the connectivity results for directed graphs can be extended. In the last part of the introduction we describe a naive approach checking for a general directed graph whether a set S is k -connected to a set T with time in $O(|S|m)$.

When each vertex is either in S or in T we can adapt the ideas presented in Section 2 for classes of graphs with small separator. Then the running time becomes linear for graphs with separators of constant size and stays in $O(n^{3/2})$ as long as there are separators of size $O(\sqrt{n})$. We do not know how to improve upon the naive approach for general directed graphs when some vertices are not in $S \cup T$.

Abstract

In a confluence of combinatorics and geometry, simultaneous representations provide a way to realize combinatorial objects that share common structure. A standard case in the study of simultaneous representations is the *sunflower case* where all objects share the same common structure. While the recognition problem for general simultaneous interval graphs – the simultaneous version of arguably one of the most well-studied graph classes – is NP-complete, the complexity of the sunflower case for three or more simultaneous interval graphs is currently open. In this work we settle this question for *proper* interval graphs. We give an algorithm to recognize simultaneous proper interval graphs in linear time in the sunflower case where we allow any number of simultaneous graphs. Simultaneous *unit* interval graphs are much more “rigid” and therefore have less freedom in their representation. We show they can be recognized in time $\mathcal{O}(|V| \cdot |E|)$ for any number of simultaneous graphs in the sunflower case where $G = (V, E)$ is the union of the simultaneous graphs. We further show that both recognition problems are in general NP-complete if the number of simultaneous graphs is not fixed. The restriction to the sunflower case is in this sense necessary.

1 Introduction

Given a family of sets \mathcal{R} , the corresponding *intersection graph* G has a vertex for each set and two vertices are adjacent if and only if their sets have a non-empty intersection. If all sets are intervals on the real line, then \mathcal{R} is an *interval representation* of G and G is an *interval graph*; see Figure 1.

In the context of intersection graph classes, much work has been devoted to efficiently computing a *representation*, which is a collection of sets or geometric objects having an intersection graph that is isomorphic to a given graph. For many well-known graph classes, such as interval graphs and chordal graphs, this is a straightforward task [14, 28]. However,

■ **Figure 1** (a) A graph, with (b) an interval representation and (c) proper interval representation.

often it is desirable to consistently represent *multiple* graphs that have subgraphs in common. This is true, for instance, in realizing schedules with shared events, embedding circuit graphs of adjacent layers on a computer chip, and visualizing the temporal relationship of graphs that share a common subgraph [19]. Likewise, in genome reconstruction, we can ask if a sequence of DNA can be reconstructed from strands that have sequences in common [13].

Simultaneous representations capture this in a very natural way. Given *simultaneous graphs* G_1, G_2, \dots, G_k where each pair of graphs G_i, G_j share some common subgraph, a *simultaneous representation* asks for a fixed representation of each vertex that gives a valid representation of each G_i . This notion is closely related to *partial representation extension*, which asks if a given (fixed) representation of a subgraph can be extended to a representation of the full graph. Partial representation extension has been extensively studied for graph classes such as interval graphs [20], circle graphs [8], as well as proper and unit interval graphs [20]. For interval graphs, Bläsius and Rutter [3] have even shown that the partial interval representation problem can be reduced to a simultaneous interval representation problem on two graphs in linear time.

Simultaneous representations were first studied in the context of embedding graphs [2, 7], where the goal is to embed each simultaneous graph without edge crossings while shared subgraphs have the same induced embedding. Unsurprisingly, many variants are NP-complete [12, 26, 1, 11]. The notion of simultaneous representation of general intersection graph classes was introduced by Jampani and Lubiw [19], who showed that it is possible to recognize simultaneous chordal graphs with two graphs in polynomial time, and further gave a polynomial time algorithm to recognize simultaneous comparability graphs and permutation graphs with two or more graphs that share the same subgraph (the *sunflower case*). They further showed that recognizing three or more simultaneous chordal graphs is NP-complete.

Golumbic et al. [15] introduced the *graph sandwich problem* for a graph class Π . Given a vertex set V and edge sets $E_1 \subseteq E_2 \subseteq \binom{V}{2}$ it asks whether there is an edge set $E_1 \subseteq E \subseteq E_2$ such that the *sandwich graph* $G = (V, E)$ is in Π . Jampani and Lubiw showed that if Π is an intersection graph class, then recognizing k simultaneous graphs in Π in the sunflower case is a special case of the graph sandwich problem where $(V, E_2 \setminus E_1)$ is a k -partite graph [19].

We consider simultaneous *proper* and *unit* interval graphs. An interval graph is proper if in an interval representation no interval properly contains another one (see Figure 1), and it is unit if all intervals have length one. Interestingly, while proper and unit interval graphs are the same graph class as shown by Roberts [25], simultaneous unit interval graphs differ from simultaneous proper interval graphs; see Figure 2. Unit interval graphs are intersection graphs and therefore the graph sandwich paradigm described by Jampani and Lubiw applies. Proper interval graphs are not since in a simultaneous representation intervals of distinct graphs may contain each other which means that the intersection graph of all intervals in the simultaneous representation is not proper.

Sunflower (*unit*) interval graphs are a generalization of *probe* (proper) interval graphs, where each sunflower graph has only one non-shared vertex. Both variants of probe graphs can be recognized in linear time [22, 23].

■ **Figure 2** A simultaneous proper interval representation of a sunflower graph \mathcal{G} consisting of two paths $G_1 = (s_1, a, b, c, s_2)$ (dashed) and $G_2 = (s_1, d, s_2)$ (dotted) with shared start and end s_1, s_2 (bold). They have no simultaneous unit interval representation: The intervals a and c enforce that b lies between s_1 and s_2 . Interval d therefore includes b in every simultaneous proper interval representation. In particular, not both can have size one.

Simultaneous interval graphs were first studied by Jampani and Lubiw [18] who gave a $\mathcal{O}(n^2 \lg n)$ -time recognition algorithm for the special case of two simultaneous graphs. Bläsius and Rutter [3] later showed how to recognize two simultaneous interval graphs in linear time. Bok and Jedličková showed that the recognition of an arbitrary number of simultaneous interval graphs is in general NP-complete [4]. However, the complexity for the sunflower case with more than two simultaneous graphs is still open.

Our Results. We settle these problems with k not fixed for simultaneous *proper* and *unit* interval graphs – those graphs with an interval representation where no interval properly contains another and where all intervals have unit length, respectively [10, 27, 9, 16]. For the sunflower case, we provide efficient recognition algorithms. The running time for proper interval graphs is linear, while for the unit case it is $\mathcal{O}(|V| \cdot |E|)$ where $G = (V, E)$ is the union of the sunflower graphs. In the full version we prove NP-completeness for the non-sunflower case. The reductions are similar to the simultaneous independent work of Bok and Jedličková for simultaneous interval graphs [4].

Organization. We begin by introducing basic notation and existing tools throughout Section 2. In Section 3 we give a characterization of simultaneous proper interval graphs, from which we develop an efficient recognition algorithm. In Section 4 we characterize simultaneous proper interval graphs that can be simultaneous unit interval graphs, and then exploit this property to efficiently search for a representation among simultaneous proper interval graph representations. Proofs of lemmas and theorems marked with \star are omitted.

2 Preliminaries

In this section we give basic notation, definitions and characterizations. Section 2.1 collects basic concepts on graph theory, orderings, and PQ-trees. Section 2.2 introduces (proper) interval graphs and presents relations between the representations of such graphs and their induced subgraphs. Finally, Section 2.3 introduces the definition and notation of simultaneous graphs.

2.1 Graphs, Orderings, and PQ-trees

Unless mentioned explicitly, all graphs in this paper are undirected. For a graph $G = (V, E)$ we denote its size $|G| := |V| + |E|$.

Let σ be a binary relation. Then we write $a_1 \leq_\sigma a_2$ for $(a_1, a_2) \in \sigma$, and we write $a_1 <_\sigma a_2$ if $a_1 \leq_\sigma a_2$ and $a_1 \neq a_2$. We omit the subscript and simply use $<$ and \leq if the ordering it refers to is clear from the context. We denote the *reversal* of a linear order σ by σ^r , and we use \circ to concatenate linear orders of disjoint sets.

A *PQ-tree* is a data structure for representing sets of linear orderings of a ground set X . Namely, given a set $\mathcal{C} \subseteq 2^X$, a *PQ-tree on X for \mathcal{C}* is a tree data structure T that represents the set $\text{CONSISTENT}(T)$ containing exactly the linear orders of X in which the elements of each set $C \in \mathcal{C}$ are consecutive. The PQ-tree T can be computed in time $O(|X| + \sum_{C \in \mathcal{C}} |C|)$ [6]. Given a PQ-tree T on the set X and a subset $X' \subseteq X$, there exists a PQ-tree T' , called the *projection* of T to X' , that represents exactly the linear orders of X' that are restrictions of orderings in $\text{CONSISTENT}(T)$. For any two PQ-trees T_1 and T_2 on the set X , there exists a PQ-tree T with $\text{CONSISTENT}(T) = \text{CONSISTENT}(T_1) \cap \text{CONSISTENT}(T_2)$, called the *intersection* of T_1 and T_2 . Both the projection and the intersection can be computed in $O(|X|)$ time [5].

2.2 Interval Graphs, Proper Interval Graphs, and Their Subgraphs

An *interval representation* $R = \{I_v \mid v \in V\}$ of a graph $G = (V, E)$ associates with each vertex $v \in V$ an interval $I_v = [x, y]$ of real numbers such that for each pair of vertices $u, v \in V$ we have $I_u \cap I_v \neq \emptyset$ if and only if $\{u, v\} \in E$, i.e., the intervals intersect if and only if the corresponding vertices are adjacent. An interval representation R is *proper* if no interval properly contains another one, and it is *unit* if all intervals have length 1. A graph is an *interval graph* if and only if it admits an interval representation, and it is a *proper (unit) interval graph* if and only if it admits a proper (unit) interval representation. It is well-known that proper and unit interval graphs are the same graph class.

► **Proposition 1** ([25]). *A graph is a unit interval graph if and only if it is a proper interval graph.*

However, this does not hold in the simultaneous case where every simultaneous unit interval representation is clearly a simultaneous proper interval representation of the same graph, but not every simultaneous proper interval representation implies a simultaneous unit interval representation; see Figure 2.

We use the well-known characterization of proper interval graphs using *straight enumerations* [10]. Two adjacent vertices $u, v \in V$ are *indistinguishable* if we have $N[u] = N[v]$ where $N[u] = \{v : uv \in E(H)\} \cup \{u\}$ is the closed neighborhood. Being indistinguishable is an equivalence relation and we call the equivalence classes *blocks* of G . We denote the block of G that contains vertex u by $B(u, G)$. Note that for a subgraph $G' \subseteq G$ the block $B(u, G')$ may contain vertices in $V(G') \setminus B(u, G)$ that have the same neighborhood as u in G' but different neighbors in G . Two blocks B, B' are *adjacent* if and only if $uv \in E$ for (any) $u \in B$ and $v \in B'$. A linear order σ of the blocks of G is a *straight enumeration* of G if for every block, the block and its adjacent blocks are consecutive in σ . A proper interval representation R defines a straight enumeration $\sigma(R)$ by ordering the intervals by their starting points and grouping together the blocks. Conversely, for each straight enumeration σ , there exists a corresponding representation R with $\sigma = \sigma(R)$ [10]. A *fine enumeration* of a graph H is a linear order η of $V(H)$ such that for $u \in V(H)$ the closed neighborhood $N_H[u]$ is consecutive in η .

► **Proposition 2** ([24, 10, 17]). *(i) A graph is a proper interval graph if and only if it has a fine enumeration. (ii) A graph is a proper interval graph if and only if it admits a straight enumeration. (iii) A straight enumeration of a connected proper interval graph is unique up to reversal.*

2.3 Simultaneous Graphs

A *simultaneous graph* is a tuple $\mathcal{G} = (G_1, \dots, G_k)$ of graphs G_i that may each share vertices and edges. Note that this definition differs from the one we gave in the introduction. This way the input for the simultaneous representation problem is a single entity. The size $|\mathcal{G}|$ of a simultaneous graph is $\sum_{i=1}^k |G_i|$. We call \mathcal{G} *connected*, if $\bigcup_{i=1}^k G_i$ is connected. A *simultaneous (proper/unit) interval representation* $\mathcal{R} = (R_1, \dots, R_k)$ of \mathcal{G} is a tuple of representations such that $R_i \in \mathcal{R}$ is a (proper/unit) interval representation of graph G_i and the intervals representing shared vertices are identical in each representation. A simultaneous graph is a *simultaneous (proper/unit) interval graph* if it admits a simultaneous (proper/unit) interval representation.

An important special case is that of *sunflower graphs*. The simultaneous graph \mathcal{G} is a *sunflower graph* if each pair of graphs G_i, G_j with $i \neq j$ shares exactly the same subgraph S , which we then call the *shared graph*. Note that, for \mathcal{G} to be a simultaneous interval graph, it is a necessary condition that $G_i \cap G_j$ is an induced subgraph of G_i and G_j for $i, j = 1, \dots, k$. In particular, in the sunflower case the shared graph S must be an induced subgraph of each G_i . The following lemma allows us to restrict ourselves to instances whose union graph $\bigcup_{\mathcal{G}} = \bigcup_{i=1}^k G_i$ is connected.

► **Lemma 3** (\star). *Let $\mathcal{G} = (G_1, \dots, G_k)$ be a simultaneous graph and let C_1, \dots, C_l be the connected components of $\bigcup_{\mathcal{G}}$. Then \mathcal{G} is a simultaneous (proper) interval graph if and only if each of the graphs $\mathcal{G}_i = (G_1 \cap C_i, \dots, G_k \cap C_i)$, $i = 1, \dots, l$ is a simultaneous (proper/unit) interval graph.*

3 Sunflower Proper Interval Graphs

In this section, we deal with simultaneous proper interval representations of sunflower graphs. We first present a combinatorial characterization of the simultaneous graphs that admit such a representation. Afterwards, we present a simple linear-time recognition algorithm. Finally, we derive a combinatorial description of all the combinatorially different simultaneous proper interval representations of a connected simultaneous graph, which is a prerequisite for the unit case.

3.1 Characterization

Let $G = (V, E)$ be a proper interval graph with straight enumeration σ and let $V_S \subseteq V$ be a subset of vertices. We call σ *compatible* with a linear order ζ of V_S if, we have for $u, v \in V_S$ that $u \leq_{\zeta} v$ implies $B(u, G) \leq_{\sigma} B(v, G)$.

► **Lemma 4.** *Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph with shared graph $S = (V_S, E_S)$. Then \mathcal{G} admits a simultaneous proper interval representation \mathcal{R} if and only if there exists a linear order ζ of V_S and straight enumerations σ_i for each G_i that are compatible with ζ .*

Proof Sketch. For a given representation \mathcal{R} the straight enumerations $\sigma_i = \sigma(R_i)$ and linear order ζ of V_S given by their left endpoints in \mathcal{R} clearly satisfy the lemma. Conversely we build a linear order of interval endpoints from each σ_i that equals a proper interval representation. As each σ_i is compatible with ζ , all endpoint orderings allow the same ordering for vertices in S , thus permitting one global ordering of all endpoints. Drawing the intervals according to this ordering then yields a simultaneous representation \mathcal{R} since it extends each individual ordering. ◀

Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph with shared graph $S = (V_S, E_S)$ and for each $G_i \in \mathcal{G}$ let σ_i be a straight enumeration of G_i . We call the tuple $(\sigma_1, \dots, \sigma_k)$ a *simultaneous enumeration* if for any $i, j \in \{1, \dots, k\}$ and $u, v \in V_S$ we have $B(u, G_i) <_{\sigma_i} B(v, G_i) \Rightarrow B(u, G_j) \leq_{\sigma_j} B(v, G_j)$. That is, the blocks containing vertices of the shared graph are not ordered differently in any straight enumeration.

► **Theorem 5** (\star). *Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph. There exists a simultaneous proper interval representation $\mathcal{R} = (R_1, \dots, R_k)$ of \mathcal{G} if and only if there is a simultaneous enumeration $(\sigma_1, \dots, \sigma_k)$ of \mathcal{G} . If $(\sigma_1, \dots, \sigma_k)$ exists, there also exists \mathcal{R} with $\sigma(R_i) = \sigma_i$ for each $R_i \in \mathcal{R}$.*

3.2 A Simple Recognition Algorithm

In this section we develop a very simple recognition algorithm for sunflower graphs that admits a simultaneous proper interval representation based on Theorem 5.

Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph with shared graph $S = (V_S, E_S)$. By Proposition 2, for each graph G_i , there exists a PQ-tree T'_i that describes exactly the fine enumerations of G_i . We denote by $T_i = T'_i|S$ the projection of T'_i to the vertices in S . The tree T_i thus describes all proper interval representations of S that can be extended to a proper interval representation of G_i . Let T denote the intersection of T_1, \dots, T_k . By definition, T represents all proper interval representations of S that can be extended to a proper interval representation of each graph G_i . Thus, \mathcal{G} admits a simultaneous proper interval representation if and only if T is not the null-tree.

If T is not the null-tree, we can obtain a simultaneous representation by choosing any ordering $O \in \text{CONSISTENT}(T)$ and constructing a simultaneous representation \mathcal{S} of S . Using the algorithm of Klavík et al. [20], we can then independently extend \mathcal{S} to representations R_i of G_i . Since the trees T_i can be computed in time linear in the size of the graph G_i , and the intersection of two trees takes linear time, the testing algorithm takes time linear in the total size of the G_i . The representation extension of Klavík et al. [20] runs in linear time. We therefore have the following theorem.

► **Theorem 6.** *Given a sunflower graph $\mathcal{G} = (G_1, \dots, G_k)$, it can be tested in linear time whether \mathcal{G} admits a simultaneous proper interval representation.*

3.3 Combinatorial Description of Simultaneous Representations

Let \mathcal{G} be a sunflower proper interval graph with shared graph S and simultaneous representation \mathcal{R} . Then, each representation $R \in \mathcal{R}$ uses the same intervals for vertices of S and implies the same straight enumeration $\sigma_S(\mathcal{R}) = \sigma_S(R) = \sigma(\{I_v \in R : v \in V(S)\})$.

► **Lemma 7.** *Let \mathcal{G} be a connected sunflower proper interval graph with shared graph S . Across all simultaneous proper interval representations \mathcal{R}' of \mathcal{G} , the straight enumeration $\sigma_S(\mathcal{R}')$ of S is unique up to reversal.*

Proof. Let \mathcal{R} be a simultaneous representation of \mathcal{G} and $\sigma_S(\mathcal{R})$ the straight enumeration of S induced by \mathcal{R} . Since \mathcal{G} is connected, for any two blocks B_i and B_{i+1} of S consecutive in $\sigma_S(\mathcal{R})$, there exists a graph $G \in \mathcal{G}$ such that B_i and B_{i+1} are in the same connected component of G . Since S is an induced subgraph of G , for any two vertices $u, v \in V(S)$ with $B(u, S) \neq B(v, S)$ we have $B(u, G) \neq B(v, G)$. This means that a straight enumeration of G implies a straight enumeration of S . Additionally, the straight enumeration of each connected component of G is unique up to reversal by Proposition 2. As a result, for any

■ **Figure 3** Simultaneous proper interval representation of G_1 (green solid), G_2 (red dotted), G_3 (blue dashed) with shared graph S (black bold). S has three blocks A , B , C . We denote the component of G_i containing a block D by C_D^i . C_A^2 , C_B^2 , C_B^3 , C_C^2 are loose. C_A^2 is independent. (C_B^2, C_B^3) is a reversible part. (C_C^2) is not a reversible part, since C_C^1 is aligned at C and not loose.

proper interval representation R of G , the blocks B_i and B_{i+1} are consecutive in $\sigma_S(R)$. This holds for any two consecutive blocks in σ , which means that the consecutivity of all blocks of S is fixed for all simultaneous representations of \mathcal{G} . As a consequence $\sigma_S(\mathcal{R})$ is fixed up to complete reversal. ◀

Let G be a proper interval graph consisting of the connected components C_1, \dots, C_k with straight enumerations $\sigma_1, \dots, \sigma_k$. Let $\sigma_1 \circ \dots \circ \sigma_k$ be a straight enumeration of G . Then we say the straight enumeration $\sigma' = \sigma_1 \circ \dots \circ \sigma_{i-1} \circ \sigma_i^r \circ \sigma_{i+1} \circ \dots \circ \sigma_k$ is *obtained from σ by reversal of C_i* . For a sunflower graph \mathcal{G} containing G with shared graph $S = (V_S, E_S)$, we call a component $C = (V_C, E_C)$ of G *loose*, if all vertices $V_S \cap V_C$ are in the same block of S . Reversal of loose components is the only “degree of freedom” among simultaneous enumerations, besides full reversal, and is formally shown in the full version.

To obtain a complete characterization, we now introduce additional terms to specify which reversals result in simultaneous enumerations (see Figure 3). Let $\mathcal{G} = (G_1, \dots, G_k)$ be a connected sunflower proper interval graph with shared graph S . We say a component C of a graph in \mathcal{G} *aligns* two vertices $u, v \in S$ if they are in different blocks of C , i.e., $B(u, C) \neq B(v, C)$. If in addition u and v are in the same block B of S , we say C is *oriented at B* . If there is another component C' among graphs in \mathcal{G} oriented at B , the orientation of their straight enumerations in a simultaneous enumeration of \mathcal{G} are dependent; that is, they cannot be reversed independently. This is shown formally in the full version.

For each block B of S , let $\mathcal{C}(B)$ be the connected components among graphs in \mathcal{G} oriented at B . Since a component may contain B without aligning vertices, we have $0 \leq |\mathcal{C}(B)| \leq k$. If $\mathcal{C}(B)$ contains only loose components, we call it a *reversible part*. Note that a reversible part $\mathcal{C}(B)$ contains at most one component of each graph G_i . Additionally, we call a loose component C *independent*, if it does not align any two vertices of S . Let $(\sigma_1, \dots, \sigma_k)$ and $(\sigma'_1, \dots, \sigma'_k)$ be tuples of straight enumerations of G_1, \dots, G_k . We say $(\sigma'_1, \dots, \sigma'_k)$ is *obtained from $(\sigma_1, \dots, \sigma_k)$ through reversal of reversible part $\mathcal{C}(B)$* , if $\sigma'_1, \dots, \sigma'_k$ are obtained by reversal of all components in $\mathcal{C}(B)$.

► **Theorem 8** (\star). *Let $\mathcal{G} = (G_1, \dots, G_k)$ be a connected sunflower graph with shared graph S and simultaneous enumeration $\rho = (\sigma_1, \dots, \sigma_k)$. Then $\rho' = (\sigma'_1, \dots, \sigma'_k)$ is a simultaneous enumeration of \mathcal{G} if and only if ρ' can be obtained from ρ or ρ^r through reversal of independent components and reversible parts.*

4 Sunflower Unit Interval Graphs

In the previous section we characterized all simultaneous enumerations for a sunflower proper interval graph \mathcal{G} . We say a simultaneous proper/unit interval representation of a sunflower graph \mathcal{G} *realizes* a simultaneous enumeration $\zeta = (\zeta_1, \dots, \zeta_k)$ of ζ , if for $i \in \{1, \dots, k\}$ the representation of G_i corresponds to the straight enumeration ζ_i . In Section 4.1 we provide a criterion which determines for a given simultaneous enumeration ζ of \mathcal{G} whether there is a

■ **Figure 4** (a): The forbidden configuration of Corollary 11. (b)–(e): The four implications of Corollary 12.

simultaneous unit interval representation of \mathcal{G} that realizes ζ . Namely, the criterion is the avoidance of a certain configuration in a partial vertex order of $\bigcup_{\mathcal{G}}$ induced by ζ . In Section 4.2 we combine these findings to efficiently recognize simultaneous unit interval graphs.

4.1 Simultaneous Enumerations of Sunflower Unit Interval Graphs

We first obtain a combinatorial characterization by reformulating the problem of finding a representation as a restricted graph sandwich problem [15].

► **Lemma 9** (\star). *A sunflower graph \mathcal{G} has a simultaneous unit interval representation that realizes a simultaneous enumeration $\zeta = (\zeta_1, \dots, \zeta_k)$ if and only if there is some graph H with $V(H) = V(\mathcal{G})$ that contains the graphs G_1, \dots, G_k as induced subgraphs and has a fine enumeration σ such that for $i \in \{1, \dots, k\}$ straight enumeration ζ_i is compatible with σ on V_i .*

Our approach is to obtain more information on what graph H and the fine enumeration σ must look like. We adapt a characterization of Looges and Olariu [21] to obtain four implications that can be used given only partial information on H and σ (as given by Lemma 9); see Figure 4. For the figures in this section we use arrows to represent a partial order between two vertices. We draw them solid green if they are adjacent, red dotted if they are non-adjacent in some graph G_i , and black dashed if they may or may not be adjacent.

► **Theorem 10** (Looges and Olariu [21]). *A vertex order of a graph $H = (V, E)$ is a fine enumeration if and only if for $v, u, w \in V$ with $v <_{\sigma} u <_{\sigma} w$ and $vw \in E$ we have $vu, uw \in E$.*

► **Corollary 11** (\star). *A vertex order of a graph $H = (V, E)$ is a fine enumeration if and only if there are no four vertices $v, u, x, w \in V$ with $v \leq_{\sigma} u \leq_{\sigma} x \leq_{\sigma} w$ and $vw \in E$ and $ux \notin E$.*

► **Corollary 12**. *Let $H = (V, E)$ be a graph with fine enumeration σ . Let $v, u, x, w \in V$ and $u \leq_{\sigma} x$ as well as $v \leq_{\sigma} w$. Then we have (see Figure 4):*

- (i) $vw \in E \wedge v \leq_{\sigma} u \wedge x \leq_{\sigma} w \Rightarrow ux \in E$
- (ii) $ux \notin E \wedge v \leq_{\sigma} u \wedge x \leq_{\sigma} w \Rightarrow vw \notin E$
- (iii) $vw \in E \wedge ux \notin E \wedge v \leq_{\sigma} u \Rightarrow w <_{\sigma} x$
- (iv) $vw \in E \wedge ux \notin E \wedge x \leq_{\sigma} w \Rightarrow u <_{\sigma} v$.

Now we introduce the forbidden configurations for *simultaneous* enumerations of sunflower unit interval graphs. Throughout this section let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph with shared graph S and simultaneous enumeration $\zeta = (\zeta_1, \dots, \zeta_k)$. Furthermore, let $V_i = V(G_i)$ and $E_i = E(G_i)$, for $i \in \{1, \dots, k\}$. Finally, let $V = V_1 \cup \dots \cup V_k$. For a straight enumeration η of some graph H we say for $u, v \in V(H)$ that $u <_{\eta} v$, if u is in a block before v , and we say $u \leq_{\eta} v$, if $u = v$ or $u <_{\eta} v$. We call \leq_{η} the *partial order on $V(H)$ corresponding to η* . Note that for distinct u, v in the same block we have neither $u >_{\eta} v$ nor $u \leq_{\eta} v$. We write $u \leq_i v$ and $u <_i v$ instead of $u \leq_{\zeta_i} v$ and $u <_{\zeta_i} v$, respectively.

■ **Figure 5** A sunflower graph $\mathcal{G} = (G_1, G_2)$ with shared vertices s_1, s_2 (black, bold). Let ζ be the simultaneous enumeration realized by the given simultaneous proper interval representation. In (G_1, ζ_1) we have the (s_1, s_2) -chain $C = (s_1, a, b, c, s_2)$ of size 5 (green, solid). In (G_2, ζ_2) we have the (s_1, s_2) -bar $B = (s_1, d, e, f, s_2)$ of size 5 (red, dotted). Hence, sunflower graph \mathcal{G} has the conflict (C, B) for the simultaneous enumeration ζ .

■ **Figure 6** (a): A simultaneous enumeration with conflict. (b): Result with added orderings after scouting, starting at s_2 and finding the conflict in s_1 .

Let $u, v \in V(S)$ with $u \neq v$. For $i \in \{1, \dots, k\}$ a (u, v) -chain of size $m \in \mathbb{N}$ in (G_i, ζ_i) is a sequence $(u = c_1, \dots, c_m = v)$ of vertices in V_i with $c_1 <_i \dots <_i c_m$ that corresponds to a path in G_i . A (u, v) -bar between u and v of size $m \in \mathbb{N}$ in (G_i, ζ_i) is a sequence $(u = b_1, \dots, b_m = v)$ of vertices in V_i with $b_1 <_i \dots <_i b_m$ that corresponds to an independent set in G_i . An example is shown in Figure 5. If there is a (u, v) -chain C in G_i of size $l \geq 2$ and a (u, v) -bar B in (G_j, ζ_j) of size at least l , then we say that (C, B) is a (u, v) -*(chain-bar)-conflict* and that \mathcal{G} has conflict (C, B) for ζ . Note that one can reduce the size of a larger (u, v) -bar by removing intervals between u and v . Thus, we can always assume that in a conflict, we have a bar and a chain of the same size $l \geq 2$. Assume \mathcal{G} has a simultaneous unit interval representation realizing ζ . If a graph $G \in \mathcal{G}$ has a (u, v) -chain of size $l \geq 2$, then the distance between the intervals I_u, I_v for u, v is smaller than $l - 2$. On the other hand, if a graph $G \in \mathcal{G}$ has a (u, v) -bar of size l , then the distance between I_u, I_v is greater than $l - 2$. Hence, sunflower graph \mathcal{G} has no conflict. The result of this section is that the absence of conflicts is not only necessary, but also sufficient.

► **Theorem 13.** *Let \mathcal{G} be a sunflower proper interval graph with simultaneous enumeration ζ . Then \mathcal{G} has a simultaneous unit interval representation that realizes ζ if and only if \mathcal{G} has no conflict for ζ .*

Recall that $V_i = V(G_i)$ for $i \in \{1, \dots, k\}$ and $V = V_1 \cup \dots \cup V_k$. Let α^* be the union of the partial orders on V_1, \dots, V_k corresponding to ζ_1, \dots, ζ_k . Set α to be the transitive closure of α^* . We call α the *partial order on V induced by ζ* . The rough idea is that the partial order on V induced by the simultaneous enumeration ζ is extended in two sweeps to a fine enumeration of some graph H that contains G_1, \dots, G_k as induced subgraphs; see Figures 6, 7. For $(u, v) \in \alpha$ we consider u to be to the left of v . The first sweep (*scouting*) goes from the right to the left and makes only necessary extensions according to Corollary 12 (iv). If there is a conflict, then it is found in this step. Otherwise, we can greedily order the vertices on the way back by additionally respecting Corollary 12 (iii) (*zipping*) to obtain a linear extension where both implications are satisfied. In the last step we decide which edges H has by respecting Corollary 12 (i).

For $h \in \{1, \dots, k\}$ we say two vertices $u, v \in V_h$ are *indistinguishable in \mathcal{G}* if we have $N_{G_i}(u) = N_{G_i}(v)$ for all $i \in \{1, \dots, k\}$ with $u, v \in V_i$. In that case u, v can be represented by the same interval in any simultaneous proper interval representation. Thus, we identify

■ **Figure 7** (a): A simultaneous enumeration without conflict. (b): Result with added orderings after scouting. (c): Resulting linear order after zipping. Note that a_1 comes before d_2 in the linear order thanks to scouting. Choosing otherwise would imply a contradiction at s_2 . (d): Resulting unit interval representation for the sandwich graph.

■ **Figure 8** (a): The vertices u_i, v_j, w_j as derived from x and X . The introduced ordering (u_i, v_j) is marked with $R_{i,j}$. (b),(c): Both cases of a chain-bar pair for u and v .

indistinguishable vertices. If $u, v \in V_h$ are not indistinguishable, then we have $N_{G_j}(u) \neq N_{G_j}(v)$ for some $j \in \{1, \dots, k\}$. In that case u, v are ordered by ζ_j and therefore by α . That is, we can assume α to be a linear order on V_i for $i \in \{1, \dots, k\}$. Note that u, v may be ordered even if they are indistinguishable in some input graphs.

For $i \in \{1, \dots, k\}$, let $G_i^c = (V_i, (V_i^c) \setminus E_i)$ be the complement of G_i . We set $E = \{(u, v) \in \alpha \mid uv \in E_1 \cup \dots \cup E_k\}$ and $F = \{(u, v) \in \alpha \mid uv \in E(G_1^c \cup \dots \cup G_k^c)\}$. We call a partial order σ on V *left-closed* if we have

$$\forall v, w, u, x \in V: (vw \in E \wedge ux \in F \wedge x \leq_\sigma w) \Rightarrow u <_\sigma v. \quad (1)$$

Note that a fine enumeration of a graph H with G_1, \dots, G_k as induced subgraphs is left-closed by Corollary 12 (iv). We describe the result of the first sweep with the following lemma.

► **Lemma 14.** *A sunflower graph \mathcal{G} has no conflict for a simultaneous enumeration ζ if and only if there is a left-closed partial order τ that extends the partial order on $V(\mathcal{G})$ induced by ζ .*

Proof Sketch. If there is a conflict (C, B) , then the partial order α induced by ζ cannot be extended to be left-closed since then for $i \in \{1, \dots, k-1\}$ the i 'th vertex of C and B must be ordered and distinct while the first vertex is shared; see Figure 6.

Otherwise, we process the vertices from the right to the left and add for each of them the implied orderings (each is considered as vertex x in the definition of left-closed). First consider the case of just two input graphs G_1, G_2 . Let X be the set of already processed vertices and let σ be the current partial order. We next process a maximal vertex $x \in V \setminus X$. Let $x \in V_i$. Then we choose u_i to be the rightmost vertex in V_i with $u_i x \in F$ and for $j \neq i$ we choose w_j to be the leftmost vertex in V_j with $x \leq w_j$ and v_j to be the leftmost vertex in V_j with $v_j w_j \in E$; see Figure 8a. Each of u_i, v_j, w_j may not exist. If they do, we extend σ to σ' by adding the ordering $u_i \leq_{\sigma'} v_j$. The other implied orderings are exactly those obtained by transitive closure.

Two vertices $u \in V_1, v \in V_2$ are only ordered by α if there is a shared vertex s with $u \leq_\alpha s \leq_\alpha v$ or $v \leq_\alpha s \leq_\alpha u$. The key observation is that if u is ordered before v due to a necessary extension, then there is a shared vertex s and a (v, s) -chain and a (u, s) -bar of equal

Figure 9 (a): Example situation for $(v_j, u_i) \in \tau_{i,j} \setminus \alpha^*$. We have the (v_j, s) -bar (v_j, b_4, b_3, b_2, s) and the (u_i, s) -chain (u_i, c_4, c_3, c_2, s) and obtain $x \leq_{\tau_{i,j}} w_j \leq_{\tau_{i,j}} b_4 \leq_{\tau_{i,j}} c_4 \leq_{\tau_{i,j}} x$. (b): Example situation for the transitivity of τ where we have a chain-bar pair for u, v as well as for v, w . We obtain $b_4 \leq_{\tau_{i,j}} c_4 \leq_{\tau_{i,j}} b'_3 \leq_{\tau_{i,j}} c'_3$ and since $u <_{\alpha} b_4$ and $w <_{\alpha} c'_3$ we get $b_4 \leq_{\tau_{i,h}} c'_3$ in an appropriate induction and with $\tau_{i,h}$ being left-closed we obtain $u \leq_{\tau_{i,h}} w$. (The base cases for the induction involve shared vertices and thereby only two input graphs.)

size (*chain-bar pair*): If we have $x \leq_{\alpha} w_j$, then there is a shared vertex $x \leq_{\alpha} s \leq_{\alpha} w_j$ and by Theorem 10 we obtain $us \in F$ and $vs \in E$, which yields a chain-bar pair; see Figure 8b. Otherwise we have a chain-bar pair for x and w_j that can be extended by u and v ; see Figure 8c. With the absence of conflicts this ensures that vertices ordered according to the left-closed property are actually distinct.

Assume a new extension would violate the property of antisymmetry. This would mean we already had $v_j <_{\sigma} u_i$, which would imply a cyclic ordering of x, w_j with elements of the (necessary) chain-bar pair for v_j, u_i in a prior step; see Figure 9a. Finally, for more than two input graphs we obtain a corresponding ordering $\tau_{i,j}$ for each pair of input graphs G_i, G_j . Let $\tau = \bigcup_{i,j \in \{1, \dots, k\}} \tau_{i,j}$ be their union. For $u <_{\tau_{i,j}} v <_{\tau_{j,h}} w$ we can prove $u <_{\tau_{i,h}} w$ by using chain-bar pairs and induction; see Figure 9b. Hence, τ is already transitive and the other properties are easy to verify. \blacktriangleleft

By respecting the orderings obtained by scouting we avoid wrong decisions when greedily adding vertices to a linear ordering in the zipping step; see Figure 7.

Lemma 15. *Let \mathcal{G} be a sunflower graph with a simultaneous enumeration ζ . There is a left-closed linear order τ that extends the partial order α on $V(\mathcal{G})$ induced by ζ if and only if there is a left-closed partial order $\sigma \supseteq \alpha$.*

Proof Sketch. Given σ we process the vertices from the left to the right. We add in each step a leftmost vertex u of the remaining vertices to a set U of the processed vertices that are linearly ordered. We denote the current order by σ' . Vertex u is then ordered before all other vertices in $V \setminus U$. To avoid that the left-closed property is violated when adding such orderings for another vertex, we ensure our extended order $\sigma'' \supseteq \sigma'$ is *right-closed on U* meaning that

$$\forall u, v \in U, w, x \in V: (vw \in E \wedge ux \in F \wedge v \leq u) \Rightarrow w < x. \quad (2)$$

To this end, we consider the current vertex u as vertex u in the definition of right-closed and add all implied orderings in σ'' . This means for each vertex $y \in Y = \{y \in V \mid \exists u' \in U: uy \in E\}$ and each vertex $z \in Z = \{z \in V \mid uz \in F\}$ we set $y \leq_{\sigma''} z$; see Figure 10a. We further extend σ'' to be transitive. Note that there are no two vertices $y \in Y, z \in Z$ with $y \leq_{\sigma} z$, since σ is left-closed and for $u' \in U$ we have $u' \leq_{\sigma} u$. With this observation we can verify that σ'' is antisymmetric and left-closed; see Figure 10b. \blacktriangleleft

■ **Figure 10** (a): orderings added during a zipping step (blue dash-dotted). All vertices in $Y = \{y, y'\}$ are ordered before those in $Z = \{z, z'\}$. (b): The case for σ'' being left-closed where we have $x \leq_{\sigma''} w$ due to transitivity. This means there is some ordering $(y, z) \in Y \times Z$ with $x \leq_{\sigma'} y \leq_{\sigma''} z \leq_{\sigma'} w$. We further have a vertex $u'' \in U$ with $u''y \in E$ and $uz \in F$. Given vertices $u', v \in V$ with $u'x \in F$ and $vw \in E$ we obtain $u' <_{\sigma'} u''$ and $u <_{\sigma'} v$ since σ' is left-closed. This yields $u' <_{\sigma''} v$.

Finally, we construct a graph $H = (V, E')$ for which the obtained linear order τ is a fine enumeration. We do so by setting $E' = \{ux \in V^2 \mid \exists vw \in E: v \leq_{\tau} u <_{\tau} x \leq_{\tau} w\}$ in accordance with Corollary 12 (i).

► **Lemma 16** (*). *Let $\mathcal{G} = (G_1, \dots, G_k)$ be a sunflower graph with a simultaneous enumeration ζ . A linear order τ that extends the partial order on $V(\mathcal{G})$ induced by ζ is a fine enumeration for some graph H that has G_1, \dots, G_k as induced subgraphs if and only if τ is left-closed.*

Combining Lemmas 9, 14, 15 and 16 we obtain Theorem 13.

► **Theorem 13.** *Let \mathcal{G} be a sunflower proper interval graph with simultaneous enumeration ζ . Then \mathcal{G} has a simultaneous unit interval representation that realizes ζ if and only if \mathcal{G} has no conflict for ζ .*

4.2 Recognizing Simultaneous Unit Interval Graphs in Polynomial Time

With Theorems 8 and 13 we can now efficiently recognize simultaneous unit interval graphs.

► **Theorem 17.** *Given a sunflower graph $\mathcal{G} = (G_1, \dots, G_k)$, we can decide in $O(|V| \cdot |E|)$ time, whether \mathcal{G} is a simultaneous unit interval graph, where $(V, E) = G^* = G_1 \cup \dots \cup G_k$. If it is, then we also provide a simultaneous unit interval representation in the same time.*

Proof Sketch. Here we establish polynomial time recognition, and the stated time is proven in the full version. As discussed earlier, we can assume that G^* is connected. With Theorem 6 we obtain a simultaneous enumeration ζ of \mathcal{G} , unless \mathcal{G} is not a simultaneous proper interval graph. By Theorem 13, the sunflower graph \mathcal{G} is a simultaneous unit interval graph if and only if there is a simultaneous enumeration η for which \mathcal{G} has no conflict. In that case η^r also has no conflict. With Theorem 8 we have that η or η^r is obtained from ζ by reversals of reversible parts and independent components. Hence, we only need to consider simultaneous enumerations obtained that way.

Since every single graph G_i is proper, it has no conflict and we only need to consider (u, v) -conflicts with $u, v \in V(S)$, where S is the shared graph. The minimal (u, v) -chains for G_i are exactly the shortest paths in G_i and thus independent from reversals. On the other hand, for the maximal size of (u, v) -bars in G_i only the reversals of the two corresponding components C, D of u, v are relevant, while components in-between always contribute their maximum independent set regardless of whether they are reversed. We can thus compute

for $i, j \in \{1, \dots, k\}$, $u, v \in V(S)$ and each of the four combinations of reversal decisions (reverse or do not reverse) for the corresponding components C, D of u, v , whether they yield a conflict at (u, v) . We can formulate a corresponding 2-SAT formula \mathcal{F} : For every independent component and every reversible part we introduce a literal that represents whether it is reversed or not. For every combination of two reversal decisions that yields a conflict we add a clause that excludes this combination. If \mathcal{F} is not satisfiable, then every simultaneous enumeration yields a conflict. Otherwise, a solution yields a simultaneous enumeration without conflict. We obtain a simultaneous unit interval representation by following the construction in Section 4.1. ◀

5 Conclusion

We studied the problem of simultaneous representations of proper and unit interval graphs. We have shown that, in the sunflower case, both simultaneous proper interval graphs and simultaneous unit intervals can be recognized efficiently. While the former can be recognized by a simple and straightforward recognition algorithm, the latter is based on the three ingredients: 1) a complete characterization of all simultaneous proper interval representations of a sunflower simultaneous graph, 2) a characterization of the simultaneous proper interval representations that can be realized by a simultaneous unit interval representation and 3) an algorithm for testing whether among the simultaneous proper interval representations there is one that satisfies this property.

Future Work. While our algorithm for (sunflower) simultaneous proper interval graphs has optimal linear running time, we leave it as an open problem whether simultaneous unit interval graphs can also be recognized in linear time.

Our main open question is about the complexity of sunflower simultaneous interval graphs. Jampani and Lubiw [18] conjecture that they can be recognized in polynomial time for any number of input graphs. However, even for three graphs the problem is still open.

Abstract

Several clustering frameworks with interactive (semi-supervised) queries have been studied in the past. Recently, clustering with same-cluster queries has become popular. An algorithm in this setting has access to an oracle with full knowledge of an optimal clustering, and the algorithm can ask the oracle queries of the form, “Does the optimal clustering put vertices u and v in the same cluster?” Due to its simplicity, this querying model can easily be implemented in real crowd-sourcing platforms and has attracted a lot of recent work.

In this paper, we study the popular correlation clustering problem (Bansal et al., 2002) under the same-cluster querying framework. Given a complete graph $G = (V, E)$ with positive and negative edge labels, correlation clustering objective aims to compute a graph clustering that minimizes the total number of disagreements, that is the negative intra-cluster edges and positive inter-cluster edges. In a recent work, Ailon et al. (2018b) provided an approximation algorithm for correlation clustering that approximates the correlation clustering objective within $(1 + \epsilon)$ with $O(\frac{k^{14} \log n \log k}{\epsilon^6})$ queries when the number of clusters, k , is fixed. For many applications, k is not fixed and can grow with $|V|$. Moreover, the dependency of k^{14} on query complexity renders the algorithm impractical even for datasets with small values of k .

In this paper, we take a different approach. Let C_{OPT} be the number of disagreements made by the optimal clustering. We present algorithms for correlation clustering whose error and query bounds are parameterized by C_{OPT} rather than by the number of clusters. Indeed, a good clustering must have small C_{OPT} . Specifically, we present an efficient algorithm that recovers an exact optimal clustering using at most $2C_{OPT}$ queries and an efficient algorithm that outputs a 2-approximation using at most C_{OPT} queries. In addition, we show under a plausible complexity assumption, there does not exist any polynomial time algorithm that has an approximation ratio better than $1 + \alpha$ for an absolute constant $\alpha > 0$ with $o(C_{OPT})$ queries. Therefore, our first algorithm achieves the optimal query bound within a factor of 2.

We extensively evaluate our methods on several synthetic and real-world datasets using real crowd-sourced oracles. Moreover, we compare our approach against known correlation clustering algorithms that do not perform querying. In all cases, our algorithms exhibit superior performance.

1 Introduction

In correlation clustering, the algorithm is given potentially inconsistent information about similarities and dissimilarities between pairs of vertices in a graph, and the task is to cluster the vertices so as to minimize disagreements with the given information [7, 10]. The correlation clustering problem was first proposed by Bansal, Blum and Chawla [7] and since then it has found numerous applications in document clustering, image segmentation, grouping gene expressions etc. [7, 10].

In correlation clustering, we are given a complete graph $G = (V, E)$, $|V| = n$, where each edge is labelled either $+$ or $-$. An optimal clustering partitions the vertices such that the number of intra-cluster negative edges and inter-cluster positive edges is minimized. The problem is known to be NP-Hard. The seminal work of Bansal et al. [7] gave a constant factor approximation for correlation clustering. Following a long series of works [7, 9, 4, 16, 12], the best known approximation bounds till date are a 3-approximation combinatorial algorithm [1] and a 2.06-approximation based on linear programming rounding [10]. The proposed linear programming relaxation for correlation clustering [9, 1, 10] is known to have an integrality gap of 2, but there does not exist yet a matching algorithm that has an approximation ratio 2 or lower.

Correlation clustering problem can be extended to weighted graphs for an $O(\log n)$ -approximation bound and is known to be optimal [12]. Moreover, when one is interested in maximizing agreements, a polynomial time approximation scheme was provided by Bansal et al. [7].

Over the last two decades, crowdsourcing has become a widely used way to generate labeled data for supervised learning. The same platforms that are used for this purpose can also be used for unsupervised problems, thus converting the problems to a semi-supervised active learning setting. This can often lead to significant improvements in accuracy. However, using crowdsourcing introduces another dimension to the optimization problems, namely minimizing the amount of crowdsourcing that is used. The setting of active querying has been studied previously in the context of various clustering problems. Balcan and Blum [6] study a clustering problem in which the only information given to the algorithm is provided through an oracle that tells the algorithm either to “merge” two clusters or to “split” a cluster. More recently, Ashtiani, Kushgrha and Ben-David [5] considered a framework of same-cluster queries for clustering; in this framework, the algorithm can access an oracle that has full knowledge of an optimal clustering and can issue queries to the oracle of the form “Does the optimal clustering put vertices u and v in the same cluster?” Because of its simplicity, such queries are highly suited for crowdsourcing and has been studied extensively both in theory community [3, 19, 2, 15] and in applied domains [23, 14, 17, 22]. Correlation clustering has also been considered in this context. Ailon, Bhattacharya and Jaiswal [2] study correlation clustering in this framework under the assumption that the number k of clusters is fixed. They gave an $(1 + \epsilon)$ approximation algorithm for correlation clustering

that runs in polynomial time and issues $O(k^{14} \log n \log k / \epsilon^6)$ queries. However, for most relevant applications, the number of clusters k is not fixed. Even for fixed k , the dependence of k^{14} is huge (consider $k = 2$ and $2^{14} = 16384$ with additional constants terms hidden under $O()$ notation).

In this paper, we give near-optimal algorithms for correlation clustering with same-cluster queries that are highly suitable for practical implementation and whose performance is parameterized by the optimum number of disagreements. Along with providing theoretical guarantees, we perform extensive experiments on multiple synthetic and real datasets. Let C_{OPT} be the number of disagreements made by the optimal clustering. Our contributions are as follows.

1. A deterministic algorithm that outputs an *optimal* clustering using at most $2C_{OPT}$ queries (Section 3).
2. An expected 2-approximation algorithm that uses at most C_{OPT} queries in expectation (Section 4).
3. A new lower bound that shows it is not possible to get an $(1 + \alpha)$ approximation for some constant $\alpha > 0$ with any polynomial time algorithm that issues $o(C_{OPT})$ queries assuming GAP-ETH (see definition in Section 5).
4. An extensive experimental comparison that not only compares the effectiveness of our algorithms, but also compares the state-of-the art correlation clustering algorithms that do not require any querying (Section 6).

Assumption of an optimum oracle [5, 2] is quite strong in practice. However, our experiments reveal that such an assumption is not required. In correlation clustering, often the \pm edges are generated by fitting an automated classifier, where each vertex corresponds to some object and is associated with a feature vector. In our experiments with real-world data, instead of an optimum oracle, we use crowdsourcing. By making only a few pair-wise queries to a crowd oracle, we show it is possible to obtain an optimum or close to optimum clustering. After our work, it came to our notice that it may be possible to use Bocker et al.'s [8] results on fixed-parameter trackability of cluster editing to adapt to our setting, and get better constants on the query complexity. This is an ongoing work. Our algorithms and techniques are vastly different from [8] and are also considerably simpler.

2 Related Work

Asthiani et al. [5] considered the k -means objective with same-cluster queries and showed that it is possible to recover the optimal clustering under k -means objective with high probability by issuing $O(k^2 \log k + k \log n)$ queries if a certain margin condition holds for each cluster. Gamlath, Huang and Svensson extended the above result when approximation is allowed [15]. Ailon et al. [2] studied correlation clustering with same-cluster queries and showed that there exists an $(1 + \epsilon)$ approximation for correlation clustering where the number of queries is a (large) polynomial in k . Our algorithms are different from those in [2] in that our guarantees are parameterized by C_{OPT} rather than by k . Kushagra et al. [18] study a restricted version of correlation clustering where the valid clusterings are provided by a set of hierarchical trees and provide an algorithm using same-cluster queries for a related setting, giving guarantees in terms of the size of the input instance (or the VC dimension of the input instance) rather than C_{OPT} . [19] studied, among other clustering problems, a random

instance of correlation clustering under same-cluster queries. Our algorithms are based on the basic 3-approximation algorithm of Ailon et al. [1] that selects a pivot vertex randomly and forms a cluster from that vertex and all of its $+$ -neighbors. They further honed this approach by choosing to keep each vertex in the pivot's cluster with a probability that is a function of the linear programming solution. Chawla et al. [10] used a more sophisticated function of the linear programming solution to design the current state-of-the-art algorithm, which gives a 2.06 approximation for correlation clustering.

3 Finding an Optimal Clustering

We are given a query access to an oracle that given any two vertices u and v returns whether or not u and v are together in a cluster in an optimal solution. Let OPT denote the optimal solution which is used by the oracle. Given a positive ($+$) edge (u, v) , if OPT puts u and v in different clusters, then we say OPT makes a mistake on that edge. Similarly for a negative ($-$) edge (u, v) , if OPT puts them together in a cluster then again OPT makes a mistake on it. Similarly, our algorithm can decide to make mistakes on certain edges and our goal is to minimize the overall number of mistakes. It is easy to see that an optimal solution for a given input graph makes mistakes only on edges that are part of a $(+, +, -)$ triangle. Moreover, any optimal solution must make at least one mistake in such a triangle.

The pseudocode for our algorithm, QUERYPIVOT, is given in Algorithm 1. The algorithm is as follows (in the following description, we give in brackets the corresponding line number for each step). We pick a pivot u arbitrarily from the set of vertices that are not clustered yet [line 5]. For each $(+, +, -)$ triangle (u, v, w) [line 10], if we have not yet determined via queries that OPT makes a mistake on $\{u, v\}$ or that OPT makes a mistake on $\{u, w\}$ [lines 11-14], then (1) we query $\{u, v\}$ [line 17] and if OPT makes a mistake on this edge, we too decide to make a mistake on this edge and proceed to the next $(+, +, -)$ triangle involving u and (2) if OPT does not make a mistake on $\{u, v\}$, then we query $\{u, w\}$ [line 23] and make a mistake on it if OPT makes a mistake on it. Note that if we have already queried one of $\{u, v\}$ or $\{u, w\}$ and found a mistake, we do not query the other edge [line 11]. Once we have gone through all $(+, +, -)$ triangles involving u then for every $v \neq u$, if we have not already decided to make a mistake on $\{u, v\}$, then if $\{u, v\}$ is a $+$ edge we keep v in u 's cluster and if $\{u, v\}$ is a $-$ edge we do not put v in u 's cluster. On the other hand, if we have decided to make a mistake on $\{u, v\}$, then if $\{u, v\}$ is a $-$ edge we keep v in u 's cluster and if $\{u, v\}$ is a $+$ edge we do not put v in u 's cluster. Finally, we remove all vertices in u 's cluster from the set of remaining vertices and recursively call the function on the set of remaining vertices.

In the pseudocode, $Queried[v] = 1$ means the algorithm has already issued a query $(pivot, v)$ to the oracle, $Mistake[v] = 1$ means it has decided to make a mistake on the edge $(pivot, v)$ based on the oracle answer, and $Oracle(pivot, v)$ returns 1 iff OPT makes a mistake on the edge $\{pivot, v\}$. We prove the following theorem that shows that QUERYPIVOT is able to recover the optimal clustering known to the oracle with a number of queries bounded in terms of C_{OPT} .

► **Theorem 3.1.** *Let C_{OPT} be the number of mistakes made by an optimal clustering. The QUERYPIVOT algorithm makes C_{OPT} mistakes and makes at most $2C_{OPT}$ queries to the oracle.*

Algorithm 1 QUERYPIVOT.

31:   end if
32: end for
33: return  $\{C\} \cup \text{QUERYPIVOT}(V \setminus C, A, Oracle)$ 

```

For a given cluster C and a vertex $w \in C$, we denote by $N_C^+(w)$ the set of vertices in C that have $+$ edges with w . Similarly, we denote by $N_C^-(w)$ the set of vertices in C that have $-$ edges.

The algorithm time complexity is dominated by the time taken to check $(+, +, -)$ triangles involved with the pivots. Let E^+ denote the set of positive edges in G . Then all the $(+, +, -)$ triangles that include a pivot can be checked in time $O(|E^+| * n)$.

► **Lemma 3.2.** *The QUERYPIVOT algorithm outputs a valid partition of the vertices.*

Proof. Note that the pivot is never removed from C . Hence, between each pair of consecutive recursive calls, at least one vertex is removed from V . The algorithm must then terminate after at most n recursive calls. Moreover, in each recursive call, the set of vertices passed to the next recursive call is disjoint from the cluster created in that recursive call. Thus, inductively, the sets returned by the algorithm must be disjoint. ◀

► **Lemma 3.3.** *Consider a clustering \mathcal{C} in which some cluster C contains vertices u, v s.t. $\{u, v\}$ is a $-$ edge and s.t. u and v do not form a $(+, +, -)$ triangle with any other vertex in C . \mathcal{C} is suboptimal.*

Proof. If we were to remove v from C and put it in a singleton cluster, we would make $|N_C^-(v)| - |N_C^+(v)|$ fewer mistakes than C . If $|N_C^-(v)| - |N_C^+(v)| > 0$, then C is suboptimal. Therefore, assume $|N_C^-(v)| \leq |N_C^+(v)|$. Now, note that $\forall w \in N_C^+(v)$, $w \in N_C^-(u)$ because otherwise, u , v , and w form a $(+, +, -)$ triangle. Thus $|N_C^+(v)| \leq |N_C^-(u)| - 1$ because $v \in N_C^-(u)$. Moreover, $|N_C^+(u)| \leq |N_C^-(v)| - 1$ because $u \in N_C^-(v)$.

Hence, if we were to remove u from C and put it in a singleton cluster, we would make $|N_C^-(u)| - |N_C^+(u)| \geq |N_C^+(v)| - |N_C^-(v)| + 2$ fewer mistakes than C . Since $|N_C^-(v)| - |N_C^+(v)| \leq 0$, $|N_C^+(v)| - |N_C^-(v)| + 2 > 0$, so C is suboptimal. \blacktriangleleft

► **Lemma 3.4.** *Consider a clustering \mathcal{C} in which a cluster C_1 contains a vertex u , a different cluster C_2 contains a vertex v , $\{u, v\}$ is a $+$ edge, and in every $(+, +, -)$ triangle that includes $\{u, v\}$, the clustering makes at least 2 edge mistakes. \mathcal{C} is suboptimal.*

Proof. If we were to remove u from C_1 and put it in C_2 , we would make $|N_{C_2}^+(u)| + |N_{C_1}^-(u)| - |N_{C_2}^-(u)| - |N_{C_1}^+(u)| = 2|N_{C_2}^+(u)| + |C_1| - |C_2| - 2|N_{C_1}^+(u)|$ fewer mistakes than C . If $2|N_{C_2}^+(u)| + |C_1| - |C_2| - 2|N_{C_1}^+(u)| > 0$, then C is suboptimal. Otherwise, note that $\forall w \in N_{C_1}^+(u)$, $w \in N_{C_1}^-(v)$ because if not, u, v, w would form a $(+, +, -)$ triangle in which the algorithm makes fewer than 2 edge mistakes. By a similar argument, $\forall w \in N_{C_2}^+(v)$, $w \in N_{C_2}^-(u)$. Thus, since in addition, $\{u, v\}$ is a $+$ edge, we have that $|N_{C_1}^+(v)| \geq |N_{C_1}^+(u)| + 1$ and $|N_{C_2}^+(u)| \geq |N_{C_2}^+(v)| + 1$. Now if we were to remove v from C_2 and put it in C_1 , the number of mistakes will reduce by $|N_{C_1}^+(v)| + |N_{C_2}^-(v)| - |N_{C_1}^-(v)| - |N_{C_2}^+(v)| = 2|N_{C_1}^+(v)| + |C_2| - |C_1| - 2|N_{C_2}^+(v)|$. Since $|N_{C_1}^+(v)| \geq |N_{C_1}^+(u)| + 1$ and $|N_{C_2}^+(v)| \leq |N_{C_2}^+(u)| - 1$, we have that $2|N_{C_1}^+(v)| + |C_2| - |C_1| - 2|N_{C_2}^+(v)| \geq 2(|N_{C_1}^+(u)| + 1) + |C_2| - |C_1| - 2(|N_{C_2}^+(u)| - 1)$. Since $2|N_{C_2}^+(u)| + |C_1| - |C_2| - 2|N_{C_1}^+(u)| \leq 0$, $2(|N_{C_1}^+(u)| + 1) + |C_2| - |C_1| - 2(|N_{C_2}^+(u)| - 1) > 0$, so C is suboptimal. \blacktriangleleft

► **Lemma 3.5.** *When given an oracle corresponding to an optimal clustering OPT , the clustering returned by the QUERYPIVOT algorithm is identical to OPT . It follows that the algorithm's clustering makes at most as many mistakes as OPT .*

Proof. We will prove inductively that in each recursive call, the cluster C returned by the algorithm is a cluster in OPT . Note that at the beginning of the first recursive call, the claim that all clusters formed so far are clusters in OPT is vacuously true because there are no clusters yet formed. Now consider an arbitrary but particular recursive call, and let u be the pivot in this recursive call. Suppose for contradiction that C is not a cluster in OPT .

Case 1: There is a vertex v such that $v \notin C$, but in OPT , v is in the same cluster as u . Let H be the cluster in OPT that contains u and v . First, observe that H must be a subset of the remaining vertices in this recursive call; otherwise, one of the clusters formed in a previous call contains some vertex in H but does not include u , contradicting the induction hypothesis because this previously formed cluster is not a cluster in OPT . Next, note that for any mistake that the algorithm makes on an edge incident on a pivot, the algorithm queries the OPT oracle and makes the mistake iff OPT makes the mistake. Then if $\{u, v\}$ is a $+$ edge, then the algorithm must have queried the oracle for $\{u, v\}$ and found that OPT makes a mistake on it because the algorithm decided to make a mistake on that edge. This implies that OPT puts u and v in different clusters, which is a contradiction. Now suppose instead that $\{u, v\}$ is a $-$ edge. Again if the algorithm queried the oracle for $\{u, v\}$, then OPT must have put u and v in different clusters, so it must be the case that the algorithm did not query the oracle for $\{u, v\}$. It follows that for any $(+, +, -)$ triangle (u, v, w) that includes $\{u, v\}$, our algorithm has queried $\{u, w\}$ and found OPT makes a mistake on the $+$ edge $\{u, w\}$. Then for any such triangle, $w \notin H$. It follows that u and v do not form a

$(+, +, -)$ triangle with any vertex in H . Since u and v are in the same cluster H in OPT , $\{u, v\}$ is a $-$ edge, and u and v do not form a $(+, +, -)$ triangle with any other vertex in H , the conditions for Lemma 3.3 are satisfied. Therefore, OPT is a suboptimal clustering, which is a contradiction.

Case 2: There is a vertex v such that $v \in C$, but in OPT , v is not in u 's cluster. As in the first case, if $\{u, v\}$ were a $-$ edge, the algorithm must make a mistake on $\{u, v\}$ and so must have queried OPT and found that OPT made a mistake on $\{u, v\}$, a contradiction. Now suppose instead that $\{u, v\}$ is a $+$ edge. If there is some vertex w that was clustered prior to this recursive call s.t. $\{u, v, w\}$ is a $(+, +, -)$ triangle in which OPT makes exactly one mistake (on $\{u, v\}$), then note that either u or v should be in the same cluster as w because one of $\{u, w\}$ and $\{v, w\}$ must be a $+$ edge; in this case, we have reached a contradiction with the inductive hypothesis because the previously formed cluster that included w did not include u or v . Then in order to show that the conditions for Lemma 3.4 are satisfied, we must show that for every vertex w in the set of remaining vertices when u is the pivot, if (u, v, w) is a $(+, +, -)$ triangle, then OPT must make at least two mistakes in the triangle. Since OPT makes a mistake on $\{u, v\}$ but the algorithm does not do so, it must be the case that the algorithm did not query $\{u, v\}$. Since the algorithm did not query $\{u, v\}$, for every $(+, +, -)$ triangle (u, v, w) that includes $\{u, v\}$ and such that w is in the set of remaining vertices when u is the pivot, OPT must make a mistake on $\{u, w\}$. Then since OPT makes a mistake on $\{u, v\}$ and on $\{u, w\}$ in any $(+, +, -)$ triangle (u, v, w) , we have by Lemma 3.4 that OPT is suboptimal clustering, which is a contradiction. \blacktriangleleft

► **Lemma 3.6.** *Let C_{OPT} be the number of mistakes made by an optimal clustering OPT . Then the QUERYPIVOT algorithm makes at most $2C_{OPT}$ queries to the oracle.*

Proof. The algorithm queries the oracle only when considering $(+, +, -)$ triangles. Note that whenever considering a particular $(+, +, -)$ triangle, if the algorithm makes a query, it makes at most two queries when considering that triangle and makes at least one mistake that had not been made when considering previous triangles. Therefore, the algorithm makes at most twice as many queries as mistakes. Since the algorithm makes exactly C_{OPT} mistakes, the algorithm makes at most $2C_{OPT}$ queries. \blacktriangleleft

Theorem 3.1 follows directly from Lemmas 3.5 and 3.6.

4 A 2-Approximation Algorithm for Correlation Clustering

A natural question that arises from QUERYPIVOT is how to use fewer queries and obtain an approximation guarantee that is better than the state-of-the-art outside the setting with same-cluster queries, which is a 2.06-approximation. In this section, we show that a randomized version of QUERYPIVOT gives a 2-approximation in expectation using at most C_{OPT} queries in expectation.

The algorithm RANDOMQUERYPIVOT(p) is as follows. We pick a pivot u uniformly at random from the vertices yet to be clustered. For each $(+, +, -)$ triangle (u, v, w) , we have two cases. (1) If $\{u, v\}$ and $\{u, w\}$ are both $+$ edges, then with probability p (chosen appropriately), we query both $\{u, v\}$ and $\{u, w\}$ and for each of these two edges we make a mistake on the edge iff OPT makes a mistake on the edge. With probability $1 - p$ we make no queries for this triangle and proceed to the next triangle. (2) If one of $\{u, v\}$ and $\{u, w\}$ is a $+$ edge and the other is a $-$ edge, then with probability p , we do the following. First, we query the $+$ edge and if OPT makes a mistake on it, then we make a mistake on it and proceed to the next triangle. If OPT does not make a mistake on the $+$ edge, then we query

Algorithm 2 RANDOMQUERYPIVOT.

```

1: Input: vertex set  $V$ , adjacency matrix  $A$ , oracle  $Oracle$ , parameter  $p$ 
2: if  $V == \emptyset$  then
3:   return  $\emptyset$ 
4: end if
5:  $pivot \leftarrow$  Random vertex in  $V$ 
6:  $T \leftarrow$  all  $(+, +, -)$  triangles that include  $pivot$ 
7:  $C \leftarrow V$ 
8:  $Queried \leftarrow$  length- $n$  array of zeros
9:  $Mistakes \leftarrow$  length- $n$  array of zeros
10: for  $(pivot, v, w) \in T$  do
11:   // Without loss of generality, suppose that  $\{pivot, v\}$  is a  $+$  edge
12:   Sample  $r$  from  $Uniform(0, 1)$ 
13:   if  $r > p$  then
14:     continue
15:   end if
16:   if  $Oracle(pivot, v) == 1$  then
17:      $Mistake[v] \leftarrow 1$ 
18:   end if
19:   if  $Mistake[v] == 0$  or  $\{pivot, w\}$  is a  $+$  edge then
20:     if  $Oracle(pivot, w) == 1$  then
21:        $Mistake[v] \leftarrow 1$ 
22:     end if
23:   end if
24: end for
25: for  $v \in V \setminus \{pivot\}$  do
26:   if  $(v \in N^-(pivot) \text{ and } Mistake[v] == 0)$  or  $(v \in N^+(pivot) \text{ and } Mistake[v] == 1)$  then
27:      $C = C \setminus \{v\}$ 
28:   end if
29: end for
30: return  $\{C\} \cup \text{RANDOMQUERYPIVOT}(V \setminus C, A, Oracle)$ 

```

the $-$ edge and make a mistake on the $-$ edge iff OPT does so. Again, with probability $1 - p$ we make no queries for this triangle and proceed to the next triangle. Once we have gone through all triangles, if we have not already decided to make a mistake on $\{u, v\}$, then if $\{u, v\}$ is a $+$ edge we keep v in u 's cluster and if $\{u, v\}$ is a $-$ edge we do not put v in u 's cluster. On the other hand, if we have decided to make a mistake on $\{u, v\}$, then if $\{u, v\}$ is a $-$ edge we keep v in u 's cluster and if $\{u, v\}$ is a $+$ edge we do not put v in u 's cluster. Finally, we remove all vertices in u 's cluster from the set of remaining vertices and recursively call the function on the set of remaining vertices. Note that given a pivot u and a $(+, +, -)$ triangle containing u , if the algorithm chooses not to query either of the edges incident on u , then the algorithm must make a mistake on the edge opposite to u in that triangle.

► **Theorem 4.1.** $\text{RANDOMQUERYPIVOT}(p)$ gives a $\max\left(2, \frac{3}{1+2p}\right)$ -approximation in expectation and uses at most $\max(4p, 1) * C_{OPT}$ queries in expectation.

► **Corollary 4.2.** When $p = 0.25$, RANDOMQUERYPIVOT gives a 2-approximation in expectation and uses at most C_{OPT} queries in expectation.

► **Lemma 4.3.** In an arbitrary but particular recursive call, the probability that RANDOMQUERYPIVOT queries edge $\{u, v\}$ on which OPT makes a mistake given that u is the pivot is equal to the probability that RANDOMQUERYPIVOT queries edge $\{u, v\}$ given that v is the pivot.

Proof. For a + edge $\{u, v\}$ on which OPT makes a mistake, the probability that the edge is queried given that one of the vertices is the pivot is a function only of the number of $(+, +, -)$ triangles that include the edge. In particular, if T is the number of $(+, +, -)$ triangles including the edge, the probability that the edge is queried is $1 - (1 - p)^T$. This number of triangles does not depend on the pivot vertex, so the claim holds if $\{u, v\}$ is a + edge. If $\{u, v\}$ is a - edge, then we claim that the probability that $\{u, v\}$ is queried given that either u or v is a function only of the number of $(+, +, -)$ triangles that include $\{u, v\}$ in which OPT makes a mistake only on this - edge. This claim is true because (1) in any $(+, +, -)$ triangle in which OPT makes a mistake on the - and a + edge, OPT must make a mistake on all of the three edges in the triangle and (2) when considering a $(+, +, -)$ triangle such that the pivot is an endpoint of the - edge, the algorithm queries the - edge iff OPT does not make a mistake on the + edge of which the pivot is an endpoint. It follows that for any $(+, +, -)$ triangle in which the algorithm queries the - edge, OPT must make a mistake only on the - edge. Since the number of $(+, +, -)$ triangles that include $\{u, v\}$ in which OPT makes a mistake only on $\{u, v\}$ does not depend on whether u or v is the pivot, the claim holds when $\{u, v\}$ is a - edge. ◀

Let $s_{uv} = 1$ if $\{u, v\}$ is a - edge and 0 otherwise. Let c_{uv}^* equal 1 if OPT makes a mistake on $\{u, v\}$ and 0 otherwise.

Let OPT^t be the number of edges $\{u, v\}$ s.t. $c_{uv}^* = 1$ and the algorithm makes a decision on $\{u, v\}$ in iteration t . Let ALG^t be the number of edges $\{u, v\}$ s.t. the algorithm makes a mistake on $\{u, v\}$ and the algorithm makes a decision on $\{u, v\}$ in iteration t .

Let V_t be the set of vertices remaining at the beginning of iteration t . Let D_{uv}^t be the event that the algorithm makes a decision on $\{u, v\}$ in iteration t .

► **Lemma 4.4.** *Let T be the number of iterations that the algorithm takes to cluster all vertices. If $E[ALG^t|V_t] \leq \alpha E[OPT^t|V_t]$, for each iteration t , then $E\left[\sum_{t=1}^T ALG^t\right] \leq \alpha E\left[\sum_{t=1}^T OPT^t\right]$.*

Proof. Define $X_0 = 0$ and for each $s > 0$, define $X_s = \sum_{t=1}^s \alpha OPT^t - ALG^t$. If the condition in the lemma holds, then X_s is a submartingale because $E[X_{s+1}|X_s] \geq X_s$. Also, T is a stopping time that is almost surely bounded (since $T \leq n$ with probability 1). By Doob's optional stopping theorem [24, p. 100], if T is a stopping time that is almost surely bounded and X is a discrete-time submartingale, then $E[X_T] \geq E[X_0]$. Then we have that $E[X_T] = E\left[\sum_{t=1}^T \alpha OPT^t - ALG^t\right] \geq E[X_0] = 0$. ◀

► **Lemma 4.5.** *The expected number of mistakes made by the algorithm's clustering is at most $\max\left(2, \frac{3}{1+2p}\right) C_{OPT}$.*

Proof Sketch. Here we give a sketch of the proof. By Lemma 4.4, if we show that $E[ALG^t - \alpha OPT^t] \leq 0$ for any t , where $\alpha \leq \max\left(2, \frac{3}{1+2p}\right)$, then the claim will follow. Let A_w^t be the event that $w \in V_t$ is the pivot in iteration t .

$$E[OPT^t|V_t] = \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} \frac{c_{uv}^*}{|V_t|} \sum_{w \in V_t} \Pr[D_{uv}^t | A_w^t]$$

Now we will write $E[ALG^t|V_t]$ by charging the algorithm's mistakes to each of OPT 's mistakes.

81:10 Same-Cluster Queries Bounded by Optimal Cost

Let M_{uv}^t be the charge incurred to $\{u, v\}$ in iteration t . We will assign charges such that $M_{uv}^t = 0$ if $c_{uv}^* = 0$. Then

$$E[ALG^t|V_t] = \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} c_{uv}^* E[M_{uv}^t] = \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} c_{uv}^* \frac{1}{|V_t|} \sum_{w \in V_t} E[M_{uv}^t | A_w^t]$$

Our goal is to compute an upper bound on $E[M_{uv}^t | A_w^t]$. To do so, we define several events.

For each edge $\{u, v\}$ s.t. $c_{uv}^* = 1$, define the following subsets of V_t : $\{u, v\}$, $\forall i \in \{1, 2, 3\}$, T_i^{uv} is the set of vertices w s.t. $\{u, v, w\}$ is a $(+, +, -)$ triangle in which OPT makes exactly i mistakes, S^{uv} is the set of vertices w s.t. $\{u, v, w\}$ is a $(+, -, -)$ or $(+, +, +)$ triangle in which OPT makes exactly 2 mistakes, $R^{uv} \equiv V_t \setminus T_1^{uv} \setminus T_2^{uv} \setminus S^{uv} \setminus \{u, v\}$. Furthermore, let T_{2u}^{uv} be the subset of T_2^{uv} s.t. $w \in T_{2u}^{uv}$ if the 2 mistakes in $\{u, v, w\}$ are both incident on u . Similarly, let S_u^{uv} be the subset of S^{uv} s.t. $w \in S_u^{uv}$ if the 2 mistakes in $\{u, v, w\}$ are both incident on u . $\forall w \in T_1^{uv}$, the probability that the algorithm makes a mistake on $\{u, v\}$ given that w is the pivot is $\Pr[D_{uv}^t | A_w^t] = 1$. Note that T_1^{uv} , T_2^{uv} , $\{u, v\}$, S^{uv} , and R^{uv} partition V_t .

We compute $E[M_{uv}^t | A_w^t]$ (or an upper bound thereof) when w is in each of the sets $\{u, v\}$, T_1^{uv} , T_{2u}^{uv} , T_{2v}^{uv} , S_u^{uv} , S_v^{uv} , and R^{uv} , which partition V_t . Similarly, we analyze $\Pr[D_{uv}^t | A_w^t]$, breaking up the calculation based on whether the pivot w is in T_1^{uv} , T_{2u}^{uv} , T_{2v}^{uv} , S_u^{uv} , S_v^{uv} , $\{u, v\}$, or R^{uv} .

In order to prove the claim, we show that

$$\sum_{w \in V_t} E[M_{uv}^t | A_w^t] \leq \max\left(2, \frac{3}{1+2p}\right) \sum_{w \in V_t} \Pr[D_{uv}^t | A_w^t]$$

Thus, we have shown that $E[ALG^t | V_t] \leq \max\left(2, \frac{3}{1+2p}\right) E[OPT^t | V_t]$. By Lemma 4.4, the claim follows. \blacktriangleleft

► Lemma 4.6. *The expected number of queries made by RANDOMQUERYPIVOT is at most $\max(4p, 1) C_{OPT}$.*

Proof. We follow an approach similar to that taken in the proof of Lemma 4.5. We will bound the number of queries made by the algorithm in each iteration t by charging queries to edges on which OPT makes a mistake and on which the algorithm makes a mistake in iteration t . Let U^t be the number of queries made by the algorithm in iteration t . We charge queries as follows to an edge $\{u, v\}$ on which OPT makes a mistake:

1. When u or v is the pivot, the algorithm makes at most 1 query on $\{u, v\}$ itself.
2. When u or v is the pivot (suppose WLOG u is the pivot), $\forall w \in T_1^{uv}$ (defined in the proof of Lemma 4.5), the algorithm makes a query on $\{u, w\}$ with probability p if $\{u, w\}$ is a $+$ edge.
3. When the pivot w is in T_1^{uv} , then with probability p at most 2 queries are made when the algorithm considers the triangle $\{u, v, w\}$.
4. Note that we need not worry about charging mistakes in $(+, +, -)$ triangles in which OPT makes 2 mistakes because when considering such a triangle the algorithm is guaranteed not to query the $-$ edge on which OPT does not make a mistake. We also need not worry about charging mistakes in $(+, +, -)$ triangles in which OPT makes 3 mistakes because each edge can be charged for any query made on that edge.

$$\begin{aligned}
 E[U^t|V_t] &\leq \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} \frac{c_{uv}^*}{|V_t|} \left[2(1 + p|T_1^{uv}|) + \sum_{w \in T_1^{uv}} 2p \right] \\
 &\leq \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} \frac{c_{uv}^*}{|V_t|} [2 + 4p|T_1^{uv}|]
 \end{aligned}$$

Recall from the proof of Lemma 4.5 that

$$E[OPT^t|V_t] = \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} \frac{c_{uv}^*}{|V_t|} \sum_{w \in V_t} \Pr[D_{uv}^t|A_w^t] \geq \sum_{\{u,v\} \subseteq E \cap (V_t \times V_t)} \frac{c_{uv}^*}{|V_t|} (2 + |T_1^{uv}|)$$

Here the second inequality follows from computing $\sum_{w \in V_t} \Pr[D_{uv}^t|A_w^t]$ (see Case 1 and 7). Clearly, $\frac{2+4p|T_1^{uv}|}{2+|T_1^{uv}|} \leq \max(4p, 1)$, so $E[U^t|V_t] \leq \max(4p, 1) E[OPT^t|V_t]$. Then by Lemma 4.4, the claim follows. ◀

Theorem 4.1 follows directly from Lemmas 4.5 and 4.6.

5 Lower bound on Query Complexity

The query complexities of the algorithms presented in this paper are linear in C_{OPT} , but it is not clear whether this number of queries is necessary for finding an (approximately) optimal solution. In this section, we show that a query complexity linear in C_{OPT} is necessary for approximation factors below a certain threshold assuming that the Gap-ETH, stated below, is true.

► **Hypothesis 5.1 (Gap-ETH).** *There is some absolute constant $\gamma > 0$ s.t. any algorithm that can distinguish between the following two cases for any given 3-SAT instance with n variables and m clauses must take time at least $2^{\Omega(m)}$. (see e.g. [13])*

- i. *The instance is satisfiable.*
- ii. *Fewer than $(1 - \gamma)m$ of the clauses are satisfiable.*

The proof of the following lemma is provided in the appendix, which appears in the extended version of the paper.

► **Lemma 5.2.** *Let C_{OPT} be the optimum number of mistakes for a given instance of correlation clustering. Assuming Hypothesis 1, there is no $(1 + \frac{\gamma}{10})$ -approximation algorithm for correlation clustering on N vertices that runs in time $2^{o(C_{OPT})} \text{poly}(N)$ where γ is as defined in Hypothesis 1.*

As a corollary to the above lemma, we obtain the following.

► **Theorem 5.3.** *There is no polynomial-time $(1 + \frac{\gamma}{10})$ -approximation algorithm for correlation clustering that uses $o(C_{OPT})$ queries.*

Proof. Suppose there exists an algorithm that approximates correlation clustering with an approximation factor of $(1 + \frac{\gamma}{10})$ and uses at most $o(C_{OPT})$ queries. We follow the algorithm but instead when the algorithm issues a query, we branch to two parallel solutions instances with the two possible query answers from the oracle. Since the number of queries is $o(C_{OPT})$, the number of branches/solutions that we obtain by this process is at most $2^{o(C_{OPT})}$. We return the one which gives the minimum number of mistakes. This gives a contradiction to Lemma 5.2. ◀

6 Experiments

In this section, we report detailed experimental results on multiple synthetic and real-world datasets. We compare the performance of the existing correlation clustering algorithms that do not issue any queries, alongside with our new algorithms. We compare three existing algorithms: the deterministic constant factor approximation algorithm of Bansal et al. [7] (BBC), the combinatorial 3-approximation algorithm of Ailon et al. [1] (ACN), and the state-of-the-art 2.06-approximation algorithm of Chawla et al. based on linear program (LP) rounding [10] (LP-Rounding). The code and data used in our experiments can be found at <https://github.com/sanjayss34/corr-clust-query-esa2019>.

6.1 Datasets

Our datasets range from small synthetic datasets to large real datasets and real crowd answers obtained using Amazon Mechanical Turk. Below we give a short description of them.

Synthetics Datasets: Small

We generate graphs with ≈ 100 nodes by varying the cluster size distribution as follows. [N] represents 10 cliques whose sizes are drawn i.i.d. from a $Normal(8, 2)$ distribution. This generates clusters of nearly equal size. [S] represents 5 clusters of size 5 each, 4 clusters of size 15 each and one cluster of size 30. This generates clusters with moderate skew. [D] represents 3 cliques whose total size is 100 and whose individual sizes are determined by a draw from a $Dirichlet((3, 1, 1))$ distribution. This generates clusters with extreme skewed distribution with one cluster accounting for more than 80% of edges.

Synthetics Datasets: Large

We generate two datasets *skew* and *sqrtn* each containing 900 nodes of fictitious hospital patients data, including name, phone number, birth date and address using the data set generator of the Febrl system [11]. *skew* contains few ($\approx \log n$) clusters of large size ($\approx \frac{n}{\log n}$), moderate number of clusters ($\approx \sqrt{n}$) of moderate size ($\approx \sqrt{n}$) and a large tail of small clusters. *sqrtn* contains \sqrt{n} clusters of size \sqrt{n} .

Noise Models for Synthetic Datasets

Initially, all intra-cluster edges are labelled with + sign and all inter-cluster edges are labelled with - sign. Next, the signs of a subset of edges are flipped according to the following distributions. Denote by C_1, C_2, \dots, C_k the clusters that we generate. Let N denote the number of vertices in a graph. Let $\ell_1 = 0.01$, $\ell_2 = 0.1$, and L be an integer. For the small datasets, we set $L = 100$, and for the large *skew* and *sqrtn* datasets, we set $L = \lfloor \ell_2 \binom{N}{2} \rfloor$.

- I. Flip sign of L edges uniformly at random.
- II. Flip sign of $\min\{\lfloor L/k \rfloor, |C_i| - 1\}$ edges uniformly at random within each clique C_i . Do not flip sign of the inter-cluster edges.
- III. Flip sign of edges as in II in addition to selecting uniformly at random $\lfloor \ell_1 |C_i| |C_j| \rfloor$ edges between each pair of cliques C_i, C_j and flipping their sign.

Real-World Datasets

We use several real-world datasets.

- In the *cora* dataset [20], each node is a scientific paper represented by a string determined by its title, authors, venue, and date; edge weights between nodes are computed using Jaro string similarity [14, 25]. The *cora* dataset consists of 1.9K nodes, 191 clusters with the largest cluster-size being 236.
- In the *gym* dataset [22], each node corresponds to an image of a gymnast, and each edge weight reflects the similarity of the two images (i.e. whether the two images correspond to the same person). The *gym* dataset consists of 94 nodes with 12 clusters and maximum cluster size is 15.
- In the *landmarks* dataset [17], each node corresponds to an image of a landmark in Paris or Barcelona, and the edge weights reflect the similarity of the two images. The *landmarks* dataset consists of 266 nodes, 13 clusters and the maximum size of clusters is 43.
- In the *allsports* dataset [23], the nodes correspond to images of athletes in one of several sports, and the edge weights reflect the similarity of the two images. The pairs of images across sports are easy to distinguish but the images within the same category of sport are quite difficult to distinguish due to various angles of the body, face and uniform. The *allsports* dataset consists of 200 nodes with 64 clusters and with a maximum size of cluster being just 5.

Since the underlying graphs are weighted, we convert the edge weights to ± 1 labels by simply labeling an edge $+$ if its weight is at least $1/2$ and $-$ otherwise (the edge weights in all of the weighted graphs are in $[0, 1]$). We also perform experiments directly on the weighted graphs [10] to show how the above rounding affects the results.

Oracle

For small datasets, we use the Gurobi (www.gurobi.org) optimizer to solve the integer linear program (ILP) for correlation clustering [10] to obtain the optimum solution, which is then used as an oracle. For larger datasets like *skew*, *sqrtn* and *cora*, ILP takes prohibitively long time to run. For these large datasets, the ground-truth clustering is available and is used as the oracle.

For practical implementation of oracles, one can use the available crowd-sourcing platforms such as the Amazon Mechanical Turk. It is possible that such an oracle may not always give correct answer. We also use such crowd-sourced oracle for experiments on real datasets. Each question is asked 3 to 5 times to Amazon Mechanical Turk, and a majority vote is taken to resolve any conflict among the answers. We emphasize that the same-cluster query setting can be useful in practice because two different sources of information can produce the edge signs and the oracle – for instance, the edge signs can be produced by a cheap, automated computational method (e.g. classifiers), while the oracle answers can be provided by humans through the crowd-sourcing mechanism explained above.

6.2 Results

We compare the results of our QUERYPIVOT and RANDOMQUERYPIVOT algorithm as well as the prior algorithms BBC [7], ACN [1] and LP-Rounding [10]. For the algorithms that are randomized (ACN, LP-Rounding and RANDOMQUERYPIVOT), we report the average of three runs. The algorithm of Bansal et al. [7] requires setting a parameter δ . We tried several values of δ on several of the datasets and chose the value that seemed to give the best performance overall.

81:14 Same-Cluster Queries Bounded by Optimal Cost

■ **Table 1** Results for Experiments on synthetic small datasets. BBC denotes the algorithm of [7], ACN denotes the 3-approximation algorithm of [1], LP Rounding denotes the algorithm of [10], QP denotes QUERYPIVOT, and RQP denotes RANDOMQUERYPIVOT(0.25). All numerical columns except those marked as “Queries” give the number of mistakes made by the algorithm.

Mode	ILP Oracle	BBC	ACN	LP Rounding	QP	QP Queries	RQP	RQP Queries
N+I	100	271	205.67	100	100	113	104.33	63.3

Sqrtn (III)		13050	12711.33	0	6449	0.0	2693.33

Synthetic Datasets

Table 1 summarizes the results of different algorithms on small synthetic datasets.

As we observe, our QUERYPIVOT algorithm always obtains the optimum clustering. Moreover, RANDOMQUERYPIVOT has a performance very close to QUERYPIVOT but often requires much less queries. Interestingly, the LP-rounding algorithm performs very well except for $N + III$. ACN and BBC algorithms have worse performance than LP-Rounding, and in most cases ACN is preferred over BBC.

For the larger synthetic datasets *skew* and *sqrtn*, as discussed the ground-truth clustering is used as an oracle. We also use the ground-truth clustering to count the number of mistakes. On these datasets, the LP-rounding algorithm caused an out-of-memory error on a machine with 256 GB main memory that we used. The linear programming formulation for correlation clustering has $O(n^3)$ triangle inequality constraints; this results in very high time and space complexity rendering the LP-rounding impractical for correlation clustering on large datasets. Table 2 summarizes the results.

As we observe, QUERYPIVOT algorithm recovers the exact ground-truth clustering in several cases. RANDOMQUERYPIVOT has a low error rate as well and uses significantly fewer queries.

■ **Table 3** Results for Real-World Datasets where mistakes are measured with respect to ground-truth clustering and the oracle is the ground-truth clustering. LP Rounding (weighted) refers to the LP rounding of [10] applied to the weighted input graph.

Dataset/ Mode	LP Rounding	LP Rounding (weighted)	BBC	ACN	QP	QP Queries	RQP	RQP Queries
Cora			62891	26065.0	4526	2188	4664.67	1474.33
Gym	221.0	332.67	449	301.67	8	150	82.67	97.33
Landmarks	29648.0	25790.0	31507	28770	3426	953	1124.67	1467.0
Allsports	230.0	226.33	227	253.33	217	41	223.67	21.0

■ **Table 4** Running times (in seconds) for the results in Table 3. For randomized algorithms, the time shown is the average over three trials.

Dataset/Mode	LP Rounding	LP Rounding (weighted)	BBC	ACN	QP	RQP
Cora			1.58	0.16	2170.33	515.59
Gym	4.96	5.09	0.004	0.0014	0.33	0.27
Landmarks	190.96	9571.32	0.048	0.00067	1.96	2.82
Allsports	41.54	42.08	0.018	0.025	13.28	12.76

Real-World Datasets

The results for the real-world datasets are reported in Table 3, 5 and 6. It is evident from Table 3 that our algorithms outperform the existing algorithms by a big margin in recovering the original clusters. Table 3 also includes results for the LP-rounding algorithm applied to the original weighted graph for the Gym, Landmarks, and Allsports datasets. We also report in Table 4 the running times for the experiments in Table 3. These numbers show that the BBC and ACN algorithms are substantially faster than the others, while our algorithms are substantially faster than the LP-rounding algorithm.

Table 5 reports the results using a faulty crowd oracle. Contrasting the results of Table 3 and 5, we observe minimal performance degradation; that is, our algorithms are robust to noise. The results in this table are important, as this setting is closest to the typical real-world application of same-cluster queries. Note that the source of information that gives the signs of the edges is different from that which is the crowd oracle. For the landmarks dataset, the original edge weights are determined by a gist detector [21], while the oracle used in Table 5 is given by high-quality crowd workers. For the gym and allsports datasets, the original edge weights are determined by (lower quality) human crowd workers, but the oracle used in Table 5 is based on high-quality crowd workers. Finally, in Table 6, we report

■ **Table 5** Results for Real-World Datasets where mistakes are measured with respect to ground-truth clustering and the oracle is the crowd.

Dataset/Mode	QP	QP Queries	RQP	RQP Queries
Gym	135	175	160.0	104.67
Landmarks	4645	1997	2172.33	1548.33
Allsports	218	41	223.67	21.0

81:16 Same-Cluster Queries Bounded by Optimal Cost

■ **Table 6** Results for Real-World Datasets where mistakes are measured with respect to the graph and the oracle is the optimal ILP solution for the graph.

Dataset/Mode	LP Rounding	BBC	ACN	QP	QP Queries	RQP	RQP Queries
Gym	276.0	464	338.0	207	171	211.0	112.67
Landmarks	4092.0	4995	5240.67	4092	267	4092.0	265.33
Allsports	33.33	65	40.67	28	36	30.33	18.67

the results using the optimum ILP solution as the oracle. For the larger datasets, it is neither possible to run the ILP nor LP-Rounding due to their huge space and time requirements. Again our algorithms perform the best, followed by the LP-rounding algorithm.

Abstract

Motivated by the classic GENERALIZED ASSIGNMENT PROBLEM, we consider the GRAPH BALANCING problem in the presence of orientation costs: given an undirected multi-graph $G = (V, E)$ equipped with edge weights and orientation costs on the edges, the goal is to find an orientation of the edges that minimizes both the maximum weight of edges oriented toward any vertex (makespan) and total orientation cost. We present a general framework for minimizing makespan in the presence of costs that allows us to: (1) achieve bicriteria approximations for the GRAPH BALANCING problem that capture known previous results (Shmoys-Tardos [Math. Progrm. ‘93], Ebenlendr-Krcál-Sgall [Algorithmica ‘14], and Wang-Sitters [Inf. Process. Lett. ‘16]); and (2) achieve bicriteria approximations for extensions of the GRAPH BALANCING problem that admit hyperedges and unrelated weights. Our framework is based on a remarkably simple rounding of a strengthened linear relaxation. We complement the above by presenting bicriteria lower bounds with respect to the linear programming relaxations we use that show that a loss in the total orientation cost is required if one aims for an approximation better than 2 in the makespan.

1 Introduction

We consider the GRAPH BALANCING problem (GB) where we are given an undirected multi-graph $G = (V, E)$ equipped with edge weights $p : E \rightarrow \mathbb{R}^+$. The goal is to orient all the edges of the graph, where each edge can be oriented to one of its endpoints. Given an orientation of the edges the load of a vertex u is the sum of weights of edges oriented toward it. The goal is to find an orientation of the edges that minimizes the maximum load over all vertices.

GB was first introduced by Ebenlendr et al. [3] and since its introduction it has attracted much attention (see, e.g., [10, 18, 6, 2, 12]). Besides being a natural graph optimization problem on its own, a main motivation for considering GB is the well known GENERALIZED ASSIGNMENT PROBLEM (GAP) (see, e.g., [15, 3, 16, 19]). In GAP we are given a collection \mathcal{M} of m machines and a collection \mathcal{J} of n jobs, along with processing times $p_{i,j}$ (the processing time of job j on machine i) and assignment costs $c_{i,j}$ (the cost of assigning job j to machine i). Each job must be assigned to one of the machines. The processing time of machine i is the sum of processing times $p_{i,j}$ over all jobs j that are assigned to i , and the makespan of an assignment is the maximum over all machines i of its processing time. Additionally, the total assignment cost of an assignment is the sum of assignment costs $c_{i,j}$ over all machines i and jobs j that are assigned to i . Given a target makespan T , we denote by $C(T)$ the minimum total assignment cost over all assignments with makespan at most T . If there are no assignments with makespan at most T , then $C(T) = \infty$. The goal in GAP, given a

target makespan T , is to find an assignment with makespan at most T and total assignment cost at most $C(T)$, or declare that no such assignment exists. We note that only T is given to the algorithm whereas $C(T)$ is not. For this bicriteria problem, the celebrated result of Shmoys and Tardos [15] provides an approximation algorithm that finds an assignment with makespan at most $2T$ and total assignment cost at most $C(T)$.

GB is captured by GAP since one can: (1) set \mathcal{M} to be V and \mathcal{J} to be E ; and (2) for each job $j \in \mathcal{J}$ (which corresponds to an edge $e \in E$) set its processing time to be p_e for the two machines that correspond to the endpoints of e and ∞ for all other machines. Note that assigning job j to machine i corresponds to orienting the edge e toward its endpoint that corresponds to machine i . There are two important things to note. First, GB was originally defined as a *single criterion* optimization problem as opposed to GAP which is a bicriteria optimization problem. Second, the weights p in GB, which represent the processing times of the jobs, are *related*, *i.e.*, the processing times do not depend on the vertex the edge is oriented to. Ebenlendr et al. [3] introduced a novel linear relaxation and rounding algorithm that achieves an approximation of 1.75 with respect to the optimal makespan. They also proved that even for this special case, no polynomial time algorithm can achieve an approximation less than 1.5 unless $P = NP$, thus extending the hardness of GAP to GB.

In this work we consider the *bicriteria* GB problem, where we are also given orientation costs, the equivalent to the assignment costs in GAP. Formally, an edge $e = (u, v)$ has orientation costs $c_{e,u}$ and $c_{e,v}$ and orienting it to u incurs a cost of $c_{e,u}$. Similarly to GAP, given a target makespan T , the goal is to find an orientation of the edges with total orientation cost at most $C(T)$ and makespan at most T .¹ To the best of our knowledge, the bicriteria GB problem was not previously considered. We say that an algorithm is a (α, β) -approximation if given a target makespan T , it outputs an orientation with makespan at most αT and total orientation cost at most $\beta C(T)$. Thus, [15] is a $(2, 1)$ -approximation to GB. We note that the algorithm of [3] cannot handle orientation costs and is in fact a $(1.75, \infty)$ -approximation for GB. A result by Wang and Sitters [18] implicitly gives a $(11/6, 3/2)$ -approximation for GB.

We study the bicriteria tradeoff between makespan and total orientation cost in GB, presenting both upper and lower bounds (the latter are with respect to the linear programming relaxations used in this work). We employ a remarkably simple general framework that allows us to achieve bicriteria approximations for GB that capture and extend known results. Furthermore, we consider extensions of GB that allow for: (1) hyperedges to be present, *i.e.*, a job can be assigned to more than two machines; and (2) processing times can be unrelated, *i.e.*, the processing time of a job might depend on the machine it is assigned to. Our results regarding these extensions improve upon the previously best known algorithms, and are also based on the general framework presented in this paper. We believe this framework might be of independent interest to other related scheduling problems.

1.1 Our Results

Our results are of three different flavors: bicriteria upper bounds for GB, bicriteria lower bounds for GB, and both upper and lower bicriteria bounds for extensions of GB (all lower bounds are with respect to the linear programming relaxations we use). Let us now elaborate on each of the above.

¹ As in GAP, the total orientation cost of an orientation is defined as the sum of orientation costs $c_{e,u}$ over all vertices u and edges e oriented toward u . $C(T)$ is defined as the minimum total orientation cost over all orientations with makespan at most T . If no such orientation exists then $C(T)$ is set to ∞ .

1.1.1 Upper Bounds

We present a general framework for minimizing makespan in the presence of costs and obtain two algorithms that achieve bicriteria approximations for GB. This is summarized in the following two theorems.

► **Theorem 1.** *There exists a polynomial time algorithm that finds an orientation that is a $(1.75 + \gamma, 1/(2\gamma+0.5))$ -approximation for GRAPH BALANCING, for every $1/12 - \epsilon \leq \gamma \leq 1/4$ where $\epsilon = \sqrt{33}/4 - 17/12 \approx 0.02$.*

► **Theorem 2.** *There exists a polynomial time algorithm that finds an orientation that is a $(1.75 + \gamma, 1 + 1/\gamma)$ -approximation for GRAPH BALANCING, for every $0 \leq \gamma \leq 1/4$.*

Both the above theorems provide a smooth tradeoff between makespan and orientation cost while capturing previous known results for GB as special cases, *i.e.*, Theorem 1 captures the $(2, 1)$ and $(11/6, 3/2)$ approximations of [15] and [18] for $\gamma = 1/4$ and $\gamma = 1/12$ respectively, whereas Theorem 2 captures the $(1.75, \infty)$ -approximation of [3] for $\gamma = 0$. Theorem 1 is depicted in Figure 1.

1.1.2 Lower Bounds

We present bicriteria lower bounds for GB. As previously mentioned, our lower bounds apply to a strengthening of the relaxation of [3], which we denote by LP_k (see subsection 3.2). The lower bound is summarized in the following theorem and is depicted in Figure 1.

► **Theorem 3.** *For every $0 \leq \gamma < 1/4$ and $\epsilon > 0$, there exists an instance for GRAPH BALANCING and target makespan T such that: (1) LP_k is feasible and has value of OPT_{LP_k} , and (2) every orientation whose makespan is at most $(1.75 + \gamma)T$ has orientation cost of at least $1/(\gamma+0.75+\epsilon)OPT_{LP_k}$.*

To the best of our knowledge, all algorithms for GB that find an orientation that achieves an approximation better than 2 with respect to the makespan use the relaxation of [3] (or no relaxation at all, *e.g.*, [6]).²

1.1.3 Extensions

Using our general framework, we present bicriteria algorithms for extensions of GB. The extensions of GB we consider allow hyperedges and unrelated weights to the edges. It is important to note that all the upper bounds presented below hold for the single criterion versions of these problems as well. In particular, we achieve an approximation strictly better than 2, with respect to the makespan, to several problems that capture GB and are not captured by the RESTRICTED ASSIGNMENT problem (RA).³ To the best of our knowledge, this is the first polynomial time algorithm with approximation factor better than 2 to the makespan for problems that capture GB and are not captured by RA. Let us now elaborate on these extensions.

² Recently, Jansen and Rohwedder [10] showed that using a different stronger relaxation called the configuration LP one can achieve an approximation of less than 1.75 to the makespan. However, this result does not produce a polynomial time algorithm that orients the edges but rather only approximates the *value* of the optimal makespan. Moreover, this result has an unbounded loss with respect to the orientation cost.

³ The RA is a special case of GAP where each job has a set of machines it can be assigned to, and has an equal processing time on each of them.

The first extension allows for light unrelated hyperedges. Formally, given $\beta \in [0, 1]$, the input can contain hyperedges whose weight with respect to the vertices it shares may vary, as long as it does not exceed β (we may assume without loss of generality that the largest weight in p equals 1). We denote this problem by GRAPH BALANCING WITH UNRELATED LIGHT HYPER EDGES (GBUH(β)). A special case of this problem was introduced by Huang and Ott in [6] who presented a $(\frac{5}{3} + \beta/3, \infty)$ -approximation when $\beta \in [4/7, 1)$. We improve upon [6] in three aspects. First, we consider the general bicriteria problem, *i.e.*, orientation costs are present, and achieve bounded loss with respect to the total orientation cost (recall that [6] cannot handle orientation costs). Second, we allow any $\beta \in [0, 1]$, where [6] allows for $\beta \in [4/7, 1)$ only. Third, we allow the hyperedges to be unrelated, *i.e.*, different weights to different endpoints, where hyperedge weights in [6] are related. Our result for this extension is summarized in the following theorem.

► **Theorem 4.** *Let $0 \leq \beta \leq 1$. For every $\max\{1/12, \beta/3 - 1/12\} \leq \gamma \leq 1/4$, there exists a polynomial time algorithm that finds an orientation that is a $(1.75 + \gamma, 1/(2\gamma+0.5))$ -approximation to GBUH(β).*

The second extension further generalizes the first one, and it also allows edges to have unrelated weights as long as the weights are greater than β . Unfortunately, we prove that this problem in its full generality is as hard to approximate as GAP. However, if it is assumed that the optimal makespan is at least 1 (as before we can assume without loss of generality that the largest weight in p equals 1), we can achieve improved results. We denote this problem by GRAPH BALANCING WITH UNRELATED LIGHT HYPER EDGES AND UNRELATED HEAVY EDGES (GBU(β)).⁴

► **Theorem 5.** *Let $\beta \geq \sqrt{2} - 1$. For every $\beta/3 - 1/12 \leq \gamma \leq 1/4$, there exists a polynomial time algorithm that finds an orientation that is a $(1.75 + \gamma, 1/(2\gamma+0.5))$ -approximation to GBU(β).*

We prove that there are values of β for which the bicriteria approximation of Theorem 5 is tight. Specifically, we prove the latter for $\beta = 1/2$ and LP_k . The lower bounds are summarized in the following theorem.

► **Theorem 6.** *For every $\epsilon > 0$, there exists an instance of GBU(0.5) that is feasible to LP_k and every orientation has a makespan of at least $11/6 - \epsilon$. Moreover, for every $1/12 \leq \gamma \leq 1/4$, target makespan T and $\epsilon > 0$, there exists an instance for GBU(0.5) that is feasible to LP_k and has a value of OPT_{LP_k} , and every orientation with makespan at most $(1.75 + \gamma)T$ has an orientation cost of at least $(1-\epsilon)/(2\gamma+0.5) \cdot OPT_{LP_k}$.*

In the third and final extension we allow the edges in GB to be unrelated, but the weights cannot vary arbitrarily. Formally, given a parameter $c \geq 1$, every edge $e = (u, v)$ satisfies $p_{e,u} \leq c \cdot p_{e,v}$ and $p_{e,v} \leq c \cdot p_{e,u}$. We denote this problem by SEMI-RELATED GRAPH BALANCING (SRGB(c)). The following theorem summarizes our algorithm for SRGB(c).

► **Theorem 7.** *There exists a polynomial time algorithm to SRGB(c), that finds an orientation that is a $(1.5 + 0.5a, 1/a)$ -approximation, where a is the root in the range $[0.5, 1]$ of the polynomial:*

$$(1/c + 1/2) \cdot a^3 + (5/(2c) - 1/2) \cdot a^2 - 7/(2c) \cdot a + 1/c.$$

⁴ While the assumption that the largest weight p equals 1 implies that the optimal makespan is least 1 for GB and GBUH(β), this is not necessarily the case when the edge weights might be unrelated. Thus, the assumption in GBU(β) that the optimal makespan is at least 1 is not without loss of generality.

■ **Figure 1** Our bicriteria bounds for GRAPH BALANCING. (a) is given in Shmoys and Tardos [15], whereas (b) is implicitly given in Wang and Sitters [18].

We remark that the approximation guaranteed by Theorem 7 is never worse than 2 since it can be proved that $a = 1 - \Omega(1/c)$, yielding a $(2 - \Omega(1/c), 1 + O(1/c))$ -approximation. It is worth noting that when $c = \infty$, which corresponds to the most general case, even the configuration LP has an integrality gap of 2 with respect to the makespan (see [4, 17]).

1.2 Our Techniques

We present a remarkably simple framework that allows us to provide bicriteria upper bounds for both GB and its extensions, *i.e.*, $\text{GBUH}(\beta)$, $\text{GBU}(\beta)$, and $\text{SRGB}(c)$. The framework is based on rounding of a strengthening of the linear relaxation of [3].

The rounding is comprised of two complementary steps, the first *local* and the second *global*. Intuitively, in the first local step, each edge can be oriented to one of its endpoints in case the relaxation indicates a strong (fractional) inclination toward that endpoint. We note that in order to quantify this inclination the weight of the edge is taken into account, where lighter edges are less likely to be oriented. Specifically, denote by $x_{e,u} \in [0, 1]$ how much the relaxation fractionally orients edge $e = (u, v)$ toward its endpoint u . The local step orients e toward u if $x_{e,u} > f(p_e)$ for some non-increasing threshold function $f : [0, 1] \rightarrow [1/2, 1]$. As previously mentioned, this step is considered *local* since only $x_{e,u}$ and p_e are used to determine whether to orient e , and if so to which of its two endpoints.⁵ In the second global step of the rounding, we consider the remaining edges which were not yet oriented in the first local step and apply the algorithm of Shmoys and Tardos [15] which finds a minimum cost perfect matching in a suitable bipartite graph. As previously mentioned, this step is considered *global* since all edges which are not yet oriented are taken into consideration when computing the matching.

The above two-phase rounding is not sufficient on its own to obtain our claimed results, and we further strengthen the relaxation of [3] by forcing additional new constraints. Intuitively, for every vertex u our constraints state that if a collection of edges S touching u has total weight of more than T then not all edges in S can be chosen. We enforce the above constraints for all subsets of size at most k , for some fixed parameter k , resulting in a strengthened linear relaxation which we denote by LP_k . It is important to note that these constraints cannot be inferred from the original relaxation of [3], and thus are required in our analysis of the above two-phase rounding.

⁵ This rounding was used in Wang and Sitters [18] with a specific “step” threshold function f to implicitly obtain a $(1^{1/6}, 3/2)$ -approximation for GB.

1.3 Additional Related Work

Lenstra et al. [11] introduced the classic well known 2-approximation to the single criterion GAP. They also proved that no polynomial time algorithm can approximate the makespan within a factor less than 1.5 unless $P = NP$. This was followed by Shmoys and Tardos [15] who introduced the bicriteria GAP and presented a $(2, 1)$ -approximation for it. A slightly improved approximation of $2 - 1/m$ for the makespan was given by Shchepin and Vakhania [14]. If the number of machines is fixed polynomial time approximation schemes are known [5, 8]. For the case of uniformly related machines (each machine i has speed s_i and assigning job j to machine i takes p_j/s_i time) Hochbaum and Shmoys [13] presented a polynomial time approximation scheme. The RESTRICTED ASSIGNMENT problem (RA) is a special case where each job has an equal processing time on the machines it can be assigned to (for every job j and machine i : $p_{i,j} \in \{p_j, \infty\}$). For this special case, Svensson [16] proved that one can approximate the value of the optimal makespan by a factor of $33/17$ using the configuration LP, that was first introduced by Bansal et al. for the SANTA CLAUS PROBLEM [1]. This was subsequently improved by Jansen and Rohwedder [9] who presented an approximation of $11/6$. If one further assumes that the processing times have only two possible values [7] presented an improved approximation of $5/3$. The above results [16, 9, 7] do not present polynomial time algorithms that produce a schedule with the promised makespan, but only approximate the value of the makespan.

When considering GB, Jansen and Rohwedder [10] recently showed a similar flavor result: using the configuration LP one can estimate the value of the optimal makespan by a factor of $1.75 - \epsilon$, for some small constant $\epsilon > 0$. However, as before, [10] does not produce an orientation in polynomial time. The special case of GB where only two processing times are present admits a (tight) 1.5-approximation (given independently by [6, 2, 12]).

To the best of our knowledge, no work on GB considered orientation costs and in particular the tradeoff between makespan and orientation cost.

1.4 Paper Organization

Section 2 contains the required preliminaries. In Section 3 we present our general framework and apply it to GB to obtain bicriteria algorithms. Section 4 contains our bicriteria lower bound for GB. Finally, in Section 5 we consider the mentioned extensions of GB and apply the framework to these extensions to obtain improved algorithms.

2 Preliminaries

Given a multi-graph $G = (V, E)$ and a vertex $u \in V$ denote by $\delta(u) \triangleq \{e \in E \mid u \in e\}$ the collection of edges incident to u . In addition define: $\mathcal{F}(u) \triangleq \{S \subseteq \delta(u) \mid \sum_{e \in S} p_e \leq 1\}$, *i.e.*, the collection of feasible subsets of edges incident to u (for simplicity of presentation we further assume without loss of generality that $T = 1$ since we can scale all processing times by T). Moreover, we denote by OPT_{LP} and OPT_{LP_k} the optimal value of a feasible solution to the relaxation LP and LP_k respectively.

The algorithm of Shmoys and Tardos [15] is a key ingredient in our framework, thus we present it not only for completion but also since understanding its inner-working helps in analyzing our algorithms. Recall that [15] is a $(2, 1)$ -approximation for GAP. We assume without loss of generality that $T = 1$ since one can scale the processing times by T . First, the relaxation in Figure 2 is solved, where \mathcal{J} is the set of jobs and \mathcal{M} is the set of machines.

$$\begin{aligned}
& (LP_{GAP}) \\
\min & \quad \sum_{j \in \mathcal{J}} \sum_{i \in \mathcal{M}} x_{i,j} c_{i,j} \\
\text{s.t.} & \quad \sum_{i \in \mathcal{M}} x_{i,j} = 1 \quad \forall j \in \mathcal{J} \quad (\text{Job}) \\
& \quad \sum_{j \in \mathcal{J}} x_{i,j} p_{i,j} \leq 1 \quad \forall i \in \mathcal{M} \quad (\text{Load}) \\
& \quad x_{i,j} = 0 \quad \forall i \in \mathcal{M}, j \in \mathcal{J} : p_{i,j} > 1 \\
& \quad x_{i,j} \geq 0 \quad \forall i \in \mathcal{M}, j \in \mathcal{J}
\end{aligned}$$

■ **Figure 2** The relaxation by Shmoys and Trados [15] to GAP.

The variable $x_{i,j}$, for each $i \in \mathcal{M}$ and $j \in \mathcal{J}$, indicates whether job j is scheduled on machine i . Note that if there is no feasible solution to the relaxation, then the algorithm declares there is no schedule with makespan at most T .

Given a solution \mathbf{x} to LP_{GAP} , the algorithm of [15] constructs a weighted bipartite graph $G = (\mathcal{J}, S, E)$, which will be described shortly. Afterwards, the algorithm finds a minimum cost perfect matching to the side \mathcal{J} , *i.e.*, each vertex in \mathcal{J} is matched to a vertex in S . Using this matching the algorithm assigns each job to a machine. The bipartite graph G is constructed as follows, where we assume that $\mathcal{J} = \{1, 2, \dots, n\}$ is the set of jobs and S is a collection of “slots”. Machine i is allocated $k_i \triangleq \lceil \sum_{j=1}^n x_{i,j} \rceil$ slots which we denote by $slot(i, 1), \dots, slot(i, k_i)$, each having a capacity of 1. For each machine i sort the jobs in a non-increasing order of their processing time $p_{i,j}$, and for each job j in this order add $x_{i,j}$ units of job j to the next non-full slot of machine i (starting from $slot(i, 1)$). If $x_{i,j}$ is larger than the remaining capacity of the slot, which we denote by r , add r units of job j to that slot and $x_{i,j} - r$ units of job j to the next slot. An edge connecting job j and a slot (i, ℓ) is added to E if some of the $x_{i,j}$ units of j were added to the slot (i, ℓ) , and its cost is set to $c_{i,j}$. A description of [15] appears in Algorithm 1.

■ **Algorithm 1** Shmoys-Tardos $(\mathbf{x}, \mathbf{p}, \mathbf{c})$.

-
- 1 Construct the bipartite graph $G = (\mathcal{J}, S, E)$ as described above.
 - 2 Find in G a minimum cost perfect matching with respect to \mathcal{J} .
 - 3 For each job $j \in \mathcal{J}$, assign j to machine i if the slot that is matched to j belongs to i .
-

We say a slot is *full* if the remaining capacity of that slot is 0. Additionally, we say a job j is on *top* of a slot if j is the first job to be inserted to that slot. It can be proved that the load on machine i in the output of Algorithm 1 is at most $1 + p_{i,1}$, where $p_{i,1}$ is the processing time of the job on top of $slot(i, 1)$, *i.e.*, the largest processing time of a job that is fractionally scheduled on machine i . Since, $p_{i,1} \leq 1$, the makespan of the assignment is at most 2. Furthermore, it can be shown that the cost of the assignment is at most $OPT_{LP_{GAP}}$, and thus at most $C(T)$.

We remark that when one is aiming to solve the single criterion version of this problem, *i.e.*, finding an assignment that minimizes the makespan, a binary search could be performed to find the smallest T such that the linear relaxation is feasible. In general, any (α, β) -approximation for the bicriteria problem implies an approximation of α for the single criteria problem.

$$\begin{aligned}
& (LP) \\
\min & \sum_{e \in E} \sum_{u \in e} x_{e,u} c_{e,u} \\
\text{s.t.} & \sum_{u \in e} x_{e,u} = 1 \quad \forall e \in E \quad (\text{Edge}) \\
& \sum_{e \in \delta(u)} x_{e,u} p_e \leq 1 \quad \forall u \in V \quad (\text{Load}) \\
& \sum_{e \in \delta(u): p_e > 0.5} x_{e,u} \leq 1 \quad \forall u \in V \quad (\text{Star}) \\
& x_{e,u} \geq 0 \quad \forall u \in V, e \in \delta(u)
\end{aligned}$$

■ **Figure 3** The relaxation by Ebenlendr et al. [3] to GB.

3 The General Framework and Graph Balancing

We start by describing the general framework in the setting of GB. For simplicity of presentation, given a target makespan T , if there exists an edge e such that $p_e > T$ the algorithm immediately declares that there is no orientation with makespan at most T . Otherwise, we scale the processing times by T . Thus, without loss of generality, $T = 1$ and $p_e \leq 1$ for every $e \in E$.

Currently, we consider the relaxation of [3], which we denote by LP , with the addition of an objective function that minimizes the orientation cost.⁶ This relaxation appears in Figure 3.

Note that the Star constraint of LP implies that at most a total fraction of 1 of *big* edges, *i.e.*, edges whose weight is larger than $1/2$, can be oriented toward u . Moreover, we note that later we strengthen this relaxation by adding additional constraints.

Once the processing times are scaled by T , the algorithm solves the relaxation LP . If there is no feasible solution to the relaxation, then the algorithm declares that there is no orientation with makespan at most T . Thus, from this point onward we assume that LP is feasible and focus on the rounding.

Recall that the rounding consists of only two steps, the first local and the second global. In the first step, some of the edges might be oriented, where an edge e is oriented toward u if $x_{e,u} > f(p_e)$ for a given threshold function $f : [0, 1] \rightarrow [1/2, 1]$. We employ the framework for threshold functions f which are monotone non-increasing, thus making lighter edges less likely to be oriented compared to heavier edges. In the second step, the remaining un-oriented edges are oriented using Algorithm 1. The framework is described in Algorithm 2. It receives as an input: (1) the graph $G = (V, E, \mathbf{p}, \mathbf{c})$; (2) \mathbf{x} a solution to the relaxation; (3) a threshold function f .

■ **Algorithm 2** Framework($G = (V, E, \mathbf{p}, \mathbf{c}), \mathbf{x}, f$).

-
- 1 For each edge e and $u \in e$: if $x_{e,u} > f(p_e)$ then orient e to u and remove e from E .
(Local Step)
 - 2 Execute Algorithm 1. (Global Step)
-

⁶ In Section 5 we also need the constraint that appears in the relaxation of [15] which states that $x_{e,u} = 0$ if $p_{e,u} > 1$, for every $e \in E$ and $u \in e$.

Note that the *Local Step* of Algorithm 2 is well defined, *i.e.*, no edge is oriented to both its endpoints. This is due to the Edge constraints and the fact that for each $p \in [0, 1]$: $f(p) \geq 1/2$. Note that the framework captures Algorithm 1 as a special case since one can choose $f \equiv 1$. We now focus on bounding the makespan and orientation cost produced by the framework, for a general threshold function f . This analysis will be useful for the rest of the paper.

Let us start by focusing on bounding the makespan. We start by presenting a simple but crucial observation. The observation states that if an edge $e = (u, v)$ was *not* oriented at the *Local Step* then $x_{e,u}$ and $x_{e,v}$ cannot vary much. It is important to note that this is the *only* place in our proof we use the fact that e is an edge, *i.e.*, the job that corresponds to e can be assigned to only two machines u and v (otherwise our algorithm could have been applied to the more general problem of RA).

► **Observation 1.** *Let $e = (u, v) \in E$ such that e was not oriented to either u or v in the *Local Step*. Then $1 - f(p_e) \leq x_{e,u} \leq f(p_e)$.*

Proof. e was not oriented toward u in the *Local Step*, and therefore $x_{e,u} \leq f(p_e)$. Additionally, the Edge constraint implies that $x_{e,v} = 1 - x_{e,u}$, and since e was not oriented toward v in the *Local Step* then $1 - x_{e,u} \leq f(p_e)$. This concludes the proof. ◀

Now we focus on bounding the makespan. Fix a vertex $u \in V$, and denote the slots that were allocated to u in Algorithm 1 by: $slot(u, 1), \dots, slot(u, k)$ or alternatively by s_1, \dots, s_k . For $i \in \{1, 2, \dots, k\}$ let e_i be the edge on top of $slot(u, i)$ and denote its processing time by p_i . We assume without loss of generality that $p_{k+1} \triangleq 0$ and $x_{e_{k+1}, u} = 1$ (one can simply add a 0 weight edge that is fully oriented toward u).⁷ Additionally, denote by e'_1, \dots, e'_t the edges that were oriented to u in the *Local Step*, and denote by q_1, \dots, q_t , their processing times respectively. Lastly, for a slot s and edge e we denote by $y_{e,s}$ the fraction that e is assigned to s .

We now introduce a new observation that lower bounds the fractional load in the first slot of u , *i.e.*, $\sum_{e \in slot(u, 1)} y_{e, s_1} p_e$. This observation will be useful in bounding the load on u .

► **Observation 2.** *The fractional load in the first slot of u is at least:*

$$\sum_{e \in slot(u, 1)} y_{e, s_1} p_e \geq (1 - f(p_1))p_1 + f(p_1)p_2.$$

Proof. From Observation 1 we know that $x_{e_1} \geq 1 - f(p_1)$. Moreover, since e_1 is the first edge to be inserted to the first slot, then it is contained fully in $slot(u, 1)$. Therefore, $y_{e_1, s_1} = x_{e_1, u} \geq 1 - f(p_1)$. Recall that $p_2 \leq p_1$. Since $slot(u, 1)$ is full and its capacity equals 1, we can conclude: $\sum_{e \in slot(u, 1)} y_{e, s_1} p_e \geq f(p_1)p_1 + (1 - f(p_1))p_2$. ◀

Now we introduce a lemma that is inspired by [15] and upper bounds the load on u .

► **Lemma 8.** *Let e'_1, \dots, e'_t be the edges that were oriented to u in the *Local Step*, and let q_1, \dots, q_t be their processing times respectively. Then,*

$$\sum_{i=1}^t q_i + \sum_{i=1}^k p_i \leq 1 + \sum_{i=1}^t (1 - f(q_i))q_i + f(p_1)p_1 + (1 - f(p_1))p_2.$$

⁷ Alternatively, we can also assume $p_{k+2} = 0$ and $x_{e_{k+2}, u} = 1$ as well.

82:10 Graph Balancing with Orientation Costs

Proof. First, recall that for every $1 \leq s \leq k-1$ $slot(u, s)$ has a capacity exactly 1. Moreover, the slots are filled with edges in decreasing order of processing time. Therefore, we can deduce that for each $1 \leq i \leq k-1$:

$$\sum_{e \in slot(u, i)} y_{e, s_i} p_e \geq \sum_{e \in slot(u, i)} y_{e, s_i} p_{i+1} = p_{i+1} \sum_{e \in slot(u, i)} y_{e, s_i} = p_{i+1}.$$

Since at most one edge from each slot can be selected in the *Global Step*, the load on u from edges that oriented to u in the *Global Step* is at most $\sum_{i=1}^k p_i$. From the above inequality, along with Observation 2, we can conclude that:

$$\begin{aligned} \sum_{i=1}^t q_i + \sum_{i=1}^k p_i &= \sum_{i=1}^t q_i + p_1 + p_2 + \sum_{i=3}^k p_i \leq \sum_{i=1}^t q_i + p_1 + p_2 + \sum_{i=2}^{k-1} \sum_{e \in slot(u, i)} y_{e, s_i} p_e \\ &\leq \sum_{i=1}^t q_i + p_1 + p_2 + \sum_{i=1}^k \sum_{e \in slot(u, i)} y_{e, s_i} p_e - \sum_{e \in slot(u, 1)} y_{e, s_1} p_e \\ &\leq \sum_{i=1}^t q_i + p_1 + p_2 + \sum_{e \in \delta(u)} x_{e, u} p_e - ((1 - f(p_1))p_1 + f(p_1)p_2) \\ &\leq \sum_{i=1}^t q_i + f(p_1)p_1 + (1 - f(p_1))p_2 + \left(1 - \sum_{i=1}^t f(q_i)q_i\right) \\ &= 1 + \sum_{i=1}^t (1 - f(q_i))q_i + f(p_1)p_1 + (1 - f(p_1))p_2. \end{aligned}$$

The last inequality follows from the Load constraint on u , and the fact that the edges e'_1, \dots, e'_t were removed from E at the end of the *Local Step*. \blacktriangleleft

Lastly, we observe that all of the *big* edges, *i.e.*, edges whose weight is larger than $1/2$, that are not oriented toward u in the *Local Step* are assigned to the first slot. This is summarized in the following observation.

► **Observation 3.** *Let e be an edge in $slot(u, i)$ such that $i > 1$. Then, $p_e \leq 1/2$.*

Proof. Assume for the sake of contradiction that $p_e > 1/2$. Since the slots are filled in a non-increasing weight order, all edges in slots $1, 2, \dots, i-1$ are filled with fractions of edges whose processing time is greater than $1/2$. Therefore, $\sum_{e \in \delta(u): p_e > 1/2} x_{e, u} > 1$, which contradicts the Star constraint on u . \blacktriangleleft

Let us now focus on the orientation cost. The following lemma upper bounds the orientation cost of the orientation produced by Algorithm 2.

► **Lemma 9.** *Given $f : [0, 1] \rightarrow [0, 1/2]$, let $c \triangleq (\inf\{f(p) | p \in [0, 1]\})^{-1}$. Then Algorithm 2 with f outputs an orientation with a cost of at most $c \cdot C(T)$.*

3.1 Graph Balancing – Upper Bound on Tradeoff Between Makespan and Orientation Cost

Let us now focus on applying the framework, with an appropriate threshold function f , to GB. First, we present a theorem that achieves part of the tradeoff claimed in Theorem 1, and only in the next subsection we show how to extend this tradeoff to fully achieve Theorem 1.

► **Theorem 10.** *There exists a threshold function f such that Algorithm 2 finds an orientation that is a $(1.75 + \gamma, 1/(2\gamma+0.5))$ -approximation, for every $1/12 \leq \gamma \leq 1/4$.*

The function f_α we use in the proof of Theorem 10 is the following:

$$f_\alpha(p_e) = \begin{cases} 1 & \text{if } p_e \leq 1/2 \\ \alpha & \text{if } p_e > 1/2 \end{cases} \quad (1)$$

where $2/3 \leq \alpha \leq 1$. The following lemma upper bounds the makespan of Algorithm 2 with the above f_α .

► **Lemma 11.** *The makespan of the orientation produced by Algorithm 2 with f_α is at most $1.5 + 0.5\alpha$, where $2/3 \leq \alpha \leq 1$.*

Proof. Consider the number of edges that were oriented toward u in the *Local Step*. First, we note that from the Star constraint on u , at most one edge can be oriented toward u in the *Local Step*. If this is not the case then let e'_1 and e'_2 be edges oriented to u in the *Local Step*. Then, $p_{e_1}, p_{e_2} > 1/2$. However, $x_{e_1,u} + x_{e_2,u} > \alpha + \alpha \geq 2/3 + 2/3 > 1$, which contradicts the Star constraint on u . Hence, there are only two cases to consider.

Case 1: Assume no edge is oriented toward u in the *Local Step*. Therefore, using Lemma 8 and Observation 3 the load on u is at most:

$$\begin{aligned} \sum_{i=1}^k p_i &\leq 1 + f_\alpha(p_1)p_1 + (1 - f_\alpha(p_1))p_2 \leq 1.5 + f_\alpha(p_1)(p_1 - 0.5) \\ &\leq 1.5 + \alpha \cdot (1 - 0.5) = 1.5 + 0.5\alpha, \end{aligned}$$

where the last inequality follows from the fact that the expression: $f_\alpha(p_1)(p_1 - 0.5)$ is maximized when $p_1 = 1$ (and thus $f_\alpha(p_1) = \alpha$).

Case 2: Assume there is exactly one edge that was oriented toward u in the *Local Step*. Recall we denote this edge as e'_1 and its processing time by q_1 . Since $q_1 > 1/2$ and $x_{e'_1,u} > \alpha$, then it must be the case that $p_1 \leq 1/2$ (otherwise Observation 1 implies that $x_{e'_1,u} + x_{e_1,u} > \alpha + 1 - \alpha = 1$, which contradicts the Star constraint for u). Therefore, from Lemma 8 the load on u in the output of Algorithm 2 is at most:

$$\begin{aligned} q_1 + \sum_{i=1}^k p_i &\leq 1 + (1 - f_\alpha(q_1))q_1 + f_\alpha(p_1)p_1 + (1 - f_\alpha(p_1))p_2 \leq 1 + (1 - \alpha)q_1 + p_1 \\ &\leq 1 + (1 - \alpha) + 0.5 = 2.5 - \alpha \leq 1.5 + 0.5\alpha. \end{aligned}$$

The second inequality follows from the fact that $p_2 \leq p_1$ and $f_\alpha(q_1) = \alpha$ (since $q_1 > 1/2$), whereas the third inequality from the fact that $p_1 \leq 1/2$. In addition, the last inequality follows from the fact that $2/3 \leq \alpha \leq 1$. ◀

Now, we are ready to conclude the proof of Theorem 10:

Proof of Theorem 10. Applying Lemma 11, Lemma 9 and choosing $\gamma = 0.5\alpha - 0.25$ finishes the proof. ◀

We now show that the analysis of Algorithm 2 with a threshold function f_α is tight. Formally, we prove the following lemma:

82:12 Graph Balancing with Orientation Costs

► **Lemma 12.** *For every $1/2 \leq \alpha < 1$ there exists an instance such that the output of Algorithm 2 with f_α has makespan at least $\max\{1.5 + 0.5\alpha, 2.5 - \alpha\}$ and orientation cost at least $1/\alpha \cdot OPT_{LP}$.*

Lemma 12 shows the analysis of Algorithm 2 with a threshold function f_α is tight. Consequently, in order to extend the bicriteria tradeoff of Theorem 10, and obtain Theorem 1, we require a different threshold function and a stronger relaxation.

3.2 Graph Balancing – Extending the Tradeoff

It is important to note that Lemma 12 implies that using Algorithm 2 with LP and the threshold function f_α cannot achieve an approximation better than $11/6$ with respect to the makespan. To this end we strengthen LP using the following constraint (which we denote by Set constraints):

$$\sum_{e \in S} x_{e,u} \leq |S| - 1 \quad \forall u \in V, \forall S \subseteq \delta(u) : S \notin \mathcal{F}(u) \text{ and } |S| \leq k \quad (\text{Set})$$

We call the new relaxation LP_k .⁸ Intuitively, the Set constraints enforce that given an infeasible set of edges S touching u not all edges of S can be oriented toward u . In fact, for our specific choice of a threshold function f we use $k = 3$. Thus, no separation oracle is required when solving the relaxation. The exact result is formulated in the following theorem:

► **Theorem 13.** *There exists a rounding function f such that Algorithm 2 finds an orientation that is a $(1.75 + \gamma, 1/(2\gamma + 0.5))$ -approximation, for every $1/12 - \epsilon/2 \leq \gamma \leq 1/12$, where $\epsilon = \sqrt{33}/2 - 17/6$.*

Note that this theorem extends the tradeoff achieved in Theorem 10, and together both theorems achieve the tradeoff of Theorem 1. The threshold function f_ϵ we use in the proof of Theorem 13 is defined as follows:

$$f_\epsilon(p_e) = \begin{cases} 2/3 - \epsilon & \text{if } p_e > 1/2 \\ 2/3 + \epsilon/2 & \text{if } 1/3 < p_e \leq 1/2 \\ 1 & \text{if } p_e \leq 1/3 \end{cases} \quad (2)$$

where $0 \leq \epsilon \leq \sqrt{33}/2 - 17/6$. The following lemma upper bounds the makespan:

► **Lemma 14.** *The output of Algorithm 2 with the threshold function f_ϵ , has a makespan of at most $11/6 - \epsilon/2$.*

Now we conclude with the proofs of Theorems 13 and 1.

Proof of Theorem 13. Follows immediately from Lemmas 14 and 9, and choosing $\gamma = 1/12 - \epsilon/2$. ◀

Proof of Theorem 1. Follows immediately from Theorems 10 and 13. ◀

⁸ Similarly to LP , for some of the extensions of GB we add that $x_{e,u} = 0$ if $p_{e,u} > 1$ (for every $e \in E$ and $u \in e$).

4 Lower Bound on The Tradeoff Between Makespan and Cost

We show that using LP_k for every $k \in \mathbb{N}$, one must loose in the total orientation cost when obtaining an approximation for the makespan that is strictly better than 2. This is in contrast to the classic result of [15] for which one can achieve an approximation factor of 2 with respect to the makespan with no loss in the assignment cost. This result is formulated in Theorem 3.

5 Extending Graph Balancing to Hyperedges and Unrelated Weights

5.1 Graph Balancing with Unrelated Light Hyperedges

Let us recall the definition of $\text{GBUH}(\beta)$, where $\beta \in [0, 1]$. The input consists of a hypergraph, where each vertex represents a machine and each hyperedge represents a job. The jobs are of two types, “light” and “heavy”. Every light hyperedge $e \in E$ is associated with weights $p_{e,u}$, one for each vertex $u \in e$ (i.e., e is unrelated since it has a different processing time for each of the machines it can be assigned to). The requirement is that $p_{e,u} \leq \beta$ for every $u \in e$. On the other hand, every heavy hyperedge $e \in E$ must in fact be an edge, i.e., $|e| = 2$. Such a heavy e is associated with a single weight $p_e \in [0, 1]$ (i.e., e is related since it has the same processing time for each of the two machines it can be assigned to). In the above, as previously mentioned, we assume without loss of generality that the largest weight equals 1. For both types, light and heavy, orienting e toward one of its endpoints is equivalent to assigning the job e represents to the machine that is represented by the vertex e was oriented to. It is important to note that when $\beta = 1$ the problem is exactly GAP, and when $\beta = 0$ the problem is exactly GB.

Our result for $\text{GBUH}(\beta)$ is summarized in Theorem 4, which improves upon the previous result of [6] (refer to Section 1 for a thorough discussion on how our result improves upon [6]). To the best of our knowledge, our result provides the first approximation better than 2 with respect to the makespan of a natural problem that captures GB but is not captured by RA.

5.2 Graph Balancing with Unrelated Light Hyperedges and Unrelated Heavy Edges

The problem of $\text{GBU}(\beta)$ further generalizes the above $\text{GBUH}(\beta)$ as it allows heavy edges to have unrelated weights. Formally, every heavy edge $e = (u, v) \in E$ is associated with two weights $p_{e,u}$ and $p_{e,v}$, i.e., e is unrelated since $p_{e,u}$ indicates the processing time of the job e represents on the machine that is represented by u . The requirement is that $p_{e,u}, p_{e,v} \in (\beta, 1]$. As mentioned earlier, it is assumed that the value of the optimal makespan is at least 1 (otherwise the problem is as hard as GAP). Our results relating to $\text{GBU}(\beta)$ are formulated in Theorems 5 and 6.

5.3 Semi-Related Graph Balancing

Consider the general problem of UNRELATED GRAPH BALANCING, which is identical to GB except that an edge can have a different weight depending on its orientation: $p_{e,u}$ and $p_{e,v}$ for every $e = (u, v) \in E$, i.e., the weights are unrelated. This generalization of GB was already considered in [17, 4], who presented lower bounds for the problem. Specifically, they showed that the even the configuration LP (which captures LP_k) has an integrality gap of 2 with respect to the makespan.

■ **Figure 4** Makespan approximation as a function of the value c .

We consider an interesting special case of the above problem where the weights are still unrelated, but cannot vary arbitrarily. Formally, each edge $e = (u, v) \in E$ has two weights depending on the vertex e is oriented to, which satisfy: $p_{e,u} \leq c \cdot p_{e,v}$ and $p_{e,v} \leq c \cdot p_{e,u}$ (where $c \geq 1$ is a parameter of the problem). We denote this problem by SEMI-RELATED GRAPH BALANCING (SRGB(c)).

Our result for SRGB(c) is formulated in Theorem 7. Note that SRGB(c) captures GB when $c = 1$, and indeed in Theorem 7 we achieve a $(11/6, 3/2)$ -approximation for SRGB(c) when $c = 1$ (similarly to Theorem 10). Moreover, when $c = \infty$ Theorem 7 achieves a $(2, 1)$ -approximation for SRGB(c), matching the integrality gap of [17, 4]. Finally, we also show that in general Theorem 7 provides a $(2 - \Omega(1/c), 1 + O(1/c))$ -approximation for SRGB(c).

Figure 4 shows the makespan approximation obtained in Theorem 7 as a function of c .

In order to prove Theorem 7 we use Algorithm 2 and LP_k (replacing p_e with $p_{e,u}$) with a suitable choice of a threshold function f .

Abstract

The Gromov-Hausdorff distance is a natural way to measure the distortion between two metric spaces. However, there has been only limited algorithmic development to compute or approximate this distance. We focus on computing the Gromov-Hausdorff distance between two metric trees. Roughly speaking, a metric tree is a metric space that can be realized by the shortest path metric on a tree. Any finite tree with positive edge weight can be viewed as a metric tree where the weight is treated as edge length and the metric is the induced shortest path metric in the tree. Previously, Agarwal et al. showed that even for trees with unit edge length, it is NP-hard to approximate the Gromov-Hausdorff distance between them within a factor of 3. In this paper, we present a fixed-parameter tractable (FPT) algorithm that can approximate the Gromov-Hausdorff distance between two general metric trees within a *multiplicative factor* of 14.

Interestingly, the development of our algorithm is made possible by a connection between the Gromov-Hausdorff distance for metric trees and the interleaving distance for the so-called merge trees. The merge trees arise in practice naturally as a simple yet meaningful topological summary (it is a variant of the Reeb graphs and contour trees), and are of independent interest. It turns out that an exact or approximation algorithm for the interleaving distance leads to an approximation algorithm for the Gromov-Hausdorff distance. One of the key contributions of our work is that we re-define the interleaving distance in a way that makes it easier to develop dynamic programming approaches to compute it. We then present a fixed-parameter tractable algorithm to compute the interleaving distance between two merge trees **exactly**, which ultimately leads to an FPT-algorithm to approximate the Gromov-Hausdorff distance between two metric trees. This exact FPT-algorithm to compute the interleaving distance between merge trees is of interest itself, as it is known that it is NP-hard to approximate it within a factor of 3, and previously the best known algorithm has an approximation factor of $O(\sqrt{n})$ even for trees with unit edge length.

1 Introduction

Given two metric spaces (X, d_X) and (Y, d_Y) , a natural way to measure their distance is via the *Gromov-Hausdorff distance* $\delta_{\mathcal{GH}}(X, Y)$ between them [15], which intuitively describes how much *additive* distance distortion is needed to make the two metric spaces isometric.

We are interested in computing the Gromov-Hausdorff distance between *metric trees*. Roughly speaking, a metric tree (X, d) is a geodesic-metric space that can be realized by the shortest path metric on a tree. Any finite tree $T = (V, E)$ with positive edge weights $w : E \rightarrow \mathbb{R}$ can be naturally viewed as a metric tree $\mathcal{T} = (|T|, d)$: the space is the underlying space $|T|$ of T , each edge e can be viewed as a segment of length $w(e)$, and the distance d is the induced shortest path metric. See Figure 1 (a) for an example. Metric trees occur commonly in practical applications: e.g., a neuron cell has a tree morphology, and can be modeled as an embedded metric tree in \mathbb{R}^3 . It also represents an important family of metric spaces that has for example attracted much attention in the literature of metric embedding and recovery of hierarchical structures, e.g., [2, 4, 3, 10, 11, 13, 23].

Unfortunately, it is shown in [1, 22] that it is not only NP-hard to compute the Gromov-Hausdorff distance between two trees, but also NP-hard to approximate it within a factor of 3 even for trees with unit edge length. A polynomial-time approximation algorithm is given in [1]; however, the approximation factor is high: it is $O(\sqrt{n})$ even for unit-edge weight trees.

Another family of tree structures that is of practical interest is the so-called *merge tree*. Intuitively, a merge tree is a rooted tree T associated with a real-valued function $f : T \rightarrow \mathbb{R}$ such that the function value is monotonically decreasing along any root-to-leaf path – We can think of a merge tree to be a tree with height function associated to it where all nodes with degree > 2 are down-forks (merging nodes); see Figure 1 (b). The merge tree is a loop-free variant of the so-called Reeb graph, which is a simple yet meaningful topological summary for a scalar field $g : X \rightarrow \mathbb{R}$ defined on a domain X , and has been widely used in many applications in graphics and visualization e.g., [7, 14, 17, 24]. Morozov et al. introduced the *interleaving distance* to compare merge trees [20], based on a natural “interleaving idea” which has recently become fundamental in comparing various topological objects. Also, several distance measures have been proposed for the Reeb graphs [5, 6, 12]. When applying them to merge trees, it turns out that two of these distance measures are equivalent to the interleaving distance. However, the same reduction in [1] to show the hardness of approximating the Gromov-Hausdorff distance can also be used to show that it is NP-hard to approximate the interleaving distance between two merge trees within a factor 3.

New work

Although the Gromov-Hausdorff distance is a natural way to measure the degree of near-isometry between metric spaces [15, 19], the algorithmic development for it has been very limited so far [1, 9, 21, 22]. In [22], Schmiedl gave an FPT algorithm for approximating the Gromov-Hausdorff distance between two *finite metrics*, where the approximation contains *both an additive and multiplicative terms*; see more discussion in *Remarks* after Theorem 20. In this paper, we present the first FPT algorithm to approximate the Gromov-Hausdorff distance for metric trees *within a constant multiplicative factor*.

Interestingly, the development of our approximation algorithm is made possible via a connection between the Gromov-Hausdorff distance between metric trees and the interleaving distance between certain merge trees (which has already been observed previously in [1]). This connection implies that any exact or approximation algorithm for the interleaving distance will lead to an approximation algorithm for the Gromov-Hausdorff distance for

metric trees of similar time complexity. Hence we can focus on developing algorithms for the interleaving distance. The original interleaving distance definition requires considering a pair of maps between the two input merge trees and their interaction. One of the key insights of our work is that we can in fact develop an equivalent definition for the interleaving distance that relies on only *a single map* from one tree to the other. This, together with the height functions equipped with merge trees (which give rises to natural ordering between points in the two trees), essentially allows us to develop a dynamic programming algorithm to check whether the interleaving distance between two merge trees is smaller than a given threshold or not: In particular in Section 4, we first give a simpler DP algorithm with slower time complexity to illustrate the main idea. We then show how we can modify this DP algorithm to improve the time complexity. Finally, we solve the optimization problem for computing the interleaving distance² in Section 5, which leads to a constant-factor (a multiplicative factor of 14) approximation FPT algorithm for the Gromov-Hausdorff distance between metric trees.

Figure 1 (a) A metric tree (T, d_T) with edge length marked. Tree nodes are white dots. $d_T(x, z) = 3 + 5 + 2 = 10$ is the length of the thickened path $\pi(x, z)$. (b) A merge tree T^h , with examples of $u \succ v$, u^ε , $T^h(x)$ and $depth(x)$ marked. (c) Tree alignment distance between T_1 and T_2 arbitrarily large, while $\delta_{\mathcal{GH}}(T_1, T_2)$ is roughly bounded by the pairwise distance difference which is small.

More on related work

There have been several tree distances proposed in the literature. Two most well-known ones are the tree edit and tree alignment distances [8], primarily developed to compare labeled trees. Unfortunately, both distances are MAX SNP-hard to compute for un-ordered trees [18, 26]. For tree edit distance, it is MAX SNP-hard even for trees with bounded degree. For the tree alignment distance, it can be computed in polynomial time for trees with bounded degree. However the tree alignment distance requires that parent-child relation to be strictly preserved, and thus the small local configuration change shown in Figure 1 (c) will incur a large tree alignment distance.

We will not survey the large literature in metric embedding which typically minimizes the metric distortion in a *multiplicative* manner. However, we mention the work of Hall and Papadimitriou [16], where, given two equal-sized point sets, they propose to find the best *bijection* under which the *additive distortion* is minimized. They show it is NP-hard to approximate this optimal additive distortion within a factor of 3 even for points in \mathbb{R}^3 .

² We note that the final time complexity for the optimization problem presented in Theorem 19 is based on an argument by Kyle Fox. His argument improves our previous n^4 factor (as in Theorem 18) by an almost n^2 factor, by performing a double-binary search, instead of a sequence search we originally used.

In contrast, the Gromov-Hausdorff distance is also *additive*, but allows for many-to-many correspondence (instead of bijection) between points from two input metric spaces. We also note that our metric trees consist of all points in the underlying space of input trees (i.e., including points in the interior of a tree edge). This makes the distance robust against adding extra nodes and short “hairs” (branches). Nevertheless, we can also consider discrete metric trees, where we only aim to align nodes of input trees (instead of all points in the underlying space of the trees). Our algorithms hold for the discrete case as well.

2 Preliminaries

Metric space, metric trees

A metric space is a pair (X, d) where X is a set and $d : X \times X \rightarrow \mathbb{R}_{\geq 0}$ satisfies: (i) for any $x, y \in X$, $d(x, y) \geq 0$ and $d(x, y) = 0$ holds only when $x = y$; (ii) $d(x, y) = d(y, x)$, and (iii) for any x, y, z , $d(x, z) \leq d(x, y) + d(y, z)$. We call d a metric on the space X . A metric space (X, d) is a finite metric tree if it is a length metric space³ and X is homeomorphic to the underlying space $|T|$ of some finite tree $T = (V, E)$.

Equivalently, suppose we are given a finite tree $T = (V, E)$ where each edge $e \in E$ has a positive weight $\ell(e) > 0$. View the underlying space $|e|$ of e as a segment with length $\ell(e)$ (i.e., it is isometric to $[0, \ell(e)]$), and we can thus define the distance $d_T(x, y)$ between any two points $x, y \in |e|$ as the length of the sub-segment $e[x, y]$. The underlying space $|T|$ of T is the union of all these segments (and thus includes points in the interior of each edge as well). For any $x, z \in |T|$, there is a unique simple path $\pi(x, z) \subset |T|$ connecting them. The (shortest path) distance $d_T(x, z)$ equal to the length of this path, which is simply the sum of the lengths of the restrictions of this path to edges in T . See Figure 1 (a). The space $|T|$ equipped with d_T is a metric tree $(|T|, d_T)$.

Given a tree $T = (V, E)$, we use the term *tree nodes* to refer to points in V , and an arbitrary $x \in |T|$ potentially from the interior of some tree edge is referred to as a *point*. Given T , we also use $V(T)$ and $E(T)$ to denote its node-set and edge-set, respectively. To emphasize the combinatorial structure behind a metric tree, in the paper we will write a metric tree (T, d_T) , with the understanding that the space is in fact the underlying space $|T|$ of T .

Note that if we restrict this metric space to only the tree nodes, we obtain a *discrete metric tree* $(V(T), d_T)$, and the distance between two tree nodes is simply the standard shortest path distance between them in a weighted graph (tree T in this case). Our algorithms developed in this paper can be made to work for the discrete metric trees as well.

Gromov-Hausdorff distance

Given two metric spaces $\mathcal{X} = (X, d_X)$ and $\mathcal{Y} = (Y, d_Y)$, a *correspondence* between them is a relation $C : X \times Y$ whose projection on X and on Y are both surjective; i.e., for any $x \in X$, there is at least one $(x, y) \in C$, and for any $y' \in Y$, there is at least one $(x', y') \in C$. If $(x, y) \in C$, then we say y (resp. x) is a pairing partner for x (resp. y); note that x (resp. y) could have multiple pairing partners. The cost of this correspondence is defined as:

$$\text{cost}(C) = \max_{(x, y), (x', y') \in C} |d_X(x, x') - d_Y(y, y')|,$$

which measures the maximum metric distortion (difference in pairwise distances) under this correspondence. The *Gromov-Hausdorff distance* between them is:

$$\delta_{\text{GH}}(\mathcal{X}, \mathcal{Y}) = \frac{1}{2} \inf_{C \in \Pi(\mathcal{X}, \mathcal{Y})} \text{cost}(C), \quad \text{where } \Pi(\mathcal{X}, \mathcal{Y}) = \text{set of correspondences between } X \text{ and } Y.$$

³ (X, d) is a length metric space if d is the same as the shortest path (i.e., intrinsic) metric it induces on X .

Merge trees

A *merge tree* is a pair (T, h) where T is a rooted tree, and the continuous function $h : |T| \rightarrow \mathbb{R}$ is *monotone* in the sense the value of h is decreasing along any root-to-leaf path. See Figure 1 (b) for an example. For simplicity, we often write the merge tree as T^h , and refer to h as the *height function*, and $h(x)$ the *height* of a point $x \in |T|$. The merge tree is a natural object: e.g., it can be used to model a hierarchical clustering tree, where the height of a tree node indicates the parameter when the cluster (corresponding to the subtree rooted at this node) is formed. It also arises as a simple topological summary of a scalar function $\tilde{h} : M \rightarrow \mathbb{R}$ on a domain M , which tracks the connected component information of the sub-level sets $\tilde{h}^{-1}(-\infty, a]$ as $a \in \mathbb{R}$ increases.

To define the interleaving distance, we modify a merge tree T^h slightly by extending a ray from $\text{root}(T^h)$ upwards with function value h goes to $+\infty$. All merge trees from now on refer to this modified version. Given a merge tree T^h and a point $x \in |T|$, $T^h(x)$ is the subtree of T^h rooted at x , and the *depth of x (or of $T^h(x)$)*, denoted by $\text{depth}(x)$, is the largest function value difference between x and any node in its subtree; that is, the height of the entire subtree $T^h(x)$ w.r.t. function h . Given any two points $u, v \in |T|$, we use $u \succeq v$ to denote that u is an ancestor of v ; $u \succ v$ if u is an ancestor of v and $u \neq v$. Similarly, $v \preceq u$ means that v is a descendant of u . Also, the degree of a node in a merge tree is defined as the downward degree of the node. We use $LCA(u, v)$ to represent the lowest common ancestor of u and v in $|T|$. For any non-negative value $\varepsilon \geq 0$, u^ε represents the unique ancestor of u in T such that $h(u^\varepsilon) - h(u) = \varepsilon$. See Figure 1 (b).

Interleaving distance

We now define the interleaving distance between two merge trees T_1^f and T_2^g , associated with functions $f : |T_1^f| \rightarrow \mathbb{R}$ and $g : |T_2^g| \rightarrow \mathbb{R}$, respectively.

► **Definition 1** (ε -Compatible maps [20]). *A pair of continuous maps $\alpha : |T_1^f| \rightarrow |T_2^g|$ and $\beta : |T_2^g| \rightarrow |T_1^f|$ is ε -compatible w.r.t T_1^f and T_2^g if the following four conditions hold:*

- (C1). $g(\alpha(u)) = f(u) + \varepsilon$ and (C2). $\beta \circ \alpha(u) = u^{2\varepsilon}$ for any $u \in |T_1^f|$;
 (C3). $f(\beta(w)) = g(w) + \varepsilon$ and (C4). $\alpha \circ \beta(w) = w^{2\varepsilon}$ for any $w \in |T_2^g|$.

To provide some intuition for this definition, note that if $\varepsilon = 0$, then $\alpha = \beta^{-1}$: In this case, the two trees T_1 and T_2 are not only isomorphic, but also the function values associated to them are preserved under the isomorphism. In general for $\varepsilon > 0$, this quantity measures how far a pair of maps are away from forming a function-preserving isomorphism between T_1^f and T_2^g . In particular, β is no longer the inverse of α . However, the two maps relate to each other in the sense that if we send a point $u \in |T_1^f|$ to $|T_2^g|$ through $\alpha : |T_1^f| \rightarrow |T_2^g|$, then bring it back via $\beta : |T_2^g| \rightarrow |T_1^f|$, we come back at an ancestor of u in $|T_1^f|$ (i.e, property (C2)). This ancestor must be at height $f(u) + 2\varepsilon$ due to properties (C1) and (C3).

► **Definition 2** (Interleaving distance [20]). *The interleaving distance between two merge trees T_1^f and T_2^g is defined as:*

$$d_I(T_1^f, T_2^g) = \inf \{ \varepsilon \mid \text{there exist a pair of } \varepsilon\text{-compatible maps w.r.t } T_1^f \text{ and } T_2^g \}. \quad (1)$$

Interestingly, it is shown in [1] that the Gromov-Hausdorff distance between two metric trees is related to the interleaving distance between two specific merge trees.

▷ Claim 3 ([1]). Given two metric trees $\mathcal{T}_1 = (T_1, d_1)$ and $\mathcal{T}_2 = (T_2, d_2)$ with node sets $V_1 = V(T_1)$ and $V_2 = V(T_2)$, respectively, let $f_u : |T_1| \rightarrow \mathbb{R}$ (resp. $g_w : |T_2| \rightarrow \mathbb{R}$) denote the geodesic distance function to the base point $u \in V_1$ (resp. $v \in V_2$) defined by $f_u(x) = -d_1(x, u)$ for any $x \in |T_1|$ (resp. $g_w(y) = -d_2(y, w)$ for any $y \in |T_2|$). Set $\mu := \min_{u \in V_1, w \in V_2} d_I(T_1^{f_u}, T_2^{g_w})$. We then have that

$$\frac{\mu}{14} \leq \delta_{\mathcal{GH}}(\mathcal{T}_1, \mathcal{T}_2) \leq 2\mu.$$

Note that to compute the quantity μ , we only need to check all pairs of *tree nodes* of T_1 and T_2 , instead of all pairs of points from $|T_1|$ and $|T_2|$.

We say a quantity A is a c -*approximation* for a quantity B if $\frac{A}{c} \leq B \leq cA$; obviously, $c \geq 1$ and $c = 1$ means that $A = B$. The above claim immediately suggests the following:

► **Corollary 4.** *If there is an algorithm to c -approximate the interleaving distance between any two merge trees in $T(n)$ time, where n is the total complexity of input trees, then there is an algorithm to $O(c)$ -approximate the Gromov-Hausdorff distance between two metric trees in $n^2T(n)$ time.*

In the remainder of this paper, we will focus on developing an algorithm to compute the interleaving distance between two merge trees T_1^f and T_2^g . In particular, in Section 3 we will first show an equivalent definition for interleaving distance, which has a nice structure that helps us to develop a fixed-parameter tractable algorithm for the decision problem of “Is $d_I(T_1^f, T_2^g) \geq \varepsilon$?” in Section 4. We show how this ultimately leads to FPT algorithms to compute the interleaving distance **exactly** and to **approximate** the Gromov-Hausdorff distance in Section 5.

3 A New Definition for Interleaving Distance

Given two merge trees T_1^f and T_2^g and $\delta > 0$, to answer the question “Is $d_I(T_1^f, T_2^g) \leq \delta$?”, a natural idea is to scan the two trees bottom up w.r.t the “height” values (i.e. f and g), while checking for possible ε -compatible maps between the partial forests of T_1^f and T_2^g already scanned. However, the interaction between the pair maps α and β makes it complicated to maintain potential maps. We now show that in fact, we only need to check for the existence of a *single* map from T_1^f to T_2^g , which we will call the ε -good map. We believe that this result is of independent interest.

► **Definition 5** (ε -good map). *A continuous map $\alpha : |T_1^f| \rightarrow |T_2^g|$ is ε -good if and only if:*

- (P1) *for any $u \in |T_1^f|$, we have $g(\alpha(u)) = f(u) + \varepsilon$;*
- (P2) *if $\alpha(u_1) \succeq \alpha(u_2)$, then we have $u_1^{2\varepsilon} \succeq u_2^{2\varepsilon}$, (note $u_1 \succeq u_2$ may not be true); and*
- (P3) *if $w \in |T_2^g| \setminus \text{Im}(\alpha)$, then we have $|g(w^F) - g(w)| \leq 2\varepsilon$, where $\text{Im}(\alpha) \subseteq |T_2^g|$ is the image of α , and w^F is the lowest ancestor of w in $\text{Im}(\alpha)$.*

A map $\rho : |T_1^{h_1}| \rightarrow |T_2^{h_2}|$ between two arbitrary merge trees $T_1^{h_1}$ and $T_2^{h_2}$ is *monotone* if for any $u \in |T_1^{h_1}|$, we have that $h_2(\rho(u)) \geq h_1(u)$. In other word, ρ carries any point u from $T_1^{h_1}$ to a point higher than it in $T_2^{h_2}$. If ρ is continuous, then it will map an ancestor of u in $T_1^{h_1}$ to an ancestor of $\rho(u)$ in $T_2^{h_2}$ as stated below (but the converse is not necessarily true):

► **Observation 6.** *Given a continuous and monotone map $\rho : |T_1^{h_1}| \rightarrow |T_2^{h_2}|$ between two merge trees $T_1^{h_1}$ and $T_2^{h_2}$, we have that if $u_1 \succeq u_2$ in $T_1^{h_1}$, then $\rho(u_1) \succeq \rho(u_2)$ in $T_2^{h_2}$.*

This implies that if $w = \rho(u)$ for $u \in |T_1^{h_1}|$, then ρ maps the subtree $T_1^{h_1}(u)$ rooted at u into the subtree $T_2^{h_2}(w)$ rooted at w . This also implies that if $w \notin \text{Im}(\rho)$, neither does any of its descendant.

Note that an ε -good map, or a pair of ε -compatible maps, are all monotone and continuous. Hence the above observations are applicable to all these maps.

The main result of this section is as follows. Its proof is in [25].

► **Theorem 7.** *Given any two merge trees T_1^f and T_2^g , then $d_I(T_1^f, T_2^g) \leq \varepsilon$ if and only if there exists an ε -good map $\alpha : |T_1^f| \rightarrow |T_2^g|$.*

4 Decision Problem for Interleaving Distance

■ **Figure 2** (a) Green component within the slab is $B_\varepsilon(u, T_1^f)$. The sum of degrees for nodes within this ε -ball is 13. The ε -degree bound $\tau_\varepsilon(T_1^f, T_2^g)$ is the largest value of this sum for any ε -ball in T_1^f or in T_2^g . (b) White dots are tree nodes of T_1^f and T_2^g . Green dots are newly augmented tree nodes in \widehat{T}_1^f and \widehat{T}_2^g .

In this section, given two merge trees T_1^f and T_2^g as well as a positive value $\delta > 0$, we aim to develop a fixed-parameter tractable algorithm for the decision problem “Is $d_I(T_1^f, T_2^g) \leq \delta$?”. The specific parameter our algorithm uses is the following: Given a merge tree T^h and any point $u \in T^h$, let $B_\varepsilon(u; T^h)$ denote the ε -ball

$$B_\varepsilon(u; T^h) = \{x \in |T| \mid \forall y \in \pi_T(u, x), |h(y) - h(u)| \leq \varepsilon\},$$

where $\pi_T(u, x)$ is the unique path from u to x in T^h . In other words, $B_\varepsilon(u; T^h)$ contains all points reachable from u via a path whose function value is completely contained with the range $[f(u) - \varepsilon, f(u) + \varepsilon]$. See Figure 2 (a) for an example: in particular, consider the restriction of T^h within the height interval $[f(u) - \varepsilon, f(u) + \varepsilon]$. There could be multiple components within this slab, and $B_\varepsilon(u; T^h)$ is the component containing u .

Parameter τ_δ : Let $\tau_\varepsilon(T_1^f, T_2^g)$ denote the largest sum of degrees of all tree nodes contained in any ε -ball in T_1^f or T_2^g , which we also refer to as the ε -degree-bound of T_1^f and T_2^g . The parameter for our algorithm for the decision problem will be $\tau_\delta = \tau_\delta(T_1^f, T_2^g)$.

4.1 A Slower FPT-Algorithm

Augmented trees

We now develop an algorithm for the decision problem “Is $d_I(T_1^f, T_2^g) \leq \delta$?” via a dynamic programming type approach. First, we will show that, even though a δ -good map is defined for all (infinite number of) points from T_1^f and T_2^g , we can check for its existence by inspecting

only a finite number of points from T_1^f and T_2^g . In particular, we will augment the input merge trees T_1^f and T_2^g with extra tree nodes, and our algorithm later only needs to consider the discrete nodes in these augmented trees to answer the decision problem.

The set of points from tree T_1^f or T_2^g at a certain height value c is called a *level* (at height c), denoted by $L(c)$. For example, in Figure 2 (a), the level $L(c_1)$ for $c_1 = f(u) + \varepsilon$, contains 2 points, while $L(c_2)$ with $c_2 = f(u) - \varepsilon$ contains 7 points. The function value of a level L is called its *height*, denoted by $height(L)$; so $height(L(c)) = c$.

► **Definition 8** (Critical-heights and Super-levels). *For the tree T_1^f , the set of critical-heights C_1 consists of the function values of all tree nodes of T_1^f ; similarly, define C_2 for T_2^g . That is,*

$$C_1 := \{f(x) \mid x \text{ is a tree node of } T_1^f\}; \text{ and } C_2 := \{g(y) \mid y \text{ is a tree node of } T_2^g\}.$$

The set of super-levels \mathcal{L}_1 w.r.t. δ for T_1^f and the set of super-levels \mathcal{L}_2 for T_2^g are:

$$\begin{aligned} \mathcal{L}_1 &:= \{L(c) \mid c \in C_1\} \cup \{L(c - \delta) \mid c \in C_2\} \text{ while} \\ \mathcal{L}_2 &:= \{L(c + \delta) \mid c \in C_1\} \cup \{L(c) \mid c \in C_2\}. \end{aligned}$$

Now sort all levels in \mathcal{L}_i in increasing order of their heights, denoted by $\mathcal{L}_1 = \{L_1^{(1)}, L_2^{(1)}, \dots, L_m^{(1)}\}$ and $\mathcal{L}_2 = \{L_1^{(2)}, \dots, L_m^{(2)}\}$, respectively. The *child-level* of super-level $L_i^{(1)}$ (resp. $L_i^{(2)}$) is $L_{i-1}^{(1)}$ (resp. $L_{i-1}^{(2)}$) for any $i \in [2, m]$; symmetrically, $L_i^{(1)}$ (resp. $L_i^{(2)}$) is the *parent-level* of $L_{i-1}^{(1)}$ (resp. $L_{i-1}^{(2)}$). Let h_1, \dots, h_m be the sequence of height values for $L_1^{(1)}, L_2^{(1)}, \dots, L_m^{(1)}$; that is, $h_i = height(L_i^{(1)})$. Similarly, let $\hat{h}_1, \hat{h}_2, \dots, \hat{h}_m$ be the corresponding sequence for $L_i^{(2)}$'s.

Note that there is a one-to-one correspondence between super-levels in \mathcal{L}_1 and \mathcal{L}_2 : specifically, for any $i \in [1, m]$, we have $\hat{h}_i = h_i + \delta$. From now on, when we refer to the i -th super-levels of \hat{T}_1^f and \hat{T}_2^g , we mean super-levels $L_i^{(1)}$ and $L_i^{(2)}$. Also observe that there is no tree node in between any two consecutive super-levels in either T_1^f or in T_2^g (all tree nodes are from some super-levels). See Figure 2 (b) for an illustration.

Next, we augment the tree T_1^f (resp. T_2^g) to add points from all super-levels from \mathcal{L}_1 (resp. from \mathcal{L}_2) also as *tree nodes*. The resulting *augmented trees* are denoted by \hat{T}_1^f and \hat{T}_2^g respectively; obviously, \hat{T}_1^f (resp. \hat{T}_2^g) has isomorphic underlying space as T_1^f (resp. T_2^g), just with additional degree-2 tree nodes. In particular, $V(\hat{T}_1^f)$ (resp. $V(\hat{T}_2^g)$) is formed by all points from all super-levels in \mathcal{L}_1 (resp. \mathcal{L}_2). See Figure 2 (b): In this figure, solid horizontal lines indicate levels passing through critical heights, while dashed ones are induced by critical height from the other tree. In what follows, given a super-level L , we use $V(L)$ to denote the set of nodes from this level. Note that $V(L_m^{(1)})$ and $V(L_m^{(2)})$ each contain only one node, which is $root(\hat{T}_1^f)$ and $root(\hat{T}_2^g)$ respectively. Given a node v from $L_i^{(1)}$ (resp. $L_i^{(2)}$), let $Ch(v)$ denote its children nodes in the augmented tree. Each child node of v must be from level $L_{i-1}^{(1)}$ (resp. $L_{i-1}^{(2)}$), as there are no tree-nodes between two consecutive super-levels.

► **Definition 9** (Valid pair). *Given a node $w \in V(\hat{T}_2^g)$ and a collection of nodes $S \subseteq V(\hat{T}_1^f)$, we say that (S, w) form a valid pair if there exists an index $j \in [1, m]$ such that (1) $S \subseteq V(L_j^{(1)})$ and $w \in V(L_j^{(2)})$ (which implies that nodes in S at height h_j while w has height $g(w) = \hat{h}_j$); and (2) all nodes in S have the same ancestor at height $h_j + 2\delta$ (which also equals $\hat{h}_j + \delta$). Intuitively, it indicates that S has the basic condition to be mapped to w under some ε -good maps.*

We say that S is valid if it participates some valid pair (and thus condition (2) above holds).

A first (slower) dynamic programming algorithm

We now describe our dynamic programming algorithm. To illustrate the main idea, we first describe a much cleaner but also slower dynamic programming algorithm $\text{DPgoodmap}()$ below. Later in Section 4.2 we modify this algorithm to improve its time complexity (which requires significant additional technical details).

Our algorithm maintains a certain quantity, called *feasibility* $F(S, w)$ for valid pairs in a bottom-up manner. Recall that we have defined the depth of a node $u \in T^h$ in a merge tree T^h as the height of the subtree $T^h(u)$ rooted at u ; or equivalently $\text{depth}(u) = \max_{x \preceq u} |h(u) - h(x)|$.

■ **Algorithm 1** $\text{DPgoodmap}(T_1^f, T_2^g, \delta)$.

Base case ($i = 1$): For each valid-pair (S, w) from level-1, set $F(S, w) = 1$ (“true”) if and only if $\text{depth}(w) \leq 2\delta$; otherwise, set $F(S, w) = 0$ (“false”).

When $i > 1$: Suppose we have already computed the feasibility values for all valid-pairs from level- $(i-1)$ or lower. Now for any valid-pair (S, w) from level- i , we set $F(S, w) = 1$ if and only if the following holds: Consider the set of children $\text{Ch}(S) \subseteq L_{i-1}^{(1)}$ of nodes in S , and w ’s children $\text{Ch}(w) = \{w_1, \dots, w_k\}$ in $L_{i-1}^{(2)}$.

If $\text{Ch}(w)$ is empty, then $F(S, w) = 1$ *only if* $\text{Ch}(S)$ is also empty; otherwise $F(S, w) = 0$.

If $\text{Ch}(w)$ is not empty, then we set $F(S, w) = 1$ if there exists a partition of $\text{Ch}(S) = S_1 \cup S_2 \cup \dots \cup S_k$ (where $S_i \cap S_j = \emptyset$ for $i \neq j$, and it is possible that $S_i = \emptyset$) such that for each $j \in [1, k]$,

(F-1) if $S_j \neq \emptyset$, then $F(S_j, w_j) = 1$; and

(F-2) if $S_j = \emptyset$, then $\text{depth}(w_j) \leq 2\delta - (\hat{h}_i - \hat{h}_{i-1})$; note that this implies that $\hat{h}_i - \hat{h}_{i-1} \leq 2\delta$ in this case.

Output: $\text{DPgoodmap}(T_1^f, T_2^g, \delta)$ returns “yes” if and only if $F(\text{root}(\hat{T}_1^f), \text{root}(\hat{T}_2^g)) = 1$.

Recall that $\text{root}(\hat{T}_1^f)$ (resp. $\text{root}(\hat{T}_2^g)$) is the only node in $V(L_m^{(1)})$ (resp. $V(L_m^{(2)})$).

We will first prove the following theorem for this slower. In Section 4.2 we show that time complexity can be reduced by almost a factor of n .

► Theorem 10.

- (i) Algorithm $\text{DPgoodmap}(T_1^f, T_2^g, \delta)$ returns “yes” if and only if $d_I(T_1^f, T_2^g) \leq \delta$.
- (ii) Algorithm $\text{DPgoodmap}(T_1^f, T_2^g, \delta)$ can be implemented to run in $O(n^3 2^\tau \tau^{\tau+1})$ time, where n is the total size of T_1^f, T_2^g , and $\tau = \tau_\delta(T_1^f, T_2^g)$ is the δ -degree-bound w.r.t. T_1^f and T_2^g .

Note that if τ is constant, then the time complexity is $O(n^3)$.

In the remainder of this section, we sketch the proof of Theorem 10.

Part (i) of Theorem 10: correctness

We first show the correctness of algorithm $\text{DPgoodmap}()$. Give a subset of nodes S' from some super-level of \hat{T}_1^f , let $\mathcal{F}_1(S')$ denote the forest consisting of all subtrees rooted at nodes in S' . For a node $w' \in T_2^g$, let $T_2(w')$ denote the subtree of T_2^g rooted at w' . We will now argue that $F(S, w) = 1$ if and only if there is a “partial” δ -good map from $\mathcal{F}_1(S) \rightarrow T_2(w)$.

More precisely: a continuous map $\alpha : \mathcal{F}_1(S) \rightarrow T_2(w)$ with (S, w) being valid is a *partial- ε -goodmap*, if properties (P1), (P2), and (P3) from Definition 5 hold (with T_1^f replaced by $\mathcal{F}_1(S)$ and T_2^g replaced by $T_2(w)$). Note that in the case of (P2), the condition in (P2) only

needs to hold for $u_1, u_2 \in \mathcal{F}_1(S)$ (implying that $\alpha(u_1), \alpha(u_2) \in T_2(w)$); that is, if $\alpha(u_1) \succeq \alpha(u_2)$ for $u_1, u_2 \in \mathcal{F}_1(S)$, then, we have $u_1^{2\varepsilon} \succeq u_2^{2\varepsilon}$. Note that while u_1 and u_2 are from $\mathcal{F}_1(S)$, $u_1^{2\varepsilon}$ and $u_2^{2\varepsilon}$ may not be in $\mathcal{F}_1(S)$ as it is possible that $f(u_1^{2\varepsilon}) = f(u_1) + 2\varepsilon \geq \text{height}(S)$. First, we observe the following:

▷ **Claim 11.** At the top level where $L_m^{(1)} = \{u = \text{root}(\widehat{T}_1^f)\}$ and $L_m^{(2)} = \{w = \text{root}(\widehat{T}_2^g)\}$ both contain only one node, if there is a partial- δ -good map from $\mathcal{F}_1(\{u\}) \rightarrow T_2(w)$, then there is a δ -good map from $|T_1^f| \rightarrow |T_2^g|$.

The correctness of our dynamic programming algorithm (part (ii) of Theorem 10) will follow from Claim 11 and Lemma 12 below. Lemma 12 is one of our key technical results, and its proof can be found in [25].

► **Lemma 12.** *For any valid pair (S, w) , $F(S, w) = 1$ if and only if there is a partial- δ -good map $\alpha : \mathcal{F}_1(S) \rightarrow T_2(w)$.*

Part (ii) of Theorem 10: time complexity

We now show that Algorithm `DPgoodmap()` can be implemented to run in the claimed time. Note that the augmented-tree nodes contain tree nodes of T_1^f and T_2^g , as well as the intersection points between tree arcs of T_1^f (resp. T_2^g) and super-levels. As there are at most $m = 2n$ number of super-levels in \mathcal{L}_1 and \mathcal{L}_2 , it follows that the total number of tree nodes in the augmented trees \widehat{T}_1^f and \widehat{T}_2^g is bounded by $O(nm) = O(n^2)$. In what follows, in order to distinguish between the tree nodes for the augmented trees (\widehat{T}_1^f and \widehat{T}_2^g) from the tree nodes of the original trees (T_1^f and T_2^g), we refer to nodes of the former as *augmented-tree nodes*, while the latter simply as *tree nodes*. It is important to note that the δ -degree-bound is defined with respect to the original tree nodes in T_1^f and T_2^g , not for the augmented trees (the one for the augmented trees can be significantly higher).

Our DP-algorithm essentially checks for the feasibility $F(S, w)$ of valid-pairs (S, w) . The following two lemmas bound the size of valid pairs, and their numbers. Their proofs are in [25].

► **Lemma 13.** *For any valid pair (S, w) , we have $|S| \leq \tau$ and $|\text{Ch}(S)| \leq \tau$, where $\tau = \tau_\delta(T_1^f, T_2^g)$ is the δ -degree-bound w.r.t. T_1^f and T_2^g .*

► **Lemma 14.** *Let $\tau = \tau_\delta(T_1^f, T_2^g)$ be the δ -degree-bound w.r.t. T_1^f and T_2^g . The total number of valid pairs that Algorithm `DPgoodmap`(T_1^f, T_2^g, δ) will inspect is bounded by $O(n^3 2^\tau)$, and they can be computed in the same time.*

To obtain the final time complexity for Algorithm `DPgoodmap`, consider computing $F(S, w)$ for a fixed valid pair (S, w) . This takes $O(1)$ time in the base case (the super-level index $i = 1$). Otherwise for the case $i > 1$, observe that $k = |\text{Ch}(w)| = \text{degree}(w) \leq \tau$, and $|\text{Ch}(S)| \leq \tau$ by Lemma 13. Hence the number of partitioning of $\text{Ch}(S)$ is bounded by $O(|\text{Ch}(S)|^k) = O(\tau^\tau)$. For each partition, checking conditions (F-1) and (F-2) takes $O(k)$ time; thus the total time needed to compute $F(S, w)$ is $O(k\tau^\tau) = O(\tau^{\tau+1})$. Combining this with Lemma 14, we have that the time complexity of Algorithm `DPgoodmap()` is bounded from above by $O(n^3 2^\tau \tau^{\tau+1})$, as claimed.

4.2 A Faster Algorithm

It turns out that we do not need to inspect all the $O(n^3 2^\tau)$ number of valid pairs as claimed in Lemma 14. We can consider only what we call sensible-pairs, which we define now.

► **Definition 15.** Given a valid-pair (S, w) , suppose S is from super-level $L_i^{(1)}$ and thus w is from super-level $L_i^{(2)}$. Then, (S, w) is a sensiblepair if either of the following two conditions hold:

- (C-1) S contains a tree node from $V(T_1^f)$, or its children $\text{Ch}(S) \subseteq L_{i-1}^{(1)}$ in the augmented tree \widehat{T}_1^f contains some tree node from $V(T_1^f)$, or the parents of nodes of S in the augmented tree \widehat{T}_1^f (which are necessarily from super-level $L_{i+1}^{(1)}$) contains some tree node from $V(T_1^f)$; or
- (C-2) w is a tree node of T_2^g , or $\text{Ch}(w) \subseteq L_{i-1}^{(2)}$ contains a tree node of T_2^g ; or the parent of w from super-level $L_{i+1}^{(2)}$ in the augmented tree \widehat{T}_2^g is a tree node of T_2^g .

Algorithm `DPgoodmap()` can be modified to Algorithm `modified-DP()` so that it only inspects sensible-pairs. The modification is non-trivial, and the reduction in the bound on number of sensible-pairs is by relating sensible-pairs to certain appropriately defined edge-list pairs $(A \subseteq E(T_1^f), \alpha \in E(T_2^g))$. The rather technical details can be found in [25]. We only summarize the main theorem below.

► **Theorem 16.**

- (i) Algorithm `modified-DP` (T_1^f, T_2^g, δ) returns “yes” if and only if $d_I(T_1^f, T_2^g) \leq \delta$.
- (ii) Algorithm `modified-DP` (T_1^f, T_2^g, δ) can be implemented to run in $O(n^2 2^\tau \tau^{\tau+2} \log n)$ time, where n is the total complexity of input trees T_1^f and T_2^g , and $\tau = \tau_\delta(T_1^f, T_2^g)$ is the δ -degree-bound w.r.t. T_1^f and T_2^g .

Note that if τ is constant, then the time complexity is $O(n^2 \log n)$.

5 Algorithms for Interleaving and Gromov-Hausdorff Distances

5.1 FPT Algorithm to Compute Interleaving Distance

In the previous section, we show how to solve the decision problem for interleaving distance between two merge trees T_1^f and T_2^g . We now show how to compute the interleaving distance δ^* , which is the smallest δ value such that $d_I(T_1^f, T_2^g) \leq \delta$ holds.

The main observation is that there exists a set Π of $O(n^2)$ number of candidate values such that δ^* is necessarily one of them. Specifically, let $\Pi_1 = \{|f(u) - g(w)| \mid u \in V(T_1^f), w \in V(T_2^g)\}$, $\Pi_2 = \{|f(u) - f(u')|/2 \mid u, u' \in V(T_1^f)\}$, and $\Pi_3 = \{|g(w) - g(w')|/2 \mid w, w' \in V(T_2^g)\}$. Set $\Pi = \Pi_1 \cup \Pi_2 \cup \Pi_3$. The proof of the following lemma can be found in [25].

► **Lemma 17.** The interleaving distance $\delta^* = d_I(T_1^f, T_2^g)$ satisfies that $\delta^* \in \Pi$.

Finally, compute and sort all candidate values in Π where by construction, $|\Pi| = O(n^2)$. Then, starting with δ being the smallest candidate value in Π , we perform algorithm `DPgoodmap` (T_1^f, T_2^g, δ) for each δ in Π in increasing order, till the first time the answer is “yes”. The corresponding δ value at the time is $d_I(T_1^f, T_2^g)$. Furthermore, note that for the degree-bound parameter, $\tau_\delta(T_1^f, T_2^g) \leq \tau_{\delta'}(T_1^f, T_2^g)$ for $\delta \leq \delta'$. Combining with Theorem 16, we can easily obtain the following trivial bound:

► **Theorem 18.** Let $\delta^* = d_I(T_1^f, T_2^g)$ and $\tau^* = \tau_{\delta^*}(T_1^f, T_2^g)$ be the degree-bound parameter of T_1^f and T_2^g w.r.t. δ^* . Then we can compute δ^* in $O(n^4 2^{\tau^*} (\tau^*)^{\tau^*+2} \log n)$ time.

However, it turns out that one can remove almost an $O(n^2)$ factor by using a double-binary search like procedure, as discovered by Kyle Fox. We include this improved result below and his argument below for completeness. See [25] for the proof.

► **Theorem 19.** Let $\delta^* = d_I(T_1^f, T_2^g)$ and $\tau^* = \tau_{\delta^*}(T_1^f, T_2^g)$ be the degree-bound parameter of T_1^f and T_2^g w.r.t. δ^* . Then we can compute δ^* in $O(n^2 2^{2\tau^*} (2\tau^*)^{2\tau^*+2} \log^3 n)$ time.

5.2 FPT-Algorithm for Gromov-Hausdorff Distance

Finally, we develop a FPT-algorithm to approximate the Gromov-Hausdorff distance between two input trees (T_1, d_1) and (T_2, d_2) . To approximate the Gromov-Hausdorff distance between two metric trees, we need to modify our parameter slightly (as there is no function defined on input trees any more). Specifically, now given a metric tree (T, d) , a ε -geodesic ball at $u \in |T|$ is simply $\widehat{B}_\varepsilon(u, T) = \{x \in |T| \mid d(x, u) \leq \varepsilon\}$.

Parameter τ : Given $\mathcal{T}_1 = (T_1, d_1)$ and $\mathcal{T}_2 = (T_2, d_2)$, define the ε -metric-degree-bound parameter $\widehat{\tau}_\varepsilon(\mathcal{T}_1, \mathcal{T}_2)$ to be the largest sum of degrees of all tree nodes within any ε -geodesic ball in T_1 (w.r.t. metric d_1) or in T_2 (w.r.t. d_2).

We obtain our main result for approximating the Gromov-Hausdorff distance between two metric trees within a factor of 14. We note that to obtain this result, we need to also relate the ε -metric-degree-bound parameter for metric trees with the ε -degree-bound parameter used for interleaving distance for the special geodesic functions we use (in fact, we will show that $\widehat{\tau}_\delta \leq \tau_\delta \leq \widehat{\tau}_{2\delta}$). The proof of the following main theorem of this section can be found [25].

► **Theorem 20.** *Given two metric trees $\mathcal{T}_1 = (T_1, d_1)$ and $\mathcal{T}_2 = (T_2, d_2)$ where the total number of vertices of T_1 and T_2 is n , we can 14-approximate the Gromov-Hausdorff distance $\widehat{\delta}^* = \delta_{GH}(\mathcal{T}_1, \mathcal{T}_2)$ in $O(n^4 \log n + n^2 2^{\widehat{\tau}+2} \log^3 n)$ time, where $\widehat{\tau} = 2\widehat{\tau}_{28\widehat{\delta}^*}(\mathcal{T}_1, \mathcal{T}_2)$ is twice the metric-degree-bound parameter w.r.t. $28\widehat{\delta}^*$.*

Remarks

We remark that the time complexity of the FPT approximation algorithm of [22] contains terms n^k , where k is the parameter and could be large in general – Indeed, k is the cardinality of an ε -net of one of the input metric spaces, and ε also appears as an additive approximation term for algorithm. In contrast, the dependency of our algorithm on the parameter $\widehat{\tau}$ is roughly $O(2^{O(\widehat{\tau})})$, and our algorithm has only constant multiplicative approximation factor. On the other hand, note that the algorithm of [22] works for general finite metric spaces. We also remark that the Gromov-Hausdorff distance between two metric spaces (X, d_X) and (Y, d_Y) measures their *additive distortion*, and thus is not invariant under scaling. In particular, suppose the input two metric spaces $\mathcal{T}_1 = (T_1, d_1)$, $\mathcal{T}_2 = (T_2, d_2)$ scale by the same amount to a new pair of input trees $\mathcal{T}'_1 = (T'_1, d'_1 = c \cdot d_1)$, $\mathcal{T}'_2 = (T'_2, d'_2 = c \cdot d_2)$. Then the new Gromov-Hausdorff distance between them $\delta_{GH}(\mathcal{T}'_1, \mathcal{T}'_2) = c \cdot \delta_{GH}(\mathcal{T}_1, \mathcal{T}_2)$. However, note that the metric-degree-bound parameter for the new trees satisfies $\widehat{\tau}_{c\delta}(\mathcal{T}'_1, \mathcal{T}'_2) = \widehat{\tau}_\delta(\mathcal{T}_1, \mathcal{T}_2)$. Hence the time complexity of our algorithm to approximate the Gromov-Hausdorff distance $\delta_{GH}(\mathcal{T}'_1, \mathcal{T}'_2)$ for scaled metric-trees \mathcal{T}'_1 and \mathcal{T}'_2 **remains the same** as that for approximating the Gromov-Hausdorff distance $\delta_{GH}(\mathcal{T}_1, \mathcal{T}_2)$.

6 Concluding Remarks

In this paper, by re-formulating the interleaving distance, we developed the first FPT algorithm to compute the interleaving distance *exactly* for two merge trees, which in turn leads to an FPT algorithm to approximate the Gromov-Hausdorff distance between two metric trees.

We remark that the connection between the Gromov-Hausdorff distance and the interleaving distance is essential, as the interleaving distance has more structure behind it, as well as certain “order” (along the function associated to the merge tree), which helps to develop dynamic-programming type of approach. For more general metric graphs (which

represent much more general metric spaces than trees), it would be interesting to see whether there is a similar relation between the Gromov-Hausdorff distance of metric graphs and the interleaving distance between the so-called Reeb graphs (generalization of merge trees).
