Preface

The papers in this volume were presented at the 11th Innovations in Theoretical Computer Science (ITCS 2020) conference. The conference was held at the University of Washington in Seattle, WA, USA, January 12-14, 2020. ITCS seeks to promote research that carries a strong conceptual message, for instance, introducing a new concept or model, opening a new line of inquiry within traditional or cross-interdisciplinary areas,introducing new techniques, or making novel connections between existing areas and ideas. The conference format is single-session and aims to promote the exchange of ideas between different areas of theoretical computer science and with other disciplines. The call for papers welcomed all submissions, whether aligned with current theory of computation research directions or deviating from them. A record 204 submissions were received. Of these, the program committee selected 86 papers. I would like to thank the authors of all submissions, whether accepted or not, for their interest in ITCS.

The program committee consisted of 32 members (plus the chair): Nikhil Bansal, CWI + TU Eindhoven; Nir Bitansky, Tel-Aviv University; Clement Canonne, Stanford; Timothy Chan, University of Illinois at Urbana-Champaign; Edith Cohen, Google and Tel-Aviv University; Shaddin Dughmi, University of Southern California; Sumegha Garg, Princeton; Ankit Garg, Microsoft research; Ran Gelles, Bar-Ilan University; Elena Grigorescu, Purdue; Tom Gur, University of Warwick; Sandy Irani, UC Irvine; Dakshita Khurana, University of Illinois at Urbana-Champaign; Antonina Kolokolova, Memorial University of Newfoundland.; Pravesh Kothari, Carnegie Mellon University; Rasmus Kyng, Harvard; Katrina Ligett, Hebrew University; Nutan Limaye, IIT Bombay; Pasin Manurangsi, UC Berkeley; Tamara Mchedlidze, Karlsruhe Institute of Technology; Dana Moshkovitz, UT Austin; Jelani Nelson, UC Berkeley; Merav Parter, Weizmann Institute; Krzysztof Pietrzak, IST Austria; Elaine Shi, Cornell; Piyush Srivastava, Tata Institute of Fundamental Research, Mumbai; Li-Yang Tan, Stanford; Madhur Tulsiani, TTIC; Gregory Valiant, Stanford; Virginia Vassilevska Williams, MIT; Ronald de Wolf, CWI and University of Amsterdam; David Woodruff, Carnegie Mellon University.

I wish to express my heartfelt thanks to them for agreeing to join the committee as well as for investing a great deal of time and effort to evaluate the submissions. I am also grateful to the many subreviewers who assisted with the reviewing process. The local organizer was Shayan Oveis Gharan from University of Washington. I would like to thank him very much for his service. I'm also grateful to Umesh Vazirani, chair of the ITCS Steering Committee, and the entire Steering Committee for their help and guidance in shaping the format of the conference. Finally, I would like to thank all the presenters and the audience at ITCS for making ITCS a wonderful experience.

Abstract

In this paper, we prove a general hardness amplification scheme for optimization problems based on the technique of direct products.

We say that an optimization problem Π is direct product feasible if it is possible to efficiently aggregate any k instances of Π and form one large instance of Π such that given an optimal feasible solution to the larger instance, we can efficiently find optimal feasible solutions to all the k smaller instances. Given a direct product feasible optimization problem Π, our hardness amplification theorem may be informally stated as follows:

If there is a distribution $\mathcal{D}$ over instances of Π of size n such that
every randomized algorithm running in time $t(n)$ fails to solve
Π on $\frac{1}{\alpha(n)}$ fraction of inputs sampled from $\mathcal{D}$,
then, assuming some relationships on $\alpha(n)$ and $t(n)$,
there is a distribution $\mathcal{D}'$ over instances of Π of size $O(n \cdot \alpha(n))$ such that
every randomized algorithm running in time $\frac{t(n)}{poly(\alpha(n))}$ fails to solve
Π on $99/100$ fraction of inputs sampled from $\mathcal{D}'$.

As a consequence of the above theorem, we show hardness amplification of problems in various classes such as NP-hard problems like Max-Clique, Knapsack, and Max-SAT, problems in P such as Longest Common Subsequence, Edit Distance, Matrix Multiplication, and even problems in TFNP such as Factoring and computing Nash equilibrium.

Acknowledgements We would like to thank Amir Abboud, Irit Dinur, and Eylon Yogev for discussions and comments.

1 Introduction

The widely believed conjecture $\mathsf{P} \neq \mathsf{NP}$ asserts that the class NP cannot be decided efficiently on the worst-case. That is, no polynomial time algorithm can decide the satisfiability of a CNF formula on *every* instance. However, the worst case hardness of NP still does not clarify its average-case hardness: how hard is to decide the satisfiability on a uniformly random instance.

Studying the average-case hardness of NP has a two-fold motivation. First, it may provide a more meaningful explanation than worst-case complexity about the intractability of NP-hard instances actually encountered in practice. In other words, if NP is hard only on the worst-case, then the theory of worst-case complexity that has been extensively developed over the last fifty years, might not be a good reflection of reality. Second, hardness on average is the cornerstone of modern cryptography as the security of any nontrivial cryptosystem requires some computational problem to be average-case hard (for some nice distribution). Additionally, showing average-case hardness for functions is a stepping stone towards proving strong derandomization results and the construction of pseudorandom generators.

The study of hardness amplification is the task of connecting the worst-case and average-case hardness. More specifically, based on a worst-case hardness (assumption) one would like to prove the average-case hardness of the problem.

1.1 Utopic Theorem of Hardness Amplification

A utopic theorem in the context of hardness amplification would assert that if a function is hard in the worst-case then it implies the average-case hardness for the same function against algorithms with essentially the same running time complexity. More formally it would look as follows:

▶ **Utopic Theorem 1** (A Utopic Hardness Amplification Theorem). *Let $\{f_n\}_{n\in\mathbb{N}}$ be a family of functions. Assume that every algorithm running in time $t(n)$, fails to compute f_n on at least $\gamma(n)$ fraction of inputs. Then there exists a family $\{g_n\}_{n\in\mathbb{N}}$ of functions, such that every algorithm running in time $t'(n)$, fails to compute g_n on at least $\gamma'(n)$ fraction of inputs.*

Ideally, we would like to achieve the above amplification for the following parameters[1]

1. $\gamma(n) = O(1/2^n)$ *and* $\gamma'(n) = 1/2 - O(1/2^n)$,
2. $t'(n) \approx t(n)$,
3. $\{f_n\}_{n\in\mathbb{N}} = \{g_n\}_{n\in\mathbb{N}}$.

We briefly elaborate here why we would like the above three setting of parameters in our utopic hardness amplification theorem. Item 1 would yield a worst-case to average-case reduction, and therefore extend all the lower bounds and hardness results that have been achieved in the theory of worst-case complexity for f to the average-case complexity of g. In fact, achieving $\gamma'(n) = 1/2 - O(1/2^n)$ would imply that no algorithm running in time $t'(n)$ can do much better than randomly guessing the output. Item 2 would imply that our worst-case complexity lower bounds meaningfully translate to lower bounds in the average-case. Item 3 expresses the notion of self-reducibility: if we are interested in understanding the average complexity of a problem, our hardness amplification theorem should enable us to do so by analyzing the worst-case complexity of the *same* problem. In summary, obtaining a hardness amplification result satisfying the three items is in a sense an attempt to bridge the gap between theory and practice. Finally, we remark that our utopic theorems would gain more importance if the family of functions for which we show hardness amplification are natural (in some broad sense).

Specifically, if we prove such a theorem for the family of deciding satisfiability of CNF formulas, then we get that the assumption that P $\neq$ NP implies that every polynomial time algorithm fails to decide satisfiability on slightly more that half of the CNF formulas –

[1] In order to succinctly specify the desirable parameters of a hardness amplification theorem, we assume here that f_n and g_n are Boolean functions.

a highly non-trivial and very desirable result that would pave the way for the construction of one-way functions from (weak) worst-case assumptions. However, as we wake up from the dream of a utopia, one may wonder if such a result can even be achieved [7].

Remarkably, nearly three decades ago, Lipton [26, 9] proved the above type of (utopic) theorem for the function of computing the permanent (a #P-complete problem) against probabilistic polynomial time algorithms. Trevisan and Vadhan [32] following a line of works [3, 24, 29] proved such an amplification result for PSPACE and almost proved such an amplification result for the class EXP (they couldn't achieve Item 3). For the class NP we are far from proving a strong hardness amplification result, and there are some known barriers while trying to convert worst-case NP-hardness into average-case hardness (see e.g. [6]). More recently, strong hardness amplification results have been proved for functions in P [4, 16, 17]. We also note that hardness amplification results have also been shown for one-way functions [34, 15, 5].

Given the above state-of-the-art picture, we raise a few natural questions and address them in this paper. There are many problems that are hard in the worst-case but easy on average. For example, 3-coloring is a well-known NP-hard problem, but it is an easy exercise to show that it can be solved in linear time with high probability on a random graph. This motivates us to distinguish within worst-case hard problems as to which of them remain hard on average. One way to go about this task is to identify which worst-case hard problem admits a hardness amplification theorem.

For which problems can we amplify hardness?
Can we identify a mathematical structure that allows us to amplify hardness?

The latter question has been implicitly addressed in literature (for example, if the problem has algebraic structure like in the case of computing permanent [26] or counting k-cliques [17]), but are quite specific and not broad enough to capture the class of problems that we believe are hard on average. In Section 1.2.1 we address the above two questions.

Next, we turn our attention to NP-hard problems. In a beautiful paper, O'Donnell [28] initiated the study of (non-uniform) hardness amplification in NP. His result was improved by [19] who showed that if for some function in NP (with n inputs) we have that any $s(n)$ size circuit fails to compute the function correctly on $1/poly(n)$ fraction of the inputs then, the hardness can be amplified to show that there is some function in NP such that any $s(\sqrt{n})^{\Omega(1)}$ size circuit fails to compute the function on $1/2 - 1/s(\sqrt{n})^{\Omega(1)}$ fraction of the inputs. However, the best uniform hardness amplification results (against algorithms as opposed to circuits) that have been achieved do not match the parameters of [19]: Trevisan [31, 8] improving on his previous work [30] showed that we can amplify hardness from $1/poly(n)$ to $1/2 - 1/polylog(n)$ for NP against randomized polynomial time algorithms (later extended to deterministic algorithms in [18]). However, it is important to note that all these hardness amplification results are for decision problems, and this leads us to our next question, do we gain anything by moving to search problems, or more precisely to the focus of this paper, to optimization problems?

Can we improve our hardness amplification results for optimization problems?
Can we prove stronger uniform hardness amplification results for MaxSAT*?*

Arguably, optimization problems are as natural as decision problems, but are strictly harder from the point of view of computational complexity. Does this mean we can either give simpler proofs of hardness amplification for optimization problems or prove stronger results? We address the above questions in Section 1.2.2.

We now shift our focus to the class P. As mentioned earlier, we have strong worst-case to average-case results established for problems in P [4, 17]. The drawback however is that they are all for counting problems. This is indeed inherent as the underlying technique these works use are the same as the one used to show worst-case to average-case reduction for the permanent problem. While counting the number of k-cliques (the problem considered in [17]) is a natural problem, and therefore hardness amplification for that problem is interesting, it still leaves the door open for proving hardness amplification for the search problem of just finding one k-clique in a graph (an easier problem and thus harder to amplify hardness).

Can we prove hardness amplification results for natural search problems in P*?*

Moreover, there is a barrier [1] to using the algebraic techniques of [4, 17] to obtain hardness amplification for important problems studied in fine-grained complexity such as computing the Longest Common Subsequence (LCS) and Edit Distance (Edit-Distance) for a pair of strings. In particular, if these string problems can be represented using low-degree polynomials, then we could obtain small speedups by using the polynomial method [11], which would imply new circuit lower bounds [2]. This suggests we might need to look beyond these algebraic techniques for proving hardness amplification for these string problems. Is there a different technique to prove hardness amplification in P? We address these aforestated questions in Section 1.2.3.

1.2 Our Results

Our main contribution is a general hardness amplification theorem for optimization problems which we state in Section 1.2.1. Next, we apply our main theorem to various problems. In Section 1.2.2 we state our hardness amplification theorems for various NP-hard problems such as Knapsack and MaxSAT. In Section 1.2.3 we state our hardness amplification theorems for various string problems in P such as LCS and Edit-Distance. Finally, in Section 1.2.4 we state our hardness amplification theorems for various problems in TFNP (believed to not be in P) such as Factoring and computing Nash equilibrium.

1.2.1 Hardness Amplification of Optimization Problems

Aggregation is a key tool in the field of hardness amplification. If a function f is hard to compute on a tiny fraction of the domain, then, intuitively, computing multiple instances of f in one shot should be hard on a larger fraction of the inputs. More formally, for a function $f : [N] \to \Sigma$ and $k \in \mathbb{N}$, its k-direct product encoding is defined as a function $f^{(k)} : [N]^k \to \Sigma^k$ mapping each tuple $(x_1, \ldots, x_k)$ into $(f(x_1), \ldots, f(x_k))$. Using standard techniques one can show a "direct product theorem" stating that if f is hard against $t(n)$ running-time algorithms on $\alpha(n)$-fraction of the domain, then $f^{(k)}$ is hard against $t'(n)$ running-time algorithms on $\approx k \cdot \alpha(n)$-fraction of its domain. But in order to utilize such a direct product result, we need to be able to stitch k-instances into a single (larger) instance. To address this task we introduce the following notion of direct product feasibility.

▶ **Definition 1** (Direct Product Feasibility; Informal statement)**.** *Let* Π *be an optimization problem. We say that* Π *is* (S, T)*-direct product feasible*[2] *if the exists a pair of deterministic algorithms* (Gen, Dec) *satisfying the following:*

[2] In the formal definition of direct product feasibility, it is defined for a pair of optimization problems (Π, Λ) for technical reasons which will be addressed later in Section 1.2.3. In the case $\Pi = \Lambda$ we formally call it as self direct product feasible and this notion coincides with the informal definition given here. For most of the applications given in this paper, self direct product feasibility notion suffices.

- Gen *takes as input* k *instances* $(I_1, \ldots, I_k)$ *of* Π *each of size* n *and outputs an instance* I' *of* Π *of size* $S(n,k)$.
- Dec *gets as input* $(I_1, \ldots, I_k)$, *the instance* I' *which is the output of* Gen *on input* $(I_1, \ldots, I_k)$, *an optimal solution for* I', *and* $i \in [k]$. *It outputs an optimal solution for the instance* I_i.
- *The running time of* Gen *and* Dec *is bounded by* $T(n,k)$.

Our main theorem is about hardness amplification for an arbitrary direct product feasible problem Π. In particular we show that if Π is hard against $t(n)$ running time randomized algorithms on a tiny fraction of the domain, then Π is hard on a much larger fraction of the domain against randomized algorithms with a similar running time.

▶ **Theorem 2** (Informal Statement). *Let* Π *be* (S,T)*-direct product feasible. Let* $\mathcal{D}(n)$ *be an efficiently samplable distribution over the instances of* Π *of size* n. *Assume the following:*

- *Any* $t(n)$ *running-time algorithm with success probability at least* $2/3$ *fails to compute an optimal solution on at least* $\alpha(n)$*-fraction of the inputs sampled from* $\mathcal{D}$.
- *Fix* $k = poly((\alpha(n))^{-1})$. *Then we have* $T(n,k) = o(t(n))$.
- *We can (deterministically) decide the optimality of a given solution to any instance in* $o(t(n))$ *time.*

Then there exists an efficiently samplable distribution $\mathcal{D}'(S(n,k))$ *over instances of* Π *of size* $S(n,k)$ *such that every* $t(n)$ *running-time algorithm with success probability at least* $2/3$ *fails to compute an optimal solution on at least* 99% *of the inputs sampled from* $\mathcal{D}'$.

Naturally, the distribution $\mathcal{D}'$ is defined as follows: Draw k independent samples $I_1, \ldots, I_k$ from $\mathcal{D}$, and output $\mathsf{Gen}(I_1, \ldots, I_k)$. The proof of our main theorem is based on a reduction using an oracle access to an algorithm that solves $\mathcal{D}'$ on 1% of the inputs, we convert it into an algorithm solving $\mathcal{D}$ on greater than $1 - \alpha(n)$ fraction of the inputs. The reduction is uniform, so in case that the algorithms $(\mathsf{Gen}, \mathsf{Dec})$ are uniform we get a uniform hardness amplification result.

Another key point is that our hardness amplification is a self-reduction, i.e., if a problem is somewhat hard against one distribution $\mathcal{D}$, then the same problem is much harder against a different distribution $\mathcal{D}'$.

To the best of our knowledge, this is the first result to study hardness amplification for optimization problems. It opens avenues to prove results in various subclasses as we will see in subsequent subsections.

1.2.2 Hardness Amplification for NP-hard Problems

In the NP world, we generalize the results of [28, 31] to optimization problems. In particular we show that if MaxSAT is hard to solve on $1/poly(n)$ fraction of the inputs of samples drawn from some samplable distribution $\mathcal{D}$. Then there exists a samplable distribution $\mathcal{D}'$ such that solving MaxSAT on $\mathcal{D}'$ is hard on at least $99/100$-fraction of the samples.

▶ **Theorem 3** (Informal Statement). *Let* $\mathcal{D}(n)$ *be a distribution over* 3-CNF *formulas with* n *variables and* $poly(n)$ *clauses, such that for every randomized algorithm* $\mathcal{A}$ *running in time* $poly(n)$, *we have:*

$$\Pr_{\Psi \sim \mathcal{D}}[\mathcal{A} \text{ finds a optimal assignment for } \Psi \text{ w.p. } \geq 2/3] \leq 1 - 1/poly(n).$$

Then there exists a distribution $\mathcal{D}'(n')$ over 3-CNF *formulas with n' variables poly(n') clauses, such that for every randomized algorithm $\mathcal{A}'$ running in time poly(n'), we have:*

$$\Pr_{\Psi' \sim \mathcal{D}'}[\mathcal{A}' \text{ finds a optimal assignment for } \Psi' \text{ w.p.} \geq 2/3] \leq 0.01.$$

Moreover, if $\mathcal{D}(n)$ is poly(n)-samplable then $\mathcal{D}'(n')$ is poly(n')-samplable.

Observe that the failure probability on $\mathcal{D}'$ is much larger than in [28, 31] and can even tend to 0 for a proper choice of our parameters. This can be achieved since we deal with optimization problems instead of decision problems.

We also remark that our reduction and the proof correctness are much simpler, and in particular we do not rely the hard core set lemma [20], a powerful and non-trivial key tool in the previous known proofs.

Our result easily extends into other NP-hard problems such as finding the largest clique in a graph, or finding smallest dominating set or vertex cover of a graph, etc.

However, there are other NP-hard problems for which establishing a hardness amplification result through Theorem 2 is not easy. A special highlight is that of proving such a result for the Knapsack problem, as it isn't immediately clear if it's direct product feasible for reasonable range of parameters. This is because, for the Knapsack problem, when we aggregate instances in the natural way, optimal solutions of one instance may interfere with other instances. Nonetheless, with some care, the direct product feasibility of Knapsack problem was established.

The Exponential Time Hypothesis (ETH) [22, 23, 10] asserts that that we cannot decide whether a given 3-CNF is satisfiable in time which is sub-exponential in the number of variables. That is a worst case assumption, and it raises a natural question arises: Can we prove stronger hardness amplification result based on ETH? In fact, can we prove a worst case to an average case hardness amplification based on ETH?

Our next theorem is a step towards proving such a worst-case to an average case reduction for MaxSAT.

▶ **Theorem 4** (Informal Statement). *Let $\mathcal{D}(n)$ be a distribution over* 3-CNF *instances with n variables and $O(n)$-clauses, such that for every randomized algorithm $\mathcal{A}$ running in time $2^{o(n)}$, we have:*

$$\Pr_{\Psi \sim \mathcal{D}}[\mathcal{A} \text{ finds an optimal assignment for } \Psi \text{ w.p.} \geq 2/3] \leq 1 - \frac{1}{2^{o(n)}}.$$

Then there exists a distribution $\mathcal{D}'(n')$ over 3-CNF *instances with n' variables and $2^{o(n')}$ clauses, such that for every polynomial time randomized algorithm $\mathcal{A}'$, we have:*

$$\Pr_{\Psi' \sim \mathcal{D}'}[\mathcal{A}' \text{ finds an optimal assignment for } \Psi' \text{ w.p.} \geq 2/3] \leq 0.01.$$

Heally et al. [19] proved a similar result for the non-uniform case. Our result is stronger in the sense that we use a weaker assumption: we rely on the ETH that is assuming that every *uniform* algorithm fails on $1/2^{o(n)}$-fraction of inputs. While Heally et al. use similar assumption against non-uniform algorithms.

1.2.3 Hardness Amplification in P

We investigate hardness amplification in P and can show results for string problems, such as LCS and Edit-Distance, which were not possible in previous works.

▶ **Theorem 5** (Informal statement). *Fix $\varepsilon > 0$. Let $\mathcal{D}(n)$ be an efficiently samplable distribution over the instances of* LCS/Edit-Distance *of length n. Assume that any $n^{2-\varepsilon}$ running-time algorithm with success probability at least $2/3$ fails to compute an optimal alignment on at least $1/n^{o(1)}$-fraction of the inputs sampled from $\mathcal{D}$. Then for some $\varepsilon' > 0$ there exists an efficiently samplable distribution $\mathcal{D}'(n^{1+o(1)})$ over instances of* LCS/Edit-Distance *of size $n^{1+o(1)}$ such that every $n^{2-\varepsilon'}$ running-time algorithm with success probability at least $2/3$ fails to compute an optimal solution on at least 99% of the inputs sampled from $\mathcal{D}'$.*

Recall from earlier in this section that Abboud [1] had pointed out a barrier to obtaining a result such as above, through algebraic techniques. Another similarity search problem that is studied along with LCS and Edit-Distance, is the problem of computing the Fréchet distance between two (discrete) curves. Strangely, this problem resists all natural approaches to show that it is direct product feasible. Therefore, it is an interesting question as to whether it is possible to show that it is direct product feasible (for relevant range of parameters) or whether it is a candidate for a problem that is not direct product feasible.

Additionally, we show hardness amplification for a very different kind of problem, that of computing the product of two matrices. We highlight this problem, as it does not directly follow from our main theorem (i.e., Theorem 2). Elaborating, a detail that was brushed under the carpet while discussing Theorem 2 was that, given an instance of an optimization problem and a candidate solution, we need to able to efficiently compute the value of the objective of the candidate solution for that instance. This naturally holds for all the problems considered in this paper except the task of computing the product of two matrices, i.e., we do not know a way to *deterministically* verify if the product of two matrices is equal to a given third matrix, which is significantly faster than actually multiplying the two given matrices and checking if it's equal to the third matrix [25, 33]. Nonetheless, we modify the proof of Theorem 2 to handle this issue.

1.2.4 Hardness Amplification in TFNP

Total problems (with not necessarily efficient verification of totality) are essentially equivalent to Optimization problems. The class TFNP is special as it is in an informal sense the intersection of Search NP and Optimization problems. Problems in TFNP capture problems in various areas such as game theory, cryptography, computational geometry, etc. We show that our general theorem can be applied to TFNP problems as well, and as an example show it for the Factoring problem and the End of a Line problem. The latter hardness amplification result directly implies the hardness amplification of various problems in game theory such as computing an approximate Nash equilibrium.

1.3 Open Problems

Our work leaves open several questions. We state a few of them below.

1.3.1 Stronger Hardness Amplification

In Theorem 4 we showed that if MaxSAT is hard to compute on $1 - 1/2^{o(n)}$-fraction of inputs for sub-exponential time algorithm, then there exists a distribution on which it is hard on a constant fraction of inputs for algorithms running in time $n^{\omega(1)}$. A natural open question is the following:

Can we improve Theorem 4 and get hardness amplified against sub-exponential time algorithms (instead of super-polynomial time algorithms)?

It seems to us that derandomized direct product theorems may serve as the key tool to address the above question (for example, see [21]). In particular, if one can prove a (strongly) derandomized version of [14] then it might be possible to both aggregate sub-exponentially many instances succinctly and sample from the (derandomized) direct product distribution efficiently.

1.3.2 Direct Product Feasibility

In this paper, we were able to show direct product feasibility for certain problems quite easily (for example, see Theorems 3 and 5), but had to work harder to prove them for some other problems (for example, Knapsack and Matrix Multiplication), and in some problem(s) were unable to establish the property of direct product feasibility (for example, computing Fréchet distance). This leads us to the following question.

Can we pinpoint what property of a problem makes it possible to establish direct product feasibility?

1.3.3 Gap Amplification versus Hardness Amplification

Direct Product theorems are key ingredients for both gap amplification and hardness amplification. Also, there are many philosophical similarities in the techniques known in literature of the aforementioned two kinds of amplifications. Thus we can ask the following (ambitious) question:

Can we obtain a trade-off between gap amplification and hardness amplification?

In particular, can we show that if one problem is hard to approximate on worst case within some factor $\alpha > 0$, then it is hard to approximate within a factor $\alpha/100$ on average? We note here that Feige [13], did answer the converse of this question, i.e., he used average case hardness assumptions to prove hardness of approximation results for various problems in NP.

It seems to us that analyzing the operation of performing a small perturbation on the given instance may be the right direction to proceed. Elaborating, consider a (worst case) hard distribution over gap instances of some problem. If we build a new distribution, which samples from the aforementioned distribution, then performs a small perturbation on the sampled gap instance, and outputs the perturbed instance, then we would still retain most of the gap in the instance sampled from the new distribution, but on the other hand, the fraction of instances on which it is hard to solve the problem should increase significantly. It would be interesting if this intuition/approach could be made to work.

A related question is to ask if we can improve our result in Theorem 4 (for example, by making progress on the question detailed in Section 1.3.1) using Gap-ETH [12, 27] (instead of ETH)?

1.3.4 Average Case Hard Problems in P

In this paper, we looked at average case hardness of some problems in P against some efficiently sampleable distribution but one can ask if we can achieve more.

Can we show for some natural problem in P *that it is hard to solve for the uniform distribution?*

Another important question stemming from cryptography [4] is whether we can construct a *fine-grained* one way function from worst case assumptions?

2 Proof Overview

We provide a proof overview for our hardness amplification result for the problem of finding the maximum clique in a graph and then in the subsequent section we will show how our general result (i.e., Theorem 2) would follow.

2.1 Hardness Amplification for Max Clique

To illustrate the main ideas behind our scheme let us focus on MaxCLIQUE, the problem of finding the largest clique in a given graph G.

Assume the existence of a distribution $\mathcal{D}$ over graphs on n vertices which is somewhat hard to compute. That is for every *randomized* algorithm $\mathcal{A}$ running in time $poly(n)$, we have

$$\Pr_{G\sim\mathcal{D}}[\mathcal{A} \text{ finds max-clique in } G \text{ w.p. } \geq 2/3] \leq 1 - 1/n. \tag{1}$$

We would like to prove the existence of a new distribution $\mathcal{D}'$ over graphs on $poly(n)$ vertices which is much harder to compute. That is, for every randomized algorithm $\mathcal{A}'$ running in time $poly(n')$, we have:

$$\Pr_{G'\sim\mathcal{D}'}[\mathcal{A}' \text{ finds max-clique in } G' \text{ w.p. } \geq 2/3] \leq 0.01. \tag{2}$$

Moreover if $\mathcal{D}$ is $poly(n)$-time samplable, then so is $\mathcal{D}'$.

Construction of New Distribution

$\mathcal{D}'$ samples a graph H as follows:

1. Independently sample $G_1, \ldots, G_k$ from $\mathcal{D}$, where $k = poly(n)$.
2. Define $V(H) = V(G_1) \dot\cup \cdots \dot\cup V(G_k)$.
3. For every $i \in [k]$, connect the vertices in $V(G_i)$ using the original edges in G_i.
4. For every $i, j \in [k]$ such that $i \neq j$, insert all the possible edges between G_i and G_j.
5. Output H.

Clearly, if $\mathcal{D}$ is $poly(n)$-time samplable, then so is $\mathcal{D}'$. Now assume for sake of contradiction, that there exists $\mathcal{A}'$ running in time $poly(n')$, violating Equation (2). We show the existence of an algorithm $\mathcal{A}$ running in time $poly(n)$ violating Equation (1).

The algorithm $\mathcal{A}$ on input graph G with n vertices is defined as follows:

1. Let $\mathcal{S}$ be an empty set.
2. Repeat following $O(n)$ times.
   a. Pick randomly $i \in [k]$.
   b. Independently sample $G_1, \ldots, G_{i-1}, G_{i+1}, \ldots G_k$ from $\mathcal{D}$.
   c. Construct H setting G_i to be G.
   d. Find clique in H using $\mathcal{A}'$.
   e. Restrict clique in H to the vertices of G and add it to $\mathcal{S}$.
3. Output the largest clique in $\mathcal{S}$.

Clearly, the running time of $\mathcal{A}$ is $poly(n)$, as $n' = poly(n)$ and the running time of $\mathcal{A}'$ is $poly(n')$. Our first observation is that for any graph H constructed by $\mathcal{A}$, and for every $i \in [k]$ the restriction of a maximal clique in H into G_i, is a maximal clique for G_i.

Let $\mathcal{A}_0$ be one iteration of step 2 of $\mathcal{A}$. If we show that $\mathcal{A}_0$ outputs maximum clique w.p. $\Omega(1/n)$ on $1 - 1/n$ fraction of samples from $\mathcal{D}$ then, $\mathcal{A}$ outputs maximum clique w.p. $2/3$ on $1 - 1/n$ fraction of samples from $\mathcal{D}$.

Now, observe that if instead of planting the given input graph G as the i-th subgraph of H, we were planting a uniformly random sample of $\mathcal{D}$, then we get a graph H which is drawn according to $\mathcal{D}'$. Consequently, if that was the case, then the success probability of $\mathcal{A}_0$ was equal the probability of $\mathcal{A}'$ and we were done.

Let $\mathcal{D}'_G$ denote the marginal distribution over H, where the graph G is planted at a random coordinate $i \in [k]$. We conclude the proof by showing that for $1 - 1/n$-fraction of instances G drawn from $\mathcal{D}$ we have:

$$\begin{aligned}&\Pr_{G' \sim \mathcal{D}'_G}\left[\mathcal{A}' \text{ finds max-clique in } G' \text{ w.p. } \geq 2/3\right] \\ \geq\ &\frac{\Pr_{G' \sim \mathcal{D}'}\left[\mathcal{A}' \text{ finds max-clique in } G' \text{ w.p. } \geq 2/3\right]}{2}.\end{aligned}$$

Towards this goal we use a result by Feige and Kilian [14] that was proven in the context of parallel repetition. Under minor manipulations their result can be stated as follows:

Let X be a universe and $\mathcal{T}$ be a distribution over X. Let $f : X^k \to \{0,1\}$. Define

$$\mu = \mathop{\mathbb{E}}_{x^k \sim \mathcal{T}^k}\left[f\left(x^k\right)\right],$$

$$\mu_x = \mathop{\mathbb{E}}_{i \in [k], x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_k \sim \mathcal{T}}\left[f(x_1, \ldots, x_{i-1}, x, x_{i+1}, \ldots x_k)\right].$$

$$\Pr_{x \sim \mathcal{T}}\left[|\mu_x - \mu| \geq k^{-1/6}\right] \leq k^{-1/6}, \tag{3}$$

To conclude the result, set X as the set of graphs with n vertices, and $\mathcal{T}$ be the distribution $\mathcal{D}$. We have $\mathcal{D}' = \mathcal{D}^k$. Define $f : X^k \to \{0,1\}$ by:

$$f(G') = 1 \iff \mathcal{A}' \text{ finds a maximal clique in } G \text{ w.p. } \geq 2/3.$$

In these notations,

$$\begin{aligned}\mu &= \Pr_{G' \sim \mathcal{D}'}\left[\mathcal{A}' \text{ finds max-clique in } G' \text{ w.p. } \geq 2/3\right] \\ \mu_x &= \Pr_{G' \sim \mathcal{D}'_G}\left[\mathcal{A}' \text{ finds max-clique in } G' \text{ w.p. } \geq 2/3\right].\end{aligned}$$

By an application of (3), and a proper choice of k, we get that for all but at most $k^{1/6}$-fraction of graphs G drawn according to $\mathcal{D}$, the success probability of $\mathcal{A}'$ on $\mathcal{D}'_G$ is $\Omega(n)$, as claimed.

2.2 Abstraction

In the previous subsection, we showed the main ingredients used for proving hardness amplification for the task of finding a maximal clique in a given graph. What were the properties of MaxCLIQUE that we utilized to prove the result?

One property that we used was that if we are given k input graphs $G_1, \ldots, G_k$, there exists an efficient way to construct a large graph H such that a maximal clique in H induces a maximal clique on each of the graphs G_i. The second property was that given a maximal clique in H there exists an efficient algorithm to construct a maximal clique on each of the graphs G_i.

These two properties are captured in Definition 1: The first property of a problem Π being Direct Product feasible is the existence of an efficient algorithm Gen stitching k instances $I_1, \ldots, I_k$ of Π into a larger instance I' of Π, such that: an optimal solution for I' induces an optimal solution for each of the instances I_i. The second property the existence of an efficient algorithm Dec converting an optimal solution for I' into an optimal solution of I'.

Once we show Π is Direct Product feasible then the rest of the proof goes through. Indeed, assuming the existence of a distribution $\mathcal{D}$ on instances of Π for which any efficient algorithm fails to compute on $1 - 1/n$ fraction of inputs, we define the distribution $\mathcal{D}', {\mathcal{D}'}_I$ as follows:

- $\mathcal{D}'$ is the k-product distribution of $\mathcal{D}$, where we pick k random samples from $\mathcal{D}'$ independently.
- ${\mathcal{D}'}_I$ is the distribution where we pick uniformly at random $i \in [k]$, and independently sample $I_1, \ldots, I_{i-1}, I_{i+1}, \ldots I_k$ from $\mathcal{D}$. Finally, we construct I' by setting I_i to be I.

Now we can use [14] to show that for most instances $I \sim \mathcal{D}$ to connect the success probability of $\mathcal{A}'$ on $\mathcal{D}'$ and ${\mathcal{D}'}_I$, to conclude the proof.

Remark about Direct Product results and Hardness Amplification

The direct product lemma at the heart of most hardness amplification results is the XOR lemma [34]. But here we critically use the fact the problem is total, so at the surface at least, our results are incomparable to the hardness amplification results for NP and EXP obtained via XOR lemmas.

Smooth and Strong PCPs

Orr Paradise
University of California, Berkeley, CA, USA

orrp@eecs.berkeley.edu

Abstract

Probabilistically checkable proofs (PCPs) can be verified based only on a constant amount of random queries, such that any correct claim has a proof that is always accepted, and incorrect claims are rejected with high probability (regardless of the given alleged proof). We consider two possible features of PCPs:

- A PCP is *strong* if it rejects an alleged proof of a correct claim with probability proportional to its distance from some correct proof of that claim.
- A PCP is *smooth* if each location in a proof is queried with equal probability.

We prove that all sets in $\mathcal{NP}$ have PCPs that are both smooth and strong, are of polynomial length, and can be verified based on a constant number of queries. This is achieved by following the proof of the PCP theorem of Arora, Lund, Motwani, Sudan and Szegedy (*JACM*, 1998), providing a stronger analysis of the Hadamard and Reed–Muller based PCPs and a refined PCP composition theorem. In fact, we show that any set in $\mathcal{NP}$ has a smooth strong *canonical* PCP of Proximity (PCPP), meaning that there is an efficiently computable bijection of $\mathcal{NP}$ witnesses to correct proofs. This improves on the recent construction of Dinur, Gur and Goldreich (*ITCS*, 2019) of PCPPs that are strong canonical but inherently non-smooth.

Our result implies the hardness of approximating the satisfiability of *"stable"* 3CNF formulae with *bounded variable occurrence*, where *stable* means that the number of clauses violated by an assignment is proportional to its distance from a satisfying assignment (in the relative Hamming metric). This proves a hypothesis used in the work of Friggstad, Khodamoradi and Salavatipour (*SODA*, 2019), suggesting a connection between the hardness of these instances and other stable optimization problems.

Acknowledgements This work was done during my time at the Weizmann Institute of Science. It originated in a question of Irit Dinur, and I am grateful to her. My heartfelt appreciation goes to Oded Goldreich for guiding me through all stages of this work, from communication of Irit's question to me and up to this very write-up. Many thanks to Madhu Sudan and Oded for providing the vector-valued low-degree test (Appendix C). I also thank Elad Granot and Roei Tell for the helpful discussions, and Amey Bhangale, Tom Gur, and Eylon Yogev for suggesting improvements to the write-up. I wish to thank an anonymous reviewer for pointing out an issue with the smoothness of the construction of Section 5.3 as it appeared in a previous version.

1 Introduction

A *probabilistically checkable proof system (PCP)* offers verification based only on a tiny amount of random locations in an alleged proof. It is *complete* and *sound*: correct claims have a proof that is always accepted, and incorrect claims are rejected with high probability

regardless of the alleged proof. The study of these systems culminated in the PCP theorem ([3, 2]), stating that membership in any set in $\mathcal{NP}$ can be verified by reading a *constant* number of random locations from a PCP of *polynomial* length.

While soundness guarantees that incorrect claims are rejected with high probability, what about *incorrect proofs* for *correct claims*? By definition, a proof of a claim is incorrect if it is not always accepted by the probabilistic verifier. But how often is it rejected? In a *strong* PCP, an alleged proof is rejected with probability proportional to its distance from a correct proof.

Strong PCPs are intuitively appealing: simply put, it is desirable to seek verification procedures that are sensitive to the correctness of the given claim *as well as the given proof*. From the perspective of property testing, the verifier of a strong PCP can be viewed as a (proximity oblivious) tester for the property of being a correct proof. In addition, strong PCPs have been used to construct better locally testable codes (see Section 1.3.1).

One immediately wonders if a *strong PCP theorem* holds as well; that is, whether any set in $\mathcal{NP}$ admits a *strong* PCP of polynomial length and constant query complexity. Dinur et al. answer this in the positive in a recent work [10],[1] however, their construction is inherently *non-smooth*, in the sense that certain locations in the proof are much more likely to be read than others.

A PCP is smooth if each location in its proof is equally likely to be read by the verifier. We expect natural PCPs to have smooth verifiers since, intuitively-speaking, we expect the verifier to treat all parts of the proof equally. Concretely, smooth PCPs are *tolerant* of errors, as a few corrupt locations in a correct proof still give high acceptance probability.[2] Prior works considered smoothness in the context of locally decodable codes (see Section 1.3.2).

Before moving on to the main result, let us motivate why smooth and strong PCPs are particularly natural in tandem. Fix a correct claim and consider two innate measures of the "incorrectness" of a proof: its probability of being rejected by the verifier and its distance from a correct proof. Denoting the first by ρ and the second by δ, a strong PCP guarantees that $\rho = \Omega(\delta)$. On the other hand, the tolerance of a smooth, constant-query PCP implies that $\rho = O(\delta)$. Thus, for a constant-query PCP that is both smooth and strong these measures coincide (up to a constant).

This work presents a construction of simultaneously smooth and strong PCPs of polynomial length for any set in $\mathcal{NP}$, verifiable by reading a constant number of bits from the proof. Specifically, we reanalyze and enhance the construction used in [3, 2] (with proof composition as in [6]) to obtain smooth and strong PCPs. The enhancements include the introduction of multi-piece PCPs, a smooth and strong-preserving transformation of these to single-piece PCPs, and a new composition theorem for smooth and strong PCPs.

Our result implies the hardness of approximating the satisfiability of *stable* 3CNF formulae with *bounded variable occurrence*, where *stability* means that the number of clauses violated by an assignment is proportional to its distance from a satisfying assignment (in the relative Hamming metric). We believe that the hardness of approximating 3SAT even under stability guarantees is related to the hardness of other stable optimization problems. Friggstad et al. provide evidence to this in [12], as they show that this result implies the hardness of approximating *perturbation-stable Euclidean k-means* (see Section 1.3.3).

---

[1] For technical reasons, their result is stated only for the class $\mathcal{UP} \subseteq \mathcal{NP}$, but can be easily adapted to suit all of $\mathcal{NP}$.

[2] Indeed, tolerance is (oppositely) related to strong PCPs which guarantee detection of errors in a correct proof. See next paragraph.

1.1 Main notions

In this section we formally define *strong PCPs* and *smooth PCPs*. But first, a reminder of standard PCPs and their basic properties.

▶ **Definition 1.1** (PCP). *A* probabilistically checkable proof system (PCP) *for a set* $S \subseteq \{0,1\}^*$ *is a probabilistic polynomial-time oracle machine* V*, called a* verifier *and denoted* V*, that satisfies the following conditions:*

- Completeness: *For all* $x \in S$ *there exists a proof* $\pi \in \{0,1\}^*$ *such that the verifier* V *accepts explicit input* x *and proof oracle* π *with probability* 1*.*
- Soundness: *For all* $x \notin S$ *and proof oracle* $\pi \in \{0,1\}^*$*, the verifier* V *rejects explicit input* x *and proof oracle* π *with probability at least* $1/2$*.*[3]

The maximal number of random coin tosses made by verifier V *on inputs of length* n *is its* randomness complexity*, denoted* $r(n)$*. The maximal number of queries made by the verifier* V *on inputs of length* n *is its* query complexity*, denoted* $q(n)$*.*

A PCP is *nonadaptive* if it determines all queries solely by its random coins and explicit input. All PCPs in this work are nonadaptive, and furthermore, they query the same number of bits regardless of the sampled coin sequence.

Notice that Definition 1.1 doesn't mention the *length* of the proof itself. That is because the number of possible locations the verifier might read in the proof can be upper-bounded based on its randomness and query complexities: a nonadaptive PCP that tosses r random coins and then makes q queries can query at most $q \cdot 2^r$ different locations in the proof. Thus, from here on we will ignore the proof length and focus on the randomness and query complexities.

1.1.1 Strong PCPs

Strong PCPs are PCPs that reject incorrect proofs even for correct claims with probability proportional to the distance of such proofs from correct ones. Throughout this work, *distance* refers to the relative Hamming distance: For a fixed alphabet Σ (one can think of $\{0,1\}$, but we will use different alphabets later), the *relative hamming distance* between strings $x, y \in \Sigma^n$ equals the fraction of locations on which they differ, and is denoted $\delta(x,y)$. If $\delta(x,y) < d$ then x is said to be *d-close* to y, and if $\delta(x,y) \geq d$ then x is *d-far* from y. The distance of a string x from a set $T \subseteq \{0,1\}^*$ is defined to be $\delta(x,T) := \min_{x' \in T \cap \{0,1\}^{|x|}} \delta(x,x')$, with the minimum over the empty set defined to be 1.

▶ **Definition 1.2** (Strong PCP). *A* strong PCP *for membership in set* S *with* strongness parameter $\alpha \in (0,1]$ *is a probabilistic polynomial-time oracle machine, called a* verifier *and denoted* V*, that satisfies the following conditions:*

- Completeness: *For all* $x \in S$ *there exists a proof* $\pi \in \{0,1\}^*$ *such that the verifier* V *accepts explicit input* x *and proof oracle* π *with probability* 1*. Such a proof* π *is called a* correct proof for x*.*
- Strong soundness:
  - *If* $x \notin S$ *then* x *has no correct proof.*
  - *Let* $\mathscr{P}(x)$ *denote the set of correct proofs for* x*. Then, the verifier rejects explicit input* x *and proof oracle* π *with probability at least* $\alpha \cdot \delta(\pi, \mathscr{P}(x))$*.*

[3] The constant $1/2$ can be replaced with any other constant $\alpha \in (0,1)$.

Note that strong soundness implies standard soundness, i.e. rejection of instances $x \notin S$ with constant probability regardless of the given proof oracle, because for these instances the verifier rejects with probability $\alpha \cdot \delta(x, \emptyset) = \alpha$.

1.1.2 Smooth PCPs

Smoothness is a straightforward notion and is defined for any oracle Turing machine. To us, oracles always have finite domains, and we associate the oracle $f\colon [n] \to \{0,1\}$ with an n-bit string $f(1)\cdots f(n)$.

▶ **Definition 1.3** (Smooth oracle machine). *A probabilistic oracle Turing machine M is* smooth *if for any explicit input and oracle, the probability that M queries each location of its oracle (in any of its queries) is equal. That is, given access to oracle f and letting $Q(j)$ be the event that M queries location j of f in any of its queries, it holds that $\mathbb{P}[Q(j)] = \mathbb{P}[Q(j')]$ for every $j, j' \in [|f|]$, where $|f|$ denotes the length of the oracle f.*

Additional discussion on smoothness and a nearly-equivalent definition can be found in Appendix B.

1.2 Contributions

1.2.1 Smooth and Strong PCPs for $\mathcal{NP}$

The main contribution is a proof of the following result.

▶ **Theorem 1.4** (Main result). *Every set in $\mathcal{NP}$ has a smooth and strong PCP with logarithmic randomness and constant query complexities.*

At this point one might wonder: A strong PCP rejects incorrect proofs with probability proportional to their distance from correct proofs – but *who are these correct proofs*? In the case of Theorem 1.4, we can say that the correct proofs for any fixed instance are obtained by a polynomial-time computable bijection of $\mathcal{NP}$-witnesses to correct proofs.

▶ **Theorem 1.5** (Main result, strengthened). *Fix a set $S \in \mathcal{NP}$, and let $\mathscr{W}(x)$ denote the set of $\mathcal{NP}$-witnesses for an instance x of S. Then, S has a PCP as in Theorem 1.4 with a polynomial-time computable* canonical proof strategy $\Pi : \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$ *such that for every $x \in \{0,1\}^*$, $\Pi(x, \cdot)$ is a bijection between the set $\mathscr{W}(x)$ and the set of correct proofs $\mathscr{P}(x)$.*

1.2.2 Hardness of approximation

Recall that the PCP theorem implies that for some $\rho \in (0,1)$, it is $\mathcal{NP}$-hard to distinguish 3CNF formulas that are satisfiable from ones in which any assignment violates at least a ρ fraction of the clauses. Theorem 1.4 yields a similar result for 3CNF formulas that are *"stable"* and have each variable occurring in a bounded number of clauses. Here *stability* means that the number of clauses violated by an assignment is (at least) proportional to its distance from a correct assignment (in the relative Hamming metric). Formally,

▶ **Definition 1.6** ((α, b)-`stable3SAT`). *A 3CNF formula φ is* α-stable *if any assignment that that is δ-far from a satisfying assignment violates at least an $\alpha\delta$ fraction of clauses in φ. A formula has* b-bounded-occurrence *if any variable occurs in at most b clauses. For constants α and b, the promise problem (α, b)-`stable3SAT` is distinguishing b-bounded-occurrence 3CNF formulas that are α-stable and satisfiable from ones in which any assignment violates at least an α fraction of the clauses.*

One motivation for our interest in stable and bounded-occurrence formulas is that they exhibit an interesting structural property. For a fixed satisfiable formula, we consider two natural measures of the "cost" (i.e., "badness") of an assignment. The first and most common one is the *fraction of clauses* violated by the assignment. The second is the *fraction of variables* on which the assignment disagrees with the closest satisfying assignment (i.e. the relative Hamming distance of the assignment from the set of satisfying assignments). We denote the first by δ and the second by ρ. Now, stable formulas have $\delta = \Omega(\rho)$, while bounded-occurrence formulas satisfy $\delta = O(\rho)$, since changing the value of a variable affects a bounded number of clauses. Hence, these two measures coincide for stable and bounded-occurrence formulas (up to a constant factor); the fraction of clauses unsatisfied by an assignment approximately reflects its distance from a satisfying assignment. Theorem 1.5 implies a hardness of approximation result for such formulas.

▶ **Corollary 1.7.** *There exist $\alpha \in (0,1)$ and $b \in \mathbb{N}$ such that (α, b)-*`stable3SAT` *is $\mathcal{NP}$-hard. Furthermore, it is $\mathcal{NP}$-hard under parsimonious Karp reductions.*

The proof of Corollary 1.7 are deferred to Appendix A. We proceed with a discussion of two of its implications.

Consider a *distance oracle* that, given a 3CNF formula φ and assignment σ, returns the (relative Hamming) distance of σ from the set of satisfying assignments of φ if φ is satisfiable, and answers arbitrarily otherwise. Efficiently finding a satisfying assignment given such an oracle can be done by greedily minimizing the distance returned by the oracle. What if instead we are given access to an *approximate* distance oracle, which returns the distance of an assignment from the set of satisfying assignments *up to some multiplicative constant*? Corollary 1.7 and the observation that precedes it imply that an approximate distance oracle is not enough to find even an approximately satisfying assignment; that is, that for some constant $\alpha \in (0,1)$, finding an assignment that satisfies more than an α-fraction of clauses is $\mathcal{NP}$-hard even when given access to an approximate distance oracle. This is because, as observed, the answers of an approximate distance oracle can be efficiently emulated for stable and bounded-degree formulas, and Corollary 1.7 asserts $\mathcal{NP}$-hardness of finding an approximately satisfying assignment for such formulas.

In addition to the aforementioned intrinsic motivation for the study of stable and bounded occurrence instances, Corollary 1.7 implies a hypothesis used in the recent work of Friggstad et al. [12, Hypothesis 1], yielding the first hardness of approximation result for perturbation-stable Euclidean k-means. More on this in Section 1.3.3.

1.2.3 Smooth and Strong Canonical PCPs of Proximity for $\mathcal{NP}$-relations

PCPs of Proximity (abbreviated *PCPPs*, aka *assignment testers*), introduced in [11, 6], are PCPs placed on an even tighter budget, with access to their input accounted for in their query complexity. Since PCPPs cannot read the entirety of their input oracle, they aren't able to distinguish inputs in the set from inputs *close* to being in the set. As such, PCPPs should satisfy a relaxed notion of soundness that requires them to reject (with high probability) only input oracles *far* from correct ones.

More generally, PCPPs verify membership of a *pair* $(x; y)$ in a *relation* $R \subseteq \{0,1\}^* \times \{0,1\}^*$, when given explicit (i.e. unaccounted) access to x and oracle (i.e. accounted) access to y, as well as access to a proof oracle.

▶ **Definition 1.8** (PCP of Proximity (PCPP)). *A* PCP of Proximity system (PCPP) *for relation* $R \subseteq \{0,1\}^* \times \{0,1\}^*$ *with* proximity parameter $\delta > 0$ *is a probabilistic polynomial-time oracle machine, called a* verifier *and denoted* V *such that the following hold:*

- Completeness: *If* $(x, y) \in R$ *then there exists a proof* π *such that the verifier* V *accepts explicit input* x*, input oracle* y *and proof oracle* π *with probability* 1*.*
- Soundness: *If* y *is* δ*-far from* $\{y' : (x, y') \in R\}$*, then for any proof oracle* π*, the verifier rejects explicit input* x*, input oracle* y *and proof oracle* π *with probability at least* $1/2$*.*

Strong canonical PCPPs

PCPP soundness is somewhat reminiscent of strong soundness, but note that in the former rejection probability is related to the distance of the *input oracle* from being correct, rather than the distance of the *proof oracle* from being correct (here we think of the explicit input as fixed).[4] Indeed, the adaptation of strong soundness to the setting of proximity verification, i.e. *strong PCPPs*,[5] combines these two requirements: a *strong PCPP* is required to reject with probability proportional the *maximum* between the distance of the input oracle y to a correct input oracle y', and the proof oracle π to a correct proof oracle π' for y'.

Actually, we won't bother to formally define strong PCPPs, because we show the existence of even *stronger* (pun intended) constructs. Our PCPPs have a *canonical* transformation of correct inputs to correct proofs, meaning that for each correct input $(x; y)$, our PCPPs have a unique *canonical proof* $\Pi(x; y)$ that is always accepted by the verifier, whereas all other strings are rejected with nonzero probability.[6] But with what probability? Right, the maximum between the distance of the input oracle y to a correct input oracle y', and the proof oracle π to the canonical proof for x and y' (i.e. $\delta(\pi, \Pi(x; y'))$).

▶ **Definition 1.9** (Strong canonical PCPP). *A* strong canonical PCPP *for relation* R *with* strongness parameter $\alpha \in (0, 1]$ *is a probabilistic polynomial-time oracle machine, called a* verifier *and denoted* V*, coupled with a polynomial-time computable* canonical proof strategy *denoted* $\Pi\colon \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$*, such that when the verifier is given explicit input* x *and access to an* input oracle y *and a* proof oracle π*, the following hold:*

- Canonical completeness: *The verifier accepts with probability* 1 *if and only if* $(x; y) \in R$ *and* π *is the corresponding canonical proof, i.e.* $\pi = \Pi(x; y)$*.*
- Strong canonical soundness: *Let* $R(x) \coloneqq \{y' : (x; y') \in R\}$*. Then, the verifier rejects with probability at least*

$$\alpha \cdot \min_{y' \in R(x)} \{\max\left(\delta(y, y'), \delta(\pi, \Pi(x; y'))\right)\}$$

In particular, if $R(x)$ *is empty then the verifier rejects with probability* α*.*

Again, strong canonical soundness implies standard PCPP soundness, e.g. rejection of any input y that is 0.1-far from $R(x)$ with constant probability, because in this case the verifier rejects with probability at least $\alpha \cdot \min\{0.1, 1\}$, where α is the (constant) strongness parameter.

---

[4] Furthermore, Definition 1.9 is *proximity-oblivious*, in the sense that rejection probability grows with the distance of the oracles from being correct, whereas Definition 1.8 offers rejection with constant probability of inputs whose distance from being correct is farther than some constant.

[5] Not to be confused with the related [17][Definition 5.7], which we will soon refer to as *strong canonical PCPPs*. See also Footnote 7.

[6] This is the bijection mentioned in Theorem 1.5.

▶ Remark 1.10. Previously (e.g. [17, 15, 10]), strong canonical PCPPs were considered only for *unambiguous relations*; that is, only for relations $R \subseteq \{0,1\}^* \times \{0,1\}^*$ for which $|R(x)| \leq 1$ for any x. Our definition is more general as it does not place a restriction on the relation R.[7] Furthermore, Definition 1.9 allows the verifier to take an explicit input (as in [6]), whereas past works studied PCPPs that have access to input and proof oracles but no (auxiliary) explicit input.

Smooth PCPPs

PCPP verifiers are oracle machines that have *two* oracles, and we say that a PCPP is smooth if it is smooth on each of its oracle. Formally, we generalize Definition 1.3 to suit a *t-oracle* Turing machine for any constant $t \in \mathbb{N}$, which is a machine that has access to a t oracles (where t is a constant).

▶ **Definition 1.11** (Smooth multi-oracle machine)**.** *A probabilistic t-oracle Turing machine M is* smooth *if for any explicit input and oracles, the probability that M queries each location of each of its oracle (in any of its queries) is equal. That is, given access to oracles $f_1, \ldots, f_t$ and letting $Q_\ell(i,j)$ be the event that the ith query of M is to location j of f_ℓ, it holds that $\mathbb{P}\left[\bigcup_{i=1}^{q} Q_\ell(i,j)\right] = \mathbb{P}\left[\bigcup_{i=1}^{q} Q_\ell(i,j')\right]$ for each $\ell \in [t]$ and every $j, j' \in [|f_\ell|]$, where $|f_\ell|$ denotes the length of the ℓth oracle f_ℓ.*

We prove the following theorem.

▶ **Theorem 1.12.** *Every $\mathcal{NP}$-relation has a smooth and strong canonical PCPP with logarithmic randomness complexity and constant query complexities.*

Notice that a PCPP for relation R yields a PCP for the set $S_R \coloneqq \{x : \exists y \ (x;y) \in R\}$: a proof that $x \in S_R$ (in the PCP for S_R) is composed of some y such that $(x;y) \in R$, followed a proof (in the PCPP for R) that $(x;y) \in R$. Furthermore, the PCP for S_R retains the strongness of the PCPP for R and, under a reweighing of the input oracle (presented in Section 2), smoothness is retained as well. Therefore, Theorem 1.5 follows from Theorem 1.12.

1.3 Related work

1.3.1 Strong (canonical) soundness

The term *strong* in the definition of strong PCPs is inspired by *strong locally testable codes (strong LTCs)*, which are codes whose local test rejects with probability proportional to the distance of the input from the code. In fact, strong canonical PCPPs have seen numerous uses in works on strong LTCs, as follows.

Goldreich and Sudan [17] defined strong canonical PCPPs in their work on strong LTCs,[8]and constructed such PCPPs for certain linear codes. An extension of this initial construction saw use by Gur and Rothblum [19] as they obtained strong LTCs that allow for a relaxed notion of local decoding (of [6, Section 4.2]). Goldreich et al. [15] later improved these

[7] In fact, our work is the first to make a semantic distinction between *strong* and *strong canonical*, recognizing strong canonical PCPPs as special type of strong PCPPs in which there is an efficient *canonical* transformation between $\mathcal{NP}$-witnesses and proofs, in addition to strong soundness. In previous works, the terms *strong PCPP* and *strong canonical PCPP* were used synonymously, which is consistent with our distinction, given that these works considered PCPPs only for unambiguous relations. See Section 1.3.1 for more on previous works using strong canonical PCPPs.

[8] See Footnote 7 for a warning on the usage of the terms *strong* and *strong canonical* in previous works.

codes, again utilizing strong canonical PCPPs. Gur et al. [18] employed strong canonical PCPPs in their work on relaxed locally correctable codes. We stress that all these works featured PCPPs for linear subspaces (e.g. linear codes).

As mentioned, Dinur et al. [10] characterized *unambiguous* $\mathcal{NP}$ *(*$\mathcal{UP}$*)* in terms of strong canonical PCPPs, under the original and more restricted definition of strong canonicality generalized in this work (see Remark 1.10).

In [14, Section 13.2.2], strong PCPs are presented from the perspective of property testing as *locally testable proofs*, in analogy to locally testable codes.

1.3.2 Smoothness

Like strongness, smoothness too has its roots in coding theory, with the work Katz and Trevisan [21] examining *smooth locally decodable codes*. These are codes whose local decoding algorithm reads each bit in an alleged codeword with *approximately* equal probability (cf. Definition 1.3, which requires the probability to be *exactly* equal). Since its inception, this property has appeared in numerous works relating to locally decodable codes, e.g. [16, 24, 13]). Goldreich and Sudan [17, Definition 5.14] considered a similar feature for their Linear Inner Proof Systems (LIPS), which are fundamentally different from PCPs.

To avoid possible confusion, it is worth pointing out that the smoothness referred to in this work is as in the aforementioned works in coding theory, and *not* as in the *smooth label cover* of Khot [22].

The PCPPs of Theorem 1.12 are used in the recent work of Alman and Chen [1] which shows an explicit construction of rigid matrices using an $\mathcal{NP}$ oracle. They make use only of the smoothness of these PCPPs, but not the additional strong canonicality feature.[9]

1.3.3 Hardness of perturbation-stable Euclidean k-means

The hardness of approximating bounded-degree `stable3SAT` (Corollary 1.7) is the starting point of the first hardness of approximation result for perturbation-stable instances of Euclidean k-means, due to Friggstad et al. [12]. This connection between `stable3SAT` and perturbation-stable problems is an interesting direction for future research, so we provide a brief description of their result.

The study of optimization on perturbation-stable instances was initiated by Bilu and Linial [8] and Awasthi et al. [4] as a way of focusing on instances that can "occur in reality" (to quote the former). We consider the *Euclidean k-means* problem and its perturbation-stable instances, which are defined as follows:

- An instance of the k-means problem consists of $k \in \mathbb{N}$, *dimension* $d \in \mathbb{N}$, a *metric* $\mu : \mathbb{R}^d \times \mathbb{R}^d \to [0, \infty)$, *data points* $X \subseteq \mathbb{R}^d$, and *candidate centers* $C \subseteq \mathbb{R}^d$. The objective is to choose *centers* $S \subseteq C$ such that $|S| = k$ so as to minimize $\mathbb{P}_{x \in X} \left[\min_{c \in S} (\mu(x, c))\right]$. An instance is *Euclidean* if μ is the Euclidean metric.
- Fix $\gamma > 1$ and metric μ. A γ-perturbation of μ is a function $\mu' : \mathbb{R}^d \times \mathbb{R}^d \to [0, \infty)$ such that for any $x \neq y \in \mathbb{R}^d$,

  $$1 \leq \frac{\mu'(x, y)}{\mu(x, y)} \leq \gamma$$

  Notice that μ' is not necessarily a metric.

[9] As opposed to [12] (see Section 1.3.3) which uses both features simultaneously.

- For some fixed $\gamma > 1$, an instance (k, d, X, C, μ) of k-means is *γ-perturbation-stable* if it has a unique optimal solution $S^* \subseteq C$, and for any γ-perturbation μ' of μ, S^* is the optimal solution of the related instance (k, d, X, C, μ'). The *γ-perturbation-stable Euclidean k-means* problem is the k-means problem as previously described, under the promise that instances are *Euclidean* and are γ-perturbation-stable.

While solving (general, non-stable) Euclidean k-means is known to be $\mathcal{NP}$-hard to approximate [5], Awasthi et al. showed that introducing some perturbation-stability makes the problem easy; namely, they show that $(\sqrt{2}+3)$-stable Euclidean k-means can be solved exactly in polynomial time. Could the introduction of *any* amount of perturbation-stability render Euclidean k-means easy, or even just easy to approximate? The answer is *no*, as demonstrated by Friggstad et al. [12]. Their result is conditioned on an hypothesis asserting hardness of approximation of *bounded-occurrence and* `stable3SAT` (see Section 1.2.2), which is implied by Corollary 1.7.

▶ **Theorem 1.13** ([12]). *Assuming Corollary 1.7, there are $\gamma > 1$ and $\varepsilon > 1$ such that γ-perturbation-stable Euclidean k-means cannot be approximated within factor ε, unless $\mathcal{RP} = \mathcal{NP}$.*

1.4 Proof outline

To prove Theorem 1.12 we construct a PCPP with the necessary properties for the *circuit valuation* relation, denoted CircuitVal, which consists of all pairs $(C; y)$ such that circuit C accepts when given y as input. Then, any $\mathcal{NP}$-relation R has a PCPP (with the same properties) that, given explicit input x, efficiently computes a circuit C_x such that $(x; y) \in R$ if and only if C_x accepts y, and then runs the PCPP of CircuitVal on explicit input C_x and the same input and proof oracles. Following are highlights of our smooth and strong canonical PCPP for CircuitVal.

Multi-piece PCPPs (Section 2)

The PCPP for CircuitVal will be a variant of the PCPP presented in [3, 2, 6]. However, even a high-level inspection of this construction reveals that it is not at all smooth: for example, one building block (the Hadamard-based PCPP, mentioned below) consists of two "pieces" from which the verifier samples uniformly random locations, with the first piece substantially shorter than the second (so its bits are queried far more often). Indeed, this PCPP is not smooth when viewed as a single proof, but when partitioned into two *proof-pieces* (given as two proof-piece oracles), the verifier is smooth *as a three-oracle machine* (one input oracle and two proof-piece oracles). We present a transformation of multi-piece PCPPs to single-piece ones that *simultaneously preserves smoothness and strong canonicality*. This is done by replacing each proof-piece with a list of copies, so that the length of each list of copies is roughly the same.[10]

[10] To be clear, the Hadamard-based PCPP is but one example of non-smoothness (or rather, multi-piece smoothness) in the construction of [3, 2, 6]; the Reed–Muller-based PCPP, as well as PCPP composition, exhibit similar traits. Thus, our transformation of multi-piece PCPPs to single-piece PCPPs is used by all components of our construction, not just by the Hadamard-based PCPP.

Composing smooth strong canonical PCPPs (Section 3)

The run of a nonadaptive PCPP verifier can be viewed as a two-step process: first, it tosses some random coins and generates a *residual (decision) circuit* and *query locations* based on the coins it tossed, and then it queries its oracles and accepts or rejects according to the residual circuit's computation of their answers. A strong canonical and *robust* PCPP is such that, in expectation, the distance of its oracles' answers from satisfying the residual circuit reflects the distance of the oracles (in their entirety) from correct ones (i.e. a correct input oracle and a canonical proof oracle). Our *composition theorem* asserts that for a smooth strong canonical and robust PCPP, replacing the residual circuit's computation with an additional probabilistic verification (by an *inner* smooth strong canonical PCPP) yields a smooth strong canonical PCPP.

With a composition theorem at hand, we turn to the construction of smooth strong canonical and robust PCPPs, whose composition gives the PCPP postulated by Theorem 1.12.

The Hadamard-based smooth strong canonical PCPP (Section 4)

This is the Hadamard-based PCPP presented in [2], used as the innermost PCPP of the composition. Its proofs are based on the Hadamard encoding of the input oracle, and its verifier checks that the proof oracle encodes the input oracle (a "consistency check"), and uses the structure of the Hadamard code to check that the input oracle satisfies the (explicitly given) circuit. To show strong canonicality, we consider three cases:

Case 1: Both the input and proof oracles are close to correct ones. That is, the input oracle y is close to an input y' that is accepted by the (explicitly given) circuit, and the proof oracle π is close to its canonical proof oracle Π' of y'. The verifier checks consistency by performing a *strong codeword test* on the proof oracle, and checks that the decoding of the proof oracle agrees with the input oracle on a random bit. Strong testability means precisely that the first check rejects with probability $\Omega(\pi, \Pi')$, and the local decoding of a random location rejects with probability $\Omega(y, y')$.

Case 2: The input oracle is far from any correct input oracle. Then, standard PCPP soundness guarantees rejection with high probability.

Case 3: The proof oracle is far from the canonical proof of the input oracle. If the proof oracle is close to the canonical proof for some input $y' \neq y$ then the consistency check between the proof oracle and the input oracle rejects with probability $\Omega(\delta(y, y'))$. Otherwise the proof oracle is far from any canonical proof, and is therefore rejected with high probability by the strong codeword test.

Lastly, as mentioned above, we observe that it is smooth as a two-piece PCPP, and can therefore be transformed to a single-piece strong canonical PCPP.

The Reed–Muller-based smooth strong canonical robust PCPP (Section 5)

This PCPP is used in the outer layers of the composition, so we must show that it is smooth and *robust* strong canonical. Again, smoothness amounts to observing that it is multi-piece smooth. The analysis of its strong canonicality follows the same lines of the Hadamard-based PCPP, this time relying on a generalization of the strong Reed–Muller codeword test (provided by Oded Goldreich and Madhu Sudan in Appendix C). We first present a smooth strong canonical robust PCPP whose proofs are over a large alphabet, and then show that alphabet reduction (encoding each letter in an error correcting code) preserves smoothness and strong canonicality.

2 Multi-piece PCPPs

As said in Section 1.4, several of the PCPPs in the [2] construction are not smooth per se, but they spread their queries smoothly on each of a few significant *proof-pieces*. Such *multi-piece* PCPPs are required to satisfy a stricter form of strong canonicality, in which the rejection probability is related to the maximum between *each proof-piece oracle* to its corresponding proof-piece in a correct proof (and, as usual, the distance of the input oracle y to a satisfying input oracle y'). Motivated by this observation, we define *multi-piece strong canonical PCPPs*.

▶ **Definition 2.1.** *For a constant t, a* t-piece strong canonical PCPP system *for relation R with* strongness parameter $\alpha \in (0,1]$ *is a probabilistic polynomial-time oracle machine, called a* verifier *and denoted V, coupled with a sequence of polynomial-time computable* canonical proof-piece strategies*, denoted $\Pi_1, \ldots, \Pi_t \colon \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$, such that when the verifier is given explicit input x and access to an* input oracle y *and a* proof-piece oracles $\pi_1, \ldots, \pi_t$*, the following hold:*

- Canonical completeness: *The verifier accepts with probability* 1 *if and only if $(x;y) \in R$ and π_i is the corresponding canonical proof-piece, i.e. $\pi_i = \Pi_i(x;y)$, for each $i \in [t]$.*
- Strong canonical soundness: *Let $R(x) \coloneqq \{y' : (x;y') \in R\}$. Then, the verifier rejects with probability at least*

$$\alpha \cdot \min_{y' \in R(x)} \{\max\left(\delta(y,y'), \delta(\pi_1, \Pi_1(x;y')), \ldots, \delta(\pi_t, \Pi_t(x;y'))\right)\}$$

In particular, if $R(x)$ is empty, then the verifier rejects with probability α.

For each $i \in [t]$, the ith proof-piece length complexity*, denoted $\ell_i(n)$, is the length of the ith proof piece. The* ith proof-piece query complexity*, denoted $q_i(n)$, is the number of queries the verifier issues to the ith proof-piece given an input of length n.*[11]

2.1 From multi-piece to single-piece

We present a smoothness-preserving transformation of strong canonical multi-piece PCPPs to strong canonical PCPPs that use a single proof oracle. This transformation is not only convenient (for example, composition of multi-piece PCPPs gives one a multi-headache), but is also necessary for Theorem 1.12 which asserts the existence of *single-piece* smooth strong canonical PCPPs for every $\mathcal{NP}$ relation.

▶ **Lemma 2.2.** *Suppose that, for some constant t, a relation R has a* t-piece *smooth strong canonical PCPP with strongness parameter α, randomness complexity $r(n)$, and query complexity $q(n)$. Then, R has a* single-piece *smooth strong canonical PCPP with strongness parameter $\alpha/3$, randomness complexity $O(r(n) + \log q(n))$ and query complexity $O(q(n))$.*

Proof. Notice that if proof-piece lengths vary significantly, then simply concatenating the proof-pieces will not do, because bits of shorter pieces are sampled with higher probability than bits of longer pieces. Instead, each proof-piece is replaced with a list of copies such that each list is of equal length (up to a factor related to the proof-piece's query complexity). That is, the number of copies in the ith list is proportional to q_i/ℓ_i, which, by multi-piece smoothness, equals the probability that a bit in the ith proof-piece is queried by the multi-piece verifier.

[11] *Tedious comment:* We require the number of queries that the verifier issues to each proof-piece to depend only on the explicit input's length. This requirement is met by the all PCPPs used in this work.

The single-piece verifier emulates the multi-piece verifier on a random choice of proof-pieces (each proof-piece sampled uniformly from its list of alleged copies), and checks consistency of the copies in each list. Some care must be taken so that the consistency check does not harm smoothness (for example, checking consistency against a fixed copy would result in its bits being queried more often than others).

Strong canonicality of the single-piece verifier then follows from examining two possible cases: The first is that the given lists are noticeably inconsistent (i.e., there is a large discrepancy between the alleged copies), in which case the consistency check rejects with good probability. Otherwise, the lists are almost entirely consistent (i.e., each list of the given proof essentially consists of copies of some proof-piece), and then strong canonicality follows from strong canonicality of the multi-piece verifier.

Following is a detailed description and analysis of the construction. Let V be the postulated t-piece smooth strong canonical PCPP verifier with canonical proof-piece strategies $\Pi_1, \ldots, \Pi_t \colon \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$. We construct a single-piece PCPP $\overline{V}$ and start by describing its canonical proof strategy $\overline{\Pi}$. Fixing $(x, y) \in R$, we use the following notation:

- r denotes the number of random coins tossed by V when given x as explicit input.
- q_i denotes the number of queries V makes to the ith proof-piece oracle when given x as explicit input. The total number of queries V makes to all proof-piece oracles is $q \coloneqq \sum_{i=1}^{t} q_i$
- $\Pi_i \coloneqq \Pi_i(x; y)$ denotes the ith canonical proof-piece of $(x; y)$, and $\ell_i \coloneqq |\Pi_i|$ denotes its length.

Now, let $\overline{\Pi_i}$ be a list of $m_i \coloneqq (q_i + 1) \prod_{j \neq i} \ell_j$ copies of Π_i.[12] Indeed, m_i is proportional to the probability that a certain fixed bit of Π_i is sampled, namely q_i/ℓ_i.[13] The canonical proof of $(x; y)$ in the single-piece PCPP $\overline{V}$ is then the concatenation of all $\overline{\Pi_i}$'s.

We describe the run of the new verifier $\overline{V}$ given explicit input x and access to input oracle y and proof oracle $\overline{\pi} = (\overline{\pi_1}, \ldots, \overline{\pi_t})$, where $\overline{\pi_i} = (\pi_i^1, \ldots, \pi_i^{m(i)})$ is a list of $m(i)$ strings, each of length ℓ_i:

1. *Emulation:* For each $i \in [t]$, sample a uniformly random index $c_i \in [m_i]$. Next, emulate V on explicit input x, input oracle y and proof-piece oracles $\pi_1^{c_1}, \ldots, \pi_t^{c_t}$, rejecting if the emulation rejected. Let J_i denote the set of locations that V queries in $\pi_i^{c_i}$.
2. *Consistency check:* For each $i \in [t]$, sample uniformly from the remaining copies $c_i' \in [m_i] \setminus \{c_i\}$ and a uniformly random $j_i \in J_i$ and check that $\pi_i^{c_i'}[j_i] = \pi_i^{c_i}[j_i]$. That is, check that $\pi_i^{c_i}$ and $\pi_i^{c_i'}$ agree on a uniformly random location from the locations queried by the emulated verifier V in Step 1.[14]

   (Note that smoothness of V implies that j_i is uniformly distributed in $[\ell_i]$ (as detailed in Appendix B.2), and that only $\pi_i^{c_i'}[j_i]$ needs to be queried in this step.)

The single-piece verifier $\overline{V}$ uses t more queries than the emulated (multi-piece) verifier V since the consistency check requires querying an additional location from each list. The number of random coins is upper-bounded by $O(t^2 \cdot (r + \log q)) = O(r + \log q)$.

---

[12] The value $q_i + 1$ is used instead of q_i to account for the additional query made by the consistency check (Step 2 in the description of $\overline{V}$).

[13] Letting $m_i \coloneqq (q_i + 1)L/\ell_i$ for any L that is a common multiple of $\{\ell_i\}_{i \in [t]}$ would have worked as well.

[14] Indeed, the consistency check can be implemented in several other ways, for example without reusing the emulation copy c_i in the consistency check (i.e. checking consistency between c_i' and some c_i''), or by uniformly sampling j_i from all of $[\ell_i]$ rather than from J_i. However, other implementations require setting m_i to other (less informative) values.

Canonical completeness follows by observing that a proof is accepted with probability 1 if and only if it is formed of consistent lists (i.e. each list holds copies of some proof-piece), such that the proof-pieces in each list form a canonical proof in the multi-piece PCPP. We prove the remaining properties:

Smoothness

Fix a location in the proof oracle $\overline{\pi}$, which is the jth location of $\pi_i^{k_i}$ for some $i \in [t]$, $k_i \in [m(i)]$ and $j \in [\ell_i]$. This location is queried if and only if one of two disjoint events occur:

- In Step 1, $k_i = c_i$ *and* $j_i \in J_i$, i.e. the jth location of $\pi_i^{c_i}$ was queried by the emulated verifier. By multi-piece smoothness of the emulated verifier V, this event occurs with probability $\frac{1}{m_i} \cdot \frac{q_i}{\ell_i}$.
- In Step 1, $k_i \neq c_i$ *and* $j_i \in J_i$. In addition, in Step 2, $k_i = c_i'$ *and* the jth location is chosen from J_i (i.e. from the set of all locations queried by the verifier). This event occurs with probability $(1 - \frac{1}{m_i}) \cdot \frac{q_i}{\ell_i} \cdot \frac{1}{m_i - 1} \cdot \frac{1}{q_i} = \frac{1}{m_i} \cdot \frac{1}{\ell_i}$.

All in all, we have that the probability that this location is queried is

$$\frac{1}{m_i} \cdot \frac{q_i}{\ell_i} + \frac{1}{m_i} \cdot \frac{1}{\ell_i} = \frac{q_i + 1}{m_i \cdot \ell_i} = \frac{1}{\prod_{i=1}^{t} \ell_i}$$

Therefore, each bit in $\overline{\pi}$ is queried with equal probability.

Strong canonical soundness

Let α be the strongness parameter of the multi-piece verifier V. We show that the (single-piece) PCPP $\overline{V}$ has strongness parameter $\alpha/3$. Fix explicit input x, input oracle y and proof oracle $\overline{\pi} = (\overline{\pi_1}, \ldots, \overline{\pi_t})$, where $\overline{\pi_i}$ is purported to contain m_i copies of the ith canonical proof-piece for $(x; y)$. If $R(x)$ is empty, then the emulated verifier (and therefore the single-piece verifier) rejects with probability $\alpha \cdot 1$ for any choice of (alleged) copies c_i, so we may focus on the case that $R(x) \neq \emptyset$. Let $y' \in R(x)$ be a minimizer of ρ, defined

$$\rho \coloneqq \max\left(\delta(y, y'), \delta\left(\overline{\pi_1}, \overline{\Pi}_1(x; y')\right), \ldots, \delta\left(\overline{\pi_t}, \overline{\Pi}_t(x; y')\right)\right) \geq \max\left(\delta(y, y'), \delta\left(\overline{\pi}, \overline{\Pi}(x; y')\right)\right) \quad (1)$$

It suffices to show that the verifier rejects with probability at least $\frac{\alpha}{3} \cdot \rho$. Assume wlog that the maximum in the left hand side of Equation (1) is obtained in the first proof-piece oracle, so $\rho = \max\left(\delta(y, y'), \delta(\overline{\pi}_1, \overline{\Pi}_1(x; y'))\right)$. We proceed by examining the case that the first proof-piece has noticeable inconsistency, and the case where it is almost entirely consistent.

Case 1: The first proof-piece list is noticeably inconsistent: $\mathbb{E}_{c_1 \neq c_1' \in [m_1]}\left[\delta(\pi_1^{c_1}, \pi_1^{c_1'})\right] \geq \rho/3$. Smoothness of the emulated verifier implies that a uniformly random location from the set of locations queried in $\overline{\pi}_1$ is distributed uniformly in $[\ell_i]$ (as detailed in Appendix B.2). Hence, the probability that the consistency check rejects equals the expected distance between two distinct (alleged) copies sampled uniformly, which is assumed to be at least $\rho/3$.

Case 2: The first proof-piece list is almost entirely consistent: $\mathbb{E}_{c_1 \neq c_1' \in [m_1]}\left[\delta(\pi_1^{c_1}, \pi_1^{c_1'})\right] < \rho/3$. By an averaging argument, there exists a "typical" copy such that all other (alleged) copies in first-proof piece list are close to it in expectation; namely, there is an $a \in [m_1]$ such that $\mathbb{E}_{c_1 \in [m_1]}\left[\delta(\pi_1^{c_1}, \pi_1^{a})\right] \leq \rho/3$. We argue that since the alleged copies are close to the typical copy (in expectation), the multi-piece verifier rejects with probability similar to that of the strong canonical single-piece verifier given the typical copy as proof.

For each c_1, let $y^{c_1} \in R(x)$ be a minimizer of $\max\left(\delta(y, y^{c_1}), \delta(\pi_1^{c_1}, \Pi_1^{c_1})\right)$ where $\Pi_1^{c_1} := \Pi_1(x; y^{c_1})$. Using strong canonicality of the emulated verifier, we can lower-bound the probability that the single-piece verifier rejects in the emulation check by

$$\begin{aligned}
&\mathop{\mathbb{E}}_{c_1 \in [m_1]}\left[\alpha \cdot \max\left(\delta(y, y^{c_1}), \delta(\pi_1^{c_1}, \Pi_1^{c_1})\right)\right] \\
&\quad \geq \alpha \cdot \mathop{\mathbb{E}}_{c_1}\left[\max\left(\delta(y, y^{c_1}), \delta(\pi_1^{a}, \Pi_1^{c_1})\right)\right] - \alpha \cdot \mathop{\mathbb{E}}_{c_1}\left[\delta(\pi_1^{c_1}, \pi_1^{a})\right] \\
&\quad \geq \alpha \cdot \max\left(\delta(y, y^{a}), \delta(\pi_1^{a}, \Pi_1^{a})\right) - \alpha \cdot \frac{\rho}{3} \qquad (2)
\end{aligned}$$

where the second inequality used the minimality of y^a, which means that for any c_1 it holds that $\max\left(\delta(y, y_1^c), \delta(\pi_1^a, \Pi_1^{c_1})\right) \geq \max\left(\delta(y, y^a), \delta(\pi_1^a, \Pi_1^a)\right)$. We can also lower-bound the distance of the typical copy π_1^a from its corresponding canonical proof piece Π_1^a by

$$\begin{aligned}
\delta(\pi_1^a, \Pi_1^a) &\geq \mathop{\mathbb{E}}_{c_1 \in [m_1]}\left[\delta(\pi_1^{c_1}, \Pi_1^a)\right] - \mathop{\mathbb{E}}_{c_1 \in [m_1]}\left[\delta(\pi_1^{c_1}, \pi_1^a)\right] \qquad (3) \\
&\geq \mathop{\mathbb{E}}_{c_1 \in [m_1]}\left[\delta(\pi_1^{c_1}, \Pi_1^a)\right] - \frac{\rho}{3} = \delta\big(\overline{\pi}_1, \overline{\Pi}_1(x; y^a)\big) - \frac{\rho}{3}
\end{aligned}$$

Combining Equations (2) and (3), we have that the verifier rejects with probability at least

$$\alpha \cdot \max\left(\delta(y, y^a), \delta\big(\overline{\pi}_1, \overline{\Pi}_1(x; y^a)\big) - \frac{\rho}{3}\right) - \alpha \cdot \frac{\rho}{3} \geq \alpha \cdot \rho - \alpha \cdot \frac{2\rho}{3} = \alpha \cdot \frac{\rho}{3}$$

where the inequality is because $y^a \in R(x)$ is not necessarily the minimizer of Equation (1), i.e. it could be that $y^a \neq y'$ (and then $\max\left(\delta(y, y^a), \delta(\overline{\pi}_1, \overline{\Pi}_1(x; y^a))\right) \geq \rho$). ◀

3 Composing smooth strong canonical PCPPs

In this section, we adapt the composition theorem of Ben-Sasson et al. [6] to the strong canonical setting.

We can think of a run of nonadaptive PCPP verifier as a two-step process: first, it tosses some random coins and generates a *residual (decision) circuit* and *query locations* based on the coins it tossed, and then it queries its oracles and feeds their answers to the residual circuit, accepting or rejecting accordingly. Hence, the verifier accepts if and only if the residual circuit and oracle answers are in CircuitVal. *PCPP composition* replaces the naive verification of this claim of membership (in CircuitVal) by a probabilistic verification. That is, an *inner verifier* probabilistically checks that the oracles' answers satisfy the *outer verifier's* residual decision circuit. The resulting *composite verifier* accepts or rejects according to the inner verifier's decision.

The strong inner verifier rejects with probability that is proportional to the distance of the oracles' answers from satisfying the outer residual circuit. As such, this distance should reflect the distance of the outer oracles (in their entirety) from correct ones. In other words, if the outer oracles are far from correct ones, the outer verifier's queries should not only be rejected, but be *far* from being accepted by its residual circuit. In such a case we say that the outer verifier is *robust*.

As in the composition of [6], when it comes to randomness and query complexities, the composite verifier enjoys the best of both worlds: broadly speaking, its query complexity is inherited from the inner verifier, and its randomness complexity is (mostly) determined by the outer verifier. So, composing an outer verifier of low randomness complexity with an inner verifier that issues a few queries yields a composite verifier with low randomness *and* query complexities. The contribution of this section is in showing that, in addition, such composition can be made to preserve smoothness and strong canonicality.

3.1 Strong canonical robust PCPPs

First, we describe the run of a nonadaptive verifier as a two-step process: first sampling random coins, then querying its oracles and computing a decision. Formally,

▶ **Definition 3.1** (PCPPs, restated)**.** *Given explicit input x and oracle access input y and proof π, a (nonadaptive) PCPP verifier for relation R of randomness complexity $r(n)$ and query complexity $q(n)$ runs as follows:*

1. Sample. *The verifier uniformly samples a* coin sequence $c \in \{0,1\}^{r(|x|)}$*. Based on x and c, the verifier generates* query locations $I := I_c := (i_1, \ldots, i_{q(|x|)})$ *and* residual circuit $D := D_c$*. Note that I contains the locations of queries to both y and π.*
2. Query and compute. *The verifier queries oracles y and π according to the query locations I. Denoting the answers to these queries by $y\pi[I]$, the verifier then computes $D(y\pi[I])$ and outputs 1 ("Yes") if and only if $y\pi[I]$ satisfies D.*

The event that the verifier V accepts, i.e. "$V^{y,\pi}(x) = 1$", is equal by definition to "$y\pi[I_c] \in \mathtt{Sat}(D_c)$", where $\mathtt{Sat}(D_c)$ denotes the set of satisfying inputs of D_c, and the randomness in both events being the coin sequence c. The decision complexity *$d(n)$ is the maximal size of a residual circuit generated when the verifier is given explicit input of length n.*

Strong canonical *robustness* guarantees that the expected distance of the oracles' answers from satisfying the residual circuit is proportional to the distance of these oracles from being correct, and is formally defined as follows.

▶ **Definition 3.2** (Strong canonical robust PCPPs)**.** *A strong canonical PCPP V for relation R with canonical proof strategy $\Pi\colon \{0,1\}^* \to \{0,1\}^*$ is a strong canonical* robust *PCPP* (RPCPP) *with strongness parameter $\alpha \in (0,1]$ if, in addition to the conditions of Definition 1.8, it satisfies* strong canonical robust soundness*:*

- *For any $(x;y)$ such that $(x;y) \notin R$ it holds that $\Pi(x;y) = \emptyset$. When given explicit input x, input oracle y and proof oracle π, the expected distance of the bits queried by V from being accepted by the residual circuit is at least*

$$\alpha \cdot \min_{y' \in R(x)} \{\max\left(\delta(y,y'), \delta(\pi, \Pi(x;y'))\right)\} \tag{4}$$

That is,

$$\mathop{\mathbb{E}}_{c}\left[\delta(y\pi[I_c], \mathtt{Sat}(D_c))\right] \geq \begin{cases} \alpha \cdot \min_{y' \in R(x)} \{\max\left(\delta(y,y'), \delta(\pi, \Pi(x;y'))\right)\} & \text{if } R(x) \neq \emptyset \\ \alpha & \text{if } R(x) = \emptyset \end{cases}$$

▶ Remark 3.3. This definition differs from a natural adaptation of the original definition of robustness ([6, Definition 2.6]) in that it requires the *expected* distance to be large, rather than require the distance be large with high probability. Markov's inequality implies that Definition 3.2 is stronger.

3.2 The composition theorem

Following the two-step description of a run of a PCPP verifier in Definition 3.1, a PCPP verifier accepts explicit input x, input oracle y and proof oracle π if and only if the answers received from its proof oracle (denoted $y\pi[I]$) satisfy its residual circuit D. In a nutshell, PCPP composition is done by replacing the verification of the claim "$y\pi[I]$ *satisfies* D" with a probabilistic verification by an *inner PCPP verifier*.

Before turning to the theorem and its proof, we define an additional property we require from outer verifiers.

▶ **Definition 3.4** (Residual circuit distance). *For some constant $\Delta > 0$, we say that a PCPP verifier V has* residual circuit distance Δ *if for any input x and coin sequence c, any two distinct inputs satisfying the residual circuit D_c are at least Δ-far apart.*

In later sections, we show that the outer PCPP whose composition yields Theorem 1.12 satisfies this additional property for some constant $\Delta > 0$. Hence, it suffices to prove the composition theorem for PCPPs with constant residual circuit distance.

▶ **Theorem 3.5.** *Assume there are $\alpha_{\text{out}}, \alpha_{\text{in}}, \Delta \in (0,1]$ and $r_{\text{out}}, r_{\text{in}}, d_{\text{out}}, d_{\text{in}}, q_{\text{in}} \colon \mathbb{N} \to \mathbb{N}$ such that the following holds:*

- *The relation R has a smooth strong canonical RPCPP, denoted V_{out}, with residual circuit distance Δ, strongness parameter α_{out} and randomness and decision complexities r_{out} and d_{out} respectively.*
- CircuitVal *has a strong canonical PCPP, denoted V_{in}, with strongness parameter α_{in} and randomness, query and decision complexities r_{in}, q_{in} and d_{in} respectively.*

Then, the relation R has a strong canonical PCPP, denoted V_{comp}, with the following properties:

- *Randomness complexity $r_{\text{out}} + r_{\text{in}} \circ d_{\text{out}}$.*
- *Query complexity $q_{\text{in}} \circ d_{\text{out}}$.*
- *Decision complexity $d_{\text{in}} \circ d_{\text{out}}$*
- *Strongness parameter $\alpha_{\text{out}} \cdot \alpha_{\text{in}} \cdot \Delta/4$*

Furthermore, if V_{in} is smooth then R has a smooth strong canonical PCPP with strongness shrinking by a third (to $\alpha_{\text{out}} \cdot \alpha_{\text{in}} \cdot \Delta/12$). If V_{in} is robust (resp. has residual circuit distance) then V_{comp} is robust (resp. has residual circuit distance).

Notice that smoothness of the outer verifier is used for strong canonicality of the composite verifier.

Proof of Theorem 3.5. We affix the term *outer*, *inner* or *composite* when discussing components of the *outer*, *inner* or *composite* verifiers. For example, an *inner canonical proof* is a proof obtained from the canonical proof strategy of the inner PCPP.

We start by describing the canonical proof strategy of the composite PCPP, which consists of two proof-piece oracles: an *outer proof-piece* denoted Π, and an *inner proof-piece* denoted T. For any explicit input x and input oracle y with $(x; y) \in R$, the outer proof-piece is the outer canonical proof that $(x; y) \in R$ (for V_{out}), and the inner proof-piece is the concatenation (over all possible coin sequences c of the outer verifier) of the inner canonical proof that $y\Pi[I_c]$ satisfies D_c (for V_{in}), which we denote by T_c. With these in mind, we proceed by describing the composite verifier.

▶ **Algorithm 3.5.1** (PCPP composition [6, Section 2.4]). The composite PCPP system has verifier V_{comp} that takes explicit input x, input oracle y, and two proof-piece oracles: an outer proof-piece π, and an inner proof-piece $\tau = (\tau_c)_c$, with c ranging over all possible coin sequences of the outer verifier. It runs as follows:

1. Emulates the *Sample* step of the outer verifier, obtaining a coin sequence c, outer query locations I_c and outer residual circuit D_c. (V_{comp} does not issue any queries yet!)
2. Emulates the inner verifier with explicit input D_c, input oracle $y\pi[I_c]$ and proof oracle τ_c. V_{comp} accepts if and only if the inner verifier accepted.

Since Algorithm 3.5.1 is the same composition used in the proof of [6, Theorem 2.7], the composite PCPP enjoys all properties described there, and in particular it is a PCPP with the required complexities. Canonical completeness follows from the canonical completeness of the outer and inner verifiers, and so we turn to prove strong canonical soundness. Then,

if V_{in} is smooth then V_{comp} is two-piece smooth, and we may apply Lemma 2.2 to obtain a smooth strong canonical composite PCPP for R while losing an additional factor $1/3$ in strongness.

Fix an explicit input x, input oracle y, and alleged proof-piece oracles and π and τ, where π corresponds to the outer proof-piece and $\tau \coloneqq (\tau_c)_c$ corresponds to the inner proof-piece. If $R(x)$ is empty then we may refer to the standard soundness analysis of the composite PCPP, so we focus on the case that $R(x)$ is nonempty. Let y' be a satisfying input that minimizes the maximal distance between the given oracles and correct oracles; that is, the maximum between $\delta(y, y')$, $\delta(\pi, \Pi)$ and $\delta(\tau, T)$, where Π and T are the canonical outer and inner proof-pieces for y'. Denote the distance between the given oracles and the correct oracles by $\delta_y \coloneqq \delta(y, y')$, $\delta_\pi \coloneqq \delta(\pi, \Pi)$ and $\delta_\tau \coloneqq \delta(\tau, T) = \mathbb{E}_c\left[\delta(\tau_c, T_c)\right]$. We shall show that the verifier rejects with probability $\alpha_{\text{out}} \cdot \alpha_{\text{in}} \cdot \Delta \cdot \max\left(\delta_y, \delta_\pi, \delta_\tau\right)/4$. The analysis considers two cases.

Case 1: $\max\left(\delta_y, \delta_\pi\right) \geq \frac{\Delta}{4} \cdot \delta_\tau$. For any fixed outer coin sequence c, the strong canonical inner verifier rejects the circuit D_c, input oracle $y\pi[I_c]$ and proof oracle τ_c with probability $\alpha_{\text{in}} \cdot \delta(y\pi[I_c], \texttt{Sat}(D_c))$. The rejection probability of the composite verifier equals the expected rejection probability of the inner verifier (over random c), therefore the composite verifier rejects with probability at least $\mathbb{E}_c\left[\alpha_{\text{in}} \cdot \delta(y\pi[I_c], \texttt{Sat}(D_c))\right]$ which, by the robust strong canonicality of the outer verifier, is at least $\alpha_{\text{out}} \cdot \alpha_{\text{in}} \cdot \max\left(\delta_y, \delta_\pi\right) \geq \alpha_{\text{out}} \cdot \alpha_{\text{in}} \cdot \frac{\Delta}{4} \cdot \max\left(\delta_y, \delta_\pi, \delta_\tau\right)$.

Case 2: $\max\left(\delta_y, \delta_\pi\right) < \frac{\Delta}{4} \cdot \delta_\tau$. As a warm-up, consider the case that $\delta_y = \delta_\pi = 0$. In this case, $y\pi[I_c]$ satisfies D_c for any outer coin sequence c. Recall that the outer verifier has constant residual circuit distance, so all other inputs that satisfy D_c are far from $y\pi[I_c]$, and therefore the inner verifier's strong canonicality implies that the composite verifier rejects with probability $\Omega(\delta(\tau_c, T_c))$. Taking expectation over the coin sequence c, we have that the composite verifier rejects with probability $\Omega(\delta_\tau) = \Omega(\max\left(\delta_y, \delta_\pi, \delta_\tau\right))$.
In the actual analysis, δ_y and δ_π are not necessarily zero, but the general ideas of the warm-up are still applicable: using the smoothness of the outer verifier, we can relate $\mathbb{E}_c\left[\delta(y\pi[I_c], \delta(y'\Pi[I_c]))\right]$ with δ_y and δ_π. Since δ_y and δ_π are assumed to be $O(\delta_\tau)$, then for sufficiently many c's it holds that $y\pi[I_c]$ is close to $y'\Pi[I_c]$. Then, the constant residual circuit distance of the verifier implies that for these c's the inner verifier rejects with probability proportional to $\delta(\tau_c, T_c)$. Details follow.
We say that a fixed coin sequence c is *good* if $y\pi[I_c]$ is $\Delta/2$-close to $y'\Pi[I_c]$. Strong canonicality of the inner verifier means that the probability it rejects circuit D_c, input oracle $y\pi[I_c]$ and proof oracle τ_c is at least

$$\alpha_{\text{in}} \cdot \min_{s \in \texttt{Sat}(D_c)} \left\{\max\left(\delta(y\pi[I_c], s), \delta(\tau_c, T_c(D_c; s))\right)\right\}$$

The outer verifier has residual circuit distance Δ, so for good coins c, $\delta(y\pi[I_c], s) \geq \Delta/2$ for all $s \in \texttt{Sat}(D_c) \setminus \{y'\Pi[I_c]\}$. Therefore, for good c's, $\max\left(\delta(y\pi[I_c], s), \delta(\tau_c, T_c(D_c; s))\right)$ is at least $\delta(\tau_c, T_c)$ when taking $s = y'\Pi[I_c]$, and is at least $\Delta/2$ when s satisfies D_c but differs from $y'\Pi[I_c]$. Hence,

$$\mathbb{P}\left[V_{\text{in}}^{\tau_c}(D_c) = 0 \,|\, c \text{ good}\right] \geq \alpha_{\text{in}} \cdot \min\left\{\Delta/2, \delta(\tau_c, T_c)\right\} \geq \frac{\alpha_{\text{in}} \cdot \Delta}{2} \cdot \delta(\tau_c, T_c) \tag{5}$$

Now, we show that since δ_y and δ_π are $O(\delta_\tau)$, then the expected distance between inner proofs over good c's upper-bounds the distance between all inner proofs δ_τ (up to constants). Smoothness of the outer verifier implies that sampling a random coin

sequence c and location j in I_c is the same as uniformly sampling from $[|y\pi|]$ (as detailed in Appendix B.2). Therefore,

$$\delta(y\pi, y'\Pi) \coloneqq \mathop{\mathbb{P}}_{k}[y\pi[k] \neq y'\Pi[k]] = \mathop{\mathbb{P}}_{j,c}[y\pi[I_c][j] \neq y'\Pi[I_c][j]] = \mathop{\mathbb{E}}_{c}[\delta(y\pi[I_c], y'\Pi[I_c])]$$

Thus,

$$\delta(y\pi, y'\Pi) \geq \frac{\Delta}{2} \cdot \mathop{\mathbb{P}}_{c}\left[\delta(y\pi[I_c], y'\Pi[I_c]) > \frac{\Delta}{2}\right] = \frac{\Delta}{2} \cdot \mathop{\mathbb{P}}_{c}[c \neg\text{good}]$$

Note that $\max(\delta_y, \delta_\pi) \geq \delta(y\pi, y'\Pi)$, so by the assumption that $\max(\delta_y, \delta_\pi) < \Delta \cdot \delta_\tau/4$ we have that $\delta_\tau/2 \geq \mathbb{P}[c \neg\text{good}]$. In addition,

$$\delta_\tau = \mathop{\mathbb{E}}_{c}[\delta(\tau_c, T_c)] \leq \mathop{\mathbb{E}}_{c}[\delta(\tau_c, T_c) \mid c \text{ good}] \cdot \mathop{\mathbb{P}}_{c}[c \text{ good}] + \mathop{\mathbb{P}}_{c}[c \neg\text{good}]$$

Which implies

$$\mathop{\mathbb{E}}_{c}[\delta(\tau_c, T_c) \mid c \text{ good}] \cdot \mathop{\mathbb{P}}_{c}[c \text{ good}] \geq \delta_\tau/2 \tag{6}$$

Using Equations (5) and (6), the probability that the composite verifier rejects the given input and proof is at least

$$\mathop{\mathbb{E}}_{c}[\mathbb{P}[V_{\text{in}}^{\tau_c}(x) = 0] \mid c \text{ good}] \cdot \mathop{\mathbb{P}}_{c}[c \text{ good}] \geq \frac{\alpha_{\text{in}} \cdot \Delta}{2} \cdot \mathop{\mathbb{E}}_{c}[\delta(\tau_c, T_c) \mid c \text{ good}] \cdot \mathop{\mathbb{P}}_{c}[c \text{ good}] \geq \frac{\alpha_{\text{in}} \cdot \Delta}{4} \cdot \delta_\tau$$

If V_{in} is a strong canonical *robust* PCPP, then we note that the lower bounds on the *rejection probability* hold for the *expected distance of the bits read from* $(y\pi[I_c], \tau_c)$ *from satisfying* V_{comp}*'s residual circuit.*[15] As for residual circuit distance: any two strings satisfying the composite residual circuit satisfy the inner residual circuit, so the residual circuit distance of the inner verifier is inherited by the composite verifier. ◀

3.3 Composing the construct of Theorem 1.12

Now that we know *how* to compose PCPPs, let's talk about *which* PCPPs we compose. For now, we postulate two smooth strong canonical (R)PCPPs of certain complexities and reckon that their composition yields a PCPP of logarithmic randomness and constant queries (their actual construction and analysis constitutes the rest of this work).

▶ **Proposition 3.6** (Hadamard-based PCPP)**.** *There exists a smooth strong canonical PCPP for* CircuitVal *of quadratic randomness and constant query complexities.*

▶ **Proposition 3.7** (Reed–Muller-based RPCPP)**.** *There exists a smooth strong canonical robust PCPP for* CircuitVal *of logarithmic randomness complexity, polylogarithmic decision complexity, and constant residual circuit distance.*

As in [2, 6], the Reed–Muller-based RPCPP is composed with itself to obtain a smooth strong canonical RPCPP of logarithmic randomness complexity, poly log log decision complexity and constant residual circuit distance. The resulting RPCPP is then composed (as an outer verifier) with an inner Hadamard-based PCPP to obtain a smooth strong canonical PCPP of logarithmic randomness and constant query complexities, proving Theorem 1.12.

[15] To transform the multi-piece robust PCPP to a single-piece robust PCPP, we note that Lemma 2.2 holds for robust PCPPs as well: for strong canonicality, rather than analyzing the *rejection probability of the verifier*, we can analyze the *expected distance from being accepted by the verifier* (using exactly the same reasoning).

4 The Hadamard-based smooth strong canonical PCPP

We now turn to the actual construction of smooth strong canonical PCPPs, starting with the Hadamard-based PCPP of [2, Section 4] as presented in [20, Chapter 4].

4.1 Algebrization and the Hadamard code

A circuit and its input can be expressed as a system of quadratic equations and an assignment, such that the input satisfies the circuit if and only if the assignment satisfies the equation system. The Hadamard-based PCPP verifier capitalizes on this fact, with the proof for an input consisting of the truth tables of evaluations of all (linear and) quadratic equations on the assignment corresponding to the input. First, let's take a more detailed look at this correspondence, which is sometimes called an *algebrization* of the combinatorial problem of circuit valuation to the algebraic problem of quadratic equation valuation.

▶ **Definition 4.1** (Computational extension). *Let C be a circuit of size n with n_0 input gates and let $y \in \{0,1\}^{n_0}$. The* computational extension of y w.r.t C *is the string corresponding to the values output by each gate of C when computing y, and is denoted $y_C \in \{0,1\}^n$. That is, $y_C[i]$ is the output of the ith gate of C when computing input y. Assuming wlog that the first n_0 gates of C are its input gates, it holds that $y = y_C[1] \cdots y_C[n_0]$.*

▶ **Definition 4.2** (Outer product). *The* outer product *of vectors $u, v \in \{0,1\}^n$, denoted $u \otimes v$, is the n^2 dimensional vector obtained by "flattening" the $n \times n$ matrix whose entry in the ith column and jth row is $u[i] \cdot v[j]$. That is, $u \otimes v[(i-1)n + j] := u[i] \cdot v[j]$ for all $i, j \in [n]$.*

▶ **Proposition 4.3.** *There exists a polynomial-time computable mapping that maps circuit C of size n with m input bits to an $n \times n^2$ matrix A_C and vector $b_C \in \{0,1\}^n$ such that input $y \in \{0,1\}^m$ satisfies C if and only if $y_C \in \{0,1\}^n$ satisfies $A_C(y_C \otimes y_C) = b_C$.*

Proof sketch. Let C be a circuit of size n that has n_0 input gates. The reduction computes $b \in \{0,1\}^n$ and $a_1, \ldots, a_n \in \{0,1\}^{n^2}$ according to Table 1, and lets A_C be the matrix whose ith row is a_i. ◀

Table 1 Mapping of gates to equations. $e_{i,j} \in \{0,1\}^{n^2}$ is all zeroes except for coordinate $(i-1)n + j$.

Gate	First input gate	Second input gate	Gate type	Reduction output
i	j	k	`AND`	$a_i := e_{i,i} + e_{j,k}$ $b_i := 0$
			`OR`	$a_i := e_{i,i} + e_{j,j} + e_{k,k} + e_{j,k}$ $b_i := 0$
			`NOT`	$a_i := e_{i,i} + e_{j,j}$ $b_i := 1$
			`OUTPUT`	$a_i := e_{i,i}$ $b_i := 1$
			`INPUT`	$a_i := \overline{0}$ $b_i := 0$

The *Hadamard encoding* of a string $y \in \{0,1\}^n$ is the evaluation of all linear equations (over $\mathbb{F}_2$) on n variables on the assignment y. Formally,

▶ **Definition 4.4.** *The* Hadamard encoding *of a vector $y \in \{0,1\}^n$ is the function* $\mathrm{Had}_y \colon \{0,1\}^n \to \{0,1\}$ *given by* $\mathrm{Had}_y(z) \coloneqq y \cdot z = \sum_{i=1}^{n} y[i]z[i] \mod 2$.

Recall some useful facts about this encoding:

▶ **Fact 4.5.** *For all $n \in \mathbb{N}$:*

Distance. *A function $f \colon \{0,1\}^n \to \{0,1\}$ is linear if and only if there exists $y \in \{0,1\}^n$ such that $f = \mathrm{Had}_y$. For all $y \neq y'$ it holds that $\delta(\mathrm{Had}_y, \mathrm{Had}_{y'}) = 1/2$, associating Had_y with its 2^n-bit-long truth table. That is to say that the Hadamard code has* relative distance $1/2$.

Strong Testability. *Consider a test that given $f \colon \{0,1\}^n \to \{0,1\}$ uniformly samples $x, x' \in \{0,1\}^n$ and accepts if and only if*

$$f(x) + f(x') = f(x + x')$$

As shown in [9], if f is δ-far from all Hadamard codewords then the test rejects with probability at least $\min(\delta/2, 1/6)$. *Note that the test makes three queries to f and tosses $2n$ random coins.*

Self-correction. *Consider a self-correction procedure that given $f \colon \{0,1\}^n \to \{0,1\}$ and $x \in \{0,1\}^n$, uniformly samples $r \in \{0,1\}^n$ and outputs $f(x+r) - f(r)$. It holds that if f is δ-close to the Hadamard codeword $\widetilde{f}$ then for all x the procedure outputs $\widetilde{f}(x)$ with probability at least $1 - 2\delta$. Note that the procedure makes two queries to f and tosses n random coins.*

4.2 The PCPP and its analysis

▶ **Algorithm 4.6** (The Hadamard-based PCPP [2])**.** The canonical proof-piece strategies of circuit C and satisfying input y are the Hadamard encodings of y_C and $y_C \otimes y_C$ (the computational extension of y, and the outer product of the latter with itself, respectively). That is, $\Pi_1(C; y) \coloneqq \mathrm{Had}_{y_C}$ and $\Pi_2(C; y) \coloneqq \mathrm{Had}_{y_C \otimes y_C}$. The *verifier* takes explicit input C and is given access to input oracle y and alleged proof-piece oracles π_1 and π_2. It performs the following tests, and accepts if and only if all of them passed:

1. *Strong codeword checks.* Perform the strong codeword test of Fact 4.5 on both π_1 and π_2.
2. *Oracle-oracle consistency check:* Check that the assignment allegedly encoded by π_2 is the outer product of the assignment allegedly encoded by π_1; that is, uniformly sample $u, v \in \{0,1\}^n$ and check that $\pi_1(u)\pi_1(v) = \pi_2(u \otimes v)$, using self-correction on π_2.
3. *Satisfaction check.* Compute the quadratic equation system (A_C, b_C) corresponding to circuit C via Proposition 4.3, and check that the assignment allegedly encoded by π_2 satisfies the quadratic equation system (A_C, b_C) by checking that it satisfies a random linear combination of equations; that is, uniformly sample $w \in \{0,1\}^n$ and check that $\pi_2(w^\top A_C) = \mathrm{Had}_{b_C}(w)$, using self-correction on π_2. Note that the verifier computes A_C and Had_{b_C} based only on the circuit C, which is given explicitly.
4. *Oracle-witness consistency check.* Check that π_1 encodes the computational extension of y; that is, uniformly sample $i \in [m]$ and check that $y[i] = \pi_1(e_i)$ using self-correction on π_1, where $e_i \in \{0,1\}^m$ is the unit vector $0^{i-1}10^{n-i}$.

It is known that Algorithm 4.6 is a PCPP for CircuitVal with polynomial randomness complexity and constant query complexity (see [2] or later reformulation in [20, Section 4.1]). It is smooth (as a two-piece PCPP), as only a single uniformly random location of y is queried,

and locations queried in π_1 and π_2 are all uniformly random. We show that it is strong canonical, and can therefore be transformed into a single-piece smooth strong canonical PCPP for CircuitVal using Lemma 2.2, thereby proving Proposition 3.6.

Proof. Fix circuit C, input oracle y and proof-piece oracles π_1 and π_2. We show that the verifier rejects with probability at least

$$\frac{5}{72} \cdot \min_{y' \in \mathtt{Sat}(C)} \{\max\left(\delta(y, y'), \delta(\pi_1, \Pi_1(C; y')), \delta(\pi_2, \Pi_2(C; y'))\right)\} \tag{7}$$

where $\mathtt{Sat}(C)$ denotes the set of satisfying inputs of C.

Let $\widetilde{\pi_1}$ and $\widetilde{\pi_2}$ be the Hadamard codewords closest to π_1 and π_2 respectively. Let $\widetilde{z} \in \{0,1\}^n$ and $\widetilde{Z} \in \{0,1\}^{n \times n}$ be the decodings of $\widetilde{\pi_1}$ and $\widetilde{\pi_2}$ respectively, so that $\widetilde{\pi_1} = \mathrm{Had}_{\widetilde{z}}$ and $\widetilde{\pi_2} = \mathrm{Had}_{\widetilde{Z}}$. Fact 4.5 implies that if π_1 or π_2 are 1/12-far from $\widetilde{\pi_1}$ or $\widetilde{\pi_2}$ (respectively) then one of the linearity tests reject with probability at least 1/24. Hence, we may assume $\max\left(\delta(\pi_1, \widetilde{\pi_1}), \delta(\pi_2, \widetilde{\pi_2})\right) \leq 1/12$. Let $\widetilde{y}$ be the n_0-bit-long prefix of $\widetilde{z}$, which corresponds to the values $\widetilde{z}$ gives to the input gates of C.

We start by reckoning that if $\widetilde{\pi_1}, \widetilde{\pi_2}$ aren't the canonical proof-pieces for $(C; \widetilde{y})$ then rejection occurs with high probability, and then show that if they *were* the canonical proof-pieces then the oracle-witness consistency check (resp. strong codeword check) rejects the input oracle (resp. proof-piece oracles) with probability proportional to $\delta(y, \widetilde{y})$ (resp. $\max\left(\delta(\pi_1, \widetilde{\pi 1}), \delta(\pi_2, \widetilde{\pi_2})\right)$).

Observe that $\widetilde{\pi_1}, \widetilde{\pi_2}$ are the canonical proof-pieces of $(C; \widetilde{y})$ if and only if the following conditions hold:

- $\widetilde{y}$ satisfies the circuit C. (Otherwise, $\widetilde{y}$ has no canonical proof.)
- $\widetilde{\pi_1}$ is the Hadamard encoding of the computational extension of $\widetilde{y}$, denoted $\widetilde{y}_C$.
- $\widetilde{\pi_2}$ is the Hadamard encoding of $\widetilde{y}_C \otimes \widetilde{y}_C$.

By Proposition 4.3, we have that $\widetilde{\pi_1}, \widetilde{\pi_2}$ are the canonical proof-pieces of $(C; \widetilde{y})$ if and only if $\widetilde{Z} = \widetilde{z} \otimes \widetilde{z}$ and $\widetilde{z}$ satisfies the equation system (A_C, b_C). With this observation in mind, we examine the following cases.

Case 1: $\widetilde{\pi_1}, \widetilde{\pi_2}$ are not the canonical proof-pieces of $\widetilde{y}$.

We claim that rejection occurs with high probability. Indeed, by the foregoing observation, one of two sub-cases must hold:

Case 1.1: $\widetilde{Z} \neq \widetilde{z} \otimes \widetilde{z}$.

In this case, oracle-oracle consistency check rejects with high probability: The inequation $\widetilde{\pi_1}(u)\widetilde{v} \neq \widetilde{\pi_2}(u \otimes v)$ holds for at least a quarter of possible $u, v \in \{0,1\}^n$,[16] therefore $\pi_1(u)\pi_1(u) \neq \widetilde{\pi_2}(u \otimes v)$ with probability at least $1/4 - 2 \cdot \delta(\pi_1, \widetilde{\pi_1}) \geq 1/12$. The self-corrected query to π_2 gives the value of $\widetilde{\pi_2}$ with probability $1 - 2 \cdot (\delta(\pi_2, \widetilde{\pi_2})) \geq 5/6$, so we have that $\pi_1(u)\pi(v) \neq \pi_2(u \otimes v)$ occurs with probability at least $(1/12) \cdot (5/6) = 5/72$.

Case 1.2: $\widetilde{Z} = \widetilde{z} \otimes \widetilde{z}$ but $\widetilde{z}$ does not satisfy the quadratic equation system (A_C, b_C).

In this case, it is the satisfaction check that rejects with high probability: By Proposition 4.3 it holds that $A_C \widetilde{Z} \neq b_C$, and notice that $\mathrm{Had}_{\widetilde{Z}}(w^\top A_C)(w) = \mathrm{Had}_{A_C \widetilde{Z}}(w)$ for all $w \in \{0,1\}^n$. Therefore, the inequation $\widetilde{\pi_2}(w^\top A_C)(w) \neq \mathrm{Had}_{b_C}(w)$ holds with probability 1/2 over the choice of a uniformly random w, as the Hadamard code has relative distance 1/2. Accounting for a single self-corrected query, the satisfaction test rejects with probability at least $(1/2) \cdot (1 - 2\delta(\pi_2, \widetilde{\pi_2})) \geq 5/12$.

[16] This follows from the fact that for two distinct $n \times n$ matrices A and B, the inequation $u^\top A v \neq u^\top B v$ for at least a quarter of all possible $u, v \in \{0,1\}^n$.

Case 2: $\widetilde{\pi_1}, \widetilde{\pi_2}$ are the canonical proof-pieces of $\widetilde{y}$.

In particular, $\widetilde{y}$ is a satisfying input for circuit C. By definition of the Hamming distance and accounting for self-correction, the oracle-witness test rejects with probability $\delta(y, \widetilde{y})(1 - 2\delta(\pi_1, \widetilde{\pi_1})) \geq 5\delta(y, \widetilde{y})/6$. Additionally the linearity tests reject with probability greater than both $\delta(\pi_1, \widetilde{\pi_1})/2$ and $\delta(\pi_2, \widetilde{\pi_2})/2$. All in all, in this case the verifier rejects with probability at least

$$\max\left(\frac{5}{6}\cdot\delta(y,\widetilde{y}), \frac{1}{2}\cdot\delta(\pi_1,\widetilde{\pi_1}), \frac{1}{2}\cdot\delta(\pi_2,\widetilde{\pi_2})\right) \geq$$
$$\frac{5}{72}\cdot\min_{y'\in\mathtt{Sat}(C)}\{\max\left(\delta(y,y'), \delta(\pi_1, \Pi_1(C;y')), \delta(\pi_2, \Pi_2 C; y')\right)\}$$

where the inequality is justified by the fact that $\widetilde{y}$ satisfies circuit C (however it does not necessarily minimize the expression on the right hand side). ◀

5 The Reed–Muller-based smooth strong canonical robust PCPP

The construction of the Reed–Muller-based RPCPP is more involved than that of the Hadamard-based PCPP. We follow its presentation in [20, Part 1] (a reorganization of [6]), noting that some components mentioned therein appeared in prior works (for example [3, 2]). We find this presentation appealing as it breaks the construction down to four bite-sized steps. Essentially, we prove that the first step yields a PCPP that is smooth and strong canonical, and that the transition between each step preserves smoothness and strong canonicality. Along the way, we will also keep track of the residual circuit distance (see Definition 3.4) and observe that it is constant.

So how do we go about proving this? First, it's worth noting that the intermediate PCPPs are multi-piece and, more importantly, issue queries to oracles of larger, non-binary alphabets. Don't worry, eventually (Section 5.4) we show how to reduce alphabet size back to binary, and of course our old friend Lemma 2.2 will reduce the number of pieces to one.[17] Anyways, the first step is constructing a smooth and strong canonical RPCPP for the algebraic problem of determining whether a function is a low-degree polynomial that is identically zero on a subcube (Section 5.1). This problem is closely related to circuit satisfiability: fixing a circuit, inputs can be encoded in a way such that the input satisfies the circuit if and only if its encoding is Zero on Subcube. Section 5.2 capitalizes on this to derive an RPCPP for the problem of circuit satisfiability, which is then transformed to an RPCPP for CircuitVal by adding a consistency test (Section 5.3).

PCPPs over larger alphabets

Though the final result of this section is a (Boolean) smooth and strong canonical RPCPP, the PCPPs used along the way are non-Boolean, meaning that their queries are answered not with bits but with elements of an alphabet of larger size. Furthermore, the intermediate multi-piece PCPPs may have different alphabets for different pieces.

So far, we did not explicitly mention which alphabet was used (indeed, it was always binary) so the previously introduced notions and definitions need not be changed, except for replacing *relative Hamming distance* with the *generalized relative Hamming distance*.

[17] As in Section 3, to transform the multi-piece robust PCPP to a single-piece robust PCPP we note that Lemma 2.2 holds for robust PCPPs as well: for strong canonicality, rather than analyzing the *rejection probability of the verifier*, we can analyze the *expected distance from being accepted by the verifier* (using exactly the same reasoning exactly).

▶ **Definition 5.1** (Generalized relative Hamming metric). *Fix sets $\Sigma_1, \ldots, \Sigma_k$ and let $x = (x_1, \ldots, x_k)$ and $y = (y_1, \ldots, y_k)$ such that $x_i, y_i \in \Sigma_i$ for all $i \in [k]$. The* generalized (relative) Hamming distance *between x and y is the fraction of locations in which x and y differ, that is $\delta(x, y) \coloneqq \mathbb{P}_i [x_i \neq y_i]$ for a uniformly random $i \in [k]$.*

Note that some of the sets $\Sigma_1, \ldots, \Sigma_k$ may not be distinct. In particular, if $\Sigma_1 = \cdots = \Sigma_k$, then the generalized relative Hamming distance coincides with the relative Hamming distance as defined way back in Section 1.1.1.

▶ Remark 5.2. A letter in the alphabet Σ_i can be represented by $\log |\Sigma_i|$ bits. However, the size of Σ_i is (deliberately) not accounted for in the generalized Hamming distance, therefore the generalized Hamming distance between x and y is not necessarily the same as the Hamming distance between the binary representation of x and y (in which x_i and y_i are each replaced with $\log |\Sigma_i|$ bits for each $i \in [k]$).

All distances referred to in Section 5 are in the generalized Hamming metric.

5.1 A smooth strong canonical RPCPP for Zero on Subcube

In this section we follow [20, Section 5.3.2] in constructing an RPCPP for the algebraic problem of determining whether a function is (close to) a low-degree polynomial that is identically zero on a subcube (formalized in Definition 5.9). Before we turn to the main construction, we present a generalization of a property tester for low-degree polynomials to sequences (vectors) of functions, which will be used in the RPCPP construction. Specifically, given oracle access to a function $f : \mathbb{F}^m \to \mathbb{F}^k$, we test whether it is close to a sequence (vector) of k low-degree polynomials (see Definition 5.3 quoted below).

▶ **Definition 5.3** (Vector-valued low-degree polynomial). *A function $f \colon \mathbb{F}^m \to \mathbb{F}^k$ is a* vector-valued multivariate polynomial of degree at most d *if for all $i \in [k]$ the projection of f to the ith coordinate is a multivariate polynomial of (total) degree at most d, where the projection of f to the ith coordinate is denoted $f_i : \mathbb{F}^m \to \mathbb{F}$ and defined by $f_i(x) \coloneqq f(x)_i$ for all $x \in \mathbb{F}^m$.*

The distance between such vector-valued functions is measured according to the generalized Hamming metric of Definition 5.1; that is, $f : \mathbb{F}^m \to \mathbb{F}^k$ is δ-far from being a low-degree vector-valued polynomial if $\mathbb{P}_x [f(x) \neq \widetilde{f}(x)] > \delta$ for any vector-valued polynomial $\widetilde{f}$ of degree at most d. We stress that $f(x) \neq \widetilde{f}(x)$ when there *exists* i such that $f_i(x) \neq \widetilde{f}_i(x)$.

Recall that the *line* $\mathcal{L}$ through $\mathbb{F}^m$ with *intercept* $x \in \mathbb{F}^m$ and *slope* $h \in \mathbb{F}^m$ is the set of points $\mathcal{L} \coloneqq \{x + ih : i \in \mathbb{F}\}$. A uniformly random line (through $\mathbb{F}^m$) is obtained by sampling $x, h \in \mathbb{F}^m$ uniformly at random and letting $\mathcal{L}$ be the line with slope h and intercept x. Throughout this section we will use $f[\mathcal{L}]$ to denote the restriction of f to the line $\mathcal{L}$.

▶ **Algorithm 5.4** (PL-VLDT). The *point-line vector-valued low-degree test (PL-VLDT)* is given access to an oracle $f \colon \mathbb{F}^m \to \mathbb{F}^k$ and a "lines" proof oracle g that maps line $\mathcal{L}$ to vector-valued univariate polynomial $g_{\mathcal{L}} : \mathcal{L} \to \mathbb{F}^k$ of degree at most d. It samples a uniformly random line $\mathcal{L}$ through $\mathbb{F}^m$ and uniformly random point $x \in \mathcal{L}$, and accepts if and only if $f(x) = g_{\mathcal{L}}(x)$.

PL-VLDT uses $2m \log |F|$ random coins and makes a single query to each of its two oracles. Its soundness proof is due to Oded Goldreich and Madhu Sudan and can be found in Appendix C. We quote the relevant proposition:

▶ **Proposition 5.5** (Proposition C.4). *Assuming $|\mathbb{F}| > 25k$, if the input oracle $f \colon \mathbb{F}^m \to \mathbb{F}^k$ is δ-far from being a vector-valued polynomial of degree at most d then for any lines oracle g, PL-VLDT rejects f and g with probability at least $\delta/40$.*

We will use a variant of PL-VLDT that has higher query complexity, but does not require an auxiliary "lines" oracle; instead, it queries f on an entire line. As shown in Proposition 5.7, this test has robust soundness, meaning that the expected distance of answers to its queries from agreeing with a univariate low-degree polynomial (and therefore being accepted by the test) is proportional to the distance of the input function from being low-degree.

▶ **Algorithm 5.6** (VLDT). The *vector-valued low-degree test* is given explicit inputs $\mathbb{F}$, m and d and access to an input oracle $f\colon \mathbb{F}^m \to \mathbb{F}^k$. It samples a uniformly random line $\mathcal{L}$ through $\mathbb{F}^m$, queries f on all points in $\mathcal{L}$, and accepts if and only if the obtained values (describing the restriction of f to $\mathcal{L}$) agree with a univariate vector-valued polynomial of degree at most d.

Algorithm 5.6 uses $2m \log |\mathbb{F}|$ random coins and makes $|\mathbb{F}|$ queries to its input. Its robust soundness is asserted in Proposition 5.7.

▶ **Proposition 5.7.** *Assuming $|\mathbb{F}| > 25k$, if the input f is δ-far from being a vector-valued polynomial of degree at most d, then the expected distance of answers to the queries of VLDT from agreeing with a univariate low-degree polynomial (and therefore being accepted by the test) is at least $\beta \cdot \delta$, for $\beta = 1/40$.*

Proof. Given a function f, we define a lines oracle g that assigns each line $\mathcal{L}$ the (univariate, vector-valued) low-degree polynomial $g_{\mathcal{L}}$ closest to $f[\mathcal{L}]$. By definition, when line $\mathcal{L}$ is sampled by VLDT, the distance of answers received from f (namely $f[\mathcal{L}]$) from being accepted is $\delta(f[\mathcal{L}], g_{\mathcal{L}})$. On the other hand, PL-VLDT rejects input oracle f and the lines oracle $g \coloneqq (g_{\mathcal{L}})_{\mathcal{L}}$ with probability $\mathbb{E}_{\mathcal{L}}\left[\mathbb{P}_{x\in\mathcal{L}}\left[f(x) \neq g_{\mathcal{L}}(x)\right]\right] = \mathbb{E}_{\mathcal{L}}\left[\delta(f[\mathcal{L}], g_{\mathcal{L}})\right]$ which, invoking Proposition 5.5, is at least $\delta/40$. Therefore, the *expected* distance of the answers that VLDT receives from being accepted is at least $\delta/40$. ◀

Finally, we recall a basic and important property of low-degree polynomials.

▶ **Fact 5.8** (The Schwartz-Zippel Lemma). *For any finite field $\mathbb{F}$ and integers m and d, if $P\colon \mathbb{F}^m \to \mathbb{F}$ is a nonzero polynomial of degree at most d, then $\mathbb{P}_x\left[P(x) = 0\right] \leq d/|\mathbb{F}|$ for $x \in \mathbb{F}^m$ sampled uniformly at random.*

With these tools in hand, the construction can commence. We analyze the smoothness and strongness of a robust PCPP for Zero on Subcube [20, Section 5.3.2], an algebraic analogue of CircuitVal, starting with a formal definition of this property.

▶ **Definition 5.9** (ZoS). *Fix a finite field $\mathbb{F}$, positive integers m and d and set $H \subseteq \mathbb{F}$. A degree d polynomial $f\colon \mathbb{F}^m \to \mathbb{F}$ is* Zero on the Subcube H^m *(*Zero on Subcube *for short) if its restriction to H^m is identically 0. We denote the set of all Zero on the Subcube polynomials by $\text{ZoS}(\mathbb{F}, m, d, H)$. When the parameters are obvious from context, the shorthand* ZoS *is used instead.*

We quote a useful characterization of Zero on Subcube polynomials that gives rise to a natural robust PCPP for the set ZoS.

▶ **Fact 5.10** ([20, Proposition 5.3.4]). *For any field $\mathbb{F}$, positive integers m and d and set $H \subseteq \mathbb{F}$, a polynomial $f\colon \mathbb{F}^m \to \mathbb{F}$ of degree at most d is zero on the subcube H^m if and only if there exists a sequence of polynomials $P_1, \ldots, P_m : \mathbb{F}^m \to \mathbb{F}$ each of degree at most d, and a sequence of polynomials $Q_1, \ldots, Q_m : \mathbb{F}^m \to \mathbb{F}$ each of degree at most $d - |H|$, such that for all $x_1, \ldots, x_m \in \mathbb{F}$ and $i \in [m]$:*

$$\begin{aligned} P_{i-1}(x_1, \ldots, x_m) &= \eta(x_i) \cdot Q_i(x_1, \ldots, x_m) + P_i(x_1, \ldots, x_m) \\ P_m(x_1, \ldots, x_m) &= 0 \end{aligned} \tag{8}$$

where $P_0 \coloneqq f$, and η is a univariate polynomial of degree $|H|$ that vanishes on H which we define by $\eta(x) \coloneqq \prod_{h\in H}(x-h)$.

The vector-valued polynomials $P = (P_1, \ldots, P_m)$ and $Q = (Q_1, \ldots, Q_m)$ are called the division witnesses *of f.*[18]

▶ **Algorithm 5.11** (ZoS-RPCPP)**.** The canonical proof-pieces for $f \in \text{ZoS}$ are the division witnesses of f, denoted $P(f) \coloneqq (P_1(f), \ldots, P_m(f))$ and $Q(f) \coloneqq (Q_1(f), \ldots, Q_m(f))$, as guaranteed by Fact 5.10. For input field $\mathbb{F}$, dimension m and degree d, given oracle access to input $f\colon \mathbb{F}^m \to \mathbb{F}$ and proof-pieces $p : \mathbb{F}^m \to \mathbb{F}^m$ and $q : \mathbb{F}^m \to \mathbb{F}^m$, the verifier samples a random line $\mathcal{L}$ through $\mathbb{F}^m$, queries f, p and q on each point in $\mathcal{L}$, and performs the following checks:

1. *Low-degree checks.* Check that the restrictions of f and p to the line $\mathcal{L}$, denoted $f[\mathcal{L}]$ and $p[\mathcal{L}]$, are vector-valued univariate polynomials of degree at most d.[19] Check that $q[\mathcal{L}]$ is a vector-valued univariate polynomial of degree at most $d - |H|$.
2. "Unbundle" the answers received from p and q to obtain $p_i(x)$ and $q_i(x)$ for each $i \in [m]$ and $x \in \mathcal{L}$. Check the following:
   a. *Division checks.* For each $i \in [m]$ and $(x_1, \ldots, x_m) \in \mathcal{L}$, check that
   $$p_{i-1}(x_1, \ldots, x_m) = \eta(x_i) \cdot q_i(x_1, \ldots, x_m) + p_i(x_1, \ldots, x_m)$$
   where $p_0 \coloneqq f$, and η is a univariate polynomial of degree $|H|$ that vanishes on H, defined $\eta(x) \coloneqq \prod_{h\in H}(x-h)$.
   b. *Identity check.* For each $(x_1, \ldots, x_m) \in \mathcal{L}$, check that
   $$p_m(x_1, \ldots, x_m) = 0$$

The verifier accepts if and only if all the above checks passed.

ZoS-RPCPP is piecwise-smooth, makes $|\mathbb{F}|$ queries to each of its three oracles and uses $2m \log |\mathbb{F}|$ random coins. Its residual circuit distance (Definition 3.4) is $1/2$ as any satisfying input to its residual circuit is composed of three univariate polynomials of degree at most d, each occupying a third of the input. As such, any two different satisfying inputs agree on at most a $2/3 \cdot d/|\mathbb{F}| \le 1/2$ fraction of locations.

▶ **Lemma 5.12.** *Suppose* ZoS-RPCPP *is given field $\mathbb{F}$ and degree d such that $1 - \beta \ge 4d/|\mathbb{F}|$, and access to oracles f, p and q. Then the expected distance (over a random line) of the answers to* ZoS-RPCPP*'s queries from being accepted is at least*

$$\frac{\beta}{12} \cdot \min_{f' \in \text{ZoS}(\mathbb{F},m,d,H)} \{\max\left(\delta(f,f'), \delta(p, P(f')), \delta(q, Q(f'))\right)\} \tag{9}$$

where β is the constant of Proposition 5.7, and $P(f')$ and $Q(f')$ are the canonical proof-pieces of f' as described in Algorithm 5.11.

Proof. Fix input oracle $p_0 \coloneqq f\colon \mathbb{F}^m \to \mathbb{F}$ and proof oracles $p = (p_1, \ldots, p_m)$ and $q = (q_1, \ldots, q_m)$ with $p_i, q_i : \mathbb{F}^m \to \mathbb{F}$. Let $\widetilde{f}$ and $\widetilde{p}$ be the vector-valued polynomials of degree at most d closest to f and p, and $\widetilde{q}$ be the polynomial of degree at most $d - |H|$ closest to q. Let $\widetilde{p_i}$ and $\widetilde{q_i}$ be the projections of p and q to their ith coordinate. Note that $p_0 \coloneqq f$ and so $\widetilde{p_0} \coloneqq \widetilde{f}$.

We start by showing that unless $\widetilde{f}$ is Zero on Subcube and $\widetilde{p}, \widetilde{q}$ are its canonical proof-pieces, then the expected distance is $\Omega(1)$.

[18] This ad-hoc term alludes to the proof of Fact 5.10: an iterative process that starts with the polynomial $f = P_0$, and in the ith iteration divides P_{i-1} by $\eta(x_i)$ to obtain quotient Q_i and remainder P_i.
[19] Indeed the term "vector-valued" is degenerate for $f\colon \mathbb{F}^m \to \mathbb{F}$ as its range is one-dimensional.

Case 1: Either f, p or q are $1/4$-far from $\widetilde{f}$, $\widetilde{p}$ or $\widetilde{q}$. Assume wlog that p is $1/4$-far from $\widetilde{p}$. By Proposition 5.7, the expected distance of $p[\mathcal{L}]$ from a univariate polynomial of degree at most d is at least $\beta/4$. However the answers of p are just a third of the answers received by all oracles, so the expected distance of $(f[\mathcal{L}], p[\mathcal{L}], q[\mathcal{L}])$ from satisfying the low-degree checks is at least $\frac{1}{3} \cdot \frac{\beta}{4}$.

Case 2: f, p and q are close to low-degree polynomials that do not satisfy Equation (8); that is, f, p and q are $1/4$-close to $\widetilde{f}$, $\widetilde{p}$ and $\widetilde{q}$ but for some i it holds that $\widetilde{p_{i-1}}$, $\widetilde{p_i}$ and $\widetilde{q_i}$ don't satisfy Equation (8). By Fact 5.8, either $\widetilde{p_{i-1}}$, $\widetilde{p_i}$ or $\widetilde{q_i}$ do not satisfy Equation (8) on at least a fraction of $1 - d/|F|$ of points in $\mathbb{F}^m$. Since p_{i-1}, p_i and q_i are $1/4$-close to $\widetilde{p_{i-1}}$, $\widetilde{p_i}$ and $\widetilde{q_i}$ respectively,[20] then p_{i-1}, p_i and q_i do not satisfy Equation (8) on at least a fraction of $1 - d/|\mathbb{F}| - 3/4 = 1/4 - d/|\mathbb{F}|$ points in $\mathbb{F}^m$. Therefore the expected distance of $(f[\mathcal{L}], p[\mathcal{L}], q[\mathcal{L}])$ from satisfying the division checks is at least $1/3 \cdot (1/4 - d/|\mathbb{F}|) \geq \beta/12$.

Case 3: p_m is $1/4$-close to $\widetilde{p_m}$ but $\widetilde{p_m} \not\equiv 0$. By Fact 5.8, $p_m(x) \neq 0$ on at least a fraction of $1/4 - d/|\mathbb{F}|$ of points $x \in \mathbb{F}^m$. As the answers of p are a third of the answers received by all oracles, the expected distance of $(f[\mathcal{L}], p[\mathcal{L}], q[\mathcal{L}])$ from satisfying the identity check is at least $1/3 \cdot (1/4 - d/|\mathbb{F}|) \geq \beta/12$.

If all three previous cases are are false, then the input oracle is close to a Zero on Subcube polynomial, and the given proof-piece oracles are close to the canonical proof-pieces for that polynomial. These proof-pieces are low-degree polynomials, therefore the distance of the given oracles from proving that the input is Zero on Subcube is exactly their distance from being low-degree polynomials (similarly, the distance of the input from being Zero on Subcube is its distance from being low-degree), and VLDT rejects with probability proportional to this distance. Details follow.

As we said, in this case $\widetilde{f}$ is zero on the subcube H^m, and $\widetilde{p}, \widetilde{q}$ are its canonical proof-pieces. Since $\delta(f, \widetilde{f}) < 1/4$ then $\widetilde{f}$ is the only low-degree polynomial $1/4$-close to f, and since $\widetilde{f} \in \text{ZoS}$ it must be that $\widetilde{f}$ is function from $\text{ZoS}(\mathbb{F}, m, d, H)$ closest to f. We conclude the proof by showing that the expected distance of all answers from satisfying is greater than Expression 9: Assume that $\delta(q, \widetilde{q})$ maximizes Expression 9. The expected distance of answers to queries made by VLDT to oracle q from satisfying is at least $\beta \cdot \delta(q, \widetilde{q})$. But as the answers of q account for a third of the all answers received, we have that the expected distance of all answers on a random line from satisfying is at least $\beta \cdot \delta(q, \widetilde{q})/3 = \beta \cdot \delta(q, Q(\widetilde{f}))/3$. If f or p maximized Expression 9 then similar arguing gives the required result. ◀

5.2 A smooth strong canonical RPCP for CircuitSat

To construct a robust PCP for CircuitSat, we first recall an algebrization (i.e. algebraic description) of circuits and their inputs such that an input satisfies the circuit if and only if an encoding of the input is zero on a certain (fixed) subcube.

▶ **Definition 5.13** (Low-degree extension). *Let $z\colon H^m \to \mathbb{F}$. The* low-degree extension of z to $\mathbb{F}^m$ *is the unique polynomial $\widehat{z} : \mathbb{F}^m \to \mathbb{F}$ of degree at most $m|H|$ that agrees with z on H^m.*[21]

[20] Indeed, notice that $\delta(p_i, \widetilde{p_i}) \leq \delta(p, \widetilde{p})$ for all $i \in [m]$ and similarly for q and $\widetilde{q}$.

[21] We will only use the uniqueness and low-degree properties of the extension, but if you insist, know that it is given by

$$\widehat{z}(x) \coloneqq \sum_{h \in H^m} z(h) \cdot \prod_{\substack{i \in [m] \\ h' \in H \setminus \{h_i\}}} \frac{x_i - h'}{h_i - h'}$$

We loosely summarize the algebrization of [20, Section 5.4.1]. A circuit C of size n is associated with a function $C'\colon [n]^3 \times \{0,1\}^3 \to \{0,1\}$ such that $C'(i_1,i_2,i_3,b_1,b_2,b_3) = 1$ if and only if assigning gates i_1, i_2 and i_3 the values $\neg b_1$, $\neg b_2$ and $\neg b_3$ necessarily results in an *invalid* or *unsatisfying* computation of the circuit. The interested reader is referred to [20] for a formal definition of these,[22] and we will describe them by example: if gate 5 is the output gate of C then $C'(5,1,2,1,0,0) = 1$ because (by definition) a satisfying computation does not have the output gate outputting the value 0. As another example, suppose that the 7th gate is an `OR` gate taking input from gates 2 and 4, then $C'(2,4,7,1,1,0) = 1$ because in a valid computation an `OR` gate taking two 0 inputs cannot output 1.

So, C' indicates when an assignment to C's gates results in an invalid or unsatisfying computation. Thus for any alleged computational extension z (see Definition 4.1), the product $F' = C'(i_1,i_2,i_3,b_1,b_2,b_3)\cdot(z[i_1]-b_1)(z[i_2]-b_2)(z[i_3]-b_3)$ will be zero if and only if z is a computational extension of a satisfying input. Another key observation is that replacing C' by its low-degree extension $\widehat{C}$ and z by its low-degree extension $\widehat{z}$ results in a product F that has low-degree. Conversely, F is Zero on Subcube (and in particular low-degree) only if z was a satisfying assignment.

We refer the reader to [20, Section 5.4.1] for a deeper discussion, which is summarized in the following statement.

▶ **Fact 5.14** (Algebrization of CircuitSat)**.** *There exists a polynomial reduction that maps a circuit C of size n to a polynomial $\widehat{C}\colon \mathbb{F}^{3m+3} \to \mathbb{F}$ of degree at most d where $m := \log n/\log\log n$, $H := [n^{1/m}]$, $d = (3m+3)|H|$ and $|\mathbb{F}| = O((d+3m|H|)^3)$, such that $\widehat{C}$ satisfies the following:*

- *For any $e\colon \mathbb{F}^m \to \mathbb{F}$, let $F_{C,e} : \mathbb{F}^{3m+3} \to \mathbb{F}$ be given by*

$$\begin{aligned} F_{C;e}(x_1,\ldots,x_{3m+3}) :=& \widehat{C}(x_1,\ldots,x_{3m+3})\cdot(e(x_1,\ldots,x_m)-x_{3m+1}) \\ &\cdot(e(x_{m+1},\ldots,x_{2m})-x_{3m+2})\cdot(e(x_{2m+1},\ldots,x_{3m})-x_{3m+3}) \end{aligned}$$

  Then, for any polynomial $e\colon \mathbb{F}^m \to \mathbb{F}$ of degree at most $m|H|$, the function $F_{C;e}$ is identically zero on H^{3m+3} if and only if e is the low-degree extension of a computational extension of an assignment that satisfies C.

▶ **Algorithm 5.15** (CircuitSat-RPCP)**.** For any circuit C and satisfying input y the canonical proof consists of four pieces: the low-degree extension of the computational extension of y denoted $\widehat{y_C}$, the polynomial $F_{C;\widehat{y_C}}$ as defined in Fact 5.14, followed by the proof-pieces (for ZoS-RPCPP) that $F_{C;\widehat{y_C}}$ is zero on the subcube H^{3m+3}, namely its division witnesses (of Fact 5.10) denoted $P(C;y)$ and $Q(C;y)$. Given explicit access to circuit C of size n, and oracle access to $e\colon \mathbb{F}^m \to \mathbb{F}$, $f : \mathbb{F}^{m'} \to \mathbb{F}$, $p : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$ and $q : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$ where $|\mathbb{F}| = O((d+1m|H|)^3)$ and $m' := 3m+3$, the verifier samples a uniformly random line $\mathcal{L}'$ through $\mathbb{F}^{m'}$ and performs the following checks:

1. *Zero on Subcube check.* Check that f is a polynomial of degree at most d' that is zero on the subcube $H^{m'}$ using ZoS-RPCPP with the random line $\mathcal{L}'$, p and q as its proof-piece oracles, and with $d' := m'|H|$ and $H = [n^{1/m}]$.
2. *Low-degree check.* Check that e is a polynomial of degree at most d using VLDT where $d = m|H|$, with the projection of $\mathcal{L}'$ onto its first m coordinates used as the random line. That is, check that $\{e(x_1,\ldots,x_m) : (x_1,\ldots,x_m,\ldots,x_{m'}) \in \mathcal{L}'\}$ agrees with a univariate polynomial of degree at most d.

[22] In [20] these notions are both referred to as *invalid configurations*.

3. *Satisfaction check.* For each $x = (x_1, \ldots, x_{m'}) \in \mathcal{L}'$, check that

$$f(x_1, \ldots, x_{3m+3}) \coloneqq \widehat{C}(x_1, \ldots, x_{3m+3}) \cdot (e(x_1, \ldots, x_m) - x_{3m+1}) \cdot (e(x_{m+1}, \ldots, x_{2m}) - x_{3m+2}) \cdot (e(x_{2m+1}, \ldots, x_{3m}) - x_{3m+3}) \tag{10}$$

where $\widehat{C}$ is as guaranteed by the algebrization of CircuitSat (Fact 5.14).
The verifier accepts if and only if all the above checks passed.

CircuitSat-RPCP tosses $m' \log |\mathbb{F}| = O(m \log |\mathbb{F}|)$ random coins. It issues a total of $6|\mathbb{F}|$ queries to all of its oracles. Namely, for each $x \in \mathcal{L}'$ it issues the following queries:

$$f(x), p(x), q(x), e(x_1, \ldots, x_m), e(x_{m+1}, \ldots, x_{2m}), e(x_{2m+1}, \ldots, x_{3m})$$

It has constant residual circuit distance (Definition 3.4), as any answer string that satisfies its decision circuit consists of 6 univariate low-degree polynomials, each composing a sixth of the entire string. Thus, two different strings satisfying its decision circuit agree on at most a $\frac{5}{6} \cdot \frac{d}{|\mathbb{F}|} \leq 1/2$ fraction of locations.

▶ **Lemma 5.16.** *Suppose* CircuitSat-RPCP *is given satisfiable circuit C and access to proof-piece oracles $e\colon \mathbb{F}^m \to \mathbb{F}$, $f : \mathbb{F}^{m'} \to \mathbb{F}$, and $p, q : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$, with $1 - \beta \geq 5d'/|\mathbb{F}|$ where β is the constant of Proposition 5.7. Then the expected distance of the answers to* CircuitSat-RPCP*'s queries from satisfying is at least*

$$\frac{\beta}{30} \cdot \min_{y' \in \mathtt{Sat}(C)} \left\{ \max \left(\delta\left(e, \widehat{y'_C}\right), \delta\left(f, F_{C;\widehat{y'_C}}\right), \delta(p, P(C; y')), \delta(q, Q(C; y')) \right) \right\} \tag{11}$$

where $\mathtt{Sat}(C)$ denotes the set of satisfying inputs of C, and $\widehat{y'_C}$, $F_{C;\widehat{y'_C}}$, $P(C; y')$ and $Q(C; y')$ are the canonical proof-pieces of y' as described in Algorithm 5.15.

Proof. Fix circuit C and oracles e, f, p and q. Let $\widetilde{e}$ be the closest polynomial to e of degree at most d, and let $\widetilde{f}$, $\widetilde{p}$, $\widetilde{q}$, $\widetilde{p_i}$ and $\widetilde{q_i}$ be the closest low-degree polynomials (as in Lemma 5.12). Consider the following cases:

Case 1: Either of the oracles are 1/5-far from their closest low-degree polynomial. By Proposition 5.7, at least $\beta/5$ of the points read on a random line must be changed in order to satisfy VLDT. The answers to queries made by the low-degree checks (either of Step 2 or Step 1) make up for at least a sixth of the all answers received, therefore the expected distance of all received answers from satisfying is at least $\beta/30$.

Case 2: All oracles are 1/5-close to low-degree polynomials, but $\widetilde{p}, \widetilde{q}$ are not the canonical proof-pieces (for ZoS-RPCPP) that $\widetilde{f}$ is Zero on Subcube. Just like in the proof of Lemma 5.12, the answers to queries made in Step 1 are $\beta/5$-far from satisfying. These answers are a half of answers to all queries, therefore the expected distance of all received answers from satisfying is at least $\beta/10$.

Case 3: All oracles are 1/5-close to low-degree polynomials, but $\widetilde{e}$ and $\widetilde{f}$ do not satisfy Equation (10). Then the expected number of points (on a random line) on which e and f violate Equation (10) is at least $1 - d'/\mathbb{F} - 4 \cdot 1/5 = 1/5 - d'/\mathbb{F}$, which is larger than $\beta/5$. Since the answers to queries made in Step 3 make up for at least two-thirds of answers to all queries, the expected distance of all answers from satisfying is at least $2\beta/15$.

If all of the above are false, then the given oracles are close to proof-pieces proving that C is satisfiable. These proof-pieces are low-degree polynomials, therefore the distance of the given oracles from proving that C is satisfiable is exactly their distance from being low-degree, and VLDT rejects with probability proportional to this distance. Details follow.

In this case, $\widetilde{e}$ is a low-degree extension of a computational extension of a satisfying assignment to C, and $\widetilde{f}$, $\widetilde{p}$ and $\widetilde{q}$ are its canonical proof-pieces. Since $\delta(e,\widetilde{e}) < 1/5$ then $\widetilde{e}$ is the only low-degree polynomial $1/5$-close to e, so it must be that $\widetilde{e} = \widehat{y'_C}$ (where y' is the minimizer of Expression 11). Assume that q maximizes Expression 11. The expected distance of answers to queries made by VLDT to q from satisfying is at least $\beta \cdot \delta(q,\widetilde{q})$. But as the answers of q account for a sixth of all answers received, the expected distance of all answers from satisfying is at least $\beta\delta(q,\widetilde{q})/6$. If the maximizers were e, f or p the claim follows using similar reasoning. ◀

5.3 A smooth strong canonical RPCPP for CircuitVal

In this section we transform CircuitSat-RPCP to an RPCP *of proximity* for CircuitVal. The RPCPP is constructed by (additionally) testing consistency of the input oracle (an allegedly satisfying input to the circuit) with the proof-piece oracle corresponding to the alleged low-degree extension of its computational extension (see Definition 4.1). Low degree extension is systematic, in the sense that the extended function is embedded in its extension, so consistency may be checked by testing that the input oracle agrees with the systematic part of its alleged low-degree extension on a uniformly random location. However, the systematic part of the proof-piece oracle is only a tiny fraction of it (as $n = o(|\mathbb{F}^m|)$), so a particularly nasty proof-piece oracle could be close to an arbitrary low-degree polynomial (therefore passing the low-degree check), whose systematic part was changed to match the input oracle (therefore passing the consistency check) – causing the verifier to accept a proof that's extremely far from the canonical one. This is resolved via self-correction: the verifier checks that the proof-piece oracle is a low-degree univariate polynomial on a random (punctured, see below) line through the location queried in the systematic part.

Unlike previous steps in this construction, some care must be taken so that the consistency check does not harm smoothness. If the verifier reads the entire line, locations in the systematic part would be queried more often than others. Indeed, the verifier does not need to read the systematic point on the line and can interpolate it from the others. But if the verifier *always* avoids reading the systematic part, its locations would be queried less often than others. Thus, the verifier chooses the puncture (i.e. point on the line not to be read) to be the location in the systematic part with probability $1 - \Theta(1/|F|^{m-1})$, and to be a different point on the line with the remaining probability.

▶ **Algorithm 5.17** (CircuitVal-RPCPP)**.** The canonical proof of a circuit and its satisfying input consists of the same four proof-pieces as in Algorithm 5.15. Given explicit access to circuit C of size n with n_0 input gates, and oracle access to input $y\colon [n_0] \to \{0,1\}$ and proof-pieces $e : \mathbb{F}^m \to \mathbb{F}$, $f : \mathbb{F}^{m'} \to \mathbb{F}$, $p : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$ and $q : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$ where $m' \coloneqq 3m+3$, the verifier performs the following checks:

1. *Satisfiability check.* Check that C is satisfiable using CircuitSat-RPCP with e, f, p and q as proof-piece oracles.
2. *Consistency check.* Sample a location in the input oracle by uniformly sampling $x \in [n_0] \equiv H^m$. Sample a random line $\mathcal{L}$ with intercept x by sampling $h \in \mathbb{F}^m$ and letting $\mathcal{L} \coloneqq (x + ih : i \in \mathbb{F})$. Let the puncture z be $z \coloneqq x$ with probability $1 - (|\mathbb{F}| - 1)/(|\mathbb{F}|^m + 1)$, and $z \coloneqq x + h$ with the remaining probability.
   Query e on the line $\mathcal{L}$ punctured at z, i.e. $e[\mathcal{L} \setminus \{z\}]$. Query $y(x)$, giving the query a weight of $|\mathcal{L}| = |\mathbb{F}|$.[23]. Do the following:

[23] Reweighting is achieved by repeating the input gate corresponding to $y(x)$ in the verifier's residual circuit.

a. Check that $e[\mathcal{L} \setminus \{x\}]$ agrees with a univariate polynomial of degree at most d. If the check passed, let $e_{\mathcal{L}} : \mathcal{L} \to \mathbb{F}$ be the unique low-degree polynomial that agrees with $e[\mathcal{L} \setminus \{z\}]$.
b. Check that $y(x) = e_{\mathcal{L}}(x)$: If $z = x$, obtain $e_{\mathcal{L}}(x)$ using interpolation (*not* by querying $e(x)$). If $z = x + h$ then $e_{\mathcal{L}}(x) = e(x)$ has already been queried and is known to the verifier.

The verifier accepts if and only if the above checks passed.

CircuitVal-RPCPP tosses $(m + m') \log |\mathbb{F}| = O(m \log |\mathbb{F}|)$ random coins. It issues a total of $8|\mathbb{F}| - 1$ (weighted) queries to its oracles: in addition to the $6|\mathbb{F}|$ queries of CircuitSat-RPCP, it queries e on $\mathcal{L} \setminus \{z\}$ in Step 2a, and issues a query of weight $|\mathbb{F}|$ to w. It has constant residual circuit distance (Definition 3.4), which is shown by an application of Fact 5.8, just as with ZoS-RPCPP and CircuitSat-RPCP.

Smoothness of CircuitVal-RPCPP

We explain how the randomized choice of puncture in Step 2 preserves smoothness. Let α denote the probability that the puncture z is at x (i.e., verifier reads $e[\mathcal{L} \setminus \{x\}]$), and $1 - \alpha$ be the probability that the puncture is at $x + h$. We show that each point in $\mathbb{F}^m$ is queried with equal probability.

- *The non-systematic part:* A point from the non-systematic part, i.e. $\mathbb{F}^m \setminus [n_0]$, is read only if it lies on the line $\mathcal{L}$ and does not equal the puncture. This occurs with probability

$$\frac{|\mathbb{F}| - 2}{|\mathbb{F}|^m} + \frac{1}{|\mathbb{F}|^m} \cdot \alpha \tag{12}$$

- *The systematic part:* Consider a point from the systematic part, i.e. $[n_0]$. If it is chosen to be the intercept x of line $\mathcal{L}$, then it is read only if the puncture is not at x but at $x + h$ – which occurs with probability $1 - \alpha$. If it is not chosen to be the intercept x, then it is queried with probability equal to that of points in the non-systematic part, as analyzed above. Thus, points in the systematic part are queried with probability

$$\frac{1}{n_0} \cdot (1 - \alpha) + \left(1 - \frac{1}{n_0}\right) \cdot \left(\frac{|\mathbb{F}| - 2}{|\mathbb{F}|^m} + \frac{1}{|\mathbb{F}|^m} \cdot \alpha\right) \tag{13}$$

Indeed, choosing $\alpha = 1 - (|F| - 1)/(|\mathbb{F}|^m + 1)$ equalizes Expressions 12 and 13.

Soundness of CircuitVal-RPCPP

Robust strong canonical soundness of CircuitVal-RPCPP follows from the following lemma.

▶ **Lemma 5.18.** *Suppose* CircuitVal-RPCPP *is given a satisfiable circuit C, input oracle $y \colon [n_0] \to \{0,1\}$ and proof-piece oracles $e : \mathbb{F}^m \to \mathbb{F}$, $f : \mathbb{F}^{m'} \to \mathbb{F}$, and $p, q : \mathbb{F}^{m'} \to \mathbb{F}^{m'}$, with $1 - \beta \geq d/|\mathbb{F}|$. Then the expected distance of the answers to* CircuitVal-RPCPP*'s queries from satisfying is at least*

$$\frac{\beta}{64} \cdot \min_{y' \in \mathtt{Sat}(C)} \left\{ \max \left(\delta(y, y'), \delta\left(e, \widehat{y'_C}\right), \delta\left(f, F_{C;\widehat{y'}}\right), \delta(p, P(C; y')), \delta(q, Q(C; y')) \right) \right\} \tag{14}$$

where $\mathtt{Sat}(C)$ *denotes the set of satisfying inputs of C, β is the constant of Proposition 5.7, and $\widehat{y'_C}$, $F_{C;\widehat{y'_C}}$, $P(C; y')$ and $Q(C; y')$ are the canonical proof-pieces of y' as described in Algorithm 5.15.*

Proof. Fix input C and oracles y, e, f, p and q. Let $\widetilde{e}$, $\widetilde{f}$, $\widetilde{p}$, $\widetilde{q}$, $\widetilde{p_i}$ and $\widetilde{q_i}$ as in the proof of Lemma 5.16, and let y' be the minimizer of Expression 14.

Following the analysis of CircuitSat-RPCP, if $\widetilde{f}$, $\widetilde{p}$ and $\widetilde{q}$ are not the canonical proof-pieces of $\widetilde{e}$ proving that it is the low-degree extension of a satisfying assignment to C, then the expected distance of answers to queries issued to e ,f, p and q from satisfying is at least $\beta/30$. Since these answers account for more than $6/8$ of all answers, then the expected distance of answers to queries issued to all oracles is at least $6/8 \cdot \beta/30$.

Otherwise $\widetilde{f}$, $\widetilde{p}$ and $\widetilde{q}$ are the canonical proofs proving that $\widetilde{e}$ encodes a satisfying assignment denoted $\widetilde{y}$. Again using the analysis of CircuitSat-RPCP we have that the expected distance of answers to queries issued to all oracles is at least

$$\frac{6}{8} \cdot \frac{\beta}{30} \cdot \max\left(\delta\left(e, \widehat{y'_C}\right), \delta\left(f, F_{C;\widehat{y'_C}}\right), \delta(p, P(C;y')), \delta(q, Q(C;y'))\right)$$

We now argue that the expected distance is proportional also to $\delta(y, y')$. With probability $\Omega(\delta(y, y'))$, either the query from y must be changed (and it has a constant fraction of the weight of all queries), or e must be changed on a constant fraction of locations on the line $\mathcal{L}$ (due to self-correction). Details follow.

Notice that if e is $1/4$-far from $\widetilde{e}$ then by Proposition 5.7 and a similar weighting argument, the distance of all answers from satisfying is at least $1/4 \cdot \beta \cdot (1/8 - 1/|\mathbb{F}|)$,[24] so what's left is to show that the expected distance is proportional to $\delta(y, \widetilde{y})$. Indeed, if the sampled location x in Step 2 is one on which y and $\widetilde{y}$ differ, i.e. such that $y(x) \neq \widetilde{e}(x)$, then either the value of $y(x)$ must be changed or $e[\mathcal{L} \setminus \{z\}]$ must be changed to agree with a univariate degree d polynomial whose value at x is $y(x)$. Even with x fixed, all points in $\mathcal{L} \setminus \{x\}$ are marginally uniform, so by linearity of expectation,

$$\mathop{\mathbb{E}}_{\text{Random } \mathcal{L} \text{ with intercept } x} [\delta(e[\mathcal{L} \setminus \{x\}], \widetilde{e}[\mathcal{L} \setminus \{x\}])] = \delta(e, \widetilde{e}) \leq 1/4$$

By Markov's inequality, for any $x \in \mathbb{F}^m$ and random line $\mathcal{L}$ with intercept x, with probability at least $1/2$ it holds that $e[\mathcal{L} \setminus \{x\}]$ is $1/2$-close to $\widetilde{e}[\mathcal{L} \setminus \{x\}]$ and therefore $e[\mathcal{L} \setminus \{z\}]$ is $2/3$-close to $\widetilde{e}[\mathcal{L} \setminus \{z\}]$ (this accounts for the case that $z = x + h$ in Step 2. Conditioned on this event, $e[\mathcal{L} \setminus \{z\}]$ must be changed on at least $1 - d/|\mathbb{F}| - 2/3 \geq 1/4$ fraction of locations to make the consistency check of Step 2 pass.

All in all, we have that with probability at least $\delta(y, \widetilde{y})/2$, at least a quarter of the answers received either from y or from e (in Step 2) must be changed so that Step 2 does not reject. As these account for at least a $(1/8 - 1/|\mathbb{F}|)$ of all answers received, we have that the expected distance is at least $\delta(y, \widetilde{y})/64$. ◀

5.4 Alphabet Reduction

So we have an RPCPP for CircuitVal, but we aren't done just yet: CircuitVal-RPCPP is *non-Boolean*, meaning that it's proofs are written using non-binary symbols. It's time to show how to transform it to a Boolean RPCPP. Actually, we will show how to transform *any* non-Boolean RPCPP to a Boolean one of comparable complexities – provided its symbols are not much larger than the number of queries it issues. Most importantly, we prove that this transformation preserves smoothness and strong canonicality.

We show this even for multi-piece RPCPPs that have different-sized alphabets for different pieces. That is, letting the ith proof-piece oracle answers its queries with symbols in the alphabet $\Sigma_i = \{0,1\}^{\sigma_i}$ it could be that not all σ_i's are equal. We call σ_i the *ith proof-piece answer-length complexity* of the RPCPP.

[24] Due to Step 2, but in fact low-degree tests occur in Step 1 as well.

▶ **Lemma 5.19.** *Suppose* CircuitVal *has a smooth and strong canonical multi-piece RPCPP with constant residual circuit distance, ith answer complexity σ_i and query complexity q, and the additional property that the verifier makes the same amount of queries to each of its oracles up to a constant multiplicative factor ρ.*[25] *Then,* CircuitVal *has a Boolean smooth and strong canonical multi-piece RPCPP with query complexity $O(q \cdot \max_{i\in[k]} \sigma_i)$, decision complexity growing by an additive factor of $\widetilde{O}(q \cdot \max_{i\in[k]} \sigma_i)$, and strongness parameter shrinking by a constant factor.*

Following [20, Section 5.4.3], the Boolean PCP is obtained by replacing each letter of the non-Boolean PCP with its encoding in an error correcting code of constant relative distance. Since each proof-piece may have different answer complexity, we choose a different code for each proof-piece. Starting with a good code (i.e., of constant relative distance and rate) for the proof-piece with maximal answer-length complexity, we take the other codes to have equal distance and *block length*, increasing the rate if necessary using code repetition. Equal block length is necessary so that the generalized Hamming distance between two non-Boolean proofs is reflected accurately by their corresponding Boolean proofs (and is not scaled with differences in answer complexities as in Remark 5.2).

The Boolean verifier emulates the non-Boolean one: for each symbol the non-Boolean verifier queries, the Boolean verifier queries all bits in the corresponding block and answers the emulated verifier with their decoding (rejecting if the block was not decodable). We then prove that any Boolean proof is either far from being composed of codewords (therefore far from being accepted by the Boolean verifier in expectation), or its expected distance from satisfying the Boolean verifier is similar to the expected distance of its *decoding* from satisfying the non-Boolean verifier, where its *decoding* refers to the non-Boolean string obtained by decoding each of its blocks. Since the distance of the Boolean proof from the canonical proof (for the Boolean verifier) is proportional to the distance of the decoded proof from the canonical proof (for the non-Boolean verifier), strong canonicality of the non-Boolean verifier implies strong canonicality of the Boolean one. A formal proof follows.

Proof of Lemma 5.19. Let $\widehat{V}$ be the smooth strong canonical RPCPP for CircuitVal with corresponding proof-piece strategies $\Pi_1, \ldots, \Pi_t$, with Π_i answering its queries with symbols in the alphabet $\Sigma_i = \{0,1\}^{\sigma_i}$. For each $i \in [t]$ let ℓ_i denote the length complexity of the ith proof-piece oracle, and let $\mathrm{ECC}_i \colon \Sigma_i \to \{0,1\}^b$ with $b = O(\max_{i\in[t]} \sigma_i)$ be an error correcting code of constant minimal distance $2c > 0$, decodable using circuits of size $\widetilde{O}(b)$. The ith canonical proof-piece of circuit C and input y is $\Gamma_i(C;y)$, where $\Gamma_i(C;y)[j] \coloneqq \mathrm{ECC}_i(\Pi_i(C;y))$ is a binary string of length b.[26]

The Boolean RPCPP verifier, denoted V, expects circuit C, input oracle y and proof-piece oracles $\gamma_1, \ldots, \gamma_t$. It emulates $\widehat{V}$ on circuit C and input oracle y as follows:

- When $\widehat{V}$ queries the jth location of the ith proof-piece oracle, issue b queries to γ_i to receive a binary string $\gamma_i[j]$ of length b. Decode $\gamma_i[j]$ using the decoding algorithm of ECC_i. If decoding failed then reject, and otherwise answer $\widehat{V}$'s query with the decoded string.
- When $\widehat{V}$ queries its input oracle, answer it according to the input oracle y, giving the query weight b.

[25] That is, for any two oracles, the ratio between the number of queries that the verifier makes to each oracle is at least ρ.

[26] To be clear, $\Pi_i(C;y)$ is a string of length ℓ_i over alphabet $\Sigma_i = \{0,1\}^{\sigma_i}$, and $\Gamma_i(C;y)$ is a string of length $\ell_i \cdot b$ over the binary alphabet.

Smoothness of V follows immediately from the smoothness of $\widehat{V}$: for each proof-piece, a bit is queried if and only if the emulated verifier queried the location which it allegedly encodes, and the the probability that the latter is queried is the same for all locations.

We show that V is a strong canonical RPCPP for CircuitVal. Fix circuit C, input oracle y and alleged proof-piece oracles $\gamma_1, \ldots, \gamma_t$. For each $i \in [t]$ and $j \in [\ell_i]$, let $\widehat{\pi}_i[j] \in \Sigma_i$ be the "best decoding" of $\gamma_i[j]$, namely, the string $x \in \Sigma_i$ that minimizes the expression $\delta(\mathrm{ECC}_i(x), \gamma_i[j])$. Let $\widehat{\gamma}_i[j]$ be the encoding of $\widehat{\pi}_i[j]$, that is $\widehat{\gamma}_i[j] \coloneqq \mathrm{ECC}_i(\widehat{\pi}_i[j])$.

▷ Claim 5.19.1. For all $i \in [t]$, the expected distance of answers to V's queries from being accepted is greater than

$$\frac{\rho}{t+1} \cdot \delta(\gamma_i, \widehat{\gamma}_i)$$

Proof of Claim 5.19.1. Fix $i \in [t]$ and denote by J the locations that V queries in γ_i. To satisfy V, the answers of γ_i to V's queries (denoted $\gamma_i[J]$) must be codewords, therefore the expected distance of $\gamma_i[J]$ from satisfying V (over J generated according to V's random coins) is at least the expected distance of $\gamma_i[J]$ from being codewords; that is, at least

$$\mathop{\mathbb{E}}_{J}\left[\delta(\gamma_i[J], \widehat{\gamma}_i[J])\right] = \mathop{\mathbb{E}}_{J,\, j \in J}\left[\delta(\gamma_i[j], \widehat{\gamma}_i[j])\right] \tag{15}$$

Smoothness of V implies that a uniformly random element of $j \in J$ is distributed uniformly at random in $[\ell_i]$ (as detailed in Appendix B.2). Thus,

$$\textit{Equation (15)} = \mathop{\mathbb{E}}_{k \in [\ell_i]}\left[\gamma_i[k], \widehat{\gamma}_i[k]\right] = \delta(\gamma_i, \widehat{\gamma}_i)$$

The distance shrinks by $\rho/(t+1)$ because $\gamma_i[J]$ make up for only (at least) a $\rho/(t+1)$ fraction of all bits read by V. ◁

▷ Claim 5.19.2. Fix a random coin sequence and suppose that the Boolean verifier V received answers $s = s_1 \cdots s_q$ from the oracles $y, \gamma_1, \ldots, \gamma_t$. Let $\widehat{s} = \widehat{s}_1 \cdots \widehat{s}_1$ denote the answers that the non-Boolean verifier $\widehat{V}$ received from oracles $y, \widehat{\pi}_1, \ldots, \widehat{\pi}_t$ when it samples the same coin sequence; in other words, letting $s_k = \gamma_i[j]$ for some i and j, we denote $\widehat{s}_k = \widehat{\pi}_i[j]$.

Let D and $\widehat{D}$ be the residual circuits generated by V and $\widehat{V}$ upon sampling the fixed random coin sequence. It holds that $\delta(s, \mathtt{Sat}(D)) \geq c \cdot \delta(\widehat{s}, \mathtt{Sat}(\widehat{D}))$, where $\mathtt{Sat}(\cdot)$ denotes the set of satisfying inputs of a circuit, and $2c$ is the distance of the error correcting codes ECC_i.

Proof of Claim 5.19.2. The proof follows from the Markov bound and a triangle inequality. Suppose there is $s' = s'_1 \cdots s'_q$ that satisfies D such that $\delta(s, s') = \Delta$. For at least a $1 - \Delta/c$ fraction of $k \in [q]$ it holds that s_k is c-close to s'_k. For these k's, s'_k is the closest codeword to s_k, because distinct codewords are $2c$-far apart, and s'_k is a codeword for it satisfies D. Therefore, for a $1 - \Delta/c$ fraction of k's it holds that s'_k encodes $\widehat{s}_k$, and it follows that $\widehat{s}$ is Δ/c-close to satisfying $\widehat{V}$. ◁

Concluding the proof of Lemma 5.19

Fix $y' \in \mathtt{Sat}(C)$ such that $\max_{i \in [t]}\{\delta(y, y'), \delta(\widehat{\pi}_i, \Pi_i(C; y'))\}$ is minimal, and let $\Pi'_i \coloneqq \Pi_i(C; y')$ and $\Gamma'_i \coloneqq \Gamma_i(C; y')$. Suppose we give $\widehat{V}$ oracle access to $y, \widehat{\pi}_1, \ldots, \widehat{\pi}_t$. Robust strong canonicality means that the expected distance of locations it reads from satisfying its residual circuit is at least

$$\alpha \cdot \max_{i \in [t]}\left(\delta(y, y'), \delta(\widehat{\pi}_i, \Pi'_i)\right)$$

By Claim 5.19.2, this implies that when the Boolean verifier V is given $y, \gamma_1, \ldots, \gamma_t$, the expected distance of locations it reads from satisfying its residual circuit is at least

$$\alpha \cdot c \cdot \max_{i \in [t]} \left(\delta(y, y'), \delta(\widehat{\pi}_i, \Pi'_i)\right)$$

Noticing that $\delta(\widehat{\pi}_i, \Pi'_i) = 2c \cdot \delta(\widehat{\gamma}_i, \Gamma'_i)$, this is at least

$$\alpha c \cdot 2c \cdot \max_{i \in [t]} \left(\delta(y, y'), \delta(\widehat{\gamma}_i, \Gamma'_i)\right) \tag{16}$$

Claim 5.19.1 means that the expected distance of answers to V from satisfying is lower bounded not merely by Expression 16, but by

$$2\alpha c^2 \cdot \max_{i \in [t]} \left(\delta(y, y'), \delta(\widehat{\gamma}_i, \Gamma'_i), \frac{\rho}{t+1} \cdot \delta(\gamma_i, \widehat{\gamma}_i)\right) \tag{17}$$

For each $i \in [t]$, if $\delta(\gamma_i, \widehat{\gamma}_i) \leq \delta(\widehat{\gamma}_i, \Gamma'_i)/2$ then by the triangle inequality $\delta(\widehat{\gamma}_i, \Gamma'_i) \geq \delta(\gamma_i, \Gamma'_i)/2$, and otherwise $\delta(\gamma_i, \widehat{\gamma}_i) > \delta(\widehat{\gamma}_i, \Gamma'_i)/2$, so Expression 17 is at least

$$2\alpha c^2 \cdot \frac{\rho}{2(t+1)} \cdot \max_{i \in [t]} \left(\delta(y, y'), \delta(\gamma_i, \Gamma'_i)\right) \geq \frac{\alpha \rho c^2}{(t+1)} \cdot \min_{y'' \in \mathtt{Sat}(C)} \left\{ \max_{i \in [t]} \left(\delta(y, y''), \delta(\gamma_i, \Gamma_i(x; y''))\right) \right\}$$

where the inequality is because y' is a satisfying input for C, but not necessarily a minimizer of the above quantity. Thus, V is robust strongly canonical.

If $\widehat{V}$ has residual circuit distance c' (Definition 3.4), then V has residual circuit distance $c \cdot c'$, because an answer string that satisfies the decision circuit of V must be formed of encodings of an answer string that satisfies $\widehat{V}$. ◀

5.5 Putting it all together

Because CircuitVal-RPCPP is the Reed–Muller-based RPCPP of [20, Section 5.4], it enjoys the (standard) soundness analysis presented in that work. Paired with the strong canonical soundness of Lemma 5.18, we have a non-Boolean smooth strong canonical RPCPP for CircuitVal of logarithmic randomness complexity, polylogarithmic query complexity and constant residual circuit distance. Decision complexity is also polylogarithmic (though we did not keep track of it explicitly). Using Lemma 5.19 we get a Boolean RPCPP for CircuitVal of similar properties, and a final application of Lemma 2.2 reduces the number of oracles to one – proving Proposition 3.7.

A Hardness of approximating bounded-occurrence stable3SAT

To see the connection between our PCP result (i.e. Theorem 1.5) and the hardness of approximating bounded-occurrence stable3SAT (i.e. Corollary 1.7), first recall the connection between standard PCPs and constraint satisfaction problems (CSPs).[27] At its heart stands a correspondence between the probability that a nonadaptive PCP verifier V for a set S accepts an input x and proof π, and the fraction of simultaneously satisfiable constraints in a CSP $\Phi_{V,x}$ over $|\pi|$ variables. Consider the CSP $\Phi_{V,x}$ of 2^r constraints that express the verifier's decision after tossing r random coins and querying its proof oracle in q locations. These are constraints over $|\pi|$ variables, with each constraint depending on the q variables corresponding to locations that the verifier queries (i.e., $\Phi_{V,x}$ is a qCSP). A proof π is an assignment to these variables; completeness means that if $x \in S$ then there is an assignment that satisfies all constraints in $\Phi_{V,x}$, and soundness means that if $x \notin S$ then no assignment satisfies more than half of the constraints in $\Phi_{V,x}$ simultaneously.

Now, what can be said about the CSP $\Phi_{V,x}$ if the PCP verifier V was also strong and smooth?

- A strong PCP verifier with strongness parameter α yields a *stable* CSP $\Phi_{V,x}$, in the sense that an assignment that is δ-far from all satisfying assignments violates an $\alpha \cdot \delta$ fraction of constraints. Like strong soundness, this property holds both when $\Phi_{V,x}$ is satisfiable (i.e. when inputs $x \in S$) and when $\Phi_{V,x}$ is unsatisfiable (i.e. when $x \notin S$). We note that in the latter case, $\Phi_{V,x}$ cannot have more than an α fraction of constraints satisfied simultaneously.
- A smooth PCP verifier yields a CSP such that each variable occurs in the same number of constraints.

Thus, Theorem 1.5 implies that for any set $S \in \mathcal{NP}$ there is an efficient parsimonious reduction from S to α-stable bounded-arity qCSPs with equal variable occurrence. To prove Corollary 1.7, we show a polynomial-time computable parsimonious reduction of α-stable qCSPs with *equal variable occurrence* to $\Omega(\alpha)$-stable qCNFs with *bounded variable occurrence* (Proposition A.1), and then reduce the latter to $\Omega(\alpha)$-stable 3CNFs with bounded variable occurrence (Proposition A.2).

Recall that a formula has *b-bounded-occurrence* if any variable appears in at most b clauses, and that the promise problem (α, b)-stable$q$SAT is distinguishing b-bounded-occurrence qCNF formulas that are α-stable and satisfiable from ones in which any assignment violates at least an α fraction of the clauses.

[27] A CSP Φ of size m over ℓ variables is a set of m functions (called *constraints*) $\Phi = \{C_1, \ldots, C_m\}$ with $C_i : \{0,1\}^\ell \to \{0,1\}$. An assignment $A : [\ell] \to \{0,1\}$ *satisfies* constraints C_i if $C_i(A(1), \ldots, A(\ell)) = 1$. We say that Φ has *arity* q (is a qCSP) if each C_i depends on at most q variables. If constraint C_i depends on variable v then we say that v *occurs* in C_i.

▶ **Proposition A.1.** *For any $q \in \mathbb{N}$ there is $b \in \mathbb{N}$ such that there is a polynomial-time computable parsimonious reduction from α-stable qCSPs with equal variable occurrence to $(\alpha/qb, b)$-stable$q$SAT.*

Proof. We will show a reduction to α/qb'-stable qCSPs with b'-bounded variable occurrence for some constant $b' \in \mathbb{N}$ (independent of q, actually). Then, q-arity of the resulting CSP implies that each of its constraints can be expressed as the conjunction of at most 2^q disjunctive clauses, and conjuncting all these clauses gives a CNF formula that is $\alpha/qb'2^q$-stable and $b'2^q$-bounded variable occurrence. Setting $b \coloneqq b'2^q$ gives the required result.

The reduction, taken from [23], replaces the occurrence of each variable in a constraint with a copy of that variable, and adds consistency (i.e. equality) constraints between copies based on an expander graph of constant degree. We stress that the stability of the obtained CNF crucially relies on the equal variable occurrence of the reduced CSP so that each variable is replaced with the same number of consistency checks, and that the new instance is not necessarily stable without this property (see [12, Appendix D]).

Fix an α-stable CSP Φ consisting of m constraints over ℓ variables, such that each constraint depends on exactly q variables and each variable occurs in exactly mq/ℓ constraints.

Fix a d-regular, explicit[28] graph G over mq/ℓ vertices, with an expansion property guaranteeing that for any set of vertices T that consists of at most a half of the vertices, there are $2|T|$ edges crossing from T to its complement (for example, the expanders of [7]). The variables of Φ' are $\{v_C\}$ for each variable v of Φ and each constraint $C \in \Phi$ in which v occurs. There are two types of constraints in Φ':

- For each constraint $C \in \Phi$, a *primal constraint* C' is added, which is simply C but with variables replaced by their corresponding (alleged) copies. For example, if $C = (x \vee \overline{y} \vee z \vee w) \wedge (\overline{w} \vee x \vee u)$, then $C' = (x_C \vee \overline{y_C} \vee z_C \vee w_C) \wedge (\overline{w_C} \vee x_C \vee u_C)$.
- For each variable v of Φ, $\frac{mq}{\ell} \cdot \frac{d}{2}$ *consistency constraints* are added to Φ': letting $\{C_1, \ldots, C_{mq/\ell}\}$ be the set of constraints in which v occurs, for each edge $\{i, j\}$ in G we add a constraint that is satisfied if and only if v_{C_i} equals v_{C_j}.

All in all, Φ' has $\ell \cdot mq/\ell = mq$ variables and $m + \ell \cdot \frac{mq}{\ell} \cdot \frac{d}{2} = (1 + qd/2)m$ constraints.

Each variable of Φ' occurs in $d+1$ constraints, and the reduction is indeed parsimonious since any assignment that satisfies Φ' must be consistent and therefore gives a satisfying assignment to Φ (and vice-versa). We show that Φ' is $\frac{\alpha}{qd}$-stable. The case that Φ is unsatisfiable follows from [23], so we focus on the case that Φ is satisfiable (and then so is Φ'). Let A' be an assignment to Φ' that violates a γ' fraction of its constraints. Let A_{Maj} be an assignment to Φ that gives each variable a value according to the majority value that A' gives to its (alleged) copies; that is, for each variable v, $A_{\mathrm{Maj}}(v) \coloneqq \mathrm{Maj}_C(A'(v_C))$. Let A'_{Maj} be the extension of A_{Maj} back to the variables of Φ'; that is, $A'_{\mathrm{Maj}}(v_C) \coloneqq A_{\mathrm{Maj}}(v)$ for each variable v and constraint C that depends on v. Let γ_{Maj} denote the fraction of constraints in Φ unsatisfied by A_{Maj}.

▷ Claim A.1.1.

$$\gamma' \geq \frac{\gamma_{\mathrm{Maj}} + \delta(A', A'_{\mathrm{Maj}})}{qd}$$

[28] I.e. there is an algorithm that constructs G in polynomial time when given mq/ℓ as input.

Proof of Claim A.1.1. To prove the claim, we show that whatever primal constraints may be satisfied by A' but not by A'_{Maj} (which works against the lower bound we need) are "made up for" in consistency clauses unsatisfied by A'. It will be nicer to deal with whole numbers rather than fractions, so we let a' (resp. a_{Maj}) denote the *number* of constraints of Φ' (resp. Φ) unsatisfied by A' (resp. A_{Maj}), and notice that the claim follows from showing that

$$a' \geq a_{\text{Maj}} + \left|\left\{v_C : A'(v_C) \neq A'_{\text{Maj}}(v_C)\right\}\right|$$

Fix a variable v, and let k be the number of constraints C such that A' disagrees with A'_{Maj} on the value assigned to v_C. Then v occurs in at most k constraints of Φ that are unsatisfied by A_{Maj} but whose corresponding primal constraint is satisfied by A'. But by the expansion property of the graph G, each of the k inconsistencies result in $2k$ consistency constraints unsatisfied by A'. ◁

Now, let B be the closest satisfying assignment to A_{Maj}. Note that the extension of B to the variables of Φ', denoted B', is a satisfying assignment to Φ', and that $\delta(A_{\text{Maj}}, B) = \delta(A'_{\text{Maj}}, B')$. Using Claim A.1.1 and stability of Φ, we have

$$\gamma' \geq \frac{\gamma_{\text{Maj}} + \delta(A', A'_{\text{Maj}})}{qd} \geq \frac{\alpha\delta(A_{\text{Maj}}, B) + \delta(A'_{\text{Maj}}, B')}{qd} \geq \frac{\alpha}{qd} \cdot \delta(A', B') \qquad \blacktriangleleft$$

▶ **Proposition A.2.** *For any $\alpha \in (0, 1]$ and $b, q \in \mathbb{N}$ there is $\alpha' \in (0, 1]$ such that there is a polynomial-time parsimonious reduction from (α, b)-`stable`q`SAT` to (α', b)-`stable3SAT`.*

Friggstad et al. show a similar reduction in [12][Section 4]. Furthermore, their reduction yields CNFs that have *exactly* three literals per clause.

Proof. We use the standard parsimonious reduction of qSAT to 3SAT to transform a formula φ to a formula φ'. The reduction operates clause-by-clause according to the following recurrence relation: for each clause $C \coloneqq (x_1 \vee \cdots \vee x_k)$ in φ (where $k \leq q$),

- If $k < 4$, add the clause C to φ' and halt.
- Otherwise, introduce a "fresh" *auxiliary variable* z, add the clauses $(x_1 \vee x_2 \vee z)$, $(\overline{x_1} \vee \overline{z})$ and $(\overline{x_2} \vee \overline{z})$ to φ', and then recurse on $C' \coloneqq (\overline{z} \vee x_3 \vee \cdots \vee x_k)$.

If φ is not satisfiable then no assignment satisfies more than an $\alpha/3q$ fraction of the clauses of φ' (by the standard soundness of this reduction), so we focus on the case that φ (and therefore φ') is satisfiable. Let A be some assignment for φ', given as an assignment X to the original variables (i.e. to φ) and an assignment Z to the auxiliary variables. Let X^* be a satisfying assignment to φ closest to X. By parsimony of the reduction, there is a unique assignment Z^* to the auxiliary variables such that $A^* \coloneqq (X^*, Z^*)$ is a satisfying assignment.

Again, it would be more convenient for us to deal with absolute quantities rather than relative quantities, so let V_A denote the number of clauses violated by A, and $\overline{\Delta}(A, A^*)$ denote the number of variables on which A and A^* disagree. Similarly define V_X, $\overline{\Delta}(X, X^*)$ and $\overline{\Delta}(Z, Z^*)$. Since φ' has b-bounded variable occurrence then the ratio between its number of variables and number of clauses is at least $1/b$, therefore it suffices to show that $V_A = \Omega(\alpha \cdot \Delta(A, A^*))$.

Now, on the one hand, α-stability of φ means that $V_X \geq \frac{\alpha}{b}\overline{\Delta}(X, X^*)$ (using the assumption that φ has b-bounded variable occurrence to transition from fractional to absolute quantities, just like in the previous paragraph). Additionally, $V_A \geq V_X/3q$ because if X doesn't satisfy a clause in φ then A doesn't satisfy at least one of the corresponding clauses in φ'. Therefore,

$$V_A \geq \frac{\alpha}{3qb} \cdot \overline{\Delta}(X, X^*) \tag{18}$$

On the other hand, the parsimony of the reduction implies that, for any clause C of φ, if X and X^* agree on all q variables occurring in C, and A satisfies all clauses introduced by C (in φ'), then it must be that Z and Z^* agree on all of the auxiliary variables introduced by C. That is, for any clause C, if Z and Z^* disagree on any of the auxiliary variables introduced by C, then either X and X^* disagree on some of the q variables occurring in C, or A violates some of the clauses introduced by C. Therefore,

$$q \cdot \overline{\Delta}(X, X^*) + V_A \geq \overline{\Delta}(Z, Z^*) \tag{19}$$

Combining Equations (18) and (19), we have that $V_A \geq \frac{\alpha}{4qb} \cdot \max\left(\overline{\Delta}(X, X^*), \overline{\Delta}(Z, Z^*)\right)$, and since $\overline{\Delta}(A, A^*) = \overline{\Delta}(X, X^*) + \overline{\Delta}(Z, Z^*)$ we have $V_A \geq \frac{\alpha}{8qb}\overline{\Delta}(A, A^*)$. ◀

B Tedious notes regarding smoothness

B.1 On uniform sampling

Recall that probabilistic Turing machines (and PCP verifiers in particular) obtain their randomness by *tossing random coins*. It is clear how this ability enables uniform sampling from sets of size that is a power of 2, but throughout this work we allow verifiers to sample uniformly random elements from sets of arbitrary (finite) size. Since the technical implementation of such sampling may affect the smoothness of the verifier, a clarification on this matter is due.

To implement a PCP verifier that uses its randomness only to sample a uniformly random element from a set $[N]$, *rejection sampling* may be employed while losing a constant factor in soundness: the verifier samples a uniformly random element $i \in [2^{\lceil \log N \rceil}]$; if $i > N$ the verifier *immediately accepts*, and otherwise it proceeds as intended. Soundness is halved because the sampled i is in $[N]$ with probability $N/2^{\lceil \log N \rceil} \geq 1/2$.

PCP verifiers in this work use their randomness *only* to sample uniformly random elements from a constant number of sets, and are implemented using rejection sampling on the product of sets from which they sample. Namely, a verifier that uniformly samples from sets $\Omega_1, \ldots, \Omega_k$ is implemented using rejection sampling on the set $\Omega_1 \times \cdots \times \Omega_k$. Still, this (only) halves soundness, and adds at most k random coin tosses (as the randomness complexity $r \coloneqq \sum_{i=1}^{k} \log |\Omega_i|$ grows to $\sum_{i=1}^{k} \lceil \log |\Omega_i| \rceil \leq r + k$).

B.2 Smoothness and uniformity

Without loss of generality, we may require that PCP verifiers query each bit in their proof with some positive probability and never query the same location more than once. Any verifier that doesn't satisfy these simplifying assumptions can be transformed into one that does: we add a single uniformly random query, and then modify the verifier so that whenever it attempts to query the same location twice, it uniformly samples from the remaining unqueried locations in the proof instead.

Now here's a thought: Suppose we have a smooth verifier that issues q queries to a proof oracle of length ℓ. We claim that if we look at a set of query locations $I \subseteq [\ell]$ generated by this verifier (based on its random coins), and subsequently choose a uniformly random element $i \in I$ from this set, then i is uniformly distributed in $[\ell]$. Why? Well, smoothness means that the probability that the verifier queries a certain location in the proof oracle in any of its q queries is equal for any certain location (it's equal to q/ℓ, if you must know). By

the previous paragraph, we can assume all queries of the verifier are distinct, so if a certain location is queried by the verifier it's queried exactly once. Therefore, a uniformly random element from the set of query locations is distributed uniformly in the proof.

Smoothness and marginal uniformity

It may seem natural to define smooth PCPs to be those whose queries are marginally uniform.[29] That is, that the first query of the verifier is distributed uniformly in the proof, and so is the second, third, and so on. We claim that there's almost no difference between this notion and ours (Definition 1.3): by the observation made in the previous paragraph, any nonadaptive PCP satisfying Definition 1.3 can be transformed into one that satisfies marginal uniformity by randomly permuting the order of its queries. Actually, even a random cyclic shift would suffice, and only incurs a $\log q$ additive overhead in randomness complexity – exponentially smaller than the original randomness complexity in the constructions used throughout this work.

C The vector-valued low-degree polynomial test

This section was kindly contributed by Oded Goldreich and Madhu Sudan. It sees the generalization of the *Point-line* low-degree polynomial test ([2, Section 7.2]) to the vector-valued setting.

▶ **Definition C.1** (Definition 5.3 restated). *A function $f\colon \mathbb{F}^m \to \mathbb{F}^k$ is a* vector-valued multivariate polynomial of degree at most d *if for all $i \in [k]$ the projection of f to the ith coordinate is a multivariate polynomial of (total) degree at most d, where the projection of f to the ith coordinate, denoted $f_i : \mathbb{F}^m \to \mathbb{F}$, is defined $f_i(x) \coloneqq f(x)_i$ for all $x \in \mathbb{F}^m$.*

▶ **Algorithm C.2** (Algorithm 5.4 restated). The *point-line vector-valued low-degree test (PL-VLDT)* is given access to an oracle $f\colon \mathbb{F}^m \to \mathbb{F}^k$ and a "lines" proof oracle g that maps line $\mathcal{L}$ to vector-valued univariate polynomial $g_{\mathcal{L}} : \mathcal{L} \to \mathbb{F}^k$ of degree at most d. It samples a uniformly random line $\mathcal{L}$ through $\mathbb{F}^m$ and uniformly random point $x \in \mathcal{L}$, and accepts if and only if $f(x) = g_{\mathcal{L}}(x)$.

▶ **Fact C.3.** *For $k = 1$, PL-VLDT is the low degree test of [2, Theorem 65], therefore if input oracle $f\colon \mathbb{F}^m \to \mathbb{F}$ is δ-far from being a polynomial of degree at most d then PL-VLDT rejects with probability at least $\delta/2$ for any lines oracle g.*

▶ **Proposition C.4** (Proposition 5.5 restated). *Assuming $|\mathbb{F}| > 25k$, if input oracle $f\colon \mathbb{F}^m \to \mathbb{F}^k$ is δ-far from being a vector-valued polynomial of degree at most d then for any lines oracle g, PL-VLDT rejects f and g with probability at least $\delta/40$.*

The proof follows three main cases. If a projection of the input is far from being a (scalar-valued) low-degree polynomial then we are done due to Fact C.3. If $\delta = \Omega(1/|\mathbb{F}|)$ then the distance of the restriction $f[\mathcal{L}]$ from being a univariate low-degree univariate polynomial is proportional to the distance of f from being a low-degree polynomial (i.e. δ) with high probability, and assuming $g_{\mathcal{L}}$ is the closest low-degree polynomial to $f[\mathcal{L}]$, rejection occurs with this very probability. The third case is when $\delta = O(1/|\mathbb{F}|)$, and then we capitalize on δ being very small to show that with probability $\Theta(|\mathbb{F}|\delta)$ the restriction $f[\mathcal{L}]$ is low-degree except for exactly one point, which is sampled with probability $1/|\mathbb{F}|$. A formal proof follows.

[29] For example, as used in [1].

Proof. Throughout this proof, *low-degree* means *of degree at most d*. For each $i \in [k]$ let $f_i : \mathbb{F}^m \to \mathbb{F}$ be the projection of f onto its ith coordinate, and let g_i be a mapping of lines through $\mathbb{F}^m$ to low-degree univariate polynomials given by $g_{\mathcal{L},i}(x) \coloneqq g_{\mathcal{L}}(x)_i \in \mathbb{F}$ for each line $\mathcal{L}$ and point $x \in \mathcal{L}$. Let $\widetilde{f}_i \colon \mathbb{F}^m \to \mathbb{F}$ be a low-degree polynomial closest to f_i, and notice that $\widetilde{f} \coloneqq (\widetilde{f}_1, \ldots, \widetilde{f}_k)$ is a vector-valued low-degree polynomial closest to f. Let δ and δ_i be the distances of f from $\widetilde{f}$ and f_i from $\widetilde{f}_i$ respectively.

First, note that if $f_i(x) \neq g_{\mathcal{L},i}(x)$ for the sampled $\mathcal{L}$ and x then the test rejects, therefore the probability that PL-VLDT rejects f and g is greater than the probability that it rejects input oracle f_i and lines oracle $(g_{\mathcal{L},i})_{\mathcal{L}}$. Hence, if there exists i such that $\delta_i \geq 1/5$ then by Fact C.3 rejection occurs with probability at least $1/10$. Therefore, we may assume that $\delta_i < 1/5$ for all $i \in [k]$. We proceed with a partial analysis that assumes that $\delta \leq 2/5$, and later show how the remaining possibilities follow.

Case 1: $\delta > 5/|\mathbb{F}|$. Points on a randomly sampled line $\mathcal{L}$ are pairwise independent and marginally uniform, so the Chebyshev inequality implies that the relative distance between $f[\mathcal{L}]$ and $\widetilde{f}[\mathcal{L}]$ is at least $\delta/2$ and at most $3\delta/2$ with probability greater than $1 - \frac{\delta(1-\delta)}{(\delta/2)^2|\mathbb{F}|} \geq 1/5$. Conditioned on this event, one of two cases must hold:

- **Case 1.1:** There is i such that $g_{\mathcal{L},i} \neq \widetilde{f}_i[\mathcal{L}]$. Note that $g_{\mathcal{L},i}$ and $\widetilde{f}_i[\mathcal{L}]$ are distinct (univariate) polynomials of degree at most d so they agree on at most d points in $\mathcal{L}$. Since $f_i[\mathcal{L}]$ disagrees with $\widetilde{f}_i[\mathcal{L}]$ on at most $3\delta|\mathbb{F}|/2 \leq 3|\mathbb{F}|/5$ points, it holds that $f[\mathcal{L}]$ and $g_{\mathcal{L}}$ agree on at most $d + 3|\mathbb{F}|/5 \leq 4|\mathbb{F}|/5$ points. Therefore rejection occurs with probability at least $4/5 \geq \delta/2$.
- **Case 1.2:** For all i it holds that $g_{\mathcal{L},i} = \widetilde{f}_i[\mathcal{L}]$. Then rejection occurs if and only if $f[\mathcal{L}]$ and $\widetilde{f}[\mathcal{L}]$ disagree on the sampled $x \in \mathcal{L}$, which occurs with probability at least $\delta/2$.

All in all, rejection occurs with probability at least $\frac{1}{5} \cdot \frac{\delta}{2} = \frac{\delta}{10}$.

Case 2: $\delta < 1/2|\mathbb{F}|$. We claim that $f[\mathcal{L}]$ and $\widetilde{f}[\mathcal{L}]$ agree on exactly 1 point with probability at least $|\mathbb{F}|\delta/2$. Again we use pairwise independence and marginal uniformity of points on a random line, this time served with a side of inclusion-exclusion. Let each line $\mathcal{L}$ have a fixed ordering $\mathcal{L} = \{x_1, \ldots, x_{|\mathbb{F}|}\}$. Then,

$$\begin{aligned}
&\mathbb{P}_{\mathcal{L}}\Big[\exists_! \; x \in \mathcal{L} \; f(x) \neq \widetilde{f}(x)\Big] \\
&\quad \geq \sum_{i \in [|\mathbb{F}|]} \mathbb{P}_{x_i}\Big[f(x_i) \neq \widetilde{f}(x_i)\Big] - \sum_{j \in [|\mathbb{F}| \setminus \{i\}]} \mathbb{P}_{x_i, x_j}\Big[f(x_i) \neq \widetilde{f}(x_i), f(x_j) \neq \widetilde{f}(x_j)\Big] \\
&\quad \geq |\mathbb{F}|\big(\delta - |\mathbb{F}|\delta^2\big) = |\mathbb{F}|\delta(1 - |\mathbb{F}|\delta) \geq |\mathbb{F}|\delta/2
\end{aligned}$$

As in Case 1, conditioned on this event rejection occurs with probability at least $4/5 \geq 1/|\mathbb{F}|$ or $1/|\mathbb{F}|$, depending on whether g and $\widetilde{f}$ agree on the random line $\mathcal{L}$. All in all, rejection occurs with probability at least $\frac{|\mathbb{F}|\delta}{2} \cdot \frac{1}{|\mathbb{F}|} = \frac{\delta}{2}$.

Now, if $\delta > 2/5$ we show that there exists $k' < k$ such that the distance of $f_{[k']} \coloneqq (f_1, \ldots, f_{k'})$ from being a vector-valued low-degree polynomial, denoted $\delta_{[k']}$, is greater than $1/5 \geq 5/|\mathbb{F}|$ and less than $2/5$, and since the rejection probability of f and g is greater than that of $f_{[k']}$ and $g_{[k']} \coloneqq (g_1, \ldots, g_{k'})$ we may then apply Case 1 to $f_{[k']}$. Indeed, $\delta_{[k']} - \delta_{[k'-1]} \leq \delta_{k'} \leq 1/5$ and $\delta_{[k]} = \delta \geq 2/5$, so by a greedy argument there must exist $k' \leq k$ such that $\delta_{[k']} \in [1/5, 2/5]$.

Finally, we tend to the case that $\delta \in [1/2|\mathbb{F}|, 5/|\mathbb{F}|]$. If there exists i such that $\delta_i \geq 1/4|\mathbb{F}|$ then by Fact C.3 rejection occurs with probability at least $1/8|\mathbb{F}| \geq \delta/40$. Otherwise, by a greedy argument there exists $k' \leq k$ such that $\delta_{[k']} \in [1/4|\mathbb{F}|, 1/2|\mathbb{F}|]$. Applying Case 2 to $f_{[k']}$, we have that rejection occurs with probability at least $\delta_{[k']}/2 \geq 1/8|\mathbb{F}| \geq \delta/40$. ◀

Approximately Strategyproof Tournament Rules: On Large Manipulating Sets and Cover-Consistence

Abstract

We consider the manipulability of tournament rules, in which n teams play a round robin tournament and a winner is (possibly randomly) selected based on the outcome of all $\binom{n}{2}$ matches. Prior work defines a tournament rule to be k-SNM-α if no set of $\leq k$ teams can fix the $\leq \binom{k}{2}$ matches among them to increase their probability of winning by $> \alpha$ and asks: for each k, what is the minimum $\alpha(k)$ such that a Condorcet-consistent (i.e. always selects a Condorcet winner when one exists) k-SNM-$\alpha(k)$ tournament rule exists?

A simple example witnesses that $\alpha(k) \geq \frac{k-1}{2k-1}$ for all k, and [22] conjectures that this is tight (and prove it is tight for $k = 2$). Our first result refutes this conjecture: there exists a sufficiently large k such that no Condorcet-consistent tournament rule is k-SNM-1/2. Our second result leverages similar machinery to design a new tournament rule which is k-SNM-2/3 for all k (and this is the first tournament rule which is k-SNM-(< 1) for all k).

Our final result extends prior work, which proves that single-elimination bracket with random seeding is 2-SNM-1/3 [22], in a different direction by seeking a stronger notion of fairness than Condorcet-consistence. We design a new tournament rule, which we call Randomized-King-of-the-Hill, which is 2-SNM-1/3 and *cover-consistent* (the winner is an uncovered team with probability 1).

1 Introduction

Consider n teams vying for a single championship via pairwise matches. A *Tournament Rule* maps (possibly randomly) the outcome of all $\binom{n}{2}$ matches to a single winner. A successful tournament rule should on one hand be fair, in that it selects a team that could reasonably be considered the best. For example, a tournament rule is Condorcet-consistent if whenever an undefeated team exists, that team is selected as the winner with probability 1. On the other hand, a successful tournament rule should also incentivize teams to win their matches. For example in a monotone tournament rule, no team can unilaterally increase their probability of winning by throwing a match.

While numerous rules satisfy the two specific properties mentioned above, these hardly suffice to call a tournament both fair and incentive compatible. Consider for example a single-elimination tournament, which is Condorcet-consistent and monotone. One might reasonably argue that single-elimination is unfair in the sense that a *covered* team may win. That is, some team x, who is beaten by y, and for which all z who beat y also beat x, could be crowned the champion (Observation 19), even though y is in some sense clearly a superior team. When multiple teams come from the same organization (e.g. in the Olympics where multiple teams from the same country participate, or in eSports where the same organization sponsors multiple teams), one could also argue that single-elimination is not incentive compatible: two teams from the same organization may wish to fix the match between them so that the team with the best chance of winning gold advances.

Prior work establishes, however, that this stronger notion of incentive compatibility (termed 2-Strongly Nonmanipulable by [1], and previously Pairwise Nonmanipulable in [2]) is incompatible even with the basic notion of Condorcet-consistency: no 2-SNM tournament rule is Condorcet-consistent (recapped in Lemma 17). This motivated [1] to seek instead tournaments that were 2-SNM and *approximately* Condorcet-consistent (i.e. guaranteed to pick an undefeated team with probability at least $\alpha > 0$, whenever one exists), and later [22] to seek tournaments which were Condorcet-consistent and *approximately* 2-SNM (i.e. the maximum probability with which two teams can improve their joint probability of winning by fixing a match is $\alpha < 1$, termed 2-SNM-α).

Like [22], we find it more reasonable to seek a tournament which is only approximately strategyproof rather than one which is only approximately Condorcet-consistent: it is hard to imagine a successful sporting event which sends an undefeated team home empty-handed. The main result of [22] proves that a Single-Elimination Bracket with Random seeding (RSEB, formally defined in Section 2) is both Condorcet-consistent and 2-SNM-1/3. This is tight, as no Condorcet-consistent tournament is 2-SNM-α for any $\alpha < 1/3$. They also define a tournament to be k-SNM-α if no set of $\leq k$ teams can fix the $\leq \binom{k}{2}$ matches between them and improve their joint probability of winning by α, establish that no Condorcet-consistent tournament rule is k-SNM-α for $\alpha < \frac{k-1}{2k-1}$ (recapped in Lemma 17), and conjecture that this is tight. The main open problem posed in their work is to prove this conjecture (recapped in Question 18). The main results of this paper extend [22] in three different directions:

- First, we resolve the main open problem posed in [22] by *refuting* their conjecture (including two weaker forms): There exists a sufficiently large k such that no Condorcet-consistent tournament rule is k-SNM-1/2 (and therefore not k-SNM-$\frac{k-1}{2k-1}$ either).
- Second, we develop a new Condorcet-consistent tournament rule which is k-SNM-2/3 for all k. All tournament rules are trivially k-SNM-1 for all k, and this is the first tournament rule known to be k-SNM-α for all k, for any $\alpha < 1$.
- Finally, we develop a new *cover-consistent* tournament rule which is 2-SNM-1/3, which we call Randomized King-of-the-Hill (RKotH).

1.1 Theorem Statements, Roadmap, and Technical Highlights

After overviewing related work in Section 1.3, and establishing preliminaries in Section 2, we develop machinery related to our first two results in Section 3. Specifically, consider the following: there are two kinds of manipulations which may cause a set S of teams to improve their joint probability of winning under a Condorcet-consistent tournament rule $r(\cdot)$. First, perhaps S contains i and every team which beats i (for some i). Then S can make i a Condorcet winner, and improve their joint probability of winning to 1 (the maximum possible). Or, perhaps every team in S loses to at least one team outside S, but S can increase their joint probability of winning anyway.

If, for a particular tournament graph T, we wish to ensure that no set S can improve their joint probability of winning by more than α under $r(\cdot)$ by creating a Condorcet winner in S, this is a fairly simple linear constraint: we must only ensure that for each team i, the joint probability of winning (under $r(T)$) of i and all teams that beat i in T is at least $1-\alpha$. For each tournament graph T, this reasoning gives a feasibility linear program (with n variables corresponding to the probability that each team wins under $r(T)$, and n linear constraints which depend on T) that every winning-probability vector $r(T)$ must satisfy in order for $r(\cdot)$ to possibly be k-SNM-α. Note that these constraints are by no means *sufficient* to guarantee k-SNM-α, however, as we have completely ignored the second type of constraints.

Inspired by this feasibility LP, we study a similar LP in Section 3, which we call the *Special Linear Program* (SLP). In particular, we show that SLP has a unique solution, and therefore well-defines a tournament rule (if the outcome of the matches is T, solve the SLP parameterized by T and select according to these probabilities). Surprisingly, this LP and its unique optimal solution have been studied decades ago [16, 10] (see Section 1.3 for further discussion of this – the LP describes the unique Nash equilibrium of a generalized rock-paper-scissor game). In Section 4, we explain why the SLP Tournament Rule is special: **if *any* tournament rule is k-SNM-1/2 for all k, then the SLP Tournament Rule is k-SNM-1/2 for all k.** The remainder of Section 4 is then just a simple six team example witnessing that the SLP Tournament Rule is *not* 3-SNM-1/2 (and therefore not k-SNM-1/2 for all k), yielding our first main result:

▶ **Theorem 1.** *There exists $k < \infty$ such that no Condorcet-consistent tournament rule is k-SNM-1/2.*

Note that Theorem 1 implies that (a) no Condorcet-consistent tournament rule is simultaneously k-SNM-$\frac{k-1}{2k-1}$ for all k, (b) there exists a k for which no Condorcet-consistent tournament rule is k-SNM-$\frac{k-1}{2k-1}$, and (c) no Condorcet-consistent tournament rule is k-SNM-1/2 for all k, thereby refuting the main conjecture of [22] along with two weaker conjectures.

We also wish to emphasize the following: in principle, if one wishes to determine whether a particular tournament rule is k-SNM-α for tournaments of n teams, one could do an exhaustive search over all $2^{\binom{n}{2}}$ tournament graphs (with some savings due to isomorphism), and all $\binom{n}{k}$ possible manipulating sets. This is a feasible search for small values of n, k. If one wishes to determine whether there *exists* a rule that is k-SNM-α for tournaments of n teams, one could still imagine an exhaustive search. But observe that the space of tournament *rules* for n teams lies in $n2^{\binom{n}{2}}$-dimensional space, and it is hard to imagine a successful exhaustive search beyond $n = 10$ (and even that is likely impossible).

Our proof establishes that no 939-SNM-1/2 tournament rule exists for $n = 1878$ teams, and there is no hope of discovering this via exhaustive search. Indeed, our own exhaustive searches found numerous candidate rules which were k-SNM-1/2 on n teams for $k, n \leq 7$

(indicating that large parameters are provably necessary before the conjecture is false). Yet, the SLP Tournament Rule is already not 3-SNM-1/2 even for 6 teams (which we found via exhaustive search), and the machinery of Sections 3 and 4 allows us to use this tiny example to conclude that no 939-SNM-1/2 tournament rules exist for $n = 1878$ teams.

In Section 5, we show how to use the machinery developed in Section 3 to propose new tournament rules. The main idea is the following: the SLP Tournament Rule, by design, does a great job discouraging manipulations that produce a Condorcet winner. In fact, no such manipulation benefits the manipulators by more than 1/2. Unfortunately, the rule itself may still be only k-SNM-1 (due to manipulations which don't produce a Condorcet winner). However, we show that a convex combination of the SLP Tournament Rule with the simple rule which selects a Condorcet winner when one exists, or a uniformly random winner otherwise can leverage the SLP properties to be less manipulable:

▶ **Theorem 2.** *There exists a Condorcet-consistent tournament rule that is k-SNM-2/3 for all k.*

▶ **Observation 3.** *The rule referred to in Theorem 2 is* not *monotone. We provide an example of its non-monotonicity in Appendix B for completeness.*

Finally, in Section 6, we shift gears and extend the results of [22] in a different direction. Specifically, we design a new tournament rule called Randomized King-of-the-Hill (RKotH) which is cover-consistent and 2-SNM-1/3. Each round, the rule checks if there is a team that is a Condorcet winner. If there is one, it declares that team the winner and terminates. Otherwise, it selects a uniformly random "prince" among the remaining teams, and then removes it and every team which the prince beats. When there is only one team left, that team is crowned champion. It is not hard to see that RKotH is cover-consistent, so the main result of this section is that RKotH is 2-SNM-1/3. The main idea in the proof is that the joint winning probability of $\{u, v\}$ when v beats u is *only* higher than when u beats v if u is selected as a prince while v still remains in contention, and at least one team which beats either u or v remains in contention as well. We are then able to show that the probability of this event is at most 1/3, and therefore the rule is 2-SNM-1/3.

▶ **Theorem 4.** *Randomized King-of-the-Hill is cover-consistent and* 2-SNM-1/3.

In fact, RKotH satisfies a property stronger than cover-consistency. It will provably pick teams that belong to the *Banks set* of the tournament, which may be strictly smaller than the set of uncovered teams. We defer the definition of the Banks and related proofs set to Section 6 but point out that the support of RKotH is *exactly* the Banks set of a tournament.

▶ **Lemma 5.** *A team v is in the Banks set of a tournament T if, and only if,* RKotH *declares v as the winner with non-zero probability.*

1.2 Extensions and Brief Discussion

While the main appeal of our results is clearly theoretical (it is hard to imagine a 939-team coalition manipulating a real tournament), the events motivating a deep study of fair and incentive compatible tournament rules are not purely hypothetical. In the popular "group stage" format, strategic manipulations have occurred on the grandest stage, including Badminton at the 2012 Olympics and the "disgrace of Gijón" in the 1982 World Cup. But narrowing one's focus exclusively to incentives (and, e.g., running a single-elimination bracket) may have negative consequences for the quality of winner selected. For example in

the 2010 World Cup, eventual winners and second seed Spain lost their opening match to Switzerland, who didn't advance out of the group stage (the implication being that Spain could be considered a "high quality winner" who would have been immediately eliminated in a single-elimination bracket). So while our particular results are valuable mostly for their theoretical contributions, the surrounding literature provides valuable insight on the tradeoff between incentive compatibility of the winner selection process and quality of the winner selected.

We also wish to briefly note that while we formally define SNM only for deterministic tournaments (i.e. the teams try to manipulate from a fixed tournament graph T to another fixed tournament graph T'), [22] establishes that all results extend to (arbitrarily correlated) distributions over tournament graphs as well (where the "real" outcomes may be a distribution $\mathcal{T}$ over tournament graphs, and the coalition may try to manipulate to a different distribution $\mathcal{T}'$). We refer the reader to [22] for a formal statement, but the main idea is that any lower bounds immediately carry over, while for every rule the largest possible manipulation occurs on a deterministic instance anyway (so positive results carry over as well).

1.3 Related work

The most related works have already been discussed above: [2] first introduces the terminology used for these problems (and establishes that no deterministic tournament rule is 2-SNM), [1] first considers randomized tournament rules and designs tournament rules which are 2-SNM but only approximately Condorcet-consistent. [22] is the most closely related, which also considers rules which are Condorcet-consistent and approximately incentive compatible. Our work can most appropriately be viewed as extending [22] in multiple directions (including resolving their main open problem) as detailed in Section 1.

Also related are some recent works which rigorously analyze the manipulability of specific tournament formats (most notably, the World Cup and related qualifying procedures) [20, 7].

Incentive compatibility of *voting rules* has an enormous history, dating back at least to seminal works of [3, 11, 21, 12]. While there are obvious conceptual connections between voting rules and tournament rules (e.g. any tournament rule can be used as a voting rule: call the "match" between alternatives x and y won by x if more voters prefer x to y), the notions of manipulability are quite different. For one, voters have preferences over alternatives whereas teams in tournaments only care about their collusion's joint probability of winning. Moreover, in a voting rule, a *voter* has a tiny role to play in every single "match," whereas in a tournament, the *teams* themselves can manipulate only matches that involve them. So there is little technical (and even conceptual) similarity between works which study incentives in voting rules versus tournament rules.

The linear program we introduce in Section 3 has been studied in a related context by two independent works [16, 10]. They consider the following two player zero-sum game. Given a tournament T the players must pick a team to represent them and reveal it simultaneously. If they pick the same team, no one wins. Otherwise, the winner is determined by the edge that they jointly query from T. The two works showed that, for any given tournament T, there is a unique mixed strategy Nash equilibrium which can be computed in polynomial time through linear programming (and this LP is exactly our $\mathsf{SLP}(T)$). Some proof techniques are similar, but our interest in $\mathsf{SLP}(T)$ is a means to drastically different end. For more on the history and properties of the solution to these LPs, known as *maximal lotteries*, see [8, 5].

The notion of uncovered teams is also extremely well-studied in computational social choice theory (see, e.g., [6, 17], the latter attributes the concept's introduction to [9] and [19] independently). Additionally, an uncovered team is equivalent to the notion of a "king" [23]

(a team x such that for all teams y, either x beats y or there exists a z who beats y such that x beats z – not to be confused with the kings of our hill) in works which study how a single-elimination bracket designer can rig the seeding to make a particular team win [24, 15, 25] or sufficient conditions under which a covered team can be crowned winner of a single-elimination bracket [14]. The volume of these works certainly helps establish that cover-consistence is a valuable endeavor beyond Condorcet-consistence, but otherwise bear no technical similarity to our work. To the best of our knowledge, this is the first paper to consider cover-consistence jointly with a notion of incentive compatibility.

Another related notion is that of the Banks set of a tournament [4], which is stricter than the set of uncovered teams. While it is NP-Complete to decide if a given team is in the Banks set of a tournament [26], there exist algorithms that can efficiently output an element from the Banks set [13]. It is worth pointing out that the algorithm we propose to sample teams from the Banks set, Algorithm 1, has a different implementation from that of [13] even if they will output the same set of teams.

2 Preliminaries

In this section we introduce notation, and develop some concepts that will be relevant throughout the paper, consistent with prior work [22, 1].

▶ **Definition 6** (Tournament). *A (round robin) tournament T on n teams is a complete, directed graph on n vertices whose edges denote the outcome of a match between two teams. Team i beats team j if the edge between them points from i to j. T_n denotes the set of all n-team tournaments.*

▶ **Definition 7** (Tournament Rule). *A tournament rule r is a function $r : T_n \to \Delta([n])$ that maps n-team tournaments $T \in T_n$ to a distribution over teams, where $r_i(T) = \Pr(r(T) = i)$ denotes the probability with which team i is declared the winner of tournament T under rule r. We will often abuse notation and refer to r as a collection of tournament rules $\{r^1(\cdot), \ldots, r^n(\cdot), \ldots\}$, of which exactly one operates on T_n (for all n).*

Like prior work, we will be interested in tournaments which satisfy natural properties. For instance, [22] concerned tournaments which always select a Condorcet winner, when one exists. Below are the main properties we consider in this paper.

▶ **Definition 8** (Condorcet-consistency). *Team i is a Condorcet winner of a tournament T if i beats every other team according to T. A tournament rule r is Condorcet-consistent if for every tournament T with a Condorcet winner i, $r_i(T) = 1$ (i.e. the tournament rule always declares the Condorcet winner as the winner of T).*

▶ **Definition 9** (cover-consistency). *Team i covers team j under T if (a) i beats j and (b) every $k \notin \{i, j\}$ which beats i also beats j. A team is covered if it is covered by at least one team. A tournament rule r is cover-consistent if for all T, $r_j(T) = 0$ when j is covered.*

▶ **Observation 10.** *Every cover-consistent rule is Condorcet-consistent.*

Proof. If T has no Condorcet winner, then a Condorcet-consistent rule can be aribtrary on T. If T has a Condorcet winner i, then i is the only uncovered team. Therefore, any cover-consistent rule will have $r_i(T) = 1$, and is Condorcet-consistent as well. ◀

Intuitively, one should think of i covering j to mean that any reasonable evaluation should declare team i better than team j. Cover-consistence proposes that no team should win if they are inferior to another by any reasonable evaluation, but does not always propose who

the winner should be. Condorcet-consistence can therefore be interpreted as a relaxation of cover-consistence, which only binds when cover-consistence would propose a unique winner. The following lemma establishes this formally.

▶ **Lemma 11** (Restated Theorem 4 from [18]). *Whenever tournament T has a unique uncovered team i, i is a Condorcet winner in T.*

Proof. We first claim that the covering relation is transitive: if i covers j and j covers k, then i covers k. Indeed, let $S(k)$ denote the teams that k defeats, $S(j)$ for j, and $S(i)$ for i. Then as j covers k and i covers j, we have $S(k) \cup \{k\} \subseteq S(j) \subseteq S(i)$, meaning that i covers k.

Therefore, if we draw the directed graph $G(T)$ with an edge from j to k iff j covers k, the graph must be acyclic. If not, then the work above establishes that a path from j to k implies that j covers k, while a path from k to j implies that k covers j, a contradiction (as we cannot have both that j beats k and k beats j). Uncovered teams are exactly those with indegree 0 in $G(T)$. If there is a unique such team i, then there must be a path from i to every other team j (follow edges backwards starting from j. This process must terminate, and can only terminate at a team with indegree 0, which must be i). Therefore, i covers every other team j, which in particular implies that i beats every other team j and is therefore a Condorcet winner. ◀

The above conditions concern natural properties of the winner selected, and essentially say that good tournament rules should never select obviously inferior teams as their winner. We are also concerned with properties regarding the procedure by which the winner is selected, and in particular how manipulable this procedure is. We formalize these properties below (which are proposed in [1, 22]).

▶ **Definition 12** (S-Adjacent Tournaments). *Two tournaments $T, T' \in T_n$ are S-adjacent when the outcomes of all matches in T, T' are identical, except for the matches between two teams in $S \subseteq [n]$. Formally, for all $i, j \in [n]$, if $|\{i, j\} \cap S| < 2$, then the edge between i and j in T is identical to the one in T'. Less formally, T and T' are S-adjacent if teams in S can manipulate the outcomes of matches* only *between pairs of teams in S and cause the tournament results to change from T to T'.*

▶ **Definition 13** (k-SNM-α). *A tournament rule r is k-strongly non-manipulable at probability α (henceforth k-SNM-α) if for all subsets $S \subseteq [n]$ with $|S| \leq k$, and all pairs T, T' of S-adjacent tournaments, $\sum_{i \in S}(r_i(T) - r_i(T')) \leq \alpha$. Informally, if a set S of $\leq k$ teams decide to manipulate their pairwise matches, they cannot improve the probability that the winner is in S by more than α. We abuse notation and use ∞-SNM-α to refer to a tournament rule which is k-SNM-α for all k.*

2.1 Technical Recap of Prior Work

Finally, let's recap [22], which serves as the starting point for our work. Their main result establishes that the Random Single-Elimination Bracket (formally defined below) is 2-SNM-1/3.

▶ **Definition 14** (Random Single-Elimination Bracket). *The Random Single-Elimination Bracket (*RSEB*) rule places n teams uniformly at random among $2^{\lceil \log_2 n \rceil}$ seeds [1] (and fills the remaining seeds with byes)[2]. Then, a single-elimination tournament is played with these seeds to determine the winner. That is, whenever i meets j in the bracket, T determines which team advances to the next round, and the other team is eliminated. Note that the only randomness in the rule is in the seeding.*

▶ **Theorem 15** ([22]). RSEB *is* 2-SNM-1/3 *and Condorcet-consistent.*

The following explicit tournament was also used in [22] for lower bounds:

▶ **Definition 16** (Balanced Tournament). *The k-balanced tournament is the tournament $T^{Bal} \in T_{2k-1}$ where team i beats exactly the $k-1$ teams in $\{i+1, i+2, ..., i+k-1 \mod (2k-1)\}$.*

▶ **Lemma 17** ([22]). *No Condorcet-consistent Tournament rule is k-SNM-α for any $\alpha < \frac{k-1}{2k-1}$.*

Proof Sketch. Consider $r(T^{\text{Bal}})$. There exists some adjacent set of teams $S = \{i-k+1 \pmod{2k-1}, \ldots, i\}$ of size k which together win with probability at most $\frac{k}{2k-1}$ in $r(T^{\text{Bal}})$. These teams can make i into a Condorcet winner, which necessarily wins with probability 1. Therefore, for any $r(\cdot)$, some set of size k can gain at least $\frac{k-1}{2k-1}$ by manipulating when the original tournament is T^{Bal}. ◀

Inspired by the tightness of Theorem 15 with the simple balanced tournament T^{Bal}, [22] conjectured that same simple tournament would be the worst-case tournament for larger k:

▶ **Open Question 18** ([22]). *Does there exist a tournament rule that is Condorcet-consistent and k-SNM-$\frac{k}{2k-1}$ for all k? What about a family of rules $\mathcal{F}$ such that for all k, F_k is k-SNM-$\frac{k-1}{2k-1}$? What about a rule that is k-SNM-1/2 for all k?*

The first results of this paper refute all three conjectures from [22] and resolve Question 18. The following results concern the difference between Condorcet-consistence and cover-consistence, as the following observation shows that RSEB is not cover-consistent.

▶ **Observation 19.** RSEB *is not cover-consistent.*

Proof. Consider a tournament with eight teams A, B, C, D, E, F, G, H, where A beats exactly $\{B, C, E\}$, and H beats exactly $\{A, B, C, E\}$. C beats D, E beats F, E beats G. Any matches not explicitly stated can be arbitrarily decided. Consider the seeded bracket shown in Figure 1. This bracket shows A can win with non-zero probability. But H covers A. Therefore, RSEB is not cover-consistent. ◀

2.2 Linear Algebra Preliminaries

Some of our proofs require linear algebra. Below are facts that we use, both proofs are in Appendix A.

▶ **Definition 20** (Unit Skew Symmetric Matrix). *An $n \times n$ matrix $A \in \mathbb{R}^{n \times n}$ is* unit skew symmetric *if $|A_{ij}| = 1 \ \forall i \neq j$, and $A_{ij} = -A_{ji} \ \forall i, j$.*

---

[1] A *seed* is a position in the tournament bracket associated to a specific number.
[2] A *bye* is a dummy team that loses to all non-bye teams.

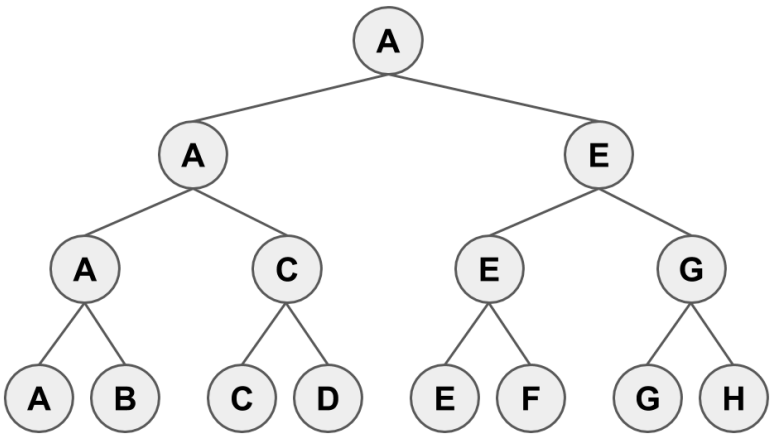

Figure 1 In this example there exists a bracket where a covered team A (covered by H) may still be declared the winner.

▶ **Proposition 21.** *If A is a unit skew symmetric matrix and n is even, rank$(A) = n$. If n is odd rank$(A) = n - 1$.*

▶ **Proposition 22.** *Let $\varepsilon \in \mathbb{R}_{\geq 0}$, $A \in \mathbb{R}^{m \times n}$, and $\vec{b} \in \mathbb{R}^m$ and denote by $P_\varepsilon := \{\vec{x} \in \mathbb{R}^n, A \cdot \vec{x} \geq \vec{b} - \varepsilon\vec{1}\} \cap [0,1]^n$. Then for all $\delta > 0$, there exists a sufficiently small $\varepsilon > 0$ such that:*

$$\max_{\vec{y} \in P_\varepsilon} \{d_{\ell_1}(P_0, \vec{y})\} \leq \delta,$$

where $d_{\ell_1}(S, \vec{x}) = \min_{\vec{y} \in S}\{|\vec{x} - \vec{y}|_1\}$.

3 A Special Linear Program $SLP(T)$

In this section we present a linear program $SLP(T)$ and characterize its optimal solutions. The analysis of $SLP(T)$ is the main tool which allows us to conclude both the non-existence of rules which are ∞-SNM-1/2 (Section 4) and the existence of a rule which is ∞-SNM-2/3 (Section 5). The main result of this section is Proposition 26, which states that $SLP(T)$ has a unique solution, and therefore yields a well-defined tournament rule. In Section 4 we show that a tournament rule that is ∞-SNM-1/2 exists *if and only if* the $SLP(T)$ rule is k-SNM-1/2 (and subsequently show that this rule is not k-SNM-1/2 via Proposition 26). Let T be a tournament graph and let $\delta_T^-(v)$ denote the set of teams that beat v in T (and $\delta_T^+(v)$ the set that v beats). Then $SLP(T)$ is the following:

***SLP(T)*:**

$$\begin{aligned} \text{minimize} \quad & \sum_{i=1}^{n} p_i & & \\ \text{subject to} \quad & \sum_{j \in \delta_T^-(i)} p_j + \frac{1}{2} p_i \geq \frac{1}{2} & & \forall i \in [n] \\ & p_i \geq 0 & & \forall i \in [n] \end{aligned}$$

Before further proceeding, let's get some (informal) intuition for why $SLP(T)$ is possibly related to Question 18. Starting from a tournament rule r, if we define $p_i := r_i(T)$, then $\sum_i p_i = 1$, $p_i \geq 0$ for all i. Moreover, if r is ∞-SNM-1/2, it must be that for all i, $\sum_{j \in \delta_T^-(i)} p_j + p_i \geq 1/2$. If not, then i together with $\delta_T^-(i)$ could collude to make i a Condorcet winner, and i would win with probability 1. So the initial probability of winning for i together with $\delta_T^-(i)$ must have been at least 1/2.

Of course, the afore-described constraints seem very weak in comparison to all of the constraints imposed by k-SNM-1/2. In particular, they only guarantee that no coalition can gain by making one of their members into a Condorcet winner (but do not guarantee that no coalition can otherwise gain by manipulating their matches). Notice now that the constraints in $SLP(T)$ are slightly stronger than this (because they have a multiplier of 1/2 instead of 1 in front of p_i in the constraint for i). In particular, the constraints in $SLP(T)$ imply Condorcet-consistence (while the afore-mentioned do not): if i is a Condorcet winner, then $\delta_T^-(i) = \emptyset$ and the constraint reads $p_i/2 \geq 1/2$ as desired. Of course, we've yet to establish a formal relationship, but at this point the reader may have some intuition for a connection between a profile of solutions to $SLP(T)$ with $\sum_i p_i \leq 1$ (for all T) and Condorcet-consistent tournament rules which are ∞-SNM-1/2.

We postpone a formal discussion of this connection (as this connection is the entire focus of Section 4), but note here that it is not particularly direct. For example, a profile of solutions to $SLP(T)$ for all $T \in T_n$ does not imply a tournament rule for n teams which is ∞-SNM-1/2. Similarly, an ∞-SNM-1/2 tournament rule for n teams does not imply a profile of solutions to $SLP(T)$ for all $T \in T_n$. However, we show that ∞-SNM-1/2 rules exist for all n *if and only if* for all n, the rule defined via profiles of solutions to $SLP(T)$ is ∞-SNM-1/2 (i.e. we will relate this LP on n teams to tournament rules for $\gg n$ teams).

We now begin our analysis of $SLP(T)$ by taking the dual, and refer to it as $D_{SLP}(T)$. Below, we use r_i as the dual variable for the constraint corresponding to team i. On the left-hand side, we've taken the dual directly. On the right hand side, we did a change of variables and redefined $q_i := r_i/2$ (so the two programs below are identical).

$D_{SLP}(T)$:

$$\begin{aligned} \text{maximize} \quad & \sum_{i=1}^{n} r_i/2 \\ \text{subject to} \quad & \sum_{j \in \delta_T^+(i)} r_j + \frac{1}{2} r_i \leq 1 \quad \forall i \in [n] \\ & r_i \geq 0 \quad \forall i \in [n] \end{aligned} \qquad \begin{aligned} \text{maximize} \quad & \sum_{i=1}^{n} q_i \\ \text{subject to} \quad & \sum_{j \in \delta_T^+(i)} q_j + \frac{1}{2} q_i \leq \frac{1}{2} \quad \forall i \in [n] \\ & q_i \geq 0 \quad \forall i \in [n] \end{aligned}$$

We now prove that the optimal value of $SLP(T)$ is always 1. This is stated in Corollary 24, which uses Lemma 23 as a building block.

▶ **Lemma 23.** *Suppose there exists a feasible solution $\vec{p}$ to $SLP(T)$ with $\sum_{i \in [n]} p_i = c$. Then $\vec{q}$ with $q_i := p_i \cdot \frac{1}{2c-1}$ is a feasible solution to $D_{SLP}(T)$ with value $\frac{c}{2c-1}$. Likewise, if there exists a feasible solution $\vec{q}$ to $D_{SLP}(T)$ with $\sum_{i \in [n]} q_i = c$, then $\vec{p}$ with $p_i := q_i \cdot \frac{1}{2c-1}$ is a feasible solution to $SLP(T)$ with value $\frac{c}{2c-1}$.*

Proof. Consider any solution $\vec{p}$ with $\sum_i p_i = c$. First, we observe that we must have $c > 1/2$. If not, there certainly exists some i with $\sum_{j \in \delta_T^-(i)} p_j + p_i/2 < 1/2$, and a constraint is violated (to see this, observe that maybe $c = 0$, in which case all the constraints are violated. Or $0 < c \leq 1/2$, in which case we can take i to be any i with $p_i > 0$). Then because

$\sum_{j\in\delta_T^-(i)} p_j + p_i/2 \geq 1/2$, we must have $\sum_{j\in\delta_T^+(i)} p_j + p_i/2 \leq c - 1/2$. As $q_i := p_i/(2c-1)$, we immediately conclude that $\sum_{j\in\delta_T^+(i)} q_j + q_i/2 \leq \frac{c-1/2}{2c-1} = 1/2$. Also, as $c > 1/2$, each $q_i \geq 0$ (and is well-defined). Therefore, $\vec{q}$ is feasible for $D_{SLP}(T)$, and it's clear that $\sum_i q_i = \frac{c}{2c-1}$. The other direction follows from identical calculations. ◀

▶ **Corollary 24.** *$SLP(T)$ always has an optimal solution with value 1.*

Proof. It is clear that $SLP(T)$ is feasible for all T, since setting $p_i = 1$ for all i is a feasible solution. Suppose we had a primal solution $\vec{p}$ with value $c < 1$. Applying Lemma 23, we can conclude $\vec{q}$ would be a dual solution with value $\frac{c}{2c-1} > c$. By weak LP duality, the existence of such a dual would verify that there are no primal solutions with value c, a contradiction.

Similarly, suppose we had an optimal primal solution $\vec{p}$ with value $c > 1$. This implies there is an optimal dual solution $\vec{q}$ with value $c > 1$. Applying the opposite direction of Lemma 23 we can conclude there is a primal solution with value $\frac{c}{2c-1} < c$, a contradiction. ◀

Now that we know the optimal value of $SLP(T)$, we wish to understand its optimal solution. We now begin taking steps towards characterizing the solution (and in particular, that it is unique).

▶ **Corollary 25.** *Let $\vec{p}$ be an optimal solution to $SLP(T)$. Then for all i s.t $p_i > 0$ and for all optimal solutions $\vec{w}$ to $SLP(T)$, $\sum_{j\in\delta_T^-(i)} w_j + \frac{1}{2}w_i = \frac{1}{2}$.*

Proof. If we apply Lemma 23 to $\vec{p}$ (which has $|\vec{p}|_1 = 1$ by Corollary 24), we conclude $\vec{p}$ is also a feasible dual solution. Hence, $\vec{p}$ is an optimal dual solution (as it has equal value in both the primal and the dual). Now consider applying the complementary slackness conditions for the alternative optimal primal $\vec{w}$, and optimal dual solution $\vec{p}$. If $p_i > 0$, we know that the corresponding primal constraint in $\vec{w}$ must be tight. This exactly states that $\sum_{j\in\delta_T^-(i)} w_j + \frac{1}{2}w_i = \frac{1}{2}$ whenever $p_i > 0$. ◀

▶ **Proposition 26.** *The optimal solution $\vec{p}$ to $SLP(T)$ is unique.*

Proof. By Corollary 24, we know that all solutions to $SLP(T)$ have value 1. Assume toward contradiction there exist two distinct solutions, $\vec{p}$ and $\vec{q}$ to $SLP(T)$ such that $|\vec{p}|_1 = 1$ and $|\vec{q}|_1 = 1$. Let $P = \{i : p_i > 0\}$ and let $Q = \{i : q_i > 0\}$. Let A be the unit skew symmetric matrix where $A_{ij} = 1$ if i beats j in T and -1 otherwise, with $A_{ii} = 0$. By Corollary 25, we know for all i in $P \cup Q$ that

$$\sum_{j\in\delta_T^-(i)} q_j + \frac{1}{2}q_i = 1/2$$

which implies for those same $i \in Q \cup P$ that (because $\sum_j q_j = 1$)

$$(A \cdot q)_i = \sum_{j\in\delta_T^+(i)} q_j - \sum_{j\in\delta_T^-(i)} q_j = 0.$$

Now, let A' denote the submatrix A restricted only to rows and columns in $P \cup Q$. Let $\vec{p}'$ and $\vec{q}'$ be the vectors $\vec{p}$ and $\vec{q}$ (respectively) restricted also to the entries in $P \cup Q$. Observe now that $(A' \cdot \vec{p}')_i = (A \cdot \vec{p})_i = 0$ for all i, and also that $(A' \cdot \vec{q}')_i = (A \cdot \vec{q})_i = 0$ (both of these follow because we have simply deleted all non-zero entries of $A \cdot \vec{p}$ and $A \cdot \vec{q}$ by restricting to $P \cup Q$).

Now we are ready to derive our contradiction. The above paragraph concludes that both $\vec{p}'$ and $\vec{q}'$ are in the null space of A', which is a unit skew symmetric matrix. But also $|\vec{p}|_1 = |\vec{q}|_1$, meaning that the null space of A' must have dimension at least 2. But this contradicts Proposition 21, which claims that the dimension can be at most 1. We therefore conclude that no such distinct $\vec{p}, \vec{q}$ can exist. ◀

Now that we know the solution to $SLP(T)$ is unique, and has $\sum_i p_i = 1$, it yields a well-defined tournament rule, which is the main takeaway from this section:

▶ **Definition 27** (SLP Tournament Rule)**.** *Let $\vec{p}(T)$ denote the (unique, by Proposition 26) solution to $SLP(T)$. Define the* SLP Tournament Rule *to select i as the winner with probability $p_i(T)$ on input T.*

4 No Condorcet-consistent ∞-SNM-$1/2$ Rule Exists

In this section we leverage our analysis of SLP to prove Theorem 1. First, we make the connection between rules that are k-SNM-α and SLP, by introducing a series of linear programs and relaxations.

Recall that for a Condorcet-consistent tournament rule r to be k-SNM-α, it must be that no coalition of size k can gain more than α probability of winning by manipulating the pairwise matches between them. In particular, if $|\delta_T^-(v)| < k$, it must be that $r_v(T) + \sum_{j \in \delta_T^-(v)} r_j(T) \geq 1 - \alpha$. Otherwise the set $\delta_T^-(v) \cup \{v\}$ can collude to make v a Condorcet winner. Formally, any k-SNM-α rule must satisfy the following feasibility $LP_0(T, \alpha, k)$ for all tournaments T.

$LP_1(T, \alpha, z)$:

$$
\begin{aligned}
p_i + \sum_{j \in \delta_T^-(i)} p_j &\geq 1 - \alpha && \forall i \in [n] \text{ such that } |\delta_T^-(i)| \leq k-1 \\
\sum_{\forall v} p_i &= 1 \\
p_i &\geq 0 && \forall i \in [n]
\end{aligned}
$$

Note that any k-SNM-α rule certainly satisfies $LP_0(T, \alpha, k)$ for all T, but that a profile of solutions to LP_0 for all $T \in T_n$ does not necessarily imply a rule which is k-SNM-α (as the LP only considers deviations which produce a Condorcet winner). Note also that the k-balanced tournament witnesses that no rule satisfies $LP_0(T, \alpha, k)$ for any $\alpha < \frac{k-1}{2k-1}$. We will also consider the case where $k \to \infty$ (and therefore, all $i \in [n]$ have $|\delta_T^-(i)| \leq k-1$, and refer to this LP simply as $LP_0(T, \alpha) := LP_0(T, \alpha, \infty)$).

Our first step will be switching from $LP_0(T, \alpha)$ to $LP_1(T, \alpha, z)$ for $z \geq 1$. Below, observe that we have made two changes. The first is insignificant: we've phrased $LP_1(T, \alpha, z)$ as a minimization LP instead of a feasibility LP. The second is a strengthening: we've changed the multiplier of p_i in the constraint corresponding to i from 1 to $\frac{z}{2z-1} \leq 1$ (so the space of feasible solutions is smaller).

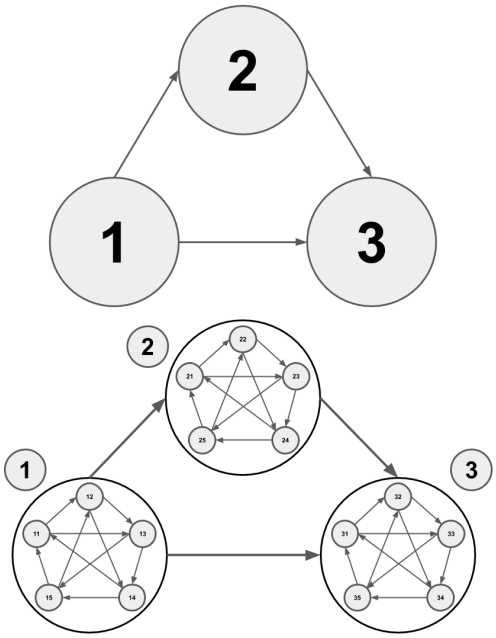

Figure 2 A tournament T (top) and its associated construction T' (bottom), as described in the proof of Lemma 28 for $z = 3$. The outcomes of the games between teams in different components of T' mimic the outcomes of the games between the representative nodes in T.

$LP_1(T, \alpha, z)$:

$$\text{minimize} \sum_{j=1}^{n} p_j$$

$$\text{subject to} \sum_{j \in \delta_T^-(i)} p_j + \frac{z}{2z-1} p_i \geq 1 - \alpha \qquad \forall i \in [n]$$

$$p_i \geq 0 \qquad \forall i \in [n]$$

Observe that $LP_1(T, 1/2, z)$ is a relaxation of $SLP(T)$ (the only difference is a multiplier of $\frac{z}{2z-1} > 1/2$ in front of p_i in the constraint corresponding to i). The main step in this section is Lemma 28 below, which formally connects $LP_1(T, 1/2, z)$ to k-SNM-α rules.

▶ **Lemma 28.** *If for all n there exists a tournament rule $r(\cdot)$ which is ∞-SNM-α, then for all $z \in \mathbb{N}_+$ and all n, there exists a tournament rule $w(\cdot)$ which is ∞-SNM-α and for which $w(T)$ is a feasible solution to $LP_1(T, \alpha, z)$ with $\sum_i p_i = 1$ for all T.*

Similarly, if for all n there exists a tournament rule $r(\cdot)$ which is k-SNM-α, then for all $z \in \mathbb{N}_+$ and all n, there exists a tournament rule $w(\cdot)$ which is $\frac{k}{2z-1}$-SNM-α [3] and for which $w(T)$ is a feasible solution to $LP_1(T, \alpha, z)$ with $\sum_i p_i = 1$ for all T.

Proof. Consider an arbitrary tournament T with n teams, and consider a related tournament T' with $n(2z-1)$ teams, labeled v_{ij}, for $i \in [n]$ and $j \in [2z-1]$. Conceptually, think that we have split each original team into a group of $2z-1$ copies. For $i \neq j$, and $x, y \in [2z-1]$, have v_{ix} beat v_{jy} in T' if and only if v_i beat v_j in T (that is, match results in T are preserved

[3] We abuse notation throughout this section to define $\frac{k}{2z-1}$-SNM-α as $\lfloor \frac{k}{2z-1} \rfloor$-SNM-$\alpha$ when the first term may not be an integer.

between different groups in T'). Within each group, have v_{ix} beat v_{iy} in T' iff $x < y < x + z \pmod{2z-1}$ (so each group is isomorphic to the z-balanced tournament, recall Definition 16 and see Figure 2 for a small example). Let $G(i)$ denote i's group, $G(i) := \{v_{ij}, j \in [2z-1]\}$.

Now, we wish to claim that if $r(\cdot)$ is a rule that is ∞-SNM-α (respectively, k-SNM-α) for $n(2z-1)$ teams, and we define $w(T)$ so that $w_i(T) := \sum_{j=1}^{2z-1} r_{ij}(T')$, then $w(\cdot)$ is a rule that is ∞-SNM-α (respectively, $\frac{k}{2z-1}$-SNM-α) for n teams, *and $w(T)$ is a feasible solution to $LP_1(T, \alpha, z)$ for all T.*

Let's first confirm that $w(T)$ is a feasible solution to $LP_1(T, \alpha, z)$ with $\sum_i p_i = 1$. The latter statement is clear: as $r(\cdot)$ is a tournament rule, we have $\sum_i p_i = \sum_i w_i(T) = \sum_{ij} r_{i,j}(T) = 1$. Next, it is also clear that $p_i \geq 0$ for all i, so we just need to check that $\sum_{j \in \delta_T^-(i)} p_j + \frac{z}{2z-1} p_i \geq 1 - \alpha$.

To this end, we know that there exists *some* adjacent set of z teams in $G(i)$ such that the total probability that these teams win is at most $\frac{z}{2z-1} \cdot p_i$. Call this set S_x and let v_{ix} denote the team in this set which loses to the others. Then the set of teams $\cup_{j \in \delta_T^-(i)} G(j) \cup S_x$ together can create a Condorcet winner (v_{ix}) in T'. Therefore, we get that this set of teams must have won with probability at least $1 - \alpha$ under $r(\cdot)$, and by definition of $w(\cdot)$ (and the choice of S_x above), we immediately get that $\sum_{j \in \delta_T^-(i)} w_j(T) + \frac{z}{2z-1} w_i(T) \geq 1 - \alpha$, as desired.

So now we know that $w(\cdot)$ satisfies $LP_1(T, \alpha, z)$ with $\sum_i p_i = 1$ for all T. We now need to confirm that it is also ∞-SNM-α (respectively, $\frac{k}{2z-1}$-SNM-α). But suppose for contradiction that $w(\cdot)$ was not k-SNM-α for some k (respectively, $\frac{k}{2z-1}$-SNM-α). This would imply the existence of tournaments T_1 and T_2 that are S-adjacent for some set $S \subseteq [n]$ (respectively, $S \subseteq [n]$, with $|S| \leq \frac{k}{2z-1}$) where $\sum_{i \in S} w_i(T_1) - \sum_{i \in S} w_i(T_2) > \alpha$. If we let T_1' and T_2' represent the corresponding tournaments that determined the values of T_1 and T_2 from $r(\cdot)$ respectively, and let $S' = \cup_{i \in S} G(i)$, we can conclude $\sum_{i \in S'} r_i(T_1') - \sum_{i \in S'} r_i(T_2') > \alpha$, contradicting the fact that r is ∞-SNM-α (respectively, that r is k-SNM-α, as $|S'| = |S| \cdot (2z-1)$ and $|S| \leq \frac{k}{2z-1}$). ◀

With Lemma 28 in hand, we're very close to our goal. In particular, we've now shown that ∞-SNM-α rules exist for all n if and only if ∞-SNM-α rules exist for all n *which additionally satisfy the constraints in $LP_1(T, \alpha, z)$ for all $z \in \mathbb{N}_+$*. Note that as $z \to \infty$, the constraints of $LP_1(T, 1/2, z)$ approach those of $SLP(T)$. So one might reasonably expect that $SLP(T)$ can be used in place of $LP_1(T, 1/2, z)$ above, specifically when $\alpha = 1/2$. Indeed, this is the case (and the only place where we use Proposition 22).

▶ **Theorem 29.** *There exists an ∞-SNM-1/2 tournament rule for all n if and only if the* SLP *Tournament Rule is ∞-SNM-1/2 for all n.*

Moreover, if the SLP *Tournament Rule is* not *∞-SNM-1/2 for all n, there exists a pair of integers $k, n < \infty$ such that no k-SNM-1/2 Tournament Rule exists on n teams.*

Proof. The proof follows from a proper application of Lemma 28 and Proposition 22. Suppose towards contradiction that the SLP Tournament Rule is not k-SNM-1/2 for some k, n. This implies that there must be some tournaments $T, T' \in T_n$ and manipulating set S which verify this fact by gaining probability $c > \frac{1}{2}$. Call $A(T), b(T)$ be the constraint matrix and vector of $SLP(T)$, respectively, when written in standard form (i.e. $A(T)$ has n rows, corresponding to the n non-trivial constraints in $SLP(T)$. $b(T)$ is just the n-dimensional vector of all 1/2s).

Now apply Proposition 22 with $A := A(T)$ and $b := b(T)$, with $\delta = \frac{c - \frac{1}{2}}{4}$, and let $\varepsilon(T)$ be the promised ε. Do the same for T', and set $\varepsilon = \min\{\varepsilon(T), \varepsilon(T')\}$. Pick now a sufficiently large z such that $\frac{z}{2z-1} - \frac{1}{2} \leq \varepsilon$ (such a z exists as $\varepsilon > 0$).

Now, observe that any feasible solution $\vec{x}$ for $LP_1(T, 1/2, z)$ satisfies $A(T) \cdot \vec{x} \geq \vec{b} - \varepsilon\vec{1}$ (and any feasible solution $\vec{y}$ for $LP_1(T', 1/2, z)$ satisfies $A(T') \cdot \vec{y} \geq \vec{b} - \varepsilon\vec{1}$). If there is an ∞-SNM-$1/2$ tournament rule (respectively, k-SNM-$1/2$ tournament rule, for k to be chosen later), Lemma 28 tells us that there exists an ∞-SNM-$1/2$ (respectively, $\frac{k}{2z-1}$-SNM-$1/2$) tournament rule y such that $y(T)$ is feasible for $LP_1(T, 1/2, z)$ and $y(T')$ is feasible for $LP_1(T', 1/2, z)$. So we know $A(T) \cdot y(T) \geq \vec{b} - \varepsilon \cdot \vec{1}$, and also that $A(T') \cdot y(T') \geq \vec{b} - \varepsilon \cdot \vec{1}$. Proposition 22 then allows us to conclude that $|y(T) - w(T)|_1 \leq \delta$, and also that $|y(T') - w(T')|_1 \leq \delta$. But now we are ready to derive a contradiction and claim that in fact $y(\cdot)$ is not ∞-SNM-$1/2$. Indeed, we know that

$$\sum_{v \in S} w_v(T) - w_v(T') \geq c,$$

by definition of S, T, T'. But from the triangle inequality, we get that:

$$\sum_{v \in S} w_v(T) - y_v(T) \leq \sum_{v \in S} |w_v(T) - y_v(T)| \leq |w(T) - y(T)|_1 \leq \delta,$$

$$\sum_{v \in S} y_v(T') - w_v(T') \leq \sum_{v \in S} |w_v(T') - y_v(T')| \leq |w(T') - y(T')|_1 \leq \delta.$$

Summing these three equations then yields:

$$\sum_{v \in S} y(T)_v - y(T')_v + 2\delta \geq c \quad \Rightarrow \quad \sum_{v \in S} y(T)_v - y(T')_v \geq \frac{c + \frac{1}{2}}{2} > \frac{1}{2}.$$

This contradicts that $y(\cdot)$ was ∞-SNM-$1/2$ (and contradicts that $y(\cdot)$ is $\frac{k}{2z-1}$-SNM-$1/2$, as long as $|S| \leq \frac{k}{2z-1}$, or $k \geq |S|(2z-1)$. Note that k can indeed be defined after z and S), as now S can manipulate from T' to T and gain $> 1/2$. ◀

To briefly recap the entire proof of Theorem 29: we first showed that the existence of ∞-SNM-α rules imply the existence of specific kinds of ∞-SNM-α rules (those which satisfy $LP_1(T, \alpha, z)$ for all $z \in \mathbb{N}_+$). Note that we relied on the existence of ∞-SNM-α rules for $n' \gg n$ in order to show the existence of our specialized ∞-SNM-α rules for n. Then, we showed that for $\alpha = 1/2$, the existence of specialized rules implies that a particular rule (the SLP Tournament Rule) is ∞-SNM-$1/2$ (and the fact that the SLP Tournament Rule is well-defined is the focus of Section 4).

Now, we make use of Theorem 29 by proving that the SLP Tournament Rule is not ∞-SNM-$1/2$.

▶ **Lemma 30.** *The* SLP *Tournament Rule is not* ∞-SNM-$1/2$.

Proof. See Figure 3 where two $\{B, C, E\}$-adjacent tournaments are evaluated under the SLP Tournament Rule. The three teams $\{B, C, E\}$ together have probability $4/9$ under T, but 1 under T', and therefore gain $5/9 > 1/2$ by manipulating. So the rule is not ∞-SNM-$1/2$.

Note that in order to verify that we have computed the SLP Tournament Rule correctly on T and T', the reader need only verify (in each graph) that the probabilities sum to 1, and the SLP constraints: for all i, $\sum_{j \in \delta_T^-(i)} p_j + p_i/2 \geq 1/2$. By Proposition 26, any such solution is the unique optimum, and therefore output by the SLP Tournament Rule. ◀

Proof of Theorem 1. The proof of Theorem 1 now follows immediately from Theorem 29 and Lemma 30. ◀

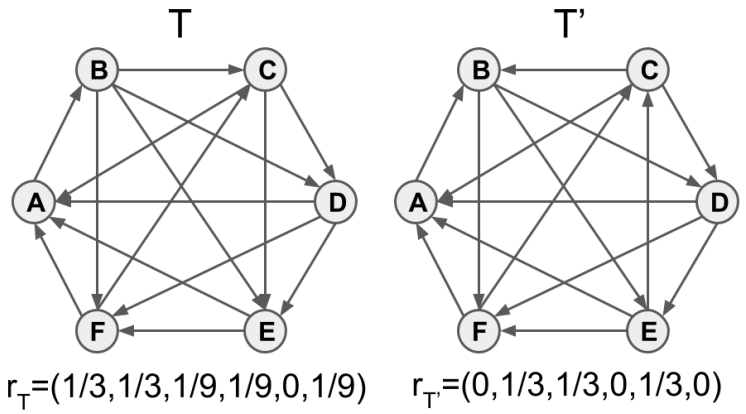

Figure 3 The tournaments T, T' are $\{B, C, E\}$ adjacent. The distribution of winners as prescribed by SLP is provided below each tournament, where the teams are presented alphabetically. Note that under T, the collusion wins with chance $4/9$ but in T' they win with probability 1, gaining $5/9$.

4.1 Concluding Thoughts on Lower Bounds

We emphasize again that our lower bounds reduce the problem of determining existence of Condorcet-consistent ∞-SNM-$1/2$ tournament rules for large $n' \gg n$ to the problem of determining whether the specific SLP Tournament Rule is ∞-SNM-$1/2$ for small n. In particular, now that we have a specific n, k for which the SLP Tournament Rule is not k-SNM-$1/2$ on n teams, we can backtrack through Theorem 29 and recover a specific k', n' for which no k'-SNM-$1/2$ (and therefore no k'-SNM-$\frac{k'-1}{2k'-1}$) Tournament Rule exists on n' teams:

In our example, there are $n = 6$ teams, and the SLP Tournament Rule is not better than 3-SNM-$5/9$. So we may take $c = 5/9$ in the proof of Theorem 29, which results in $\delta = 1/72$. Note that ε is now a function of δ via Proposition 22, and is ≈ 0.0016, so we'd set $z := \lceil \frac{1/2+\varepsilon}{2\varepsilon} \rceil = 157$. This therefore rules out the possibility of a tournament rule that is 939-SNM-$1/2$ for 1878 teams. While of course portions of the proof of Theorem 29 could be optimized to yield a smaller k', n', the point we are trying to make is that there could very well be k-SNM-$1/2$ tournament rules for n teams for quite large values of k, n, and there is virtually no hope of uncovering the non-existence for extremely large k via exhaustive search – recall that the space of tournament rules is all functions from the $2^{\binom{n}{2}}$ different complete directed graphs on n teams to the n-dimensional simplex (indeed, the authors had no luck via exhaustive search, and numerous rules appeared k-SNM-$1/2$ for small n in simulations). However, the machinery developed in this section allows us to brute-force search for manipulations of a *single* tournament, which happened to resolve for $k = 3, n = 6$ and conclude our desired claim, which would have required a significantly larger exhaust for *significantly* larger k', n'.

Finally, we note that it may be tempting to use our machinery, almost as is, to rule out Condorcet-consistent ∞-SNM-α rules for $\alpha > 1/2$. In particular, it is tempting to conclude that because Figure 3 exhibits that the SLP Tournament Rule is no better than 3-SNM-$5/9$, that there should not be an ∞-SNM-$5/9$ tournament rule for all n. Note, however, that the SLP is really special for $\alpha = 1/2$. Indeed, if we were to replace $1/2$ with $4/9$ in the SLP, we would (for instance) no longer have a unique solution. Therefore, we'd lose the well-defined SLP Tournament Rule, and still have to do a broad exhaustive search, and significantly new ideas would be needed to get leverage out of this. Still, while our current tools only

preclude rules which are ∞-SNM-1/2 (and ever so slightly more: ∞-SNM-.50016 via similar reasoning to the previous paragraph), it is reasonable to expect that our general approach (e.g. Lemma 28) may help rule out the existence of SNM-α tournament rules for $\alpha > 1/2$.

5 Less Manipulable Tournament Rules via SLP

In this section we prove Theorem 2: an ∞-SNM-2/3 tournament rule exists (for all n). Fortunately, a lot of the work has been done in Sections 3 and 4 in the form of our understanding of how feasible solutions to $SLP(T)$ and $LP_0(T, \beta, k)$ relate. We first show how any k-SNM-α rule that is a valid solution to $LP_0(T, \beta, k)$ (for some β) can be transformed into a k-SNM-$\frac{\alpha}{\alpha-\beta+1}$ rule. This transformation yields a stronger tournament rule if $\alpha \geq \beta$. Our proof then exploits the fact that an optimal solution to $SLP(T)$ satisfies $LP_0(T, 1/2, k)$ by design and, trivially, is ∞-SNM-1. The naive upper bound of $\alpha \leq 1$ suffices to yield a ∞-SNM-2/3 rule (previously no ∞-SNM-< 1 rule is known). Moreover, this reduction now allows any improved bounds (even if $\gg 2/3$) on the manipulability of the SLP Tournament Rule to imply tournament rules which are ∞-SNM-α for $\alpha < 2/3$. Below is the main lemma of this section.

▶ **Lemma 31** (Augmentation Lemma). *Let tournament rule $r(\cdot)$ be such that $r(T)$ satisfies $LP_0(T, \beta, k)$ for all tournaments T, and be k-SNM-α. Then a tournament rule $w(\cdot)$ exists which is k-SNM-$\frac{\alpha}{\alpha-\beta+1}$.*

Proof. Consider the following rule: pick a $c \in [0, 1]$ (to be chosen later). Set $w_i(T) = r_i(T) \cdot c + \frac{1-c}{n}$, if T does not have a Condorcet winner. If T has a Condorcet winner, allocate probability 1 to the Condorcet winner.

To evaluate the manipulability of this rule, first consider a manipulating set which creates a Condorcet winner. The total probability gained is at most $\beta \cdot c + (1 - c)$. To see this, observe that because the set can create a Condorcet winner, they must have total probability at least β under $r(\cdot)$ (and therefore at least $\beta \cdot c$ after scaling down by c).

Now consider a manipulating set that does not create a Condorcet winner. Then there is certainly no Condorcet winner in T', and so the extra $(1 - c)$ probability mass is still allocated uniformly (and the set gains nothing here). So the set can only gain what they would by manipulating under $r(\cdot)$ (scaled down by c), which is at most $\alpha \cdot c$.

To minimize $\max\{\alpha c, \beta c + (1 - c)\}$, set $c := \frac{1}{\alpha-\beta+1}$. This results in $w(\cdot)$ being k-SNM-$\frac{\alpha}{\alpha-\beta+1}$. ◀

Proof of Theorem 2. By construction the SLP Tournament Rule is Condorcet-consistent, and is feasible for $LP_0(T, \frac{1}{2}, k)$ for all k. Thus the SLP Tournament Rule satisfies the requirements of the augmentation lemma for $\beta = \frac{1}{2}$ and $\alpha = 1$ (as all rules are k-SNM-1 for all k) for all k, so Lemma 31 results in an ∞-SNM-2/3 rule. ◀

At this point the experienced reader may wonder about other useful properties of the SLP Tournament Rule. In Appendix B we show that the SLP Tournament Rule is *not* monotone.

6 Cover-Consistent Tournament Rules

In this section we shift gears and return to 2-SNM-α tournaments. We extend the results of [22] not in the direction of larger k or smaller α, but towards a more stringent requirement than Condorcet-consistence (cover-consistence). The main result of this section is Theorem 4, which develops a new tournament rule which is cover-consistent and 2-SNM-1/3 (the smallest α possible, by Lemma 17). We call our rule Randomized-King-of the Hill and define it below.

Algorithm 1 Pseudocode for the Randomized-King-of-the-Hill Tournament Rule.

Input: A tournament graph $T = (V, E)$ on n teams.
Output: A winning team $i \in V$.
repeat
  Choose a team $j \in V$ uniformly at random ;
  if *(j is a Condorcet winner);*
  then
    return j;
  end
  $V \leftarrow V \setminus \{j \cup \delta_T^+(j)\}$;
until;

▶ **Definition 32** (Randomized-King-of-the-Hill)**.** *The* Randomized-King-of-the-Hill *Tournament Rule (RKotH) starts every step by first checking whether there is a Condorcet winner among the remaining teams. If so, that team is declared the winner. If not, it picks a uniformly random remaining team i (which we'll call the* prince*) and removes team i and all teams which lose to i. Algorithm 1 provides pseudocode.*

The main distinction we'll emphasize between RSEB and RKotH is that RKotH is cover-consistent (Lemma 33 below), while RSEB is not (Observation 19). We later show that RKotH is also 2-SNM-1/3, just like RSEB.

▶ **Lemma 33.** *RKotH is cover-consistent.*

Proof. Consider any two teams u, v where u covers v. If RKotH is to possibly output v, the team u must be removed at some round where team x is selected. If at the start of this round, v has already been removed, then v will clearly not be declared the winner. If at the start of this round, v has not already been removed, then v is removed this round because v loses to x (as x beats u and u covers v). Therefore, v can never be declared the winner by RKotH. ◀

In fact, RKotH satisfies an even stronger property than cover-consistency. Before stating this we need to introduce some definitions.

▶ **Definition 34** (Sub tournament)**.** *A* sub tournament *of a tournament T with respect to a set of teams S is the tournament induced by the games between teams in S.*

▶ **Definition 35** (Transitive tournaments)**.** *A tournament T is* transitive *if there are no directed cycles.*

▶ **Definition 36** (Banks set)**.** *Team v is a Banks winner of tournament T if there exists a maximal (with respect to inclusion) transitive sub tournament T' of T where v is the Condorcet-winner. The* Banks set *of a tournament T is the set of Banks winners of the tournament.*

▷ Claim 37. The Banks set of a tournament is a subset of the set of uncovered teams of the tournament.

Proof. We will show the contrapositive. Consider a team v that is covered by some other team u. No maximal transitive sub tournament of T can have v as its Condorcet-winner because u beats v and everyone v beats and hence can always be added on top of v, contradicting the maximality of the sub tournament. ◁

We can now prove Lemma 5, which states that the Banks set of a tournament T is *exactly* the set of teams RKotH can declare as winner.

Proof of Lemma 5. First, we argue that any Banks winner can be output by RKotH with non-zero probability. Indeed, consider any Banks winner v, and let T' denote the maximal transitive subtournament in which v is the Condorcet winner. Name the teams in $T' \setminus \{v\}$ as $u_1, \ldots, u_k$, where u_i beats u_j for all $j < i$ (and v beats u_i for all i). Now, because T' is a maximal transitive subtournament, there does not exist any w which beats all teams in T' (otherwise we could add w to the subtournament, witnessing non-maximality). Now, consider an execution of RKotH which first selects princes in order of u_i (u_1, then u_2, etc.) and then finally v. First, observe that each u_i has not yet been eliminated by the time we hope they are selected (by definition of u_i). Second, observe that every team $w \notin T'$ must be eliminated by the end, because they lose to some team in T'. Therefore, after this execution, v is the only remaining team, and crowned champion.

It remains to show that any team in the support of RKotH is always a Banks winner. Out of all the executions of RKotH where v wins, consider one that goes through the most princes before v is picked. We claim this will be a maximal transitive sub tournament. Let $P = \{p_1, ..., p_k\}$ be the set of princes used by the algorithm in that order. Since v wins under those princes, it must beat every team in P. Moreover, since the algorithm first picks p_1, then p_2, and so on, it must be the case that p_i beats p_j for $i > j$. Otherwise p_i would be eliminated on the step where p_j was selected as the prince. Therefore, the sub tournament $v \cup P$ is transitive, and has v as its Condorcet-winner.

Consider any team $x \notin v \cup P$. If x beat teams $p_1, ..., p_i$ and lost to teams $p_{i+1}, ..., v$ for some $i \in \{0, ..., k+1\}$, then an execution that places x between p_i, p_{i+1} would be feasible. It would still output v but run for one more step than P, contradicting the maximality of P. Therefore, $v \cup P$ is a maximal transitive sub tournament where v is a Condorcet-winner, implying v is in the Banks set. ◀

We will also use the fact that RKotH is monotone in our remaining proof. Below (and for the remainder of this section), we'll refer to a *prince* as the most recently selected remaining team, and we'll refer to an *execution* of RKotH as simply an ordering over potential princes (to be selected if they haven't yet been eliminated when their turn comes).

▶ **Lemma 38.** *RKotH is monotone. That is, if T, T' are $\{u, v\}$-adjacent and u beats v in T, then $r_u(T) \geq r_u(T')$.*

Proof. Consider any execution of RKotH and consider the first time that either u or v is prince (observe that prior to this, the edge between u and v is never queried, so the execution on T and T' is identical). If either u or v is already eliminated, then it doesn't matter whether u beats v or vice versa, and the outcome is the same. Otherwise, if u is the prince and u beats v, then there is a chance that u wins. If u loses to v, then u is eliminated immediately. If v is the prince and u beats v, then there is a chance that u wins. If u loses to v, then u is eliminated immediately. Therefore, for every execution, if u wins in T', u also wins in T, and the lemma holds. ◀

The rest of this section is devoted to proving that RKotH is 2-SNM-1/3. The key approach of our proof is the following: consider any round in which both u and v still remain. The next team selected as prince might beat both u and v (in which case the outcome between u and v is never queried), lose to both u and v (in which case the outcome has not yet been queried), or beat exactly one of $\{u, v\}$ (in which case again the outcome between u and v is

never queried). The only event in which we ever query the outcome of the match is when one of $\{u, v\}$ is selected as prince while the other remains (and even then, the outcome only matters if some teams remain which beat exactly one of $\{u, v\}$). So the key approach in the proof is a coupling argument between different possible executions of RKotH (some of which make the match between u and v irrelevant, and some of which cause $\{u, v\}$ to prefer the match turn one way or the other).

Proof of Theorem 4. In order to show the rule is 2-SNM-1/3, consider two teams u, v who are trying to collude in a given tournament T. Suppose wlog that u beats v in T and let T' be the $\{u, v\}$-adjacent tournament to T where v beats u.

To begin the analysis, we first introduce some notation. Let S be the subset of teams which either beat at least one of u or v, or are u or v. For a given execution of RKotH let x denote the first prince in S on tournament T. Observe first that there must be a prince in S at some point (otherwise neither u nor v is ever eliminated), and also that x is the first prince in S on tournament T' as well (for the same execution). Let also X denote the set of princes *strictly before* x was chosen, and $Y(X)$ denote the set of un-eliminated teams after the set X of princes. We first observe that, conditioned on X, the next prince is a uniformly random element of $Y(X) \cap S$.

▶ **Lemma 39.** *For all $X \subset [n] \setminus S$, conditioned on the set X being princes so far, and the next prince being an element of S, the next prince is a uniformly random element of $Y(X) \cap S$.*

Proof. For all $X \subseteq [n] \setminus S$, conditioned on the set X being princes so far, the next prince is a uniformly random element of $Y(X)$, so each element of $Y(X) \cap S$ is selected with equal probability. ◀

The main step in the proof is the following lemma, which claims that after conditioning on X, the difference between T and T' in terms of whether one of $\{u, v\}$ wins under RKotH is small.

▶ **Lemma 40.** *For all X, let $r_{u,v}(T, X)$ denote the probability that RKotH selects a winner in $\{u, v\}$, conditioned on X being exactly the set of princes before the first prince in S. Then for all X, $|r_{u,v}(T', X) - r_{u,v}(T, X)| \leq 1/3$.*

Proof. We consider a few possible cases, conditioned on the structure of $Y(X) \cap S$, and which team is the next prince. To aid in formality, we'll use the notation $r_{u,v}(T, X|E)$ to denote the probability that RKotH selects a winner in $\{u, v\}$ on tournament T conditioned on exactly the set X of princes before the first prince in S and event E.

Case One: $Y(X) \cap S = \{u, v\}$. In this case, certainly u or v will win in tournament T and T'. This is because all remaining teams lose to both u and v, so whoever wins the match between u and v is a Condorcet winner among the remaining teams and will therefore win. So if E_1 denotes the event that $Y(X) \cap S = \{u, v\}$, we have that $r_{u,v}(T, X|E_1) = r_{u,v}(T', X|E_1)$.

Case Two: $|Y(X) \cap S| > 2$, next prince $\notin \{u, v\}$. In this case, at least one of $\{u, v\}$ are eliminated immediately, and the match result is never queried. Therefore, the result is the same under T and T'. So if E_2 denotes the event that $|Y(X) \cap S| > 2$ and the next prince is not in $\{u, v\}$, we have that $r_{u,v}(T, X|E_2) = r_{u,v}(T', X|E_2)$.

Case Three: $|Y(X) \cap S| > 2$, next prince is u. In this case, we claim it is *always better* for $\{u, v\}$ to be in T' (v beats u) versus T. To see this, first consider that maybe some remaining element of $Y(X) \cap S$ beats u. Then u certainly will not win. If u beats v, then v also will certainly not win. But if v beats u, then maybe v can win. If no remaining element of $Y(X) \cap S$ beats u, then either u will win in T, or v will win in T' (because all teams aside from u and v are eliminated). So if E_3 denotes the event that $|Y(X) \cap S| > 2$ and the next prince is u, we have that $r_{u,v}(T', X|E_3) \geq r_{u,v}(T, X|E_3)$.

Case Four: $|Y(X) \cap S| > 2$, next prince is v. This case is symmetric to the above, and it is always better for $\{u, v\}$ to be in T versus T'. So if E_4 denotes the event that $|Y(X) \cap S| > 2$ and the next prince is v, we have that: $r_{u,v}(T, X|E_4) \geq r_{u,v}(T', X|E_4)$.

So to conclude, we've seen that if $|Y(X) \cap S| = 2$, then the outcome is the same under T and T', so the lemma statement clearly holds for any X with $|Y(X) \cap S| = 2$. If $|Y(X) \cap S| > 2$, then there is *exactly* one choice for the next team which *may* cause $\{u, v\}$ to prefer T to T' (and vice versa). By Lemma 39, the next prince is drawn uniformly at random from $|Y(X) \cap S|$, so this element is selected with probability at most $1/3$. Formally, for any X with $|Y(X) \cap S| > 2$ we have:

$$\begin{aligned} r_{u,v}(T, X) - r_{u,v}(T', X) = &\Pr[E_2] \cdot (r_{u,v}(T, X|E_2) - r_{u,v}(T', X|E_2)) \\ &+ \Pr[E_3] \cdot (r_{u,v}(T, X|E_3) - r_{u,v}(T', X|E_3)) \\ &+ \Pr[E_4] \cdot (r_{u,v}(T, X|E_4) - r_{u,v}(T', X|E_4)) \\ \leq &\Pr[E_2] \cdot 0 + \Pr[E_3] \cdot 0 + \Pr[E_4] \cdot 1 \leq \frac{1}{|Y(X) \cap S|} \leq 1/3. \end{aligned}$$

Similar inequalities hold for $r_{u,v}(T', X) - r_{u,v}(T, X)$ but with the role of E_3 and E_4 swapped, allowing us to conclude that indeed $|r_{u,v}(T, X) - r_{u,v}(T', X)| \leq 1/3$. ◀

The rest of the proof now follows easily. Below, if $r_{u,v}(T)$ denotes the probability that either u or v wins under RKotH for tournament T, and $p(X)$ denotes the probability that X is exactly the set of princes before the first prince in S is selected (under tournament T), we have:

$$|r_{u,v}(T) - r_{u,v}(T')| \leq \sum_X p(X) \cdot |r_{u,v}(T, X) - r_{u,v}(T', X)| \leq 1/3.$$ ◀

While RKotH and RSEB are optimal tournament rules against collusions of size 2, their effectiveness disappears as the collusions become larger. In particular, in Appendix B we show a specific tournament against both rules for which large collusions can increase their odds of winning up to close to 1.

7 Conclusion

We extend work of [22] in three different directions: First, we refute their main conjecture (Theorem 1, Sections 3 and 4). Next, we design the first Condorcet-consistent tournament rule which is ∞-SNM-(< 1) (Theorem 2, Sections 3 and 5). Finally, we design a new tournament rule (RKotH) which is 2-SNM-1/3 (just like RSEB), but which is also cover-consistent (Theorem 4, Section 6).

Reiterating from Section 1, the main appeal of our results is clearly theoretical, and some of this appeal comes from the process itself. For example, Theorem 29 reduces the search for a Condorcet-consistent ∞-SNM-1/2 rule to determining whether or not the SLP Tournament Rule is ∞-SNM-1/2. Additionally, the same tools developed in Section 3 proved useful both for proving lower bounds and designing new tournament rules, suggesting that these tools should be useful in future works as well.

One clear direction for future work, now that the main conjecture of [22] is refuted, is to understand what the minimum α is such that an ∞-SNM-α tournament rule exists. It is also interesting to understand how large k needs to be in order for the [22] conjecture to be false. Our work does not rule out the existence of a 3-SNM-2/5 tournament rule, yet we also do not know of any 3-SNM-2/5 rule (nor even a 3-SNM-1/2 rule). More generally, our work contributes to the broad agenda of understanding the tradeoffs between incentive compatibility and quality of winner selected in tournament rules, and there are many interesting problems in this direction.

A Missing proofs from Section 2.2

To prove Proposition 21, we first need some additional machinery.

▶ **Definition 41** (Pfaffian). *The* Pfaffian *of an $n \times n$ skew-symmetric matrix A (when $n = 2k$ is even) is defined as follows. First, let Π be the set of all partitions of $[2k]$ into pairs without regard to order. If we write an element $\alpha \in \Pi$ as $\{(i_1, j_1), (i_2, j_2), \cdots (i_k, j_k)\}$ with $i_\ell < j_\ell$ for all ℓ and $i_1 < i_2 < \ldots < i_k$, then let π_α denote the permutation with $\pi_\alpha(2\ell - 1) = i_\ell$ and $\pi_\alpha(2\ell) = j_\ell$ (i.e. π_α sorts elements in the order $i_1, j_1, i_2, j_2, \ldots$). Let $A_\alpha := sgn(\pi_\alpha) \prod_{\ell=1}^{k} A_{i_\ell, j_\ell}$.[4] Then the Pfaffian of A, denoted by $Pf(A)$, is equal to $\sum_{\alpha \in \Pi} A_\alpha$.*

▶ **Theorem 42.** *When n is even, any $n \times n$ skew-symmetric matrix A satisfies $Det(A) = (Pf(A))^2$.*

Proof of Proposition 21. We will first prove the case when n is even, using Theorem 42. We first observe that as A is unit skew-symmetric, $|A_{ij}| = 1$ for all $i \neq j$. Therefore, for all $\alpha \in \Pi$, $|A_\alpha| = 1$. So the Pfaffian of A is the sum of $|\Pi|$ terms, each of which are ± 1. Therefore, if we can show that $|\Pi|$ is odd, the Pfaffian must be non-zero, Theorem 42 implies that $Det(A) \neq 0$ as well (meaning that A has full rank).

[4] Recall that the sign of a permutation π, denoted here by $sgn(\pi)$ is equal to the number of inversions in π (that is, the number of pairs $i < j$ with $\pi(i) > \pi(j)$).

It is straight forward to count the number of elements in Π: first, there are $n-1$ choices for the partner of 1. Then, there are $n-3$ choices for the partner of the smallest unpartnered element. After choosing the first ℓ pairs, there are $n-2\ell-1$ choices for the partner of the smallest unpartnered element. So there are $(n-1)\cdot(n-3)\ldots 5\cdot 3$ elements of Π, which is an odd number.

Now we consider the case where n is odd. Observe first that the submatrix of A created by removing the last row and last column is a unit skew symmetric matrix with even dimension, and therefore has rank $n-1$. Therefore, the rank of A is also at least $n-1$. By Jacobi's theorem, all skew symmetric matrices of odd dimension have determinant zero (and are therefore not of full rank). Therefore, the rank must be exactly $n-1$. ◀

Proof of Proposition 22. For a given $\delta > 0$, let Y be the set of all vectors in the unit hypercube with ℓ_1 distance strictly less than δ from some element of P_0 (i.e. there exists an element in P_0 within ℓ_1 distance strictly less than δ). It is easy to see that Y is an open set. Now let $S = [0,1]^n \setminus Y$. Note that S is closed and bounded, and therefore compact.

Definte now the function $f(\vec{y}) = \max\{0, \max_{i\in[n]} \vec{b}_i - (A\cdot\vec{y})_i\}$. First observe that $f(\cdot)$ is continuous, as it is a composition (via maximums, subtractions, etc.) of affine functions. Observe also that $\vec{y} \in P_\varepsilon$ for all $\varepsilon \geq f(\vec{y})$, and that $\vec{y} \notin P_\varepsilon$ for all $\varepsilon < f(\vec{y})$. We now consider two possible cases for $\inf_{\vec{y}\in S}\{f(\vec{y})\}$, and find our desired ε.

- Case 1: $\inf_{\vec{y}\in S}\{f(\vec{y})\} = 0$. As S is compact, f achieves its infimum over S. Therefore, there exists a $\vec{y} \in S$ with $f(\vec{y}) = 0$. Let's parse what this means. First, as $f(\vec{y}) = 0$, we know that $\vec{y} \in P_0$. But also, $P_0 \subseteq Y$, and $S \cap Y = \emptyset$. So any $\vec{y} \in S$ cannot also be in P_0, which means $f(\vec{y}) > 0$ for all $\vec{y} \in S$, meaning that we can't have $\inf_{\vec{y}\in S}\{f(\vec{y})\} = 0$ after all.
- Case 2: $\inf_{\vec{y}\in S}\{f(\vec{y})\} = c > 0$. Then let $\varepsilon = c/2$. Now, observe that all elements of S are *not* in P_ε, as they all have $f(\vec{y}) > \varepsilon$.

So to wrap up, we must have $\inf_{\vec{y}\in S}\{f(\vec{y})\} = c > 0$, and if we set $\varepsilon = c/2$, then $S \cap P_\varepsilon = \emptyset$. Therefore, as $S \cap Y = [0,1]^n$, it must be the case that all of P_ε is contained in Y. But this is exactly the desired statement: all elements of P_ε have some point in P_0 within distance δ. So take this to be our desired ε. ◀

B Further properties of the proposed tournament rules

In this section we analyze further properties of the two main tournament rules discussed on this paper. First we show that the SLP tournament rule fails to satisfy monotonicity, a very natural and desirable property from the point of view of a tournament designer.

▷ Claim 43. SLP is not a monotone tournament rule.

Proof. Consider the tournament T and it's $\{3,5\}$-adjacent tournament T', both depicted in Figure 4. In T, 5 beats 3 originally and the SLP tournament rule awarded team 5 a .2 chance of winning. If instead 5 purposely throws its game to 3, the SLP tournament rule *rewards* team 5 by increasing its chance of winning to 1/3. Therefore the SLP tournament rule is not monotone. ◁

Next we show that the optimality of RSEB, RKotH against collusions of size 2 fails to translate to larger collusions. In particular, we show that the manipulability of both rules tends to 1 as the size of the collusion increases, ruling both of them out as candidates for ∞-SNM-α for constant $\alpha < 1$. First we define a family of tournaments that will be useful in showing lower bounds for both rules. These tournaments were introduced in [22].

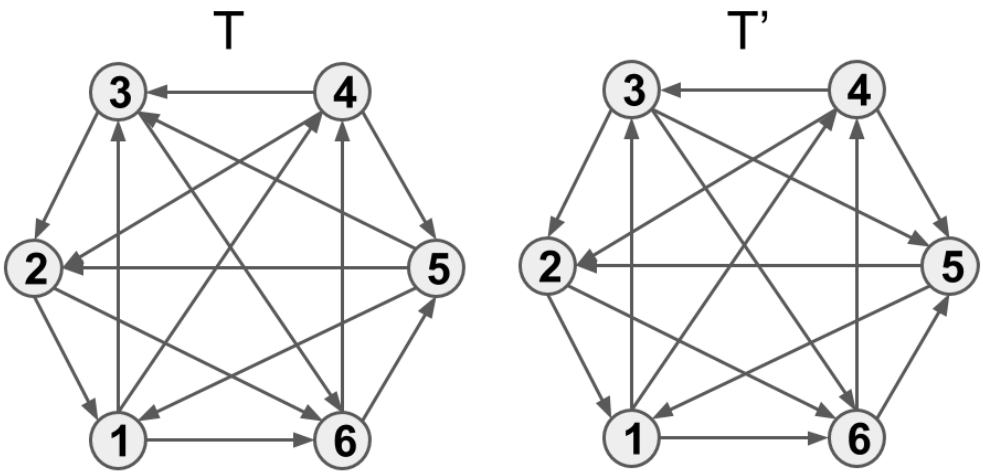

Figure 4 The tournament T can be unilaterally manipulated by team 5 to become the tournament T'.

▶ **Definition 44** (Kryptonite Tournament [22]). *A kryptonite tournament T on n teams has a* superman *team (wlog label it 1) who beats everyone except a* kryptonite *team (wlog label it n). Moreover, team n loses to every other team except 1. The outcomes of the matches between the remaining teams may be arbitrary.*

We now proceed with the main claim of this section.

▷ Claim 45. RKotH is no better than k-SNM-$(k-1)/(k+1)$ for any k. RSEB is no better than k-SNM-$(k-1)/k$ when $k+1$ is a power of 2.

Proof. Consider k and let $n = k+1$. Let T be any kryptonite tournament on n teams, with team 1 as the superman team and team n as the kryptonite team. In order for team 1 to win under RKotH, the rule must avoid selecting teams 1 and n. Under any other first choice of prince, RKotH will declare team 1 the winner. Therefore it declares team 1 the winner with probability $(k-1)/(k+1)$. However, if all teams but the superman collude they can make the kryptonite a Condorcet-winner. The collusion's combined odds of winning before were exactly $2/(k+1)$, so RKotH is at least k-SNM-$(k-1)/(k+1)$.

Now let $k+1$ be a power of two and consider the same T as before. In order for the superman team to win under RSEB it must avoid the kryptonite team in the first round. Therefore RSEB crowns the superman team winner with probability $(k-1)/k$. However, all other teams can form a collusion and turn the kryptonite team into a Condorcet-winner, increasing their winning mass by $(k-1)/k$. Therefore, RSEB is at least k-SNM-$(k-1)/k$ when $k+1$ is a power of 2. ◁

Abstract

While quantum computers hold the promise of significant computational speedups, the limited size of early quantum machines motivates the study of space-bounded quantum computation. We relate the quantum space complexity of computing a function f with *one-sided error* to the logarithm of its *span program size*, a classical quantity that is well-studied in attempts to prove formula size lower bounds.

In the more natural *bounded error* model, we show that the amount of space needed for a unitary quantum algorithm to compute f with bounded (two-sided) error is lower bounded by the logarithm of its *approximate span program size*. Approximate span programs were introduced in the field of quantum algorithms but not studied classically. However, the approximate span program size of a function is a natural generalization of its span program size.

While no non-trivial lower bound is known on the span program size (or approximate span program size) of any concrete function, a number of lower bounds are known on the *monotone span program size*. We show that the approximate monotone span program size of f is a lower bound on the space needed by quantum algorithms of a particular form, called *monotone phase estimation algorithms*, to compute f. We then give the first non-trivial lower bound on the approximate span program size of an explicit function.

Acknowledgements I am grateful to Tsuyoshi Ito for discussions that led to the construction of approximate span programs from two-sided error quantum algorithms presented in Section 3.2, and to Alex B. Grilo and Mario Szegedy for insightful comments. I thank Robin Kothari for pointing out the improved separation between certificate complexity and approximate degree in [5], which led to an improvement in from $(\log n)^{7/6}$ (using [1]) to $(\log n)^{2-o(1)}$ in Theorem 32.

1 Introduction

While quantum computers hold the promise of significant speedups for a number of problems, building them is a serious technological challenge, and it is expected that early quantum computers will have quantum memories of very limited size. This motivates the theoretical question: what problems could we solve faster on a quantum computer with limited space? Or similarly, what is the minimum number of qubits needed to solve a given problem (and hopefully still get a speedup).

We take a modest step towards answering such questions, by relating the space complexity of a function f to its *span program size*, which is a measure that has received significant attention in theoretical computer science over the past few decades. Span programs are a

model of computation introduced by Karchmer and Wigderson [10] in an entirely classical setting. They defined a span program for a Boolean function $f : \{0,1\}^n \to \{0,1\}$ as a matrix A with each of its columns labelled by an index $i \in [n]$ and a bit $b \in \{0,1\}$, and some fixed target vector in the columnspace of A. The span program *decides* f if for all x such that $f(x) = 1$, the target vector is in the span of the vectors labelled by (i, x_i) for $i \in [n]$. The *size* of the span program is the sum over i of the dimension of the span of the columns labelled by $(i, 0)$ or $(i, 1)$ (see also Definition 12). The span program size of f is then the minimum size of any span program deciding f, and was originally defined to lower bound the size of *counting branching programs*.

Several decades after the introduction of span programs, Reichardt and Špalek [18] related them to quantum algorithms, and introduced the new measure of *span program complexity* (see Definition 13). The importance of span programs in quantum algorithms stems from the ability to compile any span program for a function f into a bounded error quantum algorithm for f [17]. In particular, there is a tight correspondence between the span program *complexity* of f, and its quantum query complexity – a rather surprising and beautiful connection for a model originally introduced outside the realm of quantum computing. In contrast, the classical notion of span program *size* had received no attention in the quantum computing literature before now.

Ref. [8] defined the notion of an approximate span program for a function f. Loosely speaking, a span program *approximates* f if for every x such that $f(x) = 1$, the target is *close to* the span of the columns labelled by $\{(i, x_i)\}_{i\in[n]}$, and otherwise, the target is far from this span. They showed that even an approximate span program for f can be compiled into a bounded error quantum algorithm for f. In this work, we further relax the definition of an approximate span program for f, making analysis of such algorithms significantly easier (see Definition 15).

Let $\mathsf{S}_U(f)$ denote the *bounded error unitary space complexity of* f, or the minimum space needed by a unitary quantum algorithm[1] that computes f with bounded error (see Definition 7). For a function $f : \{0,1\}^n \to \{0,1\}$, we can assume that the input is accessed by queries, so that we do not need to store the full n-bit input in working memory, but we need at least $\log n$ bits of memory to store an index into the input. Thus, a lower bound of $\omega(\log n)$ on $\mathsf{S}_U(f)$ for some f would be non-trivial.

Letting $\mathsf{SP}(f)$ denote the minimum size of a span program deciding f, and $\widetilde{\mathsf{SP}}(f)$ the minimum size of a span program *approximating* f (see Definition 16), we have the following (see Theorem 24):

▶ **Theorem 1** (Informal). *For any Boolean function f, if $\mathsf{S}_U(f)$ denotes its bounded error unitary space complexity, and $\widetilde{\mathsf{SP}}(f)$ its approximate span program size, then*

$$\mathsf{S}_U(f) \geq \log \widetilde{\mathsf{SP}}(f).$$

Similarly, if $\mathsf{S}^1_U(f)$ denotes its one-sided error unitary space complexity, and $\mathsf{SP}(f)$ its span program size, then

$$\mathsf{S}^1_U(f) \geq \log \mathsf{SP}(f).$$

[1] A unitary quantum algorithm is a quantum algorithm in which all measurements are delayed until the end. In contrast to time complexity, the space complexity of an algorithm may be significantly smaller if we allow intermediate measurements. See [6] for a discussion of the distinction between unitary and non-unitary quantum space.

The relationship between span program size and unitary quantum space complexity is rather natural, as the span program size of f is known to lower bound the minimum size of a symmetric branching program for f, and the logarithm of the branching program size of a function f characterizes its classical deterministic space complexity.

The inequality $\mathsf{S}_U^1(f) \geq \log \mathsf{SP}(f)$, although not observed previously, follows straightforwardly from a construction of [17] for converting a one-sided error quantum algorithm for f into a span program for f – one need only observe that the size of the resulting span program is closely related to the space complexity of the algorithm. We adapt this construction to show how to convert a bounded (two-sided) error quantum algorithm for f with query complexity T and space complexity $S \geq \log T$ into an approximate span program for f with complexity $\Theta(T)$ and size $2^{\Theta(S)}$, proving $\mathsf{S}_U(f) \geq \Omega(\log \widetilde{\mathsf{SP}}(f))$. The connection between $\mathsf{S}_U(f)$ and $\log \widetilde{\mathsf{SP}}(f)$ is tight up to an additive term of the logarithm of the minimum complexity of any span program for f with optimal size. This follows from the fact that an approximate span program can be compiled into a quantum algorithm in a way that similarly preserves the correspondence between space complexity and (logarithm of) span program size, as well as the correspondence between query complexity and span program complexity (see Theorem 17). While the preservation of the correspondence between query complexity and span program complexity (in both directions) is not necessary for our results, it may be useful in future work for studying lower bounds on time and space simultaneously – somewhat analogous to branching programs, which capture both the time and space of classical algorithms.

The significance of Theorem 1 is that span program size has received extensive attention in theoretical computer science. Using results from [3], the connection in Theorem 1 immediately implies the following (Theorem 25):

▶ **Theorem 2.** *For almost all Boolean functions f on n bits, $\mathsf{S}_U^1(f) = \Omega(n)$.*

If we make a uniformity assumption that the quantum space complexity of an algorithm is at least the logarithm of its time complexity, then Theorem 2 would follow from a lower bound of $\Omega(2^n)$ on the quantum time complexity of almost all n-bit Boolean functions. Notwithstanding, the proof via span program size is evidence of the power of the technique.

In the pursuit of lower bounds on span program size of concrete functions, several nice expressions lower bounding $\mathsf{SP}(f)$ have been derived. By adapting one such lower bound on $\mathsf{SP}(f)$ to $\widetilde{\mathsf{SP}}(f)$, we get the following (see Lemma 29):

▶ **Theorem 3** (Informal). *For any Boolean function f, and* partial matrix $M \in (\mathbb{R} \cup \{\star\})^{f^{-1}(0)\times f^{-1}(1)}$ *with $\|M\|_\infty \leq 1$:*

$$\mathsf{S}_U(f) \geq \Omega\left(\log\left(\frac{\frac{1}{2}\text{-rank}(M)}{\max_{i\in[n]} \text{rank}(M \circ \Delta_i)}\right)\right),$$

where $\circ$ denotes the entrywise product, and $\Delta_i[x,y] = 1$ if $x_i \neq y_i$ and 0 else.

Above, $\frac{1}{2}$-rank denotes the approximate rank, or the minimum rank of any matrix $\widetilde{M}$ such that $|M[x,y] - \widetilde{M}[x,y]| \leq \frac{1}{2}$ for each x, y such that $M[x,y] \neq \star$. If we replace $\frac{1}{2}$-rank(M) with rank(M), we get the logarithm of an expression called the *rank measure*, introduced by Razborov [15]. The rank measure was shown by Gàl to be a lower bound on span program size, SP [7], and thus, our results imply that the log of the rank measure is a lower bound on S_U^1. It is straightforward to extend this proof to the approximate case to get Theorem 3.

Theorem 3 seems to give some hope of proving a non-trivial – that is, $\omega(\log n)$ – lower bound on the unitary space complexity of some explicit f, by exhibiting a matrix M for which the (approximate) rank measure is $2^{\omega(\log n)}$. In [15], Razborov showed that the rank

measure is a lower bound on the Boolean formula size of f, motivating significant attempts to prove lower bounds on the rank measure of explicit functions. The bad news is, circuit lower bounds have been described as "Complexity theory's Waterloo" [2]. Despite significant effort, no non-trivial lower bound on span program size for any f is known.

Due to the difficulty of proving explicit lower bounds on span program size, earlier work has considered the easier problem of lower bounding *monotone* span program size, $\mathsf{mSP}(f)$. A monotone span program is a span program where the columns of A are labelled by $(i, 1)$ for $i \in [n]$ (i.e. there are no columns associated with $(i, 0)$). For a monotone function f, the monotone span program size of f, $\mathsf{mSP}(f)$ is the minimum size of any *monotone span program* for f. We can similarly define the *approximate monotone span program size* of f, $\widetilde{\mathsf{mSP}}(f)$. Although $\log \widetilde{\mathsf{mSP}}(f)$ is *not* a lower bound on $\mathsf{S}_U(f)$, even for monotone f, it is a lower bound on the space complexity of any algorithm obtained by compiling a monotone span program. We show that such algorithms are equivalent to a more natural class of algorithms called monotone phase estimation algorithms. Informally, a phase estimation algorithm is an algorithm that works by performing phase estimation of some unitary that makes a single query to the input, and estimating the amplitude on a 0 in the phase register (see Definition 41). Phase estimation algorithms are completely general, in the sense that any unitary quantum algorithm can be transformed into a phase estimation in a way that asymptotically preserves its space and query complexity. A monotone phase estimation algorithm is a phase estimation algorithm where, loosely speaking, adding 0s to the input can only make the algorithm more likely to reject (see Definition 42). We can then prove the following (see Theorem 43):

▶ **Theorem 4** (Informal). *For any Boolean function f, any bounded error monotone phase estimation algorithm for f has space complexity at least $\log \widetilde{\mathsf{mSP}}(f)$, and any one-sided error monotone phase estimation algorithm for f has space complexity at least $\log \mathsf{mSP}(f)$.*

Fortunately, non-trivial lower bounds for the monotone span program complexity are known for explicit functions. In Ref. [3], Babai, Gàl and Wigderson showed a lower bound of $\mathsf{mSP}(f) \geq 2^{\Omega\left(\log^2(n)/\log\log(n)\right)}$ for some explicit function f, which was later improved to $\mathsf{mSP}(f) \geq 2^{\Omega(\log^2(n))}$ by Gàl [7]. In Ref. [19], a function f was exhibited with $\mathsf{mSP}(f) \geq 2^{n^\epsilon}$ for some constant $\epsilon \in (0, 1)$, and in the strongest known result, Pitassi and Robere exhibited a function f with $\mathsf{mSP}(f) \geq 2^{\Omega(n)}$ [14]. Combined with our results, each of these implies a lower bound on the space complexity of one-sided error monotone phase estimation algorithms. For example, the result of [14] implies a lower bound of $\Omega(n)$ on the space complexity of one-sided error monotone phase estimation algorithms for a certain satisfiability problem f. This lower bound, and also the one in [19], are proven by choosing f based on a constraint satisfaction problem with high *refutation width*, which is a measure related to the space complexity of certain classes of SAT solvers, so it is intuitively not surprising that these problems should require a large amount of space to solve with one-sided error.

For the case of bounded error space complexity, we also prove the following (see Theorem 32, Corollary 44):

▶ **Theorem 5** (Informal). *There exists a function $f : \{0, 1\}^n \to \{0, 1\}$ such that any bounded error monotone phase estimation algorithm for f has space complexity $(\log n)^{2-o(1)}$.*

This lower bound is non-trivial, although much less so than the best known lower bound of $\Omega(n)$ for the one-sided case. Our result also implies a new lower bound of $2^{(\log n)^{2-o(1)}}$ on the monotone span program complexity of the function f in Theorem 5.

To prove the lower bound in Theorem 5, we apply a new technique that leverages the best possible gap between the certificate complexity and approximate polynomial degree of a function, employing a function $g : \{0,1\}^{m^{2+o(1)}} \to \{0,1\}$ from [5][2], whose certificate complexity is $m^{1+o(1)}$, and whose approximate degree is $m^{2-o(1)}$. Following a strategy of [19], we use this g to construct a *pattern matrix* [20] (see Definition 37) and use this matrix in a monotone version of Theorem 3 (see Theorem 33). The fact that certificate complexity and approximate degree of total functions are related by $\widetilde{\deg}_{1/3}(g) \leq C(g)^2$ for all g is a barrier to proving a lower bound better than $(\log n)^2$ using this technique, but we also give a generalization that has the potential to prove significantly better lower bounds (see Lemma 40).

Discussion and open problems

The most conspicuous open problem of this work is to prove a lower bound of $\omega(\log n)$ on $\mathsf{S}_U(f)$ or even $\mathsf{S}^1_U(f)$ for some explicit decision function f. It is known that any space S quantum Turing machine can be simulated by a deterministic classical algorithm in space S^2 [21] so a lower bound of $\omega(\log^2 n)$ on classical space complexity would also give a non-trivial lower bound on quantum space complexity. If anything, the relationship to span program size is evidence that this task is extremely difficult.

We have shown a lower bound of $2^{(\log n)^{2-o(1)}}$ on the approximate monotone span program complexity of an explicit monotone function f, which gives a lower bound of $(\log n)^{2-o(1)}$ on the bounded error space complexity needed by a quantum algorithm of a very specific form: a monotone phase estimation algorithm. This is much worse than the best bound we can get in the one-sided case: a lower bound of $\Omega(n)$ for some explicit function. An obvious open problem is to try to get a better lower bound on the approximate monotone span program complexity of some explicit function.

Our lower bound of $(\log n)^{2-o(1)}$ only applies to the space complexity of monotone phase estimation algorithms and does not preclude the existence of a more space-efficient algorithm for f of a different form. We do know that phase estimation algorithms are fully general, in the sense that every problem has a space-optimal phase estimation algorithm. Does something similar hold for monotone phase estimation algorithms? This would imply that $\log \mathsf{m}\widetilde{\mathsf{SP}}(f)$ is a lower bound on $\mathsf{S}_U(f)$ for all monotone functions f.

In this work, we define an approximate version of the rank method, and monotone rank method, and in case of the monotone rank method, give an explicit non-trivial lower bound. The rank method is known to give lower bounds on formula size, and the monotone rank method on monotone formula size. An interesting question is whether the approximate rank method also gives lower bounds on some complexity theoretic quantity related to formulas.

Our results are a modest first step towards understanding unitary quantum space complexity, but even if we could lower bound the unitary quantum space complexity of an explicit function, there are several obstacles limiting the practical consequences of such a result. First, while an early quantum computer will have a small *quantum* memory, it is simple to augment it with a much larger classical memory. Thus, in order to achieve results with practical implications, we would need to study computational models that make a distinction between quantum and classical memories. We leave this as an important challenge for future work.

[2] An earlier version of this work used a function described in [1] with a 7/6-separation between certificate complexity and approximate degree. We thank Robin Kothari for pointing us to the improved result of [5].

Second, we are generally only interested in running quantum algorithms when we get an advantage over classical computers in the time complexity, so results that give a lower bound on the quantum space required if we wish to keep the time complexity small, such as time-space lower bounds, are especially interesting. While we do not address time-space lower bounds in this paper, one advantage of the proposed quantum space lower bound technique, via span programs, is that span programs are also known to characterize quantum query complexity, which is a lower bound on time complexity. We leave exploration of this connection for future work.

We mention two previous characterizations of $\mathsf{S}_U(f)$. Ref. [9] showed that $\mathsf{S}_U(f)$ is equal to the logarithm of the minimum width of a *matchgate circuit* computing f, and thus our results imply that this minimum matchgate width is approximately equal to the approximate span program size of f. Separately, in Ref. [6], Fefferman and Lin showed that for every function k, inverting $2^{k(n)} \times 2^{k(n)}$ matrices is complete for the class of problems f such that $\mathsf{S}_U(f) \leq k(n)$. Our results imply that evaluating an approximate span program of size $2^{k(n)}$ (for some suitable definition of the problem) is similarly complete for this class. Evaluating an approximate span program boils down to deciding if $\|A(x)^+|w_0\rangle\|$ is below a certain threshold, where $A(x)$ is the span program matrix A restricted to the rows labeled by $\{(i, x_i)\}_{i\in[n]}$, and $|w_0\rangle$ is some input-independent initial state; so these results are not unrelated[3]. We leave exploring these connections as future work.

Organization

The remainder of this paper is organized as follows. In Section 2, we present the necessary notation and quantum algorithmic preliminaries, and define quantum space complexity. In Section 3, we define span programs, and describe how they correspond to quantum algorithms. In particular, we describe how a span program can be "compiled" into a quantum algorithm, and in Section 3.2, show how a quantum algorithm can be turned into a span program, with both transformations moreorless preserving the relationships between span program size and algorithmic space, and between span program complexity and query complexity. From this correspondence, we obtain, in Section 4, expressions that lower bound the quantum space complexity of a function. While we do not know how to instantiate any of these expressions to get a non-trivial lower bound for a concrete function, in Section 5, we consider to what extent monotone span program lower bounds are meaningful lower bounds on quantum space complexity, and give the first non-trivial lower bound on the approximate monotone span program size of a function.

2 Preliminaries

We begin with some miscellaneous notation. For a vector $|v\rangle$, we let $\||v\rangle\|$ denote its ℓ_2-norm. In the following, let A be a matrix with i and j indexing its rows and columns. Define:

$$\|A\|_\infty = \max_{i,j} |A_{i,j}|, \quad \text{and} \quad \|A\| = \max\{\|A|v\rangle\| : \||v\rangle\| = 1\}.$$

[3] In the notation of Definition 12, $A(x) = A\Pi_{H(x)}$, and $|w_0\rangle = A^+|\tau\rangle$ for $|\tau\rangle$ the target. Then one can verify that the *positive witness size* of x is $w_+(x) = \left\|A(x)^+|w_0\rangle\right\|^2$ (see Definition 13).

Define the ε-rank of a matrix A as the minimum rank of any matrix B such that $\|A-B\|_\infty \leq \varepsilon$. For a matrix A with singular value decomposition $A = \sum_k \sigma_k |v_k\rangle\langle u_k|$, define:

$$\mathrm{col}(A) = \mathrm{span}\{|v_k\rangle\}_k,\ \ \mathrm{row}(A) = \mathrm{span}\{|u_k\rangle\}_k,\ \ \ker(A) = \mathrm{row}(A)^\perp,\ \ A^+ = \sum_k \frac{1}{\sigma_k}|u_k\rangle\langle v_k|.$$

The following lemma, from [12], is useful in the analysis of quantum algorithms.

▶ **Lemma 6** (Effective spectral gap lemma). *Fix orthogonal projectors Π_A and Π_B. Let $U = (2\Pi_A - I)(2\Pi_B - I)$, and let Π_Θ be the orthogonal projector onto the $e^{i\theta}$-eigenspaces of U such that $|\theta| \leq \Theta$. Then if $\Pi_A|u\rangle = 0$, $\|\Pi_\Theta \Pi_B|u\rangle\| \leq \frac{\Theta}{2}\||u\rangle\|$.*

In general, we will let Π_V denote the orthogonal projector onto V, for a subspace V.

Unitary quantum algorithms and space complexity

A *unitary quantum algorithm* $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ is a family (parametrized by n) of sequences of $2^{s(n)}$-dimensional unitaries $U_1^{(n)}, \ldots, U_{T(n)}^{(n)}$, for some $s(n) \geq \log n$ and $T(n)$. (We will generally dispense with the explicit parametrization by n). For $x \in \{0,1\}^n$, let $\mathcal{O}_x$ be the unitary that acts as $\mathcal{O}_x|j\rangle = (-1)^{x_j}|j\rangle$ for $j \in [n]$, and $\mathcal{O}_x|0\rangle = |0\rangle$. We let $\mathcal{A}(x)$ denote the random variable obtained from measuring

$$U_T \mathcal{O}_x U_{T-1} \ldots \mathcal{O}_x U_1 |0\rangle$$

with some two-outcome measurement that should be clear from context. We call $T(n)$ the *query complexity* of the algorithm, and $S(n) = s(n) + \log T(n)$ the *space complexity*. By including a $\log T(n)$ term in the space complexity, we are implicitly assuming that the algorithm must maintain a counter to know which unitary to apply next. This is a fairly mild uniformity assumption (that is, any uniformly generated algorithm uses $\Omega(\log T)$ space), and it will make the statement of our results much simpler. The requirement that $s(n) \geq \log n$ is to ensure that the algorithm has enough space to store an index $i \in [n]$ into the input.

For a (partial) function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$, we say that $\mathcal{A}$ computes f with bounded error if for all $x \in D$, $\mathcal{A}(x) = f(x)$ with probability at least $2/3$. We say that $\mathcal{A}$ computes f with one-sided error if in addition, for all x such that $f(x) = 1$, $\mathcal{A}(x) = f(x)$ with probability 1.

▶ **Definition 7** (Unitary Quantum Space). *For a family of functions $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$, the unitary space complexity of f, $\mathsf{S}_U(f)$, is the minimum $S(n)$ such that there is a family of unitary quantum algorithms with space complexity $S(n)$ that computes f with bounded error. Similarly, $\mathsf{S}_U^1(f)$ is the minimum $S(n)$ such that there is a family of unitary quantum algorithms with space complexity $S(n)$ that computes f with one-sided error.*

▶ Remark 8. Since T is the number of queries made by the algorithm, we may be tempted to assume that it is at most n, however, while every n-bit function can be computed in n queries, this may not be the case when space is restricted. For example, it is difficult to imagine an algorithm that uses $O(\log n)$ space and $o(n^{3/2})$ quantum queries to solve the following problem on $[q]^n \equiv \{0,1\}^{n\log q}$: Decide whether there exist distinct $i,j,k \in [n]$ such that $x_i + x_j + x_k = 0 \mod q$.

Phase estimation

For a unitary U acting on H and a state $|\psi\rangle \in H$, we will say we perform T *steps of phase estimation of* U *on* $|\psi\rangle$ when we compute:

$$\frac{1}{\sqrt{T}} \sum_{t=0}^{T-1} |t\rangle U^t |\psi\rangle,$$

and then perform a quantum Fourier transform over $\mathbb{Z}/T\mathbb{Z}$ on the first register, called the *phase register*. This procedure was introduced in [11]. It is easy to see that the complexity (either query or time) of phase estimation is $O(T)$ times the complexity of implementing a controlled call to U. The space complexity of phase estimation is $\log T + \log \dim(H)$. We will use the following properties:

▶ **Lemma 9** (Phase Estimation). *If $U|\psi\rangle = |\psi\rangle$, then performing T steps of phase estimation of U on $|\psi\rangle$ and measuring the phase register results in outcome 0 with probability 1. If $U|\psi\rangle = e^{i\theta}|\psi\rangle$ for $|\theta| \in (\pi/T, \pi]$, then performing T steps of phase estimation of U on $|\psi\rangle$ results in outcome 0 with probability at most $\frac{\pi}{T\theta}$.*

We note that we can increase the success probability to any constant by adding some constant number k of phase registers, and doing phase estimation k times in parallel, still using a single register for U, and taking the majority. This still has space complexity $\log \dim H + O(\log T)$.

Amplitude estimation

For a unitary U acting on H, a state $|\psi_0\rangle \in H$, and an orthogonal projector Π on H, we will say we perform M *steps of amplitude estimation of* U *on* $|\psi\rangle$ *with respect to* Π when we perform M steps of phase estimation of

$$U(2|\psi\rangle\langle\psi| - I)U^\dagger(2\Pi - I)$$

on $U|\psi\rangle$, then, if the phase register contains some $t \in \{0, \ldots, M-1\}$, compute $\tilde{p} = \sin^2 \frac{\pi t}{2M}$, which is an estimate of $\|\Pi U|\psi\rangle\|^2$ in a new register. The (time or query) complexity of this is $O(M)$ times the complexity of implementing a controlled call to U, implementing a controlled call to $2\Pi - I$, and generating $|\psi\rangle$. The space complexity is $\log T + \log \dim H + O(1)$. We have the following guarantee [4]:

▶ **Lemma 10.** *Let $p = \|\Pi U|\psi\rangle\|^2$. There exists $\Delta = \Theta(1/M)$ such that when $\tilde{p}$ is obtained as above from M steps of amplitude estimation, with probability at least $1/2$, $|\tilde{p} - p| \leq \Delta$.*

We will thus also refer to M steps of amplitude estimation as *amplitude estimation to precision* $1/M$.

3 Span Programs and Quantum Algorithms

In Section 3.1, we will define a span program, its size and complexity, and what it means for a span program to approximate a function f. In Section 3.2, we prove the following theorem, which implies Theorem 1:

▶ **Theorem 11.** *Let $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ and let $\mathcal{A}$ be a unitary quantum algorithm using T queries, and space S to compute f with bounded error. Then for any constant $\kappa \in (0,1)$, there is a span program $P_\mathcal{A}$ with size $s(P_\mathcal{A}) \leq 2^{O(S)}$ that κ-approximates f with complexity $C_\kappa \leq O(T)$. If $\mathcal{A}$ decides f with one-sided error, then $P_\mathcal{A}$ decides f.*

3.1 Span Programs

Span programs were first introduced in the context of classical complexity theory in [10], where they were used to study counting classes for nondeterministic logspace machines. While span programs can be defined with respect to any field, we will consider span programs over $\mathbb{R}$ (or equivalently, $\mathbb{C}$, when convenient, see Remark 20). We use the following definition, slightly modified from [10]:

▶ **Definition 12** (Span Program and Size). *A* span program on $\{0,1\}^n$ *consists of:*

- *Finite inner product spaces* $\{H_{j,b}\}_{j\in[n],b\in\{0,1\}} \cup \{H_{\text{true}}, H_{\text{false}}\}$. *We then define* $H = \bigoplus_{j,b} H_{j,b} \oplus H_{\text{true}} \oplus H_{\text{false}}$, *and for every* $x \in \{0,1\}^n$, $H(x) = H_{1,x_1} \oplus \cdots \oplus H_{n,x_n} \oplus H_{\text{true}}$.[4]
- *A vector space* V.
- *A* target vector $|\tau\rangle \in V$.
- *A linear map* $A : H \to V$.

We specify this span program by $P = (H, V, |\tau\rangle, A)$, *and leave the decomposition of* H *implicit. The* size *of the span program is* $s(P) = \dim H$.

To recover the classical definition from [10], we can view $A = \sum_{j,b} A\Pi_{H_{j,b}}$ as a matrix, with each of the columns of $A\Pi_{H_{j,b}}$ labeled by (j,b).

Span programs were introduced to the study of quantum query complexity in [18]. In the context of quantum query complexity, $s(P)$ is no longer the relevant measure of the complexity of a span program. Instead, [18] introduce the following measures:

▶ **Definition 13** (Span Program Complexity and Witnesses). *For* $P = (H, V, |\tau\rangle, A)$ *a span program on* $\{0,1\}^n$ *and input* $x \in \{0,1\}^n$, *we say* x *is* accepted *by the span program if there exists* $|w\rangle \in H(x)$ *such that* $A|w\rangle = |\tau\rangle$, *and otherwise we say* x *is* rejected *by the span program. Let* P_0 *and* P_1 *be respectively the set of rejected and accepted inputs to* P. *For* $x \in P_1$, *define the* positive witness complexity of x *as:*

$$w_+(x,P) = w_+(x) = \min\{\||w\rangle\|^2 : |w\rangle \in H(x), A|w\rangle = |\tau\rangle\}.$$

Such a $|w\rangle$ *is called a* positive witness for x. *For a domain* $D \subseteq \{0,1\}^n$, *we define the* positive complexity of P *(with respect to* D*) as:*

$$W_+(P,D) = W_+ = \max_{x\in P_1\cap D} w_+(x,P).$$

For $x \in P_0$, *define the* negative witness complexity of x *as:*

$$w_-(x,P) = w_-(x) = \min\{\|\langle\omega|A\|^2 : \langle\omega| \in \mathcal{L}(V,\mathbb{R}), \langle\omega|\tau\rangle = 1, \langle\omega|A\Pi_{H(x)} = 0\}.$$

Above, $\mathcal{L}(V,\mathbb{R})$ *denotes the set of linear functions from* V *to* $\mathbb{R}$. *Such an* $\langle\omega|$ *is called a* negative witness for x. *We define the* negative complexity of P *(with respect to* D*) as:*

$$W_-(P,D) = W_- = \max_{x\in P_0\cap D} w_-(x,P).$$

Finally, we define the complexity of P *(with respect to* D*) by* $C(P,D) = \sqrt{W_+W_-}$.

For $f : D \to \{0,1\}$, we say a span program P *decides* f if $f^{-1}(0) \subseteq P_0$ and $f^{-1}(1) \subseteq P_1$.

[4] We remark that while H_{true} and H_{false} may be convenient in constructing a span program, they are not necessary. We can always consider a partial function f' defined on $(n+1)$-bit strings of the form $(x,1)$ for x in the domain of f, as $f(x)$, and let $H_{n+1,1} = H_{\text{true}}$ and $H_{n+1,0} = H_{\text{false}}$.

▶ **Definition 14.** *We define the* span program size *of a function f, denoted* $\mathsf{SP}(f)$*, as the minimum $s(P)$ over families of span programs that decide f.*

We note that originally, in [10], span program size was defined

$$s'(P) = \sum_{j,b} \dim(\mathrm{col}(A\Pi_{H_{j,b}})) = \sum_{j,b} \dim(\mathrm{row}(A\Pi_{H_{j,b}})).$$

This could differ from $s(P) = \dim(H) = \sum_{j,b} \dim(H_{j,b})$, because $\dim(H_{j,b})$ might be much larger than $\dim(\mathrm{row}(A\Pi_{H_{j,b}}))$. However, if $\dim(H_{j,b}) > \dim(\mathrm{row}(A\Pi_{H_{j,b}}))$ for some j, b, then it is a simple exercise to show that the dimension of $\dim(H_{j,b})$ can be reduced without altering the witness size of any $x \in \{0,1\}^n$, so the definition of $\mathsf{SP}(f)$ is the same as if we'd used $s'(P)$ instead of $s(P)$. In any case, we will not be relying on previous results about the span program size as a black-box, and will rather prove all required statements, so this difference has no impact on our results.

While span program size has only previously been relevant outside the realm of quantum algorithms, the complexity of a span program deciding f has a fundamental correspondence with the quantum query complexity of f. Specifically, a span program P can be turned into a quantum algorithm for f with query complexity $C(P, D)$, and moreover, for every f, there exists a span program such that the algorithm constructed in this way is optimal [17]. This second direction is not constructive: there is no known method for converting a quantum algorithm with query complexity T to a span program with complexity $C(P, D) = \Theta(T)$. However, if we relax the definition of which functions are decided by a span program, then this situation can be improved. The following is a slight relaxation of [8, Definition 2.6][5].

▶ **Definition 15** (A Span Program that Approximately Decides a Function)**.** *Let $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ and $\kappa \in (0,1)$. We say that a span program P on $\{0,1\}^n$* κ-approximates *f if $f^{-1}(0) \subseteq P_0$, and for every $x \in f^{-1}(1)$, there exists an* approximate positive witness *$|\hat{w}\rangle$ such that $A|\hat{w}\rangle = |\tau\rangle$, and $\left\|\Pi_{H(x)^\perp}|\hat{w}\rangle\right\|^2 \leq \frac{\kappa}{W_-}$. We define the approximate positive complexity as*

$$\widehat{W}_+ = \widehat{W}_+^\kappa(P, D) = \max_{x \in f^{-1}(1)} \min \left\{ \||\hat{w}\rangle\|^2 : A|\hat{w}\rangle = |\tau\rangle, \left\|\Pi_{H(x)^\perp}|\hat{w}\rangle\right\|^2 \leq \frac{\kappa}{W_-} \right\}.$$

If P κ-approximates f, we define the complexity of P (wrt. D and κ) as $C_\kappa(P, D) = \sqrt{\widehat{W}_+ W_-}$.

If $\kappa = 0$, the span program in Definition 15 *decides* f (exactly), and $\widehat{W}_+ = W_+$. By [8], for any x,

$$\min \left\{ \left\|\Pi_{H(x)^\perp}|\hat{w}\rangle\right\|^2 : A|\hat{w}\rangle = |\tau\rangle \right\} = \frac{1}{w_-(x)}.$$

Thus, since $W_- = \max_{x \in f^{-1}(0)} w_-(x)$, for every $x \in f^{-1}(0)$, there does not exist an approximate positive witness with $\left\|\Pi_{H(x)^\perp}|\hat{w}\rangle\right\|^2 < \frac{1}{W_-}$. Thus, when a span program κ-approximates f, there is a gap of size $\frac{1-\kappa}{W_-}$ between the smallest positive witness error $\left\|\Pi_{H(x)^\perp}|\hat{w}\rangle\right\|^2$ of $x \in f^{-1}(1)$, the smallest positive witness error of $x \in f^{-1}(0)$.

[5] Which was already a relaxation of the notion of a span program deciding a function.

▶ **Definition 16.** *We define the* κ-approximate span program size *of a function* f*, denoted* $\widetilde{\mathsf{SP}}_\kappa(f)$*, as the minimum* $s(P)$ *over families of span programs that* κ*-approximate* f*. We let* $\widetilde{\mathsf{SP}}(f) = \widetilde{\mathsf{SP}}_{1/4}(f)$.

Then we have the following theorem, whose proof is nearly identical to that of [8, Lemma 3.6]. The only difference between [8, Lemma 3.6] and Theorem 17 below is that here we let an approximate positive witness for x be any witness with error $\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2$ at most κ/W_-, whereas in [8], an approximate positive witness must have error as small as possible. This relaxation has negligible effect on the proof.

▶ **Theorem 17.** *Let* $f : D \to \{0,1\}$ *for* $D \subseteq \{0,1\}^n$*, and let* P *be a span program that* κ*-approximates* f *with size* K *and complexity* C*, for some constant* $\kappa \in (0,1)$*. Then there exists a unitary quantum algorithm* $\mathcal{A}_P$ *that decides* f *with bounded error in space* $S = O(\log K + \log C)$ *using* $T = O(C)$ *queries to* x*.*

We note that the choice of $\kappa = 1/4$ in $\widetilde{\mathsf{SP}}(f)$ is arbitrary, as it is possible to modify a span program to reduce any constant κ to any other constant without changing the size or complexity asymptotically. This convenient observation is formalized in the following claim.

▷ Claim 18. Let P be a span program that κ-approximates $f : D \to \{0,1\}$ for some constant κ. For any constant $\kappa' \leq \kappa$, there exists a span program P' that κ'-approximates f with $s(P') = (s(P)+2)^{2^{\frac{\log \frac{1}{\kappa'}}{\log \frac{1}{\kappa}}}}$, and $C_{\kappa'}(P', D) \leq O\left(C_\kappa(P, D)\right)$.

We prove Claim 18 in Appendix A. We have the following corollary that will be useful later, where $\mathsf{m}\widetilde{\mathsf{SP}}_\kappa$ is the *monotone approximate span program size*, defined in Definition 30:

▶ **Corollary 19.** *For any* $\kappa, \kappa' \in (0,1)$ *with* $\kappa' < \kappa$*, and any Boolean function* f*,*

$$\widetilde{\mathsf{SP}}_\kappa(f) \geq \widetilde{\mathsf{SP}}_{\kappa'}(f)^{\frac{1}{2}\frac{\log \frac{1}{\kappa}}{\log \frac{1}{\kappa'}}} - 2.$$

If f *is monotone, we also have*

$$\mathsf{m}\widetilde{\mathsf{SP}}_\kappa(f) \geq \mathsf{m}\widetilde{\mathsf{SP}}_{\kappa'}(f)^{\frac{1}{2}\frac{\log \frac{1}{\kappa}}{\log \frac{1}{\kappa'}}} - 2.$$

Proof. Let P κ-approximate f with optimal size, so $s(P) = \widetilde{\mathsf{SP}}_\kappa(f)$. Then by Claim 18, there is a span program P' that κ'-approximates f with size

$$\widetilde{\mathsf{SP}}_{\kappa'}(f) \leq s(P') = \left(\widetilde{\mathsf{SP}}_\kappa(f) + 2\right)^{2^{\frac{\log \frac{1}{\kappa'}}{\log \frac{1}{\kappa}}}}.$$

The first result follows. The second is similar, but also includes the observation that if P is monotone, so is P'. ◀

▶ Remark 20. It can sometimes be useful to construct a span program over $\mathbb{C}$. However, for any span program over $\mathbb{C}$, P, there is a span program over $\mathbb{R}$, P', such that for all $x \in P_0$, $w_-(x, P') \leq w_-(x, P)$, for all $x \in P_1$, $w_+(x, P') \leq w_+(x, P)$, and $s(P') \leq 2s(P)$. Thus, we will restrict our attention to real span programs, but still allow constructions of span programs over $\mathbb{C}$ (in particular, in Section 3.2 and Section 5.2.1).

3.2 From Quantum Algorithms to Span Programs

In this section, we will show how to turn a unitary quantum algorithm into a span program, proving Theorem 11, which implies Theorem 1. The construction we use to prove Theorem 11 is based on a construction of Reichardt for turning any one-sided error quantum algorithm into a span program whose complexity matches the algorithm's query complexity [17, arXiv version]. We observe that the logarithm of the span program's size is closely related to the algorithm's space complexity. We also show that a similar construction works for two-sided error algorithms, but the resulting span program only approximately decides f.

The algorithm

Fix a function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$, and a unitary quantum algorithm $\mathcal{A}$ such that on input $x \in f^{-1}(0)$, $\Pr[\mathcal{A}(x) = 1] \leq \frac{1}{3}$, and on input $x \in f^{-1}(1)$, $\Pr[\mathcal{A}(x) = 1] \geq 1 - \varepsilon$, for $\varepsilon \in \{0, \frac{1}{3}\}$, depending on whether we want to consider a one-sided error or a bounded error algorithm. Let $p_0(x) = \Pr[\mathcal{A}(x) = 0]$, so if $f(x) = 0$, $p_0(x) \geq 2/3$, and if $f(x) = 1$, $p_0(x) \leq \varepsilon$.

We can suppose $\mathcal{A}$ acts on three registers: a query register $\mathrm{span}\{|j\rangle : j \in [n] \cup \{0\}\}$; a workspace register $\mathrm{span}\{|z\rangle : z \in \mathcal{Z}\}$ for some finite set of symbols $\mathcal{Z}$ that contains 0; and an answer register $\mathrm{span}\{|a\rangle : a \in \{0,1\}\}$. The query operator $\mathcal{O}_x$ acts on the query register as $\mathcal{O}_x|j\rangle = (-1)^{x_j}|j\rangle$ if $j \geq 1$, and $\mathcal{O}_x|0\rangle = |0\rangle$. If $\mathcal{A}$ makes T queries, the final state of $\mathcal{A}$ is:

$$|\Psi_{2T+1}(x)\rangle = U_{2T+1}\mathcal{O}_x U_{2T-1} \dots U_3 \mathcal{O}_x U_1 |0,0,0\rangle$$

for some unitaries $U_{2T+1}, \dots, U_1$. The output bit of the algorithm, $\mathcal{A}(x)$, is obtained by measuring the answer register of $|\Psi_{2T+1}(x)\rangle$. We have given the input-independent unitaries odd indicies so that we may refer to the t-th query as U_{2t}.

Let $|\Psi_0(x)\rangle = |\Psi_0\rangle = |0,0,0\rangle$ denote the starting state, and for $t \in \{1, \dots, 2T+1\}$, let $|\Psi_t(x)\rangle = U_t \dots U_1 |\Psi_0\rangle$ denote the state after t steps.

The span program

We now define a span program $P_{\mathcal{A}}$ from $\mathcal{A}$. The space H will represent all three registers of the algorithm, with an additional time counter register, and an additional register to represent a query value b.

$$H = \mathrm{span}\{|t,b,j,z,a\rangle : t \in \{0,\dots,2T+1\}, b \in \{0,1\}, j \in [n] \cup \{0\}, z \in \mathcal{Z}, a \in \{0,1\}\}.$$

We define V and A as follows, where c is some constant to be chosen later:

$$V = \mathrm{span}\{|t,j,z,a\rangle : t \in \{0,\dots,2T+1\}, j \in [n] \cup \{0\}, z \in \mathcal{Z}, a \in \{0,1\}\}$$

$$A|t,b,j,z,a\rangle = \begin{cases} |t,j,z,a\rangle - |t+1\rangle U_{t+1}|j,z,a\rangle & \text{if } t \in \{0,\dots,2T\} \text{ is even} \\ |t,j,z,a\rangle - (-1)^b|t+1,j,z,a\rangle & \text{if } t \in \{0,\dots,2T\} \text{ is odd} \\ |t,j,z,a\rangle & \text{if } t = 2T+1,\ a = 1, \text{ and } b = 0 \\ \sqrt{cT}|t,j,z,a\rangle & \text{if } t = 2T+1,\ a = 0, \text{ and } b = 0 \\ 0 & \text{if } t = 2T+1 \text{ and } b = 1. \end{cases}$$

For $t \leq 2T$, $A|t,b,j,z,a\rangle$ should be intuitively understood as applying U_{t+1} to $|j,z,a\rangle$, and incrementing the counter register from $|t\rangle$ to $|t+1\rangle$. When t is even, this correspondence is clear (in that case, the value of b is ignored). When t is odd, so $U_{t+1} = \mathcal{O}_x$, then as long as $b = x_j$, $(-1)^b|t+1,j,z,a\rangle = |t+1\rangle U_{t+1}|j,z,a\rangle$. We thus define

$$H_{j,b} = \mathrm{span}\{|t,b,j,z,a\rangle : t \in \{0,\dots,2T\} \text{ is odd}, z \in \mathcal{Z}, a \in \{0,1\}\}.$$

For even t, applying U_{t+1} is independent of the input, so we make the corresponding states available to every input; along with states where the query register is set to $j = 0$, meaning $\mathcal{O}_x$ acts input-independently; and accepting states, whose answer register is set to 1 at time $2T + 1$:

$$\begin{aligned} H_{\text{true}} = \text{span}\{|t, b, j, z, a\rangle : t \in \{0, \ldots, 2T\} \text{ is even}, b \in \{0,1\}, j \in [n], z \in \mathcal{Z}, a \in \{0,1\}\} \\ \oplus \text{span}\{|t, b, 0, z, a\rangle : t \in \{0, \ldots, 2T\}, b \in \{0,1\}, z \in \mathcal{Z}, a \in \{0,1\}\} \\ \oplus \text{span}\{|2T+1, b, j, z, 1\rangle : b \in \{0,1\}, j \in [n] \cup \{0\}, z \in \mathcal{Z}\}. \end{aligned}$$

The remaining part of H will be assigned to H_{false}:

$$H_{\text{false}} = \text{span}\{|2T+1, b, j, z, 0\rangle : b \in \{0,1\}, j \in [n] \cup \{0\}, z \in \mathcal{Z}\}.$$

Note that in defining A, we have put a large factor of $\sqrt{cT}$ in front of $A|2T+1, 0, j, z, 0\rangle$, making the vectors in H_{false} very "cheap" to use. These vectors are never in $H(x)$, but will be used as the error part of approximate positive witnesses, and the $\sqrt{cT}$ ensures they contribute relatively small error.

Finally, we define:

$$|\tau\rangle = |0, 0, 0, 0\rangle = |0\rangle|\Psi_0\rangle.$$

Intuitively, we can construct $|\tau\rangle$, the initial state, using a final state that has 1 in the answer register, and using the transitions $|t, j, z, a\rangle - |t+1\rangle U_{t+1}|j, z, a\rangle$ to move from the final state to the initial state. In the following analysis, we make this idea precise.

Analysis of $P_{\mathcal{A}}$

We will first show that for every x there is an approximate positive witness with error depending on its probability of being rejected by $\mathcal{A}$, $p_0(x)$.

▶ **Lemma 21.** *For any $x \in \{0,1\}^n$, there exists an approximate positive witness $|w\rangle$ for x in $P_{\mathcal{A}}$ such that:*

$$\||w\rangle\|^2 \leq 2T + 2, \text{ and } \left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 \leq \frac{p_0(x)}{cT}.$$

In particular, if $f(x) = 1$,

$$\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 \leq \frac{\varepsilon}{cT}.$$

Proof. Let Q_x be the linear isometry that acts as

$$Q_x|j, z, a\rangle = |x_j, j, z, a\rangle \qquad \forall j \in [n] \cup \{0\}, z \in \mathcal{Z}, a \in \{0,1\},$$

where we interpret x_0 as 0. Note that for all $|j, z, a\rangle$, and $t \in \{0, \ldots, 2T\}$, we have

$$A(|t\rangle Q_x|j, z, a\rangle) = |t, j, z, a\rangle - |t+1\rangle U_{t+1}|j, z, a\rangle.$$

Let $\Pi_a = \sum_{j \in [n] \cup \{0\}, z \in \mathcal{Z}} |j, z, a\rangle\langle j, z, a|$ be the orthogonal projector onto states of the algorithm with answer register set to a. We will construct a positive witness for x from the states of the algorithm on input x, as follows:

$$|w\rangle = \sum_{t=0}^{2T} |t\rangle Q_x |\Psi_t(x)\rangle + |2T+1\rangle|0\rangle\Pi_1|\Psi_{2T+1}(x)\rangle + \frac{1}{\sqrt{cT}}|2T+1\rangle|0\rangle\Pi_0|\Psi_{2T+1}(x)\rangle.$$

To see that this is a positive witness, we compute $A|w\rangle$, using the fact that $U_{t+1}|\Psi_t(x)\rangle = |\Psi_{t+1}(x)\rangle$:

$$\begin{aligned}
A|w\rangle &= \sum_{t=0}^{2T} \left(|t\rangle|\Psi_t(x)\rangle - |t+1\rangle U_{t+1}|\Psi_t(x)\rangle\right) \\
&\qquad + |2T+1\rangle\Pi_1|\Psi_{2T+1}(x)\rangle + |2T+1\rangle\Pi_0|\Psi_{2T+1}(x)\rangle \\
&= \sum_{t=0}^{2T} |t\rangle|\Psi_t(x)\rangle - \sum_{t=0}^{2T} |t+1\rangle|\Psi_{t+1}(x)\rangle + |2T+1\rangle|\Psi_{2T+1}(x)\rangle \\
&= \sum_{t=0}^{2T+1} |t\rangle|\Psi_t(x)\rangle - \sum_{t=1}^{2T+1} |t\rangle|\Psi_t(x)\rangle = |0\rangle|\Psi_0(x)\rangle = |\tau\rangle.
\end{aligned}$$

We next consider the error of $|w\rangle$ for x, given by $\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2$. Since $Q_x|j,z,a\rangle \in H(x)$ for all j,z,a, and $|2T+1,0\rangle\Pi_1|\Psi_{2T+1}(x)\rangle \in H_{\text{true}} \subset H(x)$, $\Pi_{H(x)^\perp}|w\rangle = \frac{1}{\sqrt{cT}}|2T+1\rangle|0\rangle\Pi_0|\Psi_{2T+1}(x)\rangle$, so

$$\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 = \frac{1}{cT}\left\|\Pi_0|\Psi_{2T+1}(x)\rangle\right\|^2 = \frac{p_0(x)}{cT}.$$

Finally, we compute the positive witness complexity of $|w\rangle$:

$$\begin{aligned}
\||w\rangle\|^2 &= \sum_{t=0}^{2T} \|Q_x|\Psi_t(x)\rangle\|^2 + \|\Pi_1|\Psi_{2T+1}(x)\rangle\|^2 + \frac{1}{cT}\left\|\Pi_0|\Psi_{2T+1}(x)\rangle\right\|^2 \\
&\leq \sum_{t=0}^{2T} \||\Psi_t(x)\rangle\|^2 + \||\Psi_{2T+1}(x)\rangle\|^2 = 2T+2.
\end{aligned}$$

◀

Next, we upper bound $w_-(x)$ whenever $f(x) = 0$:

▶ **Lemma 22.** *For any x that is rejected by $\mathcal{A}$ with probability $p_0(x) > 0$,*

$$w_-(x) \leq \frac{(c+4)T}{p_0(x)}.$$

In particular, if $f(x) = 0$, $w_-(x) \leq \frac{c+4}{2/3}T$, so $W_- \leq \frac{c+4}{2/3}T$.

Proof. We will define a negative witness for x as follows. First, define

$$|\Psi^0_{2T+1}(x)\rangle = \Pi_0|\Psi_{2T+1}(x)\rangle,$$

the rejecting part of the final state. This is non-zero whenever $p_0(x) > 0$. Then for $t \in \{0,\ldots,2T\}$, define

$$|\Psi^0_t(x)\rangle = U^\dagger_{t+1}\ldots U^\dagger_{2T+1}|\Psi^0_{2T+1}(x)\rangle.$$

From this we can define

$$\langle\omega| = \sum_{t=0}^{2T+1} \langle t|\langle\Psi^0_t(x)|.$$

We first observe that

$$\langle\omega|\tau\rangle = \langle\Psi_0^0(x)|0,0,0\rangle = \langle\Psi_{2T+1}^0(x)|U_{2T+1}\dots U_1|0,0,0\rangle = \langle\Psi_{2T+1}^0(x)|\Psi_{2T+1}(x)\rangle = p_0(x).$$

Thus

$$\langle\bar{\omega}| = \frac{1}{p_0(x)}\langle\omega|$$

is a negative witness. Next, we show that $\langle\omega|A\Pi_{H(x)} = 0$. First, for $|t,x_j,j,z,a\rangle \in H_{j,x_j}$ (so $t < 2T$ is odd), we have

$$\begin{aligned}\langle\omega|A|t,x_j,j,z,a\rangle &= \langle\omega|(|t,j,z,a\rangle - (-1)^{x_j}|t+1\rangle|j,z,a\rangle)\\ &= \langle\Psi_t^0(x)|j,z,a\rangle - (-1)^{x_j}\langle\Psi_{t+1}^0(x)|j,z,a\rangle\\ &= \langle\Psi_{t+1}^0(x)|U_{t+1}|j,z,a\rangle - (-1)^{x_j}\langle\Psi_{t+1}^0(x)|j,z,a\rangle\\ &= \langle\Psi_{t+1}^0(x)|\mathcal{O}_x|j,z,a\rangle - (-1)^{x_j}\langle\Psi_{t+1}^0(x)|j,z,a\rangle = 0.\end{aligned}$$

The same argument holds for $|t,0,0,j,z,a\rangle \in H_{\text{true}}$. Similarly, for any $|t,b,j,z,a\rangle \in H_{\text{true}}$ with $t \le 2T$ even, we have

$$\begin{aligned}\langle\omega|A|t,b,j,z,a\rangle &= \langle\omega|(|t,j,z,a\rangle - |t+1\rangle U_{t+1}|j,z,a\rangle)\\ &= \langle\Psi_t^0(x)|j,z,a\rangle - \langle\Psi_{t+1}^0(x)|U_{t+1}|j,z,a\rangle = 0.\end{aligned}$$

Finally, for any $|2T+1,b,j,z,1\rangle \in H_{\text{true}}$, we have

$$\langle\omega|A|2T+1,b,j,z,1\rangle = \langle\omega|2T+1,j,z,1\rangle = \langle\Psi_{2T+1}^0(x)|j,z,1\rangle = 0.$$

Thus $\langle\omega|A\Pi_{H(x)} = 0$ and so $\langle\bar{\omega}|A\Pi_{H(x)} = 0$, and $\langle\bar{\omega}|$ is a negative witness for x in P. To compute its witness complexity, first observe that $\langle\omega|A = \langle\omega|A\Pi_{H(x)^\perp}$, and

$$\begin{aligned}A\Pi_{H(x)^\perp} = &\sum_{s=1}^{T}\sum_{\substack{j\in[n]\cup\{0\},\\ z\in\mathcal{Z},a\in\{0,1\}}}(|2s-1,j,z,a\rangle + (-1)^{x_j}|2s,j,z,a\rangle)\langle 2s-1,\bar{x}_j,j,z,a|\\ &+\sum_{j\in[n]\cup\{0\},z\in\mathcal{Z}}\sqrt{cT}|2T+1,j,z,0\rangle\langle 2T+1,0,j,z,0|\end{aligned}$$

so, using $\langle\Psi_{2s-1}^0(x)|j,z,a\rangle = \langle\Psi_{2s}^0(x)|U_{2s}|j,z,a\rangle = (-1)^{x_j}\langle\Psi_{2s}^0(x)|j,z,a\rangle$, we have:

$$\begin{aligned}&\langle\omega|A\Pi_{H(x)^\perp}\\ =&\sum_{s=1}^{T}\sum_{\substack{j\in[n]\cup\{0\},\\ z\in\mathcal{Z},a\in\{0,1\}}}(\langle\Psi_{2s-1}^0(x)|j,z,a\rangle + (-1)^{x_j}\langle\Psi_{2s}^0(x)|j,z,a\rangle)\langle 2s-1,\bar{x}_j,j,z,a|\\ &+\sum_{j\in[n]\cup\{0\},z\in\mathcal{Z}}\sqrt{cT}\langle\Psi_{2T+1}^0(x)|j,z,0\rangle\langle 2T+1,0,j,z,0|\\ =&\sum_{s=1}^{T}\sum_{j\in[n]\cup\{0\},z\in\mathcal{Z},a\in\{0,1\}}2(-1)^{x_j}\langle\Psi_{2s}^0(x)|j,z,a\rangle)\langle 2s-1,\bar{x}_j,j,z,a|\\ &+\sum_{j\in[n]\cup\{0\},z\in\mathcal{Z}}\sqrt{cT}\langle\Psi_{2T+1}^0(x)|j,z,0\rangle\langle 2T+1,0,j,z,0|.\end{aligned}$$

Thus, the complexity of $\langle\bar{\omega}|$ is:

$$\begin{aligned}
\|\langle\bar{\omega}|A\|^2 &= \frac{1}{p_0(x)^2}\left\|\langle\omega|A\Pi_{H(x)^\perp}\right\|^2 \\
&= \frac{1}{p_0(x)^2}\sum_{s=1}^{T}\sum_{\substack{j\in[n]\cup\{0\},\\ z\in\mathcal{Z},\\ a\in\{0,1\}}} 4\left|\langle\Psi_{2s}^0(x)|j,z,a\rangle\right|^2 + \frac{1}{p_0(x)^2}\sum_{\substack{j\in[n]\cup\{0\},\\ z\in\mathcal{Z}}} cT\left|\langle\Psi_{2T+1}^0(x)|j,z,0\rangle\right|^2 \\
&= \frac{4}{p_0(x)^2}\sum_{s=1}^{T}\left\||\Psi_{2s}^0(x)\rangle\right\|^2 + \frac{cT}{p_0(x)^2}\left\||\Psi_{2T+1}^0(x)\rangle\right\|^2.
\end{aligned}$$

Because each U_t is unitary, we have $\left\||\Psi_{2s}^0(x)\rangle\right\|^2 = \left\||\Psi_{2T+1}^0(x)\rangle\right\|^2 = p_0(x)$, thus:

$$\|\langle\bar{\omega}|A\|^2 = \frac{4T}{p_0(x)} + \frac{cT}{p_0(x)} \le \frac{4+c}{2/3}T \text{ when } f(x)=0. \qquad \blacktriangleleft$$

We conclude the proof of Theorem 11 with the following corollary, from which Theorem 11 follows immediately, by appealing to Claim 18 with $\kappa = \frac{9}{10}$ and κ' any constant in $(0,1)$.

▶ **Corollary 23.** *Let $c = 5$, in the definition of $P_{\mathcal{A}}$. Then:*

- $s(P_{\mathcal{A}}) = 2^{S+O(1)}$
- *If $\mathcal{A}$ decides f with one-sided error, then $P_{\mathcal{A}}$ decides f with complexity $C \le O(T)$.*
- *If $\mathcal{A}$ decides f with bounded error, then $P_{\mathcal{A}}$ $\frac{9}{10}$-approximates f with complexity $C_\kappa \le O(T)$.*

Proof. We first compute $s(P_{\mathcal{A}}) = \dim H$ using the fact that the algorithm uses space

$$S = \log\dim\operatorname{span}\{|j,z,a\rangle : j\in[n]\cup\{0\}, z\in\mathcal{Z}, a\in\{0,1\}\} + \log T:$$

$$\dim H = (\dim\operatorname{span}\{|t,b\rangle : t\in\{0,\dots,2T+1\}, b\in\{0,1\}\})2^{S-\log T} = 2^{S+O(1)}.$$

We prove the third statement, as the second is similar. By Lemma 22, using $c=5$, we have

$$W_- \le \frac{5+4}{2/3}T = \frac{27}{2}T.$$

By Lemma 21, we can see that for every x such that $f(x)=1$, there is an approximate positive witness $|w\rangle$ for x with error at most:

$$\frac{\varepsilon}{cT} = \frac{1/3}{5T} \le \frac{1}{15T}\frac{\frac{27}{2}T}{W_-} = \frac{9}{10}\frac{1}{W_-}.$$

Furthermore, $\||w\rangle\|^2 \le 2T+2$, so $\widehat{W}_+ \le 2T+2$. Observing $C_\kappa = \sqrt{W_-\widehat{W}_+} \le \sqrt{27T(T+1)}$ completes the proof. $\blacktriangleleft$

4 Span Programs and Space Complexity

Using the transformation from algorithms to span programs from Section 3.2, we immediately have the following connections between span program size and space complexity.

▶ **Theorem 24.** *For any $f: D\to\{0,1\}$ for $D\subseteq\{0,1\}^n$, we have*

$$\mathsf{S}_U(f) \ge \Omega\left(\log\widetilde{\mathsf{SP}}(f)\right) \qquad \text{and} \qquad \mathsf{S}_U^1(f) \ge \Omega\left(\log\mathsf{SP}(f)\right).$$

Theorem 24 is a corollary of Theorem 11. Theorem 17 shows that the lower bound for $\mathsf{S}_U(f)$ in Theorem 24 is part of a *tight* correspondence between space complexity and $\log s(P) + \log C(P)$.

Theorem 2.9 of [3] gives a lower bound of $\mathsf{SP}(f) \geq \Omega(2^{n/3}/(n \log n)^{1/3})$ for almost all n-bit Boolean functions. Combined with Theorem 24, we immediately have:

▶ **Theorem 25.** *For almost all Boolean functions $f : \{0,1\}^n \to \{0,1\}$, $\mathsf{S}^1_U(f) = \Omega(n)$.*

Ideally, we would like to use the lower bound in Theorem 24 to prove a non-trivial lower bound for $\mathsf{S}_U(f)$ or $\mathsf{S}^1_U(f)$ for some concrete f. Fortunately, there are somewhat nice expressions lower bounding $\mathsf{SP}(f)$ [15, 7], which we extend to lower bounds of $\widetilde{\mathsf{SP}}(f)$ in the remainder of this section. However, on the unfortunate side, there has already been significant motivation to instantiate these expressions to non-trivial lower bounds for concrete f, with no success. There has been some success in *monotone* versions of these lower bounds, which we discuss more in Section 5.

For a function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$, and an index $j \in [n]$, we let $\Delta_{f,j} \in \{0,1\}^{f^{-1}(0)\times f^{-1}(1)}$ be defined by $\Delta_{f,j}[y,x] = 1$ if and only if $x_j \neq y_j$. When f is clear from context, we simply denote this by Δ_j. The following tight characterization of $\mathsf{SP}(f)$ may be found in, for example, [13].

▶ **Lemma 26.** *For any $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$,*

$$\begin{aligned} \mathsf{SP}(f) = \text{minimize} \quad & \sum_{j\in[n]} \operatorname{rank}(\Lambda_j) \\ \text{subject to} \quad & \forall j \in [n], \Lambda_j \in \mathbb{R}^{f^{-1}(0)\times f^{-1}(1)} \\ & \sum_{j\in[n]} \Lambda_j \circ \Delta_j = J, \end{aligned}$$

where J is the $f^{-1}(0) \times f^{-1}(1)$ all-ones matrix.

By Theorem 24, the logarithm of the above is a lower bound on $\mathsf{S}^1_U(f)$. We modify Lemma 26 to get the following approximate version, whose logarithm lower bounds $\mathsf{S}_U(f)$ when $\kappa = \frac{1}{4}$.

▶ **Lemma 27.** *For any $\kappa \in [0,1)$, and $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$,*

$$\begin{aligned} \widetilde{\mathsf{SP}}_\kappa(f) \geq \text{minimize} \quad & \sum_{j\in[n]} \operatorname{rank}(\Lambda_j) \qquad (1) \\ \text{subject to} \quad & \forall j \in [n], \Lambda_j \in \mathbb{R}^{f^{-1}(0)\times f^{-1}(1)} \\ & \left\| \sum_{j\in[n]} \Lambda_j \circ \Delta_j - J \right\|_\infty \leq \sqrt{\kappa}. \end{aligned}$$

Proof. Fix a span program that κ-approximates f with $s(P) = \widetilde{\mathsf{SP}}_\kappa(f)$, and let $\{\langle\omega_y| : y \in f^{-1}(0)\}$ be optimal negative witnesses, and $\{|w_x\rangle : x \in f^{-1}(1)\}$ be approximate positive witnesses with $\left\|\Pi_{H(x)}|w_x\rangle\right\|^2 \leq \frac{\kappa}{W_-}$. Letting $\Pi_{j,b}$ denote the projector onto $H_{j,b}$, define

$$\Lambda_j = \sum_y |y\rangle\langle\omega_y|A\Pi_{j,\bar{y}_j} \sum_x \Pi_{j,x_j}|w_x\rangle\langle x|,$$

so Λ_j has rank at most $\dim H_j$, and so $\sum_{j\in[n]} \operatorname{rank}(\Lambda_j) \leq s(P) = \widetilde{\mathsf{SP}}_\kappa(f)$.

We now show that $\{\Lambda_j\}_j$ is a feasible solution. Let $|\mathsf{err}(x)\rangle$ be the positive witness error of $|w_x\rangle$, $|\mathsf{err}(x)\rangle = \Pi_{H(x)^\perp}|w_x\rangle = \sum_{j=1}^n \Pi_{j,\bar{x}_j}|w_x\rangle$. Then we have:

$$\begin{aligned}
\langle y|\sum_{j=1}^n \Lambda_j \circ \Delta_j|x\rangle &= \langle\omega_y|A\sum_{j:x_j\neq y_j}\Pi_{j,x_j}|w_x\rangle \\
&= \langle\omega_y|A\left(|w_x\rangle - \sum_{j:x_j=y_j}\Pi_{j,x_j}|w_x\rangle - |\mathsf{err}(x)\rangle\right) \\
&= \langle\omega_y|\tau\rangle - \langle\omega_y|A\sum_{j:x_j=y_j}\Pi_{H(y)}\Pi_{j,x_j}|w_x\rangle - \langle\omega_y|A|\mathsf{err}(x)\rangle \\
&= 1 - 0 - \langle\omega_y|A|\mathsf{err}(x)\rangle \\
\left|1 - \langle y|\sum_{j=1}^n \Lambda_j\circ\Delta_j|x\rangle\right| &\leq \|\langle\omega_y|A\|\,\||\mathsf{err}(x)\rangle\| = \sqrt{w_-(y)\frac{\kappa}{W_-}} \leq \sqrt{\kappa}.
\end{aligned}$$

Above we used the fact that $\langle\omega_y|A\Pi_{H(y)} = 0$. Thus, $\{\Lambda_j\}_j$ is a feasible solution with objective value $\leq \widetilde{\mathsf{SP}}_\kappa(f)$, so the result follows. ◀

As a corollary of the above, and the connection between span program size and unitary quantum space complexity stated in Theorem 24, the logarithm of the expression in (1) with $\kappa = \frac{1}{4}$ is a lower bound on $\mathsf{S}_U(f)$, and with $\kappa = 0$, it is a lower bound on $\mathsf{S}_U^1(f)$. However, as stated, it is difficult to use this expression to prove an explicit lower bound, because it is a minimization problem. We will shortly give a lower bound in terms of a maximization problem, making it possible to obtain explicit lower bounds by exhibiting a feasible solution.

A *partial matrix* is a matrix $M \in (\mathbb{R}\cup\{\star\})^{f^{-1}(0)\times f^{-1}(1)}$. A *completion* of M is any $\overline{M} \in \mathbb{R}^{f^{-1}(0)\times f^{-1}(1)}$ such that $\overline{M}[y,x] = M[y,x]$ whenever $M[y,x]\neq\star$. For a partial matrix M, define $\mathrm{rank}(M)$ to be the smallest rank of any completion of M, and ε-$\mathrm{rank}(M)$ to be the smallest rank of any $\tilde{M}$ such that $|M[y,x]-\tilde{M}[y,x]|\leq\varepsilon$ for all y,x such that $M[y,x]\neq\star$. Let $M\circ\Delta_i$ to be the partial matrix defined:

$$M\circ\Delta_i[y,x] = \begin{cases} M[y,x] & \text{if } \Delta_i[y,x]=1 \\ 0 & \text{if } \Delta_i[y,x]=0. \end{cases}$$

Then we have the following:

▶ **Lemma 28.** *For all Boolean functions $f: D\to\{0,1\}$, with $D\subseteq\{0,1\}^n$, and all partial matrices $M\in(\mathbb{R}\cup\{\star\})^{f^{-1}(0)\times f^{-1}(1)}$ such that $\max\{|M[y,x]| : M[y,x]\neq\star\}\leq 1$:*

$$\mathsf{S}_U^1(f) \geq \Omega\left(\log\left(\frac{\mathrm{rank}(M)}{\max_{i\in[n]}\mathrm{rank}(M\circ\Delta_i)}\right)\right).$$

In [15], Razborov showed that the expression on the right-hand side in Lemma 28 is a lower bound on the logarithm of the *formula size* of f (Ref. [7] related this to $\mathsf{SP}(f)$). Later, in [16], Razborov noted that when restricted to non-partial matrices, this can never give a better bound than n. Thus, to prove a non-trivial lower bound on $\mathsf{S}_U^1(f)$ using this method, one would need to use a partial matrix. We prove the following generalization to the approximate case.

▶ **Lemma 29.** *For all Boolean functions $f: D\to\{0,1\}$, with $D\subseteq\{0,1\}^n$, and all partial matrices $M\in(\mathbb{R}\cup\{\star\})^{f^{-1}(0)\times f^{-1}(1)}$ such that $\max\{|M[y,x]| : M[y,x]\neq\star\}\leq 1$:*

$$\mathsf{S}_U(f) \geq \Omega\left(\log\left(\frac{\frac{1}{2}\text{-}\mathrm{rank}(M)}{\max_{i\in[n]}\mathrm{rank}(M\circ\Delta_i)}\right)\right).$$

Proof. Let $\{\Lambda_j\}_j$ be an optimal feasible solution for the expression from Lemma 27, so

$$\widetilde{\mathsf{SP}}_\kappa(f) \geq \sum_{j\in[n]} \operatorname{rank}(\Lambda_j), \quad \text{and} \quad \left\| \sum_{j\in[n]} \Lambda_j \circ \Delta_j - J \right\|_\infty \leq \sqrt{\kappa}.$$

Let $\overline{M}_j$ be a completion of $M \circ \Delta_j$ with $\operatorname{rank}(M \circ \Delta_j) = \operatorname{rank}(\overline{M}_j)$. Then for any x, y such that $M[y,x] \neq \star$:

$$\begin{aligned}\left| \left(\sum_{j\in[n]} \overline{M}_j \circ \Lambda_j \right)[y,x] - M[y,x] \right| &= \left| \sum_{j\in[n]} M[y,x]\Delta_j[y,x]\Lambda_j[y,x] - M[y,x] \right| \\ &\leq |M[y,x]| \left\| \sum_{j\in[n]} \Delta_j \circ \Lambda_j - J \right\|_\infty \leq \sqrt{\kappa}.\end{aligned}$$

Thus

$$\sqrt{\kappa}\text{-}\operatorname{rank}(M) \leq \operatorname{rank}\left(\sum_{j\in[n]} \overline{M}_j \circ \Lambda_j \right) \leq \sum_{j\in[n]} \operatorname{rank}(\overline{M}_j \circ \Lambda_j).$$

Using the fact that for any matrices B and C, $\operatorname{rank}(B \circ C) \leq \operatorname{rank}(B)\operatorname{rank}(C)$, we have

$$\sqrt{\kappa}\text{-}\operatorname{rank}(M) \leq \sum_{j\in[n]} \operatorname{rank}(\Lambda_j)\operatorname{rank}(\overline{M}_j) \leq \widetilde{\mathsf{SP}}_\kappa(f) \max_{j\in[n]} \operatorname{rank}(M \circ \Delta_j).$$

Setting $\kappa = \frac{1}{4}$, and noting that by Theorem 24, $\mathsf{S}_U(f) \geq \log \widetilde{\mathsf{SP}}(f) = \log \widetilde{\mathsf{SP}}_{1/4}(f)$ completes the proof. ◀

Unfortunately, as far as we are aware, nobody has used this lower bound to successfully prove any concrete formula size lower bound of $2^{\omega(\log n)}$, so it seems to be quite difficult. However, there has been some success proving lower bounds in the monotone span program case, even without resorting to partial matrices, which we discuss in the next section.

5 Monotone Span Programs and Monotone Algorithms

A monotone function is a Boolean function in which $y \leq x$ implies $f(y) \leq f(x)$, where $y \leq x$ should be interpreted bitwise. In other words, flipping 0s to 1s in the input either keeps the function value the same, or changes it from 0 to 1. A monotone span program is a span program in which $H_{i,0} = \{0\}$ for all i, so only 1-valued queries contribute to $H(x)$, and $H(y) \subseteq H(x)$ whenever $y \leq x$. A monotone span program can only decide or approximate a monotone function.

▶ **Definition 30.** *For a monotone function f, define the* monotone span program size, *denoted $\mathsf{mSP}(f)$, as the minimum $s(P)$ over (families of) monotone span programs P such that P decides f; and the* approximate monotone span program size, *denoted $\widetilde{\mathsf{mSP}}_\kappa(f)$, as the minimum $s(P)$ over (families of) monotone span programs P such that P κ-approximates f. We let $\widetilde{\mathsf{mSP}}(f) = \widetilde{\mathsf{mSP}}_{1/4}(f)$.*

In contrast to $\mathsf{SP}(f)$, there are non-trivial lower bounds for $\mathsf{mSP}(f)$ for explicit monotone functions f. However, this does *not* necessarily give a lower bound on $\mathsf{SP}(f)$, and in particular, may not be a lower bound on the one-sided error quantum space complexity of f. However,

lower bounds on $\log \mathsf{mSP}(f)$ or $\log \widetilde{\mathsf{mSP}}(f)$ do give lower bounds on the space complexity of quantum algorithms obtained from monotone span programs, and as we will soon see, $\log \mathsf{mSP}(f)$ and $\log \widetilde{\mathsf{mSP}}(f)$ are lower bounds on the space complexity of *monotone phase estimation algorithms*, described in Section 5.2. The strongest known lower bound on $\mathsf{mSP}(f)$ is the following:

▶ **Theorem 31** ([14]). *There is an explicit Boolean function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ such that*

$$\log \mathsf{mSP}(f) \geq \Omega(n).$$

We will adapt some of the techniques used in existing lower bounds on mSP to show a lower bound on $\widetilde{\mathsf{mSP}}(f)$ for some explicit f:

▶ **Theorem 32.** *There is an explicit Boolean function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ such that for any constant κ,*

$$\log \widetilde{\mathsf{mSP}}_\kappa(f) \geq (\log n)^{2-o(1)}.$$

In particular, this implies a lower bound of $2^{(\log n)^{2-o(1)}}$ on $\mathsf{mSP}(f)$ for the function f in Theorem 32. We prove Theorem 32 in Section 5.1. Theorem 32 implies that any quantum algorithm for f obtained from a monotone span program must have space complexity $(\log n)^{2-o(1)}$, which is slightly better than the trivial lower bound of $\Omega(\log n)$. In Section 5.2, we describe a more natural class of algorithms called monotone phase estimation algorithms such that $\log \widetilde{\mathsf{mSP}}(f)$ is a lower bound on the quantum space complexity of any such algorithm computing f with bounded error. Then for the specific function f from Theorem 32, any monotone phase estimation algorithm for f must use space $(\log n)^{2-o(1)}$.

5.1 Monotone Span Program Lower Bounds

Our main tool in proving Theorem 32 will be the following.

▶ **Theorem 33.** *For any Boolean function $f : D \to \{0,1\}$, $D \subseteq \{0,1\}^n$, and any constant $\kappa \in [0,1)$:*

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \max_{M \in \mathbb{R}^{f^{-1}(0) \times f^{-1}(1)} : \|M\|_\infty \leq 1} \frac{\sqrt{\kappa}\text{-rank}(M)}{\max_{j \in [n]} \text{rank}(M \circ \Delta_{j,1})},$$

where $\Delta_{j,1}[y,x] = 1$ if $y_i = 0$ and $x_i = 1$, and 0 else.

When, $\kappa = 0$, the right-hand side of the equation in Theorem 33 is the (monotone) *rank measure*, defined in [15], and shown in [7] to lower bound monotone span program size. We extend the proof for the $\kappa = 0$ case to get a lower bound on approximate span program size. We could also allow for partial matrices M, as in the non-monotone case (Lemma 29) but unlike the non-monotone case, it is not necessary to consider partial matrices to get non-trivial lower bounds.

Proof. Fix a monotone span program that κ-approximates f with size $\widetilde{\mathsf{mSP}}_\kappa(f)$. Let $\{\langle \omega_y| : y \in f^{-1}(0)\}$ be optimal negative witnesses, and let $\{|w_x\rangle : x \in f^{-1}(1)\}$ be approximate positive witnesses with $\left\|\Pi_{H(x)^\perp}|w_x\rangle\right\|^2 \leq \frac{\kappa}{W_-}$. Letting $\Pi_{j,b}$ denote the projector onto $H_{j,b}$, define

$$\begin{aligned}\Lambda_j &= \sum_{y\in f^{-1}(0)} |y\rangle\langle\omega_y|A\Pi_{j,\bar{y}_j} \sum_{x\in f^{-1}(1)} \Pi_{j,x_j}|w_x\rangle\langle x| \\ &= \sum_{\substack{y\in f^{-1}(0):\\ y_j=0}} |y\rangle\langle\omega_y|A\Pi_{j,1} \sum_{\substack{x\in f^{-1}(1):\\ x_j=1}} \Pi_{j,1}|w_x\rangle\langle x|,\end{aligned}$$

so Λ_j has rank at most $\dim H_j$, and so $\sum_{j\in[n]} \text{rank}(\Lambda_j) \leq s(P) = \widetilde{\mathsf{mSP}}_\kappa(f)$. Furthermore, Λ_j is only supported on (y,x) such that $y_j = 0$ and $x_j = 1$, so $\Lambda_j \circ \Delta_{j,1} = \Lambda_j$. Denoting the error of $|w_x\rangle$ as $|\mathsf{err}(x)\rangle = \Pi_{H(x)^\perp}|w_x\rangle = \sum_{j:x_j=0} \Pi_{j,1}|w_x\rangle$, we have

$$\begin{aligned}\langle y|\sum_{j\in[n]} \Lambda_j|x\rangle &= \sum_{j:y_j=0,x_j=1} \langle\omega_y|A\Pi_{j,1}|w_x\rangle = \langle\omega_y|A\sum_{j:y_j=0}\Pi_{j,1}\sum_{j:x_j=1}\Pi_{j,1}|w_x\rangle \\ &= \langle\omega_y|A(|w_x\rangle - |\mathsf{err}(x)\rangle) = \langle\omega_y|A|w_x\rangle - \langle\omega_y|A|\mathsf{err}(x)\rangle\end{aligned}$$

$$\left|1 - \langle y|\sum_{j\in[n]} \Lambda_j|x\rangle\right| \leq 1 - 1 + \|\langle\omega_y|A\| \, \||\mathsf{err}(x)\rangle\| \leq \sqrt{W_-}\sqrt{\frac{\kappa}{W_-}} = \sqrt{\kappa}.$$

Then for any $M \in \mathbb{R}^{f^{-1}(0)\times f^{-1}(1)}$ with $\|M\|_\infty \leq 1$, we have:

$$\left\|M - M\circ\sum_{j\in[n]}\Lambda_j\right\|_\infty \leq \|M\|_\infty \left\|J - \sum_{j\in[n]}\Lambda_j\right\|_\infty \leq \sqrt{\kappa}.$$

Thus

$$\begin{aligned}\sqrt{\kappa}\text{-rank}(M) &\leq \text{rank}\left(M\circ\sum_{j\in[n]}\Lambda_j\right) \leq \sum_{j\in[n]}\text{rank}(M\circ\Lambda_j) = \sum_{j\in[n]}\text{rank}(M\circ\Delta_{j,1}\circ\Lambda_j) \\ &\leq \sum_{j\in[n]}\text{rank}(M\circ\Delta_{j,1})\text{rank}(\Lambda_j) \leq \widetilde{\mathsf{mSP}}_\kappa(f)\max_{j\in[n]}\text{rank}(M\circ\Delta_{j,1}).\end{aligned}$$ ◀

To show a lower bound on $\widetilde{\mathsf{mSP}}(f)$ for *some* explicit $f : \{0,1\}^n \to \{0,1\}$, it turns out to be sufficient to find some high approximate rank matrix $M \in \mathbb{R}^{Y\times X}$ for finite sets X and Y, and a *rectangle cover* of M, $\Delta_1, \ldots, \Delta_n$, where each $\Delta_i \circ M$ has low rank. Specifically, we have the following lemma, which, with rank in place of approximate rank, has been used extensively in previous monotone span program lower bounds.

▶ **Lemma 34.** *Let $M \in \mathbb{R}^{Y\times X}$ with $\|M\|_\infty \leq 1$, for some finite sets X and Y and $X_1, \ldots, X_n \subseteq X$, $Y_1, \ldots, Y_n \subseteq Y$ be such that for all $(x,y) \in X\times Y$, there exists $j \in [n]$ such that $(x,y) \in X_j \times Y_j$. Define $\Delta_j \in \{0,1\}^{Y\times X}$ by $\Delta_j[y,x] = 1$ if and only if $(y,x) \in Y_j \times X_j$. There exists a monotone function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ such that for any constant $\kappa \in [0,1)$:*

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \frac{\sqrt{\kappa}\text{-rank}(M)}{\max_{j\in[n]}\text{rank}(M\circ\Delta_j)}.$$

Proof. For each $y \in Y$, define $t^y \in \{0,1\}^n$ by:

$$t^y_j = \begin{cases} 0 & \text{if } y \in Y_j \\ 1 & \text{else.}\end{cases}$$

Similarly, for each $x \in X$, define $s^x \in \{0,1\}^n$ by:

$$s^x_j = \begin{cases} 1 & \text{if } x \in X_j \\ 0 & \text{else.} \end{cases}$$

For every $(y,x) \in Y \times X$, there is some j such that $y_j \in Y_j$ and $x_j \in X_j$, so it can't be the case that $s^x \leq t^y$. Thus, we can define f as the unique monotone function such that $f(s) = 1$ for every $s \in \{0,1\}^n$ such that $s^x \leq s$ for some $x \in X$, and $f(t) = 0$ for all $t \in \{0,1\}^n$ such that $t \leq t^y$ for some $y \in Y$. Then we can define a matrix $M' \in \mathbb{R}^{f^{-1}(0) \times f^{-1}(1)}$ by $M'[t^y, s^x] = M[y,x]$ for all $(y,x) \in Y \times X$, and 0 elsewhere. We have $\varepsilon\text{-rank}(M') = \varepsilon\text{-rank}(M)$ for all ε, and $\text{rank}(M' \circ \Delta_{j,1}) = \text{rank}(M \circ \Delta_j)$ for all j. The result then follows from Theorem 33. ◀

We will prove Theorem 32 by constructing an M with high approximate rank, and a good rectangle cover $\{X_j \times Y_j\}_j$. Following [19] and [14], we will make use of a technique due to Sherstov for proving communication lower bounds, called the *pattern matrix method* [20]. We begin with some definitions.

▶ **Definition 35** (Fourier spectrum). *For a real-valued function $p : \{0,1\}^m \to \mathbb{R}$, its Fourier coefficients are defined, for each $S \subseteq [m]$:*

$$\hat{p}(S) = \frac{1}{2^m} \sum_{z \in \{0,1\}^m} p(z)\chi_S(z),$$

where $\chi_S(z) = (-1)^{\sum_{i \in S} z_i}$. It is easily verified that $p = \sum_{S \subseteq [m]} \hat{p}(S)\chi_S$.

▶ **Definition 36** (Degree and approximate degree). *The degree of a function $p : \{0,1\}^m \to \mathbb{R}$ is defined $\deg(p) = \max\{|S| : \hat{p}(S) \neq 0\}$. For any $\varepsilon \geq 0$, $\widetilde{\deg}_\varepsilon(p) = \min\{\deg(\tilde{p}) : \|p - \tilde{p}\|_\infty \leq \varepsilon\}$.*

Pattern matrices, defined by Sherstov in [20], are useful for proving lower bounds in communication complexity, because their rank and approximate rank are relatively easy to lower bound. In [19], Robere, Pitassi, Rossman and Cook first used this analysis to give lower bounds on $\mathsf{mSP}(f)$ for some f. We now state the definition, using the notation from [14], which differs slightly from [20].

▶ **Definition 37** (Pattern matrix). *For a real-valued function $p : \{0,1\}^m \to \mathbb{R}$, and a positive integer λ, the (m, λ, p)-pattern matrix is defined as $F \in \mathbb{R}^{\{0,1\}^{\lambda m} \times ([\lambda]^m \times \{0,1\}^m)}$ where for $y \in \{0,1\}^{\lambda m}$, $x \in [\lambda]^m$, and $w \in \{0,1\}^m$,*

$$F[y,(x,w)] = f(y|_x \oplus w),$$

where by $y|_x$, we mean the m-bit string containing one bit from each λ-sized block of y as specified by the entries of x: $(y^{(1)}_{x_1}, y^{(2)}_{x_2}, \ldots, y^{(m)}_{x_m})$, where $y^{(i)} \in \{0,1\}^\lambda$ is the i-th block of y.

For comparison, what [20] calls an (n,t,p)-pattern matrix would be a $(t, n/t, p)$-pattern matrix in our notation. As previously mentioned, a pattern matrix has the nice property that its rank (or even approximate rank) can be lower bounded in terms of properties of the Fourier spectrum of p. In particular, the following is proven in [20]:

▶ **Lemma 38.** *Let F be the (m, λ, p)-pattern matrix for $p : \{0,1\}^m \to \{-1,+1\}$. Then for any $\varepsilon \in [0,1]$ and $\delta \in [0, \varepsilon]$, we have:*

$$\text{rank}(F) = \sum_{S \subseteq [m] : \hat{p}(S) \neq 0} \lambda^{|S|} \quad \text{and} \quad \delta\text{-rank}(F) \geq \lambda^{\widetilde{\deg}_\varepsilon(p)} \frac{(\varepsilon - \delta)^2}{(1+\delta)^2}.$$

This shows that we can use functions p of high approximate degree to construct pattern matrices $F \in \mathbb{R}^{\{0,1\}^{\lambda m} \times ([\lambda]^m \times \{0,1\}^m)}$ of high approximate rank. To apply Lemma 34, we also need to find a good rectangle cover of some F.

A *b-certificate* for a function p on $\{0,1\}^m$ is an assignment $\alpha : S \to \{0,1\}$ for some $S \subseteq [m]$ such that for any $x \in \{0,1\}^m$ such that $x_j = \alpha(j)$ for all $j \in S$, $f(x) = b$. The size of a certificate is $|S|$. The following shows how to use the certificates of p to construct a rectangle cover of its pattern matrix.

▶ **Lemma 39.** *Let $p : \{0,1\}^m \to \{-1,+1\}$, and suppose there is a set of ℓ certificates for p of size at most C such that every input satisfies at least one certificate. Then for any positive integer λ, there exists a function $f : \{0,1\}^n \to \{0,1\}$ for $n = \ell(2\lambda)^C$ such that for any $\kappa \in (0,1)$ and $\varepsilon \in [\sqrt{\kappa}, 1]$:*

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \Omega\left((\varepsilon - \sqrt{\kappa})^2 \lambda^{\widetilde{\deg}_\varepsilon(p)}\right).$$

Proof. For $i = 1, \ldots, \ell$, let $\alpha_i : S_i \to \{0,1\}$ for $S_i \subset [m]$ of size $|S_i| \leq C$ be one of the ℓ certificates. That is, for each i, there is some $v_i \in \{-1,+1\}$ such that for any $x \in \{0,1\}^m$, if $x_j = \alpha_i(j)$ for all $j \in S_i$, then $p(x) = v_i$ (so α_i is a v_i-certificate).

We let F be the (m, λ, p)-pattern matrix, which has $\|F\|_\infty = 1$ since p has range $\{-1,+1\}$. We will define a rectangle cover as follows. For every $i \in [\ell]$, $k \in [\lambda]^{S_i}$, and $b \in \{0,1\}^{S_i}$, define:

$$X_{i,k,b} = \{(x,w) \in [\lambda]^m \times \{0,1\}^m : \forall j \in S_i, w_j = b_j, x_j = k_j\}$$
$$Y_{i,k,b} = \{y \in \{0,1\}^{\lambda m} : \forall j \in S_i, y^{(j)}_{k_j} = b_j \oplus \alpha_i(j)\}.$$

We first note that this is a rectangle cover. Fix any $y \in \{0,1\}^{\lambda m}$, $x \in [\lambda]^m$ and $w \in \{0,1\}^m$. First note that for any i, if we let b be the restriction of w to S_i, and k the restriction of x to S_i, we have $(x,w) \in X_{i,k,b}$. This holds in particular for i such that α_i is a certificate for $y|_x \oplus w$, and by assumption there is at least one such i. For such an i, we have $y^{(j)}_{x_j} \oplus w_j = \alpha(j)$ for all $j \in S_i$, so $y \in Y_{i,k,b}$. Thus, we can apply Lemma 34.

Note that if $(x,w) \in X_{i,k,b}$, and $y \in Y_{i,k,b}$, then $(y|_x \oplus w)[j] = y^{(j)}_{x_j} \oplus w_j = \alpha_i(j)$ for all $j \in S_i$, so $p(y|_x \oplus w) = v_i$. Letting $\Delta_{i,k,b}[y,(x,w)] = 1$ if $y \in Y_{i,k,b}$ and $(x,w) \in X_{i,k,b}$, and 0 else, we have that if $y \in Y_{i,k,b}$ and $(x,w) \in X_{i,k,b}$, $(F \circ \Delta_{i,k,b})[y,(x,w)] = p(y|_x \oplus w) = v_i$, and otherwise, $(F \circ \Delta_{i,k,b})[y,(x,w)] = 0$. Thus $\operatorname{rank}(F \circ \Delta_{i,k,b}) = \operatorname{rank}(v_i \Delta_{i,k,b}) = 1$. Then by Lemma 34, there exists $f : \{0,1\}^n \to \{0,1\}$ where $n = \sum_{i=1}^{\ell} (2\lambda)^{|S_i|} \leq \ell(2\lambda)^C$ such that:

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \sqrt{\kappa}\text{-}\operatorname{rank}(F) \geq \lambda^{\widetilde{\deg}_\varepsilon(p)} \frac{(\varepsilon - \sqrt{\kappa})^2}{(1+\sqrt{\kappa})^2}, \text{ by Lemma 38.} \quad ◀$$

We now prove Theorem 32, restated below:

▶ **Theorem 32.** *There is an explicit Boolean function $f : D \to \{0,1\}$ for $D \subseteq \{0,1\}^n$ such that for any constant κ,*

$$\log \widetilde{\mathsf{mSP}}_\kappa(f) \geq \Omega((\log n)^{2-o(1)}).$$

Proof. By [5, Theorem 38], there is a function p with $\widetilde{\deg}_{1/3}(p) \geq C(p)^{2-o(1)}$, which is, up to the $o(1)$ in the exponent, the best possible separation between these two quantities. In particular, this function has $\widetilde{\deg}_{1/3}(p) \geq M^{2-o(1)}$, and $C(p) \leq M^{1+o(1)}$, where $C(p)$ is the certificate complexity of p, for some parameter M (see [5] equations (64) and (65), where

p is referred to as F), and p is a function on $M^{2+o(1)}$ variables (see [5], discussion above equation (64)). Thus, there are at most $\binom{M^{2+o(1)}}{M^{1+o(1)}}$ possible certificates of size $M^{1+o(1)}$ such that each input satisfies at least one of them.

Then by Lemma 39 there exists a function $f : \{0,1\}^n \to \{0,1\}$ for some n such that $n \leq \binom{M^{2+o(1)}}{M^{1+o(1)}}(2\lambda)^{M^{1+o(1)}}$ such that for constant $\kappa < 1/36$ and constant λ:

$$\log \widetilde{\mathsf{mSP}}_\kappa(f) \geq \Omega(\widetilde{\deg}_{1/3}(p) \log \lambda) \geq M^{2-o(1)}.$$

Then we have:

$$\log n \leq \log \binom{M^{2+o(1)}}{M^{1+o(1)}} + M^{1+o(1)} \log(2\lambda) = O(M^{1+o(1)} \log M) = M^{1+o(1)}.$$

Thus, $\log \widetilde{\mathsf{mSP}}_\kappa(f) \geq (\log n)^{2-o(1)}$, and the result for *any* κ follows using Corollary 19. ◀

Since for all total functions p, $\widetilde{\deg}_{1/3}(p) \leq C(p)^2$, where $C(p)$ is the certificate complexity of p, Lemma 39 can't prove a lower bound better than $\log \widetilde{\mathsf{mSP}}(p) \geq (\log n)^2$ for any n-bit function. We state a more general version of Lemma 39 that might have the potential to prove a better bound, but we leave this as future work.

▶ **Lemma 40.** *Fix $p : \{0,1\}^m \to \{-1,+1\}$. For $i = 1, \ldots, \ell$, let $\alpha_i : S_i \to \{0,1\}$ for $S_i \subseteq [m]$ be a partial assignment such that every $z \in \{0,1\}^m$ satisfies at least one of the assignments. Let p_i denote the restriction of p to strings z satisfying the assignment α_i. Then for every positive integer λ, there exists a function $f : \{0,1\}^n \to \{0,1\}$, where $n = \sum_{i=1}^{\ell}(2\lambda)^{|S_i|}$ such that for any $\kappa \in (0,1)$ and $\varepsilon \in [\sqrt{\kappa}, 1]$:*

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \Omega\left(\frac{(\varepsilon - \sqrt{\kappa})^2 \lambda^{\widetilde{\deg}_\varepsilon(p)}}{\max_{i \in [\ell]} \sum_{S \subseteq [m] \setminus S_i : \hat{p}_i(S) \neq 0} \lambda^{|S|}}\right).$$

To make use of this lemma, one needs a function p of high approximate degree, such that for every input, there is a small assignment that lowers the degree to something small. This generalizes Lemma 39 because a certificate is an assignment that lowers the degree of the remaining sub-function to constant. However, we note that a p with these conditions is necessary but may not be sufficient for proving a non-trivial lower bound, because while $\sum_{S : \hat{p}_i(S) \neq 0} \lambda^{|S|} \geq \lambda^{\deg(p_i)}$, it may also be much larger if p_i has a dense Fourier spectrum.

Proof. Let F be the (m, λ, p)-pattern matrix. Let $\{X_{i,k,b} \times Y_{i,k,b}\}_{i,k,b}$ be the same rectangle covered defined in the proof of Lemma 39, with the difference that since the α_i are no longer certificates, the resulting submatrices of F may not have constant rank.

Let $\Delta_{i,k,b} = \sum_{y \in Y_{i,k,b}} |y\rangle \sum_{(x,w) \in X_{i,k,b}} \langle x, w|$. Then

$$F \circ \Delta_{i,k,b} = \sum_{y \in Y_{i,k,b}, (x,w) \in X_{i,k,b}} p(y|_x \oplus w) |y\rangle\langle x, w|.$$

Note that when $y \in Y_{i,k,b}$ and $(x,w) \in X_{i,b,k}$, $y|_x \oplus w$ satisfies α_i, so $p(y|_x \oplus w) = p_i(y'|_{x'} \oplus w')$, where y', x' and w' are restrictions of $y \in (\{0,1\}^\lambda)^m$, $x \in [\lambda]^m$ and $w \in \{0,1\}^m$ to $[m] \setminus S_i$. Thus, continuing from above, and rearranging registers, we have:

$$\begin{aligned} F \circ \Delta_{i,k,b} &= \sum_{y' \in (\{0,1\}^\lambda)^{[m] \setminus S_i}} \sum_{\substack{x' \in [\lambda]^{[m] \setminus S_i}, \\ w' \in \{0,1\}^{[m] \setminus S_i}}} p_i(y'|_{x'} \oplus w') |y'\rangle\langle x', w'| \otimes \sum_{\substack{\bar{y} \in (\{0,1\}^\lambda)^{S_i} : \\ \bar{y}|_k = b \oplus \alpha_i}} |\bar{y}\rangle\langle k, b| \\ &= F_i \otimes J_{2^{(\lambda-1)|S_i|}, 1} \end{aligned}$$

where F_i is the (m, λ, p_i)-pattern matrix, and $J_{a,b}$ is the all-ones matrix of dimension a by b, which always has rank 1 for $a, b > 0$. Thus

$$\operatorname{rank}(F \circ \Delta_{i,k,b}) = \operatorname{rank}(F_i)\operatorname{rank}(J_{2^{(\lambda-1)|S_i|},1}) = \operatorname{rank}(F_i) = \sum_{S\subseteq[m]\setminus S_i : \hat{p}_i(S)\neq 0} \lambda^{|S|},$$

by [20]. This part of the proof follows [19, Lemma IV.6].

Then by Lemma 34 and Lemma 38, we have:

$$\widetilde{\mathsf{mSP}}_\kappa(f) \geq \Omega\left(\frac{\sqrt{\kappa}\text{-rank}(F)}{\max_{i,k,b}\operatorname{rank}(F\circ\Delta_{i,k,b})}\right) \geq \Omega\left(\frac{\left(\frac{\varepsilon-\sqrt{\kappa}}{1+\sqrt{\kappa}}\right)^2 \lambda^{\deg_\varepsilon(p)}}{\max_i \sum_{S\subseteq[m]\setminus S_i:\hat{p}_j(S)\neq 0}\lambda^{|S|}}\right). \quad \blacktriangleleft$$

5.2 Monotone Algorithms

In Theorem 32, we showed a non-trivial lower bound on $\log \widetilde{\mathsf{mSP}}(f)$ for some explicit monotone function f. Unlike lower bounds on $\log \widetilde{\mathsf{SP}}(f)$, this does not give us a lower bound on the quantum space complexity of f, however, at the very least it gives us a lower bound on the quantum space complexity of a certain type of quantum algorithm. Of course, this is naturally the case, since a lower bound on $\widetilde{\mathsf{mSP}}(f)$ gives us a lower bound on the quantum space complexity of any algorithm for f that is obtained from a monotone span program. However, this is not the most satisfying characterization, as it is difficult to imagine what this class of algorithms looks like.

In this section, we will consider a more natural class of algorithms whose space complexity is lower bounded by $\widetilde{\mathsf{mSP}}(f)$, and in some cases $\mathsf{mSP}(f)$. We will call a quantum query algorithm a *phase estimation algorithm* if it works by estimating the amplitude on $|0\rangle$ in the phase register after running phase estimation of a unitary that makes one query. We assume that the unitary for which we perform phase estimation is of the form $U\mathcal{O}_x$. This is without loss of generality, because the most general form is a unitary $U_2\mathcal{O}_xU_1$, but we have $(U_2\mathcal{O}_xU_1)^t|\psi_0\rangle = U_1^\dagger(U\mathcal{O}_x)^t|\psi_0'\rangle$ where $|\psi_0'\rangle = U_1|\psi_0\rangle$, and $U = U_1U_2$. The weight on a phase of $|0\rangle$ is not affected by this global (t-independent) $U_1^\dagger$. Thus, we define a phase estimation algorithm as follows:

▶ **Definition 41.** *A* phase estimation algorithm $\mathcal{A} = (U, |\psi_0\rangle, \delta, T, M)$ *for* $f : D \to \{0,1\}$, $D \subseteq \{0,1\}^n$, *is defined by (families of):*

- *a unitary* U *acting on* $\mathcal{H} = \operatorname{span}\{|j, z\rangle : j \in [n], z \in \mathcal{Z}\}$ *for some finite set* $\mathcal{Z}$*;*
- *an initial state* $|\psi_0\rangle \in \mathcal{H}$*;*
- *a bound* $\delta \in [0, 1/2)$*;*
- *positive integers* T *and* $M \leq \frac{1}{\sqrt{\delta}}$*;*

such that for any $M' \geq M$ *and* $T' \geq T$*, the following procedure computes* f *with bounded error:*

1. *Let* $\Phi(x)$ *be the algorithm that runs phase estimation of* $U\mathcal{O}_x$ *on* $|\psi_0\rangle$ *for* T' *steps, and then computes a bit* $|b\rangle_A$ *in a new register* A*, such that* $b = 0$ *if and only if the phase estimate is* 0*.*
2. *Run* M' *steps of amplitude estimation to estimate the amplitude on* $|0\rangle_A$ *after application of* $\Phi(x)$*. Output* 0 *if the amplitude is* $> \delta$*.*

The query complexity *of the algorithm is* $O(MT)$*, and, the space complexity of the algorithm is* $\log\dim\mathcal{H} + \log T + \log M + 1$*.*

We insist that the algorithm work not only for M and T but for any larger integers as well, because we want to ensure that the algorithm is successful because M and T are large enough, and not by some quirk of the particular chosen values. When $\delta = 0$, the algorithm has one-sided error (see Lemma 46).

We remark on the generality of this form of algorithm. Any algorithm can be put into this form by first converting it to a span program, and then compiling that into an algorithm, preserving both the time and space complexity, asymptotically. However, we will consider a special case of this type of algorithm that is *not* fully general.

▶ **Definition 42.** *A* monotone *phase estimation algorithm is a phase estimation algorithm such that if* $\Pi_0(x)$ *denotes the orthogonal projector onto the* $(+1)$*-eigenspace of* $U\mathcal{O}_x$*, then for any* $x \in \{0,1\}^n$*,* $\Pi_0(x)|\psi_0\rangle$ *is in the* $(+1)$*-eigenspace of* $\mathcal{O}_x$*.*

Let us consider what is "monotone" about this definition. The algorithm rejects if $|\psi_0\rangle$ has high overlap with the $(+1)$-eigenspace of $U\mathcal{O}_x$, i.e., $\Pi_0(x)|\psi_0\rangle$ is large. In a monotone phase estimation algorithm, we know that the only contribution to $\Pi_0(x)|\psi_0\rangle$ is in the $(+1)$-eigenspace of $\mathcal{O}_x$, which is exactly the span of $|j,z\rangle$ such that $x_j = 0$. Thus, only 0-queries can contribute to the algorithm rejecting.

As a simple example, Grover's algorithm is a monotone phase estimation algorithm. Specifically, let $|\psi_0\rangle = \frac{1}{\sqrt{n}}\sum_{j=1}^{n}|j\rangle$ and $U = (2|\psi_0\rangle\langle\psi_0| - I)$. Then $U\mathcal{O}_x$ is the standard Grover iterate, and $|\psi_0\rangle$ is in the span of $e^{i\theta}$-eigenvectors of $U\mathcal{O}_x$ with $\sin|\theta| = \sqrt{|x|/n}$, so phase estimation can be used to distinguish the case $|x| = 0$ from $|x| \geq 1$. So $\Pi_0(x)|\psi_0\rangle$ is either 0, when $|x| \neq 0$, or $|\psi_0\rangle$, when $|x| = 0$. In both cases, it is in the $(+1)$-eigenspace of $\mathcal{O}_x$.

It is clear that a monotone phase estimation algorithm can only decide a monotone function. However, while any quantum algorithm can be converted to a phase estimation algorithm, it is not necessarily the case that any quantum algorithm for a monotone function can be turned into a monotone phase estimation algorithm. Thus lower bounds on the quantum space complexity of any monotone phase estimation algorithm for f do not imply lower bounds on $\mathsf{S}_U(f)$. Nevertheless, if we let $\mathsf{mS}_U(f)$ represent the minimum quantum space complexity of any monotone phase estimation algorithm for f, then a lower bound on $\mathsf{mS}_U(f)$ at least tells us that if we want to compute f with space less than said bound, we must use a non-monotone phase estimation algorithm.

Similarly, we let $\mathsf{mS}^1_U(f)$ denote the minimum quantum space complexity of any monotone phase estimation algorithm with $\delta = 0$ that computes f (with one-sided error).

The main theorem of this section states that any monotone phase estimation algorithm for f with space S can be converted to a monotone span program of size $2^{\Theta(S)}$ that approximates f, so that lower bounds on $\mathsf{m}\widetilde{\mathsf{SP}}(f)$ imply lower bounds on $\mathsf{mS}_U(f)$; and that any monotone phase estimation algorithm with $\delta = 0$ and space S can be converted to a monotone span program of size $2^{\Theta(S)}$ that decides f (exactly) so that lower bounds on $\mathsf{mSP}(f)$ imply lower bounds on $\mathsf{mS}^1_U(f)$. These conversions also preserve the query complexity. We now formally state this main result.

▶ **Theorem 43.** *Let* $\mathcal{A} = (U, |\psi_0\rangle, \delta, T, M)$ *be a monotone phase estimation algorithm for* f *with space complexity* $S = \log\dim\mathcal{H} + \log T + \log M + 1$ *and query complexity* $O(TM)$*. Then there is a monotone span program with complexity* $O(TM)$ *and size* $2\dim\mathcal{H} \leq 2^S$ *that approximates* f*. If* $\delta = 0$*, then this span program decides* f *(exactly). Thus*

$$\mathsf{mS}_U(f) \geq \log \mathsf{m}\widetilde{\mathsf{SP}}(f) \quad \textit{and} \quad \mathsf{mS}^1_U(f) \geq \log \mathsf{mSP}(f).$$

We prove this theorem in Section 5.2.1. As a corollary, lower bounds on $\mathsf{mSP}(f)$, such as the one from [14], imply lower bounds on $\mathsf{mS}^1_U(f)$; and lower bounds on $\mathsf{m}\widetilde{\mathsf{SP}}(f)$ such as the one in Theorem 32, imply lower bounds on $\mathsf{mS}_U(f)$. In particular:

▶ **Corollary 44.** *Let* $f : \{0,1\}^n \to \{0,1\}$ *be the function described in Theorem 32. Then* $\mathsf{mS}_U(f) \geq (\log n)^{2-o(1)}$*. Let* $g : \{0,1\}^n \to \{0,1\}$ *be the function described in Theorem 31. Then* $\mathsf{mS}^1_U(g) \geq \Omega(n)$*.*

We emphasize that while this does not give a lower bound on the quantum space complexity of f, or the one-sided quantum space complexity of g, it does show that any algorithm that uses $(\log n)^c$ space to solve f with bounded error, for $c < 2$, or $o(n)$ space to solve g with one-sided error, must be of a different form than that described in Definition 41 and Definition 42.

In a certain sense, monotone phase estimation algorithms completely characterize those that can be derived from monotone span programs, because the algorithm we obtain from compiling a monotone span program is a monotone phase estimation algorithm, as stated below in Lemma 45. However, not all monotone phase estimation algorithms can be obtained by compiling monotone span programs, and similarly, we might hope to show that an even larger class of algorithms can be converted to monotone span programs, in order to give more strength to lower bounds on $\mathsf{mS}_U(f)$.

▶ **Lemma 45.** *Let P be an approximate monotone span program for f with size S and complexity C. Then there is a monotone algorithm for f with query complexity $O(C)$ and space complexity $O(\log S + \log C)$.*

Proof. Fix a monotone span program, and assume it has been appropriately scaled. Without loss of generality, we can let $H_j = H_{j,1} = \text{span}\{|j,z\rangle : z \in \mathcal{Z}_j\}$ for some finite set $\mathcal{Z}_j$. Then, $\mathcal{O}_x = I - 2\Pi_{H(x)}$, which is only true because the span program is monotone. Let $U = 2\Pi_{\text{row}(A)} - I$. Then $U\mathcal{O}_x = (2\Pi_{\ker(A)} - I)(2\Pi_{H(x)} - I)$ is the *span program unitary*, described in [8]. The algorithm obtained from compiling a span program works by performing $O(C)$ steps of phase estimation of this unitary, applied to $|w_0\rangle = A^+|\tau\rangle$, and estimating the amplitude on 0 in the phase register to constant precision (see [8, Lemma 3.6]). This is clearly a phase estimation algorithm for f with query complexity $O(C)$ and space complexity $O(\log S + \log C)$.

The algorithm is a monotone phase estimation algorithm because $U = 2\Pi_{\text{row}(A)} - I$ is a reflection, and $|\psi_0\rangle = |w_0\rangle = A^+|\tau\rangle$ is in the $(+1)$-eigenspace of U, $\text{row}(A)$. Since U is a reflection, the $(+1)$-eigenspace of $U\mathcal{O}_x$ is exactly $(\ker(A) \cap H(x)) \oplus (\text{row}(A) \cap H(x)^\perp)$, and so $\Pi_0(x)|w_0\rangle \in \text{row}(A) \cap H(x)^\perp \subset H(x)^\perp$. ◀

5.2.1 Monotone Algorithms to (Approximate) Monotone Span Programs

In this section, we prove Theorem 43. Throughout this section, we fix a phase estimation algorithm $\mathcal{A} = (U, |\psi_0\rangle, \delta, T, M)$ that computes f, with U acting on $\mathcal{H}$. For any $x \in \{0,1\}^n$ and $\Theta \in [0, \pi]$, we let $\Pi_\Theta(x)$ denote the orthogonal projector onto the span of $e^{i\theta}$-eigenvectors of $U\mathcal{O}_x$ for $|\theta| \leq \Theta$. We will let $\Pi_x = \sum_{j\in[n], z\in\mathcal{Z}: x_j=1} |j,z\rangle\langle j,z|$.

We begin by drawing some conclusions about the necessary relationship between the eigenspaces of $U\mathcal{O}_x$ and a function f whenever a monotone phase estimation computes f. The proofs are somewhat dry and are relegated to Appendix B.

▶ **Lemma 46.** *Fix a phase estimation algorithm with $\delta = 0$ that solves f with bounded error. Then if $f(x) = 0$,*

$$\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \frac{1}{M^2},$$

and for any $d < \sqrt{8}/\pi$, if $f(x) = 1$, then

$$\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 = 0,$$

and the algorithm always outputs 1, so it has one-sided error.

▶ **Lemma 47.** *Fix a phase estimation algorithm with $\delta \neq 0$ that solves f with bounded error. Then there is some constant $c > 0$ such that if $f(x) = 0$,*

$$\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \max\{\delta(1+c), 1/M^2\}$$

and if $f(x) = 1$, for any $d < \sqrt{8}/\pi$,

$$\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 \leq \frac{\delta}{1 - \frac{d^2\pi^2}{8}}.$$

To prove Theorem 43, we will define a monotone span program $P_{\mathcal{A}}$ as follows:

$$\begin{aligned} H_{\text{true}} &= \text{span}\{|j,z\rangle : j \in [n], z \in \mathcal{Z}\} = \mathcal{H} \\ H_{j,1} &= H_j = \text{span}\{|j,z,1\rangle : z \in \mathcal{Z}\} \\ A|j,z,1\rangle &= \frac{1}{2}(|j,z\rangle - (-1)^1|j,z\rangle) = |j,z\rangle \\ A|j,z\rangle &= (I - U^\dagger)|j,z\rangle \\ |\tau\rangle &= |\psi_0\rangle. \end{aligned} \tag{2}$$

We first show that $\Pi_0(x)|\psi_0\rangle$ is (up to scaling) a negative witness for x, whenever it is nonzero:

▶ **Lemma 48.** *For any $x \in \{0,1\}^n$, we have*

$$w_-(x) = \frac{1}{\|\Pi_0(x)|\psi_0\rangle\|^2}.$$

In particular, when $\Pi_0(x)|\psi_0\rangle \neq 0$, $\Pi_0(x)|\psi_0\rangle / \|\Pi_0(x)|\psi_0\rangle\|^2$ is an optimal negative witness for x.

Proof. Suppose $\Pi_0(x)|\psi_0\rangle \neq 0$, and let $|\omega\rangle = \Pi_0(x)|\psi_0\rangle / \|\Pi_0(x)|\psi_0\rangle\|^2$. We will first show that this is a negative witness, and then show that no negative witness can have better complexity. First, we notice that

$$\langle\omega|\tau\rangle = \langle\omega|\psi_0\rangle = \frac{\langle\psi_0|\Pi_0(x)|\psi_0\rangle}{\|\Pi_0(x)|\psi_0\rangle\|^2} = 1.$$

Next, we will see that $\langle\omega|A\Pi_{H(x)} = 0$. By the monotone phase estimation property, $\mathcal{O}_x\Pi_0(x)|\psi_0\rangle = \Pi_0(x)|\psi_0\rangle$, and so $\mathcal{O}_x|\omega\rangle = |\omega\rangle$, and thus $\Pi_x|\omega\rangle = 0$, where Π_x is the projector onto $|j,z\rangle$ such that $x_j = 1$. Note that $H(x) = \text{span}\{|j,z,1\rangle : x_j = 1, z \in \mathcal{Z}\} \oplus \text{span}\{|j,z\rangle : j \in [n], z \in \mathcal{Z}\}$. Thus $\Pi_{H(x)} = \Pi_{H_{\text{true}}} + \Pi_x \otimes |1\rangle\langle 1|$. We have:

$$\langle\omega|A(\Pi_x \otimes |1\rangle\langle 1|) = \langle\omega|\Pi_x = 0.$$

Since $|\omega\rangle$ is in the $(+1)$-eigenspace of $U\mathcal{O}_x$, we have $U\mathcal{O}_x|\omega\rangle = |\omega\rangle$ so since $\mathcal{O}_x|\omega\rangle = |\omega\rangle$, $U|\omega\rangle = |\omega\rangle$. Thus

$$\langle\omega|A\Pi_{H_{\text{true}}} = \langle\omega|(I - U^\dagger) \otimes \langle 1| = (\langle\omega| - \langle\omega|) \otimes \langle 1| = 0.$$

Thus $|\omega\rangle$ is a zero-error negative witness for x. Next, we argue that it is optimal.

Suppose $|\omega\rangle$ is any optimal negative witness for x, with size $w_-(x)$. Then since $\langle\omega|\Pi_x = \langle\omega|A(\Pi_x \otimes |1\rangle\langle 1|)$ must be 0, $\mathcal{O}_x|\omega\rangle = (I - 2\Pi_x)|\omega\rangle = |\omega\rangle$, and since $\langle\omega|A\Pi_{H_{\text{true}}} = \langle\omega|(I - U^\dagger)$ must be 0, $U|\omega\rangle = |\omega\rangle$. Thus $|\omega\rangle$ is a 1-eigenvector of $U\mathcal{O}_x$, so

$$\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \left\|\frac{|\omega\rangle\langle\omega|}{\||\omega\rangle\|^2}|\psi_0\rangle\right\|^2 = \frac{|\langle\omega|\psi_0\rangle|^2}{\||\omega\rangle\|^2} = \frac{1}{\||\omega\rangle\|^2}.$$

We complete the proof by noticing that since $\langle\omega|A\Pi_{H_{\text{true}}} = 0$, we have $\langle\omega|A = \langle\omega|\langle 1|$, and $w_-(x) = \|\langle\omega|A\|^2 = \||\omega\rangle\|^2$. ◀

Next we find approximate positive witnesses.

▶ **Lemma 49.** *For any $\Theta \geq 0$, the span program $P_{\mathcal{A}}$ has approximate positive witnesses for any x with error at most $\|\Pi_\Theta(x)|\psi_0\rangle\|^2$ and complexity at most $\frac{5\pi^2}{4\Theta^2}$.*

Proof. We first define a vector $|v\rangle$ by:

$$|v\rangle = (I - (U\mathcal{O}_x)^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle.$$

Note that $I - (U\mathcal{O}_x)^\dagger$ is supported everywhere except the $(+1)$-eigenvectors of $(U\mathcal{O}_x)^\dagger$, which are exactly the $(+1)$-eigenvectors of $U\mathcal{O}_x$. Thus, $(I - \Pi_\Theta(x))|\psi_0\rangle$ is contained in this support.

Next we define $|w\rangle = \left(|\psi_0\rangle - (I - U^\dagger)|v\rangle\right)|1\rangle + |v\rangle$. Then we have:

$$A|w\rangle = |\psi_0\rangle - (I - U^\dagger)|v\rangle + (I - U^\dagger)|v\rangle = |\psi_0\rangle = |\tau\rangle.$$

So $|w\rangle$ is a positive witness, and we next compute its error for x:

$$\begin{aligned}\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 &= \left\|\Pi_{\bar{x}}\left(|\psi_0\rangle - (I - U^\dagger)|v\rangle\right)\right\|^2 \\ &= \left\||\psi_0\rangle - \Pi_{\bar{x}}(I - U^\dagger)(I - (U\mathcal{O}_x)^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle\right\|^2.\end{aligned}$$

Above, $\Pi_{\bar{x}} = I - \Pi_x$. We now observe that

$$\Pi_{\bar{x}}(I - \mathcal{O}_x U^\dagger) = \Pi_{\bar{x}}\left(\Pi_{\bar{x}} - (\Pi_{\bar{x}} - \Pi_x)U^\dagger\right) = \Pi_{\bar{x}}(I - U^\dagger).$$

Thus, continuing from above, we have:

$$\begin{aligned}\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 &= \left\||\psi_0\rangle - \Pi_{\bar{x}}(I - \mathcal{O}_x U^\dagger)(I - \mathcal{O}_x U^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle\right\|^2 \\ &= \||\psi_0\rangle - \Pi_{\bar{x}}(I - \Pi_\Theta(x))|\psi_0\rangle\|^2 = \|\Pi_{\bar{x}}\Pi_\Theta(x)|\psi_0\rangle\|^2 \leq \|\Pi_\Theta(x)|\psi_0\rangle\|^2.\end{aligned}$$

Now we compute the complexity of $|w\rangle$. First, let $U\mathcal{O}_x = \sum_j e^{i\theta_j}|\lambda_j\rangle\langle\lambda_j|$ be the eigenvalue decomposition of $U\mathcal{O}_x$. Then

$$(I - (U\mathcal{O}_x)^\dagger)^+ = \sum_{j:\theta_j \neq 0} \frac{1}{1 - e^{-i\theta_j}}|\lambda_j\rangle\langle\lambda_j| \quad \text{and} \quad I - \Pi_\Theta(x) = \sum_{j:|\theta_j|>\Theta} |\lambda_j\rangle\langle\lambda_j|.$$

We can thus bound $\||v\rangle\|^2$:

$$\begin{aligned}\||v\rangle\|^2 = \left\|(I - (U\mathcal{O}_x)^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle\right\|^2 &= \left\|\sum_{j:|\theta_j|>\Theta} \frac{1}{1 - e^{-i\theta_j}}\langle\lambda_j|\psi_0\rangle|\lambda_j\rangle\right\|^2 \\ = \sum_{j:|\theta_j|>\Theta} \frac{1}{4\sin^2\frac{\theta_j}{2}}|\langle\lambda_j|\psi_0\rangle|^2 &\leq \frac{\pi^2}{4\Theta^2}.\end{aligned}$$

Next, using $\mathcal{O}_x + 2\Pi_x = I - 2\Pi_x + 2\Pi_x = I$, we compute:

$$\begin{aligned}&\left\||\psi_0\rangle - (I - U^\dagger)|v\rangle\right\|^2 \\ =\ &\left\||\psi_0\rangle - (I - \mathcal{O}_x U^\dagger - 2\Pi_x U^\dagger)(I - \mathcal{O}_x U^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle\right\|^2 \\ =\ &\left\||\psi_0\rangle - (I - \Pi_\Theta(x))|\psi_0\rangle + 2\Pi_x U^\dagger(I - (U\mathcal{O}_x)^\dagger)^+(I - \Pi_\Theta(x))|\psi_0\rangle\right\|^2\end{aligned}$$

$$\begin{aligned}
\ldots &\leq \left(\||\Pi_\Theta(x)|\psi_0\rangle\| + 2 \left\| \Pi_x U^\dagger \sum_{j:|\theta_j|>\Theta} \frac{1}{1-e^{-i\theta_j}} \langle\lambda_j|\psi_0\rangle |\lambda_j\rangle \right\| \right)^2 \\
&\leq \left(\||\Pi_\Theta(x)|\psi_0\rangle\| + 2\sqrt{\sum_{j:|\theta_j|>\Theta} \frac{1}{4\sin^2\frac{\theta_j}{2}} |\langle\lambda_j|\psi_0\rangle|^2} \right)^2 \\
&\leq \left(\||\Pi_\Theta(x)|\psi_0\rangle\| + \frac{\pi}{\Theta} \|(I-\Pi_\Theta(x))|\psi_0\rangle\| \right)^2 \leq \frac{\pi^2}{\Theta^2}.
\end{aligned}$$

Then we have the complexity of $|w\rangle$:

$$\||w\rangle\|^2 = \left\||\psi_0\rangle - (I-U^\dagger)|v\rangle\right\|^2 + \||v\rangle\|^2 \leq \frac{\pi^2}{\Theta^2} + \frac{\pi^2}{4\Theta^2} = \frac{5\pi^2}{4\Theta^2}. \quad \blacktriangleleft$$

We conclude with the following two corollaries, whose combination gives Theorem 43.

▶ **Corollary 50.** *Let $\mathcal{A} = (U, |\psi_0\rangle, 0, T, M)$ be a monotone phase estimation algorithm for f with space complexity $S = \log\dim\mathcal{H} + \log T + \log M + 1$ and query complexity $O(TM)$. Then there is a monotone span program that decides f (exactly) whose size is $2\dim\mathcal{H} \leq 2^S$ and whose complexity is $O(TM)$.*

Proof. If $f(x) = 0$, then by Lemma 46, we have $\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \frac{1}{M^2}$, so by Lemma 48, $w_-(x) \leq M^2$. Thus $W_- \leq M^2$.

If $f(x) = 1$, then by Lemma 46, we have $\left\|\Pi_{2/T}(x)|\psi_0\rangle\right\|^2 = 0$, so by Lemma 49, there's an exact positive witness for x with complexity $O(T^2)$. Thus $W_+ \leq O(T^2)$, and so the span program $P_\mathcal{A}$ from (2) has complexity $O(TM)$. The size of the span program $P_\mathcal{A}$ is $\dim H = 2\dim\mathcal{H}$. $\blacktriangleleft$

▶ **Corollary 51.** *Let $\mathcal{A} = (U, |\psi_0\rangle, \delta, T, M)$ be a monotone phase estimation algorithm for f with space complexity $S = \log\dim\mathcal{H} + \log T + \log M + 1$ and query complexity $O(TM)$. Then there is a constant $\kappa \in (0,1)$ such that there exists a monotone span program that κ-approximates f whose size is $2\dim\mathcal{H} \leq 2^S$ and whose complexity is $O(TM)$.*

Proof. If $f(x) = 0$, then by Lemma 47, we have $\|\Pi_0(x)|\psi_0\rangle\|^2 > \delta(1+c)$ for some constant $c > 0$. Thus, by Lemma 48, $W_- \leq \frac{1}{(1+c)\delta}$.

If $f(x) = 1$, then by Lemma 49, setting $\Theta = d\pi/T$ for $d = \frac{2}{\pi}\sqrt{\frac{c}{1+c}}$, (where c is the constant from above), by Lemma 49 there is an approximate positive witness for x with error $e_x = \left\|\Pi_{2\sqrt{\frac{c}{1+c}}/T}(x)|\psi_0\rangle\right\|^2$ and complexity $O(T^2)$. By Lemma 47, we have

$$e_x \leq \frac{\delta}{1-\frac{d^2\pi^2}{8}} = \frac{\delta}{1-\frac{c}{2(1+c)}} = \frac{\delta(1+c)}{1+c-c/2} \leq \frac{1}{1+c/2}\frac{1}{W_-}.$$

Thus, letting $\kappa = \frac{1}{1+c/2} < 1$, we have that $P_\mathcal{A}$ κ-approximates f. Since the positive witness complexity is $O(T^2)$, and by Lemma 47, we also have $W_- \leq O(M^2)$, the complexity of $P_\mathcal{A}$ is $O(TM)$. The size of $P_\mathcal{A}$ is $\dim H = 2\dim\mathcal{H}$. $\blacktriangleleft$

A Proof of Claim 18

In this section, we prove Claim 18, restated below:

▷ Claim 18. Let P be a span program that κ-approximates $f : D \to \{0,1\}$ for some constant κ. For any constant $\kappa' \leq \kappa$, there exists a span program P' that κ'-approximates f with $s(P') = (s(P)+2)^{2^{\frac{\log \frac{1}{\kappa'}}{\log \frac{1}{\kappa}}}}$, and $C_{\kappa'}(P', D) \leq O\left(C_\kappa(P, D)\right)$.

Let $|w_0\rangle = A^+|\tau\rangle$. We say a span program is *normalized* if $\||w_0\rangle\| = 1$. A span program can easily be normalized by scaling $|\tau\rangle$, which also scales all positive witnesses and inverse scales all negative witnesses. However, we sometimes want to normalize a span program, while also keeping all negative witness sizes bounded by a constant. We can accomplish this using the following construction, from [8].

▶ **Theorem 52.** *Let $P = (H, V, |\tau\rangle, A)$ be a span program on $\{0,1\}^n$, and let $N = \||w_0\rangle\|^2$. For a positive real number β, define a span program $P^\beta = (H^\beta, V^\beta, |\tau^\beta\rangle, A^\beta)$ as follows, where $|\hat{0}\rangle$ and $|\hat{1}\rangle$ are not in H or V:*

$$H^\beta_{j,b} = H_{j,b}, \quad H^\beta_{\text{true}} = H_{\text{true}} \oplus \text{span}\{|\hat{1}\rangle\}, \quad H^\beta_{\text{false}} = H_{\text{false}} \oplus \text{span}\{|\hat{0}\rangle\}$$

$$V^\beta = V \oplus \text{span}\{|\hat{1}\rangle\}, \quad A^\beta = \beta A + |\tau\rangle\langle\hat{0}| + \frac{\sqrt{\beta^2+N}}{\beta}|\hat{1}\rangle\langle\hat{1}|, \quad |\tau^\beta\rangle = |\tau\rangle + |\hat{1}\rangle.$$

Then we have the following:

- $\left\|(A^\beta)^+|\tau^\beta\rangle\right\| = 1$;
- *for all $x \in P_1$, $w_+(x, P^\beta) = \frac{1}{\beta^2} w_+(x, P) + 2$;*
- *for all $x \in P_0$, $w_-(x, P^\beta) = \beta^2 w_-(x, P) + 1$.*

▶ **Corollary 53.** *Let P be a span program on $\{0,1\}^n$, and P^β be defined as above for $\beta = \frac{1}{\sqrt{W_-(P)}}$. If P κ-approximates f, then P^β $\sqrt{\kappa}$-approximates f, with $W_-(P^\beta) \leq 2$, $\widehat{W}_+(P^\beta) \leq W_-(P)\widehat{W}_+(P) + 2$ and $s(P^\beta) \leq s(P) + 2$.*

Proof. First note that by Theorem 52, $W_-(P^\beta) \leq 2$. Let $|w\rangle$ be an approximate positive witness for x in P, with $\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 \leq \frac{\kappa}{W_-(P)}$ and $\||w\rangle\|^2 \leq \widehat{W}_+(P)$. Define

$$|w'\rangle = \frac{1}{\beta(1+\kappa)}|w\rangle + \frac{\beta}{\sqrt{\beta^2+N}}|\hat{1}\rangle + \frac{\kappa}{1+\kappa}|\hat{0}\rangle.$$

One can check that $A^\beta|w'\rangle = |\tau^\beta\rangle$.

$$\begin{aligned}
\left\|\Pi_{H^\beta(x)^\perp}|w'\rangle\right\|^2 &= \frac{1}{\beta^2(1+\kappa)^2}\left\|\Pi_{H(x)^\perp}|w\rangle\right\|^2 + \frac{\kappa^2}{(1+\kappa)^2} \\
&\leq \frac{1}{\beta^2(1+\kappa)^2}\frac{\kappa}{W_-(P)} + \frac{\kappa^2}{(1+\kappa)^2} \\
&= \frac{\kappa+\kappa^2}{(1+\kappa)^2} \leq \frac{2\kappa(1+\kappa)}{W_-(P^\beta)(1+\kappa)^2} = \frac{1}{W_-(P^\beta)}\frac{2\kappa}{1+\kappa} \leq \frac{\sqrt{\kappa}}{W_-(P^\beta)},
\end{aligned}$$

where we have used $W_-(P^\beta) \leq 2$. We upper bound $\widehat{W}_+(P^\beta)$ by noting that:

$$\||w'\rangle\|^2 \leq \frac{1}{\beta^2(1+\kappa)^2}\widehat{W}_+(P) + \frac{\beta^2}{\beta^2+N} + \frac{\kappa^2}{(1+\kappa)^2} \leq W_-(P)\widehat{W}_+(P) + 2.$$

Finally, $s(P^\beta) = s(P) + 2$ because of the two extra degrees of freedom $|\hat{0}\rangle$ and $|\hat{1}\rangle$. ◀

Proof of Claim 18. We will first show how, given a span program P such that $\||w_0\rangle\|^2 \leq 1$, and P κ-approximates f, we can get a span program P' such that $\||w_0'\rangle\|^2 \leq 1$, $W_-(P') \leq W_-(P)^2$, P' κ^2-approximates f, $\widehat{W}_+(P') \leq 4\widehat{W}_+(P)$, and $s(P') = s(P)^2$.

Define P' as follows, where S is a *swap* operator, which acts as $S(|u\rangle|v\rangle) = |v\rangle|u\rangle$ for all $|u\rangle, |v\rangle \in H$:

$$H'_{j,b} = H_{j,b} \otimes H, \qquad A' = (A \otimes A)\left(\frac{I_{H\otimes H} + S}{2}\right), \qquad |\tau'\rangle = |\tau\rangle|\tau\rangle.$$

Observe that for any $|u\rangle, |v\rangle \in H$, we have

$$A'(|u\rangle|v\rangle - |v\rangle|u\rangle) = 0, \quad \text{and} \quad A'|u\rangle|u\rangle = A|u\rangle \otimes A|u\rangle.$$

Note that $A'(|w_0\rangle|w_0\rangle) = |\tau'\rangle$, so $\left\|A'^{+}|\tau'\rangle\right\| \leq \||w_0\rangle|w_0\rangle\| \leq 1$.

If $\langle\omega|$ is a negative witness for x in P, it is easily verified that $\langle\omega'| = \langle\omega| \otimes \langle\omega|$ is a negative witness in P', and

$$\|\langle\omega'|A'\|^2 = \left\|\frac{1}{2}(\langle\omega|A) \otimes (\langle\omega|A) + \frac{1}{2}(\langle\omega|A) \otimes (\langle\omega|A)\right\|^2 = \|\langle\omega|A\|^4,$$

so $w_-(x, P') \leq w_-(x, P)^2$, and $W_-(P') \leq W_-(P)^2$.

If $|w\rangle$ is an approximate positive witness for x in P, then define

$$|w'\rangle = |w\rangle|w\rangle - \Pi_{H(x)^\perp}|w\rangle\Pi_{H(x)}|w\rangle + \Pi_{H(x)}|w\rangle\Pi_{H(x)^\perp}|w\rangle - \Pi_{H(x)}|w\rangle\Pi_{\ker(A)}|w\rangle.$$

We have

$$\begin{aligned} A'|w'\rangle &= A|w\rangle A|w\rangle - \frac{1}{2}\left(A\Pi_{H(x)}|w\rangle \otimes A\Pi_{\ker(A)}|w\rangle + A\Pi_{\ker(A)}|w\rangle \otimes A\Pi_{H(x)}|w\rangle\right) \\ &= |\tau\rangle|\tau\rangle = |\tau'\rangle. \end{aligned}$$

We can bound the error as:

$$\begin{aligned} \left\|\Pi_{H'(x)^\perp}|w'\rangle\right\|^2 &= \left\|(\Pi_{H(x)^\perp} \otimes I)|w'\rangle\right\|^2 = \left\|\Pi_{H(x)^\perp}|w\rangle|w\rangle - \Pi_{H(x)^\perp}|w\rangle\Pi_{H(x)}|w\rangle\right\|^2 \\ &= \left\|\Pi_{H(x)^\perp}|w\rangle\Pi_{H(x)^\perp}|w\rangle\right\|^2 \leq \frac{\kappa^2}{W_-(P)^2} \leq \frac{\kappa^2}{W_-(P')}. \end{aligned}$$

Next, observe that

$$\begin{aligned} &(\Pi_{H(x)} + \Pi_{H(x)^\perp}) \otimes (\Pi_{H(x)} + \Pi_{H(x)^\perp}) - \Pi_{H(x)^\perp} \otimes \Pi_{H(x)} + \Pi_{H(x)} \otimes \Pi_{H(x)^\perp} \\ &= \Pi_{H(x)} \otimes \Pi_{H(x)} + \Pi_{H(x)} \otimes \Pi_{H(x)^\perp} + \Pi_{H(x)^\perp} \otimes \Pi_{H(x)^\perp} + \Pi_{H(x)} \otimes \Pi_{H(x)^\perp} \\ &= \Pi_{H(x)} \otimes I + I \otimes \Pi_{H(x)^\perp} \end{aligned}$$

so $|w'\rangle = \Pi_{H(x)}|w\rangle \otimes |w\rangle + |w\rangle \otimes \Pi_{H(x)^\perp}|w\rangle - \Pi_{H(x)}|w\rangle \otimes \Pi_{\ker(A)}|w\rangle$.

Thus, using the assumption $\||w_0\rangle\| \leq 1$, and the fact that $\Pi_{\text{row}(A)}|w\rangle = |w_0\rangle$:

$$\begin{aligned} \||w'\rangle\|^2 &= \left\|\Pi_{H(x)}|w\rangle|w\rangle + |w\rangle\Pi_{H(x)^\perp}|w\rangle - \Pi_{H(x)}|w\rangle\Pi_{\ker(A)}|w\rangle\right\|^2 \\ &= \left\|\Pi_{H(x)}|w\rangle\Pi_{\text{row}(A)}|w\rangle + |w\rangle\Pi_{H(x)^\perp}|w\rangle\right\|^2 \\ &= \left\|\Pi_{H(x)}|w\rangle|w_0\rangle\right\|^2 + \left\||w\rangle\Pi_{H(x)^\perp}|w\rangle\right\|^2 + 2\left\|\Pi_{H(x)}|w\rangle\right\|^2 \langle w_0|\Pi_{H(x)^\perp}|w\rangle \\ &\leq \widehat{W}_+(P) + \widehat{W}_+(P)\frac{\kappa}{W_-(P)} + 2\widehat{W}_+(P)\sqrt{\frac{\kappa}{W_-(P)}} \leq (1 + \kappa + 2\sqrt{\kappa})\widehat{W}_+(P). \end{aligned}$$

Note that we could assume that $\widehat{W}_-(P) \geq 1$ because $\|w_0\| \leq 1$.

We complete the proof by extending to the general case. Let P be any span program that κ-approximates f. By applying Theorem 52 and Corollary 53, we can get a span program, P_0, with $\||w_0\rangle\| = 1$, $W_-(P_0) \leq 2$, $\widehat{W}_+(P_0) \leq C(P)^2 + 2$, and $s(P_0) = s(P) + 2$, that $\sqrt{\kappa}$-approximates f. We can then apply the construction described above, iteratively, d times, to get a span program P_d that $\sqrt{\kappa}^{2^d} = \kappa^{2^{d-1}}$-approximates f, with

$$s(P_d) = s(P_0)^{2^d} = (s(P)+2)^{2^d},$$

$$W_-(P_d) \leq 2^{2^d}, \qquad \text{and} \qquad \widehat{W}_+(P_d) \leq 4^d \widehat{W}_+(P_0) \leq 4^d C(P)^2 + 2 \cdot 4^d.$$

Setting $d = \log\left(\frac{\log \frac{1}{\kappa'}}{\log \frac{1}{\kappa}}\right) + 1$ gives the desired κ'. ◁

B Proofs of Lemma 46 and Lemma 47

We will prove the lemmas as a collection of claims. Fix $T' \geq T$ and $M' \geq M$ with which to run the algorithm. Suppose $\Phi(x)$ outputs $|\psi(x)\rangle = \sqrt{p_x}|0\rangle_A|\Phi_0(x)\rangle + \sqrt{1-p_x}|1\rangle_A|\Phi_1(x)\rangle$, and let $\tilde{p}$ denote the estimate output by the algorithm. We will let $U\mathcal{O}_x = \sum_j e^{i\sigma_j(x)}|\lambda_j^x\rangle\langle\lambda_j^x|$ be an eigenvalue decomposition.

▷ Claim 54. If $f(x) = 0$ then $\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \frac{1}{M^2}$.

Proof. Since the algorithm computes f with bounded error, the probability of accepting x is at most $1/3$, so $\tilde{p} \leq \delta$ with probability at most $1/3$.

Amplitude estimation is just phase estimation of a unitary W_Φ such that $|\psi(x)\rangle$ is in the span of $e^{\pm 2i\theta_x}$-eigenvectors of W_Φ, where $p_x = \sin^2\theta_x$, $\theta_x \in [0, \pi/2)$ [4]. One can show that the probability of outputting an estimate $\tilde{p} = 0$ is $\sin^2(M'\theta_x)/(M'^2\sin^2(\theta_x))$, so

$$\frac{1}{3} \geq \frac{\sin^2(M'\theta_x)}{M'^2\sin^2(\theta_x)}.$$

If $M'\theta_x \leq \frac{\pi}{2}$, then this would give $\frac{1}{3} \geq \frac{4}{\pi^2}$, which is a contradiction. Thus, we have:

$$M'\theta_x > \frac{\pi}{2} \quad \Rightarrow \quad \frac{2\theta_x}{\pi} > \frac{1}{M'} \quad \Rightarrow \quad \sin\theta_x > \frac{1}{M'} \quad \Rightarrow \quad \sqrt{p_x} > \frac{1}{M'}.$$

Since $\Phi(x)$ is the result of running phase estimation, we have

$$p_x = \sum_j |\langle\lambda_j^x|\psi_0\rangle|^2 \frac{\sin^2(T'\sigma_j(x)/2)}{T'^2\sin^2(\sigma_j(x)/2)} \leq \|\Pi_\Theta(x)|\psi_0\rangle\|^2 + \frac{\pi^2}{T'^2\Theta^2},$$

for any Θ. In particular, if Δ is less than the spectral gap of $U\mathcal{O}_x$, we have $\|\Pi_\Delta(x)|\psi_0\rangle\| = \|\Pi_0(x)|\psi_0\rangle\|$, so

$$\frac{1}{M'^2} < \|\Pi_0(x)|\psi_0\rangle\|^2 + \frac{\pi^2}{T'^2\Delta^2}.$$

This is true for any choices $T' \geq T$ and $M' \geq M$, so we must have:

$$\frac{1}{M^2} \leq \|\Pi_0(x)|\psi_0\rangle\|^2. \qquad \triangleleft$$

▷ Claim 55. If $f(x) = 1$ and $\delta = 0$, then for any $d < \frac{\sqrt{8}}{\pi}$, $\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 = 0$.

Proof. Suppose towards a contradiction that $\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 > 0$. Then $p_x > 0$, and some sufficiently large $M' \geq M$ would detect this and cause the algorithm to output 0, so we must actually have $\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 = 0$. In fact, in order to sure that no large enough value M' detects amplitude > 0 on $|0\rangle_A$, we must have $p_x = 0$ whenever $f(x) = 1$. That means that when $f(x) = 1$, the algorithm never outputs 0, so the algorithm has one-sided error. ◁

▷ Claim 56. There is some constant c such that if $f(x) = 0$ and $\delta > 0$ then $\|\Pi_0(x)|\psi_0\rangle\|^2 > \delta(1 + c)$.

Proof. Recall that $\tilde{p} \in \{\sin^2(\pi m/M') : m = 0, \ldots, M' - 1\}$. We will restrict our attention to choices M' such that for some integer d,

$$\sin^2 \frac{d\pi}{M'} \leq \delta < \sin^2 \frac{(d + 1/3)\pi}{M'}.$$

To see that such a choice exists, let τ be such that $\delta = \sin^2 \tau$, and note that the condition holds as long as $d \leq \frac{\tau M'}{\pi} < d + 1/3$ for some d, which is equivalent to saying that $\lfloor \frac{3\tau M'}{\pi} \rfloor = 0 \mod 3$. If $K = \lfloor \frac{1}{2} \frac{\pi}{3\tau} \rfloor$, then for any $M' \geq M$, and $\ell \geq 0$, define $M_\ell = M' + \ell K$. Then for any $\ell > 0$,

$$\frac{3\tau}{\pi} M_\ell - \frac{3\tau}{\pi} M_{\ell-1} = \frac{3\tau}{\pi} K \in \left[\frac{1}{2} - \frac{3\tau}{\pi}, \frac{1}{2}\right],$$

so there must be one $\ell \in \{0, \ldots, 6\}$ such that $\lfloor \frac{3\tau}{\pi} M_\ell \rceil = 0 \mod 3$. In particular, there is some choice M_ℓ satisfying the condition such that (using some $M' \leq \frac{1}{\sqrt{\delta}}$):

$$\sqrt{\delta} M_\ell \leq \sqrt{\delta} \left(\frac{1}{\sqrt{\delta}} + 6\frac{\pi}{6\tau}\right) = 1 + \frac{\pi \sin \tau}{\tau} \leq 1 + \pi. \tag{3}$$

We will use this value as our M' for the remainder of this proof.

Let $p_x = \sin^2 \theta_x$ for $\theta_x \in [0, \pi/2]$. Let z be an integer such that $\Delta = \theta_x - \pi z/M'$ has $|\Delta| \leq \frac{\pi}{2M'}$. Then the outcome $\tilde{p} = \sin^2 \frac{\pi z}{M'}$ has probability:

$$\frac{1}{M'^2} \left| \sum_{t=0}^{M'-1} e^{i2t(\theta_x - \pi z/M')} \right|^2 = \frac{1}{M'^2} \left| \sum_{t=0}^{M'-1} e^{i2t\Delta} \right|^2 = \frac{\sin^2(M'\Delta)}{M'^2 \sin^2 \Delta} \geq \frac{4}{\pi^2},$$

since $|M'\Delta| \leq \frac{\pi}{2}$. Thus, by correctness, we must have $\sin^2(\pi z/M') > \delta \geq \sin^2 \frac{d\pi}{M'}$. Thus $z > d$, so

$$\frac{(d+1)\pi}{M'} \leq \frac{z\pi}{M'} = \theta_x - \Delta \leq \theta_x + \frac{\pi}{2M'}.$$

Thus:

$$\frac{(d + 1/3)\pi}{M'} + \frac{2\pi}{3M'} \leq \theta_x + \frac{\pi}{2M'}$$

$$\sin\left(\frac{(d + 1/3)\pi}{M'} + \frac{\pi}{6M'}\right) \leq \sin \theta_x$$

$$\sin\left(\frac{(d + 1/3)\pi}{M'}\right) \cos \frac{\pi}{6M'} + \cos\left(\frac{(d + 1/3)\pi}{M'}\right) \sin \frac{\pi}{6M'} \leq \sqrt{p_x}$$

$$\sqrt{\delta}\sqrt{1 - \sin^2 \frac{\pi}{6M'}} + \sqrt{1 - \delta} \sin \frac{\pi}{6M'} \leq \sqrt{p_x}$$

When $\sin^2 \frac{\pi}{6M'} \leq 1 - \delta$, which we can assume, the above expression is minimized when $\sin^2 \frac{\pi}{6M'}$ is as small as possible. We have, using $M' \leq \frac{1+\pi}{\sqrt{\delta}}$, from (3):

$$\sin^2 \frac{\pi}{6M'} \geq \frac{4}{36M'^2} \geq \frac{\delta}{9(1+\pi)^2}.$$

Thus, continuing from above, letting $k = \frac{1}{9(1+\pi)^2}$, we have:

$$\sqrt{\delta}\sqrt{1-k\delta} + \sqrt{1-\delta}\sqrt{k\delta} \leq \sqrt{p_x}$$
$$\delta(1-k\delta) + (1-\delta)k\delta + 2\delta\sqrt{k(1-\delta)(1-k\delta)} \leq p_x$$

Next, notice that $(1-k\delta)(1-\delta)$ is minimized when $\delta = \frac{1+k}{2k}$, but $\delta \leq \frac{1}{2} < \frac{1+k}{2k}$, so we have, using $k < 1$ and $\delta \leq 1/2$:

$$\delta(1 + k(1-2\delta) + 2\sqrt{k}\sqrt{(1-k/2)(1-1/2)}) \leq p_x$$
$$\delta(1 + 0 + \sqrt{k}) \leq p_x.$$

Since $\Phi(x)$ is the result of running phase estimation of $U\mathcal{O}_x$ for $T' \geq T$ steps, we have:

$$p_x = \sum_j |\langle \lambda_j^x | \psi_0 \rangle|^2 \frac{\sin^2(\frac{T'\sigma_j(x)}{2})}{(T')^2 \sin^2(\frac{\sigma_j(x)}{2})},$$

so in particular, for any $\Theta \in [0, \pi)$, we have

$$p_x \leq \|\Pi_\Theta(x)|\psi_0\rangle\|^2 + \sum_{j:|\sigma_j(x)|>\Theta} |\langle \lambda_j^x | \psi_0 \rangle|^2 \frac{1}{(T')^2 \sin^2(\frac{\Theta}{2})}.$$
$$\leq \|\Pi_\Theta(x)|\psi_0\rangle\|^2 + \|(I - \Pi_\Theta(x))|\psi_0\rangle\|^2 \frac{\pi^2}{(T')^2\Theta^2}.$$

In particular, for any $\Theta < \Delta$ where Δ is the spectral gap of $U\mathcal{O}_x$, we have $\|\Pi_\Theta(x)|\psi_0\rangle\| = \|\Pi_0(x)|\psi_0\rangle\|$, so for any $T' \geq T$, we have

$$\|\Pi_0(x)|\psi_0\rangle\|^2 + \frac{\pi^2}{(T')^2\Delta^2} \geq p_x \geq \delta(1+\sqrt{k}).$$

Since this holds for any $T' \geq T$, we get $\|\Pi_0(x)|\psi_0\rangle\|^2 \geq \delta(1+\sqrt{k})$. The proof is completed by letting $c = \sqrt{k}$. ◁

▷ Claim 57. If $f(x) = 1$ and $\delta > 0$ then $\left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 (1 - d^2\pi^2/8) \leq \delta$.

Proof. If $|\lambda\rangle$ is an $e^{i\theta}$-eigenvector of $U\mathcal{O}_x$ for some $|\theta| \leq d\pi/T < \sqrt{8}/T$, then the probability of measuring 0 in the phase register upon performing T steps of phase estimation is:

$$p_x(\theta) := \frac{1}{T^2}\left|\sum_{t=0}^{T-1} e^{it\theta}\right|^2 = \frac{\sin^2 \frac{T\theta}{2}}{T^2 \sin^2 \frac{\theta}{2}}.$$

Let $\varepsilon(x) = 1 - \frac{\sin^2 x}{x^2}$ for any x. It is simple to verify that $\varepsilon(x) \leq x^2/2$ for any x, and $\varepsilon(x) \in [0,1]$ for any x. So we have:

$$p_x(\theta) \geq \frac{(T\theta/2)^2(1-\varepsilon(T\theta/2))}{T^2(\theta/2)^2(1-\varepsilon(\theta/2))} \geq 1 - \varepsilon(T\theta/2) \geq 1 - \frac{T^2\theta^2}{8}.$$

Thus, we conclude that

$$p_x \geq \left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 \left(1 - \frac{T^2}{8}\frac{d^2\pi^2}{T^2}\right) = \left\|\Pi_{d\pi/T}(x)|\psi_0\rangle\right\|^2 \left(1 - \frac{d^2\pi^2}{8}\right).$$

If this is $> \delta$, then with some sufficiently large $M' \geq M$, amplitude estimation would detect this and cause the algorithm to output 0 with high probability. ◁

DEEP-FRI: Sampling Outside the Box Improves Soundness

Abstract

Motivated by the quest for scalable and succinct zero knowledge arguments, we revisit worst-case-to-average-case reductions for linear spaces, raised by [Rothblum, Vadhan, Wigderson, STOC 2013]. The previous state of the art by [Ben-Sasson, Kopparty, Saraf, CCC 2018] showed that if some member of an affine space U is δ-far in relative Hamming distance from a linear code V – this is the worst-case assumption – then most elements of U are almost-δ-far from V – this is the average case. However, this result was known to hold only below the "double Johnson" function of the relative distance δ_V of the code V, i.e., only when $\delta < 1 - (1 - \delta_V)^{1/4}$.

First, we increase the soundness-bound to the "one-and-a-half Johnson" function of δ_V and show that the average distance of U from V is nearly δ for any worst-case distance δ smaller than $1 - (1 - \delta_V)^{1/3}$. This bound is tight, which is somewhat surprising because the one-and-a-half Johnson function is unfamiliar in the literature on error correcting codes.

To improve soundness further for Reed Solomon codes we sample outside the box. We suggest a new protocol in which the verifier samples a single point z outside the box D on which codewords are evaluated, and asks the prover for the value at z of the interpolating polynomial of a random element of U. Intuitively, the answer provided by the prover "forces" it to choose one codeword from a list of "pretenders" that are close to U. We call this technique Domain Extending for Eliminating Pretenders (DEEP).

The DEEP method improves the soundness of the worst-case-to-average-case reduction for RS codes up their list decoding radius. This radius is bounded from below by the Johnson bound, implying average distance is approximately δ for all $\delta < 1 - (1 - \delta_V)^{1/2}$. Under a plausible conjecture about the list decoding radius of Reed-Solomon codes, average distance from V is approximately δ for all δ. The DEEP technique can be generalized to all linear codes, giving improved reductions for capacity-achieving list-decodable codes.

Finally, we use the DEEP technique to devise two new protocols:

- An Interactive Oracle Proof of Proximity (IOPP) for RS codes, called DEEP-FRI. The soundness of the protocol improves upon that of the FRI protocol of [Ben-Sasson et al., ICALP 2018] while retaining linear arithmetic proving complexity and logarithmic verifier arithmetic complexity.
- An Interactive Oracle Proof (IOP) for the Algebraic Linking IOP (ALI) protocol used to construct zero knowledge scalable transparent arguments of knowledge (ZK-STARKs) in [Ben-Sasson et al., eprint 2018]. The new protocol, called DEEP-ALI, improves soundness of this crucial step from a small constant $< 1/8$ to a constant arbitrarily close to 1.

1 Introduction

Arithmetization is a marvelous technique that can be used to reduce problems in computational complexity, like verifying membership in a nondeterministic language, to questions about membership of vectors in algebraic codes like Reed-Solomon (RS) and Reed-Muller (RM) codes [17, 15]. One of the end-points of such a reduction is the RS proximity testing (RPT) problem. It is a problem of inherent theoretical interest, but also of significant practical importance because it is used in recent constructions of succinct zero knowledge (ZK) arguments including Ligero [1], Aurora [5], and Scalable Transparent ARguments of Knowledge (ZK-STARKs) [2]. We discuss this connection after describing the problem and our results.

In the RPT problem a verifier is given oracle access to a function $f : D \to \mathbb{F}$, we call $D \subset \mathbb{F}$ the *evaluation domain*, and is tasked with distinguishing between the "good" case that f is a polynomial of degree at most d and the "bad" case in which f is δ-far in relative Hamming distance from all degree-d polynomials. To achieve succinct verification time, poly-logarithmic in d, we must allow the verifier some form of interaction with a prover – the party claiming that $\deg(f) \leq d$. Initially, this interaction took the form of oracle access to a probabilistically checkable proof of proximity (PCPP) [7] provided by the prover in addition to f. Indeed, in this model the RPT problem can be "solved" with PCPPs of quasilinear size $|D|\mathsf{poly}\log|D|$, constant query complexity and constant soundness [11, 13]. However, the concrete complexity of prover time, verifier time and communication complexity are rather large, even when considering practical settings that involve moderately small instance sizes.

To improve prover, verifier, and communication complexity for concrete (non-asymptotic) size problems, the Interactive Oracle Proofs of Proximity (IOPP) model is more suitable [18, 6, 4]. This model can be viewed as a multi-round PCPP. Instead of having the prover write down a single proof π, in the IOPP setting the proof oracle is produced over a number of rounds of interaction, during which the verifier sends random bits and the prover responds with additional (long) messages to which the verifier is allowed oracle access. The additional rounds of interaction allow for a dramatic improvement in the asymptotic and concrete complexity of solving the RPT problem. In particular, the Fast RS IOPP (FRI) protocol of [3] has linear prover arithmetic complexity, logarithmic verifier arithmetic complexity and constant soundness. Our results regarding the RPT problem improve the soundness of this protocol and offer a better protocol in terms of soundness in the high-error regime (also known as the "list decoding" regime).

Soundness analysis of FRI reduces to the following natural "worst-case-to-average-case" question regarding linear spaces, which is also independently very interesting for the case of general (non-RS) codes. This question was originally raised in a different setting by [20] and we start by discussing it for general linear codes before focusing on the special, RS code, case.

1.1 Maximum distance vs average distance to a linear code

Recall that the relative Hamming distance between $u, v \in \mathbb{F}^D$, denoted $\Delta(u, v)$, is the fraction of entries $i \in D$ such that $u_i \neq v_i$, and the relative Hamming distance between u and a set $V \subset \mathbb{F}^D$ is $\Delta(u, U) = \min_{v \in V} \Delta(u, v)$. Suppose that $U \subset \mathbb{F}^D$ is a "line", a 1-dimensional[1] affine space over $\mathbb{F}$. Let $u^* \in \mathbb{F}^D$ denote the origin of this line and u be its slope, so that $U = \{u_x = u^* + xu \mid x \in \mathbb{F}\}$. For a fixed linear space $V \subset \mathbb{F}^D$, pick u^* to be the element in U that is farthest from V, denoting by $\delta_{\max}$ its relative Hamming distance (from V). This is our worst-case assumption. Letting $\delta_x = \Delta(u_x, V)$, what can be said about the *expected* distance $\mathbf{E}_{x \in \mathbb{F}}[\delta_x]$ of u_x from V?

Rothblum, Vadhan and Wigderson showed that $\mathbf{E}_x[\delta_x] \geq \frac{\delta_{\max}}{2} - o(1)$ for all spaces U and V, where, here and below, $o(1)$ denotes negligible terms that approach 0 as $|\mathbb{F}| \to \infty$ [20]. A subset of the co-authors of this paper [9] improved this to $\mathbf{E}[\delta_x] \geq 1 - \sqrt{1 - \delta_{\max}} - o(1)$, showing the average distance scales roughly like the Johnson list-decoding function of $\delta_{\max}$, where $J(x) := 1 - \sqrt{1 - x}$. In both of these bounds the expected distance is strictly smaller than $\delta_{\max}$. However, the latter paper also showed that when V is a (linear) error correcting code with large relative distance δ_V, if $\delta_{\max}$ is smaller than the "double Johnson" function of δ_V, given by $J^{(2)}(x) := J(J(x))$, then the average distance hardly deteriorates,

$$\mathbf{E}[\delta_x] \geq \min\left(\delta_{\max}, J^{(2)}(\delta_V)\right) - o(1) = \min\left(\delta_{\max}, 1 - \sqrt[4]{1 - \delta_V}\right) - o(1) \tag{1}$$

and the equation above summarizes the previous state of affairs on this matter.

Our first result is an improvement of Equation (1) to the "one-and-a-half-Johnson" function $J^{(1.5)}(x) = 1 - (1 - x)^{1/3}$. Lemma 1 says that for codes V of relative Hamming distance δ_V,

$$\mathbf{E}[\delta_x] \geq \min\left(\delta_{\max}, J^{(1.5)}(\delta_V)\right) - o(1) = \min\left(\delta_{\max}, 1 - \sqrt[3]{1 - \delta_V}\right) - o(1). \tag{2}$$

Our second result shows that Equation (2) is tight, even for the special case of V being an RS code. We find this result somewhat surprising because the $J^{(1.5)}(x)$ function is not known to be related to any meaningful coding theoretic notion. The counter-example showing the tightness of Equation (2) arises for very special cases, in which (i) $\mathbb{F}$ is a binary field (of characteristic 2), (ii) the rate ρ is precisely $1/8 = 2^{-3}$ and, most importantly, (iii) the evaluation domain D equals all of $\mathbb{F}$.Roughly speaking, the counter-example uses functions $u^*, u : \mathbb{F}_{2^n} \to \mathbb{F}_{2^n}$ that are $3/4 = 1 - \rho^{2/3}$-far from polynomials of degree $\rho 2^n$ yet *pretend* to be low-degree because for all $x \in \mathbb{F}_{2^n} \setminus \{0\}$ the function $u^* + xu$ is $1/2 = \sqrt[3]{\rho}$-close to a polynomial of degree $\rho 2^n$. See Lemma 22 for details.

Our next set of results, which we discuss below, show how to go beyond the above limitation through a new interactive proximity proving technique.

1.2 Domain Extension for Eliminating Pretenders (DEEP)

The case that interests us most is when V is an RS code (although we will return to the discussion of general linear codes later). Henceforth, the RS code of rate ρ evaluated over D is

$$\mathsf{RS}[\mathbb{F}, D, \rho] := \{f : D \to \mathbb{F} \mid \deg(f) < \rho|D|\}.$$

RS codes are maximum distance separable (MDS), meaning that $\delta_V = 1 - \rho$ and so Equation (2) simplifies to

$$\mathbf{E}[\delta_x] \geq \min(\delta_{\max}, 1 - \sqrt[3]{\rho}) - o(1). \tag{3}$$

[1] The generalization of our results to spaces U of dimension > 1 is straightforward by partitioning U into lines through u^* and applying these results to each line.

This improved bound can be translated, using some extra work, to FRI soundness analysis with similar guarantees. Specifically, Equation (3) implies that for $f : D \to \mathbb{F}$ that is δ-far from $\mathsf{RS}[\mathbb{F}, D, \rho]$, the soundness error of a single invocation of the FRI QUERY test (which requires $\log |D|$ queries) is at most $\max\{1-\delta, \sqrt[3]{\rho}\}$, and this can be plugged into ZK-STARKs like [2] and ZK-SNARGs like Aurora [5]. Roughly speaking, if the rejection probability is of δ-far words is $\max(\delta, \delta_0)$ then to reach soundness error less than $2^{-\lambda}$ for codes of blocklength n, communication complexity (and verifier complexity) scale roughly like $\frac{\lambda}{\log \delta_0} \cdot c \cdot \log n$ for some constant c. Thus, the improvement from Equation (1) to Equation (2) translates to a 25% reduction in verifier complexity (from $\frac{4\lambda}{\log \rho} \cdot c \cdot \log n$ to $\frac{3\lambda}{\log \rho} \cdot c \cdot \log n$).

To break the soundness bound of Equation (2) and thereby further reduce verifier complexity in the afore-mentioned systems, we suggest a new method. We discuss it first for RS codes, then generalize to arbitrary linear codes. If $u^*, u : D \to \mathbb{F}$ are indeed the evaluation of two degree d polynomials, say, P^* and P, our verifier will artificially *extend the domain* D to a larger one $\bar{D}$, sample uniformly $z \in \bar{D}$ and ask for the evaluation of $P^*(z)$ and $P(z)$. The answers provided by the prover can now be applied to modify each of u^* and u in a *local* manner to reflect the new knowledge, and along the way also prune down the large list of polynomials which u^* and u might pretend to be. If $\alpha_z^* = P^*(z), \alpha_z = P(z)$ are the honest prover's answers to the query z, then $(X - z)$ divides $P^*(X) - \alpha_z^*$ and likewise $(X - z)|P(X) - \alpha_z$. Letting $\alpha_x = \alpha^* + x\alpha$ and $P_x(X) = P^*(X) + xP(X)$ it follows that $(X - z)|P_x(X) - \alpha_x$. Consider now the soundness of this procedure. In the extreme case that u^* has a small list of polynomials that, each, somewhat agree with it, then with high probability over z, any answer provided by the prover will agree with at most one of the polynomials in this list. The proof of our main technical result, Theorem 3, formalizes this intuition. For radius δ, let L_δ^* be the maximal list size,

$$L_\delta^* = \max_{u^* \in \mathbb{F}^D} |\{v \in V \mid \Delta(u^*, v) < \delta\}|$$

where Δ denotes relative Hamming distance. Let $V|_{u_x(z)=\alpha_x}$ be the restriction of V to codewords that are evaluations of polynomials of degree at most d that, additionally, evaluate to α_x on z. Our main Theorem 3 shows that if $\Delta(u^*, V) = \delta_{\max}$ then for any pair of answers α_z^*, α_z given in response to query z,

$$\mathbf{E}_{z,x}\left[\Delta(u_x, V|_{u_x(z)=\alpha_x})\right] \geq \delta_{\max} - L_\delta^* \cdot \left(\frac{\rho|D|}{|\bar{D}|}\right)^{1/3} - o(1). \tag{4}$$

The Johnson bound (Theorem 20) says that when $\delta < J(1-\rho) = 1 - \sqrt{\rho}$ we have $L_\delta^* = O(1)$ and this improves the worst-case-to-average-case result from that of Equation (2) to a bound that matches the Johnson bound:

$$\mathbf{E}_{z,x}[\Delta(u_x, V|_{u_x(z)=\alpha_x})|] \geq \min(\delta_{\max}, J(\delta_V)) - o(1) = \min(\delta_{\max}, \sqrt{\rho}) - o(1). \tag{5}$$

The exact behavior of the list size of Reed-Solomon codes beyond the Johnson bound is a famous open problem. It may be the case that the list size is small for radii far greater than the Johnson bound; in fact, for most domains D this is roughly known to hold [21]. If it holds that that list sizes are small all the way up to radius equal to the distance $\delta_V = 1 - \rho$ (i.e., if Reed-Solomon codes meet list-decoding capacity), then Equation (5) implies that the technique suggested here has optimal soundness for (nearly) all distance parameters.

1.3 DEEP-FRI as an application of domain extended sampling

Applying the technique of domain extension for eliminating pretenders to the FRI protocol requires a modification that we discuss next, after recalling that protocol.

Fast RS IOPP (FRI)

The FRI protocol can be described as a process of "randomly folding" an inverse Fast Fourier Transform (iFFT). The classical iFFT receives as input a function $f : \langle\omega\rangle \to \mathbb{F}$ where ω generates a multiplicative group of order 2^k for integer k. The iFFT computes (in arithmetic complexity $O(k2^k)$) the interpolating polynomial $\tilde{f}(X)$ of the function f. This computation follows by computing (in linear time) a pair of functions $f_0, f_1 : \langle\omega^2\rangle \to \mathbb{F}$, recalling $|\langle\omega^2\rangle| = \frac{1}{2}|\langle\omega\rangle|$. Their interpolants $\tilde{f}_0, \tilde{f}_1$ are then used to compute in linear time the original interpolant $\tilde{f}$ of f.

The FRI protocol is an IOPP, which means that a prover interacts with a verifier by submitting oracles in response to randomness received by the verifier (as explained earlier in this section). The prover's goal in the FRI protocol is to convince the verifier that the function f, to which the verifier has oracle access, is a member of the RS code evaluated over $\langle\omega\rangle$ and of rate ρ. Thus, the protocol starts with the prover committing to f as above. The verifier now samples a random $x^{(0)} \in \mathbb{F}$ and sends it to the prover, completing the first round of interaction. In the second round, the prover commits to a function $f^{(1)} : \langle\omega^2\rangle \to \mathbb{F}$ that is supposedly the $x^{(0)}$-linear combination of f_0, f_1 used in the iFFT above; namely, $f^{(1)}$ should be equal to $f_0 + x^{(0)} f_1$. It turns out that if f is indeed of degree less than $\rho|\langle\omega\rangle|$ then for all $x^{(0)}$ sampled by the verifier, the second function $f^{(1)}$ is of degree less than $\rho|\langle\omega^2\rangle|$ as well. The tricky part is showing that when f is δ-far from $\mathsf{RS}[\mathbb{F}, \langle\omega\rangle, \rho]$ this also holds with high probability (over x) for $f^{(1)}$ and some δ' that is as close as possible to δ. (One can show that invariably we have $\delta' \leq \delta$, i.e., the green line of Figure 1 is an upper bound on soundness of both FRI and the new DEEP-FRI protocol described below.)

The worst-case-to-average-case results of Equation (2) and Lemma 1 can be converted to similar improvements for FRI, showing that for $\delta < 1 - \sqrt[3]{\rho}$ we have $\delta' \approx \delta$. This follows directly from the techniques of [9, Section 7] (see the red line in Figure 1). But to use the new DEEP technique of Equation (4) and Theorem 3 in order to improve soundness of an RS-IOPP, we need to modify the FRI protocol, leading to a new protocol that is aptly called DEEP-FRI. Instead of constructing $f^{(1)}$ directly, our verifier first samples $z^{(0)} \in \mathbb{F}$ and queries the prover for the evaluation of the interpolant of $f^{(0)}$ on $z^{(0)}$ and $-z^{(0)}$. After the answers $\alpha_{z^{(i)}}, \alpha_{-z^{(i)}}$ have been recorded, the verifier proceeds by sampling $x^{(0)}$ and expects the prover to submit $f^{(1)}$, which is the linear combination of f'_0, f'_1 derived from the modification f' of f that takes into account the answers $\alpha_{z^{(i)}}, \alpha_{-z^{(i)}}$. Assuming $\tilde{f}$ is the interpolant of f, an honest prover would set $f'(X) := (\tilde{f}(X) - U(X))/(Z(X))$ where $U(X)$ is the degree ≤ 1 polynomial that evaluates to $\alpha_{z^{(0)}}$ on $z^{(0)}$ and to $\alpha_{-z^{(0)}}$ on $-z^{(0)}$ and $Z(X)$ is the monic degree 2 polynomial whose roots are $z^{(0)}$ and $-z^{(0)}$. As shown in Section 4, the soundness bounds of Equation (4) and Theorem 3 now apply to DEEP-FRI. This shows that the soundness of DEEP-FRI, i.e., the rejection probability of words that are δ-far from $\mathsf{RS}[\mathbb{F}, D, \rho]$) is roughly δ for any δ that is smaller than the maximal radius for which list-sizes are "small". Figure 1 summarizes the results described here.

Practical Implications to reducing RPT query complexity

A number of recent implementations of zero knowledge (ZK) argument systems rely on RPT protocols [1, 2, 5]. These systems are notable for their (i) lack of reliance on number theoretic cryptographic assumptions (like hardness of the discrete log problem) and their (ii) *transparency* – all verifier messages are public random coins (so-called Arthur-Merlin

protocols)[2]. The FRI and DEEP-FRI protocols are efficient RPT solutions and, in fact, the FRI protocol is already deployed in code in the Github repositories libSTARK and libIOP. To construct a ZK system with sufficiently small soundness error, smaller than $2^{-\lambda}$, one needs to bound the soundness error of the RPT used in it. Viewed from this angle, the previous analysis of FRI by [9] proved that $\frac{\lambda\rho}{4}$ queries to the FRI protocol suffice to reduce soundness error below $2^{-\lambda}$. Lemma 2 lowers this number to $\frac{\lambda\rho}{3}$ for FRI. Theorem 8 shows that a number $\frac{\lambda\rho}{2}$ of queries for the same target soundness is enough for DEEP-FRI, and assuming Conjecture 21 the number of queries reduces to $\lambda\rho$, which is optimal as it matches the soundness error upper bound for FRI and DEEP-FRI.

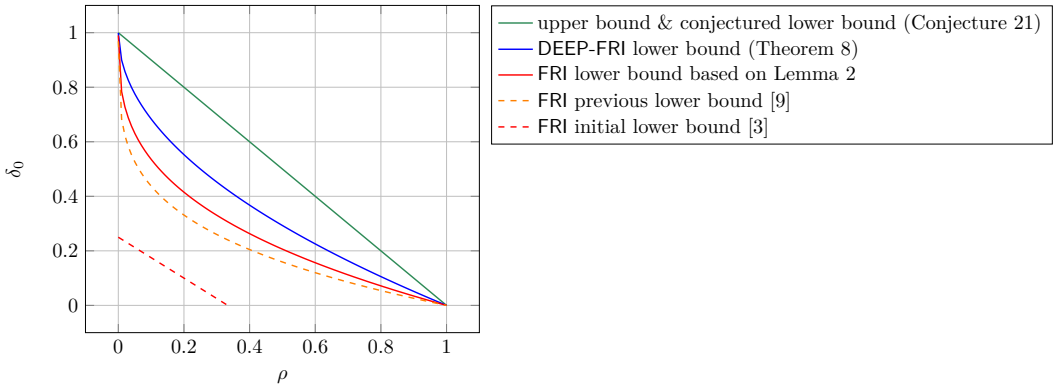

Figure 1 FRI and DEEP-FRI soundness threshold δ_0 as a function of RS code rate ρ, for a single invocation of the QUERY phase, as field size $q \to \infty$. $\delta_0(\rho)$ is defined to be the largest distance parameter δ for which soundness (rejection probaiblity) of a single invocation of the FRI/DEEP-FRI QUERY is $\delta - o(1)$. Higher lines are better. The top line is the trivial upper bound on soundness which applies to both FRI and DEEP-FRI; the bottom line is the soundness of the original analysis of [3]. Dashed lines represent prior results. The red line is the (tight) soundness lower bound for FRI and the blue line is a lower bound on DEEP-FRI soundness. Under a plausible conjecture for Reed-Solomon list-decodability (Conjecture 21), the actual soundness is as high as the green line.

Organization of the rest of the paper

Section 2 gives an improved worst-to-average case reductions for general spaces. Section 3 presents our main technical result, showing that the DEEP method improves worst-to-average case reductions for RS codes up to the Johnson bound (provably) and perhaps even beyond. Details of the two main applications of the DEEP method follow: the DEEP-FRI protocol in Section 4 obtains better soundness than the state of the art FRI protocol, and the DEEP-ALI protocol which improves soundness in ZK-STARK systems is explained in Section 5.

2 Improved High-error Distance Preservation

Our first result gives better distance preservation results for linear codes V of relative distance λ. The previous state-of-the-art [9] said that when a 1-dimensional affine space U contains some element u^* that is $\delta_{\max} = \Delta(u^*, V)$ far from V, then

$$\mathbf{E}_{u \in U}[\Delta(u, V)] \geq \min(\delta_{\max}, 1 - J^{(2)}(\lambda)) - o(1).$$

[2] By contrast, the ZK-SNARK used, e.g., in the Zcash cryptocurrency, relies on a setup phase involving non-transparent randomness (and revealing the random coins that are used to create the system would compromise its security).

The following lemma improves the average-case distance to

$$\mathbf{E}_{u\in U}[\Delta(u,V)] \geq \min(\delta_{\max}, 1 - J^{(1.5)}(\lambda)) - o(1).$$

Later on, in Appendix B, we will show that this result is tight (for a sub-family of RS codes).

▶ **Lemma 1** (One-and-half Johnson distance preservation). *Let $V \subseteq \mathbb{F}_q^n$ be a linear code of distance $\lambda = \Delta(V) \triangleq \min\{\Delta(v,v') \mid v \neq v', v, v' \in V\}$. Let $\epsilon, \delta > 0$ with $\epsilon < 1/3$ and $\delta < 1 - (1 - \lambda + \epsilon)^{1/3}$.*

Suppose $u^* \in \mathbb{F}_q^n$ is such that $\Delta(u^*, V) > \delta + \epsilon$. Then for all $u \in \mathbb{F}_q^n$, there are at most $2/\epsilon^2$ values of $x \in \mathbb{F}_q$ such that $\Delta(u^* + xu, V) < \delta$.

This result is the contra-positive statement of the following, more informative, version of it, that we prove below.

▶ **Lemma 2** (One-and-half Johnson distance preservation – positive form). *Let $V \subseteq \mathbb{F}_q^D$ be a linear code of distance $\lambda = \Delta(V)$. Let $\epsilon, \delta > 0$ with $\epsilon < 1/3$ and $\delta < 1 - (1 - \lambda + \epsilon)^{1/3}$. Let $u, u^* \in \mathbb{F}_q^D$ satisfy*

$$\Pr_{x\in\mathbb{F}_q}[\Delta(u^* + xu, V) < \delta] \geq \frac{2}{\epsilon^2 q}. \tag{6}$$

Then there exist $v, v^* \in V$ and $C \subseteq D$ such that the following three statements hold simultaneously:

- $|C| \geq (1 - \delta - \epsilon)|D|$,
- $u|_C = v|_C$, *and*
- $u^*|_C = v^*|_C$.

Observe that if u, u^* satisfy Equation (6) then the v, v^*, C deduced by Lemma 2 have the property that for *all* $x \in \mathbb{F}_q$, we have $\Delta(u^* + xu, v^* + xv) \leq \delta + \epsilon$. In other words, the existence of v, v^* and C almost completely explains Equation (6).

Quantitatively weaker statements in this vein were proved by [16, 3] in the low-error case, and by [12, 9] in the high-error case. The proofs of the latter two results used combinatorial tools (the Kővári-Sós-Turán bound and the Johnson bound respectively) that are closely related to one another. Our improved proof below is direct, and is based on the same convexity principle that underlies both the Kővári-Sós-Turán and Johnson bounds.

Proof. Let $u_x = u^* + xu$. Let $A = \{x \mid \Delta(u^* + xu, V) < \delta\}$. For each $x \in A$, let $v_x \in V$ be an element of V that is closest to u_x, and let $S_x \subseteq D$ be the agreement set of u_x and v_x, defined as $S_x = \{y \in D \mid u_x(y) = v_x(y)\}$.

For x, β, γ picked uniformly from A and y picked uniformly from D, we have:

$$\begin{aligned}\mathbf{E}_{x,\beta,\gamma}[|S_x \cap S_\beta \cap S_\gamma|/|D|] &= \mathbf{E}_{y,x,\beta,\gamma}[1_{y\in S_x\cap S_\beta\cap S_\gamma}] = \mathbf{E}_y[\mathbf{E}_x[1_{y\in S_x}]^3] \\ &\geq \mathbf{E}_{y,x}[1_{y\in S_x}]^3 \geq (1-\delta)^3 > 1 - \lambda + \epsilon.\end{aligned}$$

The second equality above follows from the independence of the events $y \in S_x, y \in S_\beta, y \in S_\gamma$ given $y \in D$. The first inequality is Jensen's and the last inequality is by assumption on $\delta, \lambda, \epsilon$.

Thus $\Pr_{x,\beta,\gamma}[|S_x \cap S_\beta \cap S_\gamma| \geq (1 - \lambda)|D|] \geq \epsilon$. Note that

$$\Pr_{x,\beta,\gamma}[x, \beta, \gamma \text{ are not all distinct}] < 3/|A|.$$

Since $|A| \geq 2/\epsilon^2 > \frac{6}{\epsilon}$ (recall $\epsilon < 1/3$), we have that $3/|A| \leq \epsilon/2$ and hence x, β, γ are all distinct with probability at least $1 - \epsilon/2$. Thus with probability at least $\epsilon/2$ over the choice of x, β, γ, we have that x, β, γ are all distinct and $|S_x \cap S_\beta \cap S_\gamma| > (1 - \lambda)|D|$. This means

that there are distinct x_0, β_0 such that $\Pr_\gamma[|S_{x_0} \cap S_{\beta_0} \cap S_\gamma| > (1-\lambda)|D|] \geq \epsilon/2$. Fix a γ where this happens. Let $S = S_{x_0} \cap S_{\beta_0} \cap S_\gamma$. We have that $(x_0, u_{x_0}), (\beta_0, u_{\beta_0}), (\gamma, u_\gamma)$ are collinear. Thus $(x_0, u_{x_0}|_S), (\beta_0, u_{\beta_0}|_S), (\gamma, u_\gamma|_S)$ are all collinear. By definition of S, we get that: $(x_0, v_{x_0}|_S), (\beta_0, v_{\beta_0}|_S), (\gamma, v_\gamma|_S)$ are all collinear. Since $|S| > (1-\lambda)|D|$ (and recalling that λ is the distance of V), we get that v_γ is determined by $v_\gamma|_S$ via a linear map. This means that $(x_0, v_{x_0}), (\beta_0, v_{\beta_0}), (\gamma, v_\gamma)$ are all collinear.

Thus $\epsilon/2$-fraction of the $\gamma \in A$ have the "good" property that (γ, v_γ) is on the line passing through (x_0, v_{x_0}) and (β_0, v_{β_0}). Write this line as $v^* + xv$ and notice that for all "good" γ we have $v_\gamma = v^* + \gamma v$. Let $A' \subseteq A$ denote the set of good elements for this line, recording that $|A'| \geq |A| \cdot \epsilon/2 \geq 1/\epsilon$.

Thus for $x \in A'$, $\Delta(u^* + xu, v^* + xv) < \delta$. Consider the set $C \subset D$ that is defined by $C = \{y \in D \mid u^*(y) = v^*(y) \text{ AND } u(y) = v(y)\}$. For each $y \in D \setminus C$ there exists at most a single value of $x \in \mathbb{F}_q$ satisfying $u^*(y) + x \cdot u(y) = v^*(y) + x \cdot v(y)$ because $(u^*(y) - v^*(y)) + x \cdot (u(y) - v(y))$ has at most one value x on which it vanishes.

This implies

$$\delta \geq \mathbf{E}_{x \in A'}[\Delta_D(u_x, v_x)] \geq \frac{|D \setminus C|}{|D|} \cdot \left(1 - \frac{1}{|A'|}\right) \geq \left(1 - \frac{|C|}{|D|}\right) \cdot (1 - \epsilon) \geq 1 - \frac{|C|}{|D|} - \epsilon.$$

Rearranging, we get $\frac{|C|}{|D|} \geq 1 - (\delta + \epsilon)$ and this completes the proof. ◀

3 The DEEP Theorem – Using Domain Extension for Eliminating Pretenders (DEEP) and Improving Soundness

We now come to the statement of our improved-soundness distance preservation result. We describe it first for the special case of RS codes. A weighted variant of the theorem is shown in Appendix C.1 because it is used later in the DEEP-FRI protocol (Section 4). We end with Appendix C.2 in which we present a general version of the folowing result, that applies to all linear codes.

3.1 DEEP Theorem for RS codes

The vectors u^*, u discussed in the previous section are now viewed as functions $u^*, u : D \to \mathbb{F}_q$ and we are interested in the distance of a random linear combination $u_x = u^* + x \cdot u$ from the code $V = \mathsf{RS}[\mathbb{F}_q, D, \rho]$, where $x \in \mathbb{F}_q$ is sampled uniformly. Lemma 1 established that if $\max(\Delta(u^*, V), \Delta(u, V)) = \delta_{\max}$, then with high probability (over x), the function u_x will have distance at least $\approx \min(\delta_{\max}, 1 - \rho^{1/3})$ from V.

Lemma 2 roughly gets used in the following way in the FRI protocol. There are two functions $u^*, u : D \to \mathbb{F}_q$ and there is a prover who claims that both are evaluations of low degree polynomials. In order to verify this, the verifier uniformly samples $x \in \mathbb{F}_q$ and considers the function $u_x = u^* + x \cdot u$. Lemma 2 shows that if any of u^*, u is far from being evaluations of a low degree polynomial, then so is $u^* + x \cdot u$. This then gets exploited in the FRI protocol using FFT type ideas.

We now precede the random process of sampling $x \in \mathbb{F}_q$ with a step of *domain extension*, explained next. Assume a prover claims that both u and u^* are evaluations of low degree polynomials (say $P(Y)$ and $P^*(Y)$). So these polynomials can be evaluated also outside of D. Based on this, a verifier first samples $z \in \mathbb{F}_q$ uniformly and asks the prover to reply with two field elements $a^*, a \in \mathbb{F}_q$ which are supposedly equal to $P^*(z), P(z)$, respectively. After receiving these answers, the verifier proceeds as before, sampling uniformly $x \in \mathbb{F}_q$. Then,

setting $b = a^* + x \cdot a$, we examine the distance of u_x from the sub-code $V_{z,b} \subset V$ comprised of all members of V whose interpolating polynomial evaluates to b on input z. The code $V_{z,b}$ is the additive coset (shifted by b) of a low-degree ideal, the ideal generated by $(X - z)$ (cf. Lemma 6).

Using the Johnson Bound (Theorem 20) we prove that with high probability u_x is at least $\approx \min(\delta_{\max}, 1 - \rho^{1/2})$ far from $V_{z,b}$. Assuming RS codes have a larger list-decoding radius (Conjecture 21), we show that with high probability u_x is $\approx \delta_{\max}$-far from $V_{z,b}$ for nearly all values of $\delta_{\max}$. Later, in Section 4, we shall use the improved distance preservation to construct the DEEP-FRI protocol for testing proximity to the RS code with improved soundness.

The statement we give below is given more generally in terms of the list size bound $\mathcal{L}(\mathbb{F}_q, D, d = \rho|D|, \delta)$; we instantiate it later with the Johnson bound and with Conjecture 21. It is useful to keep in mind that this will be used in a setting where q is much larger than $|D|$ (and hence d), and where L^*_δ is small.

▶ **Theorem 3** (DEEP method for RS codes). *Let $\rho > 0$ and let $V = \mathsf{RS}[\mathbb{F}_q, D, \rho]$. For $z, b \in \mathbb{F}_q$, we let*

$$V_{z,b} = \{Q(Y)|_D \in V \mid Q(z) = b\}.$$

For $\delta > 0$ let $L^*_\delta = \mathcal{L}(\mathbb{F}_q, D, d = \rho|D|, \delta)$.

Let $u, u^* \in \mathbb{F}_q^D$. For each $z \in \mathbb{F}_q$, let $B_z(X) \in \mathbb{F}_q[X]$ be an arbitrary linear function. Suppose that for some $1/3 > \epsilon > 0$ the following holds,

$$\Pr_{x,z\in\mathbb{F}_q}[\Delta(u^* + xu, V_{z,B_z(x)}) < \delta] \geq \max\left(2L^*_\delta\left(\frac{d}{q} + \epsilon\right)^{1/3}, \frac{4}{\epsilon^2 q}\right). \tag{7}$$

Then there exist $v, v^* \in V$ and $C \subset D$ such that: (i) $|C| \geq (1 - \delta - \epsilon)|D|$, (ii) $u|_C = v|_C$, and (iii) $u^*|_C = v^*|_C$. Consequently, we have $\Delta(u, V), \Delta(u^*, V) \leq \delta + \epsilon$.

Proof. To simplify notation set $\eta = \max\left(2L^*_\delta\left(\frac{d}{q} + \epsilon\right)^{1/3}, \frac{4}{\epsilon^2 q}\right)$, and let $u_x = u^* + xu$. Let $\mathcal{E}[x, z]$ denote the event "$\exists P(Y) \in \mathsf{List}(u_x, V, \delta), P(z) = B_z(x)$". The assumption of Equation (7) now reads as $\Pr_{x,z\in\mathbb{F}_q}[\mathcal{E}[x, z]] \geq \eta$. Thus we get, $\Pr_x[\Pr_z[\mathcal{E}[x, z]] \geq \eta/2] \geq \eta/2$. Let $A = \{x \in \mathbb{F}_q \mid \Pr_z[\mathcal{E}[x, z]] \geq \eta/2]\}$ and notice $|A| \geq \eta q/2$.

For $x \in \mathbb{F}_q$, pick $P_x \in V$ to be a member $P \in \mathsf{List}(u_x, V, \delta)$ that maximizes

$$\Pr_{z\in\mathbb{F}_q}[P(z) = B_z(x)].$$

Let $S_x = \{z \in \mathbb{F}_q \mid P_x(z) = B_z(x)\}$ and set $\mu_x = |S_x|/q$. By definition, $|\mathsf{List}(u_x, V, \delta)| \leq L^*_\delta$, and so by the pigeonhole principle, for each $x \in A$ we have $\mu_x \geq \frac{\eta}{2L^*_\delta}$.

For x, β, γ picked uniformly from A, and z picked uniformly from $\mathbb{F}_q$, we have:

$$\begin{aligned}\mathbf{E}_{x,\beta,\gamma}[|S_x \cap S_\beta \cap S_\gamma|/q] &= \mathbf{E}_{z,x,\beta,\gamma}[1_{z\in S_x\cap S_\beta\cap S_\gamma}] = \mathbf{E}_z[\mathbf{E}_x[1_{z\in S_x}]^3] \\ &\geq \mathbf{E}_{z,x}[1_{z\in S_x}]^3 \geq \left(\frac{\eta}{2L^*_\delta}\right)^3 > \frac{d}{q} + \epsilon.\end{aligned}$$

The second equality above follows from the independence of x, β, γ. The first inequality is an application of Jensen's inequality and the last inequality is by assumption on η. Thus $\Pr_{x,\beta,\gamma}[|S_x \cap S_\beta \cap S_\gamma| > d] \geq \epsilon$. Note that $\Pr_{x,\beta,\gamma}[x, \beta, \gamma$ are not all distinct$] < 3/|A|$. Since $|A| \geq \eta q/2 \geq 2/\epsilon^2 \geq 6/\epsilon$ we have $3/|A| \leq \epsilon/2$. Thus $\Pr_{x,\beta,\gamma}[x, \beta, \gamma$ are all distinct and $|S_x \cap S_\beta \cap S_\gamma| > d] \geq \epsilon/2$.

This means that there are distinct x_0, β_0 such that $\Pr_\gamma[|S_{x_0} \cap S_{\beta_0} \cap S_\gamma| > d] \geq \epsilon/2$. Consider some γ where this happens. Let $S = S_{x_0} \cap S_{\beta_0} \cap S_\gamma$. By construction we know that for all $z \in \mathbb{F}_q$, $(x_0, B_z(x_0)), (\beta_0, B_z(\beta_0)), (\gamma, B_z(\gamma))$ are collinear. So, in particular, for $z \in S$ this holds.

By definition of S, we get that for each $z \in S$, $(x_0, P_{x_0}(z)), (\beta_0, P_{\beta_0}(z)), (\gamma, P_\gamma(z)) \in \mathbb{F}_q \times \mathbb{F}_q$ are collinear. Since $|S| > d$, we have that P_γ is uniquely determined by $P_\gamma|_S$ by a linear map. This allows us to conclude that $(x_0, P_{x_0}), (\beta_0, P_{\beta_0}), (\gamma, P_\gamma) \in \mathbb{F}_q \times \mathbb{F}_q[Y]$ are collinear in the $\mathbb{F}_q$-vector space $\mathbb{F}_q \times \mathbb{F}_q[Y]$.

Thus, an $\epsilon/2$-fraction of the $\gamma \in A$ have the "good" property that (γ, P_γ) is on the line passing through (x_0, P_{x_0}) and (β_0, P_{β_0}). Write this line as $\{P^* + xP \mid x \in \mathbb{F}\}$ and notice that for all "good" γ we have $P_\gamma = P^* + \gamma P$. Let $A' \subseteq A$ denote the set of good elements for this line, recording that $|A'| \geq |A| \cdot \epsilon/2 \geq 1/\epsilon$. By definition of $\mathsf{List}(u_x, V, \delta)$ and the assumption $P_x \in \mathsf{List}(u_x, V, \delta)$, we have that $\Delta(u_x, P_x) < \delta$ for $x \in A'$.

Consider the set $C \subset D$ defined by $C = \{y \in D \mid u^*(y) = P^*(y) \text{ AND } u(y) = P(y)\}$. For each $y \in D \setminus C$ there exists at most a single value of $x \in \mathbb{F}_q$ satisfying $u_x(y) = P_x(y)$ because $u_x(y) - P_x(y) = (u^*(y) - P^*(y)) + x \cdot (u(y) - P(y))$ has at most one value x on which it vanishes. This implies

$$\delta \geq \max_{x \in A'}\{\Delta_D(u_x, P_x)\} \geq \frac{|D \setminus C|}{|D|} \cdot \left(1 - \frac{1}{|A'|}\right) \geq \left(1 - \frac{|C|}{|D|}\right) \cdot (1 - \epsilon) \geq 1 - \frac{|C|}{|D|} - \epsilon.$$

Rearranging, we get $\frac{|C|}{|D|} \geq 1 - (\delta + \epsilon)$. Taking $v = P$ and $v^* = P^*$ completes the proof. ◀

4 First Application – DEEP-FRI

In this section we describe the new fast RS IOPP, called DEEP-FRI. We start by recalling the FRI protocol from [3], describing it nearly verbatim as in [10, Section 7].

4.1 FRI

Our starting point is a function $f^{(0)} : L^{(0)} \to \mathbb{F}$ where $\mathbb{F}$ is a finite field, the evaluation domain $L^{(0)} \subset \mathbb{F}$ is a coset of a group[3] contained in $\mathbb{F}$, and $|L^{(0)}| = 2^{k^{(0)}}$. We assume the target rate is $\rho = 2^{-\mathcal{R}}$ for some positive integer $\mathcal{R}$. The FRI protocol is a two-phase protocol (the two phases are called COMMIT and QUERY) that convinces a verifier that $f^{(0)}$ is close to the Reed-Solomon code $\mathsf{RS}[\mathbb{F}, L^{(0)}, \rho]$.

The COMMIT phase of the FRI protocol involves $\mathsf{r} = k^{(0)} - \mathcal{R}$ rounds. Before any communication, the prover and verifier agree on a sequence of (cosets of) sub-groups $L^{(i)}$, where $|L^{(i)}| = 2^{k^{(0)}-i}$. Let $\mathsf{RS}^{(i)}$ denote the Reed-Solomon code $\mathsf{RS}[\mathbb{F}, L^{(i)}, \rho|L^{(i)}|]$.

The main ingredient of the FRI protocol is a special algebraic hash function H_x, which takes a seed $x \in \mathbb{F}$, and given as input a function $f : L^{(i)} \to \mathbb{F}$, it produces as output a hash whose length is $1/2$ as long as f. More concretely, $H_x[f]$ is a function

$$H_x[f] : L^{(i+1)} \to \mathbb{F}$$

with the following properties:

1. **locality:** For any $s \in L^{(i+1)}$, $H_x[f](s)$ can be computed by querying f at just two points in its domain (these two points are $(q^{(i)})^{-1}(s)$).

[3] The group can be additive, in which case $\mathbb{F}$ is a binary field, or multiplicative, in which case it is not.

2. **completeness:** If $f \in \mathsf{RS}^{(i)}$, then for all $x \in \mathbb{F}$, we have that $H_x[f] \in \mathsf{RS}^{(i+1)}$.
3. **soundness:** If f is far from $\mathsf{RS}^{(i)}$, then with high probability over the choice of seed x, $H_x[f]$ is quite far from $\mathsf{RS}^{(i+1)}$.

These last two properties roughly show that for random x, H_x preserves distance to Reed-Solomon codes. For the precise description of H_x see Appendix E and [9].

The high-level idea of the FRI protocol can then be described as follows. First we are in the COMMIT phase of the protocol. The verifier picks a random $x^{(0)} \in \mathbb{F}$ and asks the prover to write down the hash $H_{x^{(0)}}[f^{(0)}] : L^{(1)} \to \mathbb{F}$. By Properties 2 and 3 above, our original problem of estimating the distance of $f^{(0)}$ to $\mathsf{RS}^{(0)}$ reduces to estimating the distance of $H_{x^{(0)}}[f^{(0)}]$ to $\mathsf{RS}^{(1)}$ (which is a problem of $1/2$ the size). This process is then repeated: the verifier picks a random $x^{(1)} \in \mathbb{F}$ and asks the prover to write down $H_{x^{(1)}}[H_{x^{(0)}}[f^{(0)}]]$, and so on. After r rounds of this, we are reduced to a constant sized problem which can be solved in a trivial manner. However, the verifier cannot blindly trust that the functions $f^{(1)}, \ldots$ that were written down by the prover truly are obtained by repeatedly hashing $f^{(0)}$. This has to be checked, and the verifier does this in the QUERY phase of the protocol, using Property 1 above.

We describe the phases of the protocol below.

COMMIT **Phase:**

1. For $i = 0$ to $\mathsf{r} - 1$:
   - **a.** The verifier picks uniformly random $x^{(i)} \in \mathbb{F}$ and sends it to the prover.
   - **b.** The prover writes down a function $f^{(i+1)} : L^{(i+1)} \to \mathbb{F}$. (In the case of an honest prover, $f^{(i+1)} = H_{x^{(i)}}[f^{(i)}]$.)
2. The prover writes down a value $C \in \mathbb{F}_q$. (In the case of an honest prover, $f^{(\mathsf{r})}$ is the constant function with value $= C$).

QUERY **Phase:** (executed by the Verifier)

1. Repeat ℓ times:
   - **a.** Pick $s^{(0)} \in L^{(0)}$ uniformly at random.
   - **b.** For $i = 0$ to $\mathsf{r} - 1$:
     - **i.** Define $s^{(i+1)} \in L^{(i+1)}$ by $s^{(i+1)} = q^{(i)}(s^{(i)})$.
     - **ii.** Compute $H_{x^{(i)}}[f^{(i)}](s^{(i+1)})$ by making 2 queries to $f^{(i)}$.
     - **iii.** If $f^{(i+1)}(s^{(i+1)}) \neq H_{x^{(i)}}[f^{(i)}](s^{(i+1)})$, then REJECT.
   - **c.** If $f^{(\mathsf{r})}(s^{(\mathsf{r})}) \neq C$, then REJECT.
2. ACCEPT

The previous state of the art regarding the soundness of FRI is given by the following statement from [9]. In what follows let $J_\epsilon(x) = 1 - \sqrt{1 - x(1-\epsilon)}$.

▶ **Theorem 4** (FRI soundness (informal)). *Suppose $\delta^{(0)} \triangleq \Delta(f^{(0)}, \mathsf{RS}^{(0)}) > 0$. Let $n = |L^{(0)}|$. Then for any $\epsilon > 0$ there exists $\epsilon' > 0$ so that with probability at least*

$$1 - \frac{2 \log n}{\epsilon^3 |\mathbb{F}|} \tag{8}$$

over the randomness of the verifier during the COMMIT *phase, and for any (adaptively chosen) prover oracles $f^{(1)}, \ldots, f^{(\mathsf{r})}$, the* QUERY *protocol with repetition parameter ℓ outputs* accept *with probability at most*

$$\left(1 - \min\left\{\delta^{(0)}, 1 - (\rho^{1/4} + \epsilon')\right\} + \epsilon \log n\right)^{\ell}. \tag{9}$$

▶ Remark 5. Using the improved distance preservation of Lemma 2 in the analysis of FRI from [9], one immediately improves the factor 1/4 in the exponent in Equation (11) to an exponent of 1/3 (details omitted).

4.2 DEEP-FRI

We now describe our variation of FRI, that we call DEEP-FRI, for which we can give improved soundness guarantees, at the cost of a small increase in the query complexity (but no increase in the proof length or the number of queries to committed proofs – which is important in applications).

Before we can describe our protocol we introduce the operation of "quotienting", which allows us to focus our attention on polynomials taking certain values at certain points.

4.2.1 Quotienting

Suppose we a set $L \subseteq \mathbb{F}_q$ and a function $f : L \to \mathbb{F}_q$. Suppose further that we are given a point $z \in \mathbb{F}_q$ and a value $b \in \mathbb{F}_q$.

We define the function $\mathsf{QUOTIENT}(f, z, b) : L \to \mathbb{F}_q$ as follows. Let $Z(Y) \in \mathbb{F}_q[Y]$ be the polynomial $Z(Y) = Y - z$. Then we define $\mathsf{QUOTIENT}(f, z, b)$ to be the function $g : L \to \mathbb{F}_q$ given by:

$$g(y) = \frac{f(y) - b}{Z(y)}$$

(or more succinctly, $g = \frac{f-b)}{Z}$).

▶ **Lemma 6.** *Let $L \subseteq \mathbb{F}_q$. Let $z \in \mathbb{F}_q$ with $z \notin L$. Let $d \geq 1$ be an integer.*

Let $f : L \to \mathbb{F}_q$, and $b \in \mathbb{F}_q$. Let $g = \mathsf{QUOTIENT}(f, z, b)$. Then the following are equivalent:

- *There exists a polynomial $Q(X) \in \mathbb{F}_q[X]$ of degree at most $d - 1$ such that $\Delta(g, Q) < \delta$.*
- *There exists a polynomial $R(X) \in \mathbb{F}_q[X]$ of degree at most d such that $\Delta(f, R) < \delta$ and $R(z) = b$.*

Proof. If there is such a polynomial $Q, \deg(Q) \leq d - 1$ that agrees with g on all but a δ-fraction of entries, we can take $R = QZ + b$. Notice $\deg(R) \leq d$ because $\deg(Z) = 1$.

Conversely, if there is such a polynomial R that agrees with f on all but a δ-fraction of entries, we can take $Q = (R - b)/Z$. This is indeed a polynomial because $R - b$ vanishes on z, so $Z|(R - b)$ in the ring of polynomials.

Finally, by construction R agrees with f whenever g agrees with R and this completes the proof. ◀

4.3 DEEP-FRI

Recall: We have linear spaces $L^{(0)}, L^{(1)}, \ldots, L^{(\mathsf{r})}$, with dimensions $k, k-1, \ldots, k-\mathsf{r}$. We further have 1 dimensional subspaces $L_0^{(0)}, L_0^{(1)}, \ldots, L_0^{(\mathsf{r})}$ with $L_0^{(i)} \subseteq L^{(i)}$.

For this, it will be helpful to keep in mind the case that the domain $L^{(0)}$ is much smaller than the field $\mathbb{F}_q$ (maybe $q = |L^{(0)}|^{\Theta(1)}$).

▶ **Protocol 7** (DEEP-FRI).
Input: a function $f^{(0)} : L^{(0)} \to \mathbb{F}_q$ which is supposed to be of degree $< d^{(0)}$.

COMMIT **Phase:**

1. For each $i \in [0, \mathsf{r}-1]$:
   a. The verifier picks a uniformly random $z^{(i)} \in \mathbb{F}_q$.
   b. The prover writes down a degree one polynomial $B^{(i)}_{z^{(i)}}(X) \in \mathbb{F}_q[X]$ (which is supposed to be such that $B^{(i)}_{z^{(i)}}(x)$ equals the evaluation of the low degree polynomial $H_x[f^{(i)}]$ at $z^{(i)}$).
   c. The verifier picks uniformly random $x^{(i)} \in \mathbb{F}_q$.
   d. The prover writes down a function

$$f^{(i+1)} : L^{(i+1)} \to \mathbb{F}_q.$$

   (which on input y is supposed to equal $\mathsf{QUOTIENT}(H_{x^{(i)}}[f^{(i)}], z^{(i)}, B^{(i)}_{z^{(i)}}(x))$.)
2. The prover writes down a value $C \in \mathbb{F}_q$.

QUERY **Phase:**

1. Repeat ℓ times:
   a. The verifier picks a uniformly random $s^{(0)} \in D$.
   b. For each $i \in [0, \mathsf{r}-1]$:
      i. Define $s^{(i+1)} \in L^{(i+1)}$ by $s^{(i+1)} = q^{(i)}(s^{(i)})$.
      ii. Compute $H_{x^{(i)}}[f^{(i)}](s^{(i+1)})$ by making 2 queries to $f^{(i)}$.
      iii. If $H_{x^{(i)}}[f^{(i)}](s^{(i+1)}) \neq f^{(i+1)}(s^{(i+1)}) \cdot (s^{(i+1)} - z^{(i)}) + B^{(i)}_{z^{(i)}}(x^{(i)})$, then REJECT.
   c. If $f^{(\mathsf{r})}(s^{(\mathsf{r})}) \neq C$, then REJECT.
2. ACCEPT.

4.4 Analysis

The following theorem proves the soundness of the DEEP-FRI protocol.

▶ **Theorem 8** (DEEP-FRI). *Fix degree bound* $d^{(0)} = 3 \cdot 2^{\mathsf{r}} - 2$ *and* $\mathsf{RS}^{(0)} = \mathsf{RS}[\mathbb{F}_q, L^{(0)}, d^{(0)}]$. *Let* $n = |L^{(0)}|$.

For some $\epsilon, \delta > 0$, *let*

$$\delta^* = \delta - 2\mathsf{r}\epsilon,$$

$$\mathcal{L}^* = \mathcal{L}(\mathbb{F}_q, L^{(0)}, d^{(0)}, \delta^*),$$

$$\nu^* = 2\mathcal{L}^* \left(\frac{d^{(0)}}{q} + \epsilon \right)^{1/3} + \frac{4}{\epsilon^2 q}.$$

Then the following properties hold when the DEEP-FRI *protocol is invoked on oracle* $f^{(0)} : L^{(0)} \to \mathbb{F}_q$,

1. ***Prover complexity*** *is* $O(n)$ *arithmetic operations over* $\mathbb{F}$
2. ***Verifier complexity*** *is* $O(\log n)$ *arithmetic operations over* $\mathbb{F}$ *for a single invocation of the* QUERY *phase; this also bounds communication and query complexity (measured in field elements).*
3. ***Completeness*** *If* $f^{(0)} \in \mathsf{RS}^{(0)}$ *and* $f^{(1)}, \ldots, f^{(\mathsf{r})}$ *are computed by the prover specified in the* COMMIT *phase, then the* DEEP-FRI *verifier outputs* accept *with probability* 1.

4. ***Soundness*** *Suppose* $\Delta(f^{(0)}, \mathsf{RS}^{(0)}) > \delta$. *Then with all but probability*

$$\mathsf{err}_{\mathsf{COMMIT}} \leq \mathsf{r} \cdot \nu^* \leq (\log n) \cdot \nu^*. \tag{10}$$

and for any (adaptively chosen) prover oracles $f^{(1)}, \ldots, f^{(\mathsf{r})}$, *the* QUERY *protocol with repetition parameter* ℓ *outputs* accept *with probability at most*

$$\mathsf{err}_{\mathsf{QUERY}} \leq (1 - \delta^* + (\log n) \cdot \epsilon)^{\ell} \tag{11}$$

Consequently, the soundness error of FRI *is at most*

$$\mathsf{err}\,(\delta) \leq (\log n) \cdot \nu^* + (1 - \delta^* + (\log n) \cdot \epsilon)^{\ell} \tag{12}$$

We give a consequence below with a specific setting of parameters based on the Johnson bound.

▶ **Example 9.** Continuing with the notation of Theorem 8, fix degree bound $d^{(0)} = 3 \cdot 2^{\mathsf{r}} - 2$ and assume $n = |L^{(0)}| < \sqrt{q}$. Let $\mathsf{RS}^{(0)} = \mathsf{RS}[\mathbb{F}_q, L^{(0)}, d^{(0)}]$ and let $\rho = d^{(0)}/n$ be its rate.

Let $f^{(0)} : L^{(0)} \to \mathbb{F}_q$ be a function, and let $\delta^{(0)} = \Delta(f^{(0)}, RS^{(0)})$. Then with all but probability $\mathsf{err}_{\mathsf{COMMIT}} \leq O(q^{-\Omega(1)})$, the query phase will accept with probability at most: $\mathsf{err}_{\mathsf{QUERY}} \leq (\max(1 - \delta^{(0)}, \sqrt{\rho}) + o(1))^{\ell}$ as $n \to \infty$.

Proof. Note that $d^{(0)} \leq n \leq \sqrt{q}$.

Set $\delta = \min(\delta^{(0)}, 1 - \sqrt{\rho} - q^{-1/13})$, and apply the previous theorem. Theorem 20 implies that $\mathcal{L}^* < q^{1/13}/(2\sqrt{\rho}) = O(q^{1/13})$. Set $\epsilon = q^{-6/13}$. Hence

$$\nu^* = 2\mathcal{L}^* \left(d^{(0)} q^{-1} + q^{-6/13}\right)^{1/3} + 4q^{-6/13} = O(q^{-1/13}),$$

which implies $\mathsf{err}_{\mathsf{COMMIT}} \leq \tilde{O}(q^{-1/13})$.

If $\delta = \delta^{(0)}$, then $1 - \delta^* + (\log n)\epsilon = 1 - \delta + o(1)$. Otherwise $\delta = 1 - \sqrt{\rho} - q^{-1/13}$, and so

$$1 - \delta^* + (\log n)\epsilon = \sqrt{\rho} + q^{-1/13} + (\log n)\epsilon = \sqrt{\rho} + q^{-1/13} + (\log n) q^{-6/13}.$$

Thus $\mathsf{err}_{\mathsf{QUERY}} \leq (\max(1 - \delta, \sqrt{\rho}) + o(1))^{\ell}$. ◀

We now give an example setting of DEEP-FRI under the optimistic Conjecture 21.

▶ **Example 10.** Assume Conjecture 21. Continuing with the notation of Theorem 8, fix degree bound $d^{(0)} = 3 \cdot 2^{\mathsf{r}} - 2$ and $n = |L^{(0)}|$. Let $\mathsf{RS}^{(0)} = \mathsf{RS}[\mathbb{F}_q, L^{(0)}, d^{(0)}]$ and let $\rho = d^{(0)}/n$ be its rate.

Let $C = C_\rho$ be the constant given by Conjecture 21. Suppose $q > n^{24C}$.

Let $f^{(0)} : L^{(0)} \to \mathbb{F}_q$ be a function, and let $\delta^{(0)} = \Delta(f^{(0)}, RS^{(0)})$. Then with all but probability $\mathsf{err}_{\mathsf{COMMIT}} \leq O(q^{-\Omega(1)})$, the query phase will accept with probability at most: $\mathsf{err}_{\mathsf{QUERY}} \leq (1 - \delta^{(0)} + o(1))^{\ell}$ as $n \to \infty$.

Proof. Set $\epsilon = q^{-1/(6C)}$.

Set $\delta = \min(\delta^{(0)}, 1 - \rho - q^{-1/(6C)})$. Conjecture 21 gives us:

$$\mathcal{L}^* < n^C q^{1/6}.$$

We then apply the previous theorem. We get $\nu^* \ll O(\mathcal{L}^* \cdot (d/q + \epsilon)^{1/3} + \frac{1}{\epsilon^2 q}) \ll q^{-1/12}$, and this gives us the claimed bound on $\mathsf{err}_{\mathsf{COMMIT}}$.

For the bound on $\mathsf{err}_{\mathsf{QUERY}}$, we note that $\delta = \delta^{(0)} + o(1)$. This is because *every* function is within distance $1 - \rho$ of $\mathsf{RS}^{(0)}$ (this follows easily from polynomial interpolation). Thus

$$1 - \delta^* + (\log n)\epsilon = \delta + o(1),$$

and we get the desired bound on $\mathsf{err}_{\mathsf{COMMIT}}$. ◀

Verifier complexity and completeness follow by construction (see, e.g., [3] for detailed analysis of these aspects). We start by analyzing prover time and showing it is linear. In the rest of the section we prove the soundness bound of Theorem 8.

4.5 Prover complexity

The prover is involved in two sub-steps of the COMMIT phase, Items 1b and 1d. Inspection reveals that Item 1d requires $O(|L^{(i)}|)$ arithmetic operations. In what follows we show that Item 1b can also be computed in similar asymptotic complexity. To show this it suffices to prove the following claim.

▷ Claim 11 (Fast DEEP evaluation). Let $f : L \to \mathbb{F}$ be a function and L be a group (additive or multiplicative) of size 2^k for integer k. Let $P_f(X)$ be the interpolant of f as defined in Appendix A. There exists an algorithm that, given $z \in \mathbb{F}$, computes $P_f(z)$ using $O(|L|)$ arithmetic operations.

Proof. We compute within $O(|L|)$ arithmetic operations a pair (f', z') satisfying

- $f' : L' \to \mathbb{F}$ where L' is a group of size 2^{k-1}.
- $z' \in \mathbb{F}$.
- $P_f(z) = P_{f'}(z')$ where $P_{f'}$ is the interpolant of f'.

This suffices to solve the problem by induction, noticing the total sum of arithmetic operations is a geometric sum (the base case, in which $|L| = O(1)$, is trvially solvable using $O(1)$ arithmetic operations).

To construct f' let L_0 be a subgroup of L of size 2. The quadratic polynomial $q(X)$ whose roots are L_0 induces a 2-to-1 map on L. Let $L' = \{q(x) \mid x \in L\}$ be the image of this map on L and notice that L' is a group of size $|L|/2$, and for each $y \in L'$ there exists a unique pair, denoted $x_y, x'_y \in L$, such that $y = q(x_y) = q(x'_y)$. Furthermore, there exists a unique bivariate polynomial $Q_f(X, Y)$ satisfying:

- $\deg_X(Q_f) \leq 1$
- $\deg_Y(Q_f) \leq \deg(P_f)/2$
- $P_f(X) = Q_f(X, q(X)) \mod Y - q(X)$

See [3, Claim 4.2] for a proof. We define $z' = q(z)$ and for $y \in L'$ define $f'(y) = Q_f(z, y)$. By the third item above we have $f'(z') = Q_f(z, z') = Q_f(z, q(z)) = P_f(z)$. The second item above shows that $P_{f'}(Y)$ is the interpolant of f' because $\deg(P_{f'}) < |L'|$ and both f' and $P_{f'}$ agree on all of L'. This implies $P_{f'}(z') = f'(z')$ which we showed equals $P_f(z)$, so $P_f(z) = P_{f'}(z')$ as required. All that is left is to argue that f' can be computed from f using $O(|L|)$ arithmetic operations. This follows from the first bullet because each entry $f'(y)$ can be computed from $f(x_y)$ and $f(x'_y)$ by interpolating the degree-1 polynomial $Q_f(X, y)$ and evaluating it at z to obtain $Q_f(z, y) = f'(y)$. This completes the proof. ◁

4.6 Preparations

We do the analysis below for the case $\ell = 1$. The generalization to arbitrary ℓ easily follows.

Define $d^{(0)} = 3 \cdot 2^{\mathsf{r}} - 2$, and $d^{(i+1)} = d^{(i)}/2 - 1$. It is easy to check that $d^{(\mathsf{r})} = 1$. Define $\mathsf{RS}^{(i)} = \mathsf{RS}[\mathbb{F}_q, L^{(i)}, d^{(i)}]$. In the case of the honest prover (when $f^{(0)} \in \mathsf{RS}^{(0)}$), we will have $f^{(i)} \in \mathsf{RS}^{(i)}$ for all i.

Our analysis of the above protocol will track the agreement of $f^{(i)}$ with $\mathsf{RS}^{(i)}$. This agreement will be measured in a certain weighted way, which we define next.

4.6.1 The success probability at $s \in L^{(i)}$

There is a natural directed forest that one can draw on the vertex set

$$L^{(0)} \cup L^{(1)} \cup \ldots \cup L^{(\mathsf{r})},$$

namely, where $s \in L^{(i)}$ is joined to $q^{(i)}(s) \in L^{(i+1)}$ (and we say that s is a child of $q^{(i)}(s)$). Note that every vertex not in $L^{(0)}$ has two children.

Let $i \leq \mathsf{r} - 1$ and $s_0 \in L^{(i)}$. Let $s \in L^{(i+1)}$ be the parent of s_0, and let $s_1 \in L^{(i)}$ the sibling of s_0. We color s_0 GREEN if $f^{(i+1)}(s)$ is consistent with $f^{(i)}|_{\{s_0,s_1\}}$ according to the test

$$H_{x^{(i)}}[f^{(i)}](s) = f^{(i+1)}(s) \cdot (s - z^{(i)}) + B^{(i)}_{z^{(i)}}(x^{(i)})$$

and we color s_0 RED otherwise. Notice that a vertex and its sibling get the same color.

For $s \in L^{(\mathsf{r})}$, we color s GREEN if $f^{(\mathsf{r})}(s) = C$ and RED otherwise.

The QUERY phase of the protocol can be summarized as follows: we pick a uniformly random $s^{(0)} \in L^{(0)}$ and consider the path $s^{(0)}, s^{(1)}, s^{(2)} \ldots, s^{(\mathsf{r})}$ going through all its ancestors. If all these vertices are GREEN, then we ACCEPT, otherwise we REJECT.

To capture this, we define functions $\eta^{(i)} : L^{(i)} \to \mathbb{R}$ as follows. For $s \in L^{(i)}$, let $\eta^{(i)}(s)$ be the fraction of leaf-descendants $s^{(0)}$ of s for which the path from $s^{(0)}$ to s (including $s^{(0)}$ but not including s) consists exclusively of GREEN vertices. Observe that $p_{ACCEPT} = \mathbb{E}_{s \in L^{(\mathsf{r})}}[\eta^{(\mathsf{r})}(s) \cdot 1_{f^{(\mathsf{r})}(s)=C}]$ equals the probability that the QUERY phase accepts.

The exact quantity that we will track is as i increases is the weighted agreement:

$$\alpha^{(i)} = \mathsf{agree}_{\eta^{(i)}}[f^{(i)}, \mathsf{RS}^{(i)}].$$

Notice that

$$\alpha^{(0)} = 1 - \Delta(f^{(0)}, \mathsf{RS}^{(0)}),$$

and the acceptance probability, p_{ACCEPT} satisfies:

$$p_{ACCEPT} \leq \alpha^{(\mathsf{r})}.$$

Our main intermediate claim is that with high probability over the choice of $x^{(i)}, z^{(i)}, B^{(i)}_{z^{(i)}}$, we have that $\alpha^{(i+1)}$ is not much more than $\alpha^{(i)}$. This gives us that p_{ACCEPT} is not much more than $1 - \Delta(f^{(0)}, \mathsf{RS}^{(0)})$, as desired.

4.6.2 Operations AVG and ZERO

We define two important operations.

1. AVG. For a function $w : L^{(i-1)} \to \mathbb{R}$, we define the function $\mathsf{AVG}[w] : L^{(i)} \to \mathbb{R}$ as follows. Let $s \in L^{(i)}$, and let $\{s_0, s_1\} = (q^{(i-1)})^{-1}(s)$. Then define:

$$\mathsf{AVG}[w](s) = \frac{w(s_0) + w(s_1)}{2}.$$

2. ZERO. For a function $w : L^{(i)} \to \mathbb{R}$, and a set $S \subseteq L^{(i)}$, we define the function $\mathsf{ZERO}[w, S] : L^{(i)} \to \mathbb{R}$ as follows. For $s \in L^{(i)}$, we set:

$$\mathsf{ZERO}[w, S](s) = \begin{cases} 0 & s \in S \\ w(s) & s \notin S \end{cases}.$$

We can use these two operations to express $\eta^{(i+1)}$ in terms of $\eta^{(i)}$. Let $E^{(i+1)}$ denote the set of all $s \in S^{(i+1)}$ both of whose children are RED (i.e., the test

$$H_{x^{(i)}}[f^{(i)}](s) = f^{(i+1)}(s) \cdot (s - z^{(i)}) + B^{(i)}_{z^{(i)}}(x^{(i)})$$

fails at s).

Define $\theta^{(i+1)} : L^{(i+1)} \to \mathbb{R}$ by

$$\theta^{(i+1)} = \mathsf{AVG}[\eta^{(i)}].$$

Then we have:

$$\eta^{(i+1)} = \mathsf{ZERO}(\theta^{(i+1)}, E^{(i+1)}).$$

Analogous to our definition of

$$\alpha^{(i)} = \mathsf{agree}_{\eta^{(i)}}(f^{(i)}, \mathsf{RS}^{(i)}),$$

we define

$$\beta^{(i+1)} = \mathsf{agree}_{\theta^{(i+1)}}(H_{x^{(i)}}[f^{(i)}], \{P(Y) \in \mathbb{F}_q[Y] \mid \deg(P) \le d^{(i+1)} \text{ and } P(z^{(i)}) = B^{(i)}_{z^{(i)}}(x^{(i)})\}).$$

The following two lemmas control the growth of $\alpha^{(i)}$ and $\beta^{(i)}$.

▶ **Lemma 12.** *For all i, with probability at least $1 - \nu^*$ over the choice of $x^{(i)}, z^{(i)}$, we have:*

$$\beta^{(i+1)} \le \max(\alpha^{(i)}, 1 - \delta^*) + \epsilon.$$

We prove this using Theorem 25 in Appendix F.

▶ **Lemma 13.** *For all i,*

$$\alpha^{(i)} \le \beta^{(i)}.$$

We prove this using Lemma 6 in Appendix F.

We can now complete the proof of Theorem 8.

Proof. As observed earlier, $\alpha^{(0)} = 1 - \Delta(f^{(0)}, \mathsf{RS}^{(0)}) < 1 - \delta$.

The two lemmas above imply that with probability at least $1 - \mathsf{r}\nu^*$,

$$\alpha^{(\mathsf{r})} \le \max(\alpha^{(0)}, 1 - \delta^*) + \mathsf{r} \cdot \epsilon < (1 - \min(\delta, \delta^*) + \mathsf{r} \cdot \epsilon).$$

Finally, we use the observation that $p_{ACCEPT} \le \alpha^{(\mathsf{r})}$ to complete the proof. ◀

5 Second Application – The DEEP Algebraic Linking IOP (DEEP-ALI) protocol

The techniques used earlier in Theorem 3 and Section 4 can also be used to improve soundness in other parts of an interactive oracle proof (IOP) protocol. We apply them here to obtain a Scalable Transparent IOP of Knowledge (STIK) [2, Definition 3.3] with better soundness than the prior state of the art, given in [2, Theorem 3.4].

Proof systems typically use a few steps of reduction to convert problems of membership in a nondeterministic language L to algebraic problems regarding proximity of a function (or a sequence of functions) to an algebraic code like Reed-Solomon (or, in earlier works,

Reed-Muller). The goal of such a reduction is to maintain a large *proximity gap* γ, meaning that for instances in L, an honest prover will provide information that leads to codewords, whereas for instances not in L, any oracles submitted by the prover will be converted by the reduction, with high probability, to functions that are γ-far from the code. Considerable effort is devoted to increasing γ because it is the input to the proximity protocols (like FRI and DEEP-FRI) and the soundness of those protocols is correlated to γ (as discussed earlier, e.g., in Theorem 8).

The STIK protocol is a special case of this paradigm. It requires the prover to provide oracle access to a function $f : D \to \mathbb{F}$ that is supposedly an RS encoding of a witness for membership of the input instance in L. A set of t-local constraints is applied to f to construct a function $g : D \to \mathbb{F}$, along with a gap-gurantee: If f is indeed an encoding of a valid witness for the instance, then the resulting function $g : D \to \mathbb{F}$ is also be a member of an RS code. One of the tests that the verifier performs is a *consistency test* between f and g, and, prior to this work, this consistency test was applied to the functions f and g *directly*. This leads to a rather small gap $\gamma \leq \frac{1}{8}$ which results in a small soundness guarantee from the RPT protocol applied to f, g later on.

In this section we apply the DEEP technique to this setting. After f and g have been provided, the verifier samples a random $z \in \mathbb{F}_q$ and asks for the values of the interpolating polynomials of f, g on all t entries needed to check the consistency test. Our verifier now applies the QUOTIENT operation to f, g, using the information obtained from the prover. Crucially, we prove that a *single* consistency test, conducted over a large domain $D' \supset D$, suffices to improve the proximity gap to roughly $1 - \sqrt{\rho}$, a value that approaches 1 as $\rho \to 0$. Assuming Conjecture 21 the proximity gap is nearly-optimal, at $\gamma \approx 1 - \rho$ (compare with with the value $\gamma \leq 1/8$ obtained by prior works). Details follow.

We focus on the the Algebraic linking IOP protocol (ALI) of [2, Theorem B.15], and present a new protocol that we call DEEP-ALI (Protocol 17) that obtains the aforementioned improved proximity gap(s).

In what follows, we will first recall (a variant of) the language (or, more accurately, binary relation) which was the input to the ALI protocol of [2] and is likewise the input to our DEEP-ALI protocol. The description of the protocol follows in Section 5.2. Its basic properties are specified in Section 5.3 and we analyze its soundness in Theorem 15 and Section 5.4.

5.1 The Algebraic Placement and Routing (APR) Relation

In what follows we use the notation $\tilde{f}$ to refer to a polynomial in $\mathbb{F}[x]$. Note that the operator $|_D$ for $D \subseteq \mathbb{F}$ takes a polynomial to a function: $\tilde{f}\,|_D \colon D \to \mathbb{F}$.

We start by defining a simplified version of the Algebraic placement and routing relation (APR). See [2, Definition B.10]. In particular, we only use one witness polynomial. This relation will be the input to the reduction used in Protocol 17.

▶ **Definition 14.** *The relation R_{APR} is the set of pairs $(\mathtt{x}, \mathtt{w})$ satisfying:*

1. ***Instance format:*** *The instance $\mathtt{x}$ is a tuple $(\mathbb{F}_q, d, \mathcal{C})$ where:*
   - *$\mathbb{F}_q$ is a finite field of size q.*
   - *d is an integer representing a bound on the degree of the witness.*
   - *$\mathcal{C}$ is a set of $|\mathcal{C}|$ tuples (M^i, P^i, Q^i) representing constraints. M^i is the* mask *which is a sequence of field elements $M^i = \{M^i_j \in \mathbb{F}_q\}_{j=1}^{|M^i|}$. P^i is the* condition *of the constraint which is a polynomial with $|M^i|$ variables. $Q^i \in \mathbb{F}_q[x]$ is the* domain polynomial *of the constraint which should vanish on the locations where the constraint should hold.*

We further introduce the following notation:
- *Let* $\mathcal{M} = \{M_j^i \mid 1 \le i \le |\mathcal{C}|$ *and* $1 \le j \le |M^i|\} \subseteq \mathbb{F}_q$ *be the* full mask.
- *Let* $d_{\mathcal{C}} = \max_i \deg(P^i)$ *be the maximal total degree of the* P^i*s.*
- *Let* $Q_{\text{lcm}} \in \mathbb{F}_q[x]$ *be the least common multiple of the* Q^i*s.*

2. ***Witness format:*** *The witness* $\mathtt{w}$ *is a polynomial* $\tilde{f} \in \mathbb{F}_q[x]$*. A constraint* (M, P, Q) *is said to hold at a location* $x \in \mathbb{F}_q$ *if* $P(\tilde{f}(x \cdot M_1), \ldots, \tilde{f}(x \cdot M_{|M|})) = 0$*. We say that* $\tilde{f}$ *satisfies the constraint if the constraint holds at every* $x \in \mathbb{F}_q$ *for which* $Q(x) = 0$*.*
We say that $\mathtt{w}$ *satisfies the instance if and only if* $\deg(\tilde{f}) < d$ *and* $\tilde{f}$ *satisfies all of the constraints.*

To see that the notion of the R_{APR} relation defined above is strong enough, we follow the ideas from [2] and show a reduction from an Algebraic Intermediate Representation (AIR, see [2, Definition B.3]) to an APR. The following uses the notation from [2, Definition B.3]. Let $\mathtt{x} = (\mathbb{F}_q, T, \mathsf{w}, \mathcal{P}, C, \mathsf{B})$ be an instance of R_{AIR}. Pick a multiplicative subgroup $\langle\gamma\rangle \subseteq \mathbb{F}_q^\times$ of size $T \cdot \mathsf{w}$ and pick $\tilde{f}$ such that $\tilde{f}(\gamma^{t\mathsf{w}+j}) = w_j(t)$ for $t \in [T]$ and $i \in [\mathsf{w}]$ (here $[n] = \{0, \ldots, n-1\}$). For all the constraints in $\mathcal{P}$, choose the mask $M = \{1, \gamma, \ldots, \gamma^{2\mathsf{w}-1}\}$ and choose the domain polynomial whose zeros are $\{\gamma^{t\mathsf{w}}\}_{t \in [T-1]}$ ($Q(x) = (x^T - 1)/(x - \gamma^{-\mathsf{w}})$). Replace each boundary constraint $(i, j, \alpha) \in \mathsf{B}$ with a regular constraint with mask $M = \{1\}$, $P(x) = x - \alpha$ and $Q(x) = x - \gamma^{i\mathsf{w}+j}$.

5.2 The DEEP-ALI protocol

We now describe our new protocol, that achieves improved soundness, as stated in the following theorem.

▶ **Theorem 15** (DEEP-ALI soundness)**.** *Fix a code rate* $0 < \rho < 1$ *and a distance parameter* $0 < \delta \le 1 - \rho$*. Let* $D, D' \subseteq \mathbb{F}_q$ *be two evaluation domains such that* $|D| = d\rho^{-1}$ *and* $|D'| = d \cdot d_{\mathcal{C}}\rho^{-1}$*. Let* RPT_D*,* $\text{RPT}_{D'}$ *be two IOPPs with perfect completeness for the codes* $\mathsf{RS}[\mathbb{F}_q, D, (d - |\mathcal{M}|)/|D|])$ *and* $\mathsf{RS}[\mathbb{F}_q, D', (dd_{\mathcal{C}} - 1)/|D'|])$ *respectively. Let* ϵ, ϵ' *be the bounds on the soundness error (acceptance probability) for words that are at least* δ*-far from the corresponding code. Denote*

$$L = \max\{\mathcal{L}(\mathbb{F}_q, D, d, \delta), \mathcal{L}(\mathbb{F}_q, D', d \cdot d_{\mathcal{C}}, \delta)\}.$$

Then, there exists an IOP for R_{APR} *with perfect completeness and soundness error* $\epsilon + \epsilon' + \frac{2L^2(d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}}))}{q}$*.*

▶ **Example 16.** Fix a code rate $0 < \rho < 1$. Choosing DEEP-FRI as the RPT protocol and setting $\delta = 1 - \sqrt{\rho} - q^{-1/13}$ as in Example 9, using ℓ repetitions, we obtain an IOP for R_{APR} with perfect completeness and soundness error that approaches $2\rho^{\ell/2}$ as $q \to \infty$ assuming the parameters d, $d_{\mathcal{C}}$, $\deg(Q_{\text{lcm}})$ of the APR are constant with respect to q.

Proof. Theorem 20 implies that $L \le q^{1/13}/(2\sqrt{\rho}) = O(q^{1/13})$. Hence the expression $2L^2(d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}}))/q$ approaches 0 as $q \to \infty$. Moreover, Example 9 implies that ϵ, ϵ' approach $\rho^{\ell/2}$. ◀

We now describe the protocol that achieves the soundness of Theorem 15.

▶ **Protocol 17** (DEEP-ALI)**.**
1. The prover sends an oracle $f : D \to \mathbb{F}$ (which should be $\tilde{f}\,|_D$).
2. The verifier sends random coefficients $\alpha = (\alpha_1, \ldots, \alpha_{|\mathcal{C}|}) \in \mathbb{F}_q^{|\mathcal{C}|}$.

3. The prover sends an oracle $g_\alpha : D' \to F$ (which should be $\tilde{g}_\alpha \mid_{D'}$, where

$$\tilde{g}_\alpha(x) = \sum_{i=1}^{|\mathcal{C}|} \alpha_i \cdot \frac{P^i(\tilde{f}(x \cdot M_1^i), \ldots, \tilde{f}(x \cdot M_{|M^i|}^i))}{Q^i(x)}. \tag{13}$$

   Note that $\deg(\tilde{g}_\alpha) < d \cdot d_{\mathcal{C}})$.
4. The verifier sends a random value $z \in \mathbb{F}_q$.
5. Denote $\mathcal{M}_z = \{z \cdot M_j^i \mid 1 \le i \le |\mathcal{C}| \text{ and } 1 \le j \le |M^i|\}$. The prover sends $a_{\alpha,z} : \mathcal{M}_z \to \mathbb{F}$ (which should be $\tilde{f}|_{\mathcal{M}_z}$). The verifier deduces $b_{\alpha,z}$, the alleged value of $\tilde{g}_\alpha(z)$, using Equation (13).
6. Let $U(x)$, $Z(x)$ as defined in Section 4.2.1 for $\mathsf{QUOTIENT}(f, a_{\alpha,z})$ and let

$$h^1(x) = h^1_{\alpha,z}(x) = \mathsf{QUOTIENT}(f, a_{\alpha,z}) = \frac{f(x) - U(x)}{Z(x)},$$

$$h^2(x) = h^2_{\alpha,z}(x) = \mathsf{QUOTIENT}(g_\alpha, \{z \mapsto b_{\alpha,z}\}) = \frac{g_\alpha(x) - b_{\alpha,z}}{x - z},$$

   and note that the verifier has oracle access to h^1 and h^2 using the oracles f and g_α.
7. They use RPT_D and $\mathrm{RPT}_{D'}$ to prove that h^1 is at most δ-far from $\mathsf{RS}[\mathbb{F}_q, D, (d-|\mathcal{M}|)/|D|]$ (in other words, it is close to a polynomial of degree $< d - |\mathcal{M}|$) and that h^2 is at most δ-far from $\mathsf{RS}[\mathbb{F}_q, D', (dd_{\mathcal{C}} - 1)/|D'|]$.

5.3 Properties of DEEP-ALI

Note that in the original ALI protocol, the equivalent to the expression $P^i(\tilde{f}(x \cdot M_1^i), \ldots, \tilde{f}(x \cdot M_{|M^i|}^i))/Q^i(x)$ is sampled at Q random locations from the evaluation domain, where Q is the number of queries.

The main idea in DEEP-ALI is to use Quotienting to allow the verifier to choose *one* random element z from the *entire* field, and check the consistency between $\tilde{f}$ and $\tilde{g}$ only at $x = z$.

The fact that DEEP-ALI allows to sample from the entire field introduces several advantages over the ALI protocol from [2]:

Soundness. As described above, the reduction in ALI has lower bound 1/8 on the distance from the code for inputs that are not in the language, even for $\rho \to 0$. In DEEP-ALI the lower bound on the distance is $1 - \sqrt{\rho}$.

Query complexity. In ALI the verifier queries $|\mathcal{M}| \cdot \mathsf{Q}$ field elements as we need $|\mathcal{M}|$ elements to evaluate $P^i(\tilde{f}(x \cdot M_1^i), \ldots, \tilde{f}(x \cdot M_{|M^i|}^i))$. In DEEP-ALI the verifier queries $O(|\mathcal{M}| + \mathsf{Q})$ field elements as the evaluation of P^i is done once.

Verifier complexity. Previously, the verifier complexity was $\Omega(\mathsf{Q} \cdot T_{\text{arith}})$ (where T_{arith} is the arithmetic complexity of evaluating all the constraints). The verifier complexity in DEEP-ALI depends on $\mathsf{Q} + T_{\text{arith}}$ as we evaluate the constraints only once.

Prover complexity. It is possible to alter Definition 14 and DEEP-ALI to work with several witness polynomials $f_1, \ldots, f_{\mathsf{w}}$ (as was done in ALI). The prover complexity in this case will depend on $(\mathsf{w}\rho^{-1} + d_{\mathcal{C}}\rho^{-1} + T_{\text{arith}}d_{\mathcal{C}}) \cdot d$ instead of $(\mathsf{w}d_{\mathcal{C}}\rho^{-1} + T_{\text{arith}}d_{\mathcal{C}}) \cdot d$ (in ALI).

5.4 Soundness analysis

The proof of Theorem 15 will follow from the following lemma:

▶ **Lemma 18.** *Let $\mathcal{E}$ be the event that the* DEEP-ALI *verifier accepts. If*

$$\Pr[\mathcal{E}] \geq \epsilon + \epsilon' + \frac{2L^2(d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}}))}{q},$$

then there exists a polynomial of degree $< d$ satisfying the constraints.

Proof. Let $L(f) \subseteq \mathsf{RS}[\mathbb{F}_q, D, \rho]$ be the set of codewords that are at most δ-far from f. Similarly define $L(g_\alpha)$. We have $|L(f)|, |L(g_\alpha)| \leq L$.

Let $\mathcal{E}_1$ be the event where the verifier accepts and h^1 and h^2 are at most δ-far from the corresponding codes. Denote $\eta = 2L^2(d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}}))/q$. Then, $\Pr[\mathcal{E}_1] \geq \eta$. $\mathcal{E}_1$ implies that there exists a polynomial $\tilde{h}^1 = \tilde{h}^1_{\alpha,z}$ of degree $< d - |\mathcal{M}|$ such that $\left|\{x \in D : \tilde{h}^1(x) \neq \frac{f(x)-U(x)}{Z(x)}\}\right| < \delta|D|$. Hence $Z(x) \cdot \tilde{h}^1(x) + U(x) \in L(f)$. Similarly there exists a polynomial $\tilde{h}^2 = \tilde{h}^2_{\alpha,z}$ of degree $< d \cdot d_{\mathcal{C}} - 1$ such that $(x - z)\tilde{h}^2(x) + b \in L(g_\alpha)$.

Fix $\tilde{r}^1(x)$ (independent of α and z) to be the element in $L(f)$ maximizing the probability that $\tilde{r}^1(x) = Z(x) \cdot \tilde{h}^1(x) + U(x)$ given $\mathcal{E}_1$. Let $\mathcal{E}_2 \subseteq \mathcal{E}_1$ be the event that $\tilde{r}^1(x) = Z(x) \cdot \tilde{h}^1(x) + U(x)$. It follows that $\Pr[\mathcal{E}_2] \geq \eta/L$.

Fix $\tilde{r}^2_\alpha(x) \in L(g_\alpha)$ maximizing the probability that $\tilde{r}^2_\alpha(x) = (x - z)\tilde{h}^2(x) + b$ given $\mathcal{E}_2$ (note that $\tilde{r}^2_\alpha$ depends on α as the oracle g_α was sent only after the verifier sent α), and let $\mathcal{E}_3 \subseteq \mathcal{E}_2$ be the event where $\tilde{r}^2_\alpha(x) = (x - z)\tilde{h}^2(x) + b$. We have $\Pr[\mathcal{E}_3] \geq \eta/L^2$. This implies, $\Pr_\alpha[\Pr_z[\mathcal{E}_3] \geq \eta/(2L^2)] \geq \eta/(2L^2)$.

The event $\mathcal{E}_3$ implies

$$\tilde{r}^1 \mid_{\mathcal{M}_z} = U \mid_{\mathcal{M}_z} = a_{\alpha,z},$$
$$\tilde{r}^2_\alpha(z) = b_{\alpha,z}.$$

Recall that $b_{\alpha,z}$ was defined according to (13), so

$$b_{\alpha,z} = \sum_{i=1}^{|\mathcal{C}|} \alpha_i \cdot \frac{P^i(a_{\alpha,z}(z \cdot M^i_1), \ldots, a_{\alpha,z}(z \cdot M^i_{|M^i|}))}{Q^i(z)}.$$

Substituting values for $a_{\alpha,z}$ and $b_{\alpha,z}$ and multiplying by $Q_{\text{lcm}}(z)$ we obtain:

$$Q_{\text{lcm}}(z) \cdot \tilde{r}^2_\alpha(z) = \sum_{i=1}^{|\mathcal{C}|} \alpha_i \cdot P^i(\tilde{r}^1(z \cdot M^i_1), \ldots, \tilde{r}^1(z \cdot M^i_{|M^i|})) \cdot \frac{Q_{\text{lcm}}(z)}{Q^i(z)}. \tag{14}$$

Both sides of the equation are polynomials of degree $< d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}})$ in z. For every α for which $\Pr_z[\mathcal{E}_3] \geq \eta/(2L^2) = (d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}}))/q$, we have at least $d \cdot d_{\mathcal{C}} + \deg(Q_{\text{lcm}})$ many z's satisfying (14) and thus the two polynomials in (14) are identical. Let $G_\alpha(x)$ denote the the right-hand side of (14) (replacing z with x).

So far we have:

$$\Pr_\alpha[G_\alpha(x) \text{ is divisible by } Q_{\text{lcm}}(x)] \geq \eta/(2L^2) > 1/q.$$

Note that the set of α's satisfying this event forms a vector space. If its dimension was less than $|\mathcal{C}|$ then the probability would have been $\leq 1/q$. Hence this event holds for every α. Substituting the elements of the standard basis, we get that for every $1 \leq i \leq |\mathcal{C}|$,

$$P^i(\tilde{r}^1(x \cdot M^i_1), \ldots, \tilde{r}^1(x \cdot M^i_{|M^i|})) \cdot \frac{Q_{\text{lcm}}(x)}{Q^i(x)} \text{ is divisible by } Q_{\text{lcm}}(x).$$

Substituting any x for which $Q^i(x) = 0$ gives $P^i(\tilde{r}^1(x \cdot M^i_1), \ldots, \tilde{r}^1(x \cdot M^i_{|M^i|})) = 0$ which implies that $\tilde{r}^1$ satisfies all the constraints, as required. ◀

5.5 Further optimizations for practical implementation

As we saw, it makes sense to work with several witness polynomials rather than one, as it improves the prover complexity. Another optimization is to apply the RPT only once for both h^1 and h^2 by taking a random linear combination of the two (and using Theorem 3). To make this work, the prover writes the degree $< d \cdot d_{\mathcal{C}}$ polynomial $\tilde{g}(x)$ as:

$$\tilde{g}(x) = \sum_{i=0}^{d_C-1} x^i \tilde{g}_i(x^{d_C}),$$

where the $\tilde{g}_i$s are of degree $< d$, and it sends oracles to $\tilde{g}_i \mid_D$ instead of $\tilde{g} \mid_{D'}$. In total, we will have to run RPT on $\mathsf{w} + d_{\mathcal{C}}$ polynomials of degree $< d$, so we choose only one evaluation domain $D \subseteq \mathbb{F}_q$ satisfying $|D| = d\rho^{-1}$.

A Preliminaries

Functions

For a set D, we will be working with the space of functions $u : D \to \mathbb{F}$, denoted $\mathbb{F}^D$. For $u \in \mathbb{F}^D$ we use $u(z)$ to denote the zth entry of u, for $z \in D$. For $C \subset D$ we use $f|_C$ to denote the restriction of f to C. For two functions $f, g : D \to \mathbb{F}$ we write $f = g$ when the two functions are equal as elements in $\mathbb{F}^D$ and similarly say $f|_C = g|_C$ when their restrictions are equal as elements in $\mathbb{F}^C$.

Distance

We use $\Delta_D(u, v) = \Pr_{z \in D}[u(z) \neq v(z)]$ for relative Hamming distance, and omit D when it is clear from context. For a set $S \subset \mathbb{F}^D$ we use $\Delta_D(v, S) = \min_{s \in S} \Delta_D(v, s)$ and $\Delta_D(S) = \min_{s \neq s' \in S} \Delta_D(s, s')$ denotes the minimal relative distance of S. For $u \in \mathbb{F}^D$ let $B(u, \delta)$ denote the Hamming ball in $\mathbb{F}^D$ of normalized radius δ centered at u,

$$B(u, \delta) = \left\{u' \in \mathbb{F}^D \mid \Delta_D(u, u') < \delta\right\}.$$

Linear codes

An $[n, k, d]_q$-linear error correcting code is a linear space $V \subset \mathbb{F}_q^n$ of dimension k over $\mathbb{F}_q$ with minimal Hamming distance d. A generating matrix for V is a matrix $G \in \mathbb{F}_q^{n \times k}$ of rank k such that $V = \left\{Gx \mid x \in \mathbb{F}_q^k\right\}$.

Polynomials and RS codes

The *interpolant* of $f : D \to \mathbb{F}_q$ is the unique polynomial of degree $< |D|$ whose evaluation on D is f. The degree of f, denoted $\deg(f)$, is the degree of its interpolant. The RS code evaluated over domain $D \subset \mathbb{F}$ and rate ρ is denoted $\mathsf{RS}[\mathbb{F}, D, \rho] = \{f : D \to \mathbb{F} \mid \deg(f) < \rho|D|\}$. Sometimes it will be more convenient to work with degree rather than rate, in which case we abuse notation and define $\mathsf{RS}[\mathbb{F}, D, d] = \{f : D \to \mathbb{F} \mid \deg(f) < d\}$. We use capital letters like P, Q to denote polynomials and when we say $P \in \mathsf{RS}[\mathbb{F}, D, \rho]$ we mean that $\deg(P) < \rho|D|$ and associate P with the RS codeword that is its evaluation on D. We also use $\tilde{f}$ to denote the interpolant of a function f.

A.1 List Decoding

▶ **Definition 19** (List size for Reed-Solomon Codes). *For $u \in \mathbb{F}^D$, a set $V \subset \mathbb{F}^D$, and distance parameter $\delta \in [0, 1]$, let $\mathsf{List}(u, V, \delta)$ be the set of elements in V that are at most δ-far from u in relative Hamming distance. Formally, using $B(u, \delta)$ to denote the Hamming ball of relative radius δ centered around u, we have $\mathsf{List}(u, V, \delta) = B(u, \delta) \cap V$.*

*The code V is said to be (δ, L)-*list-decodable *if $|\mathsf{List}(u, V, \delta)| \leq L$ for all $u \in \mathbb{F}_q^D$.*

For $D \subseteq \mathbb{F}_q$, let $\mathcal{L}(\mathbb{F}_q, D, d, \delta)$ be the maximum size of $\mathsf{List}(u, V, \delta)$ taken over all $u \in \mathbb{F}_q^D$ for $V = \mathsf{RS}[\mathbb{F}_q, D, \rho = d/|D|]$.

We recall the fundamental Johnson bound, which says that sets with large minimum distance have nontrivial list-decodability. The particular version below follows, e.g., from [14, Theorem 3.3] by setting $d = (1 - \rho)|D|$ and $e = (1 - \sqrt{\rho} - \varepsilon)|D|$ there.

▶ **Theorem 20** (Johnson bound). *Let $V \subset \mathbb{F}^D$ be a code with minimum relative distance $\delta \in (0, 1)$. Then V is $(1-\sqrt{1-\delta}-\varepsilon, 1/(2\varepsilon\sqrt{1-\delta}))$-list-decodable for every $\varepsilon \in (0, 1-\sqrt{1-\delta})$.*

When V is a maximum distance separable (MDS) code like a Reed-Solomon code of rate ρ we have $\rho = 1 - \delta$, so V is $(1 - \sqrt{\rho} - \varepsilon, 1/(2\varepsilon\sqrt{\rho}))$-list-decodable for every $\varepsilon \in (0, 1 - \sqrt{\rho})$.

In particular, for Reed-Solomon codes this implies the following list-decodability bound:

$$\mathcal{L}(\mathbb{F}_q, D, d = \rho|D|, 1 - \sqrt{\rho} - \varepsilon) \leq O\left(\frac{1}{\varepsilon\sqrt{\rho}}\right).$$

Extremely optimistically, we could hope that Reed-Solomon codes are list-decodable all the way up to their distance with moderate list sizes. Staying consistent with the known limitations [8], we have the following brave conjecture.

▶ **Conjecture 21** (List decodability of Reed-Solomon Codes up to Capacity). *For every $\rho > 0$, there is a constant C_ρ such that every Reed-Solomon code of length n and rate ρ is list-decodable from $1 - \rho - \varepsilon$ fraction errors with list size $\left(\frac{n}{\varepsilon}\right)^{C_\rho}$. That is:*

$$\mathcal{L}(\mathbb{F}_q, D, d = \rho|D|, 1 - \rho - \varepsilon) \leq \left(\frac{|D|}{\varepsilon}\right)^{C_\rho}.$$

B Tightness of the one-and-a-half Johnson bound

Lemma 1 says that when V is a linear code with minimum distance λ, and u^* is some element that is δ-far from V, then for any u we have with high probability

$$\Delta(u^* + xu, V) \geq \min(\delta, J^{(1.5)}(\lambda) = 1 - (1 - \lambda)^{1/3}).$$

The rightmost term seems quite strange, as the $J^{(1.5)}(\cdot)$ function is unfamiliar in other settings of coding theory. However, as we show next, in certain settings this function gives the correct bound!

▶ **Lemma 22** (Tightness of one-and-a-half Johnson bound)**.** *For every member V_n of following family of RS codes $\left\{V_n = \mathsf{RS}[\mathbb{F}_{2^n}, \mathbb{F}_{2^n}, \rho = 2^{-3}] \mid n \in \mathbb{N}\right\}$ there exist $u_n^*, u_n \in \mathbb{F}_{2^n}^{\mathbb{F}_{2^n}}$ satisfying the following:*

- $\delta_{\max} \triangleq \Delta(u_n^*, V_n) = \Delta(u_n, V_n) = \frac{3}{4} = 1 - \rho^{2/3}$
- $\forall x \neq 0, \Delta(u_n^* + xu_n, V_n) \leq \frac{1}{2} = 1 - \rho^{1/3} = J^{(1.5)}(\Delta(V_n))$

Consequently, $\mathbf{E}[\delta_x] \leq J^{(1.5)}(\Delta(V_n)) + o(1) \leq \delta_{\max} - \frac{1}{4} + o(1)$.

We shall need to following claim in our proof of the lemma.

▷ Claim 23. For every $x \in \mathbb{F}_{2^n} \setminus \{0\}$ there exists a polynomial $P_x(Y) \in \mathbb{F}_{2^n}[Y]$ of the form

$$P_x(Y) = Y^{2^{n-1}} + xY^{2^{n-2}} + \tilde{P}_x, \quad \deg(\tilde{P}_x) < 2^{n-3}.$$

that has 2^{n-1} distinct roots in $\mathbb{F}_{2^n}$.

Proof. For $x \neq 0$ let $\beta_x = 1/x^2$, noticing β_x is unique because the map $\beta \mapsto \beta^2$ is bijective on $\mathbb{F}_{2^n}$. Let $\mathsf{Tr}(Z) \triangleq \sum_{i=0}^{n-1} Z^{2^i}$ be the trace function from $\mathbb{F}_{2^n}$ to $\mathbb{F}_2$. Define

$$S_x = \{y \in \mathbb{F}_{2^n} \mid \mathsf{Tr}(\beta_x y) = 0\}.$$

It is well known that $|S_x| = 2^{n-1}$ because the trace function has 2^{n-1} roots in $\mathbb{F}_{2^n}$. So we define

$$\begin{aligned} P_x(Y) &= \frac{1}{\beta_x^{2^{n-1}}} \cdot \mathsf{Tr}(\beta_x Y) = Y^{2^{n-1}} + \frac{1}{\beta_x^{2^{n-2}}} Y^{2^{n-2}} + \tilde{P}_x \\ &= Y^{2^{n-1}} + xY^{2^{n-2}} + \tilde{P}_x, \quad \deg(\tilde{P}_x(Y)) < 2^{n-3}. \end{aligned}$$

The last equality follows because $\beta_x^{2^{n-2}} = x$. ◀

Proof of Lemma 22. Consider V_n in this family and let $\mathbb{F} = \mathbb{F}_{2^n}$. Define $u^* : \mathbb{F} \to \mathbb{F}$ to be the function $u^*(y) = y^{2^{n-1}}$ and let $u : \mathbb{F} \to \mathbb{F}$ be the function $u(y) = y^{2^{n-2}}$.

By Claim 23, for every $x \in \mathbb{F} \setminus \{0\}$ there is some $v_x \in V_n$ and P_x with 2^{n-1} roots in $\mathbb{F}$ such that

$$P_x - (u^* + xu) + v_x = 0.$$

Then

$$\Delta(u^* + xu, v_x) = \Pr_{y \in \mathbb{F}}[u^*(y) + xu(y) \neq v_x(y)] = \Pr_y[P_x(y) \neq 0] = 1/2.$$

Thus we get that for all $x \in \mathbb{F} \setminus \{0\}$

$$\Delta(u^* + xu, V) \leq 1/2.$$

On the other hand,

$$\Delta(u, V) \geq 3/4,$$

because for all $v \in V_n$, $u - v$ is a polynomial of degree at most $2^{n-2} = |\mathbb{F}|/4$. This completes the proof. ◀

▶ Remark 24. Since this example is based on Reed-Solomon codes, it also easily translates into a limitation on the soundness of FRI. In particular, it means that the improvement to the soundness of FRI given in Remark 5 is optimal.

C DEEP Theorem – weighted version and general linear spaces

In this Section we provide a weighted version for Theorem 3 and generalize it to arbitrary linear spaces.

C.1 Weighted version

For application to Reed-Solomon Proximity Testing, it is more convenient to have a weighted version of the previous result. We briefly introduce some notation for dealing with weights, and then state the new version.

Let $u, v \in \mathbb{F}_q^D$. Let $\eta \in [0,1]^D$ be a vector of weights. We define the η-agreement between u and v by:

$$\mathsf{agree}_\eta(u,v) = \frac{1}{|D|} \sum_{i \in D | u_i = v_i} \eta(i).$$

For a subspace $V \subseteq \mathbb{F}_q^n$, we define

$$\mathsf{agree}_\eta(u,V) = \max_{v \in V} \mathsf{agree}_\eta(u,v).$$

▶ **Theorem 25.** *Let $\rho > 0$ and let $V = \mathsf{RS}[\mathbb{F}_q, D, d = \rho \cdot |D|]$. For $z, b \in \mathbb{F}_q$, we let*

$$V_{z,b} = \{Q(Y) \in V \mid Q(z) = b\}.$$

For $\alpha < 1$, let $L^* = \mathcal{L}(\mathbb{F}_q, D, d = \rho|D|, 1-\alpha)$ be the list-size for list-decoding V from $(1-\alpha)$-fraction errors (without weights).

Let $u, u^* \in \mathbb{F}_q^D$. For each $z \in \mathbb{F}_q$, let $B_z(X) \in \mathbb{F}_q[X]$ be an arbitrary linear function. Suppose that

$$\Pr_{x,z \in \mathbb{F}_q}[\mathsf{agree}_\eta(u^* + xu, V_{z,B_z(x)}) > \alpha] \geq \max\left(2L^*\left(\frac{d}{q} + \epsilon\right)^{1/3}, \frac{4}{\epsilon^2 q}\right), \tag{15}$$

Then there exist $v, v^* \in V$ and $C \subset D$ such that:

- $\sum_{y \in C} \eta(y) > (\alpha - \epsilon)|D|$,
- $u|_C = v|_C$,
- $u^*|_C = v^*|_C$.

Consequently, we have $\mathsf{agree}_\eta(u,V), \mathsf{agree}_\eta(u^*,V) \geq \alpha - \epsilon$.

The proof is nearly identical to the proof of Theorem 3 so we only highlight the changes. First, we observe that if $\eta_1 : D \to [0,1]$ is the the constant function with value 1, then $\mathsf{agree}_\eta(u,v) \leq \mathsf{agree}_{\eta_1}(u,v) = 1 - \Delta(u,v)$. Thus the set

$$\{Q(Y) \in \mathbb{F}_q[Y] \mid \deg(Q) \leq d, \mathsf{agree}_\eta(u^* + xu, Q) > \alpha\}$$

is contained in

$$\{Q(Y) \in \mathbb{F}_q[Y] \mid \deg(Q) \leq d, \Delta(u^* + xu, Q) < 1 - \alpha\}.$$

The size of this latter set is bounded by L^*, and thus the size of the former set is too. The proof then proceeds as before, until the very end, where we have a set $A' \subseteq \mathbb{F}_q$, with $|A'| \geq \frac{2}{\epsilon}$, and polynomials $P, P^* \in V$ such that for each $x \in A'$, $\mathsf{agree}_\eta(u^* + xu, P^* + xP) > \alpha$.

Then we take $C = \{y \in C \mid u^*(y) = P^*(y), u(y) = P(y)\}$, and our goal is to show that $\sum_{y\in C} \eta(y) > (\alpha - \epsilon)|D|$. To this end, consider:

$$\begin{aligned}
\alpha &< \frac{1}{|A'|} \sum_{x\in A'} \mathsf{agree}_\eta(u^* + xu, P^* + xP) \\
&= \frac{1}{|D| \cdot |A'|} \sum_{x\in A'} \sum_{y\in D} (\eta(y) \cdot 1_{u^*(y)+xu(y)=P^*(y)+xP(y)}) \\
&= \frac{1}{|D|} \sum_{y\in D} \eta(y) \left(\frac{1}{|A'|} \sum_{x\in A'} 1_{u^*(y)+xu(y)=P^*(y)+xP(y)} \right) \\
&\leq \frac{1}{|D|} \sum_{y\in C} \eta(y) + \frac{1}{|D|} \sum_{y\in D\setminus C} \eta(y) \cdot \frac{1}{|A'|} \\
&\leq \frac{1}{|D|} \sum_{y\in C} \eta(y) + \epsilon/2.
\end{aligned}$$

This implies that $\sum_{y\in C} \eta(y) > (\alpha - \epsilon)|D|$, and the rest of the proof is the same as before.

C.2 DEEP Lemma for general linear codes

Theorem 3 can be generalized to apply to arbitrary linear codes, and this is the focus of this section. We explain the basic principles for an $[n, k, d]_q$-linear code V with generating matrix $G \in \mathbb{F}_q^{k\times n}$, viewing codewords as evaluations of linear forms on the columns of G.

Let $D \subset \mathbb{F}_q^k$ be the set of columns of G. A linear form $\ell \in F_q^k$ can be "evaluated" at any any element x of D. Similarly, if we fix a set of points $S \subseteq \mathbb{F}_q^k$ (thinking $|S| \gg |D|$), we may evaluate the linear form ℓ at any point of S – this corresponds to evaluation outside the original domain D.

If we are given a function $u : D \to \mathbb{F}_q$ which is supposed to be the evaluations of a linear form ℓ on D, we can ask about what the evaluation of this linear form at a point $z \in S$ is. This is the viewpoint from which the DEEP lemma generalizes to general codes.

We start with two functions $u, u^* : D \to \mathbb{F}_q$ (which are supposed to correspond to linear forms, say $\ell \in \mathbb{F}_q^k$ and $\ell^* \in \mathbb{F}_q^k$. We have a verifier who samples $z \in S$ and asking for $a = \ell(z)$ and $a^* = \ell^*(z)$. Given these answers, the verifier now samples $x \in \mathbb{F}_q$ and computes $b = a^* + xa$ which is supposedly equal to $\ell^*(z) + \ell(z)$ (if u^* and u are indeed codewords of V). The result below says that if S is the set of columns of an error correcting code with good distance, and V has small list size for list-decoding up to radius δ, then with high probability, the function $u_x = u^* + xu$ has distance at least $\approx \min\{\Delta(u^*, V), \delta\}$ from the sub-code of V corresponding to the linear forms that evaluate to b on z.

▶ **Definition 26** (Robust). *A set $S \subseteq \mathbb{F}^k$ is called σ-robust if every subset of S of size σ contains a basis for $\mathbb{F}^k$.*

The following claim is well-known in coding theory (cf. [19, Problem 2.8]).

▷ Claim 27. Fix a full-rank matrix $G \in \mathbb{F}_q^{k\times N}, N \geq k$, and let $C = \left\{x \cdot M \mid x \in \mathbb{F}_q^k\right\}$ be the linear code generated by it. Then the set of columnss of G is σ-robust if and only if the minimum distance of C is at least $N - \sigma + 1$.

▶ **Lemma 28** (DEEP method for general linear codes). *Let V be an $[n,k,d]_q$-code that is (δ, L^*_δ)-list decodable for some $\delta > 0$, and fix $G \in \mathbb{F}_q^{k\times n}$ to be its generating matrix. Let $S \subset \mathbb{F}_q^k$ be a σ-robust set of size N. For $z \in S, b \in \mathbb{F}_q$, let*

$$V_{z,b} = \{v \in V \mid v = G \cdot \ell_v \ \textit{AND}\ \langle \ell_v, z\rangle = b\}$$

where $\langle v, z\rangle = \sum_{i=1}^k v_i, z_i$.

Let $u, u^* \in \mathbb{F}_q^n$. For each $z \in S$, let $B_z(X) \in \mathbb{F}_q[X]$ be an arbitrary linear function. Suppose that for some $\epsilon > 0$ the following holds,

$$\Pr_{x\in\mathbb{F}_q, z\in S}[\Delta(u^* + xu, V_{z,B_z(x)}) < \delta] \geq \max\left(2L^*_\delta\left(\frac{\sigma}{N} + \epsilon\right)^{1/3}, \frac{4}{\epsilon^2 q}\right), \tag{16}$$

Then there exist $v, v^* \in V$ and $C \subset [n]$ such that:

- $|C| \geq (1 - \delta - \epsilon)n$,
- $u|_C = v|_C$,
- $u^*|_C = v^*|_C$.

Consequently, we have $\Delta(u, V), \Delta(u^*, V) \leq \delta + \epsilon$.

The proof is analogous to the proof in the Reed-Solomon case, and appears in Appendix D.

Discussion

For the special case of RS codes, the DEEP method can be used to locally modify the problem and reduce degree. Indeed, the subcode $V_{z,b}$ in the case of RS codes corresponds is comprised of functions $f : D \to \mathbb{F}$ that are evaluations of polynomials of degree d whose interpolating polynomial P_f satisfies $P_f(z) = b$. From such a codeword, one can construct a new codeword $f_{z,b} : D \to \mathbb{F}$ defined by $f_{z,b}(x) = \frac{f(x)-b}{z}$, which is well-defined for all $z \notin D$. Notice that the transformation from f to $f_{z,b}$ is *1-local*, meaning that each entry of $f_{z,b}$ is constructed by making a single query to f. Furthermore, this transformation maps a subset of the code $RS[\mathbb{F}, D, d]$ to the code $\mathsf{RS}[\mathbb{F}, D, d-1]$, so we may use this transformation in RS IOPPs (as will done in the following section).

In contrast, for a general k-dimensional linear code V, the subcode $V_{z,b}$, while being an affine subspace of V, has less structure. In particular, it is not clear how to locally convert this subcode to a "nice" code of dimension $k-1$. An interesting middle ground, left to future work, is the case of algebraic codes like Reed Muller codes and Algebraic Geometry codes which resemble RS codes.

D Proof of the DEEP lemma for general codes

Proof of Lemma 28. To simplify notation set $\eta = \max\left(2L^*_\delta\left(\frac{\sigma}{N} + \epsilon\right)^{1/3}, \frac{4}{\epsilon^2 q}\right)$, and let $u_x = u^* + xu$.

Let $\mathcal{E}[x,z]$ denote the event "$\exists v \in \mathsf{List}(u_x, V, \delta), \langle v, z\rangle = B_z(x)$".

The assumption of Equation (16) now reads as

$$\Pr_{x\in\mathbb{F}_q, z\in S}[\mathcal{E}[x,z]] \geq \eta.$$

Thus we get,

$$\Pr_{x\in\mathbb{F}_q}[\Pr_{z\in S}[\mathcal{E}[x,z]] \geq \eta/2] \geq \eta/2 \tag{17}$$

Let

$$A = \left\{ x \in \mathbb{F}_q \mid \Pr_{z \in S}[\mathcal{E}[x,z]] \geq \eta/2] \right\}$$

and notice $|A| \geq \eta q/2$.

For $x \in \mathbb{F}_q$, pick $v_x \in V$ to be a member of $\mathsf{List}(u_x, V, \delta)$ that maximizes $\Pr_{z \in S}[P(z) = B_z(x)]$. Let $S_x = \{z \in S \mid \langle v_x, z \rangle = B_z(x)\}$ and set $\mu_x = |S_x|/s$. By definition, $|\mathsf{List}(u_x, V, \delta)| \leq L^*_\delta$, and so by the pigeonhole principle, for each $x \in A$ we have $\mu_x \geq \frac{\eta}{2L^*_\delta}$.

For x, β, γ picked uniformly from A we have

$$\begin{aligned}
\mathbf{E}_{x,\beta,\gamma \in A}\left[\frac{|S_x \cap S_\beta \cap S_\gamma|}{s}\right] &= \mathbf{E}_{z \in S, x,\beta,\gamma \in \mathbb{F}_q}[1_{z \in S_x \cap S_\beta \cap S_\gamma}] \\
&= \mathbf{E}_{z \in S}[\mathbf{E}_{x \in \mathbb{F}_q}[1_{z \in S_x}]^3] \\
&\geq \mathbf{E}_{z \in S, x \in \mathbb{F}_q}[1_{z \in S_x}]^3 \\
&\geq \left(\frac{\eta}{2L^*_\delta}\right)^3 \\
&> \frac{\sigma}{N} + \epsilon.
\end{aligned}$$

The second equality above follows from the independence of x, β, γ. The first inequality is an application of Jensen's inequality and the last inequality is by assumption on η.

Thus

$$\Pr_{x,\beta,\gamma}[|S_x \cap S_\beta \cap S_\gamma| > \sigma] \geq \epsilon.$$

Note that $\Pr_{x,\beta,\gamma}[x, \beta, \gamma \text{ are not all distinct}] < 3/|A|$. Since $|A| \geq \eta q/2 \geq 2/\epsilon^2 \geq 6/\epsilon$ we have $3/|A| \leq \epsilon/2$. Thus $\Pr_{x,\beta,\gamma}[x, \beta, \gamma \text{ are all distinct and } |S_x \cap S_\beta \cap S_\gamma| > \sigma] \geq \epsilon/2$.

This means that there are distinct x_0, β_0 such that

$$\Pr_\gamma[|S_{x_0} \cap S_{\beta_0} \cap S_\gamma| > d] \geq \epsilon/2.$$

Consider some γ where this happens. Let $\tilde{S} = S_{x_0} \cap S_{\beta_0} \cap S_\gamma$. Extend each of u^*, u to functions over domain S by defining for all $z \in S \setminus [n]$ $u^*(z) = B_z(0)$ and $u(z) = B_z(1)$, and for $x \in \mathbb{F}_q$ let $u_x(z) = u^*(z) + xu(z)$. Since V is systematic, we define $v_x(z) = \langle v_x|_{[k]}, z \rangle$ and thus extend v_x to domain $\tilde{S}$. By construction we know

$$(x_0, u_{x_0}), (\beta_0, u_{\beta_0}), (\gamma, u_\gamma)$$

are collinear. So, in particular,

$$(x_0, u_{x_0}|_{\tilde{S}}), (\beta_0, u_{\beta_0}|_{\tilde{S}}), (\gamma, u_\gamma|_{\tilde{S}}) \in \mathbb{F}_q \times \mathbb{F}_q^{\tilde{S}}$$

are likewise collinear, as a special case. By definition of $\tilde{S}$, we get that:

$$(x_0, v_{x_0}|_{\tilde{S}}), (\beta_0, v_{\beta_0}|_{\tilde{S}}), (\gamma, v_\gamma|_{\tilde{S}}) \in \mathbb{F}_q \times \mathbb{F}_q^{\tilde{S}}$$

are also collinear. Since $|\tilde{S}| > \sigma$ and S is σ-robust we conclude that v_γ is uniquely determined by $v_\gamma|_{\tilde{S}}$. This allows us to conclude that

$$(x_0, v_{x_0}), (\beta_0, v_{\beta_0}), (\gamma, v_\gamma) \in \mathbb{F}_q \times \mathbb{F}_q^n$$

are all collinear, recalling that $v_{x_0} \in \mathsf{List}(u_{x_0}, V, \delta)$.

Thus, an $\epsilon/2$-fraction of the $\gamma \in A$ have the "good" property that (γ, v_γ) is on the line passing through (x_0, v_{x_0}) and (β_0, v_{β_0}). Write this line as $v^* + xv$ and notice that for all "good" γ we have $v_\gamma = v^* + \gamma v$. Let $A' \subseteq A$ denote the set of good elements for this line, recording that $|A'| \geq |A| \cdot \epsilon/2 \geq 1/\epsilon$. By definition of $\mathsf{List}(u_x, V, \delta)$ and the assumption $v_x \in \mathsf{List}(u_x, V, \delta)$, we have that $\Delta(u_x, v_x) < \delta$ for $x \in A'$.

Consider the set $C \subset [n]$ defined by

$$C = \{y \in [n] \mid u^*(y) = v^*(y) \text{ AND } u(y) = v(y)\}.$$

For each $y \in [n] \setminus C$ there exists at most a single value of $x \in \mathbb{F}_q$ satisfying $u_x(y) = v_x(y)$ because

$$u_x(y) - v_x(y) = (u^*(y) - v^*(y)) + x \cdot (u(y) - v(y))$$

has at most one value x on which it vanishes. This implies

$$\delta \geq \mathbf{E}_{x \in A'}[\Delta_{[n]}(u_x, v_x)] \geq \frac{|[n] \setminus C|}{n} \cdot \left(1 - \frac{1}{|A'|}\right) \geq \left(1 - \frac{|C|}{n}\right) \cdot (1 - \epsilon) \geq 1 - \frac{|C|}{n} - \epsilon.$$

Rearranging, we get $\frac{|C|}{n} \geq 1 - (\delta + \epsilon)$ and this completes the proof. ◀

E The algebraic hash function

We now describe the algebraic hash function H_x.

The description of the hash function requires fixing some choices of certain subspaces. For each $i \in [0, \mathsf{r}]$ we choose $\mathbb{F}_2$-subspaces $L_0^{(i)}$ and $L^{(i)}$, satisfying the following properties.

1. $L_0^{(i)} \subseteq L^{(i)}$ with $\dim(L_0^{(i)}) = 1$,
2. $L^{(i+1)} = q^{(i)}(L^{(i)})$, where $q^{(i)}(X)$ is the *subspace polynomial* of $L_0^{(i)}$,

$$q^{(i)}(X) = \prod_{\alpha \in L_0^{(i)}} (X - \alpha),$$

thus this is an $\mathbb{F}_2$-linear map with kernel $L_0^{(i)}$). In particular, $\dim(L^{(i+1)}) = \dim(L^{(i)}) - 1$. Let $\mathcal{S}^{(i)}$ denote the set of cosets of $L_0^{(i)}$ contained in $L^{(i)}$.

Given $x \in \mathbb{F}$ and $f : L^{(i)} \to \mathbb{F}$, the hash of f with seed x is defined to be the function $H_x[f] : L^{(i+1)} \to \mathbb{F}$ as follows. For $s \in L^{(i+1)}$, let $s_0, s_1 \in L^{(i)}$ be the two roots of $q^{(i)}(X) - s$. Let $P_{f,s}(X) \in \mathbb{F}[X]$ be the unique degree ≤ 1 polynomial satisfying

$$P_{f,s}(s_0) = f(s_0),$$

$$P_{f,s}(s_1) = f(s_1).$$

Then we define

$$H_x[f](s) = P_{f,s}(x). \tag{18}$$

Observe that $H_x[f](s)$ can be computed by querying f on the set $\{s_0, s_1\}$ (this set is a coset of $L_0^{(i)}$, and we denote it by $S_s^{(i)}$).

To understand H_x better, it is instructive to see what it does to $\mathsf{RS}^{(i)}$. Let $f \in \mathsf{RS}^{(i)}$. The underlying polynomial $f(X)$ thus has degree at most $\rho|L^{(i)}|$. We may write $f(X)$ in base $q^{(i)}(X)$ as:

$$f(X) = a_0(X) + a_1(X)q^{(i)}(X) + \ldots + a_t(X)(q^{(i)}(X))^t, \tag{19}$$

where each $a_i(X)$ has degree at most 1, and $t \le \rho|L^{(i)}|/2$. Since the polynomials $f(X)$ and $P_{f,s}(X)$ agree on the roots of $q(X) - s$, we get that $f(X) \equiv P_{f,s}(X) \mod (q^{(i)}(X) - s)$. From Equation (19), we get that

$$P_{f,s}(X) = a_0(X) + a_1(X)s + \ldots + a_t(X)s^t.$$

In particular, for all $x \in \mathbb{F}$,

$$H_x[f](s) = P_{f,s}(x) = a_0(x) + a_1(x)s + \ldots + a_t(x)s^t,$$

and thus

$$H_x[f] \in \mathsf{RS}^{(i+1)}.$$

F Proof of Lemma 12 and Lemma 13

We first prove Lemma 12.

Proof of Lemma 12. Set $\gamma = \max(\alpha^{(i)}, 1 - \delta^*)$.

For simplicity, denote $f^{(i)}$ by f.

Recall the notation $P_{f,s}$ from the definition of the algebraic hash function H_x in Section E. We have that for each $s \in L^{(i+1)}$, $H_x[f](s) = P_{f,s}(x)$ is a linear function of x. Thus we can write $H_x[f] = u^* + xu$ for $u^*, u \in \mathbb{F}_q^{L^{(i+1)}}$, and for any fixed s, we have the formal polynomial equality $P_{f,s}(X) = u^*(s) + Xu(s)$.

We are interested in bounding the probability of the event $\beta^{(i+1)} > \gamma + \epsilon$. In other words, we want to bound the probability that there exists a polynomial $Q(Y) \in \mathbb{F}_q[Y]$ with $\deg(Q) < d^{(i+1)} + 1$ such that:

- $\mathsf{agree}_{\theta^{(i+1)}}(u^* + xu, Q) > \gamma + \epsilon$,
- $Q(z^{(i)}) = B^{(i)}_{z^{(i)}}(x)$.

This is exactly the scenario of Theorem 25. That Lemma tells us that if the probability in question is larger than ν^*, then there exist polynomials $P(Y), P^*(Y)$ of degree $\le d^{(i+1)}$ and a set $T \subseteq L^{(i+1)}$ such that:

- $$\frac{1}{|L^{(i+1)}|} \sum_{s \in L^{(i+1)}} \theta^{(i+1)} > \gamma,$$
- $u|_T = P|_T$,
- $u^*|_T = P^*|_T$.

Let

$$\hat{P}(X, Y) \triangleq P^*(Y) + X \cdot P(Y)$$

and notice that $\deg_X(\hat{P}) \le 1$, $\deg_Y(\hat{P}) \le d^{(i+1)}$.

Consider the polynomial $R(X) \triangleq \hat{P}(X, q^{(i)}(X))$. We have

$$\deg(R) \le 2d^{(i+1)} + 1 = d^{(i)} - 1 < d^{(i)}.$$

We claim that R agrees with f on $\tilde{T} = \bigcup_{s \in T} S^{(i)}_s$.

Take any $s \in T$ and let $S^{(i)}_s = \{s_0, s_1\} \in \mathcal{S}^{(i)}$ be the pair of roots of the polynomial $q^{(i)}(X) - s$.

First we show that the polynomials $P_{f,s}(X)$ and $\hat{P}(X,s)$ are identical. Indeed, $\hat{P}(X,s)) = P^*(s) + XP(s) = u^*(s) + Xu(s) = P_{f,s}(X)$. It follows that

$$f(s_0) = \hat{P}(s_0,s) = \hat{P}\left(s_0, q^{(i)}(s_0)\right) = R(s_0)$$

and similarly $f(s_1) = R(s_1)$. Therefore, R and f agree on $\tilde{T}$, as claimed.

We now use the above information to show that $\alpha^{(i)} = \mathsf{agree}_{\eta^{(i)}}(f,R) > \gamma$, which contradicts the definition of γ. Indeed,

$$\begin{aligned}
\mathsf{agree}_{\eta^{(i)}}(f,R) &= \frac{1}{|L^{(i)}|} \sum_{r \in L^{(i)} | f(r) = R(r)} \eta^{(i)}(r) \\
&\geq \frac{1}{|L^{(i)}|} \sum_{r \in \tilde{T}} \eta^{(i)}(r) \\
&= \frac{1}{|L^{(i)}|} \sum_{s \in T} \sum_{r \in S_s^{(i)}} \eta^{(i)}(r) \\
&= \frac{1}{|L^{(i)}|} \sum_{s \in T} |S_s^{(i)}| \cdot \theta^{(i)}(s) \quad \text{Since } \theta(s) \text{ equals the average of } \eta(r) \mid r \in S_s^{(i)} \\
&= \frac{1}{|L^{(i+1)}|} \sum_{s \in T} \theta^{(i)}(s) \\
&> \gamma.
\end{aligned}$$

This is the desired contradiction. ◀

Next we prove Lemma 13.

Proof of Lemma 13. By definition,

$$\beta^{(i)} = \mathsf{agree}_{\theta^{(i)}}(H_{x^{(i-1)}}[f^{(i-1)}], \{P(Y) \in \mathbb{F}_q[Y] \mid \deg(P) \leq d^{(i)} \text{ and } P(z^{(i-1)}) = B^{(i-1)}_{z^{(i-1)}}(x^{(i-1)})\})$$

Next, by the properties of quotienting, Lemma 6,

$$\begin{aligned}
\beta^{(i)} &= \mathsf{agree}_{\theta^{(i)}}(H_{x^{(i-1)}}[f^{(i-1)}], \{P(Y) \in \mathbb{F}_q[Y] \mid \deg(P) \leq d^{(i)} \text{ and } P(z^{(i-1)}) = B^{(i-1)}_{z^{(i-1)}}(x^{(i-1)})\}) \\
&= \mathsf{agree}_{\theta^{(i)}}(\mathsf{QUOTIENT}(H_{x^{(i-1)}}[f^{(i-1)}], z^{(i-1)}, B^{(i-1)}_{z^{(i-1)}}(x^{(i-1)})), \\
&\qquad \{P(Y) \in \mathbb{F}_q[Y] \mid \deg(P) \leq d^{(i)} - 1\}).
\end{aligned}$$

Now observe that $\eta^{(i)}$ is obtained from $\theta^{(i)}$ by zeroing out coordinates in $E^{(i)}$, and the only coordinates where $f^{(i)}$ can differ from $\mathsf{QUOTIENT}(H_{x^{(i-1)}}[f^{(i-1)}], z^{(i-1)}, B^{(i-1)}_{z^{(i-1)}}(x^{(i-1)}))$ are in $E^{(i)}$. Thus:

$$\begin{aligned}
\beta^{(i)} &\geq \mathsf{agree}_{\theta^{(i)}}(f^{(i)}, \{P(Y) \in \mathbb{F}_q[Y] \mid \deg(P) \leq d^{(i)} - 1\}) \\
&= \mathsf{agree}_{\theta^{(i)}}(f^{(i)}, \mathsf{RS}^{(i)}) \\
&= \alpha^{(i)}.
\end{aligned}$$

This completes the proof. ◀

Abstract

We show new hardness results for the class of Polynomial Local Search problems (PLS):

- Hardness of PLS based on a falsifiable assumption on bilinear groups introduced by Kalai, Paneth, and Yang (STOC 2019), and the Exponential Time Hypothesis for randomized algorithms. Previous standard model constructions relied on non-falsifiable and non-standard assumptions.
- Hardness of PLS relative to random oracles. The construction is essentially different than previous constructions, and in particular is unconditionally secure. The construction also demonstrates the hardness of parallelizing local search.

The core observation behind the results is that the *unique proofs* property of incrementally-verifiable computations previously used to demonstrate hardness in PLS can be traded with a simple *incremental completeness* property.

1 Introduction

Local search is a well known approach for tackling optimization problems. Local search algorithms seek solutions that are *locally optimal* – they commonly try to improve on a given solution by considering small perturbations of it, called *neighbors*, and testing whether they are better according to some value function. Indeed, many algorithms use this approach with empirical success, for instance, the Simplex linear programming algorithm, the Lin-Kernighan TSP algorithm, and various machine learning algorithms [43, 38, 31]. Nevertheless, the approach has its limitations and many natural local search problems are not known to admit polynomial-time algorithms.

Aiming to characterize the computational complexity of local search, Johnson, Papadimitriou, and Yannakakis [33] introduced the class Polynomial Local Search (PLS). The class is defined by its canonical complete problem Local-Search (LS) [33, 29]. Here the input consists of two polynomial-size circuits: a *successor circuit* $\mathcal{S} : \{0,1\}^n \to \{0,1\}^n$, which given a string x outputs a string x', and a *value circuit* $\mathcal{F}$, which given a string x outputs an integer value. The goal is to find a string x which is locally optimal in the sense that $\mathcal{F}(x) \geq \mathcal{F}(\mathcal{S}(x))$. Here strings correspond to solutions, with a value assigned by $\mathcal{F}$, and the

[1] Member of the Check Point Institute of Information Security.

successor assigned by $\mathcal{S}$ represents "the best" neighbor. Important problems that are known to be PLS complete include finding a locally optimal max-cut [49] and finding pure Nash equilibrium in congestion games [22].

As observed in [33], PLS belongs to the class TFNP of *total search problems* in NP; namely, a local optimal solution always exists (and can be efficiently verified). As a result, it is unlikely that PLS contains NP-hard problems, as this would imply that NP = coNP [33, 41]. This barrier is shared of course by other prominent subclasses of TFNP, perhaps the most famous example being the class PPAD that captures the hardness of finding Nash equilibrium in bimatrix games [18, 14]. Accordingly, researchers have turned to seek for alternative evidence of hardness.

One natural place to look for such evidence is cryptography. Indeed, cryptography typically relies on problems closer to the boundary of P than to NP hard problems. For some subclasses of TFNP (such as PPP, PPA, and Ramsey) evidence of hardness has been shown based on standard cryptographic assumptions [45, 12, 32, 36, 50]. Establishing the hardness of PLS (and PPAD), however, has been far more elusive. Hubáček and Yogev [29], building on [7, 23], demonstrated a hard problem in PLS ∩ PPAD based on *indistinguishability obfuscation* [4], a strong cryptographic primitive, yet to be constructed under standard assumptions.[2] Similar hardness was then shown by Choudhuri et al. [16] assuming hardness of #SAT and the soundness of the Fiat-Shamir transform for the sumcheck protocol, which in turn can be based on *optimally-secure fully-homomorphic encryption against quasi-polynomial attackers* [13]. More recently, the same has been shown based on the hardness of iterated squaring and soundness of Fiat-Shamir for the iterated-squaring protocol of Pietrzak [46] by both Choudhuri et al. [15] and Ephraim et al. [21].

Basing the hardness of PLS (or PPAD) on standard assumptions remains an open problem.

1.1 Our Results

We provide new results regarding the hardness of PLS. Our first result shows worst-case hardness of PLS based on *the KPY assumption* on bilinear groups and the randomized Exponential Time Hypothesis (ETH). The KPY assumption was introduced recently by Kalai, Paneth, and Yang [34] toward the construction of publicly-verifiable delegation schemes. The assumption is similar in spirit to previous standard assumptions that generalize Decisional Diffie Hellman (e.g., [8, 9]). It is polynomially falsifiable and holds in the generic group model. Randomized ETH postulates that solving SAT in the worst case requires exponential-time even for randomized algorithms [30].

▶ **Theorem 1** (Informal). *Under the KPY assumption on bilinear groups and randomized* ETH*,* PLS *is hard in the worst case.*

The result is, in fact, more general and shows a reduction of PLS hardness to a certain type of incrementally-verifiable computation schemes (IVC) [51]. We then derive the required IVC from the work of [34]. We can also show average-case hardness at the cost of assuming superpolynomial hardness of the KPY assumption and average-case randomized ETH. See further details in the technical overview.

Our second result is a construction of PLS instances that are unconditionally hard in *the random oracle model*.

[2] More accurately, they show a hard problem in the class *Continuous Local Search* (CLS), which is known to be in PLS ∩ PPAD [19].

▶ **Theorem 2** (Informal). *Relative to a random oracle,* Local-Search *is unconditionally hard-on-average.*

Previously, Choudhuri et al. [16] showed hardness of CLS $\subseteq$ PLS $\cap$ PPAD relative to a random oracle, but their result is conditioned on hardness of #SAT (the construction does not relativize with respect to this hardness and hence it cannot be derived from the random oracle itself). Indeed, our construction is quite different from theirs. Whereas their construction is based on the sum-check protocol [39] (which explains the non-black-box reliance on #SAT hardness), ours comes from recent advancements in *proofs of sequential work* motivated by blockchain applications [40, 17, 20].

The reliance on proofs of sequential work, in fact, translates to a result on the hardness of parallelizing local search. Such hardness, in the random oracle model, was recently shown for CLS (and in particular for both PLS and PPAD) by Ephraim et al. [21] further assuming that repeated squaring modulo a composite is hard to parallelize [47]. Specifically, they construct CLS instances that can be solved in some tuneable sequential polynomial time, but cannot be solved much faster by parallel algorithms. Our result gives a similar kind of hardness for PLS in the random oracle model, without relying on any unproven computational assumptions. We elaborate on this in the technical overview below.

2 Technical Overview

To motivate our approach, we start by recalling previous approaches taken toward proving PLS (or rather CLS) hardness.

2.1 Hardness via Incremental Computation

So far, the common approach toward arguing cryptographic hardness of PLS went through an intermediate problem called Sink-of-Verifiable-Line (SVL) [1, 7]. An instance of SVL consists of a successor circuit $\mathcal{S}$ and a verifier circuit $\mathcal{V}$. The successor $\mathcal{S}$ implicitly defines a step-by-step (or, incremental) computation $s_{t+1} := \mathcal{S}(s_t)$ starting from a canonical source s_0 and ending at a sink s_T, for some superpolynomial T:

$$s_0 \xrightarrow{\mathcal{S}} \ldots \xrightarrow{\mathcal{S}} s_T$$

The verifier $\mathcal{V}(s^*, t)$ is promised to accept any s^* as the t-th state if and only if it is correct, namely $s^* = \mathcal{S}^{(t)}(s_0)$. The goal is to find the sink $s_T = \mathcal{S}^{(T)}(s_0)$, given $(\mathcal{S}, \mathcal{V})$.

It is not hard to see that solving SVL can be reduced to solving a local search problem in PLS [29], and thus it is sufficient to prove the hardness of SVL.

Valiant's Incrementally-Verifiable Computation and Uniqueness. A natural way to approach SVL hardness is Valiant's notion of incrementally-verifiable computation (IVC) [51]. According to this notion, we can take a Turing machine computation given by a machine M and input x with a configuration graph:

$$M_x^0 \to \ldots \to M_x^T \ ,$$

and associate with each intermediate configuration M_x^t a short proof π_t, attesting to its correctness. The proofs are incremental – the next proof π_{t+1} can be efficiently computed from π_t.

At first glance, this general notion seems to directly yield SVL hardness. Indeed, we can take any polynomial-space machine M solving some hard search problem R on input x and consider the corresponding incrementally-verifiable computation:

$$(M_x^0, \pi_0) \xrightarrow{\mathcal{S}} \ldots \xrightarrow{\mathcal{S}} (M_x^T, \pi_T) \ .$$

Here the successor simply advances the computation of M and incrementally computes the corresponding proofs. The SVL verifier is derived directly from the IVC verifier.

The reason that the above simple transformation does not work is that *the IVC proofs may not be unique*. In particular, a correct intermediate configuration may have many different accepting proofs attesting to its correctness, whereas SVL requires that only a single string can be accepted as the t-th node (for any t). Choudhuri et al. [16] show that the SVL uniqueness requirement can be somewhat relaxed and traded with *computational uniqueness* meaning that it is computationally hard to find more than a single proof for any given statement (even if such proofs exist).

So far, however, incrementally-verifiable computation with (even computational) uniqueness has not been achieved under standard assumptions. This is, in fact, the case even for specific (hard) computations, let alone for general ones.

2.2 Incremental Completeness

We show that the hardness of PLS does not require SVL hardness nor IVC with unique proof. Rather, we observe that IVC with a conceptually simple *incremental completeness* property suffices. Then we derive such IVC for polynomially-long computations from the delegation scheme construction of Kalai, Paneth, Yang [34] and combine it with ETH to obtain PLS hardness. We next explain the notion of incremental completeness and why it suffices. In the next subsection, we explain how it is obtained.

Incremental-Complete IVC and PLS Hardness. An incremental complete IVC has the property that given *any* accepting proof π for an intermediate state M_x^t of the computation, running the prover results in an accepting proof π' for the next state M_x^{t+1}. This differs from Valiant's original formulation where completeness is only guaranteed for the prescribed proof generated by iteratively applying the prover t times.

Let us now describe how to construct hard Local-Search instances from incrementally-complete IVC. Once again, we start from some hard computation given by a polynomial-space machine M and instance x. Rather than considering a verifiable computation chain, we shall consider a DAG with nodes of the form (t, C, π), where t is a timestamp, C is an alleged configuration of $M(x)$ at time t, and π is an IVC proof. We call such a node *valid* if the corresponding proof is accepting. For simplicity, we assume for now that the IVC is also perfectly sound, meaning that valid nodes are always such that C is the correct configuration M_x^t. Note that for every time t, there may very well be multiple corresponding valid nodes. We can visualize this as multiple "parallel universes", which the verifiable computation lives in simultaneously. Incremental completeness says that in *every* such universe, as time moves forward, the computation may proceed. In particular, by induction, we always reach a *sink* of the form (T, M_x^T, π) that contains the last state of the computation.

This naturally gives an LS instance. Valid nodes (t, M_x^t, π) are given value t and are always succeeded by another valid node $(t+1, M_x^{t+1}, \pi')$ derived by advancing the computation and incrementing the IVC proof. Invalid nodes are given value -1 and are succeeded by some canonical source in the DAG $(0, M_x^0, \varepsilon)$, where ε is the empty proof, which by convention is

accepted as a proof for M_x^0. The local maximums of the corresponding instance are exactly the sinks of the DAG, which by incremental completeness are of the form (T, M_x^T, π), containing the last state. Therefore, finding a local-maximum reduce to solving the underlying hard computational task given by the computation $M(x)$.

Our actual construction does not assume perfect soundness of the IVC, but only computational soundness. There may exist so called *fooling nodes* (t, C^*, π^*) that pass verification although C^* is not the correct configuration M_x^t. These nodes may be local maximums and finding them may not reduce to solving the underlying problem. Nonetheless, finding fooling local maximum corresponds to breaking the soundness of the IVC, which is computationally infeasible.

2.3 Obtaining IVC with Incremental Completeness

Valiant [51] put forth a general approach toward constructing IVC by *recursive proof composition*. Oversimplifying, the basic idea is that to move from the t-th configuration $C = M_x^t$ and proof π_t to the next configuration $C' = M_x^{t+1}$ and proof π_{t+1}, the new proof π_{t+1} asserts that:

1. There exists a proof π that passes IVC verification as a valid proof that $C = M_x^t$ (this part is recursive in the sense that it relies on IVC verification for smaller times stamps),
2. C' is obtained from C by applying M_x's transition function.

For this to be feasible, each "single-step proof" is computed using a succinct non-interactive NP proof system where verification time (and in particular, the size of the proof) is fixed and is not affected by the complexity of the NP relation. We observe that *any IVC construction following the above blueprint is incrementally complete* by definition as long as the succinct NP proof system used has perfect completeness.

Succinct Proof Systems. Succinct proofs for NP with unconditional soundness are unlikely to exist [26, 27]. Accordingly, Valiant suggested to instantiate the blueprint using computationally sound succinct arguments. This brings about some extra complications in following the blueprint. For once, proving that a previous proof *exists* is meaningless in the case of computational soundness. Rather we need the guarantee that a proof exists and can be efficiently found. Such systems are known as *succinct non-interactive arguments of knowledge* (SNARKs) and admit an efficient knowledge extractor that can efficiently extract a witness from a convincing prover.

Using such SNARKs enables the construction of IVC for arbitrary poly-time computations (or superpolynomial ones, if the SNARK is superpolynomially secure) [51, 5], and the corresponding constructions are incrementally complete by the fact that the underlying SNARKs are perfectly complete. (The actual constructions are somewhat different from the described blueprint; in particular, to deal with issues such as blowup in knowledge extraction complexity, they aggregate proofs in a tree-like fashion rather than a chain, in order to reduce the depth of the recursion. Incremental completeness holds just the same.)

Following the above, we can obtain an incrementally-complete IVC, and thus PLS hardness from SNARKs. However, the existence of SNARKs is a strong non-falsifiable assumption. It is only known under non-standard *knowledge assumptions* and its construction from standard assumptions is subject to barriers [24, 6].

Incrementally-Complete IVC from Weaker Succinct Arguments. In a recent work, Kalai, Paneth, and Yang [34] considered a relaxation of SNARKs called *quasi-arguments* that instead of standard knowledge extraction only requires a certain weaker *no-signaling extraction*

requirement. Unlike SNARKs, such arguments are not subject to any known lower bounds, and were in fact constructed from the learning with errors assumption in their privately-verifiable form [35, 44, 11, 3] and recently also in their publicly-verifiable form based on the so called KPY assumption in bilinear groups [34].

Furthermore, Kalai, Paneth, and Yang show that similarly to SNARKs such quasi-arguments can, in fact, be recursively composed toward verifying a long computation, provided that the computation is *deterministic*. Their explicit goal was not to construct IVC but rather to bootstrap quasi-arguments with a long common reference string (CRS) to succinct arguments with a short CRS. However, this is done by implicitly constructing an IVC (this connection is also apparent in previous constructions of SNARKs with a short CRS from ones with a long CRS [5]). The resulting IVC, like other IVCs based on recursive composition, is incrementally complete.

The Class of Supported Computations and the Reliance on ETH. In its native form, the IVC derived from the KPY construction supports computations of arbitrary polynomial length $T = \lambda^{O(1)}$ in the security parameter λ, with fixed prover-verifier running time (say, λ). However, as explained earlier, to get PLS hardness, we would like to apply the IVC for a hard (and thus superpolynomial) computation.

To circumvent this difficulty, we employ a fine-grained reduction. The idea is to construct instances which are tailor-made to be hard for LS algorithms of a specific polynomial running time. Fix any constant $c > 0$ and n^c-time algorithm $\mathcal{A}$ that supposedly solve LS (here n is the size of the LS instance $(\mathcal{S}, \mathcal{F})$). Consider a search problem R and a Turing machine M that solves it in polynomial time $T(\lambda)$, while no randomized algorithm can solve it in time T^δ for constant $\delta < 1$. If we can bound the *blowup* of the IVC reduction by at most $T^{\delta/c}$, we can use $\mathcal{A}$ to construct a randomized adversary $\mathcal{A}'$ that solves R in time T^δ and get a contradiction.

The blowup of the IVC reduction is polynomially related to (a) the input size, (b) the space used by M, and (c) the efficiency of the IVC scheme. Accordingly, we require a computation where there is an arbitrarily large (polynomial) gap between the space used and the hardness of the underlying problem. To this end, we use the randomized ETH assumption. By appropriately choosing the size of the underlying SAT instance, we get computations that can be solved using fixed-space and some polynomial time via brute-force but not in much faster polynomial time, even by randomized algorithms. To bound the blowup due to the IVC efficiency, we follow the efficiency analysis by [34] and adapt it to the incremental setting. (In the body, we show the above in the non-uniform setting: assuming non-uniform ETH and using standard non-uniform derandomization techniques while taking special care to bound the associated blowup.)

We note that the above only gives worst-case hardness. That is, we do not show a single distribution that is hard for all polynomial-time algorithms. Assuming slight super-polynomial security of the KPY assumption and average-case randomized ETH, we can get average-case PLS hardness by essentially the same reduction (in fact, we can slightly weaken average-case ETH to a slightly subexponential time hypothesis).

2.4 Unconditional Hardness in the Random Oracle Model

Our second result, in the random model, is based on recent advancements in *proofs of sequential work* (PoSW) [40]. Roughly speaking, in a PoSW, the prover is given a statement χ and a time parameter T, and can generate a corresponding proof π by making T sequential steps. The soundness requirement is that provers that make $\ll T$ sequential steps, will fail to

generate a valid proof for χ, except with negligible probability (namely, proof computation is not parallelizable). The construction we present relies on the PoSW of Cohen and Pietrzak [17] and its extension by Döttling, Lai, and Malavolta [20] to so called *incremental proof of sequential work*; both are proven sound in the random oracle model. We now move to recalling how these systems work, and explain how we derive from them hard PLS instances relative to random oracles.

The CP PoSW. To construct a PoSW, Cohen and Pietrzak [17] suggest an elegant tree labeling procedure that is inherently sequential. They consider a binary tree whose edges are directed from the leaves toward the root. In addition, they add directed edges from every node ℓ having a sibling r on the right, to all the leaves in the tree rooted at r. We call this the CP graph (see Figure 1 in Section 6 for an illustration). The nodes of the CP graph are then given random labels as follows: the label of any given node is obtained by applying a random oracle $\mathsf{H}_\chi = \mathsf{H}(\chi, \cdot)$ to the labels of its incoming nodes (the oracle is seeded with χ to guarantee an independent oracle for every statement). Intuitively, the added edges enforce that in order to compute the labels of some subtree rooted at some r, it is first necessary to compute the labels of its left sibling ℓ; in this sense, labeling must be done sequentially.

To turn this into an actual proof of sequential work π for χ, the prover publishes the label of the root of the entire tree. The verifier then responds with random challenge leaves to which the prover answers by providing all the labels in the corresponding paths toward the root along with the labels of the siblings along the path, as in standard Merkle tree authentication (indeed here the tree serves both the purpose of of a commitment and of enforcing the sequential nature). Finally, they make the proof non interactive by using the Fiat-Shamir transform. Cohen and Pietrzak prove that to successfully compute an accepting proof, a prover must sequentially call the random oracle $\approx T$ times, where T is the size of the tree.

Incremental PoSW and the DLM Construction. Cohen and Piertzak further show that the standard streaming algorithm for Merkle commitments [42], can also be applied to their labeling procedure. That is, one can keep track of a small amount of nodes (about $\log T$), each a root of some tree in a gradually growing forest, and when needed, merging two nodes on the same level. In other words, the CP labeling can be done by an incremental computation with small space.

One thing that is of course missing toward getting PLS hardness is verifiability of the corresponding intermediate states. One Naïve idea toward such local verifiability is to apply the CP proof strategy for each subtree in the incremetal labeling process. Indeed, each such subtree is, in fact, CP labeled on its own, so we can use Fiat-Shamir to compute random challenges for that particular subtree. While this is a step in the right direction it is still not enough for the goal of PLS hardness, since the intermediate proofs themselves are not computed incrementally – computing each local proof may take time proportional the size of the corresponding subtree.

Döttling, Lai, and Malavolta [20] suggested a neat idea to make the CP proofs incrementally computable.[3] Roughly speaking rather than sampling fresh challenges for each subtree, they suggested to derive them at random from the previously computed challenges of this subtree. In a bit more detail, whenever merging two subtrees rooted at ℓ and r into a new

[3] They were motivated by blockhains and aimed to make PoSW a process that can be advanced in a distributed fashion by different parties.

(taller) subtree, we assume by induction that each of the two already has a set of corresponding challenges S_ℓ and S_r, where say the size of each one is some parameter k. Then, for the new subtree, rooted at their parent v, we choose a new set S_v of k challenges by choosing k challenges at random from the $2k$ challenges in $S_\ell \cup S_r$ (this is again done non-interactive using Fiat-Shamir). Each of the challenges is again just a Merkle authentication path, which can be easily augmented to an authentication path for v. They prove that this choice of challenges guarantees, for every intermediate state, essentially the same soundness as the original CP construction guarantees for the final state.

Incremental Completeness and PLS Hardness. What we get from the DLM incremental PoSW (in the random oracle) is somewhat analogous to an IVC system in the standard model. However, while in the standard model we applied general IVC over some long (hard) computation, here there is no such underlying hardness. Rather, *the difficulty is only in computing the accepting proofs themselves*. Similarly to our standard model approach, here too we can address the concept of incremental completeness. Indeed, we observe that merging two accepting proofs in the DLM construction always yields an accepting proof. From here incremental completeness follows. Formally, we need to slightly augment the DLM construction to enforce consistency among different subtrees in a forest to guarantee such incremental completeness (see Section 6 for the details).

Choosing the parameters appropriately, yields problems in PLS relative to a random oracle which are exponentially hard-on-average. This translates to sub-exponential hardness of the canonical LS probalem (due to polynomial blowup of the reduction). Also, by choosing the size of the tree to be a polynomial of our choice, we get search problems in PLS which are moderately hard but "depth-robust" in the sense that they cannot be solved much faster by parallel algorithms [21]. This follows from the sequential hardness of DLM.

2.5 More Related Work on Total Search Problems

The class TFNP was introduced by Megiddo and Papadimitriou [41]. They observed that TFNP is unlikely to include NP hard problems as this would imply that NP = coNP. Furthermore, it is strongly believed that TFNP does not have complete problems (see for instance discussion in [25]). Toward understanding of the complexity of total search problems, Papadimitriou [45] introduced several "syntactic" subclasses of TFNP that cluster problems according to the mathematical argument used to establish their totality. Recently, Goldberg and Papadimitriou [25] presented a subclass called *provable* TFNP that contains previously defined subclasses (and can be seen as generalizing them) and admits complete problems.

A long line of works have investigated the complexity of TFNP and its subclasses, searching for efficient algorithms on one hand and evidence of hardness on the other. As explained earlier in the intro, cryptography is a natural place to look for such evidence. Indeed, basing the hardness of TFNP or its subclasses, on standard cryptographic assumptions, has been successful in several cases. For example, Papadimitriou [45] observed that PPP is hard assuming one-way permutations or collision-resistant hash functions, and Jeřábek [32], building on the work of Buresh-Oppenheim [12], demonstrated the hardness of PPA assuming factoring is hard. Hubáček, Naor and Yogev [28] showed TFNP-hardness assuming any average-case hard NP language exists (in particular one-way functions) and derandomization assumptions. Komargodski, Naor, and Yogev [37] showed that hardness of the class Ramsey is equivalent to the existence of multi-collision resistant hash functions.

As discussed earlier, demonstrating hardness for PPAD and PLS has been more challenging and so far only achieved under non-standard cryptographic assumptions. Trying to explain our failure so far to base such hardness on standard cryptographic primitives, Rosen, Segev

and Shahaf [48] show that TFNP hard instances constructed in a black box way from random oracles (or some variants thereof) must have a nearly exponential number of solutions (which is indeed the case in our result in the random oracle model).

Finally, we note that in the smooth complexity setting, several PLS complete problems, with natural noise distributions, have been shown to be solvable in smooth polynomial-time. This include finding locally optimal Max-Cut [2] and finding pure Nash equilibrium in network coordination games [10]. These algorithms suggest an explanation of why local search may be empirically easy, while hard instances exist under reasonable assumptions and can be sampled.

Organization

In Section 3, we recall some preliminaries including the definition of PLS. In Section 4, we construct a computational reduction from a search problem having an incremental complete IVC to LS. In Section 5, we instantiate the computational reduction under the KPY assumption and ETH to demonstrate PLS hardness in the plain model. In Section 6, we argue the hardness of PLS relative to a random oracle.

3 Preliminaries

Notation. Throughout, λ will denote security parameters. When the input size is not the security parameter, we denote it by n. For $a \leq b$ integers we denote by $[a, b]$ the set $\{a, ..., b\}$ and by $[a]$ the set $[1, a]$.

3.1 PLS Definition

The complexity class *polynomial local search* (PLS) consists of all TFNP search problems polynomial-time reducible to the Local-Search problem [33, 29] we denote by LS.

▶ **Definition 3** (Local-Search). *The search problem* LS *is the following: given two polynomial-size circuits* $\mathcal{S} : \{0,1\}^n \to \{0,1\}^n$ *and* $\mathcal{F} : \{0,1\}^n \to \mathbb{N}$*, find a string* $v \in \{0,1\}^n$ *such that* $\mathcal{F}(\mathcal{S}(v)) \leq \mathcal{F}(v)$.

We refer to $\mathcal{S}$ as the *successor circuit* and to $\mathcal{F}$ as the *value circuit*. Intuitively, the circuits $\mathcal{S}$ and $\mathcal{F}$ could be seen as representing an implicit DAG over $\{0,1\}^n$. In this graph, a node v is connected to $u = \mathcal{S}(v)$ if and only if $\mathcal{F}(u) > \mathcal{F}(w)$. This is a DAG since $\mathcal{F}$ induce a topological ordering. Notice also that every sink corresponds to a local maximum with respect to $\mathcal{F}$. With this perspective, the totality of LS follows from the fact *every finite DAG has a sink*.

Oracle aided PLS. We denote by $\mathcal{C}^{\mathcal{O}} = \{\mathcal{C}^{\mathcal{O}}_\lambda\}$ an oracle aided circuit family. That is a circuit family with oracle gates to $\mathcal{O}_\lambda : \{0,1\}^{r(\lambda)} \to \{0,1\}^{\ell(\lambda)}$. The complexity class $\mathsf{PLS}^{\mathcal{O}}$ relative to an oracle $\mathcal{O}$, is naturally defined as all $\mathsf{TFNP}^{\mathcal{O}}$ search problem polynomial-time reducible to $\mathsf{LS}^{\mathcal{O}}$.

▶ **Definition 4** (Oracle Aided Local-Search). *The search problem* $\mathsf{LS}^{\mathcal{O}}$ *is the following: given two polynomial-size, oracle aided, circuits* $\mathcal{S}^{\mathcal{O}} : \{0,1\}^n \to \{0,1\}^n$ *and* $\mathcal{F}^{\mathcal{O}} : \{0,1\}^n \to \mathbb{N}$*, find a string* $v \in \{0,1\}^n$ *such that* $\mathcal{F}^{\mathcal{O}}(\mathcal{S}^{\mathcal{O}}(v)) \leq \mathcal{F}^{\mathcal{O}}(v)$.

4 PLS Hardness from IVC

In this section, we give a computational reduction from search problems having an IVC with incremental completeness to LS. This, in turn, establishes that any (worst/average-case) hard search problem, having an IVC with incremental completeness, implies the hardness of PLS (in the worst/average-case, respectively). We start by formally defining IVC with incremental completeness.

4.1 IVC with Incremental Completeness

Conventions. Let M be a Turing machine with $T = T(\lambda)$ and $S = S(\lambda)$ bounds on its run time and space, respectively, for input of length λ. Throughout, we assume w.l.o.g that M always makes exactly T steps and the size of a configuration is exactly S. Let $x \in \{0,1\}^\lambda$ be an input to M, we denote by $M_x^t \in \{0,1\}^S$ the configuration in the t step of the computation $M(x)$. We denote by $M_x : \{0,1\}^S \to \{0,1\}^S$ the transition circuit between configurations.

▶ **Definition 5** (IVC with Incremental Completeness)**.** *Let M be a Turing machine with $T = T(\lambda)$ and $S = S(\lambda)$ bounds on its run time and space, respectively, for input of length λ.*

An Incremental Verifiable Computation scheme (IVC) for M, with incremental completeness, consists of three algorithms $\mathsf{IVC} = (\mathsf{IVC.G}, \mathsf{IVC.P}, \mathsf{IVC.V})$:

- $\mathsf{IVC.G}(x)$ *is a randomized algorithm that given $x \in \{0,1\}^\lambda$ outputs public parameters pp.*
- $\mathsf{IVC.P}(pp, t, C, \pi)$ *is a deterministic algorithm that given public parameters pp, a natural number t, an arbitrary configuration C and arbitrary proof π, outputs a proof π'.*
- $\mathsf{IVC.V}(pp, t, C, \pi)$ *is a deterministic algorithm that given public parameters pp, a natural number t, an arbitrary configuration C and arbitrary proof π, outputs* ACC *or* REJ.

We make the following requirements:

1. ***Incremental Completeness:*** *For every security parameter $\lambda \in \mathbb{N}$:*
   a. *For every input $x \in \{0,1\}^\lambda$, time $t \in [0, T-1]$ and candidate proof $\pi \in \{0,1\}^*$:*

$$\Pr\left[\begin{array}{l|l} \mathsf{IVC.V}(pp,t,M_x^t,\pi) = \mathsf{ACC} \implies & pp \leftarrow \mathsf{IVC.G}(x) \\ \mathsf{IVC.V}(pp,t+1,M_x^{t+1},\pi') = \mathsf{ACC} & \pi' = \mathsf{IVC.P}(pp,t,M_x^t,\pi) \end{array}\right] = 1 \ ,$$

   where M_x^t, M_x^{t+1} are the configurations in the t and $t+1$ steps of the computation of $M(x)$, respectively.
   b. *For every input $x \in \{0,1\}^\lambda$:*

$$\Pr\left[\mathsf{IVC.V}(pp,0,M_x^0,\varepsilon) = \mathsf{ACC} \;\middle|\; pp \leftarrow \mathsf{IVC.G}(x)\right] = 1 \ ,$$

   where M_x^0 is the first configuration of the computation of $M(x)$, and ε is the empty proof.
2. ***Soundness:*** *For every efficient adversary $\mathcal{A}$, there exists a negligible function μ such that for every $\lambda \in \mathbb{N}$ and $x \in \{0,1\}^\lambda$:*

$$\Pr\left[\begin{array}{l|l} C^* \neq M_x^t & pp \leftarrow \mathsf{IVC.G}(x) \\ \mathsf{IVC.V}(pp,t,C^*,\pi^*) = \mathsf{ACC} & (t, C^*, \pi^*) \leftarrow \mathcal{A}(x, pp) \end{array}\right] \leq \mu(\lambda) \ ,$$

   where M_x^t is the configuration in the t step of the computation of $M(x)$.
3. ***Efficiency:*** *The efficiency of* IVC*, denoted by $\mathbb{T}_{\mathsf{IVC}}(\lambda)$, is the maximal worst-case run-time among $\mathsf{IVC.G}, \mathsf{IVC.P}, \mathsf{IVC.V}$ for input having security parameter λ. We require $\mathbb{T}_{\mathsf{IVC}}(\lambda) \leq p(\lambda)$ for a fixed polynomial p.*

4.2 Computationally Sound Karp Reduction

As discussed in the introduction, since we use IVC with computational soundness, the reduction we give is also computationally sound. In what follows, we define the notion of computationally sound Karp reduction.

For $R, R' \in \mathsf{FNP}$, a computationally sound reduction from R to R' consists of a pair of efficient algorithms $(\mathcal{X}, \mathcal{W})$. Where $\mathcal{X}(x)$ is a randomized algorithm that given an instance x of R, samples an instance $x' \leftarrow \mathcal{X}(x)$ of R'. $\mathcal{W}(w')$ is a deterministic algorithm that translates a witness w' for x', to a candidate witness w of x. We require that its infeasible to find w', such that $w = \mathcal{W}(w')$ is not a witness for x in R.

▶ **Definition 6** (Computational Karp Reduction). *For $R, R' \in \mathsf{FNP}$, a computational Karp reduction from R to R' consists of a pair $(\mathcal{X}, \mathcal{W})$, where $\mathcal{X}(x)$ is a randomized efficient algorithm and $\mathcal{W}(w)$ is a deterministic efficient algorithm. We make the following requirement:*

- ***Computational Soundness:*** *For every efficient adversary $\mathcal{A}$, there exists a negligible function μ such that for every $\lambda \in \mathbb{N}$ and $x \in \{0,1\}^\lambda$ for which R_x is non-empty:*

$$\Pr\left[\begin{array}{l|l} w' \in R'_{x'} & x' \leftarrow \mathcal{X}(x) \\ w \notin R_x & w' \leftarrow \mathcal{A}(x') \\ & w = \mathcal{W}(w') \end{array}\right] \leq \mu(\lambda) \ ,$$

where R_x and $R'_{x'}$ are the set of witnesses for x in R and x' in R' respectively.

▶ **Definition 7** (Reduction Efficiency). *The efficiency of a computational Karp reduction $(\mathcal{X}, \mathcal{W})$, denoted $\mathbb{T}_{\mathsf{Red}}(\lambda)$, is the maximum of $\mathbb{T}_{\mathcal{X}}(\lambda), \mathbb{T}_{\mathcal{W}}(\lambda)$ where:*

1. *$\mathbb{T}_{\mathcal{X}}(\lambda)$ is the worst-case run-time of $\mathcal{X}$ for input $x \in \{0,1\}^\lambda$.*
2. *$\mathbb{T}_{\mathcal{W}}(\lambda)$ is the worst-case run-time of $\mathcal{W}$ for input $w' \in \left\{ w' \;\middle|\; \begin{array}{l} x \in \{0,1\}^\lambda \\ x' \in \mathsf{Supp}(\mathcal{X}(x)) \\ w' \in R_{x'} \end{array} \right\}$.*

Note that $\mathbb{T}_{\mathsf{Red}}(\lambda)$ is a bound on instance size sampled using $\mathcal{X}$.

4.3 The Hardness Reduction

Using the notion of computational Karp reduction, our hardness result is formalized in the following theorem.

▶ **Theorem 8** (IVC Reduction). *Let $R \in \mathsf{FNP}$, solvable by a polynomial-space Turing machine M. If there exists an IVC scheme with incremental completeness for M, there exists a computationally sound Karp reduction $(\mathcal{X}, \mathcal{W})$ from R to LS. The efficiency of the reduction is*

$$\mathbb{T}_{\mathsf{Red}} = \mathrm{poly}(\mathbb{T}_{\mathsf{IVC}}, S, \lambda, |M|) \ ,$$

where $S(\lambda)$ is a bound on M space and $\mathbb{T}_{\mathsf{IVC}}(\lambda)$ is the efficiency of the IVC. The polynomial doesn't depend on the IVC scheme, M nor R.

▶ Remark 9 (Efficiency Independent of T). Jumping ahead, the fact that $\mathbb{T}_{\mathsf{Red}}$ does not depend directly on the time of the computation T, plays an important role in the fine-grained reduction for polynomial-time computations presented in Section 5.

Next, we describe the reduction and in the following section we analyze its security.

4.3.1 The Reduction

Let $\mathsf{IVC} = (\mathsf{IVC.G}, \mathsf{IVC.P}, \mathsf{IVC.V})$ be an incremental verifiable computation scheme with incremental completeness for M. Let $S = S(\lambda)$ be the polynomial bound on space on M when executed on $x \in \{0,1\}^\lambda$, guaranteed by the statement. Recall that we denote by M_x^t the configuration in the t step of the computation of $M(x)$. We assume w.l.o.g that the configuration size is exactly S. Let $T = T(\lambda) = 2^{S(\lambda)} \leq 2^{\mathrm{poly}(\lambda)}$ be an upper bound on the running time of M. We further assume w.l.o.g that M always makes exactly T steps. With the above notation, the configuration graph of M when executing x is:

$$M_x^0 \longrightarrow \cdots \longrightarrow M_x^T \ .$$

In the following, we describe the construction of $\mathcal{X}(x)$ for an input $x \in \{0,1\}^\lambda$. Recall that we denote by $M_x : \{0,1\}^S \to \{0,1\}^S$ the transition circuit of $M(x)$, taking a configuration as input and returning the next configuration as output.

Instance translation. The algorithm $\mathcal{X}(x)$ begins by sampling $pp \leftarrow \mathsf{IVC.G}(x)$. Given pp, we apply a deterministic procedure I to generate an LS instance $(\mathcal{S}, \mathcal{F}) = I(x, pp)$. The constructed LS instance corresponds to a graph on vertices of fixed polynomial length $\ell = \ell(\lambda) \geq \lambda$. Each vertex is of the form $(t, C, \pi) \in \{0,1\}^\ell$ where t is parsed as an integer in $[0, T]$, C as a configuration of length S and π as a proof for the IVC padded to length ℓ if needed. We describe the successor $\mathcal{S}$ and value circuits $\mathcal{F}$ formally in the following.

▶ Remark 10. We assume w.l.o.g that M_x always outputs something. If the transition function of M fails to generate the next configuration given C, it will simply output M_x^0, the initial state.

▶ Remark 11. We assume w.l.o.g that $\mathcal{F}$ outputs values in $[-1, T]$.

In what follows, $v_0 := (0, M_x^0, \varepsilon)$ where M_x^0 is the initial state of $M(x)$ and ε is the empty proof.

Successor Circuit $\mathcal{S}(t, C, \pi)$

Hardwired: The public parameters pp, and the input x.
Algorithm:
1. If $\mathsf{IVC.V}(pp, t, C, \pi) = \mathsf{REJ}$, output v_0.
2. If $t = T$, output (t, C, π).
3. Compute $C' = M_x(C)$, $\pi' = \mathsf{IVC.P}(pp, t, C, \pi)$. Output $(t+1, C', \pi')$.

Value Circuit $\mathcal{F}(t, C, \pi)$

Hardwired: The public parameters pp.
Algorithm:
1. If $\mathsf{IVC.V}(pp, t, C, \pi) = \mathsf{REJ}$, output -1.
2. Else, output t.

Witness translation. The algorithm $\mathcal{W}(t, C, \pi)$ simply returns the content of the output tape in the configuration C.

Efficiency. The successor circuit M_x is of size $\text{poly}(S, \lambda, |M|)$. The computations related to IVC are of size $\text{poly}(\mathbb{T}_{\mathsf{IVC}})$ by Turing machine simulation. All other computations are polynomial in the input length ℓ. We have that $\ell = \text{poly}(S, \mathbb{T}_{\mathsf{IVC}})$. It follows that $\mathbb{T}_{\mathsf{Red}} = \text{poly}(\mathbb{T}_{\mathsf{IVC}}, S, \lambda, |M|)$. All the above polynomials don't depend on M nor IVC.

By the fact M is poly-space and the efficiency requirement of IVC, that is $\mathbb{T}_{\mathsf{IVC}} \leq \text{poly}(\lambda)$, both $\mathcal{X}, \mathcal{W}$ are polynomial-time algorithms, as required. In turn, this further implies that $\mathcal{S}, \mathcal{F}$ are of size $\text{poly}(\lambda)$. Since the length is a polynomial such that $\ell(\lambda) \geq \lambda$, we have that $\mathcal{S}, \mathcal{F}$ are polynomial-size circuits.

4.4 Security Analysis

Fix $\lambda \in \mathbb{N}$ and $x \in \{0,1\}^\lambda$. Let $(\mathcal{S}, \mathcal{F})$ be an instance in the support of $\mathcal{X}(x)$ and let pp be the public parameters hardwired in $(\mathcal{S}, \mathcal{F})$. We prove that all local maximums of $(\mathcal{S}, \mathcal{F})$ are one of two types:

- **Honest:** Nodes (T, M_x^T, π) where $\mathsf{IVC.V}(pp, t, M_x^T, \pi) = \mathsf{ACC}$.
- **Fooling:** Nodes (t, C^*, π^*) for which $C^* \neq M_x^t$ and $\mathsf{IVC.V}(pp, t, C^*, \pi^*) = \mathsf{ACC}$.

The proof of the following claim use the incremental completeness of IVC.

▷ Claim 12. All local maximums of $(\mathcal{S}, \mathcal{F})$ are honest-type or fooling-type.

Proof of claim. Let $v = (t, C, \pi)$ be a local maximum of $(\mathcal{S}, \mathcal{F})$, that is $\mathcal{F}(\mathcal{S}(v)) \leq \mathcal{F}(v)$. We have that $\mathsf{IVC.V}(pp, t, C, \pi) = \mathsf{ACC}$, as otherwise it is given value -1 and is connected to $v_0 = (0, M_x^0, \varepsilon)$ which is of value 0. If $C \neq M_x^t$ then v is a fooling-type local maximum and if $C = M_x^t$ and $t = T$ then v is an honest-type local maximum.

We are left with the case $C = M_x^t$ and $t < T$. By construction, $\mathcal{S}(v) = (t+1, M_x^{t+1}, \pi')$ for $\pi' = \mathsf{IVC.P}(pp, t, M_x^t, \pi)$. By incremental completeness, $\mathsf{IVC.V}(pp, t+1, M_x^{t+1}, \pi') = \mathsf{ACC}$ and thus $\mathcal{F}(\mathcal{S}(v)) = t+1$ while $\mathcal{F}(v) = t$. Therefore it is not a local maximum, proving the claim. ◁

Note that only honest-type local maximums translate by $\mathcal{W}$ to a valid witness for R, the underlying search problem. While there exist fooling-type local maximums, by the security of the IVC, finding them efficiently is infeasible. We proceed to prove Theorem 8.

Proof of Theorem 8. Let $\mathcal{A}$ be an efficient adversary that attempts breaking the computational soundness of the reduction $(\mathcal{X}, \mathcal{W})$. Let $\lambda \in \mathbb{N}$ and $x \in \{0,1\}^\lambda$ be such that R_x is non-empty. We denote by $\varepsilon = \varepsilon(x)$ the probability of success of $\mathcal{A}$. That is

$$\varepsilon(x) := \Pr\left[\begin{array}{l|l} \mathcal{F}(\mathcal{S}(w')) \leq \mathcal{F}(w') & (\mathcal{S}, \mathcal{F}) \leftarrow \mathcal{X}(x) \\ w \notin R_x & w' \leftarrow \mathcal{A}(\mathcal{S}, \mathcal{F}) \\ & w = \mathcal{W}(w') \end{array}\right] .$$

It follows by Claim 12 that all witnesses w' for $(\mathcal{S}, \mathcal{F})$ such that $\mathcal{W}(w') = w \notin R_x$ are fooling-type local maximums. Indeed, for every honest-type local maximum, W outputs the content of the output tape of M_x^T. As M solves R and R_x is non-empty, we have that the output tape of M_x^T, the last configuration, consists of w such that $w \in R_x$.

Consider $\mathcal{A}' = \{\mathcal{A}'_\lambda\}_{\lambda \in \mathbb{N}}$ that attempts breaking the soundness of the IVC defined as follows. Recall $I(x, pp)$ is the deterministic procedure used by $\mathcal{X}$ to construct the circuits $\mathcal{S}$ and $\mathcal{F}$.

$\mathcal{A}'(x, pp)$:

1. Compute $(\mathcal{S}, \mathcal{F}) = I(x, pp)$.
2. Simulate $w' \leftarrow \mathcal{A}(\mathcal{S}, \mathcal{F})$.
3. Output $w' = (t, C, \pi)$.

Note that, every fooling-type local maximum corresponds to (t, C^*, π^*) breaking the IVC scheme. Further notice that the distribution $(\mathcal{S}, \mathcal{F}) = I(x, pp)$ for $pp \leftarrow \mathsf{IVC.G}(x)$ is, by definition, the distribution of $\mathcal{X}(x)$. Therefore, the success probability of $\mathcal{A}'(x, pp)$ is at least $\varepsilon(x)$. Using the soundness of IVC, there exists a negligible function μ such that for every $\lambda \in \mathbb{N}$ and $x \in \{0,1\}^\lambda$ such that R_x is non-empty we have the following:

$$\varepsilon(x) \leq \Pr\left[\begin{array}{l|l} C^* \neq M_x^t & pp \leftarrow \mathsf{IVC.G}(x) \\ \mathsf{IVC.V}(pp, t, C^*, \pi^*) = \mathsf{ACC} & (t, C^*, \pi^*) \leftarrow \mathcal{A}'(x, pp) \end{array}\right] \leq \mu(\lambda) \ .$$

Establishing the computational soundness of the reduction. The efficiency part of the theorem has been argued in Section 4.3. ◀

4.5 Applying the Reduction

In this section we present results that establish that a computational Karp reduction from an underlying hard (worst-case/average-case) problem R to LS implies the hardness of LS (in worst-case/average-case respectively). The proofs for the following propositions are given in the full version of this paper.

4.5.1 Worst-Case Hardness

The existence of a computational Karp reduction from R to LS and an efficient solver for LS implies, in a straightforward way, the existence of an efficient randomized solver for R, successful with high probability. Proposition 13 extends this and show the existence of a deterministic solver for R. This is by standard non-uniform derandomization techniques. We use n to denote the size of LS instances and λ the size of R instances.

▶ **Proposition 13** (Worst-Case Hardness). *Let R be an FNP search problem having a computational Karp reduction to LS. Assume there exists a adversary $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ of polynomial-size $s(n)$ solving LS in the worst-case. Then there exists an adversary $\mathcal{A}' = \{\mathcal{A}_\lambda\}_{\lambda\in\mathbb{N}}$ solving R in the worst-case. The size of $\mathcal{A}'$ is*

$$\mathsf{size}(\mathcal{A}') = \mathrm{poly}(s(\mathbb{T}_{\mathsf{Red}}), \mathbb{T}_R, \lambda) \ ,$$

where $\mathbb{T}_{\mathsf{Red}}(\lambda)$ is the efficiency of the reduction and $\mathbb{T}_R(\lambda)$ is the efficiency of the NP verification $R(x, y)$.

4.5.2 Average-Case Hardness

▶ **Proposition 14** (Average-Case Hardness). *If there exists a hard-on-average FNP problem R, with a computationally sound Karp reduction from R to LS, then LS is hard-on-average.*

Using the computational Karp reduction constructed in Section 4.3, we get the following corollary:

▶ **Corollary 15** (IVC Average-Case Hardness). *Let R be a hard-on-average FNP problem. If there exists an IVC scheme with incremental completeness for a polynomial-space Turing machine M solving R, then LS is hard-on-average.*

5 Instantiation under the KPY Assumption and ETH

In Section 4, we were able to prove that an IVC scheme with incremental completeness for some superpolynomially hard computation suffices to show that LS is hard. It is left to instantiate the above under the KPY assumption and construct an IVC scheme for a superpolynomially hard computation. Unfortunately, under the KPY assumption we are able to construct IVC schemes only for polynomial computations[4]. In this section, we show how to circumvent this difficulty by employing a fine-grained reduction and further assuming the non-uniform exponential time hypothesis (ETH). Finally proving the worst-case hardness of LS under the KPY assumption and non-uniform ETH.

▶ Remark 16. For ease of notation, in the following section we assume w.l.o.g $\lambda > 1$.

5.1 IVC From KPY Assumption

The proof of Theorem 18 is given in the full version of this paper.

▶ Remark 17 (Dependence of Constants). In the following, we use the constant c instead of big O notation in order to emphasize that the constant is independent of α.

▶ **Theorem 18** (IVC from KPY Assumption)**.** *Fix any constants $c, \varepsilon > 0$. Let α be a large enough constant and let M be a Turing machine of run-time $T(\lambda) \leq c\lambda^{\alpha}$, configuration size $S(\lambda) \leq c\lambda$ and description size $|M| \leq c \log_2 \alpha$. Under the KPY assumption, there exists an IVC scheme with incremental completeness for M having efficiency $\mathbb{T}_{\mathsf{IVC}} = \lambda^{\varepsilon\alpha}$.*

▶ Remark 19 (Non-Uniform Reduction). The security reduction of the IVC scheme given in Theorem 18 is non-uniform and therefore we require that the IVC scheme, and accordingly the KPY assumption, to hold against non-uniform polynomial-time attackers. This is to be expected when dealing with worst-case hardness.

5.2 Fixed Space Polynomial Hardness via ETH

In this section, assuming the non-uniform ETH assumption, we show the existence of arbitrarily polynomially hard computations for circuits that can be solved by Turing machines using a fixed amount of space and slightly larger polynomial time.

▶ **Assumption 20** (Non-Uniform ETH)**.** *There exists a constant $\delta > 0$ such that no circuit family of size $O(2^{\delta n})$ solves* 3SAT*, where n is the length of the input 3CNF formula.*

▶ **Proposition 21** (Polynomial Hardness)**.** *Under the non-uniform* ETH *assumption, there exists constants $c, \delta > 0$ such that for every constant $\alpha > 1$ there exists a search problem $R_\alpha \in$ FNP satisfying the following:*

- ***Algorithm:*** *There exists a Turing machine M_α of run-time $T(\lambda) \leq c\lambda^{\alpha}$, configuration size $S(\lambda) \leq c\lambda$ and description size $|M_\alpha| \leq c \log \alpha$ solving R_α.*
- ***Lower Bound:*** *No circuit family of size $O(\lambda^{\delta\alpha})$ can solve R_α.*

Proof. Consider

$$R_\alpha := \left\{ (x 0^{2^{|x|/\alpha} - |x|}, w) \;\middle|\; (x, w) \in \mathsf{3SAT} \right\} .$$

[4] This is for polynomial security of the KPY assumption. A super-polynomial security of the KPY assumption yields an IVC scheme for computations of a corresponding superpolynomial length.

Algorithm. The naive brute force algorithm for R_α satisfy the requirement. In the following α is not suppressed by O notation. For $x \in \{0,1\}^n$ and input of the form $x0^{2^{n/\alpha}-n}$, brute force takes $O(2^n)$ time while the whole input is of size $\lambda = 2^{n/\alpha}$. The description size is $O(\log \alpha)$ and the memory used is $O(\lambda)$.

Lower Bound. Let $\delta > 0$ be the constant assumed to exist by non-uniform ETH. Every circuit family of size $O(\lambda^{\delta\alpha})$ solving R_α can be turned to a circuit of size $O(2^{\delta\alpha})$ solving 3SAT. Contradicting non-uniform ETH. ◀

5.3 Putting Things Together

In this section, we put things together to prove that under non-uniform ETH and the KPY assumption we have PLS $\not\subseteq$ FP/Poly.

▶ **Theorem 22** (PLS Hardness). *Assuming non-uniform* ETH *and the KPY assumption we have* PLS $\not\subseteq$ FP/Poly.

Toward proving the theorem, we start by bounding the blowup associated with the IVC reduction when applied to the brute-force computation solving R_α defined by Proposition 21.

▶ **Lemma 23** (Bounding the Blowup). *Fix a constant $\varepsilon > 0$. Let α be a large enough constant. Under the KPY assumption, there exists a computationally sound Karp reduction $(\mathcal{X}, \mathcal{W})$ from R_α to* LS *with efficiency $\mathbb{T}_{\mathsf{Red}} \leq \lambda^{\varepsilon\alpha}$.*

Proof. Fix $\varepsilon > 0$ and let $\varepsilon' > 0$ be a constant to be chosen later. Let c be the constant guaranteed by Proposition 21. That is, for every $\alpha > 1$ there exists a Turing machine M_α of run-time $T \leq c\lambda^\alpha$, configuration size $S \leq c\lambda$ and description size $|M_\alpha| \leq c \log_2 \alpha$ solving R_α. Let α be a large enough constant such that Theorem 18 apply to M_α with constant ε'. This gives an IVC scheme with incremental completeness for M_α having efficiency $\mathbb{T}_{\mathsf{IVC}} \leq \lambda^{\varepsilon'\alpha}$.

Applying Theorem 8 using the aforementioned IVC results in a computationally sound Karp reduction $(\mathcal{X}, \mathcal{W})$ from R_α to LS with efficiency:

$$\mathbb{T}_{\mathsf{Red}} \leq (\mathbb{T}_{\mathsf{IVC}} \cdot S \cdot \lambda \cdot |M_\alpha|)^\eta \leq \lambda^{\varepsilon'\alpha\eta} \cdot (c\lambda \log_2 \alpha)^{3\eta} \leq \lambda^{4\varepsilon'\alpha\eta} \ ,$$

where η is a constant independent of α and ε and the last inequality is true for large α. By taking $\varepsilon' < \varepsilon/4\eta$ we get $\mathbb{T}_{\mathsf{Red}} \leq \lambda^{\varepsilon\alpha}$. This completes the proof the lemma. ◀

We are now ready to prove Theorem 22.

Proof of Theorem 22. Assume toward contradiction that under non-uniform ETH and the KPY assumption we have that PLS $\subseteq$ FP/Poly. Hence, there exists a constant η and adversary $\mathcal{A} = \{\mathcal{A}_n\}_{n\in\mathbb{N}}$ of size $s(n) = n^\eta$ solving LS instances of size n.

Let $\varepsilon > 0$ be a constant to be chosen later. By bounding the blowup lemma, Lemma 23, there exists a large enough constant α such that there is a computationally sound Karp reduction $(\mathcal{X}, \mathcal{W})$ from R_α to LS having efficiency $\mathbb{T}_{\mathsf{Red}} \leq \lambda^{\varepsilon\alpha}$. Note that the efficiency of the NP verifier for R_α is $\mathbb{T}_{\mathsf{R}_\alpha} = O(\lambda)$ with a constant independent of α. By Proposition 13, there exists an adversary $\mathcal{A}' = \{\mathcal{A}'_\lambda\}_{\lambda\in\mathbb{N}}$, solving R_α instances of size λ of circuit size:

$$\mathsf{size}(\mathcal{A}'_\lambda) \leq \mathrm{poly}\left(s(\mathbb{T}_{\mathsf{Red}}), \mathbb{T}_{\mathsf{R}_\alpha}, \lambda\right) \leq \mathrm{poly}\left(\lambda^{\varepsilon\alpha\eta}, \lambda\right) \underbrace{\leq}_{\alpha > 1/\varepsilon\eta} \mathrm{poly}\left(\lambda^{\varepsilon\alpha\eta}\right) = O(\lambda^{\varepsilon\alpha\xi}) \ ,$$

where ξ is a constant independent of ε and α. Let $\delta > 0$ be the constant associated with the lower bound of R_α. Recall δ is fixed and independent of α. By choosing $\varepsilon < \delta/\xi$ we have

$$\mathsf{size}(\mathcal{A}'_\lambda) = O(\lambda^{\varepsilon\alpha\xi}) = O(\lambda^{\delta\alpha}) \ .$$

A contradiction to the lower bound. We conclude that PLS $\not\subseteq$ FP/Poly. This completes the proof. ◀

6 Unconditional PLS Hardness in the ROM

In this section we show that relative to a random oracle, there exists exponentially average-case hard problems in PLS. We further show, relative to a random oracle, the existence of depth-robust moderately hard problems in PLS. Our result is based on the incremental proofs of sequential work (iPoSW) construction by Döttling, Lai, and Malavolta [20]. We modify the DLM construction such that an incremental completeness analogous is achieved. We proceed to reduce breaking the modified DLM scheme to LS relative to a random oracle.

6.1 Graph Related Definitions

We recall some graph related definitions used in the DLM scheme.

Notation. Throughout, we consider directed acyclic graphs (DAGs) $G = (V, E)$ where $V \subseteq \{0,1\}^{\leq d}$ is the vertex set and we refer to the parameter d as the depth of G. A vertex $v \in V$ is a parent of $u \in V$ if $(v, u) \in E$. The set of parents of u is denoted by $\mathsf{parents}(u)$. A vertex v is an ancestor of u if there is a directed path from v to u in G. The set of ancestors of u is denoted by $\mathsf{ancestors}(u)$. Any vertex $v \in V \cap \{0,1\}^n$ is called a leaf. Denote by $\mathsf{leaves}(u)$ the set of all leaf nodes that are ancestors of u.

6.1.1 CP Graphs

We recall the definition of CP graphs (see Figure 1), a family of directed acyclic graphs defined first in the PoSW construction of Cohen and Pietrzak [17]. We denote the aforementioned graph family by $CP = \{CP_d\}_{d\in\mathbb{N}}$.

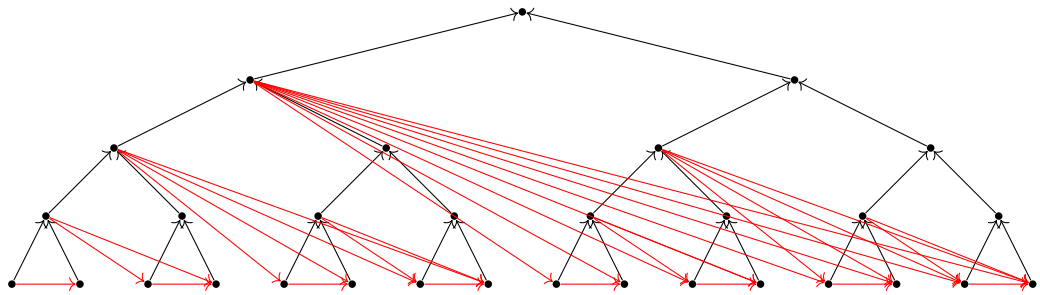

Figure 1 The CP_4 graph; red edges corresponds to E''.

▶ **Definition 24** (CP Graphs, [17]). *Let $B_d = (V, E')$ be the complete binary tree of depth d with edges pointing from the leaves to the root. The graph $CP_d = (V, E)$ is constructed from B_d with some added edges E''. Where E'' contains (v, u) for any leaf $u \in \{0,1\}^d$ and any v which is a left sibling to a node on the path form u to the root. Formally, $E = E' \cup E''$ where:*

$$E'' := \{(v, u) \mid u \in \{0,1\}^d, u = a||1||a', v = a||0, \text{ for some } a, a' \in \{0,1\}^{\leq d}\} \ .$$

The following fact on non-leaves in CP graphs is used in the construction and analysis.

▶ **Fact 25** (Left and Right Parents). *Let $CP_d = (V, E)$ and let $v \in V$ be a non-leaf node which is not the root. The node v has exactly two parents ℓ and r. We have the following:*

$$\mathsf{leaves}(v) = \mathsf{leaves}(\ell) \cup \mathsf{leaves}(r) \ .$$

6.1.2 Graph Labeling

▶ **Definition 26** (Partial Vertex Labeling). *For a graph $G = (V, E)$, a partial vertex labeling is a function $\mathcal{L} : V \to \{0,1\}^* \cup \{\perp\}$. The label for node $u \in V$ is denoted by $\mathcal{L}[u]$.*

▶ **Definition 27** (Valid DAG Labeling). *Let $G = (V, E)$ be a DAG with $V \subseteq \{0,1\}^*$ and let $f : \{0,1\}^* \to \{0,1\}^w$ be a labeling function. The labeling of G with respect to f is defined recursively, for every $v \in V$:*

$$\mathcal{L}[v] := f(v, \mathcal{L}[p_1], ..., \mathcal{L}[p_r]) \ ,$$

where $(p_1, ..., p_r) = \mathsf{parents}(v)$, ordered in lexicographic order.

Note that the above labeling is well defined since G is a acyclic and can be computed with $|V|$ queries to f in a topological order.

In the following lemma we recall the CP labeling procedure given in [17]. See Figure 2 for an illustration of the procedure.

▶ **Lemma 28** (CP Labeling Procedure, Lemma 3 in [17]). *The labeling of CP_d with respect to $f : \{0,1\}^* \to \{0,1\}^w$ can be computed in a topologicial ordering using $O(w \cdot d)$ bits of memory.*

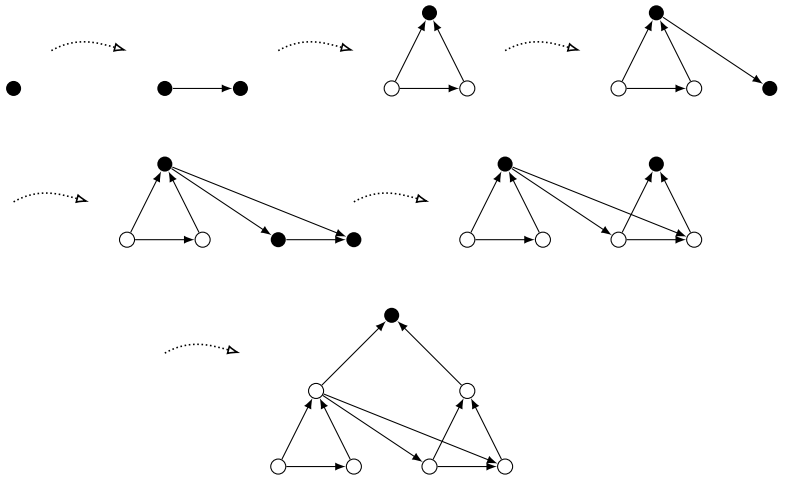

Figure 2 The CP labeling procedure for CP_2; black nodes represent labels the algorithm keep track of; denoted $\mathcal{U}_t$ when computing the t label.

We require additional properties from the labeling procedure for the modified DLM scheme. For that purpose, we give a description of the procedure bellow and prove additional lemmas regarding it.

Labeling Procedure Description. The algorithm is recursive. The base case CP_1 is easy. For $d > 1$, let v be the root of CP_d and let ℓ, r be the left and right parents of v, respectively. The subtree rooted by ℓ is isomorphic to CP_{d-1} and hence its labels can be computed recursively. Keep track of the last label $\mathcal{L}[\ell]$ and proceed to the subtree rooted by r. Apart from edges coming from ℓ to the leaves, it is isomorphic to CP_{d-1}. One can use $\mathcal{L}[\ell]$, which is in memory, and recursively compute the right subtree. Keep track of the last label $\mathcal{L}[r]$. Compute the root label $\mathcal{L}[v] = f(v, \mathcal{L}[\ell], \mathcal{L}[r])$ and forget both $\mathcal{L}[\ell]$ and $\mathcal{L}[r]$. Output the root label $\mathcal{L}[v]$.

Incremental Labeling. We consider an incremental version of the above procedure. Fix $d \in \mathbb{N}$ and let $v_1, v_2, \ldots, v_T$ be the topological ordering in which labels are being outputted by the CP labeling procedure with depth d. Let $\mathcal{U}_t \subseteq V$ be the set of nodes the procedure keep track of after outputting v_t. For the incremental version, we are interested in algorithms that efficiently compute $\mathcal{U}_t$ and v_t given t.

▶ **Lemma 29** (Computing $\mathcal{U}_t$ Efficiently). *For CP_d, computing $\mathcal{U}_t$ can be done in* poly(d) *time.*

Proof. The algorithm is recursive and follows the same post-order traversal as the labeling procedure. For CP_d, let v be the root node and let ℓ, r be its left and right parents respectively. If $t = 2^{d+1} - 1$ return the root node, $\{v\}$. If $t \leq 2^d - 1$, proceed to recursively compute $\mathcal{U}_t$ on the left subtree rooted by ℓ, which is isomorphic to CP_{d-1}. Output the resulting set. Else $t > 2^d - 1$, recursively compute $\mathcal{U}_{t-(2^d-1)}$ on the subtree rooted by r while ignoring the extra edges from ℓ. This graph is also isomorphic to CP_{d-1}. Append ℓ to the resulting set and output.

The algorithm correctness follows by induction. For efficiency, notice that the depth of the recursion is d and every level takes poly(d) time. ◀

▶ **Lemma 30** (Computing v_t Efficiently). *For CP_d, computing v_t can be done in* poly(d) *time.*

Proof. Notice that by construction of the CP labeling procedure, $v_1, \ldots, v_T$ is a post-order traversal on the binary tree B_d which is the base of CP_d. Finding the t-th node in a post-order traversal can be done by a simple recursion with efficiency poly(d). ◀

▶ **Lemma 31** (One Vertex at a Time). *For every $t \in [2, T]$ we have $\mathcal{U}_t = \{v_t\} \biguplus (\mathcal{U}_t \cap \mathcal{U}_{t-1})$.*

Proof. The theorem statement is equivalent to proving $\mathcal{U}_t \backslash \mathcal{U}_{t-1} = \{v_t\}$. By definition we have that $v_t \in \mathcal{U}_t$. Apart from v_t, the procedure only forget nodes, hence $\mathcal{U}_t \subseteq \{v_t\} \cup \mathcal{U}_{t-1}$. It is left to show that $v_t \notin \mathcal{U}_{t-1}$. Indeed, using the aforementioned, by induction $\mathcal{U}_{t-1} \subseteq \{v_1, \ldots, v_{t-1}\}$, in particular $v_t \notin \mathcal{U}_{t-1}$. ◀

6.2 Construction

In this section, we present a modified version of the incremental proof of sequential work (iPoSW) due to [20]. The main difference, apart from syntax, is that we require stricter conditions when verifying nodes.

Parameters. Let λ be a computational security parameter. Let $T(\lambda) = T = 2^{\lambda+1} - 1$ and let $s(\lambda) = s = \Theta(\lambda^3)$ that is a power of 2. Let $\mathsf{H} : \{0,1\}^* \to \{0,1\}^\lambda$ and $\mathsf{H}' : \{0,1\}^* \to \{0,1\}^{3s}$ be independently chosen random oracle ensembles depending on λ.

▶ Remark 32 (Random Coins Count). The use of $3s$ random coins allows to sample a statistically close to uniform subset. See [20] for details.

Syntax. The scheme consists of two algorithms, $\mathsf{DLM.P}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi), \mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$ with the following syntax.

1. $\mathsf{DLM.P}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$ is a deterministic algorithm with oracle access to H, H'. Given a statement χ, a natural number t and a proof π, it outputs a proof π'.
2. $\mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$ is a deterministic algorithm with oracle access to H, H'. Given a statement χ, a natural number t and a proof π, it outputs ACC or REJ.

Proof Structure. The proofs π are of the form $\pi = (\mathcal{L}, (u_i, S_{u_i}, \mathcal{P}_{u_i})_{i=1}^m)$ where:

- $\mathcal{L}$ is a partial vertex labeling for CP_λ.
- u_i is a node of CP_λ.
- S_{u_i} is a set of challenge leaves, indexed by the node u_i.
- $\mathcal{P}_{u_i}$ is a set of candidate authentication paths, indexed by the node u_i.
- $\mathsf{Path} \in \mathcal{P}_{u_i}$ is an ordered list of the form $\mathsf{Path} = (w_j)_j$ where each w_j is a node of CP_λ.

▶ Remark 33 (Labeling Data Structure). The partial vertex labeling $\mathcal{L}$ is given by a dictionary data structure. Where keys are nodes v and the value associated is the corresponding label $\mathcal{L}[v]$. A node which is not in the dictionary is given the default value $\perp$. Let n be the amount of nodes v for which $\mathcal{L}[v] \neq \perp$. We use a dictionary implementation where size and retrieval time are poly(n).

6.2.1 Algorithms Description

Conventions. A random oracle salted with the statement $\chi \in \{0,1\}^*$ is denoted by $\mathsf{H}_\chi := \mathsf{H}(\chi, \cdot)$. Let $v_1, v_2, \ldots, v_T$ be the topological order given by Lemma 28 for nodes of CP_λ. Recall that $\mathcal{U}_t$ is the list of nodes the CP labeling procedure keeps track of when computing the label for v_t. We extend the definition such that $\mathcal{U}_0 = \emptyset$.

$\mathsf{DLM.P}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$

Input:

1. String $\chi \in \{0,1\}^\lambda$.
2. Time $t \in [T]$.
3. Candidate proof $\pi = (\mathcal{L}, (u_i, S_{u_i}, \mathcal{P}_{u_i})_{i=1}^m)$.

Algorithm:

1. If $\{u_1, \ldots, u_m\} \neq \mathcal{U}_{t-1}$ output ε.
2. Set $\mathcal{L}[v_t] = \mathsf{H}_\chi(v_t, \mathcal{L}[p_1], ..., \mathcal{L}[p_r])$ where $(p_1, ..., p_r) = \mathsf{parents}(v_t)$ in lexicographic order.
3. If v_t is a leaf, let $S_{v_t} = \{v_t\}$ and $\mathcal{P}_{v_t} = \{(v_t)\}$.
4. Otherwise, v_t has two parents, $\ell, r \in \mathcal{U}_{t-1}$.
   a. Sample a random subset S_{v_t} of size $\min(s, |\mathsf{leaves}(v_t)|)$ from $S_\ell \cup S_r$ using $\mathsf{rand} \leftarrow \mathsf{H}'_\chi(v_t, \mathcal{L}[v_t])$ as random coins.
   b. Let $\mathcal{P}_{v_t} = \emptyset$. For every $\mathsf{Path} \in \mathcal{P}_\ell \cup \mathcal{P}_r$ starting from a leaf in S_{v_t}, extend with v_t and append to $\mathcal{P}_{v_t}$.
5. Remove labels from $\mathcal{L}$ for all nodes but $\left\{ v \;\middle|\; \begin{array}{l} u \in \mathcal{U}_t \\ \mathsf{Path} \in \mathcal{P}_u \\ w \in \mathsf{Path} \\ v = w \text{ or } v \in \mathsf{parents}(w) \end{array} \right\}$.
6. Output $\pi' = (\mathcal{L}, (u, S_u, \mathcal{P}_u)_{u \in \mathcal{U}_t})$.

Note that in the above we use the efficient algorithms due to computing $\mathcal{U}_t$ efficiently Lemma 29 and computing v_t efficiently Lemma 30 to compute $\mathcal{U}_{t-1}, \mathcal{U}_t$ and v_t. We also use one vertex at a time Lemma 31 in Line 5 and Line 6.

$\mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$

Input:

1. String $\chi \in \{0,1\}^\lambda$.
2. Time $t \in [T]$.
3. Candidate proof $\pi = (\mathcal{L}, (u_i, S_{u_i}, \mathcal{P}_{u_i})_{i=1}^m)$.

Algorithm:

1. Verify that $\{u_1, \ldots, u_m\} = \mathcal{U}_{t-1}$ and distinct. Otherwise, output REJ.
2. Verify that the nodes having label in $\mathcal{L}$ are $\left\{ v \;\middle|\; \begin{array}{l} u \in \mathcal{U}_{t-1} \\ \mathsf{Path} \in \mathcal{P}_u \\ w \in \mathsf{Path} \\ v = w \text{ or } v \in \mathsf{parents}(w) \end{array} \right\}$.
   Otherwise output REJ.
3. For every $i = 1 \ldots m$:
   a. Validate $S_{u_i} \subseteq \mathsf{leaves}(u_i)$ and is of size $\min(s, |\mathsf{leaves}(u_i)|)$. Otherwise output REJ.
   b. Check that every path in $\mathcal{P}_{u_i}$ is a valid path from a leaf in S_{u_i} to u_i. Check that every leaf in S_{u_i} has exactly one corresponding path in $\mathcal{P}_{u_i}$. Otherwise output REJ.
   c. Let $(\mathsf{Path}_1, \ldots, \mathsf{Path}_k) = \mathcal{P}_{u_i}$ ordered in lexicographic order of corresponding source leaves.
   d. For $j = 1, \ldots, k$:
      i. If $\mathsf{VerifyMerklePath}^{\mathsf{H}}(\mathsf{Path}_j, \mathcal{L}, \chi)$ rejects, output REJ.
      ii. If $\mathsf{VerifyRandChoice}^{\mathsf{H}'}(\mathsf{Path}_j, \mathcal{L}, j, \chi)$ rejects, output REJ.
4. Output ACC.

In the above description we used the subroutines $\mathsf{VerifyAuthPath}$ and $\mathsf{VerifyRandChoice}^{\mathsf{H}'}$ that are described in the following.

Merkle Authentication Path Verification $\mathsf{VerifyAuthPath}^{\mathsf{H}}(\mathsf{Path}, \mathcal{L}, \chi)$. Let $\mathsf{Path} = (w_j)_j$ be a candidate authentication path. For every node w_j with $(p_1, \ldots, p_r) = \mathsf{parents}(w_j)$ ordered in lexicographic order, verify

$$\mathcal{L}[w_j] = \mathsf{H}_\chi(w_j, \mathcal{L}[p_1], \ldots, \mathcal{L}[p_r]) \ .$$

If all checks pass, output ACC, otherwise output REJ.

Random Choice Verification $\mathsf{VerifyRandChoice}^{\mathsf{H}'}(\mathsf{Path}, \mathcal{L}, \mathsf{ind}, \chi)$. We give a sketch of the verification, for further details see [20]. Let $\mathsf{Path} = w_1 \to \cdots \to w_r$ be a path where $w_1 \in \mathsf{leaves}(w_r)$. In order to verify the random choice done by H'_χ, we recreate the choice going from the top down. We are given ind, the index of Path in $\mathcal{P}$ ordered by source leaves. This is also the index of the leaf that was picked in the last random choice.

Note that since s is a power of 2, the random choice procedure we use in the prover either choose an s subset from $2s$ set or take the whole set. Starting from w_r, use H'_χ to generate the random coins rand. Using rand pick an s subset from the set $[2s]$. Let i be the ind-th element in the resulting subset. If $i \le s$, we know that w_{r-1} should be a left parent to w_r. Otherwise $i > s$ which tells us that w_{r-1} should be a right parent. We continue to w_{r-1} with $\mathsf{ind} = i$ if $i \le s$ and $\mathsf{ind} = i - s$ otherwise. We continue with this procedure until we get to a node with less than s leaves. If all verifications of the path passed, output ACC and otherwise output REJ.

Efficiency. All the computations done above are polynomial in the input length that is of size $\text{poly}(\lambda, |\pi|)$. Notice that due to the restriction on the size of $\mathcal{L}$ (Line 2 of DLM.V), the size of all accepted proofs is $\text{poly}(\lambda)$. Therefore, for all accepted proofs the runtime is $\text{poly}(\lambda)$ for a fixed polynomial. Hence, we may modify DLM.V to reject and DLM.P to output ε once this $\text{poly}(\lambda)$ time limit exceeds. This way, the efficiency of DLM.V and DLM.P is $\text{poly}(\lambda)$ for every input.

▶ Remark 34 (Proofs are Not Unique). Proofs in the DLM scheme are not computationally unique. To see this, consider an adversary that attempts to find a collision for accepting proofs of time $t = \Theta(s^2) = \Theta(\lambda^6)$ that is of the form $2^{k+1} - 1$. The first proof is generated honestly. For the second proof, select randomly $u \in \mathsf{leaves}(v_t)$. Compute the proof honestly up until the label for u is computed. Alter the label for u. Continue as the honestly generated proof. With overwhelming probability, the two proofs generated are different. The second proof is accepting if there is no authentication path starting with u. Since t is of the form $2^{k+1} - 1$, there are s authentication paths starting with leaves in $\mathsf{leaves}(v_t)$. Also, all the leaves have the same probability to be chosen. There are 2^k leaves, therefore the probability u is selected is $s/2^k = \Omega(1/\lambda^3)$. The described adversary is efficient and successful with noticeable probability.

6.2.2 Incremental Completeness

The proof for the next proposition is in the full version of this paper.

▶ **Proposition 35** (Incremental Completeness of Modified DLM). *For every security parameter $\lambda \in \mathbb{N}$, time $t \in [T-1]$, candidate proof $\pi \in \{0,1\}^*$ and statement $\chi \in \{0,1\}^\lambda$:*

$$\textit{If } \mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi) = \mathsf{ACC} \textit{ then } \mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, t+1, \pi') = \mathsf{ACC} \ ,$$

where $\pi' = \mathsf{DLM.P}^{\mathsf{H},\mathsf{H}'}(\chi, t, \pi)$.

6.2.3 Soundness

In this section, we state the soundness property of the modified DLM system. While we altered the DLM construction, we did so by enforcing stricter verification conditions. Accordingly, we inherit the soundness of the original scheme – every valid proof in the modified scheme corresponds to a valid proof in the original scheme without the use of the random oracle in the correspondence.

▶ **Theorem 36** (DLM Soundness, Follows From [20]). *Let $\mathcal{A}^{\mathsf{H},\mathsf{H}'} = \{\mathcal{A}_\lambda^{\mathsf{H},\mathsf{H}'}\}$ be an oracle aided adversary that makes at most $q = q(\lambda)$ total queries to both H and H'. For every $\lambda, d \in \mathbb{N}$ with $d \leq \lambda$, such that $\mathcal{A}$ makes less than 2^d sequential queries to H we have:*

$$\Pr\left[\mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, T_d, \pi) = \mathsf{ACC} \;\middle|\; \begin{array}{l} \chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathsf{H},\mathsf{H}'}(\chi) \end{array}\right] \leq O(q^2) 2^{-\Omega(\lambda)} \ ,$$

where $T_d = 2^{d+1} - 1$.

▶ **Corollary 37** (Sequential Hardness). *Let $d = d(\lambda) \leq \lambda$ be a depth parameter. For every oracle aided adversary $\mathcal{A}^{\mathsf{H},\mathsf{H}'} = \{\mathcal{A}_\lambda^{\mathsf{H},\mathsf{H}'}\}_{\lambda \in \mathbb{N}}$ of depth 2^d and size $2^{o(\lambda)}$, we have for every $\lambda \in \mathbb{N}$:*

$$\Pr\left[\mathsf{DLM.V}^{\mathsf{H},\mathsf{H}'}(\chi, T_d, \pi) = \mathsf{ACC} \;\middle|\; \begin{array}{l} \chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathsf{H},\mathsf{H}'}(\chi) \end{array}\right] \leq 2^{-\Omega(\lambda)} \ ,$$

where $T_d = 2^{d+1} - 1$.

6.2.3.1 Single Oracle

The DLM construction is described in terms of two random oracles H, H' (which is done mostly to simplify the analysis). From hereon, it will be simpler to think of a single random oracle $\mathcal{O} : \{0,1\}^* \to \{0,1\}$. The algorithms $\mathsf{DLM.P}^{\mathcal{O}}, \mathsf{DLM.V}^{\mathcal{O}}$ simulate oracle calls to H, H' in the above construction by setting an appropriate prefix for every output bit in H and H'. The security reduction incurs a multiplicative polynomial loss in efficiency and a multiplicative logarithmic loss in depth (both in terms of λ).

Indeed, consider an adversary $\mathcal{A}$ attempting to break the scheme with $\mathcal{O}$. In order reduce this adversary to $\mathcal{A}'$ attacking the scheme using H, H' we modify the oracle gates to $\mathcal{O}$ in $\mathcal{A}$ by examining the prefix and simulating the output of the associate output bit in H or H'. In this reduction, comparing the prefix, incurs a logarithmic loss in depth and polynomial loss in size of the new adversary $\mathcal{A}'$. We conclude this in the following corollary.

▶ **Corollary 38** (Single Oracle Sequential Hardness). *Let $d = d(\lambda) \leq \lambda$ be a depth parameter. For every oracle aided adversary $\mathcal{A}^{\mathcal{O}} = \{\mathcal{A}^{\mathcal{O}}_\lambda\}_{\lambda\in\mathbb{N}}$ of depth $o(2^d/\log\lambda)$ and size $2^{o(\lambda)}$, we have for every $\lambda \in \mathbb{N}$:*

$$\Pr\left[\mathsf{DLM.V}^{\mathcal{O}}(\chi, T_d, \pi) = \mathsf{ACC} \;\middle|\; \begin{array}{c}\chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathcal{O}}(\chi)\end{array}\right] \leq 2^{-\Omega(\lambda)} \quad ,$$

where $T_d = 2^{d+1} - 1$.

By considering $d = \lambda$, we derive the following corollary:

▶ **Corollary 39** (Exponential Hardness). *For every oracle aided adversary $\mathcal{A}^{\mathcal{O}} = \{\mathcal{A}^{\mathcal{O}}_\lambda\}_{\lambda\in\mathbb{N}}$ of size $2^{o(\lambda)}$ and $\lambda \in \mathbb{N}$:*

$$\Pr\left[\mathsf{DLM.V}^{\mathcal{O}}(\chi, T_\lambda, \pi) = \mathsf{ACC} \;\middle|\; \begin{array}{c}\chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathcal{O}}(\chi)\end{array}\right] \leq 2^{-\Omega(\lambda)} \quad ,$$

where $T_\lambda = 2^{\lambda+1} - 1$.

6.3 Hard instances

In this section, we consider the problem $R^{\mathcal{O}}_d$, where instances are strings χ and a witness for χ is a corresponding proof of sequential work in the modified DLM scheme for time $T_d = 2^{d+1} - 1$. We show that $R^{\mathcal{O}}_d$ lies in $\mathsf{PLS}^{\mathcal{O}}$.

▶ Remark 40 (Efficiently Computable Depth Parameter). In the following, a depth parameter $d(\lambda)$ is a polynomial-time computable function. We require this for the efficiency of the reduction.

▶ **Definition 41.** *Let $d = d(\lambda) \leq \lambda$ be a depth parameter. The search problem $R^{\mathcal{O}}_d$ is defined as follows:*

$$R^{\mathcal{O}}_d = \left\{(\chi, \pi) \;\middle|\; \mathsf{DLM.V}^{\mathcal{O}}(\chi, T_d(|\chi|), \pi) = \mathsf{ACC}\right\} \quad ,$$

where $T_d(\lambda) = 2^{d(\lambda)+1} - 1$.

Note that $R^{\mathcal{O}}_d$ is in $\mathsf{TFNP}^{\mathcal{O}}$. It is in $\mathsf{FNP}^{\mathcal{O}}$ by the efficiency of DLM. It is total by the completeness of DLM, since for every χ, there exists a proof π that passes verification – the honestly generated proof.

6.3.1 The Reduction to Local Search

Fix a depth parameter $d = d(\lambda) \leq \lambda$. We construct a polynomial-time search reduction (f_d, g_d) from $R_d^{\mathcal{O}}$ to $\mathsf{LS}^{\mathcal{O}}$.

Instance Translation. Let $\chi \in \{0,1\}^\lambda$ be an instance for the problem $R_d^{\mathcal{O}}$. We construct an $\mathsf{LS}^{\mathcal{O}}$ instance $f_d(\chi) = (\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}})$ in the following. Intuitively, we embed the computation of the modified DLM PoSW in an $\mathsf{LS}^{\mathcal{O}}$ instance such that local maximums correspond to valid proofs for time $T_d = 2^{d+1} - 1$. Concretely, every node will be of a fixed polynomial length $\ell = \ell(\lambda) \geq \lambda$. Every vertex is of the form $(t, \pi) \in \{0,1\}^\ell$ where t is parsed as an integer $t \in [T_d]$ and π as a proof of the modified DLM scheme with padding to length ℓ if needed.

Let π_1 be a valid proof for time $t = 1$ in the modified DLM scheme. For the node (t, π), if the proof π is verified with respect to time t, the node will be given value t and be connected to $(t+1, \pi')$ where π' is the proof the prover generates given π. If π is rejected, it is given value -1 and is connected to $(1, \pi_1)$. A formal definition of the circuits is given bellow.

Successor Circuit $\mathcal{S}^{\mathcal{O}}(t, \pi)$

Hardwired: The instance χ.
Algorithm:
1. If $\mathsf{DLM.V}^{\mathcal{O}}(\chi, t, \pi) = \mathsf{REJ}$, output $(1, \pi_1)$.
2. If $t = T_d$, output (t, π).
3. Compute $\pi' = \mathsf{DLM.P}^{\mathcal{O}}(\chi, t, \pi)$ and output $(t+1, \pi')$.

Value Circuit $\mathcal{F}^{\mathcal{O}}(t, \pi)$

Hardwired: The instance χ.
Algorithm:
1. If $\mathsf{DLM.V}^{\mathcal{O}}(\chi, t, \pi) = \mathsf{REJ}$, output -1.
2. Else, output t.

Witness Translation. The function $g_d(t, \pi)$ outputs π.

Efficiency. By the efficiency of the modified DLM scheme and the efficiency of the depth parameter $d(\lambda)$, the instance translation f_d is done in $\mathrm{poly}(\lambda)$ time. The witness translation g_d is also done in $\mathrm{poly}(\lambda)$ time since the length of nodes ℓ is of size $\mathrm{poly}(\lambda)$. This further implies that $\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}}$ are of size $\mathrm{poly}(\lambda)$. Since the input length is a polynomial such that $\ell(\lambda) \geq \lambda$, this implies that $\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}}$ are polynomial-size circuits.

6.3.2 Security Analysis

In the following claim we rely on the incremental completeness of the modified DLM Section 6.2.2.

▷ Claim 42. Let $d = d(\lambda) \leq \lambda$ be a depth parameter. Fix $\lambda \in \mathbb{N}$ and $\chi \in \{0,1\}^\lambda$. Let $w = (t, \pi)$ be a local maximum of $(\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}}) = f_d(\chi)$. We have $\mathsf{DLM.V}^{\mathcal{O}}(\chi, t, \pi) = \mathsf{ACC}$ and $t = T_d$.

Proof. We have $\mathsf{DLM.V}^{\mathcal{O}}(\chi, t, \pi) = \mathsf{ACC}$ as otherwise w is given value -1 and his successor is $(1, \pi_1)$ of value 1. If $t < T_d$ then w is given value t and is connected to $(t+1, \pi')$ for $\pi' = \mathsf{DLM.P}^{\mathcal{O}}(\chi, t, \pi)$. By incremental completeness Proposition 35, we have that $\mathsf{DLM.P}(\chi, t+1, \pi') = \mathsf{ACC}$. Therefore, the value of $(t+1, \pi')$ is $t+1$, and w is not a local maximum. We are left with $t = T_d$. This concludes the claim. ◁

▶ **Theorem 43** (Hard Problems in $\mathsf{PLS}^{\mathcal{O}}$). *For every depth parameter $d = d(\lambda) \leq \lambda$, the search problem $R_d^{\mathcal{O}}$ lies in $\mathsf{PLS}^{\mathcal{O}}$.*

Proof. The class $\mathsf{PLS}^{\mathcal{O}}$ consists of all $\mathsf{TFNP}^{\mathcal{O}}$ search problems that are polynomial-time reducible to $\mathsf{LS}^{\mathcal{O}}$. The search problem $R_d^{\mathcal{O}} \in \mathsf{TFNP}^{\mathcal{O}}$ and by Claim 42, the tuple (f_d, g_d) is a valid polynomial-time reduction to $\mathsf{PLS}^{\mathcal{O}}$. Indeed, for every string χ, we have that all witnesses w' for the instance $(\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}}) = f_d(\chi)$ are mapped under g_d to $w = \pi$ such that $\mathsf{DLM.V}^{\mathcal{O}}(\chi, T_d, \pi) = \mathsf{ACC}$ – a valid witness to $R_d^{\mathcal{O}}$. Hence $R_d^{\mathcal{O}} \in \mathsf{PLS}^{\mathcal{O}}$. A proof is given in the full version. ◀

▶ **Corollary 44** (Exponential Hardness in $\mathsf{PLS}^{\mathcal{O}}$). *There exists search problems in $\mathsf{PLS}^{\mathcal{O}}$ that are average-case exponentially hard.*

Proof. By Theorem 43, for every depth parameter $d = d(\lambda) \leq \lambda$, the search problem $R_d^{\mathcal{O}}$ is in $\mathsf{PLS}^{\mathcal{O}}$. By Corollary 39, for $d = \lambda$ the search problem $R_\lambda^{\mathcal{O}}$ is exponentially average-case hard. ◀

This implies that $\mathsf{LS}^{\mathcal{O}}$ is sub-exponentially hard due to the polynomial blowup the reduction incurs. We formulate it in the following corollary. In the following, n stands for the size of the $\mathsf{LS}^{\mathcal{O}}$ instance $(\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}})$ and λ stands for the security parameter that is given as input to the sampler. A proof is given in the full version of this paper.

▶ **Corollary 45.** *There exists an efficient sampler HARD of $\mathsf{LS}^{\mathcal{O}}$ instances and a constant $\delta > 0$ such that for every oracle aided adversary $\mathcal{A}^{\mathcal{O}} = \{\mathcal{A}_n^{\mathcal{O}}\}_{n \in \mathbb{N}}$ of size at most 2^{n^δ} and for every $\lambda \in \mathbb{N}$:*

$$\Pr\left[\mathcal{F}^{\mathcal{O}}(\mathcal{S}^{\mathcal{O}}(w)) \leq \mathcal{F}^{\mathcal{O}}(w) \;\middle|\; \begin{array}{l}(\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}}) \leftarrow \mathsf{HARD}(1^\lambda) \\ w \leftarrow \mathcal{A}(\mathcal{S}^{\mathcal{O}}, \mathcal{F}^{\mathcal{O}})\end{array}\right] \leq 2^{-\Omega(\lambda)} \quad ,$$

where $\mathcal{O} : \{0,1\}^* \to \{0,1\}$ is a random oracle.

6.4 Depth Robust Instances

In this section, we deduce the existence of depth-robust, moderately hard, search problems in $\mathsf{PLS}^{\mathcal{O}}$. That is, search problems with instances that can be solved in polynomial time yet also require high sequential time.

▶ **Proposition 46** (Depth Robust Problems in $\mathsf{PLS}^{\mathcal{O}}$). *Fix any constant $\varepsilon > 0$. For any large enough constant α, consider $R_d^{\mathcal{O}}$ for $d(\lambda) = \alpha \log_2 \lambda$ a depth parameter. The following properties hold for $\lambda > 1$:*

- ***Moderately Hard:*** *The search problem $R_d^{\mathcal{O}}$ can be solved in time $\lambda^{(1+\varepsilon)\alpha}$.*
- ***Depth Robust:*** *If $\mathcal{A}$ is an adversary of depth $\lambda^{(1-\varepsilon)\alpha}$ and size $2^{o(\lambda)}$ then:*

$$\Pr\left[(\chi, \pi) \in R_d^{\mathcal{O}} \;\middle|\; \begin{array}{l}\chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathcal{O}}(\chi)\end{array}\right] \leq 2^{-\Omega(\lambda)} \quad .$$

Proof. Fix $\varepsilon > 0$ throughout the proof. We start by proving that $R_d^{\mathcal{O}}$ is moderately hard.

▷ Claim 47 (Moderately Hard). The search problem $R_d^{\mathcal{O}}$, where $d(\lambda) = \alpha \log_2 \lambda$, can be solved in time $\lambda^{(1+\varepsilon)\alpha}$ when α is a large enough constant.

Proof. Fix $\lambda > 1$ and let $\chi \in \{0,1\}^\lambda$ be an instance of $R_d^{\mathcal{O}}$. We have $T_d = 2^{\alpha \log_2 \lambda + 1} - 1 \leq 2\lambda^\alpha \leq \lambda^{\alpha+1}$. By efficiency of DLM, the run-time of $\mathsf{DLM.P}^{\mathcal{O}}$ is at most λ^c for some fixed constant c, independent of ε and α. The proof π_1 for time $t = 1$ can also be generated in poly(λ) time. We assume w.l.o.g that it can be generated in time λ^c. By completeness of DLM, generating π_1 and applying the prover $T_d - 1$ times on it, results in a valid proof for time $t = T_d$. This is a valid witness for the instance χ in $R_d^{\mathcal{O}}$. The above algorithm takes at most

$$T_d \cdot \lambda^c \leq \lambda^{\alpha+1} \cdot \lambda^c \leq \lambda^{(1+\varepsilon)\alpha} \ ,$$

where the last inequality holds for large enough α, concretely $\alpha > (c+1)/\varepsilon$. ◁

We proceed to show that $R_d^{\mathcal{O}}$ is depth robust.

▷ Claim 48 (Depth Robust). Let α be a large enough constant and let $d = \alpha \log_2 \lambda$. For every adversary $\mathcal{A}$ of depth $\lambda^{(1-\varepsilon)\alpha}$ and size $2^{o(\lambda)}$ we have for every $\lambda \in \mathbb{N}$:

$$\Pr\left[(\chi,\pi) \in R_d^{\mathcal{O}} \;\middle|\; \begin{array}{c} \chi \leftarrow \{0,1\}^\lambda \\ \pi \leftarrow \mathcal{A}^{\mathcal{O}}(\chi) \end{array}\right] \leq 2^{-\Omega(\lambda)} \ .$$

Proof. This is a direct application of single oracle sequential hardness Corollary 38. We have $T_d = 2^{\alpha \log_2 \lambda + 1} - 1 \geq \lambda^\alpha$. Hence $\lambda^{(1-\varepsilon)\alpha} = o(T_d / \log \alpha)$ and the claim follows by Corollary 38. ◁

The above two claims conclude the proof of the proposition. ◀

Abstract

The problem of constructing error-resilient interactive protocols was introduced in the seminal works of Schulman (FOCS 1992, STOC 1993). These works show how to convert any two-party interactive protocol into one that is resilient to constant-fraction of error, while blowing up the communication by only a constant factor. Since these seminal works, there have been many followup works which improve the error rate, the communication rate, and the computational efficiency.

All these works only consider only an increase in communication complexity and did not consider an increase in *round complexity*. This work is the first one that considers the blowup of round complexity in noisy setting. While techniques from other papers can be easily adapted encode protocols with arbitrarily round complexity this coding schemes will lead to large(and usually unbounded) increase in round complexity of the protocol.

In this work, we show how to convert any protocol Π, with *no a priori* known *communication bound*, into an error-resilient protocol Π', with comparable computational efficiency, that is resilient to constant fraction of adversarial error, while blowing up both the communication complexity and the *round complexity* by at most a constant factor. We consider the model where in each round each party may send a message of *arbitrary length*, where the length of the messages and the length of the protocol may be *adaptive*, and may depend on the private inputs of the parties and on previous communication. We consider the adversarial error model, where ϵ-fraction of the communication may be corrupted, where we allow each corruption to be an *insertion* or *deletion* (in addition to toggle).

In addition, we try to minimize the blowup parameters: In particular, we construct such Π' with $(1+\tilde{O}\left(\epsilon^{1/4}\right))$ blowup in communication and $O(1)$ blowup in rounds. We also show how to reduce the blowup in rounds at the expense of increasing the blowup in communication, and construct Π' where both the blowup in rounds and communication, approaches one (i.e., no blowup) as ϵ approaches zero. We give "evidence" that our parameters are "close to" optimal.

1 Introduction

Communication over a noisy channel is a fundamental problem in computer science, engineering and related fields. Starting from the seminal work of Shannon [30], this problem of error-resilient communication has been extensively studied. Today, we have "good" error-correcting codes – ones that achieve constant information rate as well as constant error rate. The two main error models that were considered are the *stochastic* error model, where the errors are distributed according to some distribution (such as the binary symmetric channel), and the *adversarial* error model, where errors may occur adaptively and adversarially, so long as the prescribed error rate is not exceeded. This work considers the latter (stronger) adversarial error model. In addition, we consider (adversarial) insertion and deletion errors.

In a sequence of innovative works, Schulman [27, 28, 29] initiated the study of error-resilience in the context of *interactive protocols*. Specifically, he considered the setting where two parties are interacting via a protocol over a noisy channel, where the noise could be stochastic or adversarial. Since Schulman's seminal works, there have been many followup works, that improve the error rate [9, 16, 17, 6, 1, 10], the information rate [24, 19, 12], the computational efficiency [15, 2, 4, 3], and very recently that are been beautiful works that generalize the error model of the adversary to allow insertions and deletions [8, 21, 31]. There have also been several works that consider the multi-party setting [26, 23, 7, 14]. We refer the reader to [11] for a fantastic survey on previous work on interactive coding. The focus of this work is on the 2-party setting and the adversarial error model.

All previous works consider only an increase of total communication without looking on number of rounds required to perform the task. In cryptography and in distributed computing, protocols that consist of long messages are considered, and it is desirable to keep the round complexity as low as possible. In fact, much research (in both cryptography and distributed computing) focuses on reducing the round complexity of various protocols, as often the round complexity is the bottleneck, and not the communication complexity. We argue that since we consider *interactive* protocols, we should aim for error resilient protocols, that not only blow up the communication by at most a constant factor, but also blow up the number of rounds by at most a constant factor.

Our model is the typical synchronous model used in cryptography and distributed algorithms. In our model we assume that the original protocol can be very versatile that is each party can decide how many bit he wants to send next based on previous communication and his private input. Therefore not only that number of rounds and communication of each player depends not only on the communication over the channel but also on players private input. We want to mention that more versatile original protocol is the harder it is to make a coding scheme for it. We elaborate on this model in Section 1.1.

Moreover, we emphasize that we do not assume that the communication (or round) complexity is fixed or a priori known. This is in contrast to all previous works, which assume that the communication (and round) complexity T is fixed and known in advance, and that the adversary can corrupt at most ϵT bits.[1] We note that such an assumption is often unrealistic and results in protocols where the communication complexity is always *worse-case*.

[1] We mention the work of Agrawal *et. al.* [1], which does assume that the communication complexity of the underlying errorless protocol is a priori known. However, with the goal of maximizing the error rate, the communication complexity in the error-resilient protocol is not fixed and is not a priori known. We emphasize that in our work, we do not even assume that the parties a priori know the communication complexity in the underlying errorless protocol.

In this work, we allow the communication and round complexity to differ from execution to execution, depending on the inputs, or "types" of the parties, and construct an error-resilient protocol that preserves this per-execution communication (and round) complexity. We note that the fact that we allow such adaptive (and not a priori known) communication length adds substantial technical difficulties to our work, which we elaborate on in Section 1.4.[2]

Our Results in a Nutshell. We show how to convert any protocol, where messages can be of arbitrary length, and where the communication and round complexity are not a priori known, into an error-resilient one, with comparable (computational) efficiency guarantees, that is secure against constant fraction of adversarial error, while incurring a constant blowup both to the communication complexity and to the round complexity. We allow the adversary not only to toggle with the bits of communication, but also allow the adversary to *insert* and *delete* bits. We elaborate on our communication model and error model in Section 1.1.

Moreover, we try to minimize the (constant) overhead in communication and rounds: In particular, we obtain $(1 + \tilde{O}(\epsilon^{1/4}))$ blowup in communication and $O(1)$ blowup in rounds. We also show how to reduce the blowup in rounds at the expense of slightly increasing the blowup in communication, and construct an error-resilient protocol where both the blowup in rounds and communication approaches one as ϵ approaches zero. We elaborate on our results (and on the exact parameters we obtain) in Section 1.2, we give a high-level overview of our techniques in Section 1.4, and give "evidence" that our parameters are "close to" optimal in Section 2.3 (after formally stating our main theorem in Section 2.2).

Our Technical Hurdles

The reader may at first think that dealing with short messages is the "hard case", since for long messages we can use standard error-correcting codes. We argue that this intuition is misleading. First, when considering adversarial error, applying an error-correcting code to each message separately does not help, since the entire message can be corrupted (even if the message is long), and indeed in this work we focus on adversarial error. We mention, however, that even for the case of stochastic error, dealing with messages of varying lengths, where some messages may be short while other messages may be long, is challenging.

Before explaining the difficulties that arise in this setting, we note that if we knew a priori the number of rounds and the communication complexity of the underlying protocol, then we could have "smoothed" it out perfectly, so that all the messages would have been of equal length,[3] and then we could have used a protocol (and analysis) from prior works.

Since we do not have such a bound, we cannot perfectly smooth out the underlying protocol. Nevertheless, we must somehow smooth out the protocol, since a party cannot send a long message before she is "sufficiently confident" that the transcript so far is correct, as otherwise, this long message will be wasted (even if the adversary does not corrupt it at all). Therefore, we "approximately" smoothen out the underlying protocol, by guaranteeing that each message is of length at least half and at most twice the length of the previous message. We refer the reader to Section 1.4 and Section 3 for details.

[2] We believe (though we haven't checked) that the tree-code based interactive coding schemes may easily be adapted to the setting where the communication complexity is not a priori bounded, by having each party construct an (infinitely growing) tree code. However, in tree-code based schemes the parties are computationally inefficient and there is a large blowup to the round complexity.

[3] This approach blows up the communication and round complexity by a constant factor. If the goal is to optimize this blowup (as we do in this work) then one cannot afford to perfectly smoothen out the protocol, in which case our techniques are needed.

We mention that in order to minimize the blowup, we consider two small constants $\alpha, \beta > 0$ (that depend on the error rate) and guarantee that the length of each message is at least $\alpha\ell$ and at most $\frac{\ell}{\beta}$, where ℓ is the length of the message preceding it. This is not important for the high-level overview.

We emphasize, that even after smoothing the underlying protocol, the length of the messages can still grow (or shrink) at an exponential rate, which brings rise to several challenges. For example, similar to many previous works (such as[27, 2, 19]), when a party realizes that there was an error she backtracks. In our setting we need to be extremely cautious when we backtrack. Note that the adversary can cause us to backtrack even though we are synchronized, by making us believe that we are out of sync. Previous works ensure that the adversary needs to invest enough error for such backtracking, and hence such "false" backtracking is costly for the adversary. However, in the case where messages are of varying length, this analysis becomes extremely delicate, since the adversary can corrupt a short message (by investing a small amount of his error budget), and thus falsely cause the parties to backtrack and delete a previous long message. Indeed, as opposed to previous protocols, we do not erase when we backtrack. Rather, we keep this transcript as "questionable". We refer the reader to Section 1.4 and Section 4 for details.

Moreover, when messages are of varying lengths, even if the protocol is (approximately) smooth, and even if we backtrack carefully, ensuring that the round complexity does not blow up, does not only require a careful (and significantly more complex) analysis, but also requires additional new ideas.

For example, the protocols in previous works, perform an equality test after every chunk of length d (for some parameter d), where in this equality test the parties check whether they are in sync by sending each other a hash of their transcript so far. In our setting, messages may be very long, and we cannot chop a message to chunks of d bits each, since this will blow up the round complexity. Instead, it is tempting to simply append to each message a hash of length that is proportional to the message length (e.g., append a hash of length $\lfloor \frac{\ell}{d} \rfloor$ to a message of length ℓ). However, as we show in Section 1.4 and Section 5, in order to ensure a constant blowup in round complexity, we must not only allow the length of the hash value to depend on the length of the message it is being appended to, but rather it should also depend on the length of the *entire history*. This is the case since if the protocol has messages of varying lengths, the adversary can corrupt a single long message, in a way that causes many hash collisions in future short messages. Thus, by corrupting one (long) message many rounds can be wasted.

In order to get around this problem, we allow the length of the hash to depend on the length of the entire history. Moreover, we consider randomized (i.e., seeded) hash function, where the party sends the hash value together with the hash seed, so that the adversary does not know which hash function will be used ahead of time. However, with a seed of length w one can hash messages of length at most 2^w, and the history may be longer than 2^w. Thus, in our scheme some of the seed is chosen ahead of time and some of the seed is chosen with each message. We refer the reader to Section 1.4 and Section 5 for details.

Moreover, the fact that the communication complexity is not a priori known creates an additional problem. Following previous works (such as [2, 3, 19]), we first construct a protocol in the *common random string* (CRS) model (this is done in Section 5), and then we remove the CRS (in Section 6). Removing the CRS in previous work was straightforward: First show that the CRS can be made relatively short (of size proportional to the communication complexity) by using a δ-biased source, and then argue that one of the parties can simply send the CRS using a (standard) error correcting code. In our case this cannot be done since we do not have an a priori bound on the communication complexity.

We give an overview on how we overcome the technical hurdles mentioned above in Section 1.4, but warn the reader that overcoming these challenges is quite difficult, and results in a very complex analysis.

We next explain our model in more detail.

1.1 Our Model

1.1.1 The Noiseless Model

We consider 2-party protocols, between two parties, Alice and Bob. In our model, at every round i, Alice and Bob do the following: Alice chooses $\ell_A(i) \in \mathbb{N}$ (greater than 0) and a message $m_A(i) \in \{0,1\}^{\ell_A(i)}$, based on her view of previous communication and her private input, and sends $m_A(i)$ to Bob. Similarly, Bob chooses $\ell_B(i) \in \mathbb{N}$ and a message $m_B(i) \in \{0,1\}^{\ell_B(i)}$, based on his view of previous communication and his private input, and sends $m_B(i)$ to Alice. At some round, one of the parties aborts, and both parties report an output.

More generally, we allow Bob's message in the i'th round to depend, not only on all previous communication and his private input, but also on Alice's message in the i'th round. This corresponds to the synchronous model where in each round i, Alice and Bob do not send their messages simultaneously, but rather first Alice sends her message and only then Bob sends his message (which may depend on Alice's message). This model is known as the message-passing model, and is the most common model used in cryptography (and distributed algorithms). We note that our results also apply to the synchronous simultaneous message model, and the choice of presenting our results in the synchronous message-passing model was due to the fact that we think that this model is more standard.

We denote the input of Alice by x, and we denote the input of Bob by y. Note that a pair of inputs (x, y) define ℓ_A and ℓ_B for all rounds, and also define the number of rounds. Thus, in the noiseless setting, for any protocol we can define $\mathrm{CC}(x, y)$, which is the communication complexity of the protocol for the input pair (x, y). Similarly, we can define $\mathrm{R}(x, y)$, which is the number of rounds for the input pair (x, y).

1.1.2 The Noisy Model

In this work, we consider the adversarial error model, and assume that the adversary can corrupt any ϵ-fraction of the bits, for some a priori fixed small constant $\epsilon > 0$. We allow the adversary, not only to toggle with the bits, but he can also insert and delete bits.

In our model, where messages can be of arbitrary length, protecting protocols against insertions and deletions is extremely important, since otherwise the parties can securely encode information via the *length* of the messages. Specifically, in our model, where messages can be of varying lengths, one can trivially protect protocols against (adversarial) toggle corruptions while incurring only a constant factor blowup in the communication complexity, albeit an *unbounded blowup* in the round complexity, as follows: First convert the protocol to a protocol where each party sends a single bit in each round. Then, encode this bit as follows: If the bit is zero then encode it via a single bit (zero or one), and if the bit is 1 then encode it via any two bits. Upon receiving an encoded message the parties will decode without looking at the content of the message, but rather only by the length of the message.

We note that most previous work on interactive coding do not consider insertion and deletions. Indeed, in the synchronous model, where the parties send one bit per round, insertions and deletions are not interesting, since the parties "can tell" when an insertion or deletion occurs.

An exception are the recent works of [8, 21, 31]. These works consider insertion and deletions in the *asynchronous* model. More specifically, they consider an adversary who can insert a message from one party and delete a message from the other party, and thus cause the parties to be out-of-synch with regard to which round they are on (though similarly to previous work, they are in the bit-by-bit model, thus their protocols incur a large blowup to the round complexity, and they assume an a priori bound on the communication complexity).

In our work, we consider the *synchronous* model, where the parties always agree on the number of speaking alternations (which in our case is exactly the number of rounds). We emphasize, however, that the work of [21] shows a generic method for converting any error-resilient protocol in the synchronized model into one that that is error resilient in the asynchronized model. We believe that one can use their approach (and in particular the use of a synchronization code [20]) to boost our result from the synchronous model to the asynchronous model.

In the adversarial error model, in our work and in all previous works, there is an a priori fixed constant ϵ and it is assumed that the adversary can corrupt at most ϵT bits, where T is the number of bits communicated. In most previous work, the value of T was assumed to be a priori known (and fixed). As mentioned above, in this work, we allow the length of the protocol to depend on previous communication. This models the real world setting, where we cannot a priori predict the length of our conversations, and it can depend on our private inputs (or on our "types").

In this model, care should be taken when defining the adversarial error model. One possibility is to allow the adversary to corrupt ϵT bits, where T is the number of bits that would have been transmitted assuming no error.[4]

We note, however, that with such a definition the adversary can use his ϵT bits of corruption budget, and cause the parties to abort prematurely. Namely, he can convince both parties that the other party is "boring" (i.e., that the other party has an input such that if they were executing the error-free protocol without error, the number of bits exchanged would have been less than ϵT). In such case both parties would abort prematurely and the adversary would "win".

Instead, we allow the adversary to corrupt only ϵ-fraction of the bits that were actually communicated. We note that a similar model was used in the work of Agrawal et al. [1], where their goal was to get optimal error-rate, and to that end, they considered error-resilient protocols with an adaptive speaking order and where the communication complexity may depend on the error pattern.[5] We emphasize that this adversarial model is stronger than alternative (natural) models, such as the the prefix model that allows the adversary to corrupt ϵ-fraction of any prefix of the transcript.

In this work, we also add a bound ϵ' on the number of rounds that the adversary can "fully" corrupt, where we say that a round is *fully corrupt* if the adversary corrupts more than δ-fraction of the bits, for some small constant δ (which depends on the error bound ϵ). We note that all previous works also had such a bound (implicitly), since in previous works there was no distinction between rounds and communication. In contrast, in our model, a bound on the number of bits corrupted does not imply a bound on the number of rounds that are fully corrupted. For example, consider the protocol in which there is one long message of length ℓ, followed by $\epsilon\ell$ messages, each consisting of a single bit. In such a protocol, not corrupting the long message gives the adversary the budget to corrupt all the short messages.

[4] We note that the adversary knows T since we assume (similarly to all previous work that consider the adversarial error model), that the adversary knows the private inputs of the parties.

[5] As mentioned above, the work of [1] does assume an a priori known bound on the communication complexity of the underlying (errorless) protocol.

We emphasize that bounding the number of rounds that are fully corrupted is necessary, since without such a bound, it is impossible to ensure a small blowup in round complexity. This argument is deferred to Section 2.3 where we give evidence to the optimality of our parameters.

1.2 Our Results

In what follows, we denote our error parameters by ϵ and ϵ', where ϵ corresponds to the fraction of corrupted bits, and ϵ' corresponds to the fraction of (fully) corrupted messages. We show that for any (small enough) constants $\epsilon, \epsilon' > 0$ there exist blowup parameters $\alpha, \alpha' > 0$ such that one can convert any protocol into an error resilient one (with respect to ϵ and ϵ'), with α blowup in communication, and essentially α' blowup in rounds (with an additional term that depends logarithmically on the communication complexity). We can set $\alpha' = O(1)$ we obtain a blowup of $\alpha = \tilde{O}\left(\epsilon^{1/4}\right)$ in communication complexity. Alternatively, one can set α, α' such that they both approach 0 as ϵ, ϵ' approach 0.

Our error-resilient protocol is randomized, even if the original protocol was deterministic. This is similar to all previous works that construct computationally efficient interactive coding schemes that are robust to adversarial error (starting with the work of [2]). Schulman [28] (followed by many followup works) gave a deterministic interactive coding scheme, at the price of computational inefficiency. The parties in the error resilient scheme run in exponential time in T, where T is an upper bound on the length of the underlying protocol.[6] Recently, Gelles et al. [13] gave a deterministic and efficient construction for the case of random error. However, constructing a deterministic interactive coding scheme that is resilient to adversarial error and is computationally efficient remains an interesting open problem.

We are now ready to state our main theorem. The most general theorem can be found in Section 2, and in what follows we present our theorem in a regime of parameters that we think is of particular interest.

In what follows, we let $t_{\min}$ denote the minimum value for which the underlying error-free protocol Π transmits at least $t_{\min}$ bits.

▶ **Theorem 1** (Main Theorem (informal)). *For any sufficiently small $\epsilon \geq 0$ and for any $\epsilon' \leq \epsilon^{1/4}$, there exist blowup parameters α and α', and a polynomial time probabilistic oracle machine S, such that the following holds. For any adversary $\mathcal{A}$ that corrupts at most ϵ-fraction of the bits of the simulated protocol $\Pi'_{\mathcal{A}}$ (which is the protocol Π' executed with the adversary $\mathcal{A}$), and "fully" corrupts at most ϵ'-fraction of the messages of $\Pi'_{\mathcal{A}}$, where $\mathcal{A}$ "fully" corrupt a message if he corrupts at least α^2-fraction of the bits of the message, we have the following guarantees.*

1. $\mathrm{CC}(\Pi'_{\mathcal{A}}) \geq t_{\min}$.
2. $\Pr\left[\mathrm{CC}(\Pi'_{\mathcal{A}}) > (1+\alpha)\mathrm{CC}(\Pi)\right] = \exp\left(-\mathrm{CC}(\Pi'_{\mathcal{A}})\right)$.
3. $\Pr\left[R(\Pi'_{\mathcal{A}}) > (1+\alpha')R(\Pi) + \alpha' \log \mathrm{CC}(\Pi)\right] = \exp\left(-R(\Pi'_{\mathcal{A}})\right)$.
4. $\Pr\left[(\mathsf{Output}(\Pi'_{\mathcal{A}}) \neq \mathsf{Trans}(\Pi))\right] = \exp\left(-\mathrm{CC}(\Pi'_{\mathcal{A}})\right)$.

Moreover, we can choose the parameter α, α' such that $\alpha = \tilde{O}(\epsilon^{1/4})$ and $\alpha' = O(1)$, or we can choose α, α' such that α and α' approach 0 as ϵ approaches 0.

The purpose of $t_{\min}$. In the theorem above, without adding the restriction that $CC(S^A, S^B) \geq t_{\min}$, the simulated protocol could have aborted as soon as more than ϵ-fraction of error was detected. In particular, if the first bit was noticeably corrupted, then the parties in

[6] Braverman [5] showed how to improve the parties' runtime to be sub-exponential in T.

the simulated protocol could have safely aborted. Thus, without adding the restriction that $CC(S^A, S^B) \geq t_{\min}$, this theorem does not even generalize previous works, which all assume an a priori fixed transcript size t and assume the adversary makes at most ϵt corruptions. Adding this restriction, gives the adversary an initial budget of $\epsilon t_{\min}$ corruption bits. Moreover, since the error probability is exponentially small in the actual transcript length, the requirement $CC(S^A, S^B) \geq t_{\min}$ guarantees a low error probability.

There was a long line of works that consider the case of unknown noise of

1.3 Related Works

This work is the first one that considers the blowup of round complexity in noisy setting. While techniques from other papers can be easily adapted encode protocols with arbitrarily round complexity this coding schemes will lead to large(and usually unbounded) increase in round complexity of the protocol. However there are many papers that considered models related to our model. We want to mention that in other papers consider an effect of message length(what mean also the round complexity) on the rate of the communication complexity of the coding one can see it non-explicitly in [24, 19] and more explicitly in [22]. In non-noisy setting there was a long line of works showing that reducing round complexity may cause an exponential gap in communication complexity.

The paper [1] considered a very adaptive models of the protocols where total communication is not known in advance. There was also a large line of works considering the case when to total amount of noisy in unknown see survey by Gelles [11] for more details.

1.4 Overview of Our Techniques

In this section we give a high-level overview of the main ideas behind our construction and our analysis. In this overview, we do not focus on getting "optimal" parameters, and focus on constructing an error-resilient scheme that blows up the round and communication complexity by a constant factor. We note that all the conceptual ideas in this work are needed even to achieve constant overhead.

We start with an arbitrary protocol Π.

Smoothness. We first convert Π into a smooth protocol, with the property that after a message of length ℓ comes a message of length at most 2ℓ, and before a message of length ℓ comes a message of length at least $\ell/2$. We mention that in the actual protocol, to minimize the blowup in rounds and communication, we define (α, β)-smoothness, where α and β are functions of the error rate ϵ, and the guarantee is that after a message of length ℓ comes a message of length at least $\alpha\ell$ and at most $\frac{\ell}{\beta}$, and we show how to convert any protocol Π into an (α, β)-smooth protocol.

As mentioned above, the reason we need to smoothen Π is that otherwise, if after receiving a short message a party sends a long message, then the adversary by corrupting the short message, can cause the long message to be wasted, thus effectively allowing him to corrupt the long message by only using the budget needed to corrupt the short message.

Intuitively, we smoothen Π by instructing a party who wishes to send a long message after receiving a short message, to do so "cautiously", by sending the long message over several rounds, each time increasing the message length by at most a factor of 2.

To ensure that this does not cause a blowup to the round complexity, we make sure that a party does not send a short message after receiving a long one. Otherwise, suppose Alice always sends long messages (each of length ℓ) and Bob always sends single bit messages. Then

by having Alice send her messages "cautiously", as explained above, the round complexity will blowup by a factor of $\log \ell$, which is too large. Instead, we instruct Bob to send longer messages, of length $\alpha\ell$, so that the adversary will need to invest enough budget to corrupt Bob's message; in particular, enough to allow Alice to send her length ℓ message safely.

We refer the reader to Section 3 for the formal definition of smoothness, and to Lemma 6 for how to convert a protocol into a smooth one.

From now on we assume the protocol Π is smooth, and show how to convert it into an error resilient one.

Message adversary. We first note that we can focus our attention only on adversaries, that rather than corrupting individual bits, corrupt messages, where the price of corrupting a message m is the maximum between the length of m and the length of the corrupted version of m. If the adversary chooses to corrupt a message m then he may corrupt it adversarially, and if the adversary chooses not to corrupt a message then he cannot make any changes to it.

The reason we can focus on such adversaries is that we can easily convert any protocol that is resilient to errors made by message adversaries into a protocol that is error resilient to any adversary by applying an error correcting code to each message, and hence if only a small fraction of a message is corrupted (smaller than the allowed error rate) then this corruption can be ignored, since it is immediately corrected by the error correcting code. We use the error correcting code of Guruswami and Li [18], that is resilient to insertion and deletions, and has a minimal blowup of $1 + \tilde{O}(\sqrt{\epsilon})$ to the message length.

Thus, from now on, throughout this section, we ignore the layer of error correcting code, and consider only message adversaries.

1.4.1 The Protocol in the Ideal Hash Model

We first show how to convert any protocol Π into a protocol that is error resilient in the *Ideal Hash Model*. As in previous works (starting with the original work of [27]), our starting point is the idea of using hashing to check for consistency. Namely, in the protocol Alice and Bob check equality of their partial transcripts, by sending to each other hashes of their partial transcripts.

In the Ideal Hash Model, we assume the existence of an "ideal" hash function, that is known to all parties and does not need to be communicated, and in the analysis we assume that the number of hash collisions is bounded, yet adversarially chosen (where the cost for each hash collision is proportional to the length of the hash value). We later elaborate on how we remove this ideal model assumption, by implementing this ideal hash using a real hash function.

For the sake of simplicity, throughout this overview we think of the parties appending to each message they send a hash of their transcript so far. We mention however, that in the actual protocol, since we want to optimize the communication blowup, we append a hash only to "long enough" messages, i.e., messages of length at least d, for a carefully chosen parameter $d \in \mathbb{N}$. In particular, we do not append a hash to short messages, and instead add a hash in every round that divides d (to take care of the case where all the messages are short).

Each party, upon receiving a message, first checks the consistency of the corresponding hash with its current transcript. If an inconsistency occurs, the parties enter a *correction mode*.

Correction Mode. In correction mode, the parties realize that their transcripts are inconsistent, and they need to rewind their transcript to a point where they believe they are consistent, yet without backtracking too much. Note that once an error is detected, the parties cannot simply rewind their transcript one round at a time, since the adversary can cause them to completely get out of sync. Moreover, they cannot send each other the round number they are currently simulating, as was done in [2], since this will blowup the communication by too much. Instead, we adapt the idea of backtracking to a "meeting point", an idea that was originated in [27] and used in [19]. For the sake of completeness, we explain this idea below.

Once the parties realize they are not in sync, they enter a correction mode, and once in error mode, they send two hashes of their transcript: One hash of the entire transcript, and the other of the transcript up until the second largest round. If a consistency was found they go back to the point of consistency. Otherwise, they send two hashes of their transcript until the largest, and second largest, round which is a multiple of 2. Again, if a consistency was found they go back to the point of consistency. Otherwise, in the i'th try, they send two hashes of their transcript until the largest, and second largest, round which is a multiple of 2^{i-1}.

In order to avoid the situation where the adversary invests $O(1)$ corruptions, and causes a party to go back 2^i steps, and thus lose 2^i bits of a possibly good transcript, the parties go back 2^i steps only after receiving roughly 2^i confirmations. The confirmations cannot be in a single round, since then the adversary could corrupt a single round and cause the parties to go back (possibly) 2^i rounds. Thus, instead these confirmations should span roughly 2^i rounds, and each party keeps a counter of how many confirmations it has.

One important missing piece is that they can be out of sync with respect to which are the meeting points. Thus, we also append to the message a hash of E, which denotes the number of rounds the party is in the error mode, and this length determines where the meeting points should be (which is roughly the power of 2 closest to E).

In previous works, once the parties backtrack, they erase the (seemingly) inconsistent transcript and continue to simulate the actual protocol. One important point where our protocol differs from all previous work, is that in our protocol the parties cannot afford to erase their (seemingly) inconsistent transcripts. This is due to the fact that the messages in the (seemingly) inconsistent part may be very long. For example, consider the case where the last message added to the transcript is of length 1, the one prior is of length 2, the one prior is of length 4, then length 8, and so on. Suppose no errors occurred and everything is consistent. The adversary can corrupt the hash appended to the short (1 bit) message, making the parties believe that their transcripts are inconsistent. The parties will backtrack, but the adversary will continue to make them believe that they are inconsistent, so that they erase i messages. This means erasing 2^i bits of communication, which is way more than the parties can afford to erase. Therefore, in our protocol, rather than erasing the (seemingly) inconsistent transcript, we keep it as questionable, and enter what we call a *verification mode*.

Verification Mode. In the verification mode, the parties simply test whether their questionable messages are consistent. They do this round-by-round, by sending a hash of the messages corresponding to each round. If their hashes agree, they mark the round as valid, and continue to the next round. If they arrive to a round where their messages do not agree, they don't immediately erase all the questionable transcript. Rather, they erase it only after they are "sufficiently" confident that they are inconsistent. To this end, they

send longer and longer hashes until the number of bits of hash are proportional to the (seemingly) inconsistent transcript, and if the inconsistency persists then the parties erase their questionable transcript, and continue to simulate the underlying protocol.

This protocol is formally presented in Section 4, and the formal analysis in the Ideal Hash Model can be found in Section 4.2 and proof will appear in full version.

1.4.2 Our Protocol in the Shared Randomness Model

We next show how to implement the ideal hash functions with a specific hash function. To this end, we construct a function family $\mathcal{H} = \{h_x\}$, where each hash function h_x is associated with a (possibly long) seed x.

We consider the *shared randomness model*, where the parties are allowed to share a (possibly long) random string. We later show how to eliminate the need for shared randomness. But for now, we assume that the shared randomness is as long as we need. In particular, we use a different hash function (i.e, a different seed) for each equality test, and assume that the shared random string contains all these seeds. Since the length of the protocol is adaptive and not a priori bounded, the length of the common random string is also not a priori bounded.[7]

We emphasize that the shared randomness (and in particular the seeds) are known to the adversary. Therefore the adversary, given a seed x, can try to skew the protocol and cause the parties to send many messages whose hashes collide.

Note that the adversary has $\binom{t}{\epsilon t} = 2^{\tilde{O}(\epsilon)t}$ different ways to corrupt the t bits of the communication. Thus, he can cause hash collisions in approximately $\tilde{O}(\epsilon)t$ bits. If we append each message of size ℓ with $O(\ell)$ bits of hash, the adversary will be able to cause hash collisions in messages with total volume of $\tilde{O}(\epsilon)t$, which is within the allowed error range. Indeed, our main challenge is to bound the number of *rounds* with hash collisions, a challenge that previous works did not need to deal with since in their setting, communication complexity and round complexity are equivalent.

If we a priori knew the length of the transcript t and the number of rounds R, then we could add $U = \frac{t}{R}$ bits of hash to each message, and since the adversary can cause only $\tilde{O}(\epsilon)t$ bits of hash collisions, the number of rounds in which the adversary can cause a hash collision, is bounded by $\tilde{O}(\epsilon)R$, which is again within our allowed error range.

Since we don't have such a bound, it is tempting to append to each message sent in round r a hash of length $U_r = \frac{t_r}{r}$, where t_r is the communication up to the round r. But the following example shows that such a padding does not suffice, and the adversary can still force too many rounds with hash collisions.

Consider a protocol that consists of $\tilde{O}(1/\epsilon)$ chunks such that chunk 0 consists of k single bit messages, and each chunk $i \neq 0$ consists of a single (long) message of length $2^i k$, followed by $\tilde{O}(\epsilon)k$ single bit messages. Note that in this case, the total number of hash bits in chunk i is $\approx 2^i$, and thus an adversary that corrupts the long message of this chunk can cause hash collisions in all the rounds of the chunk, resulting with a total of $O(R)$ rounds with hash collisions.[8]

[7] We later show how we convert any such protocol in the *unbounded* shared randomness model into one that uses only private randomness.

[8] to be more precise, we need a long enough message at the end of the protocol to give the adversary enough budget to corrupt all of the long messages.

To overcome this issue, the idea is to partition the protocol to chunks (which we call regimes), and append to each message a hash of length that is proportional to the average length of a message in the chunk. To be precise, we append to each message a hash of length $U_r = \max_{r'<r} \frac{t_r - t_{r'}}{r - r'}$. Unfortunately, in this case the total amount of hash bits being added can be as large as $t \log t$, which we cannot afford.

To overcome this issue, in each round, instead of sending all the U_r bits of hash, we send only a hash of these bits, where the seed of this (outer) hash is chosen using private randomness. Specifically, rather than sending $H_x(T)$ (which consists of U_r bits), the party chooses a random seed S, and sends $H_S(H_x(T))$, together with S. This reduces the number of bits being communicated from U_r to $\log U_r$. Since the adversary does not a priori know the private randomness chosen by the parties, he cannot corrupt the history to cause a hash collision in H_S in too many rounds. Moreover, since we saw that he cannot cause hash collisions in $H_x(T)$ in too many rounds, these hash functions are "safe". We note that a similar idea of using a randomized hash function was used by Haeupler [19], for the sake of improving the rate of his interactive coding scheme. We refer the reader to Section 5 formal description of the hash function.

Finally, to conclude the analysis, we need to show that adding these (randomized) hash functions does not blow up the communication by too much. More precisely, one needs to show that $\sum_r \log U_r = O(t)$. This analysis is extremely delicate and requires several new ideas.

1.4.3 The Protocol in the Private Randomness Model

Finally, we show how to remove the need for shared randomness, while using only the private randomness of the parties. Namely, we show how to convert any protocol Π in the shared random string model, to one that uses only private randomness.

The basic idea is to follow the approach used in previous works (such as [2, 19]), and replace the long shared randomness with $2^{-O(T)}$-biased randomness, where T is an upper bound on the communication complexity. Such $2^{-O(T)}$-biased randomness can be generated using only $O(T)$ random bits. So, the basic idea is to send these $O(T)$ bits of randomness in advance, using an error correcting code. If we indeed had a bound T on the communication complexity, then this idea would work, and we would be done.

However, in our setting, we do not have an a priori bound on the communication complexity. In particular, if the communication complexity exceeds $O(T)$, then the adversary has the budget to corrupt more than $O(T)$ bits, and hence can completely corrupt the randomness s. We overcome this problem by sending more (and "safer") randomness as the communication complexity increases.

The protocol starts when one of the paries, say Alice, samples the shared random string $s_1 \in \{0,1\}^{O(t_{\min})}$ on her own (using her private randomness), and sends it to Bob. Then the parties execute Π with s_1 as the shared randomness. Once the communication complexity exceeds $O(t_{\min}/\epsilon)$, where ϵ is the corruption rate of the adversary, the random string s_1 is no longer "safe", and the the parties exchange a new random string s_2 of length $O(t_1)$, where t_1 is the current communication complexity. In addition to sending the new random string s_2 the parties also resend the previous random string s_1. The reason for resending previous seeds is that by resending the seeds the goal is to ensure that if one of the seeds was ever corrupted then the parties will "catch" the adversary, since the adversary does not have enough budget to continue to corrupt that seed, and the first time that he does not corrupt it, the parties will notice the inconsistency and abort, with the guarantee that the adversary performed too many errors.

In a similar way, after the communication complexity exceed $t_2 = O(t_1/\epsilon)$ a party will choose at random s_3 such that $|s_1| + |s_2| + |s_3| = t_2$, and will send (s_1, s_2, s_3), where t_2 is the current communication complexity, etc. As mentioned above, we ensure that if at any point, a message encoding randomness was decoded incorrectly, then eventually the paries will abort, and "catch" the adversary with injecting too many errors. This guarantee simplifies the analysis: Either at some point a randomness message was decoded incorrectly, in which case the adversary is "caught" with injecting too many errors, or all the parties always agree on the randomness, in which case correctness follows from the correctness of the underlying protocol in the shared randomness model.

A minor problem with the above idea is the following: a randomness message (s_1, s_2) may have been corrupted and converted into a protocol message, and a few rounds later a protocol message could have been corrupted and converted into the same randomness (s_1, s_2). To ensure that the parties will notice such corruption, we add to the randomness also the rounds $r_1, \ldots, r_k$ in which randomness were sent.

However, there is still a problem with the above idea, which is that in the early stage of the protocol, the shared random string has relatively large bias since it is generated using a short seed, and yet the adversary may have the budget to corrupt many bits, since the total communication may be large. It can be shown that such a powerful adversary can make too many hash collisions in the first part of the protocol.

To overcome this problem, we "enforce" that the adversary corrupts at most $O(\epsilon)$ fraction of any prefix of the protocol. To do so, in each time t_i, in addition to sending $(s_1, ..., s_{i+1})$ (together with $(r_1, \ldots, r_i)$), the parties send the transcript they have seen so far. If the parties detect that the adversary made significantly more than the allowed ϵ fraction of error, they abort, causing him to fail by exceeding his allotted corruption budget.

The formal protocol is described in Section 6.

2 Our Results

In this section we present our main theorem, and give an intuitive argument for why our parameters seem to be optimal. We start by introducing notations and definitions that we use in our theorem, and throughout the manuscript.

2.1 Notations and Definitions

For any 2-party protocol $\Pi = (A, B)$, we denote by $\mathsf{Trans}(\Pi)$ the transcript of Π, which consists of all the messages exchanged throughout an execution of the protocol Π. We denote by $\mathsf{Output}(\Pi)$ the output of the parties after executing Π. We think of the protocol Π as being a deterministic protocol with no inputs. This is without loss of generality since we can always hard-wire the randomness and input into the protocol. We denote by $\mathrm{CC}(\Pi)$ the communication complexity of Π, and we denote by $R(\Pi)$ its communication complexity.

We consider simulators for simulating an interactive protocols. A simulator is a probabilistic oracle machine, that uses a protocol $\Pi = (A, B)$ as an oracle, and produces a new protocol $\Pi' = (S^A, S^B)$ that outputs the transcript of Π (even in the presence of error). For any adversary $\mathcal{A}$ we denote by $\Pi'_{\mathcal{A}}$ the protocol Π' executed with the adversary $\mathcal{A}$.

▶ **Definition 2.** *We say that an adversary $\mathcal{A}$ corrupts at most ϵ-fraction of the bits of a protocol Π' if the number of corruptions made by $\mathcal{A}$ is at most $\epsilon \mathrm{CC}(\Pi'_{\mathcal{A}})$, where each corruption is either a toggle, an insertion or a deletion. The adversary $\mathcal{A}$ can be computationally unbounded, and its corruptions may depend arbitrarily on states of both parties in Π'.*

▶ **Definition 3.** *We say that a message is γ-corrupted if the adversary corrupts at least γ-fraction of the bits of the message.*

We say that $f(x) = \tilde{O}(g(x))$ if there exists a $c \in \mathbb{N}$ such that $f(x) = O\left(g(x)\log^c\left(g(x)\right)\right)$ and we say that $f(x) = \tilde{\Omega}(g(x))$ if there exists $c \in \mathbb{N}$ such that $f(x) = \Omega\left(g(x)\log^{-c}\left(g(x)\right)\right)$.

2.2 Our Main Theorem

▶ **Theorem 4.** *There exists a universal constant $\alpha_0 \geq 0$ such that for any blowup parameters $\alpha \leq \alpha_0$ and $\alpha' \leq 1$, there exist parameters $\epsilon = \tilde{\Omega}\left(\alpha^{3+\frac{1}{\alpha'}}\right)$, $\epsilon' = \tilde{\Omega}(\alpha{\alpha'}^3)$, and $\delta = \alpha^{O(1/\alpha')}$, and there exists a probabilistic oracle machine S, such that for any protocol $\Pi = (A, B)$, in which the parties always transmit at least $t_{\min}$ bits (even in the presence of error), and for any adversary $\mathcal{A}$ that corrupts at most ϵ-fraction of the bits of the simulated protocol $\Pi'_{\mathcal{A}}$, the protocol $\Pi'_{\mathcal{A}}$ (which is the protocol Π' executed with the adversary $\mathcal{A}$), satisfies the following properties.*

1. $\mathrm{CC}(\Pi'_{\mathcal{A}}) \geq t_{\min}$.
2. *There exists $t_0 = (1 + \tilde{O}(\alpha))\mathrm{CC}(A, B)$ such that for all $t > t_0$*

$$\Pr[\mathrm{CC}(\Pi'_{\mathcal{A}}) > t] \leq 2 \cdot 2^{-\delta t} ,$$

where the probability over the private randomness of S.

3. *There exists $r_0 = (1 + O(\alpha'))\, R(A, B) + O\left(\frac{1}{\log\frac{2}{\alpha'}}\log \mathrm{CC}(A, B) + 1\right)$ such that for any $r \geq r_0$, if at most ϵ'-fraction of the messages are α^2-corrupted, then*

$$\Pr\left[R(\Pi'_{\mathcal{A}}) > r\right] \leq 2 \cdot 2^{-\delta r} ,$$

where the probability over the private randomness of S.

4. *For any $t > 0$,*

$$\Pr\left[(\mathsf{Output}(\Pi'_{\mathcal{A}}) \neq \mathsf{Trans}(\Pi)) \ \wedge \ (\mathrm{CC}(\Pi'_{\mathcal{A}}) > t)\right] \leq 2 \cdot 2^{-\delta t} ,$$

where the probability over the private randomness of S.

5. *S is a probabilistic polynomial time oracle machine, and hence the computational efficiency of S^A and S^B is comparable to that of A and B, respectively.*

In Section 2.3 below, we give an intuitive argument for why our parameters seem to be optimal. Then, the rest of the manuscript is devoted to proving Theorem 4. Before, explaining our choice of parameters, in what follows, we give a high-level overview of the structure of the proof of Theorem 4.

Road Map. We first convert $\Pi = (A, B)$ into a smooth protocol Π_{smooth}. We show how this can be done in Section 3. Then, in Section 4, we show how to convert any smooth protocol Π_{smooth} into a protocol Π_{ideal}, which is error-resilient in the ideal hash model. In this model, we assume that the adversary is a "message adversary", which means that if he corrupts even a single bit of a message the price he pays for such a corruption is the length of the entire message (more precisely, the maximum between the length of the original message and the length of the corrupted version of it). Moreover, we assume that the number of hash collisions is bounded and adversarially chosen. We refer the reader to Section 4 for details.

In Section 5, we show how to convert Π_{ideal} into a protocol Π_{rand_1}, which is error resilient in the common random string model, assuming the adversary is a "message adversary". Loosely speaking, this is done by instantiating the ideal hash using public (and private)

randomness. In Section 6, we show how to instantiate the common random string using private randomness, to obtain a protocol Π_{rand_2} that is error resilient against any "message adversary". Finally, we convert Π_{rand_2} into $\Pi' = (S^A, S^B)$, where Π' is the same as Π_{rand_2}, except that each message is sent encoded with the error correcting code that is resilient to insertions and deletions. In Section 7, we "put it all together" and prove that Π' is the error resilient protocol guaranteed in Theorem 4 above.

2.3 Intuition Behind our Parameters

In what follows, we give an intuitive argument for why our parameters seem to be optimal. We emphasize that this is by no means a proof of optimality, but rather an intuition for where these parameters came from.

As mentioned above, since messages can be of arbitrary length, and since we do not want to blow up the round complexity by much, we must use an error-correcting code that is resilient to (adversarial) insertions and deletions. To date, the maximal rate error-correcting code that is resilient to (adversarial) insertions and deletions is due to Guruswami and Li [18]. This code blows up the message length by $1 + \tilde{O}(\sqrt{\epsilon})$ and is resilient to ϵ fraction of errors.

Moreover, as argued in Section 1.4, in order to ensure a small blowup in communication our error-resilient protocol must be relatively "smooth". In other words, in the error-resilient protocol, after a message of length ℓ we should not send a message much longer than ℓ, since then the adversary will corrupt the length ℓ message and as a result will cause the next long message to be obsolete. Suppose for simplicity (for now) that all the messages are all of the same length ℓ.

Suppose our protocol has blowup $1 + \tilde{O}(\alpha)$ in communication complexity. Thus, we can use the error-correcting code of [18] that blows up the message length by at most $(1 + \tilde{O}(\alpha))$. This code is resilient to α^2 fraction of errors. Thus, by corrupting $\alpha^2\ell$ bits of a message the adversary can make the next round completely obsolete. Since the adversary can corrupt ϵ-fraction of the bits, he can make $\frac{\epsilon}{\alpha^2}$-fraction of the rounds obsolete, which implies that it must be the case that $\frac{\epsilon}{\alpha^2} \leq \alpha$, which in turn implies that $\alpha > \epsilon^{1/3}$.

Note, however, that we cannot assume that all the messages are of the same length since this will blow up the round complexity by too much. And yet, as mentioned above, we do need to assume that the error-resilient protocol is somewhat "smooth", since otherwise the communication complexity will blow up by too much. Thus, we let $\beta > 0$ be a parameter, such that in the error-resilient protocol after a message of length ℓ comes a message of length at most $\beta^{-1}\ell$. Now, an adversary corrupting $\tilde{O}(\alpha^2 \cdot \ell)$ bits of a message can cause $\beta^{-1}\ell$ bits to be obsolete. Thus, intuitively, the parties may waste $\alpha^{-2} \cdot \beta^{-1}$ bits of communication per each corruption. This, together with the fact that the adversary has an ϵ-fraction of corruption budget and the fact that the communication blows up by at most $1 + \tilde{O}(\alpha)$, implies that $\alpha^{-2} \cdot \beta^{-1} \cdot \epsilon < \alpha$, which in turn implies that

$$\alpha^3 \cdot \beta > \epsilon. \tag{1}$$

Therefore, on the one hand we would like to make β as large as possible, to improve the communication rate; on the other hand, increasing β blows up the round complexity. At first it seems that requiring this smoothing condition (i.e., that after a message of length ℓ comes a message of length at most $\beta^{-1}\ell$), will blow up the round complexity by too much. The reason is the following: Consider the real world example, where each message sent by Alice is of length ℓ, and each message sent by Bob is of length 1. Thus, to ensure that Alice is not wasting ℓ bits of communication due to a single error in Bob's message, we need to

make the protocol smooth and have Alice send her message slowly, first sending the first β^{-1} bits, then after getting a bit of approval from Bob, Alice will send the next β^{-2} bits of her message, and so on. Thus, the number of rounds it will take Alice to send her message is roughly $\log_{\frac{1}{\beta}}(\ell)$. This will cause a blowup of roughly $\log_{\frac{1}{\beta}}(\ell)$ to the round complexity, which is way too much.

To avoid this blowup, we want to make sure that after a long message does not come a message which is too short, since short messages may cause a blowup to the round complexity (if the following message is long). However, this should be done while adding at most an α fraction to the communication complexity. Thus, we also smooth the protocol in the "other direction" and require that after a message of length ℓ comes a message of length at least $\alpha\ell$. Thus, going back to our example above, where Alice is talkative (sends messages of length ℓ) and where Bob sends messages of length 1, we first convert this to another protocol where Bob sends messages of length $\alpha\ell$. This does not change the round complexity at all, and changes the communication complexity by at most an α-factor. Now, we smoothen out this protocol, by having Alice, rather than sending her ℓ bit message in "one shot", she will first send $\beta^{-1}\alpha\ell$ bits, then send the next $\beta^{-2}\alpha\ell$ bits, and so on. Note that this will cause a blowup of $\log_{\frac{1}{\beta}}(\alpha^{-1})$ in the round complexity. Since we allow a blowup of at most α' to the round complexity (without taking into account the blowup due to error, or the additive term), we take β so that $\log_{\frac{1}{\beta}}(\alpha^{-1}) \leq \alpha'$, and thus we must take β such that $\beta \leq \alpha^{1/\alpha'}$. This together with Equation (1), implies that

$$\alpha^{3+1/\alpha'} > \epsilon,$$

as in Theorem 4 above.

It remains to explain the additive term in the round blowup and the multiplicative term that depends on the round error-rate ϵ'. For the latter, clearly, if ϵ'-fraction of the rounds were completely corrupted, these rounds need to be redone, and this incurs a blowup of $1+\epsilon'$ to the round complexity. As to the former, suppose the original protocol consists of a short message followed by a very long message, to make this protocol error resilient we will have to blow up the round complexity by essentially $\log_{\frac{1}{\beta}} \mathrm{CC}$, where CC is the communication complexity of the original protocol. This is the reason we have the log additive term in the round complexity.

Finally, we explain why $\epsilon' = \alpha \cdot \mathsf{poly}(\alpha')$. We note that for the purpose of our application (Theorem 1) the exact power of α' is not important. Consider a protocol that consists of a single bit per round. In this case we can effort to add a hash check only every α^{-1} rounds. In this case, the adversary can corrupt the first message of each chunk of α^{-1} rounds, which would render the entire chunk useless. Thus, a corruption of ϵ'-fraction of the rounds, may result with a round blowup of $\epsilon'\alpha^{-1} \leq \alpha'$, which implies that indeed $\epsilon' \leq \alpha\alpha'$.

3 Smooth Protocols

Throughout this section, we refer to "rounds" in a protocol as a one way communication. Namely, the number of rounds in a protocol is equal to the number of messages that are sent in the protocol. We note that in Section 4 we diverge from this interpretation, and refer to "rounds" as a back-and-forth communication between Alice and Bob. This inconsistency allows us to simplify the notation and the presentation. Note that these two interpretations can be interchanged, while incurring a blowup of at most 2 in the round complexity.

Let Π be an arbitrary 2-party protocol. We denote by m_r the messages sent in the r^{th} round in Π. In this section we show how to convert any protocol Π into a *smooth* protocol S^{Π}. In what follows we denote by M_r the message sent in the r^{th} round in S^{Π}.

▶ **Definition 5.** *A protocol is (α, β)-smooth if for every round r the following holds:*

$$\alpha \cdot \max\{|M_{r-1}|, |M_{r-2}|, |M_{r-3}|\} \leq |M_r| \leq \frac{1}{\beta} \cdot \min\{|M_{r-1}|, |M_{r-2}|, |M_{r-3}|\} \quad (2)$$

▶ **Lemma 6.** *For any $\alpha < \frac{1}{4}$ and $\beta \leq \frac{\alpha}{8}$, the following holds: Any protocol Π can be efficiently converted into an (α, β)-smooth protocol S^{Π} such that*

1. $\mathrm{CC}(S^{\Pi}) \leq \mathrm{CC}(\Pi) \cdot (1 + 50\alpha)$.
2. $R(S^{\Pi}) \leq R(\Pi) \cdot (1 + 8\log_{2\beta} \alpha) + 4\log_{\frac{1}{2\beta}} \cdot \mathrm{CC}(\Pi) + 4$
3. *If Π is computationally efficient then so is S^{Π}.*

We defer the proof of Lemma 6 to full version.

▶ Remark 7. In Sections 4, 5, and 6, we show how to convert a smooth protocol into an error-resilient one. Similarly to previous error-resilient protocols in the literature, we will first pad the smooth protocol, and only then we convert the padded protocol into an error-resilient one. However, we will need to pad our protocol in a smooth way. This is done as follows: Suppose we want to pad our protocol with anywhere between L and $2L$ bits of 0's. Suppose that the last message in the smooth protocol is of length ℓ, then we add a message of length $\left\lfloor \frac{\ell}{\beta} \right\rfloor$, followed by a message of length $\left\lfloor \frac{\ell}{\beta^2} \right\rfloor$, and so on, until we add between βL and L bits, after which we add L bits (if we haven't added so already).

Note that such a padding results in a smooth protocol, where the communication complexity increases by at least L and at most $2L$ bits. The number of additional rounds required to do this padding is at most $\log_{\frac{1}{\beta}} L + 1$.

From now on, when we say that we convert a protocol Π to a smooth protocol, we assume that the resulting smooth protocol is padded appropriately.

4 Interactive Coding in the Ideal Hash Model

In this section, we show how to convert any protocol Π into an error resilient protocol, and analyze its properties in the **Ideal Hash Model**. This model assumes the existence of an ideal hash. In our protocol, Alice and Bob check equality of their partial transcripts, by sending to each other hashes of their partial transcripts. In this section, we consider the Ideal Hash Model, where when we analyze the communication complexity of the protocol we do not take into account the length of the hash values, and simply assume that the number of hash collisions is bounded, yet adversarially chosen. (We explain how we bound the number of collisions below). In Sections 5 and 6, we show how to remove this ideal model assumption, by implementing this ideal hash using a real hash function. In these sections, we use hash values that are short enough so the communication blowup is small, and yet we prove that with high probability the amount of hash collisions is bounded.

Moreover, we consider an adversary that either leaves a message (and corresponding hash) intact, or "fully" corrupts it. More precisely, we say that the hash is corrupted if and only if a collision occurs. In the analysis of this ideal error-resilient protocol, we say that a message is corrupted if the adversary corrupts any bit of the message (or if he corrupts the corresponding hash). We let the budget of corrupting a message be the maximum between the original message length, and the corrupted one. In particular, even if the adversary corrupted a single bit of a long message of length n (or if he corrupts only the hash corresponding to this message), we count it as n corruptions. We recall that the reason for this budgeting is that in our actual error-resilient protocol we will apply the error correcting code of Guruswami and Li [18] to each message (and hash) separately. Thus, in order to corrupt a message, the adversary will need to corrupt a constant fraction of the bits in the message. We refer the reader to Section 7 for details.

In what follows, we set

$$\alpha \leq 0.01 \ \ , \ \ \alpha' \leq 1 \ , \ \ d \geq \frac{1}{\alpha} \ \text{ and } \ \beta \leq \min\left\{\alpha^{\frac{1}{\alpha'}}, \frac{1}{5\alpha d^2}\right\}. \tag{3}$$

We assume for simplicity that α^{-1} and β^{-1} are integers. We assume without loss of generality, that the underlying protocol Π is (α, β)-smooth. This is without loss of generality since by Lemma 6, we can convert Π to an (α, β)-smooth protocol while increasing its communication complexity by a multiplicative factor of $(1 + O(\alpha))$, and increase the number of rounds by a multiplicative factor of $(1+O(\alpha'))$ and an additive factor of at most $\log \mathrm{CC}(\Pi)$, as desired.

4.1 The Protocol

We note that this (ideal) protocol is quite similar to the error-resilient protocol of Haeupler [19]. The main difference being that we need to first convert the protocol into a smooth one (whereas the protocol considered in [19] is perfectly smooth since in each round each party sends a single bit to the other party). Moreover, and more importantly, since our protocol is not perfectly smooth, when the parties backtrack, they do not erase the questionable transcript (since the messages in the questionable part may grow exponentially). Instead, the parties keep this transcript as questionable, and enter a "verification" state where they check consistency round-by-round. We note that in [19] the questionable transcript is simply erased.

In what follows, we present the (error-resilient) protocol only from Alice's perspective. Bob's perspective is symmetric. During the (error-resilient) protocol, Alice has a private variable T_A, which she believes to be a prefix of the transcript she is trying to reconstruct. T_A is initiated to $\emptyset$. We denote by m_A the message that Alice sends in the error resilient protocol.

In what follows, we define all the other notations (in addition to m_A and T_A) that are used in the protocol description:

$$S_A, R_A, \ell_A, \ell^+, \ell^-, w_A, R_A^{(1)}, R_A^{(2)},$$

where all of these variables are defined as functions of T_A and m_A.

From now on we think of each round as consisting of consecutive two messages: a message sent by Alice and a following message sent by Bob. We note that this diverges from the way we defined rounds in Section 3, where we thought of each round as containing a single message (sent by one party). The only reason for this inconsistency is that it is more convenient in terms of notations. It is important to note that this is only a notational convenience and does not affect our final result in any way.

For each variable used in our protocol

$$v_A \in \{T_A, m_A, S_A, R_A, \ell_A, \ell^+, \ell^-, w_A, R_A^{(1)}, R_A^{(2)}\},$$

we denote by $v_{A,r}$ the value of v_A that Alice uses when sending her round r message, and we occasionally omit r when it is clear from the context.

- During the protocol Alice has a state

  $$S_A \in \{\text{Simulation}, \text{Verification}\} \cup \mathbb{N}.$$

  Loosely speaking, Alice is in a Simulation state when she believes that the transcript T_A that she is holding is indeed a prefix of the correct transcript.

If $S_A \in \mathbb{N}$ then we say that Alice is in a Correction state. If Alice is in Correction state, then S_A is the first round (in the error-resilient protocol) that Alice has entered this state. Alice enters a Correction state when she thinks her beliefs are wrong (for example, when the hashes indicate that T_A and T_B are inconsistent). During this state, Alice tries to go back to an earlier round in the transcript (corresponding to the original protocol) which she believes to be correct. We denote this round by R_A. Alice will continue the simulation from $T_A[R_A]$, which denotes the truncated transcript of T_A to round R_A. As mentioned above, as opposed to the protocol of Haeupler [19], in our protocol, she does not delete the suffix of T_A, and rather she keeps this suffix as questionable. The reason she does not erase this questionable suffix, is that it may be the correct suffix (and the only reason it is questioned is due to an error), and in this case it may be too expensive to delete and reconstruct, since in our case the messages in the questionable suffix may grow at an exponential rate.

After a Correction state, Alice enters either another Correction state or a Verification state, where she decides whether to completely delete, partially delete, or keep, the questionable suffix. After the Verification state (assuming there were no errors), Alice enters Simulation state again.

We define $r - S_A$ to be zero, when $S_A \in \{\text{Simulation}, \text{Verification}\}$.

- As mentioned above, R_A denotes the round in T_A that Alice simulates. If $S_A = \text{Simulation}$ then R_A is equal to the number of rounds in T_A.
- Let $m_{A,r}$ be the message that Alice sends in round r (of the error resilient protocol), and let $\ell_{A,r}$ denote its size. Let $m_{B,r}$ be the message that Alice received from Bob in round r, and let $\ell_{B,r}$ denote its size. We define $\ell_{\max,r} = \max\{\ell_{A,r}, \ell_{B,r}\}$. Note that if Bob's message was corrupted then $\ell_{B,r}$ may be arbitrarily large. However, our (error-resilient) protocol has the property that if Bob's message was not corrupted then $\ell_{B,r} \leq \frac{\ell_{A,r}}{\beta}$.
  We define

$$\ell_r^+ = \min\left\{\frac{\ell_{A,r}}{\beta}, 2\ell_{\max,r}\right\}$$

  and

$$\ell_r^- = \min\left\{\frac{\ell_{A,r}}{\beta}, \max\left\{\beta^{-1}, \alpha\ell_{\max,r}\right\}\right\}.$$

- Let $w_{A,r}$ be $2^{\lfloor \log(r-S_A)\rfloor}$ if $S_{A,r} \in \mathbb{N}$, and let $w_{A,r}$ be 0 otherwise. In other words, $w_{A,r}$ is the number of rounds that the party has been in Correction state, rounded to the closest power of two.
- If $w_A = 0$ then let $R_A^{(1)} = R_A$. Otherwise, let $R_A^{(1)} < R_A$ be maximal that divided w_A.
- $R_A^{(2)} \triangleq R_A^{(1)} - w_A$.
- In the protocol, at each round r, Alice sends hashes to Bob if and only if $r = 0 \pmod d$ or $\ell_{A,r} \geq d$, in which case she sends five hashes, one hash corresponding to each of the following strings:

$$\left(T_A[R_A], T_A[R_A+1], T_A[R_A^{(1)}], T_A[R_A^{(2)}], S_A\right).$$

  We note that if R_A is equal to the number of rounds in T_A, then Alice will not know the partial transcript $T_A[R_A+1]$. In this case we define $T_A[R_A+1] = T_A[R]$.

Alice in round r. Upon receiving a message from Bob, parse the message as

$$(m_{B,r-1}, H(T_{B,r-1}[R_{B,r-1}]), H(T_{B,r-1}[R_{B,r-1}+1]),$$
$$H(T_{B,r-1}[R^{(1)}_{B,r-1}]), H(T_{B,r-1}[R^{(2)}_{B,r-1}]), H(S_{B,r-1})).$$

We assume that in this ideal model, parsing is easy. When we implement this ideal hash function in Section 5, we will make sure that indeed Alice will be able to parse correctly (assuming the message was not corrupted). Denote the size of $m_{B,r-1}$ by $\ell_{B,r-1}$.

1. If $S_{A,r-1} =$ Simulation then do the following:

   a. If a hash was sent by Bob (i.e., if $\ell_{B,r-1} \geq d$ or d divides $r-1$) then check that

   $$H(S_{B,r-1}) = \text{Simulation} \quad \text{and} \quad H(T_{A,r-1}[R_{A,r-1}]) = H(T_{B,r-1}[R_{B,r-1}]).$$

   b. Check that the (partial) transcript $(T_{A,r-1}[R_{A,r-1}], m_{A,r-1}, m_{B,r-1})$ satisfies the (α, β)-smoothness condition.
   c. If one of these conditions does not hold then let
      - $m_{A,r} = 0^{\ell^-_{r-1}}$
      - $S_{A,r} = r$
      - $(T_{A,r}, R_{A,r}) = (T_{A,r-1}, R_{A,r-1})$.
   d. Else, set
      - $T_{A,r} = (T_{A,r-1}, m_{A,r-1}, m_{B,r-1})$
      - $R_{A,r} = R_{A,r-1} + 1$
      - $m_{A,r} = \Pi(T_{A,r})$
      - $S_{A,r} = S_{A,r-1} =$ Simulation.

2. If $S_{A,r-1} =$ Verification then check if all the following conditions hold:

   a. $|m_{B,r-1}| \geq \beta^{-1}$.
   b. $H(S_{A,r-1}) = H(S_{B,r-1})$
   c. $H(T_{A,r-1}[R_{A,r-1}]) = H(T_{B,r-1}[R_{B,r-1}])$.

   If one of these conditions does not hold then let
   - $m_{A,r} = 0^{\ell^-_{r-1}}$
   - $S_{A,r} = r$
   - $(T_{A,r}, R_{A,r}) = (T_{A,r-1}, R_{A,r-1})$.

   Else, do the following:

   a. If number of rounds in $T_{A,r-1}$ is greater than $R_{A,r-1}+1$, and

   $$H(T_{A,r-1}[R_{A,r-1}+1]) = H(T_{B,r-1}[R_{B,r-1}+1]),$$

   then let
   - $m_{A,r} = 0^{\ell^-_{r-1}}$
   - $R_{A,r} = R_{A,r-1} + 1$
   - $(S_{A,r}, T_{A,r}) = (S_{A,r-1}, T_{A,r-1})$.

   b. Else, if $m_{A,r-1} = m_{B,r-1} = 1^\ell$ for some $\ell > |T_{A,r-1}| - |T_{A,r-1}[R_{A,r-1}]|$, then set
   - $T_{A,r} = T_{A,r-1}[R_{A,r-1}]$
   - $R_{A,r}$ be the number of rounds in $T_{A,r}$
   - $m_{A,r} = \Pi(T_{A,r})$
   - $S_{A,r} =$ Simulation.

c. Else, if $\ell^+_{r-1} > |T_{A,r-1}| - |T_{A,r-1}[R_{A,r-1}]|$ then let
- $m_{A,r} = 1^{\ell^+_{r-1}}$
- $(T_{A,r}, R_{A,r}, S_{A,r}) = (T_{A,r-1}, R_{A,r-1}, S_{A,r-1})$.

d. Else, let
- $m_A = 0^{\ell^+_{r-1}}$
- $(T_{A,r}, R_{A,r}, S_{A,r}) = (T_{A,r-1}, R_{A,r-1}, S_{A,r-1})$.

3. Else, do the following:

a. Compute the values v^0_r, v^1_r, v^2_r as follows:
If $H(S_{A,r-1}) \neq H(S_{B,r-1})$ then set $v^0_r \leftarrow v^0_{r-1} + 1$.
Else, if $H(T_{A,r-1}[R^{(1)}_{A,r-1}]) \in \left\{H(T_{B,r-1}[R^{(1)}_{B,r-1}]), H(T_{B,r-1}[R^{(2)}_{B,r-1}])\right\}$ then set $v^1_r \leftarrow v^1_{r-1} + 1$.
Else, if $H(T_{A,r-1}[R^{(2)}_{A,r-1}]) \in \left\{H(T_{B,r-1}[R^{(1)}_{B,r-1}]), H(T_{B,r-1}[R^{(2)}_{B,r-1}])\right\}$ then set $v^2_r \leftarrow v^2_{r-1} + 1$.

b. If $r - S_{A,r-1}$ is not a power of 2,[9] then set
- $m_{A,r} = 0^{\ell^-_{r-1}}$
- $(T_{A,r}, R_{A,r}, S_{A,r}) = (T_{A,r-1}, R_{A,r-1}, S_{A,r-1})$.

c. Else, if $v^0_{r-1} > \frac{1}{2}(r - S_{A,r-1})$ then let
- $S_{A,r} = r$
- $m_{A,r} = 0^{\ell^-_{r-1}}$
- Set $v^0_r = v^1_r = v^2_r = 0$.

d. Else, if $v^1_r > \frac{1}{4}(r - S_{A,r-1})$ then let
- $S_{A,r} =$ Verification
- $R_{A,r} = R^{(1)}_{A,r-1}$
- $m_{A,r} = 0^{\ell^-_{r-1}}$
- Set $v^0_r = v^1_r = v^2_r = 0$.

e. Else, if $v^2_r > \frac{1}{4}(r - S_{A,r-1})$ then let
- $S_{A,r} =$ Verification
- $R_{A,r} = R^{(2)}_{A,r-1}$
- $m_{A,r} = 0^{\ell^-_{r-1}}$
- Set $v^0_r = v^1_r = v^2_r = 0$.

f. Else, set $v^1_r = v^2_r = 0$, and let
- $m_{A,r} = 0^{\ell^-_{r-1}}$
- $(v^0_r, R_{A,r}, S_{A,r}, T_{A,r}) = (v^0_{r-1}, R_{A,r-1}, S_{A,r-1}, T_{A,r-1})$.

Send $m_{A,r}$, and if $r = 0 (\text{mod } d)$ or $|m_{A,r}| \geq d$ then append to $m_{A,r}$ also

$$\left(H(T_{A,r}[R_{A,r}]), H(T_{A,r}[R_{A,r}+1]), H(T_{A,r}[R^{(1)}_{A,r}]), H(T_{A,r}[R^{(2)}_{A,r}]), H(S_{A,r})\right).$$

Remark. Bob behaves identically to Alice, except in Steps 1 and 2b, when Bob computes his next message corresponding to the underlying protocol Π, he computes it by $m_{B,r} = \Pi(T_{B,r}, m_{A,r})$, whereas recall that Alice computed it by $m_{A,r} = \Pi(T_{A,r})$.

[9] Recall that we define $r - S_A = 0$ if $S_A \in \{\text{Simulation}, \text{Verification}\}$, and we consider 0 to be power of 2.

4.2 Analysis

Terminology. In what follows, we introduce terminology that we use in the analysis.

We allow the adversary to create collisions in the ideal hash function, in which case we say that the hash was corrupted. We say that a message is corrupted if the adversary corrupts any bit of the message, or corrupts the associated hash. We define the budget of corrupting a message m to be the maximum between the length of m and the length of the corrupted version of m. Thus, even if the adversary corrupts a few bits of a long message of length n (or corrupts the associated hash), then we count it as n corruptions. On the other hand, if the adversary corrupted a single bit message by converting it into a long n-bit message, then we count it as n corruptions.

We analyze the correctness of the (error-resilient) protocol assuming a bound on these message corruptions.

▶ **Definition 8.** *We say that the corrupted messages have* volume e *if the sum of lengths of corrupted messages (where each such length is the maximum between the length of the original message and the length of the corrupted version of it) is e.*

Using this terminology we prove the following theorem.

▶ **Theorem 9.** *Let $\Pi = (A, B)$ be any (α, β)-smooth protocol, and let $\Pi' = (S^A, S^B)$ be the simulated protocol defined above. Let $\mathcal{A}$ be any adversary in Π', who corrupts at most e' messages of total volume of at most e. Then, the protocol Π', executed with the adversary $\mathcal{A}$, denoted by $\Pi'_{\mathcal{A}}$, satisfies the following.*

1. $CC(\Pi'_{\mathcal{A}}) \geq t_{\min}$*, where $t_{\min}$ is a lower bound of the communication of any instance of* Π.
2. $CC(\Pi'_{\mathcal{A}}) \leq CC(A, B) + 18\beta^{-1}e + 20d\beta^{-1}e'$.
3. $R(\Pi'_{\mathcal{A}}) \leq R(A, B) + 906d \log \frac{1}{\beta} e'$.
4. *The parties outputs transcripts of size at most* $\mathrm{CC}(\Pi'_{\mathcal{A}})$ *that agree with* Π *on the first*

$$CC(\Pi'_{\mathcal{A}}) - 18\beta^{-1}e - 20d\beta^{-1}e' \ ,$$

   many bits.
5. *S is a polynomial time oracle machine.*

▶ Remark 10. We will apply Theorem 9 with an adversary $\mathcal{A}$ that corrupts at most $e' = O(\min\{\epsilon' \cdot R(\Pi'_{\mathcal{A}}), \frac{\epsilon}{d} CC(\Pi'_{\mathcal{A}})\})$ messages of total volume at most $e = O(\epsilon \cdot CC(\Pi'_{\mathcal{A}}))$, where $\epsilon \leq O(\alpha \cdot \beta)$ and $\epsilon' \leq \frac{\alpha'}{d \cdot \log \beta^{-1}}$. Thus,

$$\begin{aligned}
&CC(\Pi'_{\mathcal{A}}) \leq \\
&CC(A, B) + 18\beta^{-1}e + 20d\beta^{-1}e' \leq \\
&CC(A, B) + 0(\beta^{-1}\epsilon \cdot CC(\Pi'_{\mathcal{A}})) + O\left(d\beta^{-1}\frac{\epsilon}{d} CC(\Pi'_{\mathcal{A}})\right) \leq \\
&CC(A, B)(1 + O(\alpha)),
\end{aligned}$$

and

$$\begin{aligned}
&R(\Pi'_{\mathcal{A}}) \leq \\
&R(A, B) + 906d \log \frac{1}{\beta} e' \leq \\
&R(A, B) + O(d \log \frac{1}{\beta} \epsilon' \cdot R(\Pi'_{\mathcal{A}})) \leq \\
&R(A, B)(1 + O(\alpha')),
\end{aligned}$$

as desired.

Moreover, we will apply this theorem with a protocol Π which is padded by $18\beta^{-1}e + 20d\beta^{-1}e' = O(\alpha \cdot CC(\Pi'_{\mathcal{A}}))$ zeros. Thus, Item 4 from Theorem 9 implies correctness.

For example, one can set $\alpha = O(\min\{\sqrt{\epsilon}, (\epsilon')^{1/3}\})$, and set $\beta = O(\alpha)$, $d = \frac{1}{\alpha}$, $\alpha' = 1$, to obtain an error resilient protocol in the ideal hash model with constant blowup in round complexity and $1 + O(\alpha)$ blowup in communication complexity.

We defer the proof of Theorem 9 to full version.

5 Hash Implementation with Shared Randomness

Recall that in Section 4, we presented an interactive coding scheme with the desired guarantees, in the ideal hash model, where we assume that the number of hash collisions is bounded, and where the budget for making a collision is proportional to the message length (where the message length is the maximum between the length of the message that was sent and the corrupted version of it). We denote this ideal protocol by Π.

In this section, we show how to implement the ideal hash with a real hash function. Loosely speaking, given a hash function h, we convert the protocol Π to the protocol Π^h which is identical to Π, where the ideal hash function is replaced by h. In order to maintain the desired efficiency and error-resilience guarantees, we need to ensure that, on the one hand, these hash values are not too long; and on the other hand there are not too many hash collisions (i.e., that these hashes form a good equality test). To ensure the latter condition holds, it is easy to see that we cannot use a single (deterministic) hash function. Instead we use a *family* of *randomized* hash functions.

We construct a function family $\mathcal{H} = \{h_x\}$, where each hash function h_x is associated with a (possibly long) seed x. In this section, we consider the *shared randomness model*, where the parties are allowed to share a (possibly long) random string. In Section 6 we show how to eliminate the need for shared randomness.

In this section we assume that the shared randomness is as long as we need. In particular, we use a different hash function (i.e, a different seed) for each equality query. Since the length of the protocol is adaptive and not a priori bounded[10], the length of the common random string is also not a priori bounded. We assume that there is a separate segment of the common random string for each round r, and each such segment contains five hash seeds, since in Π, in rounds that a party sends an ideal hash, the party sends five ideal hashes.

We emphasize that the shared randomness (and in particular the seeds) are known to the adversary. Therefore the adversary, given a seed x can try to skew the protocol and cause the parties to send many messages whose hashes collide. To get around this, we construct a hash family, where each h_x is a *randomized* hash function. When a party sends a hash of a value V, the party will choose randomness S and will send $(S, h_x(V, S))$. On the one hand, the randomness S needs to be short, since otherwise this will blowup the communication complexity by too much. On the other hand, the adversary cannot predict S, and thus will not be able to skew the messages of the parties towards ones which the hashes collide. We note that a similar idea of using a randomized hash function was used by Haeupler [19], for the sake of improving the rate of his interactive coding scheme.

Before presenting our randomized hash family, we start with some preliminaries.

[10] In Section 6, we convert any such protocol in the *unbounded* shared randomness model into one that uses only private randomness.

5.1 Preliminaries

Chernoff bounds.

▶ **Lemma 11.** *For any $N \in \mathbb{N}$, and any N independent Bernoulli random variables $X_1, \ldots, X_N$, each with mean $\leq \gamma$, it holds that*

$$\Pr[\sum_{i=1}^{N} X_i > 2\gamma N] \leq e^{-\frac{1}{3}\gamma N}.$$

▶ **Definition 12.** *A distribution D over $\mathbb{F}_2^n$ is* δ-bias *if for any $v \in \mathbb{F}_2^n \setminus \{0^n\}$, we have that*

$$\left| \Pr_{x \sim D} \left[\sum_{i=1}^{n} v_i x_i = 0 \right] - \frac{1}{2} \right| \leq \delta \ .$$

▶ **Lemma 13** ([25])**.** *There exists an absolute constant $C \in \mathbb{N}$ and an efficiently computable function $G : \{0,1\}^* \to \{0,1\}^*$ such that for any size k and a uniformly random string $S \in \{0,1\}^{Ck}$, we have that $G(S) \in \{0,1\}^{2^k}$ is a 2^{-k}-biased distribution of length 2^k.*

▶ **Lemma 14** (6.3 from [19])**.** *There exists a hash family $\mathcal{F} = \{\mathcal{F}_L\}_{L \in \mathbb{N}}$, such that for every $L \in \mathbb{N}$ it holds that $\mathcal{F}_L = \{f_x\}_{x \in \{0,1\}^{2L}}$, and for every $x \in \{0,1\}^{2L}$, $f_x : \{0,1\}^{\leq L} \to \{0,1\}$. Moreover, for any $k \in \mathbb{N}$ and for any vectors $V_1^A, ..., V_k^A, V_1^B, ..., V_k^B \in \{0,1\}^{\leq L}$ the following holds:*

1. *For uniform $x = (x_1, \ldots, x_k) \in (\{0,1\}^{2L})^k$ it holds that for each $i \in [k]$, the probability that $f_{x_i}(V_i^A) = f_{x_i}(V_i^B)$ is $\frac{1}{2}$ whenever $V_i^A \neq V_i^B$, and 1 whenever $V_i^A = V_i^B$. Moreover, for each $i \in [k]$ these probabilities are independent.*
2. *For δ-biased distribution $x = (x_1, \ldots, x_k) \in (\{0,1\}^{2L})^k$, it holds that the distribution*

$$\left(\mathbf{1}_{f_{x_1}(V_1^A) = f_{x_1}(V_1^B)}, \ldots, \mathbf{1}_{f_{x_k}(V_k^A) = f_{x_k}(V_k^B)} \right)$$

is δ-close to the case where x is uniform.

5.2 Our Hash Function

We are now ready to construct our family of randomized hash functions. We first define the randomized hash family $\mathcal{H}' = \{h'_x\}$, which uses the hash family $\mathcal{F}$ from Lemma 14. Recall that the hash values of $\mathcal{H}'$ should not be too long, since this will result in a large blowup in communication complexity.

In our construction, as opposed to previous constructions [2, 3, 19], the length of each hash value depends not only on the length of the message it is appended to, but it also depends on the length of the *entire* communication up until the point that the hash was sent. We note that if we were only concerned with the communication blowup and were not concerned with the round blowup, then we could have the length of the hash value depend only on the length of the message it is sent with (in similar spirit to prior work). However, as we argue below, in order to ensure a constant blowup in round complexity, we must allow the length of the hash value to also depend on the length of the entire history. This is illustrated in the following example: Suppose that a short message is sent, and prior to this short message were a few very long messages (in a way that satisfies the smoothness criterion). By corrupting a few long messages, the adversary can cause a hash collision in many short messages (with hash), which will result with a large blowup to the round complexity.

Hence, we allow the length of the hash value, not only to depend on the length of the message it is appended to, but also to depend on the length of the communication history. Note that the parties do not necessarily agree on the history length even if no errors occur in the current round, since the adversary may insert and delete bits throughout the protocol, in which case they will fail to parse the message and hash pair correctly.

Thus, we define the hash family $\mathcal{H} = \{h_x\}$, where the output of h_x includes the output of h'_x, the randomness used by h'_x (which is needed in order check for equality), and also the length of the hash value. Namely, we define

$$h_x(V) = (S, h'_x(V;S), 1 \cdot 0^w),$$

where S is the (private) randomness used by h'_x, and w is the length of $H'_x(V;S)$.

We next define h'_x. As we mentioned, the length of the hash values (denoted by w) may differ from one round to the next, as they depend on the communication complexity so far, and on the length of the current message sent. We will specify how w is defined below. But we first, define h'_x assuming w is known.

The seed x is random in $\left(\{0,1\}^{2L}\right)^L$, where we assume that L is greater than the input V (which is bounded by the communication complexity of the protocol up until the point where the hash is sent). For any $y = (y_1, \ldots, y_L) \in \left(\{0,1\}^{2L}\right)^L$ and for any $k \leq L$, let

$$f^k_y(V) = (f_{y_1}(V), ..., f_{y_k}(V)).$$

where $\mathcal{F} = \{f_y\}$ is the hash family from Lemma 14. The randomness for h'_x is denoted by S and is of size $2C \cdot w$. Let h'_x be the randomized hash function, that takes as input a variable V, randomness S, and outputs

$$h'_x(V;S) = f^w_{G(S)}(Z),$$

where

$$Z = \begin{cases} (f_x^{2^w}(V), 0) & \text{if } |V| \geq 2^w \\ (V, 1) & \text{if } |V| < 2^w \end{cases}$$

In what follows we show how the length w of the hash values are chosen. To this end we need to define the following variables with respect to a certain round r.

- Let Q^A be the set of all rounds r in which Alice send a hash to Bob.
  Note that these are exactly the set of rounds r such that r divides d or Alice send a message of length $\geq d$.
  We define Q^B analogously.
- Let a^A_r be the number of messages that Alice sent with a hash until (and including) round r. Namely,

  $$a^A_r = |\{r' \leq r : r' \in Q^A\}|.$$

  We define a^B_r analogously.
- Let t^A_r be all the communication received by Alice until (and including) round r. We define t^B_r analogously.
- For every r, if Alice sends the message in round r then define

  $$u_r = \max_{r' \in Q^A \cap [r-1]} \log \frac{t^A_r - t^A_{r'}}{a^A_r - a^A_{r'}}.$$

  The definition is analogous in the case that Bob sends the message in round r.

- For every round r, let ℓ_r denote the length of the message to be sent in round r, and let

$$w_r = \lceil \alpha \ell_r \rceil + \lceil u_r \rceil + 9 \left\lceil \log \frac{1}{\gamma} \right\rceil + 6,$$

where $\alpha, \gamma > 0$ are parameters of the scheme, where $\gamma < \alpha$ (it will be instructive to think of $\gamma = \epsilon$, where ϵ is the corruption budget of the adversary, and of α as the communication blowup in the error-resilient protocol).

5.3 Analysis

We denote by E the set of all messages $m_{A,r}$ or $m_{B,r}$ that were not corrupted but had a hash associated with them that formed a hash collision. Recall that for any set of messages T, we denote by $|T|$ the volume of T (i.e., the number of bits in T), and we denote by $|T|'$ the number of messages in T.

▶ **Lemma 15.** *Fix $\epsilon < 0.0005$. The protocol $\Pi^{\mathcal{H}}$ defined in Section 5.2 satisfies the following: If $\Pi^{\mathcal{H}}$ consists of $\leq t$ bits and $\leq r$ rounds, then for any adversary that corrupts messages with total volume at most ϵt, we get that*

1. *With probability $\geq 1 - 10 \cdot e^{-\frac{\alpha\gamma}{3 \log \frac{1}{\gamma}} t}$ (over the common and private randomness),*

$$|E| \leq 20\gamma t.$$

2. *With probability $\geq 1 - 10e^{-\frac{2}{3}\gamma r}$ (over the common and private randomness),*

$$|E|' \leq 70\gamma r.$$

5.4 Communication Bound

In this section we will bound the blowup of the communication of $\Pi^{\mathcal{H}}$, defined in Section 5.2. To this end, fix any adversary $\mathcal{A}$ for the protocol $\Pi^{\mathcal{H}}$, that corrupts at most e' messages of total volume at most e. We define a corresponding adversary $\mathcal{D}$ for the protocol Π, that corrupts at most e' message of total volume at most e, as follows:

The adversary $\mathcal{D}$ sends the exact same messages as $\mathcal{A}$ does, excluding the hash values. Recall that for each message in $\Pi^{\mathcal{H}}_{\mathcal{A}}$, the part that belongs to the hash value is well-defined by the suffix of the message $1 \cdot 0^w$, and hence the adversary $\mathcal{D}$ is well defined.

▶ **Lemma 16.**

$$\mathrm{CC}(\Pi^{\mathcal{H}}_{\mathcal{A}}) \leq (1 + 50C\alpha)\,\mathrm{CC}(\Pi_{\mathcal{D}}) + e + 600C \log \frac{1}{\gamma} \cdot k$$

where C is the universal constant from Lemma 13, and k is the number of rounds with hash in $\Pi_{\mathcal{D}}$.

The proof of this lemma is deferred to full version.

6 Hash Implementation with Private Randomness

In this section we show how to implement the ideal hashes in protocol Π, defined in Section 4, without resorting to shared randomness, but rather using only private randomness. To this end, we will slightly modify the protocol Π, into a new protocol Π'.

High-level overview of Π'. Lets first recall the approach used in previous works [2, 19]. In these works, the long shared randomness is replaced with δ-biased randomness, where $\delta = 2^{-\alpha t}$ and t is a bound on the communication complexity. Such δ-biased randomness can be generated using only $O(\alpha t)$ random bits. Hence, in previous works, these $O(\alpha t)$ bits of randomness are sent in advance (using an error correcting code). If we indeed had a bound t on the communication complexity, then this idea would work, as explained below.

Recall that the randomness is used for equality testing. From Lemma 14, we know that for any oblivious adversary (i.e., one that is independent of the randomness), the fraction of collisions in the case where the seed is random is δ-close to the fraction of collisions in the case where the seed is δ-biased. Denoting by N the number of possible oblivious adversaries, and by taking a union bound over all possible oblivious adversaries, we conclude that the probability that there exists an oblivious adversary that causes "too many" hash collisions in the case where the seed is δ-based is bounded by the same probability where the seed is truly random plus an additive term of δN. We note that

$$N \leq 2^{H(\epsilon)t} \cdot 4^{\epsilon t} = 2^{O(\epsilon \log \frac{1}{\epsilon} t)},$$

and thus

$$\delta N = 2^{-\alpha t} \cdot 2^{O(\epsilon \log \frac{1}{\epsilon} t)} = 2^{-\Omega(\alpha t)}.$$

Therefore, the probability that there exists an oblivious adversary that causes "too many" hash collisions is at most $2^{-\Omega(\alpha t)}$. Note that we can view any (non-oblivious) adversary as one that chooses an oblivious adversary as a function of the public randomness, and runs this oblivious adversary. Therefore, we conclude that for any (non-oblivious) adversary the probability that there are "too many" hash collisions is bounded by $2^{-\Omega(\alpha t)}$.

However, in our setting, we do not have an a priori bound on the communication complexity. In particular, if we replace the CRS with δ-biased randomness, where $\delta = 2^{-\alpha t}$ for some t, and if the adversary has a corruption budget of more than $O(\alpha t)$ bits (i.e., the communication complexity is larger than $\frac{\alpha t}{\epsilon}$), then our protocol is no longer safe. We overcome this problem by sending more randomness as the communication complexity increases.

More specifically, the parties start by assuming that the communication complexity is some small $t_{\min}$, where $t_{\min}$ is a lower bound on the communication complexity. So, the protocol starts when one of the paries, say Alice, chooses a random string $s \in \{0,1\}^{\alpha t_{\min}}$, and sends it to Bob.[11]

Once $t_1 \geq \frac{\alpha t_{\min}}{\epsilon}$ bits are sent in the protocol, the safety of this randomness could be compromised, since the adversary has enough budget to compromise $\alpha t_{\min}$ bits. Hence, each party, before sending its message, will check whether sending this message will cause the communication complexity to exceed $\frac{\alpha t_{\min}}{\epsilon}$. If so, then instead of sending the message, the party will send new randomness. This time, the party will choose at random s_2 of size $\alpha t_1 - |s_1|$ and send (s_1, s_2). If this randomness is inconsistent with the first randomness sent (s_1) then the party receiving the randomness aborts.

Once the communication complexity is $t_2 \geq \frac{\alpha t_1}{\epsilon}$, again the safety of the previous randomness could have been compromised, and hence as above, if a party is about to send a message that will cause the communication complexity to exceed $\frac{\alpha t_1}{\epsilon}$, then instead of sending the message, the party will choose at random s_3 such that $|s_1| + |s_2| + |s_3| = \alpha t_2$,

[11] As before, we ignore the error-correcting code, since we consider only message adversaries, that corrupt messages as opposed to bits, and the budget for corrupting a message is the length of the message (or the length of the corrupted message, whichever is longer).

and will send (s_1, s_2, s_3), etc. If at any point the randomness received is inconsistent with the previous random string then the party aborts. We refer to these special messages that transmit randomness by *system messages*.

There is a slight problem with this idea: How does Bob know which message sent by Alice corresponds to a message in the initial protocol Π, and which is a system message? We fix this problem by appending 1's to system messages, and appending 0's to messages corresponding to Π. However, recall, that we do not want to blowup the communication complexity. Hence we only append these bits to long messages. This is enough, since system messages are always long.

Note that according to our protocol the parties first receive randomness s_1, then they receive new randomness (s_1, s_2), and so on. We ensure that if at any point, a system message was decoded incorrectly, then eventually the paries will abort, and "catch" the adversary with injecting too many errors. This guarantee simplifies the analysis: Either at some point a system message was decoded incorrectly, in which case the adversary is "caught" with injecting too many errors, or all the parties always agree on the randomness, in which case correctness follows from the correctness of the underlying protocol in the shared randomness model.

To ensure that indeed the parties will always notice when a system message was corrupted, we add to the system message the rounds $r_1, \ldots, r_k$ in which system messages were sent. This is done to circumvent the case where the message (s_1, s_2) was corrupted and converted into a protocol message, and a few rounds later a protocol message was corrupted and converted into the same system message (s_1, s_2). If we do not include the round number then the parties may never notice that there was a point in the protocol where they did not agree on the shared randomness. In order to avoid dealing with such cases, we simply include the round numbers of the system messages.

Finally, we notice that even though we ensure that the parties always agree on the shared randomness (assuming the adversary does not inject too many errors), there is still a subtle issue. Note that the first random string s_1 is δ-biased for $\delta = 2^{-\alpha t_{\min}}$. As we saw in previous work, this suffices if the number of oblivious adversaries, restricted to the first $t_{\min}$-bits, is bounded by $2^{O(\alpha t_{\min})}$. However, in our setting, since the total communication may be significantly larger than $t_{\min}$, the number of such oblivious adversaries can be as large as $2^{t_{\min}}$, in which case the number of rounds with hash collisions can be large. To overcome this problem, we ensure that in the first $t_{\min}$ bits of communication, the adversary cannot inject too many errors (without being "caught"). This is done by re-sending the first $t_{\min}$ bits after $t_{\min}/\alpha$ bits of the protocol were transmitted, and the parties abort if these $t_{\min}$ bits are ϵ/α-far from the first $t_{\min}$ bits of the transcript. More precisely, to each system message sent after t bits of the protocol were communicated, we append the first αt bits of the transcript.

In what follows we present our protocol Π'. For the sake of simplicity, after each system message is sent, the party receiving a system message replies with an "echo" message, by simply repeating the system message. The purpose of this "echo" message is simply to allow the other party to send his protocol message (which he didn't have the budget to send in the previous round).

The protocol Π'. Let $b > 2$, and let $\alpha \leq \frac{1}{3200C}$, where C is the constant defined in Lemma 13. Fix any $d \in \mathbb{N}$ and $\gamma > 0$ such that

$$\gamma \leq \min\left\{\frac{1}{d}, 2^{-b}\right\} \quad \text{and} \quad d \geq \frac{\log \frac{1}{\gamma}}{\alpha}. \tag{4}$$

For convenience the reader can think of $b = 2$ and $\gamma = \frac{1}{d}$.

Let Π be the protocol, in the ideal hash model, defined in Section 4, instantiated with α and d as above, and with any $\alpha' > 0$. Let $t_{\min}$ be a lower bound on the communication complexity of Π, where

$$t_{\min} \geq \max\{\alpha^{-2}, 250C\alpha^{-1}\log d\}, \tag{5}$$

and let

$$W = \alpha t_{\min}.$$

Let $\mathcal{H}$ be the hash family defined in Section 5. The protocol Π' makes oracle access to the protocol $\Pi^{\mathcal{H}}$ (defined in Section 5).

In protocol Π', each party maintains a transcript T initialized to $\emptyset$, an integer k initialized to 0, k strings $s_1, ..., s_k$, k partial transcripts $P_1, \ldots, P_k$, and k rounds $r_1, ..., r_k$ that will be determined during the protocol. Intuitively, T is the transcript corresponding to Protocol $\Pi^{\mathcal{H}}$, $s_1, \ldots, s_k$ are k seeds that are used to generate the hash function implementing the ideal hash, and $r_1, \ldots, r_k$ correspond to rounds in $\Pi^{\mathcal{H}}$ where the common randomness changes. Similarly to Π (and $\Pi^{\mathcal{H}}$), in Π' we interpret the (partial) transcripts as strings.[12] .

In Π', if a party aborts, it always waits until at least $t_{\min}$ bits are sent before aborting the protocol, so as to fulfill the requirement that the communication complexity of Π' is at least $t_{\min}$.

In the first round of Π' Alice does the following:

1. Choose $s_1 \in_R \{0,1\}^W$, and let $k = 1$, $r_1 = 0$, and $P_1 = \emptyset$.
2. Send $(s_1, P_1, r_1, 1)$.

We next describe the protocol from Alice's point of view, given her private state

$$(T, k, s_1, \ldots, s_k, r_1, \ldots, r_k, P_1, \ldots, P_k).$$

Bob's view is symmetric (by switching between A and B). Upon receiving a message m_B, Alice does the following

1. If in the previous round Alice computed her message in step 4(e)ii of the protocol (or if the previous round was the first round of the protocol) then check that m_B is an echo of (i.e., equal to) the message sent by Alice in the previous round. If not then halt, and otherwise goto Step 4c.
2. Otherwise, denote $\ell = |m_B|$.
3. If $\ell \geq b^k W$ and the least significant bit of m_B is 1, then do the following:

   a. If there exists $s, P, r \in \{0,1\}^{b^k W}$, where r is a binary representation of $|T|'$, such that

   $$(s_1, ..., s_k, s, P_1, ..., P_k, P, r_1, ..., r_k, r, 1) = m_B,$$

   and such that P can be obtained from a prefix of T by corrupting messages of volume at most $\frac{|P|}{bd\log d}$, then define $s_{k+1} = s$, define $r_{k+1} = r$, $P_{k+1} = P$, update $k \leftarrow k+1$, and send (an echo message) m_B.

   b. Else, abort the protocol.

[12] This is done by standard encoding, where after each bit of the transcript we add a bit that represents whether the message ended or not. Thus, a transcript of length ℓ can be described by a string of length 2ℓ.

4. Else, do the following:
   a. If $\ell \geq b^k W$ then let m'_B be the message m_B when the least significant bit of m_B is truncated. Otherwise, let $m'_B = m_B$.
   b. Update $T \leftarrow T \cup \{m'_B\}$
   c. Define $m_A = \Pi^{\mathcal{H}}(T)$, using $x = x(s_1, \ldots, s_k, r_1, \ldots, r_k)$ as the shared randomness, where the exact function x is defined later. If there is no m_A to send then abort.
   d. If $|T \cup m_A| < \frac{b^k W}{400C\alpha}$ then do the following:
      i. Update $T \leftarrow T \cup \{m_A\}$.
      ii. Let $\ell = |m_A|$.
      iii. If $\ell < b^k W$ then send m_A, and otherwise send $(m_A, 0)$.
   e. Else,
      i. Let $s_{k+1}, P_{k+1}, r_{k+1} \in \{0,1\}^{b^k W}$ such that s_{k+1} is a uniformly chosen random string, P_{k+1} consists of the first $b^k W$ bits of T (where T is viewed as string) and r_{k+1} is a binary representation of $|T|'$.[13]
      ii. Send

$$(s_1, \ldots, s_k, s_{k+1}, P_1, \ldots, P_k, P_{k+1}, r_1, \ldots, r_k, r_{k+1}, 1).$$

      iii. $k \leftarrow k + 1$.

▶ **Theorem 17.** *Fix any adversary $\mathcal{A}$ for Π' that corrupts $\epsilon' R(\Pi'_{\mathcal{A}})$ of the messages of total volume at most $\epsilon \mathrm{CC}(\Pi'_{\mathcal{A}})$, for $\epsilon \leq \frac{\alpha}{bd \log d}$, where $\Pi'_{\mathcal{A}}$ denotes the protocol Π' executed with the adversary $\mathcal{A}$. Then there exists an adversary $\mathcal{D}$ for the protocol Π, that corrupts at most $\epsilon' R(\Pi_{\mathcal{D}}) + 2\epsilon' \log_b \mathrm{CC}(\Pi_{\mathcal{D}})$ messages of total volume at most $2\epsilon \mathrm{CC}(\Pi_{\mathcal{D}})$,[14] such that the following holds:*

1. *$\Pi'_{\mathcal{A}}$ always sends at least $t_{\min}$ bits.*
2. *$\mathrm{CC}(\Pi'_{\mathcal{A}}) \leq (1 + 2600C\alpha)\,\mathrm{CC}(\Pi_{\mathcal{D}})$.*
3. *$R(\Pi'_{\mathcal{A}}) \leq R(\Pi_{\mathcal{D}}) + 2\log_b \mathrm{CC}(\Pi_{\mathcal{D}})$.*
4. *When $\Pi'_{\mathcal{A}}$ ends, both Alice and Bob (separately) can efficiently compute their view of the transcript of $\Pi_{\mathcal{D}}$.*
5. *The adversary $\mathcal{D}$ chooses the hash collisions in a probabilistic manner such that for every t and every r, with probability $\geq 1 - 20 \cdot 2^{-\frac{\gamma}{3d}t}$, the volume of hash collisions in the first t bits of $\Pi_{\mathcal{D}}$ is at most $35\gamma t$, and with probability $\geq 1 - 80r \cdot 2^{-\frac{7\gamma^8}{d}r}$, the number of rounds with hash collisions in the first r rounds of $\Pi_{\mathcal{D}}$ is at most $100\gamma r$.*
6. *Π' is efficiently computable if Π is efficiently computable.*

The proof of Theorem 17 is deferred to full version.

7 Putting it all Together

In this section, we prove our main theorem (Theorem 4), using the theorems from previous sections. We restate our main theorem for the sake of convenience.

▶ **Theorem 18.** *There exists a universal constant $\alpha_0 \geq 0$ such that for any blowup parameters $\alpha \leq \alpha_0$ and $\alpha' \leq 1$, there exist parameters $\epsilon = \tilde{\Omega}\left(\alpha^{3+\frac{1}{\alpha'}}\right)$, $\epsilon' = \tilde{\Omega}(\alpha\alpha'^3)$, and $\delta = \alpha^{O(1/\alpha')}$, and there exists a probabilistic oracle machine S, such that for any protocol $\Pi = (A, B)$,*

[13] The binary representation of $|T|'$ has length $\leq b^k W$ since $b^k W \geq \frac{1}{\alpha}$ and so $\log |T|' \leq \log \frac{b^k W}{\alpha} \leq b^k W$.
[14] $\Pi_{\mathcal{D}}$ denotes the protocol Π executed with the adversary $\mathcal{D}$.

in which the parties always transmit at least $t_{\min}$ bits (even in the presence of error), and for any adversary $\mathcal{A}$ that corrupts at most ϵ-fraction of the bits of the simulated protocol $\Pi' = (S^A, S^B)$, the protocol $\Pi'_{\mathcal{A}}$ (which is the protocol Π' executed with the adversary $\mathcal{A}$), satisfies the following properties.

1. $\mathrm{CC}(\Pi'_{\mathcal{A}}) \geq t_{\min}$.
2. *There exists* $t_0 = (1 + \tilde{O}(\alpha))\mathrm{CC}(A, B)$ *such that for all* $t > t_0$

$$\Pr[\mathrm{CC}(\Pi'_{\mathcal{A}}) > t] \leq 2 \cdot 2^{-\delta t} ,$$

   where the probability over the private randomness of S.
3. *There exists* $r_0 = (1 + O(\alpha'))\, R(A, B) + O\left(\frac{1}{\log \frac{2}{\alpha'}} \log \mathrm{CC}(A, B) + 1\right)$ *such that for any $r \geq r_0$, if at most ϵ'-fraction of the messages are α^2-corrupted, then*

$$\Pr\left[R(\Pi'_{\mathcal{A}}) > r\right] \leq 2 \cdot 2^{-\delta r} ,$$

   where the probability over the private randomness of S.
4. *For any $t > 0$,*

$$\Pr\left[(\mathsf{Output}(\Pi'_{\mathcal{A}}) \neq \mathsf{Trans}(\Pi)) \ \wedge \ (\mathrm{CC}(\Pi'_{\mathcal{A}}) > t)\right] \leq 2 \cdot 2^{-\delta t} ,$$

   where the probability over the private randomness of S.
5. *S is a probabilistic polynomial time oracle machine, and hence the computational efficiency of S^A and S^B is comparable to that of A and B, respectively.*

In the proof of this theorem, we use an error correcting code from a recent work of Guruswami and Li [18].

▶ **Theorem 19** ([18]). *For every $\alpha > 0$ there is an explicit encoding scheme* $\mathrm{Enc}, \mathrm{Dec} : \{0,1\}^* \to \{0,1\}^*$ *with the following properties:*

1. *For any $m \in \{0,1\}^*$ we have* $|\mathrm{Enc}(m)| = (1 + \tilde{O}(\alpha))|m|$.
2. *For any $m \in \{0,1\}^*$ and any y that can be obtained from* $\mathrm{Enc}(m)$ *by* $\alpha^2 \cdot |\mathrm{Enc}(m)|$ *insertions and deletions,* $\mathrm{Dec}(y) = m$.
3. Enc *and* Dec *are computable by a polynomial time Turing machine.*

In the proof of Theorem 18 we use the following padding claim.

▷ Claim 20. Let $\alpha, \beta \leq 0.1$, and $L_0 \geq \alpha^{-1}$. Then any $(\alpha, 2\beta)$-smooth protocol Π can be efficiently converted into an (α, β)-smooth protocol Π' such that

- Π can be computed from the first $(1 - 2\alpha)$ fraction of bits of Π'.
- $\mathrm{CC}(\Pi) + L_0 \leq \mathrm{CC}(\Pi') \leq (1 + 13\alpha)\mathrm{CC}(\Pi) + 3L_0$.
- $R(\Pi') \leq R(\Pi) + \log_{\frac{1}{\beta}} \mathrm{CC}(\Pi) + \log_{\frac{1}{\beta}} L_0 + 1$.

The proof of this claim is deferred to full version.

Proof of Theorem 18. Fix any $\alpha \leq \alpha_0$ and $\alpha' \leq 1$. Let C be the constant from Lemma 13 (see Section 5). Let Enc, Dec be the encoding scheme from Theorem 19 with the parameter α. Recall that for all m, $|\mathrm{Enc}(m)| = (1 + \tilde{O}(\alpha))|m|$. Let α_1 be the maximal constant that satisfies,

$$\forall m : |\mathrm{Enc}(m)| \leq 2|m|. \tag{6}$$

We define $\alpha_0 = \min\{\alpha_1, \frac{1}{3200C}\}$. Given α, α' define,

$$\beta = \frac{\alpha^{\frac{1}{\alpha'}}}{320 \log^2 \frac{1}{\alpha}} , \ \gamma = \frac{\alpha^{\frac{4}{\alpha'}}}{2^{40}} , \ b = \frac{2}{\alpha'} , \ d = \frac{\log \frac{1}{\gamma}}{\alpha} , \ L_0 = 250C\alpha^{-2} \log d ,$$

$$\epsilon = \min\left\{\frac{\alpha^3}{2bd\log d}, \frac{\alpha^3\beta}{320}\right\} \ , \ \epsilon' = \frac{\alpha{\alpha'}^3}{\log^3\frac{1}{\alpha}}, \text{ and } \delta = \gamma^9 \ .$$

These parameters were chosen to satisfy the following claim.

▷ Claim 21. Our parameters satisfy the following:[15]

1. $\epsilon = \tilde{\Omega}(\alpha^{3+\frac{1}{\alpha'}})$, $\epsilon' = \tilde{\Omega}(\alpha{\alpha'}^3)$ and $\delta = \alpha^{O(1/\alpha')}$.
2. $\alpha < \frac{1}{4}$ and $\beta \leq \frac{\alpha}{16}$.
3. $\alpha, \beta < 0.1$ and $L_0 \geq \alpha^{-1}$.
4. $\alpha \leq 0.01$, $\alpha' \leq 1$, $d \geq \frac{1}{\alpha}$ and $\beta \leq \min\left\{\alpha^{\frac{1}{\alpha'}}, \frac{1}{5\alpha d^2}\right\}$.
5. $\gamma \leq \min\left\{\frac{1}{d}, 2^{-b}\right\}$, $d \geq \frac{\log\frac{1}{\gamma}}{\alpha}$, and $L_0 \geq \max\{\alpha^{-2}, 250C\alpha^{-1}\log d\}$.
6. $\frac{2\epsilon}{\alpha^2} \leq \frac{\alpha}{bd\log d}$.
7. $18\beta^{-1}(35\gamma + \frac{4\epsilon}{\alpha^2}) + 20d\beta^{-1}(35\gamma + 4\epsilon) \leq \alpha$.
8. $(100\gamma + \epsilon') \cdot 906d\log\frac{1}{\beta} \leq \alpha'$ and $1812d\log\frac{1}{\beta}\epsilon' \leq \frac{1}{\log\frac{2}{\alpha'}}$.
9. $\delta \leq \frac{1}{(10\alpha^{-1}+10)L_0}$, and for all $x > 0$ we have that

$$2\cdot 2^{-\delta x} \geq \min\left\{1, \frac{120d}{\gamma}\cdot 2^{-\frac{\gamma}{3d}x} + \gamma^{-17}\cdot 2^{-\frac{3}{2}\gamma^8 x}\right\} \ .$$

The protocol Π' is defined as follows:

1. Convert Π into a $(\alpha, 2\beta)$-smooth protocol Π_{smooth} by applying Lemma 6 (Section 3) to Π, with respect to parameters $(\alpha, 2\beta)$. These parameters satisfy the requirements in Lemma 6 by Item 2.
2. Convert Π_{smooth} into Π_{pad} using Claim 20 (above) with parameters α, β, L_0. These parameters satisfy the requirements in Claim 20 by Item 3.
3. Convert Π_{pad} to the error-resilient protocol Π_{ideal}, which is error-resilient in the ideal hash model, by applying the protocol from Section 4 to Π_{pad}, with parameters $\alpha, \alpha', \beta, d$. Jumping ahead, note that by Item 4, these parameters satisfy Equation (3) which is required in order to apply Theorem 9.
4. Convert Π_{ideal} to the protocol Π_{rand}, which is obtained by instantiating the ideal hash using private randomness, obtained by applying the protocol described in Section 6 to Π_{ideal}. Jumping ahead, note that by Items 5 and 6, imply that Equations (4) and (5) are satisfied and the requirements of Theorem 17 are satisfied with respect to any adversary $\mathcal{A}$ that corrupts messages of total volume $\leq \frac{2\epsilon}{\alpha^2}\mathrm{CC}((\Pi_{\mathsf{rand}})_{\mathcal{A}})$.
5. Convert Π_{rand} to $\Pi' = (S^A, S^B)$, where Π' is the same as Π_{rand}, except that each message is sent encoded with the error correcting code from Theorem 19 with parameter α.

▶ **Lemma 22.** *The protocol $\Pi' = (S^A, S^B)$ satisfies the conditions of Theorem 18.*

The proof of Lemma 22 is deferred to full version. ◀

[15] Each of the following items will later be used to apply a different theorem from previous sections.

Abstract

In the 1970's, Lovász built a bridge between graphs and alternating matrix spaces, in the context of perfect matchings (FCT 1979). A similar connection between bipartite graphs and matrix spaces plays a key role in the recent resolutions of the non-commutative rank problem (Garg-Gurvits-Oliveira-Wigderson, FOCS 2016; Ivanyos-Qiao-Subrahmanyam, ITCS 2017). In this paper, we lay the foundation for another bridge between graphs and alternating matrix spaces, in the context of independent sets and vertex colorings. The corresponding structures in alternating matrix spaces are *isotropic spaces* and *isotropic decompositions*, both useful structures in group theory and manifold theory.

We first show that the maximum independent set problem and the vertex c-coloring problem reduce to the maximum isotropic space problem and the isotropic c-decomposition problem, respectively. Next, we show that several topics and results about independent sets and vertex colorings have natural correspondences for isotropic spaces and decompositions. These include algorithmic problems, such as the maximum independent set problem for bipartite graphs, and exact exponential-time algorithms for the chromatic number, as well as mathematical questions, such as the number of maximal independent sets, and the relation between the maximum degree and the chromatic number. These connections lead to new interactions between graph theory and algebra. Some results have concrete applications to group theory and manifold theory, and we initiate a variant of these structures in the context of quantum information theory. Finally, we propose several open questions for further exploration.

1 Introduction

1.1 Between graphs and matrix spaces: some known bridges

The bridge between perfect matchings and full-rank matrices

It is well-known that some graph-theoretic problems reduce to certain problems about linear spaces of matrices. A classical example, tracing back to Tutte [105], and then more systematically examined by Lovász [79, 81], concerns perfect matchings.

Let $\mathbb{F}$ be a field, and $[n] := \{1, \ldots, n\}$. Let $G = ([n], E)$ be a simple and undirected graph, so E can be viewed as a subset of $\{\{i, j\} : i, j \in [n], i \neq j\}$. For $n \in \mathbb{N}$ and $\{i, j\}$ where $i, j \in [n]$, $i < j$, the elementary alternating[1] matrix $A_{i,j}$ of size $n \times n$ is the matrix with the (i, j)th entry being 1, the (j, i)th entry being -1, and the rest entries being 0. Let $\mathcal{A}_G$ be the linear space of alternating matrices spanned by $A_{i,j}$, $\{i, j\} \in E$. Then when the field is large enough, G has a perfect matching if and only if $\mathcal{A}_G$ contains a full-rank matrix.

A similar construction for bipartite graphs is also classical. Let $G = (L \cup R, E)$ be a bipartite graph where $L = R = [n]$, so E can be viewed as a subset of $[n] \times [n]$. For $n \in \mathbb{N}$ and $i, j \in [n]$, the elementary matrix $E_{i,j}$ of size $n \times n$ is the matrix with the (i, j)th entry being 1, and the rest entries being 0. Let $\mathcal{B}_G$ be the linear space of matrices spanned by $E_{i,j}$, $(i, j) \in E$. Then when the field is large enough, G has a perfect matching if and only if $\mathcal{B}_G$ contains a full-rank matrix.

As noted by Lovász [79], these observations give efficient randomized algorithms for deciding the existence of perfect matchings on bipartite graphs and graphs over a large enough $\mathbb{F}$ via the celebrated Schwartz-Zippel lemma [97, 117]. Furthermore, because the determinant polynomial can be evaluated efficiently in parallel [14, 31], these are actually randomized NC algorithms.

This work of Lovász has inspired several prominent results, including randomized NC algorithms for constructing perfect matchings [66, 87], and the recent breakthrough of quasi-NC algorithms for perfect matchings on bipartite graphs [46] and on general graphs [100].

[1] An $n \times n$ matrix A over $\mathbb{F}$ is *alternating*, if for any $v \in \mathbb{F}^n$, $v^t A v = 0$. An alternating matrix is always skew-symmetric (i.e. $A^t = -A$), and a skew-symmetric matrix is also alternating over fields of characteristic not 2.

Furthermore, derandomizing the corresponding algorithm for *general* linear spaces of matrices – not necessarily those of the form $\mathcal{B}_G$ or $\mathcal{A}_G$ – is now known as the symbolic determinant identity testing problem, and turns out to be of fundamental significance in complexity theory, as that would imply strong circuit lower bounds which are considered to be beyond current techniques [28, 65].

In the following, we shall call linear spaces of (alternating) matrices as (alternating) matrix spaces. For a field $\mathbb{F}$, we use $\mathrm{M}(s \times t, \mathbb{F})$ to denote the linear space of all $s \times t$ matrices over $\mathbb{F}$, and write $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ to denote that $\mathcal{B}$ is a matrix space in $\mathrm{M}(s \times t, \mathbb{F})$. Let $\mathrm{M}(n, \mathbb{F}) := \mathrm{M}(n \times n, \mathbb{F})$, and $\Lambda(n, \mathbb{F})$ be the linear space of all $n \times n$ alternating matrices over $\mathbb{F}$.

The bridge between shrunk subsets and shrunk subspaces

For bipartite graphs, a structure closely related to perfect matchings is the following. Given a bipartite graph $G = (L \cup R, E)$ where $L = R = [n]$, we say that a subset $S \subseteq L$ is a shrunk[2] subset of G, if $|S| > |N(S)|$ where $N(S)$ is the set of neighbours of S in R. The celebrated Hall's marriage theorem [55] says that G has a perfect matching if and only if it does not have a shrunk subset.

On the matrix space side, it is then natural to define the so-called shrunk subspaces. Specifically, given a matrix space $\mathcal{B} \leq \mathrm{M}(n, \mathbb{F})$, a subspace $U \leq \mathbb{F}^n$ is a shrunk subspace of $\mathcal{B}$, if $\dim(U) > \dim(\mathcal{B}(U))$ where $\mathcal{B}(U) := \langle \cup B(U) : B \in \mathcal{B} \rangle$, and $B(U)$ denotes the image of U under B.

As in the perfect matching case, a bipartite graph G has a shrunk subset if and only if $\mathcal{B}_G$ has a shrunk subspace [81]. However, for general matrix spaces, the natural analogue of Hall's theorem, namely a matrix space contains full-rank matrices if and only if it has no shrunk subspaces, does not hold, as evidenced by the space of all 3×3 alternating matrices. (The only if direction trivially holds, though.) Therefore, the bridge between shrunk subsets and shrunk subspaces is different from the one between perfect matchings and full-rank matrices.

The problem of testing whether a matrix space has a shrunk subspace arises naturally from several mathematical and computational displines, including algebraic complexity, non-commutative algebra, invariant theory, and analysis [48, 49, 61]. Not surprisingly then, this problem has had several names. We adopt the *non-commutative rank problem* which seems widely used now, and refer an interested reader to [48, 61] for the origin of this name.

With all these motivations, the non-commutative rank problem recently received considerable attention, and substantial progress has been made. First raised by Cohn [34] four decades ago in the study of free fields, it was more recently reached at by Mulmuley in the context of derandomizing the Noether's Normalization Lemma [85, 86], and also by Hrubeš and Wigderson in the context of non-commutative arithmetic circuits with divisions [56]. Only known to be in PSPACE before 2015 [35], this problem was shown to be in P over the rational number field [48] and over any field [61].

The techniques supporting the solutions to the non-commutative rank problem are reminiscent of the corresponding techniques for the perfect matching problem on bipartite graphs. In [48], it is the scaling algorithm [78, 99], generalized to the quantum operator setting [54]. In [61], it is the classical augmenting path algorithm, generalized to the matrix

[2] We call S to be "shrunk" instead of "shrinking", as we think of the bipartite graph G as shrinking the set S.

space setting [58, 60]. Ingredients from invariant theory are also crucial. For [48], Garg et al. needed the exponential upper bound on generating the ring of matrix semi-invariants [38]. For [61], Ivanyos et al. need the polynomial upper bound [39], which in turn relies crucially on the regularity lemma developed in [60].

1.2 Between graphs and matrix spaces: a new bridge

In this paper we lay the foundation for yet another bridge between graphs and matrix spaces. We focus on undirected simple graphs, hence it is natural, as Tutte and Lovász did with perfect matchings, to work with alternating matrix spaces. We start from independent sets and vertex colorings, two central structures in graph theory with numerous results from various motivations [40, 63]. By identifying analogues of them in the alternating matrix space setting, we arrive at isotropic spaces and isotropic decompositions, which we define now.

▶ **Definition 1.** *Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ be an alternating matrix space. A subspace $U \leq \mathbb{F}^n$ is an* isotropic space *of $\mathcal{A}$, if for any $u, u' \in U$, and any $A \in \mathcal{A}$, we have $u^t A u' = 0$. For $c \in \mathbb{N}$, an* isotropic c-decomposition *of $\mathcal{A}$ is a direct sum decomposition of $\mathbb{F}^n$ into c nonzero subspaces $U_1 \oplus \cdots \oplus U_c$, where every U_i is an isotropic space.*

Recall that for a graph $G = ([n], E)$, an independent set of G is a subset $S \subseteq [n]$ such that for any $i, j \in S$, there is no edge from E connecting these two vertices. A vertex c-coloring of G is a partition of the vertex set into c independent sets. Therefore, the definitions of isotropic spaces and isotropic decompositions do mimic those of independent sets and vertex colorings. It is then natural to introduce the following definitions and the corresponding algorithmic problems.

▶ **Definition 2.** *Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. The* isotropic number *of $\mathcal{A}$, denoted as $\alpha(\mathcal{A})$, is the maximum $d \in \mathbb{N}$ such that $\mathcal{A}$ has an isotropic space of dimension d. The* isotropic decomposition number*, denoted as $\chi(\mathcal{A})$, is the minimum $c \in \mathbb{N}$ such that $\mathcal{A}$ admits an isotropic c-decomposition.*

Given $d \in \mathbb{N}$ and a linear basis of $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, the maximum isotropic space problem *asks to decide whether $\alpha(\mathcal{A}) \geq d$. Given $c \in \mathbb{N}$ and a linear basis of $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, the* isotropic c-decomposition problem *asks to decide whether $\chi(\mathcal{A}) \leq c$.*

Note that $\alpha(\cdot)$ and $\chi(\cdot)$ are used to denote the independent number and the chromatic number of graphs [40], and these choices are deliberate. Also note that for any $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, we have $\alpha(\mathcal{A}) \geq 1$, and $\chi(\mathcal{A}) \leq n$. Indeed, due to the alternating condition, any $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ enjoys the property that any 1-dimensional subspace of $\mathbb{F}^n$ is an isotropic space of $\mathcal{A}$. It follows that any direct sum decomposition of $\mathbb{F}^n$ into n dimension-1 subspaces is an isotropic n-decomposition of $\mathcal{A}$. This property corresponds nicely to that for any undirected simple graph, every single vertex is an independent set. On the other hand, symmetric matrix spaces do not satisfy this property in general. Therefore, this small but pleasant coincidence suggests that working with alternating matrix spaces is a natural choice in this setting.

Our first result follows what Lovász did with perfect matchings, and provides a first indication on the new connection. Recall that given a graph $G = ([n], E)$, we can associate an alternating matrix spaces $\mathcal{A}_G \leq \Lambda(n, \mathbb{F})$, spanned by those elementary alternating matrices $A_{i,j}$ with $\{i, j\} \in E$.

▶ **Theorem 3.** *Let G and $\mathcal{A}_G$ be as above. Then we have*

1. *G has a size-s independent set if and only if $\mathcal{A}_G$ has a dimension-s isotropic space. In particular, $\alpha(G) = \alpha(\mathcal{A}_G)$.*
2. *G has a vertex c-coloring if and only if $\mathcal{A}_G$ has an isotropic c-decomposition. In particular, $\chi(G) = \chi(\mathcal{A}_G)$.*

The proof is in Section 4. Theorem 3 demonstrates that the maximum isotropic space problem and the isotropic decomposition problem are genuine generalizations[3] of the maximum independent set problem and the vertex c-coloring problem, respectively. It also implies the following.

▶ **Corollary 4.** *The maximum isotropic space problem and the isotropic* 3*-decomposition problem for alternating matrix spaces are NP-hard.*

Emboldened by Theorem 3, we propose to view isotropic spaces and decompositions as linear algebraic analogues of independent sets and vertex colorings, and study these two structures from the perspectives of graph theory and algorithms. This leads to natural and interesting mathematical and algorithmic problems, whose solutions bring together strategies, techniques, and results from several areas, including graph theory, algorithm design, computer algebra, and algebraic complexity. We regard these results as laying the foundation of a new bridge between graphs and alternating matrix spaces.

While our investigation started with an analogy, isotropic spaces and decompositions are actually classical notions, with natural interpretations in group theory and manifold theory. Therefore, some of our results have concrete applications to these areas. We also initiate a variant of this theory in quantum information, and find an interesting information theoretic interpretation of isotropic spaces in quantum error correction. These demonstrate the usefulness of this new bridge.

Before we go on to detailed descriptions of our results, we set up some notation. We use $\mathbb{F}_q$, $\mathbb{Q}$, $\mathbb{R}$, and $\mathbb{C}$ to denote the finite field with q elements, the rational number field, the real number field, and the complex number field, respectively. Elements in $\mathbb{F}^n$ are *column* vectors. In algorithms, subspaces of $\mathbb{F}^n$ and $\Lambda(n, \mathbb{F})$ are represented by linear bases. We may write $\Lambda(n, \mathbb{F}_q)$ as $\Lambda(n, q)$ for convenience. For more details on the computation model, see Section 2.1.

We also recall some well-known graph-theoretic and/or algorithmic results [40], which will be useful in seeing the analogues.

1. Whether a graph is bipartite can be tested in deterministic polynomial time.
2. On bipartite graphs, the maximum independent set problem is in P.
3. Any n-vertex and m-edge graph has an independent set of size $\geq \frac{n^2}{2m+n}$ [104][4].
4. The number of maximal independent sets on an n-vertex graph is $\leq 3^{\frac{n}{3}}$ [84].
5. The chromatic number of an n-vertex graph can be computed in time $(1+3^{\frac{1}{3}})^n \cdot \mathrm{poly}(n)$ [72][5].

All the above results will be found to have natural correspondences in the alternating matrix space setting. The reader may find some fun in trying to formulate the correspondences by him/herself.

1.3 Linear algebraic analogues of bipartite testing and maximum independent set on bipartite graphs

After Corollary 4, the isotropic 2-decomposition problem is of particular interest, as the vertex 2-coloring problem just asks whether a graph is bipartite, which can be tested efficiently by breadth-first search. A moment's thought sugggests that a breadth-first search type idea seems not applicable to the isotropic 2-decomposition problem (see also Appendix A).

[3] Note that for the maximum isotropic space problem and the isotropic decomposition problem, we consider all alternating matrix spaces, not necessarily of the form $\mathcal{A}_G$ coming from a graph G.

[4] This follows from Turán's celebrated result in extremal graph theory, which is usually stated for cliques, and implies this by simply taking the complement graph.

[5] This classical result of Lawler was from the 1970's, and the current status of the art is $2^n \cdot \mathrm{poly}(n)$ [17].

Fortunately, it turns out that this problem has been studied in computer algebra over finite fields by Brooksbank, Maglione, and Wilson in [20]. Their strategy can be readily applied to $\mathbb{R}$ and $\mathbb{C}$, using some ingredients from [59].

▶ **Theorem 5** ([20, Theorem 3.6], [59])**.** *The isotropic 2-decomposition problem can be solved in randomized polynomial time over $\mathbb{F}_q$ with q odd, and in deterministic polynomial time over $\mathbb{R}$ and $\mathbb{C}$. Furthermore, over $\mathbb{F}_q$ with q odd, the algorithm also outputs the linear bases of the two subspaces in an isotropic 2-decomposition.*

While a proof for $\mathbb{F}_q$ was already sketched in [20], we still give an exposition of this proof in Section 5. Besides indicating how to handle $\mathbb{R}$ and $\mathbb{C}$, we wish to give some reader a flavor of how the so-called $*$-algebra technique, pioneered by Wilson [111, 112] in computer algebra, is applied to this setting. This technique was recently shown to be useful in polynomial identity testing and multivariate cryptography [59].

Theorem 5 and its proof reveal that the isotropic spaces and the isotropic decompositions do have connections with, and implications to, other disciplines, just like the case of non-commutative ranks. Furthermore, a quantum variant of the theory can be developed, and the corresponding isotropic 2-decomposition problem can be solved efficiently using quantum information theoretic techniques (see Section 12). As mentioned above, the techniques used to solve the non-commutative rank problem also have their roots in algebra [61] and quantum information [48]. Perhaps it is not so coincidental that techniques from these areas are useful again.

In fact, the non-commutative rank problem arises naturally in our context. Since a bipartite graph is just a graph admitting a vertex 2-coloring, it is natural to make the following definition.

▶ **Definition 6.** *An alternating matrix space is* bipartite*, if it admits an isotropic 2-decomposition.*

A well-known fact in graph theory is that, on bipartite graphs, the maximum independent set problem can be solved in deterministic polynomial time, through a reduction to the minimum vertex cover problem. The latter problem is equivalent to the maximum matching problem via Kőnig's theorem. It is then interesting to examine whether bipartite alternating matrix spaces admit an efficient algorithm for the maximum isotropic space problem. It turns out that the isotropic number of a bipartite alternating matrix space is closely related to the non-commutative rank of some matrix space, as we shall see now.

We have mentioned the decision version of the non-commutative rank problem in Section 1.1. We now define the non-commutative rank in a slightly more general setting. Given $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$, its non-commutative rank is $\mathrm{ncrk}(\mathcal{B}) := s + t - \max\{\dim(U) + \dim(V) : \forall u \in U, v \in V, B \in \mathcal{B}, u^t B v = 0\}$ [47]. Note that the recent works [48, 61] used a slightly different formulation in the setting $s = t$.

Given a bipartite $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, up to isometry (i.e. the action of $T \in \mathrm{GL}(n, \mathbb{F})$ sending $\mathcal{A}$ to $T^t \mathcal{A} T := \{T^t A T : A \in \mathcal{A}\}$), every $A \in \mathcal{A}$ is of the form $\begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix}$, where B is of size $s \times t$ (see Section 3). Let $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ be the space of such B arising from some $A \in \mathcal{A}$. Then we have:

▶ **Theorem 7.** *Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ and $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ be from above. Then $\alpha(\mathcal{A}) = n - \mathrm{ncrk}(\mathcal{B})$.*

Thanks to the solution of the non-commutative rank problem over any field [61], and Theorem 5 in the case of $\mathbb{F}_q$ with odd q, we have

▶ **Corollary 8.** *The maximum isotropic space problem for bipartite alternating matrix spaces of size $n \times n$ over $\mathbb{F}_q$, q odd, can be solved in randomized* $\mathrm{poly}(n, \log q)$ *time.*

The proofs of Theorem 7 and Corollary 8 are in Section 6. In some sense, the non-commutative rank may be considered as corresponding to the minimum vertex cover size in the bipartite alternating matrix space setting. However, unlike in the graph case, where the relation between independent sets and vertex covers is so straightforward, the proof of Theorem 7 requires some twists, because of the "flexibility" of vectors and matrices.

Having seen the implication of the non-commutative rank problem to our setting, let us examine the following mathematical problem that arises naturally in our context, whose solution turns out to come from algebraic geometry. Again, let us trace back to the graph setting, and consider $\alpha(n, m) := \min\{\alpha(G) : G \text{ a graph with } n \text{ vertices and } m \text{ edges}\}$, where $\alpha(G)$ is the independence number. A celebrated result of Turán [104] in extremal graph theory implies that

$$\alpha(n, m) \leq \left\lceil \frac{n^2}{2m + n} \right\rceil. \tag{1}$$

Turning to the alternating matrix space setting, it is natural to define $\alpha(\mathbb{F}, n, m) := \min\{\alpha(\mathcal{A}) : \mathcal{A} \leq \Lambda(n, \mathbb{F}), \dim(\mathcal{A}) = m\}$. This quantity has been studied by Buhler, Gupta, and Harris [22] in relation to abelian subgroups of p-groups [4, 23]. The main result of [22], proved using algebraic geometric techniques, is as follows: for any $m > 1$, we have

$$\alpha(\mathbb{F}, n, m) \leq \left\lfloor \frac{m + 2n}{m + 2} \right\rfloor, \tag{2}$$

where the equality is attainable over algebraically closed fields[6]. This inequality was also obtained earlier by Ol'shanskii [89]. Comparing Equations 1 and 2, we see that $\alpha(n, m)$ and $\alpha(\mathbb{F}, n, m)$ behave quite differently. For example, by Equation 1, every graph with n vertices and $2n$ edges has an independent set of size at least $n/5$. On the other hand, by Equation 2, there exists a dimension-$2n$ alternating matrix space in $\Lambda(n, \mathbb{F})$ with no isotropic space of dimension ≥ 2.

Motivated by the discussion in the last paragraph, we study the algorithmic problem of deciding whether there exists an isotropic space of dimension ≥ 2 for $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. This is equivalent to ask whether $\mathcal{A}$ has an isotropic $(n - 1)$-decomposition. Note that the corresponding problem on graphs is trivial, as a graph has an independent set of size ≥ 2 if and only if it is not the complete graph. It turns out that over $\mathbb{Q}$, this problem is substantially more difficult.

▶ **Theorem 9.** *Over $\mathbb{Q}$, assuming the generalized Riemann hypothesis, there is a randomized polynomial-time reduction from deciding quadratic residuosity modulo squarefree composite numbers to the problem of deciding whether an alternating matrix space has an isotropic space of dimension ≥ 2.*

The proof is in Section 7. It relies crucially on Rónyai's fundamental work on computing algebra structures [92]. One ingredient here is the introduction of the existential singularity problem for matrix spaces, which turns out to have rich connections to several mathematical disciplines (see Problem 25 and Section 7.1).

[6] While in [22] the main result was stated for fields of characteristic $\neq 2$, the proof, at least the inequality, works for any characteristic.

1.4 Linear algebraic analogues of bounding the number of maximal independent sets and exact exponential algorithms for chromatic numbers

An independent set on a graph is maximal if it is not properly contained in some other independent set. The study of maximal independent sets is a classical demonstration of how graph theory and algorithm study are intertwined.

In the 1960's, Erdős and Moser raised the question of bounding the number of maximal independent sets on a graph. It was subsequently solved by Moon and Moser [84], and alternative proofs have been found [108, 115]. They show that the number of maximal independent set of an n-vertex graph is upper bounded by $3^{n/3}$, and this bound is tight. (Some refinement is required when n is not a multiple of 3.) Since the 1970's, the problem of outputting all maximal independent sets or maximal cliques received considerable attention [7, 64, 73, 103]. One application was provided by Lawler [72], who showed that the Moon-Moser bound together with dynamic programming give an algorithm for computing the chromatic number of an n-vertex graph in time $(1 + \sqrt[3]{3})^n \cdot \mathrm{poly}(n)$. This algorithm was the starting point of exact exponential-time algorithms for chromatic numbers. Subsequent improvements [15, 25, 44] lead to the breakthrough by Björklund, Husfeldt, and Koivisto, who presented an algorithm in time $2^n \cdot \mathrm{poly}(n)$ [17].

Getting back to alternating matrix spaces, the natural correspondence would be maximal isotropic spaces. Formally, for an alternating matrix space $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, an isotropic space is *maximal*, if there is no isotropic space properly containing it. We then ask analogous questions over finite fields, namely upper bounding the number of maximal isotropic spaces of $\mathcal{A} \leq \Lambda(n, \mathbb{F}_q)$, and exact exponential-time algorithms for computing the isotropic decomposition number $\chi(\mathcal{A})$. Interestingly, on one hand, these problems demonstrate behaviours different from the combinatorial counterpart. On the other hand, strategies and techniques from graph theory and algorithm design do carry over, in a non-trivial way, to these problems. Again, such phenomena have been witnessed in the non-commutative rank problem, and it is interesting to see these happening in this context. Furthermore, our result on the number of maximal isotropic spaces has a direct application to group theory, as we will see in Section 1.6.

We now describe our results in more details. To start with, we note that, as in the graph setting, an easy greedy algorithm outputs one maximal isotropic space (see Proposition 18). We then consider the number of maximal isotropic spaces for alternating matrix spaces in $\Lambda(n, q)$, analogously as done by Moon and Moser for graphs [84]. A trivial upper bound is the number of all subspaces of $\mathbb{F}_q^n$. This number, $q^{\frac{1}{4}n^2+\Theta(n)}$, is well-known and classical (see Fact 29). Any alternating matrix space spanned by a single full-rank alternating matrix has $q^{\frac{1}{8}n^2+\Theta(n)}$ maximal isotropic spaces, providing a lower bound. This is also classical but perhaps not that well-known (see Proposition 30). We show a non-trivial upper bound as follows.

▶ **Theorem 10.** *The number of maximal isotropic spaces of any $\mathcal{A} \leq \Lambda(n, q)$ is upper bounded by $q^{\frac{1}{6}n^2+O(n)}$.*

The proof is in Section 8. We adapt the proof strategy of the upper bound on maximal independent sets by Wood [115]. This requires analogues of certain graph-theoretic concepts such as degrees and neighbours in the alternating matrix space setting, which have been developed in [90]. It works up to some point, but after that, we have to resort to certain linear algebraic techniques. We leave closing the gap between $q^{\frac{1}{8}n^2+\Omega(n)}$ and $q^{\frac{1}{6}n^2+O(n)}$ an interesting open problem.

The proof of Theorem 10 is constructive (see Corollary 35), so we can enumerate all maximal isotropic spaces in time $q^{\frac{1}{6}n^2+O(n)}$. We then consider the problem of computing the isotropic decomposition number for $\mathcal{A} \leq \Lambda(n,q)$. A naive brute-force algorithm, namely enumerating all direct sum decompositions of $\mathbb{F}_q^n$, runs in time $q^{n^2+O(n)}$. Inspired by Lawler's strategy in [72], we combine our Corollary 35 with a dynamic programming idea to obtain the following.

▶ **Theorem 11.** *The isotropic decomposition number of $\mathcal{A} \leq \Lambda(n,q)$ can be computed in time $q^{\frac{5}{12}n^2+O(n)}$.*

The proof is in Section 9. An open question is whether the strategy in [17] for chromatic numbers can be adapted to obtain an algorithm for isotropic decomposition numbers in time $q^{\frac{1}{4}n^2+O(n)}$. This is because the number of subspaces of $\mathbb{F}_q^n$ is $q^{\frac{1}{4}n^2+\Theta(n)}$, while the algorithm in [17] runs in time $2^n \cdot \mathrm{poly}(n)$ where 2^n is the number of subsets of $[n]$.

1.5 Complexity-theoretic upper bound over $\mathbb{C}$, and the dependence of the independence number on the maximum degree

We first consider complexity-theoretic upper bounds for the maximum isotropic space problem and the isotropic 3-decomposition problem. Clearly, these problems are in NP over finite fields. Over $\mathbb{C}$, we have the following, by resorting to a celebrated result of Koiran on the Hilbert Nullstellensatz problem [69]. The proof is in Section 10.

▶ **Proposition 12.** *Let $\mathcal{A} \leq \Lambda(n,\mathbb{C})$ be given by a linear basis consisting of integral matrices. The maximum isotropic space problem and the isotropic 3-decomposition problem are in PSPACE unconditionally, and in PH assuming the generalized Riemann hypothesis.*

Our next result has two diverse motivations.

The first motivation is from linear algebra. Given a single alternating matrix A, its canonical form suggests that $\langle A \rangle$ admits an isotropic 2-decomposition (see Section 2). Given a pair of alternating matrices A_1 and A_2, it is also known that $\langle A_1, A_2 \rangle$ admits an isotropic 2-decomposition [51, 52, 96] (see also [20, Lemma 3.7]). A natural question is what happens for alternating matrix spaces of dimension 3, or in general, any constant c.

The second motivation is from graph theory. Given a graph $G = ([n], E)$, let $\Delta(G)$ be the maximum degree over vertices of G. It is well-known that a simple greedy algorithm yields that $\chi(G) \leq \Delta(G) + 1$ [40, pp. 122]. For $\mathcal{A} \leq \Lambda(n,\mathbb{F})$, the *degree* of $v \in \mathbb{F}^n$ in $\mathcal{A}$ can be defined as $\deg_{\mathcal{A}}(v) := \dim(\langle Av : A \in \mathcal{A} \rangle)$ [90]. As mentioned in Section 1.4, this notion was already useful in the proof of Theorem 10. Let $\Delta(\mathcal{A}) = \max\{\deg_{\mathcal{A}}(v) : v \in \mathbb{F}^n\}$. It is then natural to ask the relation between $\chi(\mathcal{A})$ and $\Delta(\mathcal{A})$ in analogy to the graph setting. This question is closely related to the one in the last paragraph, since $\deg_{\mathcal{A}}(v) \leq \dim(\mathcal{A})$ for any $v \in \mathbb{F}^n$, so $\Delta(\mathcal{A}) \leq \dim(\mathcal{A})$.

We now present the following result, also deduced from a greedy algorithm.

▶ **Proposition 13.** *Let $\mathcal{A} \leq \Lambda(n,\mathbb{F})$. Then $\chi(\mathcal{A}) \leq O(\Delta(\mathcal{A}) \cdot \log n)$. Furthermore, an isotropic C-decomposition with $C = O(\Delta(\mathcal{A}) \cdot \log n)$ can be found in polynomial time.*

The proof is in Section 10. Note that this implies that when $\dim(\mathcal{A})$ is a constant, then $\chi(\mathcal{A}) \leq O(\log n)$. We leave it an open problem for further improvement of the bound in Proposition 13.

1.6 Applications of our results

After studying problems on alternating matrix spaces mostly by way of analogy with graphs, it is natural to ask whether some results have concrete applications. The answer is quite affirmative.

In this subsection, we first provide two applications to finite groups, one being computational, and the other being enumerative. As will be explained below, these applications are based on a family of finite groups, for which testing isomorphism has long been known to be difficult, and is becoming more urgent in light of Babai's recent breakthrough on graph isomorphism [9].

We then describe a variant of our theory in the context of quantum information theory, and present an information theoretic interpretation of isotropic spaces in the context of quantum error correction. In Section 3.1, we also present the connections to manifold theory, and mention a potential application. All these suggest that our results could be of interest to group theorists, quantum information theorists, and geometers, in particular to those who work on the computational aspects of these disciplines.

Of course, these applications and connections are not surprising to readers in these fields, because alternating bilinear maps, and therefore alternating matrix tuples and spaces[7], naturally arise in group theory via the commutator bracket, and in manifold geometry via the cup product in cohomology. Therefore, certain isotropic spaces and decompositions have natural group-theoretic or geometric interpretations (see Section 3.1).

On the other hand, these applications may look exotic to some other readers, as they will be stated purely in group theoretic or quantum information theoretic terms. This is natural and expected, after a bridge is built. Indeed, the present bridge enables us to transfer problems, techniques, and results in graph theory and algorithm study, to other mathematical and computational disciplines which otherwise seem barely related to graph theory.

We now describe the first application to finite groups, more specifically, to computing with matrix groups over finite fields. Matrix groups over finite fields given by generators form an important model of computing with finite groups. In theoretical computer science, the study of this model led to the inventions of the black-box group model by Babai and Szemerédi [11], and the Arthur-Merlin class by Babai [8]. Though some algorithms with worst-case analyses can be found in [13], even the very basic membership testing problem was only recently known to be solvable in randomized polynomial time under a number-theoretic oracle [10].

Overall, our knowledge about this model is rather limited, and many questions await investigations. One interesting problem is to compute an abelian subgroup of the largest size. Large abelian subgroups, besides motivations from computational group theory [95], are useful in controlling the character degrees of the group, which in turn are useful in the group-theoretic approach for fast matrix multiplication [33]. As a consequence of Corollary 4, we have the following result, whose proof is in Section 11.

▶ **Theorem 14.** *Let p be an odd prime. Given a matrix group G over $\mathbb{F}_p$, and $s \in \mathbb{N}$, deciding whether G has an abelian subgroup of order $\geq s$ is NP-hard.*

The proof of Theorem 14 relies on the connection between alternating matrix spaces over $\mathbb{F}_p$, and p-groups of class 2 and exponent p for odd p, via Baer's correspondence [12] (see Section 3.1).

[7] For the relations among alternating matrix tuples and spaces, and alternating bilinear maps, see Sec. 2 and B.

It has long been known that p-groups of class 2 and exponent p form a bottleneck for testing isomorphism of finite groups. To solve the group isomorphism problem in time polynomial in the group order is a long-standing open problem [83]. This problem is becoming more prominent in light of Babai's breakthrough on graph isomorphism [9], as Babai indicated the group isomorphism problem as a key bottleneck to put graph isomorphism in P [9, arXiv version, Section 13.2]. Some interesting progress on testing isomorphism of such p-groups was recently made by utilizing the connection to alternating matrix spaces [76].

Let us turn to the second application to finite groups. The question of bounding the number of maximal abelian subgroups has been considered for various group families [6, 42, 109, 116], but to the best of our knowledge, there had been no results on this question for p-groups of class 2 and exponent p. Let P be such a group, so that the center $Z(P) \cong \mathbb{Z}_p^m$ and the central quotient $P/Z(P) \cong \mathbb{Z}_p^n$. The number of maximal abelian subgroups is upper bounded trivially by $p^{\frac{1}{4}n^2+O(n)}$, the number of subgroups of $\mathbb{Z}_p^n$. Our Theorem 10 then provides the following improvement, whose proof is in Section 11.

▶ **Theorem 15.** *Let P be as above. Then the number of maximal abelian subgroups of P is upper bounded by $p^{\frac{1}{6}n^2+O(n)}$.*

Recall that the proof of Theorem 10 starts by following the strategy of Wood's proof [115] of bounding the number of maximal independent sets on a graph. We view this as an interesting and somewhat unexpected example of transferring techniques from graph theory to group theory.

We also initiate a quantum variant of the theory in Section 12. There, the objects are a special type of quantum channels, and isotropic spaces and isotropic decompositions are defined on the Kraus operators of such channels. Furthermore, we require the isotropic decompositions to be orthogonal. One can then transform classical connected graphs into such channels, and prove an analogue of Theorem 3. More surprisingly, we also obtain an efficient isotropic 2-decomposition algorithm, as an analogue of Theorem 5, by resorting to the recent development on the periodicity of quantum Markov chains [53].

We then present an information theoretic interpretation for isotropic spaces in the context of quantum error correction. Briefly speaking, from the viewpoint of certain natural generalizations of quantum gate fidelities [88], isotropic spaces can be viewed as the opposite structure of noiseless subspaces (Proposition 47), which have been studied intensively in quantum error correction [68, 77]. Indeed, noiseless subspaces are shelters for the information residing in them under quantum noise, while the information in an isotropic space would be completely destroyed by quantum noise.

Let us conclude this subsection with a remark on these applications. After building a bridge, we expect it to serve as a two-way street between the two sides. However, in reality there is usually more traffic in one direction than the other. For example, the traffic between perfect matchings and full-rank matrices mostly goes from the algebra side to the combinatorial side, e.g., the randomized NC algorithm for perfect matchings [79]. The traffic between shrunk subsets and shrunk subspaces mostly goes in the other direction, e.g., linear algebraic analogues of augmenting paths [58] and scaling [54]. So far, our applications in this work mostly go in the direction from combinatorics to algebra, following the pattern of the shrunk subset vs. shrunk subspace case. It will be very interesting to explore implications in the other direction in the future.

1.7 Outlook

Summary of our contributions

The concepts of isotropic spaces and isotropic decompositions for alternating bilinear maps are classical, with natural interpretations in group theory and manifold theory. Our key new insight is that they can be viewed and studied as linear algebraic analogues of independent sets and vertex colorings. This insight leads us to study algorithmic and mathematical problems about isotropic spaces and isotropic decompositions, by drawing inspirations from results and techniques from graph theory and algorithm study. The techniques used to address the problems range from combinatorics, to algebra, and to quantum information.

We believe that this investigation is fruitful, for the following reasons.

1. First, it discloses new algorithmic and mathematical questions. For example, in Section 1.4 we proposed and studied upper bounding the number of maximal isotropic spaces, and exact exponential-time algorithms for isotropic decomposition numbers over finite fields.
2. Second, the results obtained have concrete applications to other mathematical and computational disciplines. For example, in Section 1.6, we described the applications of our results to finite groups and quantum information.
3. Third, it sheds new lights on known results from different research directions. For example, in Section 1.3 we compared Turán's extremal graph result with Buhler, Gupta, and Harris' algebraic geometric result.

This investigation then lays the foundation for yet another bridge between graphs and alternating matrix spaces, adding to the classical ones established by Tutte and Lovász.

Open ends

Several interesting open problems have been mentioned before, and here we give a summary and propose some new ones.

1. By Theorem 10, the number of maximal isotropic spaces of $\mathcal{A} \leq \Lambda(n, q)$ is upper bounded by $f(n, q) = q^{\frac{1}{6}n^2+O(n)}$. There exists an alternating matrix space with $g(n, q) = q^{\frac{1}{8}n^2+\Omega(n)}$ many maximal isotropic spaces (see Section 1.4). Either improve the current upper bound $f(n, q)$, or construct an alternating matrix space with more than $g(n, q)$ maximal isotropic spaces. Note that resolving this problem would lead to a sharp bound on the number of maximal abelian subgroups of p-groups of class 2 and exponent p.
2. Improve the exact exponential-time algorithm for computing the isotropic decomposition number for $\mathcal{A} \leq \Lambda(n, q)$ in Theorem 11. An interesting question is whether the strategy in [17] can be adapted here. The results in [16] should be useful in this context.
3. Despite Theorem 9, the complexities of deciding whether an alternating matrix space has an isotropic space of dimension ≥ 2 are not clear over various fields. Even over $\mathbb{Q}$, our proof for Theorem 9 relies on a special case of the underlying existential singularity problem for matrix spaces (see Section 7.1), so it is left open even for the general case of that problem over $\mathbb{Q}$.
4. Investigate the behaviours of the isotropic and isotropic decomposition numbers in the linear algebraic Erdős-Rényi model [18, 76].
5. Improve the dependence of the isotropic decomposition number on the maximum degree, or the dimension of the alternating matrix space (see Proposition 13). Note that this problem has motivations from classical geometry (see the discussions before Proposition 13).

The structure of the paper

We present certain preliminaries in Section 2. Then in Section 3, we collect some basic facts and properties about isotropic spaces and decompositions, including their meanings in group theory and manifold geometry in Section 3.1. We then prove Theorem 3 in Section 4, which is the basis connecting the graph-theoretic structures and those structures on alternating matrix spaces. We then prove all the main results mentioned above in the following sections. (We have mentioned the corresponding section numbers when describing those results.) An appendix then follows, containing some background material and discussions on certain conceptual questions.

2 Preliminaries

Notation

For $n \in \mathbb{N}$, $[n] := \{1, \ldots, n\}$. We use $\uplus$ for disjoint union of sets. The base of the logarithm is 2 unless otherwise stated.

Let $\mathbb{F}$ be a field. We use $\mathbb{F}^n$ to denote the vector space of *column* vectors of length n over $\mathbb{F}$. The standard basis of $\mathbb{F}^n$ consists of vectors $e_1, \ldots, e_n$, where e_i is the vector with the ith entry being 1, and other entries being 0. The linear span of several vectors or matrices is denoted by $\langle \cdot \rangle$.

For $n, d \in \mathbb{N}$, let $\mathrm{M}(n \times d, \mathbb{F})$ be the linear space of $n \times d$ matrices over $\mathbb{F}$, and $\mathrm{GL}(n \times d, \mathbb{F})$ the set of $n \times d$ matrices over $\mathbb{F}$ of rank $\min(n, d)$. We also let $\mathrm{M}(n, \mathbb{F}) := \mathrm{M}(n \times n, \mathbb{F})$, and $\mathrm{GL}(n, \mathbb{F}) := \mathrm{GL}(n \times n, \mathbb{F})$. Dimension-$d$ subspaces of $\mathbb{F}^n$ will be understood as represented by elements from $\mathrm{GL}(n \times d, \mathbb{F})$. Given $A \in \mathrm{M}(n \times d, \mathbb{F})$, the transpose of A is denoted by $A^t \in \mathrm{M}(d \times n, \mathbb{F})$. For convenience, we sometimes write a vector v in $\mathbb{F}^n$ as $v = (v_1, \ldots, v_n)^t$. Let $\mathbb{K}/\mathbb{F}$ be a quadratic extension, and let $\overline{\alpha}$ denote the image of $\alpha \in \mathbb{K}$ under the quadratic involution. For a matrix $A \in \mathrm{M}(n \times d, \mathbb{K})$, $A^\dagger$ denotes the conjugate transpose of A.

Depending on the context, $\mathbf{0}$ may denote either the zero space, a zero vector, or a zero matrix. The identity matrix in $\mathrm{M}(n, \mathbb{F})$ is denoted by I_n; we may drop the subscript n when it is understood from the context. Given a matrix $A \in \mathrm{M}(n, \mathbb{F})$, its kernel and image are denoted by $\ker(A)$ and $\mathrm{im}(A)$, respectively. For $U \leq \mathbb{F}^n$, the image of U under A is denoted by $A(U)$.

Linear algebra

Given $U \leq \mathbb{F}^n$, a complementary subspace, or just a complement, is some $V \leq \mathbb{F}^n$ such that $V \cap U = \mathbf{0}$, and $\langle U \cup V \rangle = \mathbb{F}^n$. Note that complement subspaces of U are not unique. Indeed, the number of complements of a dimension-d subspace $U \leq \mathbb{F}_q^n$ is $q^{d(n-d)}$. The space orthogonal to U is $\{v \in \mathbb{F}^n : \forall u \in U, v^t u = 0\}$. (Over $\mathbb{C}$, the conjugate transpose is used.) Note that the space orthogonal to U is not necessarily a complement to U.

On matrix spaces

Given a matrix space $\mathcal{A} \leq \mathrm{M}(s \times t, \mathbb{F})$, the image of $U \leq \mathbb{F}^t$ under $\mathcal{A}$ is $\mathcal{A}(U) := \langle \cup_{A \in \mathcal{A}} A(U) \rangle$. The dimension of $\mathcal{A}$ is denoted by $\dim(\mathcal{A})$. The (maximum) rank of $\mathcal{A}$ is $\mathrm{rk}(\mathcal{A}) := \max\{\mathrm{rk}(A) : A \in \mathcal{A}\}$. Let $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ be another matrix space. We say that $\mathcal{A}$ and $\mathcal{B}$ are *equivalent*, if there exist $C \in \mathrm{GL}(s, \mathbb{F})$ and $D \in \mathrm{GL}(t, \mathbb{F})$, such that $\mathcal{A} = C\mathcal{B}D := \{CBD : B \in \mathcal{B}\}$. When working with $\mathcal{A}$, an equivalence transformation is meant to left multiply $\mathcal{A}$ with some $C \in \mathrm{GL}(s, \mathbb{F})$ and right multiply it with some $D \in \mathrm{GL}(s, \mathbb{F})$.

On alternating matrices

Let $A, B \in \Lambda(n, \mathbb{F})$. We say that A and B are *isometric*, if there exists $T \in \mathrm{GL}(n, \mathbb{F})$, such that $A = T^t B T$. Given a dimension-d $U \leq \mathbb{F}^n$ represented by $T \in \mathrm{GL}(n \times d, \mathbb{F})$, the *restriction* of A to U by T, denoted as $A|_{U,T}$, is $T^t A T \in \Lambda(d, \mathbb{F})$. The radical of A is the subspace $\{u \in \mathbb{F}^n : \forall v \in \mathbb{F}^n, v^t A u = 0\}$, which is just $\ker(A)$. The rank of A is always even. If $\mathrm{rk}(A) = 2r$, then A is isometric to $\begin{bmatrix} \mathbf{0} & I_r & \mathbf{0} \\ -I_r & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}$ (see e.g. [71, Chap. XV, Sec. 8]). We say that $A \in \Lambda(n, \mathbb{F})$ is *non-degenerate*, if A is full-rank (so n is even).

On alternating matrix spaces

Let $\mathcal{A}, \mathcal{B} \leq \Lambda(n, \mathbb{F})$. We say that $\mathcal{A}$ and $\mathcal{B}$ are *isometric*, if there exists $T \in \mathrm{GL}(n, \mathbb{F})$, such that $\mathcal{A} = T^t \mathcal{B} T := \{T^t B T : B \in \mathcal{B}\}$. Given a dimension-$d$ $U \leq \mathbb{F}^n$ represented by $T \in \mathrm{GL}(n \times d, \mathbb{F})$, the *restriction* of $\mathcal{A}$ on U via T is $\mathcal{A}|_{U,T} := \{T^t A T : A \in \mathcal{A}\} \leq \Lambda(d, \mathbb{F})$. When it does not cause confusion, we may not write T explicitly, and just say the restriction of $\mathcal{A}$ to U, denoted by $\mathcal{A}|_U$. This corresponds to the concept of induced subgraphs in graph theory. Indeed, we see that U is an isotropic space if and only if $\mathcal{A}|_U$ is the zero (alternating matrix) space. Given $v \in \mathbb{F}^n$, the *radical of v in $\mathcal{A}$*, denoted as $\mathrm{rad}_{\mathcal{A}}(v)$, is $\{u \in \mathbb{F}^n : \forall A \in \mathcal{A}, u^t A v = 0\}$ which is a subspace of $\mathbb{F}^n$. Elements in $\mathrm{rad}_{\mathcal{A}}(v)$ correspond to non-neighbours in graph theory. The *codegree* of v in $\mathcal{A}$, denoted as $\mathrm{codeg}_{\mathcal{A}}(v)$, is $\dim(\mathrm{rad}_{\mathcal{A}}(v))$. Note that $\mathrm{codeg}_{\mathcal{A}}(v) \geq 1$ for nonzero v, as $v \in \mathrm{rad}_{\mathcal{A}}(v)$. The *degree* of v in $\mathcal{A}$ is $\deg_{\mathcal{A}}(v) := n - \mathrm{codeg}_{\mathcal{A}}(v)$. More generally, for $U \leq \mathbb{F}^n$, $\mathrm{rad}_{\mathcal{A}}(U) = \{v \in \mathbb{F}^n : \forall u \in U, \forall A \in \mathcal{A}, u^t A v = 0\}$. When $\mathcal{A}$ is clear from the context, we may drop the subscript $\mathcal{A}$ in $\mathrm{rad}_{\mathcal{A}}(v)$, $\mathrm{codeg}_{\mathcal{A}}(v)$, $\deg_{\mathcal{A}}(v)$, etc.. It is easy to see that for any $v \in \mathrm{rad}(U)$, we have $U \leq \mathrm{rad}(v)$, or in other words, $U \leq \mathrm{rad}(\mathrm{rad}(U))$.

A vector $v \in \mathbb{F}^n$ is called *isolated* in $\mathcal{A}$, if for any $A \in \mathcal{A}$, $Av = \mathbf{0}$, which is equivalent to say that $\deg(v) = 0$. This corresponds to the concept of isolated vertices in graph theory. The *radical* of $\mathcal{A}$, $\mathrm{rad}(\mathcal{A})$, is the subspace of $\mathbb{F}^n$ consisting of all isolated vectors. We say that $\mathcal{A}$ is *non-degenerate*, if $\mathrm{rad}(\mathcal{A}) = \mathbf{0}$, and *degenerate* otherwise. If $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ is degenerate with $\dim(\mathrm{rad}(\mathcal{A})) = d > 0$, then $\mathcal{A}$ is isometric to $\mathcal{A}'$ where each $A \in \mathcal{A}'$ is of the form $\begin{bmatrix} A' & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}$, where $A' \in \Lambda(n - d, \mathbb{F})$.

Sets, tuples, and spaces

Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ be given by a linear basis $A_1, \ldots, A_m \in \Lambda(n, \mathbb{F})$. We can collect them as a set $\mathsf{A} = \{A_1, \ldots, A_m\} \subseteq \Lambda(n, \mathbb{F})$. Sometimes it is also useful to impose an order on them, and form a tuple $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, \mathbb{F})^m$. We shall use calligraphic fonts for spaces, bold fonts for tuples, and sans serif fonts for sets.

Suppose $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ is given by a linear basis $A_1, \ldots, A_m \in \Lambda(n, \mathbb{F})$. Then it is clear that, given $U \leq \mathbb{F}^n$, for any $u, u' \in U$ and any $A \in \mathcal{A}$, $u^t A u' = 0$, if and only if for any $u, u' \in U$ and any $i \in [m]$, $u^t A_i u' = 0$. We therefore can define isotropic spaces, and isotropic decompositions, for sets or tuples of alternating matrices. In particular, since alternating matrix tuples represent alternating bilinear maps naturally (see Appendix B), this observation suggests that isotropic spaces and decompositions for alternating matrix spaces and for alternating bilinear maps are basically the same object. Furthermore, many, though not all, concepts introduced in Section 2 about alternating matrix spaces can be translated natually to alternating bilinear maps, including degrees, degeneracy, radicals, etc..

(Indeed, some notions there are actually borrowed from alternating bilinear maps.) On the other hand, note that the maximum rank in $\mathcal{A}$ is more natually associated with the space perspective. More discussions on the relation between these two notions are in Appendix B.

Therefore, in the context of isotropic spaces and decompositions, the choices between alternating matrix spaces and tuples usually do not matter much. The tuple perspective is more natural from the algorithm perspective, because the input of an alternating matrix space to an algorithm is usually an ordered basis. The space perspective is more natural for forming the analogy with graphs, and more naturally allows for some more notions including the maximum rank, which is important in e.g. the proof of Theorem 9. The set perspective will be used in the quantum variant of the theory in Section 12. Therefore, it is best to keep all three perspectives in mind, and see how they fit into our problems.

2.1 Computational models

We will work with two computational models, depending on the problems. The first model may be called the exact model; see e.g. [80]. This is the model to work with, if field extensions are unavoidable. In this model, input matrices or vectors are over a field $\mathbb{E}$ where $\mathbb{E}$ is a finite field extension over its prime field $\mathbb{F}$, so $\mathbb{F}$ is either a field of prime order or $\mathbb{Q}$. Suppose $\dim_{\mathbb{F}}(\mathbb{E}) = d$. Then $\mathbb{E}$ is an extension of $\mathbb{F}$ by a single generating element α. We represent α by the minimal polynomial of α over $\mathbb{F}$, and an isolating interval for α in the case of $\mathbb{R}$, or an isolating rectangle for α in the case of $\mathbb{C}$. Note that from this representation, one can approximate the numerical value of α arbitrarily closely. When we say that we work over $\mathbb{R}$ or $\mathbb{C}$, the input is given as over some number field $\mathbb{E}$ in $\mathbb{R}$ or $\mathbb{C}$. The algorithm is allowed to work with extension fields of $\mathbb{E}$ in $\mathbb{R}$ or $\mathbb{C}$, as long as the extension degrees are polynomially bounded.

The second model may be called the arithmetic model. In this model, only basic field operations are performed, and the issue of working with different field extensions does not arise. Still, over number fields we will be concerned with the bit complexities, though it is possible that we may be able to only bound the number of arithmetic steps, but not the bit complexities.

We shall mostly work with $\mathbb{F}_q$, $\mathbb{Q}$, $\mathbb{R}$, and $\mathbb{C}$ in this article, though some results extend to number fields naturally. Sometimes, we make further restrictions like requiring q to be odd, or the input to be integral.

3 Basic facts and properties

In this section we collect some basic results about isotropic spaces and isotropic decompositions.

On the definitions

The following is a somewhat more intuitive definition of these two notions.

Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, and let $U \leq \mathbb{F}^n$ be an isotropic space. Suppose $d = \dim(U)$. Then form a change of basis matrix $T \in \mathrm{GL}(n, \mathbb{F})$, such that its first d columns form a basis of U, and the rest columns together with the first d ones span $\mathbb{F}^n$. Then for any $A \in \mathcal{A}$, we see that $T^t AT$ is of the form $\begin{bmatrix} \mathbf{0} & B \\ -B^t & C \end{bmatrix}$ where $\mathbf{0}$ is of size $d \times d$. It is not hard to see that $\mathcal{A}$ has a dimension-d isotropic space if and only if there exists such a change of basis matrix T.

Similarly, $\mathcal{A}$ has an isotropic c-decomposition, if and only if there exist $T \in \mathrm{GL}(n, \mathbb{F})$, and $d_1, \ldots, d_c \in \mathbb{Z}^+$ with $\sum_i d_i = n$, such that for any $A \in \mathcal{A}$, $T^t A T = \begin{bmatrix} \mathbf{0} & A_{1,2} & \ldots & A_{1,c} \\ -A_{1,2}^t & \mathbf{0} & \ldots & A_{2,c} \\ \vdots & \vdots & \ddots & \vdots \\ -A_{1,c}^t & -A_{2,c}^t & \ldots & \mathbf{0} \end{bmatrix}$, where the ith $\mathbf{0}$ on the diagonal is of size d_i.

Computing the radical

For many problems about isotropic spaces, given a degenerate $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, usually it is possible to reduce to the non-degenerate case. This is facilitated by the fact that the radical of $\mathcal{A}$ is easy to compute.

▶ **Observation 16.** *Suppose $\mathcal{A} = \langle A_1, \ldots, A_m \rangle \leq \Lambda(n, \mathbb{F})$ is given by a linear basis. There is a polynomial-time algorithm that computes a linear basis of* $\mathrm{rad}(\mathcal{A})$.

Proof. Observe that $\mathrm{rad}(\mathcal{A}) = \cap_{i=1}^n \ker(A_i)$. Computing $\ker(A_i)$ and the intersection of $\ker(A_i)$'s are standard linear algebraic tasks that can be performed as stated. ◀

Isotropic spaces and radicals of subspaces

Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. Recall that for $U \leq \mathbb{F}^n$, we defined $\mathrm{rad}_{\mathcal{A}}(U) = \{v \in \mathbb{F}^n : \forall u \in U, v^t A u = 0\}$. The following observation is immediate.

▶ **Observation 17.** *Let $U \leq \mathbb{F}^n$ and $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. Then we have the following.*

1. *U is an isotropic space of $\mathcal{A}$ if and only if $U \subseteq \mathrm{rad}(U)$.*
2. *U is a maximal isotropic space of $\mathcal{A}$ if and only if $U = \mathrm{rad}(U)$.*

An easy application of Observation 17 gives a greedy algorithm for computing one maximal isotropic space.

▶ **Proposition 18.** *Given a matrix space $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, a maximal isotropic space can be computed in polynomially many arithmetic steps.*

Proof. We first present the algorithm. Recall that e_i is the ith standard basis vector of $\mathbb{F}^n$.

1. Let $U = \langle e_1 \rangle$.
2. While $U \subsetneq \mathrm{rad}(U)$:
   a. Take any $u \in \mathrm{rad}(U) \setminus U$.
   b. $U \leftarrow \langle U, u \rangle$.
3. Output U.

To see the correctness, note that in Step (2.a), by the choice of u, we have $U \subseteq \mathrm{rad}(\langle U, u \rangle)$ and $u \in \mathrm{rad}(\langle U, u \rangle)$, so $\langle U, u \rangle$ is an isotropic space by Observation 17 (1). In Step (3), U satisfies $U = \mathrm{rad}(U)$, so U is maximal by Observation 17 (2).

To see the running time, note that the while loop will be executed by at most n times, since $\dim(U)$ increases by 1 in each execution. Each step involves basic linear algebraic computations which require only polynomially many arithmetic operations. ◀

Over $\mathbb{R}$ or $\mathbb{C}$, the bit sizes in the above algorithm may blow up, at least with a straightforward implementation, due to the iterative computations of the radicals.

On field extensions

Let $\mathbb{K}$ be an extension field of $\mathbb{F}$. Given $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, we let $\mathcal{A}_{\mathbb{K}} \leq \Lambda(n, \mathbb{K})$ be the alternating matrix spaces when we allow linear combinations over $\mathbb{K}$, or in other words, $\mathcal{A}_{\mathbb{K}} = \mathcal{A} \otimes_{\mathbb{F}} \mathbb{K}$. We may write $\mathcal{A}$ as $\mathcal{A}_{\mathbb{F}}$ for further distinction. For $\mathcal{A}_{\mathbb{K}}$ we allow for isotropic spaces to come from $\mathbb{K}^n$. Since isotropic spaces and c-decompositions of $\mathcal{A}_{\mathbb{F}}$ naturally give isotropic spaces and c-decompositions of $\mathcal{A}_{\mathbb{K}}$, we have the following (see also [50, Lemma 6]).

▶ **Proposition 19.** *Let $\mathcal{A}_{\mathbb{F}} \leq \Lambda(n, \mathbb{F})$ and $\mathcal{A}_{\mathbb{K}} \leq \Lambda(n, \mathbb{K})$ be as above. Then $\alpha(\mathcal{A}_{\mathbb{F}}) \leq \alpha(\mathcal{A}_{\mathbb{K}})$, and $\chi(\mathcal{A}_{\mathbb{F}}) \geq \chi(\mathcal{A}_{\mathbb{K}})$.*

In Proposition 19, the inqualities for $\alpha(\cdot)$ and $\chi(\cdot)$ could be strict, as shown by Buhler, Gupta, and Harris [22, pp. 277]. Recall that in Section 1.3 we defined $\alpha(\mathbb{F}, n, m) = \{\alpha(\mathcal{A}) : \mathcal{A} \leq \Lambda(n, \mathbb{F}), \dim(\mathcal{A}) = m\}$, and Buhler et al. showed that $\alpha(\mathbb{F}, n, m) \leq \lceil \frac{m+2n}{m+2} \rceil$, when $m > 1$ and the characteristic of $\mathbb{F}$ is not 2. Furthermore the equality can be attained for algebraically closed fields. Buhler et al. then demonstrated examples over $\mathbb{F}_q$ and $\mathbb{Q}$, for which the inequality is strict. Consider the example over $\mathbb{Q}$, which is some $\mathcal{A} \leq \Lambda(n, \mathbb{Q})$ of dimension n. They show that $\alpha(\mathcal{A}_{\mathbb{Q}}) = 1$ and $\alpha(\mathcal{A}_{\mathbb{C}}) = 2$, which is equivalent to that $\chi(\mathcal{A}_{\mathbb{Q}}) = n$ and $\chi(\mathcal{A}_{\mathbb{C}}) \leq n - 1$. This gives the desired separations. Some interesting discussions on $\mathbb{R}$ vs $\mathbb{C}$ can be found in [22, Sec. 3].

3.1 Isotropic spaces and decompositions in group theory and manifold theory

In this subsection, we explain the origins of isotropic spaces and decompositions for alternating matrix spaces in group theory and manifold theory. These are classical, so the purpose here is to provide references for interested readers who have not met with these before.

Group theory

Let p be a prime > 2. We consider p-groups of class 2 and exponent p, that is, a group G of prime power order, with the commutator subgroup $[G, G]$ contained in the centre $Z(G)$, and every group element $g \in G$ satisfying $g^p = 1$.

Let P be such a group of order p^ℓ. We have that the commutator subgroup $[P, P] \cong \mathbb{Z}_p^m$, and the commutator quotient $P/[P, P] \cong \mathbb{Z}_p^n$. The commutator bracket then gives an alternating bilinear map $\phi : P/[P, P] \times P/[P, P] \to [P, P]$, or, after fixing bases of $[P, P]$ and $P/[P, P]$, an alternating bilinear map $\phi : \mathbb{Z}_p^n \times \mathbb{Z}_p^n \to \mathbb{Z}_p^m$. On the other hand, given an alternating bilinear map $\phi : \mathbb{F}_p^n \times \mathbb{F}_p^n \to \mathbb{F}_p^m$, one can construct a p-group of class 2 and exponent p, P_ϕ, called the *Baer group* corresponding to ϕ, as follows. The group elements are $(v, u) \in \mathbb{F}_p^n \times \mathbb{F}_p^m$, and the group multiplication $\circ$ is by $(v_1, u_1) \circ (v_2, u_2) = (v_1 + v_2, u_1 + u_2 + \frac{1}{2} \cdot \phi(v_1, v_2))$. This sets up a two-way correspondence between p-groups of class 2 and exponent p and alternating biliear maps.

Having set up the connection, let us see the group-theoretic interpretations of isotropic spaces and decompositions. The following is classical: an isotropic space of ϕ corresponds to a normal abelian subgroup of P containing the commutator subgroup (see e.g. [4]). More recently, Lewis and Wilson proposed the concept of a hyperbolic pair of P [75], which just consists of two normal abelian subgroups of P which together generate P, and whose intersection equals $[P, P]$. A natural generalization is then the following. A hyperbolic c-system of P consists of c normal abelian subgroups $A_1, A_2, \ldots, A_c$, such that P is generated by A_i, and for any $i, j \in [c]$, $i \neq j$, $A_i \cap A_j = [P, P]$. A hyperbolic c-system then naturally corresponds to an isotropic c-decomposition of ϕ.

Manifold theory

We then turn to the manifold theory side. We shall just walk through some examples of the connection, and point the interested reader to the survey [41] for more detailed information.

Let M be a compact Kähler manifold. Let $H^i(M;\mathbb{C})$ be the ith cohomology group of M with coefficients in $\mathbb{C}$. The cup product $\smile: H^1(M;\mathbb{C}) \times H^1(M;\mathbb{C}) \to H^2(M;\mathbb{C})$ is a skew-symmetric bilinear map. Then as an application of results by Castelnuovo and de Franchis, Catanese [29] showed that there exists a constant holomorphic map $f : M \to C$, where C is a curve of genus $g \geq 2$, if and only if, $\smile$ has a dimension-g maximal isotropic space. Catanese went on to generalize this connection much further in [29].

Let M be a smooth closed orientable n-dimensional manifold. Let $H^i(M;\mathbb{Q})$ be the ith cohomology group of M with coefficients in $\mathbb{Q}$. Gelbukh showed that an isotropic space of $\smile$ corresponds to a geometric structure on M [50, Lemma 10, Definition 11, Theorem 13], called an isotropic system, which consists of smooth closed orientable connected codimension-one submanifolds that are homologically non-intersecting, homologically independent, and intersecting transversely. The isotropic index defined in [50] for an alternating bilinear map is just the isotropic number introduced in Definition 1. In particular, our Theorem 3 shows that computing this isotropic index is NP-hard. The relations of isotropic indices with other basic notions in manifold cohomology, including the first Betti number and the co-rank of the fundamental group, are also studied there.

4 Proof of Theorem 3

Recall that we have a graph $G = ([n], E)$, and an alternating matrix space $\mathcal{A}_G$ which is spanned by those elementary alternating matrices $A_{i,j}$ where $\{i, j\} \in E$.

(1) Isotropic spaces and independent sets

We need to show that $G = ([n], E)$ has a size-s independent set if and only if $\mathcal{A}_G$ has a dimension-s isotropic space.

For the only if direction, let $T = \{i_1, \ldots, i_s\}$ be a size-s independent set of G. Let U be the subspace of $\mathbb{F}^n$ spanned by $e_{i_1}, \ldots, e_{i_s}$; recall that e_i denotes the ith standard basis vector of $\mathbb{F}^n$. It is easy to verify that U is an isotropic space of $\mathcal{A}$ of dimension s.

For the if direction, let $U = \langle u_1, \ldots, u_s \rangle$ be a dimension-s isotropic space of $\mathcal{A}_G$. We form an $n \times s$ matrix U such that the ith column of U is u_i, that is, $U = [u_1, \ldots, u_s] \in \mathrm{GL}(n \times s, \mathbb{F})$. Suppose $U^t = [w_1, \ldots, w_n] \in \mathrm{GL}(s \times n, \mathbb{F})$, $w_i \in \mathbb{F}^s$. Since U is of rank s, there exist integers $i_1, \ldots, i_s$, $1 \leq i_1 < \cdots < i_s \leq n$, such that $w_{i_1}, \ldots, w_{i_s}$ are linearly independent. We now claim that $\{i_1, \ldots, i_s\}$ forms an independent set of the original graph $G = ([n], E)$. If not, suppose $\{i_j, i_{j'}\}$, $1 \leq j < j' \leq s$, is in E. As U is an isotropic space of $\mathcal{A}_G$, we have that for any $\{k, \ell\} \in E$, $U^t A_{k,\ell} U = \mathbf{0}$. As $A_{k,\ell} = e_k e_\ell^t - e_\ell e_k^t$, we have

$$U^t A_{k,\ell} U = U^t (e_k e_\ell^t - e_\ell e_k^t) U = w_k w_\ell^t - w_\ell w_k^t = 0,$$

which implies that w_k and w_ℓ are linearly dependent. It follows that w_{i_j} and $w_{i_{j'}}$ are linearly dependent. We then arrive at a contradiction.

(2) Isotropic decompositions and vertex colorings

We need to show that $G = ([n], E)$ has a vertex c-coloring if and only if $\mathcal{A}_G$ has an isotropic c-decomposition.

For the only if direction, assume G has a vertex c-coloring, and let $[n] = T_1 \uplus T_2 \uplus \cdots \uplus T_c$ be a partition of $[n]$ into disjoint union of independent sets. Suppose $|T_j| = t_j$, and $T_j = \{i_{j,1}, \ldots, i_{j,t_j}\} \subseteq [n]$. Let $U_j = \langle e_{i_{j,1}}, \ldots, e_{i_{j,t_j}} \rangle \leq \mathbb{F}^n$, so $\mathbb{F}^n = U_1 \oplus U_2 \oplus \cdots \oplus U_c$. By (1), every U_j is an isotropic space. This gives an isotropic c-decomposition of $\mathcal{A}_G$.

For the if direction, let $\mathbb{F}^n = U_1 \oplus U_2 \oplus \cdots \oplus U_c$ be an isotropic c-decomposition. Let $d_i = \dim(U_i)$, and $b_i = \sum_{j=1}^{i} d_j$, for $i \in [c]$. Set $b_0 = 0$. Let $P = [p_1, \ldots, p_n]$ be an $n \times n$ invertible matrix, where $p_i \in \mathbb{F}^n$, such that $p_{b_{i-1}+1}, \ldots, p_{b_i}$ form a basis of U_i. By abuse of notation, we also let $U_i = [p_{b_{i-1}+1}, \ldots, p_{b_i}] \in \mathrm{GL}(n \times d_i, \mathbb{F})$, so $P = [U_1, \ldots, U_c]$. Let $W_i = U_i^t = [w_{i,1}, \ldots, w_{i,n}] \in \mathrm{GL}(d_i \times n, \mathbb{F})$. Since U_i is an isotropic space, by (1), we know that for any $\{k, \ell\} \in E$, $w_{i,k}$ and $w_{i,\ell}$ are linearly dependent.

We then use the following simple linear algebraic result, which is a consequence of the Laplacian expansion. For $A, B \subseteq [n]$ of the same size, we let $C|_{A,B}$ to denote the submatrix of C with row indices from A and column indices from B.

▶ **Lemma 20.** *Let $P = [U_1, \ldots, U_c] \in \mathrm{GL}(n, \mathbb{F})$, $U_i \in \mathrm{GL}(n \times d_i, \mathbb{F})$, and suppose $\det(P) \neq 0$. Then there exists a partition of $[n] = T_1 \uplus T_2 \uplus \cdots \uplus T_c$, where $|T_i| = d_i$, such that $\forall i \in [c]$, $\mathrm{rk}(U_i|_{T_i,[d_i]}) = d_i$.*

We claim that the partition of $[n] = T_1 \uplus T_2 \uplus \cdots \uplus T_c$ from Lemma 20 gives a vertex c-coloring of G. To see this, observe that, the condition $\mathrm{rk}(U_i|_{T_i,[d_i]}) = d_i$ is equivalent to that the vectors $w_{i,j}$, $j \in T_i$, are linearly independent. This implies that G cannot have edges of the form $\{k, \ell\}$ where $k, \ell \in T_i$, as otherwise $w_{i,k}$ and $w_{i,\ell}$ would be linearly dependent. Hence T_i is an independent set for any $i \in [c]$. This completes the proof of the second part of Theorem 3.

5 An exposition of the proof of Theorem 5

As mentioned in Section 1.3, we give an exposition of the proof of Theorem 5 for $\mathbb{F}_q$ in [20], using some ingredients from [59] to handle $\mathbb{R}$ and $\mathbb{C}$. The main purpose is to give the reader a flavor of how the so-called $*$-algebra technique is applied in this context. We could not give all the details here, as that would be too long and unnecessary; the interested reader may wish to go to [21, 59, 111], which contain detailed proofs for using $*$-algebras to solve several closely related problems.

Recall that we are given $\mathcal{A} = \langle A_1, \ldots, A_m \rangle \leq \Lambda(n, \mathbb{F})$, and our goal is to find a non-trivial direct sum decomposition $\mathbb{F}^n = U_1 \oplus U_2$, such that $\mathcal{A}|_{U_i} = \mathbf{0}$ for $i = 1, 2$. We first reduce to the non-degenerate setting as follows. Suppose $\mathcal{A}$ is degenerate, that is, there exists $T \leq \mathbb{F}^n$ of dimension n' such that $\mathcal{A}' = \mathcal{A}|_T$ is non-degenerate. Then it is not hard to verify that $\mathcal{A}$ admits an isotropic 2-decomposition if and only if $\mathcal{A}'$ admits an isotropic 2-decomposition.

In the following we assume that $\mathcal{A}$ is non-degenerate. Let $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, \mathbb{F})^m$. The adjoint algebra of $\mathbf{A}$ is defined as $\mathrm{Adj}(\mathbf{A}) := \{D \in \mathrm{M}(n, \mathbb{F}) : \exists B \in \mathrm{M}(n, \mathbb{F}), \forall i \in [m], B^t A_i = A_i D\}$. Since $\mathbf{A}$ is non-degenerate, if such B exists, then it is unique. Then a natural involution (an anti-automorphism of order at most 2) on $\mathrm{Adj}(\mathbf{A})$ is to send $D \in \mathrm{Adj}(\mathbf{A})$ to this unique B satisfying $B^t A_i = A_i D$ for any $i \in [m]$, also denoted as D^*. The adjoint algbera is the key device for the algorithm.

We now translate the isotropic 2-decomposition problem for $\mathcal{A}$, and therefore $\mathbf{A}$, to a problem about $\mathrm{Adj}(\mathbf{A})$. Any direct sum decomposition $\mathbb{F}^n = U_1 \oplus U_2$ can be encoded as a projection matrix $P \in \mathrm{M}(n, \mathbb{F})$, that is, $P^2 = P$, $\mathrm{im}(P) = U_1$, $\ker(P) = U_2$. The key observation in [20] is that, P corresponds to an isotropic 2-decomposition if and only if $P \in \mathrm{Adj}(\mathbf{A})$ and $P^* = I - P$. This means that we need to search for an idempotent P in $\mathrm{Adj}(\mathbf{A})$ satisfying $P^* = I - P$. Following [20], we call such an idempotent a hyperbolic idempotent.

To do that, we utilize the $*$-algebra structure of $\mathrm{Adj}(\mathbf{A})$. For this, we recall in a nutshell the structure of $*$-algebras. Let $\mathfrak{A}$ be a $*$-algebra. The Jacobson radical of $\mathfrak{A}$, denoted by $\mathrm{rad}(\mathfrak{A})$, is the largest nilpotent ideal of $\mathfrak{A}$, and it is invariant under $*$. The factor algebra $\mathfrak{A}/\mathrm{rad}(\mathfrak{A})$ is semi-simple, namely it is a direct sum of simple algebras. Let $\mathfrak{A}/\mathrm{rad}(\mathfrak{A}) \cong S_1 \oplus \cdots \oplus S_k$, where each S_i is simple. The $*$ either switches between S_i and S_j, $i \neq j$, or preserves S_i. Both cases are referred to as $*$-simple. The former case is called the exchange type. In the latter case, S_i is a simple algebra with an involution. Over any field, Wedderburn's theory gives a characterization of such simple algebras (see e.g. [5, Chap. 5]). Based on this, involutions on simple algebras are also classified [3, Chap. X.4], and explicit lists for $\mathbb{F}_q$, $\mathbb{R}$, and $\mathbb{C}$ can be found in [59].

Given this structure, the idea is to reduce the search for a hyperbolic idempotent from general $*$-algebras to simple $*$-algebras. Clearly, if $\mathfrak{A}$ contains a hyperbolic idempotent, then $\mathfrak{A}/\mathrm{rad}(\mathfrak{A})$, and each $*$-simple summand of $\mathfrak{A}/\mathrm{rad}(\mathfrak{A})$, all contain hyperbolic idempotents. On the other hand, suppose each $*$-simple summand of $\mathfrak{A}/\mathrm{rad}(\mathfrak{A})$ contains a hyperbolic idempotent. Then the sum of these idempotents is a hyperbolic idempotent for $\mathfrak{A}/\mathrm{rad}(\mathfrak{A})$. From here, to obtain a hyperbolic idempotent for $\mathfrak{A}$, we can use the classical idempotent lifting technique (see e.g. [112, Lemma 5.10]).

Therefore, it remains to handle the $*$-simple case. Let $\mathbb{K}$ denote some appropriate division algebra containing $\mathbb{F}$. The reader may as well think of $\mathbb{K}$ as an extension field, as for $\mathbb{F}_q$, $\mathbb{R}$, and $\mathbb{C}$, the only "non-field" case is the quaternion algebra over $\mathbb{R}$. The exchange type is easy to handle: it is $*$-isomorphic to $\mathrm{M}(\ell, \mathbb{K}) \oplus \mathrm{M}(\ell, \mathbb{K})^{op}$ with $(A, B)^* = (B, A)$. So one hyperbolic idempotent can be $(I, \mathbf{0})$. The simple case is more interesting. It is isomorphic to $\mathrm{M}(\ell, \mathbb{K})$ with the involution defined by some non-degenerate classical form F; this includes alternating, symmetric, and Hermitian ones.[8] Then for $A \in \mathrm{M}(\ell, \mathbb{K})$, $A^* = F^{-1}A^\dagger F$, where $\dagger$ denotes either transpose (for alternating and symmetric) or conjugate transpose (for Hermitian). The problem is then to find a hyperbolic idempotent, or equivalently, an isotropic 2-decomposition, for this form F. But now this is a single form, so one can bring it to say a canonical form, and examine case by case.

For example, over $\mathbb{C}$, there are two types, symmetric and alternating. (The Hermitian type does not appear because $*$ is required to preserve $\mathbb{C}$.) A non-degenerate alternating form can always be transformed to $\begin{bmatrix} \mathbf{0} & I \\ -I & \mathbf{0} \end{bmatrix}$, so isotropic 2-decomposable. A non-degenerate symmetric form can be transformed to the identity matrix I. When I is of odd size ℓ, then it does not admit an isotropic 2-decomposition. Because if so, then I is isometric to $J = \begin{bmatrix} \mathbf{0} & A \\ A^t & \mathbf{0} \end{bmatrix}$, where A is of size $i \times (\ell - i)$. But then $\mathrm{rk}(J)$ is either $2i$ or $2(\ell - i)$, an even number, so J is degenerate, a contradiction. When I is of even size ℓ, then it has an isotropic 2-decomposition. This is because we have $\begin{bmatrix} 1 & i \\ i & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & i \\ i & 1 \end{bmatrix} = \begin{bmatrix} 0 & 2i \\ 2i & 0 \end{bmatrix}$. We can then use this to bring I to $\begin{bmatrix} \mathbf{0} & 2iI' \\ 2iI' & \mathbf{0} \end{bmatrix}$, where I' is the $\ell/2 \times \ell/2$ identity matrix. Similar reasonings can be carried over $\mathbb{R}$ and $\mathbb{F}_q$.

To make the above procedure constructive, we need to compute the algebra structure efficiently. This can be done, over $\mathbb{F}_q$ with randomness [93] and over $\mathbb{C}$ deterministically [43,94]. We also need to compute the $*$-algebra structure, e.g. the forms associated with a simple $*$-algebra, by [21, 59, 111]. Finally, we need to compute the canonical forms of various forms by [107, 113].

[8] While in principle this is correct, depending on the field, some type may not exist. For details see [59].

For the algorithm analysis, we work in the exact model, as going to extension fields is already unavoidable in computing the algebra structure. Over $\mathbb{F}_q$, one can always recover, from the solutions in the simple cases, an explicit hyperbolic projection matrix P over the original field, and then we can obtain the bases of the two subspaces in an isotropic 2-decomposition by computing the image and kernel of P. Over $\mathbb{R}$ and $\mathbb{C}$, one can represent this projection matrix as a product of matrices over different extension fields [59, Sec. 3.5].

This concludes an exposition of the algorithm.

6 Proof of Theorem 7

Let us first recall the alternative definition of non-commutative rank for a slightly more general situation. Given $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$, an isotropic pair is a pair of vector spaces (U, V), $U \leq \mathbb{F}^s$, $V \leq \mathbb{F}^t$, such that for any $u \in U, v \in V$, and any $B \in \mathcal{B}$, we have $u^t B v = 0$. The non-commutative rank of $\mathcal{B}$ is then defined as $\mathrm{ncrk}(\mathcal{B}) := (s+t) - \max\{c+e : c = \dim(U), e = \dim(V), (U, V) \text{ is an isotropic pair of } \mathcal{B}\}$. Note that the recent works [48, 61] mostly deal with the setting that $s = t$. Suppose $\mathrm{ncrk}(\mathcal{B}) = r$. By equivalence transformations, we can assume that every $\mathcal{B}$ is of the form $\begin{bmatrix} B_1 & B_2 \\ \mathbf{0} & B_3 \end{bmatrix}$, where B_2 is of size $a \times b$ such that $a + b = r$.

We review the setting for Theorem 7. Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ be a bipartite alternating matrix space. By isometric transformations, we can assume that every $A \in \mathcal{A}$ is of the form $\begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix}$ where $B \in \mathrm{M}(s \times t, \mathbb{F})$, $s + t = n$. All such B form a matrix space $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$. We call such $\mathcal{B}$ a matrix space induced from the bipartite structure of $\mathcal{A}$.

Before proving Theorem 7, let us examine some examples of isotropic spaces of $\mathcal{A}$.

1. First note that $\alpha(\mathcal{A}) \geq \max\{s, t\}$.
2. Second, suppose $\mathrm{ncrk}(\mathcal{B}) = r$, so there exists $P \in \mathrm{GL}(s, \mathbb{F})$ and $Q \in \mathrm{GL}(t, \mathbb{F})$, such that every matrix in $P\mathcal{B}Q$ is of the form $\begin{bmatrix} B_1 & B_2 \\ \mathbf{0} & B_3 \end{bmatrix}$, where B_2 is of size $a \times b$ such that $a + b = r$. Let $R = \begin{bmatrix} P^t & \mathbf{0} \\ \mathbf{0} & Q \end{bmatrix}$. Then we have
$$\begin{aligned} R^t A R &= \begin{bmatrix} P & \mathbf{0} \\ \mathbf{0} & Q^t \end{bmatrix} \begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix} \begin{bmatrix} P^t & \mathbf{0} \\ \mathbf{0} & Q \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{0} & PBQ \\ -(PBQ)^t & \mathbf{0} \end{bmatrix} \\ &= \begin{bmatrix} \mathbf{0} & \mathbf{0} & B_1 & B_2 \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & B_3 \\ -B_1^t & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ -B_2^t & -B_3^t & \mathbf{0} & \mathbf{0} \end{bmatrix}, \end{aligned}$$
from which we get an isotropic space, consisting of the zero blocks in the middle part, of dimension $n - r$. (Note that the zero matrix at the $(2, 3)$ position is of size $(s - a) \times (t - b)$, and the isotropic space corresponding to the zero blocks in the middle part is of size $(s - a) + (t - b) = (s + t) - (a + b) = n - r$.)
3. The third example we now describe represents a difference from the graph-theoretic setting. Suppose $s = t$, and every $B \in \mathrm{M}(s, \mathbb{F})$ is symmetric. So $n = 2s$. Then let $U = \{u \in \mathbb{F}^n = \mathbb{F}^{2s} : u = (u_1, \ldots, u_s, u_1, \ldots, u_s)^t \in \mathbb{F}^n\} \leq \mathbb{F}^n$. That is, U consists of those vectors whose ith component equals the $(i + s)$th component, for $i \in [s]$, and

$\dim(U) = s$. We claim that U is an isotropic space of $\mathcal{A}$. To see this, for a given $u \in U$, we can write it as $\begin{bmatrix} v \\ v \end{bmatrix}$ where $v \in \mathbb{F}^s$. So for $A \in \mathcal{A}$ such that $A = \begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix}$, we have $\begin{bmatrix} v^t & v^t \end{bmatrix} \begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix} \begin{bmatrix} v \\ v \end{bmatrix} = -v^t B^t v + v^t B v = -v^t B v + v^t B v = 0$.

The proof of Theorem 7 basically suggests that isotropic spaces of the third type are not going to matter for the comparison with $\alpha(\mathcal{A})$. We now go into the proof.

Proof of Theorem 7. Let $r = \mathrm{ncrk}(\mathcal{B})$ and $d = \alpha(\mathcal{A})$.

We first show that $\alpha(\mathcal{A}) \geq n - \mathrm{ncrk}(\mathcal{B})$. Note that $r \leq \min\{s,t\}$, because we have the trivial isotropic pairs $(\mathbb{F}^s, \mathbf{0})$ and $(\mathbf{0}, \mathbb{F}^t)$. If $r = \min\{s,t\}$, note that $n - \min\{s,t\} = \max\{n-s, n-t\} = \max\{s,t\}$, and we do have isotropic spaces of dimensions s and t, respectively, by (1) from above. If $r < \min\{s,t\}$, then by (2) from above, there is an isotropic space of dimensions $n - r$. This shows that $\alpha(\mathcal{A}) \geq n - \mathrm{ncrk}(\mathcal{B})$.

We then show that $\alpha(\mathcal{A}) \leq n - \mathrm{ncrk}(\mathcal{B})$, or equivalently, $\mathrm{ncrk}(\mathcal{B}) \leq n - \alpha(\mathcal{A})$. Again, if $\alpha(\mathcal{A}) = \max\{s,t\}$, then $\mathrm{ncrk}(\mathcal{B}) \leq n - \max\{s,t\} = \min\{s,t\}$, which trivially holds. So we assume that $\alpha(\mathcal{A}) > \max\{s,t\}$. Let U be an isotropic space of dimension $d = \alpha(\mathcal{A})$, and take an $n \times d$ matrix whose columns form a basis of U, which, by abuse of notation, is also denoted by U. Let $U = \begin{bmatrix} v'_1 & v'_2 & \dots & v'_d \\ w'_1 & w'_2 & \dots & w'_d \end{bmatrix}$, where $v'_i \in \mathbb{F}^s$, and $w'_i \in \mathbb{F}^t$. Let $V' = \begin{bmatrix} v'_1 & v'_2 & \dots & v'_d \end{bmatrix}$, and $W' = \begin{bmatrix} w'_1 & w'_2 & \dots & w'_d \end{bmatrix}$. By doing a linear combination over the columns, we can assume that U is of the form $\begin{bmatrix} V & \mathbf{0} \\ W'' & W \end{bmatrix}$ where $V \in \mathrm{M}(s \times c, \mathbb{F})$, $W'' \in \mathrm{M}(t \times c, \mathbb{F})$, and $W \in \mathrm{M}(t \times e, \mathbb{F})$, such that $c + e = d$, $\mathrm{rk}(V) = c$, and $\mathrm{rk}(W) = e$. By abuse of notation, let V be the subspace of $\mathbb{F}^s$ spanned by columns in V, and W the subspace of $\mathbb{F}^t$ spanned by columns in W.

▷ Claim 21. Let V and W be as above. Then (V, W) form an isotropic pair for $\mathcal{B}$.

Proof. From above we have that $U = \begin{bmatrix} V & \mathbf{0} \\ W'' & W \end{bmatrix}$, and suppose $U = \begin{bmatrix} v_1 & v_2 & \dots & v_d \\ w_1 & w_2 & \dots & w_d \end{bmatrix}$. This means that $v_i = \mathbf{0}$ for $c < i \leq d$. Since U is an isotropic space of $\mathcal{A}$, we have, for any $i, j \in [d]$, and $A = \begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix} \in \mathcal{A}$, $\begin{bmatrix} v_i^t & w_i^t \end{bmatrix} \begin{bmatrix} \mathbf{0} & B \\ -B^t & \mathbf{0} \end{bmatrix} \begin{bmatrix} v_j \\ w_j \end{bmatrix} = -w_i^t B^t v_j + v_i^t B w_j = -v_j^t B w_i + v_i^t B w_j = 0$, so $v_i^t B w_j = v_j^t B w_i$. In particular, for any column vector $v \in V$ and any column vector $w \in W$, we have $v^t B w = \mathbf{0}^t B w'' = 0$ for some column vector $w'' \in W''$. This concludes the proof. ◁

We then get that $\mathrm{ncrk}(\mathcal{B}) \leq (s+t) - (c+e) = n - d = n - \alpha(\mathcal{A})$, and the proof is concluded. ◀

We now set out to prove Corollary 8. For this we need one more ingredient. In the literature [48, 61], the computation of the non-commutative ranks only deals with the case when $s = t$. To use that for general $\mathrm{M}(s \times t, \mathbb{F})$ we need a little twist.

▶ **Proposition 22.** *Over any field $\mathbb{F}$, computing the non-commutative rank of $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ can be done in deterministic polynomial time.*

Proof. If $s = t$, this follows from [61]. Without loss of generality, let us assume then $s < t$. We shall construct some $\mathcal{C} \leq \mathrm{M}(t, \mathbb{F})$ as follows. First, for any $B \in \mathcal{B}$, let $B' = \begin{bmatrix} \mathbf{0} \\ B \end{bmatrix}$, where $\mathbf{0}$ is of size $(t-s) \times t$, so $B' \in \mathrm{M}(t, \mathbb{F})$. Second, recall that $E_{i,j}$ is the elementary matrix with the (i,j)th entry being 1, and the rest entries being 0. Then $\mathcal{C}$ is the matrix space spanned by all B' and $E_{i,j}$ with $1 \leq i \leq t - s$ and $1 \leq j \leq t$.

We claim that $\mathrm{ncrk}(\mathcal{B})+(t-s) = \mathrm{ncrk}(\mathcal{C})$. To see that $\mathrm{ncrk}(\mathcal{B})+(t-s) \geq \mathrm{ncrk}(\mathcal{C})$, let (U, V) be an isotropic pair of $\mathcal{B}$, where $U \leq \mathbb{F}^s$, $V \leq \mathbb{F}^t$, such that $\mathrm{ncrk}(\mathcal{B}) = s+t-\dim(U)-\dim(V)$. Let $U' \leq \mathbb{F}^t$ be the image of U under the embedding $\mathbb{F}^s$ to $\mathbb{F}^t$ by sending e_i to e_{i+t-s}. Clearly, (U', V) is an isotropic pair for $\mathcal{C}$, so $\mathrm{ncrk}(\mathcal{C}) \leq 2t - \dim(U') - \dim(V) = (t-s) + s + t - \dim(U) - \dim(V) = (t-s) + \mathrm{ncrk}(\mathcal{B})$.

To show that $\mathrm{ncrk}(\mathcal{B}) + (t-s) \leq \mathrm{ncrk}(\mathcal{C})$, let (U, V) be an isotropic pair of $\mathcal{C}$. If $\mathrm{ncrk}(\mathcal{C}) = t$, then the equality is trivial. So in the following we assume $\mathrm{ncrk}(\mathcal{C}) < t$. We claim that if $V \neq \mathbf{0}$, then U is a subspace of $\langle e_{t-s+1}, \ldots, e_t \rangle$. Suppose not, then U contains a vector $u = [u_1, \ldots, u_t]^t$ with some $u_i \neq 0$ for $1 \leq i \leq t-s$. Because $E_{i,j}$ is present in $\mathcal{C}$ for $1 \leq j \leq t$, for $v \in \mathbb{F}^n$ to satisfy that $u^t E_{i,j} v = 0$ for any $1 \leq j \leq t$, v has to be $\mathbf{0}$. This implies that V has to be $\mathbf{0}$. Therefore all isotropic pairs of $\mathcal{C}$, except a trivial one $(\mathbb{F}^t, \mathbf{0})$, are also isotropic pairs of $\mathcal{B}$. Therefore, if $\mathrm{ncrk}(\mathcal{C}) < t$, and (U, V) is an isotropic pair for $\mathrm{ncrk}(\mathcal{C})$ such that $\mathrm{ncrk}(\mathcal{C}) = 2t - \dim(U) - \dim(V) < t$, we have $V \neq \mathbf{0}$, so $U \leq \langle e_{t-s+1}, \ldots, e_t \rangle$. Let U' be the image of U under the projection from $\mathbb{F}^t$ to $\mathbb{F}^s$ by sending $(v_1, \ldots, v_t)^t$ to $(v_{t-s+1}, \ldots, v_t)^t$. We see then $\dim(U') = \dim(U)$, and (U', V) is an isotropic space for $\mathcal{B}$. From this we can conclude the proof. ◀

We are now ready to prove Corollary 8.

Proof of Corollary 8. Given $\mathcal{A} \leq \Lambda(n, \mathbb{F}_q)$, q odd, first put it into the explicit bipartite form using Theorem 5, which also produces the bases of the two subspaces in an isotropic 2-decomposition. Then for a matrix space $\mathcal{B} \leq \mathrm{M}(s \times t, \mathbb{F})$ induced from the bipartite structure, compute its non-commutative rank $r = \mathrm{ncrk}(\mathcal{B})$ using Proposition 22. The isotropic number of $\mathcal{A}$ is then $n - r$, by Theorem 7. ◀

▶ Remark 23. To obtain analogues of Corollary 8 over $\mathbb{R}$ and $\mathbb{C}$, the bottleneck is that over $\mathbb{R}$ and $\mathbb{C}$, Theorem 5 only outputs the projection matrix as the product of a sequence of matrices over different extension fields. This prevents us from working with the bases of the subspaces in an isotropic 2-decomposition directly. Of course, if we are content with approximating those algebraic numbers up to certain precision, we can use the representation of the projection as a product of matrices over different extension fields to get such, and then work with that.

7 Proof of Theorem 9

Let us first work with general $\mathbb{F}$, and then restrict to our target field $\mathbb{Q}$ at some point. Recall that the problem is to decide whether an alternating matrix space $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ has an isotropic space of dimension 2. We first make the following easy observation.

▶ **Observation 24.** *Let $\mathcal{A} = \langle A_1, \ldots, A_m \rangle \leq \Lambda(n, \mathbb{F})$. Then $\mathcal{A}$ has an isotropic space of dimension 2, if and only if there exist linearly independent $v, w \in \mathbb{F}^n$ such that for any $A \in \mathcal{A}$, $v^t A w = 0$, which is further equivalent to that for any $i \in [m]$, $v^t A_i w = 0$.*

We now need to prove some auxiliary results. Let $\mathcal{B} = \langle B_1, \ldots, B_m \rangle \leq \mathrm{M}(n, \mathbb{F})$, and let $\mathbf{B} = (B_1, \ldots, B_m) \in \mathrm{M}(n, \mathbb{F})^m$. Here is a natural problem about matrix spaces.

▶ **Problem 25.** The existential singularity problem for matrix spaces, or the linear $\exists$-singularity problem, asks the following: given $\mathcal{B} \in \mathrm{M}(n, \mathbb{F})$, decide whether there exists a singular (e.g. non-full-rank) *non-zero* matrix in $\mathcal{B}$.

The linear ∃-singularity problem turns out to be quite interesting. We discuss this problem in detail in Section 7.1. For the sake of proving Theorem 9, we need the following result, whose proof can be found there.

▶ **Lemma 26.** *Over $\mathbb{Q}$, assuming the generalized Riemann hypothesis, there is a randomized polynomial-time reduction from deciding quadratic residuosity modulo squarefree composite numbers to the linear ∃-singularity problem.*

We then show that the linear ∃-singularity problem reduces to deciding whether an alternating matrix space has an isotropic space of dimension 2. This reduction works over any field.

For this purpose, it will be convenient to define an intermediate problem, which may be viewed as just a reformulation of Problem 25.

Recall that $\mathcal{B} = \langle B_1, \ldots, B_m \rangle \leq \mathrm{M}(n, \mathbb{F})$, and $\mathbf{B} = (B_1, \ldots, B_m) \in \mathrm{M}(n, \mathbb{F})^m$. Think of $\mathbf{B}$ as a 3-tensor $T_{\mathbf{B}}$ of size $n \times n \times m$, such that $T_{\mathbf{B}}(i, j, k) = B_k(i, j)$. That is, B_k's are the slices according to the third index (lateral slices). We will also be interested in the matrices obtained according to the first index (horizontal slices) and the second index (vertical slices). Specifically, define $\mathbf{B}^v$ be the n-tuple of $n \times m$ matrices that are vertical slices of $T_{\mathbf{B}}$. That is, $\mathbf{B}' = (B'_1, \ldots, B'_n) \in \mathrm{M}(n \times m, \mathbb{F})^n$, where $B'_j = [B_1 e_j, \ldots, B_m e_j]$, or in other words, $B'_j(i, k) = T_{\mathbf{B}}(i, j, k) = B_k(i, j)$. Similarly we can define the matrix tuple consisting of the horizontal slices of $T_{\mathbf{B}}$.

We now consider the matrix space $\mathbf{B}' \in \mathrm{M}(n \times m, \mathbb{F})^n$. For $v = (v_1, \ldots, v_m)^t \in \mathbb{F}^m$, its right degree in $\mathbf{B}'$ is defined to be the rank of $[B'_1 v, \ldots, B'_m v] = v_1 B_1 + \cdots + v_m B_m$. Therefore, every non-zero $v \in \mathbb{F}^n$ has right degree n in $\mathbf{B}'$, if and only if every matrix in $\mathcal{B}$ is of rank n. Lemma 26 then immediately implies the following.

▶ **Corollary 27.** *Over $\mathbb{Q}$, assuming the generalized Riemann hypothesis, there is a randomized polynomial-time reduction from deciding quadratic residuosity modulo squarefree composite numbers to deciding whether there exists a non-zero $v \in \mathbb{F}^m$ of right degree $< n$ w.r.t. a matrix tuple $\mathbf{B}' \in \mathrm{M}(n \times m, \mathbb{F})$.*

Given $\mathbf{B}' = (B'_1, \ldots, B'_n) \in \mathrm{M}(n \times m, \mathbb{F})$, we construct a tuple of alternating matrices of size $(n+m) \times (n+m)$, as follows. For $i \in [n]$, let $A_i = \begin{bmatrix} \mathbf{0} & B'_i \\ -B'^t_i & \mathbf{0} \end{bmatrix}$. For $1 \leq i < j \leq n$, let $C_{i,j} = e_i e_j^t - e_j e_i^t$. For $1 \leq k < \ell \leq m$, let $D_{k,\ell} = e_{n+k} e_{n+\ell}^t - e_{n+\ell} e_{n+k}^t$. Note that $C_{i,j}$ and $D_{k,\ell}$ are elementary alternating matrices. Let $\mathbf{A} = (A_1, \ldots, A_n, C_{1,2}, \ldots, C_{n-1,n}, D_{1,2}, \ldots, D_{m-1,m})$. We now claim the following.

▷ Claim 28. Let $\mathbf{B}' \in \mathrm{M}(n \times m, \mathbb{F})^n$ and $\mathbf{A} \in \Lambda(n+m, \mathbb{F})^{n+\binom{n}{2}+\binom{m}{2}}$ be as above. Let $\mathcal{A} = \langle \mathbf{A} \rangle \leq \Lambda(n+m, \mathbb{F})$. Then there exists a non-zero $v' \in \mathbb{F}^m$ of right degree $< n$ in $\mathbf{B}'$ if and only if $\mathcal{A}$ has an isotropic space of dimension 2.

Proof. By Observation 24, to decide whether $\mathcal{A}$ has an isotropic space of dimension ≥ 2, we only need to test whether there exist linearly independent $u, v \in \mathbb{F}^{n+m}$, such that for any $E = A_i$, or $C_{i,j}$, or $D_{k,\ell}$, $u^t E v = 0$.

The only if direction is easy to verify. Suppose $v' \in \mathbb{F}^m$ is of right degree $n-1$ w.r.t. $\mathbf{B}'$, namely $[B'_1 v', \ldots, B'_m v']$ is of rank $< n$. Then take any non-zero $u' \in \mathbb{F}^n$ in the left kernel of $[B'_1 v', \ldots, B'_m v']$, and we have that for $i \in [m]$, $u'^t B'_i v' = 0$. Now construct $u = \begin{bmatrix} u' \\ \mathbf{0} \end{bmatrix} \in \mathbb{F}^{n+m}$, and $v = \begin{bmatrix} \mathbf{0} \\ v' \end{bmatrix} \in \mathbb{F}^{n+m}$. For $i \in [n+m]$, let the ith component of u (resp. v) be u_i (resp.

v_i). Then for $i \in \{n+1, \ldots, n+m\}$, $u_i = 0$. For $i \in [n]$, $v_i = 0$. Clearly, u and v are linearly independent. Furthermore, it is easy to verify that (1) $u^t A_i v = u'^t B'_i v' = 0$, (2) $u^t C_{i,j} v = u_i v_j - u_j v_i = u_i \cdot 0 - u_j \cdot 0 = 0$, as $i, j \in [n]$, and similarly (3) $u^t D_{k,\ell} v = 0$. Then u and v spans a dimension-2 isotropic space of $\mathcal{A}$.

For the if direction, suppose u and v are linearly independent vectors in $\mathbb{F}^{n+m}$, and satisfy that for any $E = A_i$, or $C_{i,j}$, or $D_{k,\ell}$, $u^t E v = 0$. Write $u = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$, where $u_1 \in \mathbb{F}^n$ and $u_2 \in \mathbb{F}^m$. Similarly write $v = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$, where $v_1 \in \mathbb{F}^n$ and $v_2 \in \mathbb{F}^m$. By $u^t C_{i,j} v = 0$, we have that u_1 and v_1 are linearly dependent. By $u^t D_{k,\ell} v = 0$, we have that u_2 and v_2 are linearly dependent. We first observe that it cannot be the case that $u_1 = v_1 = \mathbf{0}$, nor $u_2 = v_2 = \mathbf{0}$. As otherwise, say if $u_1 = v_1 = \mathbf{0}$, then because u_2 and v_2 are linearly dependent, we have u and v are linearly dependent, a contraction. Therefore, without loss of generality, we assume that $u_1 \neq \mathbf{0}$, so $v_1 = \alpha_1 u_1$ for some $\alpha_1 \in \mathbb{F}$. We then have two cases. In the first case, if $u_2 = \mathbf{0}$, then $v_2 \neq \mathbf{0}$, and $v' = v - \alpha_1 u$ and u are linearly independent. In the second case, if $u_2 \neq \mathbf{0}$, then $v_2 \neq \alpha_1 u_2$, as otherwise u and v would be linearly dependent. Then again, letting $v' = v - \alpha_1 u$, we have u and v' are linearly independent. Clearly, u and v' still satisfy that for any $E = A_i$, or $C_{i,j}$, or $D_{k,\ell}$, $u^t E v' = 0$. Write v' as $\begin{bmatrix} v'_1 \\ v'_2 \end{bmatrix}$ where $v'_1 \in \mathbb{F}^n$, and $v'_2 \in \mathbb{F}^m$, so $v'_1 = \mathbf{0}$, and $v'_2 \neq \mathbf{0}$. We then have $u_2 = \alpha_2 v'_2$. Letting $u' = u - \alpha_2 v'$, we have u' and v' are linearly independent, and for any $E = A_i$, or $C_{i,j}$, or $D_{k,\ell}$, $u'^t E v' = 0$. Write u' as $\begin{bmatrix} u'_1 \\ u'_2 \end{bmatrix}$ where $u'_1 \in \mathbb{F}^n$, and $u'_2 \in \mathbb{F}^m$, so $u'_1 \neq \mathbf{0}$, and $u'_2 = \mathbf{0}$. It is then straightforward to verify that the condition $u'^t A_i v' = 0$ is equivalent to $u'^t_1 B'_i v'_2 \neq 0$. Recall that neither u'_1 nor v'_2 is the zero vector; this just translates to say that v'_2 is of right degree $< n$ w.r.t. $\mathbf{B}'$. ◁

Theorem 9 follows by combining Claim 28 and Corollary 27.

7.1 The existential singularity problem for matrix spaces

In this subsection, we discuss on Problem 25, which we believe is a very interesting problem in its own right. We therefore examine this problem over various fields, and prove Lemma 26 over $\mathbb{Q}$.

The affine version of Problem 25 has been studied in [24]. More specifically, the $\exists$-singularity problem for affine matrix spaces asks to decide whether an affine matrix space contains a non-full-rank matrix (not necessarily nonzero). In [24], this problem was called the singularity problem. This may cause some confusion, because in [48, 61] the singularity problem for matrix spaces is to decide whether all matrices in a matrix space are singular. For clarification, we then call the problem in [24] the affine $\exists$-singularity problem, and Problem 25 the linear $\exists$-singularity problem.

In [24], it was shown that the affine $\exists$-singularity problem is NP-hard over $\mathbb{F}_q$, $\mathbb{Q}$, or $\mathbb{R}$. We first note that the linear $\exists$-singularity problem reduce to that for affine matrix spaces, but the inverse direction is not clear.[9] Furthermore, the proof strategy of [24] cannot be adapted directly to tackle Problem 25, because of the introduction of field constants in the reduction. In particular, the use of field constants in the transformation from algebraic branching programs to symbolic determinants by Valiant [106] seems particularly crucial. Indeed, as we will see below, the $\exists$-singular problems for matrix spaces and for affine matrix spaces demonstrate quite different behaviors.

[9] To reduce the matrix space case to the affine case is easy: if $\mathcal{B} = \langle B_1, \ldots, B_m \rangle$, then form m affine spaces $B_i + \langle B_1, \ldots, B_{i-1}, B_{i+1}, \ldots, B_m \rangle$.

Matrix spaces in which every nonzero matrix is of full-rank has been studied in mathematics for a long time. More broadly, if $\mathcal{B} \leq \mathrm{M}(n, \mathbb{F})$ satisfies that every nonzero matrix in $\mathcal{B}$ is of a fixed rank r, we say that $\mathcal{B}$ satisfies the fixed rank r condition. Such matrix spaces are of interests in algebraic geometry (mostly when over algebraically closed fields), differential topology (mostly when over $\mathbb{R}$), number theory (mostly when over $\mathbb{Q}$), and algebra (mostly when over finite fields). It turns out that several results from these different branches of mathematics will be useful for our algorithmic purposes as well.

To start with, the following quantity has been studied extensively in the literature. Let $\rho(n, r, \mathbb{F})$ be the maximum dimension over those $\mathcal{B} \leq \mathrm{M}(n, \mathbb{F})$ satisfying the fixed rank r condition. Also let $\tau(n, r, \mathbb{F})$ be the maximum dimension over those affine matrix spaces $\mathcal{C} \subseteq \mathrm{M}(n, \mathbb{F})$ satisfying the fixed rank r condition. Also let $\rho(n, \mathbb{F}) := \rho(n, n, \mathbb{F})$, and $\tau(n, \mathbb{F}) := \tau(n, n, \mathbb{F})$. As pointed out in [37], $\rho(n, \mathbb{F}) \leq n$, and $\tau(n, \mathbb{F}) = \binom{n}{2}$. Two remarks are due here. First, $\rho(n, \mathbb{F})$ can be much smaller than n for certain fields; see below. Second, the $\binom{n}{2}$ bound for $\tau(n, \mathbb{F})$ can be easily achieved at $I_n + \mathcal{U}$ where $\mathcal{U}$ is the linear space of strictly upper triangular matrices. This distinction already suggests that the difference between the linear and the affine cases can be significant.

In this following, we discuss on $\mathbb{C}$, $\mathbb{R}$, and $\mathbb{Q}$, comparing the linear and affine settings, and presenting some algorithms for the linear case, including a proof of Lemma 26. We refer the interested reader to [98] for the finite field case.

Over $\mathbb{C}$

The affine $\exists$-singularity problem over $\mathbb{C}$ is only known to be in RP [24].

We then turn to the linear $\exists$-singularity problem over $\mathbb{C}$. Sylvester showed that $\rho(n, \mathbb{C}) \leq 1$ [101], and Westwick generalized that to $\rho(n, r, \mathbb{C}) \leq 2n - 2r + 1$ [110]. Some subsequent developments include [19, 57].

Sylvester's result immediately translates to a deterministic efficient algorithm for the linear $\exists$-singularity problem over $\mathbb{C}$: if the input matrix space $\mathcal{B} \leq \mathrm{M}(n, \mathbb{C})$ is of dimension ≥ 2, then return "exists." Otherwise, $\mathcal{B} = \langle B \rangle$, and return "exists" if and only if B is of full-rank.

Over $\mathbb{R}$

The affine $\exists$-singularity problem over $\mathbb{R}$ is NP-hard [24].

We then turn to the linear $\exists$-singularity problem over $\mathbb{R}$. Based on the Radon-Hurwitz construction and Adams' vector field theorem [1], $\rho(n, \mathbb{R})$ is equal to the so-called Hurwitz-Radon function (see [2]). For $n \in \mathbb{N}$, write n in the form of $2^{4a+b} \cdot (2c+1)$ where $b \in \{0, 1, 2, 3\}$, and the Hurwitz-Radon function is $HR(n) = 8a + 2^b$. The significance of this result for our algorithmic purpose is that $HR(n) \leq 2(\log n + 4)$. Some subsequent developments include [30, 70, 82].

Therefore, the linear $\exists$-singularity problem over $\mathbb{R}$ admits the following quasipolynomial-time algorithm. If the input matrix space $\mathcal{B} \leq \mathrm{M}(n, \mathbb{C})$ is of dimension $\geq HR(n)$, then return "exists." Otherwise, $\mathcal{B} = \langle B_1, \ldots, B_m \rangle$ where $m \leq HR(n) \leq 2(\log n + 4)$. We form m affine spaces, $\mathcal{C}_i := B_i + \langle B_1, \ldots, B_{i-1}, B_{i+1}, \ldots, B_m \rangle$, for every $i \in [m]$. The question then becomes whether any of the $\mathcal{C}_i$'s contains a singular matrix. This can be done by computing $f_i := \det(B_1 x_1 + \cdots + B_{i-1} x_{i-1} + B_i + B_{i+1} x_{i+1} + \cdots + B_m x_m)$ explicitly. Since the polynomial f_i, involving $O(\log n)$ variables, is of degree n, f_i has $n^{O(\log n)}$ monomials,

and we can fully write out f_i in time polynomial in $n^{O(\log n)}$.[10] After that, we can use the existential theory of reals [27, 91] to determine whether f_i has a non-trivial zero in time $n^{O(\log n)}$. Return "exists" if and only if one of these f_i's is solvable. This concludes the proof.

Over $\mathbb{Q}$

The affine $\exists$-singularity problem over $\mathbb{Q}$ is NP-hard [24].

We then turn to the linear $\exists$-singularity problem over $\mathbb{Q}$. To start with, observe that $\rho(n, \mathbb{Q}) \geq n$. This is because we can take a degree-n extension field $\mathbb{K}$ over $\mathbb{Q}$, and use the regular representation of $\mathbb{K}$. We now prove Lemma 26, which suggests that the linear $\exists$-singularity problem is not so easy either.

Proof of Lemma 26. We consider a special case of Problem 25 as follows. Assume $\mathcal{B} \leq \mathrm{M}(n, \mathbb{Q})$ is closed under matrix multiplication, so $\mathcal{B}$ forms an algebra over $\mathbb{Q}$. In this setting, Problem 25 just asks whether $\mathcal{B}$ is not a division algebra. We can even specialize further by considering $\mathcal{B}$ being a central simple algebra over $\mathbb{Q}$.

In [92], Rónyai considered the problem of testing whether a central simple algebra over $\mathbb{Q}$ of dimension 4 is isomorphic to $\mathrm{M}(2, \mathbb{Q})$. He showed that assuming the generalized Riemann hypothesis, there is a randomized efficient reduction from deciding quadratic residuosity modulo squarefree composite numbers to this problem. In [92], the algebras are represented by structural constants, but these can be turned into matrix representations in $\mathrm{M}(4, \mathbb{Q})$ (see e.g. [62]). It follows that there is an analogous reduction for matrix algebras.

We can then conclude the proof, because such an algebra is either isomorphic to $\mathrm{M}(2, \mathbb{Q})$ (in which there exists a nonzero singular matrix) or a division algebra (in which every nonzero matrix is full-rank). ◀

8 Proof of Theorem 10

8.1 Some basic statistics

All results in this subsection are either classical or straightforward. We collect them here, and provide proofs, partly for completeness, and partly because we will use some of the arguments here in the following.

We first recall the following bound on the number of subspaces of $\mathbb{F}_q^n$.

▶ **Fact 29.**

1. *For $d \leq \mathbb{N}$, $0 \leq d \leq n$, the number of dimension-d subspaces of $\mathbb{F}_q^n$ is equal to the Gaussian binomial coefficient*

$$\binom{n}{d}_q := \frac{(q^n - 1) \cdot (q^n - q) \cdot \ldots \cdot (q^n - q^{d-1})}{(q^d - 1) \cdot (q^d - q) \cdot \ldots \cdot (q^d - q^{d-1})}.$$

2. *The Gaussian binomial coefficient satisfies:*

$$q^{(n-d)d} \leq \binom{n}{d}_q \leq q^{(n-d)d+d}.$$

3. *The number of subspaces of $\mathbb{F}_q^n$ is $q^{\frac{1}{4}n^2+\Theta(n)}$.*

[10] There are several ways of doing this. One approach is to transform the determinant expression into an arithmetic circuit, and then compute along this circuit to get the final polynomial.

Proof. (1) is well-known. For (2), it is enough to verify that for any prime power q, and $n, d, k \in \mathbb{N}$, $n \geq d > k$, we have

$$q^{n-d} \leq \frac{q^n - q^k}{q^d - q^k} \leq q^{n-d+1}.$$

For (3), it is well-known that $\binom{n}{d}_q$ achieves maximal over d at $d = \lfloor n/2 \rfloor$. So we have

$$q^{\frac{1}{4}n^2 - \frac{1}{4}} \leq \binom{n}{\lfloor n/2 \rfloor}_q \leq \sum_{d=0}^{n} \binom{n}{d}_q \leq (n+1) \cdot \binom{n}{\lfloor n/2 \rfloor}_q \leq q^{\frac{1}{4}n^2 + \lfloor n/2 \rfloor + \log(n+1)},$$

from which the result follows. ◀

Analogously, we consider the number of isotropic spaces of a non-degenerate alternating form $A \in \Lambda(n, q)$.

▶ **Proposition 30.** *Let $A \in \Lambda(n, q)$, n even, be a non-degenerate alternating matrix. Then we have the following.*

1. *For $d \in \mathbb{N}$, $0 \leq d \leq n/2$, the number of dimension-d isotropic spaces of A is*

$$I(A, d) := \frac{(q^n - 1) \cdot (q^{n-1} - q) \cdot \ldots \cdot (q^{n-(d-1)} - q^{d-1})}{(q^d - 1) \cdot (q^d - q) \cdot \ldots \cdot (q^d - q^{d-1})}.$$

   For $d \in \mathbb{N}$, $d > n/2$, there are no dimension-d isotropic spaces.
2. *For $d \in \mathbb{N}$, $0 \leq d \leq n/2$, $I(A, d)$ is bounded as follows:*

$$q^{nd - \frac{3}{2}d^2 + \frac{1}{2}d} \leq I(A, d) \leq q^{nd - \frac{3}{2}d^2 + \frac{3}{2}d}.$$

3. *The number of isotropic spaces of A is $q^{\frac{1}{6}n^2 + \Theta(n)}$.*
4. *The number of maximal isotropic spaces of A is $q^{\frac{1}{8}n^2 + \Theta(n)}$.*

Proof. For (1), suppose we have chosen $u_1, \ldots, u_i$ such that $\langle u_1, \ldots, u_i \rangle$ is an isotropic space. We then need to select the next eligible u_{i+1}, such that $\langle u_1, \ldots, u_{i+1} \rangle$ forms an isotropic space. Since u_{i+1} needs to satisfy $u_{i+1}^t A u_j = 0$ for $1 \leq j \leq i$, and A is non-degenerate, u_{i+1} should be from a dimension-$(n-i)$ subspace, namely the subspace orthogonal to Au_j, $1 \leq j \leq i$. Furthermore, u_{i+1} is not in $\langle u_1, \ldots, u_i \rangle$. So there are $q^{n-i} - q^i$ choices of u_{i+1} in the ith step. This explains the numerator. The denominator is of such form, because for each isotropic space there are these many ordered bases.

For (2), it follows from the same argument as the proof for Fact 29 (2).

For (3), note that $nd - \frac{3}{2}d^2$ achieves its maximum at $d = \frac{1}{3}n$.

For (4), note that maximal isotropic spaces are of dimension $n/2$. This is because for any isotropic space U of dimension $d < n/2$, we can choose an eligible u_{d+1} as in the proof for (1), such that $\langle U, u_{d+1} \rangle$ is also an isotropic space. ◀

▶ **Proposition 31.** *Let $A \in \Lambda(n, q)$, n even, be a non-degenerate alternating matrix. Then all isotropic spaces of A can be enumerated in time $q^{\frac{1}{6}n^2 + O(n)}$.*

Proof. We enumerate isotropic spaces according to dimensions in an increasing order. Each subspace of $\mathbb{F}_q^n$ is represented by an ordered basis. We will maintain a list L of all isotropic subspaces, and for each isotropic space U of dimension d, maintain a list of isotropic spaces of dimension $d+1$ that contain U, denoted as $L(U)$. Note that for a fixed U, there are at most q^{n-d} such spaces. In other words, we will record the lattice of isotropic spaces.

Suppose we have enumerated all isotropic spaces of dimensions $\leq d$. To enumerate isotropic spaces of dimension $d+1$, we maintain a list of such spaces. Then for each isotropic space U of dimension d, and for each $u \in \mathrm{rad}(U) \setminus U$, we form $U' = \langle u, U \rangle$, and test whether U' is in $L(U)$. If not, then we add U' to L. We also add it to $L(U)$, and for every dimension d-subspace $\tilde{U}$ of U', add U' to $L(\tilde{U})$. Otherwise we move on.

Clearly, in the above procedure, each isotropic space will added, and only added to L once. This procedure runs in time $N \cdot q^{O(n)}$, where N denotes the number of isotropic spaces of A. We can then conclude by resorting to Proposition 30 (3). ◀

When working with maximal isotropic spaces, it is enough to restrict our attention to just non-degenerate matrix spaces.

▶ **Observation 32.** *For $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, any maximal isotropic space of $\mathcal{A}$ contains* $\mathrm{rad}(\mathcal{A})$.

8.2 A non-trivial upper bound on the number of maximal isotropic spaces

For $\mathcal{A} \leq \Lambda(n, q)$, let $\mathrm{MI}(\mathcal{A})$ be the set of maximal isotropic spaces of $\mathcal{A}$, and $\mathrm{NMI}(\mathcal{A})$ be the number of maximal isotropic spaces of $\mathcal{A}$, e.g. the size of $\mathrm{MI}(\mathcal{A})$. Let $\mathrm{MaxNMI}(n, q)$ be the maximum of $\mathrm{NMI}(\mathcal{A})$ over all $\mathcal{A} \leq \Lambda(n, q)$. By Fact 29 (3) and Proposition 30 (4),

$$q^{\frac{1}{4}n^2+O(n)} \geq \mathrm{MaxNMI}(n, q) \geq q^{\frac{1}{8}n^2+\Omega(n)}.$$

Theorem 10, slightly reformulated

Let $\mathrm{MaxNMI}(n, q)$ be as above. Then $\mathrm{MaxNMI}(n, q) \leq q^{\frac{1}{6}n^2+C\cdot n}$ for some large enough absolute constant C.

Let us illustrate the proof strategy for Theorem 10, before we enter the details.

The starting point of our proof is the alternative proof bounding the number of maximal independent sets by Wood [115].

The core of Wood's argument is the following. Let $G = (V, E)$ be a graph on n vertices. Recall that we want to prove that the number of maximal independent sets in G is no more than $g(n) = 3^{\frac{n}{3}}$. We shall do an induction on n. Let $v \in V$ be a vertex of minimal degree d. Let $N(v)$ be the set of neighbours of v together with v (e.g. the closed neighbourhood of v). Then any maximal independent set I contains some $w \in N(v)$, as otherwise $I \cup \{v\}$ would be a larger independent set. If I contains $w \in N(v)$, then $I \setminus \{w\}$ would be a maximal independent set of $G|_{V \setminus N(w)}$, the induced subgraph of G on $V \setminus N(w)$. Since $G|_{V \setminus N(w)}$ is of size $\leq n - d - 1$, we then have

$$g(n) \leq (d+1) \cdot g(n-d-1). \tag{3}$$

From this relation and the induction hypothesis, the result follows in a rather straightforward fashion.

In the following, we will develop a linear algebraic analogue of Equation 3. However, just applying this does not suffice, when there are many vectors of degree 1.

We remedy this by showing that in this setting, the maximum rank is large, which allows us to use an argument similar to one in Proposition 30. More specifically, recall that in Proposition 30 (3), we showed that the number of isotropic spaces of a non-degenerate alternating matrix is bounded from above by $q^{\frac{1}{6}n^2+O(n)}$. Note that any maximal isotropic space of $\mathcal{A}$ is an isotropic space of any $A \in \mathcal{A}$. So if $\mathcal{A}$ contains a non-degenerate A, we

can immediately obtain Theorem 10 in this case. However, there are non-degenerate matrix spaces that do not contain non-degenerate alternating matrices. For example, the following is an alternating matrix space of maximum rank 2, written in a parametrized form:

$$A = \begin{bmatrix} 0 & x_1 & \dots & x_n \\ -x_1 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ -x_n & 0 & \dots & 0 \end{bmatrix}.$$

For our purpose, we will need to bound the number of isotropic spaces for matrix spaces of rank $> \frac{2}{3}n$. So the following lemma is required; its proof is postponed to Section 8.2.1.

▶ **Lemma 33.** *Let $A \in \Lambda(n, q)$ be of rank $> \frac{2}{3}n$. Then the number of isotropic spaces of A is bounded from above by $q^{\frac{1}{6}n^2+Dn}$ for some large enough absolute constant D.*

We are now ready to prove Theorem 10.

Proof of Theorem 10. Let $\mathcal{A} \leq \Lambda(n, q)$. By Observation 32, for our purpose, we can assume that $\mathcal{A}$ is non-degenerate. Let $g_q(n) = q^{\frac{1}{6}n^2+Cn}$. We prove by an induction on n. Assume $\mathrm{MaxNMI}(\ell, q) \leq g_q(\ell)$ holds for any $\ell < n$. Our goal is to show that $\mathrm{NMI}(\mathcal{A}) \leq g_q(n)$.

Let $d = \min\{\deg_{\mathcal{A}}(v) : v \in \mathbb{F}_q^n, v \neq \mathbf{0}\}$. As $\mathcal{A}$ is non-degenerate, $d \geq 1$. Take any $v \in \mathbb{F}_q^n$ of degree d, and let $c = n - d$ be the codegree of v. Let $N(v) := (\mathbb{F}_q^n \setminus \mathrm{rad}_{\mathcal{A}}(v)) \cup \{v\} = \{u \in \mathbb{F}_q^n : \exists A \in \mathcal{A}, u^t Av \neq 0\} \cup \{v\}$. We call $N(v)$ the closed neighbourhood of v. Note that $|N(v)| = q^n - q^c + 1$.

Let $U \leq \mathbb{F}_q^n$ be a maximal isotropic space of $\mathcal{A}$. Clearly, $U \cap N(v) \neq \emptyset$. As otherwise, we have $U \subseteq \mathrm{rad}(v)$ and $v \notin U$. This is equivalent to that $v \in \mathrm{rad}(U)$ and $v \notin U$. It follows that $U \subsetneq \mathrm{rad}(U)$, so by Observation 17, U is not maximal, a contradiction.

Therefore there exists some $w \in N(v) \cap U$. It follows that $U \subseteq \mathrm{rad}(w)$. Since U is maximal isotropic in $\mathcal{A}$, U is also a maximal isotropic space of $\mathcal{A}|_{\mathrm{rad}(w)}$. As $\deg(w) \geq \deg(v) = d$, $\dim(\mathrm{rad}(w)) \leq c$. Furthermore, note w is an isolated vector in $\mathcal{A}|_{\mathrm{rad}(w)}$. We then have

$$\begin{aligned} \mathrm{NMI}(\mathcal{A}) &\leq \sum_{w \in N(v)} \mathrm{NMI}(\mathcal{A}|_{\mathrm{rad}(w)}) && (4) \\ &\leq (q^n - q^c + 1) \cdot g_q(c-1), && (5) \end{aligned}$$

where the second inequality is due to the induction hypothesis. Note that on the right hand side, we have $g_q(c-1)$ instead of $g_q(c)$, because w is an isolated vector in $\mathcal{A}|_{\mathrm{rad}(w)}$, and Observation 32. The reader may want to compare this with Equation 3.

Now suppose $d \geq 2$, that is, $c \leq n - 2$. We then have

$$\begin{aligned} \mathrm{NMI}(\mathcal{A}) &\leq q^n \cdot g_q(n-3) \\ &\leq q^n \cdot q^{\frac{1}{6}(n-3)^2+C(n-3)} \\ &= q^{\frac{1}{6}n^2+Cn+(\frac{3}{2}-3C)} \\ &\leq q^{\frac{1}{6}n^2+Cn}. \end{aligned}$$

Note that the second inequality is by the induction hypothesis, and the last inequality holds as long as $C \geq 1$.

Now suppose $d = 1$. In this case, Equation 5 is not enough for our purpose. We then need the following refinement. Partition $N(v)$ as $N_1(v) \cup N_{\geq 2}(v)$, where $N_1(v) = \{w \in \mathbb{F}_q^n : w \in N(v), \deg(w) = 1\}$, and $N_{\geq 2}(v) = N(v) \setminus N_1(v)$. A refinement of Equation 4 gives that

$$\mathrm{NMI}(\mathcal{A}) \leq |N_1(v)| \cdot g_q(n-2) + |N_{\geq 2}(v)| \cdot g_q(n-3). \quad (6)$$

If $|N_1(v)| \leq q^{\frac{2}{3}n}$, then we have

$$\begin{aligned}\mathrm{NMI}(\mathcal{A}) &\leq q^{\frac{2}{3}n} \cdot g_q(n-2) + q^n \cdot g_q(n-3)\\ &\leq q^{\frac{2}{3}n} \cdot q^{\frac{1}{6}(n-2)^2+C(n-2)} + q^n \cdot q^{\frac{1}{6}(n-3)^2+C(n-3)}\\ &\leq q^{\frac{1}{6}n^2+Cn+(\frac{2}{3}-2C)} + q^{\frac{1}{6}n^2+Cn+(\frac{3}{2}-3C)}\\ &\leq q^{\frac{1}{6}n^2+Cn-1} + q^{\frac{1}{6}n^2+Cn-1}\\ &\leq q^{\frac{1}{6}n^2+Cn}.\end{aligned}$$

Note that the second inequality is by the induction hypothesis, the second to the last inequality holds as long as $C \geq 1$.

If $|N_1(v)| > q^{\frac{2}{3}n}$, then we first prove the following.

▷ Claim 34. We have $\mathrm{rk}(\mathcal{A}) > \frac{2}{3}n$.

Proof for Claim 34. Suppose $\dim(\mathcal{A}) = m$. Let $s = \lfloor \frac{2}{3}n \rfloor + 1$, the smallest integer larger than $\frac{2}{3}n$. We will show that there exists a linear basis of some $\tilde{\mathcal{A}}$ that is isometric to $\mathcal{A}$, $\tilde{A}_1, \ldots, \tilde{A}_m \in \Lambda(n, q)$, such that

$$\tilde{A}_1 = \begin{bmatrix} B_1 & -C_1^t \\ C_1 & D_1 \end{bmatrix}, \tilde{A}_2 = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & D_2 \end{bmatrix}, \ldots, \tilde{A}_m = \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & D_m \end{bmatrix}, \tag{7}$$

where $B_1 \in \Lambda(s, q)$, $C_1 \in M((n-s) \times s, q)$, and $D_i \in \Lambda(n-s, q)$. From this linear basis, it is clear that $\begin{bmatrix} B_1 \\ C_1 \end{bmatrix}$ is of rank $s > \frac{2}{3}n$, as otherwise $\tilde{\mathcal{A}}$ would be degenerate. It would follow then that $\mathrm{rk}(\mathcal{A}) = \mathrm{rk}(\tilde{\mathcal{A}}) > \frac{2}{3}n$.

We first start with an arbitrary linear basis of $\mathcal{A}$, say $A_1, \ldots, A_m \in \Lambda(n, q)$. Recall that v is of degree 1, and $|N_1(v)| > q^{\frac{2}{3}n}$. For later convenience, rename v as u_1. Then there exist $u_2, u_3, \ldots, u_s \in \mathbb{F}_q^n$, such that for $i \geq 2$, $u_i \in N_1(v)$, and $u_1, \ldots, u_s$ are linearly independent. As otherwise, suppose the maximum number of linearly independent u_i's from $N_1(v)$ we can find is $t < s$. Then since $N_1(v) > q^{\frac{2}{3}n} \geq q^t = |\langle u_1, \ldots, u_t \rangle|$, we can find $u_{t+1} \in N_1(v) \setminus \langle u_1, \ldots, u_t \rangle$, a contradiction.

We then can arrange a change of basis matrix T whose first s columns are $u_1, \ldots, u_s$. Apply this change of basis matrix T (by $T^t \cdot T$) to $A_1, \ldots, A_m$ to get a linear basis $\bar{A}_1, \ldots, \bar{A}_m$ for $\bar{\mathcal{A}} = T^t \mathcal{A} T$. Recall that e_i denotes the ith standard basis vector. Since u_i's are of degree 1, for any $i \in [s]$, we have $\bar{\mathcal{A}}(e_i)$ is of dimension 1. For $2 \leq i \leq s$, since $u_i \in N(v)$, we have

$$e_i^t(\bar{A}_1, \ldots, \bar{A}_m)e_1 \neq (0, \ldots, 0). \tag{8}$$

Without loss of generality, assume $\bar{A}_1 e_1 \neq \mathbf{0}$. As $\bar{\mathcal{A}}(e_1)$ is of dimension 1, we have for any $2 \leq j \leq m$, $\bar{A}_j e_1 = \lambda_j \bar{A}_1 e_1$ for some $\lambda_j \in \mathbb{F}_q$. We claim that for any $2 \leq i \leq s$, the ith entry of $\bar{A}_1 e_1$, $\bar{A}_1 e_1(i) \neq 0$. If not, then for any $2 \leq j \leq m$, $\bar{A}_j e_1(i) = \lambda_j \bar{A}_1 e_1(i) = 0$. This is equivalent to say that $e_i^t(\bar{A}_1, \ldots, \bar{A}_m)e_1 = 0$, contradicting Equation 8.

As $\bar{A}_i$'s are alternating matrices, we have for any i, j, k, $(\bar{A}_i e_j)(k) = -(\bar{A}_i e_k)(j)$. It follows that for $2 \leq i \leq s$, $\bar{A}_1 e_i(1) = -\bar{A}_1 e_1(i) \neq 0$, and for $2 \leq j \leq m$, $\bar{A}_j e_i(1) = -\bar{A}_j e_1(i) = -\lambda_j \bar{A}_1 e_1(i) = \lambda_j \bar{A}_1 e_i(1)$. Since $\bar{\mathcal{A}}(e_i)$ is of dimension 1 for $2 \leq i \leq s$, we infer that for $2 \leq j \leq m$ and $2 \leq i \leq s$, $\bar{A}_j e_i = \lambda_j \bar{A}_1 e_i$. We then let $\tilde{A}_1 = \bar{A}_1$, and for $2 \leq j \leq m$, $\tilde{A}_j = \bar{A}_j - \lambda_j \bar{A}_1$. Clearly, $\tilde{A}_1, \ldots, \tilde{A}_m$ still form a basis of $\tilde{\mathcal{A}}$, and they are of the form in Equation 7. The claim then follows. ◁

Combining Claim 34 and Lemma 33, the proof is concluded. ◀

8.2.1 Proof of Lemma 33

Let c be the corank of A. We then have $c < \frac{1}{3}n$.

Let $(u_1, \ldots, u_d)$ be an ordered basis of an isotropic space U of A of dimension d. For $i \in [d]$, let $U_i = \langle u_1, \ldots, u_i \rangle$, and let $a_i = \dim(A(U_i))$. We also let $U_0 = \mathbf{0}$, and $a_0 = 0$. Note that $U = U_d$, and we also let $a = a_d$. We call such an isotropic space of (d, a) type. Note that $\dim(\langle U_i, \mathrm{rad}(A) \rangle) = \dim(U_i) + \dim(\mathrm{rad}(A)) - \dim(U_i \cap \mathrm{rad}(A)) = \dim(A(U_i)) + \dim(\mathrm{rad}(A)) = a_i + c$.

After fixing $u_1, \ldots, u_i$, a valid u_{i+1} can come from two sources.

1. If $u_{i+1} \notin \langle U_i, \mathrm{rad}(A) \rangle$, then since u_{i+1} needs to satisfy $u_{i+1}^t A u_j = 0$ for $j = 1, \ldots, i$, the number of choices of u_{i+1} is upper bounded by $q^{n-a_i} - q^i$.
2. If $u_{i+1} \in \langle U_i, \mathrm{rad}(A) \rangle$, then the number of choices of u_{i+1} is upper bounded by $q^{c+a_i} - q^i$.

So the following indices are important: for $i \in [a]$, let b_i be the smallest $j \in [d]$ such that $a_j = \dim(A(U_j)) = i$. We then have $0 < b_1 < b_2 < \cdots < b_a \leq d$. We also let $b_0 = 0$ and $b_{a+1} = d$. We call such an ordered basis of $(b_1, \ldots, b_a)$ type of an isotropic space of (d, a) type.

The number of possible types of an isotropic space is trivially upper bounded by n^2, and the number of possible types of ordered bases of isotropic spaces of type (d, a) is upper bounded by $\binom{d}{a} \leq 2^d \leq 2^n$. So by a multiplicative factor of $n^2 \cdot 2^n$, we can restrict to consider ordered basis $(u_1, \ldots, u_d)$ of a fixed type $\mathbf{b} = (b_1, \ldots, b_a)$. By the discussion above, if $j = b_i$, then the number of choices for u_j is upper bounded by $t_{d,a,\mathbf{b}}(j) := q^{n-(i-1)} - q^{j-1}$. If $b_i < j < b_{i+1}$, the number of choices for u_j is upper bounded by $t_{d,a,\mathbf{b}}(j) := q^{c+i} - q^{j-1}$. Recall that $(q^n - q^i)/(q^d - q^i) \leq q^{n-d+1}$, for any q and $i < d \leq n$. If $j = b_i$, we have

$$t_{d,a,\mathbf{b}}(j)/(q^d - q^{j-1}) \leq q \cdot q^{n-(i-1)-d}. \tag{9}$$

If $b_i < j < b_{i+1}$, we have

$$t_{d,a,\mathbf{b}}(j)/(q^d - q^{j-1}) \leq q \cdot q^{(c+i)-d} \leq q \cdot q^{(c+a)-d} \tag{10}$$

Each dimension-d subspace of $\mathbb{F}_q^n$ has $(q^d - 1)(q^d - q) \ldots (q^d - q^{d-1})$ ordered bases, and each ordered basis of an isotropic space of type (d, a) is of a particular type. The number of dimension-d isotropic spaces of type (d, a) can be upper bounded by

$$\begin{aligned}
& \sum_{\text{type } \mathbf{b}=(b_1,\ldots,b_a)} \frac{t_{d,a,\mathbf{b}}(1) \cdot \ldots \cdot t_{d,a,\mathbf{b}}(d)}{(q^d - 1) \cdot \ldots \cdot (q^d - q^{d-1})} \\
= & \sum_{\text{type } \mathbf{b}=(b_1,\ldots,b_a)} \frac{t_{d,a,\mathbf{b}}(1)}{q^d - 1} \cdot \ldots \cdot \frac{t_{d,a,\mathbf{b}}(j)}{q^d - q^{j-1}} \cdot \ldots \cdot \frac{t_{d,a,\mathbf{b}}(d)}{q^d - q^{d-1}} \\
\leq & \sum_{\text{type } \mathbf{b}=(b_1,\ldots,b_a)} q^d \cdot q^{na - \sum_{i=1}^{a}(i-1) - da} \cdot q^{(c+a)(d-a) - d(d-a)} \\
\leq & \; 2^n \cdot q^{na - a^2/2 + (c+a)(d-a) - d^2 + d + a/2}.
\end{aligned}$$

Let us explain the first inequality. The q^d term is because of the q terms on the right hand sides of Equations 9 and 10. The $q^{na - \sum_{i=1}^{a}(i-1) - da}$ is by collecting those terms from Equation 9, and the $q^{(c+a)(d-a) - d(d-a)}$ term is by collecting those terms from Equation 10.

It is then clear that we need to bound $f(n, d, a) = na - a^2/2 + (c + a)(d - a) - d^2$ for $1 \leq a \leq d \leq n$. After some arrangement, we have

$$f(n, d, a) = -\frac{3}{2}(a - \frac{1}{3}(n + d - c))^2 + \frac{1}{6}(n + d - c)^2 - d^2 + dc.$$

We then distinguish between two cases.

1. Case (i): when $\frac{1}{3}(n+d-c) \le d$ holds, namely $d \ge (n-c)/2$. Only in this case, a can be set to $\frac{1}{3}(n+d-c)$, and the maximum can be set to $g(n,d) := \frac{1}{6}(n+d-c)^2 - d^2 + dc$. After some arrangement, we have

$$g(n,d) = -\frac{5}{6}(d - \frac{1}{5}(n+2c))^2 + \frac{1}{30}(n+2c)^2 + \frac{1}{6}(n-c)^2.$$

Since $c < n/3$, we have $(n-c)/2 > (n+2c)/5$. Recall that $d \ge (n-c)/2$. So $g(n,d)$ achieves maximal at $d = (n-c)/2$. Plugging this in, the maximal value is

$$h(n) := g(n,(n-c)/2) = -\frac{3}{8}(c - \frac{1}{3}n)^2 + \frac{1}{6}n^2 < \frac{1}{6}n^2.$$

2. Case (ii): when $\frac{1}{3}(n+d-c) > d$ holds, namely $d < (n-c)/2$. In this case, $f(n,d,a)$ achieves the maximal value at $a = d$, and

$$f(n,d,d) = -\frac{3}{2}(d - \frac{1}{3}n)^2 + \frac{1}{6}n^2 \le \frac{1}{6}n^2,$$

where the inequality becomes an equality at $d = n/3$.

Since in both cases, the maximal value is no more than $\frac{1}{6}n^2$, we can then conclude the proof.

8.3 Turning Theorem 10 into an algorithm

The proof of Theorem 10 can be turned into an algorithm for enumerating all maximal isotropic spaces in time $q^{\frac{1}{6}n^2+O(n)}$. We briefly indicate some algorithmic issues for doing this. Firstly, note that in time $q^{O(n)}$, one can compute $\deg_{\mathcal{A}}(v)$ for all $v \in \mathbb{F}_q^n$. Secondly, the Equation 4 naturally suggests a recursive algorithm structure. In the cases when $d \ge 2$, or $d = 1$ and $|N_1(v)| \le q^{\frac{2}{3}n}$, this recursive structure readily gives the desired algorithm. If $d = 1$ and $|N_1(v)| > q^{\frac{2}{3}n}$, we need to make the proofs of Claim 34 and Lemma 33 constructive. Then for each isotropic space of some $A \in \Lambda(n,\mathbb{F})$, A of rank $> \frac{2}{3}n$, test whether it is maximal using Observation 17.

For Claim 34, note that the selection of u_i's from $N_1(v)$ can be done easily in a greedy way. Other steps are readily constructive. For Lemma 33, we use the same procedure as in Proposition 31, whose running time is bounded in time $q^{\frac{1}{6}n^2+O(n)}$ by Lemma 33.

We then have the following.

▶ **Corollary 35.** *Given $\mathcal{A} \le \Lambda(n,q)$, all maximal isotropic spaces can be enumerated in time $q^{\frac{1}{6}n^2+O(n)}$.*

9 Proof of Theorem 11

Review of Lawler's algorithm

We first review Lawler's dynamic programming idea for computing the chromatic number [72], and then adapt that idea to our problem.

Given a graph $G = (V,E)$, Lawler's algorithm for computing $\chi(G)$ goes as follows. The idea is to build a table storing $\chi(H)$ for every induced subgraph H of G. Note that this table is of size 2^n. To fill in this table, the starting point is the empty graph with chromatic number 0. Suppose we have computed the chromatic numbers of those induced subgraphs of size $< \ell$. Let $H = (U,F)$ be an induced subgraph of size ℓ. Then the chromatic number of H can be computed by the following formula:

$$\chi(H) = 1 + \min_{I \subseteq U}\{\chi(H[U \setminus I])\},$$

where I goes over all maximal independent sets of H, and $H[U \setminus I]$ is the induced subgraph of H restricting to vertex set $U \setminus I$. Since there are at most $3^{\ell/3}$ maximal independent sets of H and they can be enumerated in time $O(3^{\ell/3} \cdot n)$, the exponential part of the time complexity of this algorithm is $\sum_{\ell=0}^{n} \binom{n}{\ell} \cdot 3^{\ell/3} = (1 + \sqrt[3]{3})^n$.

Directly applying Lawler's idea to isotropic numbers

The above idea can be adapted to compute $\chi(\mathcal{A})$ for $\mathcal{A} \leq \Lambda(n, q)$ as follows. To start with, recall that in the above algorithm we used the following simple fact: if a graph G admits a vertex c-coloring, then there is a vertex c-coloring in which one part is a maximal independent set. We leave the reader to check that the analogue of this fact in the alternating matrix space setting also holds.

Given $\mathcal{A} \leq \Lambda(n, q)$, we also store a table storing $\chi(\mathcal{B})$ for every induced alternating matrix spaces $\mathcal{B}$ of $\mathcal{A}$. Note that this table is of size $q^{\frac{1}{4}n^2+O(n)}$. To fill in this table, the starting point is the zero space with isotropic decomposition number 0. Suppose we have computed the isotropic decomposition numbers of those induced alternating matrix spaces of dimension $< \ell$. Let $\mathcal{B} \leq \Lambda(\ell, q)$ be an induced alternating matrix space corresponding to $U \leq \mathbb{F}_q^n$ of dimension ℓ. Then the isotropic decomposition number of $\mathcal{B}$ can be computed by the following formula

$$\chi(\mathcal{B}) = 1 + \min_{V \leq U, W \leq U} \{\chi(\mathcal{B}|_W)\},$$

where V goes over all maximal isotropic spaces of $\mathcal{B}$, and W goes over all complement subspaces of V in U. Note that here we also need to enumerate all complements of V, while in the graph setting, the complement set is unique. Recall that by Theorem 10, there are at most $q^{\frac{1}{6}\ell^2+O(\ell)}$ maximal isotropic spaces of $\mathcal{B}$, and they can be enumerated in time $q^{\frac{1}{6}\ell^2+O(\ell)}$. This gives a bound on the number of V. We bound the number of W using the trivial $q^{\frac{1}{4}\ell^2+O(\ell)}$ bound. Note that we will need to test whether W is a complement of V, which can be done easily. Another more efficient approach would be to enumerate all complements of U in time $q^{d(n-d)} \cdot \mathrm{poly}(n, \log q)$ (see [76, Proposition 17 in the arXiv version]).

So to fill in those entries corresponding to alternating matrix spaces induced by ℓ-dimensional subspaces, the time complexity is bounded by

$$\begin{aligned}
& \binom{n}{\ell}_q \cdot q^{\frac{1}{6}\ell^2+O(\ell)} \cdot q^{\frac{1}{4}\ell^2+O(\ell)} \\
\leq\ & q^{\ell(n-\ell)+\ell} \cdot q^{\frac{1}{6}\ell^2+O(\ell)} \cdot q^{\frac{1}{4}\ell^2+O(\ell)} \\
=\ & q^{\ell n - \frac{7}{12}\ell^2+O(\ell)} \\
=\ & q^{-\frac{7}{12}(\ell-\frac{6}{7}n)^2+\frac{3}{7}n^2+O(\ell)} \\
\leq\ & q^{\frac{3}{7}n^2+O(n)}.
\end{aligned}$$

Summing over $\ell \in \{0, 1, \ldots, n\}$, we see that the total time complexity is also bounded by $q^{\frac{3}{7}n^2+O(n)}$.

A new dynamic programming scheme

In the above, we see that directly following Lawler's dynamic programming scheme does lead to an improved algorithm for computing the isotropic decomposition number. However, a key difference with the classical setting, namely the magnitude of complement subspaces, impacts the analysis. In the following, we shall use another dynamic programming scheme, still combined with the $q^{\frac{1}{6}n^2+O(n)}$ upper bound on the number of maximal isotropic spaces, to achieve the $q^{\frac{5}{12}n^2+O(n)}$ running time as promised in Theorem 11.

To do that, we first make a simple observation.

▶ **Observation 36.** *Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. Then $\chi(\mathcal{A}) \leq k$, if and only if, there exist k maximal isotropic spaces $U_1, \ldots, U_k$, such that $\mathbb{F}^n = \langle \cup_{i\in[k]} U_i \rangle$.*

Proof. For the only if direction, recall that every isotropic space is contained in a maximal one. For the if direction, note that from $U_1, \ldots, U_k$, we can construct $U'_1, \ldots, U'_k$, such that $U'_i \leq U_i$, and $U'_1, \ldots, U'_k$ form a direct sum decomposition of $\mathbb{F}^n$. This shows that $\chi(\mathcal{A}) \leq k$. ◀

The key to our algorithm is the following function. For $k \in [n]$ and $W \leq \mathbb{F}_q^n$, let $f(k, U)$ be the boolean function such that $f(k, W) = 1$ if and only if $W = \langle \cup_{i\in[k]} U_i : U_i \text{ maximal isotropic} \rangle$. For example, $f(1, W) = 1$ if and only if W is a maximal isotropic space.

The following is then a dynamic programming scheme computing $f(k, W)$ for every $k \in [n]$ and $W \leq \mathbb{F}_q^n$. Let $\mathcal{A} \leq \Lambda(n, q)$ be an alternating matrix space. We assume that $\chi(\mathcal{A}) > 1$, as $\chi(\mathcal{A}) = 1$ if and only if $\mathcal{A}$ is the zero space.

1. Use Corollary 35 to compute the set of maximal isotropic spaces of $\mathcal{A}$, and let MI be this set.
2. Build a table f, indexed by (k, W) where $k \in [n]$ and $W \leq \mathbb{F}_q^n$, and initiate $f(k, W) = 0$ for every k and W.
3. For every $W \leq \mathbb{F}_q^n$, do:
   a. If W is maximal isotropic, then $f(1, W) = 1$.
4. For $k = 2, \ldots, n$, do:
   a. For every $W \leq \mathbb{F}_q^n$ and every $T \in MI$, do:
      i. If $f(k-1, W) = 1$, then let $U = \langle W \cup T \rangle$, and set $f(k, U) = 1$.
      ii. If $U = \mathbb{F}_q^n$, then return "$\chi(\mathcal{A}) = k$."

To prove the correctness of the algorithm, we first note that by induction, the algorithm correctly computes $f(k, W)$ for every k and W. Then suppose the algorithm returns with reporting that $\chi(\mathcal{A}) = k$. Note that in this case, it does find k maximal isotropic subspaces covering the whole space $\mathbb{F}_q^n$. So by Observation 36, $\chi(\mathcal{A}) \leq k$. So we are left to show that $\chi(\mathcal{A}) \geq k$. By way of contradiction, suppose $\chi(\mathcal{A}) = k' < k$, so by Observation 36, there exist maximal isotropic subspaces $U_1, \ldots, U_{k'}$ that cover $\mathbb{F}_q^n$. Let $W = \langle U_2 \cup \cdots \cup U_{k'} \rangle$. Then W is a proper subspace of $\mathbb{F}_q^n$, as otherwise by Observation 36 $\chi(\mathcal{A}) \leq k' - 1 < k'$, contradicting that $\chi(\mathcal{A}) = k'$. But this means that $f(k' - 1, W) = 1$, so in Step (4.a), when enumerating W and $T = U_1$, the algorithm would go through steps (4.a.i) and (4.a.ii), and outputs that $\chi(\mathcal{A}) = k'$. This gives us the desired contradiction.

To estimate the running time of the algorithm, note that Step (1) costs $q^{\frac{1}{6}n^2+O(n)}$ by Corollary 35. All subspaces can be enumerated in time $q^{\frac{1}{4}n^2+O(n)}$ by the same technique as in the proof of Proposition 31. The total running time is then dominated by the loop in steps (4) and (4.a), which is $n \cdot q^{\frac{1}{6}n^2+O(n)} \cdot q^{\frac{1}{4}n^2+O(n)} = q^{\frac{5}{12}n^2+O(n)}$. This concludes the proof of Theorem 11.

10 Proofs for Propositions 12 and 13

Proof of Proposition 12. When $\mathbb{F} = \mathbb{C}$ and the input instance is over $\mathbb{Z}$, we shall formulate the maximum isotropic space problem as a problem about the solvability of a system of integeral polynomial equations over $\mathbb{C}$. The result would follow then by using Koiran's result that the Hilbert Nullstellensatz is in PH, assuming the generalized Riemann hypothesis [69]. We first cite Koiran's result as follows, following the formulation of [86, Theorem 2.10].

▶ **Theorem 37** ([69]). *The problem Hilbert's Nullstellensatz of deciding whether a given system of multivariate integral polynomials, specified as arithmetic circuits, has a solution over* $\mathbb{C}$ *is in PSPACE unconditionally, and in* $RP^{NP} \subseteq \Pi_2$ *assuming the generalized Riemann hypothesis.*

Therefore, to put the maximum isotropic space problem over $\mathbb{C}$ in PSPACE unconditionally, and in PH assuming the generalized Riemann hypothesis, for instances given by integral alternating matrices, we only need to formulate this problem as deciding the solvability of a system of integral polynomials represented by arithmetic circuits. This can be done as follows. Suppose we are given $\mathcal{A} = \langle A_1, \ldots, A_m \rangle \leq \Lambda(n, \mathbb{C})$ where A_i's are integral matrices, and we want to know whether there exists an isotropic space of dimension d for $\mathcal{A}$. Then $\mathcal{A}$ has an isotropic space of dimension d if and only if there exists an invertible matrix T such that for any $i \in [m]$, the left-upper $d \times d$ submatrix of $T^t A_i T$ consists of all zero entries. We then set up an $n \times n$ variable matrix $X = (x_{i,j})_{i,j \in [n]}$, and a variable y. For every $i \in [m]$, set the entries of the left-upper $d \times d$ submatrix of $X^t A_i X$ to be zero. This gives md^2 integral quadratic polynomials in $x_{i,j}$'s. To enforce that the valid solutions are from invertible matrices, we set up the equation $\det(X) \cdot y = 1$, which is also an integral polynomial. Note that the polynomial $\det(X)$ can be expressed as a small arithmetic circuit. It is straightforward to verify that these $(md^2 + 1)$ equations in $x_{i,j}$ and y have a non-trivial solution if and only if $\mathcal{A}$ has a dimension-d isotropic space.

For isotropic 3-decomposition problem, the idea is basically the same. The only small complication is that we need to specify the dimensions of the three isotropic spaces in a 3-isotropic decomposition. But the number of possibilities is at most n^3, which we can enumerate. After fixing some (d_1, d_2, d_3), where $d_i \in \mathbb{Z}^+$, $n \geq d_1 \geq d_2 \geq d_3 \geq 1$, and $d_1 + d_2 + d_3 = n$, we can construct a system of integral polynomial equations to express the condition that there exists a 3-isotropic decomposition with these dimensions, just as in the case of the maximum isotropic space problem. This concludes the proof. ◀

Proof of Proposition 13. Recall that we have $\mathcal{A} \leq \Lambda(n, \mathbb{F})$, and our goal is to prove $\chi(\mathcal{A}) \leq O(\Delta(\mathcal{A}) \cdot \log n)$. Here, $\Delta(\mathcal{A}) := \max\{\deg_{\mathcal{A}}(v) : v \in \mathbb{F}^n\}$, and $\deg_{\mathcal{A}}(v) := \dim(\langle Av : A \in \mathcal{A} \rangle)$. We will also use a greedy algorithm to construct an isotropic C-decomposition with $C \leq O(\Delta(\mathcal{A}) \cdot \log n)$.

For $v \in \mathbb{F}^n$, recall that $\mathrm{rad}_{\mathcal{A}}(v) = \{u \in \mathbb{F}^n : u^t A v = 0\}$. Consider the following algorithm.

1. Set $k = 0$, and $U = \mathbf{0}$;
2. While $\dim(U) < n$, do:
   a. Set $k = k + 1$;
   b. Let W be any complementary subspace of U;
   c. Let $S = \emptyset$;
   d. While $\dim(W) > |S|$, do:
      i. Take any $w \in W \setminus \langle S \rangle$; // $\langle \emptyset \rangle := \mathbf{0}$
      ii. $S = S \cup w$;
      iii. $W = W \cap \mathrm{rad}_{\mathcal{A}}(w)$;
   e. Let $U_k = \langle S \rangle$;
   f. $U = \langle U \cup U_k \rangle$;
3. Return $U_1 \oplus U_2 \oplus \cdots \oplus U_k$.

We first argue that $U_1 \oplus U_2 \oplus \cdots \oplus U_k$ is an isotropic k-decomposition of $\mathcal{A}$. To see this, we note that because of Step (2.d.iii), the condition $W \subseteq \mathrm{rad}(\langle S \rangle)$ holds in the loop of Step (d), so $\langle S \rangle$ maintains as an isotropic space by Observation 17.

We then show that $k = O(\Delta(\mathcal{A}) \cdot \log n)$ when the algorithm terminates. For this, let $d_i = \dim(U_i)$, and $D_i = d_1 + \cdots + d_i$. Observe that $\dim(\mathrm{rad}_{\mathcal{A}}(w)) \geq n - \Delta(\mathcal{A})$. It follows that $\dim(W \cap \mathrm{rad}_{\mathcal{A}}(w)) = \dim(W) + \dim(\mathrm{rad}_{\mathcal{A}}(w)) - \dim(\langle W \cup \mathrm{rad}_{\mathcal{A}}(w)\rangle) \geq \dim(W) + (n - \Delta(\mathcal{A})) - \dim(\langle W \cup \mathrm{rad}_{\mathcal{A}}(w)\rangle) \geq \dim(W) - \Delta(\mathcal{A})$. Therefore, in the computing procedure of U_i, we have $d_i = \dim(U_i) \geq \frac{n - D_{i-1}}{\Delta(\mathcal{A})}$. This implies that $n - D_i = n - D_{i-1} - d_i \leq (n - D_{i-1})(1 - 1/\Delta(\mathcal{A}))$. Therefore, adding a new U_i to the direct sum decomposition decreases the value of $n - D_i$ by a factor of at least $1 - 1/\Delta(\mathcal{A})$. Therefore the algorithm terminates in at most $\log_{1-1/\Delta(\mathcal{A})} \frac{1}{n} = O(\Delta(\mathcal{A}) \cdot \log n)$ steps. ◀

11 Proofs of theorems 14 and 15

In this section we prove theorems 14 and 15. While the proofs are straightforward for experts, we include details for completeness. We shall refer to some facts in Section 3.1 from time to time.

Proof of Theorem 14. Recall that the goal is to show that deciding whether a matrix group contains an abelian subgroup of order $\geq s$ is NP-hard for some $s \in \mathbb{N}$. We shall reduce the maximum isotropic space problem, which is NP-hard by Corollary 4, to this problem.

For this we shall need the following classical construction[11]. Let p be an odd prime, and let $\mathcal{A} \leq \Lambda(n, p)$ be given by an ordered linear basis $\mathbf{A} = (A_1, \ldots, A_m)$. Recall that e_i denotes the ith standard basis vector. From $\mathbf{A}$, for $i \in [n]$, construct $B_i = [A_1 e_i, \ldots, A_m e_i] \in \mathrm{M}(n \times m, p)$. That is, the jth column of B_i is the ith column of A_j. Then for $i \in [n]$, construct

$$\tilde{B}_i = \begin{bmatrix} 1 & e_i^t & 0 \\ 0 & I_n & B_i \\ 0 & 0 & I_m \end{bmatrix} \in \mathrm{GL}(1 + n + m, p),$$

and for $j \in [m]$, construct

$$\tilde{C}_j = \begin{bmatrix} 1 & 0 & e_j^t \\ 0 & I_n & 0 \\ 0 & 0 & I_m \end{bmatrix} \in \mathrm{GL}(1 + n + m, p).$$

Let $G_{\mathbf{A}}$ be the matrix group generated by $\tilde{B}_i$ and $\tilde{C}_j$. Then it can be verified easily that, $G_{\mathbf{A}}$ is isomorphic to the Baer group (see Section 3.1) corresponding to the alternating bilinear map defined by $\mathbf{A}$ (see Appendix B). In particular, $[G, G] \cong \mathbb{Z}_p^m$, and $G/[G, G] \cong \mathbb{Z}_p^n$. By the correspondence between isotropic spaces of $\mathcal{A}$ and abelian normal subgroups of $G_{\mathbf{A}}$ containing the commutator subgroup (see Section 3.1), deciding whether $\mathcal{A}$ has an isotropic space of dimension $\geq d$ is equivalent to deciding whether $G_{\mathbf{A}}$ has an abelian subgroup of order $\geq s = p^{m+d}$. This completes the reduction. ◀

Proof of Theorem 15. Let P be a p-group of class 2 and exponent p, and let $\phi : P/[P, P] \times P/[P, P] \to [P, P]$ be the commutator map. The proof of Theorem 15 basically follows from the correspondence between abelian subgroup containing $[P, P]$ and isotropic spaces of ϕ as described in Section 3.1. The only small caveat here is that we need a bound on the dimension of $P/Z(P)$ instead of the dimension of $P/[P, P]$. To overcome this, we first observe that a maximal abelian subgroup of P necessarily contains the center $Z(P)$, which in turn contains $[P, P]$ by the class-2 condition. Then we only need to note that $Z(P)/[P, P]$ corresponds to the radical of ϕ, and recall that the number of maximal isotropic spaces only depends on the non-degenerate part of ϕ by Observation 32. The proof then can be concluded. ◀

[11] We thank James B. Wilson for communicated this construction to us.

12 A quantum variant of the theory

One way to extend isotropic spaces and isotropic decompositions to the quantum information setting is as follows. Briefly speaking, firstly we restrict to the complex number field $\mathbb{C}$. Secondly, instead of tuples of alternating matrices, we will consider tuples of matrices which represent a so-called irreducible quantum channels. Thirdly, instead of general linear groups, we will consider unitary groups.

For detailed explanations, we need some notation. For $A \in \mathrm{M}(n, \mathbb{C})$ we use $A \succeq 0$ to denote that A is positive semi-definite, and $A \succ 0$ to denote that A is positive definite. For $\mathsf{B} = \{B_1, \ldots, B_m\} \subseteq \mathrm{M}(n, \mathbb{C})$, we let $\tilde{\mathsf{B}} : \mathrm{M}(n, \mathbb{C}) \to \mathrm{M}(n, \mathbb{C})$ be the function sending $A \in \mathrm{M}(n, \mathbb{C})$ to $\sum_{i=1}^{m} B_i A B_i^\dagger$. It is clear that $\tilde{\mathsf{B}}$ can be represented as an $n^2 \times n^2$ matrix $\sum_{i=1}^{m} B_i \otimes B_i^*$, where B_i^* stands for the entry-wise complex conjugation of B_i.

Let $\mathrm{D}(n, \mathbb{C}) \subseteq \mathrm{M}(n, \mathbb{C})$ be the set of $n \times n$ semi-positive definite matrices with unit trace over $\mathbb{C}$, and let $\mathrm{D}^+(n, \mathbb{C}) \subseteq \mathrm{D}(n, \mathbb{C})$ consist of those positive definite matrices in $\mathrm{D}(n, \mathbb{C})$. Elements from $\mathrm{D}(n, \mathbb{C})$ are known as quantum states.

Let $\mathrm{QC}(n, \mathbb{C})$ be the set of sets of matrices $\mathsf{B} = \{B_1, \ldots, B_m\} \subseteq \mathrm{M}(n, \mathbb{C})$ satisfying $\sum_{i=1}^{m} B_i^\dagger B_i = I$. Functions of the form $\tilde{\mathsf{B}}$ for $\mathsf{B} \in \mathrm{QC}(n, \mathbb{C})$ are known as quantum channels, as they are completely positive and trace preserving.

We then define isotropic spaces and decompositions in the quantum setting. To define isotropic spaces, we essentially follow the same pattern as in the alternating matrix space setting. For isotropic decompositions, we shall require that the direct sum decomposition is also an orthogonal one, as the underlying spaces of quantum channels are Hilbert spaces which come with a norm.

▶ **Definition 38.** *Let* $\mathsf{B} = \{B_1, \ldots, B_m\} \in \mathrm{QC}(n, \mathbb{C})$. *An isotropic space of* B *is a subspace* $U \leq \mathbb{C}^n$, *such that for any* $u, u' \in U$, *and any* B_i, *we have* $u^\dagger B_i u' = 0$. *An isotropic c-decomposition of* B *is an orthogonal direct sum decomposition of* $\mathbb{C}^n = U_1 \oplus U_2 \oplus \cdots \oplus U_c$ *such that each* U_i *is a non-zero isotropic space of* B.

12.1 From connected graphs to irreducible quantum channels

In this subsection, we establish a connection between independent sets and vertex colorings of connected graphs, and isotropic spaces and decompositions of a particular type of quantum channels, called irreducible channels (defined below).

We obtain two main results. The first result, Proposition 40, reduces certain problems for connected graphs to the corresponding ones for irreducible quantum channels. This result corresponds to Theorem 3. The second result, Theorem 42, gives an efficient algorithm for isotropic 2-decomposition in this setting. This result corresponds to Theorem 5, but the techniques are completely different.

Let $\mathrm{IQC}(n, \mathbb{C}) \subseteq \mathrm{QC}(n, \mathbb{C})$ consist of those $\mathsf{B} \in \mathrm{QC}(n, \mathbb{C})$ satisfying the following: there exists a unique fixed $\rho \in \mathrm{D}(n, \mathbb{C})$ of $\tilde{\mathsf{B}}$, and further $\rho \in \mathrm{D}^+(n, \mathbb{C})$, where ρ is said to be fixed of $\tilde{\mathsf{B}}$ if $\tilde{\mathsf{B}}(\rho) = \rho$. Such B and $\tilde{\mathsf{B}}$ are called *irreducible*. Irreducible quantum channels have been studied in e.g. [36] and [114, Sec. 6.2]. In particular, the definition of irreducible quantum channels follows from [36, Theorem 13]. Furthermore, given $\mathsf{B} \in \mathrm{QC}(n, \mathbb{C})$, let M be the $n^2 \times n^2$ matrix representation of $\tilde{\mathsf{B}}$. Then $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$ if and only if the algebraic and geometric multiplicities of the eigenvalue 1 of M are both 1, and any 1-eigenvector is of full-rank.

We first observe that a simple and connected graph can be realized as an irreducible quantum channel as follows. This is classical, but for completeness we spell out the details. Let $G = ([n], E)$ be a connected graph. For each $i \in [n]$, let d_i be the degree of i. We construct the following set of matrices $\mathsf{B}_G = \{\frac{1}{\sqrt{d_j}} \cdot E_{i,j}, \frac{1}{\sqrt{d_i}} \cdot E_{j,i} : \{i,j\} \in E\}$. Note that $|\mathsf{B}_G| = 2|E|$.

▶ **Proposition 39.** *Let G and B_G be as above. Then $\mathsf{B}_G \in \mathrm{IQC}(n, \mathbb{C})$.*

Proof. We first verify that $\tilde{\mathsf{B}}_G$ is a quantum channel. For this, observe that $(\frac{1}{\sqrt{d_j}} \cdot E_{i,j})^\dagger \frac{1}{\sqrt{d_j}} \cdot E_{i,j} = \frac{1}{d_j} E_{j,i} E_{i,j} = \frac{1}{d_j} E_{j,j}$. Since each vertex i connecting to j contributes one such term, and it follows that $\sum_{E \in \mathsf{B}_G} E^\dagger E = I$. We then verify that $\tilde{\mathsf{B}}_G$ is irreducible. For this, consider $P = (p_{i,j})$ where $p_{i,j} = 1/d_i$, which represents the transition matrix of the Markov chain naturally associated with G. Since G is connected, this Markov chain is irreducible, so there exists a unique probability distribution, e.g. a row vector $s = (s_1, \ldots, s_n)$ satisfying $s_i > 0$, $\sum_i s_i = 1$, such that $sP = s$ (see e.g. [74, Corollary 1.17]). It can then be verified that the matrix $S = \mathrm{diag}(s_1, \ldots, s_n) \in \mathrm{D}^+(n, \mathbb{C})$ is fixed by $\tilde{\mathsf{B}}_G$. To see that this is the unique fixed state, we represent $\tilde{\mathsf{B}}_G$ as an $n^2 \times n^2$ matrix M_G. It is not hard to see that by conjugating with a permutation matrix, M_G is of the form $\begin{bmatrix} P & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}$. Therefore, the algebraic and geometric multiplicities of the eigenvalue 1 of M_G are the same as those for P, which are 1 by the Perron-Frobenius theory. It follows that B is irreducible. ◀

▶ **Proposition 40.** *Let $G = ([n], E)$ be a connected graph, and let $\mathsf{B}_G \in \mathrm{IQC}(n, \mathbb{C})$ be as above.*

1. *G has a size-s independent set if and only if B_G has a dimension-s isotropic space;*
2. *G has a vertex c-coloring if and only if B_G has an isotropic c-decomposition.*

Proof. (1) The only if direction is trivial. For the if direction, let U be a dimension-s isotropic space of B_G. Then U is also a dimension-s isotropic space of the alternating matrix space $\langle E_{i,j} - E_{j,i} : \{i,j\} \in E\rangle$, because it is a subspace of $\langle \mathsf{B}_G \rangle$. We can then conclude by resorting to Theorem 3.

(2) The only if direction is trivial; observe that the direct sum decomposition obtained from a vertex coloring as in Theorem 3 is also an orthogonal direct sum decomposition. For the if direction, we observe that, an orthogonal direct sum decomposition into isotropic spaces for B_G is also one for the alternating matrix space $\langle E_{i,j} - E_{j,i} : \{i,j\} \in E\rangle$. We can then conclude by resorting to Theorem 3. ◀

Since the maximum independent set problem and the vertex 3-coloring problem on connected graphs are also NP-hard, we have the following.

▶ **Corollary 41.** *The maximum isotropic space problem and the isotropic 3-decomposition problem for $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$ are NP-hard.*

This also leaves the isotropic 2-decomposition problem an interesting question. For this, we can resort to the techniques developed for quantum Markov chains, mostly notably, based on recent works of periodicity of quantum channels [53].

▶ **Theorem 42.** *Suppose we are given $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$ such that every matrix in B are over $\mathbb{Q}$. There exists an algorithm that decides whether B admits an isotropic 2-decomposition in polynomial time.*

Proof. The key observation is to characterize isotropic 2-decompositions using the *periodicity* of irreducible quantum channels.

▶ **Definition 43** ([45]). *Given* $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$*, the* period *of* B *is the maximum integer* m *for which there exists an orthogonal direct sum decomposition* $\mathbb{C}^n = U_1 \oplus \cdots \oplus U_m$ *such that for any* $i \in [m]$*, and any* $B \in \mathsf{B}$*, we have* $B(U_{i \boxminus 1}) \leq U_i$*, where* $\boxminus$ *indicates subtraction modulo* m *in the range of* $[m]$*.*

The following lemma relates isotropic 2-decompositions with periodicity.

▶ **Lemma 44.** *Given* $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$*,* B *admits an isotropic* 2*-decomposition if and only if the period of* B *is* $2k$ *for some integer* k*.*

Proof. For the if direction, let $\mathbb{C}^n = U_1 \oplus U_2 \oplus \cdots \oplus U_{2k}$ be the orthogonal direct sum decomposition corresponding to the period of B. Let $V_1 = \langle U_i : i = 2j - 1, j \in [k] \rangle$, and $V_2 = \langle U_i : i = 2j, j \in [k] \rangle$. Then $V_1 \oplus V_2$ is an orthogonal direct sum decomposition, and for any $B \in \mathsf{B}$, $B(V_1) \leq V_2$, and $B(V_2) \leq V_1$. By the orthogonal condition, $v_1^\dagger v_2 = 0$ for any $v_1 \in V_1, v_2 \in V_2$. We then have for any $i = 1, 2$, any $v_i, v_i' \in V_i$, and any $B \in \mathsf{B}$, we have $v_i^\dagger B v_i' = 0$. That is, V_1 and V_2 are isotropic spaces.

For the only if direction, let $\mathbb{C}^n = V_1 \oplus V_2$ be an isotropic 2-decomposition. Let P_1 be the projection into V_1 along V_2, and P_2 the projection into V_2 along V_1. We have $P_1 + P_2 = I$, and $P_i^\dagger = P_i$. Since V_1 and V_2 are isotropic spaces, for any $B \in \mathsf{B}$, and any $i = 1, 2$, $P_i B P_i = \mathbf{0}$. Using $P_1 + P_2 = I$, it follows that $P_2 B = B P_1$, and $P_1 B = B P_2$. We are then in the position to apply [45, Lemma 4.2], to conclude that the period of B is $2k$ for some integer k. ◀

Given Lemma 44, it is enough to compute the period of B, and this can be done by resorting to the algorithm in [53]. For completeness, we give a brief sketch of the idea. By Lemma 13 of [53], the period of irreducible quantum channel is equivalent to be the number of eigenvalues with magnitude one of the quantum channel. Using the terminologies in the present article, we have the following lemma.

▶ **Lemma 45** ([53, Lemma 13]). *Given* $\mathsf{B} \in \mathrm{IQC}(n, \mathbb{C})$*, the period of* B *is equal to the number of eigenvalues of* $\tilde{\mathsf{B}}$ *with magnitude one.*

Given this lemma, we can explicitly write out the form of $\tilde{\mathsf{B}}$ as an $n^2 \times n^2$ matrix, and compute its eigenvalues using e.g. [26] in the exact model (Section 2.1). Therefore, each eigenvalue α is represented by an irreducible polynomial $f(x)$ and a separating rectangle in the complex plane. To decide whether α has magnitude 1 can be done efficiently by resorting to techniques from [80]. ◀

Finally, we remark that the investigation in this subsection is not completely satisfactory. It would be more satisfying to consider isotropic spaces and isotropic decompositions for arbitrary quantum channels, not just the irreducible ones. We adopt the current strategy, partly because for irreducible channels, the periodicity is well-studied and well-connected with isotropic 2-decomposition. We leave it a future work to study isotropic spaces and decompositions in the general setting.

12.2 Quantum gate subspace-fidelity and isotropic spaces

We provide one quantum information theoretic interpretation for isotropic spaces, by relating it to quantum gate (state) fidelity [88, Section 9] and noiseless subspaces in quantum error correction [68, 77]. For the sake of readers who have little quantum information knowledge, we shall proceed by introducing all the necessary notions from quantum information, even though most of them are standard.

In quantum information theory, the fidelity is a measure of the "closeness" of two quantum states, generalizing the fidelity of two distributions over finite events. It expresses the probability that one state will pass a test (quantum measurements) to identify as the other. Formally, the fidelity of two quantum states $\rho, \sigma \in \mathrm{D}(n, \mathbb{C})$ is defined by

$$F(\rho, \sigma) = [\mathrm{tr}(\sqrt{\sqrt{\rho}\sigma\sqrt{\rho}})]^2.$$

It is worth noting that $0 \leq F(\rho, \sigma) \leq 1$. Furthermore,

- $F(\rho, \sigma) = 0$ if and only if ρ and σ are orthogonal, i.e., $\mathrm{tr}(\rho\sigma) = 0$;
- $F(\rho, \sigma) = 1$ if and only if $\rho = \sigma$.

Quantum state fidelity induces quantum gate fidelity. Unitary channels (i.e. channels of the form $\tilde{V}(A) = VAV^\dagger$ for some unitary matrix $V \in M(n, \mathbb{C})$) are exactly the channels that do not introduce mixedness (i.e., decoherence) into states. Therefore, in experimental settings, they are considered to be the ideal type of channels to be implemented [88, Section 8]. However, no implementation of a channel is perfect, as there is no closed (isolated) system, so environment errors are unavoidable, which cause the channel actually implemented to be not unitary. The gate fidelity is a tool for comparing how well the implemented quantum channel $\tilde{\mathsf{B}}$ approximates the desired unitary channel $\tilde{V}$. Specifically, the gate fidelity on a pure state ($uu^\dagger$ for a normalized vector $u \in \mathbb{C}^n$) is a function defined as follows:

$$F_{\tilde{\mathsf{B}},\tilde{V}}(u) = F(\tilde{\mathsf{B}}(uu^\dagger), Vuu^\dagger V^\dagger) = u^\dagger V^\dagger \tilde{\mathsf{B}}(uu^\dagger) Vu = u^\dagger [\tilde{V}^\dagger \circ \tilde{\mathsf{B}}(uu^\dagger)]u,$$

where $\tilde{V}^\dagger(A) = V^\dagger AV$. In particular, $F_{\tilde{\mathsf{B}},\tilde{V}}(u) = F_{\tilde{V}^\dagger \circ \tilde{\mathsf{B}},\tilde{I}}(u)$, where $\tilde{I}$ is the identity channel. Then the gate fidelity on all states is defined as follows:

$$F(\tilde{\mathsf{B}}) = \min_{u \in \mathbb{C}^n} F_{\tilde{\mathsf{B}},\tilde{I}}(u) = \min_{\rho \in D(n,\mathbb{C})} F_{\tilde{\mathsf{B}},\tilde{I}}(\rho)$$

The second equation in the above follows from the joint concavity property of the state fidelity F (see [88, Equation 9.121]).

As we can see, quantum gate fidelity is a global property over $\mathbb{C}^n$. But in some cases, we only need a subspace of $\mathbb{C}^n$ as the state space of quantum information processing. This consideration motivates the following notions, which we call them quantum gate maximum and minimum subspace-fidelities, respectively. For a subspace $U \subseteq \mathbb{C}^n$,

$$F_U^{min}(\tilde{\mathsf{B}}) = \min_{u \in U} F_{\tilde{\mathsf{B}},\tilde{I}}(u), \qquad \text{and } F_U^{max}(\tilde{\mathsf{B}}) = \max_{u \in U} F_{\tilde{\mathsf{B}},\tilde{I}}(u).$$

Note that $F_U^{min}(\tilde{\mathsf{B}})$ and $F_U^{max}(\tilde{\mathsf{B}})$ quantify the worst-case and best-case behavior of the system by minimizing and maximizing over all possible initial states, respectively. Obviously, $0 \leq F_U^{min}(\tilde{\mathsf{B}}) \leq F_U^{max}(\tilde{\mathsf{B}}) \leq 1$ as $0 \leq F(\rho, \sigma) \leq 1$. We also have $F(\tilde{\mathsf{B}}) = \min_{U \subseteq \mathbb{C}^n} F_U^{min}(\tilde{\mathsf{B}}) = \min_{U \subseteq \mathbb{C}^n} F_U^{max}(\tilde{\mathsf{B}})$, where the second equation follows by examining one-dimensional subspaces.

One key notion in quantum error correction is that of noiseless subspaces, which have been intensively discussed in the setting where $\tilde{\mathsf{B}}$ as a noise model [68, 77]. Intuitively, noiseless subspaces are shelters under quantum noise $\tilde{\mathsf{B}}$, as they perfectly preserve quantum states under $\tilde{\mathsf{B}}$.

▶ **Definition 46.** *Let* $\mathsf{B} = \{B_1, \ldots, B_m\} \in \mathrm{QC}(n, \mathbb{C})$. *An noiseless subspace of* B *is a non-zero subspace* $U \leq \mathbb{C}^n$, *such that for any* $u \in U$, *and any* B_i, *we have* $B_i u = u$.

The following result formally shows that noiseless subspaces and isotropic subspaces are totally opposite from the viewpoint of the two quantum gate subspace-fidelities.

▶ **Proposition 47.** *Let* $\mathsf{B} = \{B_1, \ldots, B_m\} \in \mathrm{QC}(n, \mathbb{C})$.

- $F_U^{max}(\tilde{\mathsf{B}}) = 0$ *if and only if* U *is an isotropic space;*
- $F_U^{max}(\tilde{\mathsf{B}}) = 1$ *if and only if there is a noiseless subspace in* U*;*
- $F_U^{min}(\tilde{\mathsf{B}}) = 1$ *if and only if* U *is a noiseless subspace;*
- $F_U^{min}(\tilde{\mathsf{B}}) = 0$ *if and only if there is an isotropic space in* U.

Proof. These four claims are directly from the definitions of isotropic spaces, noiseless subspaces, quantum gate minimum subspace-fidelity and maximum subspace-fidelity. ◀

Knill devised an efficient algorithm to find all noiseless subspaces for a given $\tilde{\mathsf{B}}$ [67]. So we have a quite good understanding on $F_U^{min}(\tilde{\mathsf{B}}) = 1$. On the other hand, isotropic subspaces fully characterize $F_U^{max}(\tilde{\mathsf{B}}) = 0$. Therefore, isotropic spaces reveal the structure of the worst-case behavior of the channel.

Let us further point out another potential application of isotropic spaces in quantum control. A basic task of controlling quantum systems is to transfer all unknown quantum states into some targeting subspace [32, 102]. So designing a control scheme as a quantum channel with a non-trivial isotropic space (the dimension greater than 1) can turn all quantum states residing in the isotropic space into the orthogonal complement of it.

A Breadth-first search in the alternating matrix space setting

Indeed, suppose $\mathcal{A} \leq \Lambda(n, \mathbb{F})$ admits an isotropic 2-decomposition as $\mathbb{F}^n = U_1 \oplus U_2$. Note that U_1 and U_2 are not known to us. To follow the idea of breadth-first search, we would start from a vector $v \in \mathbb{F}^n$, and then find its neighbours, and then its neighbours' neighbours, etc.. Intuitively, for $v \in \mathbb{F}^n$, we can view the linear span of Av, $A \in \mathcal{A}$ as those neighbours of v, denoted by $V_1 \leq \mathbb{F}^n$. Then the linear span of AV_1, $A \in \mathcal{A}$, may be considered as the neighbours of V_1. Continuing this way, if $v \in U_1$, we do see that V_i's alternates between subspaces of U_1 and U_2. It follows that $V_i \cap V_{i+1} = \mathbf{0}$, from which we can compute U_1 and U_2 after this sequence stabilizes. However, if v is neither in U_1 nor in U_2, it is not clear how to read any information about U_1 and U_2. In fact, it is possible that the linear span of Av is the hyperplane orthogonal to v, so it is impossible to tell whether such U_1 and U_2 exist.

B The relation between alternating bilinear maps and alternating matrix spaces

We first recall the relation between alternating bilinear maps and alternating matrix tuples. Let $\phi : U \times U \to V$ be an alternating bilinear map, that is, for any $u \in U$, $\phi(u, u) = \mathbf{0}$. Fix bases of U and V, so that $U \cong \mathbb{F}^n$ and $V \cong \mathbb{F}^m$. Then ϕ can be represented by an m-tuple of alternating matrices $(A_1, \ldots, A_m) \in \Lambda(n, \mathbb{F})^m$, such that $\phi(u, u') = (u^t A_1 u', \ldots, u^t A_m u')^t$. Conversely, given an m-tuple of alternating matrices, one can define an alternating bilinear map as such. Two alternating bilinear maps $\phi, \psi : U \times U \to V$ are isometric, if there exist $A \in \mathrm{GL}(U)$, $B \in \mathrm{GL}(V)$, such that $\phi = B \circ \psi \circ A$. (Some authors prefer to call this isometric as pseudo-isometric [21].)

Let $\mathcal{A} \leq \Lambda(n, \mathbb{F})$. Let $\mathbf{A} = (A_1, \ldots, A_m) \in \Lambda(n, \mathbb{F})^m$ be an ordered basis of $\mathcal{A}$. Then $\mathbf{A}$ defines an alternating bilinear map $\phi_{\mathbf{A}} : \mathbb{F}^n \times \mathbb{F}^n \to \mathbb{F}^m$ as above. While difference choices of ordered bases give different alternating bilinear maps, it is easy to see that ordered bases from isometric alternating matrix spaces give isometric alternating bilinear maps.

Hard Properties with (Very) Short PCPPs and Their Applications

Abstract

We show that there exist properties that are maximally hard for testing, while still admitting PCPPs with a proof size very close to linear. Specifically, for every fixed ℓ, we construct a property $\mathcal{P}^{(\ell)} \subseteq \{0,1\}^n$ satisfying the following: Any testing algorithm for $\mathcal{P}^{(\ell)}$ requires $\Omega(n)$ many queries, and yet $\mathcal{P}^{(\ell)}$ has a constant query PCPP whose proof size is $O(n \cdot \log^{(\ell)} n)$, where $\log^{(\ell)}$ denotes the ℓ times iterated log function (e.g., $\log^{(2)} n = \log \log n$). The best previously known upper bound on the PCPP proof size for a maximally hard to test property was $O(n \cdot \text{polylog } n)$.

As an immediate application, we obtain stronger separations between the standard testing model and both the tolerant testing model and the erasure-resilient testing model: for every fixed ℓ, we construct a property that has a constant-query tester, but requires $\Omega(n/\log^{(\ell)}(n))$ queries for every tolerant or erasure-resilient tester.

1 Introduction

Probabilistically checkable proofs (PCPs) are one of the landmark achievements in theoretical computer science. Loosely speaking, PCPs are proofs that can be verified by reading only a very small (i.e., constant) number of bits. Beyond the construction of highly efficient proof systems, PCPs have myriad applications, most notably within the field of hardness of approximation.

A closely related variant of PCPs, called *probabilistically checkable proofs of proximity* (PCPPs), was introduced independently by Ben-Sasson *et al.* [5] and Dinur and Reingold [13]. In the PCPP setting, a verifier is given oracle access to both an input x and a proof π. It should make a few (e.g., constant) number of queries to both oracles to ascertain whether $x \in \mathcal{L}$. Since the verifier can only read a few of the input bits, we only require that it rejects inputs that are *far* (in Hamming distance) from $\mathcal{L}$, no matter what proof π is provided. PCPPs are highly instrumental in the construction of standard PCPs. Indeed, using modern terminology, both the original algebraic construction of PCPs [1] (see also [5]) as well as Dinur's [12] combinatorial proof utilize PCPPs.

By combining the seminal works of Ben-Sasson and Sudan [7] and Dinur [12], one can obtain PCPs and PCPPs with only poly-logarithmic (multiplicative) overhead. More specifically, the usual benchmark for PCPPs is with respect to the `CircuitEval` problem, in which the verifier is given explicit access to a circuit C and oracle access to both an input x and a proof π, and needs to verify that x is close to the set $\{x' : C(x') = 1\}$. The works of [7, 12] yield a PCPP whose length is quasilinear in the size $|C|$ of the circuit C.[1]

Given the important connections both to constructions of efficient proof-systems, and to hardness of approximation, a central question in the area is whether this result can be improved: Do PCPPs with only a *constant* overhead exist? In a recent work, Ben Sasson *et al.* [6] construct PCPs with constant overhead, albeit with very large query complexity (as well as a non-uniform verification procedure).[2] To verify that $C(x) = 1$ the verifier needs to make $|C|^{\delta}$ queries, where $\delta > 0$ can be any fixed constant.

Given the lack of success (despite the significant interest) in constructing constant-query PCPPs with constant overhead, it may be the case that there exist languages that do not have such efficient PCPPs. A natural class of candidate languages for which such PCPPs may not exist are languages for which it is *maximally* hard to test whether $x \in \mathcal{L}$ or is far from such, *without* a PCPP proof. In other words, languages (or rather properties) that do not admit sub-linear query testers. Thus, we investigate the following question:

> *Supposing that $\mathcal{L}$ requires $\Omega(n)$ queries for every (property) tester, must any constant-query* PCPP *for $\mathcal{L}$ have proof length $n \cdot (\log n)^{\Omega(1)}$?*

1.1 Our Results

Our first main result answers the above question negatively, by constructing a property that is maximally hard for testing, while admitting a very short PCPP. For the exact theorem statement, we let $\log^{(\ell)}$ denote the ℓ times iterated log function. That is, $\log^{(\ell)}(n) = \log(\log^{(\ell-1)}(n))$ for $\ell \geq 1$ and $\log^{(0)} n = n$.

▶ **Theorem 1** (informal restatement of Theorem 30). *For every constant integer $\ell \in \mathbb{N}$, there exists a property $\mathcal{P} \subseteq \{0,1\}^n$ such that any testing algorithm for $\mathcal{P}$ requires $\Omega(n)$ many queries, while $\mathcal{P}$ admits a (constant query[3]) PCPP system with proof length $O(n \cdot \log^{(\ell)}(n))$.*

---

[1] Note that a PCPP for `CircuitEval` can be easily used to construct a PCP for `CircuitSAT` with similar overhead (see [5, Proposition 2.4]).

[2] Although it is not stated in [6], we believe that their techniques can also yield PCPPs with similar parameters.

[3] For detection radius (or proximity parameter) $\varepsilon > 0$ and constant soundness, the particular query complexity of the PCPP system is bounded by $(2^{\ell}/\varepsilon)^{O(\ell)}$.

We remark that all such maximally hard properties cannot have constant-query PCPP proof-systems with a *sub-linear* length proof string (see Proposition 13), leaving only a small gap of $\log^{(\ell)}(n)$ on the proof length in Theorem 1.

Beyond demonstrating that PCPPs with extremely short proofs exist for some hard properties, we use Theorem 1 to derive several applications. We proceed to describe these applications next.

Tolerant Testing

Recall that property testing (very much like PCPPs) deals with solving approximate decision problems. A tester for a property $\mathcal{P}$ is an algorithm that given a sublinear number of queries to its input x, should accept (with high probability) if $x \in \mathcal{P}$ and reject if x is *far* from $\mathcal{P}$ (where, unlike PCPPs, the tester is not provided with any proof).

The standard setting of property testing is arguably fragile, since the testing algorithm is only guaranteed to accept all functions that exactly satisfy the property. In various settings and applications, accepting only inputs that exactly have a certain property is too restrictive, and it is more beneficial to distinguish between inputs that are close to having the property, and those that are far from it. To address this question, Parnas, Ron and Rubinfeld [26] introduced a natural generalization of property testing, in which the algorithm is required to accept functions that are close to the property. Namely, for parameters $0 \leq \varepsilon_0 < \varepsilon_1 \leq 1$, an $(\varepsilon_0, \varepsilon_1)$-*tolerant testing algorithm* is given an oracle access to the input, and is required to determine (with high probability) whether a given input is ε_0-close to the property or whether it is ε_1-far from it. As observed in [26], any standard testing algorithm whose queries are uniformly (but not necessarily independently) distributed, is inherently tolerant to some extent. Nevertheless, for many problems, strengthening the tolerance requires applying advanced methods and devising new algorithms (see e.g., [16, 23, 10, 8, 9]).

It is natural to ask whether tolerant testing is strictly harder than standard testing. This question was explicitly studied by Fischer and Fortnow [15], who used PCPPs with polynomial size proofs to show that there exists a property $\mathcal{P} \subseteq \{0,1\}^n$ that admits a tester with constant query complexity, but such that every tolerant tester for $\mathcal{P}$ has query complexity $\Omega(n^c)$ for some $0 < c < 1$. Using modern quasilinear PCPPs [7, 12] in combination with the techniques of [15] it is possible to construct a property demonstrating a better separation, of constant query complexity for standard testing versus $\Omega(n/\text{polylog}\, n)$ for tolerant testing.

Using Theorem 1 we can obtain an improved separation between testing and tolerant testing:

▶ **Theorem 2** (informal restatement of Theorem 46). *For any constant integer $\ell \in \mathbb{N}$, there exist a property of boolean strings $\mathcal{P} \subseteq \{0,1\}^n$ and a constant $\varepsilon_1 \in (0,1)$ such that $\mathcal{P}$ is ε-testable for any $\varepsilon > 0$ with a number of queries[4] independent of n, but for any $\varepsilon_0 \in (0, \varepsilon_1)$, every $(\varepsilon_0, \varepsilon_1)$-tolerant tester for $\mathcal{P}$ requires $\Omega(n/\text{polylog}^{(\ell)} n)$ many queries.*

Erasure-Resilient Testing

Another variant of the property testing model is the *erasure-resilient testing* model. This model was defined by Dixit et. al. [14] to address cases where data cannot be accessed at some domain points due to privacy concerns, or when some of the values were adversarially erased. More precisely, an α-erasure-resilient ε-tester gets as input parameters $\alpha, \varepsilon \in (0,1)$,

[4] The query complexity of the intolerant ε-tester has the same asymptotic bound as in Theorem 1.

as well as oracle access to a function f, such that at most an α fraction of its values have been erased. The tester has to accept with high probability if there is a way to assign values to the erased points of f such that the resulting function satisfies the desired property. The tester has to reject with high probability if for every assignment of values to the erased points, the resulting function is still ε-far from the desired property.

Similarly to the tolerant testing scenario, PCPPs were also used in [14] to show that there exists a property of boolean strings of length n that has a tester with query complexity independent of n, but for any constant $\alpha > 0$, every α-erasure-resilient tester is required to query $\Omega(n^c)$ many bits for some $c > 0$, thereby establishing a separation between the models. Later, in [27] PCPP constructions were used to provide a separation between the erasure-resilient testing model and the tolerant testing model.

Similarly to the tolerant testing case, we use Theorem 1 to prove a stronger separation between the erasure-resilient testing model and the standard testing model.

▶ **Theorem 3** (informal restatement of Theorem 47). *For any constant integer $\ell \in \mathbb{N}$, there exist a property of boolean strings $\mathcal{P} \subseteq \{0,1\}^n$ and a constant $\varepsilon_1 \in (0,1)$ such that $\mathcal{P}$ is ε-testable for any $\varepsilon > 0$ with number of queries[5] independent of n, but for any $\alpha = \Omega(1/\log^{(\ell)} n)$ and $\varepsilon \in (0, \varepsilon_1)$ such that $\varepsilon < 1 - \alpha$, any α-erasure-resilient ε-tester is required to query $\Omega(n/\text{polylog}^{(\ell)} n)$ many bits.*

Secret Sharing applications

As an additional application of our techniques we also obtain a new type of *secret sharing scheme*. Recall that in a secret sharing scheme, a secret value $b \in \{0,1\}$ is shared between n parties in such a way that only an authorized subset of the users can recover the secret. We construct a secret sharing scheme in which no subset of $o(n)$ parties can recover the secret and yet it is possible for each one of the parties to recover the secret, if given access to a PCPP-like proof, with the guarantee that no matter what proof-string is given, most parties will either recover b or reject.

We obtain such a secret sharing scheme through a notion called *Probabilistically Checkable Unveiling of a Shared Secret (*PCUSS*)*, which will be central in our work. This notion is loosely described in Subsection 1.2 and formally defined in Section 4.

1.2 Techniques

Central to our construction are (univariate) polynomials over a finite field $\mathbb{F}$. A basic fact is that a random polynomial $p : \mathbb{F} \to \mathbb{F}$ of degree (say) $|\mathbb{F}|/2$, evaluated at any set of at most $|\mathbb{F}|/2$ points, looks exactly the same as a totally random function $f : \mathbb{F} \to \mathbb{F}$. This is despite the fact that a random function is very far (in Hamming distance) from the set of low degree polynomials. Indeed, this is the basic fact utilized by Shamir's secret sharing scheme [29].

Thus, the property of being a degree-$|\mathbb{F}|/2$ univariate polynomial is a hard problem to decide for any tester, in the sense that such a tester must make $\Omega(|\mathbb{F}|)$ queries to the truth table of the function in order to decide. Given that, it seems natural to start with this property in order to prove Theorem 1. Here we run into two difficulties. First, the property of being a low degree polynomial is defined over a large alphabet, whereas we seek a property over boolean strings. Second, the best known PCPPs for this property have quasi-linear length [7], which falls short of our goal.

[5] Again, the query complexity of the (non erasure resilient) ε-tester has the same asymptotic bound as in Theorem 1.

To cope with these difficulties, our approach is to use composition, or more accurately, an iterated construction. The main technical contribution of this paper lies in the mechanism enabling this iteration. More specifically, rather than having the property contain the explicit truth table of the low degree polynomial p, we would like to use a more redundant representation for encoding each value $p(\alpha)$. This encoding should have several properties:

- It must be the case that one needs to read (almost) the entire encoding to be able to decode $p(\alpha)$. This feature of the encoding, which we view as a secret-sharing type of property, lets us obtain a hard to test property over boolean strings.
- The encoding need not be efficient, and in fact it will be made long enough to eventually subsume the typical length of a PCPP proof-string for the low degree property, when calculated with respect to an *unencoded* input string.
- Last but not least, we need the value to be decodable using very few queries, when given access to an auxiliary PCP-like proof string. This would allow us to "propagate" the PCPP verification of the property across iterations.

In more detail, we would like to devise a (randomized) encoding of strings in $\{0,1\}^k$ by strings in $\{0,1\}^m$. The third requirement listed above can be interpreted as saying that given oracle access to $v \in \{0,1\}^m$ and explicit access to a value $w \in \{0,1\}^k$, it will be possible verify that v indeed encodes w using a PCPP-like scheme, i.e. by providing a proof that can be verified with a constant number of queries. We refer to this property as a *probabilistically checkable unveiling (*PCU*)*[6]. Note that in our setting a single value w may (and usually will) have more than one valid encoding.

Going back to the first requirement of the encoding, we demand that without a proof, one must query at least $\Theta(m)$ bits of v to obtain *any* information about the encoded w, or even discern that v is indeed a valid encoding of some value. Given this combination of requirements, we refer to the verification procedure as a *Probabilistically Checkable Unveiling of a Shared Secret (*PCUSS*)*.

Low degree polynomials can be used to obtain a PCUSS based on Shamir's secret sharing scheme. More specifically, to encode a k bit string w, we take a random polynomial whose values on a subset $H \subseteq \mathbb{F}$ are exactly equal to the bits of w. However, we provide the values of this polynomial only over the sub domain $\mathbb{F} \setminus H$. Then, the encoded value is represented by the (interpolated) values of g over H, which admit a PCU scheme. On the other hand, the "large independence" feature of polynomials makes the encoded value indiscernible without a a supplied proof string, unless too many of the values of g over $\mathbb{F} \setminus H$ are read, thus allowing for a PCUSS.

This construction can now be improved via iteration. Rather than explicitly providing the values of the polynomial, they will be provided by a PCUSS scheme. Note that the PCUSS scheme that we now need is for strings of a (roughly) exponentially smaller size. The high level idea is to iterate this construction ℓ times to obtain the ℓ iterated log function in our theorems.

At the end of the recursion, i.e., for the smallest blocks at the bottom, we utilize a linear-code featuring both high distance and high dual distance, for a polynomial size PCUSS of the encoded value. This is the only "non-constructive" part in our construction, but since the relevant block size will eventually be less than $\log\log(n)$, the constructed property will still be uniform with polynomial calculation time (the exponential time in $\text{poly}(\log\log(n))$, needed to construct the linear-code matrix, becomes negligible).

[6] In fact, we will use a stronger variant where the access to w is also restricted.

Our PCUSS in particular provides a property that is hard to test (due to its shared secret feature), and yet has a near-linear PCPP through its unveiling, thereby establishing Theorem 1. We utilize this property for separation results in a similar manner to [15] and [14], by considering a weighted version of a "PCPP with proof" property, where the proof part holds only a small portion of the total weight. The PCPP proof part enables a constant query test, whereas if the PCPP proof is deleted, efficient testing is no longer possible.

1.3 Related work

Short PCPPs

For properties which can be verified using a circuit of size n, [5] gave PCPP constructions with proof length $n \cdot \exp(\text{poly}(\log\log n))$ and with a query complexity of $\text{poly}(\log\log n)$, as well as slightly longer proofs with constant query complexity. Later, Ben-Sasson and Sudan [7] gave constructions with quasilinear size proofs, but with slightly higher query complexity. The state of the art construction is due to Dinur [12] who, building on [7], showed a PCPP construction with proof length that is quasilinear in the circuit size and with constant query complexity. In a recent work Ben Sasson *et al.* [3] constructed an *interactive* version of PCPPs [4, 28] of strictly linear length and constant query complexity.

Tolerant Testing

The tolerant testing framework has received significant attention in the past decade. Property testing of dense graphs, initiated by [19], is inherently tolerant by the canonical tests of Goldreich and Trevisan [21]. Later, Fischer and Newman [16] (see also [2]) showed that every testable (dense) graph property admits a tolerant testing algorithm for *every* $0 < \varepsilon_0 < \varepsilon_1 < 1$, which implies that $O(1)$ query complexity testability is equivalent to distance approximation in the dense graph model. Some properties of boolean functions were also studied recently in the tolerant testing setting. In particular, the properties of being a *k-junta* (i.e. a function that depends on k variables) and being *unate* (i.e., a function where each direction is either monotone increasing or monotone decreasing) [9, 24, 11].

Erasure-resilient Testing

For the erasure resilient model, in addition to the separation between that model and the standard testing model, [14] designed efficient erasure-resilient testers for important properties, such as monotonicity and convexity. Shortly after, in [27] a separation between the erasure-resilient testing model and the tolerant testing model was established. The last separation requires an additional construction (outside PCPPs), which remains an obstacle to obtaining better than polynomial separations.

2 Preliminaries

We start with some notation and central definitions. For a set A, we let 2^A denote the power-set of A. For two strings $x, y \in \{0,1\}^*$ we use $x \sqcup y$ to denote string concatenation.

For an integer k, a field $\mathbb{F} = \text{GF}(2^k)$ and $\alpha \in \mathbb{F}$, we let $\langle\langle \alpha \rangle\rangle \in \{0,1\}^k$ denote the binary representation of α in some canonical way.

For two sets of strings A and B we use $A \sqcup B$ to denote the set $\{a \sqcup b \mid a \in A,\ b \in B\}$. For a collection of sets $\{A(d)\}_{d \in D}$ we use $\bigsqcup_{d \in D} A(d)$ to denote the set of all possible concatenations $\bigsqcup_{d \in D} a_d$, where $a_d \in A(d)$ for every $d \in D$.

Throughout this paper we use boldface letters to denote random variables, and assume a fixed canonical ordering over the elements in all the sets we define. For a set D, we write $\boldsymbol{v} \sim D$ to denote a random variable resulting from a uniformly random choice of an element $v \in D$.

2.1 Error correcting codes and polynomials over finite fields

The relative Hamming distance of two strings $x, y \in \Sigma^n$ is defined as $\mathrm{dist}(x,y) = \frac{1}{n} \cdot |\{i \in [n] \mid x_i \neq y_i\}|$. For a string $x \in \Sigma^n$ and a non-empty set $S \subseteq \Sigma^n$, we define $\mathrm{dist}(x,S) = \min_{y \in S} \mathrm{dist}(x,y)$. The following plays a central role in many complexity-related works, including ours.

▶ **Definition 4.** *A* code *is an injective function $C : \Sigma^k \to \Sigma^n$. If Σ is a finite field and C is a linear function (over Σ), then we say that C is a* linear code. *The* rate *of C is defined as k/n, whereas the* minimum relative distance *is defined as the minimum over all distinct $x, y \in \Sigma^k$ of* $\mathrm{dist}(C(x), C(y))$.

*An ε-*distance code *is a code whose minimum relative distance is at least ε. When for a fixed $\varepsilon > 0$ we have a family of ε-distance codes (for different values of k), we refer to its members as* error correcting codes.

In this work we use the fact that efficient codes with constant rate and constant relative distance exist. Moreover, there exist such codes in which membership can be decided by a quasi-linear size Boolean circuit.

▶ **Theorem 5** (see e.g., [30]). *There exists a linear code $\mathsf{Spiel} : \{0,1\}^k \to \{0,1\}^{100k}$ with constant relative distance, for which membership can be decided by a $k \cdot \mathrm{polylog}\, k$ size Boolean circuit.*

Actually, the rate of the code in [30] is significantly better, but since we do not try to optimize constants, we use the constant 100 solely for readability. In addition, the code described in [30] is *linear time decodeable*, but we do not make use of this feature throughout this work.

We slightly abuse notation, and for a finite field $\mathbb{F}$ of size 2^k, view the encoding given in Theorem 5 as $\mathsf{Spiel} : \mathbb{F} \to \{0,1\}^{100k}$, by associating $\{0,1\}^k$ with $\mathbb{F}$ in the natural way. Note that for $f : \mathbb{F} \to \mathbb{F}$, it holds that $\langle\!\langle f(\beta) \rangle\!\rangle \in \{0,1\}^k$ for every $\beta \in \mathbb{F}$, and therefore $\mathsf{Spiel}(f(\beta)) \in \{0,1\}^{100k}$. We slightly abuse notation, and for a function $f : \mathbb{F} \to \mathbb{F}$ we write $\mathsf{Spiel}(f)$ to denote the length $100k \cdot 2^k$ bit string $\bigsqcup_{\beta \in \mathbb{F}} \mathsf{Spiel}(f(\beta))$ (where we use the canonical ordering over $\mathbb{F}$).

▶ **Definition 6.** *Let $\mathcal{C}_{\mathbb{F}}$ denote the set of polynomials $g : \mathbb{F} \to \mathbb{F}$ such that $\deg(g) \leq \frac{|\mathbb{F}|}{2}$.*

The following lemma of [22], providing a fast univariate interpolation, will be an important tool in this work.

▶ **Lemma 7** ([22]). *Given a set of pairs $\{(x_1, y_1), \ldots, (x_r, y_r)\}$ with all x_i distinct, we can output the coefficients of $p(x) \in \mathbb{F}[X]$ of degree at most $r-1$ satisfying $p(x_i) = y_i$ for all $i \in [r]$, in $O(r \cdot \log^3(r))$ additions and multiplications in $\mathbb{F}$.*

The next lemma states that a randomly chosen function $\boldsymbol{\lambda} : \mathbb{F} \to \mathbb{F}$ is far from any low degree polynomial with very high probability.

▶ **Lemma 8.** *With probability at least $1 - o(1)$, a uniformly random function $\boldsymbol{\lambda} : \mathbb{F} \to \mathbb{F}$ is $1/3$-far from $\mathcal{C}_{\mathbb{F}}$.*

Proof. Consider the size of a ball of relative radius $1/3$ around some function $\lambda : \mathbb{F} \to \mathbb{F}$ in the space of functions from $\mathbb{F}$ to itself. The number of points (i.e., functions from $\mathbb{F} \to \mathbb{F}$) contained in this ball is at most

$$\binom{|\mathbb{F}|}{|\mathbb{F}|/3} \cdot |\mathbb{F}|^{|\mathbb{F}|/3} \leq (3e|\mathbb{F}|)^{|\mathbb{F}|/3}.$$

By the fact that the size of $\mathcal{C}_{\mathbb{F}}$ is $|\mathbb{F}|^{|\mathbb{F}|/2+1}$, the size of the set of points that are at relative distance at most $1/3$ from any point in $\mathcal{C}_{\mathbb{F}}$ is at most

$$|\mathbb{F}|^{|\mathbb{F}|/2+1} \cdot (3e|\mathbb{F}|)^{|\mathbb{F}|/3} = o(|\mathbb{F}|^{|\mathbb{F}|}).$$

The lemma follows by observing that there are $|\mathbb{F}|^{|\mathbb{F}|}$ functions from $\mathbb{F}$ to itself. ◀

2.1.1 Dual distance of linear codes

We focus here specifically on a linear code $C : \mathbb{F}^k \to \mathbb{F}^n$, and consider the linear subspace of its image, $V_C = \{C(x) : x \in \mathbb{F}^k\} \subseteq \mathbb{F}^n$. We define the *distance* of a linear space as $\text{dist}(V) = \min_{v \in V \setminus \{0^n\}} \text{dist}(v, 0^n)$, and note that in the case of V being the image V_C of a code C, this is identical to $\text{dist}(C)$. For a linear code, it helps to investigate also *dual distances*.

▶ **Definition 9.** *Given two vectors $u, v \in \mathbb{F}^n$, we define their* scalar product *as $u \cdot v = \sum_{i \in [n]} u_i v_i$, where multiplication and addition are calculated in the field $\mathbb{F}$. Given a linear space $V \subseteq \mathbb{F}^n$, its* dual space *is the linear space $V^\perp = \{u : \forall v \in V, u \cdot v = 0\}$. In other words, it is the space of vectors who are orthogonal to all members of V. The* dual distance *of the space V is simply defined as $\text{dist}(V^\perp)$.*

For a code C, we define its *dual distance*, $\text{dist}^\perp(C)$, as the dual distance of its image V_C. We call C an *η-dual-distance* code if $\text{dist}^\perp(C) \geq \eta$. The following well-known lemma is essential to us, as it will relate to the "secret-sharing" property that we define later.

▶ **Lemma 10** (See e.g., [25, Chapter 1, Theorem 10])**.** *Suppose that $C : \mathbb{F}^k \to \mathbb{F}^n$ is a linear η-dual distance code, let $Q \subset [n]$ be any set of size less than $\eta \cdot n$, and consider the following random process for picking a function $\boldsymbol{u} : Q \to \mathbb{F}$: Let $\boldsymbol{w} \in \mathbb{F}^k$ be drawn uniformly at random, and set $\boldsymbol{u}$ be the restriction of $C(\boldsymbol{w})$ to the set Q. Then, the distribution of $\boldsymbol{u}$ is identical to the uniform distribution over the set of all functions from Q to $\mathbb{F}$.*

2.2 Probabilistically checkable proofs of proximity (PCPP)

As described briefly in the introduction, a PCPP verifier for a property $\mathcal{P}$ is given access to an input x and a proof π, as well as a *detection radius* $\varepsilon > 0$ and *soundness parameter* $\delta > 0$. The verifier should make a constant number of queries (depending only on ε, δ) to the input x and the proof π, and satisfy the following. If $x \in \mathcal{P}$, then there exists π for which the verifier should always accept x. If $\text{dist}(x, \mathcal{P}) > \varepsilon$, the verifier should reject x with probability at least δ, regardless of the contents of π. More formally, we define the following.

▶ **Definition 11** (PCPP)**.** *For $n \in \mathbb{N}$, let $\mathcal{P} \subset \{0,1\}^n$ be a property of n-bit Boolean strings, and let $t \in \mathbb{N}$. We say that $\mathcal{P}$ has a $q(\varepsilon, \delta)$-*query, length-t Probabilistically Checkable Proof of Proximity (PCPP) system *if the following holds: There exists a verification algorithm V that takes as input $\varepsilon, \delta > 0$ and $n \in \mathbb{N}$, makes a total of $q(\varepsilon, \delta)$ queries on strings $w \in \{0,1\}^n$ and $\pi \in \{0,1\}^t$, and satisfies the following:*

1. *(Completeness) If $w \in \mathcal{P}$, then there exists a proof $\pi = \boldsymbol{Proof}_{\mathcal{P}}(w) \in \{0,1\}^t$ such that for every $\varepsilon, \delta > 0$, the verifier V accepts with probability 1.*
2. *(Soundness) If $\mathrm{dist}(w, \mathcal{P}) > \varepsilon$, then for every alleged proof $\pi \in \{0,1\}^t$, the verifier V rejects with probability greater than δ.*

Note that soundness is easy to amplify: Given a PCPP as above with parameters ε, δ, t and query complexity $q(\varepsilon, \delta)$, one can increase the soundness parameter to $1 - \tau$ (for any $\tau > 0$) by simply running $\Theta(\log(1/\tau)/\delta)$ independent instances of the verification algorithm V, and rejecting if at least one of them rejected; the query complexity then becomes $\Theta\left(q(\varepsilon, \delta) \cdot \log(1/\tau)/\delta\right)$, while the parameters ε and t remain unchanged.

The following lemma, establishing the existence of a quasilinear PCPP for any property $\mathcal{P}$ that is verifiable in quasilinear time, will be an important tool throughout this work.

▶ **Lemma 12** (Corollary 8.4 in [12], see also [20]). *Let $\mathcal{P}$ be a property of Boolean strings which is verifiable by a size t Boolean circuit. Then, there exists a length-t' PCPP system $\mathcal{P}$ with parameters $\varepsilon, \delta > 0$, that makes at most $q(\varepsilon, \delta)$ queries, where $t' = t \cdot \mathrm{polylog}\, t$.*

Specifically, $q(\varepsilon, \delta) = O(\varepsilon^{-1})$ suffices for any $\delta < 0.99$.

As described briefly in the introduction, maximally hard properties cannot have a constant query PCPP proof systems with a sublinear length proof string.

▶ **Proposition 13.** *Let $\mathcal{P} \subseteq \{0,1\}^n$ and $\varepsilon > 0$ be such that any ε-tester for $\mathcal{P}$ has to make $\Omega(n)$ many queries. Then, any constant query PCPP system for $\mathcal{P}$ (where e.g. $\delta = 1/3$) must have proof length of size $\Omega(n)$.*

Proof. Suppose that there exists a PCPP for $\mathcal{P}$ with $O(1)$ queries and proof length $t = o(n)$. Since the PCPP verifier has constant query complexity, we may assume that it is non adaptive and uses $q = O(1)$ queries. By an amplification argument as above, we can construct an amplified verifier that makes $O(q \cdot t) = o(n)$ queries, with soundness parameter $1 - 2^{-t}/3$. By the fact that the verifier is non-adaptive, it has the same query distribution regardless of the proof string. Therefore, we can run 2^t amplified verifiers in parallel while reusing queries, one verifier for each of the 2^t possible proof strings. If any of the 2^t amplified verifiers accept, we accept the input. If the input belongs to $\mathcal{P}$, one of the above 2^t verifiers will accept (the one that used the correct proof). If the input was ε-far from $\mathcal{P}$, then by a union bound, the probability that there was any accepting amplified verifier is at most $1/3$. This yields an $o(n)$ tester for $\mathcal{P}$, which contradicts our assumption. ◀

2.3 Testing, tolerant testing and erasure-resilient testing

In this subsection we define notions related to the property testing framework. We also formally define a few variants of the original testing model that will be addressed in this work. A *property* $\mathcal{P}$ of n-bit boolean strings is a subset of all those strings, and we say that a string x *has* the property $\mathcal{P}$ if $x \in \mathcal{P}$.

Given $\varepsilon \geq 0$ and a property $\mathcal{P}$, we say that a string $x \in \{0,1\}^n$ is *ε-far* from $\mathcal{P}$ if $\mathrm{dist}(x, \mathcal{P}) > \varepsilon$, and otherwise it is *$\varepsilon$-close* to $\mathcal{P}$. We next define the notion of a *tolerant* tester of which standard (i.e. intolerant) testers are a special case.

▶ **Definition 14** (Intolerant and tolerant testing). *Given $0 \leq \varepsilon_0 < \varepsilon_1 \leq 1$, a q-query $(\varepsilon_0, \varepsilon_1)$-*testing *algorithm T for a property $\mathcal{P} \subseteq \{0,1\}^n$ is a probabilistic algorithm (possibly adaptive) making q queries to an input $x \in \{0,1\}^n$ that outputs a binary verdict satisfying the following two conditions.*

1. *If* $\text{dist}(x, \mathcal{P}) \leq \varepsilon_0$*, then* T *accepts* x *with probability at least* $2/3$.
2. *If* $\text{dist}(x, \mathcal{P}) > \varepsilon_1$*, then* T *rejects* x *with probability at least* $2/3$.

When $\varepsilon_0 = 0$*, we say that* T *is an* ε_1-testing algorithm *for* $\mathcal{P}$*, and otherwise we say that* T *is an* $(\varepsilon_0, \varepsilon_1)$-tolerant testing algorithm *for* $\mathcal{P}$.

Next, we define the erasure-resilient testing model. We start with some terminology. A string $x \in \{0,1,\perp\}^n$ is α-erased if x_i is equal to $\perp$ on at most αn coordinates. A string $x' \in \{0,1\}^n$ that differs from x only on coordinates $i \in [n]$ for which $x_i = \perp$ is called a *completion* of x. The (pseudo-)distance $\text{dist}(x, \mathcal{P})$ of an α-erased string x from a property $\mathcal{P}$ is the minimum, over every completion x' of x, of the relative Hamming distance of x' from $\mathcal{P}$. Note that for a string with no erasures, this is simply the Hamming distance of x from $\mathcal{P}$. As before, x is ε-far from $\mathcal{P}$ if $\text{dist}(x, \mathcal{P}) > \varepsilon$, and ε-close otherwise.

▶ **Definition 15** (Erasure-resilient tester)**.** *Let* $\alpha \in [0,1)$ *and* $\varepsilon \in (0,1)$ *be parameters satisfying* $\alpha + \varepsilon < 1$*. A* q*-query* α*-erasure-resilient* ε*-tester* T *for* $\mathcal{P}$ *is a probabilistic algorithm making* q *queries to an* α*-erased string* $x \in \{0,1,\perp\}^n$*, that outputs a binary verdict satisfying the following two conditions.*

1. *If* $\text{dist}(x, \mathcal{P}) = 0$ *(i.e., if there exists a completion* x' *of* x*, such that* $x' \in \mathcal{P}$*), then* T *accepts* x *with probability at least* $2/3$.
2. *If* $\text{dist}(x, \mathcal{P}) > \varepsilon$ *(i.e., if every completion of* x' *of* x *is* ε*-far from* $\mathcal{P}$*), then* T *rejects* x *with probability at least* $2/3$.

The next lemma will be useful to prove that some properties are hard to test. The lemma states that if we have two distributions whose restrictions to any set of queries of size at most q are identical, then no (possibly adaptive) algorithm making at most q queries can distinguish between them.

▶ **Definition 16** (Restriction)**.** *Given a distribution* $\mathcal{D}$ *over functions* $f : D \to \{0,1\}$ *and a subset* $Q \subseteq D$*, we define the* restriction $\mathcal{D}|_Q$ of $\mathcal{D}$ to Q *to be the distribution over functions* $g : Q \to \{0,1\}$*, that results from choosing a function* $f : D \to \{0,1\}$ *according to* $\mathcal{D}$*, and setting* g *to be* $f|_Q$*, the restriction of* f *to* Q.

▶ **Lemma 17** ([17], special case)**.** *Let* $\mathcal{D}_1$ *and* $\mathcal{D}_2$ *be two distributions of functions over some domain* D*. Suppose that for any set* $Q \subset D$ *of size at most* q*, the restricted distributions* $\mathcal{D}_1|_Q$ *and* $\mathcal{D}_2|_Q$ *are identically distributed. Then, any (possibly adaptive) algorithm making at most* q *queries cannot distinguish* $\mathcal{D}_1$ *from* $\mathcal{D}_2$ *with any positive probability.*

3 Code Ensembles

It will be necessary for us to think of a generalized definition of an encoding, in which each encoded value has multiple legal encodings.

▶ **Definition 18** (Code ensemble)**.** *A* code ensemble *is a function* $\mathcal{E} : \Sigma^k \to 2^{\Sigma^m}$*. Namely, every* $x \in \Sigma^k$ *has a set of its valid encodings from* Σ^m*. We define the distance of the code ensemble as*

$$\min_{x \neq x' \in \{0,1\}^k} \min_{(v,u) \in \mathcal{E}(x) \times \mathcal{E}(x')} \text{dist}(v, u).$$

It is useful to think of a code ensemble $\mathcal{E} : \Sigma^k \to 2^{\Sigma^m}$ as a *randomized mapping*, that given $x \in \Sigma^k$, outputs a uniformly random element from the set of encodings $\mathcal{E}(x)$. Using the above we can define a *shared secret* property. In particular, we use a strong information

theoretic definition of a shared secret, in which $o(m)$ bits do not give *any information at all* about the encoded value. Later on, we construct code ensembles with a shared secret property.

▶ **Definition 19** (Shared Secret). *For $m, k \in \mathbb{N}$ and a constant $\zeta > 0$, we say that a code ensemble $\mathcal{C} : \{0,1\}^k \to 2^{(\{0,1\}^m)}$ has a* ζ-shared secret *property if it satisfies the following. For any $Q \subseteq [m]$ of size $|Q| \leq \zeta m$, any $w, w' \in \{0,1\}^k$ such that $w \neq w'$, and any $t \in \{0,1\}^{|Q|}$ it holds that*

$$\underset{\boldsymbol{v} \sim \mathcal{C}(w)}{\boldsymbol{Pr}}[\boldsymbol{v}|_Q = t] = \underset{\boldsymbol{v}' \sim \mathcal{C}(w')}{\boldsymbol{Pr}}[\boldsymbol{v}'|_Q = t].$$

Namely, for any $w \neq w'$ and any $Q \subseteq [m]$ of size at most ζm, the distribution obtained by choosing a uniformly random member of $\mathcal{C}(w)$ and considering its restriction to Q, is identical to the distribution obtained by choosing a uniformly random member of $\mathcal{C}(w')$ and considering its restriction to Q.

3.1 A construction of a hard code ensemble

We describe a construction of a code ensemble for which a linear number of queries is necessary to verify membership or to decode the encoded value. This code will be our *base* code in the iterative construction. The existence of such a code ensemble is proved probabilistically, relying on the following simple lemma.

▶ **Lemma 20.** *Fix constant $\alpha, \beta > 0$ where $\beta \log(e/\beta) < \alpha$. Let $s, t \in \mathbb{N}$ so that $s \leq (1-\alpha)t$. Then, with probability $1 - o(1)$, a sequence of s uniformly random vectors $\{v_1, \ldots, v_s\}$ from $\{0,1\}^t$ is linearly independent, and corresponds to a β-distance linear code.*

Proof. The proof follows from a straightforward counting argument. If we draw s uniformly random vectors $v_1, \ldots, v_s \in \{0,1\}^t$, then each non-trivial linear combination of them is in itself a uniformly random vector from $\{0,1\}^t$, and hence has weight less than β with probability at most

$$2^{-t} \cdot \binom{t}{\beta t} \leq 2^{-t} \left(\frac{et}{\beta t}\right)^{\beta t} = 2^{-t} \cdot 2^{\beta \log(e/\beta) t} = 2^{(\gamma - 1)t},$$

where we set $\gamma = \beta \log(e/\beta) < \alpha$.

By a union bound over all $2^s \leq 2^{(1-\alpha)t}$ possible combinations, the probability that there exists a linear combination with weight less than β is at most $2^{(\gamma-\alpha)t} = o(1)$. If this is not the case, then $v_1, \ldots, v_s$ are linearly independent, and moreover, $\{v_1, \ldots, v_s\}$ corresponds to a β-distance linear code (where we use the fact that the distance of a linear code is equal to the minimal Hamming weight of a non-zero codeword). ◀

Our construction makes use of a sequence of vectors that correspond to a high-distance and high-dual distance code, as described below.

▶ **Definition 21** (Hard code ensemble $\mathcal{H}_k$). *Let $k \in \mathbb{N}$ and let $\{v_1, \ldots, v_{3k}\}$ be a sequence of vectors in $\{0,1\}^{4k}$ such that* $\mathrm{Span}\{v_1, \ldots, v_{3k}\}$ *is a* $1/30$*-distance code, and that* $\mathrm{Span}\{v_{k+1}, \ldots, v_{3k}\}$ *is a* $1/10$*-dual distance code. Let*

$$A = \begin{bmatrix} | & & | \\ v_1 & \cdots & v_{3k} \\ | & & | \end{bmatrix}.$$

We define the code ensemble $\mathcal{H}_k : \{0,1\}^k \to 2^{\{0,1\}^{4k}}$ *as*

$$\mathcal{H}_k(w) = \{Au \ : \ u \in \{0,1\}^{3k} \text{ where } u|_{\{1,\ldots,k\}} = w\},$$

where all operations are over GF(2)*.*

The next lemma states that a collection of random vectors $\{v_1, \ldots, v_{3k}\}$ in $\{0,1\}^{4k}$ satisfies the basic requirements of a code ensemble $\mathcal{H}_k$ with high probability (that is, with probability tending to one as $k \to \infty$), and hence such a code ensemble exists.

▶ **Lemma 22.** *A set* $\{v_1, \ldots, v_{3k}\}$ *of random vectors in* $\{0,1\}^{4k}$ *satisfies with high probability the following two conditions:* $\mathrm{Span}\{v_1, \ldots, v_{3k}\}$ *is a* 1/30*-distance code, and furthermore,* $\mathrm{Span}\{v_{k+1}, \ldots, v_{3k}\}$ *is a* 1/10*-dual distance code. In particular, for all* k *large enough the code ensemble* $\mathcal{H}_k$ *exists.*

Proof. We apply Lemma 20 multiple times. First, picking $t = 4k$, $s = 3k$, $\alpha = 1/4$, and $\beta = 1/30$, we conclude that $v_1, \ldots, v_{3k}$ with high probability correspond to a 1/30-distance code.

To show that with high probability the code spanned by the last $2k$ vectors has high dual distance, we compare the following two processes, whose output is a linear subspace of $(\mathrm{GF}(2))^{4k}$, that we view as a code: (i) Choose $2k$ vectors and return their span. (ii) Choose $4k - 2k = 2k$ vectors and return the dual of their span. Conditioning on the chosen $2k$ vectors being linearly independent, the output distributions of these two processes are identical. Indeed, by a symmetry argument it is not hard to see that under the conditioning, the linear subspace generated by Process (i) is uniformly distributed among all rank-$2k$ subspaces V of $(\mathrm{GF}(2))^{4k}$. Now, since we can uniquely couple each such V with its dual $V^\perp$ (also a rank-$2k$ subspace) and since $V = (V^\perp)^\perp$, this means that the output distribution of Process (ii) is uniform as well.

However, it follows again from Lemma 20 (with $t = 4k$, $s = 2k$, $\alpha = 1/2$, and any $\beta > 0$ satisfying the conditions of the lemma) that the chosen $2k$ vectors are independent with high probability. This means that (without the conditioning) the output distributions of Process (i) and Process (ii) are $o(1)$-close in variation distance. Applying Lemma 20 with $t = 4k$, $s = 2k$, $\alpha = 1/2$, and $\beta = 1/10$ we get that the distance of the code generated by Process (i) is at least $\beta = 1/10$ with high probability. However, the latter distance equals by definition to the dual distance of the code generated by Process (ii). By the closeness of the distributions, we conclude that the dual distance of Process (i) is also at least 1/10 with high probability. ◀

We next state a simple but important observation regarding membership verification.

▶ **Observation 23.** *Once a matrix* A *with the desired properties is constructed (which may take* $\exp(k^2)$ *time if we use brute force), given* $w \in \{0,1\}^k$*, the membership of* v *in* $\mathcal{H}_k(w)$ *can be verified in* $\mathrm{poly}(k)$ *time (by solving a system of linear equations over* GF(2)*).*

4 PCUs and PCUSSs

Next, we define the notion of Probabilistically Checkable Unveiling (PCU). This notion is similar to PCPP, but here instead of requiring our input to satisfy a given property, we require our input to encode a value $w \in \{0,1\}^k$ (typically using a large distance code ensemble). We then require that given the encoded value w, it will be possible to prove in a PCPP-like fashion that the input is indeed a valid encoding of w.

▶ **Definition 24** (PCU). *Fix $m, t, k \in \mathbb{N}$, and let $\mathcal{C} : \{0,1\}^k \to 2^{\{0,1\}^m}$ be a code ensemble. We say that $\mathcal{C}$ has a $q(\varepsilon,\delta)$-query, length-t* PCU *if the following holds. There exists a verification algorithm V that takes as inputs $\varepsilon, \delta > 0$, $m \in \mathbb{N}$, and $w \in \{0,1\}^k$, makes at most $q(\varepsilon,\delta)$ queries to the strings $v \in \{0,1\}^m$ and $\pi \in \{0,1\}^t$, and satisfies the following:*

1. *If $v \in \mathcal{C}(w)$, then there exists a proof $\pi = \boldsymbol{Proof}_{\mathcal{C}}(v) \in \{0,1\}^t$ such that for every $\varepsilon, \delta > 0$, the verifier V accepts with probability 1.*
2. *If $\mathrm{dist}(v, \mathcal{C}(w)) > \varepsilon$, then for every alleged proof $\pi \in \{0,1\}^t$, the verifier V rejects v with probability greater than δ.*

In order to facilitate the proof of the main theorem, we utilize a more stringent variant of the above PCU definition. Instead of supplying $w \in \{0,1\}^k$ to the algorithm, we supply oracle access to a a string $\tau \in \{0,1\}^{100k}$ that is supposed to represent $\mathsf{Spiel}(w)$, along with the proof π, and the algorithm only makes $q(\varepsilon,\delta)$ queries to the proof string π, the original encoding v *and* the string τ. For cases where $v \in \mathcal{C}(w)$, we use $\mathbf{Value}(v)$ to denote $\mathsf{Spiel}(w)$.

▶ **Definition 25** (Spiel-PCU). *Fix $m, t, k \in \mathbb{N}$, and let $\mathcal{C} : \{0,1\}^k \to 2^{\{0,1\}^m}$ be a code ensemble. We say that $\mathcal{C}$ has a $q(\varepsilon,\delta)$-query, length-t* Spiel-PCU *if the following holds. There exists a verification algorithm V that takes as inputs $\varepsilon, \delta > 0$, $m \in \mathbb{N}$, makes at most $q(\varepsilon,\delta)$ queries to the strings $v \in \{0,1\}^m$, $\tau \in \{0,1\}^{100k}$ and $\pi \in \{0,1\}^t$, and satisfies the following:*

1. *If there exists $w \in \{0,1\}^k$ for which $v \in \mathcal{C}(w)$ and $\tau = \boldsymbol{Value}(v) = \mathsf{Spiel}(w)$, then there exists a proof $\pi = \boldsymbol{Proof}_{\mathcal{C}}(v) \in \{0,1\}^t$ such that for every $\varepsilon, \delta > 0$, the verifier V accepts with probability 1.*
2. *If for every $w \in \{0,1\}^k$ either $\mathrm{dist}(\tau, \mathsf{Spiel}(w)) > \varepsilon$ or $\mathrm{dist}(v, \mathcal{C}(w)) > \varepsilon$, then for every alleged proof $\pi \in \{0,1\}^t$, the verifier V rejects v with probability greater than δ.*

Note that a code ensemble admitting a Spiel-PCU automatically admits a PCU. Indeed, given the string w, an oracle for $\mathsf{Spiel}(w)$ can be simulated.

The following lemma states the existence of Spiel-PCU for efficiently computable code ensembles, and will be used throughout this work. The proof follows from Lemma 12 together with a simple concatenation argument.

▶ **Lemma 26.** *Let $k, m, t \in \mathbb{N}$ be such that $t \geq m$, and let $\mathcal{C} : \{0,1\}^k \to 2^{\{0,1\}^m}$ be a code ensemble. If given $w \in \{0,1\}^k$ and $v \in \{0,1\}^m$, it is possible to verify membership of v in $\mathcal{C}(w)$ using a circuit of size t, then there is a $q(\varepsilon,\delta)$-query, length-t'* Spiel-PCU *for $\mathcal{C}$ where $t' = t \cdot \mathrm{polylog}\, t$.*

Proof. Assume without loss of generality that $m \geq |\mathsf{Spiel}(0^k)|$. Let $\xi = \left\lfloor \frac{m}{|\mathsf{Spiel}(0^k)|} \right\rfloor$ (note that $\xi \geq 1$), and define

$$\mathcal{C}_{eq} \stackrel{\text{def}}{=} \left\{ v \sqcup (\mathsf{Spiel}(w))^{\xi} \;\middle|\; \exists w \in \{0,1\}^k \text{ for which } v \in \mathcal{C}(w) \right\},$$

where $(\mathsf{Spiel}(w))^{\xi}$ denotes the ξ-times concatenation of $\mathsf{Spiel}(w)$.

For any string u it is possible to check, using a quasilinear size circuit (see [30]), that the substring that corresponds to the domain of $(\mathsf{Spiel}(w))^{\xi}$ is a ξ-times repetition of $\mathsf{Spiel}(w)$ for some w. After doing so, we decode w using a quasilinear size circuit (as in [30]), and then, by the premise of the lemma, we can verify membership in $\mathcal{C}(w)$ using a circuit of size t. Therefore, membership in $\mathcal{C}_{eq}$ can be decided using a $O(t)$ size boolean circuit, and therefore by Lemma 12 admits a PCPP system whose proof length is quasilinear in t.

Given an input v to Spiel-PCU, let $v' = v \sqcup (\mathsf{Spiel}(w))^{\xi}$ and use the PCPP system for $\mathcal{C}_{eq}$, with detection radius $\varepsilon/3$ and soundness parameter δ, where each query to v' is emulated by a corresponding query to v or $\mathsf{Spiel}(w)$. Note that if $v \in \mathcal{C}(w)$, then $v' \in \mathcal{C}_{eq}$, so the PCPP system for $\mathcal{C}_{eq}$ will accept with probability 1.

Next, suppose that $\mathrm{dist}(v, \mathcal{C}(w)) > \varepsilon$, and observe that this implies that v' is at least $\varepsilon/3$-far from $\mathcal{C}_{eq}$. Thus, by the soundness property of the PCPP for $\mathcal{C}_{eq}$, the verifier rejects with probability at least δ, regardless of the contents of the alleged proof π it is supplied with. ◀

Next we define Probabilistically Checkable Unveiling of a Shared Secret (PCUSS).

▶ **Definition 27.** *For $m, k, t \in \mathbb{N}$, we say that a function $\mathcal{C}\colon \{0,1\}^k \to 2^{(\{0,1\}^n)}$ has a $q(\varepsilon,\delta)$-query, length-t* PCUSS*, if $\mathcal{C}$ has a shared secret property, as well as $\mathcal{C}$ has a $q(\varepsilon,\delta)$-query, length-t* PCU*. Similarly, when $\mathcal{C}$ has a shared secret property (for constant ζ), as well as $\mathcal{C}$ has a $q(\varepsilon,\delta)$-query, length-t* Spiel-PCU*, we say that $\mathcal{C}$ has a $q(\varepsilon,\delta)$-query, length-t* Spiel-PCUSS*.*

Note that $\mathcal{C}$ admitting a Spiel-PCUSS directly implies that it admits a PCUSS with similar parameters.

The following lemma establishes the existence of a Spiel-PCUSS for $\mathcal{H}_k$, where $\mathcal{H}_k$ is the code ensemble from Definition 21.

▶ **Lemma 28.** *For any $k \in \mathbb{N}$, $\mathcal{H}_k$ has a $q(\varepsilon,\delta)$-query, length-t'* Spiel-PCUSS *where $t' = \mathrm{poly}(k)$.*

Proof. By Observation 23, given w, membership in $\mathcal{H}_k(w)$ can be checked in $\mathrm{poly}(k)$ time, which means that there exists a polynomial size circuit that decides membership in $\mathcal{H}_k(w)$. Combining the above with Lemma 26 implies a $q(\varepsilon,\delta)$-query, length-t' Spiel-PCU where $t' = \mathrm{poly}(k)$. By Lemma 10, the large dual distance property of $\mathcal{H}_k$ implies its shared secret property for some constant ζ, which concludes the proof of the lemma. ◀

5 PCUSS construction

In this section we give a construction of code ensembles that admit a PCUSS. First we show that our code ensemble has a PCU with a short proof. Specifically,

▶ **Lemma 29.** *For any fixed $\ell \in \mathbb{N}$ and any $k \in \mathbb{N}$, there exists $n_0(\ell, k)$ and a code ensemble $\mathcal{E}^{(\ell)} : \{0,1\}^k \to 2^{(\{0,1\}^n)}$, such that for all $n > n_0(\ell, k)$, the code ensemble $\mathcal{E}^{(\ell)}$ has a $q(\varepsilon,\delta)$-query length-t* PCU*, for $t = O(n \cdot \mathrm{polylog}^{(\ell)} n)$.*

Later, we prove that our code ensemble has a shared secret property, which implies that it has a PCUSS (which implies Theorem 1, as we shall show).

▶ **Theorem 30.** *For any fixed $\ell \in \mathbb{N}$ and any $k \in \mathbb{N}$, there exists $n_0(\ell, k)$ and a code ensemble $\mathcal{E}^{(\ell)} : \{0,1\}^k \to 2^{(\{0,1\}^n)}$, such that for all $n > n_0(\ell, k)$, the code ensemble $\mathcal{E}^{(\ell)}$ has a $q(\varepsilon,\delta)$-query length-t* PCUSS*, for $t = O(n \cdot \mathrm{polylog}^{(\ell)} n)$.*

Specifically, by the discussion before Lemma 37, for any fixed soundness parameter $0 < \delta < 1$ it suffices to take

$$q(\varepsilon,\delta) \leq \left(2^{\ell}/\varepsilon\right)^{O(\ell)},$$

and for the high soundness regime where $\delta = 1 - \tau$ (and $\tau > 0$ is small), it suffices to have

$$q(\varepsilon,\delta) \leq \left(2^{\ell}/\varepsilon\right)^{O(\ell)} \log(1/\tau).$$

5.1 The iterated construction

Our iterative construction uses polynomials over a binary finite field $\mathrm{GF}(2^t)$. In our proof we will need to be able to implement arithmetic operations over this field efficiently (i.e., in $\mathrm{poly}(t)$ time). This can be easily done given a suitable representation of the field: namely, a degree t irreducible polynomial over $\mathrm{GF}(2)$. It is unclear in general whether such a polynomial can be found in $\mathrm{poly}(t)$ time. Fortunately though, for $t = 2 \cdot 3^r$ where $r \in \mathbb{N}$, it is known that the polynomial $x^t + x^{t/2} + 1$ is irreducible over $\mathrm{GF}(2)$ (see, e.g., [18, Appendix G]). We will therefore restrict our attention to fields of this form. At first glance this seems to give us a property that is defined only on a sparse set of input lengths. However, towards the end of this section, we briefly describe how to bypass this restriction.

We next formally define our iterated construction, starting with the "level-0" construction as a base case. The constants c, d in the definition will be explicitly given in the proof of Lemma 36. Additionally, for any $\ell \in \mathbb{N}$, we shall pick a large enough constant c_ℓ that satisfies several requirements for the "level-ℓ" iteration of the construction.

▶ **Definition 31** (Iterated coding ensemble). *For $k \in \mathbb{N}$ and $w \in \{0,1\}^k$, we define the* base code ensemble of w *(i.e., level-ℓ code ensemble of w for $\ell = 0$) as*

$$\mathcal{E}_k^{(0)}(w) = \mathcal{H}_k(w).$$

Let $c, d \in \mathbb{N}$ be large enough global constants, fix $\ell > 0$, let c_ℓ be large enough, and let $\mathbb{F}$ be a finite field for which $|\mathbb{F}| \geq \max\{c_\ell, c \cdot k\}$.

We define the level-ℓ code ensemble of $w \in \{0,1\}^k$ over $\mathbb{F}$ *as follows. Let $r \in \mathbb{N}$ be the smallest integer such that $(\log|\mathbb{F}|)^d \leq 2^{2 \cdot 3^r}$, set $\mathbb{F}' = \mathrm{GF}\left(2^{2 \cdot 3^r}\right)$ and $k' = \log|\mathbb{F}|$. Note that these satisfy the recursive requirements of a level-$(\ell-1)$ code ensemble provided that c_ℓ is large enough (specifically we require $(\log|\mathbb{F}|)^{d-1} > c$, so that $|\mathbb{F}'| \geq ck'$). Finally, let $H \subseteq \mathbb{F}$ be such that $|H| = k$, and define*

$$\mathcal{E}_{\mathbb{F},k}^{(\ell)}(w) = \bigcup_{g \in \mathcal{C}_\mathbb{F}:\ g|_H = w} \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}_{\mathbb{F}',k'}^{(\ell-1)}(\langle\!\langle g(\beta) \rangle\!\rangle).$$

(Note that for $\ell = 1$ we just use $\mathcal{E}_{\mathbb{F},k}^{(1)}(w) = \bigcup_{g \in \mathcal{C}_\mathbb{F}:\ g|_H = w} \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}_{k'}^{(0)}(\langle\!\langle g(\beta) \rangle\!\rangle)$).

That is, $v \in \mathcal{E}_{\mathbb{F},k}^{(\ell)}(w)$ if there exists a polynomial $g \in \mathcal{C}_\mathbb{F}$ such that $v = \bigsqcup_{\beta \in \mathbb{F} \setminus H} v_\beta$, where $v_\beta \in \mathcal{E}_{\mathbb{F}',k'}^{(\ell-1)}(\langle\!\langle g(\beta) \rangle\!\rangle)$ for every $\beta \in \mathbb{F} \setminus H$ and $g|_H = w$ (where we identify the 0 and 1 elements of $\mathbb{F}$ with 0 and 1 bits respectively). When the context is clear, we sometimes omit the subscripts.

Our choice of the constants c, d, c_ℓ needs to satisfy the following conditions. The constant c is chosen such that H will not be an overly large portion of $\mathbb{F}$ (this requirement is used in Lemma 42). The constant d is needed to subsume the length of PCPP proof string which is part of the construction (this requirement is used in Lemma 36). Finally, the constant c_ℓ needs to be large enough to enable iteration (as explained in Definition 31 itself).

Let $\ell \geq 0$ be some fixed iteration. The following simple observation follows by a simple inductive argument using the definition of the level-ℓ coding ensemble, and in particular that $|\mathbb{F}'| = \mathrm{polylog}\,|\mathbb{F}|$.

▶ **Observation 32.** *For $\ell > 0$, let $n = |\mathbb{F}|$ and $w \in \{0,1\}^k$. If $v \in \mathcal{E}^{(\ell)}(w)$, then $m_\mathbb{F}^{(\ell)} \stackrel{\text{def}}{=} |v| = n \cdot \mathrm{poly}(\log n) \cdot \mathrm{poly}(\log\log n) \cdots \mathrm{poly}(\log^{(\ell)} n)$, where $\log^{(\ell)} n$ is the* log *function iterated ℓ times.*

When the field $\mathbb{F}$ is clear from context, we shall usually write $m^{(\ell)}$ as a shorthand for $m^{(\ell)}_{\mathbb{F}}$. The following lemma, proved in the next subsection, establishes the existence of short length Spiel-PCUs for our code ensembles.

▶ **Lemma 33.** *For any $\ell \geq 0$, the code ensemble $\mathcal{E}^{(\ell)}_{\mathbb{F},k}$ admits a $q(\varepsilon,\delta)$-query, length-t* Spiel-PCU *for $t = O(m^{(\ell)} \cdot \mathrm{polylog}^{(\ell)} m^{(\ell)})$.*

5.2 Proof of Lemma 33

We start by defining the PCU proof string for a given $v \in \mathcal{E}^{(\ell)}_{\mathbb{F},k}(w)$ for some $w \in \{0,1\}^k$.

▶ **Definition 34** (The PCU Proof String)**.** *For $\ell = 0$, let $v \in \mathcal{E}^{(0)}_k(w)$ and $\boldsymbol{Value}^{(0)}(v) = \mathsf{Spiel}(w)$. We define the proof string for v, $\boldsymbol{Proof}^{(0)}(v)$, as the one guaranteed by Lemma 28 (note that the length of $\boldsymbol{Proof}^{(0)}(v)$ is $\mathrm{poly}(k)$).*

For $\ell > 0$, let $g \in \mathcal{C}_{\mathbb{F}}$ and $w \in \{0,1\}^k$ be such that $v \in \bigsqcup_{\beta\in\mathbb{F}\setminus H} \mathcal{E}^{(\ell-1)}(\langle\!\langle g(\beta)\rangle\!\rangle)$, $\boldsymbol{Value}^{(\ell)}(v) = \mathsf{Spiel}(w)$ and $g|_H = w$. In addition, set $S_v \stackrel{\text{def}}{=} \bigsqcup_{\beta\in\mathbb{F}\setminus H} \boldsymbol{Value}^{(\ell-1)}(v_\beta) = \bigsqcup_{\beta\in\mathbb{F}\setminus H} \mathsf{Spiel}(g(\beta))$. The proof string for $v \in \mathcal{E}^{(\ell)}_{\mathbb{F},k}$ is defined as follows.

$$\boldsymbol{Proof}^{(\ell)}(v) = S_v \sqcup \bigsqcup_{\beta\in\mathbb{F}\setminus H} \boldsymbol{Proof}^{(\ell-1)}(v_\beta) \sqcup \boldsymbol{Proof}_{\mathcal{L}}(S_v)$$

where the code ensemble $\mathcal{L} : \{0,1\}^k \to 2^{\{0,1\}^{O(|\mathbb{F}|\cdot\log|\mathbb{F}|)}}$ is defined as follows. Given $w \in \{0,1\}^k$, $S \in \mathcal{L}(w)$ if and only if there exists a polynomial $g \in \mathcal{C}_{\mathbb{F}}$ such that the following conditions are satisfied.

1. $g|_H = w$.
2. $S = \bigsqcup_{\beta\in\mathbb{F}\setminus H} \mathsf{Spiel}(g(\beta))$.

The following lemma establishes the existence of a Spiel-PCU for $\mathcal{L}$.

▶ **Lemma 35.** *$\mathcal{L}$ has a $q(\varepsilon,\delta)$-query length-t* Spiel-PCU *for $t = O(|\mathbb{F}| \cdot \mathrm{polylog}\,|\mathbb{F}|)$.*

Proof. By Theorem 5, there exists a quasilinear size circuit that decodes $\mathsf{Spiel}(\alpha)$. Using such a circuit, we can decode $g(\beta)$ from S for every $\beta \in \mathbb{F}$. Then, using all the values $g(\beta)$ and w (where the i-th bit of w correspond to the value of the i-th element in H according to the ordering), we use Theorem 7 to interpolate the values and achieve a representation of a polynomial $g : \mathbb{F} \to \mathbb{F}$. If $g \in \mathcal{C}_{\mathbb{F}}$ we accept S and otherwise we reject. Since deciding if $S \in \mathcal{L}(w)$ has a quasilinear size circuit, by Lemma 26, there is a quasilinear length Spiel-PCU for $\mathcal{L}$. ◀

Having defined $\mathbf{Proof}^{(\ell)}$, we first provide an upper bound on the bit length of the prescribed proof string. For $\ell > 0$, let $z^{(\ell)}_{\mathbb{F},k}$ denote the bit length of the proof for membership in $\mathcal{E}^{(\ell)}$ as defined in Definition 34, where for $\ell = 0$ we replace the (nonexistent) field $\mathbb{F}$ with $|w|$.

The following lemma, establishing the proof string's length, relies on our choice of the constant d in Definition 31. In particular, d needs to be large enough to subsume the size of $\mathbf{Proof}_{\mathcal{L}}(\cdot)$

▶ **Lemma 36.** *For any $\ell \geq 0$, we have that $z^{(\ell)}_{\mathbb{F},k} = O\big(m^{(\ell)} \cdot \mathrm{polylog}^{(\ell)} m^{(\ell)}\big)$.*

Proof. The proof follows by induction on ℓ. The base case ($\ell = 0$) follows directly from the definition of $\mathcal{P}^{(0)}$ by our convention that $\log^{(0)}|w| = |w|$.

Consider $\ell > 0$, and note that since the size of S_v is $O(|\mathbb{F}| \log |\mathbb{F}|)$, the size of $\mathbf{Proof}_{\mathcal{L}}(S_v)$ is $O(|\mathbb{F}| \cdot \text{polylog } |\mathbb{F}|)$. By combining the above with the definition of the proof string we have

$$z^{(\ell)}_{\mathbb{F},k} \leq |\mathbb{F}| \cdot \text{polylog } |\mathbb{F}| + |\mathbb{F}| \cdot z^{(\ell-1)}_{\mathbb{F}',k'}.$$

Now, assume that $z^{(\ell-1)}_{\mathbb{F}',k'} = O(m^{(\ell-1)} \cdot \text{polylog}^{(\ell-1)}|\mathbb{F}'|)$. Note that since the global constant d was chosen so that $|\mathbb{F}| \cdot |\mathbb{F}'| \geq |\mathbf{Proof}_{\mathcal{L}}(S_v)|$, we have that $|\mathbb{F}| \cdot z^{(\ell-1)}_{\mathbb{F}',k'} \geq |\mathbb{F}| \cdot |\mathbb{F}'| \geq |\mathbf{Proof}_{\mathcal{L}}(S_v)|$. Therefore,

$$m^{(\ell)} = \Theta(|\mathbb{F}| \cdot m^{(\ell-1)}) = \Omega(|\mathbb{F}| \cdot |\mathbb{F}'|) = \Omega(|\mathbb{F}| \cdot \text{polylog } |\mathbb{F}|),$$

so that $|\mathbb{F}| \cdot \text{polylog } |\mathbb{F}| = O(m^{(\ell)})$, and

$$z^{(\ell)}_{\mathbb{F},k} = O(|\mathbb{F}| \cdot z^{(\ell-1)}_{\mathbb{F}'}).$$

In addition, by the fact that $m_\ell = \Theta(|\mathbb{F}| \cdot m^{(\ell-1)})$ and the induction hypothesis we obtain

$$|\mathbb{F}| \cdot z^{(\ell-1)}_{\mathbb{F}',k'} = O(|\mathbb{F}| \cdot m^{(\ell-1)} \cdot \text{polylog}^{(\ell-1)}|\mathbb{F}'|) = O(m^{(\ell)} \cdot \text{polylog}^{(\ell)}|\mathbb{F}|) = O(m^{(\ell)} \cdot \text{polylog}^{(\ell)} m_\ell).$$

So overall, we get that $z^{(\ell)}_{\mathbb{F},k} = O(m^{(\ell)} \cdot \text{polylog}^{(\ell)} m^{(\ell)})$ as required. ◀

Next, for an alleged proof $\pi = \mathbf{Proof}^{(\ell)}(v)$, we use the notation $\pi|_{\text{Dom}(X)}$ to denote the restriction of π to the bits that correspond to X in π as defined in Definition 34. For example, $\pi|_{\text{Dom}(\mathbf{Value}^{(\ell-1)}(v_\beta))}$ refers to the bits that represent $\mathbf{Value}^{(\ell-1)}(v_\beta)$.

We introduce the verifier procedure for $\mathcal{E}^{(\ell)}_{\mathbb{F},k}$ (see Figure 1), and prove its completeness and soundness. For technical considerations, the verifier procedure is only defined when the soundness parameter δ is small enough (as a function of ℓ); the soundness amplification argument from Subsection 2.2 can easily take care of the situation where δ is larger, by running sufficiently many independent instances of the verification step.

Before proceeding to the completeness and soundness proofs, let us analyze the query complexity. Denote by $Q_\ell(\varepsilon, \delta)$ the query complexity of the verifier in the above procedure for a given $\ell \geq 0$. It follows from the recursive description of `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$ and the proof of Lemmas 26 and 35 that the query complexity satisfies the recurrence relation $Q_\ell(\varepsilon, \delta) \leq O(1/\varepsilon) \cdot Q_{\ell-1}(\varepsilon/O(1)), \delta \cdot O(1)) + q^*(\Theta(\varepsilon), \Theta(\delta))$, where $q^*(\varepsilon^*, \delta^*) = O((\varepsilon^*)^{-1})$ is the query complexity of Dinur's PCP [12] with detection radius ε^* and soundness parameter $\delta^* \leq 1/2$; and furthermore, that $Q_0(\varepsilon, \delta) \leq q^*(\Theta(\varepsilon), \Theta(\delta))$. Thus, we conclude by induction that, provided that $\delta \leq 2^{-\ell-1}$,

$$Q_\ell(\varepsilon, \delta) \leq \frac{C}{\varepsilon} \cdot \frac{C^2}{\varepsilon} \cdot \ldots \cdot \frac{C^\ell}{\varepsilon} \cdot q^*(\varepsilon/2^{O(\ell)}, \delta \cdot 2^\ell) = 2^{O(\ell^2)} \varepsilon^{-O(\ell)},$$

where $C > 0$ is a large enough absolute constant. To achieve any given soundness $\delta > 1/2$, we can amplify by repeating the verifier procedure with parameter $\delta' = 2^{-\ell-1}$ a total of $2^{O(\ell)} \cdot \log\left((1-\delta)^{-1}\right)$ times and rejecting if any of these instances rejected. The query complexity is bounded by

$$2^{O(\ell^2)} \varepsilon^{-O(\ell)} \cdot 2^{O(\ell)} \cdot \log\left((1-\delta)^{-1}\right) = (2^\ell/\varepsilon)^{O(\ell)} \cdot \log\left((1-\delta)^{-1}\right),$$

as desired. The next two lemmas establish the completeness and soundeness of the verifier procedure, respectively.

`Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$

Input: Parameters $\varepsilon, \delta \in (0,1)$ where $\delta \leq 2^{-\ell-1}$, an input $v \in \{0,1\}^{m^{(\ell)}}$, an alleged value $\tau \in \{0,1\}^{100k}$ of v, and an alleged proof $\pi \in \{0,1\}^{z^{(\ell)}_{\mathbb{F},k}}$ for v.

1. If $\ell = 0$, use the PCU for $\mathcal{E}^{(0)}$ with parameters ε and δ.
2. If $\ell > 0$:
   a. Use the PCU verifier for $\mathcal{L}$ with radius $\varepsilon/300$ and soundness δ, to verify the unveiling of $\pi|_{\mathrm{Dom}(S_v)}$, using τ as the value oracle and $\pi|_{\mathrm{Dom}(\mathbf{Proof}_{\mathcal{L}}(S_v))}$ as the proof oracle.
   b. For $6/\varepsilon$ many times:
      i. Pick $\boldsymbol{\beta} \in \mathbb{F} \setminus H$ uniformly at random.
      ii. Use the PCU verifier procedure for $\mathcal{E}^{(\ell-1)}$ with parameters $\varepsilon/3$ and 2δ, to verify the unveiling of $v_{\boldsymbol{\beta}}$, using $\pi|_{\mathrm{Dom}(\mathbf{Value}^{(\ell-1)}(v_\beta))}$ as the value oracle and $\pi|_{\mathrm{Dom}(\mathbf{Proof}^{(\ell-1)}(v_{\boldsymbol{\beta}}))}$ as the proof oracle.

If any of the stages rejected then **Reject**, and otherwise **Accept**.

Figure 1 Description of `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$.

▶ **Lemma 37.** *If there exist $w \in \{0,1\}^k$ for which $v \in \mathcal{E}^{(\ell)}_{\mathbb{F},k}(w)$, then* `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$ *accepts v with probability 1 when supplied with oracle access to the corresponding $\boldsymbol{Proof}^{(\ell)}(v)$ and $\tau = \boldsymbol{Value}^{(\ell)}(v) = \mathsf{Spiel}(w)$.*

Proof. The proof follows by induction on ℓ. The base case follows directly from Lemma 28. Hence, the verifier for $\mathcal{E}^{(0)}$ supplied with $\mathbf{Proof}^{(0)}(v)$ as the proof oracle and $\mathbf{Value}^{(\ell)}(v)$ as the value oracle, will accept v with probability 1.

Assume that `Verifier-Procedure` $_{\mathcal{E}^{(\ell-1)}}$ accepts with probability 1 any valid encoding v' when supplied with the corresponding oracles for $\mathbf{Value}^{(\ell-1)}(v')$ and $\mathbf{Proof}^{(\ell-1)}(v')$. Let $v \in \mathcal{E}^{(\ell)}$ and write $v = \bigsqcup_{\beta \in \mathbb{F} \setminus H} v_\beta$, where there exist $w \in \{0,1\}^k$ and $g \in \mathcal{C}_{\mathbb{F}}$ such that for all $\beta \in \mathbb{F} \setminus H$, $v_\beta \in \mathcal{E}^{(\ell-1)}(g(\beta))$, where $g|_H = w$ and $\tau = \mathbf{Value}^{(\ell)}(v) = \mathsf{Spiel}(w)$. Then, by the definition of the language $\mathcal{L}$ and the first two components of $\mathbf{Proof}^{(\ell)}(v)$, Step (2a) of `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$ will always accept. In addition, for every $\beta \in \mathbb{F} \setminus H$, we have that $v_\beta \in \mathcal{E}^{(\ell-1)}$, and therefore by the induction hypothesis, Step (2b) of `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$ will accept the corresponding unveiling for any picked $\beta \in \mathbb{F} \setminus H$. ◀

▶ **Lemma 38.** *If for every $w \in \{0,1\}^k$ either $\mathrm{dist}(\tau, \mathsf{Spiel}(w)) > \varepsilon$ or $\mathrm{dist}(v, \mathcal{E}^{(\ell)}(w)) > \varepsilon$ (or both), then with probability greater than δ,* `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}}$ *will reject v regardless of the contents of the supplied proof string.*

Proof. Let $\tau \in \{0,1\}^{100k}$ be an alleged value for v, and $\pi \in \{0,1\}^{z^{(\ell)}_{\mathbb{F},k}}$ be an alleged proof string for v. We proceed by induction on ℓ. For $\ell = 0$ we use the PCU verifier for $\mathcal{E}^{(0)}$ with error ε and soundness δ to check that v is a member of the code ensemble $\mathcal{E}^{(0)}$ and τ is its value. If the PCU verifier for $\mathcal{E}^{(0)}$ rejects with probability at most δ, then there exist $w \in \{0,1\}^k$ such that $\mathrm{dist}(v, \mathcal{E}^{(0)}(w)) \leq \varepsilon$ and $\mathrm{dist}(\tau, \mathsf{Spiel}(w)) \leq \varepsilon$, and the base case is complete.

Next assume that the lemma holds for $\ell - 1$. If the PCU verifier for $\mathcal{L}$ in Step (2a) rejects with probability at most δ, then there exist a function $g \in \mathcal{C}_{\mathbb{F}}$ and $w \in \{0,1\}^k$ for which $g|_H = w$ so that

$$\mathrm{dist}(\pi|_{\mathrm{Dom}(S_v)}, \mathsf{Spiel}(g|_{\mathbb{F}\setminus H})) \leq \varepsilon/300 \qquad \text{and} \qquad \mathrm{dist}(\tau, \mathsf{Spiel}(w)) \leq \varepsilon/300.$$

In particular, the leftmost inequality means that for at most $\frac{\varepsilon}{3}|\mathbb{F}\setminus H|$ of the elements $\beta \in \mathbb{F}\setminus H$, it holds that

$$\mathrm{dist}(\pi|_{\mathrm{Dom}(\mathbf{Value}^{(\ell-1)}(v_\beta))}, \mathsf{Spiel}(g(\beta)) > 1/100.$$

We refer to elements $\beta \in \mathbb{F} \setminus H$ satisfying the above inequality as *bad* elements, and to the rest as *good* elements. Let G denote the set of good elements.

Next, we show that if the loop that uses the PCU verifier for $\mathcal{E}^{(\ell-1)}$ in Step (2b) rejects with probability at most δ, then for at most an $\varepsilon/3$ fraction of the good $\beta \in \mathbb{F} \setminus H$, it holds that

$$\mathrm{dist}\left(v_\beta, \mathcal{E}^{(\ell-1)}(\langle\!\langle g(\beta)\rangle\!\rangle)\right) > \varepsilon/3.$$

Assume that there are more than $\frac{\varepsilon}{3} \cdot |G|$ good elements such that $\mathrm{dist}\left(v_\beta, \mathcal{E}^{(\ell-1)}(\langle\!\langle g(\beta)\rangle\!\rangle)\right) > \varepsilon/3$. Then, by our induction hypothesis, each of them will be rejected by the PCU verifier for $\mathcal{E}^{(\ell-1)}$ with probability more than 2δ. In addition, with probability at least $1/2$ we sample at least one such good β, and then during this iteration the verifier in Step (2b(ii)) rejects with conditional probability more than 2δ, and hence the verifier will reject with overall probability more than δ. Summing everything up, when the input is rejected with probability at most δ,

$$\mathrm{dist}\left(v, \bigsqcup_{\beta\in\mathbb{F}\setminus H} \mathcal{E}^{(\ell-1)}(\langle\!\langle g(\beta)\rangle\!\rangle)\right) \leq \varepsilon/3 + (1-\varepsilon/3)\cdot\varepsilon/3 + (1-\varepsilon/3)^2\cdot\varepsilon/3 \leq \varepsilon,$$

where the three summands are respectively the contribution to the distance of the bad elements, the good elements with v_β being far from any level $\ell - 1$ encoding of $\langle\!\langle g(\beta)\rangle\!\rangle$, and all the other elements. ◀

The proof of Lemma 33 follows directly by combining Lemma 36, Lemma 37 and Lemma 38.

The following corollary follows directly from Lemma 33 and the definition of Spiel-PCU (Definition 25), and implies Lemma 29.

▶ **Corollary 39.** *Let $\mathbb{F}$ be a finite field and $k \in \mathbb{N}$ which satisfy the requirements in Definition 31. Then, for every $\ell \geq 0$ the coding ensemble $\mathcal{E}^{(\ell)}_{\mathbb{F},k} : \{0,1\}^k \to 2^{\left(\{0,1\}^{m^{(\ell)}}\right)}$ has a $q(\varepsilon,\delta)$-query, length-t Spiel-PCU for $t = O(m^{(\ell)}\mathrm{polylog}^{(\ell)}m^{(\ell)})$.*

5.3 The Lower Bound

We turn to prove the linear query lower bound for the testability of our property. We start by defining distributions over strings of length $m^{(\ell)}$.

Distribution $\mathcal{D}^{(\ell)}_{\mathsf{yes}}(w)$: Given $w \in \{0,1\}^k$, we define the distribution $\mathcal{D}^{(\ell)}_{\mathsf{yes}}(w)$ to be the uniform distribution over elements in $\mathcal{E}^{(\ell)}(w)$.

Distribution $\mathcal{D}^{(\ell)}_{\mathsf{no}}$: An element v from $\mathcal{D}^{(\ell)}_{\mathrm{no}}$ is drawn by the following process. For $\ell = 0$, $\boldsymbol{v}$ is a uniformly random string in $\{0,1\}^{4k}$. For $\ell > 0$, we pick a uniformly random function $\boldsymbol{\lambda} : \mathbb{F} \setminus H \to \mathbb{F}$, and let v be a uniformly random element of $\bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}^{(\ell-1)}(\langle\!\langle \boldsymbol{\lambda}(\beta) \rangle\!\rangle)$

▶ **Lemma 40.** *For any $\ell \geq 0$, every $w \in \{0,1\}^k$ and $q = o(m^{(\ell)}/10^{\ell})$, any algorithm making at most q queries cannot distinguish (with constant probability) between $\boldsymbol{v} \sim \mathcal{D}^{(\ell)}_{yes}(w)$ and $\boldsymbol{u}$ which is drawn according to any of the following distributions:*
1. *$\mathcal{D}^{(\ell)}_{yes}(w')$ for any $w' \neq w$.*
2. *$\mathcal{D}^{(\ell)}_{no}$.*

Note that Item (1) in the above follows immediately from Item (2). Additionally, the first item implies the shared secret property of the code ensemble $\mathcal{E}^{(\ell)}$. Furthermore, we remark that that above lemma implies a more stringent version of PCUSS. In addition to the shared secret property, Item (2) implies that the ensemble $\mathcal{E}^{(\ell)}$ is indistinguishable from strings that are mostly far from any encoding (i.e., drawn from $\mathcal{D}^{(\ell)}_{\mathrm{no}}$).

The proof of Lemma 40 follows by induction over ℓ. Before we continue, we introduce some useful lemmas that will be used in the proof.

▶ **Lemma 41.** *For any $\ell \geq 0$ and $w, w' \in \{0,1\}^k$ for which $w \neq w'$ it holds that*

$$\min_{(v,v') \in \mathcal{E}^{(\ell)}(w) \times \mathcal{E}^{(\ell)}(w')} \mathrm{dist}(v, v') = \Theta\left(1/4^{\ell+1}\right).$$

Proof. The proof follows by induction over ℓ. The base case for $\ell = 0$ follows directly by the fact that the code from Definition 21 has high distance, and in particular $\mathrm{dist}(\mathcal{E}^{(0)}(w), \mathcal{E}^{(0)}(w')) > 1/10$. Assume that the lemma holds for $\ell - 1$. Namely, for $w, w' \in \{0,1\}^{k'}$ for which $w \neq w'$ it holds that

$$\min_{(v,v') \in \mathcal{E}^{(\ell-1)}(w) \times \mathcal{E}^{(\ell-1)}(w')} \mathrm{dist}(v, v') = \Theta\left(1/4^{\ell}\right).$$

Let $\tilde{w}, \tilde{w}' \in \{0,1\}^k$ be such that $\tilde{w}' \neq \tilde{w}$. Then we can write $(\tilde{v}, \tilde{v}') \in \mathcal{E}^{(\ell)}(\tilde{w}) \times \mathcal{E}^{(\ell)}(\tilde{w}')$ as

$$\tilde{v} = \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}^{(\ell-1)}(\langle\!\langle g(\beta) \rangle\!\rangle) \qquad \text{and} \qquad \tilde{v}' = \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}^{(\ell-1)}(\langle\!\langle g'(\beta) \rangle\!\rangle),$$

for some $g, g' \in \mathcal{C}_{\mathbb{F}}$ such that $g|_H = \tilde{w}$ and $g'|_H = \tilde{w}'$. By the fact that g and g' are degree $|\mathbb{F}|/2$ polynomials (which are not identical), we have that g and g' disagree on at least $|\mathbb{F} \setminus H|/4$ of the elements $\beta \in \mathbb{F} \setminus H$. By applying the induction hypothesis on the minimum distance between $\mathcal{E}^{(\ell)}(\langle\!\langle g(\beta) \rangle\!\rangle)$ and $\mathcal{E}^{(\ell)}(\langle\!\langle g'(\beta) \rangle\!\rangle)$, for all β such that $g(\beta) \neq g'(\beta)$, we have that

$$\min_{(\tilde{v},\tilde{v}') \in \mathcal{E}^{(\ell)}(\tilde{w}) \times \mathcal{E}^{(\ell)}(\tilde{w}')} \mathrm{dist}(\tilde{v}, \tilde{v}') > \frac{1}{4} \cdot \Theta\left(\frac{1}{4^{\ell}}\right) = \Theta\left(1/4^{\ell+1}\right). \qquad \blacktriangleleft$$

▶ **Lemma 42.** *For any $\ell \geq 0$, with probability at least $1 - o(1)$, a string v drawn from $\mathcal{D}^{(\ell)}_{no}$ satisfies $\mathrm{dist}(v, \mathcal{E}^{(\ell)}(w)) = \Theta\left(1/4^{\ell+1}\right)$ for all $w \in \{0,1\}^k$.*

Proof. The proof follows by induction over ℓ. For $\ell = 0$, fix some $w \in \{0,1\}^k$. Consider the size of a ball of relative radius $1/40$ around some $v \in \mathcal{E}^{(0)}(w)$ in the space of all strings $\{0,1\}^{4k}$. The number of strings contained in this ball is at most

$$\binom{4k}{k/10} \leq (40e)^{k/10} = 2^{k/10 \cdot \log(40e)}.$$

Thus, the size of the set of strings which are at relative distance $1/40$ from any legal encoding of some word $w \in \{0,1\}^k$ is at most

$$2^{3k} \cdot 2^{k/10 \cdot \log(40e)} = o(2^{4k}).$$

This implies that with probability at least $1 - o(1)$, a random string from $\{0,1\}^{4k}$ is $1/40$-far from $\mathcal{E}^{(0)}(w)$ for any $w \in \{0,1\}^k$.

For any $\ell > 0$, consider v' sampled according to $\mathcal{D}^{(\ell)}_{\text{no}}$. Then, v' can be written as

$$v' = \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}^{(\ell-1)}(\langle\langle \boldsymbol{\lambda}(\beta) \rangle\rangle),$$

where $\boldsymbol{\lambda} : \mathbb{F} \setminus H \to \mathbb{F}$ is a uniformly random function. On the other hand, each member $\tilde{v}$ of $\mathcal{P}^{(\ell)}$ can be written as

$$\tilde{v} = \bigsqcup_{\beta \in \mathbb{F} \setminus H} \mathcal{E}^{(\ell-1)}(\langle\langle g(\beta) \rangle\rangle),$$

for some $g \in \mathcal{C}_{\mathbb{F}}$ such that $g|_H = w$ for some $w \in \{0,1\}^k$. Note that by Lemma 41, whenever $\boldsymbol{\lambda}(\beta) \neq g(\beta)$, we have that the minimum distance between any $\tilde{v} \in \mathcal{E}^{(\ell-1)}(\langle\langle g(\beta) \rangle\rangle)$ and $v' \in \mathcal{E}^{(\ell-1)}(\langle\langle \boldsymbol{\lambda}(\beta) \rangle\rangle)$ is at least $\Theta(1/4^\ell)$. In addition, by Lemma 8, we have that that with probability at least $1 - o(1)$, a uniformly random function $\boldsymbol{\lambda} : \mathbb{F} \to \mathbb{F}$ is $1/3$-far from any $g \in \mathcal{C}_{\mathbb{F}}$. By the restrictions on k in Definition 31, which implies that $|H| \leq |F|/c$, we can ensure (by the choice of c) that with probability at least $1 - o(1)$, that a uniformly random $\boldsymbol{\lambda} : \mathbb{F} \setminus H \to \mathbb{F}$ is at least $1/4$-far from the restriction $g|_{\mathbb{F} \setminus H}$. This implies that for at least $|\mathbb{F} \setminus H|/4$ of the elements $\beta \in \mathbb{F} \setminus H$, we have that $\boldsymbol{\lambda}(\beta) \neq g(\beta)$. Therefore, we have that $\text{dist}(v', \mathcal{E}^{(\ell)}(w)) = \frac{1}{4} \cdot \Theta\left(\frac{1}{4^\ell}\right) = \Theta\left(1/4^{\ell+1}\right)$ for all $w \in \{0,1\}^k$, and the proof is complete. ◀

▶ **Lemma 43.** *Fix any $\ell > 0$, and suppose that for any $w' \in \{0,1\}^{k'}$, and for any set Q' of at most $q^{(\ell-1)}_{\mathbb{F}',k'}$ queries (where $\mathbb{F}'$ and k' are picked according to the recursive definition of the level ℓ-encoding, and for $q^{(0)}$ we substitute k' for the nonexistent $\mathbb{F}'$) the restricted distributions $\mathcal{D}^{(\ell-1)}_{yes}(w')|_{Q'}$ and $\mathcal{D}^{(\ell-1)}_{no}|_{Q'}$ are identical. Then, for any $w \in \{0,1\}^k$, and any set Q of at most $\frac{|\mathbb{F} \setminus H|}{10} \cdot q^{(\ell-1)}_{\mathbb{F}',k'}$ queries, the restricted distributions $\mathcal{D}^{(\ell)}_{yes}(w)|_Q$ and $\mathcal{D}^{(\ell)}_{no}|_Q$ are identical.*

Proof. Let $Q \subset [m^{(\ell)}]$ be the set of queries, and fix a canonical ordering over the elements in $\mathbb{F} \setminus H$. Let $\boldsymbol{v}$ be an element drawn according to distribution $\mathcal{D}^{(\ell)}_{\text{yes}}(w)$, and let $\boldsymbol{v}'$ be an element drawn according to distribution $\mathcal{D}^{(\ell)}_{\text{no}}$. The sampling process from $\mathcal{D}^{(\ell)}_{\text{yes}}(w)$ can be thought of as first drawing a uniformly random function $\boldsymbol{g} \in \mathcal{C}_{\mathbb{F}}$ such that $\boldsymbol{g}|_H = w$, and for every $\beta \in \mathbb{F} \setminus H$, letting $\boldsymbol{v}_\beta$ be a uniformly random element in $\mathcal{E}^{(\ell-1)}(\langle\langle \boldsymbol{g}(\beta) \rangle\rangle)$.

For each $\beta \in \mathbb{F} \setminus H$ we set $Q_\beta = Q \cap \text{Dom}(v_\beta)$, and define the set of *big clusters*

$$I = \left\{ \beta \in \mathbb{F} \setminus H \ : \ |Q_\beta| \geq q^{(\ell-1)}_{\mathbb{F}',k'} \right\}.$$

Note that since $|Q| \leq |\mathbb{F} \setminus H| \cdot q^{(\ell-1)}_{\mathbb{F}',k'}/10$, we have that $|I| \leq |\mathbb{F} \setminus H|/10$.

By the fact that $\boldsymbol{g}$ is a uniformly random polynomial of degree $|\mathbb{F}|/2 > |I|$, we have that $\boldsymbol{g}|_I$ is distributed exactly as $\boldsymbol{\lambda}|_I$ (both are a sequence of $|I|$ independent uniformly random values), which implies that $\boldsymbol{v}|_{\bigcup_{j \in I} Q_j}$ is distributed exactly as $\boldsymbol{v}'|_{\bigcup_{j \in I} Q_j}$.

Next, let $\mathbb{F} \setminus (I \cup H) = \{i_1, \ldots, i_{|\mathbb{F} \setminus (I \cup H)|}\}$ be a subset ordered according to the canonical ordering over $\mathbb{F}$. We proceed by showing that $\boldsymbol{v}|_{\bigcup_{j \in I \cup \{i_1, \ldots, i_t\}} Q_j}$ is distributed identically to $\boldsymbol{v}'|_{\bigcup_{j \in I \cup \{i_1, \ldots, i_t\}} Q_j}$ by induction over t.

The base case ($t = 0$) corresponds to the restriction over $\bigcup_{j \in I} Q_j$, which was already proven above. For the induction step, let $T = \{i_1, \ldots, i_{t-1}\} \subseteq \mathbb{F} \setminus (I \cup H)$ be an ordered subset that agrees with the canonical ordering on $\mathbb{F}$, and let $i_t \in \mathbb{F} \setminus (H \cup T \cup I)$ be the successor of i_{t-1} according to the ordering. We now prove that for each $x \in \{0,1\}^{m^{(\ell)}}$ for which $\boldsymbol{v}|_{\bigcup_{j \in I \cup T} Q_j}$ has a positive probability of being equal to $x|_{\bigcup_{j \in I \cup T} Q_j}$, conditioned on the above event taking place (and its respective event for v'), $\boldsymbol{v}|_{Q_{i_t}}$ is distributed exactly as $\boldsymbol{v'}|_{Q_{i_t}}$.

Observe that conditioned on the above event, $\boldsymbol{v}|_{Q_{i_t}}$ is distributed exactly as a uniformly random element in $\mathcal{E}^{(\ell-1)}(\boldsymbol{\rho})$ for some $\boldsymbol{\rho} \in \{0,1\}^{k'}$ (which follows some arbitrary distribution, possibly depending on $x|_{\bigcup_{j \in I \cup T} Q_j}$), while $\boldsymbol{v'}|_{Q_{i_t}}$ is distributed exactly as a uniformly random element in $\mathcal{E}^{(\ell-1)}(\boldsymbol{y})$ for a uniformly random $\boldsymbol{y} \in \{0,1\}^{k'}$. By the fact that $|Q_{i_t}| \leq q^{(\ell-1)}_{\mathbb{F}',k'}/10$, we can apply the induction hypothesis and conclude that $\boldsymbol{v}|_{Q_{i_t}}$ is distributed exactly as $\boldsymbol{v'}|_{Q_{i_t}}$, because by our hypothesis both are distributed identically to the corresponding restriction of $\mathcal{D}^{(\ell-1)}_{\text{no}}$, regardless of the values picked for $\boldsymbol{\rho}$ and $\boldsymbol{y}$. This completes the induction step for t. The lemma follows by setting $t = |\mathbb{F} \setminus H \cup I|$. ◀

▶ **Lemma 44.** *For any $\ell \geq 0$, $w \in \{0,1\}^k$ and any set of queries $Q \subset [m^{(\ell)}]$ such that $|Q| = O\left(\frac{m^{(\ell)}}{10^\ell}\right)$, the restricted distributions $\mathcal{D}^{(\ell)}_{yes}(w)|_Q$ and $\mathcal{D}^{(\ell)}_{no}|_Q$ are identically distributed.*

Proof. By induction on ℓ. For $\ell = 0$ and any $w \in \{0,1\}^k$, by the fact that our base encoding $\mathcal{E}^{(0)}(w)$ is a high dual distance code, we can select (say) $q^{(0)} = k/c$ (for some constant $c > 0$), making the assertion of the lemma trivial.

Assume that for any $w' \in \{0,1\}^{k'}$, and any set of queries Q' of size up to $O(m^{(\ell-1)}/10^{\ell-1})$ the conditional distributions $\mathcal{D}^{(\ell-1)}_{\text{yes}}(w')|_{Q'}$ and $\mathcal{D}^{(\ell-1)}_{\text{no}}|_{Q'}$ are identically distributed. Then, by Lemma 43, we have that for any $w \in \{0,1\}^k$ and any set of queries Q of size at most

$$O\left(\frac{|\mathbb{F} \setminus H|}{10^\ell} \cdot m^{(\ell-1)}\right),$$

the restricted distributions $\mathcal{D}^{(\ell)}_{\text{yes}}(w)|_Q$ and $\mathcal{D}^{(\ell)}_{\text{no}}|_Q$ are identically distributed. Note that by definition of the level ℓ-encoding, $m^{(\ell)} = |\mathbb{F} \setminus H| \cdot m^{(\ell-1)}$, which implies the conclusion of the lemma. ◀

Proof of Lemma 40. Lemma 40 follows directly by combining Lemma 17, and Lemma 44. ◀

Combining Lemma 40 with the definition of Spiel-PCU (Definition 25) establishes that we have constructed a Spiel-PCUSS, which implies Theorem 30.

▶ **Corollary 45.** *Let $\mathbb{F}$ be a finite field and $k \in \mathbb{N}$ which satisfy the requirements in Definition 31. Then, for every $\ell \geq 0$, the coding ensemble $\mathcal{E}^{(\ell)}_{\mathbb{F},k} : \{0,1\}^k \to 2^{\left(\{0,1\}^{m^{(\ell)}}\right)}$ has $q(\varepsilon,\delta)$-query length-t Spiel-PCUSS for $t = O(m^{(\ell)}\text{polylog}^{(\ell)}m^{(\ell)})$.*

5.4 Handling arbitrary input lengths

As mentioned in the beginning of this section, our construction of code ensembles relies on the fact that operations over a finite field $\text{GF}(2^t)$ can be computed efficiently. In order to do so we need to have an irreducible polynomial of degree t over $\text{GF}(2)$, so that we have a representation $\text{GF}(2^t)$. Given such a polynomial, operations over the field can be

implemented in polylogarithmic time in the size of the field. By [18] (Appendix G), we know that for $t = 2 \cdot 3^r$ where $r \in \mathbb{N}$, we do have such a representation. However, the setting of t restricts the sizes of the fields that we can work with, which will limit our input size length.

We show here how to extend our construction to a set of sizes that is "log-dense". For a global constant c', our set of possible input sizes includes a member of $[m', c'm']$ for every m'. Moving from this set to the set of all possible input sizes now becomes a matter of straightforward padding.

For any $n \in \mathbb{N}$, let r be the smallest integer such that $n < 2^{2 \cdot 3^r}$ and let $\mathbb{F} = \mathrm{GF}(2^{2 \cdot 3^r})$. We make our change only at the level-ℓ construction. First, we use $4d$ instead of d in the calculation of the size of $\mathbb{F}'$. Then, instead of using $\mathbb{F} \setminus H$ as the domain for our input, we use $E \setminus H$, for any arbitrary set $E \subseteq \mathbb{F}$ of size $n \geq \max\{4k, |\mathbb{F}|^{1/4}, c_\ell\}$ that contains H. Then, for the level-ℓ, instead of considering polynomials of degree $|\mathbb{F}|/2$, we consider polynomials of degree $|E|/2$. The rest of the construction follows the same lines as the one defined above. This way, all of our operations can be implemented in polylogarithmic time in $|E|$.

6 Separations of testing models

In this section we use Theorem 30 to prove a separation between the standard testing model, and both the tolerant and the erasure resilient testing models. Specifically, we prove the following.

▶ **Theorem 46** (Restatement of Theorem 2). *For every constant $\ell \in \mathbb{N}$, there exist a property $\mathcal{Q}^{(\ell)}$ and $\varepsilon_1 = \varepsilon_1(\ell) \in (0,1)$ such that the following hold.*

1. *For every $\varepsilon \in (0,1)$, the property $\mathcal{Q}^{(\ell)}$ can be ε-tested using a number of queries depending only on ε (and ℓ).*
2. *For every $\varepsilon_0 \in (0, \varepsilon_1)$, any $(\varepsilon_0, \varepsilon_1)$-tolerant tester for $\mathcal{Q}^{(\ell)}$ needs to make $\Omega(N/10^\ell \cdot \mathrm{polylog}^{(\ell)} N)$ many queries on inputs of length N.*

▶ **Theorem 47** (Restatement of Theorem 3). *For every constant $\ell \in \mathbb{N}$, there exist a property $\mathcal{Q}^{(\ell)}$ and $\varepsilon_1 = \varepsilon_1(\ell) \in (0,1)$ such that the following hold.*

1. *For every $\varepsilon \in (0,1)$, the property $\mathcal{Q}^{(\ell)}$ can be ε-tested using a number of queries depending only on ε (and ℓ).*
2. *For every $\varepsilon \in (0, \varepsilon_1)$ and any $\alpha = \Omega(1/\log^{(\ell)} N)$ satisfying $\varepsilon + \alpha < 1$, any α-erasure resilient ε-tester for $\mathcal{Q}^{(\ell)}$ needs to make $\Omega(N/10^\ell \cdot \mathrm{polylog}^{(\ell)} N)$ many queries on inputs of length N.*

In order to prove the separation we use the code ensemble $\mathcal{E}^{(\ell)}_{\mathbb{F},k}$ where k is set to 0. Namely, we consider $\mathcal{E}_{\mathbb{F},0}(\emptyset)$. Note that in this case, the code ensemble becomes a property (i.e. a subset of the set of all possible strings).

Next, we define the property that exhibits the separation between the standard testing model and both the tolerant testing model and the erasure resilient model. We prove Theorem 46 and mention the small difference between the proof of Theorem 46 and the proof of Theorem 47.

▶ **Definition 48.** *Fix a finite field $\mathbb{F}$ and a constant integer $\ell \in \mathbb{N}$ and let $\varepsilon(\ell) = \Theta(1/4^\ell)$. Let $n \stackrel{\text{def}}{=} m^{(\ell)}_{\mathbb{F}}$, $z^{(\ell)}_{\mathbb{F},0} \leq n \cdot \mathrm{polylog}^{(\ell)} n$ denote the length of the proof for the* PCUSS *from Theorem 30, and let $N = (\log^{(\ell)} n + 1) \cdot z^{(\ell)}_{\mathbb{F},0}$. Let $\mathcal{Q}^{(\ell)} \subseteq \{0,1\}^N$ be defined as follows. A string $x \in \{0,1\}^N$ satisfies $\mathcal{Q}^{(\ell)}$ if the following hold.*

1. *The first $z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n$ bits of x consist of $s = \frac{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{n}$ copies of $y \in \mathcal{E}^{(\ell)}_{\mathbb{F},0}$.*
2. *The remaining $z^{(\ell)}_{\mathbb{F},0}$ bits of x consist of a proof string $\pi \in \{0,1\}^{z^{(\ell)}_{\mathbb{F},0}}$, for which the* `Verifier-Procedure` $_{\mathcal{E}^{(\ell)}_{\mathbb{F},0}}$ *in Figure 1 accepts y given oracle access to y and π.*

We first show that $\mathcal{Q}^{(\ell)}$ can be tested using a constant number of queries in the standard testing model.

`Testing Algorithm for` $\mathcal{Q}^{(\ell)}$

Input: Parameter $\varepsilon \in (0,1)$, an oracle access to $x \in \{0,1\}^N$.

1. Set $s \stackrel{\text{def}}{=} \frac{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{n}$.
2. Repeat $4/\varepsilon$ times:
   a. Sample $\boldsymbol{j} \in [n]$ and $\boldsymbol{i} \in [s] \setminus \{1\}$ uniformly at random.
   b. If $x_{\boldsymbol{j}} \neq x_{(\boldsymbol{i}-1)\cdot n+\boldsymbol{j}}$, then **Reject**.
3. Let $v = (x_1, \ldots, x_n)$, $\pi = (x_{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n+1}, \ldots, x_{(\log^{(\ell)} n+1) z^{(\ell)}_{\mathbb{F},0}})$ and τ be the empty string.
4. Run the PCU verifier for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$ with parameters $\varepsilon/3$ and $\delta = 2/3$ on v, using π as the alleged proof for v, and τ as the alleged value for v.
5. If the PCU verifier rejects, then **Reject**; otherwise **Accept**.

Figure 2 Description of `Testing Algorithm for` $\mathcal{Q}^{(\ell)}$.

For Item 4 in Figure 2, recall that running the PCU verifier with parameter $\delta = 2/3$ actually involves running multiple instances of the verifier with smaller δ, as discussed in Subsection 5.2.

▶ **Lemma 49.** *The property $\mathcal{Q}^{(\ell)}$ has a tester with query complexity depending only on ε.*

Proof. We show that the algorithm described in Figure 2 is a testing algorithm for $\mathcal{Q}^{(\ell)}$. We assume that n is large enough so that $\log^{(\ell)} n > 6/\varepsilon$.

Assume that $x \in \mathcal{Q}^{(\ell)}$. Then, there exists a string $y \in \mathcal{E}^{(\ell)}_{\mathbb{F},0}$ with $x_1, \ldots, x_{z^{(\ell)}_{\mathbb{F},0} \log^{(\ell)} n} = (y)^s$ (where $(y)^s$ is the concatenation of s copies of y), and $x_{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n+1}, \ldots, x_{(\log^{(\ell)}+1) z^{(\ell)}_{\mathbb{F},0}} = \pi \in \{0,1\}^{z^{(\ell)}_{\mathbb{F},0}}$, where π is a proof that makes the PCU verifier for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$ accept when given oracle access to y and π. Therefore, the algorithm in Figure 2 accepts x.

Next, assume that x is ε-far from $\mathcal{Q}^{(\ell)}$, and let $y' = x_1, \ldots, x_n$. Note that if the string $x_1, \ldots, x_{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}$ is $\varepsilon/2$-far from being $(z')^s$, then the loop in Step 2 rejects x with probability at least $2/3$, and we are done. If $x_1, \ldots, x_{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}$ is $\varepsilon/2$-close to $(y')^s$, then y' must be $\varepsilon/3$-far from $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$. To see this, assume toward a contradiction that y' is $\varepsilon/3$-close to $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$. Then, by modifying at most $\frac{\varepsilon \cdot z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{2}$ bits, we can make $x_1, \ldots, x_{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}$ equal to $(y')^s$. Since, by our assumption y' is $\varepsilon/3$-close to $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$, we can further modify the string $(y')^s$ to $(\tilde{y})^s$, where $\tilde{y} \in \mathcal{E}^{(\ell)}_{\mathbb{F},0}$, by changing at most $\frac{\varepsilon \cdot z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{3}$ bits. Finally, by changing at most $z^{(\ell)}_{\mathbb{F},0}$ bits from π, we can get a proof string $\tilde{\pi}$ which will make the PCPP verifier accept $\tilde{y}$. By our assumption that $6/\varepsilon < \log^{(\ell)} n$, the total number of changes to the input string x is at most

$$\frac{\varepsilon \cdot z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{2} + \frac{\varepsilon \cdot z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{3} + z^{(\ell)}_{\mathbb{F},0} \leq \varepsilon \cdot (\log^{(\ell)} n + 1) \cdot z^{(\ell)}_{\mathbb{F},0} = \varepsilon N,$$

which is a contradiction to the fact that x is ε-far from $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$.

Finally, having proved that y' is $\varepsilon/3$-far from $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$, the PCU verifier for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$ (when called with parameters $\varepsilon/3$ and $\delta = 2/3$) rejects with probability at least $2/3$. ◀

▶ **Lemma 50.** *For every constant $\ell \in \mathbb{N}$, there exists $\varepsilon_1 \stackrel{\text{def}}{=} \Theta(1/4^\ell)$ such that for every $\varepsilon_0 < \varepsilon_1$, any $(\varepsilon_0, \varepsilon_1)$-tolerant tester for $\mathcal{Q}^{(\ell)}$ needs to make at least $\Omega\left(\frac{N}{10^\ell \cdot \text{polylog}^{(\ell)} N}\right)$ many queries.*

Proof. Fix some constant $\ell \in \mathbb{N}$. The proof follows by a reduction from $2\varepsilon_1$-testing of $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$. Given oracle access to a string $y \in \{0,1\}^n$ which we would like to $2\varepsilon_1$-test for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$, we construct an input string $x \in \{0,1\}^N$ where $N = (\log^{(\ell)} n + 1) \cdot z^{(\ell)}_{\mathbb{F},0}$ as follows.

$$x \stackrel{\text{def}}{=} (y)^{\frac{z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n}{n}} \sqcup (0)^{z^{(\ell)}_{\mathbb{F},0}}.$$

That is, we concatenate $z^{(\ell)}_{\mathbb{F},0} \cdot \log^{(\ell)} n / n$ copies of y, and set the last $z^{(\ell)}_{\mathbb{F},0}$ bits to 0. Note that a single query to the new input string x can be simulated using at most one query to the string y.

If $y \in \mathcal{E}^{(\ell)}_{\mathbb{F},0}$, then for large enough n we have that x is ε_0-close to $\mathcal{Q}^{(\ell)}$, since the last $z^{(\ell)}_{\mathbb{F},0}$ bits that are set to 0 are less than an ε_0-fraction of the input length.

On the other hand, if $\text{dist}(x, \mathcal{E}^{(\ell)}_{\mathbb{F},0}) > 2\varepsilon_1$, since each copy of y in x is $2\varepsilon_1$-far from $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$, then x is $\frac{2\varepsilon_1 \cdot \log^{(\ell)} n}{\log^{(\ell)} n + 1}$-far from $\mathcal{Q}^{(\ell)}$ (note that $\frac{\log^{(\ell)} n}{\log^{(\ell)} n + 1} > 1/2$). Therefore, an $(\varepsilon_0, \varepsilon_1)$-tolerant tester for $\mathcal{Q}^{(\ell)}$ would imply an $2\varepsilon_1$-tester for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$ with the same query complexity. By Lemma 40, since for some $\varepsilon_1 = \Theta(1/4^\ell)$, every $2\varepsilon_1$-tester for $\mathcal{E}^{(\ell)}_{\mathbb{F},0}$ requires $\Omega(n/10^\ell)$ queries on inputs of length n, any $(\varepsilon_0, \varepsilon_1)$-tolerant tester for $\mathcal{Q}^{(\ell)}$ requires to make $\Omega\left(\frac{N}{10^\ell \cdot \text{polylog}^{(\ell)} N}\right)$ many queries. ◀

Proof of Theorem 46. The proof follows by combining Lemma 49 and Lemma 50. ◀

Proof of Theorem 47. The proof of Theorem 47 is almost identical to the proof of Theorem 46. The only difference is that we replace Lemma 50 with a counterpart for erasure resilient testing, where instead of setting the last $z^{(\ell)}_{\mathbb{F},0}$ bits of x to $(0)^{z^{(\ell)}_{\mathbb{F},0}}$, we use $(\perp)^{z^{(\ell)}_{\mathbb{F},0}}$, noting that the relative size of this part of the input is $1/(s+1) = \Theta(1/\log^{(\ell)}(N))$. ◀

Abstract

We answer a question, posed implicitly in [18, §11], [11, Rem. 15.44] and explicitly in [9, Problem 9.8], showing the border rank of the Kronecker square of the little Coppersmith-Winograd tensor is the square of the border rank of the tensor for all $q > 2$, a negative result for complexity theory. We further show that when $q > 4$, the analogous result holds for the Kronecker cube. In the positive direction, we enlarge the list of explicit tensors potentially useful for the laser method. We observe that a well-known tensor, the 3×3 determinant polynomial regarded as a tensor, $\det_3 \in \mathbb{C}^9 \otimes \mathbb{C}^9 \otimes \mathbb{C}^9$, could potentially be used in the laser method to prove the exponent of matrix multiplication is two. Because of this, we prove new upper bounds on its Waring rank and rank (both 18), border rank and Waring border rank (both 17), which, in addition to being promising for the laser method, are of interest in their own right. We discuss "skew" cousins of the little Coppersmith-Winograd tensor and indicate why they may be useful for the laser method. We establish general results regarding border ranks of Kronecker powers of tensors, and make a detailed study of Kronecker squares of tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$.

1 Introduction

The exponent ω of matrix multiplication is defined as

$$\omega := \inf\{\tau \mid \mathbf{n} \times \mathbf{n} \text{ matrices may be multiplied using } O(\mathbf{n}^\tau) \text{ arithmetic operations}\}.$$

The exponent is a fundamental constant governing the complexity of the basic operations in linear algebra. It is conjectured that $\omega = 2$. There was steady progress in the research for upper bounds from 1968 to 1988: after Strassen's famous $\omega < 2.81$ [39], Bini et al. [8], using border rank (see below), showed $\omega < 2.78$, then a major breakthrough by Schönhage [36] (the asymptotic sum inequality) was used to show $\omega < 2.55$, then Strassen's *laser method*

was introduced and used by Strassen to show $\omega < 2.48$, and refined by Coppersmith and Winograd to show $\omega < 2.3755$ [18]. Then there was no progress until 2011 when a series of improvements by Stothers, Williams, and Le Gall [38, 45, 33] lowered the upper bound to the current state of the art $\omega < 2.373$.

Strassen's 1968 result is obtained by an explicit algorithm for multiplying matrices. This algorithm is more efficient than the standard one in practical implementation as soon as the size of the matrices is around 1000×1000, see [6]. Bini et al. exhibited a matrix multiplication algorithm that is in principle implementable exactly (at a cost of a constant size blow-up which does not effect the exponent) but as presented is only a sequence of algorithms that limits to an exact one. This gave rise to the notion of *border rank* to describe this phenomenon. To explain border rank, it is best to adopt the language of *tensors*.

A bilinear map $b : \mathbb{C}^{\mathbf{a}} \times \mathbb{C}^{\mathbf{b}} \to \mathbb{C}^{\mathbf{c}}$ may be regarded as a trilinear form $\widehat{b} : \mathbb{C}^{\mathbf{a}} \times \mathbb{C}^{\mathbf{b}} \times \mathbb{C}^{\mathbf{c}} \to \mathbb{C}$ defined by $\widehat{b}(X, Y, \alpha) = \alpha \cdot b(X, Y)$ where $b(X, Y)$ is regarded as a column vector of $\mathbb{C}^{\mathbf{c}}$, α is regarded as a row vector and $\cdot$ is the row-column multiplication. In this language, matrix multiplication, as a trilinear map, becomes $M_{\mathbf{l},\mathbf{m},\mathbf{n}}(X, Y, Z) = \mathrm{trace}(XYZ)$, where X, Y, Z are matrices of size $\mathbf{l} \times \mathbf{m}$, $\mathbf{m} \times \mathbf{n}$ and $\mathbf{n} \times \mathbf{l}$, respectively. It is known [11, §14.1] that the complexity of performing a bilinear map is captured, up to a factor of four, by the *tensor rank* of the corresponding tensor. Thus, this geometric quantity may be used to determine ω.

Let A, B, C be fixed vector spaces. A tensor $T \in A \otimes B \otimes C$ has *rank one* if $T = a \otimes b \otimes c$ for some $a \in A$, $b \in B$, $c \in C$. The *rank* of T, denoted $\mathbf{R}(T)$, is the smallest r such that T is sum of r rank one tensors. The *border rank* of T, denoted $\underline{\mathbf{R}}(T)$, is the smallest r such that T is the limit of a sequence of rank r tensors. One has $\underline{\mathbf{R}}(T) \leq \mathbf{R}(\mathbf{T})$ and the inequality can be strict: Let $T = a_1 \otimes b_1 \otimes c_2 + a_1 \otimes b_2 \otimes c_1 + a_2 \otimes b_1 \otimes c_1$, then $\mathbf{R}(\mathbf{T}) = 3$ and $\underline{\mathbf{R}}(T) = 2$ as

$$T = \lim_{t \to 0} \frac{1}{t}[(a_1 + ta_2) \otimes (b_1 + tb_2) \otimes (c_1 + tc_2) - a_1 \otimes b_1 \otimes c_1].$$

Bini [7] proved that the border rank of matrix multiplication also captures its complexity. More precisely,

$$\omega = \inf\{\tau : \underline{\mathbf{R}}(M_{\langle \mathbf{n} \rangle}) \in O(\mathbf{n}^{\tau})\}.$$

Schönhage's advance comes from his discovery that it can be more efficent to perform two matrix multiplications together than one at a time. For tensors $T \in A \otimes B \otimes C$ and $T' \in A' \otimes B' \otimes C'$, define a new tensor $T \oplus T' \in (A \oplus A') \otimes (B \oplus B') \otimes (C \otimes C')$ whose computation is equivalent to computing T and T'. He gave explicit examples of matrix multiplication tensors where $\underline{\mathbf{R}}(T \oplus T') \ll \underline{\mathbf{R}}(T) + \underline{\mathbf{R}}(T')$. To explain how he exploited this we need some more definitions:

Given $T \in A \otimes B \otimes C$ and $T' \in A' \otimes B' \otimes C'$, the *Kronecker product* of T and T' is the tensor $T \boxtimes T' := T \otimes T' \in (A \otimes A') \otimes (B \otimes B') \otimes (C \otimes C')$, regarded as 3-way tensor. Given $T \in A \otimes B \otimes C$, the *Kronecker powers* of T are $T^{\boxtimes N} \in A^{\otimes N} \otimes B^{\otimes N} \otimes C^{\otimes N}$, defined iteratively. We have $\mathbf{R}(T \boxtimes T') \leq \mathbf{R}(T)\mathbf{R}(T')$, and similarly for border rank. The matrix multiplication tensor has the following important self-reproducing property: $M_{\langle \mathbf{l},\mathbf{m},\mathbf{n} \rangle} \boxtimes M_{\langle \mathbf{l}'\mathbf{,m}'\mathbf{n}' \rangle} = M_{\langle \mathbf{ll}'\mathbf{,mm}'\mathbf{,nn}' \rangle}$.

Given $T, T' \in A \otimes B \otimes C$, we say that T *degenerates* to T' if $T' \in \overline{GL(A) \times GL(B) \times GL(C) \cdot T}$, the closure of the orbit of T under the natural action of $GL(A) \times GL(B) \times GL(C)$ on $A \otimes B \otimes C$. Here $GL(A)$ denote the general linear group of invertible linear maps $A \to A$. Border rank is upper semi-continuous under degeneration: if T' is a degeneration of T, then $\underline{\mathbf{R}}(T') \leq \underline{\mathbf{R}}(T)$.

Schönhage observed that if one takes a high Kronecker power of $(M_{\langle \mathbf{l},\mathbf{m},\mathbf{n}\rangle} \oplus M_{\langle \mathbf{l}',\mathbf{m}',\mathbf{n}'\rangle})$, that because of the reproducing property, it will be a sum of matrix multiplication tensors, some of them quite large. One can then perform a degeneration to obtain a single very large matrix multiplication tensor and exploit the strict sub-additivity to get an upper bound on this large matrix multiplication tensor. This is his celebrated *asymptotic sum inequality*.

After Schönhage, Strassen realized that the starting tensor need not be a sum of matrix multiplication tensors, as long as some high power of it degenerates to a large matrix multiplication tensor. This gave rise to his *laser method*, where the starting tensor "resembles" the sum of disjoint matrix multiplication tensors. All upper bounds since 1984 are obtained via Strassen's laser method. The best starting tensor for Strassen's method (so far) was discovered by Coppersmith and Winograd, the *big Coppersmith-Winograd tensor*.

In 2014 [4] gave an explanation for the limited progress since 1988, followed by further explanations in [3, 2, 13, 1]: there are limitations to the laser method applied to the big Coppersmith-Winograd tensor and other auxiliary tensors. These limitations are referred to as *barriers*. Our main motivation is to eventually overcome these barriers via auxilary tensors that avoid them, or, failing that, to prove structural results explaining the failure. We deal with the *little Coppersmith-Winograd tensor*, which was known to potentially avoid the barriers and a new series of tensors that are skew versions of the little Coppersmith-Winograd tensor that we show also potentially avoid the barriers. We are interested in two kinds of barriers: to proving the exponent is two, and barriers to proving the exponent is less than 2.3.

▶ Remark 1. A different approach to upper bounds was introduced by Cohn and Umans [15] using the Fourier-transform on finite groups. One can show $\omega < 2.41$ by this method [13, 14].

Definitions and notation

Let A, B, C be complex vector spaces. We will work with tensors in $A \otimes B \otimes C$. Let $GL(A)$ denote the general linear group of invertible linear maps $A \to A$. Unless stated otherwise, we write $\{a_i\}$ for a basis of A, and similarly for bases of B and C. Often we assume that all tensors involved in the discussion belong to the same space $A \otimes B \otimes C$; this is not restrictive, since we may re-embed the spaces A, B, C into larger spaces whenever it is needed. We say that two tensors are *isomorphic* if they are the same up to a change of bases in A,B and C.

One may define border rank in terms of degeneration: $\underline{\mathbf{R}}(T) \leq r$ if and only if $M_{\langle 1\rangle}^{\oplus r}$ degenerates to T. The *border subrank* of T, denoted $\underline{\mathbf{Q}}(T)$, is the largest q such that T degenerates to $M_{\langle 1\rangle}^{\oplus q}$.

The *asymptotic rank* of T is $\underset{\sim}{\mathbf{R}}(T) := \lim_{N\to\infty} \underline{\mathbf{R}}(T^{\boxtimes N})^{1/N}$. Thus $\omega = \log_{\mathbf{m}} \underset{\sim}{\mathbf{R}}(M_{\langle \mathbf{m}\rangle})$ for any $\mathbf{m} > 2$. The *asymptotic subrank* of T is $\underset{\sim}{\mathbf{Q}}(T) = \lim_{N\to\infty} \underline{\mathbf{Q}}(T^{\boxtimes N})^{1/N}$. These limits exist and are finite, see [41]. Moreover $\underset{\sim}{\mathbf{R}}(T) \leq \underline{\mathbf{R}}(T)$ and $\underset{\sim}{\mathbf{Q}}(T) \geq \underline{\mathbf{Q}}(T)$.

A tensor $T \in A \otimes B \otimes C$ is *concise* if the induced linear maps $T_A : A^* \to B \otimes C$, $T_B : B^* \to A \otimes C$, $T_C : C^* \to A \otimes B$ are injective. We say that a concise tensor $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$ has *minimal rank* (resp. *minimal border rank*) if $\mathbf{R}(T) = m$ (resp. $\underline{\mathbf{R}}(T) = m$).

The laser method and the Coppersmith-Winograd tensors

So far, the best upper bounds for ω have been obtained using the laser method applied to the big Coppersmith-Winograd tensor, which is

$$T_{CW,q} := \sum_{j=1}^{q} a_0 \otimes b_j \otimes c_j + a_j \otimes b_0 \otimes c_j + a_j \otimes b_j \otimes c_0 + \\ + a_0 \otimes b_0 \otimes c_{q+1} + a_0 \otimes b_{q+1} \otimes c_0 + a_{q+1} \otimes b_0 \otimes c_0 \in (\mathbb{C}^{q+2})^{\otimes 3}.$$

It was used to obtain the current world record $\omega < 2.373$ and all bounds below $\omega < 2.41$. The barrier identified in [4] said that $T_{CW,q}$ cannot be used to prove $\omega < 2.3$ using the standard laser method, and a geometric identification of this barrier in terms of asymptotic subrank was given in [13]: $\underset{\sim}{\mathbf{Q}}(M_{\langle \mathbf{n} \rangle}) = \mathbf{n}^2$ which is maximal, which is used to show any tensor with non-maximal asymptotic subrank cannot be used to prove $\omega = 2$ by the laser method, and Strassen [43] had shown $\underset{\sim}{\mathbf{Q}}(T_{CW,q})$ is non-maximal.

The second best tensor for the laser method so far has been the little Coppersmith-Winograd tensor, which is

$$T_{cw,q} := \sum_{j=1}^{q} a_0 \otimes b_j \otimes c_j + a_j \otimes b_0 \otimes c_j + a_j \otimes b_j \otimes c_0 \in (\mathbb{C}^{q+1})^{\otimes 3}. \tag{1}$$

The laser method was used to prove the following inequality:

▶ **Theorem 2.** *[18] For all k and q,*

$$\omega \leq \log_q(\frac{4}{27}(\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes k}))^{\frac{3}{k}}). \tag{2}$$

More precisely, the ingredients needed for the proof but not the statement appears in [18]. It was pointed out in [11, Ex. 15.24] that the statement holds with $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes k})^{\frac{3}{k}}$ replaced by $\underset{\sim}{\mathbf{R}}(T_{cw,q})^3$ and the proof implicitly uses (2). The equation does appear in [29, Thm. 5.1.5.1].

An easy calculation shows $\underline{\mathbf{R}}(T_{cw,q}) = q+2$ (one more than minimal). Applying Theorem 2 to $T_{cw,8}$ with $k = 1$ gives $\omega \leq 2.41$ [18]. Theorem 2 shows that, unlike $T_{CW,q}$, $T_{cw,2}$ is not subject to the barriers of [4, 3, 2, 13] for proving $\omega = 2$, and $T_{cw,q}$, for $2 \leq q \leq 10$ are not subject to the barriers for proving $\omega < 2.3$. Thus, if any Kronecker power of $T_{cw,q}$ for $2 \leq q \leq 10$ is strictly sub-multiplicative, one can get new upper bounds on ω, and if it were the case that $\underset{\sim}{\mathbf{R}}(T_{cw,2}) = 3$, one would obtain that ω is two. Hence the questions:

▶ **Question 3.** *For given q, k, what is $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes k})$? Does there exist $q \in \{2, \ldots, 10\}$ and $k \in \mathbb{N}$ such that $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes k}) < [\underline{\mathbf{R}}(T_{cw,q})]^k$?*

▶ Remark 4. Although we know little about asymptotic rank of explicit tensors beyond matrix multiplication, most tensors have asymptotic rank less than their border rank: For all tensors $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$, with $m > 3$, outside a set of measure zero (more precisely, for all tensors outside a proper subvariety), Lickteig showed that $\underline{\mathbf{R}}(T) = \lceil \frac{m^3}{3m-2} \rceil$ [35]. Strassen [42, Lemma 3.5] implicitly showed that for any $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$, if $\underline{\mathbf{R}}(T) > m^{\frac{2\omega}{3}} > m^{1.6}$, then $\underset{\sim}{\mathbf{R}}(T) < \underline{\mathbf{R}}(T)$. It is worth recalling Strassen's proof: any $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$ is a degeneration of $M_{\langle 1,m,m \rangle} \in \mathbb{C}^{m^2} \otimes \mathbb{C}^m \otimes \mathbb{C}^m$, so $T^{\boxtimes 3}$ is a degeneration of $M_{\langle m^2,m^2,m^2 \rangle} = M_{\langle 1,m,m \rangle} \boxtimes M_{\langle m,1,m \rangle} \boxtimes M_{\langle m,m,1 \rangle}$. In particular $\underline{\mathbf{R}}(T^{\boxtimes 3}) \leq \underline{\mathbf{R}}(M_{\langle m^2,m^2,m^2 \rangle})$ and $\underset{\sim}{\mathbf{R}}(T)^3 = \underset{\sim}{\mathbf{R}}(T^{\boxtimes 3}) \leq \underset{\sim}{\mathbf{R}}(M_{\langle m^2,m^2,m^2 \rangle}) = m^{2\omega}$, so $\underset{\sim}{\mathbf{R}}(T) \leq m^{\frac{2\omega}{3}}$. Since $\omega < 2.4$ we conclude. In particular, note that $\underset{\sim}{\mathbf{R}}(T) \leq m^{1.6}$ for all $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$.

2 Results

2.1 Lower bounds for Kronecker powers of $T_{cw,q}$

We address Problem 9.8 in [9], which was motivated by Theorem 2: Is $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes 2}) < (q+2)^2$? We give an almost complete answer:

▶ **Theorem 5.** *For all $q > 2$, $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes 2}) = (q+2)^2$, and $15 \leq \underline{\mathbf{R}}(T_{cw,2}^{\boxtimes 2}) \leq 16$.*

We also examine the Kronecker cube:

▶ **Theorem 6.** *For all $q > 4$, $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes 3}) = (q+2)^3$.*

Proofs are given in §4.

Proposition 25 below, combined with the proofs of Theorems 6 and 5, implies

▶ **Corollary 7.** *For all $q > 4$ and all N,*

$$\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes N}) \geq (q+1)^{N-3}(q+2)^3,$$

and $\underline{\mathbf{R}}(T_{cw,4}^{\boxtimes N}) \geq 36 \times 5^{N-2}$.

Previously, in [10] it had been shown that $\underline{\mathbf{R}}(T_{cw,q}^{\boxtimes N}) \geq (q+1)^N + 2^N - 1$ for all q, N, whereas the bound in Corollary 7 is $(q+1)^N + 3(q+1)^{N-1} + 3(q+1)^{N-2} + (q+1)^{N-3}$.

Previous to this work one might have hoped to prove $\omega < 2.3$ simply by using the Kronecker square of, e.g., $T_{cw,7}$. Now, the smallest possible calculation to give a new upper bound on ω from a tensor that has been used in the laser method would be e.g., to prove the fourth Kronecker power of a small Coppersmith-Winograd tensor achieves the lower bound of Corollary 7 (which we do not expect to happen). Of course, one could work directly with the matrix multiplication tensor, in which case the cheapest possible upper bound would come from proving the border rank of the 6×6 matrix multiplication tensor equaled its known lower bound of 69 from [30].

The following corollary of Theorems 5 and 6 is immediate by the semi-continuity property of border rank, as most tensors of border rank $m+1$ in $\mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$ may be degnerated to $T_{cw,m-1}$, in fact the set of tensors of border rank $m+1$ is an orbit closure and $T_{cw,m-1}$ lives on the boundary of the orbit.

▶ **Corollary 8.** *Most tensors $T \in \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$ of border rank $m+1$, satisfy $\underline{\mathbf{R}}(T^{\boxtimes 2}) = \underline{\mathbf{R}}(T)^2 = (m+1)^2$ for $m \geq 4$ and $\underline{\mathbf{R}}(T^{\boxtimes 3}) = \underline{\mathbf{R}}(T)^3 = (m+1)^3$ for $m \geq 6$. More precisely all tensors outside of a Zariski closed subset of the set of tensors of border rank $m+1$. In particular the set of such is of full measure.*

2.2 A skew cousin of $T_{cw,q}$

In light of the negative results for complexity theory above, one might try to find a better tensor than $T_{cw,q}$ that is also not subject to the barriers. In [16], when q is even, we introduced a skew cousin of the big Coppersmith-Winograd tensor, which has the largest symmetry group of any tensor in its space satisfying a natural genericity condition. However this tensor turns out not to be useful for the laser method. Inspired by it, we introduce a skew cousin of the small Coppersmith-Winograd tensor when q is even:

$$T_{skewcw,q} := \sum_{j=1}^{q} a_0 \otimes b_j \otimes c_j + a_j \otimes b_0 \otimes c_j + \sum_{\xi=1}^{\frac{q}{2}} (a_\xi \otimes b_{\xi+\frac{q}{2}} - a_{\xi+\frac{q}{2}} \otimes b_\xi) \otimes c_0 \in (\mathbb{C}^{q+1})^{\otimes 3}. \quad (3)$$

In the language of [11], $T_{skewcw,q}$ has the same "block structure" as $T_{cw,q}$, which immediately implies Theorem 2 also holds for $T_{skewcw,q}$:

▶ **Theorem 9.** *For all k,*

$$\omega \leq \log_q\left(\frac{4}{27}(\underline{\mathbf{R}}(T_{skewcw,q}^{\boxtimes k}))^{\frac{3}{k}}\right). \quad (4)$$

In particular, the known barriers do not apply to $T_{skewcw,2}$ for proving $\omega = 2$ and to any $T_{skewcw,q}$ for $q \leq 10$ for proving $\omega < 2.3$. Unfortunately, we have

▶ **Proposition 10.** $\underline{\mathbf{R}}(T_{skewcw,q}) \geq q + 3$.

Proposition 10 is proved in §4.

Thus $\underline{\mathbf{R}}(T_{skewcw,q}) > \underline{\mathbf{R}}(T_{cw,q})$ for all q, in particular $\underline{\mathbf{R}}(T_{skewcw,2}) = 5$, as for all $T \in \mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$, $\underline{\mathbf{R}}(T) \leq 5$.

However, unlike $T_{cw,2}$, substantial strict sub-multiplicativity holds for the Kronecker square of $T_{skewcw,2}$:

▶ **Theorem 11.** $\underline{\mathbf{R}}(T^{\boxtimes 2}_{skewcw,2}) \leq 17$.

▶ Remark 12. Regarding border rank strict submultiplicativity of Kronecker powers for other explicit tensors, little is known. For matrix multiplication, the only explicit drop under a Kronecker power that is known to our knowledge is [37]: $\underline{\mathbf{R}}(M^{\boxtimes 2}_{\langle 2\rangle}) \leq 46 < 49$.

Previous to this work, we are only aware of one class of tensors other than $M_{\langle 2\rangle}$ for which any bound on the Kronecker squares other than the trivial $\underline{\mathbf{R}}(T^{\boxtimes 2}) \leq \underline{\mathbf{R}}(T)^2$ is known. In [12], they show that

$$\begin{aligned} T_{CGJ,m} :=& a_1 \otimes b_1 \otimes c_1 + a_2 \otimes b_2 \otimes c_2 + a_3 \otimes b_3 \otimes c_3 + (\textstyle\sum_{i=1}^{3} a_i) \otimes (\sum_{j=1}^{3} b_j) \otimes (\sum_{j=1}^{3} c_k) \\ &+ 2(a_1 + a_2) \otimes (b_1 + b_3) \otimes (c_2 + c_3) + a_3 \otimes (\textstyle\sum_{s=4}^{m} b_s \otimes c_s) \in \mathbb{C}^3 \otimes \mathbb{C}^m \otimes \mathbb{C}^m \end{aligned}$$

satisfies $\underline{\mathbf{R}}(T_{CGJ,m}) = m + 2$ and $\underline{\mathbf{R}}(T^{\otimes 2}_{CGJ,m}) \leq (m+2)^2 - 1$. Of course, for any tensor T, $\underline{\mathbf{R}}(T^{\boxtimes 2}) \leq \underline{\mathbf{R}}(T^{\otimes 2})$, and strict inequality, e.g., with $M_{\langle 2\rangle}$ is possible. This is part of a general theory in [12] for constructing examples with a drop of one when the last non-trivial secant variety is a hypersurface.

We also show

▶ **Theorem 13.** $\mathbf{R}(T^{\boxtimes 2}_{skewcw,2}) \leq 18$.

Theorems 11 and 13 are proved in §5.

2.3 Two familiar tensors with no known laser method barriers

Recall from above that either $\underset{\sim}{\mathbf{R}}(T_{cw,2}) = 3$ or $\underset{\sim}{\mathbf{R}}(T_{skewcw,2}) = 3$ would imply $\omega = 2$.

Let $\det_3 \in (\mathbb{C}^9)^{\otimes 3}$ and $\mathrm{perm}_3 \in (\mathbb{C}^9)^{\otimes 3}$ be the 3×3 determinant and permanent polynomials considered as tensors. We observe that if either of these has minimal asymptotic rank, then $\omega = 2$: either $\underset{\sim}{\mathbf{R}}(\det_3) = 9$ or $\underset{\sim}{\mathbf{R}}(\mathrm{perm}_3) = 9$ would imply $\omega = 2$. This observation is an immediate consequence of the following lemma:

▶ **Lemma 14.** *We have the following isomorphisms of tensors:*

$T^{\boxtimes 2}_{cw,2} \cong \mathrm{perm}_3$

$T^{\boxtimes 2}_{skewcw,2} \cong \det_3$.

Lemma 14 is proved in §3.

Lemma 14 thus implies Theorems 11 and 13 may be restated as saying $\underline{\mathbf{R}}(\det_3) \leq 17$ and $\mathbf{R}(\det_3) \leq 18$. Although it is not necessarily relevant for complexity theory, we actually prove stronger statements, which are important for geometry:

A symmetric tensor $T \in S^3\mathbb{C}^m \subseteq \mathbb{C}^m \otimes \mathbb{C}^m \otimes \mathbb{C}^m$ has *Waring rank one* if $T = a \otimes a \otimes a$ for some $a \in \mathbb{C}^3$. The *Waring rank* of T, denoted $\mathbf{R}_S(T)$, is the smallest r such that T is sum of r tensors of Waring rank one. The *Waring border rank* of T, denoted $\underline{\mathbf{R}}_S(T)$, is the smallest r such that T is limit of a sequence of tensors of Waring rank r.

We actually show:

▶ **Theorem 15.** $\mathbf{R}_S(\det_3) \leq 18$.

and

▶ **Theorem 16.** $\underline{\mathbf{R}}_S(\det_3) \leq 17$.

Proofs are respectively given in §5.1 and §5.2.

2.4 Generic tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$

▶ Remark 17. A generic tensor in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ has border rank five. Our numerical experiments suggest that for all $T \in \mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$:

$$\underline{\mathbf{R}}(T^{\boxtimes 2}) \leq 22 < 25. \tag{5}$$

This is obtained by starting with a tensor whose entries are obtained from making draws according to a uniform distribution on $[-1, 1]$, and proving the result for that tensor. The data to perform an example of this computation is available in Appendix A at `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`.

▶ **Problem 18.** *Write a proof of* (5). *Even better, give a geometric proof.*

The inequality (5) is not too surprising because $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ is *secant defective*, in the sense that by a dimension count, one would expect the maximum border rank of a tensor to be 4, but the actual maximum is 5. This means that for a generic tensor, there is a 8 parameter family of rank 5 decompositions, and it is not surprising that the naïve 64-parameter family of decompositions of the square might have decompositions of lower border rank on the boundary.

3 Symmetries of tensors and the proof of Lemma 14

3.1 Symmetry groups of tensors and polynomials

The group $GL(A) \times GL(B) \times GL(C)$ acts naturally on $A \otimes B \otimes C$. The map $\Phi : GL(A) \times GL(B) \times GL(C) \to GL(A \otimes B \otimes C)$ has a two dimensional kernel $\ker \Phi = \{(\lambda \mathrm{Id}_A, \mu \mathrm{Id}_B, \nu \mathrm{Id}_C) : \lambda\mu\nu = 1\} \simeq (\mathbb{C}^*)^2$.

In particular, the group $(GL(A) \times GL(B) \times GL(C))/(\mathbb{C}^*)^{\times 2}$ is naturally identified with a subgroup of $GL(A \otimes B \otimes C)$. Given $T \in A \otimes B \otimes C$, the *symmetry group* of a tensor T is the stabilizer of T in $(GL(A) \times GL(B) \times GL(C))/(\mathbb{C}^*)^{\times 2}$, that is

$$G_T := \{g \in (GL(A) \times GL(B) \times GL(C))/(\mathbb{C}^*)^{\times 2} \mid \; g \cdot T = T\}. \tag{6}$$

Let $\mathfrak{S}_k$ be the permutation group on k elements. We record the following observation:

▶ **Proposition 19.** *For any tensor $T \in A \otimes B \otimes C$, $G_{T^{\boxtimes N}} \supset \mathfrak{S}_N$.*

Proof. Write $T^{\boxtimes N} = \sum_{I,J,K} T^{I,J,K} a_I \otimes b_J \otimes c_K$ where $I = (i_1, \ldots, i_N)$, $a_I = a_{i_1} \otimes \cdots \otimes a_{i_N}$, etc.. For $\sigma \in \mathfrak{S}_N$, define $\sigma \cdot T = \sum_{I,J,K} T^{IJK} a_{\sigma(I)} \otimes b_{\sigma(J)} \otimes c_{\sigma(K)}$. Since $T^{IJK} = T^{i_1 j_1 k_1} \cdots T^{i_N j_N k_N}$ we have $T^{IJK} = T^{\sigma(I),\sigma(J),\sigma(K)}$ and we conclude. ◀

▶ Remark 20. For a symmetric tensor (equivalently, a homogeneous polynomial), $T \in S^d A$, one may also consider the symmetry group $G^s_T := \{g \in GL(A) \mid g \cdot T = T\}$ where the action is the induced action on polynomials.

3.2 Proof of Lemma 14

Write $(-1)^\sigma$ for the sign of a permutation σ. Let

$$\det_3 = \sum_{\sigma,\tau\in\mathfrak{S}_3} (-1)^\tau a_{\sigma(1)\tau(1)} \otimes b_{\sigma(2)\tau(2)} \otimes c_{\sigma(3)\tau(3)},$$
$$\mathrm{perm}_3 = \sum_{\sigma,\tau\in\mathfrak{S}_3} a_{\sigma(1)\tau(1)} \otimes b_{\sigma(2)\tau(2)} \otimes c_{\sigma(3)\tau(3)}$$

be the 3×3 determinant and permanent polynomials regarded as tensors in $\mathbb{C}^9\otimes\mathbb{C}^9\otimes\mathbb{C}^9$.

Proof of Lemma 14. After the change of basis $\tilde{b}_0 := -b_0$ and $\tilde{c}_1 := c_2$, $\tilde{c}_2 := -c_1$, we obtain

$$\begin{aligned} T_{skewcw,2} = {} & a_0\otimes b_1\otimes \tilde{c}_2 - a_0\otimes b_2\otimes \tilde{c}_1 + a_2\otimes \tilde{b}_0\otimes c_1 \\ & - a_1\otimes \tilde{b}_0\otimes \tilde{c}_2 + a_1\otimes b_2\otimes c_0 - a_2\otimes b_1\otimes c_0. \end{aligned}$$

This shows that, after identifying the three spaces, $T_{skewcw,2} = a_0\wedge a_1\wedge a_2$ is the unique (up to scale) skew-symmetric tensor in $\mathbb{C}^3\otimes\mathbb{C}^3\otimes\mathbb{C}^3$. In particular, $T_{skewcw,2}$ is invariant under the action of SL_3 on $\mathbb{C}^3\otimes\mathbb{C}^3\otimes\mathbb{C}^3$.

Consequently, the stabilizer of $T_{skewcw,2}^{\boxtimes 2}$ in $GL(\mathbb{C}^9)$ contains (and in fact equals) $SL_3^{\times 2}\rtimes\mathbb{Z}_2$. This is the stabilizer of the determinant polynomial $\det_3$. Since the determinant is characterized by its stabilizer, we conclude.

The tensor $T_{cw,2}$ is symmetric and, after identifying the three spaces, it coincides with $a_0(a_1^2+a_2^2)\in S^3\mathbb{C}^3$. After the change of basis $\tilde{a}_1 := a_1+a_2$, $\tilde{a}_2 := a_1-a_2$, we obtain $T_{cw,2} = a_0\tilde{a}_1\tilde{a}_2\in S^3\mathbb{C}^3$ is the square-free monomial of degree 3. The stabilizer of $T_{cw,2}$ under the action of GL_3 on $S^3\mathbb{C}^3$ is $\mathbb{T}_3^{SL}\rtimes\mathfrak{S}_3$, where $\mathbb{T}_3^{SL}$ denotes the torus of diagonal matrices with determinant one, and $\mathfrak{S}_3$ acts permuting the three basis elements.

Consequently, the stabilizer of $T_{cw,2}^{\boxtimes 2}$ in $GL(\mathbb{C}^9)$ contains (and in fact equals) $(\mathbb{T}_3^{SL}\rtimes\mathfrak{S}_3)^{\times 2}\rtimes\mathbb{Z}_2$. This is the stabilizer of the permanent polynomial perm_3. Since the permanent is characterized by its stabilizer, we conclude. ◀

▶ Remark 21. For the reader's convenience, here are short proofs that $\det_m, \mathrm{perm}_m$ are characterized by their stabilizers: To see $\det_m$ is characterized by its stabilizer, note that $SL_m\times SL_m = SL(E)\times SL(F)$ acting on $S^m(E\otimes F)$ decomposes it to

$$\bigoplus_{|\pi|=m} S_\pi E\otimes S_\pi F$$

which is multiplicity free, with the only trivial module $S_{1^m}E\otimes S_{1^m}F = \Lambda^m E\otimes\Lambda^m F$. To see that perm_m is characterized by its stabilizer, take the above decomposition and consider the $\mathbb{T}^{SL(E)}\times\mathbb{T}^{SL(F)}$-invariants, these are the weight zero spaces $(S_\pi E)_0\otimes(S_\pi F)_0$. By [24], one has the decomposition of the weight zero spaces as $\mathfrak{S}_m^E\times\mathfrak{S}_m^F$-modules to $(S_\pi E)_0\otimes(S_\pi F)_0 = [\pi]_E\otimes[\pi]_F$. The only such that is trivial is the case $\pi=(d)$.

▶ Remark 22. Even Kronecker powers of $T_{skewcw,2}$ are invariant under $SL_3^{\times 2k}$, and coincide, up to a change of basis, with the *Pascal determinants* (see, e.g., [27, §8.3]), $T_{skewcw,2}^{\boxtimes 2k} = PasDet_{k,3}$, the unique, up to scale, tensor spanning $(\Lambda^3\mathbb{C}^3)^{\otimes 2k}\subset S^3((\mathbb{C}^3)^{\otimes 2k})$.

▶ Remark 23. One can regard the 3×3 determinant and permanent as trilinear maps $\mathbb{C}^3\times\mathbb{C}^3\times\mathbb{C}^3\to\mathbb{C}$, where the three copies of $\mathbb{C}^3$ are the first, second and third column of a 3×3 matrix. From this point of view, the trilinear map given by the determinant is $T_{skewcw,2}$ as a tensor and the one given by the permanent is $T_{cw,2}$ as a tensor. This perspective, combined with the notion of product rank, immediately provides the upper bounds $\underline{\mathbf{R}}(\mathrm{perm}_3)\leq 16$ (which is also a consequence of Lemma 14) and $\underline{\mathbf{R}}(\det_3)\leq 20$, see [19, 26].

▶ Remark 24. A similar change of basis as the one performed in the second part of proof of Lemma 14 shows that, up to a change of basis, $T_{skewcw,q} \in \Lambda^3\mathbb{C}^{q+1}$. In particular, its even Kronecker powers are symmetric tensors.

4 Koszul flattenings and lower bounds for Kronecker powers

In this section we review Koszul flattenings, prove a result on propagation of Koszul flattening lower bounds under Kronecker products, and prove Theorems 5 and 6. We give two proofs of Theorem 5 because the first is elementary and method of the second generalizes to give the proof of Theorem 6.

4.1 Definition

Respectively fix bases $\{a_i\}$, $\{b_j\}$, $\{c_k\}$ of the vector spaces A, B, C. Given $T = \sum_{ijk} T^{ijk} a_i \otimes b_j \otimes c_k \in A \otimes B \otimes C$, define the linear map

$$\begin{aligned} T_A^{\wedge p} : \Lambda^p A \otimes B^* &\to \Lambda^{p+1} A \otimes C \\ X \otimes \beta &\mapsto \textstyle\sum_{ijk} T^{ijk} \beta(b_j)(a_i \wedge X) \otimes c_k. \end{aligned}$$

Then [31, Proposition 4.1.1] states

$$\underline{\mathbf{R}}(T) \geq \frac{\operatorname{rank}(T_A^{\wedge p})}{\binom{\dim(A)-1}{p}}. \tag{7}$$

This type of lower bound has a long history: in general, one takes the space $A \otimes B \otimes C$ and linearly embeds it into a large space of matrices. Then if a rank one tensor maps to a rank q matrix, a rank r tensor maps to a rank at most rq matrix, so the size $rq+1$ minors give equations testing for border rank r. In this case the size of the matrices is $\binom{\mathbf{a}}{p}\mathbf{b} \times \binom{\mathbf{a}}{p+1}\mathbf{c}$ and a rank one tensor maps to a matrix of rank $\binom{\mathbf{a}-1}{p}$. Here $\mathbf{a} = \dim A$, $\mathbf{b} = \dim B$ and $\mathbf{c} = \dim C$.

In practice, one takes a subspace $A'^* \subseteq A^*$ of dimension $2p+1$ and restricts T (considered as a trilinear form) to $A'^* \times B^* \times C^*$ to get an optimal bound, so the denominator $\binom{\dim(A)-1}{p}$ is replaced by $\binom{2p}{p}$ in (7). Write $\phi : A \to A/(A'^*)^\perp =: A'$ for the projection onto the quotient: the corresponding Koszul flattening map gives a lower bound for $\underline{\mathbf{R}}(\phi(T))$, which, by linearity, is a lower bound for $\underline{\mathbf{R}}(T)$. The case $p = 1$ is equivalent to Strassen's equations [40]. There are numerous expositions of Koszul flattenings and their generalizations, see, e.g., [27, §7.3], [5, §7.2], [20], [28, §2.4], or [21].

Proof of Proposition 10. Write $q = 2u$. Fix a space $A' = \langle e_0, e_1, e_2 \rangle$. Define $\phi : A \to A'$ by

$$\begin{aligned} &\phi(a_0) = e_0, \\ &\phi(a_i) = e_1 \quad \text{for } i = 1, \dots, u, \\ &\phi(a_s) = e_2 \quad \text{for } s = u+1, \dots, q. \end{aligned}$$

As an element of $\Lambda^3 A$, we have $T_{skewcw,q} = a_0 \wedge \sum_{i=1}^{u} a_i \wedge a_{u+i}$.

We prove that if $T = T_{skewcw,q}$ then $\operatorname{rank}(T_{A'}^{\wedge 1}) = 2(q+2)+1$. This provides the lower bound $\underline{\mathbf{R}}(T) \geq \left\lceil \frac{2(q+2)+1}{2} \right\rceil = q+3$.

We record the images via $T_{A'}^{\wedge 1}$ of a basis of $A' \otimes B^*$. Fix the range of $i = 1, \ldots, u$:

$$\begin{aligned}
T_{A'}^{\wedge 1}(e_0 \otimes \beta_0) &= (e_0 \wedge e_1) \otimes \textstyle\sum_{i=1}^{u} c_{u+i} - (e_0 \wedge e_2) \otimes \sum_{i=1}^{u} c_i,\\
T_{A'}^{\wedge 1}(e_0 \otimes \beta_i) &= (e_0 \wedge e_2) \otimes c_0,\\
T_{A'}^{\wedge 1}(e_0 \otimes \beta_{u+i}) &= (e_0 \wedge e_1) \otimes c_0,\\
T_{A'}^{\wedge 1}(e_1 \otimes \beta_0) &= (e_1 \wedge e_2) \otimes \textstyle\sum_{i=1}^{u} c_{u+i},\\
T_{A'}^{\wedge 1}(e_1 \otimes \beta_i) &= (e_0 \wedge e_1) \otimes c_{u+i} + e_1 \wedge e_2 \otimes c_0,\\
T_{A'}^{\wedge 1}(e_1 \otimes \beta_{u+i}) &= e_0 \wedge e_1 \otimes c_i,\\
T_{A'}^{\wedge 1}(e_2 \otimes \beta_0) &= (e_1 \wedge e_2) \otimes \textstyle\sum_{i=1}^{u} c_i,\\
T_{A'}^{\wedge 1}(e_2 \otimes \beta_i) &= e_0 \wedge e_2 \otimes c_{u+i},\\
T_{A'}^{\wedge 1}(e_2 \otimes \beta_{u+i}) &= (e_0 \wedge e_2) \otimes c_i - e_1 \wedge e_2 \otimes c_0.
\end{aligned}$$

Notice that the image of $\sum_{i=1}^{u}(e_1 \otimes \beta_i) - \sum_{i=1}^{u}(e_2 \otimes \beta_{u+i}) - e_0 \otimes \beta_0$ is (up to scale) $e_1 \wedge e_2 \otimes c_0$.

This shows that the image of $T_{A'}^{\wedge 1}$ contains

$$\Lambda^2 A' \otimes c_0 + e_1 \wedge e_2 \otimes \langle \textstyle\sum_{i=1}^{u} c_i, \sum_{i=1}^{u} c_{u+i} \rangle + \langle e_0 \wedge e_1, e_0 \wedge e_2 \rangle \otimes \langle c_1, \ldots, c_q \rangle.$$

These summands are in disjoint subspaces, so we conclude

$$\operatorname{rank}(T_{A'}^{\wedge 1}) \geq 3 + 2 + 2q = 2q + 5. \qquad \blacktriangleleft$$

4.2 Propagation of lower bounds under Kronecker products

A tensor $T \in A \otimes B \otimes C$, with $\dim B = \dim C$ is 1_A-*generic* if $T(A^*) \subseteq B \otimes C$ contains a full rank element. Here is a partial multiplicativity result for Koszul flattening lower bounds under Kronecker products:

▶ **Proposition 25.** *Let $T_1 \in A_1 \otimes B_1 \otimes C_1$ with $\dim B_1 = \dim C_1$ be a tensor with a Koszul flattening lower bound for border rank $\underline{\mathbf{R}}(T) \geq r$ given by ${T_1}_{A_1}^{\wedge p}$ (possibly after a restriction ϕ). Let $T_2 \in A_2 \otimes B_2 \otimes C_2$, with $\dim B_2 = \dim C_2 = \mathbf{b}_2$ be 1_{A_2}-generic. Then*

$$\underline{\mathbf{R}}(T_1 \boxtimes T_2) \geq \left\lceil \frac{\operatorname{rank}({T_1}_{A_1}^{\wedge p}) \cdot \mathbf{b}_2}{\binom{2p}{p}} \right\rceil. \tag{8}$$

In particular, if $\frac{\operatorname{rank}({T_1}_{A_1}^{\wedge p})}{\binom{2p}{p}} \in \mathbb{Z}$, then $\underline{\mathbf{R}}(T_1 \boxtimes T_2) \geq r\mathbf{b}_2$.

Proof. After applying a restriction ϕ as described above, we may assume $\dim A_1 = 2p + 1$ so that the lower bound for T_1 is

$$\underline{\mathbf{R}}(T_1) \geq \left\lceil \frac{\operatorname{rank}({T_1}_{A_1}^{\wedge p})}{\binom{2p}{p}} \right\rceil.$$

Let $\alpha \in A_2^*$ be such that $T(\alpha) \in B_2 \otimes C_2$ has full rank $\mathbf{b}_2$, which exists by 1_{A_2}-genericity. Define $\psi : A_1 \otimes A_2 \to A_1$ by $\psi = \operatorname{Id}_{A_1} \otimes \alpha$ and set $\Psi := \psi \otimes \operatorname{Id}_{B_1 \otimes C_1 \otimes B_2 \otimes C_2}$. Then $(\Psi(T_1 \boxtimes T_2)_{A_1}^{\wedge p})$ provides the desired lower bound.

Indeed, the linear map $(\Psi(T_1 \boxtimes T_2)_{A_1}^{\wedge p})$ coincides with ${T_1}_{A_1}^{\wedge p} \boxtimes T_1(\alpha)$. Since matrix rank is multiplicative under Kronecker product, we conclude. $\blacktriangleleft$

4.3 First proof of Theorem 5

When $q = 3$, the result is true by a direct calculation using the $p = 2$ Koszul flattening with a sufficiently generic $\mathbb{C}^5 \subset A^*$, which is left to the reader. In what follows we treat the case $q > 3$.

Write $a_{ij} = a_i \otimes a_j \in A^{\otimes 2}$ and similarly for $B^{\otimes 2}$ and $C^{\otimes 2}$. Let $A' = \langle e_0, e_1, e_2\rangle$ and define the linear map $\phi_2 : A^{\otimes 2} \to A'$ via

$$\begin{aligned}
&\phi_2(a_{00}) = \phi_2(a_{01}) = \phi_2(a_{10}) = e_0 + e_1,\\
&\phi_2(a_{11}) = e_0,\\
&\phi_2(a_{02}) = \phi_2(a_{20}) = e_1 + e_2\\
&\phi_2(a_{33}) = \phi_2(a_{21}) = e_2\\
&\phi_2(a_{0i}) = \phi_2(a_{i0}) = e_1 \quad \text{for } i = 3, \dots, q\\
&\phi_2(a_{ij}) = 0 \quad \text{for all other pairs } (i, j).
\end{aligned}$$

Write $T_q := T^{\boxtimes 2}_{cw,q}|_{A^{*\prime}\otimes B^{*\otimes 2}\otimes C^{*\otimes 2}}$. Consider the $p = 1$ Koszul flattening $(T_q)^{\wedge 1}_{A'} : A' \otimes B^{\otimes 2^*} \to \Lambda^2 A' \otimes C^{\otimes 2}$.

We are going to prove that $\operatorname{rank}((T_q)^{\wedge 1}_{A'}) = 2(q+2)^2$. This provides the lower bound $\underline{\mathbf{R}}(T^{\boxtimes 2}_{cw,q}) \geq (q+2)^2$ and equality follows because of the submultiplicativity properties of border rank under Kronecker product.

We proceed by induction on q. When $q = 4$ one does a direct computation with the $p = 1$ Koszul flattening, which is left to the reader, and which provides the base of the induction.

Write $W_j = a_0 \otimes b_j \otimes c_j + a_i \otimes b_0 \otimes c_j + a_i \otimes b_i \otimes c_0$. Then $T_{cw,q} = \sum_{j=1}^{q} W_j$, so that $T^{\boxtimes 2}_{cw,q} = \sum_{ij} W_i \boxtimes W_j$.

If $q \geq 4$, write $T_{cw,q} = T_{cw,q-1} + W_q$, so $T^{\boxtimes 2}_{cw,q} = T^{\boxtimes 2}_{cw,q-1} + T_{cw,q-1} \boxtimes W_q + W_q \boxtimes T_{cw,q-1} + W_q \boxtimes W_q$. Let $S_q = (T_{cw,q-1} \boxtimes W_q + W_q \boxtimes T_{cw,q-1} + W_q \boxtimes W_q)|_{A'\otimes B^{*\otimes 2}\otimes C^{*\otimes 2}}$.

Write $U_1 = A' \otimes \langle \beta_{ij} : i, j = 0, \dots, q-1\rangle$ and $U_2 = A' \otimes \langle \beta_{qi}, \beta_{iq} : i = 0, \dots, q\rangle$ so that $U_1 \oplus U_2 = A' \otimes B^{\otimes 2*}$. Similarly, define $V_1 = \Lambda^2 A' \otimes \langle c_{ij} : i, j = 0, \dots, q-1\rangle$ and $V_2 = \Lambda^2 A' \otimes \langle c_{qi}, c_{iq} : i = 0, \dots, q\rangle$, so that $V_1 \oplus V_2 = \Lambda^2 A' \otimes C^{\otimes 2}$. Observe that $(T_{q-1})^{\wedge 1}_{A'}$ is identically 0 on U_2 and its image is contained in V_1. Moreover, the image of U_1 under $(S_q)^{\wedge 1}_{A'}$ is contained in V_1. Representing the Koszul flattening in blocks, we have

$$(T_{q-1})^{\wedge 1}_{A'} = \begin{bmatrix} M_{11} & 0 \\ 0 & 0 \end{bmatrix} \qquad (S_q)^{\wedge 1}_{A'} = \begin{bmatrix} N_{11} & N_{12} \\ 0 & N_{22} \end{bmatrix}$$

therefore $\operatorname{rank}((T_q)^{\wedge 1}_{A'}) \geq \operatorname{rank}(M_{11} + N_{11}) + \operatorname{rank}(N_{22})$.

First, we prove that $\operatorname{rank}(M_{11} + N_{11}) \geq \operatorname{rank}(M_{11}) = 2(q+1)^2$. This follows by a degeneration argument. Consider the linear map given by pre-composing the Koszul flattening with the projection onto U_1. Its rank is semicontinuous under degeneration. Since $T^{\boxtimes 2}_{cw,q}$ degenerates to $T^{\boxtimes 2}_{cw,q-1}$, we deduce $\operatorname{rank}(M_{11} + N_{11}) \geq \operatorname{rank}(M_{11})$. The equality $\operatorname{rank}(M_{11}) = 2(q+1)^2$ follows by the induction hypothesis.

We show that $\operatorname{rank}(N_{22}) = 2(2q+3)$. The following equalities are modulo V_1. Moreover, each equality is modulo the tensors resulting from the previous ones. They are all straightforward applications of the Koszul flattening map, which in these cases, can always

be performed on some copy of $W_i \boxtimes W_j$.

$$
\begin{aligned}
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{qj}) \equiv e_1 \wedge e_0 \otimes c_{qj} \quad \text{for } j = 3, \ldots, q\\
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{jq}) \equiv e_1 \wedge e_0 \otimes c_{jq} \quad \text{for } j = 3, \ldots, q\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{3q}) \equiv e_0 \wedge e_1 \otimes c_{0q}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{q3}) \equiv e_0 \wedge e_1 \otimes c_{q0}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{q1}) \equiv e_0 \wedge e_1 \otimes c_{q1}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{1q}) \equiv e_0 \wedge e_1. \otimes c_{1q}
\end{aligned}
$$

Further passing modulo $\langle e_0 \wedge e_1 \rangle \otimes C$, we obtain

$$
\begin{aligned}
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{0q}) \equiv e_0 \wedge e_2 \otimes c_{2q}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{q0}) \equiv e_0 \wedge e_2 \otimes c_{q2}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{q2}) \equiv e_0 \wedge e_2 \otimes c_{0q}\\
&(S_q)^{\wedge 1}_{A'}(e_0 \otimes \beta_{2q}) \equiv e_0 \wedge e_2 \otimes c_{q0}\\
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{20}) \equiv e_1 \wedge e_2 \otimes c_{0q}\\
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{02}) \equiv e_1 \wedge e_2 \otimes c_{q0}\\
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{q0}) \equiv e_1 \wedge e_2 \otimes c_{2q}\\
&(S_q)^{\wedge 1}_{A'}(e_1 \otimes \beta_{0q}) \equiv e_1 \wedge e_2 \otimes c_{q2},
\end{aligned}
$$

and modulo the above,

$$
\begin{aligned}
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{qj}) \equiv e_2 \wedge (e_0 + e_1) \otimes c_{qj} \quad \text{for } j = 3, \ldots, q\\
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{jq}) \equiv e_2 \wedge (e_0 + e_1) \otimes c_{jq} \quad \text{for } j = 3, \ldots, q\\
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{q1}) \equiv e_2 \wedge (e_0 + e_1) \otimes c_{q1}\\
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{1q}) \equiv e_2 \wedge (e_0 + e_1) \otimes c_{1q}.
\end{aligned}
$$

Finally passing modulo $\langle e_1 \wedge e_2 \rangle$, we have

$$
\begin{aligned}
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{q0}) \equiv e_2 \wedge e_0 \otimes c_{q1}\\
&(S_q)^{\wedge 1}_{A'}(e_2 \otimes \beta_{0q}) \equiv e_2 \wedge e_0 \otimes c_{1q}.
\end{aligned}
$$

All the tensors listed above are linearly independent. Adding all the contributions together, we obtain

$$\operatorname{rank}((S_q)^{\wedge 1}_{A'}) = [2(q-3)+1] + 4 + 8 + 2 + [2(q-3)+1] + 4 = 2(2q+3)$$

as desired, and since $2(q+3)^2 = 2(q+1)^2 + 2(2q+3)$, this concludes the proof. ◀

4.4 A short detour on computing ranks of equivariant maps

We briefly explain how to exploit Schur's Lemma (see, e.g., [23, §1.2]) to compute the rank of an equivariant linear map. This is a standard technique, used extensively e.g., in [32, 25] and will reduce the proof of Theorems 5 and 6 to the computation of the ranks of specific linear maps in small dimension.

Let G be a reductive group. In the proof of Theorems 5 and 6, G will be the product of symmetric groups. Let Λ_G be the set of irreducible representations of G. For $\lambda \in \Lambda_G$, let W_λ denote the corresponding irreducible module.

Suppose U, V are two representations of G. Write $U = \bigoplus_{\lambda\in\Lambda_G} W_\lambda^{\oplus m_\lambda}$, $V = \bigoplus_{\lambda\in\Lambda_G} W_\lambda^{\oplus \ell_\lambda}$, where m_λ is the multiplicity of W_λ in U and ℓ_λ is the multiplicity of W_λ in V. The direct summand corresponding to λ is called the *isotypic component* of type λ.

Let $f : U \to V$ be a G-equivariant map. By Schur's Lemma [23, §1.2], f decomposes as $f = \oplus f_\lambda$, where $f_\lambda : W_\lambda^{\oplus m_\lambda} \to W_\lambda^{\oplus \ell_\lambda}$. Consider multiplicity spaces M_λ, L_λ with $\dim M_\lambda = m_\lambda$ and $\dim L_\lambda = \ell_\lambda$ so that $W_\lambda^{\oplus m_\lambda} \simeq M_\lambda \otimes W_\lambda$ as a G-module, where G acts trivially on M_λ and similarly $W_\lambda^{\oplus \ell_\lambda} \simeq L_\lambda \otimes W_\lambda$.

By Schur's Lemma, the map $f_\lambda : M_\lambda \otimes W_\lambda \to L_\lambda \otimes W_\lambda$ decomposes as $f_\lambda = \phi_\lambda \otimes \mathrm{Id}_{[\lambda]}$, where $\phi_\lambda : M_\lambda \to L_\lambda$. Thus $\mathrm{rank}(f)$ is uniquely determined by $\mathrm{rank}(\phi_\lambda)$ for $\lambda \in \Lambda_G$.

The ranks $\mathrm{rank}(\phi_\lambda)$ can be computed via restrictions of f. For every λ, fix a vector $w_\lambda \in W_\lambda$, so that $M_\lambda \otimes \langle w_\lambda\rangle$ is a subspace of U. Here and in what follows, for a subset $X \subset V$, $\langle X\rangle$ denotes the span of X. Then the rank of the restriction of f to $M_\lambda \otimes \langle w_\lambda\rangle$ coincides with the rank of ϕ_λ.

We conclude

$$\mathrm{rank}(f) = \textstyle\sum_\lambda \mathrm{rank}(\phi_\lambda)\cdot \dim W_\lambda.$$

The second proof of Theorem 5 and proof of Theorem 6 will follow the algorithm described above, exploiting the symmetries of $T_{cw,q}$. Consider the action of the symmetry group $\mathfrak{S}_q$ on $A \otimes B \otimes C$ defined by permuting the basis elements with indices $\{1, \dots, q\}$. More precisely, a permutation $\sigma \in \mathfrak{S}_q$ induces the linear map defined by $\sigma(a_i) = a_{\sigma(i)}$ for $i = 1, \dots, q$ and $\sigma(a_0) = a_0$. The group $\mathfrak{S}_q$ acts on B, C similarly, and the simultaneous action on the three factors defines an $\mathfrak{S}_q$-action on $A \otimes B \otimes C$. The tensor $T_{cw,q}$ is invariant under this action.

4.5 Second Proof of Theorem 5

When $q = 3$, as before, one uses the $p = 2$ Koszul flattening with a sufficiently generic $\mathbb{C}^5 \subset A^*$.

For $q \geq 4$, we apply the $p = 1$ Koszul flattening map to the same restriction of $T_{cw,q}^{\boxtimes 2}$ as the first proof, although to be consistent with the code at the website, we use the less appealing swap of the roles of a_2 and a_3 in the projection ϕ.

Since $T_{cw,q}$ is invariant under the action of $\mathfrak{S}_q$, $T_{cw,q}^{\boxtimes 2}$ is invariant under the action of $\mathfrak{S}_q \times \mathfrak{S}_q$, acting on $A^{\otimes 2} \otimes B^{\otimes 2} \otimes C^{\otimes 2}$. Let $\Gamma := \mathfrak{S}_{q-3} \times \mathfrak{S}_{q-3}$ where $\mathfrak{S}_{q-3}$ is the permutation group on $\{4, \dots, q\}$, so $T_{cw,q}^{\boxtimes 2}$ is invariant under the action of Γ. Note that Γ acts trivially on A', so $(T_q)^{\wedge 1}_{A'}$ is Γ-equivariant, because in general, Koszul flattenings are equivariant under the product of the three general linear groups, which is $GL(A') \times GL(B^{\otimes 2}) \times GL(C^{\otimes 2})$ in our case. (We remind the reader that $T_q := T_{cw,q}^{\boxtimes 2}|_{A^{*\prime}\otimes B^{*\otimes 2}\otimes C^{*\otimes 2}}$.) We now apply the method described in §4.4 to compute $\mathrm{rank}((T_q)^{\wedge 1}_{A'})$.

Let [triv] denote the trivial $\mathfrak{S}_{q-3}$-representation and let V denote the standard representation, that is the Specht module associated to the partition $(q-4, 1)$ of $q-3$. We have $\dim[\mathrm{triv}] = 1$ and $\dim V = q-4$. (When $q = 4$ only the trivial representation appears.)

The spaces B, C are isomorphic as $\mathfrak{S}_{q-3}$-modules and they decompose as $B = C = [\mathrm{triv}]^{\oplus 5} \oplus V$. After fixing a 5-dimensional multiplicity space $\mathbb{C}^5$ for the trivial isotypic component, we write $B^* = C = \mathbb{C}^5 \otimes [\mathrm{triv}] \oplus V$. To distinguish the two $\mathfrak{S}_{q-3}$-actions, we write $B \otimes B = ([\mathrm{triv}]_L^{\oplus 5} \oplus V_L) \otimes ([\mathrm{triv}]_R^{\oplus 5} \oplus V_R)$.

Thus,

$$\begin{aligned} B^{*\otimes 2} = C^{\otimes 2} =& (\mathbb{C}^5 \otimes [\mathrm{triv}]_L \oplus V_L) \otimes (\mathbb{C}^5 \otimes [\mathrm{triv}]_R \oplus V_R) \\ =& (\mathbb{C}^5 \otimes \mathbb{C}^5) \otimes ([\mathrm{triv}]_L \otimes [\mathrm{triv}]_R) \quad \oplus \\ & \mathbb{C}^5 \otimes ([\mathrm{triv}]_L \otimes V_R) \quad \oplus \\ & \mathbb{C}^5 \otimes (V_L \otimes [\mathrm{triv}]_R) \quad \oplus \\ & (V_L \otimes V_R). \end{aligned}$$

Write $W_1, \ldots, W_4$ for the four irreducible representations in the decomposition above and let $M_1, \ldots, M_4$ be the four corresponding multiplicity spaces.

Recall from [22] that a basis of V is given by standard Young tableaux of shape $(q-4, 1)$ (with entries in $4, \ldots, q$ for consistency with the action of $\mathfrak{S}_{q-3}$); let w_{std} be the vector corresponding to the standard tableau having $4, 6, \ldots, q$ in the first row and 5 in the second row. We refer to [22, §7] for the straightening laws of the tableaux. Let w_{triv} be a generator of the trivial representation [triv].

For each of the four isotypic components in the decomposition above, we fix a vector $w_i \in W_i$ and explicitly realize the subspaces $M_i \otimes \langle w_i \rangle$ of $B^{*\otimes 2}$ as follows:

W_i	w_i	$\dim M_i$	$M_i \otimes \langle w_i \rangle$
$[\mathrm{triv}]_L \otimes [\mathrm{triv}]_R$	$w_{\mathrm{triv}} \otimes w_{\mathrm{triv}}$	25	$\begin{smallmatrix}\langle \beta_{ij} : i,j=0,\ldots,3\rangle \oplus \\ \langle \sum_{j=4}^{q} \beta_{ij} : i=0,\ldots,3\rangle \oplus \\ \langle \sum_{i=4}^{q} \beta_{ij} : j=0,\ldots,3\rangle \oplus \\ \langle \sum_{i,j=4}^{q} \beta_{ij} \rangle\end{smallmatrix}$
$[\mathrm{triv}]_L \otimes V_R$	$w_{\mathrm{triv}} \otimes w_{std}$	5	$\begin{smallmatrix}\langle \beta_{i5}-\beta_{i4} : i=0,\ldots,3\rangle \oplus \\ \langle \sum_{i=4}^{q} (\beta_{i5}-\beta_{i4}) \rangle\end{smallmatrix}$
$V_L \otimes [\mathrm{triv}]_R$	$w_{std} \otimes w_{\mathrm{triv}}$	5	$\begin{smallmatrix}\langle \beta_{5j}-\beta_{4j} : j=0,\ldots,3\rangle \oplus \\ \langle \sum_{j=4}^{q} (\beta_{5j}-\beta_{4j}) \rangle\end{smallmatrix}$
$V_L \otimes V_R$	$w_{std} \otimes w_{std}$	1	$\langle \beta_{55} - \beta_{45} - \beta_{54} + \beta_{44} \rangle$.

The subspaces in $C^{\otimes 2}$ are realized similarly.

Since $(T^{\boxtimes 2}_{cw,q})^{\wedge 1}_{A'}$ is Γ-equivariant, by Schur's Lemma, it has the isotypic decomposition $(T^{\boxtimes 2}_{cw,q})^{\wedge 1}_{A'} = f_1 \oplus f_2 \oplus f_3 \oplus f_4$, where

$$f_i : A' \otimes (M_i \otimes W_i) \to \Lambda^2 A' \otimes W_i.$$

As explained in §4.4, it suffices to compute the ranks of the four restrictions $\Phi_i : A' \otimes M_i \otimes \langle w_i \rangle \to \Lambda^2 A' \otimes M_i \otimes \langle w_i \rangle$.

Using the bases presented in the fourth column of the table above, we write down the four matrices representing the maps $\Phi_1, \ldots, \Phi_4$.

The map Φ_4 is represented by the 3×3 matrix

$$\begin{pmatrix} -1 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{pmatrix},$$

so $\mathrm{rank}(\Phi_4) = 2$.

The map Φ_2 is represented by the 15×15 matrix (here $q' = q - 3$)

$$\begin{pmatrix}
0 & -1 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\
-1 & -1 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & -1 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -1 & 0 & 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & -1 & q' & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 \\
-1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & q' & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1
\end{pmatrix}$$

We prove the matrix above and those that follow are as asserted for all q in §7. The proof goes by showing each entry must be a low degree polynomial in q, and then one simply tests enough small cases to fix the polynomials. Thus $\operatorname{rank}(\Phi_2) = 12$, and similarly for Φ_3.

The map Φ_1 is represented by a 75×75 matrix that can be presented in block form

$$\begin{pmatrix}
-X & Y & 0 \\
-Z & 0 & Y \\
0 & -Z & X
\end{pmatrix}$$

with X the matrix

$$\begin{pmatrix}
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\

0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0&0
\end{array}\right)$$

We compute $\operatorname{rank}(\Phi_1) = 72$.

Although these matrices are of fixed size, they are obtained via intermediate tensors whose dimensions depend on q, which created a computational challenge. Two ways of addressing the challenge (including the one utilized in the code) are explained in §7.

The relevant matrices and the implementation of the method of §7 to justify them for all q, together with the code for the computation of their ranks are available at the website `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix D. The ranks are bounded below by taking a matrix M (which has some entries depending linearly on q), multiplying it on the left by a rectangular matrix P whose entries are rational functions of q, and on the right by a rectangular matrix Q whose entries are constant, to obtain a square matrix PMQ that is upper triangular with ± 1 on the diagonal, and thus its rank is its dimension. Finally one checks that the least common multiple of the denominators of the entries of P has no integral solution when $q > 4$.

Adding all the contributions gives

$$\begin{aligned}\operatorname{rank}(T^{\wedge 1}_{A'}) &= 2\cdot\dim(V\otimes V) + 12\cdot\dim([\mathrm{triv}]\otimes V) +\\ &\quad + 12\cdot\dim(V\otimes[\mathrm{triv}]) + 72\cdot\dim([\mathrm{triv}]\otimes[\mathrm{triv}]) =\\ &= 2\cdot(q-4)^2 + 12\cdot(q-4) + 12\cdot(q-4) + 72\cdot 1 = 2(q+2)^2.\end{aligned}$$

This concludes the proof of Theorem 5.

▶ Remark 26. One might have hoped to exploit the full symmetry group $\mathfrak{S}_q \times \mathfrak{S}_q$ to simplify the argument further. However there is no choice of a restriction map ψ which is $\mathfrak{S}_{q-s}\times\mathfrak{S}_{q-s}$-invariant for $s < 3$ that gives rise to a Koszul flattening map of sufficiently high rank to prove the result.

4.6 Proof of Theorem 6

We will use a Koszul flattening with $p = 2$, so we need a 5 dimensional subspace of $(A^*)^{\otimes 3}$. Let

$$A'^* := \left\langle \begin{array}{c} \alpha_{000},\\ \sum_{i=1}^{q}(\alpha_{i00}+\alpha_{0i0}+\alpha_{00i}),\\ \alpha_{001}+\alpha_{010}+\alpha_{012}+\alpha_{102}+\alpha_{110}+\alpha_{121}+\alpha_{200}+\alpha_{211},\\ \alpha_{022}+\alpha_{030}+\alpha_{031}+\alpha_{100}+\alpha_{103}-\alpha_{120}+\alpha_{210}+\alpha_{212}+\alpha_{300},\\ \alpha_{002}+\alpha_{004}+\alpha_{011}+\alpha_{014}+\alpha_{020}+\alpha_{023}+\alpha_{032}+\alpha_{040}+\alpha_{100}+\alpha_{122}+\alpha_{220}+\alpha_{303} \end{array} \right\rangle.$$

Write $\phi_3 : A^{\otimes 3} \to A'$ for the resulting projection map and, abusing notation, for the induced map $A^{\otimes 3} \otimes B^{\otimes 3} \otimes C^{\otimes 3} \to A' \otimes B^{\otimes 3} \otimes C^{\otimes 3}$. Write $T = \phi_3(T^{\boxtimes 3}_{cw,q})$, suppressing the q from the notation. Consider the Koszul flattening:

$$(T)^{\wedge 2}_{A'} : \Lambda^2 A' \otimes B^{*\otimes 2} \to \Lambda^3 A' \otimes C^{\otimes 2}.$$

We will show $\operatorname{rank}((T)^{\wedge 2}_{A'}) = 6(q+2)^3$, which implies $\underline{\mathbf{R}}(T^{\boxtimes 3}_{cw,q}) \geq (q+2)^3$.

In order to compute $\operatorname{rank}((T)^{\wedge 2}_{A'})$, we follow the same strategy as before. The code to generate these matrices is available at `www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix D. The explanation of how we proved they are as asserted is outlined in §7.

The map $(T)^{\wedge 2}_{A'}$ is invariant under the action of $\Gamma = \mathfrak{S}_{q-4} \times \mathfrak{S}_{q-4} \times \mathfrak{S}_{q-4}$ where the first copy of $\mathfrak{S}_{q-4}$ permutes the basis elements with indices $5, \ldots, q$ of the first factors, and similarly for the other copies of $\mathfrak{S}_{q-4}$. Let [triv] be the trivial $\mathfrak{S}_{q-4}$-representation and let V be the standard representation, namely the Specht module associated to the partition $(q-5, 1)$. Here $\dim V = q-5$, so if $q = 5$, only the trivial representation appears.

The $\mathfrak{S}_{q-4}$-isotypic decomposition of B (and C) is $\mathbb{C}^6 \otimes [\text{triv}] \oplus V$ and this induces the decomposition of $B^{*\otimes 3} \simeq C^{\otimes 3}$ given by

$$\begin{aligned} B^{*\otimes 3} \simeq C^{\otimes 3} = &(\mathbb{C}^6)^{\otimes 3} \otimes ([\text{triv}]_1 \otimes [\text{triv}]_2 \otimes [\text{triv}]_3) \oplus \\ &(\mathbb{C}^6)^{\otimes 2} \otimes [([\text{triv}]_1 \otimes [\text{triv}]_2 \otimes V_3) \oplus \\ &([\text{triv}]_1 \otimes V_2 \otimes [\text{triv}]_3) \oplus \\ &(V_1 \otimes [\text{triv}]_2 \otimes [\text{triv}]_3)] \oplus \\ &(\mathbb{C}^6) \otimes [([\text{triv}]_1 \otimes V_2 \otimes V_3) \oplus \\ &(V_1 \otimes V_2 \otimes [\text{triv}]_3) \oplus \\ &(V_1 \otimes [\text{triv}]_2 \otimes V_3)] \oplus \\ &V_1 \otimes V_2 \otimes V_3 \end{aligned}$$

consisting of eight isotypic components. As in the previous proof, for each of the eight irreducible components W_i, we consider $w_i \in W_i$ and we compute the rank of the restriction to $\Lambda^2 A' \otimes M_i \otimes \langle w_i \rangle$ of the Koszul flattening; call this restriction Φ_i.

The ranks of the restrictions are recorded in the following table:

W_i	$\dim(\Lambda^2 A' \otimes M_i)$	$\operatorname{rank}(\Phi_i)$
$[\text{triv}]_1 \otimes [\text{triv}]_2 \otimes [\text{triv}]_3$	$6^3 \cdot \binom{5}{2} = 2160$	2058
$[\text{triv}]_1 \otimes [\text{triv}]_2 \otimes V_3$ (and permutations)	$6^2 \cdot \binom{5}{2} = 360$	294
$[\text{triv}]_1 \otimes V_2 \otimes V_3$ (and permutations)	$6 \cdot \binom{5}{2} = 60$	42
$V_1 \otimes V_2 \otimes V_3$	$\binom{5}{2} = 10$	6

The relevant matrices and the implementation of §7 to justify them for all q, with the code computing their ranks are available at `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix D. As before, the ranks are bounded below by taking a matrix M (which has some entries depending linearly on q), multiplying it on the left by a rectangular matrix P whose entries are rational functions of q, and on the right by a rectangular matrix Q whose

entries are constant, to obtain a square matrix PMQ that is upper triangular with ± 1 on the diagonal, and thus its rank is its dimension. Finally one checks that the least common multiple of the denominators of the entries of P has no integral solution when $q > 4$.

Adding all the contributions together, we obtain

$$\begin{aligned}\operatorname{rank}(T^{\wedge 2}_{A'}) =& 6 \cdot \dim(V \otimes V \otimes V) + \\ & 42 \cdot 3 \cdot \dim([\mathrm{triv}] \otimes V \otimes V) + \\ & 294 \cdot 3 \cdot \dim([\mathrm{triv}] \otimes [\mathrm{triv}] \otimes V) + \\ & 2058 \cdot \dim([\mathrm{triv}] \otimes [\mathrm{triv}] \otimes [\mathrm{triv}]) = 6 \cdot (q+2)^3.\end{aligned}$$

This concludes the proof.

5 Upper bounds for Waring rank and border rank of $\det_3$

5.1 Proof of Theorem 15

We give the rank 18 decomposition for $\det_3$ explicitly, as a collection of 18 linear forms on $\mathbb{C}^9 = \mathbb{C}^3 \otimes \mathbb{C}^3$ whose cubes add up to $\det_3$. The linear forms are given in coordinates recorded in the matrices below: the 3×3 matrix (ζ_{ij}) represents the linear forms $\sum_{ij} \zeta_{ij} x_{ij}$. This presentation highlights some of the symmetries of the decomposition.

Let $\vartheta = \exp(2\pi i/6)$ and let $\overline{\vartheta}$ be its inverse. The tensor $\det_3 = T^{\boxtimes 2}_{skewcw,2} = \det(x_{ij}) \in S^3(\mathbb{C}^3 \otimes \mathbb{C}^3)$ satisfies

$$\det_3 = \sum_1^{18} L_i^3$$

where $L_1, \ldots, L_{18}$ are the 18 linear forms given by the following coordinates:

$$L_1 = \begin{pmatrix} -\vartheta & 0 & 0 \\ 0 & -\frac{1}{3} & 0 \\ 0 & 0 & \overline{\vartheta} \end{pmatrix} \quad L_2 = \begin{pmatrix} -\overline{\vartheta} & 0 & 0 \\ 0 & -\frac{1}{3} & 0 \\ 0 & 0 & \vartheta \end{pmatrix} \quad L_3 = \begin{pmatrix} -\overline{\vartheta} & 0 & 0 \\ 0 & \frac{1}{3}\overline{\vartheta} & 0 \\ 0 & 0 & \overline{\vartheta} \end{pmatrix}$$

$$L_4 = \begin{pmatrix} -1 & 0 & 0 \\ 0 & 0 & -\overline{\vartheta} \\ 0 & -\frac{1}{3}\vartheta & 0 \end{pmatrix} \quad L_5 = \begin{pmatrix} \overline{\vartheta} & 0 & 0 \\ 0 & 0 & 1 \\ 0 & -\frac{1}{3}\vartheta & 0 \end{pmatrix} \quad L_6 = \begin{pmatrix} \vartheta & 0 & 0 \\ 0 & 0 & -\vartheta \\ 0 & -\frac{1}{3}\vartheta & 0 \end{pmatrix}$$

$$L_7 = \begin{pmatrix} 0 & \frac{1}{3}\overline{\vartheta} & 0 \\ -\vartheta & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad L_8 = \begin{pmatrix} 0 & \frac{1}{3}\overline{\vartheta} & 0 \\ -\overline{\vartheta} & 0 & 0 \\ 0 & 0 & -\overline{\vartheta} \end{pmatrix} \quad L_9 = \begin{pmatrix} 0 & \frac{1}{3}\vartheta & 0 \\ -\overline{\vartheta} & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

$$L_{10} = \begin{pmatrix} 0 & -\frac{1}{3}\vartheta & 0 \\ 0 & 0 & \overline{\vartheta} \\ -1 & 0 & 0 \end{pmatrix} \quad L_{11} = \begin{pmatrix} 0 & -\frac{1}{3}\overline{\vartheta} & 0 \\ 0 & 0 & \vartheta \\ -1 & 0 & 0 \end{pmatrix} \quad L_{12} = \begin{pmatrix} 0 & \frac{1}{3} & 0 \\ 0 & 0 & -1 \\ -1 & 0 & 0 \end{pmatrix}$$

$$L_{13} = \begin{pmatrix} 0 & 0 & 1 \\ -1 & 0 & 0 \\ 0 & -\frac{1}{3} & 0 \end{pmatrix} \quad L_{14} = \begin{pmatrix} 0 & 0 & 1 \\ \overline{\vartheta} & 0 & 0 \\ 0 & \frac{1}{3}\vartheta & 0 \end{pmatrix} \quad L_{15} = \begin{pmatrix} 0 & 0 & 1 \\ \vartheta & 0 & 0 \\ 0 & \frac{1}{3}\overline{\vartheta} & 0 \end{pmatrix}$$

$$L_{16} = \begin{pmatrix} 0 & 0 & \overline{\vartheta} \\ 0 & -\frac{1}{3}\vartheta & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad L_{17} = \begin{pmatrix} 0 & 0 & \overline{\vartheta} \\ 0 & -\frac{1}{3}\overline{\vartheta} & 0 \\ -\overline{\vartheta} & 0 & 0 \end{pmatrix} \quad L_{18} = \begin{pmatrix} 0 & 0 & \vartheta \\ 0 & -\frac{1}{3}\overline{\vartheta} & 0 \\ 1 & 0 & 0 \end{pmatrix}$$

The equality can be verified by hand. A Macaulay2 file performing the calculation is available at `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix B. ◀

5.2 Proof of Theorem 16

As in the case of Theorem 15, we prove Theorem 16 by explicitly giving 17 linear forms, depending on a parameter t, whose cubes provide a border rank 17 expression for $\det_3$. The algebraic numbers involved are more complicated than in the previous case.

The result was achieved by numerical methods, which allowed us to sparsify the decomposition and ultimately determine the value of the coefficients. The linear forms in the decomposition are described below.

Consider

$$L_1(t) = \begin{pmatrix} z_1 & 0 & 0 \\ 0 & z_2 t & 0 \\ -1 & 0 & 0 \end{pmatrix} \quad L_2(t) = \begin{pmatrix} z_3 & 0 & 0 \\ z_4 & 0 & z_5 t \\ z_6 & 0 & 0 \end{pmatrix} \quad L_3(t) = \begin{pmatrix} -z_{36} & z_7 t & 0 \\ -z_{38} & 0 & -z_{39} t \\ 0 & 0 & t \end{pmatrix}$$

$$L_4(t) = \begin{pmatrix} 0 & 0 & t \\ -z_{34} & 0 & 0 \\ 0 & z_8 t & -z_{35} t \end{pmatrix} \quad L_5(t) = \begin{pmatrix} 0 & -z_{19} t & -z_{20} t \\ 0 & 0 & 0 \\ -1 & 0 & 0 \end{pmatrix} \quad L_6(t) = \begin{pmatrix} -z_{22} & z_9 t & 0 \\ -z_{23} & 0 & -z_{24} t \\ -z_{25} & 0 & 0 \end{pmatrix}$$

$$L_7(t) = \begin{pmatrix} z_{10} & z_{11} t & 0 \\ z_{12} & 0 & z_{13} t \\ z_{14} & 0 & 0 \end{pmatrix} \quad L_8(t) = \begin{pmatrix} z_{15} & -t & 0 \\ z_{16} & 0 & z_{17} t \\ z_{18} & 0 & 0 \end{pmatrix} \quad L_9(t) = \begin{pmatrix} 0 & z_{19} t & z_{20} t \\ 0 & z_{21} t & 0 \\ 1 & 0 & 0 \end{pmatrix}$$

$$L_{10}(t) = \begin{pmatrix} -z_{41} & 0 & 0 \\ 0 & 0 & 0 \\ -z_{44} & 0 & 0 \end{pmatrix} \quad L_{11}(t) = \begin{pmatrix} z_{22} & 0 & 0 \\ z_{23} & 0 & z_{24} t \\ z_{25} & 0 & 0 \end{pmatrix} \quad L_{12}(t) = \begin{pmatrix} -z_{31} & z_{26} t & 0 \\ 0 & z_{27} t & 0 \\ 0 & 0 & t \end{pmatrix}$$

$$L_{13}(t) = \begin{pmatrix} z_{28} & z_{29} t & 0 \\ z_{30} & 0 & -t \\ 0 & t & 0 \end{pmatrix} \quad L_{14}(t) = \begin{pmatrix} z_{31} & z_{32} t & 0 \\ 0 & 0 & 0 \\ 0 & z_{33} t & -t \end{pmatrix} \quad L_{15}(t) = \begin{pmatrix} 0 & 0 & -t \\ z_{34} & 0 & 0 \\ 0 & 0 & z_{35} t \end{pmatrix}$$

$$L_{16}(t) = \begin{pmatrix} z_{36} & z_{37} t & 0 \\ z_{38} & 0 & z_{39} t \\ 0 & z_{40} t & -t \end{pmatrix} \quad L_{17}(t) = \begin{pmatrix} z_{41} & z_{42} t & 0 \\ 0 & z_{43} t & 0 \\ z_{44} & 0 & 0 \end{pmatrix}$$

The coefficients $z_1, \ldots, z_{44}$ are algebraic numbers described as follows. Let y_* be a real root of the polynomial

$$x^{27} - 2x^{26} + 17x^{25} - 29x^{24} + 81x^{23} + 52x^{22} - 726x^{21} + 3451x^{20} - 10901x^{19} + 25738x^{18} - 50663x^{17} + 72133x^{16} - 72973x^{15} + 10444x^{14} + 138860x^{13} - 308611x^{12} + 427344x^{11} - 267416x^{10} - 196096x^9 + 762736x^8 - 1236736x^7 + 1092352x^6 - 537600x^5 - 42240x^4 + 684032x^3 - 1136640x^2 + 1146880x - 520192.$$

For $i = 1, \ldots, 44$, we consider algebraic numbers y_j in the field extension $\mathbb{Q}[y_*]$, described as a polynomial of degree (at most) 26 in y_* with rational coefficients. Notice that all the y_j's are real. The expressions of the $y_1, \ldots, y_{44}$ in terms of y_* are provided in the file `yy_exps` at `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix C. Let z_j be the unique real cubic root of y_j.

We are going to prove that, with this choice of coefficients z_j,

$$t^2 \det_3 + O(t^3) = \sum_{i=1}^{17} L_i(t)^3. \tag{9}$$

The condition $t^2 \det_3 + O(t^3) = \sum_{i=1}^{17} L_i(t)^3$ is equivalent to the fact that the degree 0 and the degree 1 components of $\sum_{i=1}^{17} L_i(t)^3$ vanish and that the degree 2 component equals $\det_3$. Given the sparse structure of the $L_i(t)$, this reduces to a system of 54 cubic equations in the 44 unknowns $z_1, \ldots, z_{44}$. Our goal is to show that the algebraic numbers described above are a solution of this system.

We show that the z_i's satisfy each equation as follows. After evaluating the equations at the z_i's, there are two possible cases

1. all monomials appearing in the equation are elements of $\mathbb{Q}[y_*]$; we say that this is an equation of type 1; there are 14 such equations;
2. at least one monomial appearing in the equation is not an element of $\mathbb{Q}[y_*]$; we say that this is an equation of type 2; there are 40 such equations.

For equations of type 1, we provide expressions of each monomial in terms of y_*. To verify that each expression is indeed equal to the corresponding monomial, it suffices to compare the cube of the given expression and the expression obtained by evaluating the monomial at the y_j's. Finally, the equation can be verified in $\mathbb{Q}[y_*]$. This is performed by the file `checkingType1eqns.m2`.

For equations of type 2, let u be one of the monomials which do not belong to $\mathbb{Q}[y_*]$. We claim that it is possible to choose the monomial in such a way that $\mathbb{Q}[u^3] = \mathbb{Q}[y_*]$. For each equation, we choose one of the monomials and we verify the claim as follows. The element u^3 has an expression in terms of y_* which equals the chosen monomial evaluated at the y_i's. Let M_u be the 27×27 matrix with rational entries such that

$$(1, u^3, \cdots, u^{3\cdot 26}) = \left(1, y_*, \ldots, y_*^{26}\right) \cdot M_u;$$

M_u can be computed directly by considering the expressions of the powers of u^3 in terms of y_*. Then $\mathbb{Q}[u^3] = \mathbb{Q}[y_*]$ if and only if M_u is full rank.

In particular y_* has an expression in terms of u^3, which can be computed inverting the matrix M_u. A consequence of this is that $\mathbb{Q}[u] = \mathbb{Q}[y_*, u]$.

At this point, we observe that $\mathbb{Q}[u]$ contains the other monomials occurring in the equation as well. To see this, we proceed as in the case of equations of type 1. For each monomial occurring in the equation, we provide an expression in terms of u (in fact, to speed up the calculation, we provide an expression in terms of u and y_*, which is equivalent to an expression in u because $\mathbb{Q}[u^3] = \mathbb{Q}[y_*]$ and y_* has a unique expression in terms of u^3); we compare the cube of this expression (appropriately reduced modulo the minimal polynomial of y_* and the relation between u^3 and y_*) with the expression obtained by evaluating the monomial at the y_i's (expressed in terms of y_*). This shows that all monomials occurring in the expression belong to $\mathbb{Q}[u]$, and verifies that the given expressions are indeed equal to the corresponding monomials. Finally, the equation is verified in $\mathbb{Q}[u]$ as in the case of type 1. This is performed by the file `checkingType2eqns.m2`. ◀

5.2.1 Discussion of how the decomposition was obtained

Many steps were accomplished by finding solutions of polynomial equations by nonlinear optimization. In each case, this was accomplished using a variant of Newton's method applied to the mapping of variable values to corresponding polynomial values. The result of this procedure in each case is limited precision machine floating point numbers.

First, we attempted to solve the equations describing a Waring rank 17 decomposition of $\det_3$ with nonlinear optimization, namely, $\det_3 = \sum_{i=1}^{17} (w_i')^{\otimes 3}$, where $w_i' \in \mathbb{C}^{3\times 3}$. Instead of finding a solution to working precision, we obtained a sequence of local refinements to an approximate solution where the norm of the defect is slowly converging to to zero, and some of the parameter values are exploding to infinity. Numerically, these are Waring decompositions of polynomials very close to $\det_3$.

Next, this approximate solution needed to be upgraded to a solution to equation (9).

We found a choice of parameters in the neighborhood of a solution, and then applied local optimization to solve to working precision. We used the following method: Consider the linear mapping $M : \mathbb{C}^{17} \to S^3(\mathbb{C}^{3\times 3})$, $M(e_i) = (w_i')^{\otimes 3}$, and let $M = U\Sigma V^*$ be its

singular value decomposition (with respect to the standard inner products for the natural coordinate systems). We observed that the singular values seemed to be naturally partitioned by order of magnitude. We estimated this magnitude factor as $t_0 \approx 10^{-3}$, and wrote Σ' as Σ where we multiplied each singular value by $(t/t_0)^k$, with k chosen to agree with this observed partitioning, so that the constants remaining were reasonably sized. Finally, we let $M' = U\Sigma' V^*$, which has entries in $\mathbb{C}[[t]]$. M' is thus a representation of the map M with a parameter t.

Next, for each i, we optimized to find a best fit to the equation $(a_i + tb_i + t^2c_i)^{\otimes 3} = M'(e_i)$, which is defined by polynomial equations in the entries of a_i, b_i and c_i. The a_i, b_i and c_i we constructed in this way proved to be a good initial guess to optimize equation (9), and we immediately saw quadratic convergence to a solution to machine precision. At this point, we greedily sparsified the solution by speculatively zero-ing values and re-optimizing, rolling back one step in case of failure. After sparsification, it turned out the c_i were not needed. The resulting matrices are those given in the proof.

To compute the minimal polynomials and other integer relationships between quantities, we used Lenstra-Lenstra-Lovász integer lattice basis reduction [34]. As an example, let $\zeta \in \mathbb{R}$ be approximately an algebraic number of degree k. Let N be a large number inversely proportional to the error of ζ. Consider the integer lattice with basis $\{e_i + \lfloor N\zeta^i \rfloor e_{k+1}\} \subset \mathbb{Z}^{k+2}$, for $0 \leq i \leq k$. Then elements of this lattice are of the form $v_0e_0 + \cdots + v_ke_k + Ee_{k+1}$, where $E \approx Np(\zeta)$, $p = v_0 + v_1x + \cdots x_kx^k$. Polynomials p for which ζ is an approximate root are distinguished by the property of having relatively small Euclidean norm in this lattice. Computing a small norm vector in an integer lattice is accomplished by LLL reduction of a known basis.

For example, the fact that the number field of degree 27 obtained by adjoining any z_α^3 to $\mathbb{Q}$ contains all the rest was determined via LLL reduction, looking for expressions of z_α^3 as a polynomial in z_β^3 for some fixed β. These expressions of z_α^3 in a common number field can be checked to have the correct minimal polynomial, and thus agree with our initial description of the z_α. LLL reduction was also used to find the expressions of values as polynomials in the primitive root of the various number fields.

After refining the known value of the parameters to $10,000$ bits of precision using Newton's method, LLL reduction was successful in identifying the minimal polynomials. The degrees were simply guessed, and the results checked by evaluating the computed polynomials in the parameters to higher precision.

▶ Remark 27. With the minimal polynomial information, it is possible to check that equation (9) is satisfied to any desired precision by the parameters.

6 Tight Tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$

Following an analysis started in [17], we consider Kronecker squares of *tight* tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$. We compute their symmetry groups and numerically provide bounds to their tensor rank and border rank, highlighting the submultiplicativity properties.

We refer to [44, 11, 17] for an exposition of the role of tightness in Strassen's work and in the laser method. We point out that $T_{CW,q}$ and $T_{cw,q}$ are tight. (If one uses the combinatorial definition of tightness, which depends on a choice of basis, they are not tight in their standard presentations.)

6.1 Tight tensors

Recall the map $\Phi : GL(A) \times GL(B) \times GL(C) \to GL(A \otimes B \otimes C)$ from Section 3.1 defining the action of $GL(A) \times GL(B) \times GL(C)$ on $A \otimes B \otimes C$. Its differential $d\Phi$ defines a map at the level of Lie algebras, mapping $\mathfrak{gl}(A) \oplus \mathfrak{gl}(B) \oplus \mathfrak{gl}(C)$ to a subalgebra of $\mathfrak{gl}(A \otimes B \otimes C)$, isomorphic to $(\mathfrak{gl}(A) \oplus \mathfrak{gl}(B) \oplus \mathfrak{gl}(C))/\mathbb{C}^2$. Write $\mathfrak{g}_T \subseteq \mathfrak{gl}(A) \oplus \mathfrak{gl}(B) \oplus \mathfrak{gl}(C)$ for the annihilator of T under this action.

A tensor $T \in A \otimes B \otimes C$ is *tight* if $\mathfrak{g}_T/\mathbb{C}^2$ contains a regular semisimple element. Tightness can be defined combinatorially with respect to a basis, see e.g. [17, Def. 1.3]. In particular, the combinatorial definition makes it clear that tightness depends on the support of a tensor in a given basis; we say that a support $\mathcal{S}$ is tight if every tensor having support $\mathcal{S}$ is tight.

Given concise tensors $T_1 \in A_1 \otimes B_1 \otimes C_1$ and $T_2 \in A_2 \otimes B_2 \otimes C_2$, [17, Theorem 4.1] shows that

$$\mathfrak{g}_{T_1 \boxtimes T_2} \supseteq \mathfrak{g}_{T_1} \otimes \mathrm{Id}_{A_2 \otimes B_2 \otimes C_2} + \mathrm{Id}_{A_1 \otimes B_1 \otimes C_1} \otimes \mathfrak{g}_{T_2}; \tag{10}$$

moreover if $\mathfrak{g}_{T_1} = 0$ and $\mathfrak{g}_{T_2} = 0$ then equality holds $\mathfrak{g}_{T_1 \boxtimes T_2} = 0$.

The strict containment in (10) occurs, for instance, in the case of the matrix multiplication tensor. In [17], we posed the problem of characterizing tensors $T \in A \otimes B \otimes C$ such that $\mathfrak{g}_T \otimes \mathrm{Id}_{A \otimes B \otimes C} + \mathrm{Id}_{A \otimes B \otimes C} \otimes \mathfrak{g}_T$ is strictly contained in $\mathfrak{g}_{T^{\boxtimes 2}} \subset \mathfrak{gl}(A^{\otimes 2}) + \mathfrak{gl}(B^{\otimes 2}) + \mathfrak{gl}(C^{\otimes 2})$.

Proposition 29 provides several additional examples of tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ for which this containment is strict.

6.2 Tight supports in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$

From [17, Proposition 2.14], one obtains an exhaustive list of unextendable tight supports for tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$, up to the action of $\mathbb{Z}_2 \times \mathfrak{S}_3$, where $\mathfrak{S}_3$ acts permuting the factors and $\mathbb{Z}_2$ acts by reversing the order of the basis elements. In fact, tightness is invariant under the action of the full $\mathfrak{S}_3$ acting by permutation on the basis vectors. This additional simplification, pointed out by J. Hauenstein, provides the following list of 9 unextendable tight supports up to the action of $((\mathfrak{S}_3)^{\times 3}) \rtimes \mathfrak{S}_3$.

$$\mathcal{T}_1 = \{(1,1,3),(1,2,2),(2,1,2),(3,3,1)\};$$
$$\mathcal{T}_2 = \{(1,1,3),(1,3,2),(2,3,1),(3,2,2)\};$$
$$\mathcal{T}_3 = \{(1,1,3),(1,2,2),(1,3,1),(2,1,2),(3,2,1)\};$$
$$\mathcal{T}_4 = \{(1,1,3),(1,2,2),(2,1,2),(2,3,1),(3,2,1)\};$$
$$\mathcal{T}_5 = \{(1,1,3),(1,2,2),(2,3,1),(3,1,2),(3,2,1)\};$$
$$\mathcal{T}_6 = \{(1,1,3),(1,3,2),(2,2,2),(3,1,2),(3,3,1)\};$$
$$\mathcal{T}_7 = \{(1,1,3),(1,2,2),(1,3,1),(2,1,2),(2,2,1),(3,1,1)\};$$
$$\mathcal{T}_8 = \{(1,1,3),(1,3,2),(2,2,2),(2,3,1),(3,1,2),(3,2,1)\};$$
$$\mathcal{T}_9 = \{(1,2,3),(1,3,2),(2,1,3),(2,2,2),(2,3,1),(3,1,2),(3,2,1)\};$$

Supports $\mathcal{S}_2$ and $\mathcal{S}_3$ of [17] are equivalent to support $\mathcal{S}_1 = \mathcal{T}_1$; supports $\mathcal{S}_8$ and $\mathcal{S}_{10}$ are equivalent to support $\mathcal{S}_6 = \mathcal{T}_4$.

The following result characterizes tight tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ up to isomorphism.

▶ **Proposition 28.** *Let $T \in \mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ be a tight tensor with unextendable tight support in some basis. Then, up to permuting the three factors, T is isomorphic to exactly one of the following.*

$$
\begin{aligned}
T_1 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_2 \otimes c_2 + a_2 \otimes b_1 \otimes c_2 + a_3 \otimes b_3 \otimes c_1 \\
T_2 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_3 \otimes c_2 + a_2 \otimes b_3 \otimes c_1 + a_3 \otimes b_2 \otimes c_2 \\
T_3 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_2 \otimes c_2 + a_1 \otimes b_3 \otimes c_1 + a_2 \otimes b_1 \otimes c_2 + a_3 \otimes b_2 \otimes c_1 \\
T_4 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_2 \otimes c_2 + a_2 \otimes b_1 \otimes c_2 + a_2 \otimes b_3 \otimes c_1 + a_3 \otimes b_2 \otimes c_1 \\
T_5 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_2 \otimes c_2 + a_2 \otimes b_3 \otimes c_1 + a_3 \otimes b_1 \otimes c_2 + a_3 \otimes b_2 \otimes c_1 \\
T_6 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_3 \otimes c_2 + a_2 \otimes b_2 \otimes c_2 + a_3 \otimes b_1 \otimes c_2 + a_3 \otimes b_3 \otimes c_1 \\
T_7 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_2 \otimes c_2 + a_1 \otimes b_3 \otimes c_1 + a_2 \otimes b_1 \otimes c_2 + a_2 \otimes b_2 \otimes c_1 + a_3 \otimes b_1 \otimes c_1 \\
T_8 :=& a_1 \otimes b_1 \otimes c_3 + a_1 \otimes b_3 \otimes c_2 + a_2 \otimes b_2 \otimes c_2 + a_2 \otimes b_3 \otimes c_1 + a_3 \otimes b_1 \otimes c_2 + a_3 \otimes b_2 \otimes c_1 \\
T_{9,\mu} :=& a_1 \otimes b_2 \otimes c_3 + a_1 \otimes b_3 \otimes c_2 + a_2 \otimes b_1 \otimes c_3 + a_2 \otimes b_2 \otimes c_2 + a_2 \otimes b_3 \otimes c_1 + a_3 \otimes b_1 \otimes c_2 \\
& + \mu \cdot a_3 \otimes b_2 \otimes c_1 .
\end{aligned}
$$

Proof. The result of [17, Proposition 2.14] and the discussion above shows that T is, up to permutation of the factors, equivalent to a tensor with support $\mathcal{T}_i$ for some $i = 1, \ldots, 9$.

For $i = 1, \ldots, 8$, it is straightforward to verify that all tensors with support $\mathcal{T}_i$ are isomorphic, via the change of bases given by three diagonal matrices.

The case of $\mathcal{T}_9$ is slightly more involved but essentially the same argument shows that a tensor T with support $\mathcal{T}_9$ is isomorphic to $T_{9,\mu}$, for some μ.

Finally, we have to show that any two of the tensors in the statement are not isomorphic. For tensors having distinct supports, this is a consequence of Proposition 29 below: indeed, if T, T' are two of the tensors above, Proposition 29 shows that either $\dim \mathfrak{g}_T \neq \dim \mathfrak{g}_{T'}$ or $\dim \mathfrak{g}_{T^{\boxtimes 2}} \neq \dim \mathfrak{g}_{T'^{\boxtimes 2}}$.

As for the tensors with support $\mathcal{T}_9$, we proceed as follows. Let $T = T_{9,\mu}$ and $T' = T_{9,\mu'}$ with $\mu \neq \mu'$. We show that T is not isomorphic to T'. Suppose by contradiction that there is a triple of 3×3 matrices $g = (g_A, g_B, g_C) \in GL_3 \times GL_3 \times GL_3$ with $g(T) = T'$. One sees that in each case, g_A, g_B, g_C have to be diagonal matrices, and an explicit calculation shows that there is no triple of diagonal matrices such that $g(T) = T'$. ◀

We point out that T_7 is isomorphic to the Coppersmith-Winograd tensor $T_{CW,1}$, as well as to the structure tensor of the algebra $\mathbb{C}[x]/(x^3)$.

The tensors $T_{cw,2}$ and $T_{skewcw,2}$ are degenerations of $T_{9,\mu}$, respectively for $\mu = 1$ and $\mu = -1$. In particular, they do not have an unextendable tight support in some basis.

▶ **Proposition 29.** *For $i = 1, \ldots, 9$, the following table records $\dim \mathfrak{g}_{T_i}$ and $\dim \mathfrak{g}_{T_i^{\boxtimes 2}}$.*

T	$\dim \mathfrak{g}_T$	$\dim \mathfrak{g}_{T^{\boxtimes 2}}$
T_1	5	22
T_2	3	9
T_3	5	13
T_4	4	9
T_5	3	7
T_6	2	5
T_7	6	28
T_8	1	2
$T_{9,-1}$	5	10
$T_{9,\mu}$ *(for $\mu \neq 0, -1$)*	1	2

In summary

$$\dim \mathfrak{g}_{T^{\boxtimes 2}} > 2 \dim \mathfrak{g}_T$$

for tight tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ with unextendable tight supports $\mathcal{T}_1, \ldots, \mathcal{T}_7$.

Proof. For $T_1, \ldots, T_8$ and for the $T_{9,-1}$, the proof follows by a direct calculation. The first part of the file `symmetryTightSupports.m2` at `www.math.tamu.edu/~jml/CGLVkronsupp.html`, Appendix E computes the dimension of the symmetry algebras of interest in these cases.

The second part of the file deals with the case $T_{9,\mu}$ when $\mu \neq -1$. By tightness, $\dim \mathfrak{g}_{T_{9,\mu}} \geq 1$.

Consider the linear map $\omega_{T_{9,\mu}} : \mathfrak{gl}(A)+\mathfrak{gl}(B)+\mathfrak{gl}(C) \to A\otimes B\otimes C$ defined by $(X,Y,Z) \mapsto (X,Y,Z).T_{9,\mu}$. Then $\mathfrak{g}_{T_{9,\mu}} = [\ker(\omega_{T_{9,\mu}})]/\mathbb{C}^2$, where $\mathbb{C}^2$ corresponds to $\ker d\Phi$.

The second part of the file `symmetryTightSupports.m2` computes a matrix representation of $\omega_{T_{9,\mu}}$, depending on a parameter μ (`t` in the file). Let F_μ be this 27×27 matrix representation. Then, it suffices to select a 24×24 submatrix whose determinant is a nonzero univariate polynomial in μ. If μ is a value for which $\dim \mathfrak{g}_{T_{9,\mu}} > 1$, then μ has to be a root of this univariate polynomial.

In the example computed in the file, we select a 24×24 submatrix whose determinant is $(\mu+1)^6\mu$, showing that the only possible values of μ for which $\dim \mathfrak{g}_{T_{9,\mu}} > 1$ are $\mu = 0$ or $\mu = -1$. The case $\mu = -1$ was considered separately. The case $\mu = 0$ does not correspond to a unextendable support, so it is not of interest. We point out that however, $\omega_{T_{9,0}} = 24$, namely $\dim \mathfrak{g}_{T_{9,0}} = 1$.

For $T_{9,\mu}^{\boxtimes 2}$, we follow essentially the same argument. By tightness, and (10), we obtain $\dim \mathfrak{g}_{T_{9,\mu}^{\boxtimes 2}} \geq 2$. The third part of `symmetryTightSupports.m2` computes a matrix representation of the map $\omega_{T_{9,\mu}^{\boxtimes 2}}$, depending on a parameter μ: this is a 729×243 matrix of rank at most 239.

In the example computed in the file, we select a 239×239 submatrix whose determinant is the univariate polynomial $\mu^8(\mu+1)^{12}$. As before, we conclude. ◀

We also provide the values of the border rank of the tensors in $\mathbb{C}^3 \otimes \mathbb{C}^3 \otimes \mathbb{C}^3$ having unextendable tight support and numerical evidence for the values of border rank of their Kronecker square. They are recorded in the following table. The values of the border rank for the T_i's are straightforward to verify. The lower bounds for the Kronecker squares are obtained via Koszul flattenings. In the cases labeled by N/A the upper bounds coincide with the multiplicative upper bound; in the other cases, the upper bound is obtained via numerical method, and the last column of the table records the ℓ_2 distance (in the given basis) between the tensor obtained via the numerical approximation and the Kronecker square.

T	$\underline{\mathbf{R}}(T)$	$\underline{\mathbf{R}}(T^{\boxtimes 2})$	ℓ_2 error for upper bound in $T^{\boxtimes 2}$ decomposition
T_1	3	9	N/A
T_2	4	$[11, 14]$	0.000155951
T_3	4	$[11, 14]$	0.00517612
T_4	4	14	0.0144842
T_5	4	$[11, 15]$	0.0237172
T_6	4	$[11, 15]$	0.00951205
T_7	3	9	N/A
T_8	4	$[14, 16]$	N/A
$T_{9,-1}$	5	$[16, 19]$	0.0231353
$T_{9,\mu}$ (for $\mu \neq 0, -1$)	4	$[15, 16]$	N/A

7 Justification of the matrices

In this section, describe two ways of proving that the matrices appearing in the second proof of Theorem 5 and the proof of Theorem 6 are as asserted, one of which is carried out explicitly in the code at `http://www.math.tamu.edu/~jml/CGLVkronsupp.html`.

The computational issue is that, although the sizes of the matrices are fixed, they are obtained via intermediate matrices whose dimensions depend on q so one needs a way of encoding such matrices and tensors efficiently. The first method of proof critically relies on the definition of a class of tensors, which we call *box parameterized*, whose entries and dimensions depend on a parameter q in a very structured way. In this proof one shows the entries of the output matrices are low degree, say δ, polynomials in q, and then by computing the first $\delta+1$ cases directly, one has proven they are as asserted for all q. The second method, which is implemented in the code, does not rely on the structure to prove anything, but the structure allows an efficient coding of the tensors that significantly facilitates the computation.

A k-way sequence of tensors $T_q \in A_1^q \otimes \cdots \otimes A_k^q$ parametrized by $q \in \mathbb{N}$ is *basic box parameterized* if it is of the form

$$T_q = p(q)\sum_{(i_1,\ldots,i_k)\in\Phi} t_{i_1,\ldots,i_k},$$

where $\{a_{\alpha,s}\}$ is a basis of A_α^q, $t_{i_1,\ldots,i_k} = a_{1,i_1}\otimes\cdots\otimes a_{k,i_k}$, p is a polynomial, and the index set Φ is defined by conditions $f_jq+h_j \le i_j \le g_jq+d_j$, $f_j,g_j\in\{0,1\}$, $h_j,d_j\in\mathbb{Z}_{\ge 0}$, for each j, and any number of equalities $i_j = i_k$ between indices.

We sometimes abuse notation and consider Φ to be its set of indices or the set of equations and inequalities defining the set of indices; no confusion should arise.

Tensor products of basic box parameterized tensors are basic box parameterized:

$$\begin{aligned}&(p_1(q)\textstyle\sum_{(i_1,\ldots,i_k)\in\Phi_1} t_{i_1,\ldots,i_k}) \otimes (p_2(q)\sum_{(j_1,\ldots,j_l)\in\Phi_2} j_{i_1,\ldots,j_l})\\ &= p_1(q)p_2(q)\textstyle\sum_{(i_1,\ldots,i_k,j_1,\ldots,j_l)\in\Phi_1\times\Phi_2} t_{i_1,\ldots,i_k,j_1,\ldots,j_l}.\end{aligned}$$

We next show that contraction of a basic box parameterized tensor is basic box parameterized when $q \ge \max_{i,j}\{|h_i-h_j|,|d_i-d_j|\}$, where i and j range over those indices related by equality to the ones being contracted. To do this, we first show they are closed under summing along a coordinate (with the same restriction on q), which we may take to be i_1 without loss of generality. (This corresponds to contracting with the vector $\sum_{i_1} a^*_{1,i_i} \in (A_1^q)^*$.) That is, we wish to show

$$p(q)\textstyle\sum_{(i_1,\ldots,i_k)\in\Phi} t_{i_2,\ldots,i_k}$$

is basic box parameterized with the above restriction on q. For this consider two cases. First, suppose there is a coordinate $j\neq 1$ so that $i_1 = i_j \in \Phi$. To construct the summed tensor, adjoin to Φ equalities $i_j = i_k$ for all k for which $i_1 = i_k \in \Phi$. Then, deleting i_1 from the indices and replacing the bounds on i_j with

$$\max(f_jq+h_j, f_1q+h_1) \le i_j \le \min(g_jq+d_j, g_1q+d_1)$$

yields the summed tensor. The max and the min can be replaced with one of their arguments provided $q \ge \max(|h_1-h_j|,|d_1-d_j|)$, so the sum is basic box parameterized with our restriction on q. Otherwise, suppose there is no coordinate so that $i_1 = i_j \in \Phi$. Then the summed tensor is $(g_1q+d_1-f_1q-h_1+1)p(q)\sum_{(i_2,\ldots,i_k)\in\Phi} t_{i_2,\ldots,i_k}$, which is basic box parameterized.

Finally, to compute the contraction, say between indices i_j and i_k, adjoin $i_j = i_k$ as a condition to Φ and then sum over i_j and then over i_k using the previous technique.

Call a tensor *box parameterized* if it is a finite sum of basic box parameterized tensors. Clearly box parameterized tensors are closed under tensor products and contraction, possibly with an easily computed restriction on q.

Now, $T_{cw,q} \in (\mathbb{C}^{q+1})^{\otimes 3} = A \otimes B \otimes C$ is clearly box parameterized as a 3-way tensor. The tensors $\phi_2 \in A' \otimes (A^{\otimes 2})^*$ (where $\dim A' = 3$) and $\phi_3 \in A' \otimes (A^{\otimes 3})^*$ (where $\dim A' = 5$) defining the projection maps are box parameterized as 3-way and 4-way tensors, respectively. The tensors $KF_1 \in (A' \otimes B^{\otimes 2} \otimes C^{\otimes 2})^* \otimes ((A')^* \otimes B^{\otimes 2}) \otimes (\Lambda^2 A' \otimes C^{\otimes 2}))$ and $KF_2 \in (A' \otimes B^{\otimes 3} \otimes C^{\otimes 3})^* \otimes ((\Lambda^2 A')^* \otimes B^{\otimes 3}) \otimes (\Lambda^3 A' \otimes C^{\otimes 3}))$ defining the Koszul flattenings are also box parameterized, as they are the tensor product of tensors of fixed size with identity tensors, which are basic box parameterized. From this, we see that the corresponding Koszul flattenings are box parameterized, viewed in $A'^* \otimes B^{\otimes 2} \otimes \Lambda^2 A' \otimes C^{\otimes 2}$ as a 6-way tensor for the square and $\Lambda^2 A'^* \otimes B^{\otimes 3} \otimes \Lambda^3 A' \otimes C^{\otimes 3}$ as an 8-way tensor for the cube.

Finally, consider the change of basis map which block diagonalizes the flattening according to Schur's lemma. We explain the square case, the cube case is available in the Appendix. This change of basis is the Kronecker product of the 3×3 identity with the Kronecker square of the map represented by the following $q+1 \times q+1$ matrix

$$\begin{pmatrix}
1 & & & & & & & & \\
& 1 & & & & & & & \\
& & 1 & & & & & & \\
& & & 1 & & & & & \\
& & & & 1 & 1 & 1 & \cdots & 1 \\
& & & & -1 & 1 & & & \\
& & & & & -1 & 1 & & \\
& & & & & & & \ddots & 1 \\
& & & & & & & & -1 \quad 1
\end{pmatrix}$$

Let E_0 denote the projection operator to the isotypic component of the trivial representation. In bases, this corresponds to the first five rows of the matrix above. Let E_1 denote the projection onto the standard representation, which corresponds to the sixth row. It is easy to see that the first 6 columns of the inverse is the matrix

$$\frac{1}{q-3}\begin{pmatrix}
q-3 & & & & & & \\
& q-3 & & & & & \\
& & q-3 & & & & \\
& & & q-3 & & & \\
& & & & 1 & -(q-4) \\
& & & & 1 & 1 \\
& & & & \vdots & \\
& & & & 1 & 1
\end{pmatrix}$$

Write F_0 for the inclusion of the trivial representation into the space in the original basis, which is represented by the first five columns of this matrix, and F_1 for the inclusion of the standard representation which is represented by the sixth column. Write V_0 for the trivial representation of $\mathfrak{S}_{q-3}$ and V_1 for the standard representation. Then,

$$f_{V_i \boxtimes V_j} = (\mathrm{Id}_{A'} \boxtimes E_i \boxtimes E_j) \circ (T_{cw,q}^{\otimes 2})_{A'}^{\wedge 2} \circ (\mathrm{Id}_{\Lambda^2 A'} \boxtimes F_i \boxtimes F_j).$$

(These four maps were labeled $f_1, \ldots, f_4$ in §4.5.) Since E_i and $(q-3)F_i$ are clearly box parametrized, it follows that $(q-3)^2 f_{V_i \boxtimes V_j}$ is box parametrized. A similar argument shows that the cube $(q-3)^3 f_{V_i \boxtimes V_j \boxtimes V_k}$ is box parameterized.

At this point the first method shows the entries of the matrices are low degree polynomials in q so one can conclude by checking the first few cases.

The fact that all tensors involved are basic box parameterized guided us how to encode these maps efficiently so that they could be computed by direct calculation, which provides the second method and is described in Appendix D.

Abstract

We consider space-efficient algorithms and conditional time lower bounds for finding cycles and walks in graphs. We give a reduction that connects the running time of undirected $2k$-cycle to finding directed odd cycles, s-t connectivity in directed graphs, and Max-3-SAT. For example, we show that if $2k$-cycle on $O(n)$-edge graphs can be solved in $O(n^{1.5-\epsilon})$ time for some $\epsilon > 0$ then, a $2^{n(1-\epsilon')}$ time algorithm exists for Max-3-SAT for some $\epsilon' > 0$. Additionally, we give a tight combinatorial lower bound for $2k$-cycle detection, specifically when k is odd, of $m^{2k/(k+1)+o(1)}$ given the Combinatorial k-Clique Hypothesis.

On the algorithms side, we present a randomized algorithm for directed s-t connectivity using $O(\lg(n)^2)$ space and $O(n^{\lg(n)/2+o(\lg(n))})$ expected time, giving a time improvement over Savitch's famous algorithm, which takes at least $n^{\lg(n)-o(\lg(n))}$ time. Under the conjecture that every $O(\lg(n)^2)$-space algorithm for directed s-t connectivity requires $n^{\Omega(\lg(n))}$ time, we show that undirected $2k$-cycle in $O(\lg(n))$ space requires $n^{\Omega(\lg(k))}$ time.

1 Introduction

The k-cycle problem, determining whether a graph on n nodes and m edges contains a cycle of length k, is a fundamental subgraph detection problem. Past work has explored efficient algorithms for detecting/counting, odd/even, directed/undirected cycles in both sparse and dense graphs (e.g. [17, 5, 2, 8, 18]). In this paper, we explore k-cycle algorithms using small space, e.g., $\text{poly}(\log n)$.

When $k \geq \Omega(n)$, for example, $k = n/2$, detecting a k-cycle is well-known to be NP-hard [9]. When k is constant and algorithms are given $O(n^2)$ space, odd cycles can be detected in matrix multiplication time [3, 5]. When k is constant and algorithms are given $O(n)$ space, even cycles can be detected in $O(n^2)$ time [17]. Given an undirected sparse graph, detecting a $2k$-cycle can be done faster, specifically $O(m^{2k/(k+1)})$ time [5]. However, this work leaves open the question of what happens in the very small space regime.

When algorithms are allowed $O(\lg(n) \cdot \lg(k))$ space, the Savitch algorithm can be used to solve k-cycle detection in time $n^{\lg(k)+o(\lg(k))}$ time. In particular, the Savitch algorithm can be used to detect if two nodes s and t are connected by a path of length at most k in a

directed graph, using $n^{O(\lg(k))}$ time and $O(\lg(n) \cdot \lg(k))$ space. We explore the relationship between small space k-cycle detection and algorithms for s-t connectivity, and show that the complexities of the two problems are tightly connected. To the best of our knowledge, no s-t connectivity algorithms have been reported running in $O(\lg^2 n)$ space and $n^{0.999 \cdot \lg(n)}$ time.

Our Results

The primary contribution of this paper is a reduction from directed k'-cycle to undirected $2k$-cycle for constant k' and k such that $k = k' \operatorname{poly}\lg(k)$. We use this reduction to show hardness for even cycle detection in both small space and in sparse graphs.

We prove that, for small-space algorithms, the time complexities of k-cycle detection and k-path detection are equivalent up to constant factors in the exponent. We show that an $n^{o(\lg(k))}$ time and $O(\lg(n))$ space algorithm for the $2k$-cycle detection problem would imply an algorithm for s-t running in $n^{o(\lg(n))}$ time and $O(\lg^2(n))$ space, a significant improvement over Savitch's algorithm.

We propose two natural lower bound hypotheses, and derive interesting consequences from them. The first hypothesis is that s-t connectivity in $O(\lg^2(n))$ space requires $n^{\Omega(\lg(n))}$ time. The second (stronger) hypothesis is that s-t connectivity in $\operatorname{poly}\lg(n)$ space requires $n^{\Omega(\lg(n))}$ time. We call these hypotheses the Weak Savitch Hypothesis (WSH) and the Strong Savitch Hypothesis (SSH) respectively.

▶ **Definition 1.** *The Weak Savitch Hypothesis (WSH) states that given a directed graph G with n nodes and two specified nodes s and t determining if a path exists from s to t requires $n^{\Omega(\lg(n))}$ time if the algorithm can only use $O(\lg^2(n))$ space.*

▶ **Definition 2.** *The Strong Savitch Hypothesis (SSH) states that given a directed graph G with n nodes and two specified nodes s and t determining if a path exists from s to t requires $n^{\Omega(\lg(n))}$ time if the algorithm can only use $O(\operatorname{poly}\lg(n))$ space.*

Both of our Hypotheses are about the s-t connectivity problem, two well known algorithms for s-t connectivity are:

- Savitch's algorithm [12] running in time $\tilde{O}(n^{\lg n})$ and space $O(\lg^2 n)$.
- Depth-First search running in polynomial time and space $\tilde{O}(n)$.

The only improvement over these for any space greater than $\lg^2 n$ is the algorithm of Barnes, Buss, Ruzzo and Schieber [4] who gave a space $O(n/2^{\sqrt{\lg(n)}})$, polynomial time algorithm. They are also able to give a time space tradeoff of space s where $s > \lg^2 n$ and time $2^{O(\lg^2(n/s))}\operatorname{poly}(n)$. This time space tradeoff would require $n^{1-o(1)}$ space to achieve $n^{o(\lg n)}$ time. Our hypotheses are much weaker and only claim the non-existence of $n^{o(\lg n)}$ time algorithms for $O(\lg^2(n))$ space and $O(\operatorname{poly}\lg(n))$ space respectively.

We prove the following hardness for $2k$-cycle under Weak Savitch Hypothesis.

▶ **Theorem 3.** *Assuming Weak Savitch Hypothesis (WSH) solving k-cycle in undirected graphs in $O(\lg n)$ space requires $n^{\Omega(\lg k)}$ time.*

Could we strengthen the hypotheses (Weak Savitch Hypothesis (WSH) and the Strong Savitch Hypothesis (SSH)) to state that there are no $n^{(1-\epsilon)\lg(n)}$ time algorithms for any constant $\epsilon > 0$, instead of merely saying there is no $n^{o(\lg(n))}$ time algorithms? We prove that such a hypothesis would actually be false for randomized algorithms.

▶ **Theorem 4.** *There is a randomized algorithm for directed st-connectivity which runs in expected time $n^{\lg n/2+o(\lg n)}$ and $O(\lg^2(n))$ space.*

Our randomized algorithm works as follows. First, for sufficiently short path lengths (up to $\lg(n)$) we run Savitch's algorithm as usual. For longer path lengths, instead of trying to find the middle vertex of the path we look for any vertex which is approximately in the middle. We show that this minor modification can actually speed up Savitch's algorithm by a quadratic factor. Similar ideas were used by Zwick [19] to give algorithms for All pairs shortest paths problem in arbitrary space regime.

Other Implications

Our k'-cycle to $2k$-cycle reduction ($k = k' \text{poly} \lg(k)$) has many more implications. We give lower bounds for sparse even-cycle detection by reducing Max-3-SAT to sparse even-cycle detection and give a tight combinatorial lower bound for sparse even-cycle. We achieve this by combining our reduction and previous hardness results for directed k-cycle [10].

▶ **Theorem 5.** *If undirected $2k$-cycle, for any large enough constant k can be solved in a graph G with $m = O(n)$ in time $O(m^{1.5-\epsilon})$ then max-3-SAT can be solved in time $O^*(2^{(1-\epsilon')n})$.*

We additionally present a very simple reduction from detecting odd k-cycles to detecting $2k$-cycles. This reduction is inspired by a reduction from Dahlgaard et al. [5]. Our results here are tight, but only in the "combinatorial" regime. The notion of *combinatorial algorithms* is not formally defined, however, it is a commonly used notion (e.g. [10, 1]) which informally just excludes fast matrix multiplication as a subroutine (e.g. [6, 15]). The category of combinatorial algorithms considered generally assumes boolean matrix multiplication requires $n^{3-o(1)}$ time, and attempts to capture algorithms that are fast in practice [16]. We can obtain a combinatorial lower bound for the undirected $2k$-cycle detection of $\Theta(m^{2-o(1)})$ time, for all large enough constants k, if the Combinatorial k-Clique Hypothesis is true.

Additionally for *odd* k we show a tight bound for combinatorial $2k$-cycle detection. If you can detect $2k$-cycles combinatorially in time $m^{(1-\epsilon)2k/(k+1)}$ for some $\epsilon > 0$ then you violate the Combinatorial k-Clique Hypothesis. Dahlgaard et al. present an algorithm for all $2k$-cycles that runs in time $m^{2k/(k+1)}$. So for odd k, we have a tight combinatorial lower bound for $2k$-cycles.

Previous Work

Over the years, there have been many algorithmic results for the cycle detection problem. In arbitrary space, $2k$-cycle can be solved in $O(n^2)$ space as long as k is a constant [17]. This beats the matrix multiplication (n^ω) time algorithms for odd k-cycle detection assuming the matrix multiplication constant is larger than two ($\omega > 2$) [2]. Dahlgaard et al. give an algorithm for sparse even $2k$-cycle detection which runs in $O(m^{2k/(k+1)})$ time, where m is the number of edges in the input graph [5]. These algorithms require $\Omega(m)$ space to run. In very small space finding a k-cycle takes much longer, and as we show in this paper has a strong relationship to s-t connectivity in small space. Savitch's algorithm solves s-t connectivity in space $\lg^2(n)$ in time $n^{\lg(n)-o(\lg(n))}$ [12]. In this paper we present a randomized algorithm which runs in space $\lg^2(n)$ in time $n^{\lg(n)/2+o(\lg(n))}$, improving over the Savitch algorithm. The problem of solving s-t connectivity in less than $\lg^2(n)$ space has also been explored. Gopalan et al. present a randomized time space tradeoff for the s-t connectivity problem where given $\lg^2(n)/\lg(d)$ space they acheive a running time of $O(n^{d \lg(n)/\lg(d)})$ for $d \in [2, n]$ [7].

While we provide a reduction from directed k-cycle for arbitrarily large k to even cycle, a previous paper reduced 3-cycle specifically to even cycle [5]. Their reduction technique inspired ours. They give a lower bound of $m^{3/2-o(1)}$ for even cycle relying on a combinatorial

conjecture for the running time of 3-cycle detection. Notably, they assume no combinatorial $n^{3-o(1)}$ algorithm exists for 3-cycle detection. We give a matching lower bound of $m^{3/2-o(1)}$ using a *non-combinatorial* hypothesis.

Furthermore, our reduction gives an improved lower bound of $m^{2-o(1)}$ using a combinatorial assumption. Giving a tight combinatorial lower bound for the even cycle problem. We give a combinatorial lower bound of $m^{\frac{2k}{k+1}-o(1)}$ for the undirected $2k$-cycle detection problem for odd k. This is closely related to the running time of $O(m^{2k/(k+1)})$ for the algorithm detecting *even* k cycles combinatorially by Dahlgaard et al. [5]. We can additionally use a simple reduction inspired by Dahlgaard et al. [5] and a reduction from k-clique to sparse k-cycle from previous work [10] to give a tight combinatorial lower bound for the $4k+2$-cycle problem. to give a lower bound of $m^{\frac{2k}{k+1}-o(1)}$ for detecting $2k = 4k'+2$ cycles. This shows optimality of the Dahlgaard et al algorithm for half of all even k-cycle detection problems.

By giving a reduction from directed k'-cycle to $2k$-cycle we can show $n^{\Omega(\lg(k))}$ hardness for $2k$-cycle in $O(\lg(n))$ space. However, one can not show this hardness using the 3-cycle reduction of Dahlgaard et al., because 3-cycle has an $O(n^3)$-time logspace algorithm.

In the weaker model of AC_0 formulas a $n^{\Omega(\lg(k))}$ lower bound is known unconditionally for the $\leq k$ connectivity problem [11].

Improving low-space algorithms for directed st-connectivity is a longstanding open problem [14]. Barnes, Buss, Ruzzo and Schieber [4] gave a sublinear space $O(n/2^{\sqrt{\lg(n)}})$, polynomial time algorithm. Even their results only give $(\lg n)^{O(\lg n)}$ factor improvements over Savitch if we restrict to polylog space. Hence for polylog space they require $n^{\lg n(1-o(1))}$ time. Melkebeek and Prakriya [13] gave a unambiguous algorithm running in polynomial time and $O(\lg^{3/2} n)$ space. The time and space here are both better than the ones in our hypotheses but unambiguous Turing machines are possibly much more powerful then deterministic ones.

Organization

In Section 2 we cover definitions and preliminaries. In Section 3 we present a faster s-t connectivity algorithm. In Section 4 we give our reduction between directed k-cycle and even k-cycle. In Section 5 we cover the implications of our reduction.

2 Preliminaries

We will always assume k in the k-cycle/walk problems to be a constant unless stated otherwise.

Notation

We will use the notation $\tilde{O}(f(n))$ to suppress sub-polynomial factors $\left(f(n)^{o(1)}\right)$.

Definitions

▶ **Definition 6.** *A k-cycle in a graph G is a set of k distinct vertices, $x_1, \ldots, x_k$ in G such that the edges $(x_1, x_2), \ldots, (x_{k-1}, x_k), (x_k, x_1)$ all exist in G.*

A k-walk in a graph G is a set of k not necessarily distinct vertices, $x_1, \ldots, x_k$ in G such that the edges $(x_1, x_2), \ldots, (x_{k-1}, x_k)$ all exist in G.

Throughout the paper we will take k to be a large enough constant. We will have runtimes of the form $n^{\Theta(\lg(k))}$ where Θ hides a constant independent of k; such notation only makes sense for k that can grow unboundedly.

We will assume throughout that all graphs are presented in adjacency list format. This is done for simplicity and not assuming this has no effect on our results.

▶ **Reminder of Definition 1.** *The Weak Savitch Hypothesis (WSH) states that given a directed graph G with n nodes and two specified nodes s and t determining if a path exists from s to t requires $n^{\Omega(\lg(n))}$ time if the algorithm can only use $O(\lg^2(n))$ space.*

▶ **Reminder of Definition 2.** *The Strong Savitch Hypothesis (SSH) states that given a directed graph G with n nodes and two specified nodes s and t determining if a path exists from s to t requires $n^{\Omega(\lg(n))}$ time if the algorithm can only use $O(\text{poly}\lg(n))$ space.*

Currently the best known algorithms for directed s t connectivity which run in time $n^{o(\lg(n))}$ require $n^{1-o(1)}$ space[4].

3 Making Savitch run faster

3.1 Savitch's Algorithm

We begin by recalling Savitch's classical algorithm.

Algorithm 1 Savitch's Algorithm.

Input: Graph $G = (V, E)$, vertices s, t, $k \geq 0$
Output: If there exists a path of length at most k from s to t.

```
function SA(G, s, t, k)
    if k = 1 then
        Output TRUE if (s, t) ∈ E, otherwise FALSE
    Let |V| = n.
    for v ∈ [n] do
        if SA(G, s, v, ⌊k/2⌋) ∧ SA(G, v, t, ⌈k/2⌉) = TRUE then
            Output TRUE
    Output ret
```

▶ **Lemma 7** ([12]). *Savitch's algorithm solves directed $\leq k$-reachability in time $T_S(n,k) = \tilde{O}(n^{\lg(k)})$ using space $O(\lg(k)\lg(n))$.*

Savitch's Algorithm [12] solves the directed $s - t$ connectivity problem as follows. It considers the more general problem of $\leq k$ connectivity. $k = n$ is equivalent to $s - t$ connectivity. For determining if there is a path of length at most k between s and t, we guess the middle vertex v in such a path, then recursively try to solve $\leq k/2$ connectivity for (s, v) and (v, t). This gives us the recurrence:

$$T(n,k) \leq n(2 \cdot T(n,k/2)) + \text{poly}(n)$$

with the base case $T(n,1) = O(\text{poly}(n))$. This base case is unaffected by being in adjacency list format or adjacency matrix format. This solves to $T(n,n) = \tilde{O}(n^{\lg n})$.

We now turn improving the running time of s-t connectivity in $O(\lg^2(n))$ space.

Similarly to the Savich's algorithm we will be guessing a node in the middle of the hypothetical path. However, Savich's algorithm requires the node that is exactly in the middle of the path. In our algorithm we will accept a node that is approximately in the middle. There is a trade-off with approximating. By approximating we improve the probability of

an accept. Consider if we accepted any node that was with $\epsilon_k \cdot k$ nodes of the true middle of a k length path, then we have a $2\epsilon_k/n$ probability of correctly guessing such a node. However, this approximation factor trades off how much progress we make with a correct guess. In Savich's Algorithm each correct guess halves the path length. In contrast, with an approximation factor of ϵ_k we divide the path into the less favorable $1/2 - \epsilon_k$ and $1/2 + \epsilon_k$ split. This trade-off is optimal when ϵ_k is approximately $1/\lg(n)$, so we accept any node that is in the middle $1/\lg(n)$ fraction of a k length path.

Our square-root speedup intuitively comes from improving the probability of correctly guessing from $1/n$ to $k/(\lg(n) \cdot n)$. This approaches n as k approaches $\lg(n)$, but achieves a huge savings when k is much larger than $\lg(n)$.

▶ **Reminder of Theorem 4.** *There is a randomized algorithm for directed st-connectivity which runs in expected time* $n^{\lg n/2+o(\lg n)}$ *and* $O(\lg^2(n))$ *space.*

Proof. For sufficiently short path lengths (up to $\lg(n)$) we run Savitch's algorithm as usual. For longer path lengths, instead of trying to find the middle vertex of the path we look for any vertex which is approximately in the middle. We describe the algorithm in full detail below.

Algorithm 2 Improved Savitch's Algorithm.

Input: Graph $G = (V, E)$, vertices s, t
Output: If there exists a path from s to t in G.

function ISA(G, s, t)
    Output $ISA_2(G, s, t, n)$
function $ISA_2(G, s, t, k)$
    if $k \leq \lg(n)$ **then**
        Output SA(G, s, t, k)
    let V_r be a list of randomly sampled nodes from V.
    for $v \in V_r$ **do**
        if $ISA_2(G, s, v, k/2 + k/\lg(n))) \wedge ISA_2(G, v, t, k/2 + k/\lg(n)) =$ TRUE **then**
            Output TRUE
    Output FALSE

In Savitch's algorithm we try to guess the middle vertex in a path. Our improvement derives from the fact that we only look for a vertex which is approximately in the middle.

Savitch's algorithm considers the subproblem of $\leq k$ connectivity. We consider a more relaxed notion described below.

$ISA_2(G, s, t, k)$ returns YES if there exists a path of length at most k between s and t and returns NO if there is no path between s and t. ISA_2 as implemented may return either YES or NO if there is a path from s to t but no path of length at most k. Returning YES on larger length paths does not affect correctness as in st-connectivity we are only concerned about existence of a path, not a bounded length path.

Suppose there exists an at most k length path between s and t. We guess a vertex v hoping that v is one of the middle $2\delta_k = 2k/\lg(n)$ vertices in this path. We will guess v uniformly at random. The probability of a correct guess is $\epsilon_k = 2\delta_k/n$.

If our guess is correct distance between (s, v) and (v, t) are at most $k/2 + \delta_k$ hence we can recurse on $ISA_2(G, s, v, k/2 + \delta_k)$ and $ISA_2(G, v, t, k/2 + \delta_k)$.

Let $T(n, k, s, t)$ be the random variable which denotes the time for solving $ISA_2(G, s, t, k)$ using Algorithm 2.

Let $T_E(n,k) = \max_{s,t} \mathbb{E}[T(n,k,s,t)]$.

Setting $\delta_k = \max(k/(\lg n), 1)$ gives us the following recurrence for $k \geq \lg(n)$:

$$T_E(n,k) \leq \sum_{i=1}^{\infty} \Pr[i^{th} \text{ guess was the first correct guess}] \cdot i \cdot (2T_E(n, k/2 + \delta_k)) + \text{poly}(n))$$

$$T_E(n,k) \leq \sum_{i=1}^{\infty} \left((1-\epsilon_k)^{i-1} \epsilon_k \cdot i \cdot (2T_E(n, k/2 + \delta_k)) + \text{poly}(n)\right).$$

We can rewrite this equation as:

$$\begin{aligned} T_E(n,k) &\leq \left(\sum_{i=1}^{\infty} i\left((1-\epsilon_k)^{i-1}\epsilon_k\right)\right) \cdot (2T_E(n, k/2 + \delta_k) + \text{poly}(n)) \\ &\leq (1/\epsilon_k) \cdot (2T_E\left(n, k/2 + \delta_k\right) + \text{poly}(n)) \\ &\leq 2\,(1/\epsilon_k) \cdot T_E\left(n, k/2 + \delta_k\right) + \text{poly}(n). \end{aligned}$$

Now we can plug in $\epsilon_k = 2\delta_k/n$ and $\delta_k = \max(k/(\lg n), 1)$ to get the following:

$$\begin{aligned} T_E(n,k) &\leq (n/\delta_k) \cdot T_E\left(n, k/2 + \delta_k\right) + \text{poly}(n) \\ &\leq \frac{n \lg(n)}{k} \cdot T_E\left(n, k/2 + k/\lg(n)\right) + \text{poly}(n). \end{aligned}$$

For $k \geq \lg(n)$, at each recursion step k gets multiplied by $(1/2 + 1/\lg(n))$. Let k_j denote its value after j steps and k_0 denotes its initial value. For directed st connectivity $k_0 = n$.

For $k_0 = n$ and for $j \leq b = \lceil -\frac{\lg(n/\lg(n))}{\lg(1/2+1/\lg(n))} \rceil$ we have $k_j = k_0(1/2+1/\lg(n))^j = n(1/2+1/\lg(n))^j$ as for $j < b$, $n(1/2+1/\lg(n))^j > \lg(n)$. Note that b is positive ($\lg(1/2+1/\lg(n))$ is negative). Note that $k_b = n(1/2+1/\lg(n))^j \leq \lg(n)$.

$$T_E(n,n) \leq \left(\prod_{j=0}^{b-1} \frac{n\lg(n)}{k_j}\right) \cdot (T_E(n,k_b) + \text{poly}(n)).$$

As $k_j = n(1/2+1/\lg(n))^j$ for $j \leq b$ and $k_b \leq \lg(n)$

$$T_E(n,n) \leq \left(\prod_{j=0}^{b-1} \frac{n\lg(n)}{n(1/2+1/\lg(n))^j}\right) \cdot (T_E(n,\lg(n)) + \text{poly}(n)).$$

When we are looking for paths of length at most $\lg(n)$ we will call the original Savitch's algorithm. So, $T_E(n,\lg(n)) = T_S(n,\lg(n)) = \tilde{O}(n^{\lg\lg n}) = n^{o(\lg(n))}$ by Lemma 7. Recalling that b is positive and $b = \lceil -\frac{\lg(n/\lg(n))}{\lg(1/2+1/\lg(n))} \rceil$:

$$\begin{aligned} T_E(n,n) &\leq \left(\prod_{j=0}^{b-1} \frac{\lg(n)}{(1/2+1/\lg(n))^j}\right) \cdot (n^{o(\lg(n))} + \text{poly}(n)) \\ &\leq \left(\frac{\lg^b(n)}{(1/2+1/\lg(n))^{b^2/2}}\right) \cdot (n^{o(\lg(n))}) \end{aligned}$$

As $b = \lceil -\frac{\lg(n/\lg(n))}{\lg(1/2+1/\lg(n))} \rceil$, $\lg^b(n) = n^{o(\lg(n))}$ we have

$$\begin{aligned}
T_E(n,n) &\leq (1/2+1/\lg(n))^{-b^2/2} \cdot n^{o(\lg(n))} \\
&\leq 2^{-\frac{\lg(1/2+1/\lg(n))\lg^2(n)}{2\lg(1/2+1/\lg(n))^2}} \cdot n^{o(\lg(n))} \\
&\leq 2^{-\frac{\lg^2(n)}{2\lg(1/2+1/\lg(n))}} \cdot n^{o(\lg(n))} \\
&\leq 2^{\frac{\lg^2(n)}{2(1-\lg(1+2/\lg(n)))}} \cdot n^{o(\lg(n))} \\
&\leq 2^{\frac{\lg^2(n)}{2(1-2/\lg(n)))}} \cdot n^{o(\lg(n))} \\
&\leq 2^{\frac{\lg^2(n)}{2}} \cdot n^{o(\lg(n))} \\
&\leq n^{(\lg(n)/2+o(\lg(n)))}.
\end{aligned}$$

So $T_E(n,n) \leq n^{(\lg(n)/2+o(\lg(n)))}$, giving the desired result. ◀

4 Reductions Between k-cycle Problems

In this section we will give a reduction from directed k' cycle to $2k$ cycle, where k' is odd and $k' \leq k/\lg^{O(1)}(k)$. This will allow us to give lower bounds for even cycle as well as odd cycle in the sparse setting. First, we will need a helper lemma about the existence of primes with appropriate properties.

▶ **Lemma 8.** *There exists a constant $k^\star$ such that $\forall k \geq k^\star$ we can write $2k = \sum_{i=0}^{4} z_i r_i$ where $z_i \in \mathbb{N}, r_i \leq \lg^{O(1)}(k), \sum |z_i r_i - 2k/5| \leq \lg^{O(1)}(k)$ and any four of r_i's together have a common prime factor which does not divide k.*

Proof. Let p_i for $0 \leq i \leq 4$ be distinct prime numbers which do not divide k. By the prime number theorem we can take $p_i \leq \lg^2(k)$ for large enough constant k. Define $r_i = \prod_{j \neq i} p_j$. This allows us to satisfy the requirements that $r_i \leq \lg^{O(1)}(k)$ and any four of r_i's together have a common prime factor which does not divide k.

As the $gcd(r_i) = 1$, by Eulid's gcd algorithm there exists integers y_i such that $1 = \sum y_i r_i$ hence there exists integers z_i for which $2k = \sum z_i r_i$. Choose z_i's such that $\sum |z_i r_i - 2k/5|$ is minimized. Assume $\sum |z_i r_i - 2k/5| > 10 \lg^{11}(k)$. This implies that there exists a j, j' such that $z_j r_j - 2k/5 > \lg^{11}(k)$ and $z_{j'} r_{j'} - 2k/5 < -\lg^{11}(k)$. We can substitute z_j with $z_j - p_j$ and $z_{j'}$ with $z_{j'} + p_{j'}$. This maintains the sum $\sum z_i r_i = 2k$ as $r_j p_j = r_{j'} p_{j'}$. The substitution decreases $z_j r_j - 2k/5$ by $\prod p_i < \lg^{10}(k) < \lg^{11}(k)$ and increases $z_{j'} r_{j'} - 2k/5$ by $\prod p_i < \lg^{10}(k) < \lg^{11}(k)$. Hence both $|z_j r_j - 2k/5|$ and $|z_{j'} r_{j'} - 2k/5|$ decrease while $|z_i r_i - 2k/5|$ for $i \neq j, j'$ remain the same. This gives a contradiction as we chose z_i's to minimize $\sum |z_i r_i - 2k/5|$. So we can assume that $\sum |z_i r_i - 2k/5| \leq 10 \lg^{11}(k)$. This also implies that for all i, $z_i r_i > 2k/5 - \lg^{O(1)}(k)$ hence $z_i > 0$ for large enough k. ◀

Given a sparse graph G there are many possible ways for the input to be formatted. Given an adjacency list format there exist two different efficient algorithms for returning if (u, v) is an edge in the graph. If one is worried about space and not time (as we are in our $O(\lg(n))$ space lower bounds) there is a $O(\lg(n))$ space $O(\lg(n))$ time algorithm. Simply binary search through the adjacency list input to find (u, v). If one is worried about time and not space then one can hash the adjacency list giving a $O(n)$ space data structure that has lookup time $O(1)$. We don't care about $\lg(n)$ factors in our time and thus default to the $O(\lg(n))$ space and time algorithm.

▶ **Theorem 9.** *There exists a constant $k^\star$ such that $\forall k \geq k^\star$, there exists $k' \geq k/(\lg^{O(1)} k)$ such that a n-node, m edge instance of directed k' cycle can be reduced to $\tilde{O}(m)$ node, $\tilde{O}(m)$ edge instance of $2k$ cycle on graph G. Further any bit in the description of G can be produced by a $O(\lg(n))$ space and $O(\lg(n))$ time.*

Proof. Take z_i, r_i's satisfying Lemma 8 for k. Set $k' = \sum z_i$. Let G be a instance of directed k' cycle with n nodes and m edges. We will first apply color coding using Lemma 20, to produce a k' partite graph. This graph will only have edges between "adjacent" partitions. As explained in Lemma 20.

Let $s_i = \sum_{j<i} z_j$. We create a new graph G' by replacing each directed edge in between the s_i to the $s_{(i+1 \mod 5)}$(cyclically) parts by a r_i length path with undirected edges. As we are replacing z_i partitions of edges by an r_i length path this gives a natural partition of G' with $\sum z_i r_i = 2k$ parts.

$$\begin{aligned}\text{Number of nodes and edges in } G' &\leq \max(r_i) \cdot m \\ &\leq \lg^{O(1)}(k) \cdot m \quad \text{[By Lemma 8]} \\ &\leq O(m) \qquad \text{[As } k \text{ is a constant]}\end{aligned}$$

We will now show that the new graph G' has a $2k$-cycle iff G had a directed k'-cycle.

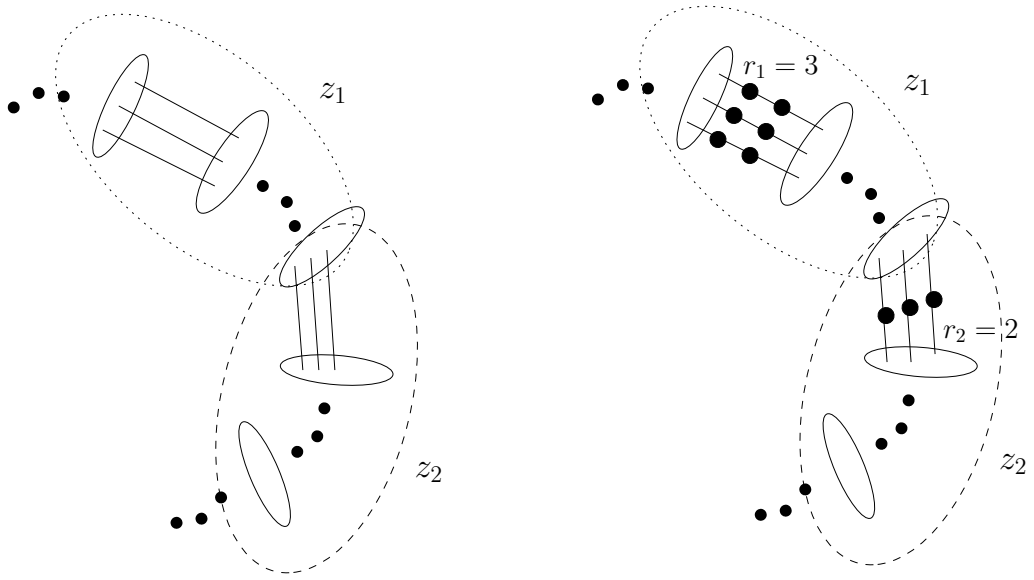

Figure 1 Depicting the edge transformation from G to G'. The dotted oval contains z_1 edge sets. The dashed oval contains z_2 edge sets. Every edge in the dotted oval is turned into r_1 edges by replacing the edge with a path. Every edge in the dashed oval is turned into r_2 edges by replacing the edge with a path.

Each edge in the graph G' is part of one of the introduced r_i length paths. If one of the edges from an r_i length path is used for a $2k$ cycle then all the edges in the path must be used as intermediate vertices in the path have no other edges that the edges in the path itself. Hence we can think of our $2k$ cycle as composed of meta-edges of lengths r_i. Suppose for constructing the $2k$ cycle we only use at most 4 out of the 5 possible r_i lengths. Then we cannot construct a $2k$ cycle as these four r_i's share a common prime factor which does not occur in $2k$. Hence we need to use all 5 possible r_i lengths. Wlog we can assume that we start from 0^{th} partition. There are 2 approaches to hitting all 5 possible r_i length paths:

1. Go around all the $2k$ partitions.
2. Do not go around all partitions.

For type 1, note that we can never back-track as otherwise we will have more than $2k$ edges. If we find a $2k$ cycle using type 1 without backtracking this exactly corresponds to a directed k' cycle in G by replacing all meta-edges by the corresponding edge of G.

For type 2 paths note that we must hit all of the 5 possible lengths.

Let group i be the set of edges produced in G' from the edges between the s_i and $s^{th}_{i+1 \mod 5}$ partitions in G. To pass from one side of group i to the next requires passing through at least z_i paths of length r_i. So passing from one side of group i to the other requires a path of length at least $z_i r_i$.

To hit all possible lengths we must have at least one edge from all five groups. To pass through all five groups at minimum requires doubling back through three groups. To double back through a group requires two paths each of length $z_i r_i$. See Figure2 for a depiction.

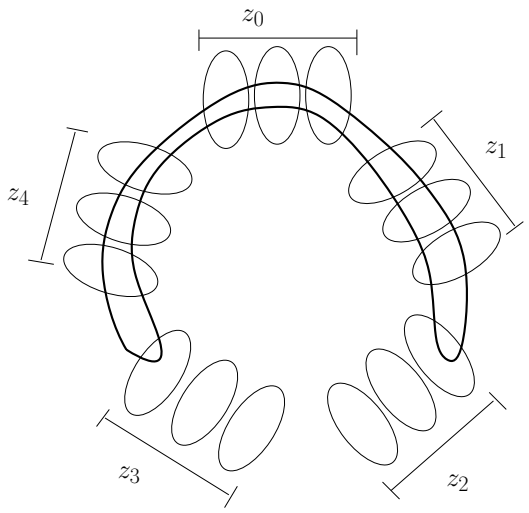

Figure 2 In bold we depict a path passing through partitions, reaching at least one r_i length path of each of the 5 possible lengths. Each oval represents a partition of s_j. Between each partition is a path of one of the lengths r_i. Note that to reach all five the path must "double back" through three partitions.

For simplicity understand r_{i+c} and z_{i+c} in the next equation to be $r_{(i+c \mod 5)}$ and $z_{(i+c \mod 5)}$ respectively. So the minimum length of a type two cycle is

$$\min_i \left(2r_i + 2z_{i+1}r_{i+1} + 2z_{i+2}r_{i+2} + 2z_{i+3}r_{i+3} + 2r_{i+4}\right).$$

By Lemma 8 $\sum|z_j r_j - 2k/5| \leq \lg^{O(1)}(k)$, so $\sum|2z_j r_j - 4k/5| \leq 2\lg^{O(1)}(k)$.
Thus, $\sum_{j=i+1}^{i+3}|2z_j r_j - 4k/5| \leq 2\lg^{O(1)}(k)$. Finally giving

$$\sum_{j=i+1}^{i+3} 2z_j r_j \geq \frac{12}{5}k - 2\lg^{O(1)}(k) = 2.4k - 2\lg^{O(1)}(k) > 2k.$$

A type 2 $2k$-cycle, which doesn't form a cycle through all partitions, must have length greater than $2k$. So, no such cycle exists.

Thus, the only $2k$-cycles in this graph correspond exactly to a directed k'-cycle in the original graph. ◀

5 Implications of k-Cycle Reductions

We now discuss the implications of the reduction from directed k'-cycle to undirected $2k$-cycle. We will start by showing that the algorithms for $2k$-cycle in $\lg(n)$ space are tight up to constant factors in the exponent. Next, we will give lower bounds for $2k$-cycle from Max-3-SAT.

5.1 2k-Cycle $\lg(n)$ Space Algorithms are Tight

Given the Weak Savitch Hypothesis we can show that undirected $2k$-cycle problems have nearly optimal algorithms.

In this section we give a reduction that, for all large enough k, reduces directed k'-cycle to undirected $2k$-cycle. That is, there is some constant $k^\star$ such that for all $k > k^\star$ we can reduce directed k'-cycle to undirected $2k$-cycle. Furthermore, in our reduction $k' = \Theta(k/\lg(k))$. So, for all $k > k^\star$ we have that $2k$-cycle reduces from directed $\Theta(k/\lg(k))$-cycle.

Following Lemmas 10 and 11 are very similar to lemmas in previous work and are roughly folklore. We present their proofs for completeness.

▶ **Lemma 10.** *If the Weak Savitch Hypothesis is true then $\leq k-$connectivity in an directed graph G with n nodes requires $n^{\Omega(\lg k)}$ time if we are restricted to $O(\lg n)$ space.*

Proof. We can consider the Savitch algorithm for determining if there is a path of length $\leq \ell$ between two nodes in a graph with n nodes. The Savitch algorithm [12] as described in Section 3 has the following recurrence :

$$T(n, \ell) \leq 2nT(n, \ell/2) + \text{poly}(n).$$

Where the standard base case is $T(n, 1) = O(\lg(n))$. This gives an algorithm running in time $O(n^{(\lg \ell)}\text{poly}(n))$.

If Weak Savitch Hypothesis is true then there exists some constant $\epsilon \geq 0$ such that no algorithm solving st connectivity (equivalent to $\leq n$ connectivity) in $\lg^2(n)$ space runs in time $n^{\epsilon \lg(ell)}$.

If an algorithm for k-path runs in $n^{o(\lg(k))}$ and $O(\lg n)$ space then we can repeatedly use it to find an $\leq \ell$ length path. Specifically, we will run the k-path algorithm where we treat an edge as existing if there is an ℓ/k walk between two nodes. To determine if such an edge exists we will recurse. This gives us the following recurrence:

$$T(n, \ell) \leq n^{o(\lg(k))}T(n, \ell/k) + \tilde{O}(1).$$

For $\ell = n$, this recurrence gives us $T(n, n) \leq n^{o(\lg(k))\lg_k(n)}$ This running time can be simplified to $O(n^{o(\lg(k))\lg(n)/\lg(k)})$.

For all ϵ there exists some sufficiently large but constant k such that $o(\lg(k))/\lg(k) \leq \epsilon$ which contradicts the Weak Savitch Hypothesis. ◀

▶ **Lemma 11.** *Assuming Weak Savitch Hypothesis (WSH) directed, k-cycle cannot be solved in $O(\lg n)$ space and $n^{o(\lg k)}$ time.*

Proof. Suppose directed k-cycle is in $O(\lg n)$ space and $n^{o(\lg k)}$ time. Suppose we are given an instance of $k-1$-walk $(G = (V, E), a, b)$. Construct a new graph G' with k copies of each vertex v named $v_1, v_2, \ldots, v_k$. Add u_i, u_{i+1} as an edge. Add (u_i, v_{i+1}) as an edge in G' if (u, v) was an edge in G. Also add (a_k, b_1) as an edge. Now there is a k-cycle in G' iff there was a $k-1$-walk from a to b in G. As the number of vertices in G' is kn and k

is a constant hence we have a $O(\lg n)$ space and $n^{o(\lg k)}$ time algorithm for (un)directed k-walk. By Lemma 10 this contradicts Weak Savitch Hypothesis (WSH). Note that we will not actually construct G' instead we use $O(\lg n)$ space and have a $O(\lg n)$ time algorithm that serves as an oracle for G'. ◀

▶ **Reminder of Theorem 3.** *Assuming Weak Savitch Hypothesis (WSH) solving k-cycle in undirected graphs in $O(\lg n)$ space requires $n^{\Omega(\lg k)}$ time.*

Proof. By Lemma 11 we know that k'-cycle in directed graphs cannot be solved in $O(\lg n)$ space and $n^{o(\lg k')}$.

Suppose we have a $O(\lg n)$ space and $n^{o(\lg k)}$ time algorithm for k-cycle in undirected sparse graphs for even k. Then let k' be the largest integer satisfying the definition in Theorem 9. Then by Theorem 9 we can reduce directed k'-cycle to k-cycle and solve it in time $n^{o(\lg k)} = n^{o(\lg k')}$ because $k' \geq k/\lg^{O(1)}(k)$. Note that as in the reduction we can produce each bit in $O(\lg(n))$ space and time $O(\lg(n))$ our space and running time bounds are not affected. The reduction only increases the number of vertices by a constant factor and k is large enough. Using Lemma 11 gives a contradiction. ◀

▶ **Corollary 12.** *Assuming Weak Savitch Hypothesis (WSH) detecting k-cycles in undirected sparse graphs in $O(\lg(n))$ space takes $n^{\Theta(\lg k)}$ time.*

Proof. By Theorem 3 we have that k-cycle in log space requires $n^{\Omega(\lg k)}$ time. By Lemma 21 we have that k-cycle can be solved in log space and $n^{O(\lg k)}$ time. Thus, the k-cycle problem requires $n^{\Theta(\lg k)}$ time, conditioned on WSH.

◀

Note that we can replace the Weak Savitch Hypothesis with the Strong Savitch Hypothesis in these proofs. They will in fact make the statements stronger. If the Strong Savitch Hypothesis is true then k-cycle in undirected graphs cannot be solved in $O(\text{poly}\lg(n))$ space and $n^{o(\lg k)}$ time.

5.2 Even Cycle Lower Bounds From Max-CSP

Previous work [10] has connected efficiently detecting directed k-cycles in sparse graphs with solving the Max-L-SAT problem [10]. In fact, this work connects directed k-cycle detection to Max-L-CSP problems, where every clause is representable by a L degree Boolean polynomial. In this section we will limit our focus to the Max-3-SAT and Max-L-SAT problems.

If, for some particular constant L, one believes that the Max-L-SAT problem requires $2^{n(1-o(1))}$ time, then from this we get a super linear lower bound for constant length even cycle. In fact, we get a super linear lower bound for constant length undirected even cycle in sparse graphs where $m = O(n)$. Such a super linear linear lower bound for undirected even cycle has not previously been obtained.

Our reduction provides a lower bound for sparse undirected even cycle from assumptions made about difficult exponential time Constraint Satisfaction Problems (CSPs). Notably, we are able to provide super linear lower bounds for even cycles from assumptions stated in the paper of Lincoln, Vassilevska Williams and Williams [10].

▶ **Theorem 13** (Sparse Directed k-Cycle is Hard [10])**.** *If directed k-cycle, for any large enough k, can be solved in a graph G in time $O(m^{c_k-\epsilon})$, where $c_k = k/(k - \lceil k/3 \rceil + 1)$ then max-3-SAT can be solved in time $O^*(2^{(1-\epsilon')n})$.*

Using our reduction and the above theorem we can provide a lower bound for undirected sparse cycle.

▶ **Reminder of Theorem 5.** *If undirected $2k$-cycle, for any large enough constant k can be solved in a graph G with $m = O(n)$ in time $O(m^{1.5-\epsilon})$ then max-3-SAT can be solved in time $O^*(2^{(1-\epsilon')n})$.*

Proof. By applying Theorem 9 we transform an input graph into one that has $m = O(n)$. Furthermore, it shows that if undirected $2k$-cycle, for all constant k, can be solved in time $O(m^{1.5-\epsilon})$ then, there exists an infinite sequence of increasing odd cycle lengths solved in time $O(m^{1.5-\epsilon})$.

Given an infinite increasing sequence of odd cycle lengths they solve the same length of directed cycle. Then, there exists some $k \geq \frac{1}{\epsilon}3 \geq \frac{1}{\epsilon}\frac{9}{4}$ which, if solved in $O(m^{1.5-\epsilon})$ time is solved faster than $O(m^{c_k-\epsilon})$, where $c_k = k/(k - \lceil k/3 \rceil + 1)$ time.

Thus, undirected even cycle can not be solved in time $O(m^{1.5-\epsilon})$ ◀

We can give a more precise result due to our reduction's tight relationship between $k' = \lg^{O(1)}(k)k$. Note that $2k$-cycle can be reduced to k'-cycle where $k' = \Theta(2k/\lg^{O(1)}(2k))$ then. Given this $2k$-cycle requires $\Omega(m^{c_{k'}-o(1)})$, where $c_{k'} = k'/(k' - \lceil k'/3 \rceil + 1)$. Thus we have that $2k$- cycle requires at least $\Omega(n^{1.5-O(\lg^{O(1)}(k)/k)})$ time.

We would like to note that no super-linear hardness was known for even cycles prior to this. And, here, we have connected the hardness of even cycles to that of Max-3-SAT.

We would further like to note that we can combine our reduction with the more general result of [10], which gets super linear hardness for directed cycle from Max-L-SAT. Max-L-SAT is more believably $2^{n-o(n)}$ hard the larger L is. From Max-L-SAT we continue to show super-linear hardness for undirected $2k$-cycle problems. However, instead of showing $O(m^{1.5-O(1)})$ hardness the result is instead $O(m^{\frac{L}{L-1}-o(1)})$ hardness.

5.3 Combinatorial Even Cycle Lower Bounds From the Combinatorial K-Clique Conjecture

Abboud, Backurs and, Vassilevska Williams present the Combinatorial k-Clique Hypothesis (CKCH) [1]. First, what is a *combinatorial* algorithm? In her survey Vassilevska Williams defines it as follows: *"The desire for more practical algorithms motivates the notion of "combinatorial" algorithms. This notion is not well-defined, however it roughly means that the runtime should have a small constant in the big-O, and that the algorithm is feasibly implementable.[16]"* Generally, combinatorial assumptions assume that matrix multiplication requires $n^{3-o(1)}$ time, that is there is no fast matrix multiplication allowed. Given this context, we now re-produce the Combinatorial k-Clique Hypothesis from [1].

▶ **Definition 14** (Combinatorial k-Clique Hypothesis [1])**.** *Let C be the smallest constant such that a* combinatorial *algorithm running in $O(n^{Ck/3})$ time exists for detecting a k-clique in a n node $O(n^2)$ edge graph, for all sufficiently large constants k.*

The Combinatorial k-Clique Hypothesis states that $C = 3$[1]*.*

More informally, no $O(n^{k(1-\epsilon)})$ *combinatorial* algorithm exists for the k-clique problem.

We can once again use the k-clique to k-cycle reduction of Lincoln, Vassilevska Williams and Williams [10]. Their reduction is itself combinatorial.

[1] See the discussion on page 2 of Abboud, Backurs and, Vassilevska Williams [1]. For a short formal statement see Hypothesis 1.3 in Lincoln, Vassilevska Williams and Williams [10].

▶ **Theorem 15** (Combinatorial Sparse k-Cycle Lower Bound [10]). *Detecting a directed odd k-cycle in a graph with n nodes and $m = n^{(k+1)/(k-1)}$ in time $O((nm)^{(1-\epsilon)}) = O(m^{(1-\epsilon)2k/(k+1)}) = O(n^{(1-\epsilon)2k/(k-1)})$ for any constant $\epsilon > 0$ violates the Combinatorial k-Clique Hypothesis* [2].

▶ **Corollary 16.** *Detecting a directed k-cycle in a graph with n nodes and $m = n^{k/(k-2)}$ in time $O(nm^{(1-\epsilon)}) = O(m^{(2k-2)/k})$ for any constant $\epsilon > 0$ violates the Combinatorial k-Clique Hypothesis.*

Proof. There is an immediate reduction from directed k-cycle to directed $k+1$-cycle that adds $O(n)$ edges to the graph to get a lower bound for even k. For odd k we have a better lower bound. ◀

Recall that Dahlgaard et al. have an algorithm for even $2k$-cycle detection that runs in $\tilde{O}\left(m^{2k/(k+1)}\right)$ time [5]. We will show that this algorithm is optimal for even $k > 3$ that are twice an odd number. That is, the half of even numbers represented by $4k+2$ for integer $k \geq 1$.

▶ **Theorem 17.** *Let $2k = (4k'+2)$ for some constant integer k'.*
Detecting $2k$-cycles combinatorially requires time $m^{(1-o_k(1))2k/(k+1)}$ if the Combinatorial k-Clique Hypothesis is true.

Proof. We will start with Theorem 15. Note that $2k'+1$ is odd. Take the directed instance and use color coding to produce a $2k'+1$-partite undirected instance. Furthermore, this graph is a $2k'+1$-cycle graph. That is, partition $P_{(i)}$ only has edges to partitions $P_{(i-1 \mod (k'+1))}$ and $P_{(i+1 \mod (2k'+1))}$.

To solve an undirected odd $2k'+1$-cycle problem in a $2k'+1$-cycle graph we will create an instance of $4k'+2$-cycle by replacing every edge (u, v) with a node, x_{uv} and two edges $(u, x_{u,v})$ and $(x_{u,v}, v)$.

Any $4k'+2$-cycle in this new graph with contain $2k'+1$ x_{uv} type nodes. In fact these x_{uv} type nodes will be every other node. If an x_{uv} type node is in a cycle so are u and v. So, a $4k'+2$ length path will look like $v_1, x_{v_1v_2}, v_2, x_{v_2v_3}, v_3 \ldots, v_{2k'}, x_{v_{2k'}v_{2k'+1}}, v_{2k'+1}$. The existence of a $4k'+2$ length path in our new graph corresponds exactly to there being a $2k'+1$ length path in the original graph.

Theorem 15 tells us that there is a $m^{(4k'+2)/(2k'+2)-o(1)}$ combinatorial lower bound if Combinatorial k-Clique Hypothesis is true. In our new graph m has grown by a factor of only two. If we plug in $2k = 4k'+2$ we get the desired lower bound of $m^{2k/(k+1)-o(1)}$ from Combinatorial k-Clique Hypothesis. ◀

The above result works for specific even cycles i.e. when $2k = 4k'+2$, next we prove a lower bound which holds for $2k$ cycles for all large enough k.

▶ **Corollary 18.** *If there exists a constant $\epsilon > 0$ such that for some $k > \frac{2}{\epsilon}$ directed k-cycle can be detected in $O(m^{2-\epsilon})$ time using a combinatorial algorithm then the Combinatorial k-Clique Hypothesis is violated.*

Proof. For $k > \frac{2}{\epsilon}$, $m^{2-\epsilon} = O(m^{(2k-2)/(k)(1-\delta)})$ for some constant δ. So, by Corollary 16 such an algorithm would violate the Combinatorial k-Clique Hypothesis. ◀

[2] See the discussion after Hypothesis 1.3 in the introduction of Lincoln, Vassilevska Williams and Williams [10].

▶ **Theorem 19.** *Assume the Combinatorial k-Clique Hypothesis. Then, for all constant $\epsilon > 0$ there exits a k_0 such that for all $k \geq k_0$ even $2k$-cycles in an undirected graph with n nodes and $m = O(n)$ edges requires $\Omega(m^{2-\epsilon})$ time.*

Proof. By Theorem 9 there exits a $k' \geq k/(\lg^{O(1)} k)$ such that if directed k' cycle requires $\Omega(m^{2-\epsilon})$ then so does undirected $2k$ cycle on a graph with $O(m)$ vertices and $O(m)$ edges.

As long as $k' = k/(\lg^{O(1)} k) > 2/\epsilon$ we know that directed k' cycle is $\Omega(m^{2-\epsilon})$ hard. As for a large enough k, $k/(\lg^{O(1)} k) > 2/\epsilon$ we have that for large enough k undirected $2k$ cycle on graphs with $m = O(n)$ requires $\Omega(m^{2-\epsilon})$ time. ◀

Note that for all constant k there exist $O(n^2)$ combinatorial algorithms for undirected $2k$-cycle [17]. So, this suggests that these algorithms are optimal, for *combinatorial* algorithms for all large enough k.

6 Conclusion

We present a faster algorithm for small space cycle detection. We also present lower bounds for the efficiency of k-cycle in this small space regime. We show the running time of odd as well as even k-cycle must grow as $n^{\Omega(\lg(k))}$ when given only $O(\lg^2(n))$ space.

There are many future directions of research. We leave open several algorithms questions as well as questions about lower bounds.

While we get tight upper and lower bounds in the regime we consider, there are many open questions about k-cycle outside of this regime. What is the space-time trade-off for these k-cycle algorithms when the space available is polynomial in n? For example, how efficient are algorithms when given $n^{1/8}$ space? Additionally, our results apply to large constant k, but do not imply statements for specific fixed k. What are the fastest small space algorithms for $k = 3, 4, 5 \ldots$? Finally, our results are not very *fine-grained*, we are agnostic to the specific constants in the exponents of these algorithms. So, what is the specific constant? Can k-cycle algorithms be solved in small space in $n^{\lg(k)/2}$ time? $n^{\lg(k)/100}$ time?

We also leave open related algorithmic questions about s t connectivity in small space. We present a s t connectivity algorithm in small space which runs in $n^{\lg(n)/2}$ expected time. Can a deterministic algorithm have the same running time? What are the fastest randomized and deterministic algorithms for the s t connectivity problem?

We leave open lower bounds questions as well. Can we find matching, or at least non-trivial, lower bounds for k-cycle algorithms in small polynomial space. Relatedly, we get combinatorial lower bounds for even cycle in arbitrary space. Can one find tight *non-combinatorial* lower bounds for even cycle in arbitrary space?

A Basic Lemmas for the Paper

The ideas in various lemmas below are not novel. These are just important working lemmas for the rest of the paper. We cite lemmas we use directly. For those lemmas that are variations on previous work we attempt to reference where the ideas came from.

We will be using color coding to simplify many proofs. To see an example of the output graphs from color coding look at Figure 3.

▶ **Lemma 20** (Color Coding [3]). *Let E be the edge set of the graph G. Given a graph G one can produce $c = \lg(n)^{k^2}$ graphs $G_1, \ldots, G_c$ in $\tilde{O}(|E|)$ time such that:*

- *each graph has k partitions $P_1, \ldots, P_k$ and edges exist only between P_i and $P_{i+1 \mod k}$,*
- *each graph G_i has at most $|E|$ edges and $|V|$ vertices,*
- *if and only if G contains a k-cycle, at least one of the graphs G_i will contains a k-cycle,*
- *and finally if G contains a k-cycle in at least one of the graphs G_i the k cycle will have one node from every partition.*

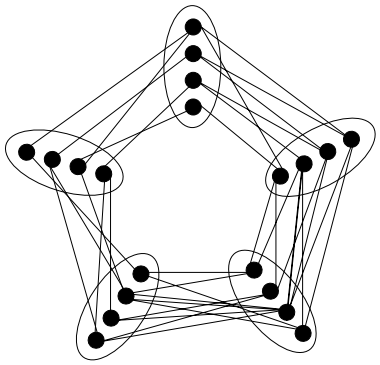

Figure 3 An example of the output of color coding with five colors. There are five partitions and the partions are themselves in a cycle.

▶ **Lemma 21.** *An algorithm exists to detect if a directed k-cycle exists using the edge (s,t) in a graph G with n nodes and $O(n^2)$ edges in time $n^{O(\lg(k))}$ using space $O(\lg(k)\lg(n))$.*

Proof. If a non-colorful cycle we start by using the color coding Lemma 20, to produce graphs with k partitions such that our k-cycle, if it exists, uses one node from each partition in one of these graphs. We consider only the color coded graphs where s and t are in partitions V_1 and V_k respectively. If we start with colorful k-cycle then we simply use the colors themselves for color coding.

Now, if we could detect if a k-path exists between s and t which uses one node from every partition we are done. To do this we will guess, in sequence, each of the n possible choices of nodes that could be in the middle partition. Then, we will recursively solve this same colorful path problem on both shorter paths. The running time of this algorithm is given by the following recurrence with base case $T(n,2) = n^{O(1)}$:

$$T(n,k) = n2T(n,k/2) + O(1).$$

Solving this recurrence gives us $T(n,k) = 2^{\lg(k)} n^{\lg(k)} n^{O(1)}$. When simplified we find $T(n,k) = n^{\lg(k)+o(\lg(k))} = n^{O(\lg(k))}$. This gives us the desired result.

Keeping these guesses in memory requires $\lg(n)$ bits per guess of a node and we must track $O(\lg(k))$ guesses at a time. This gives us $O(\lg(k)\lg(n))$ space. ◀

The above lemma is using the same ideas as Savitch [12].

High-Dimensional Expanders from Expanders

Abstract

We present an elementary way to transform an expander graph into a simplicial complex where all high order random walks have a constant spectral gap, i.e., they converge rapidly to the stationary distribution. As an upshot, we obtain new constructions, as well as a natural probabilistic model to sample constant degree high-dimensional expanders.

In particular, we show that given an expander graph G, adding self loops to G and taking the tensor product of the modified graph with a high-dimensional expander produces a new high-dimensional expander. Our proof of rapid mixing of high order random walks is based on the decomposable Markov chains framework introduced by [11].

1 Introduction

Expander graphs are graphs which are sparse, yet well-connected. They play important roles in applications such as the construction of pseudorandom generators and error-correcting codes [23]. Motivated by both purely theoretical questions, such as the topological overlapping problem, and applications in computer science, such as PCPs, a generalization of expansion to high dimensional complexes has recently emerged. We work with d–dimensional complexes, which not only have vertices and edges, but also hyperedges of k vertices, for any $k \leqslant d+1$. Whereas in the one-dimensional world of graphs, the properties of edge expansion, spectral

expansion and rapid mixing of random walks are equivalent, their generalization to several different characterizations of "expansion" have been developed for these high–dimensional complexes. In particular, the high-dimensional extension of spectral expansion is simple to state, and implies rapid mixing of high order walks [14] and agreement expanders [6].

We construct bounded-degree high–dimensional expanders of all constant–sized dimensions, where the high order random walks have a constant spectral gap, and thus mix rapidly. We base our HDX's from existing T-regular one-dimensional constructions, which can be sampled readily from the space of all T-regular graphs. This endows a natural distribution from which we can sample HDX's of our construction as well. After the first version of this paper was written, it was brought to our notice by a reviewer that the construction in this paper has been previously discussed in the community. Nevertheless, a contribution of our work is a rigorous analysis of the expansion properties of this construction.

One sufficient, but not necessary criterion that implies rapid mixing is *spectral*, which comes from the graph theoretic notion below.

▶ **Definition 1** (Informal). *A d–dimensional λ–spectral expander is a d–dimensional simplicial complex (i.e. a hypergraph whose faces satisfy downward closure) such that*

- *(Global Expansion) The vertices and edges (sets of two vertices) of the complex constitute a λ–spectral expander graph,*
- *(Local Expansion) For every hyperedge E of size $\leqslant d-1$ in the hypergraph, the vertices and edges in the "neighborhood" of E also constitute a λ–spectral expander. (The precise definition of "neighborhood" will be discussed later.)*

Most known constructions of bounded-degree high–dimensional spectral expanders are heavily algebraic, rather than combinatorial or randomized. In contrast, there are a wealth of different constructions for bounded-degree (one-dimensional) expander graphs [10]. Some of these are also algebraic, such as the famous LPS construction of Ramanujan graphs [19], but there are also many simple, probabilistic constructions of expanders. In particular, Friedman's Theorem says that with high probability, random d-regular graphs are excellent expanders [8].

Unfortunately, random d–dimensional hypergraphs with low degrees are not d–dimensional expander graphs. For a hypergraph with n vertices, we need a roughly $n\left(\frac{\log n}{n}\right)^{1/d}$-degree Erdos-Renyi graph to make the neighborhood of every hyperedge of size $\leqslant d-1$ to be connected with high probability. While random low degree hypergraphs are not high–dimensional expanders, our construction provides simple probabilistic high–dimensional expanders of all dimensions.

1.1 Summary of our results

Construction

We construct an H–dimensional simplicial complex $\mathcal{Q}$ on $n \cdot s$ vertices, from a graph G of n vertices and a (small) H–dimensional complete simplicial complex $\mathcal{B}$ on s vertices. To construct $\mathcal{Q}$, we replace each vertex v of G with a copy of $\mathcal{B}$ which we denote $\mathcal{B}_v$. Denote the copy of a vertex $w \in \mathcal{B}$ in $\mathcal{B}_v$ by (v, w). The faces of $\mathcal{Q}$ are chosen in the following way: for every face $\{w_1, w_2, \ldots, w_k\}$ in $\mathcal{B}$, add it $\{(v_1, w_1), (v_2, w_2), \ldots, (v_k, w_k)\}$ to the complex, where for some edge e in G, the vertices $v_1, \ldots v_k$ are each one of the endpoints of e; in particular there are 2 choices for each v_i. The main punchline of our work is that when G is a (triangle-free) expander graph, the high order random walks on $\mathcal{Q}$ mix rapidly. Specifically, we prove:

▶ **Theorem 2** (Main theorem, informal version of Theorem 35). *Suppose G is a triangle-free expander graph with two-sided spectral gap ρ. For every k such that $1 \leqslant k < H$, there is a constant C depending on k, H, s, ρ, but independent of n such that the Markov transition matrix for the up-down walk on the k-faces of $\mathcal{Q}$ has two-sided spectral gap C.*

First attempt at proving rapid mixing of high order random walks

[13], which introduced the notions of up-down and down-up random walks, and subsequent works [6, 14, 15, 1] developed and followed the "local-to-global paradigm" to prove rapid mixing of high order random walks. In particular, each of these works would:

A. Establish that all the links of a relevant simplicial complex have "small" second eigenvalue.

B. Prove or cite a statement about how rapid mixing follows from small second eigenvalues of links (such as Theorem 4).

Then, step A and step B together would imply that the up-down and down-up random walks on the simplicial complexes they cared about mixed rapidly. This immediately motivates first bounding the second eigenvalue of the links of our construction, and applying the quantitatively strongest known version of the type of theorem alluded to in step B. Thus, in Section 4 we analyze the second eigenvalue of all links of $\mathcal{Q}$ and prove:

▶ **Theorem 3** (Informal version of Theorem 37). *The two-sided spectral gap of every link in $\mathcal{Q}$ is bounded by approximately $\frac{1}{2}$.*

And the "quantitatively strongest" known "local-to-global" theorem is

▶ **Theorem 4** (Informal statement of [14, Theorem 5]). *If the second eigenvalue of every link of a simplicial complex $\mathcal{S}$ is bounded by λ, then the up-down walk on k-faces of $\mathcal{S}$, $\mathcal{S}_k^{\uparrow\downarrow}$ satisfies:*

$$\lambda_2(\mathcal{S}_k^{\uparrow\downarrow}) \leqslant \left(1 - \frac{1}{k+1}\right) + k\lambda.$$

Observe that the upper bound on the second eigenvalue of all links must be strictly less than $\frac{1}{k(k+1)}$ to conclude any meaningful bounds on the mixing time of the up-down random walk. Thus, unfortunately, Theorem 3 in conjunction with Theorem 4 fails to establish rapid mixing.

Hence, we depart from the local-to-global paradigm and draw on alternate techniques.

Decomposing Markov chains

Each k-face of $\mathcal{Q}$ is either completely contained in a *cluster* $\{(v, ?)\}$ for a single vertex v in G, or straddles two clusters corresponding to vertices connected by an edge, i.e., is contained in $\{(v, ?)\} \cup \{(u, ?)\}$. Consider performing an up-down random walk on the space of k-faces of $\mathcal{Q}$ (henceforth $\mathcal{Q}_k^{\uparrow\downarrow}$). If we record the single cluster or pair of clusters containing the k-face the random walk visits at each timestep, it would resemble:

$$\{17, 19\} \to \{17, 19\} \to \{17, 19\} \to \{17\} \to \{17\} \to \{17, 155\} \to \{17, 155\} \to \{17, 155\} \to \{155\} \to \{155, 203\} \to \{155, 203\} \to \{155, 203\} \to \{155, 203\} \to \{155, 203\} \to \{203\} \to \{6, 203\} \to \{6, 203\} \to \cdots$$

In the above illustration of a random walk, let us restrict our attention to the segment of the walk where the k-faces are all contained in, say, the pair of clusters $\{155, 203\}$. Intuitively, we expect the random walk restricted to those k-faces to mix rapidly and also exit the set

quickly by virtue of the state space being constant-sized. In particular, if we keep the random walk running for $t \approx C \log n$ steps for some large constant C, it would seem that the number of "exit events"[1] is roughly $\alpha \cdot C \log n$ for some other constant α. The sequence of "exit events" can be viewed as a random walk on the space of edges and vertices of G, and since there are *many* steps in this walk, the expansion properties of G tell us that the location of the random walk after t steps is distributed according to a relevant stationary distribution. In light of these intuitive observations of rapidly mixing in the walks within cluster pairs and also rapidly mixing in a walk on the space of cluster pairs, one would hope that the up-down walk on k-faces mixes rapidly.

This hope is indeed fulfilled and is made concrete in a framework of Jerrum et al. [11]. In their framework, there is a Markov chain M on state space Ω. They show that if Ω can be partitioned into $\Omega_1, \ldots, \Omega_\ell$ such that the chain "restricted" (for some formal notion of restricted) to each Ω_i, and an appropriately defined "macro-chain" (where each partition Ω_i is a state) each have a constant spectral gap, then the original Markov chain M has a constant spectral gap as well. Our proof of the fact that $\mathcal{Q}_k^{\uparrow\downarrow}$ has a constant spectral gap utilizes this result of [11]. This framework of decomposable Markov chains is detailed in Section 2.2.1, and the analysis of the spectral gap of the down-up random walk[2] is in Section 5.

1.2 Related Work

While high–dimensional expanders have been of relatively recent interest, already many different (non-equivalent) notions of high–dimensional expansion have emerged, for a variety of different applications.

The earliest notions of high–dimensional expansion were topological. In this vein of work, [17, 9] introduced coboundary expansion, [7] defined cosystolic expansion, and [7, 12] defined skeleton expansion. To our knowledge, most existing constructions of these types of expanders rely on the Ramanujan complex. We refer the reader to a survey by Lubotzky [18] for more details on these alternate notions of high dimensional expansion and their uses.

To describe notions of high dimensional expansion that are relevant to computer scientists, we need to first highlight a key property of (one-dimensional) expander graphs–that random walks on them mix rapidly to their stationary distribution. The notion of a random walk on graphs was generalized to simplicial complexes in the work of Kaufman and Mass [13] to the "up-down" and "down-up" random walks, whose states are k-faces of a simplicial complex. They were interested in bounded–degree simplicial complexes where the up-down random walk mixed to its stationary distribution rapidly. They then proceed to show that the known construction of Ramanujan complexes from [20] indeed satisfy this property.

A key technical insight in their work that the rapid mixing of up-down random walks follows from certain notions of *local spectral expansion*, i.e., from sufficiently good *two-sided* spectral expansion of the underlying graph of every link. A quantitative improvement between the relationship between the two-sided spectral expansion of links and rapid mixing of random walks was made in [6], and this improvement was used to construct agreement expanders based on the Ramanujan complex construction. Later, [14] showed that one-sided spectral expansion of links actually sufficed to derive rapid mixing of the up-down walk on k-faces.

---

[1] Transitions like $\{17, 19\} \to \{17\}$, $\{155\} \to \{155, 203\}$, and so on.

[2] Which is actually equivalent to proving a spectral gap on the up-down random walk but is more technically convenient. See Fact 33.

1.2.1 HDX Constructions

Although this combinatorial characterization of high–dimensional expansion is slightly weaker than some of the topological characterizations mentioned above, few constructions are known for *bounded degree* HDX's with dimension $\geqslant 2$. Most of these rely on heavy algebra. In contrast, for one-dimensional expander graphs, there are a wealth of different constructions, including ones via graph products and randomized ones. [8] states that even a random d-regular graph is an expander with high probability.

The most well-known construction of bounded-degree high–dimensional expanders are the Ramanujan complexes [20]. These require the *Bruhat-Tits building*, which is a high-dimensional generalization of an infinite regular tree. The underlying graph has degree $q^{O(d^2)}$, where q is a prime power satisfying $q \equiv 1 \pmod 4$. The links can be described by *spherical buildings*, which are complexes derived from subspaces of a vector space, and are excellent expanders.

Dinur and Kaufman showed that given any $\lambda \in (0,1)$, and any dimension d, the d–skeleton of any $d + \lceil 2/\lambda \rceil$–dimensional Ramanujan complex is a d–dimensional λ–spectral expander [6]. Here, the degree of each vertex is $(2/\lambda)^{O((d+2/\lambda)^2)}$. In other words, they "truncate" the Ramanujan complexes, throwing out all faces of size greater than some number k. Their primary motivation was to obtain agreement expanders, which find uses towards PCPs.

Recently, Kaufman and Oppenheim [15] present a construction of one–sided high–dimensional expanders, which are coset complexes of elementary matrix groups. The construction guarantees that for any $\lambda \in (0,1)$ and any dimension d, there exists a infinite family of high–dimensional expanders $\{X_i\}_{i\in\mathbb{N}}$, such that (1) every X_i are d–dimensional λ–one–sided–expander; (2) every X_i's 1-skeleton has degree at most $\Theta\left(\sqrt{\frac{(1/\lambda+d-1)^{(d+2)^2}}{2\log(1/\lambda+d-1)}}\right)$; (3) as i goes to infinity the number of vertices in X_i also goes to infinity.

Even more recently, Chapman, Linial, and Peled [5] also provided a combinatorial construction of two-dimensional expanders. They construct an infinite family of (a,b)-regular graphs, which are a-regular graphs whose links with respect to single vertices are b-regular. The primary motivation for their construction comes from the theory of PCPs. They prove an Alon-Boppana type bound on $\lambda_2(G)$ for any (a,b)-regular graph, and construct a family of graphs where this bound is tight. They also build an (a,b)-regular two-dimensional expander using any non-bipartite graph G of sufficiently high girth; they achieve a local expansion only depending on the girth, and the global expansion depending on the spectral gap of G. Like ours, their construction also resembles existing graph product constructions of one-dimensional expanders.

2 Preliminaries and Notation

2.1 Spectral Graph Theory

While we can describe our constructions combinatorially, our analysis of both the mixing times of certain walks as well as the local expansion will heavily rely on understanding graph spectra.

▶ **Definition 5.** *For an edge-weighted directed graph G on n vertices, we use* $\mathrm{Adj}(G)$ *to denote its (normalized) adjacency matrix, i.e. the matrix given by*

$$\mathrm{Adj}(G)_{(u,v)} = \frac{\mathbf{1}_{(u,v)\in E(G)} \cdot w((u,v))}{\sum_{v:(u,v)\in E(G)} w((u,v))}$$

and write its (right) eigenvalues as

$$1 = \lambda_1(G) \geqslant \lambda_2(G) \geqslant \ldots \geqslant \lambda_n(G) \geqslant -1.$$

Let $\mathsf{Spectrum}(G)$ *to indicate the set* $\{\lambda_i(G)\}$*. We write* $\mathsf{OneSidedGap}(G)$ *for the spectral gap of* G*, which is the quantity* $1 - \lambda_2(G)$*. Graphs with* $\mathsf{OneSidedGap}(G) \geqslant \mu$ *are one-sided* μ*-expanders.*

Most of the graphs we analyze achieve a stronger condition; that the second largest eigenvalue magnitude is not too large. Formally, we write $|\lambda|_i$ *for the* i*-th largest eigenvalue in absolute value. In particular,* $|\lambda|_2 = \max\{|\lambda_2|, |\lambda_n|\}$*. The absolute spectral gap of* G*, denoted* $\mathsf{TwoSidedGap}(G)$*, is the quantity* $1 - |\lambda|_2$*. Graphs with* $\mathsf{TwoSidedGap}(G) \geqslant \mu$ *are two-sided* μ*-expanders.*

▶ Remark 6. For an *undirected* weighted graph, we simply have $w((u, v)) = w((v, u))$, and use this to define the adjacency matrix the same way.

2.1.1 Graph Tensors

Our construction can roughly be described as a tensor product, defined below.

▶ **Definition 7.** *The tensor product* $G \times H$ *of two graphs* G *and* H *is given by*
1. *Vertex set* $V(G \times H) = V(G) \times V(H)$*,*
2. *Edge set* $E(G \times H) = \{((u_1, v_1), (u_2, v_2)) : (u_1, u_2) \in E(G)$ *and* $(v_1, v_2) \in E(H)\}$*.*

The adjacency matrix $\mathrm{Adj}(G \times H)$ is the tensor (Kronecker) product $\mathrm{Adj}(G) \otimes \mathrm{Adj}(H)$. Due to this structure, $\mathsf{Spectrum}(G \times H) = \{\lambda_i \mu_j : \lambda_i \in \mathsf{Spectrum}G,\ \mu_j \in \mathsf{Spectrum}(H)\}$. As 1 is the largest eigenvalue of both $\mathrm{Adj}(G)$ and $\mathrm{Adj}(H)$, it follows that both

$$\mathsf{OneSidedGap}(G \times H) = \min(1 - 1 \cdot \mu_2, 1 - \lambda_2 \cdot 1) = \min(\mathsf{OneSidedGap}(G), \mathsf{OneSidedGap}(H))$$
$$\mathsf{TwoSidedGap}(G \times H) = \min(1 - 1 \cdot |\mu|_2, 1 - |\lambda|_2 \cdot 1) = \min(\mathsf{TwoSidedGap}(G), \mathsf{TwoSidedGap}(H))$$

2.2 Markov Chains

We provide a basic overview of the Markov chain concepts used to analyze our high order walks. We refer to [16] for a detailed and thorough treatment of the fundamentals of Markov chains.

▶ **Definition 8.** *A Markov chain* $M = (\Omega, P)$ *is given by states* Ω *and a transition matrix* P *where* $P[i, j]$ *is the probability of going to state* j *from state* i*. We may also write this quantity as* $M[j \to i]$*.*

▶ Remark 9. The literature often defines $P_{i,j}$ as the probability $\mathbf{Pr}(i \to j)$, so their P is the transpose of ours. However, we work with column (right) eigenvectors to analyze the spectrum of P, while this alternate convention uses row (left) eigenvectors, so both conventions yield the same results.

▶ **Definition 10.** *We can view any Markov chain* M *as a weighted, directed graph* G*, defined by* $V(G) = \mathsf{States}(M)$*,* $E(G) \coloneqq \{(i, j) : i, j \in V(G), M[i \to j] > 0\}$*, and* $w((i, j)) = M[j \to i]$*.*

The transition matrix of M *is* $\mathrm{Adj}(G)$*, and we also refer to* $\mathsf{Spectrum}(G)$ *as the spectrum of* M*. Every adjacency matrix has* $\lambda_1 = 1$*, so transition matrix of* M *has an eigenvector* π_M *(normalized so that entries sum to* 1*) for the eigenvalue* 1*. We call* π_M *a stationary distribution of* M*.*

▶ Remark 11. We may use the term "graph" in lieu of "chain" when we want to indicate the random walk defined by the transition matrix $\mathrm{Adj}(G)$.

The next property we introduce is present for every Markov chain we analyze.

▶ **Definition 12.** *The Markov chain $M = (\Omega, P)$ is time-reversible if for any integer $k \geqslant 1$:*

$$\pi_M(x_0)M[x_0 \to x_1] \cdots M[x_{k-1} \to x_k] = \pi_M(x_k)M[x_k \to x_{k-1}] \cdots M[x_1 \to x_0]$$

Intuitively, it means that if start at the stationary distribution and run the chain for a sequence of time states, the reverse sequence has the same probability of occurring. Time reversibility helps us compute stationary distributions via the *detailed balance equations*. (This is especially helpful when there are a huge number of symmetric states.)

▶ **Fact 13.** *The Markov chain $M = (\Omega, P)$ is time-reversible if and only if it satisfies the detailed balance equations: for all $x, y \in \Omega$,*

$$\pi_M(x)M[x \to y] = \pi_M(y)M[y \to x]$$

▶ **Definition 14.** *The ε-mixing time of a Markov chain M is the smallest t such that for any distribution ν over the states of M,*

$$\|\pi_M - P^t\nu\|_1 \leqslant \varepsilon$$

where π_M is the stationary distribution of M.

▶ **Theorem 15.** *For any Markov chain M, the ε-mixing time $t_{\text{mix}}(\varepsilon)$ satisfies:*

$$t_{\text{mix}}(\varepsilon) \leqslant \log\left(\frac{1}{\varepsilon \min \pi_M}\right) \cdot \frac{1}{\mathsf{TwoSidedGap}(M)}.$$

2.2.1 Decomposing Markov Chains

Consider a finite-state time reversible Markov chain M whose structure gives rise to natural state-space partition, M can be decomposed into a number of restriction chains and a projection chain. [11] show that the spectral gap for the original chain can be lower bounded in terms of the spectral gaps for the restriction and projection chains.

We now formally define the decomposition of a Markov chain. Consider an ergodic Markov chain on finite state space Ω with transition probability $P\colon \Omega^2 \to [0,1]$. Let $\pi\colon \Omega \to [0,1]$ denote its stationary distribution, and let $\{\Omega_i\}_{i\in[m]}$ be a partition of the state space into m disjoint sets, where $[m] \coloneqq \{1, \ldots, m\}$.

The *projection chain* induced by the partition $\{\Omega_i\}$ has state space $[m]$ and transitions

$$\overline{P}(i,j) = \left(\sum_{x\in\Omega_i} \pi(x)\right)^{-1} \sum_{x\in\Omega_i y\in\Omega_j} \pi(x)P(x,y).$$

The above expression corresponds to the probability of moving from any state in Ω_i to any state in Ω_j in the original Markov chain.

For each $i \in [m]$, the *restriction chain* induced by Ω_i has state space Ω_i and transitions

$$P_i(x,y) = \begin{cases} P(x,y), & x \neq y, \\ 1 - \sum_{z\in\Omega_i\setminus\{x\}} P(x,z), & x = y. \end{cases}$$

$P_i(x,y)$ is the probability of moving from state $x \in \Omega_i$ to state y when leaving Ω_i is not allowed.

Regardless of how we define the projection and restriction chains for a time reversible Markov chain, they all inherit one useful property from the original chain.

▶ **Fact 16.** *Let $M = (\Omega, P)$ be a time-reversible Markov chain. Then, for any decomposition of M, the projection and restriction chains are also time-reversible.*

We ultimately want to study the spectral gap of random walks. Luckily, the original Markov chain's spectral gap is related to the restriction and projection chains' spectral gaps in the following way:

▶ **Theorem 17** ([11, Theorem 1])**.** *Consider a finite-state time-reversible Markov chain decomposed into a projection chain and m restriction chains as above. Define γ to be maximum probability in the Markov chain that some state leaves its partition block,*

$$\gamma \coloneqq \max_{i\in[m]} \max_{x\in\Omega_i} \sum_{y\in\Omega\setminus\Omega_i} P(x,y).$$

Suppose the projection chain satisfies a Poincaré inequality with constant $\bar{\lambda}$, and the restriction chains satisfy inequalities with uniform constant $\lambda_{\min}$. Then the original Markov chain satisfies a Poincaré inequality with constant

$$\lambda \coloneqq \min\left\{\frac{\bar{\lambda}}{3}, \frac{\bar{\lambda}\lambda_{\min}}{3\gamma+\bar{\lambda}}\right\}.$$

Recall that if λ satisfies a Poincaré inequality, it is a lower bound on the spectral gap (cf. [16]).

2.3 High-Dimensional Expanders

The generalization from expander graphs to hypergraphs (more specifically, simplicial complexes) requires great care. We now formally establish the high dimensional notions of "neighborhood", "expansion," and "random walk."

▶ **Definition 18.** *A simplicial complex $\mathcal{S}$ is specified by vertex set $V(\mathcal{S})$ and a collection $\mathcal{F}(\mathcal{S})$ of subsets of $V(\mathcal{S})$, known as faces, that satisfy the "downward closure" property: if $A \in \mathcal{F}(\mathcal{S})$ and $B \subseteq A$, then $B \in \mathcal{F}(\mathcal{S})$. Any face $S \in \mathcal{F}(\mathcal{S})$ of cardinality $(k+1)$ is called a k-face of $\mathcal{S}$. We use k-$\mathsf{faces}(\mathcal{S})$ to denote the subcollection of k-faces of $\mathcal{F}(\mathcal{S})$. We say $\mathcal{S}$ has dimension d, where $d = \max\{|F| : F \in \mathcal{F}(\mathcal{S})\} - 1$.*

▶ **Example 19.** A 1-dimensional complex $\mathcal{S}$ is a graph with vertex set $V(\mathcal{S})$ and edge set 1-$\mathsf{faces}(\mathcal{S})$.

▶ **Definition 20.** *To formally define random walks and Markov chains on a $\mathcal{S}$, we need to associate $\mathcal{S}$ with a weight function $w : \mathcal{F}(\mathcal{S}) \to \mathbb{R}_+$. We want our weight function to be balanced, meaning for $F \in k$-$\mathsf{faces}(\mathcal{S})$:*

$$w(F) = \sum_{J\in(k+1)\text{-}\mathsf{faces}(\mathcal{S}):J\supset F} w(J)$$

If we restrict ourselves to balanced w, it suffices to only define w over d-$\mathsf{faces}(\mathcal{S})$ and propagate the weights downward to the lower order faces.

▶ **Definition 21.** *The (weighted) k-skeleton of $\mathcal{S}$ is the complex with vertex set $V(\mathcal{S})$ and all faces in $\mathcal{F}(\mathcal{S})$ of cardinality at most $k+1$, with weights inherited from $\mathcal{S}$.*

▶ **Example 22.** The 1-skeleton of $\mathcal{S}$ only contains its vertices (0-faces) and edges (1-faces). It can be characterized as a graph with edge weights, so we can also compute $\mathsf{OneSidedGap}(1\text{-}\mathsf{skeleton}(\mathcal{S}))$ and $\mathsf{TwoSidedGap}(1\text{-}\mathsf{skeleton}(\mathcal{S}))$.

▶ **Definition 23.** *For $S \in k\text{-faces}(\mathcal{S})$ for $k \leqslant H-1$, we associate a particular $(H-k)$-dimensional complex known as the link of S defined below.*

$$\mathsf{link}(S) := \{T \setminus S : T \in \mathcal{F}(\mathcal{S}), S \subseteq T\}$$

If $\mathcal{S}$ was equipped with weight function w, then $\mathsf{link}(S)$ "inherits" it. We associate $\mathsf{link}(S)$ with weight function w_S given by $w_S(T) = w(S \cup T)$. If w is balanced, then w_S is also balanced. We call a $\mathsf{link}(S)$ a t-link if $|S|$ has cardinality t.

▶ **Example 24.** In a graph, the link of a vertex is simply its neighborhood.

▶ **Definition 25.** *The global expansion of $\mathcal{S}$, denoted $\mathsf{GlobalExp}(\mathcal{S})$, is the expansion of its weighted 1-skeleton.*

▶ **Definition 26.** *The local expansion of $\mathcal{S}$, denoted $\mathsf{LocalExp}(\mathcal{S})$ is*

$$\mathsf{LocalExp}(\mathcal{S}) := \min_{0 \leqslant k \leqslant H-1} \min_{S \in k\text{-faces}(\mathcal{S})} \mathsf{TwoSidedGap}(1\text{-skeleton}(\mathsf{link}(S))).$$

In words, it is equal to the expansion of the worst expanding link.

▶ **Example 27.** We use $\mathcal{K}^{(H)}_{H+2}$ to denote the *complete H-dimensional complex* on vertex set $[H+2]$, i.e., the pure H-dimensional simplicial complex obtained by making the set of $(H+1)$-faces equal to all subsets of $[H+2]$ of size $H+1$. The 1-skeleton is then a clique on $H+2$ vertices whose expansion is $1-\frac{1}{H+1}$ and the 1-skeleton of a t-link is a clique on $H+2-t$ vertices, which has expansion $1-\frac{1}{H+1-(t-1)}$. As a result, $\mathsf{TwoSidedGap}\left(\mathcal{K}^{(H)}_{H+2}\right) = \frac{1}{2}$.

▶ Remark 28. We often use $\mathrm{Adj}(\mathcal{S})$ to refer to the adjacency matrix of the 1-skeleton of $\mathcal{S}$, and we may also use $\lambda_i(\mathcal{S})$ to refer to the i-th largest eigenvalue of $\mathrm{Adj}(\mathcal{S})$.

Previously, we mentioned that there are several different notions of high dimensional expansion: some geometric or topological, some combinatorial. We now formally define high dimensional spectral expansion, which is a more combinatorial and graph theoretic notion:

▶ **Definition 29.** *$\mathcal{S}$ is a two-sided λ-local spectral expander if $\mathsf{GlobalExp}(\mathcal{S}) \geqslant \lambda$ and $\mathsf{LocalExp}(\mathcal{S}) \geqslant \lambda$.*

2.3.1 High Order Walks on Simplicial Complexes

Let $\mathcal{S}$ be a H-dimensional simplicial complex and with weight function $w : k\text{-faces}(\mathcal{S}) \to \mathbb{R}_{\geqslant 0}$ on the k-faces of $\mathcal{S}$, for $k \leqslant H$. For each $k < H$, we can define a natural (periodic) Markov chain on a state space consisting of k-faces and $(k+1)$-faces of $\mathcal{S}$.

- At a $(k+1)$-face J, there are exactly $(k+2)$ faces $F \in k\text{-faces}(\mathcal{S})$ such that $F \subset J$, due to the downward closure property. We transition from J to each k-face F with probability $\frac{1}{k+2}$.
- At a k-face F, we transition to each $(k+1)$-face J satisfying $J \supset F$ with probability $\frac{w(J)}{w(F)}$. (Note that w must be balanced for these transitions to be well-defined.)

Restricting the above chain to only odd or even time steps gives us two new random walks: one entirely on $k\text{-faces}(\mathcal{S})$ and one entirely on $(k+1)\text{-faces}(\mathcal{S})$.

▶ **Definition 30** (Down-up walk on k-faces of $\mathcal{S}$). *Let $\mathcal{S}^{\downarrow\uparrow}_{k+1}$ be the Markov chain with state space equal to k-faces$(\mathcal{S})$ and transition probabilities $\mathcal{S}_{\downarrow\uparrow}[J \to J']$ described by the process above, where there is an implicit transition down to a k-face and back up to a $(k+1)$-face. Then:*

$$\mathcal{S}_{\downarrow\uparrow}[J \to J'] = \begin{cases} \frac{1}{k+1} \sum_{F \in k\text{-faces}(\mathcal{S}): F \subset J} \frac{w(J)}{w(F)} & \text{if } J = J' \\ \frac{1}{k+1} \cdot \frac{w(J')}{w(J \cap J')} & \text{if } J \cap J' \in k\text{-faces}(\mathcal{S}) \\ 0 & \text{otherwise} \end{cases}$$

▶ **Definition 31** (Up-down walk on k-faces of $\mathcal{S}$). *Let $\mathcal{S}_{\uparrow\downarrow}$ be the Markov chain with state space equal to k-faces$(\mathcal{S})$ and transition probabilities $\mathcal{S}_{\uparrow\downarrow}[F \to F']$ described by the process above, where there is an implicit transition up to a $(k+1)$-face and back down to a k-face. Then:*

$$\mathcal{S}_{\downarrow\uparrow}[F \to F'] = \begin{cases} \frac{1}{k+1} & \text{if } F = F' \\ \frac{w(F \cup F')}{w(F)} & \text{if } F \cup F' \in (k+1)\text{-faces}(\mathcal{S}) \\ 0 & \text{otherwise} \end{cases}$$

▶ Remark 32. In the literature, we also see $\mathcal{S}^{\downarrow\uparrow}_{k+1}$ written as $\mathcal{S}^{\vee}_{k+1}$, and $\mathcal{S}^{\uparrow\downarrow}_{k}$ written as $\mathcal{S}^{\wedge}_{k}$.

We now present some facts about these high order walks without proof. We refer to [14, 1] for proofs of these facts.

▶ **Fact 33.** *The transition matrices for $\mathcal{S}^{\downarrow\uparrow}_{k+1}$ and $\mathcal{S}^{\uparrow\downarrow}_{k}$ share the same eigenvalues. The nonzero eigenvalues occur with the same multiplicity. A straightforward but important consequence of this fact is*

$$\text{Spectrum}(\mathcal{S}^{\downarrow\uparrow}_{k+1}) = \text{Spectrum}(\mathcal{S}^{\uparrow\downarrow}_{k+1})$$

▶ **Fact 34.** *The Markov chains $\mathcal{S}^{\downarrow\uparrow}_{k}$ and $\mathcal{S}^{\uparrow\downarrow}_{k}$ have the same stationary distribution on k-faces$(\mathcal{S})$, which is proportional to $w(F)$ for each $F \in k$-faces$(\mathcal{S})$. We will call this distribution $\pi_k(\cdot)$.*

For the remainder of the paper, we will assume a uniform weight function on d-faces$(\mathcal{S})$, which is useful for applications like sampling bases of a matroid [1]. When using the uniform weighting scheme, for $F \in k$-faces$(\mathcal{S})$, there is a natural interpretation of $\pi_k(F)$: the fraction of d-faces that contain F as a subface. (We also note that we will use symbolic variables to represent various weight values, and that it is straightforward to adapt our computations to cases where we have uniform weights over k-faces$(\mathcal{S})$ for any k.)

3 Local Densification of Expanders

For a graph G and H-dimensional simplicial complex $\mathcal{S}$, we give a way to combine the two to produce a bounded-degree H-dimensional complex LocalDensifier$(G, \mathcal{S})$ of constant expansion. First, construct a graph G' with

1. vertex set equal to $V(G) \times V(\mathcal{S})$, and
2. edge set equal to $\{\{(v_1, b_1), (v_2, b_2)\} : \{b_1, b_2\} \in 1\text{-faces}(\mathcal{S}), \{v_1, v_2\} \in E(G) \text{ or } v_1 = v_2\}$.

$\mathsf{LocalDensifier}(G, \mathcal{S})$ is then defined as the H-dimensional pure complex whose H-faces are all cliques on $H+1$ vertices $\{(v_1, b_1), (v_2, b_2), \ldots, (v_{H+1}, b_{H+1})\}$ such that there exists an edge $\{a, b\}$ in G for which $v_1, \ldots, v_{H+1} \in \{a, b\}$.

To describe a k-face of $\mathsf{LocalDensifier}(G, \mathcal{S})$, we may also use the ordered pair (F, f), where F is a k-face of $\mathcal{S}$, and f is a function mapping each element of F to a vertex of G. Because of the local densifier's tensor structure, $\mathsf{image}(f)$ is either a single vertex, or a pair of vertices that form an edge in G.

Linear algebraically, we can think of this graph construction as adding a self loop to each vertex of G and then taking the tensor product with the 1-skeleton of $\mathcal{S}$.

Our construction is $\mathcal{Q} := \mathsf{LocalDensifier}(G, \mathcal{B})$, where $\mathcal{B}$ is equal to $\mathcal{K}_s^{(H)}$, the H-dimensional complete complex on some constant $s \geqslant H+1$ vertices, and G is a T-regular triangle-free expander graph on n vertices. We endow $\mathcal{Q}$ with a balanced weight function w induced by setting the weights of all H-faces to 1.

As a first step to understanding this construction, we inspect the weights induced on k-faces for $k < H$. Consider a k-face $F := \{(v_1, b_1), \ldots, (v_{k+1}, b_{k+1})\}$. A short calculation reveals that if $v_1, \ldots, v_{k+1}$ are all equal, then $w(F)$ is equal to $w_{J,k} := \binom{s}{H-k} \cdot [T2^{H-k} - (T-1)]$ and otherwise, $w(F)$ is equal to $w_{I,k} := \binom{s}{H-k} \cdot [2^{H-k}]$. Henceforth, write w_J and w_I instead of $w_{J,k}$ and $w_{I,k}$ when k is understood from context.

We now list out what we prove about $\mathcal{Q}$. Most importantly, we show:

▶ **Theorem 35.** *For every $1 \leqslant k < H$, the Markov transition matrix $\mathcal{Q}_k^{\downarrow\uparrow}$ for down-up (and equivalently up-down) random walks on the k-faces satisfies:*

$$\mathsf{TwoSidedGap}\left(\mathcal{Q}_k^{\downarrow\uparrow}\right) \geqslant \frac{\mathsf{TwoSidedGap}(G)}{64T^2(k+1)^2(s-k)(2^k-1)} \ .$$

We dedicate Section 5 to proving Theorem 35.

As an immediate corollary of Theorem 35 and Theorem 15, we get that

▶ **Corollary 36.** *Let N_k denote the number of k-faces in $\mathcal{Q}$. Then the ϵ-mixing time of $\mathcal{Q}_k^{\downarrow\uparrow}$ satisfies:*

$$t(\varepsilon) \leqslant \frac{64T^2(k+1)^2(s-k)(2^k-1)}{\mathsf{TwoSidedGap}(G)} \cdot \log\left(\frac{2N_k}{\varepsilon}\right) \ .$$

We note that $N_k = \Theta(n)$.

We also derive bounds on the expansion of links of $\mathcal{Q}$. In particular, as a direct consequence of Theorem 41 and the discussion of the expansion properties of the complete complex in Example 27, we conclude:

▶ **Theorem 37.** *We can prove the following bounds on the local and global expansion of $\mathcal{Q}$:*

$$\mathsf{GlobalExp}(\mathcal{Q}) \geqslant \left[\frac{1}{2} - \frac{1}{2 \cdot (T2^H + 1)}\right] \cdot \mathsf{TwoSidedGap}(G), \text{ and}$$
$$\mathsf{LocalExp}(\mathcal{Q}) \geqslant \frac{1}{2}.$$

▶ Remark 38. Suppose $\boldsymbol{G}$ is a random T-regular (triangle-free) graph and $H \geqslant T$. Then the corresponding (random) simplicial complex $\boldsymbol{\mathcal{Q}}$, as a consequence of Friedman's Theorem [8][3], with high probability satisfies

$$\begin{aligned}\mathsf{TwoSidedGap}\left(\boldsymbol{\mathcal{Q}}_k^{\downarrow\uparrow}\right) &\geqslant \frac{T-2\sqrt{T-1}-o_n(1)}{64T^3(k+1)^2(s-k)(2^k-1)}\\ \mathsf{GlobalExp}(\mathcal{S}_{\boldsymbol{\mathcal{Q}}}) &\geqslant \frac{T-2\sqrt{T-1}-o_n(1)}{T+1}, \text{ and}\\ \mathsf{LocalExp}(\mathcal{S}) &\geqslant 1/2.\end{aligned}$$

Thus, $\boldsymbol{\mathcal{Q}}$ endows a natural distribution over simplicial complexes that gives a high-dimensional expander with high probability.

▶ Remark 39. If G is *strongly explicit*, such as an expander from [21, 3], then $\mathcal{Q}$ is also strongly explicit since the tensor product of two strongly explicit graphs is also strongly explicit.

4 Local Expansion

For this entire section, we will mainly work with the complex $\mathsf{LocalDensifier}(G,\mathcal{S})$, so when we use $\mathsf{link}(\cdot)$ without a subscript, it will be with respect to $\mathsf{LocalDensifier}(G,\mathcal{S})$. Next, fix a face $\sigma = (F,f) \in k\text{-}\mathsf{faces}(\mathsf{LocalDensifier}(G,\mathcal{S}))$. In order to study the expansion of the 1-skeleton of $\mathsf{link}(\sigma)$, we need to first compute the weights on its 1-faces.

Let $\tau = \{(v_1,b_1),(v_2,b_2)\} \in 2\text{-}\mathsf{faces}(\mathsf{link}(\sigma))$, where as before, $v_i \in V(G)$ and $b_i \in 1\text{-}\mathsf{faces}(\mathcal{S})$. There are several cases we need to consider:

1. Case 1: $|\mathsf{image}(f)| = 2$.
   Here, $w_\sigma(\tau) = w(\tau \cup \sigma)$, which is proportional to the number of H-faces (F',f') that contain $\tau \cup \sigma$. The face $\tau \cup \sigma$ already has $(k+3)$ vertices, so there are $\binom{S}{H-(k+2)}$ possibilities of F'. There are $2^{H-(k+2)}$ choices for f', since $\mathsf{image}(f')$ must equal $\mathsf{image}(f)$.
2. Case 2: $|\mathsf{image}(f)| = 1$.
   a. Case 2(a): $v_1 = v_2 \in \mathsf{image}(f)$ and $\{b_1,b_2\} \in 2\text{-}\mathsf{faces}(\mathsf{link}_{\mathcal{S}}(F))$.
      Again, there are $\binom{S}{H-(k+2)}$ possibilities for F'. Since $v_1 = v_2 \in \mathsf{image}(f)$, we will have $T \cdot [2^{H-(k+2)} - 1] + 1$ choices for f', as v_1 has T neighbors in G, and when f' is not constant on v_1, there are T choices for the other value it can take.
   b. Case 2(b): $v_1 \neq v_2$ but $(v_1,v_2) \in E(G)$, and $\{b_1,b_2\} \in 2\text{-}\mathsf{faces}(\mathsf{link}_{\mathcal{S}}(F))$.
      Again, we have $\binom{S}{H-(k+2)}$ possibilities for F, but we only have $2^{H-(k+2)}$ choices for f'; the image of f' must be $\{v_1,v_2\}$.
   c. Case 2(c): $v_1 = v_2 \notin \mathsf{image}(f)$ but $v_1 \cup \mathsf{image}(f) \in E(G)$, and $\{b_1,b_2\} \in 2\text{-}\mathsf{faces}(\mathsf{link}_{\mathcal{S}}(F))$.
      The analysis is identical to that of Case 2(b)

For simplicity, we'll assign weights to the elements of $2\text{-}\mathsf{faces}(\mathsf{LocalDensifier}(G,\mathcal{S}))$ as below:

$$w(\{(v_1,b_1),(v_2,b_2)\}) = \begin{cases} w_{S,k} := 2^{H-(k+2)} & \text{for Case 1, 2(b), and 2(c)} \\ w_{C,k} := 1 + T(2^{H-(k+2)} - 1) & \text{for Case 2(a)} \end{cases}$$

(Here, the C and S denote "center" and "satellite," whose meanings will be more natural when discussing $\mathsf{link}(\sigma)$ when $\sigma \neq \emptyset$.)

[3] Friedman's theorem says that a random T-regular graph, whp, has two-sided spectral gap $\frac{T-2\sqrt{T-1}-o_n(1)}{T}$. Additionally, random graphs are triangle-free with constant probability.

▶ Remark 40. Note that if we choose $\sigma = \emptyset$ (so $k = -1$), we simply get the weights of the 1-skeleton of $\mathsf{LocalDensifier}(G, \mathcal{S})$ itself, which will be useful for computing global expansion.

▶ **Theorem 41.** *Let G be a triangle-free T-regular graph and let $\mathcal{S}$ be a pure H-dimensional simplicial complex. Then*

$$\mathsf{GlobalExp}(\mathsf{LocalDensifier}(G, \mathcal{S})) = \min\left\{\frac{T2^{H-1}}{T2^H - (T-1)} \cdot \mathsf{TwoSidedGap}(G), \mathsf{GlobalExp}(\mathcal{S})\right\}, \text{ and}$$

$$\mathsf{LocalExp}(\mathsf{LocalDensifier}(G, \mathcal{S})) = \mathsf{TwoSidedGap}(\mathcal{S}).$$

Proof. Let $\widetilde{G}$ be the graph obtained by adding self-loops to G, with transitions

$$\widetilde{G}[i \to j] = \begin{cases} \frac{w_{C,-1}}{w_{C,-1}+Tw_{S,-1}} & \text{if } i = j \\ \frac{w_{S,-1}}{w_{C,-1}+Tw_{S,-1}} & \text{otherwise} \end{cases}$$

For large H, the self loop probabilities approach $\frac{1}{2}$, while the others approach $\frac{1}{2T}$.

First, observe that $\mathrm{Adj}(\mathsf{LocalDensifier}(G, \mathcal{S})) = \mathrm{Adj}(\widetilde{G}) \otimes \mathrm{Adj}(\mathcal{S})$. Thus,

$$\mathsf{Spectrum}(\mathsf{LocalDensifier}(G, \mathcal{S})) = \{\lambda\mu : \lambda \in \mathsf{Spectrum}(\widetilde{G}), \mu \in \mathsf{Spectrum}(\mathcal{S})\}.$$

and hence the second largest absolute eigenvalue is no more than $\max\{\lambda_1(\widetilde{G})|\lambda|_2(\mathcal{S}), \lambda_1(\mathcal{S})|\lambda|_2(\widetilde{G})\}$, which is simply equal to $\max\{|\lambda|_2(\widetilde{G}), |\lambda|_2(\mathcal{S})\}$. This implies that

$$\mathsf{GlobalExp}(\mathsf{LocalDensifier}(G, \mathcal{S})) = \min\{\mathsf{TwoSidedGap}(\widetilde{G}), \mathsf{GlobalExp}(\mathcal{S})\}.$$

By Lemma 59,

$$\begin{aligned}\mathsf{TwoSidedGap}(\widetilde{G}) &= (1 - \frac{w_{C,-1}}{w_{C,-1} + Tw_{S,-1}}) \cdot \mathsf{TwoSidedGap}(G) \\ &= \frac{T2^{H-1}}{T2^H - (T-1)} \cdot \mathsf{TwoSidedGap}(G)\end{aligned}$$

the first part of the theorem statement follows.

Next, we lower bound $\mathsf{LocalExp}(\mathsf{LocalDensifier}(G, \mathcal{S}))$. For any face S in $\mathsf{LocalDensifier}(G, \mathcal{S})$, there exists an edge $\{u, v\}$ in G such that S is contained in $\{u, v\} \times S'$ where S' is a face of $\mathcal{S}$. If S contains vertices from both $\{u\} \times S'$ and $\{v\} \times S'$, then $\mathsf{link}(S)$ is isomorphic to $\mathsf{LocalDensifier}(\mathsf{edge}, \mathsf{link}(S'))$ where edge denotes a single-edge graph.

$$\mathsf{Spectrum}(\mathsf{LocalDensifier}(\mathsf{edge}, \mathsf{link}(S'))) = \{0\} \cup \mathsf{Spectrum}(\mathsf{link}(S'))$$

and hence

$$\mathsf{TwoSidedGap}(1\text{-}\mathsf{skeleton}(\mathsf{link}(S))) = \mathsf{TwoSidedGap}(\mathcal{S}).$$

Without loss of generality, the remaining case is if S contains vertices from only $\{u\} \times S'$. In this case, $\mathsf{link}(S)$ is isomorphic to $\mathsf{LocalDensifier}(\mathsf{star}, \mathsf{link}(S'))$ where star denotes a star graph with T satellites.

$$\mathsf{Spectrum}(\mathsf{LocalDensifier}(\mathsf{star}, \mathsf{link}(S'))) = \{\lambda\mu : \lambda \in \mathsf{Spectrum}(\mathsf{link}(S')), \mu \in \mathsf{Spectrum}(M)\} \quad (1)$$

where M is star with self loops added on each vertex. We'll call the center vertex of M the "center" vertex, and we'll call the remaining vertices the "satellites."

Using $w_{C,k}$ and $w_{S,k}$ for Cases 2(a), 2(b), and 2(c) computed above, we can also find the appropriate weights for M.

$$M[i \to j] = \begin{cases} \frac{w_{C,k}}{w_{C,k} + T w_{S,k}} & \text{if } i = j,\ i \text{ is the center} \\ \frac{w_{S,k}}{w_{C,k} + T w_{S,k}} & \text{if } i \text{ is the center vertex, } j \text{ is a satellite} \\ \frac{1}{2} & \text{if } i \text{ is a satellite} \end{cases}$$

We can completely classify the eigenspaces of $\mathrm{Adj}(M)$ and determine their corresponding eigenvalues as follows.

1. The vector with value $\frac{w_{C,k}+Tw_{S,k}}{2w_{S,k}}$ on the center of the star and 1 on satellites is an eigenvector of $\mathrm{Adj}(M)$ with eigenvalue 1.
2. The $(T-1)$-dimensional subspace of vectors which are 0 on the center of the star, and whose entries sum to 0 is an eigenspace for eigenvalue $1/2$.
3. The vector with value $-T$ on the center and 1 on the satellites is an eigenvector with eigenvalue $\frac{1}{2} - \frac{w_{C,k}}{w_{C,k}+Tw_{S,k}}$. For large H, this eigenvalue approaches 0.

Since the above classification gives $T+1$ eigenvectors it is complete and it is clear that the second largest absolute eigenvalue of M_2 is bounded by $1/2$ and thus in this case as well, using (1), we can infer

$$\mathsf{TwoSidedGap}(\text{1-skeleton}(\mathsf{link}(S))) \geqslant \min\{\mathsf{TwoSidedGap}(\mathcal{S}), 1/2\}.$$

which means

$$\mathsf{LocalExp}(\mathsf{LocalDensifier}(G, \mathcal{S})) \geqslant \min\{\mathsf{TwoSidedGap}(\mathcal{S}), 1/2\}. \qquad \blacktriangleleft$$

5 Spectral Gap of High Order Walks

5.1 Offsets and Colors

We now inspect the structure of the k-faces of our construction $\mathcal{Q}$ in more detail.

▶ **Definition 42** (k-faces of $\mathcal{Q}$)**.** *The set of k-faces of $\mathcal{Q}$ is exactly equal to the set of tuples (F, f) where F is a k-face of $\mathcal{B}$ and f is a labeling of each element by endpoints of some edge $\{u, v\}$ in G. We call (F, f) t-offset if either $|\{x \in F : f(x) = u\}| = t$ or $|\{x \in F : f(x) = v\}| = t$.*

▶ Remark 43. Suppose $t \leqslant k+1-t$. Note that a $(k+1-t)$-offset state is also t-offset, but we will stick to the convention of describing such states as t-offset. For example, a $(k+1)$-offset state is also 0-offset, but we will only use the term 0-offset.

▶ **Definition 44** (Coloring of k-faces of $\mathcal{Q}$)**.** *We color a k-face (F, f) of $\mathcal{Q}$ with $\mathsf{image}(f)$. Each 0-offset face is then colored with a vertex of G and the remaining faces are each colored with an edge of G.*

In the rest of the section, we study the spectral gap of the Markov chain $\mathcal{Q}_k^{\downarrow\uparrow}$, the down-up random walk on k-faces of $\mathcal{Q}$ induced by certain special weight functions – weight functions $w : k\text{-}\mathsf{faces}(\mathcal{Q}) \to \mathbb{R}_{\geqslant 0}$ with the property that there are two values w_I and w_J such that

$$w((F, f)) = \begin{cases} w_J & \text{if } (F, f) \text{ is 0-offset} \\ w_I & \text{otherwise.} \end{cases}$$

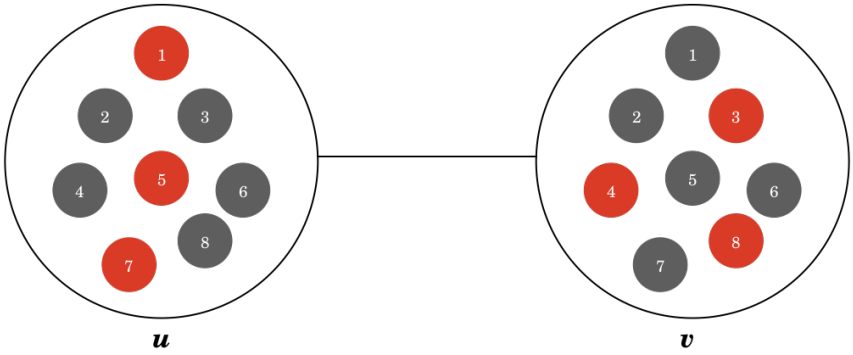

Figure 1 A 5-face in $\mathcal{Q}$. Corresponding 5-face in $\mathcal{B}$ is $\{1, 3, 4, 5, 7, 8\}$ is given by red vertices. Labeling is $(1, u), (3, v), (4, v), (5, u), (7, u), (8, v)$. $\{u, v\}$ is an edge in G. Color of 5-face is $\{u, v\}$.

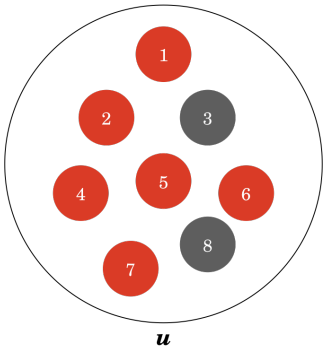

Figure 2 A 0-offset 5-face. Color of 5-face is $\{u\}$.

For instance, if we impose uniform weights on the highest dimensional faces of our complex, the propagated weights on the k-th level will satisfy the above property. The w_I and w_J values for this setup is in Appendix 1.

For the sequel, we use D to refer to the quantity $Tw_I + w_J$. The transition probabilities between states (F, f) and (F', f') depends on a number of conditions such as whether they are 0-offset or 1-offset or a different type, whether they arise from the same k-face in $\mathcal{B}$, and the colors of (F, f) and (F', f') respectively. We provide a detailed treatment of the transition probabilities $\mathcal{Q}_k^{\downarrow\uparrow}[(F, f) \to (F', f')]$ in Table 1 in Appendix A. From the transition probability table we observe that:

▶ **Observation 45.** *For all k-faces in $\mathcal{Q}_k^{\downarrow\uparrow}$, the self-loop probability is at least $\frac{1}{s-k} \cdot \frac{w_J}{D}$. Therefore, the smallest eigenvalue of $\mathcal{Q}_k^{\downarrow\uparrow}$ is at least $\frac{1}{s-k} \cdot \frac{w_J}{D} - 1$.*

5.2 High-Level Picture of $\mathcal{Q}_k^{\downarrow\uparrow}$

As noted in the previous subsection, each k-face can be described by three parameters: a base face $F \in k\text{-faces}(\mathcal{B})$, a "color" set C that is either a single vertex or an edge in $E(G)$, and a function $f : F \to C$. The walk $\mathcal{Q}_k^{\downarrow\uparrow}$ is difficult to analyze directly, but by grouping states based on these three parameters, we can decompose the walk into a projection and restriction chain, and analyze it using the tools from [11].

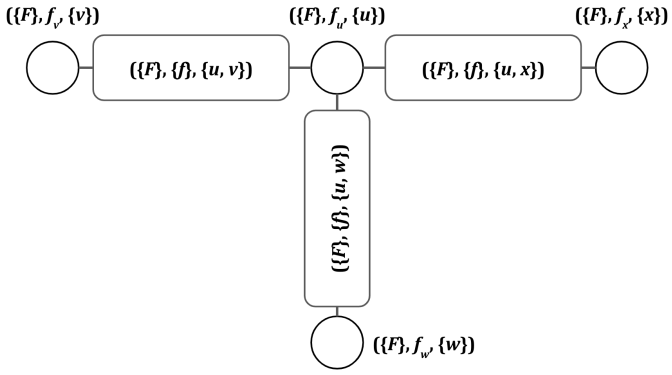

Figure 3 This figure illustrates $\mathcal{Q}_k^{\downarrow\uparrow}$, with states clustered by their color. The rounded rectangles correspond to colors that are edges, while circles correspond to colors that are single vertices. In each cluster, the $\{F\}$ indicates that all F could be represented. Similarly, $\{f\}$ indicates that any f with $\mathsf{image}(f)$ as the color set can be represented. We use f_u to denote the constant function on u.

At the outermost level, we can first group states into subchains based on their color. All subchains whose color is an edge (the rounded rectangles in Figure 3) are isomorphic to each other; similarly, all subchains whose color is a single vertex (the circles in Figure 3) are also isomorphic to each other. At first, it seems promising to partition $\mathcal{Q}_k^{\downarrow\uparrow}$ into these subchains; however, it is inconvenient that these subchains are not *all* isomorphic. To remedy this, we split the single-vertex-colored subchains into T isomorphic copies (with some changes to transition probabilities), and absorb them into the edge-colored subchains. This is detailed in the next section.

If we use this partition, the projection chain resembles a random walk on the *line graph* of G. Each restriction chain corresponds to all states of a single color C. The states are still represented by any base face $F \in k\text{-}\mathsf{faces}(\mathcal{B})$ and any function $f : F \to C$. To analyze each of these restriction chains, it is simplest to apply [11] once more.

Now, we first group states by which base face F they correspond to. The subchains derived from fixing a particular F (the rectangles in Figure 4) are all isomorphic to each other, which leads to a much simplified analysis. Using this partition, the projection chain is simply the k-down-up walk on $\mathcal{B}$. Each restriction chain is thus over states corresponding to a fixed base face F and fixed color C, but the function $f : F \to C$ is allowed to vary. At this point, we may assume $|C| = 2$; thus f corresponds to assigning every element of F one of two elements. The inner restriction chain can be modeled by a hypercube.

Thus, the spectral gap of $\mathcal{Q}_k^{\downarrow\uparrow}$ is a combination of the spectral gaps of (1) the line graph of G, (2) the k-down-up walk on $\mathcal{B}$, and (3) the random walk on a hypercube.

5.3 Splitting 0-Offset Vertices

Towards our end goal of lower bounding the spectral gap of $\mathcal{Q}_k^{\downarrow\uparrow}$, we find it convenient to analyze a related Markov chain $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$, since the related chain has a natural partition into isomorphic subchains. $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ has the property that its spectrum contains that of $\mathcal{Q}_k^{\downarrow\uparrow}$, which lets us translate a lower bound on the spectral gap of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ to a lower bound on the spectral gap of $\mathcal{Q}_k^{\downarrow\uparrow}$.

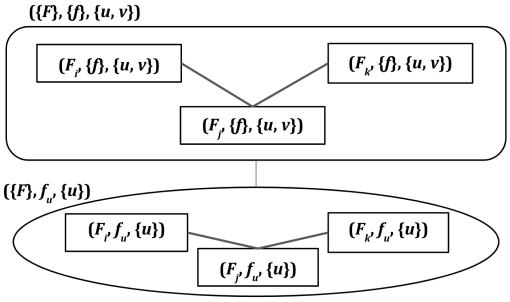

Figure 4 This figure illustrates a subchain of $\mathcal{Q}_k^{\downarrow\uparrow}$, for particular color $\{u, v\}$ and $\{u\}$. We can further cluster the states in this subchain by which face F in $\mathcal{B}$ they represent. Again, $\{f\}$ indicates that f can be any function with $\mathsf{image}(f)$ as the color.

▶ **Definition 46** (Split chain $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ and coloring of states in $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$). *We identify each state in* $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$ *with a tuple* (F, f, c) *where* (F, f) *is a face in* k-$\mathsf{faces}(\mathcal{Q})$ *and* c *is a color.*

1. *For each* 0*-offset face* (F, f) *in* k-$\mathsf{faces}(\mathcal{Q})$*, let* $\{u\}$ *be the color of* F*, and let the neighbors of* u *in* G *be* $v_1, \ldots, v_T$*.* $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$ *contains the states* $(F, f, \{u, v_1\}), \ldots, (F, f, \{u, v_T\})$ *in place of the state* (F, f, u)*.*
2. *For each remaining* k*-face* (F, f) *of* $\mathcal{Q}$ *(i.e. each* k*-face that isn't* 0*-offset),* $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$ *contains* $(F, f, \mathsf{image}(f))$*.*

For each pair of states $(F, f, c), (F', f', c')$ *in* $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$*,*

$$\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}[(F, f, c) \to (F', f', c')] = \begin{cases} \frac{\mathcal{Q}_k^{\downarrow\uparrow}[(F,f)\to(F',f')]}{T} & \text{if } (F', f') \text{ is 0-offset} \\ \mathcal{Q}_k^{\downarrow\uparrow}[(F, f) \to (F', f')] & \text{otherwise.} \end{cases}$$

Intuitively, we want to split any transition to a 0-offset face in $\mathcal{Q}$ into T separate transitions in $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$, since each 0-offset face is also split into T new states.

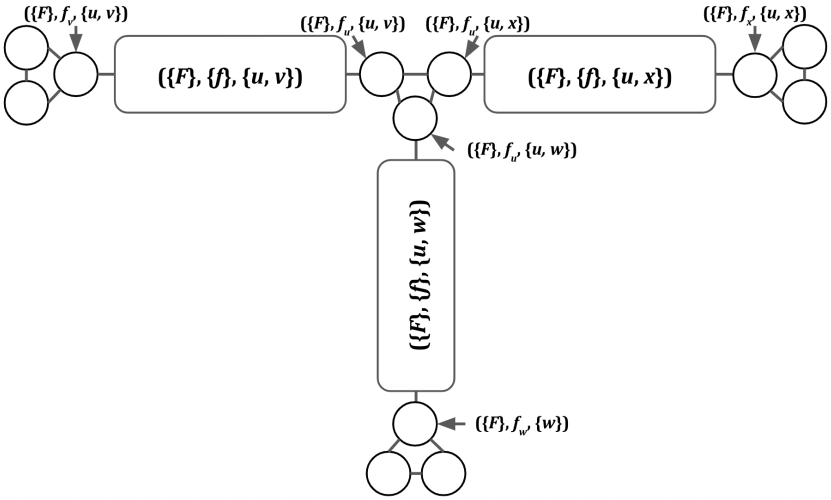

Figure 5 This figure illustrates the post-split vertices of Definition 46. The new vertices can take on any F, but their mappings f will be constant functions.

▶ **Definition 47.** *We say two* k*-faces* (F, f, e) *and* (F', f', e') *have identical base* k*-faces if* $F = F'$ *and different base* k*-faces if* $F \neq F'$*.*

▶ **Definition 48.** *Given a state (F, f, e) such that (F, f) is a 1-offset face, there is a single vertex v such that $f(v)$ is different from $f(u)$ for all u in $F \setminus \{v\}$. We call this vertex v a lonely vertex.*

In the next lemma, we show that the spectrum of the original Markov chain $\mathcal{Q}_k^{\downarrow\uparrow}$ is contained in that of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$.

▶ **Lemma 49.** $\mathrm{Spec}\left(\mathcal{Q}_k^{\downarrow\uparrow}\right) \subseteq \mathrm{Spec}\left(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}\right)$*, and therefore,* $\lambda_2(\mathcal{Q}_k^{\downarrow\uparrow}) \leqslant \lambda_2(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$.

The proof can be found in Appendix B.

5.3.1 Stationary Distribution of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$

If we want to apply the projection and restriction framework to $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$, we first need to compute its stationary distribution. To do this, we take advantage of the time-reversibility of the high order random walks, and apply the detailed balance equations. The transition probabilities in $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ are laid out in detail in Appendix A.

▶ **Lemma 50.** *The stationary distribution of the Markov chain $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ is given by:*

$$\pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(x) = \begin{cases} \dfrac{1}{|E(G)|} \cdot \dfrac{1}{\binom{s}{k+1}} \cdot \dfrac{1}{2} \cdot \dfrac{w_J}{(2^k-1)Tw_I + w_J} & \text{for } x \text{ 0-offset} \\ \dfrac{1}{|E(G)|} \cdot \dfrac{1}{\binom{s}{k+1}} \cdot \dfrac{1}{2} \cdot \dfrac{Tw_I}{(2^k-1)Tw_I + w_J} & \text{otherwise} \end{cases}$$

Proof. Via the detailed balance equations, we first observe that all vertices with the same offset have the same stationary distribution. Now, let x be any 0-offset vertex and y be any 1-offset vertex. Using the detailed balance equations, we have:

$$\pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(x) \cdot \frac{w_I}{(k+1)(s-k)D} = \pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(y) \cdot \frac{w_J}{(k+1)(s-k)DT}$$

Now, let x be any t-offset vertex, with $t \geqslant 1$, and let y be any $(t+1)$-offset vertex. Again, using the detailed balance equations:

$$\pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(x) \cdot \frac{1}{2(k+1)(s-k)} = \pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(y) \cdot \frac{1}{2(k+1)(s-k)}$$

From here, we see that all 0-offset faces have one stationary distribution probability, and all other faces also share the same stationary probability. The relations above tell us that for a 0-offset vertex x, and a t-offset vertex y with $t \geqslant 1$:

$$\frac{\pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(x)}{\pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(y)} = \frac{w_J}{Tw_I}$$

Normalizing so that $\sum_{x \in \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}} \pi_{\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}}(x) = 1$ gives the desired result. ◀

5.4 Outer Projection and Restriction Chains

Now, we can further decompose $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ into a projection chain and m isomorphic restriction chains, where $m = |E(G)|$, since we will have one partition element for each edge in G. Formally, we partition $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$ into m disjoint sets $\Omega_1 \cup \cdots \cup \Omega_m$, where $\Omega_i = \{(F, f, c) \mid c = e_i\}$.

5.4.1 The Outer Projection Chain

The partition Ω induces a projection chain $([m], P_o)$. The state space is $[m]$. The edge set is

$$E(P_o) = \{\{i,j\} \mid \exists (F,f,e_i) \in \Omega_i \text{ and } (G,g,e_j) \in \Omega_j \text{ s.t. } \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}[(F,f,e_i) \to (G,g,e_j)] > 0\}$$

In words, we have an edge between i and j if there are transitions from Ω_i to Ω_j.
We obtain the following lower bound on the spectral gap of P_o.

▶ **Lemma 51.** *The spectral gap of P_o is*

$$\frac{\mathsf{TwoSidedGap}(G)}{2} \cdot \frac{w_J + Tw_I}{w_J + (2^k-1)Tw_I} \geqslant \frac{\mathsf{TwoSidedGap}(G)}{2(2^k-1)} \ .$$

A detailed account of the transitional probabilities of the projection chain $([m], P_o)$ can be found in Appendix C.1 and the proof of the lemma can be found in Appendix C.2.

5.4.2 The Outer Restriction Chain

Each partition block Ω_i induces a restriction chain $R_{o,i}$. We show that all restriction chains $R_{o,i}$ for $i \in [m]$ are isomorphic.

▶ **Lemma 52.** *For any $i \neq j$, $i,j \in [m]$, the restriction chains $R_{o,i}$ and $R_{o,j}$ are isomorphic.*

The proof is in Appendix D.1. The transition probabilities of a restriction chain $R_{o,i}$ is deduced in Appendix D.2.

5.4.3 Stationary Distribution of $R_{o,1}$

To compute the spectral gap of $R_{o,1}$, we will further decompose the chain in the next section. In order to apply the projection and restriction framework once more to $R_{o,1}$, we must again compute a stationary distribution.

▶ **Lemma 53.** *The stationary distribution of the outer restriction chain is given by:*

$$\pi_{R_{o,1}}(x) = \begin{cases} \dfrac{1}{\binom{s}{k+1}} \cdot \dfrac{1}{2} \cdot \dfrac{w_J}{(2^k-1)Tw_I + w_J} & \text{for } x \text{ 0-offset} \\ \dfrac{1}{\binom{s}{k+1}} \cdot \dfrac{1}{2} \cdot \dfrac{Tw_I}{(2^k-1)Tw_I + w_J} & \text{otherwise} \end{cases}$$

Proof. By Fact 16, $R_{o,1}$ is also time-reversible. We proceed using the same analysis we used for Lemma 50. At the very end, we use a slightly different normalization to get the desired result. ◀

5.5 Inner Projection and Restriction Chains

Now, we are left to study the outer restriction chain, which, for a fixed $e \in E(G)$, is composed of all (F,f,e) in $\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$. Again, we further decompose this chain into projection and restriction chains which are easier to analyze.

We group all (F,f,e) with the same $F \in k\text{-}\mathsf{faces}(\mathcal{B})$ into the same restriction state space Ω_F, which induces a projection chain resembling $\mathcal{B}_{\downarrow\uparrow}$, the down-up walk on k-faces of $\mathcal{B}$, and a restriction chain resembling a lazy random walk on a $(k+1)$-dimensional hypercube.

5.5.1 The Projection Chain

By defining the projection restriction chains as above, we end up with isomorphic restriction chains for each $F \in k\text{-faces}(\mathcal{B})$. Thus, we can identify each of the states of the inner projection chain P_I with some face $F \in k\text{-faces}(\mathcal{S})$. Let $\{F_i\}$ be this partition based on face.

Given $F, F' \in k\text{-faces}(\mathcal{S})$, we can only transition from F to F' either when $F = F'$, or when $F \cap F' \in (k-1)\text{-faces}$. This coincides with the feasible transitions in $\mathcal{B}_{\downarrow\uparrow}$.

We detail the transition probabilities in $\mathcal{B}_{\downarrow\uparrow}$ in Appendix E.2 and are able to obtain the following bounds on the spectral gap of the outer projection chain:

▶ **Lemma 54.** $\mathsf{OneSidedGap}(P_I) \geqslant \dfrac{1}{2T(k+1)}$.

The proof of Lemma 54 can be found in Appendix E.3.

5.5.2 The Restriction Chain

Each restriction chain R_I can be treated as a $(k+1)$-dimensional hypercube with self loops. To see this, note that each restriction chain is a set of states (F, f, e) in $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$ where both F and e are the same. There are thus 2^{k+1} states in each restriction chain, since for each x, we have two choices for $f(x)$. Associating x where $f(x) = u$ to a 0-coordinate in a hypercube vertex, and x where $f(x) = v$ to a 1-coordinate, gives us a bijection from the restriction chain to the hypercube.

The transition probabilities are summarized in Appendix F.1, and we show:

▶ **Lemma 55.** *If we impose uniform weights on the highest order faces,*

$$\mathsf{OneSidedGap}(R_I) \geqslant \frac{w_J}{2Tw_I} \cdot \frac{2w_J}{D(k+1)(s-k)} \geqslant \frac{1}{(k+1)(s-k)} \ .$$

We defer the proof of Lemma 55 to Appendix F.2. We also give relevant background in Appendix F.3.

5.6 Rapid Mixing for High Order Random Walks

Now we put together the decomposition theorem, the lower bounds for the spectral gaps of the project and restriction chains, and Observation 45 to obtain the following lower bound on the two-sided spectral gap of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$:

▶ **Theorem 56** (Restatement of Theorem 35)**.** *The k down-up random walk $\mathcal{Q}_k^{\downarrow\uparrow}$ has one-sided spectral gap,*

$$\mathsf{TwoSidedGap}(\mathcal{Q}_k^{\downarrow\uparrow}) \geqslant \frac{\mathsf{TwoSidedGap}(G)}{64T(k+1)^2(s-k)(2^k-1)} \ . \tag{2}$$

Proof. Use $\mathsf{OneSidedGap}(M)$ to denote the spectral gap of a Markov chain M. We deduce from Lemma 49 and Theorem 17 that

$$
\begin{aligned}
&\mathsf{OneSidedGap}(\mathcal{Q}_k^{\downarrow\uparrow}) \\
&\quad \geqslant \mathsf{OneSidedGap}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}) && \text{(Lemma 49)} \\
&\quad \geqslant \min\left\{ \frac{\mathsf{OneSidedGap}(P_o)}{3}, \frac{\mathsf{OneSidedGap}(P_o)\mathsf{OneSidedGap}(R_{o,1})}{3\gamma_o + \mathsf{OneSidedGap}(P_o)} \right\} && \text{(Theorem 17 on } \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}) \\
&\quad \geqslant \min\left\{ \frac{\mathsf{OneSidedGap}(P_o)}{3}, \right. \\
&\qquad \frac{\mathsf{OneSidedGap}(P_o)}{3\gamma_o + \mathsf{OneSidedGap}(P_o)} \cdot \frac{\mathsf{OneSidedGap}(P_I)}{3}, \\
&\qquad \left. \frac{\mathsf{OneSidedGap}(P_o)}{3\gamma_o + \mathsf{OneSidedGap}(P_o)} \cdot \frac{\mathsf{OneSidedGap}(P_I)\mathsf{OneSidedGap}(R_I)}{3\gamma_I + \mathsf{OneSidedGap}(P_I)} \right\} && \text{(Theorem 17 on } R_{o,1}), \\
&\text{where}
\end{aligned}
$$

$$\gamma_o = \max_{i\in[m]} \max_{x\in\Omega_i} \sum_{y\in\Omega\setminus\Omega_i} \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}(x,y) < 1$$

$$\gamma_I = \max_{F\in k\text{-}\mathsf{faces}(\mathcal{S})} \max_{x\in V(R_I)} \sum_{y\in V(R_{o,1})\setminus V(R_I)} R_{o,1}(x,y) < 1.$$

Furthermore, Lemma 51, Lemma 54 and Lemma 55 provide lower bounds for $\mathsf{OneSidedGap}(P_o)$, $\mathsf{OneSidedGap}(P_I)$, and $\mathsf{OneSidedGap}(R_I)$. If we substitute the spectral-gap lower bounds, and an upper bound of 1 for both γ_o and γ_I, we obtain a lower bound on $\mathsf{OneSidedGap}(\mathcal{Q}_k^{\downarrow\uparrow})$:

$$\mathsf{OneSidedGap}(\mathcal{Q}_k^{\downarrow\uparrow}) \geqslant \frac{\mathsf{TwoSidedGap}(G)}{64T(k+1)^2(s-k)(2^k-1)}. \tag{3}$$

Observation 45 gives a lower bound on $1 - |\lambda_{\min}(\mathcal{Q}_k^{\downarrow\uparrow})|$ larger than the right hand side of (3), which immediately lets us upgrade the statement (3) to (2), thus proving the theorem. ◀

A Transition Probabilities of the Down-Up Walk

If we impose uniform weights at the highest order faces, then

$$w_I = 2^{H-k}$$
$$w_J = T2^{H-k} - (T-1)$$

For ease of notation, we use define another variable $D = Tw_I + w_J$, which will arise very often. Note that for the uniform weights case, w_J is only slightly smaller than Tw_I, which will help with some of our asymptotics.

Table 1 Transition Probabilities in $\mathcal{Q}_k^{\downarrow\uparrow}$.

B Spectrum of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$: Proof of Lemma 49

Given a right eigenvector v of $\mathcal{Q}_k^{\downarrow\uparrow}$ for eigenvalue λ, we exhibit a right eigenvector $\widetilde{v}$ of $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$, also for eigenvalue λ. Let

$$\widetilde{v}[(F,f,c)] = \begin{cases} \frac{v[(F,f)]}{T} & \text{if } (F,f) \text{ is 0-offset} \\ v[(F,f)] & \text{otherwise.} \end{cases}$$

We now verify that $\widetilde{v}$ is indeed a right eigenvector of $\widetilde{P}$.

$$\begin{aligned}
\widetilde{P}\widetilde{v}[(F,f,c)] &= \sum_{(F',f',c')\in\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})} \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}[(F',f',c')\to(F,f,c)]\widetilde{v}[F',f',c'] \\
&= \sum_{\substack{(F',f',c')\in\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}) \\ (F',f') \text{ 0-offset}}} \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}[(F',f',c')\to(F,f,c)]\frac{v[F',f']}{T} + \\
&\quad \sum_{\substack{(F',f',c')\in\mathsf{States}(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}) \\ (F',f') \text{ not 0-offset}}} \widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}[(F',f',c')\to(F,f,c)]v[F',f']
\end{aligned}$$

Table 2 Transition Probabilities in $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$.

		$t-1$-offset	Yes	Yes		t
			No	Yes		$t(s-(k+1))$
	majority	t-offset	Yes	Yes	$\frac{k+1-t}{k+1}\cdot\frac{1}{s-k}\cdot\frac{1}{2}$	1
			No	Yes	$\frac{1}{k+1}\cdot\frac{1}{s-k}\cdot\frac{1}{2}$	$(k+1-t)(s-(k+1))$
		$t+1$-offset	Yes	Yes		$k+1-t$
			No	Yes		$(k+1-t)(s-(k+1))$

If (F,f,c) is a 0-offset face, then the above quantity is equal to

$$\begin{aligned}
&\sum_{\substack{(F',f')\in k\text{-faces}(\mathcal{Q})\\(F',f')\ 0\text{-offset}}} \frac{\mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]}{T}\cdot\frac{v[F',f']}{T}\cdot T + \sum_{\substack{(F',f')\in k\text{-faces}(\mathcal{Q})\\(F',f')\text{ not }0\text{-offset}}} \frac{\mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]}{T}v[(F',f')]\\
&\qquad = \frac{1}{T}\sum_{(F',f')\in k\text{-faces}(\mathcal{Q})} \mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]v[(F',f')]\\
&\qquad = \frac{1}{T}\lambda v[(F,f)]\\
&\qquad = \lambda\widetilde{v}[(F,f,c)].
\end{aligned}$$

And if (F,f,c) is not a 0-offset face, then the quantity is equal to

$$\begin{aligned}
&\sum_{\substack{(F',f')\in k\text{-faces}(\mathcal{Q})\\(F',f')\ 0\text{-offset}}} \mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]\cdot\frac{v[F',f']}{T}\cdot T + \sum_{\substack{(F',f')\in k\text{-faces}(\mathcal{Q})\\(F',f')\text{ not }0\text{-offset}}} \mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]v[(F',f')]\\
&\qquad = \frac{1}{T}\sum_{(F',f')\in k\text{-faces}(\mathcal{Q})} \mathcal{Q}_k^{\downarrow\uparrow}[(F',f')\to(F,f)]v[(F',f')]\\
&\qquad = \lambda v[(F,f)]\\
&\qquad = \lambda\widetilde{v}[(F,f,c)].
\end{aligned}$$

Since for every right eigenvector v of P, we can exhibit a right eigenvector $\widetilde{v}$ of $\widetilde{P}$, we can conclude that $\mathrm{Spec}\left(\mathcal{Q}_k^{\downarrow\uparrow}\right)\subseteq\mathrm{Spec}\left(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}\right)$.

C Spectral Gap of Outer Projection Chain

C.1 Transition Probabilities of Outer Projection Chain

The table below summarizes the types of transition probabilities that occur between i and j in P_o. Each row corresponds to a specific vertex of "Source" type, and provides (1) the transition probability to a specific vertex of "Target" type (where "Same k-face" denotes a transition from (F, f) to (F, f')), and (2) the number of such transitions that occur from the source.

Source	Target	Same k-face	Probability	Count in Ω_j, $j \neq i$, $(i,j) \in E(G)$
0-offset	0-offset	Yes	$\frac{1}{s-k} \cdot \frac{w_J}{DT}$	1
		No	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$	$(k+1)(s-(k+1))$
	1-offset	Yes	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	$(k+1)$
		No	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	$(k+1)(s-(k+1))$
1-offset	0-offset	Yes	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$	1
		No	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$	$s-(k+1)$
	1-offset	Yes	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	1
		No	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	$s-(k+1)$

Using the table, Lemma 50, and the definition of projection chain from [11], the transition probabilities of P_o are:

$$P_o[i \to j] = \begin{cases} \frac{1}{2T} \cdot \frac{Tw_I + w_J}{[(2^k-1)Tw_I + w_J]}, & i \neq j, \text{ and } (i,j) \in E(P_o), \\ 1 - \left(\frac{T-1}{T}\right) \cdot \left(\frac{Tw_I + w_J}{(2^k-1)Tw_I + w_J}\right), & i = j, \\ 0 & \text{otherwise.} \end{cases}$$

C.2 Proof of Lemma 51

Due to the symmetry of the transition probabilities and the partition Ω, the spectrum of of P_o is easily computed from the spectrum of the following graph L:

- $V(L) = [m]$,
- $E(L) = \{(i,j) \in E(P_o) \mid i \neq j\}$.

▶ **Observation 57.** *L is the line graph of the base expander G.*

Proof. By definition of the partition Ω, there is a natural bijection between vertices in $V(L)$ and edges in $E(G)$. By construction, $(i,j) \in E(L)$ if and only if there exists $\{(F,f,e_i),(G,g,e_j)\} \in E(\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow})$ such that $(F,f,e_i) \in \Omega_i$ and $(G,g,e_j) \in \Omega_j$. In the chain $\widetilde{\mathcal{Q}}_k^{\downarrow\uparrow}$, two states (F,f,e_i) and (G,g,e_j) from different partition sets are connected only if they share a common endpoint in G. Thus, $\{i,j\} \in E(P_o)$ only if e_i, e_j are adjacent in G. The if direction is straightforward from the construction of P_o. So L is the line graph of G. ◀

The relationship between $\mathsf{Spectrum}(L(G))$ and $\mathsf{Spectrum}(G)$ is also well understood.

▶ **Theorem 58** ([22]). *If G is a graph of degree d with n vertices and $L(G)$ its line graph, then the characteristic polynomials $\chi(G,\lambda)$ and $\chi(L(G),\lambda)$ satisfy*

$$\chi(L(G),\lambda) = (\lambda+2)^{n(\frac{d}{2}-1)}\chi(G,\lambda+2-d).$$

Proof of Lemma 51. Using Observation 57 and Theorem 58, we relate the spectrum of L to the spectrum of G. Specifically, if λ is an eigenvalue of the normalized adjacency matrix of G, then $\frac{\lambda T+T-2}{2T-2}$ is an eigenvalue of the normalized adjacency matrix of L. From this, one can deduce that $\mathsf{TwoSidedGap}(L) = \frac{T}{2T-2} \cdot \mathsf{TwoSidedGap}(G)$.

$$P_o = \left(1 - \left(\frac{T-1}{T}\right) \cdot \frac{(w_J + Tw_I)}{(w_J + (2^k-1)Tw_I)}\right) \cdot I + \frac{T-1}{T} \cdot \frac{(w_J + Tw_I)}{w_J + (2^k-1)Tw_I} \cdot \mathrm{Adj}(L)$$

It follows that if v, λ is an eigenvector, eigenvalue pair of $\mathrm{Adj}(L)$, then

$$v, 1 - \left(\frac{T-1}{T}\right) \cdot \frac{(w_J + Tw_I)}{(w_J + (2^k-1)Tw_I)} + \lambda \cdot \frac{T-1}{T} \cdot \frac{(w_J + Tw_I)}{w_J + (2^k-1)Tw_I}$$

is an eigenvector, eigenvalue pair of P_o. Therefore,

$$\begin{aligned}\mathsf{TwoSidedGap}(P_o) &= \mathsf{TwoSidedGap}(L) \cdot \frac{T-1}{T} \cdot \frac{w_J + Tw_I}{w_J + (2^k-1)Tw_I} \\ &= \frac{\mathsf{TwoSidedGap}(G)}{2} \cdot \frac{w_J + Tw_I}{w_J + (2^k-1)Tw_I}.\end{aligned}$$

◀

D Outer Restriction Chains

D.1 Proof of Lemma 52

Let $e_i, e_j \in E(G)$ be the edges corresponding to Ω_i, Ω_j respectively. Suppose $e_i = \{u_i, v_i\}$ and $e_j = \{u_j, v_j\}$. Define a map $t_{ij} \colon e_i \to e_j$ to be $t_{ij}(u_i) = u_j, t_{ij}(v_i) = v_j$. Then $R_{o,i}$ and $R_{o,j}$ are isomorphic under the map $M_{ij} \colon \Omega_i \to \Omega_j, (F, f, e_i) \to (F, t_{ij} \circ f, e_j)$.

D.2 Transition Probabilities of Outer Restriction Chains

Since the restriction chains are isomorphic, we can focus on $R_{o,1}$ without loss of generality. Using the decomposition rule given in Section 2.2.1, we can compute the transition probabilities of $R_{o,1}$:

- For all 0-offset (F, f, e_1), the self loop probability is

  $$\frac{T-1}{T} + \frac{w_J}{DT(s-k)}.$$

  The transition probability to each of its $(k+1)(s-k-1)$ adjacent 0-offset neighbors (F', f, e_1) is

  $$\frac{w_J}{DT(k+1)(s-k)}.$$

  The transition probability to each of its $(k+1)(s-k)$ non-0-offset neighbors (F', f') is

  $$\frac{w_I}{D(k+1)(s-k)}.$$

- For all 1-offset (F, f, e_1), the self loop probability is

  $$\frac{(T-1)}{T(k+1)} + \frac{w_I}{D(k+1)(s-k)} + \frac{k}{2(k+1)(s-k)}.$$

The transition probability to each of its $(s-k)$ 0-offset neighbors (F', f') is

$$\frac{w_J}{DT(k+1)(s-k)}.$$

The transition probability to each of its k non-0-offset neighbors with identical base k-face (F, f', e_1) is

$$\frac{1}{2(k+1)(s-k)}.$$

The transition probability to each of its $(s-k-1)$ non-0-offset neighbors with a different base k-face (F', f', e_1) reached by deleting the lonely[4] vertex and adding back a different lonely vertex is

$$\frac{w_I}{D(k+1)(s-k)}.$$

The transition probability to each of its $2k(s-k-1)$ non-0-offset neighbors with a different base k-face (F', f', e_1) reached by deleting a non-lonely vertex and adding back any other vertex is

$$\frac{1}{2(k+1)(s-k)}.$$

- For the remaining (F, f, e_1), the self loop probability is

$$\frac{1}{2(s-k)}.$$

The transition probability to each of its $(k+1)$ neighbors with an identical base k-face (F, f', e_1) is

$$\frac{1}{2(k+1)(s-k)}.$$

The transition probability to each of its $2(k+1)(s-k-1)$ neighbors with a different base k-face (F', f', e_1) is also

$$\frac{1}{2(k+1)(s-k)}.$$

E Spectral Gap of Inner Projection Chain

E.1 Lazy Random Walks

Both the inner projection and the inner restriction chains have self-loops, so it will be useful to first present some preliminary results on lazy random walks. If we start with Markov chain $\widetilde{M} = (\Omega, \widetilde{P})$ and wish to add a uniform self loop probability to each state to get Markov chain $M = (\Omega, P)$, we write P as a convex combination of $\widetilde{P}$ and I:

$$P = c \cdot I + (1-c) \cdot \widetilde{P}, \text{ where } 0 \leqslant c \leqslant 1$$

Since this convex combination will appear a few different times throughout this paper, we'll prove a basic fact about the spectral gap of P:

[4] Recall that "lonely" was defined in Definition 48

▶ **Lemma 59.** *For $M = (\Omega, P)$ as defined above:*

$$\mathsf{OneSidedGap}(M) = (1-c) \cdot \mathsf{OneSidedGap}(\widetilde{M})$$

Proof. Let λ be any eigenvalue of $\widetilde{P}$, with associated eigenvector v. Then, v is also an eigenvector for P for eigenvalue:

$$c + (1-c) \cdot \lambda(M)$$

To see this, $Pv = \left[c \cdot I + (1-c) \cdot \widetilde{P}\right] v = cv + (1-c)\left(\widetilde{P}v\right) = [c + (1-c) \cdot \lambda]\, v$. The spectrum of $\widetilde{M}$ is a linear shift and scaling of the spectrum of M, and the spectral gap scales by $(1-c)$. ◀

E.2 Transition Probabilities of Outer Projection Chain

The table below indicates the transition probabilities from a specific face of "Source" type in F_i to various "Target" faces in F_j for $j \neq i$. In the last column, we count transitions to *any* F_j, rather than a specific F_j; this made our computations much easier. Due to the symmetry of the $\{F_i\}$ partition elements, to get the transition from F_i to a specific F_j, we simply divide the transition probability to $\bigcup_{j \neq i} F_j$ by the number of F_j adjacent to F_i, which is $(k+1)(s-(k+1))$.

Source	Delete	Target	Probability	Count in F_j, $j \neq i$
0-offset	anything	0-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$	1
		1-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	1
1-offset	minority	0-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$	1
		1-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$	1
	majority	1-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1
		2-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1
t-offset	minority	t-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1
		$(t-1)$-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1
	majority	t-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1
		$(t+1)$-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$	1

Using the table above, Lemma 53, and the framework of [11], the specific transition probabilities for each state in the projection chain are:

- $p := \dfrac{1}{T(k+1)(s-k)} \cdot \dfrac{[(2^k-2)T+1]Tw_I + w_J}{(2^k-1)Tw_I + w_J}$ to each of its $(k+1)(s-(k+1))$ neighbors.
- $1-(k+1)(s-(k+1))p$ for self loops, which can be verified to be nonzero.

E.3 Proof of Lemma 54

Let $\widetilde{\mathcal{B}_{\downarrow\uparrow}}$ be the non-lazy version (i.e. no self loops) of $\mathcal{B}_{\downarrow\uparrow}$. Since in our construction, $\mathcal{B}_{\downarrow\uparrow}$ is a complete complex, $w(F)$ is uniform over $F \in k$-faces, so all transitions in $\widetilde{\mathcal{B}_{\downarrow\uparrow}}$ are also uniform. To understand the spectrum of P_I, we can express the transition matrix of P_I as:

$$(k+1)(s-(k+1))p \cdot \widetilde{\mathcal{B}_{\downarrow\uparrow}} + [1-(k+1)(s-(k+1))p] \cdot \nVdash$$

Luckily, for $\mathcal{B}_{\downarrow\uparrow}$ a complete complex, the spectrum of $\widetilde{\mathcal{B}_{\downarrow\uparrow}}$ is well understood. The following can be deduced from the main theorem of [14].

▶ **Theorem 60.** $\mathsf{OneSidedGap}(\mathcal{B}_{\downarrow\uparrow}) \geqslant \dfrac{1}{(k+1)}$.

We can now compute the second largest eigenvalue of the non-lazy walk $\widetilde{\mathcal{B}_{\downarrow\uparrow}}$.

▶ **Corollary 61.** $\mathsf{OneSidedGap}(\widetilde{\mathcal{B}_{\downarrow\uparrow}}) \geqslant \dfrac{1}{(k+1)} + \dfrac{1}{(k+1)(s-k-1)}$.

Proof. Since we are working with a complete complex, all weights on sets of a given size are uniform. Thus, the self-loop probability of $\mathcal{B}_{\downarrow\uparrow}$ is $\frac{1}{s-k}$.

We can next write $\mathcal{B}_{\downarrow\uparrow} = \frac{1}{s-k} \cdot I + (1 - \frac{1}{s-k}) \cdot \widetilde{\mathcal{B}_{\downarrow\uparrow}}$. Using Lemma 59, we conclude that

$$\mathsf{OneSidedGap}(\widetilde{\mathcal{B}_{\downarrow\uparrow}}) = \frac{\mathsf{OneSidedGap}(\mathcal{B}_{\downarrow\uparrow})}{(1 - \frac{1}{s-k})}$$

We get the desired result after substituting $\frac{1}{(k+1)}$ as a lower bound for $\mathsf{OneSidedGap}(\widetilde{\mathcal{B}_{\downarrow\uparrow}})$. ◀

Proof of Lemma 54. By Lemma 59 again, we have

$$\mathsf{OneSidedGap}(P_I) = \mathsf{OneSidedGap}(\widetilde{\mathcal{B}_{\downarrow\uparrow}}) \cdot (k+1)(s-(k+1))p.$$

Substituting for p:

$$\begin{aligned}
\mathsf{OneSidedGap}(P_I) &\geqslant \left[\frac{1}{(k+1)} + \frac{1}{(k+1)(s-k-1)}\right] \cdot \left[\frac{s-k-1}{T(s-k)} \cdot \frac{[(2^k-2)T+1]Tw_I + w_J}{(2^k-1)Tw_I + w_J}\right] \\
&\geqslant \left[\frac{1}{(k+1)} + \frac{1}{(k+1)(s-k-1)}\right] \cdot \frac{1}{2T} \\
&\geqslant \frac{1}{2T(k+1)}
\end{aligned}$$

It can be verified that $\dfrac{1}{2T}$ is a lower bound on $\dfrac{s-k-1}{T(s-k)} \cdot \dfrac{[(2^k-2)T+1]Tw_I + w_J}{(2^k-1)Tw_I + w_J}$. ◀

F Spectral Gap of Inner Restriction Chain

F.1 Transition Probabilities of Inner Restriction chain

The transition probabilities can be summarized succinctly:

Source	Delete	Target	Probability
0-offset	anything	1-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_I}{D}$
1-offset	minority	0-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{w_J}{DT}$
	majority	2-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$
t-offset	minority	$(t-1)$-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$
	majority	$(t+1)$-offset	$\frac{1}{k+1} \cdot \frac{1}{s-k} \cdot \frac{1}{2}$

F.2 Proof of Lemma 55

We can also define a related chain U, that has the same state space and transitions as R, but the self loop probabilities are uniform across all vertices. More precisely:

- For *all* hypercube vertices, the self loop probability is $1 - \dfrac{w_I}{D(S-k)}$. The transition probability to each of their $(k+1)$ neighbors in the hypercube is

$$\frac{w_I}{D(k+1)(s-k)}.$$

The goal of this section is to bound on the spectral gap of R_I. Our approach relates the spectrum of R to the spectrum of U. Due to the uniformity of the self loop probabilities, the spectrum of U is easy to compute.
For ease, we will write $\widetilde{D} = 2w_J + w_I T(2^{k+1} - 2)$. The key bound on $\mathsf{OneSidedGap}(R_I)$, which we provide a proof of in Appendix F.4 is the following:

▶ **Lemma 62.**

$$\mathsf{OneSidedGap}(R_I) \geqslant \frac{w_J \widetilde{D}}{2^{k+1} \cdot (Tw_I)^2} \cdot \mathsf{OneSidedGap}(U) \geqslant \frac{w_J}{2Tw_I} \cdot \mathsf{OneSidedGap}(U) \ .$$

We are able to explicitly compute $\mathsf{OneSidedGap}(U) = \frac{2w_I}{D(k+1)(s-k)}$ (see Lemma 67). The conclusion of Lemma 55 is then immediate.

F.3 Variational Characterization of Spectral Gap

We will also use a different, variational characterization of the spectral gap of a time-reversible Markov chain (Ω, P), which will prove useful when working with self loops that have different probabilities. This characterization provides bounds on λ_2 without forcing us to analyze the chain's entire spectrum [4].

▶ **Definition 63.** *Let $M = (\Omega, P)$ be a time-reversible Markov chain. For functions $f, g : \Omega \to \mathbb{R}$, the Dirichlet form corresponding to M is:*

$$\mathcal{E}_M(f, g) = \frac{1}{2} \sum_{x \in \Omega} \sum_{y \in \Omega} \pi_M(x) M[x \to y] \cdot [f(x) - f(y)][g(x) - g(y)]$$

We may omit the subscript M when there is no ambiguity.

▶ **Definition 64.** *Again, let (Ω, P) be a time-reversible Markov chain with stationary distribution π_M. For a functions $f : \Omega \to \mathbb{R}$, the variance corresponding to M is:*

$$\mathbf{Var}_M(f) = \frac{1}{2} \sum_{x \in \Omega} \sum_{y \in \Omega} \pi_M(x) \pi_M(y) \cdot [f(x) - f(y)]^2$$

We may omit the subscript M when there is no ambiguity. This definition is equivalent to

$$\mathbf{Var}_M(f) = \mathbf{E}_{\pi_M}[f^2] - \mathbf{E}_{\pi_M}[f]^2$$

These definitions are equivalent because for X, Y i.i.d, $\mathbf{Var}(X) = \frac{1}{2}\mathbf{E}[(X - Y)^2]$.

▶ **Theorem 65.** *Let $M = (\Omega, P)$ be a time-reversible Markov Chain. Then:*

$$\mathsf{OneSidedGap}(M) = \inf \left\{ \frac{\mathcal{E}_M(f, f)}{\mathbf{Var}_M(f)} \mid f : \Omega \to \mathbb{R}, \mathbf{Var}_M(f) \neq 0 \right\}$$

Often, we will not be able to compute the exact spectral gap of a chain, but it will suffice to have a lower bound on it. We can determine whether λ is a lower bound on $\mathsf{OneSidedGap}(M)$ by checking if it satisfies the *Poincaré inequality*:

▶ **Definition 66.** *We say $\lambda \geqslant 0$ satisfies the Poincaré inequality if for all $f : \Omega \to \mathbb{R}$:*

$$\lambda \cdot \mathbf{Var}_M(f) \leqslant \mathcal{E}_M(f, f)$$

By the variational characterization of spectral gap, we would also have $\lambda \leqslant \mathsf{OneSidedGap}(M)$.

F.4 Proof of Lemma 62

▶ **Lemma 67.** *Let H be the uniform, non-lazy walk on the $(k+1)$-dim. hypercube. Then $\lambda_2(H) = \frac{2}{k+1}$.*

Proof. See [2] for a thorough treatment of Cayley graphs. The $(k+1)$-dimensional hypercube is the Cayley graph derived from the cyclic group $\mathbb{Z}_2^{k+1}$. ◀

▶ **Observation 68.** *$\lambda(U)$ is $\frac{2w_I}{D(k+1)(S-k)}$.*

Proof. Let P_H denote the transition matrix of a uniform random walk on a $(k+1)$-dimensional hypercube, with no self loops. Then, the transition matrix P_U of U can be expressed as:

$$P_U = \left(1 - \frac{w_I}{D(S-k)}\right) \cdot I + \frac{w_I}{D(S-k)} \cdot P_H$$

By Lemma 59, we have $\lambda(U) = \lambda(H) \cdot \frac{w_I}{D(S-k)}$, so we get the desired result via Lemma 67. ◀

We also observe that the stationary distribution of U, which we will call π_U, is uniform over the 2^{k+1} states. The stationary distribution of R_I, denoted π_{R_I} can also be described explicitly.

▶ **Observation 69.** *The stationary distribution π_{R_I} of chain R_I is*

$$\pi_{R_I}(x) = \begin{cases} \frac{w_J}{2w_J + w_I T(2^{k+1}-2)} & \text{if } x \in \{\vec{0}, \vec{1}\} \\ \frac{Tw_I}{2w_J + Tw_I(2^{k+1}-2)} & \text{otherwise} \end{cases}$$

Proof. By time reversibility of R_I [11], the detailed balance equations imply that for all y that are t-offset, for $t \geqslant 1$, the stationary probability $\pi_{R_I}(y)$ is the same, and $\pi_{R_I}(\vec{0}) = \pi_{R_I}(\vec{1})$.

Let x be 0-offset and y be 1-offset. Again, by time-reversibility of R_i and detailed balance:

$$\pi_{R_I}(x) \cdot \frac{w_I}{D(k+1)(S-k)} = \pi_{R_I}(y) \cdot \frac{w_J}{DT(k+1)(S-k)}$$

This tells us $\pi_{R_I}(x) = \frac{w_J}{Tw_I} \cdot \pi_{R_I}(y)$. Solving for $\sum_{x \in \{0,1\}^{k+1}} \pi_{R_I}(x) = 1$ gives the desired result. ◀

Recall that we write $\widetilde{D} = 2w_J + w_I T(2^{k+1} - 2)$.

Proof of Lemma 62. Let g be a real-valued function over the k-faces of LocalDensifier$(G, \mathcal{S})$. Using Theorem 65, it suffices to prove that for all g,

$$\frac{\mathcal{E}_{R_I}(g,g)}{\mathbf{Var}_{R_I}(g,g)} \geqslant \frac{w_J \widetilde{D}}{2^{k+1} \cdot (Tw_I)^2} \cdot \frac{\mathcal{E}_U(g,g)}{\mathbf{Var}_U(g,g)}$$

First, we compute both $\mathcal{E}_U(g,g)$ and $\mathcal{E}_R(g,g)$.

$$\begin{aligned} \mathcal{E}_U(g,g) &= \frac{1}{2} \sum_{x,y \in \{0,1\}^{(k+1)}} \pi_U(x) \cdot [g(x) - g(y)]^2 \cdot P_U(x,y) \\ &= \frac{1}{2} \cdot \frac{1}{2^{(k+1)}} \cdot \frac{w_I}{D(k+1)(S-k)} \sum_{x,y \in \{0,1\}^{(k+1)}} [g(x) - g(y)]^2 \end{aligned}$$

$$\begin{aligned}
\mathcal{E}_{R_I}(g,g) &= \frac{1}{2}\sum_{x,y\in\{0,1\}^{(k+1)}:x\in\{\vec{0},\vec{1}\}} \pi_{R_I}(x)\cdot[g(x)-g(y)]^2\cdot P_{R_I}(x,y)\\
&\quad+\frac{1}{2}\sum_{x,y\in\{0,1\}^{(k+1)}:x\notin\{\vec{0},\vec{1}\}} \pi_{R_I}(x)\cdot[g(x)-g(y)]^2\cdot P_{R_I}(x,y)\\
&= \frac{1}{2}\sum_{x,y\in\{0,1\}^{(k+1)}:x\in\{\vec{0},\vec{1}\}} \frac{w_J}{\widetilde{D}}\cdot[g(x)-g(y)]^2\cdot\frac{w_I}{D(k+1)(S-k)}\\
&\quad+\frac{1}{2}\sum_{x\in\{0,1\}^{(k+1)}:x\text{ 1-balanced}} \frac{Tw_I}{\widetilde{D}}\cdot\left(\sum_{y\in\{0,1\}^{(k+1)}:y\text{ 0-balanced}}[g(x)-g(y)]^2\cdot\frac{w_J}{DT(k+1)(S-k)}\right.\\
&\quad\left.+\sum_{y\in\{0,1\}^{(k+1)}:y\text{ not 0-balanced}}[g(x)-g(y)]^2\cdot\frac{1}{2(k+1)(S-k)}\right)\\
&\quad+\frac{1}{2}\sum_{x,y\in\{0,1\}^{(k+1)}:x,y\notin\{\vec{0},\vec{1}\}} \frac{Tw_I}{\widetilde{D}}\cdot[g(x)-g(y)]^2\cdot\frac{1}{2(k+1)(S-k)}\\
&\geqslant \frac{1}{2}\cdot\frac{w_Iw_J}{\widetilde{D}D(k+1)(S-k)}\sum_{x,y\in\{0,1\}^{(k+1)}}[g(x)-g(y)]^2
\end{aligned}$$

From the above computations, we can conclude that

$$\mathcal{E}_{R_I}(g,g)\geqslant\frac{2^{(k+1)}\cdot w_J}{\widetilde{D}}\cdot\mathcal{E}_U(g,g)$$

Similarly, we can compute both $\mathbf{Var}_U(g)$ and $\mathbf{Var}_R(g)$:

$$\begin{aligned}
\mathbf{Var}_U(g) &= \frac{1}{2}\sum_{x,y\in\{0,1\}^{k+1}}\pi_U(x)\pi_U(y)[f(x)-f(y)]^2\\
&= \frac{1}{2}\cdot\frac{1}{2^{2(k+1)}}\sum_{x,y\in\{0,1\}^{k+1}}[f(x)-f(y)]^2\\
\mathbf{Var}_{R_I}(g,g) &= \frac{1}{2}\sum_{x,y\in\{\vec{0},\vec{1}\}}\pi_{R_I}(x)\pi_{R_I}(y)[f(x)-f(y)]^2\\
&\quad+\frac{1}{2}\sum_{\substack{x\in\{\vec{0},\vec{1}\},\ y\in\{0,1\}^{k+1}\setminus\{\vec{0},\vec{1}\}\text{ or}\\ x\in\{0,1\}^{k+1}\setminus\{\vec{0},\vec{1}\},\ y\in\{\vec{0},\vec{1}\}}}\pi_{R_I}(x)\pi_{R_I}(y)[f(x)-f(y)]^2\\
&\quad+\frac{1}{2}\sum_{x,y\in\{\vec{0},\vec{1}\}}\pi_{R_I}(x)\pi_{R_I}(y)[f(x)-f(y)]^2\\
&= \frac{1}{2}\sum_{x,y\in\{\vec{0},\vec{1}\}}\frac{w_J^2}{\widetilde{D}^2}[f(x)-f(y)]^2+\frac{1}{2}\sum_{\substack{x\in\{\vec{0},\vec{1}\},\ y\in\{0,1\}^{k+1}\setminus\{\vec{0},\vec{1}\}\text{ or}\\ x\in\{0,1\}^{k+1}\setminus\{\vec{0},\vec{1}\},\ y\in\{\vec{0},\vec{1}\}}}\frac{Tw_Iw_J}{\widetilde{D}^2}[f(x)-f(y)]^2\\
&\quad+\frac{1}{2}\sum_{x,y\in\{\vec{0},\vec{1}\}}\frac{(Tw_I)^2}{\widetilde{D}^2}[f(x)-f(y)]^2\\
&\leqslant \frac{1}{2}\cdot\frac{(Tw_I)^2}{\widetilde{D}^2}\sum_{x,y\in\{0,1\}^{k+1}}[f(x)-f(y)]^2
\end{aligned}$$

From the above computations, we can conclude that

$$\mathbf{Var}_{R_I}(g)\leqslant\frac{2^{2(k+1)}\cdot(Tw_I)^2}{\widetilde{D}^2}\mathbf{Var}_U(g)$$

Combining this with what we know about $\mathcal{E}_{R_I}(g,g)$ and $\mathcal{E}_U(g,g)$, we conclude the lemma. ◀

Approximating Cumulative Pebbling Cost Is Unique Games Hard

Abstract

The cumulative pebbling complexity of a directed acyclic graph G is defined as $\mathsf{cc}(G) = \min_P \sum_i |P_i|$, where the minimum is taken over all legal (parallel) black pebblings of G and $|P_i|$ denotes the number of pebbles on the graph during round i. Intuitively, $\mathsf{cc}(G)$ captures the amortized Space-Time complexity of pebbling m copies of G in parallel. The cumulative pebbling complexity of a graph G is of particular interest in the field of cryptography as $\mathsf{cc}(G)$ is tightly related to the amortized Area-Time complexity of the Data-Independent Memory-Hard Function (iMHF) $f_{G,H}$ [7] defined using a constant indegree directed acyclic graph (DAG) G and a random oracle $H(\cdot)$. A secure iMHF should have amortized Space-Time complexity as high as possible, e.g., to deter brute-force password attacker who wants to find x such that $f_{G,H}(x) = h$. Thus, to analyze the (in)security of a candidate iMHF $f_{G,H}$, it is crucial to estimate the value $\mathsf{cc}(G)$ but currently, upper and lower bounds for leading iMHF candidates differ by several orders of magnitude. Blocki and Zhou recently showed that it is NP-Hard to compute $\mathsf{cc}(G)$, but their techniques do not even rule out an efficient $(1+\varepsilon)$-approximation algorithm for any constant $\varepsilon > 0$. We show that for *any* constant $c > 0$, it is Unique Games hard to approximate $\mathsf{cc}(G)$ to within a factor of c.

Along the way, we show the hardness of approximation of the DAG Vertex Deletion problem on DAGs of constant indegree. Namely, we show that for any $k, \varepsilon > 0$ and given a DAG G with N nodes and constant indegree, it is Unique Games hard to distinguish between the case that G is (e_1, d_1)-reducible with $e_1 = N^{1/(1+2\varepsilon)}/k$ and $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$, and the case that G is (e_2, d_2)-depth-robust with $e_2 = (1-\varepsilon)ke_1$ and $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$, which may be of independent interest. Our result generalizes a result of Svensson who proved an analogous result for DAGs with indegree $\mathcal{O}(N)$.

1 Introduction

The black pebbling game is a powerful abstraction that allows us to analyze the complexity of functions f_G with a static data-dependency graph G. In particular, a directed acyclic graph (DAG) $G = (V, E)$ can be used to encode data-dependencies between intermediate values produced during computation e.g., if L_v is the v^{th} intermediate value and $L_v := L_j \times L_i$ then the DAG G would include directed edges (i, v) and (j, v) indicating that L_v depends on the previously computed values L_i and L_j. A black pebbling of G is a sequence $P = (P_0, \ldots, P_t) \subseteq V$ of pebbling configurations. Intuitively, a pebbling configuration P_i describes the set of data labels that have been computed and stored in memory at time i. The rules of the pebbling game stipulate that we must have $\mathsf{parents}(v) = \{u \ : \ (u, v) \in E\} \subseteq P_i$ for each newly pebbled node $v \in P_{i+1} \setminus P_i$ i.e., before we can compute a new data value L_v, we must first have the labels of each dependent data value L_u available in memory.

Historically, much of the literature has focused on the sequential black pebbling game where we require that $|P_{i+1} \setminus P_i| \leq 1$ for all round i. In recent years, the parallel black pebbling game has seen renewed interest due to the rapid expansion of parallel computing, e.g., GPUs, FPGAs. In the more general parallel black pebbling game, there is no such restriction on the number of new pebbles in each round, i.e., on a parallel architecture, it is possible to determine L_v for each node $v \in P_{i+1} \setminus P_i$ simultaneously since the dependent data-values are already in memory.

There are several natural ways to measure the cost of a pebbling. The space complexity of a DAG G asks for a legal pebbling $P = (P_0, \ldots, P_t)$ that minimizes the maximum space usage $\max_{i \leq t} |P_i|$ – even if the time t is exponential in the number of nodes N. Space-time complexity asks for a legal pebbling $P = (P_0, \ldots, P_t)$ that minimizes the space-time product $t \times \max_{i \leq t} |P_i|$. Alwen and Serbinenko [7] observed that in the parallel black pebbling game, the space-time of pebbling $G^{\times m}$, m independent copies of a DAG G, does not always scale linearly with m. In particular, for some DAGs G the total space-time cost of pebbling $G^{\times m}$ is roughly equal to the space-time cost of pebbling a single instance of G for $m = \tilde{\mathcal{O}}(\sqrt{N})$!

Alwen and Serbinenko [7] introduced the notion of the cumulative pebbling cost $\mathsf{cc}(G)$ of a DAG G to model the amortized space-time costs in the parallel black pebbling game. Formally, the cumulative pebbling cost of a pebbling P is given by $\mathsf{cc}(P) = \sum_i |P_i|$ and $\mathsf{cc}(G) = \min_P \mathsf{cc}(P)$, where the minimum is taken over all legal (parallel) black pebblings of G. The cumulative pebbling cost is a fundamental metric that is worth studying. It captures the amortized space-time cost of pebbling m copies of G in parallel, i.e., in the limit we have $\mathsf{cc}(G) = \lim_{m \to \infty} \mathtt{ST}(G^{\times m})/m$ where the space-time cost of a pebbling $P = (P_1, \ldots, P_t)$ is $\mathtt{ST}(P) = t \times \max_i |P_i|$ and the notation $G^{\times m}$ denotes a new graph consisting of m disjoint copies of G.

In this paper, we address the following question:

Given a DAG G, can we (approximately) compute $\mathsf{cc}(G)$?

This is a natural question in settings where we want to evaluate the function f_G (with data-dependency DAG G) on many distinct inputs – $\mathsf{cc}(G)$ models the amortized cost of computing f_G. The question is also highly relevant to the cryptanalysis of Data-Independent Memory-Hard Functions (iMHFs). In the context of password hashing we want to find a (constant indegree) DAG G with maximum cumulative pebbling complexity, e.g., to maximize

the cost of a brute-force attacker who wants to evaluate the function f_G on every input in a password cracking dictionary. Thus, given a DAG G one might wish to lower-bound $\mathsf{cc}(G)$ before using G in the design of a memory-hard password hashing algorithm.

Cumulative Pebbling Complexity in Cryptography

In many natural contexts such as password hashing and Proofs of Work, it is desirable to lower bound the amortized space-time cost, e.g., in the random oracle model it is known that the cumulative memory complexity of a (side-channel resistant) iMHF $f_{G,H}$ is $\Omega(\mathsf{cc}(G))$, where $f_{G,H}$ is a labeling function defined in terms of the DAG G and a random oracle H [7]. Thus, in the field of cryptography there has been a lot of interest in designing constant indegree graphs with cumulative pebbling cost $\mathsf{cc}(G)$ as large as possible and in analyzing the pebbling cost $\mathsf{cc}(G)$ of candidate iMHF constructions $f_{G,H}$, e.g., see [2, 5, 3, 6, 4, 14].

From an asymptotic standpoint many of the open questions have been (nearly) resolved. Alwen and Blocki [2] showed that for any DAG G with N nodes and constant indegree we have $\mathsf{cc}(G) = \mathcal{O}\left(N^2 \log\log N/\log N\right)$, while Alwen et al. [5, 4] gave constructions with $\mathsf{cc}(G) = \Omega(N^2/\log N)$. For Argon2i, the winner of the password hashing competition, we have the upper bound $\mathsf{cc}(G) = \mathcal{O}\left(N^{1.767}\right)$ and the lower bound $\mathsf{cc}(G) = \tilde{\Omega}\left(N^{1.75}\right)$ [14].

Most of these upper/lower bounds exploited a relationship between $\mathsf{cc}(G)$ and a combinatorial property called depth-robustness. A DAG $G = (V, E)$ is (e, d)-reducible if we can find a subset $S \subseteq V$ with $|S| \leq e$ such that any directed path P in G of length d contains at least one node in S. On the other hand, if G is not (e, d)-reducible, then we say that G is (e, d)-depth robust. Depth-robustness is known to be both necessary [2] and sufficient [5] for secure iMHFs. In particular, any (e, d)-reducible DAG G with N nodes and indegree $\mathsf{indeg}(G)$ has $\mathsf{cc}(G) \leq \min_{g \geq d}\left(eN + gN \times \mathsf{indeg}(G) + \frac{N^2 d}{g}\right)$ [2] while any (e, d)-depth robust DAG G has $\mathsf{cc}(G) \geq ed$ [5]. The later observation was used to build a constant indegree graph G with $\mathsf{cc}(G) = \Omega(N^2/\log N)$ by showing that the constructed G is $(\Omega(N/\log N), \Omega(N))$-depth robust. The former observation was used to prove that any constant indegree graph has $\mathsf{cc}(G) = \mathcal{O}\left(N^2 \log\log N/\log N\right)$ by exploiting the observation that any such DAG G is $\left(\mathcal{O}\left(N \log\log N/\log N\right), \Omega(N/\log^2 N)\right)$-reducible (simply set $g = \mathcal{O}\left(N \log\log N/\log N\right)$ in the above [2] bound).

Although many of the open questions have been (nearly) resolved from an asymptotic standpoint, from a concrete security standpoint for all practical iMHF candidates G, the best known upper and lower bounds on $\mathsf{cc}(G)$ differ by several orders of magnitude. In fact, Blocki et al. [11] recently found that for practical parameter settings ($N \leq 2^{24}$), Argon2i provides better resistance to known pebbling attacks than DRSample [4] despite the fact that DRSample ($\mathsf{cc}(G) = \Omega(N^2/\log N)$) is asymptotically superior to Argon2i ($\mathsf{cc}(G) = \tilde{\Omega}\left(N^{1.75}\right)$). Of course it is certainly possible that an improved pebbling strategy for Argon2i will reverse this finding tomorrow making it difficult to provide definitive recommendations about which construction is superior in practice.

Given a DAG G, one might try to resolve these questions directly by (approximately) computing $\mathsf{cc}(G)$. Blocki and Zhou [15] previously showed that the problem of computing $\mathsf{cc}(G)$ is NP-Hard. However, their result does not even rule out the existence of a $(1+\varepsilon)$-approximation algorithm for any constant $\varepsilon > 0$.

1.1 Our Contributions

Our main result is the hardness of any constant factor approximation to the cost of graph pebbling even for DAGs with constant indegree[1].

▶ **Theorem 1.** *Given a DAG G with constant indegree, it is Unique Games hard to approximate $\mathsf{cc}(G)$ within any constant factor. (See Theorem 13.)*

Along the way to proving our main result, we show that for any constant $k > 0, \varepsilon > 0$, given a constant indegree graph G, it is Unique Games hard to distinguish between the following two cases: (1) G is (e_1, d_1)-reducible with $e_1 = N^{1/(1+2\varepsilon)}/k$ and $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$ and (2) G is (e_2, d_2)-depth-robust with $e_2 = (1-\varepsilon)ke_1$ and $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$. This intermediate result (see Corollary 8) generalizes a result of Svensson [45], who proved an analogous result for DAGs G with arbitrarily large indegree $\mathsf{indeg}(G) = \mathcal{O}(N)$.

Corollary 8 may be of independent interest as depth-robust graphs have found many other applications in cryptography including Proofs of Sequential Work [37], Proofs of Space [24], Proofs of Replication [39, 25] and (relaxed) locally correctable codes for computationally bounded channels [10, 12]. Testing the depth-robustness of a DAG G is especially relevant to the analysis of (tight) Proofs of Space/Replication – several constructions rely on (unproven) conjectures about the concrete depth-robustness of particular DAGs e.g., see [16, 25].

1.2 Technical Ingredients

To prove our result we use three technical ingredients. The first ingredient is a reduction of Svensson [45] that it is Unique Games hard to distinguish between a DAG G (with $\mathsf{indeg}(G) = \mathcal{O}(N)$) that is (e_1, d_1)-reducible or (e_2, d_2)-depth-robust. The second technical ingredient is γ-Extreme Depth-Robust Graphs [6] with bounded indegree. We use γ-Extreme Depth-Robust Graphs to modify the construction of Svensson [45] and show that the same result holds for graphs with much smaller indegree. Finally, we use low depth superconcentrators to boost the lower bound on cc to $\min\{e_2N, d_2N\}/8$ instead of e_2d_2 in the case the graph is (e_2, d_2)-depth robust. We prove that this can be done without significantly increasing the pebbling cost in the case the graph is (e_1, d_1)-reducible.

1.2.1 Technical Ingredient 1

Our first technical ingredient is a result of Svensson [45], who proved that for any constant $k > 0, \varepsilon > 0$, it is Unique Games hard to distinguish between the following two cases (1) G is (e_1, d_1)-reducible with $e_1 = N/k$ and $d_1 = k$, or (2) G is (e_2, d_2)-depth robust with $e_2 = N(1-1/k)$ and $d_2 = \Omega(N^{1-\varepsilon})$. To prove this, Svensson gave a reduction that transforms from any instance of Unique Games $\mathcal{U}$ to a directed acyclic graph $G_{\mathcal{U}}$ on N nodes such that $G_{\mathcal{U}}$ is (e_1, d_1)-reducible for $e_1 \approx N/k$ and $d = k$ if $\mathcal{U}$ is satisfiable. Otherwise, if $\mathcal{U}$ is unsatisfiable, it can be shown that $G_{\mathcal{U}}$ is (e_2, d_2)-depth robust. This is a potentially useful starting point because the pebbling complexity of a graph $G_{\mathcal{U}}$ is closely related to its depth-robustness. In particular, in the second case, a result of Alwen et al. [5] establishes that $\mathsf{cc}(G_{\mathcal{U}}) \geq e_2d_2$ and in the first case, a result of Alwen and Blocki shows that $\mathsf{cc}(G_{\mathcal{U}}) \leq \min_{g \geq d_1} \left(e_1N + gN \times \mathsf{indeg}(G_{\mathcal{U}}) + \frac{N^2 d_1}{g} \right)$ [2].

[1] Each node v in a data-dependency DAG G model an atomic unit of computation. Thus, in practice we expect G to have indegree 2 or 3. If $L_v = g(L_{v_1}, \ldots, L_{v_k})$ is a function of $k \gg 2$ previously computed values $L_{v_1}, \ldots, L_{v_k}$ then we would have generated several additional intermediate data-values while evaluating $g(\cdot)$. These data-values should have been included as nodes in G which is supposed to have a node for every intermediate data-value.

Challenges of Applying Svensson's Construction

While the pebbling complexity of $G_{\mathcal{U}}$ is related to depth-robustness, there is still a vast gap between the upper/lower bounds. In particular, in Svensson's construction we have $\mathsf{indeg}(G_{\mathcal{U}}) = \mathcal{O}(N)$, so the $gN \times \mathsf{indeg}(G_{\mathcal{U}})$ term could be as large as $gN^2 \gg e_2 d_2$. Thus, we would need to be able to reduce the indegree significantly to obtain a gap between $\mathsf{cc}(G_{\mathcal{U}})$ in the two cases. (In fact, we can show the that pebbling cost is exactly $\mathsf{cc}(G_{\mathcal{U}}) = \frac{N(L+1)}{2}$ independent of the Unique Games instance $\mathcal{U}$ – see Lemma 17 in the appendix.) We remark that a naïve attempt to reduce indegree in Svensson's construction $G_{\mathcal{U}}$ by replacing every node v (as in [5]) with a path of length $N + \mathsf{indeg}(v)$ would result in a constant indegree graph $G'_{\mathcal{U}}$ with $N' \approx 2N^2$ nodes that will not be useful for our purposes. The new graph $G'_{\mathcal{U}}$ would be (e_1, d_1)-reducible in the first case with $e_1 = N/k = \mathcal{O}\left(\sqrt{N'}/k\right)$ and $d_1 = 2kN = \mathcal{O}\left(\sqrt{N'}k\right)$. In the second case, the DAG $G'_{\mathcal{U}}$ would be (e_2, d_2)-depth robust with $e_2 \approx ke_1$ and $d_2 = \mathcal{O}\left(N'^{1-\varepsilon/2}\right)$. We would now have $\mathsf{cc}(G'_{\mathcal{U}}) \leq \min_{g \geq d_1}\left(e_1 N' + 2gN' + \frac{N'^2 d_1}{g}\right) = \omega(e_1 N')$ for our upper bound while the lower bound is at most $e_2 d_2 \approx ke_1 N'^{1-\varepsilon/2}$. At the end of the day, the graph $G_{\mathcal{U}}$ is still quite far from what we need.

1.2.2 Technical Ingredient 2: γ-Extreme Depth-Robust Graphs

It does not seem to be possible to obtain a suitable graph $G_{\mathcal{U}}$ by applying indegree reduction techniques to Svensson's Construction in a black-box manner. Instead, we open up the black-box and show how to reduce the indegree using a recent technical result of Alwen et al. [6]. A DAG $G_{\gamma,N}$ on N nodes is said to be γ-extreme depth-robust if it is (e, d)-depth robust for any $e, d > 0$ such that $e + d \leq (1-\gamma)N$. Alwen et al. [6] showed that for any constant $\gamma > 0$, there exists a family $\{G_{\gamma,N}\}_{N=1}^{\infty}$ of γ-extreme depth robust DAGs with maximum indegree $\mathcal{O}(\log N)$. While Alwen et al. [6] were not focused on outdegree, it is not too difficult to see that their construction yields a single family of DAGs with maximum indegree and outdegree $\mathcal{O}(\log N)$.

In Svensson's construction, the DAG $G_{\mathcal{U}}$ is partitioned into $L = N^{1-\varepsilon}$ symmetric layers i.e., if u_ℓ (the copy of node u in layer ℓ_1) is connected to v_{ℓ_2} (the copy of node v in layer $\ell_2 > \ell_1$) then for *any* layers $i < j \leq L$, the directed edge (u_i, v_j) exists. The fact that this edge is "copied" $\mathcal{O}\left(L^2\right)$ times for every pair of layers $i < j$ significantly increases the indegree. However, Svensson's argument that $G_{\mathcal{U}}$ is depth-robust in the second case relies on the existence of each of these edges. To reduce the indegree we start with a γ-extreme depth robust DAG $G_{\gamma,L}$ on L nodes and only keep edges between nodes u_i and v_j in layers i and j if there is a path of length ≤ 2 between nodes i and j in $G_{\gamma,L}$. The new graph can also be shown to have degree at most $\mathcal{O}\left(\mathsf{indeg}(G_L) \times \mathsf{outdeg}(G_L) \times N/L\right) = \mathcal{O}\left(N^{\varepsilon} \log^2 N\right)$. Despite the fact that the indegree is vastly reduced, we are still able to modify Svensson's argument to prove that (for a suitable constant $\gamma > 0$) our new graph is still (e_2, d_2)-depth robust with $e_2 \approx ke_1$ and $d_2 = \mathcal{O}\left(N^{1-\varepsilon}\right)$ – note that the new graph is clearly still (e_1, d_1)-reducible if $\mathcal{U}$ is satisfiable since we only remove edges from Svensson's construction.

We can then apply the generic black-box indegree reduction of [5] to reduce the indegree to 2 by replacing every node with a path of length $N^{2\varepsilon}$. This established our first technical result that even for constant indegree DAGs, it is Unique Games hard to distinguish between the following two cases: (1) G is (e_1, d_1)-reducible with $e_1 = N^{1/(1+2\varepsilon)}/k$ and $d_1 = kN^{2\varepsilon/(1+2\varepsilon)}$, and (2) G is (e_2, d_2)-depth-robust with $e_2 = (1-\varepsilon)ke_1$ and $d_2 = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$.

1.2.3 Technical Ingredient 3: Superconcentrators

Although indegree reduction is a crucial step toward showing hardness of approximation for graph pebbling complexity, we still cannot apply known results that relate (e_1, d_1)-reducibility and (e_2, d_2)-depth robustness to pebbling complexity, since there is still no gap between the pebbling complexity of the two cases. In particular, we are always stuck with the $e_1 N$ term in the upper bound of [2] which is *already* much larger than the lower bound $e_2 d_2$ from [6]. To overcome this result we rely on superconcentrators. A *superconcentrator* is a graph that connects N input nodes to N output nodes so that any subset of k inputs and k outputs are connected by k vertex disjoint paths. Moreover, the total number of edges in the graph should be $\mathcal{O}(N)$.

Blocki et al. [11] recently proved that G', the *superconcentrator overlay* of an (e, d)-depth robust graph, has pebbling cost $\mathsf{cc}(G') \geq \max\{eN, dN\}/8$, which is a significant improvement on the lower bound $\mathsf{cc}(G') \geq ed$ when $e = o(N)$ and $d = o(N)$. This allows us to increase the lower-bound in case 2, but we need to be careful that we do not significantly increase the pebbling cost in case 1. To do this we rely on the existence of superconcentrators with depth $\mathcal{O}(\log N)$ [40] and we give a significantly improved pebbling attack on the superconcentrator overlay DAG G' in case 1 when the original graph is (e_1, d_1)-reducible. With the improved pebbling attack, we are able to show that $\mathsf{cc}(G) \geq e_1 kN/16$ in case 2 and that $\mathsf{cc}(G) \leq 16 e_1 N$ in case 1. Since k is an arbitrary constant, this implies that it is Unique Games hard to approximate $\mathsf{cc}(G)$ to within any constant factor $c > 0$.

2 Related Work

Pebbling games have found a number of applications under various formulations and models (see the survey [38] for a more thorough review). The sequential black pebbling game was introduced by Hewitt and Paterson [29], and by Cook [19] and has been particularly useful in exploring space/time trade-offs for various problems like matrix multiplication [47], fast fourier transformations [43, 47], integer multiplication [46] and many others [17, 44]. In cryptography it has been used to construct/analyze Proofs of Space [24, 41], Proofs of Work [23, 37] and Memory-Hard Functions [26]. Alwen and Serbinenko [7] argued that the parallel version of the black pebbling game was more appropriate for Memory-Hard Functions and they proved that any iMHF attacker in the parallel random oracle model corresponds to a pebbling strategy with equivalent cumulative memory cost.

The space cost of the black pebbling game is defined to be $\max_i |P_i|$, which intuitively corresponds to minimizing the maximum space required during computation of the associated function. Gilbert et al. [27] studied the space-complexity of the black-pebbling game and showed that this problem is PSPACE-Complete by reducing from the truly quantified boolean formula (TQBF) problem. In our case, the decision problem is $\mathsf{cc}(G) \leq k$ is in NP because the optimal pebbling strategy cannot last for more than N^2 steps since *any* graph with N nodes has $\mathsf{cc}(G) \leq N^2$.

Red-Blue Pebbling

Given a DAG $G = (V, E)$, the goal of the red-blue pebbling game [30] is to place pebbles on all sink nodes of G (not necessarily simultaneously) from an empty starting configuration. Intuitively, red pebbles represent values in cache and blue pebbles represent values stored in memory. Blue pebbles must be converted to red pebbles (e.g., loaded into cache) before

they can be used in computation, but there is a limit m (cache-size) on the number of red-pebbles that can be used. Red-blue pebbling games have been used to study memory-bound functions [22] (functions that incur many expensive cache-misses [1]).

Ren and Devadas introduced the notion of bandwidth hard functions and used the red-blue pebbling game to analyze the energy cost of a memory hard function [42]. In their model, red-moves (representing computation performed using data in cache) have a smaller cost c_r than blue-moves c_b (representing data movements to/from memory) and a DAG G on N nodes is said to be bandwidth hard if any red-blue pebbling has cost $\Omega(N \cdot c_b)$. Ren and Devadas showed that the bit reversal graph [35], which forms the core of iMHF candidate Catena-BRG [26], is maximally bandwidth hard. Subsequently, Blocki et al. [13] gave a pebbling reduction showing that any attacker random oracle model (pROM) can indeed be viewed as a red-blue pebbling with equivalent cost. They also show that it is NP-Hard to compute the minimum cost red-blue pebbling of a DAG G i.e., the decision problem "is the red-blue pebbling cost $\leq k$?" is NP-Complete (A result of Demaine and Liu [20, 36] implies that the problem is PSPACE-Hard to compute the red-blue pebbling cost when $c_r = 0$ i.e., computation is free). In general, the red-blue cost of G is always lower bounded by $c_r N$ and upper-bounded by $2c_b N + c_r N$. The question of a more efficient c-approximation algorithm for $c = o(c_b/c_r)$ remains open.

Unique Games

Recently, the Unique Games Conjecture and related conjectures have received a lot of attention for their applications in proving hardness of approximation. Khot et al. [32] showed that the Goemans-Williamson approximation algorithm for Max-Cut [28] is optimal, assuming the Unique Games Conjecture. Khot and Regev [34] showed that Minimum Vertex Cover problem is Unique Games hard to solve within a factor of $2 - \varepsilon$, which is nearly tight from the guarantee that a simple greedy algorithm gives. The Unique Games Conjecture also leads to tighter approximation hardness for other problems including Max 2-SAT [32] and Betweenness [18]. Although a previous stronger version of the conjecture asked whether Unique Games instances required exponential time algorithms in the worst case, Arora et al. [8] gave a subexponential time algorithm for Unique Games. Lately, focus has also been drawn toward studying the related Label Cover Problem, such as the 2-Prover-1-Round Games, i.e. the 2-to-1 Games Conjecture [21] and the 2-to-2 Games Conjecture [33].

3 Preliminaries

We use the notation $[N]$ to denote the set $\{0, 1, \ldots, N-1\}$. Given a directed acyclic graph $G = (V, E)$ and a node $v \in V$, we use $\mathsf{parents}(v) = \{u : (u, v) \in E\}$ (resp. $\mathsf{children}(v) = \{u : (v, u) \in E\}$) to denote the parents (resp. children) of node v. We use $\mathsf{indeg}(v) = |\mathsf{parents}(v)|$ (resp. $\mathsf{outdeg}(v) = |\mathsf{children}(v)|$) to denote the number of incoming (resp. outgoing) edges into (resp. out of) the vertex v. We also define $\mathsf{indeg}(G) = \max_{v \in V} \mathsf{indeg}(v)$ and $\mathsf{outdeg}(G) = \max_{v \in V} \mathsf{outdeg}(v)$. Given a set $S \subseteq V$ of nodes, we use $G - S$ to refer to the graph obtained by deleting all nodes in S and all edges incident to S. We also use $G[S] = G - (V \setminus S)$ to refer to the subgraph induced by the nodes S, i.e., deleting every other node in $V \setminus S$. Given a node $v \notin S$, we use $\mathsf{depth}(v, G - S)$ to refer to the longest directed path in $G - S$ ending at node v and we use $\mathsf{depth}(G - S) = \max_{v \notin S} \mathsf{depth}(v, G - S)$ to refer to the longest directed path in $G - S$. Given a subset B, we will also use $\mathsf{depth}_B(v, G - S)$ to refer to the maximum number of nodes in the set B contained in any directed path in $G - S$ that ends at node v. We define $\mathsf{depth}_B(G - S) = \max_{v \notin S} \mathsf{depth}_B(v, G - S)$ analogously.

▶ **Definition 2** (Unique Games). *An instance* $\mathcal{U} = (G = (V, W, E), [R], \{\pi_{v,w}\}_{v,w})$ *of Unique Games consists of a regular bipartite graph* $G(V, W, E)$ *and a set* $[R]$ *of labels. Each edge* $(v, w) \in E$ *has a constraint given by a permutation* $\pi_{v,w} : [R] \to [R]$*. The goal is to output a labeling* $\rho : (V \cup W) \to [R]$ *that maximizes the number of satisfied edges, where an edge is satisfied if* $\rho(v) = \pi_{v,w}(\rho(w))$*.*

▶ **Conjecture 3** (Unique Games Conjecture, [31]). *For any constants* $\alpha, \beta > 0$*, there exists a sufficiently large integer* R *(as a function of* α, β*) such that for Unique Games instances with label set* $[R]$*, no polynomial time algorithm can distinguish whether: (1) the maximum fraction of satisfied edges of any labeling is at least* $1 - \alpha$*, or (2) the maximum fraction of satisfied edges of any labeling is less than* β*.*

Graph Pebbling

The goal of the (black) pebbling game is to place pebbles on all sink nodes of some input directed acyclic graph (DAG) $G = (V, E)$. The game proceeds in rounds, and each round i consists of a number of pebbles $P_i \subseteq V$ placed on a subset of the vertices. Initially, the graph is unpebbled, $P_0 = \emptyset$, and in each round $i \geq 1$, we may place a pebble on $v \in P_i$ if either all parents of v contained pebbles in the previous round ($\mathsf{parents}(v) \subseteq P_{i-1}$) or if v already contained a pebble in the previous round ($v \in P_{i-1}$). In the sequential pebbling game, at most one new pebble can be placed on the graph in any round (i.e., $|P_i \backslash P_{i-1}| \leq 1$), but this restriction does not apply in the parallel pebbling game.

We use $\mathcal{P}_G^{\parallel}$ to denote the set of all valid parallel pebblings of G. The *cumulative cost* of a pebbling $P = (P_1, \ldots, P_t) \in \mathcal{P}_G^{\parallel}$ is the quantity $\mathsf{cc}(P) := |P_1| + \ldots + |P_t|$ that represents the sum of the number of pebbles on the graph during every round. The (parallel) *cumulative pebbling cost* of G, denoted $\mathsf{cc}(G) := \min_{P \in \mathcal{P}_G^{\parallel}} \mathsf{cc}(P)$, is the cumulative cost of the best legal pebbling of G.

A DAG G is (e, d)-*reducible* if there exists a subset $S \subseteq V$ of size $|S| \leq e$ such that $\mathsf{depth}(G - S) < d$. That is, there are no directed paths containing d vertices remaining, once the vertices in the set S are removed from G. If G is not (e, d)-reducible, we say that it is (e, d)-depth robust.

4 Reduction

Svensson [45] showed that for any constant $k, \epsilon > 0$ it is Unique Games hard to distinguish between whether a DAG G is (e_1, d_1)-reducible for $e_1 = N/k$ and $d_1 = k$ or G is (e_2, d_2)-depth robust with $e_2 = N(1 - 1/k)$ and $d_2 = \Omega(N^{1-\varepsilon})$. To prove this, Svensson showed how to transform a Unique Games instance $\mathcal{U} = (G = (V, W, E), [R], \{\pi_{v,w}\}_{v,w})$ into a graph $G_{\mathcal{U}}$ such that $G_{\mathcal{U}}$ is (e_1, d_1)-reducible if it is possible to satisfy $1 - \alpha$ fraction of the edges and $G_{\mathcal{U}}$ is (e_2, d_2)-depth robust if it is not possible to satisfy β-fraction of the edges. To obtain inapproximability results for cc, it is crucial to substantially reduce the indegree of this construction.

4.1 Review of Svensson's Construction

To construct $G_{\mathcal{U}}$, Svensson first constructs a layered bipartite DAG $\hat{G}_{\mathcal{U}}$, which encodes the unique games instance $\mathcal{U}$ and later transforms $\hat{G}_{\mathcal{U}}$ into the required DAG $G_{\mathcal{U}}$. For completeness, we provide a full description of the DAG $\hat{G}_{\mathcal{U}}$ in the appendix. We will focus our discussion here on the essential properties of the DAG $\hat{G}_{\mathcal{U}}$.

The graph $\hat{G}_{\mathcal{U}}$ has a number of *bit-vertices* B partitioned into *bit-layers* $B = B_0 \cup \ldots \cup B_L$, where B_i is the set of bit-vertices in bit-layer i. Each B_i can be partitioned into sets $B_{i,w}$ for $w \in W$. Similarly, $\hat{G}_{\mathcal{U}}$ has a number of *test-vertices* T partitioned into *test-layers* $T = T_0 \cup \ldots \cup T_{L-1}$, where T_i is the set of test-vertices in test-layer i. Outgoing edges for test-layer T_ℓ must be directed into a bit vertex in layer $B_{\ell'}$ with $\ell' > \ell$. Similarly, outgoing edges from B_ℓ must be directed into a test vertex in layer $T_{\ell'}$ with $\ell' \geq \ell$. Each T_i can be partitioned into sets $T_{i,v}$ for $v \in V$. The constraints in our Unique Games instance $\mathcal{U}$ are encoded as edges between the bit vertices and test vertices. We use $N = |T|$ to denote the total number of test nodes and remark that the parameter L is set such that $L \geq N^{1-\epsilon}$.

$\hat{G}_{\mathcal{U}}$ also displays symmetry between the layers in the sense that $B_\ell = \{b_1^\ell, \ldots, b_m^\ell\}$ and $T_\ell = \{t_1^\ell, \ldots, t_p^\ell\}$, so that the number of bit-vertices in each bit-layer is the same and the number of test-vertices in each test-layer is the same.

Symmetry

In Svensson's construction, we have exactly m bit vertices in every layer $B_\ell = \{b_1^\ell, \ldots, b_m^\ell\}$ and exactly p test vertices in every layer $T_\ell = \{t_1^\ell, \ldots, t_p^\ell\}$. The edges between B_ℓ and T_ℓ (resp. T_ℓ and $B_{\ell+1}$) encode the edge constraints in the unique games instance $\mathcal{U}$. Furthermore, the construction is symmetric so that directed edge (b_i^ℓ, t_j^ℓ) exists if and only if for *every* $\ell' \geq \ell$ the edge $(b_i^\ell, t_j^{\ell'})$ exists. Thus for any $\ell' \geq \ell$, the edges between B_ℓ and $T_{\ell'}$ encode the constraints in $\mathcal{U}$. Similarly, the directed edge $(t_j^\ell, b_i^{\ell+1})$ exists if and only if any $\ell' > \ell$ the edge $(t_j^\ell, b_i^{\ell'})$ exists. We remark that this means that the indegree of the graph $\hat{G}_{\mathcal{U}}$ is at least L (and can be as large as $\Omega(N)$ in general).

Robustness of $\hat{G}_{\mathcal{U}}$

Svensson argues that if it is possible to satisfy a $1-\alpha$ fraction of the constraints in $\mathcal{U}$, then there exists a subset $S \subseteq T$ of at most $|S| \leq e_1$ test-vertices such that $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \leq d_1$. Similarly, if it is not possible to satisfy a β-fraction of the constraints, then for any subset $S \subseteq T$ of at most $|S| \leq e_2$ test-vertices, we have $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \geq d_2$. This does not directly show that $\hat{G}_{\mathcal{U}}$ is depth-robust since we are not allowed to delete bit-vertices. However, one can easily transform $\hat{G}_{\mathcal{U}}$ into a graph $G_{\mathcal{U}}$ on the $N = |T|$ test nodes such that $G_{\mathcal{U}}$ is (e, d)-depth robust if and only if for all subsets $S \subseteq T$ of $|S| \leq e$ test vertices in $\hat{G}_{\mathcal{U}}$, we have $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \geq d$. It is worth mentioning that we can view these guarantees as a form of *weighted* depth-robustness where all test-vertices have weight 1 and all bit-vertices have weight ∞, i.e., if $1-\alpha$ fraction of the constraints in $\mathcal{U}$, then we can find a subset S of nodes with weight $\mathsf{weight}(S) \leq e_1$ such that $\mathsf{depth}(\hat{G}_{\mathcal{U}} - S) \leq d_1$, and if it is not possible to satisfy β-fraction of the constraints, then for any subset S with $\mathsf{weight}(S) \leq e_2$ we have $\mathsf{depth}(\hat{G}_{\mathcal{U}} - S) \geq d_1$.

Graph Coloring and Robustness

An equivalent way to view the problem of *weighted* reducibility (resp. depth-robustness) is in terms of graph coloring. This view is central to Svensson's argument. In particular, if we can find a depth reducing set $S \subseteq T$ of size $|S| \leq e$ such that $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \leq d$, then we can define a d-coloring $\chi : B \to [d]$ of each of the bit-vertices such that the coloring χ is consistent with every remaining test node $v \in T \setminus S$. Here, consistency means that $\max_{b \in \mathsf{parents}(v)} \chi(b) < \min_{b \in \mathsf{children}(v)} \chi(b)$. In fact, it is not too difficult to see that there is a subset $S \subseteq T$ of $|S| \leq e$ test-vertices such that $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \leq d$ if and only if there

is a d-coloring χ such that $\left|\{v \ : \ \max_{b\in\mathsf{parents}(v)}\chi(b) \geq \min_{b\in\mathsf{children}(v)}\chi(b)\}\right| \leq e$, i.e., given a d-coloring χ of the bit vertices, we can simply select $S = \{v \ : \ \max_{b\in\mathsf{parents}(v)}\chi(b) \geq \min_{b\in\mathsf{children}(v)}\chi(b)\}$ of inconsistent test-vertices and then for every $u \in B$ we can inductively show that $\mathsf{depth}_B(u, \hat{G}_{\mathcal{U}} - S) \leq \chi(u)$.

Brief Overview of Svensson's Proof

Svensson defines $\chi(w,i)$ to denote the largest color that is smaller than the colors of at least $(1-\delta)$ fraction of the bit-vertices in $B_{i,w}$, i.e., $\chi(w,i) = \max\{\text{color } c : \Pr_{b\in B_{i,w}}[\chi(b) \geq c] \geq 1-\delta\}$. Suppose that it is not possible to satisfy a $\beta = \frac{\delta\eta^2}{t^2k^2}$-fraction of the constraints in $\mathcal{U}$ for tunable parameters $t, \eta > 0$ that are part of Svensson's construction. The core piece of Svensson's proof is demonstrating that if the set $S = \{v \ : \ \max_{b\in\mathsf{parents}(v)}\chi(b) \geq \min_{b\in\mathsf{children}(v)}\chi(b)\}$ of inconsistent test-vertices has size $|S| \leq (1-32\delta)|T|$, then we can find some $w \in W$ such that $\Pr[\chi(w,i) > \chi(w,i+1)] \geq 32\delta^2$ for some constant c that depends on various parameters of the construction. Svensson notes that by symmetry of the construction $\hat{G}_{\mathcal{U}}$, we can assume without loss of generality that $\chi(i,w) \leq \chi(i+1,w)$ for any $i \leq L$. We remark that this will *not* necessarily be the case after our indegree reduction step. Thus, it immediately follows that χ uses more than $32|T|\delta^2$ colors, i.e., $\mathsf{depth}_B(u, \hat{G}_{\mathcal{U}} - S) \geq 32|T|\delta^2$.

4.2 Reducing the Indegree

As previously discussed, Svensson's construction has indegree that is too large for the purposes of bounding the pebbling complexity by finding a gap between known results implied by (e_1, d_1)-reducibility and (e_2, d_2)-depth robustness. To perform indegree reduction, we use a γ-extreme depth-robust graph $G_{\gamma,L+1}$ with $L+1$ vertices in a procedure $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ to decide which edges in $\hat{G}_{\mathcal{U}}$ to keep and which edges to discard. Intuitively, we will keep the edge $(b_\ell, t_{\ell'})$ from a bit vertex $b_\ell \in B_\ell$ on layer $\ell \leq \ell'$ to test vertex $t_{\ell'} \in T_{\ell'}$ on layer ℓ' if and only if $\ell = \ell'$ or $G_{\gamma,L+1}$ contains the edge (ℓ, ℓ'). Similarly, we will keep the edge $(t_\ell, b_{\ell'})$ from a test vertex $t_\ell \in T_\ell$ on layer $\ell < \ell'$ to bit vertex $b_{\ell'} \in B_{\ell'}$ on layer ℓ' if and only if $(\ell, \ell') \in G_{\gamma,L+1}$. The result is a new DAG $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ with substantially smaller indegree and outdegree $\mathcal{O}\left(N^\varepsilon \log^2 N\right)$ instead of $\mathcal{O}(N)$.

Transformation $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$

Input: An instance $\hat{G}_{\mathcal{U}} = (V, E)$ of the Svensson's construction, whose vertices are partitioned into $L+1$ bit-layers $B_0, \ldots, B_L$ and L test-layers $T_0, \ldots, T_{L-1}$, a γ-extreme depth robust graph $G_{\gamma,L+1} = (V_\gamma = [L+1], E_\gamma)$.

1. Let $G' = (V, E)$ be a copy of $\hat{G}_{\mathcal{U}}$.
2. If $e = (b, t)$ is an edge in G, where $b \in B_i$ and $t \in T_j$, delete e from G' if $i \neq j$ and $(i, j) \notin E_\gamma$.
3. If $e = (t, b)$ is an edge in G, where $b \in B_i$ and $t \in T_j$, delete e from G' if $(j, i) \notin E_\gamma$.

Output: G'

We remark that we only delete edges from $\hat{G}_{\mathcal{U}}$. Thus for any subset $S \subseteq T$ of $|S| \leq e_1$ test vertices, we have $\mathsf{depth}_B(\hat{G}_{\mathcal{U}} - S) \geq \mathsf{depth}_B(\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}}) - S)$. Hence, $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ is certainly not more depth-robust than $\hat{G}_{\mathcal{U}}$. The harder argument is showing that the graph $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ is still depth-robust when our unique games instance $\mathcal{U}$ has no assignment satisfying a β fraction of the edges.

Assuming that the Unique Games instance is unsatisfiable, Lemma 4 implies that as long as $32\delta^2|T|$ test-vertices are consistent with our coloring, we can find some $w \in W$ such that w is *locally consistent* on at least $32\delta^2 L$ layers, i.e., w is locally consistent on layer ℓ if $\forall \ell' > \ell$ we have $\chi(w,\ell') > \chi(w,\ell)$.

The parameters η, t in Lemma 4 are tunable parameters of the reduction.

▶ **Lemma 4.** *Let χ be any coloring of $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$. If the Unique Games instance has no labeling that satisfies a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints and at least $32\delta^2|T|$ test vertices are consistent with χ, then there exists $w \in W$ with*

$$\Pr_{\ell\in[L]}[\chi(w,\ell') > \chi(w,\ell) \text{ for all } \ell' > \ell \text{ with } (\ell,\ell') \in E_\gamma] \geq 32\delta^2.$$

We remark that the proof of Lemma 4 closely follows Svensson's argument with a few modifications. While the modifications are relatively minor, specifying these modifications requires a complete description of Svensson's construction. We refer an interested reader to Appendix B for details and for the formal proof of Lemma 4.

Lemma 5 now shows that $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ is still depth-robust in case 2. The main challenge is that after we sparsify the graph, we can no longer assume that $\chi(w,\ell') > \chi(w,\ell)$ for all $\ell' > \ell$ without loss of generality, e.g., even if there are many i's for which $\chi(w,i+1) > \chi(w,i)$ we could have a sequence like $\chi(w,1) = 1, \chi(w,2) = 2, \chi(w,3) = 2, \chi(w,4) = 2, \chi(w,5) = 1, \chi(w,6) = 2, \ldots$. We rely on the fact that $G_{\gamma,L+1}$ is extremely depth-robust to show that for any sufficiently large subset $\mathtt{LC} \subseteq [L]$ of layers for which w is *locally consistent*, there must be a subsequence $\mathtt{P}_w \subseteq \mathtt{LC}$ of length $|\mathtt{P}_w| \geq |\mathtt{LC}| - \gamma L$ over which $\chi(w,\cdot)$ is strictly increasing.

▶ **Lemma 5.** *If the Unique Games instance has no labeling that satisfies a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints and $\gamma \leq 31\delta^2$, then for every set $S \subseteq T$ of at most $|S| \leq (1-32\delta)|T|$ test-vertices the graph $G' = \mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ has a path of length $\delta^2 L$.*

Proof. Suppose the Unique Games instance has no labeling that satisfies a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints. Let S contain at most $(1-32\delta)|T|$ and define the labeling $\chi(b) = \mathsf{depth}_B(b, G'-S)$. By Lemma 4, there exists $w \in W$ with

$$\Pr_{\ell\in[L]}[\chi(w,\ell') > \chi(w,\ell) \text{ for all } \ell' > \ell \text{ with } (\ell,\ell') \in E_\gamma] \geq 32\delta^2.$$

Let $\mathtt{LC} \subseteq [L]$ denote the subset of layers over which w is locally consistent. We remark that each $\ell \in \mathtt{LC}$ corresponds to a node in $G_{\gamma,L+1}$ and that $G_{\gamma,L+1}[\mathtt{LC}]$ contains a path $\mathtt{P}_w = (\ell_1, \ldots, \ell_k)$ of length $k \geq |\mathtt{LC}| - \gamma L \geq (32\delta^2 - \gamma)L$. We also note that $\chi(w,\ell_{i+1}) > \chi(w,\ell_i)$ for each $i < k$. Hence, $\chi(w,\ell_k) \geq k$, which means that $\mathsf{depth}_B(b, G'-S) \geq (32\delta^2-\gamma)L \geq \delta^2 L$ as long as $\gamma \leq 31\delta^2$. ◀

Theorem 6, our main technical result in this section, states that it is Unique Games hard to distinguish between (e_1,d_1)-reducible and (e_2,d_2)-depth robust graphs even for a DAG G with N vertices and $\mathsf{indeg}(G) = \mathcal{O}\left(N^\varepsilon \log^2 N\right)$.

▶ **Theorem 6.** *For any integer $k \geq 2$ and constant $\varepsilon > 0$, given a DAG G with N vertices and $\mathsf{indeg}(G) = \mathcal{O}\left(N^\varepsilon \log^2 N\right)$, it is Unique Games hard to distinguish between the following cases: (1) (Completeness): G is $\left(\left(\frac{1-\varepsilon}{k}\right)N, k\right)$-reducible, and (2) (Soundness): G is $\left((1-\varepsilon)N, N^{1-\varepsilon}\right)$-depth robust.*

Proof. Recall that we can transform $G' = \mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ into an unweighted graph G over the $N = |T|$ test-vertices. In particular, we add the edge (u, v) to G if and only if there was a path of length 2 from u to v in G'. We remark that the indegree is $\mathsf{indeg}(G) = \mathcal{O}\left(N^{\varepsilon} \log^2 N\right)$ and that for any $S \subseteq T$, we have $\mathsf{depth}(G - S) \leq \mathsf{depth}_B(G' - S) \leq \mathsf{depth}(G - S) + 1$. Completeness now follows immediately from Theorem 20 under the observation that we only removed edges from Svensson's construction. Soundness follows immediately from Theorem 20 and Lemma 5. ◀

Obtaining DAGs with Constant Degree

We can now apply a second indegree reduction procedure $\mathsf{IDR}(G, \gamma)$. For a graph $G = (V, E)$, the procedure $\mathsf{IDR}(G, \gamma)$ replaces each node $v \in V$ with a path $P_v = v_1, \ldots, v_{\delta+\gamma}$, where δ is the indegree of G. For each edge $(u, v) \in E$, we add the edge $(u_{\delta+\gamma}, v_j)$ whenever (u, v) is the j^{th} incoming edge of v, according to some fixed ordering. [5] give parameters e_2 and d_2 so that $\mathsf{IDR}(G, \gamma)$ is (e_2, d_2)-depth robust if G is (e, d)-depth robust. For a formal description of $\mathsf{IDR}(G, \gamma)$, see Appendix B. We complete the reduction by giving parameters e_1 and d_1 so that $\mathsf{IDR}(G, \gamma)$ is (e_1, d_1)-reducible if G is (e, d)-reducible.

▶ **Lemma 7.** *There exists a polynomial time procedure* $\mathsf{IDR}(G, \gamma)$ *that takes as input a DAG* G *with* N *vertices and* $\mathsf{indeg}(G) = \delta$ *and outputs a graph* $G' = \mathsf{IDR}(G, \gamma)$ *with* $(\delta + \gamma)N$ *vertices and* $\mathsf{indeg}(G') = 2$*. Moreover, the following properties hold: (1) If* G *is* (e, d)*-reducible, then* $\mathsf{IDR}(G, \gamma)$ *is* $(e, (\delta + \gamma) \cdot d)$*-reducible, and (2) If* G *is* (e, d)*-depth robust, then* $\mathsf{IDR}(G, \gamma)$ *is* $(e, \gamma \cdot d)$*-depth robust.*

▶ **Corollary 8.** *For any integer* $k \geq 2$ *and constant* $\varepsilon > 0$*, given a DAG* G *with* N *vertices and maximum indegree* $\mathsf{indeg}(G) = 2$*, it is Unique Games hard to decide whether* G *is* (e_1, d_1)*-reducible or* (e_2, d_2)*-depth robust for (Completeness):* $e_1 = \frac{1}{k} N^{\frac{1}{1+2\varepsilon}}$ *and* $d_1 = kN^{\frac{2\varepsilon}{1+2\varepsilon}}$*, and (Soundness):* $e_2 = (1 - \varepsilon)N^{\frac{1}{1+2\varepsilon}}$ *and* $d_2 = 0.9N^{\frac{1+\varepsilon}{1+2\varepsilon}}$*.*

5 Putting the Pieces Together

We would now like to apply Theorem 18 and Theorem 19. However, the upper bound on $\mathsf{cc}(G)$ that we obtain from Theorem 18 will not be better than $e_1 N = \frac{1}{k} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$, while the lower bound we obtain from Theorem 19 is just $(1 - \varepsilon)N^{\frac{2+\varepsilon}{1+2\varepsilon}}$, so we do not get our desirable gap between the upper and lower bounds. We therefore discard Theorem 18 and Theorem 19 altogether and instead apply a graph transformation with explicit bounds on pebbling complexity.

▶ **Definition 9** (Superconcentrator)**.** *A graph* G *with* $\mathcal{O}(N)$ *vertices is called a* superconcentrator *if there exists* N *input vertices, denoted* $\mathsf{input}(G)$*, and* N *output vertices, denoted* $\mathsf{output}(G)$*, such that for all* $S_1 \subseteq \mathsf{input}(G), S_2 \subseteq \mathsf{output}(G)$ *with* $|S_1| = |S_2| = k$*, there are* k *vertex disjoint paths from* S_1 *to* S_2*.*

Pippenger gives a superconcentrator construction with depth $\mathcal{O}(\log N)$.

▶ **Lemma 10** ([40])**.** *There exists a superconcentrator* G *with at most* $42N$ *vertices, containing* N *input vertices and* N *output vertices, such that* $\mathsf{indeg}(G) \leq 16$ *and* $\mathsf{depth}(G) \leq \log(42N)$*.*

Now we define the overlay of a superconcentrator on a graph G (see Figure 1).

▶ **Definition 11** (Superconcentrator Overlay)**.** *Let* $G = (V(G), E(G))$ *be a fixed DAG with* N *vertices and* $G_S = (V(G_S), E(G_S))$ *be a (priori fixed) superconcentrator with* N *input vertices* $\mathsf{input}(G_S) = \{i_1, \cdots, i_N\} \subseteq V(G_S)$ *and* N *output vertices* $\mathsf{output}(G_S) = \{o_1, \cdots, o_N\} \subseteq$

$V(G_S)$. *We call a graph* $G' = (V(G_S), E(G_S) \cup E_I \cup E_O)$ *a* superconcentrator overlay *where* $E_I = \{(i_u, i_v) : (u, v) \in E(G)\}$ *and* $E_O = \{(o_i, o_{i+1}) : 1 \leq i < N\}$ *and denote as* $G' = \mathsf{superconc}(G)$.

We will denote the interior nodes as $\mathsf{interior}(G') = G' \setminus (\mathsf{input}(G') \cup \mathsf{output}(G'))$ where $\mathsf{input}(G') = \mathsf{input}(G_S)$ and $\mathsf{output}(G') = \mathsf{output}(G_S)$. We remark that when using Pippenger's construction of superconcentrators, it is easy to show that $\mathsf{superconc}(G)$ is $\left(e + \frac{N}{d}, 2d + \log(42N)\right)$-reducible whenever G is (e, d)-reducible, which implies that

$$\mathsf{cc}(\mathsf{superconc}(G)) \leq \min_{g \geq d} \left(e + \frac{N}{d}\right) 42N + 2g(42N) + \frac{42N}{g} \left(2d + \log(42N)\right) 42N.$$

For more details, we refer an interested reader to Lemma 24 and Corollary 25 in Appendix D. However, these results are not quite as strong as we would like. By comparison, we have the following lower bound on the pebbling complexity from [11]:

$$\mathsf{cc}(\mathsf{superconc}(G)) \geq \min\left(\frac{eN}{8}, \frac{dN}{8}\right).$$

In Lemma 12 we obtain a *significantly tighter* upper bound on $\mathsf{cc}(\mathsf{superconc}(G))$ with an improved pebbling strategy described at the end of this section.

▶ **Lemma 12.** *Let* G *be an* (e, d)*-reducible graph with* N *vertices with* $\mathsf{indeg}(G) = 2$*. Then* $\mathsf{cc}(\mathsf{superconc}(G)) \leq \min_{g \geq d} \left\{2eN + 4gN + \frac{43dN^2}{g} + \frac{24N^2 \log(42N)}{g} + 42N \log(42N) + N\right\}$.

With the improved attack in Lemma 12, we can tune parameters appropriately to obtain our main result, Theorem 13.

▶ **Theorem 13.** *Given a DAG* G*, it is Unique Games hard to approximate* $\mathsf{cc}(G)$ *within any constant factor.*

Proof. Let $k \geq 2$ be an integer that we shall later fix and similarly, let $\varepsilon > 0$ be a constant that we will later fix. Given a DAG G with N vertices, then it follows by Corollary 8 that it is Unique Games hard to decide whether G is (e_1, d_1)-reducible or (e_2, d_2)-depth robust for $e_1 = \frac{1}{k} N^{\frac{1}{1+2\varepsilon}}$, $d_1 = kN^{\frac{2\varepsilon}{1+2\varepsilon}}$ and $e_2 = (1-\varepsilon)N^{\frac{1}{1+2\varepsilon}}$ and $d_2 = 0.9N^{\frac{1+\varepsilon}{1+2\varepsilon}}$. If G is (e_1, d_1)-reducible, then by Lemma 12, $\mathsf{cc}(\mathsf{superconc}(G)) \leq \min_{g \geq d} \{2e_1 N + 4gN + \frac{43d_1N^2}{g} + \frac{24N^2 \log(42N)}{g} + 42N \log(42N) + N\}$. Observe that $2e_1 N = \frac{2}{k} N^{(2+2\varepsilon)/(1+2\varepsilon)}$, whereas for $g = e_1$ and sufficiently large N, $4gN + \frac{43d_1N^2}{g} + \frac{24N^2 \log(42N)}{g} + 42N \log(42N) + N \leq \frac{5}{k} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$. Hence for sufficiently large N,

$$\mathsf{cc}(\mathsf{superconc}(G)) \leq \frac{7}{k} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}.$$

On the other hand, if G is (e_2, d_2)-depth robust, then by Lemma 23, $\mathsf{cc}(\mathsf{superconc}(G)) \geq \min\left(\frac{e_2 N}{8}, \frac{d_2 N}{8}\right)$. Specifically,

$$\mathsf{cc}(\mathsf{superconc}(G)) \geq \frac{e_2 N}{8} = \frac{1-\varepsilon}{8} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}.$$

Let $c > 1$ be any constant. Setting $\varepsilon = 0.1$ and $k = \lceil \frac{560}{9} c^2 \rceil$, we get that if G is (e_1, d_1)-reducible, then $\mathsf{cc}(\mathsf{superconc}(G)) \leq \frac{9}{80c^2} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$ but if G is (e_2, d_2)-reducible, then $\mathsf{cc}(\mathsf{superconc}(G)) \geq \frac{9}{80} N^{\frac{2+2\varepsilon}{1+2\varepsilon}}$. Hence, it is Unique Games hard to approximate $\mathsf{cc}(G)$ with a factor of c. ◀

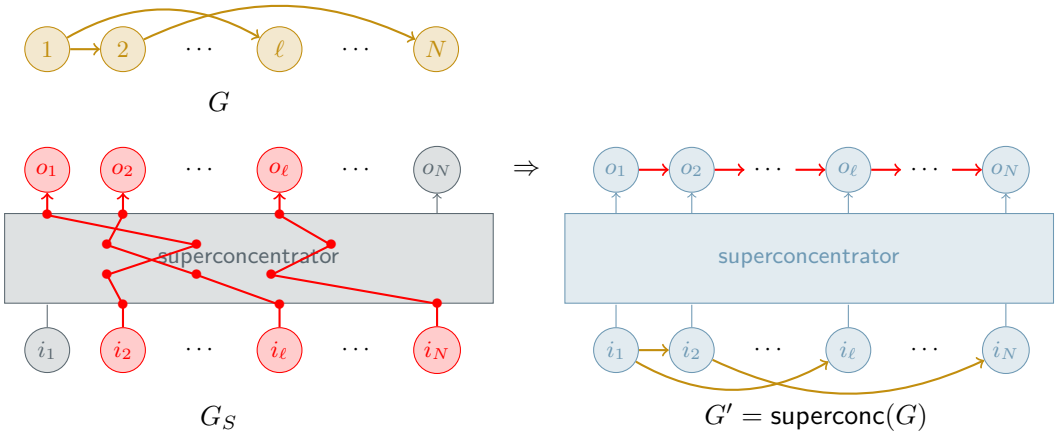

Figure 1 An example of the superconcentrator overlay $G' = \mathsf{superconc}(G)$. We remark that as illustrated in G_S, for any k inputs and k outputs (highlighted in red), there exist k vertex disjoint paths in a superconcentrator.

Improved Pebbling Strategy for $G' = \mathsf{superconc}(G)$

Step 1: Pebble the input nodes $\mathsf{input}(G') = G$.
Step 2: Efficiently pebble $\mathsf{interior}(G')$ using the property of superconcentrator.
Step 3: Pebble all nodes in $\mathsf{output}(G')$ by alternating between light and ballon phases.

- Light Phase - Walk pebble across the interval $I_i = [o_{(i-1)g+1}, o_{ig}]$ in g steps.
  - Precondition for the i^{th} light phase:
    - **(1)** Pebbles on all nodes $v \in \mathsf{parents}(o_{(i-1)g+1})$.
    - **(2)** Pebbles on all nodes $v \in \mathsf{parents}(I_i) \setminus I_i$.
    - **(3)** Pebbles on the set S where S is a (e, d)-depth reducing set for G.
  - Postcondition for the i^{th} light phase:
    - **(1)** Pebbles on the set S and node o_{ig}.
- Balloon Phase - Recover all the missing pebbles in $\mathsf{input}(G') \cup \mathsf{interior}(G')$ for the upcoming light phase.
  - Precondition for the i^{th} balloon phase:
    - **(1)** Pebbles on the set S.
    - **(2)** Pebble on node o_{ig+1} (the first node in the next light phase interval.)
  - Postcondition for the i^{th} balloon phase:
    - **(1)** Pebbles on all nodes in $\mathsf{input}(G') \cup \mathsf{interior}(G') = G' \setminus \mathsf{output}(G')$.
    - **(2)** Pebble on node o_{ig+1} (the first node in the next light phase interval.)

Figure 2 An improved pebbling strategy for $G' = \mathsf{superconc}(G)$. It brought ideas from [2].

Proof of Lemma 12. We will examine the pebbling cost of $\mathsf{superconc}(G)$ for each step shown in Figure 2.

- Step 1: We need to place pebbles on all input nodes in G'. By Theorem 18, the pebbling cost of $\mathsf{input}(G') = G$ will be upper bounded by[2]

$$\mathsf{cc}(G) \leq \min_{g \geq d} \left\{ eN + 2gN + \frac{N^2 d}{g} \right\}.$$

- Step 2: Start with a configuration with pebbles on every node in $\mathsf{input}(G')$. We have that $\mathsf{depth}(G') \setminus \mathsf{input}(G') = \log(42N)$. Therefore, in time $\log(42N)$, we can place pebbles on every node in $\mathsf{input}(G') \cup \mathsf{interior}(G')$. Hence, the total pebbling cost in Step 2 will be at most $42N \log(42N)$.
- Step 3: The goal for step 3 is to walk a pebble across the output nodes starting from o_1 to o_N. To save cost during this step, we should alternate light phases and balloon phases repeatedly N/g times in total since we walk pebble across the interval $I_i = [o_{(i-1)g+1}, o_{ig}]$ of length g in $\mathsf{output}(G')$ in each phase. Let S be a (e, d)-depth reducing set for G. In each light phase, to walk a pebble across the interval I_i, we should keep pebbles on S and $\mathsf{parents}(I_i) \setminus I_i$. Since each node in I_i has two parents outside the interval and we keep one pebble in I_i (the current node) for each step, the maximum number of pebbles to keep would be $|S| + 2g + 1 = e + 2g + 1$ for each step. Hence, the maximum pebbling cost to walk pebble across I_i in i^{th} light phase is $(e + 2g + 1)g$. In each balloon phase, we recover the pebbles in $\mathsf{input}(G') \cup \mathsf{interior}(G')$ for the next light phase. Since S is a (e, d)-depth reducing set, we have that $\mathsf{depth}(G' \setminus (S \cup \mathsf{output}(G'))) \leq d + \log(42N)$. Therefore, recovering the pebbles will cost at most $(d + \log(42N))42N$ for each balloon phase. Hence, the total pebbling cost for Step 3 will be at most $[(e + 2g + 1)g + (d + \log(42N))42N] \frac{N}{g}$.

Taken together, we have that

$$\begin{aligned}\mathsf{cc}(\mathsf{superconc}_2(G)) &\leq \min_{g \geq d} \left\{ \underbrace{eN + 2gN + \frac{N^2 d}{g}}_{\text{Step 1}} + \underbrace{42N \log(42N)}_{\text{Step 2}} + \underbrace{[(e + 2g + 1)g + (d + \log(42N)42N] \frac{N}{g}}_{\text{Step 3}} \right\} \\ &\leq \min_{g \geq d} \left\{ 2eN + 4gN + \frac{43dN^2}{g} + \frac{24N^2 \log(42N)}{g} + 42N \log(42N) + N \right\}\end{aligned}$$

as desired. ◀

[2] Note that Theorem 18 shows the upper bound of the pebbling cost to pebble the last node of G. Here, the difference is that we have to pebble all nodes in $\mathsf{input}(G') = G$, not the last node of G only. However, [2] says that we can recover all nodes concurrently by running one more balloon phase and such cost is already contained in the term $N^2 d/g$. Therefore, we have the same upper bound for $\mathsf{cc}(G)$.

A Svensson's Construction

In this section, we review Svensson's Construction. Given an instance $\mathcal{U}$ of Unique Games, Svensson first constructs a weighted instance $\hat{G}_{\mathcal{U}}$ of the DAG reducibility problem. Recall that in the weighted DAG reducibility problem, we are given a DAG G with weights on each node and a target depth d and the goal is to find a minimum weight subset S such that $(G - S)$ contains no path of length d. Given (e_1, d_1) and (e_2, d_2) with $e_1 < e_2$ and $d_1 > d_2$ a weaker goal is simply to distinguish between the following cases: (1) there is a set S of weight at most e_1 s.t. $(G - S)$ contains no path of length d_1, and (2) for all sets S of weight at most e_2 the graph $(G - S)$ contains a path of length d_2. Svensson constructs $\hat{G}_{\mathcal{U}}$ s.t. distinguishing between these cases allows us to solve the original Unique Games instance $\mathcal{U}$.

A.1 Notation

We first review some notation that is used to describe Svensson's initial construction. For $x \in [k]^R$ and a subset S of not necessarily distinct indices of $[R]$, let

$$C_{x,S} = \{z \in [k]^R \,:\, z_j = x_j \forall j \notin S\}$$

denote the sub-cube whose coordinates not in S are fixed according to x. Let

$$C_{x,S,v,w} = \{z \in [k]^R \,:\, z_j = x_{\pi_{v,w}(j)} \forall \pi_{v,w}(j) \notin S\}$$

denote the image of the sub-cube $C_{x,s}$ under $\pi_{v,w}$. Similarly, let

$$C^{\oplus}_{x,S} = \{z \oplus \mathbf{1} \,:\, z \in C_{x,S}\},$$

where $\oplus$ denotes addition modulo k and $\mathbf{1}$ denotes an R-dimensional vector with all elements 1, and let

$$C^{\oplus}_{x,S,v,w} = \{z \oplus \mathbf{1} \,:\, z \in C_{x,S,v,w}\}.$$

A.2 Construction

In Svensson's initial construction, nodes are divided into two sets: bit-vertices and test-vertices. Bit-vertices are assigned weight infinity to guarantee that these nodes are not deleted. Test-vertices are assigned weight one. Here, we focus on the construction of $\hat{G}_{\mathcal{U}}$ though the graph $\hat{G}_{\mathcal{U}}$ is later transformed into an instance $G_{\mathcal{U}}$ of the unweighted DAG reducibility problem, i.e., distinguishing between the cases that $G_{\mathcal{U}}$ is (e_1, d_1)-reducible and (e_2, d_2)-depth robust is sufficient to solve the original Unique Games instance $\mathcal{U}$. See Figure 3 for a simple example of $\hat{G}_{\mathcal{U}}$ along with the transformation to the unweighted instance $G_{\mathcal{U}}$. The DAG $\hat{G}_{\mathcal{U}}$ is defined formally as follows:

- For some L to be fixed, there are $L+1$ layers of bit-vertices. Each bit-layer ℓ with $0 \le \ell \le L$ the DAG $\hat{G}_{\mathcal{U}}$ contains bit-vertices $b^{\ell}_{w,x}$ for each $w \in W$ and $x \in [k]^R$. Each bit-vertex is assigned weight ∞.
- There are L layers of test-vertices. For each $0 \le \ell \le L-1$, the DAG $\hat{G}_{\mathcal{U}}$ contains test-vertices $t^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ for every $x \in [k]^R$, every sequence of indices $S = (s_1, \ldots, s_{\varepsilon R}) \in [R]^{\varepsilon R}$, every $v \in V$ and every sequence $(w_1, \ldots, w_{2t})$ of $2t$ not necessarily distinct neighbors of v. Each test-vertex is assigned weight 1.
- If $\ell \le \ell'$ and $z \in C_{x,S,v,w_j}$, then there is an edge from bit-vertex $b^{\ell}_{w_j,z}$ to test-vertex $t^{\ell'}_{x,S,v,w_1,\ldots,w_{2t}}$ for each $1 \le j \le 2t$.
- If $\ell > \ell'$ and $z \in C^{\oplus}_{x,S,v,w_j}$, then there is an edge from test-vertex $t^{\ell'}_{x,S,v,w_1,\ldots,w_{2t}}$ to bit-vertex $b^{\ell}_{w_j,z}$ for each $1 \le j \le 2t$.
- If T is the total number of test-vertices, then L is selected so that $\delta^2 L \ge T^{1-\delta}$.

A.3 Transformation

As mentioned before, in the Svensson's construction, the bit-vertices are given weight ∞ so that they are never deleted, and the graph can be simplified in the following manner without altering the reduction. The transformation to $G_{\mathcal{U}}$ is defined formally as follows:

- For each $0 \le \ell \le L-1$, there exists a vertex $v^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ for every $x \in [k]^R$, every sequence of indices $S = (s_1, \ldots, s_{\varepsilon R}) \in [R]^{\varepsilon R}$, every $v \in V$ and every sequence $(w_1, \ldots, w_{2t})$ of $2t$ not necessarily distinct neighbors of v.
- If γ is the number of vertices in each layer, then L is selected so that $\delta^2 L \ge (\gamma L)^{1-\delta}$.
- There exists an edge between $v^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ and $v^{\ell'}_{x',S',v',w'_1,\ldots,w'_{2t}}$ if and only if $\ell < \ell'$ and there exist i, j such that $C^{\oplus}_{x,S,v,w_i} \cap C_{x',S',v',w'_j}$ is nonempty.

▶ **Example 14.** In this example, we will illustrate how to reduce from a Unique Games instance $\mathcal{U}$ to a Svensson's construction $\hat{G}_{\mathcal{U}}$, and a simplification procedure from $\hat{G}_{\mathcal{U}}$ to $G_{\mathcal{U}}$ by examining a simple toy example.

Consider the following Unique Games instance $\mathcal{U} = (G = (V, W, E), [R], \{\pi_{v,w}\}_{v,w})$ with $V = \{v_1\}, W = \{w_1\}, E = \{(v_1, w_1)\}, \pi_{v_1,w_1} : \{1,2\} \to \{2,1\}$, a labeling $\rho : (V \cup W) \to [R]$ such that $\rho(v_1) = 1, \rho(w_1) = 2$, and with the parameters $R = 2, k = 2, t = 1, \delta = 0.1$ and $\epsilon = 0.5$. Then we have the following observations when constructing $\hat{G}_{\mathcal{U}}$:

- Each bit-layer ℓ with $0 \le \ell \le L$ contains bit-vertices $b^{\ell}_{w,x}$ for each $w \in W$ and $x \in [k]^R$. Hence, the number of bit-vertices in each layer is $|W| \times |[k]^R| = 1 \times 2^2 = 4$. That is, for each layer i, we have the following bit-vertices:

  $b^{i}_{w_1,(11)}, b^{i}_{w_1,(12)}, b^{i}_{w_1,(21)}$, and $b^{i}_{w_1,(22)}$.

- Each test-layer ℓ with $0 \leq \ell \leq L-1$ contains test-vertices $t^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ for every $x \in [k]^R$, every sequence of indices $S = (s_1, \ldots, s_{\varepsilon R}) \in [R]^{\varepsilon R}$, every $v \in V$ and every sequence $(w_1, \ldots, w_{2t})$ of $2t$ not necessarily distinct neighbors of v. Since $\varepsilon R = 1$ and v_1 has only one neighbor w_1, the number of test-vertices in each layer is $|[k]^R| \times |S| \times |V| \times |N_G(v_1)^{2t}| = 2^2 \times 2 \times 1 \times 1^2 = 8$, where $N_G(v)$ denotes the set of neighbors of v in a graph G. That is, for each layer i, we have the following test-vertices (from now on, we omit the subscript $v, w_1, \ldots, w_{2t}$ in this example since there is only one such case for each test-vertex):

  $$t^i_{(11),(1)}, t^i_{(12),(1)}, t^i_{(21),(1)}, t^i_{(22),(1)}, t^i_{(11),(2)}, t^i_{(12),(2)}, t^i_{(21),(2)}, \text{ and } t^i_{(22),(2)}.$$

- There exists an edge from bit vertex $b^{\ell}_{w_1,z}$ to test-vertex $t^{\ell'}_{x,S}$ if $\ell \leq \ell'$ and $z \in C_{x,S,v_1,w_1}$. We recall that $C_{x,S,v_1,w_1} = \{z \in [k]^R : z_j = x_{\pi_{v_1,w_1}(j)}\ \forall \pi_{v_1,w_1}(j) \notin S\}$. Now it is easy to see that if $S = \{1\}$, $z \in C_{x,S,v_1,w_1}$ if and only if $z_1 = x_2$, and if $S = \{2\}$, $z \in C_{x,S,v_1,w_1}$ if and only if $z_2 = x_1$. Therefore, we have an edge from $b^i_{w_1,(12)}$ to $t^j_{(11),(1)}, t^j_{(21),(1)}, t^j_{(21),(2)}$, and $t^j_{(22),(2)}$ for all $0 \leq i \leq j < L$, and so on.
- There exists an edge from test-vertex $t^{\ell'}_{x,S}$ to bit-vertex $b^{\ell}_{w_1,z}$ if $\ell > \ell'$ and $z \in C^{\oplus}_{x,S,v_1,w_1}$, where $\oplus$ denotes addition modulo $k = 2$ and $C^{\oplus}_{x,S,v_1,w_1} = \{z \oplus 1 : z \in C_{x,S,v_1,w_1}\}$. Hence, for example, if there is an edge from $b^i_{w_1,(12)}$ to $t^j_{x,S}$ then there should be an edge from $t^j_{x,S}$ to $b^{j'}_{w_1,(21)}$ for all $j' > j$ since $(12) \oplus \mathbf{1} = (12) \oplus (11) = (21)$.

When transforming $\hat{G}_{\mathcal{U}}$ into $G_{\mathcal{U}}$, we can observe that $C^{\oplus}_{x,S,v_1,w_1} \cap C_{x',S',v_1,w_1}$ is nonempty if and only if there is a path between two test-vertices through one bit-vertex. Taken together, we have the following structure of graphs reduced from a Unique Games instance $\mathcal{U}$, as shown in Figure 3. ◀

B Modified Construction

Given an instance $\hat{G}_{\mathcal{U}}$ of the Svensson's construction and a γ-extreme depth-robust graph $G_{\gamma,L+1} = (V_\gamma = [L+1], E_\gamma)$, we formally define our modified instance $G' = \mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ in the following manner.

Transformation $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$

Input: An instance $\hat{G}_{\mathcal{U}} = (V, E)$ of the Svensson's construction, whose vertices are partitioned into $L+1$ bit-layers $B_0, \ldots, B_L$ and L test-layers $T_0, \ldots, T_{L-1}$, a γ-extreme depth robust graph $G_{\gamma,L+1} = (V_\gamma = [L+1], E_\gamma)$.

1. Let $G' = (V, E)$ be a copy of $\hat{G}_{\mathcal{U}}$.
2. If $e = (b, t)$ is an edge in $\hat{G}_{\mathcal{U}}$, where $b \in B_i$ and $t \in T_j$, delete e from G' if $i \neq j$ and $(i, j) \notin E_\gamma$.
3. If $e = (t, b)$ is an edge in $\hat{G}_{\mathcal{U}}$, where $b \in B_i$ and $t \in T_j$, delete e from G' if $(j, i) \notin E_\gamma$.

Output: G'

We give an illustration of the Sparsify procedure in Figure 4.

Correspondingly, our modified instance can also be simplified in the following manner without altering the reduction.

- For a input parameter γ, let $G_{\gamma,L+1} = (V_\gamma = [L+1], E_\gamma)$ be an $\frac{\gamma}{2}$-extreme depth robust graph with $L+1$ vertices, which we use $[L+1]$ to represent.

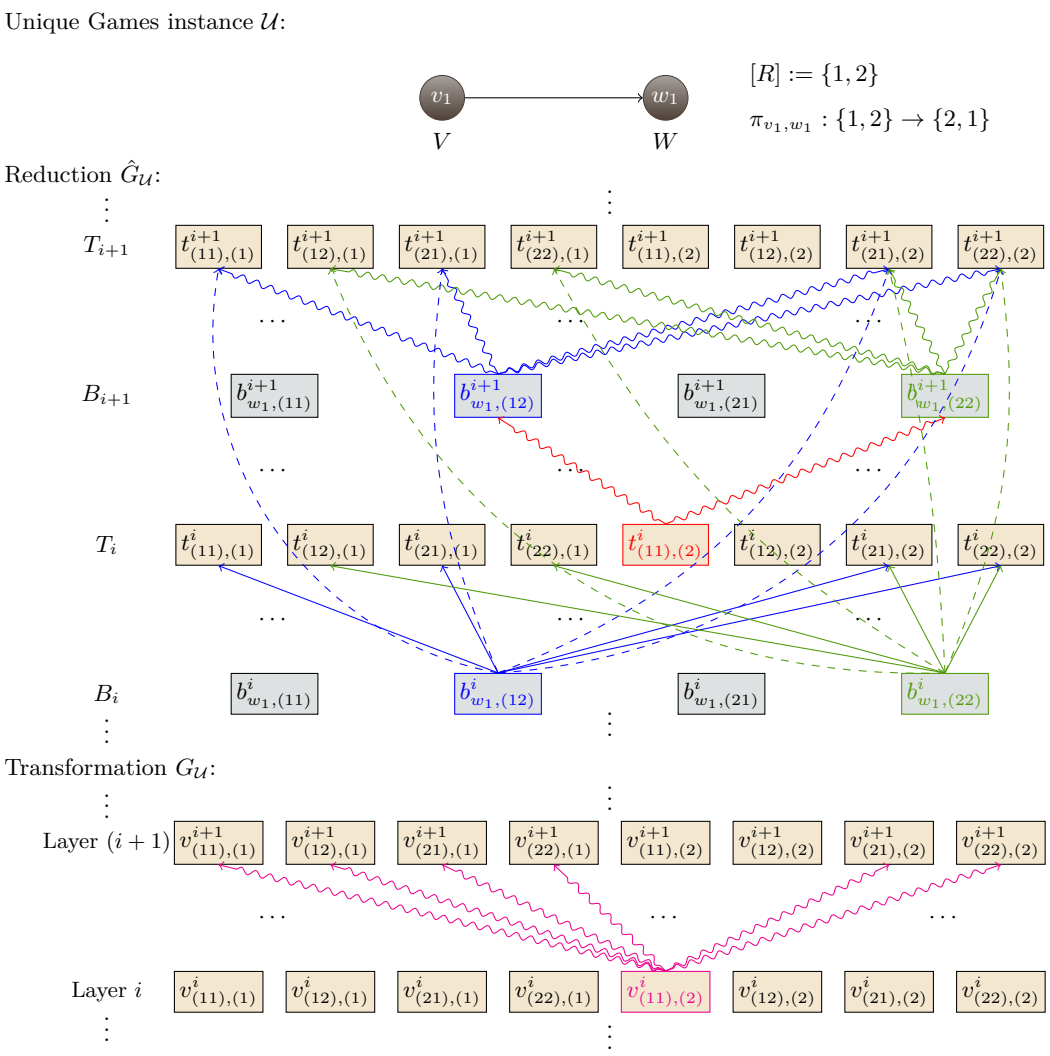

Figure 3 An example of reduction $\hat{G}_{\mathcal{U}}$ from a Unique Games instance $\mathcal{U}$ and a transformation into $G_{\mathcal{U}}$ illutrated in Example 14. We remark that in $\hat{G}_{\mathcal{U}}$ and $G_{\mathcal{U}}$, we only drew edges from the highlighted vertices for simplicity and readability. In $G_{\mathcal{U}}$, we only keep test-vertices from $\hat{G}_{\mathcal{U}}$ and connect two vertices if there is a path between those two through one bit-vertex. Therefore, we can easily check that totally 6 edges (shown in snaked magenta edges) going out from the vertex $v^i_{(11),(2)}$ in $G_{\mathcal{U}}$ comes from the edges $(t^i_{(11),(2)}, b^{i+1}_{w_1,(12)})$ and $(t^i_{(11),(2)}, b^{i+1}_{w_1,(22)})$ (shown in a snaked red edge) and edges from $b^{i+1}_{w_1,(12)}$ and $b^{i+1}_{w_1,(22)}$ to the test layer T_{i+1} (shown in snaked blue/green edges) in $\hat{G}_{\mathcal{U}}$. We also note that the edges starting from the i^{th} bit layer B_i go to every upper test layers T_j for all $j \geq i$. Those edges are represented as dashed ones.

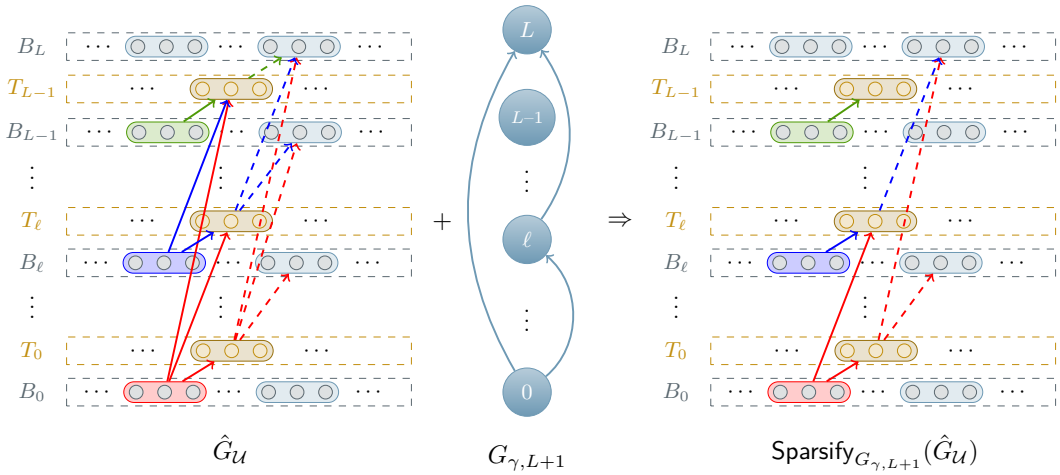

Figure 4 A description of the transformation $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$ where $\hat{G}_{\mathcal{U}}$ is Svensson's construction and $G_{\gamma,L+1}$ is a γ-extreme depth-robust graph. We remark that the edges between the subsets of nodes indicate that every node in the input subset is connected to every node in the output subset (in this example, there should be $3 \times 3 = 9$ edges from B_0 to T_0.)

- For each $0 \leq \ell \leq L-1$, there exists a vertex $v^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ for every $x \in [k]^R$, every sequence of indices $S = (s_1, \ldots, s_{\varepsilon R}) \in [R]^{\varepsilon R}$, every $v \in V$ and every sequence $(w_1, \ldots, w_{2t})$ of $2t$ not necessarily distinct neighbors of v.
- If γ is the number of vertices in each layer, then L is selected so that $\delta^2 L \geq (\gamma L)^{1-\delta}$.
- There exists an edge between $v^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ and $v^{\ell'}_{x',S',v',w'_1,\ldots,w'_{2t}}$ if and only if $\ell < \ell'$, the edge (ℓ, ℓ') is in E_γ, and there exist i, j such that $C^{\oplus}_{x,S,v,w_i} \cap C_{x',S',v',w'_j}$ is nonempty.

We first recall the following definition of influence of the i^{th} coordinate:

$$\mathsf{Infl}_i(f) = \mathbb{E}_x\left[\mathsf{Var}(f) | x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_R\right].$$

We now reference the key theorem used in Svensson's analysis.

▶ **Theorem 15** ([31, 45]). *For every $\varepsilon, \delta > 0$ and integer k, there exists $\eta > 0$ and integers t, d such that any collection of functions $f_1, \ldots, f_t : [k]^R \to \{0,1\}$ that satisfies*

- $\forall j, \mathbb{E}[f_j] \geq \delta$
- $\forall i \in [R]$, $\forall 1 \leq \ell_1 \neq \ell_2 \leq t$: $\min\left\{\mathsf{Infl}^d_i(f_{\ell_1}), \mathsf{Infl}^d_i(f_{\ell_2})\right\} \leq \eta$

has

$$\Pr_{x,S_\varepsilon}\left[\bigwedge_{j=1}^{t} f_j(C_{x,S_\varepsilon}) \equiv 0\right] \leq \delta.$$

We now show that the transformed graph maintains similar properties as Svensson's construction, given an instance of Unique Games. The following statement is analogous to Lemma 4.7 in [45].

▶ **Reminder of Lemma 4.** *Let χ be any coloring of $\mathsf{Sparsify}_{G_{\gamma,L+1}}(\hat{G}_{\mathcal{U}})$. If the Unique Games instance has no labeling that satisfies a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints and at least $32\delta^2|T|$ test vertices are consistent with χ, then there exists $w \in W$ with*

$$\Pr_{\ell \in [L]}\left[\chi(w,\ell') > \chi(w,\ell) \text{ for all } \ell' > \ell \text{ with } (\ell,\ell') \in E_\gamma\right] \geq 32\delta^2.$$

Proof of Lemma 4. As in [45], an equivalent formulation of the problem is finding a coloring χ in $\{1, 2, \ldots, k\}$ to each bit-vertex to minimize the number of unsatisfied test-vertices. Unlike in [45], we say a test-vertex $t^{\ell}_{x,S,v,w_1,\ldots,w_{2t}}$ is satisfied if

$$\max_{\substack{1\le j\le 2t\\ z\in C_{x,S,v,w_j}}} \chi\left(b^{\ell'}_{w_j,z}\right) < \min_{\substack{1\le j\le 2t\\ z\in C^{\oplus}_{x,S,v,w_j}}} \chi\left(b^{\ell''}_{w_j,z}\right),$$

for all $\ell' \le \ell < \ell''$ with $(\ell', \ell'') \in E_\gamma$, so that all the predecessors of ℓ are assigned lower colors than the successors of ℓ.

We also define the color $\chi(w, \ell)$ for $w \in W$ and $0 \le \ell \le L$ as the maximum color that satisfies

$$\Pr_x\left[\chi(b^{\ell}_{w,x}) \ge \chi(w, \ell)\right] \ge 1 - \delta.$$

For $w \in W$ and $0 \le \ell \le L - 1$, define the indicator function $f^{\ell}_w : [k]^R \to \{0, 1\}$ by

$$f^{\ell}_w(x) = \begin{cases} 0 & \text{if } \chi\left(b^{\ell'}_{w,x}\right) > \chi(w, \ell) \text{ for all } \ell' > \ell \text{ with } (\ell, \ell') \in E_\gamma,\\ 1 & \text{otherwise.}\end{cases}$$

We call a test-vertex $w \in W$ good in test-layer ℓ if for $\chi(w, \ell') > \chi(w, \ell)$ for every edge of the form (ℓ, ℓ') in the γ-extreme depth-robust graph $G_{\gamma,L+1} = (V_\gamma = [L + 1], E_\gamma)$.

▷ Claim 16. If the Unique Games instance has no labeling satisfying a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints and a fraction 16δ of the vertices of test-layer ℓ are satisfied, then at least a 2δ fraction of the vertices are good in test-layer ℓ.

Proof. Let A_ℓ be the set of satisfied vertices of test-layer ℓ so that for all $\ell' \le \ell < \ell''$ with $(\ell', \ell'') \in E_\gamma$, it follows that

$$\Pr_{x,S,v,w_1,\ldots,w_{2t}}\left[\max_{\substack{1\le j\le 2t\\ z\in C_{x,S,v,w_j}}} \chi\left(b^{\ell'}_{w_j,z}\right) < \min_{\substack{1\le j\le 2t\\ z\in C^{\oplus}_{x,S,v,w_j}}} \chi\left(b^{\ell''}_{w_j,z}\right)\right] \ge 16\delta,$$

since at least 16δ fraction of the vertices in A_ℓ are satisfied. We call a tuple $(v, w_1, \ldots, w_{2t})$ good if

$$\Pr_{x,S}\left[\max_{\substack{1\le j\le 2t\\ z\in C_{x,S,v,w_j}}} \chi\left(b^{\ell'}_{w_j,z}\right) < \min_{\substack{1\le j\le 2t\\ z\in C^{\oplus}_{x,S,v,w_j}}} \chi\left(b^{\ell''}_{w_j,z}\right)\right] \ge 8\delta,$$

for all $\ell' \le \ell < \ell''$ with $(\ell', \ell'') \in E_\gamma$. Observe that at least 8δ fraction of the tuples are good.

From the definition of $\chi(w, \ell')$, we have that $\Pr_x\left[\chi\left(b^{\ell'}_{w,x}\right)\right] \ge 1 - \delta$. Hence for a good tuple, it follows that

$$7\delta \le \Pr_{x,S}\left[\max_{1\le j\le 2t} \chi(w_j, \ell') < \min_{\substack{1\le j\le 2t\\ z\in C^{\oplus}_{x,S,v,w_j}}} \chi\left(b^{\ell''}_{w_j,z}\right)\right] \le \Pr_{x,S}\left[\bigwedge_{j=1}^{2t} f^{\ell}_{w_j}(C_{x,S,v,w_j}) \equiv 0\right],$$

for all $\ell' \le \ell < \ell''$ with $(\ell', \ell'') \in E_\gamma$.

Therefore by Theorem 15, at least one of the following cases holds:

1. more than t of the functions have $\mathbb{E}\left[f_{w_j}^{\ell}\right] < \delta$ so that $\chi(w_j, \ell') > \chi(w_j, \ell)$ for every edge of the form (ℓ, ℓ') in E_γ, or
2. there exist $1 \leq \ell_1 \neq \ell_2 \leq t$ and $j \in \mathcal{I}[w_{\ell_1}], j' \in \mathcal{I}[w_{\ell_2}]$ such that $\pi_{v,w_{\ell_1}}(j) = \pi_{v,w_{\ell_2}}(j')$, where

$$\mathcal{I}[w] = \{i \in [R] : \mathsf{Infl}_i^d(f_w^{\ell}) \geq \eta\}.$$

If Condition 1 holds for at least $\frac{1}{2}$ of the good tuples, or equivalently a 4δ fraction of all tuples, then at least a 2δ fraction of the test-vertices are good in test-layer ℓ because we can pick a vertex $w_j \in W$ uniformly at random by picking a tuple $(v, w_1, \ldots, w_{2t})$ and then taking one of the vertices $w_1, \ldots, w_{2t}$ at random. Conditioned on the (at least) 2δ probability that the tuple is good and satisfies Condition 1, the probability that $\chi(w_j, \ell') > \chi(w_j, \ell)$ for every edge of the form (ℓ, ℓ') in E_γ for the sampled vertex w_j is at least $\frac{1}{2}$. Therefore, $\Pr_w[\chi(w, \ell') > \chi(w, \ell)$ for all $\ell' > \ell$ with $(\ell, \ell') \in E_\gamma] \geq 2\delta$, so that at least 2δ fraction of the test-vertices are good in test-layer ℓ.

By way of contradiction, we can show that if Condition 2 were to hold for more than half of the good tuples, the assumption that the Unique Games instance has no labeling satisfying a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints is violated. The argument holds exactly as Claim 4.8 in [45], but we repeat it here for completeness.

For every $w \in W$, let $\rho(w)$ be a random label from $\mathcal{I}[w]$. For every $v \in V$, let w be a random neighbor of v and let $\rho(v) = \pi_{v,w}(\rho(w))$. If Condition 2 holds for half of the good tuples, then a random tuple has this property with at least probability 4δ. Thus with probability at least $\frac{1}{4t^2}$, $w = w_{\ell_1}$ and $w' = w_{\ell_2}$ for w, w' randomly picked from the set $\{w_1, \ldots, w_{2t}\}$. Moreover, [45, 9] observes that with probability at least $\frac{\eta^2}{k^2}$, the labeling procedure defines $j = \rho(w)$ and $j' = \rho(w')$. Hence if Condition 2 holds for half of the good tuples,

$$\Pr_{v,w,w'}[\pi_{v,w}(\rho(w)) = \pi_{v,w'}(\rho(w'))] \geq \frac{4\delta\eta^2}{4t^2k^2},$$

so that over the randomness of the labeling procedure,

$$\Pr_{(v,w)}[\rho(v) = \pi_{v,w}(\rho(w))] \geq \frac{\delta\eta^2}{t^2k^2},$$

which contradicts the assumption that the Unique Games instance has no labeling satisfying a fraction $\frac{\delta\eta^2}{t^2k^2}$ of the constraints is violated. ◁

Consider a subgraph induced by all bit-vertices and a fraction 32δ of the test-vertices and consider the minimum number of colors required for a coloring χ to satisfy the 32δ fraction of the test-vertices. Since at least 16δ fraction of the test-vertices are good in at least 16δ fraction of the test-layers, then by Claim 16,

$$\Pr_{\ell \in [L], w \in W}[\chi(w, \ell') > \chi(w, \ell) \text{ for all } \ell' > \ell \text{ with } (\ell, \ell') \in E_\gamma] \geq 16\delta \cdot 2\delta = 32\delta^2.$$

Therefore, there exists $w \in W$ with $\Pr_{\ell \in [L]}[\chi(w, \ell') > \chi(w, \ell)$ for all $\ell' > \ell$ with $(\ell, \ell') \in E_\gamma] \geq 32\delta^2$. ◀

Interestingly, we can exactly compute the pebbling complexity of the simplified Svensson's construction, when the graph is only represented with the test-vertices.

▶ **Lemma 17.** *Given a (simplified) Svensson's construction $G_{\mathcal{U}}$ that consists of N vertices partitioned across L layers,* $\mathsf{cc}(G_{\mathcal{U}}) = \frac{N(L+1)}{2}$.

Proof. We first show that the pebbling complexity of $G_{\mathcal{U}}$ is at least $\frac{N(L+1)}{2}$. Observe that the Svensson's construction contains $\frac{N}{L}$ vertices in each layer and furthermore, for each pair of layers i and j, there is a perfect matching between vertices of layer i and vertices of layer j among the edges connecting layers i and j. Let $\mathcal{M}_{i,j}$ be the subset of edges between i and j that is perfect matching.

For a given pebble u in layer j, let v_i be the vertex in layer i matched to u by $\mathcal{M}_{i,j}$. To pebble a vertex u in layer j, all of its parents must contain pebbles in the previous round. Namely, there must be a pebble on v_i for all $1 \leq i < j$ in the previous round. Since each $\mathcal{M}_{i,j}$ is a perfect matching, there must be $j-1$ pebbles on the graph solely for the purpose of pebbling node u in layer j. Thus pebbling each node in layer j induces a pebbling cost of at least $j-1$. Since there are $\frac{N}{L}$ pebbles in each layer and L layers, then the total pebbling cost is at least $\frac{N}{L}\sum_{j=1}^{L}(j-1) = \frac{N(L+1)}{2}$, which lower bounds $\mathsf{cc}(G_{\mathcal{U}})$.

On the other hand, consider the natural pebbling where all the pebbles in layer j are pebbled in round j, and no pebble is ever removed. Then the graph is completely pebbled in L rounds, since layer L is pebbled in round L. Moreover, the cost of pebbling round j is $\frac{N}{L}(j-1)$. Hence, the pebbling cost is $\frac{N}{L}\sum_{j=1}^{L}(j-1) = \frac{N(L+1)}{2}$, which upper bounds $\mathsf{cc}(G_{\mathcal{U}})$. ◀

Finally, we give a formal description of the procedure $\mathsf{IDR}(G,\gamma)$. Recall that $\mathsf{IDR}(G,\gamma)$ for a graph $G=(V,E)$ replaces each vertex $v \in V$ with a path $P_v = v_1,\ldots,v_{\delta+\gamma}$, where δ is the indegree of G. For each edge $(u,v) \in E$, we add the edge $(u_{\delta+\gamma}, v_i)$ whenever (u,v) is the i^{th} incoming edge of v, according to some fixed ordering. [5] give parameters e_2 and d_2 so that $\mathsf{IDR}(G,\gamma)$ is (e_2,d_2)-depth robust if G is (e,d)-depth robust. We complete the reduction by giving parameters e_1 and d_1 so that $\mathsf{IDR}(G,\gamma)$ is (e_1,d_1)-reducible if G is (e,d)-reducible.

Transformation $\mathsf{IDR}(G,\gamma)$

Input: An DAG $G=(V,E)$ with indegree δ, parameter γ.

1. Let the vertices of G be $[|V|]$.
2. Initialize G' to be a graph with $(\delta+\gamma)|V|$ vertices and let these vertices be $[(\delta+\gamma)|V|]$
3. If $(\delta+\gamma)n+1 \leq u < (\delta+\gamma)n$ for some integer n, add edge $(u, u+1)$ to G'.
4. If (u,v) is the i^{th} incoming edge of v by some fixed predetermined ordering, then add $(u_{\delta+\gamma}, v_i)$ to G'.

Output: G'

We given an illustration of the IDR transformation in Figure 5.

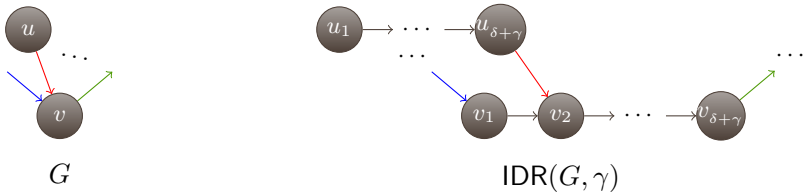

Figure 5 An example of the transformation $\mathsf{IDR}(G,\gamma)$. We remark that if the red edge (u,v) is the 2^{nd} incoming edge of v, then in $\mathsf{IDR}(G,\gamma)$ we should add $(u_{\delta+\gamma}, v_2)$ to G'.

C Useful Theorems

We rely on the following results in our constructions and proofs.

▶ **Theorem 18** ([2]). *Let G be a DAG with N vertices and indegree δ. If G is (e,d)-reducible, then* $\mathsf{cc}(G) \leq \min_{g \geq d} \left\{ eN + \delta g N + \frac{N^2 d}{g} \right\}$.

▶ **Theorem 19** ([5]). *Let G be a DAG with N vertices and indegree δ. If G is (e,d)-depth robust, then* $\mathsf{cc}(G) \geq ed$.

While Theorem 18 and Theorem 19 are nice results that relate the pebbling complexities of (e_1, d_1)-reducible and (e_2, d_2)-depth robust graphs, these statements are ultimately misleading in that $d \leq N$ and thus there will never be a gap between the pebbling complexities of the graphs.

▶ **Theorem 20** ([45]). *For any integer $k \geq 2$ and constant $\varepsilon > 0$, given a DAG G with N vertices, it is Unique Games hard to distinguish between the following cases:*

- *(Completeness): G is $\left(\left(\frac{1-\varepsilon}{k}\right) N, k\right)$-reducible.*
- *(Soundness): G is $\left((1-\varepsilon)N, N^{1-\varepsilon}\right)$-depth robust.*

▶ **Definition 21.** *Given a parameter $0 < \gamma < 1$, a DAG $G = (V, E)$ is* γ-extreme depth-robust *if G is (e,d)-depth robust for any e, d such that $e + d \leq (1-\gamma)N$.*

▶ **Theorem 22** ([6]). *For any fixed $0 < \gamma < 1$, there exists a constant $c_1 > 0$ such that for all integers $N > 0$, there exists an γ-extreme depth robust graph G with N vertices and* $\mathsf{indeg}(G), \mathsf{outdeg}(G) \leq c_1 \log N$.

▶ **Lemma 23** ([11]). *Let G be an (e,d)-depth robust graph with N vertices. Then*

$$\mathsf{cc}(\mathsf{superconc}(G)) \geq \min\left(\frac{eN}{8}, \frac{dN}{8}\right).$$

D Missing Proofs

▶ **Reminder of Lemma 7.** *There exists a polynomial time procedure $\mathsf{IDR}(G, \gamma)$ that takes as input a DAG G with N vertices and $\mathsf{indeg}(G) = \delta$ and outputs a graph $G' = \mathsf{IDR}(G, \gamma)$ with $(\delta + \gamma)N$ vertices and $\mathsf{indeg}(G') = 2$. Moreover, the following properties hold: (1) If G is (e,d)-reducible, then $\mathsf{IDR}(G, \gamma)$ is $(e, (\delta+\gamma)\cdot d)$-reducible, and (2) If G is (e,d)-depth robust, then $\mathsf{IDR}(G, \gamma)$ is $(e, \gamma \cdot d)$-depth robust.*

Proof of Lemma 7. Alwen et al. [5] show that $\mathsf{IDR}(G, \gamma)$ is $(e, \gamma \cdot d)$-depth robust if G is (e,d)-depth robust. It remains to show that $\mathsf{IDR}(G, \gamma)$ is $(e, (\delta+\gamma)\cdot d)$-reducible if G is (e,d)-reducible.

Given an (e,d)-reducible graph $G = (V, E)$ of N vertices, we use $[N]$ to represent the vertices of G and let $G' = \mathsf{IDR}(G, \gamma)$ so that the vertices of G' can be associated with $[(\delta+\gamma)N]$. Let S be a set of e vertices in G such that $\mathsf{depth}(V - S) < d$. Let S' be a set of e vertices in G' so that $(\delta+\gamma)v \in S'$ for each vertex $v \in S$.

Suppose, by way of contradiction, that there exists a path P' of length $(\delta+\gamma)\cdot d$ in $G' - S'$. Observe that if $y, z \in G'$ such that $(\delta+\gamma)a + 1 \leq y \leq (\delta+\gamma)(a+1)$ and $(\delta+\gamma)b + 1 \leq z \leq (\delta+\gamma)(b+1)$ for integers $a < b$, then y cannot be connected to z unless $y = (\delta+\gamma)(a+1)$. Hence that if P' contains vertex $u \in G'$ such that $(\delta+\gamma)c + 1 \leq u \leq (\delta+\gamma)(c+1)$ and u

is not one of the final $\delta+\gamma-1$ vertices of P', then $(\delta+\gamma)(c+1) \in P'$. Thus by a simple Pigeonhole argument, there exists at least d integers $j_1, j_2, \ldots, j_d$ such that $(\delta+\gamma)j_n \in P'$ for $1 \leq n \leq d$ and moreover there exists an edge in P' from each vertex $(\delta+\gamma)j_n$ to some vertex w such that $(\delta+\gamma)(j_{n+1}-1)+1 \leq w \leq (\delta+\gamma)j_{n+1}$ for $1 \leq n \leq d-1$. However, this implies that $j_1, \ldots, j_d$ is a path in G by construction of $\mathsf{IDR}(G,\gamma)$. Moreover, since $(\delta+\gamma)v \in S'$ for each vertex $v \in S$, this implies that $j_1, \ldots, j_d$ is a path of length d in $G-S$, which contradicts the assumption that $\mathsf{depth}(G-S) < d$. ◀

▶ **Reminder of Corollary 8.** *For any integer $k \geq 2$ and constant $\varepsilon > 0$, given a DAG G with N vertices and maximum indegree $\mathsf{indeg}(G) = 2$, it is Unique Games hard to decide whether G is (e_1, d_1)-reducible or (e_2, d_2)-depth robust for (Completeness): $e_1 = \frac{1}{k}N^{\frac{1}{1+2\varepsilon}}$ and $d_1 = kN^{\frac{2\varepsilon}{1+2\varepsilon}}$, and (Soundness): $e_2 = (1-\varepsilon)N^{\frac{1}{1+2\varepsilon}}$ and $d_2 = 0.9N^{\frac{1+\varepsilon}{1+2\varepsilon}}$.*

Proof of Corollary 8. Suppose G' is a graph with M vertices. By applying Lemma 7 to Theorem 6 and setting $k = M^{2\varepsilon}$ and $\gamma = M^{2\varepsilon} - \delta$, then we start from a graph with M vertices and end with a graph G with $N = M^{1+2\varepsilon}$ vertices or equivalently, $M = N^{1/(1+2\varepsilon)}$. Thus, $G = \mathsf{IDR}(G', \gamma)$ is (e,d)-reducible for $e = \frac{(1-\varepsilon)M}{k} = \frac{1-\varepsilon}{k}N^{1/(1+2\varepsilon)}$ and $d = kM^{2\varepsilon} = kN^{2\varepsilon/(1+2\varepsilon)}$. Since $e < \frac{M}{k}$, it is clearly the case that $G = \mathsf{IDR}(G', \gamma)$ is (e_1, d_1)-reducible for $e_1 = \frac{M}{k} > e$ and $d_1 = d = kN^{2\varepsilon/(1+2\varepsilon)}$ as we delete more nodes and the depth reducibility guarantees the same upper bound of the remaining depth. On the other hand, $\mathsf{IDR}(G', \gamma)$ is (e_2, d_2)-depth robust for $e_2 = (1-\varepsilon)M = (1-\varepsilon)N^{1/(1+2\varepsilon)}$, while $d_2 = \gamma M^{1-\varepsilon} = (M^{2\varepsilon} - \delta)M^{1-\varepsilon}$. By Theorem 6, $\delta = \mathcal{O}\left(M^{\varepsilon}\log^2 M\right)$ so that for sufficiently large M, $d_2 = 0.9M^{1+\varepsilon} = 0.9N^{(1+\varepsilon)/(1+2\varepsilon)}$. ◀

▶ **Lemma 24.** *If G is (e,d)-reducible, then $\mathsf{superconc}(G)$ is $\left(e + \frac{N}{d}, 2d + \log(42N)\right)$-reducible, where N is the number of vertices in $\mathsf{superconc}(G)$.*

Proof. Let $G = (V, E)$ be a (e,d)-reducible DAG with N vertices. Let $G' = \mathsf{superconc}(G)$ and suppose G' has M vertices, which we designate $[M]$. Thus, there exists a set $S \subseteq V$ such that $|S| \leq e$ and $\mathsf{depth}(G-S) < d$. Let T be the set of $\frac{N}{d}$ vertices $\{M, M-d, M-2d, \ldots, M-N+d\}$, so that $T \subseteq \mathsf{output}(G')$. We claim $\mathsf{depth}(G'-S-T) < 2d + \log(42N)$.

Suppose by way of contradiction that there exists a path P in $G'-S-T$ of length at least $2d+\log(42N)$. By Lemma 10, the depth of any path from an input node to an output vertex is at most $\log(42N)$. Moreover, all edges added in the superconcentrator overlay are either between input vertices or two output vertices. Hence, then at least $2d$ vertices of P have to lie in either the first N vertices or the last N vertices of G'. Because P does not contain vertices of T, there is no path of length of length d in the last N vertices of G', so there must be a path of length d in the first N vertices of G', which contradicts $\mathsf{depth}(G-S) < d$.

Therefore, G' is $\left(e + \frac{N}{d}, 2d + \log(42N)\right)$-reducible. ◀

From Lemma 24 we immediately obtain an upper bound on the pebbling complexity of $\mathsf{superconc}(G)$ by applying Theorem 18 to Lemma 24. However, the upper bound is not as strong as we would like.

▶ **Corollary 25.** *Let G be an (e,d)-reducible graph with N vertices. Then*

$$\mathsf{cc}(\mathsf{superconc}(G)) \leq \min_{g \geq d}\left(e + \frac{N}{d}\right)42N + 2g(42N) + \frac{42N}{g}\left(2d + \log(42N)\right)42N.$$

Scheduling with Predictions and the Price of Misprediction

Abstract

In many traditional job scheduling settings, it is assumed that one knows the time it will take for a job to complete service. In such cases, strategies such as shortest job first can be used to improve performance in terms of measures such as the average time a job waits in the system. We consider the setting where the service time is not known, but is predicted by for example a machine learning algorithm. Our main result is the derivation, under natural assumptions, of formulae for the performance of several strategies for queueing systems that use predictions for service times in order to schedule jobs. As part of our analysis, we suggest the framework of the "price of misprediction," which offers a measure of the cost of using predicted information.

1 Introduction

While machine learning research seems to be growing at an exponential rate, there seems to be surprisingly little overlap with "traditional" algorithms and data structures and their analysis. Here we attempt to bridge this gap for the area of job scheduling, providing a general framework that may prove useful for additional problems.

Although we begin with settings with a finite number of jobs in order to provide insight into our approach, our main results are in the area of queueing systems. In this setting, we assume there is some algorithm (such as a neural network or other machine learning algorithm) that predicts the job time[1] upon entry; we model this predictor via a density function $g(x, y)$, so that $g(x, y)$ is the probability density for a job having actual service time x and predicted service time y. We emphasize that only the predicted service time is known to the system on the job's arrival, and we need not assume that the joint distribution is known in order to perform the scheduling. Rather, we use the joint distribution to derive equations for queue performance. This probabilistic model is sensible under the assumption that the true distribution of jobs is not changing over time, and the prediction quality is not changing over time; such assumptions frequently appear in settings utilizing machine learning.

In standard queueing theory, under standard assumptions such as Poisson arrivals, and independent service times, one can derive formulae for the behavior of many natural scheduling strategies, including *shortest job first* (SJF) and *shortest remaining processing time* (SRPT), which both minimize the average time a job spends in the system. (Shortest job first assumes

[1] We use the terms job time, service time, and processing time interchangeably; historically these different terms have all been used.

no preemption; shortest remaining processing time allows preemption.) In the setting where job times are predicted, we refer to the corresponding natural strategies as *shortest predicted job first* (SPJF) and *shortest predicted remanining processing time* (SPRPT). Our main result is to derive formulae for the expected time a job spends in the system for such strategies; the formulae can be computed in terms of the density function $g(x, y)$. We further provide some empirical evidence from simulations that even weak predictions can yield very good performance.

More generally, we consider the cost of using predictions in place of accurate job service times, and introduce the concept of the *price of misprediction* to describe this cost. Our results provide the price of misprediction for these basic strategies.

We emphasize that our goal here is *not* to develop specific prediction methods, and we do not do so in this work. Rather, our goal is to show that given a real or hypothetical prediction system matching our assumptions, we can develop equations for its performance. This general framework may apply to a variety of machine learning methods. In this way, we aim to extend traditional queueing theoretic formulations to the general setting where machine learning prediction systems are available. Just as queueing theoretic models and results have historically guided many real-world systems (see, e.g., [12, 16, 17] for background), our motivation stems from the idea that extending such models and results to setting with predictions will enhance the use of machine learning prediction in real-world systems that use queues. Indeed, we further hope that our approach may prove useful for the analysis of other traditional algorithms and data structures.

2 Related Work

While traditional algorithmic analysis focuses on worst-case algorithm behavior, there is a growing movement to develop frameworks that go beyond worst-case analysis [27]. While such frameworks have existed in the past, most notably via probabilistic analysis (e.g., [24]), semi-random models (e.g., [7, 9]), and smoothed analysis [31], one natural approach that has received little attention is the use of machine-learning-based approaches to provide predictions to algorithms, with the goal of realizing provable performance guarantees. (The idea of using machine learning to give hints as to which *heuristic* algorithm to employ has been considered in meta-heuristics for several large-scale problems, most notably for satisfiability [33]; this is a distinct line of work.)

Notable recent work with this theme is that of Lykouris and Vassilvitskii [20], who show how to use prediction advice from machine learning algorithms to improve online algorithms for caching in a way that provides provable performance guarantees, using the framework of competitive analysis. A series of recent papers consider the setting of optimization with noise, such as in settings when sampling data in order to obtain values used in an optimization algorithm for submodular functions [2, 14, 3, 4, 5, 26]. Other recent works analyze the performance of learned Bloom filter structures [19, 23], a variation on Bloom filters [6] that make use of machine learning algorithms that predict whether an element is in a given fixed set as a subfilter structure, and heavy hitter algorithms that use predictions [15]. One prior work in this vein has specifically looked at scheduling with predictions in the setting of a fixed collection of jobs, and considered variants of shortest predicted processing time that yield good performance in terms of the competitive ratio, with the performance depending on the accuracy of the predictions [25].

In scheduling for queues, some works have looked at the effects of using imprecise information, usually for load balancing in multiple queue settings. For example, Mitzenmacher considers using old load information to place jobs (in the context of the power of two

choices) [21]. A strategy called TAGS studies an approach to utilizing multiple queues when no information exists about the service time; jobs that run more than some threshold in the first queue are cancelled and passed to the second queue, and so on [11].

For single queues, the setting examined in this paper, Wierman and Nuyens look at variations of SRPT and SJF with inexact job sizes, bounding the performance gap based on bounds on how inexact the estimates can be [32]. Dell'Amico, Carra, and Michardi note that such bounds may be impractical, as outliers in estimating job sizes occur frequently; they empirically study scheduling policies for queueing systems with estimated sizes [8]. We note [8] points out there are natural methods to estimate job size, such as by running a small portion of the code in a coding job; we expect this or other inputs would be features in a machine learning formulation. Recent work by Scully and Harchol-Balter have considered scheduling policies that are based on the amount of service received, where the scheduler only knows the service received approximately, subject to adversarial noise, and the goal is to develop robust policies [29]. Our work differs from these past works in providing a model specifically geared toward studying performance with machine-learning based predictions, along with corresponding analyses. Finally, we note that our policies appear to fit within the more general framework of SOAP policies presented by Scully et al. [30] This provides an alternative approach to analyzing the policies studied here. We present derivations here based on the original analyses of SJF and SRPT, as we feel they are more instructive and straightforward.

3 Price of Misprediction

3.1 A Simple Example

To demonstrate our framework, we start with a simple example. Consider a collection of n jobs $j_1, \ldots, j_n$, each of one of two types, short or long. Short jobs require time s to process and long jobs require time ℓ to process, with $s < \ell$. Jobs are to be ordered and then processed sequentially. When the job times are known, shortest job first is known to minimize the average waiting time over all jobs. (Here and throughout waiting time is the time spent in the system before starting being served.) If there are n_s short jobs and n_ℓ long jobs the average waiting time is

$$\frac{1}{n}\left(n_s\frac{n_s-1}{2}s + n_\ell\frac{n_\ell-1}{2}\ell + n_\ell n_s s\right).$$

That is, on average each of the n_s jobs waits for half of the remaining $n_s - 1$ short jobs, and similarly for the long jobs, and the long jobs further have to wait for all of the short jobs.

We note that asymptotically if we drop lower order terms this is approximately

$$\frac{n_s^2 s + n_\ell^2 \ell + 2n_s n_\ell s}{2n}.$$

For simplicity, we will generally work with asymptotic expressions throughout.

If one has no information about the type of all of the jobs, the optimal policy (under the assumption that an adversary can present the jobs in a worst-case order) is to randomize the order of the jobs. In this case, using linearity of expectations, we can find the overall expected waiting time by finding the expected waiting time of each job. A simple calculation shows that if there are n_s short jobs and n_ℓ long jobs the expected waiting time is

$$\frac{1}{n}\left(n_s\left(\frac{n_s-1}{2}s + \frac{n_\ell}{2}\ell\right) + n_\ell\left(\frac{n_s}{2}s + \frac{n_\ell-1}{2}\ell\right)\right).$$

Asymptotically, this is approximately

$$\frac{n_s^2 s + n_\ell^2 \ell + n_s n_\ell (s+\ell)}{2n}.$$

Finally, in the prediction setting, when a job's type is predicted we assume short jobs are misclassified as long jobs with some probability p and long jobs are misclassified as short jobs with some probability q. We consider the policy of *shortest-predicted-job-first*; that is, we apply shortest-job-first based on the predictions. Our analysis requires multiple cases, as we must consider the expected waiting time for a job conditioned on whether it was classified correctly or incorrectly. Considering all of these four cases leads to the following expression for the expected waiting time when mispredictions occur:

$$\begin{aligned}
&\frac{1}{n}\Bigg((1-p)n_s\left(\frac{(1-p)(n_s-1)}{2}s + \frac{qn_\ell}{2}\ell\right)\\
&+ pn_s\left((1-p)(n_s-1)s + \frac{p(n_s-1)}{2}s + \frac{(1-q)n_\ell}{2}\ell + qn_\ell\ell\right)\\
&+ (1-q)n_\ell\left(\frac{(1-q)(n_\ell-1)}{2}\ell + q(n_\ell-1)\ell + \frac{pn_s}{2}s + (1-p)n_s s\right)\\
&+ qn_\ell\left(\frac{q(n_\ell-1)}{2}\ell + \frac{(1-p)n_s}{2}s\right)\Bigg).
\end{aligned}$$

Asymptotically, this is approximately

$$\frac{n_s^2 s + n_\ell^2 \ell + n_s n_\ell ((2-(p+q))s + (p+q)\ell)}{2n}.$$

This differs from the optimal (asymptotic) expression additively by $n_s n_\ell \frac{(p+q)(\ell-s)}{2n}$; it depends specifically on the "total error" $p+q$.

Following the standard terminology[2], we might refer to the ratio between the expected waiting time with imperfect information and the expected waiting time with perfect information as the *price of misprediction*. We propose the following definition:

▶ **Definition 1.** *Let $M_A(Q;I)$ be the value of some measure (such as the expected waiting time) for a system Q given information I about the system using algorithm A, and let $M_A(Q;P)$ be the value of that metric using predicted information P in place of I when using algorithm A. Then the price of misprediction is defined as $M_A(Q;I)/M_A(Q;P)$.*

We note that often the "price of" terminology is used to compare to an optimal algorithm, while here we are suggesting comparing to a (perhaps non-optimal) algorithm with perfect information. Of course one could also compare against optimal algorithms, as one does for online algorithms; see [20], for example.

In the example of short and long jobs above, the asymptotic price of misprediction for the waiting time is the ratio R given by:

$$R = \frac{n_s^2 s + n_\ell^2 \ell + n_s n_\ell ((2-(p+q))s + (p+q)\ell)}{n_s^2 s + n_\ell^2 \ell + n_s n_\ell (s+\ell)}$$

[2] The terms "price of anarchy" [18] and "price of stability" [1] are commonly used in game theoretic situations, and in particular in job scheduling, when multiple players act in their own self interest instead of cooperating. One could also view this as a multiplicative form of regret, but we think this terminology is more general and potentially helpful.

We can find where the ratio is maximized by considering $n_s = \gamma n$ for a constant γ. Some algebraic work yields that:

$$R \leq 1 + \frac{(p+q)(\sqrt{l/s}-1)}{2},$$

giving a bound on the price of misprediction. Note that the setting with no information, or a random ordering, is equivalent to the case $p = q = 1/2$, in which case R is bounded by $1 + (\sqrt{l/s}-1)/2$.

3.2 General Predictions

More generally, we can consider a setting where each job can be described as an independent random variable, where the random variable for a job is given by a density distribution $g(x, y)$; that is, $g(x, y)$ is the density function for a job, where a job has service time x and predicted service time y. We assume that $g(x, y)$ is "well-behaved" throughout this work, so that it is continuous and all necessary derivatives exist. (The analysis can be readily modified to handle point masses or other discontinuities in the distribution.)

It is convenient to let $f_s(x) = \int_{y=0}^{\infty} g(x, y)\, dy$ be the density function for the service time, and $f_p(y) = \int_{x=0}^{\infty} g(x, y)\, dx$ be the density function for the predicted service time. If there are n total jobs, the expected waiting time for a job using shortest job first given full information is given by

$$(n-1)\int_{x=0}^{\infty} f_s(x)\left(\int_{z=0}^{x} z f_s(z)\, dz\right) dx,$$

while the expected waiting time for a job using predicted information using shortest predicted job first is given by

$$(n-1)\int_{y=0}^{\infty} f_p(y)\left(\int_{x=0}^{\infty}\int_{z=0}^{y} x g(x, z)\, dz\, dx\right) dy.$$

In words, in the full information case, to compute the expected waiting time for a job, given its service time, we can determine the probability each other job has a smaller service time and the conditional value of that smaller service time to compute the waiting time. In the predicted information case, to compute the expected waiting time for a job given its predicted service time, we must determine the probability each other job has a smaller predicted service time and the conditional value of the actual service time of a job given that it has a smaller predicted service time to compute the waiting time.

Note that the factors of $n-1$ are cancelled in the ratio of the expected waiting times, and the function g suffices to determine to price of misprediction. As an example motivated by the prevalence of exponential distributions in queueing theory, suppose that service times are exponentially distributed with mean 1, and a job with service time x has a prediction that is distributed according to an exponential distribution with mean x. Then $g(x, y) = e^{-x-y/x}/x$, $f_s(x) = e^{-x}$, and $f_p(y) = \int_{x=0}^{\infty} \frac{e^{-x-y/x}}{x}\, dx$. We note $f_p(y)$ does not appear to have a simple closed form, though it is expressible in terms of Bessel functions.[3] In fact the price of misprediction can be shown to be exactly 4/3 using the integration features of Mathematica, and we can directly and formally prove it is exactly equal to 4/3 through a subtle argument allowing us to evaluate the corresponding integrals; this argument is given in the appendix.

[3] This was determined using the integration features of Mathematica 11.3.

In comparison, using no information and just scheduling in sequential order the expected waiting time is a factor of 2 worse than when using full information. This example, while not meant to match a real-world example,provides the right high-level intuition, in that it shows that even a weak predictor can yield significant improvements. Indeed, this is natural; for a predictor to work well in this setting, it simply has to order most of the jobs correctly in the queue.

The key here is that the price of misprediction can be computed (at least numerically) given the density distribution g. In practice, one might use this framework to determine the benefit of using a predictor; for example, one might seek to trade off the reduction in total waiting time with the cost of developing or using better prediction methods. While g may not be known exactly, we expect in practice good approximations for g can be determined empirically, which in turn will allow a good approximation for the price of misprediction or related quantities.

We note that, for suitably good prediction schemes, ordering by predicted service time should naturally correspond to ordering by the expected service time. That is, denote a job by (X, Y), where X is a random variable representing the true service time and Y is a random variable representing the predicted service time. Then suppose the density distribution g satisfies for any y_1, y_2 with $y_1 < y_2$ the natural inequality

$$\mathbf{E}[X \mid Y = y_1] < \mathbf{E}[X \mid Y = y_2].$$

In this case ordering by predicted service times yields an ordering according to expected service times.

We now extend these ideas to queueing theoretical models.

4 Single Queue Models

In this section, we present results providing formulae for prediction-based variants of shortest job first and shortest remaining processing time for single queue systems, which yield expressions for the price of misprediction. We briefly review the appropriate analysis methods for standard queues, starting with jobs with priorities, and then extend them prediction setting.

4.1 Priority-based Systems

Consider a queueing system with k types of jobs, $t_1, \ldots, t_k$. We assume Poisson arrivals, and that the arrival rate for type t_i is λ_i, with $\sum_{i=1}^{k} \lambda_i = \lambda$. A natural setting is that the ith type of job has service time q_i, with $q_1 < q_2 < \ldots < q_k$. In this case, with complete information about the service times, the shortest job first (SJF) strategy (without preemption) corresponds to a priority-based strategy, with the types corresponding to priorities; t_1 has the highest priority, and so on. More generally, the ith type of job may have a service time distribution, rather than a fixed service time. We describe this more general case, where job t_i has service distribution S_i; here the natural setting is $\mathbf{E}[S_1] < \mathbf{E}[S_2] < \ldots < \mathbf{E}[S_k]$, and if the types are prioritized by expected service time, the strategy is expected shortest job first (ESJF).

We describe some standard formula for priority systems, following the framework of [12]. Let $\rho_i = \lambda_i \mathbf{E}[S_i]$; this represents the load on the system from jobs of type i. Further, let $\rho = \sum_{i=1}^{k} \rho_i$, and $W(i)$ be the distribution of the waiting time in the queue for jobs

of type i in equilibrium. Also, let S be service time distribution of an incoming job, so $\mathbf{E}[S] = \sum_{i=1}^{k} \lambda_i \mathbf{E}[S_i]/\lambda$, and $\rho = \lambda \mathbf{E}[S]$. Then the following is known (see Equation (31.1) of [12]):

$$\mathbf{E}[W(i)] = \frac{\rho \mathbf{E}[S^2]}{2\mathbf{E}[S]\left(1 - \sum_{j=1}^{i} \rho_j\right)\left(1 - \sum_{j=1}^{i-1} \rho_j\right)}.$$

We now consider a system where types are not known but are predicted, for example according to a machine learning algorithm. For convenience, going forward, we refer to the *true type* of a job for its type, and refer to the machine prediction for a job as the *predicted type* where appropriate. We may represent the machine learning algorithm by a matrix M where m_{ij} is the probability that a job of true type i has predicted type j; here we are assuming that each job labelling can be treated as independent. In this case, let λ'_i be the arrival rate of jobs with predicted type i. Then

$$\lambda'_i = \sum_{j=1}^{k} \lambda_j m_{ji}.$$

Correspondingly, the distribution of service times for jobs having predicted type i is that the job has service time given by S_ℓ with probability

$$\lambda_\ell m_{\ell i} / \sum_{j=1}^{k} \lambda_j m_{ji}.$$

If we use S'_i to represent the distribution of service times for jobs having predicted type i, then

$$\mathbf{E}[S'_i] = \frac{\sum_{j=1}^{k} \lambda_j \mathbf{E}[S_j] m_{ji}}{\sum_{j=1}^{k} \lambda_j m_{ji}}.$$

Of course the expected service time S' over all jobs is

$$\mathbf{E}[S'] = \sum_{i=1}^{k} \lambda_i \mathbf{E}[S_i] = \mathbf{E}[S].$$

Assuming we prioritize jobs now according to their predicted type, we may again use the standard formula for priority systems. We derive the corresponding result. First, let

$$\rho'_i = \lambda'_i \mathbf{E}[S_i] = \sum_{j=1}^{k} \lambda_j \mathbf{E}[S_j] m_{ji}.$$

Also let $W'(i)$ be the distribution of the waiting time in the queue for jobs of predicted type i in equilibrium. Then

$$\begin{aligned}\mathbf{E}[W'(i)] &= \frac{\rho' \mathbf{E}[(S')^2]}{2\mathbf{E}[(S')]\left(1 - \sum_{j=1}^{i} \rho'_j\right)\left(1 - \sum_{j=1}^{i-1} \rho'_j\right)} \\ &= \frac{\rho \mathbf{E}[S^2]}{2\mathbf{E}[S]\left(1 - \sum_{j=1}^{i} \rho'_j\right)\left(1 - \sum_{j=1}^{i-1} \rho'_j\right)}.\end{aligned}$$

Hence, by summing over all possible types, we can see that the price of misprediction for the expected waiting time corresponds to the following expression:

$$\frac{\sum_{i=1}^{k} \lambda'_i \left(\left(1-\sum_{j=1}^{i} \rho'_j\right)\left(1-\sum_{j=1}^{i-1} \rho'_j\right)\right)^{-1}}{\sum_{i=1}^{k} \lambda_i \left(\left(1-\sum_{j=1}^{i} \rho_j\right)\left(1-\sum_{j=1}^{i-1} \rho_j\right)\right)^{-1}}.$$

4.2 Shortest Job First

We now show that the performance of shortest predicted job first, which we denote as SPJF, can be readily expressed as a limiting case of the priority analysis, similarly to how shortest job first is the limiting case of a priority queue based on service time. (Here we roughly follow the methodology of Section 31.3 of [12].) To start, we recall the formula for shortest job first; this is easily obtained as the limit of the priority system setting, where there are an infinitely many possible "priorities", and the priority corresponds to the service time. Here again let S be the service distribution of an incoming job. Further, let $f_s(x)$ be the corresponding density function, $\rho_x = \lambda \int_{t=0}^{x} t f_s(t) dt$, and $\rho = \lambda \int_{t=0}^{\infty} t f_s(t) dt$. We consider $W(x)$, the time spent waiting in the queue (not being served) for jobs with service time x in equilibrium. Then for standard shortest job first without preemption, where we know the exact service times without prediction, it is known that

$$\mathbf{E}[W(x)] = \frac{\rho \mathbf{E}[S^2]}{2\mathbf{E}[S]\left(1-\rho_x\right)^2}.$$

The overall expected time waiting in a queue, which we denote by $\mathbf{E}[W]$ where W is the waiting time in queue of an incoming job, is then simply

$$\mathbf{E}[W] = \int_{x=0}^{\infty} f(x)\mathbf{E}[W(x)]\, dx.$$

We now generalize this to SPJF. For a non-preemptive queue that uses a service time estimate, if $g(x, y)$ is the joint distribution that a job has service time x and predicted service time y, we again let $f_s(x) = \int_{y=0}^{\infty} g(x, y)\, dy$ be the density function for the service time, and $f_p(y) = \int_{x=0}^{\infty} g(x, y)\, dx$ be the density function for the predicted service time. We also let $\rho'_y = \lambda \int_{t=0}^{y} \int_{x=0}^{\infty} x g(x, t)\, dx\, dt$ to be the load on the system associated with jobs of predicted service time up to y. With the assumption that each job's service time characteristics are independently determined according to $g(x, y)$, if we let $W'(y)$ be the distribution of time spent waiting in the queue for a job with predicted service time y in equilibrium, then

$$\mathbf{E}[W'(y)] = \frac{\rho \mathbf{E}[S^2]}{2\mathbf{E}[S]\left(1-\rho'_y\right)^2},$$

where $W'(y)$ is the distribution of time in the queue for jobs with predicted service time y. Integrating over service time or predicted services time gives us that the price of misprediction is given by:

$$\frac{\int_{y=0}^{\infty} \frac{f_p(y)}{(1-\rho'_y)^2}\, dy}{\int_{x=0}^{\infty} \frac{f_s(x)}{(1-\rho_x)^2}\, dx}.$$

Let us again consider the example of service times that are exponentially distributed with mean 1, where a job with service time x has a prediction that is distributed according to an exponential distribution with mean x. Then the price of misprediction can be expressed as

$$\frac{\int_{y=0}^{\infty} \frac{\int_{x=0}^{\infty} \frac{e^{-x-y/x}}{x}\,dx}{(1-\lambda\int_{t=0}^{y}\int_{x=0}^{\infty} e^{-x-y/x}\,dx\,dt)^2}\,dy}{\int_{x=0}^{\infty} \frac{e^{-x}}{(1-\lambda(1-(x+1)e^{-x}))^2}\,dx}.$$

While there does not appear to be a simple closed form for this expression, it can be readily evaluated numerically for a given λ.

We note that a similar analysis can be used for preemptive shortest predicted job first (PSPJF), where a job may be preempted by another job that has an originally shorter predicted time (note that the time a job has been serviced is not considered). This is because preemptive shortest job first (PSJF) can be represented as the limit of a preemptive priority-based system (as in Section 32.3 of [12]), leading to a similar analysis. (We provide the analysis in the appendix.)

4.3 Shortest Remaining Processing Time

A more challenging variation involves extending the shortest remaining processing time (SRPT) policy to predictions. With complete information, SRPT maintains the remaining processing time for each job, and the job being processed can be preempted by an incoming job with service time smaller than the remaining processing time. To generalize to the prediction setting, we follow the framework of Schrage and Miller [28], who presented an analysis of SRPT. (See also [10] for a similar derivation, or [12] for an alternative.) Because the system is preemptive, it makes sense to consider the total time in the system, rather than the waiting time (as jobs may have further waits after they start being served). Because of the complexity of the expressions, we do not have a clean form for the price of misprediction, but they can be found from the derived formulae.

Before starting, we note a key issue in using SPRPT and how we describe the predicted remaining service time. Suppose that the original predicted service time for a job is y, but the actual service time is $x > y$. If the amount of service received by the job has been t, then the remaining service time is $x - t$, and it is natural to use $y - t$ as the predicted remaining service time. Of course, at some point we will have $t > y$, and the predicted remaining service time will be negative, which seems unsuitable.

Here we simply use $(y - t)^+ = \max(y - t, 0)$ as the predicted remaining service time. We recognize that this remains problematic; clearly the predicted remaining service time should be positive, and ideally would be a function $f(y, t)$. However, determining the appropriate function would appear to require some knowledge of the joint distribution $g(x, y)$; our aim here is to explore simple, general approaches that are agnostic to the underlying distribution g, such as SPRPT. We therefore leave the question of how to optimize the estimate of the predicted remaining time to achieve the best performance in this context as future work. It is worth noting, though, that [8] finds empirically that with sufficiently heavy-tailed service distributions and inaccurate predictions, large jobs whose service times are significantly underestimated can delay many short jobs, leading to very poor performance. They correspondingly suggest policies to deal with these situations, either sharing the processor among jobs in some cases, or suggesting PSJF over SPRPT.

We again use $g(x, y)$ for the joint distribution that a job has service time x and predicted service time y, and let $f_s(x) = \int_{y=0}^{\infty} g(x, y)\,dy$, $f_p(y) = \int_{x=0}^{\infty} g(x, y)\,dx$, $\rho_x = \lambda \int_{t=0}^{x} t f_s(t)\,dt$, and $\rho'_y = \lambda \int_{t=0}^{y}\int_{x=0}^{\infty} g(x, t)x\,dx\,dt$. The expected time in the system in equilibrium for a job

can be expressed as the sum of its residence time (time in the system once it has started receiving service) and it waiting time (time spent waiting before being served). For SRPT, a job with service time x has mean residence time

$$\int_{t=0}^{x} \frac{dt}{1-\rho_t};$$

one can think of this as the remaining service times drop from t to 0, at any instant there is a possible addition (given by the $1/(1-\rho_t)$ factor) due to preemptions.

The corresponding mean residence time for a job of service time x and predicted service time y under SPRPT is

$$\int_{t=0}^{x} \frac{dt}{1-\rho'_{(y-t)^+}}.$$

That is, here the predicted remaining processing time drops from y to $(y-t)^+ = \max(y-t, 0)$; it is possible the predicted remaining processing time is 0, but the job continues to require service, in which case we leave its predicted remaining processing time at 0, and it cannot be preempted. It follows that the mean residence time $\mathbf{E}[R(y)]$ for a job of predicted service time y is

$$\mathbf{E}[R(y)] = \int_{x=0}^{\infty} \frac{g(x,y)}{f_p(y)} \int_{t=0}^{x} \frac{dt}{1-\rho'_{(y-t)^+}}\, dx.$$

We now compute the waiting time, which is more difficult. The steady-state probability that an arriving job finds the server working on a job whose remaining predicted processing time is less than q is given by

$$b(q) = \rho'_q + \lambda \int_{t=q}^{\infty} \int_{x=0}^{\infty} g(x,t)(x-(t-q))^+\, dx\, dt.$$

The first term comes from arrivals with predicted service time less than q; the second term comes from jobs that start with predicted service time greater than q, but later their remaining predicted service time falls below q.

If $Y(q)$ is the length of a busy period where all jobs processed have predicted remaining processing times less than q, then the waiting time $W(q)$ for a job of predicted service time q is given by:

$$\mathbf{E}[W(q)] = b(q)\frac{\mathbf{E}[Y(q)^2]}{2\mathbf{E}[Y(q)]}.$$

To find the first two moments of $Y(q)$, we use the fact that the length of the busy period $Y(q)$ has the same distribution as the busy period for a first-come, first-served server where the job that initiates the busy period has processing time according to some distribution $Z(q)$, where additional jobs have a processing time distribution $X(q)$, and the arrivals are Poisson with rate $\lambda F_p(q)$, for $F_p(q) = \int_{x=0}^{q} f_p(x)dx$. We require the first two moments of $Z(q)$ and $X(q)$.

The moments for $X(q)$ are fairly straightforward, as $X(q)$ corresponds to the processing time of a job with predicted processing time at most q:

$$\mathbf{E}[X(q)] = \frac{1}{F_p(q)} \int_{t=0}^{q} \int_{x=0}^{\infty} g(x,t)x\, dx\, dt,$$

and

$$\mathbf{E}[X(q)^2] = \frac{1}{F_p(q)} \int_{t=0}^{q} \int_{x=0}^{\infty} g(x,t)x^2\, dx\, dt.$$

To determine the first two moments of $Z(q)$, we note that there are two ways a job can start the corresponding busy period. It either arrives when a busy period is not in progress and has predicted processing time at most q, or it is a job with predicted processing time greater than q (which starts a busy period when the predicted processing time reaches q). Note that in the second case, if the predicted processing time t is greater than q, but the actual processing time x is such that $x < t - q$, then the job cannot start a busy period, as the job will finish before the remaining predicted processing time reaches q. (Ideally, such situations should not occur with a suitably good predictor, but it must be taken into account.) Hence the probability a job initiates a corresponding busy period is

$$d(q) = (1 - b(q))F_p(q) + \int_{t=q}^{\infty}\int_{x=t-q}^{\infty} g(x,t)\,dx\,dt.$$

If we let (for typesetting reasons)

$$a_1(q) = (1 - b(q))\int_{t=0}^{q}\int_{x=0}^{\infty} g(x,t)x\,dx\,dt + \int_{t=q}^{\infty}\int_{x=t-q}^{\infty} g(x,t)(x-(t-q))\,dx\,dt$$

and

$$a_2(q) = (1 - b(q))\int_{t=0}^{q}\int_{x=0}^{\infty} g(x,t)x^2\,dx\,dt + \int_{t=q}^{\infty}\int_{x=t-q}^{\infty} g(x,t)(x-(t-q))^2\,dx\,dt$$

then

$$\mathbf{E}[Z(q)] = a_1(q)/d(q),$$

and

$$\mathbf{E}[Z(q)^2] = a_2(q)/d(q).$$

We now use the facts (see, e.g., Problem 49 of [10])

$$\mathbf{E}[Y(q)] = \frac{\mathbf{E}[Z(q)]}{1-\rho'_q}$$

and

$$\mathbf{E}[Y(q)^2] = \frac{\mathbf{E}[Z(q)^2]}{(1-\rho'_q)^2} + \lambda\mathbf{E}[Z(q)]F_p(q)\frac{\mathbf{E}[X(q)^2]}{(1-\rho'_q)^3}.$$

This yields

$$\mathbf{E}[W(q)] = b(q)\left(\frac{a_2(q)}{2a_1(q)(1-\rho'_q)} + \lambda F_p(q)\frac{\mathbf{E}[X(q)^2]}{2(1-\rho'_q)^2}\right).$$

The expected time in the system for a job is simply $\int_{y=0}^{\infty} f_p(y)\mathbf{E}[W(y)+R(y)]dy$. From this value (and the corresponding equations for standard SRPT) one can compute the price of misprediction for the total expected time in the system. (Of course, the expected service time can be subtracted if desired.)

5 Simulation Results

We present a small number of simulation results to demonstrate that our equations are accurate and, at least in the cases we have examined, the price of misprediction is generally reasonably small. Correspondingly, this implies that even a small amount of predictive power yields significantly better performance than standard First-In First-Out (FIFO) queueing. We focus on high load settings, as under low load all systems perform well. We also note that additional simulations we have performed further substantiate our high-level conclusions. (Our simulation was written in C and runs on a standard laptop.)

We first compare simulation results against the results from our equations; we also provide results for schemes with full information for comparison. Our results are for the setting with Poisson arrivals, service times are exponential with mean 1, and predicted service times are exponential with mean x when the actual service time is x. For consistency, we provide the total expected time in the system (waiting and service). The results of the equations were computed using Mathematica 11.3 and numerical integration. The calculations for SPRPT and PSPJF are somewhat lengthy and can lead to numerical stability issues; we found integrating up to predicted times of at most 50 gives accurate answers while being computable in reasonable time, approximately half an hour on a modern laptop. (Predicted service times greater than 50 are very rare; they occur with probability less than $5 \cdot 10^{-7}$.) We did not optimize the calculations and expect this could be improved. The results of simulations were from our own implementation of a queue simulator. The simulations are the results of averaging the average time over 1000 trials, where in each trial we recorded the time in system of each completed job. The trials were each run for 1 000 000 time units, with jobs completing in the first 100 000 time units discarded from the calculations of the averages to remove bias from starting with an empty system.

Table 1 shows both that the results from equations for SPJF match very closely to the simulation results, and that the performance is not too much worse than when the service times are known. With regards to accuracy, the difference is less than 1%, which appears due to simulation variance. With regard to performance, using predicted times naturally becomes increasingly worse as load grows, but the difference still shows the benefits of using imperfect information. Recall that, with no information, for standard queueing schemes such as FIFO the expected time in the system is $1/(1-\lambda)$; for example, $\lambda = 0.99$ leads to an expected time in the system of 100. We see that under high loads, the gains from prediction remain substantial.

Table 2 Results from simulations and equations for Preemptive Shortest Job First (PSJF) and Preemptive Shortest Predicted Job First (PSPJF).

0.99	17.6269	17.6130	28.7302	28.7847	100.00

Table 2 shows results for the same simulation setting using PSJF and PSPJF, with similar conclusions; indeed, in this case, the numerical results are very similar.

Table 3 shows similar results for the same simulation setting using SRPT and SPRPT. For SPRPT, the results from equations align a little less closely to the simulation results, but the difference remains than 1%. Given the complexity of the equations, and the higher variability in the time in system for SPRPT, this is unsurprising.

Figure 1 provides another example of prediction performance. Here we fix $\lambda = 0.95$, and consider two types of service distributions: exponential with mean 1, and a Weibull distribution with cumulative distribution $1 - e^{-\sqrt{2x}}$. (The Weibull distribution is more heavy-tailed, but also has mean 1.) The simulations are again the average of the measured time in system, averaged from results of 1000 trials, in the same manner as previously. Here the predictions depend on a scale parameter α; a job with service time x has a predicted service time that is uniform over $[(1-\alpha)x, (1+\alpha)x]$. By varying α, we can see the impact on performance as prediction accuracy diminishes. Note that when $\alpha = 0$ the predicted service time equals the true service time. In these examples, we observe that performance degrades gracefully with α, a feature we see across values of λ in other experiments not presented. The main point here is that even weak predictors may perform well under SPJF, PSPJF, and SPRPT; as long as they generally lead jobs to be processed in the right order, they can yield substantial benefits. (We note the standard deviation over trials ranges from 2-4%, with higher variance for simulations with the Weibull distribution.)

We do point out some specific features of note. First, SPJF and PSPJF obtain essentially the same performance with exponential service times, but are notably different with Weibull distributed service times. Second, for the Weibull distribution, PSPJF is much better than

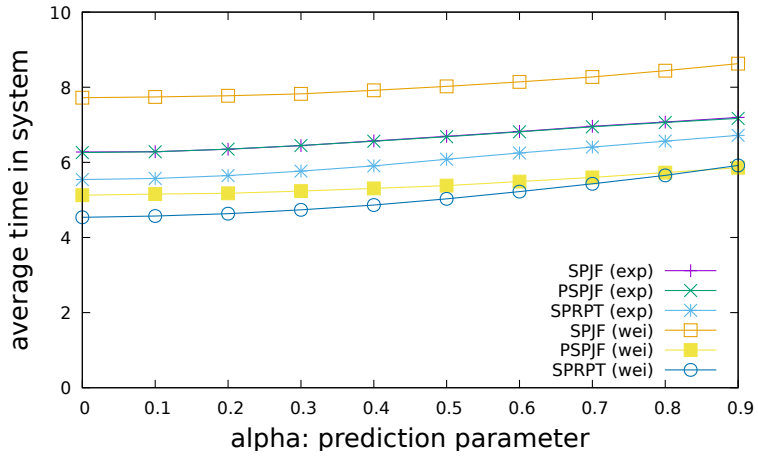

Figure 1 Results from simulations at $\lambda = 0.95$ for exponential and Weibull distributions. A job with service time x has predicted service time uniform over $[(1-\alpha)x, (1+\alpha)x]$. Performance degrades gracefully with α. Note $\alpha = 0$ corresponds to the full information case, as then the predicted service time equals the true service time.

SPJF, and even becomes slightly better than SPRPT with large prediction errors. Both of these feature are explained in large part by noting that the preemption of PSPJF is particularly helpful when large jobs are significantly underestimated, as in those settings without the preemption a large job can hold service for a long time, blocking shorter jobs; this has also been noted previously in [8]. Under the Weibull distribution for service, there are many much larger jobs than when the service times are exponentailly distributed. We expect our equations for the expected time in system for SPJF, PSPJF, and PSRPT may allow us to gain more insight into these kinds of behaviors, with provable results instead of simulation-based results.

6 Conclusion

We have demonstrated that the analyses of various single-queue job scheduling approaches can be generalized to the setting where predicted service times are used in place of true values, under the assumption that the predictions can be modeled as joint distribution with a corresponding density function. Such analyses can be used to determine the price of misprediction, or the potential benefits of better prediction, for such systems.

In future work, we plan to provide analyses of multiple queue systems using predicted service times. Multiple queue systems are quite common in practice, but can have more highly variable performance depending on how the workload is divided among queues. Natural strategies to consider include the power of two choices [22] and size interval task assignment (SITA) [13]. We expect analysis of such systems may require additional techniques, but will show that in this setting also even mildly accurate predictions can provide significant value.

In the problems considered here, we were able to determine *exact* formulae for performance, based on our probabilistic assumptions. It would be interesting to consider more general job scheduling scenarios with fewer assumptions, perhaps using methods more akin to online analysis, as in [20].

We believe this work suggests there is great potential in analyzing the large variety of job scheduling problems, as well as other similar traditional algorithmic problems, in the context of prediction.

A Proof of $4/3$ price of misprediction for the finite case

We recall the setting where there are n jobs, service times are exponential with mean 1, the predicted service times are exponential with mean x when the actual service time is x, and we seek to determine the expected waiting time. Since we care only about the expectation, we may consider the expected waiting time with just a pair of jobs; linearity yields the price of misinformation is the same.

When using the correct service times, the expected waiting time of a job with the shortest job first is

$$\int_{x=0}^{\infty} e^{-x} \left(\int_{z=0}^{x} z e^{-z} \, dz \right) dx,$$

which is easily found to evaluate to $1/4$. When using predicted service times, the expected waiting time is

$$\int_{y=0}^{\infty} f_p(y) \left(\int_{x=0}^{\infty} \int_{z=0}^{y} e^{-x-z/x} \, dz \, dx \right) dy,$$

where $f_p(y) = \int_{x=0}^{\infty} \frac{e^{-x-y/x}}{x} \, dx$. This does not appear to evaluate to a closed form of simple functions. However, suppose we use as our prediction an exponentially distributed service time with mean $1/x$ instead of x. This effectively reverses the predicted order, but leads to an easier integral calculation. Since the expected waiting time for a job over both orderings is trivially 1, finding the expected waiting time for the reverse order suffices.

For the reversed order,

$$\begin{aligned} f_p(y) &= \int_{x=0}^{\infty} x e^{-x-yx} \, dx \\ &= \frac{1}{(y+1)^2}, \end{aligned}$$

and the integral becomes

$$\begin{aligned}
&\int_{y=0}^{\infty} \frac{1}{(y+1)^2} \left(\int_{x=0}^{\infty} \int_{z=0}^{y} x^2 e^{-x-xz}\, dz\, dx \right) dy \\
&= \int_{y=0}^{\infty} \frac{1}{(y+1)^2} \left(\int_{x=0}^{\infty} (xe^{-x} - xe^{-x-yx})\, dx \right) dy \\
&= \int_{y=0}^{\infty} \frac{1}{(y+1)^2} \left(\int_{x=0}^{\infty} (xe^{-x} - xe^{-x-yx})\, dx \right) dy \\
&= \int_{y=0}^{\infty} \left(\frac{1}{(y+1)^2} - \frac{1}{(y+1)^4} \right) dy \\
&= 2/3.
\end{aligned}$$

The expected waiting time where predictions are exponential with mean x is therefore $1/3$, and the price of misprediction is $4/3$ as claimed.

B Derivation for PSPJF

We consider the expected time a job spends in the system in equilibrium for preemptive shortest predicted job first (PSPJF), where a job may be preempted by another job that has an originally shorter predicted time (note that the time a job has been serviced is not considered). The analysis is similar to both SPJF and SPRPT.

Here we consider the expected waiting time and the expected residence time in steady-state. We again use $g(x, y)$ for the joint distribution that a job has service time x and predicted service time y, and let $f_s(x) = \int_{y=0}^{\infty} g(x, y)\, dy$, $f_p(y) = \int_{x=0}^{\infty} g(x, y)\, dx$, $F_p(y) = \int_{t=0}^{y} f_p(y)\, dt$, and $\rho'_y = \lambda \int_{t=0}^{y} \int_{x=0}^{\infty} g(x, t) x\, dx\, dt$. As a job will be preempted by another job with smaller predicted service time, the mean residence time for a job of service time x and predicted service time y is

$$\frac{x}{1 - \rho'_y}.$$

This is because the residence time with preemptions is the same as the busy period started by a job of length x and predicted length y, where the only jobs that need to be considered in the busy period have predicted length at most y. This leads to the additional $1/(1 - \rho'_y)$ factor.

It follows that the mean residence time $\mathbf{E}[R(y)]$ for a job of predicted service time y is

$$\mathbf{E}[R(y)] = \int_{x=0}^{\infty} \frac{x g(x, y)}{f_p(y)(1 - \rho'_y)}\, dx.$$

The expected waiting time for a job with predicted service time y is the same as for a shortest job first system, except that the job only waits for jobs of predicted service times as most y. It follows that

$$\mathbf{E}[W(y)] = \frac{\lambda \int_{t=0}^{y} \int_{x=0}^{\infty} x^2 g(x, t)\, dx\, dt}{2\left(1 - \rho'_y\right)^2}.$$

Note that here we have simplified the expression, which would originally have had a factor

$$\rho'_y \frac{\left(\int_{t=0}^{y} \int_{x=0}^{\infty} x^2 g(x, t)\, dx\, dt\right) / F_p(y)}{\left(\int_{t=0}^{y} \int_{x=0}^{\infty} x g(x, t)\, dx\, dt\right) / F_p(y)}.$$

The integral expressions are the second and first moments of the expected service time for a job with predicted service time at most y. As $\rho'_y = \lambda \int_{t=0}^{y} \int_{x=0}^{\infty} g(x,t)x \, dx \, dt$, the expression for $\mathbf{E}[W(y)]$ follows.

The expected time in the system for a job is then again simply $\int_{y=0}^{\infty} f_p(y)\mathbf{E}[W(y) + R(y)] \, dy$.

Reducing Inefficiency in Carbon Auctions with Imperfect Competition

Abstract

We study auctions for carbon licenses, a policy tool used to control the social cost of pollution. Each identical license grants the right to produce a unit of pollution. Each buyer (i.e., firm that pollutes during the manufacturing process) enjoys a decreasing marginal value for licenses, but society suffers an increasing marginal cost for each license distributed. The seller (i.e., the government) can choose a number of licenses to put up for auction, and wishes to maximize the societal welfare: the total economic value of the buyers minus the social cost. Motivated by emission license markets deployed in practice, we focus on uniform price auctions with a price floor and/or price ceiling. The seller has distributional information about the market, and their goal is to tune the auction parameters to maximize expected welfare. The target benchmark is the maximum expected welfare achievable by any such auction under truth-telling behavior. Unfortunately, the uniform price auction is not truthful, and strategic behavior can significantly reduce (even below zero) the welfare of a given auction configuration.

We describe a subclass of "safe-price" auctions for which the welfare at any Bayes-Nash equilibrium will approximate the welfare under truth-telling behavior. We then show that the better of a safe-price auction, or a truthful auction that allocates licenses to only a single buyer, will approximate the target benchmark. In particular, we show how to choose a number of licenses and a price floor so that the worst-case welfare, at any equilibrium, is a constant approximation to the best achievable welfare under truth-telling after excluding the welfare contribution of a single buyer.

1 Introduction

Licenses for carbon and other emissions are a market-based policy tool for reducing pollution and mitigating the effects of climate change. Roughly speaking, a government agency distributes pollution licenses to firms according to some mechanism. At the end of a period of time (e.g., a year), firms must submit licenses to cover their pollution or else face severe penalties. Different ways of distributing licenses are possible. For example, if licenses are simply sold at a fixed price to anyone who wishes to pay, then this is equivalent to a *carbon tax* where polluters must pay a linear fee to offset their emissions. Alternatively, in a *cap-and-trade* mechanism, the agency releases a fixed number C of pollution licenses, either via a pre-determined allocation at no price (e.g., based on prior pollution or industry averages) or via auction, and then polluters can trade these licenses on the open market. Many emission trading systems take features of both schemes, combining a cap-and-trade market with a *price floor* $\underline{p}$, where each license must be sold above the reserve price of $\underline{p}$, and/or a *price ceiling* $\overline{p}$, where an extra license beyond the cap can always be purchased at a price of $\overline{p}$. In general, such a pollution license market is referred to as an Emission Trading System (ETS).

There are many important ETS in effect today. The EU ETS has thousands of participating firms and has raised billions of dollars in auction revenue over the past 10 years [2]. The Western Climate Initiative runs a license auction that is linked between California and Quebec [4, 1], and the Regional Greenhouse Gas Initiative (RGGI, pronounced "Reggie") serves New England and the New York region [3]. These markets differ in the details of their implementations, but in each case, licenses are distributed on a regular schedule, with a significant quantity of those licenses sold at auction.

One can model such a license auction as a multi-unit auction; that is, an auction for multiple identical goods. There is no bound on the supply of goods, but there is a cost of production corresponding to the social cost of more pollution. The social cost is typically assumed to be increasing and convex, and the value for licenses for each buyer is commonly assumed to be increasing and concave [27]. Each of the ETS described above uses a uniform-price auction rule to resolve this multi-unit auction. Such auctions proceed roughly as follows. Participating firms declare bids, which take the form of a non-decreasing concave function that describes their willingness-to-pay for varying quantities of licenses. This can alternatively be viewed as a list of non-increasing marginal bids for each successive license. Any marginal bids below the reserve price $\underline{p}$ are removed, and licenses are then distributed to the highest remaining marginal bids while supplies last. Each firm then pays a fixed price p per license, where p is set to some value between the lowest marginal winning bid and the highest marginal losing bid. Such auctions are not truthful, but are common in practice due to their many advantageous properties; see, e.g., Chapter 7 of [22].

Implementing a uniform-price auction for carbon licenses presents an optimization challenge: good outcomes require that the system designer correctly sets the quantity of licenses to distribute and/or the price (either direct price or auction reserve) at which they will be sold. The goal is to maximize *social welfare*: the aggregate value that firms receive for their licenses (i.e., by producing goods) minus the externality on society caused by polluting the corresponding amount during production. This optimization problem is complicated by uncertainty. Even if the social cost of pollution is fully known, the designer may not know what the demand for licenses will be, which makes it hard to predict the optimal level of pollution to allow. The goal of the designer, then, is to set the parameters of the uniform price auction to maximize the expected outcome over uncertainty in the market. Notably, the presence of social costs significantly increases the complexity of multi-unit auctions,

since efficiency becomes a mixed-sign objective. Even a slight misallocation of the licenses, resulting in a small reduction of received value, might have a disproportionately large effect on net welfare. In practice, inefficient allocations may be partially resolved in the trade phase of cap-and-trade systems. However, there are significant trading frictions, so it is imperative to choose an initial allocation, via the auction, that is as efficient as possible.

Since uniform price auctions are not truthful, one must account for strategic behavior of participating firms. A notable feature of ETS markets in practice is that, despite their size, they commonly have a small number of participants with significant market power.[1] The presence of dominant players suggests imperfect competition and raises the issue of strategic manipulation, in which large individual firms try to influence the market in their favor. One particular concern is demand reduction, where firms reduce their bids to suppress the price determined by the auction. We ask: how should one set auction parameters to (approximately) maximize welfare, in the face of strategic bidding?

1.1 Our Results

In this paper we apply ideas from theoretical computer science to approach the design of carbon license auctions with strategic firms. In this new domain, we use facts regarding uniform price auctions to understand what is happening in these markets and probabilistic analysis to handle the uncertainty of valuation realizations. We then apply a Price of Anarchy analysis to give strategic guarantees. As a result, we provide a concrete recommendation for how to set the parameters of the mechanism used in practice – a recommendation with provable approximation guarantees.

A market instance is described by a convex social cost curve and, for each participating firm, an independent distribution over concave valuations. To capture the relevant space of auctions, we formalize a class of allocation rules that we call *cap-and-price auctions*.[2] These auctions are parameterized by a maximum number of licenses to allocate, a price floor, and a price ceiling. They proceed by running a uniform-price auction for the given number of licenses, subject to the price floor and ceiling. Given a market instance, there is some choice of cap-and-price auction that maximizes the expected welfare generated under non-strategic (truth-telling) behavior. This optimal non-strategic solution will serve as a benchmark, which we denote OPT. Our main result is an auction that approximates OPT at any equilibrium of strategic behavior.

We show that, in general, the welfare obtained at an equilibrium of a cap-and-price auction can be negative, even for the auction that optimizes welfare under non-strategic bidding. This motivates our main question: given a cap-and-price mechanism that achieves a certain expected welfare W under truth-telling behavior, can one modify the auction parameters so that the expected welfare is an $O(1)$ approximation to W at any Bayes-Nash equilibrium? To answer this question, we describe a subclass of cap-and-price auctions that use *safe prices*. A *safe-price auction* is a cap-and-price auction in which the price floor is at least the average social cost, per license, of selling all of that auction's licenses. We show that for any such auction the worst-case welfare at any Bayes-Nash equilibrium is within a constant factor of the welfare under truth-telling. This result proceeds by transforming the market instance into a corresponding instance without social costs, and makes use of bounds on the Bayes-Nash price of anarchy for uniform-price auctions [20, 13].

[1] For example, in the EU ETS, the top 10 firms together control approximately 30 percent of all licenses allocated and traded; see [9], page 127.

[2] Note, we are focused on the auction phase in this paper and do not model the trade phase of these systems.

To construct an auction that approximates OPT at equilibrium, it therefore suffices to find a safe-price auction whose non-strategic welfare approximates that of the best unconstrained cap-and-price auction. However, as it turns out, there are market instances for which no constant approximation by a safe-price auction is possible. Such a situation can occur if there is a single firm that drives most of the demand for licenses, and this demand has very high variance. We show that this is essentially the only barrier to our desired price of anarchy result: one can always construct an auction that achieves a constant approximation to OPT minus the welfare obtainable by allocating licenses to any one single auction participant. In other words, as long as no single firm accounts for most of the expected welfare of the carbon license market, one can find a cap and price floor so that the welfare at any equilibrium is within a constant of the optimal outcome achievable without strategic behavior. We argue that this assumption is reasonable, since presumably the motivation for running a carbon license market in the first place is that the demand for emission licenses is distributed across multiple firms. An alternative way to view this result is that one can always achieve a constant approximation to our benchmark by either running a safe-price auction, or by selling to only a single firm.

Along the way, we also show that for any cap-and-price auction that sells all of its licenses with probability $q > 0$, there is a safe-price auction whose welfare (under truth-telling) is within a factor $O(1/q)$ of the original auction's welfare. In particular, if our benchmark is implemented by a cap-and-price auction that distributes all of its licenses with constant probability, then we can construct a safe-price auction whose welfare at any Bayes-Nash equilibrium is a constant approximation to the benchmark.

Note that our results are applicable for any setting with imperfect competition where a uniform price auction is used to allocate goods with a production or social cost. For instance, they may apply to allocating queries to a database, where the social cost is privacy. Another example might be allocating medallions to taxi and rideshare drivers in New York City, where the social cost is congestion.

1.2 Related Work

Our work is related to rich line of literature in economics comparing emission licence auction formats and flat "carbon tax" pricing methods to control the externalities of pollution. Weitzman [27] proposed a model of demand uncertainty and initiated a study comparing price-based vs quantity-based screening in the context of pollution externalities. Kerr and Cramton [10] noted that auctions tend to generate more efficient outcomes than grandfathered contracts (i.e., pre-determined allocations based on prior usage), which distort incentives to reduce pollution and efficiently redistribute licenses. Cramton, McKay, Ockenfels and Stoft [11] subsequently lay out arguments in favor of tax-based approaches. Murray, Newell, and Pizer [23] analyze the use of price ceilings in emission license auctions, and argue that they provide benefits of both auction-based and tax-based systems, improving efficiency in dynamic markets with intertemporal arbitrage. For a recent overview of auction-based systems used in practice, from both the economic and legal perspectives, we recommend [9].

A similar line of literature studied alternative approaches to the related electricity markets, where individual providers sell electricity into a central grid. Whereas the main issue in emission license sales is the social externality of production, the main focus in electricity markets was incentivizing participation of small firms. The primary discussion focused on using uniform pricing versus discriminatory pricing in the resulting procurement auction [12, 24].

Within the theoretical computer science community, there have been numerous studies of the efficiency of auction formats at equilibrium. For multi-unit auctions without production costs (or, equivalently, no social cost of pollution), the price of anarchy of the uniform-price auction was shown to be constant for full-information settings, and this was subsequently extended to Bayes-Nash equilibria [20, 13]. Our work can be seen as an extension of that work to the setting with a convex cost of allocation. Auctions with production costs have also been studied [6, 15], but primarily from the perspective of mechanism design, where the goal is to develop allocation and payment rules to achieve efficient outcomes. In the present work we do not take a mechanism design approach; we instead restrict our attention to (non-truthful) uniform price auctions, as these are used in practice, and study bounds on the worst-case welfare at equilibrium under different choices of the auction parameters.

Uniform-price auctions with costs can be viewed as games for which the designer has a mixed-sign objective (i.e., total value generated minus the social cost of production). Prior work on the price of anarchy under mixed-sign objectives has focused primarily on routing games [25, 7, 8]. Results in this space tend to be negative, motivating alternative measures of performance (such as minimizing a transformed measure of total cost) that avoid the pitfalls of mixed-sign optimization. Our work shows that in an auction setting, use of an appropriately-chosen thresholding rule (in the form of a reserve price) can enable a constant approximation to our mixed-sign objective of total value minus a convex social cost.

There is a vast amount of work on auctions with externalities, such as the seminal work of [16], and other work including externalities in advertising auctions [14], characterizations of equilibria in auctions with externalities [19], and more. However, these externalities are private and held by the buyers, as opposed to public and suffered by the seller as in this paper. In this case, the externality functions more like a production cost, as described above.

Kesselheim, Kleinberg and Tardos [17] study the price of anarchy of an energy market auction, which is a similar application to the carbon license auction that we study. Their focus is on the uncertainty of the supply and temporal nature of the auction, and not on externalities of production, and hence their technical model is quite different.

The theory of bidding in uniform-price auctions with imperfect competition is well-developed in the economic theory literature. Much of this work focuses specifically on the efficiency and revenue impact of demand reduction, and how modifications to the auction format or context might impact it. Demand reduction occurs at equilibrium even in very simple settings of full information, can dramatically reduce welfare, and is a concern in practice [28, 26, 5]. One way to reduce the inefficiency of demand reduction is to perturb the supply, either by allowing the seller to adjust the supply after bids are received [21], or by randomizing the total quantity of goods for sale (or otherwise smoothing out the allocation function) [18]. Such results are typically restricted to full-information settings. Moreover, these approaches are not necessarily appropriate in the sale of government-issued licenses, where one typically expects commitment and certainty about the quantity being sold. In contrast, we forego a precise equilibrium analysis and instead argue that setting a sufficiently high price floor can likewise mitigate the impact of demand reduction.

1.3 Roadmap

Our main result is a cap-and-price auction whose welfare in equilibrium approximates the maximum welfare of a cap-and-price auction with non-strategic reporting in markets without a single dominant bidder. In Section 2, we introduce our model and formally define cap-and-price auctions. In Section 3, we first show that we can restrict attention to cap-and-price auctions with an infinite price ceiling (i.e., ones who never sell more licenses than the cap).

We then derive a class of such cap-and-price auctions, which we call safe-price auctions, whose performance in equilibrium approximates the performance in a non-strategic setting. Thus it suffices to show that the best safe-price auction approximates the best cap-and-price auction in a non-strategic setting. However, this is not true: we give an example where it can be unboundedly worse. In Section 4, we demonstrate that the only barrier to this is the existence of a dominant bidder, yielding our main result.

2 Preliminaries

There are n firms seeking to purchase carbon licenses. Licenses are identical, and each permits one pollution unit. Each firm i has a monotone non-decreasing concave *valuation curve* $V_i(\cdot)$ that maps a number of pollution units $x \in \mathbb{Z}_{\geq 0}$ to a value $\mathbb{R}_{\geq 0}$; this is the value they enjoy for polluting this amount. The profile of valuation curves $\mathbf{V} = (V_1, \ldots, V_n)$ is drawn from a publicly-known distribution F over profiles, where the draw of $V_i(\cdot)$ is the private information of firm i. Valuations are drawn independently across firms, so $F = F_1 \times \ldots \times F_n$ is a product distribution and $V_i \sim F_i$.

There is a publicly known monotone non-decreasing convex *cost function* $Q(\cdot)$ that maps a number of pollution units $x \in \mathbb{Z}_{\geq 0}$ to the value of externality that society faces for having this much pollution. Given a valuation profile $(V_1, \ldots, V_n)$, the *welfare* of a given allocation rule $\mathbf{x} = (x_1, \ldots, x_n)$ is $\sum_i V_i(x_i) - Q(\sum_{i=1}^n x_i)$. Our objective is to maximize expected welfare.

Given some integer $x \geq 0$, we write $V(x)$ for the maximum aggregate value that could be obtained by optimally dividing x licenses among the firms. That is,

$$V(x) = \max_{\vec{y} \in \mathbb{Z}_+^n : ||y||_1 = x} \sum_i V_i(y_i).$$

We refer to V as the *combined valuation curve*. As each $V_i(\cdot)$ is weakly concave, so is $V(\cdot)$. We will sometimes abuse notation and write $V \sim F$ to mean that V is distributed as the aggregate value when $(V_1, \ldots, V_n) \sim F$. We'll write $W(V, x) = V(x) - Q(x)$ for the welfare generated by allocating x licenses optimally among the firms.

We'll write $v_i(j) = V_i(j) - V_i(j-1)$ for firm i's marginal value for aquiring license j, for each $j \geq 1$. By the monotonicity and concavity of $V_i(\cdot)$, $v_i(\cdot)$ is non-increasing. We'll also write $V_i(j|k) = V_i(j+k) - V_i(k)$ for the marginal value of j additional items given k already allocated. We'll write $d_i(p) = \max\{j : v_i(j) \geq p\}$ for the number of units demanded by bidder i at price p.

We will study equilibria and outcomes of license allocation auctions. An auction takes as input a reported valuation V_i from each firm i. The auction then determines an allocation $\mathbf{x} = (x_1, \ldots, x_n)$ and a price $p_i \geq 0$ that each firm must pay. The auctions we consider will be uniform price auctions, where the auction determines a per-license price p and each firm i pays $p_i = p \cdot x_i$. Given an implicit uniform-price auction, we will tend to write $x_i(\tilde{\mathbf{V}})$ (resp., $p(\tilde{\mathbf{V}})$) for the allocation to agent i (resp., per-unit price) when agents report according to $\tilde{\mathbf{V}}$. For a given valuation profile $\mathbf{V}$, we'll also write $U_i(\tilde{\mathbf{V}})$ for the utility enjoyed by firm i when agents bid according to $\tilde{\mathbf{V}}$:

$$U_i(\tilde{\mathbf{V}}) = V_i(x_i(\tilde{\mathbf{V}})) - p(\tilde{\mathbf{V}}) \cdot x_i(\tilde{\mathbf{V}}).$$

Finally, given an auction M and a distribution F over input profiles, we will write $W(M, F)$ for the expected welfare of M on input distribution F. We will sometimes drop the dependence of F and simply write $W(M)$ when F is clear from context. We emphasize that $W(M)$ is a

non-strategic notion of welfare; it is the expected welfare of M with respect to *inputs* drawn from F, or equivalently the welfare of M under truthful reporting when agent valuations are distributed according to F. Let $\mathbf{x}^M(V) = (x_1^M(V), \ldots, x_n^M(V))$ be the allocation rule of mechanism M for realization V. Then

$$W(M) = \mathbb{E}_{V \sim F}\left[\sum_i V_i\left(x_i^M(V)\right) - Q\left(\sum_i x_i^M(V)\right)\right].$$

A *Bayes-Nash equilibrium* of a uniform-price auction is a choice of bidding strategies $\sigma = (\sigma_1, \ldots, \sigma_n)$ for each agent, mapping each realized valuation curve V_i to a (possibly randomized) reported valuation $\sigma_i(V_i)$, so that each agent maximizes their expected utility by bidding according to σ_i given that other agents are bidding according to σ_{-i}. That is, for all V_i and all $\tilde{V}_i$, we have

$$\mathbb{E}_{V_{-i} \sim F_{-i}}[U_i(\sigma_i(V_i), \sigma_{-i}(V_{-i}))] \geq \mathbb{E}_{V_{-i} \sim F_{-i}}[U_i(\tilde{V}_i, \sigma_{-i}(V_{-i}))].$$

We make a standard assumption of *no overbidding* on behalf of the firms uniform-price auction, which is motivated by the fact that overbidding is a weakly-dominated strategy.

Motivated by license auctions used in practice, we study a particular form of uniform price auction that we call a *cap-and-price auction* which forces prices to be within some fixed interval.[3]

▶ **Definition 1.** *A* cap-and-price auction $M(C, \underline{p}, \overline{p})$ *is parameterized by a quantity* $C \geq 1$*, a price floor* $\underline{p}$*, and a price ceiling* $\overline{p} > \underline{p}$*. The allocation and price are determined as follows:*

1. *If* $\sum_i d_i(\overline{p}) \geq C$*, then* $x_i = d_i(\overline{p})$ *for all* i *and* $p = \overline{p}$*.*
2. *If* $\sum_i d_i(\underline{p}) < C$*, then* $x_i = d_i(\underline{p})$ *for all* i *and* $p = \underline{p}$*.*
3. *Otherwise, choose* $p = V(C) - V(C-1)$*, the* C^{th} *highest bid, and choose* $\vec{x}$ *to be any optimal allocation of* C *licenses among the firms:* $x \in \arg\max_{\vec{y} \in \mathbb{Z}_+^n : ||y||_1 = C} \sum_i V_i(y_i)$*.*

We can think of this as a uniform price auction of up to C licenses (case 3 above), where the price is set to the lowest winning marginal bid, with two modifications. First, there is a reserve price $\underline{p}$, so that possibly fewer than C licenses are sold if there is not enough demand at price $\underline{p}$; this is case 2. Second, if the lowest winning marginal bid would be larger than $\overline{p}$, then the price is lowered to $\overline{p}$ and firms can purchase as many licenses as they like at this price; this is case 1.

Given social cost function Q and valuation distribution F, we will write OPT for the optimal expected welfare obtained by any cap-and-price auction under truthful reporting. That is, $\text{OPT} = \max_{C, \underline{p}, \overline{p}}\{W(M(C, \underline{p}, \overline{p}))\}$. We will also tend to write C^*, $\underline{p}^*$, and $\overline{p}^*$ for the parameters that achieve this maximum. We emphasize that this is a non-strategic notion: OPT is the maximum expected welfare attainable when bidders report truthfully. We view OPT as a benchmark against which we will compare performance at Bayes-Nash equilibrium. Note also that, in general, OPT may be strictly less than the expected welfare of the unconstrained welfare-optimal allocation; an example is provided in Appendix C.

3 Safe-Price Auctions

We will derive a class of cap-and-price auctions, which we will call safe-price auctions, whose performance in equilibrium approximates their non-strategic welfare. The hope is that the non-strategic welfare of this class then approximates the non-strategic welfare of the larger class of cap-and-price auctions.

[3] Note the cap is not a hard constraint, but rather governs which prices bind.

▶ **Definition 2.** *A* safe-price auction *is a cap-and-price auction $M(C, \underline{p}, \overline{p})$ parameterized by a license quantity C, a price floor $\underline{p} = Q(C)/C$, and price ceiling $\overline{p} = \infty$. We will write $M(C)$ for the safe-price auction with license quantity C, and $P(C) = Q(C)/C$ for the associated safe price.*

This definition restricts cap-and-price auctions in two ways. The first is that the price ceiling is now infinite. The second is that we have imposed a lower bound on the price floor.[4] The first restriction is for convenience; the following lemma shows that it does not cause much loss in welfare. Motivated by this lemma, we will restrict our attention from now on to auctions with no price ceiling, that is, $\overline{p} = \infty$. We notate such mechanisms $M = (C, \underline{p})$. Note that, in the language of definition 1, case (1) can no longer occur. That is, when is there is no price ceiling, only exactly C or less than C licenses will be allocated.

▶ **Lemma 3.** *For any distribution F and any cap-and-price auction $M(C, \underline{p}, \overline{p})$, there exist a cap C' and price floor $\underline{p}'$ such that $W(M(C', \underline{p}', \infty)) \geq \frac{1}{2} W(M(C, \underline{p}, \overline{p}))$.*

The proof of Lemma 3 appears in Appendix A.1. The main idea is to decompose the expected welfare of a cap-and-price auction $M(C, \underline{p}, \overline{p})$ into the welfare attained from the first (at most) C licenses sold plus the incremental welfare attained from any licenses sold after the first C. The first can be approximated by $M(C, \underline{p}, \infty)$; the latter, if non-negative, can be approximated by $M(\infty, \overline{p}, \infty)$.

The second way safe-price auctions restrict price-and-cap auctions is with a lower bound on the price floor. As the following example shows, the equilibrium welfare of cap-and-price auctions, even those with an infinite price ceiling, suffer from a problem known as demand reduction in which a bidder improves her price, and hence utility, by asking for fewer units. This can have drastic consequences on welfare, causing it to become negative, due to the existence of the social cost. In particular, this means the approximation of such auctions, relative to the best welfare attainable in non-strategic settings, is unbounded.

▶ **Example 4.** Consider two agents, 1 and 2. Their distributions over valuations will be point-masses, so that the valuations are actually deterministic. These valuation functions are given by the following marginals: $v_1(1) = 10$, $v_1(2) = 10$, $v_2(1) = 6$, $v_2(2) = 1$, and all other marginals are 0. We will have $C = 2$, $\underline{p} = 0$, $\overline{p} = \infty$, and the social cost function is given by $Q(x) = 9x$. Under truthful reporting, the auction $M(C, \underline{p})$ allocates 2 licenses to agent 1 at a price of 6 each, resulting in a welfare of $V_1(2) - Q(2) = 20 - 18 = 2$. However, we note that firm 1 could improve their utility from 8 to 9 by instead reporting a modified valuation $\tilde{V}$ given by $\tilde{v}_1(1) = 10$ and $\tilde{v}_1(2) = 1$. If agent 2 continues to report truthfully, $M(C, \underline{p})$ will allocate 1 license to each agent at a price of 1 each, resulting in a welfare of $V_1(1) + V_2(1) - Q(2) = 16 - 18 = -2$. One can verify that this is indeed a pure Nash equilibrium of the auction, and hence a Bayes-Nash equilibrium as well.

The issue illustrated in Example 4 is that strategic behavior can cause licenses to be allocated to agents whose marginal values for these licenses are below $Q(C)/C$, causing the aggregate value derived from allocating C licenses to fall below $Q(C)$. Safe-price auctions seek to prevent this by imposing a sufficiently high price floor.

Indeed, the following lemma shows that price floors do indeed circumvent the issue in the above example. Namely, we show safe-price auctions have good equilibria, compared to their own non-strategic welfare. This is the main result of this section, and motivates us to focus on analyzing the non-strategic welfare of safe-price auctions.

[4] In fact we set $\underline{p}$ to be *equal* to $P(C)$, but our results still hold if this is relaxed to $\underline{p} \geq P(C)$.

▶ **Lemma 5.** *For any safe-price auction $M(C)$, the expected welfare at any Bayes-Nash equilibrium is at least $(\frac{1}{3.15}) \cdot W(M(C))$.*

Proof. Fix a license cap C and write $\underline{p} = Q(C)/C$ for the corresponding safe price, and recall that $M(C) = M(C, \underline{p})$. We claim that this auction is strategically equivalent to a modified auction, as follows. First, since each agent pays at least $\underline{p}$ per license, we can define $\hat{v}_i(j) = v_i(j) - \underline{p}$ for the residual marginal utility of agent i for their j^{th} license, after taking into account that they must pay at least $\underline{p}$. Then from each agent's perspective, playing in $M(C, \underline{p})$ with marginal values $v_i(j)$ gives the same utility as playing in $M(C, 0)$ with marginal values $\hat{v}_i(j)$. The welfare generated by the original auction is $V(x) - Q(x)$, which is equal to $\hat{V}(x) - (Q(x) - \underline{p}x)$. So the welfare generated by M is equivalent to the welfare generated with modified valuations $\hat{V}$, where the marginal social cost of each unit of pollution is reduced by $\underline{p}$. But now note that from the definition of $\underline{p}$, $Q(x) - \underline{p}x \leq 0$ for all $x \leq C$. So in an auction with a cap of C, the welfare is at least the welfare obtained with a social cost of 0; it is always non-negative.

We conclude that the welfare generated by $M(C, \underline{p})$, at any equilibrium, is equal to the welfare generated at an equilibrium of the standard uniform price auction with modified valuations $\hat{V}$. Theorem 3 of [13] (which bounds the welfare in Bayes-Nash equilibria of uniform auctions without costs) therefore applies[5], and the welfare at any equilibrium is at least $\frac{1}{3.15}$ times the optimum achievable under the modified valuations, which is at most $W(M(C))$. ◀

4 Welfare Approximation

Motivated by Lemma 5, we would like to show that the non-strategic welfare of safe-price auctions approximates that of cap-and-price auctions. Unfortunately, there are cases where this does not hold, as demonstrated by Example 6. The example consists of just a single firm that dominates the market and whose demand for licenses has high variance. The firm's value is always large enough that even at a low price and high license cap, the resulting allocation has high net welfare. However, safe-price auctions will generate much lower welfare. Roughly speaking, for any number of licenses C that the auction designer selects as the cap for a safe-price auction, significant welfare will be lost from realizations where the firm's demand is much higher than C, and the corresponding safe price will exclude welfare gains from realizations where the firm's demand is much lower than C. If the variance is high enough, this will cause overall welfare to be low regardless of the choice of C.

▶ **Example 6.** We will present an example for which the expected welfare of any safe-price auction $M(C)$ is at most an $O(1/n)$-approximation to OPT. Let $Q(x) = x^2$. There is a single firm participating in the auction. That firm's valuation curve is drawn according to a distribution F over n different valuation curves, which we'll denote $V^{(1)}, \ldots, V^{(n)}$. For all i, valuation $V^{(i)}$ is defined by $V^{(i)}(x) = \max\{2^{i+1} \cdot x, 2^{2i+1}\}$. The probability that $V^{(i)}(\cdot)$ is drawn from F is proportional to $\frac{1}{2^{2i}}$. That is, the firm has valuation $V^{(i)}$ with probability $\frac{1}{\beta 2^{2i}}$, where $\beta = \sum_{i=1}^{n} 2^{-2i} = \frac{1}{3}(1 - 2^{-2n})$ is the normalization constant. Note that a cap-and-price auction with cap $C = \infty$ and price floor $\underline{p} = 1$ achieves welfare $\sum_{i=1}^{n} 2^{2i} \frac{1}{\beta 2^{2i}} = \frac{1}{\beta} \cdot n$, so OPT is at least this large.[6]

[5] The proof of the 3.15 bound in [13] is actually for a uniform-second-price auction that charges the highest losing bid, or $V(C+1) - V(C)$; however, the proof is also correct for charging a price of the lowest winning bid $V(C) - V(C-1)$.

[6] In fact, this is the "first-best" welfare obtainable at every possible realization, so this is actually the best possible cap-and-price auction and hence the exact value of OPT.

Consider a safe-price auction with cap C'. Suppose that $C' \in (2^k, 2^{k+1}]$ for some $k \geq 1$. Then the safe price is $P(C') = Q(C')/C' = (C')^2/C' = C' > 2^k$. If the firm has valuation $V^{(i)}$ with $i \leq k-1$, then all marginal values are strictly below $P(C')$, then no licenses are allocated and the welfare generated is 0. On the other hand, if the firm has valuation $V^{(i)}$ for any $i \geq k$, then since at most $C' \leq 2^{k+1}$ licenses can be purchased, the auction generates welfare at most $2^{i+1}(2^{k+1}) - (2^{k+1})^2 = 2^{2k+2}(2^{i-k} - 1)$.

The total expected welfare of $M(C')$ is therefore at most

$$\sum_{i=k}^{n} 2^{2k+2}(2^{i-k} - 1) \cdot \frac{1}{\beta 2^{2i}} = \frac{4}{\beta} \sum_{i=k}^{n} 2^{-2(i-k)}(2^{i-k} - 1) \leq \frac{4}{\beta} = O(1).$$

Since $\textsc{opt} \geq \frac{1}{\beta} \cdot n$ but $W(M(C')) = O(1)$ for all C', we conclude that no auction with a safe price achieves an $o(n)$-approximation to $\textsc{opt}$. This concludes the example.

Example 6 is driven by a single firm that dominates the market and has high variance in their demand. We next show that this is the *only* barrier to a good approximation: either a safe-price auction is constant-approximate, or else one can approximate the optimal welfare by selling to just a single firm. To this end, we will be interested in the expected maximum welfare attainable by allocating licenses to just one firm, which we will denote $W^{(1)}$. That is,

$$W^{(1)} = \mathbb{E}_{V \sim F}\left[\max_{i, x \geq 0}\{V_i(x) - Q(x)\}\right].$$

The following theorem is our main result.

▶ **Theorem 7.** *There exists a constant c such that, for any cap C and price floor $\underline{p}$, there exists C' such that $c \cdot W(M(C')) + W^{(1)} \geq W(M(C, \underline{p}))$.*

Note that a corollary of Theorem 7 (combined with Lemmas 3 and 5) is that for any cap-and-price auction $M(C, \underline{p}, \overline{p})$, there exists some C' such that the expected welfare of any Bayes-Nash equilibrium of $M(C')$ is at least a constant factor of $W(M(C, \underline{p}, \overline{p})) - W^{(1)}$. That is, the worst-case equilibrium welfare is a constant-factor approximation to the best welfare achievable by any cap-and-price auction under truth-telling, excluding the welfare contribution of a single firm.

Also, $W^{(1)}$ is the expected welfare of a truthful mechanism that we will call $M^{(1)}$. In $M^{(1)}$, the firms first participate in a second-price auction for the right to buy licenses. The firm with the highest bid wins, and they pay the second-highest bid. The winning firm can then purchase any number of licenses $x \geq 0$, for which they pay $Q(x)$ (in addition to their payment from the initial second-price auction). Since the utility obtained by firm i if they win the initial auction is precisely $\max_x\{V_i(x) - Q(x)\}$, and since a second-price auction is truthful and maximizes welfare, we can conclude that $W(M^{(1)}) = W^{(1)}$. Then another corollary of Theorem 7 is that one can approximate the non-strategic welfare of any cap-and-price auction using either a safe-price auction (in which case the approximation holds at any Bayes-Nash equliibrium), or using the (truthful) mechanism $M^{(1)}$ that allocates licenses to at most one firm.

We are now ready to prove Theorem 7. Fix a cost function Q and distribution F, and choose the optimal cap C and price floor p such that $W(M(C, p))$ is maximized. Let $d(\cdot)$ and $x(\cdot)$ be the demand and allocation functions for $M(C, p)$. For any given realization of preferences V, there is a total demand $d(V) = \sum_i d_i(p)$, where again, $d_i(p) = \arg\max_x V_i(x) - px$. Recall also that $W(x, V) = V(x) - Q(x)$ is the welfare generated by allocation x given aggregate valuation V.

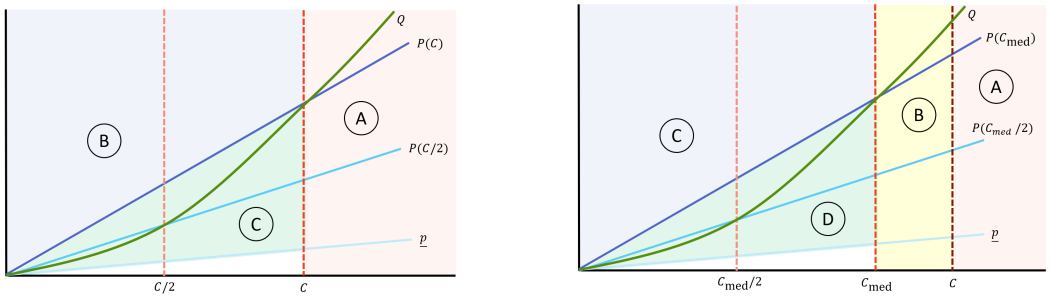

Figure 1 A visualization of the proofs of Theorem 8 (a) and Theorem 7 (b). The x-axis represents quantity of licenses; the y-axis represents value. The expected welfare of benchmark $W(M(C, \underline{p}))$ is divided into separate contributions, based on the location of allocation outcome $(x, V(x))$; these are depicted as shaded regions. Each of these contributions is bounded by either the welfare of a safe-price auction or the welfare obtained from a single buyer. Figure (a) is the (simpler) partition used in Theorem 8, and (b) is the partition used in Theorem 7.

We will begin by proving a simpler version of Theorem 7, which is parameterized by $q := \Pr[d(V) \geq C]$, the probability that the auction sells C licenses. When q is bounded away from 0, we show that there is a safe-price auction that achieves an $O(1/q)$-approximation to $W(M(C, p))$. We note that this result does not require firm valuations to be independent, and holds even if the valuations are drawn from an arbitrarily correlated distribution F. We will explain in Section 4.1 how to extend the argument to the general case of Theorem 7, with details deferred to the appendix.

▶ **Theorem 8.** *For the welfare-optimal cap C and price floor p, there exists a cap C' such that $(1 + 2/q) \cdot W(M(C')) \geq W(M(C, p))$.*

Proof. The welfare generated by $M(C, p)$ can be broken down as follows:

$$W(M(C,p)) = \Pr_{V\sim F}[d(V) \geq C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) \geq C] + \Pr_{V\sim F}[d(V) < C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) < C].$$

The first term is the contribution to the welfare from events where C licenses are sold (or, equivalently, at least C licenses are demanded). The second term is the contribution from events where the total demand for licenses is less than C.

Consider price $P(C)$, the safe price for quantity C. We wish to decompose the second term in the expression above into marginal values above $P(C)$ and those below $P(C)$. For this, we need to introduce some notation. Write θ_i for the largest $j \geq 1$ such that $v_i(j) \geq P(C)$, or $\theta_i = 0$ if $V_i(1) < P(C)$. Write $x_i^{>} = \min\{x_i, \theta_i\}$, and write $x_i^{<} = x_i - x_i^{>}$. Then $x_i^{>}$ is the part of allocation x_i for which firm i has marginal value at least $P(C)$ per unit, and $x_i^{<}$ is the part of x_i for which firm i has a marginal value less than $P(C)$ per unit. We'll also define $V_i^{<}$ as $V_i^{<}(x) = V_i^{<}(x|\theta_i)$; this is the marginal value of i for receiving x additional licenses after already having received θ_i licenses. Note then that $V_i(x_i) = V_i(x_i^{>}) + V_i^{<}(x_i^{<})$, for all i. We then have

$$\begin{aligned}
&\Pr_{V\sim F}[d(V) < C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) < C] \\
&\quad = \int_{V\,:\,d(V)<C} \left(\sum_i V_i(x_i(V)) - Q(x(V)) \right) dFV \\
&\quad \le \int_{V\,:\,d(V)<C} \left(\sum_i V_i(x_i^{>}(V)) - Q(x^{>}(V)) \right) dFV \\
&\qquad + \int_{V\,:\,d(V)<C} \left(\sum_i V_i^{<}(x_i^{<}(V)) - Q(x^{<}(V)) \right) dFV
\end{aligned}$$

where the final inequality used the fact that $Q(x) \ge Q(x^{<}) + Q(x^{>})$, due to the convexity of Q. We conclude that

$$W(M(C,p)) \le \Pr_{V\sim F}[d(V) \ge C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) \ge C] \tag{1A}$$

$$+ \int_{V\,:\,d(V)<C} \left(\sum_i V_i(x_i^{>}(V)) - Q(x^{>}(V)) \right) dFV \tag{1B}$$

$$+ \int_{V\,:\,d(V)<C} \left(\sum_i V_i^{<}(x_i^{<}(V)) - Q(x^{<}(V)) \right) dFV \tag{1C}$$

so that $W(M(C,p)) \le (1\text{A}) + (1\text{B}) + (1\text{C})$. See Figure 1(a) for an illustration.

We claim that the welfare obtained from the first two terms, (1A) and (1B), are covered by the safe-price auction with cap C. The intuition is that a price floor of $P(C)$ does not interfere with the welfare contribution due to licenses with marginal values greater than $P(C)$. One subtlety is that some of the licenses in the summation (1A) might have marginal values less than $P(C)$, but it turns out that it can only improve welfare to exclude such licenses from the allocation.

▷ Claim 9. $W(M(C)) \ge (1\text{A}) + (1\text{B})$.

Proof. Write d' and x' for the demand and allocation under auction $M(C)$, respectively. We have

$$\begin{aligned}
W(M(C)) = &\Pr_{V\sim F}[d(V) \ge C] \cdot \mathbb{E}[W(x'(V), V) \mid d(V) \ge C] \\
&+ \Pr_{V\sim F}[d(V) < C] \cdot \mathbb{E}[W(x'(V), V) \mid d(V) < C].
\end{aligned}$$

Note that we intentionally use $d(V)$, the demand for $M(C,p)$, rather than $d'(V)$ in the expressions above. The second term is precisely (1B), since $x'_i = x_i^{>}$ from the definition of $x^{>}$. We claim that the first term is at least (1A). To see why, fix any V with $d(V) \ge C$ (and corresponding allocation $x = x(V)$ where necessarily $|x| = C$), and note that $x'_i \le x_i$ for all i. Furthermore, $V_i(x'_i) \ge V_i(x_i) - (x_i - x'_i)P(C)$, since x'_i is simply x_i after possibly excluding some items with marginal value less than $P(C)$. Thus, since $|x| = C$,

$$V(x') - |x'| \cdot P(C) \ge V(x) - |x| \cdot P(C) = V(x) - Q(|x|).$$

Also, by convexity, we have $Q(y) \le y \cdot P(C)$ for all $y \in [0, |x|]$. In particular, we have $V(x') - Q(|x'|) \ge V(x') - |x'| \cdot P(C) \ge V(x) - Q(|x|)$, and hence

$$\begin{aligned}
&\Pr_{V\sim F}[d(V) \ge C] \cdot \mathbb{E}[W(x'(V), V) \mid d(V) \ge C] \\
&\ge \Pr_{V\sim F}[d(V) \ge C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) \ge C]
\end{aligned}$$

as claimed. ◁

The more difficult part of the proof of Theorem 8 is to account for term (1C). This represents the contribution of licenses whose marginal values lie below $P(C)$, and are therefore excluded when the price floor is set to $\underline{p} = P(C)$. What we show is that the welfare contribution from all such licenses is approximated by $W(M(C/2))$, the welfare obtained by the safe auction with cap $C/2$.[7] We do this in three steps. First, we show that any optimal cap-and-price auction $M(C, \underline{p})$ must generate non-negative expected welfare conditional on selling C licenses. The intuition is that if the expected welfare from selling C licenses is negative, then it must be strictly preferable to reduce the quantity of licenses.

▶ **Lemma 10.** *If cap C and price floor p are chosen to maximize $W(M(C,p))$, then*

$$\mathbb{E}_{V\sim F}[W(M(C,p)) \mid d(V) \geq C] \geq 0,$$

where $d(V)$ is the total quantity of licenses demanded at price p.

The proof of Lemma 10 appears in Appendix B.1. Next, for any cap-and-price auction M, we provide an upper bound on the total welfare contribution that comes from events where $x < C$ licenses are sold, and the average marginal value of the sold licenses, $V(x)/x$, is less than $P(C)$. In fact, it will be useful to state the lemma more generally: we provide a more general bound that applies to any $\tilde{C} \leq C$ and any valuation that is at most $P(\tilde{C}) \cdot x$ (not necessarily $V(x)$). The lemma bounds the total welfare contribution, $P(\tilde{C}) \cdot x - Q(x)$, by the difference in price between (a) $\tilde{C}$ licenses sold at the safe price for $\tilde{C}$, and (b) the same $\tilde{C}$ licenses sold at the safe price for $\tilde{C}/2$.

▶ **Lemma 11.** *Choose some quantity $\tilde{C}$ and a number of licenses $x \leq \tilde{C}$. Then $P(\tilde{C}) \cdot x - Q(x) \leq \tilde{C} \cdot (P(\tilde{C}) - P(\tilde{C}/2))$.*

The proof of Lemma 11 appears in Appendix B.2. We are now ready to bound the contribution of (1C). The intuition is as follows. By Lemma 11, the contribution from (1C) is at most (a constant times) the gap between the line $y = P(C) \cdot x$ and the curve $Q(x)$ at point $x = C/2$. But recall that $\Pr[d(V) \geq C] = q$, and Lemma 10 implies that, on average, the expected marginal value of licenses allocated subject to this event is at least $P(C)$. Therefore, if we set a license cap of $C/2$, then with probability at least q all $C/2$ licenses will be sold at an average expected marginal value of at least $P(C)$. The welfare generated in this case covers the "gap" at $C/2$, and hence covers the loss due to excluding licenses with marginal values at most $P(C)$.

▷ Claim 12. $W(M(C/2)) \geq \frac{1}{2}q \cdot (1\text{C})$.

Proof. Write d' and x' for the demand and allocation under mechanism $M(C/2)$, respectively. Choose any V such that $d(V) \geq C$. For any such V, $d'(V) \leq d(V)$, and is formed by removing items with marginal value at most $P(C/2)$. In particular, since $x'(V) \leq d'(V)$, we have $V(x'(V)) \geq V(C) - (C - x'(V)) \cdot P(C/2)$. Noting that $Q(|x'(V)|) \leq |x'(V)| \cdot P(C)$ since $x'(V) \leq x(V)$, we have

$$\begin{aligned} V(x'(V)) - Q(|x'(V)|) &\geq V(x'(V)) - |x'(V)| \cdot P(C) \\ &\geq V(C) - (C - |x'(V)|) \cdot P(C/2) - |x'(V)| \cdot P(C). \end{aligned}$$

[7] For convenience we will assume C is even for the remainder of this section. When C is odd, the result holds for at least one of the floor or the ceiling of $C/2$. Details appear in the full version.

Taking an expectation over all V such that $d(V) \geq C$, we note that Lemma 10 implies $\mathbb{E}[V(C)] \geq C \cdot P(C)$. We therefore have

$$\begin{aligned}\mathbb{E}[V(x'(V)) - Q(|x'(V)|)] &\geq C \cdot P(C) - (C - \mathbb{E}[|x'(V)|]) \cdot P(C/2) - \mathbb{E}[|x'(V)|] \cdot P(C) \\ &= (C - \mathbb{E}[|x'(V)|])(P(C) - P(C/2)) \\ &\geq (C/2) \cdot (P(C) - P(C/2))\end{aligned}$$

where in the last inequality we used that $|x'(V)| \leq C/2$ by definition. Since $\Pr[d(V) \geq C] = q$, we therefore have that

$$\begin{aligned}W(M(C/2)) \geq \Pr[d(V) \geq C] \cdot \mathbb{E}[V(x'(V)) - Q(|x'(V)|) \mid d(V) \\ \geq C] \geq q(C/2) \cdot (P(C) - P(C/2).\end{aligned}$$

We now claim that $(C/2) \cdot (P(C) - P(C/2) \geq (1C)/2$, completing the proof. To see why, note that for any $x^* < C$ and any V, $V^<(x^*) - Q(|x^*|) \leq |x^*| \cdot P(C) - Q(|x^*|)$. Thus $(1C) \leq \max_{x^*}\{|x^*| \cdot P(C) - Q(|x^*|)\}$. But note that for any $x^* > C/2$, we have $Q(x^*) > |x^*|P(C/2)$, and hence $|x^*| \cdot P(C) - Q(|x^*|) \leq |x^*| \cdot (P(C) - P(C/2)) \leq (C) \cdot (P(C) - P(C/2))$. Also, for any $x^* < C/2$, $Q(|x^*|)$ lies above the line joining $(C/2, Q(C/2))$ and $(C, Q(C))$, and hence $|x^*| \cdot P(C) - Q(|x^*|)$ is at most the distance between $|x^*| \cdot P(C)$ and this line, which is at most $(C) \cdot (P(C) - P(C/2))$. So in either case we have $\max_{x^*}\{|x^*| \cdot P(C) - Q(|x^*|)\} \leq C \cdot (P(C) - P(C/2))$ as required. ◁

Combining Claim 9 and Claim 12 we have that $W(M(C)) + (2/q)W(M(C/2)) \geq W(M(C, \underline{p}))$, which completes the proof of Theorem 8. ◀

As a corollary, Theorem 8 combined with Lemma 5 and Lemma 3 implies that for any cap and price auction $M(C, \underline{p}, \overline{p})$, there exists a safe-price auction $M(C')$ such that, at any Bayes-Nash equilibrium of $M(C')$, the expected welfare generated is at least $\frac{1}{3.15} \cdot \frac{1}{2} \cdot \frac{1}{1+2/q} \cdot W(M(C, \underline{p}, \overline{p}))$. In particular, if q is a constant bounded away from 0, then $M(C')$ obtains a constant fraction of $W(M(C, \underline{p}, \overline{p}))$ at any Bayes-Nash equilibrium.

4.1 The General Case

We complete the proof of Theorem 7 in Appendix B.3. Here we describe at a high level what steps are needed to complete the argument. We will focus on the case where $\Pr[d(V) \geq C] < 1 - 1/e$, since if $\Pr[d(V) \geq C] \geq 1 - 1/e$ then Theorem 7 follows from Theorem 8.

Recall that in Claim 12, we used the assumption that $\Pr[d(V) \geq C] = q$ to argue that the welfare gained in $M(C/2)$ in the event that $d(V) \geq C$ covers the welfare lost from marginals lying below $P(C)$, up to a constant factor. If the probability that $d(V) \geq C$ is small, then this may no longer be true. To handle this, we consider a reduced cap $C_{\text{med}} < C$ set to be the largest integer such that $\Pr[d(V) \geq C_{\text{med}}] \geq 1 - 1/e$. Our hope is to reproduce the argument from Claim 12, but substituting C_{med} for C. To this end, we divide the welfare of $M(C, \underline{p})$ into *four* parts: all welfare under the event that $d(V) > C$; all welfare from individual agents whose demand is at least C_{med}; the contribution of marginal values greater than $P(C_{\text{med}})$ (but with individual firms demanding at most C_{med}) when $d(V) < C$, and the contribution of marginal values less than $P(C_{\text{med}})$ when $d(V) < C$. See Figure 1(b) for an illustration.

As in the proof of Theorem 8, the contribution due to events where $d(V) > C$ can be covered by the welfare of $M(C, P(C))$.

The contribution from agents who individually demand at least C_{med} licenses is a new case that we didn't have to handle in Theorem 8. It is here that we use $M^{(1)}$, allocating to any single agent. Because the *total* demand is at most than C_{med} with probability at least

$1/e$, independence implies that the expected number of agents who demand more than C_{med} licenses is at most 1, given that the probability that none have demand more C_{med} must be at least $1/e$. So the total contribution to welfare of all such events is at most $W(M^{(1)})$.

If $d(V) \leq C_{\text{med}}$, then the contribution from marginal values that are at least $P(C_{\text{med}})$ can be covered by the welfare of $M(C_{\text{med}}, P(C_{\text{med}}))$, precisely as in Claim 9. We must also handle the case that $d(V) \in [C_{\text{med}}, C]$, and consider the welfare contribution of agents that do not (individually) demand more than C_{med} licenses. Here we use independence: the total quantity demanded by such "small" agents is likely to concentrate, so it is unlikely that the total demand will be larger than $2C_{\text{med}}$. Thus, by imposing a cap of C_{med}, we lose at most a constant factor of the welfare from marginal values greater than $P(C_{\text{med}})$.

The final step is to show that $W(M(C_{\text{med}}/2))$ obtains at least a constant fraction of the welfare generated by marginal values less than $P(C_{\text{med}})$, similarly to Claim 12. When proving Claim 12, we used Lemma 10 to argue about the welfare generated by events where $d(V) > C$. Unfortunately, Lemma 10 does not extend to C_{med}: it could be that the expected welfare generated by $M(C_{\text{med}}, P(C_{\text{med}}))$, conditional on selling C_{med} licenses, is negative. However, we *can* prove an upper bound on how negative this expected welfare can be. After all, if the expected welfare is sufficiently negative sufficiently often, it would be welfare-improving to increase the price floor of $M(C, \underline{p})$ from $\underline{p}$ to $P(C_{\text{med}})$, contradicting the supposed optimality of $M(C, \underline{p})$. This turns out to be enough to prove a bound similar to Claim 12.

Combining these bounds, we can conclude that each of the four parts of the welfare of $M(C, \underline{p})$ can be covered by either a safe-price auction or by $M^{(1)}$, which completes the proof of the theorem.

A Omitted Proofs from Section 3

A.1 Proof of Lemma 3

Recall the statement of Lemma 3: for any distribution F and any cap-and-price auction $M(C, \underline{p}, \overline{p})$, there exist a cap C' and price floor $\underline{p}'$ such that $W(M(C', \underline{p}', \infty)) \geq \frac{1}{2}W(M(C, \underline{p}, \overline{p}))$.

Proof. We show that given any mechanism $M = (C_1, \underline{p}, \overline{p})$, we can construct a mechanism M' with price ceiling ∞ such that $W(M') \geq \frac{1}{2}W(M)$.

We can decompose the expected welfare of M into (a) the welfare attained from the first (at most) C_1 licenses sold, and (b) the incremental welfare attained from any licenses sold after the first C_1.

Note that the auction $M^1 = (C_1, \underline{p}, \infty)$, which is M but with price ceiling set to ∞, achieves welfare precisely equal to the former of these two parts. This is because M^1 always allocates at most C_1 licenses, and will allocate them efficiently subject to all marginal values being at least $\underline{p}$.

Next consider the second of these two parts of the welfare of M. If the expected welfare in the second part is negative, then we are already done, so suppose not. Whenever more than C_1 licenses are sold, all licenses are sold at price $\overline{p}$, and therefore have marginal value at least $\overline{p}$. Auction $M^2 = (\infty, \overline{p}, \infty)$, with no license cap and with a price floor of $\overline{p}$, will also sell all such licenses that have marginal value at least $\overline{p}$. We note, however, that M^2 additionally also includes the marginal contribution of the first C_1 licenses. But we claim that this contribution is non-negative: when the event occurs that more than C_1 licenses are sold, the marginal contribution of the first C_1 licenses to the welfare can only be greater than that of those beyond the first C_1. Thus, since the expected welfare in the second part is non-negative, the welfare is only higher if we also include the contribution of the first C_1 licenses whenever more than C_1 licenses are sold. This is precisely the welfare of auction $M^2 = (\infty, \overline{p}, \infty)$, so the welfare of M^2 is therefore at least that of the second of the two parts of the welfare of M.

We conclude that $W(M^1) + W(M^2) \geq W(M)$, and hence either $W(M^1)$ or $W(M^2)$ is at least $\frac{1}{2}W(M)$. ◀

B Omitted Proofs from Section 4

B.1 Proof of Lemma 10

First recall the statement of the lemma. If C and p are chosen to maximize $W(M(C, p))$, then $\mathbb{E}[W(V, x(V)) \mid d(V) \geq C] \geq 0$.

Proof. Suppose not. Then it must be that $\mathbb{E}[W(V, x(V)) \mid d(V) \geq C] < 0$. We will show this implies $W(M(C-1, p)) > W(M(C, p))$, contradicting the optimality of C. To see why, note that when $d(p) < C$, the welfare of the two auctions is identical. Write x and x' for the allocation functions from $M(C, p)$ and $M(C-1, p)$, respectively. When $x \geq C$, we have $x' = C - 1$, and $V(x') \geq \frac{C-1}{x} \cdot V(x)$ by concavity. Similarly, $Q(x') \leq \frac{C-1}{x} \cdot Q(x)$ by convexity. Thus, for any V such that $d(V) \geq C$ and hence $x(V) = C$, we have

$$V(x'(V)) - Q(x'(V)) \geq \frac{C-1}{x(V)}(V(x(V)) - Q(x(V))) = \frac{C-1}{C}(V(x(V)) - Q(x(V))).$$

Taking expectations, we therefore have

$$\begin{aligned}\mathbb{E}[V(x'(V)) - Q(x'(V)) \mid d(V) \geq C] &\geq \frac{C-1}{C}(\mathbb{E}[V(x(V)) - Q(x(V)) \mid d(V) \geq C]) \\ &> \mathbb{E}[V(x(V)) - Q(x(V)) \mid d(V) \geq C]\end{aligned}$$

where the last inequality follows because $\mathbb{E}[V(x(V)) - Q(x(V)) \mid d(V) \geq C] < 0$ by assumption. This implies $W(M(C-1,p)) > W(M(C,p))$, which is the desired contradiction. ◀

B.2 Proof of Lemma 11

First recall the statement of the lemma. Choose some quantity $\tilde{C}$ and a number of licenses $x \leq \tilde{C}$. Then $P(\tilde{C}) \cdot x - Q(x) \leq \tilde{C} \cdot (P(\tilde{C}) - P(\tilde{C}/2))$.

Proof. Suppose $x \geq \tilde{C}/2$. Then $Q(x) \geq \frac{x}{\tilde{C}/2} \cdot Q(\tilde{C}/2)$ by convexity. So $P(\tilde{C}) \cdot x - Q(x) \leq x \cdot \big(P(\tilde{C}) - Q(\tilde{C}/2)/(\tilde{C}/2)\big) \leq \tilde{C} \cdot (P(\tilde{C}) - P(\tilde{C}/2))$ as claimed.

Next suppose $x < \tilde{C}/2$. Then $(x, P(\tilde{C}) \cdot x)$ and $(x, Q(x))$ both lie between the line through the origin with slope $P(\tilde{C})$, and the line between $(\tilde{C}, Q(\tilde{C}))$ and $(\tilde{C}/2, Q(\tilde{C}/2))$. Their difference is therefore at most twice the difference between those two lines at x-coordinate $\tilde{C}/2$, which is $(\tilde{C}/2) \cdot (P(\tilde{C}) - P(\tilde{C}/2))$. ◀

B.3 Omitted Details from the Proof of Theorem 7

Recall the statement of Theorem 7: for any cap C and price floor $\underline{p}$, there exists C' and a constant c such that $c \cdot W(M(C')) + W(M^{(1)}) \geq W(M(C, \underline{p}))$.

As in the proof of Theorem 8, the welfare generated by $M(C,p)$ can be broken down as follows:

$$\begin{aligned}W(M(C,p)) = &\Pr_{V\sim F}[d(V) \geq C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) \geq C] \\ &+ \Pr_{V\sim F}[d(V) < C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) < C]\end{aligned}$$

We will break down the second term into three sub-terms. Recall that we can assume $\Pr[d(V) \geq C] \leq 1 - 1/e$. Choose $C_{\text{med}} < C$ so that $\Pr[d(V) \geq C_{\text{med}}] = 1 - 1/e$. We will write $x_i = x_i^* + x_i^> + x_i^<$. If $x_i \geq C_{\text{med}}$ then we set $x_i^* = x_i$ and $x_i^> = x_i^< = 0$, otherwise we set $x_i^* = 0$. In this latter case, we set $x_i^>$ and $x_i^<$ similarly as in case 1, except that we consider marginal values above and below $P(C_{\text{med}})$ rather than $P(C)$. That is, if θ_i is the largest $j \geq 1$ such that $v_i(j) \geq P(C_{\text{med}})$ (or $\theta_i = 0$ if $v_i(1) < P(C_{\text{med}})$), we have $x_i^> = \min\{x_i, \theta_i\}$ and $x_i^< = x_i - x_i^>$. And as before, we will define $V_i^<$ as $V_i^<(x) = V_i^<(x|\theta_i)$, the valuation of i counting only those marginal values less than $P(C_{\text{med}})$.

Using convexity of Q as in case 1, we then have

$$W(M(C,p)) \leq \Pr_{V\sim F}[d(V) \geq C] \cdot \mathbb{E}[W(x(V), V) \mid d(V) \geq C] \tag{2A}$$

$$+ \int_{V\,:\,d(V)<C} (\sum_i V_i(x_i^*(V)) - Q(x^*(V)))dFV \tag{2B}$$

$$+ \int_{V\,:\,d(V)<C} (\sum_i V_i(x_i^>(V)) - Q(x^>(V)))dFV \tag{2C}$$

$$+ \int_{V\,:\,d(V)<C} (\sum_i V_i^<(x_i^<(V)) - Q(x^<(V)))dFV \tag{2D}$$

so that $W(M(C,p)) \leq (2A) + (2B) + (2C) + (2D)$.

As in Theorem 8, we have that $W(M(C)) \geq (2A)$. For $(2B)$, note that the probability that every bidder i has $x_i < C_{\text{med}}$ is at least $1/e$, from the definition of C_{med}. If we write p_i for the probability that $x_i < C_{\text{med}}$, then we have $\prod_i p_i \geq 1/e$. Subject to this condition, the value of $\sum_i (1-p_i)$ is maximized by setting all p_i equal, in which case we have $\sum_i (1-p_i) \leq n(1-e^{-1/n}) \leq 1$. But this means that the expected number of agents with $x_i \geq C_{\text{med}}$ is at most 1. Thus, $(2B)$ is at most the value of allocating to just a single bidder with $x_i > C_{\text{med}}$, which is at most the maximum possible welfare attainable from allocating to any one bidder. We therefore have that $W(M^{(1)}) \geq (2B)$.

We next claim that $W(M(C_{\text{med}})) \geq (2C)/4$. To see why, note that

$$\begin{aligned}
&\int_{V\,:\,d(V)<C} \left(\sum_i V_i(x_i^{>}(V)) - Q(x^{>}(V))\right) dFV \\
&\leq 2\int_{V\,:\,d(V)<C} 1[x(V) < 2C_{\text{med}}] \cdot \left(\sum_i \left(V_i(x_i^{>}(V)) - x_i^{>} \cdot \tfrac{Q(x^{>}(V))}{x^{>}(V)}\right)\right) dFV \\
&\leq 4\int_{V\,:\,d(V)<C} 1[x(V) < 2C_{\text{med}}] \cdot \left(\sum_i \left(\sum_{j \leq x_i^{>}} v_i(j)/2\right) - x_i^{>} \cdot \tfrac{Q(\min\{C_{\text{med}}, x^{>}(V)\})}{\min\{C_{\text{med}}, x^{>}(V)\}}\right) dFV \\
&\leq 4W(M(C_{\text{med}}))
\end{aligned}$$

where the last inequality follows because, when imposing a cap of C_{med} on an allocation of total size at most $2C_{\text{med}}$, the value obtained is at least the top half of all marginal values, which is more than half of all marginal values.

Finally, we claim that $W(M(C_{\text{med}}/2)) \geq (2D)/21$. Define $\Psi := (C_{\text{med}}/2) \cdot (P(C_{\text{med}}) - P(C_{\text{med}}/2))$. Then Lemma 11, combined with the fact that the total demand is at most C_{med} with probability $1/e$, implies that $(2D) \leq (2/e) \cdot \Psi$.

We claim that for $\beta = \frac{8}{3(e-1)} \approx 1.55$, we must have $\Pr[V(C_{\text{med}}) < Q(C_{\text{med}}) - \beta \cdot \Psi \mid d(V) > C_{\text{med}}] \leq 1/4$. That is, conditional on having total demand at least C_{med}, the probability that the welfare generated at C_{med} is more negative than $-\beta \cdot \Psi$ is at most $1/4$. Suppose not: then consider the difference in welfare between $M(C,p)$ and $M(C, P(C_{\text{med}}))$. The difference is that (2D) would be removed, as would any (negative) contribution with $V(C_{\text{med}}) < Q(C_{\text{med}})$ and $d(V) > C_{\text{med}}$. As we noted above, the total contribution of (2D) to the welfare is at most $2\Psi/e$. But the contribution due to the event $V(C_{\text{med}}) < Q(C_{\text{med}}) - \Psi$ and $d(V) > C_{\text{med}}$ is at most $-(\beta\Psi)(1-1/e)(3/4)$. So as long as $\beta \geq (8/3(e-1)) \approx 1.55$, we would have $W(M(C, P(C_{\text{med}}))) > W(M(C,p))$. This contradicts the optimality of $M(C,p)$.

We can therefore assume $\Pr[V(C_{\text{med}}) \geq Q(C_{\text{med}}) - \beta\Psi \mid d(V) > C_{\text{med}}] \geq 1/4$. By concavity of V and convexity of Q, this means $\Pr[V(C_{\text{med}}/2) \geq Q(C_{\text{med}}/2) + (2-\beta)\Psi/2 \mid d(V) > C_{\text{med}}] \geq 1/4$. Since $d(V) \geq C_{\text{med}}$ with probability at least $1-1/e$, the total welfare generated by $M(C_{\text{med}}/2)$ from the events $d(V) \geq C_{\text{med}}$ is at least $(2-\beta)(1-1/e)\Psi/8$, and hence $W(M(C_{\text{med}}/2)) \geq (2-\beta)(1-1/e)\Psi/8$. Since $(2-\beta)(1-1/e)e/16 \geq 1/21$, the result follows.

We conclude that

$$W(M(C)) + W(M^{(1)}) + 4W(M(C_{\text{med}})) + 21W(M(C_{\text{med}}/2)) \geq W(M(C, \underline{p})).$$

This implies Theorem 7, with $c = 26$.

C Cap-and-Price Auction Outcomes are not Fully Efficient

We note that cap-and-price auctions cannot always implement the fully optimal allocation rule for every distribution F. For an allocation rule to be implementable by some $M(C, \underline{p}, \overline{p})$, it must be that on every input $\mathbf{V}$, either the total allocation is C, or the total allocation is

at most C and each agent wins precisely their marginal bids above $\underline{p}$, or the total allocation is at least C and each agent wins precisely their marginal bids above $\overline{p}$. When there is uncertainty about $\mathbf{V}$, such a restricted allocation rule might return suboptimal allocations on some realizations.

In fact, we note that there are cases where, even under truthful reporting, no cap-and-price auction can achieve a non-vanishing approximation of the unrestricted welfare-optimal allocation.

▶ **Example 13.** We present an example for which the expected welfare of any cap-and-price auction $M(C, \underline{p})$ is at most an $O(1/n)$-approximation to the unrestricted allocation that can optimize individually for each realization of the valuation curves, the welfare of which we call the "first-best welfare" in line with economics terminology.

Let $Q(x) = x^2$. There is a single firm participating in the auction. That firm's valuation curve is drawn according to a distribution F over n different valuation curves, which we'll denote $V^{(1)}, \ldots, V^{(n)}$. For all i, valuation $V^{(i)}$ is defined by $V^{(i)}(x) = 2^{i+1} \cdot x$. These curves are depicted in Figure 2. The probability that $V^{(i)}(\cdot)$ is drawn from F is proportional to $\frac{1}{2^{2i}}$. That is, the firm has valuation $V^{(i)}$ with probability $\frac{1}{\beta 2^{2i}}$, where $\beta = \sum_{i=1}^{n} 2^{-2i} = \frac{1}{3}(1 - 2^{-2n})$ is the normalization constant.

Then in expectation over the realizations of $V(\cdot)$, the *first-best* welfare is

$$\sum_{i=1}^{n} 2^{2i} \frac{1}{\beta 2^{2i}} = \frac{1}{\beta} \cdot n.$$

Consider a cap-and-price auction $M(C, \underline{p})$. For any cap C, the optimal price floor is to set $\underline{p} = 2C$. This eliminates all possible negative welfare contributions at C. As a sanity check, any smaller price floor allows negative contributions, yet any larger price floor excludes positive contributions. For $C' \in (2^k, 2^{k+1}]$, , if the firm has valuation $V^{(i)}$ with $i \leq k$, then all marginal values are strictly below $\underline{p}$, so no licenses are allocated and the welfare generate is 0. On the other hand, if the firm has valuation $V^{(i)}$ for any $i \geq k+1$, then since at most $C < 2^{k+1}$ licenses can be purchased, the auction generates welfare at most $2^{i+1}(2^{k+1}) - (2^{k+1})^2 = 2^{2k+2}(2^{i-k} - 1)$. This yields expected welfare

$$\begin{aligned}
\sum_{i=k+1}^{n} 2^{2k+2}(2^{i-k} - 1) \cdot \frac{1}{\beta 2^{2i}} &= \frac{1}{\beta} \sum_{i=k+1}^{n} 2^{-2(i-k-1)}(2^{i-k} - 1) \\
&= \frac{1}{\beta} \sum_{j=1}^{n-k} 2^{-2(j-1)}(2^{j} - 1) \\
&\leq \frac{1}{\beta} \sum_{j=1}^{n-k} 2^{-(j-1)} \\
&= \frac{1}{\beta}(2 - 2^{-(n-k-1)}) \\
&\leq \frac{2}{\beta} = o(n).
\end{aligned}$$

In comparison to OPT, any cap-and-price policy is off by an order of n, so no $o(1/n)$-approximation to the first-best welfare is possible. This concludes the example.

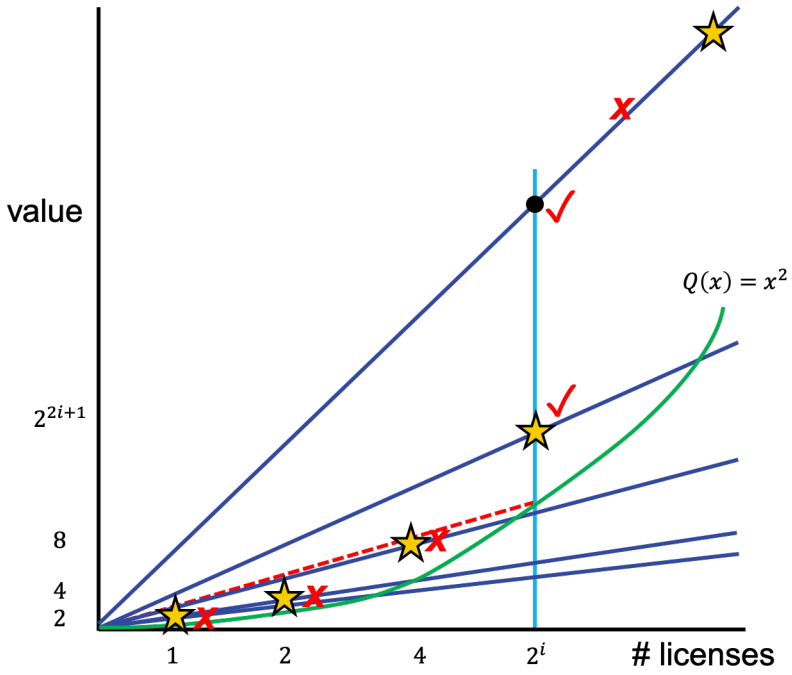

Figure 2 A depiction of Example 13, with the welfare achieve by the vertical cap and dashed price floor denoted by the checks and x's.

Preference-Informed Fairness

Abstract

In this work, we study notions of fairness in decision-making systems when individuals have diverse preferences over the possible outcomes of the decisions. Our starting point is the seminal work of Dwork et al. [ITCS 2012] which introduced a notion of *individual fairness* (IF): given a task-specific similarity metric, every pair of individuals who are similarly qualified according to the metric should receive similar outcomes. We show that when individuals have diverse preferences over outcomes, requiring IF may unintentionally lead to less-preferred outcomes for the very individuals that IF aims to protect (e.g. a protected minority group). A natural alternative to IF is the classic notion of fair division, *envy-freeness* (EF): no individual should prefer another individual's outcome over their own. Although EF allows for solutions where all individuals receive a highly-preferred outcome, EF may also be overly-restrictive for the decision-maker. For instance, if many individuals agree on the best outcome, then if any individual receives this outcome, they all must receive it, regardless of each individual's underlying qualifications for the outcome.

We introduce and study a new notion of *preference-informed individual fairness* (PIIF) that is a relaxation of both individual fairness and envy-freeness. At a high-level, PIIF requires that outcomes satisfy IF-style constraints, but allows for deviations provided they are in line with individuals' preferences. We show that PIIF can permit outcomes that are more favorable to individuals than any IF solution, while providing considerably more flexibility to the decision-maker than EF. In addition, we show how to efficiently optimize any convex objective over the outcomes subject to PIIF for a rich class of individual preferences. Finally, we demonstrate the broad applicability of the PIIF framework by extending our definitions and algorithms to the multiple-task targeted advertising setting introduced by Dwork and Ilvento [ITCS 2019].

1 Introduction

Increasingly, algorithms are used to make consequential decisions about individuals. Examples range from determining which content users see online to deciding which applicants are considered in lending and hiring decisions. Automated decision-making comes with benefits, but it also raises substantial societal concerns (cf. [26] for a recent perspective). One prominent concern is that these algorithms might discriminate against individuals or groups in a way that violates laws or social and ethical norms [1, 29, 10, 7]. Thus there is an urgent need for frameworks and tools to mitigate the risks of algorithmic discrimination. A growing literature attempts to tackle these challenges by exploring different fairness criteria and ways to achieve them.

One prominent framework for establishing fairness in algorithmic decision-making systems comes from the seminal work of Dwork et al. [12], which introduced the notion of *individual fairness* (IF). IF relies on a task-specific similarity metric that specifies, for every pair of individuals, how similar they are with respect to the task at hand. Given such a metric, individual fairness requires that similar individuals (according to the metric) be treated similarly, i.e., assigned similar outcome distributions. This is formalized via a Lipschitz condition, requiring that for any two individuals i and j, the distance between their outcome distributions is bounded by their distance according to the metric. Although coming up with a good metric can be challenging, metrics arise naturally in prominent existing examples (e.g. credit or insurance risk scores), and in natural scenarios (e.g. a metric specified by an external regulator). Given an appropriate metric, individual fairness provides powerful protections from discrimination.

Accounting for individuals' preferences

Our work is motivated by settings in which individuals may hold diverse preferences over the possible outcomes. Natural examples of such settings include recommendation systems on professional employment websites where job-searchers have diverse considerations (geography, work-life balance, company culture, etc.) that affect their interest in potential employers, and targeted advertising systems where different users have a wide variety of preferences over the subset of ads they'd like to see out of an enormous set of possibilities. While the metric-based IF constraints prevent myriad forms of discrimination that can arise in automated decision-making systems, we argue that when individuals have different preferences over outcomes, IF can be too restrictive. Specifically, we show that in such settings, ignoring individuals' preferences (as IF does) can come at a high cost to *the very individuals that IF aims to protect*.

We illustrate this observation using a simple example. Consider a university organizing a career expo focused on software developer positions. The university would like to assign each graduating student to (at most) a single interview slot with a prospective employer. To prevent discrimination, the university would like to enforce individual fairness. For simplicity, we assume that there is an unbiased metric for judging qualifications for software development roles across employers based on GPA in the CS major. Consider candidates i, j, and k, who are all similarly qualified, and suppose there are three employers X, Y, and

Z. When the candidates are polled for their preferences, i prefers $X \succ Y \succ Z$, j prefers $Y \succ Z \succ X$, and k prefers $Z \succ X \succ Y$ (possibly due to geographic and work-life balance considerations). Despite the diversity of their preferences, since i, j, and k are all similarly qualified, IF requires that the candidates receive similar distributions over interviews with the employers X, Y, and Z. Thus, IF *rules out the allocation where each candidate gets their most-preferred interview.*

This toy example demonstrates that IF can be overly-restrictive, preventing some solutions where every individual is very happy with their outcome. Moreover, under IF, even the most socially-conscious decision-maker may be forced to disregard the preferences of some groups of individuals in order to satisfy the constraints. For example, if a decision-maker is required by IF to give similar members of majority and minority populations similar outcomes, then the decision-maker may choose the IF solution that gives everyone the outcome preferred by the majority, running the risk of ignoring the preferences of historically-marginalized groups of individuals.

Faced with this shortcoming of IF, we consider alternative notions of fairness that may be better suited to handle settings where individuals hold rich preferences over outcomes. The most natural alternative notion is *envy-freeness* (EF) [32, 14], a classic game-theoretic concept of fair division. A set of outcomes is said to be envy-free if no individual prefers the outcome given to any other individual over their own. At first glance, EF seems like a promising solution concept that addresses the concerns raised about IF: the decision where every individual receives their most-preferred outcome is EF. Indeed, Balcan et al. [4] recently presented EF as an alternative to IF in the context of fair classification.

However, we argue that EF may also be overly-restrictive, constraining the decision-maker in unreasonable ways. Returning to the example of the career expo, suppose another individual ℓ has similar preferences to i, ($X \succ Y \succ Z$), but ℓ has a significantly lower GPA than i. Consider an allocation where i receives their most-preferred interview X, but ℓ does not receive any interview. In this case, ℓ envies i so this solution does not satisfy EF; nevertheless, the solution is reasonable from a fairness perspective. Since i has a much better GPA than ℓ, it doesn't seem unfair to give i the interview with X over ℓ, especially if the interview spots are limited.

This expanded example highlights the need for distinguishing between outcome distributions that might make some (or even all) individuals *unhappy*, from distributions that are *unfairly discriminatory*; articulating this distinction was an important conceptual contribution of the definition of individual fairness [12]. Indeed, the unqualified individual ℓ might be unhappy that they do not receive an interview; further, they might be even less happy when they see that the qualified individual i received an interview with their top choice X. In the eyes of the task-specific similarity metric, however, these two individuals are *different* – according to their GPAs, one is qualified, the other – unqualified. Thus, IF does not consider such an outcome discriminatory. Furthermore, deciding to assign no one to interviews (qualified and unqualified alike) might make no one happy, but it is not unfairly discriminatory, since all individuals are treated similarly.

In this work, we adopt the perspective that given a suitable metric, solutions that are individually fair provide strong protections from discrimination, even though they might not be envy-free. Armed with this perspective, we seek to relax the IF requirements to allow for a richer set of solutions, while still providing meaningful protections against discrimination.

1.1 This Work: Preference-Informed Fairness

Building on the perspective from [12], we propose and study the notion of *preference-informed individual fairness* (PIIF). Our guiding principle is:

Allocations that deviate from individual fairness may be considered fair, provided the deviations are in line with individuals' preferences.

Before describing PIIF, we establish some notation. We model a decision-maker's policy π as a mapping from individuals to allocations, i.e., distributions over outcomes. We assume that each individual i has preferences over the possible allocations, where $p \succeq_i q$ denotes that i (weakly) prefers allocation p to allocation q. To discuss notions of individual fairness, we assume that D is a divergence where $D(p, q)$ measures some distance between two allocations p, q (e.g. the total-variation distance), and d is the task-specific metric where $d(i, j)$ specifies the similarity between individuals i and j.

Using this notation, we can restate the notions of IF and EF as follows. A policy π is *individually-fair* (IF) if for all pairs of individuals i, j, the Lipschitz condition $D(\pi(i), \pi(j)) \leq d(i, j)$ is satisfied.[1] A policy π is *envy-free* (EF) if for all individuals i, for all other individuals j, $\pi(i) \succeq_i \pi(j)$.

Preference-informed individual fairness

As in both IF and EF, PIIF establishes fairness by comparing the allocation of each individual i to the allocation of every other individual j. For each such comparison, PIIF requires that either $\pi(i)$ satisfies individual fairness with respect to $\pi(j)$ or i prefers their allocation $\pi(i)$ over some alternative allocation that would have satisfied individual fairness with respect to $\pi(j)$. More technically, for π to be considered PIIF for each individual i, we require that for every other individual j there exists some alternative allocation $p^{i;j}$ that i could have received that satisfies the IF Lipschitz condition with respect to $\pi(j)$ and where i (weakly) prefers their actual allocation $\pi(i)$ to the IF alternative $p^{i;j}$.

▶ **Definition 1** (PIIF). *A policy π that maps individuals to allocations satisfies Preference-Informed Individual Fairness with respect to a divergence D, a similarity metric d, and individual preferences $\{\succeq_i\}$, if for every individual i, for every other individual j, there exists an alternative allocation $p^{i;j}$ such that:*

- *$p^{i;j}$ is individually fair w.r.t $\pi(j)$:* $D\left(p^{i;j}, \pi(j)\right) \leq d(i, j)$.
- *i (weakly) prefers $\pi(i)$ over $p^{i;j}$:* $\pi(i) \succeq_i p^{i;j}$.

We emphasize that, in general, $p^{i;j} \neq p^{j;i}$; that is, the alternative chosen for i with respect to j's allocation need not be the same as that chosen for j with respect to i. Figure 1 provides a succinct summary of the definitions of IF, EF, and PIIF.

PIIF preserves the spirit of the core interpersonal fairness guarantee of IF: for each individual i, for every individual j who is similar to i, either i's outcome distribution is similar to j's, or i receives an even better (more-preferred) outcome distribution. The main advantage of PIIF over IF is that it allows for a much richer solution space, which can lead to preferable outcomes for individuals. Further, PIIF does not restrict the allocations unnecessarily; as in IF, the constraints only bind when a pairs of individuals are sufficiently similar according to the metric. In other words, PIIF – unlike EF – permits solutions that may be disappointing to some individuals (i.e. where i envies j) but should not be considered discriminatory (because i and j are substantially different according to the task at hand).

[1] Throughout, we assume that d and D are scaled appropriately to be in the same "units." That is, without loss of generality, we assume the relevant Lipschitz constant in the IF-style constraints is 1.

Individual Fairness (IF)
for every i, for every j:
$D(\pi(i), \pi(j)) \leq d(i, j)$

Envy-Freeness (EF)
for every i, for every j:
$\pi(i) \succeq_i \pi(j)$

Preference-Informed Individual Fairness (PIIF)
for every i, for every j, there exists $p^{i;j}$ s.t.
$D(p^{i;j}, \pi(j)) \leq d(i, j)$
$\pi(i) \succeq_i p^{i;j}$

Figure 1 Summary of individual fairness notions.

Referring back to the career expo example, we note that the allocation where the three qualified candidates i, j, and k (deterministically) interview with their preferred employer is PIIF. To see this, consider i comparing their outcome to those of j and k under such an interview assignment. Comparing with j, i prefers outcome X to receiving outcome Y, which would satisfy the IF constraint with respect to j. Similarly, she prefers X to Z, which would satisfy the IF constraint with respect to k. Indeed, since i receives her preferred outcome, one can argue that there is no discrimination against i in the allocation. Similar reasoning applies to j and to k. In fact, the allocation where each individual deterministically receives their preferred outcome is always PIIF, a property we find desirable for a fairness definition. Further, consider the allocation of ℓ, who we assumed was significantly less qualified than i (and thus, j and k). If ℓ is sufficiently dissimilar to all other candidates, then the scheduler can assign ℓ to any interview and still satisfy PIIF. To see this, note that if $d(\ell, i)$ is sufficiently large, we can always take $p^{\ell;i} = \pi(\ell)$, and the constraints for individual ℓ with respect to i will be satisfied (with identical arguments when comparing ℓ to j and k).

1.2 Our Contributions

Our running example illustrates that in many reasonable situations (involving rich and diverse individual preferences over outcomes), the existing notions of individual fairness and envy-freeness may not capture an appropriate notion of fairness or may unnecessarily constrain the decision-maker. In high-stakes domains, such as employment and personalized content selection, both limitations are significant and may hinder adoption of fairness-conscious decision-making. We propose PIIF as a relaxation of IF that addresses the identified shortcomings of existing notions while still providing meaningful protections against discrimination. We view this as an important conceptual contribution in its own right.

With the motivation and definition for PIIF in place, we provide a comprehensive characterization of the relationship between PIIF and other individual notions of fairness. In Section 2, we show formally that PIIF can be viewed as a relaxation of both IF and EF; that is, any solution that satisfies either IF or EF also satisfies PIIF. Further, we demonstrate that PIIF is a non-trivial relaxation of both notions, by proving that there exist settings in which PIIF solutions cannot be captured by IF or EF constraints alone, for *any* choice of metrics d, D and preferences.

To introduce PIIF, we have argued qualitatively that relaxing IF to PIIF allows for more preferable outcomes for individuals. We quantify these claims by comparing the *social welfare* of a decision-maker's policy achievable under PIIF and under IF. In Section 3, we show optimal bounds on the ratio of the best social welfare under PIIF to that under IF; the ratio can grow *linearly* in the number of individuals classified or in the number of possible outcomes grows.

With the definition and properties of PIIF in place, we turn our attention to the algorithmic question of how to achieve PIIF. In Section 4, we show that for a rich family of individual preferences, there is an efficient algorithm to minimize a convex objective subject to PIIF. The result follows by observing that for structured classes of preferences, the set of PIIF constraints is convex. In particular, to optimize over PIIF, we can augment the convex program defined for IF in [12] to capture the additional preference constraints. As such, optimization subject to PIIF is only slightly more complex than optimization subject to IF.

Finally, we demonstrate the versatility of the PIIF framework, by applying preference-informed fairness in the context of targeted advertising (as studied by [13]). Recent empirical findings demonstrate that the ad allocation algorithms run by online advertising platforms may result in discrimination [11, 24, 1] and are thus facing legal scrutiny [31, 29, 6]. As such, developing formal frameworks for understanding fairness in such advertising systems is of great importance. In Section 5, we extend our definition of PIIF and our results to the multiple-task setting defined [13] to model fairness desiderata for the domain of large-scale targeted advertising. We show that in this practically-motivated setting, IF still may restrict the social welfare considerably compared to PIIF *even when the individuals' similarity and preferences are perfectly aligned!* The ratio of the best social welfare under PIIF to that of IF grows *linearly* in the number of tasks.

Organization

Sections 2-5 contain the technical details and proofs of our major contributions with some results deferred to the appendix. We conclude in Section 6 with comparisons to other related works and a discussion of the strengths and limitations of the current approach of preference-informed fairness as well as directions for future investigations.

2 Preference-Informed Individual Fairness

Preliminaries

Given a set of individuals $\mathcal{X}$, we consider policies that assign every individual to an outcome in the set C. We allow randomized allocation rules $\pi : \mathcal{X} \to \Delta(C)$, where for each individual $i \in \mathcal{X}$, their allocation $\pi(i) \in \Delta(C)$ represents a distribution over outcomes $c \in C$. We model individuals' preferences by assuming that every individual $i \in \mathcal{X}$ has a reflexive and transitive binary relation $\succeq_i$ that encodes their preferences over allocations in $\Delta(C)$; for $p, q \in \Delta(C)$, we use $p \succeq_i q$ to denote that i (weakly) prefers p to q.[2] We use $\succeq$ to denote the set of individuals' preference relations, $\succeq = \{\succeq_i\}_{i \in \mathcal{X}}$.

One important structured class of preference relations are those that admit a *utility function*. Here, we assume each individual $i \in \mathcal{X}$ has a real-valued function over allocations $u_i : \Delta(C) \to \mathbb{R}$, where $u_i(\pi(i))$ represents the utility to individual i from the allocation given by π. Given such a utility function, $p \succeq_i q$ if and only if $u_i(p) \geq u_i(q)$.

With this technical notation in place, for completeness, we restate the three definitions of fairness.

▶ **Definition 2** (Individual Fairness). *Given a divergence $D : \Delta(C) \times \Delta(C) \to [0, 1]$ and a similarity metric $d : \mathcal{X} \times \mathcal{X} \to [0, 1]$, a policy $\pi : \mathcal{X} \to \Delta(C)$ is (D, d)-individually fair if for every two individuals $i, j \in \mathcal{X} \times \mathcal{X}$, the following Lipschitz condition holds.*

$$D(\pi(i), \pi(j)) \leq d(i, j) \tag{1}$$

[2] $\succeq_i$ need not be *total* nor *antisymmetric* over $\Delta(C)$.

▶ **Definition 3** (Envy Freeness). *Given a set of preferences $\succeq$, a policy $\pi : \mathcal{X} \to \Delta(C)$ is $\succeq$-envy-free if for all individuals $i \in \mathcal{X}$, and for all other individuals $j \in \mathcal{X}$,*

$$\pi(i) \succeq_i \pi(i) \tag{2}$$

▶ **Definition 4** (Preference-Informed Individual Fairness). *Given a divergence $D : \Delta(C) \times \Delta(C) \to [0,1]$, a similarity metric $d : \mathcal{X} \times \mathcal{X} \to [0,1]$, and a set of preferences $\succeq$, a policy $\pi : \mathcal{X} \to \Delta(C)$ is $(D, d, \preceq)$-PIIF if for all individuals $i \in \mathcal{X}$, for all other individuals $j \in \mathcal{X}$, there exists an allocation $p^{i;j} \in \Delta(C)$ such that:*

$$D\left(p^{i;j}, \pi(j)\right) \leq d(i,j) \tag{3}$$

$$\pi(i) \succeq_i p^{i;j} \tag{4}$$

Often, the divergence D, metric d, and preferences $\succeq$ will be fixed. In these contexts, we use $\Pi^{\text{IF}}, \Pi^{\text{EF}}, \Pi^{\text{PIIF}}$ to denote the set of IF, EF, and PIIF solutions, respectively.

2.1 PIIF relaxes IF and EF

We have argued informally that PIIF captures the appealing aspects of both IF (strong discrimination protections) and EF (respecting the preferences of individuals) without being overly prescriptive in a way that might hurt individuals or the decision-maker. Our first result formalizes these claims, by characterizing PIIF as a relaxation of both IF and EF. We show that any policy that is either IF or EF is also PIIF.

▶ **Proposition 5.** *Fixing a divergence, the metric, and preferences, $\Pi^{\text{IF}} \subseteq \Pi^{\text{PIIF}}$ and $\Pi^{\text{EF}} \subseteq \Pi^{\text{PIIF}}$.*

As solution concepts, both IF and EF are always feasible, but for very different reasons: for IF, any allocation that treats all individuals identically is feasible; for EF, the allocation that gives everyone their most-preferred outcome is envy-free. Thus, both of these extreme solutions will also be feasible for PIIF. In general, PIIF will be a strict relaxation of these concepts that allows for interpolation between the notions. Intuitively, more diverse preferences of individuals tend to give rise to richer sets of PIIF solutions compared to IF, and nontrivial metrics d (i.e., further from the all-zeros "metric") give rise to richer sets of PIIF solutions compared to EF. Given the right framing, the proof of this result is almost immediate.

Proof. To see that an IF policy π satisfies PIIF, for each i, we take $p^{i;j} = \pi(i)$ for all j. Consider an allocation $\pi \in \Pi^{\text{IF}}$. From the perspective of any individual $i \in \mathcal{X}$, when comparing to individual $j \in \mathcal{X}$, if $p^{i;j} = \pi(i)$, then, by the fact that π satisfies IF, condition (3) is satisfied. By reflexivity of $\succeq_i$, (4) is also satisfied, so $\pi \in \Pi^{\text{PIIF}}$.

To see that an EF policy π satisfies PIIF, for each i, we take $p^{i;j} = \pi(j)$ for all j. Consider an allocation $\pi \in \Pi^{\text{EF}}$. From the perspective of any $i \in \mathcal{X}$, when comparing to $j \in \mathcal{X}$, if $p^{i;j} = \pi(j)$, then, condition (3) is satisfied trivially because $D(\pi(j), \pi(j)) = 0$. Since π satisfies EF, we know that $\pi(j) \preceq_i \pi(i)$, so condition (4) also holds; thus $\pi \in \Pi^{\text{PIIF}}$. ◀

PIIF generalizes IF and EF

We remark that this intuition also shows that PIIF is a *generalization* of both IF and EF; that is, both notions can be "implemented" as special cases of PIIF. To implement IF, we can set all individual's preference relation $\succeq_i$ to be the trivial reflexive relation, where for all allocations p, $p \succeq_i p$, and for all nontrivial pairs $p \neq q$, p and q are incomparable. To

implement EF, we simply take $d(i,j) = 0$ for all i, j pairs. In other words, we can think of the set of IF solutions as those where we require the alternative allocation for i compared to j to be i's actual allocation $p^{i;j} = \pi(i)$, and we can think of the set of EF solutions as those where we require the alternative allocation for i compared to j to be j's allocation $p^{i;j} = \pi(j)$.

PIIF is a meaningful relaxation of IF and EF

A natural question to ask is whether we need to introduce a new definition of individual fairness. In particular, we might hope that we could "implement" PIIF using IF with a metric that incorporates preferences or with EF with preferences that incorporate distances. We argue that when there is a rich set of possible outcomes and a correspondingly-rich set of possible preferences, such an approach is infeasible. In particular, PIIF captures constraints that could not be cast within the language of IF or EF alone.

To build intuition, we revisit the career expo example: suppose that two similarly qualified individuals i and j have a similar top choice (say, X), but disagree on their second choice (i prefers Y, whereas j prefers Z). Do these individuals have similar preferences or divergent ones? Intuitively, a fair assignment could give them similar probabilities of seeing X, but different probabilities of seeing Y and Z. Individual fairness treats all outcomes symmetrically for all individuals, and does not let us make such distinctions. The following proposition strengthens this intuition, demonstrating that there are in fact settings in which EF preferences cannot be encoded using any IF metric, and vice versa. Note that this implies that PIIF – a relaxation of both notions – captures constraints that cannot be cast within the language of IF or EF alone.

▶ **Proposition 6.** *There exists a set of preferences $\succeq$ such that for any choice of divergence D and metric d*

$$\Pi^{\succeq\text{-EF}} \neq \Pi^{(D,d)\text{-IF}}.$$

There exists a divergence-metric pair D, d such that for any choice of preferences $\succeq$,

$$\Pi^{(D,d)\text{-IF}} \neq \Pi^{\succeq\text{-EF}}.$$

Proof. In both constructions, we will assume there are two disjoint groups of individuals $S, T \subseteq \mathcal{X}$. Consider two outcomes $p, q \in C$. Suppose $\succeq$ is such that for some $i \in S$ and $j \in T$, $p \succ_i q$ and $q \succ_j p$. Consider any D and d: if $D(p,q) \leq d(j,i)$, then assigning p to j and q to i will be (D,d)-IF, but it is not $\succeq$-EF; otherwise, if $D(p,q) > d(i,j)$, then assigning p to S and q to T will not be (D,d)-IF, even though it is $\succeq$-EF. Thus, no D, d can capture $\succeq$-EF.

Now take D to be total variation distance and consider a metric d where $d(i,j) = 0$ for $i, j \in S \times S$ and $T \times T$, and $d(i,j) = 1$ for $i, j \in S \times T$. Under this metric, assigning any fixed allocation to everyone in S and any (potentially-different) fixed allocation to everyone in T is (D,d)-IF. Consider some $\succeq$. If there is some $i \in S$ such that $p \succ_i q$ or if there is some $j \in T$ such that $q \succ_j p$, then the (D,d)-IF allocation that assigns q to every $i \in S$ and p to every $j \in T$ is not $\succeq$-EF.

Thus, for all individuals in $i \in S \cup T$, $\succeq_i$ must be either the relation, where $p \equiv q$ or the trivial reflexive relation where p and q are incomparable. Suppose $i, j \in S \times S$ both have $\succeq_i = \succeq_j = \equiv$. Then, the solution that assigns p to i and q to j is $\succeq$-EF, but violates the Lipschitz condition of (D,d)-IF. On the other hand, if there is some $i \in S$ that holds the trivial reflexive relation, then the (D,d)-IF solution that assigns p to all of S and q to all of T will not satisfy $\succeq$-EF, because $p \not\succeq_i q$. ◀

2.2 Metric Envy-Freeness

We arrived at PIIF by starting with the metric-based IF as a strong notion of nondiscrimination and relaxing the notion to incorporate individuals' preferences and allow for a richer set of solutions while providing a meaningful protections against discrimination. A conceptually-different approach towards these goals would start with preference-based EF, but allow the decision-maker some freedom by incorporating distances between individuals. In particular, consider the following relaxation of EF, which we call *Metric Envy-Freeness* (MEF), that intuitively captures the idea that no individual should envy the allocation of any other *similar* individual.

▶ **Definition 7.** *Suppose each individual $i \in \mathcal{X}$ has a utility function $u_i : \Delta(C) \to \mathbb{R}$; let $\mathcal{U} = \{u_i\}_{i\in\mathcal{X}}$. Given a similarity metric $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^+$, a policy $\pi : X \to \Delta(C)$ satisfies $(d,\mathcal{U})$-metric-envy-freeness if for every individual $i \in \mathcal{X}$, for every other individual $j \in \mathcal{X}$,*

$$u_i(\pi(i)) \geq u_i(\pi(j)) - d(i,j)$$

This definition starts with the envy-freeness constraint for utility-based preferences, but then relaxes the constraint between i and j by their distance according to the metric. For the metric-utility comparison of MEF to be meaningful, we assume that utilities and metric distances are normalized to one another; without loss of generality, assume that each utility and metric distance is bounded in $[0, 1]$. For each pair i, j, the notion interpolates between two extremes based on the value of $d(i, j)$: if $d(i, j) = 0$, then envy-freeness binds; when $d(i, j) = 1$, the allocation i receives is not constrained by the allocation j receives.

As $d(i, j) \geq 0$ for all pairs of individuals, MEF is clearly a relaxation of EF. That said, it's not immediately obvious how MEF relates to IF or PIIF. While conceptually different, we show that MEF captures a closely-related notion of fairness to PIIF, in the special case where preferences are given by structured utility functions. To relate MEF to PIIF, we need to assume the following Lipschitz conditions.

▶ **Definition 8** (Lipschitz utility)**.** *A utility function $u : \Delta(C) \to \mathbb{R}$ is ℓ-Lipschitz with respect to $D : \Delta(C) \times \Delta(C) \to \mathbb{R}^+$ if $|u(p) - u(q)| \leq \ell \cdot D(p, q)$.*

Lipschitz utility functions are quite natural. For instance, taking D to be the total variation distance, if individuals' preferences admit an expected utility function, where each outcome has utility in $[0, 1]$, then individuals' utilities will be 1-Lipschitz. In other words, individuals' utilities are not highly sensitive to very small changes in the allocation they receive.

▶ **Definition 9** (Reverse-Lipschitz utility)**.** *A utility function $u : \Delta(C) \to \mathbb{R}$ is ℓ-reverse-Lipschitz with respect to $D : \Delta(C) \times \Delta(C) \to \mathbb{R}^+$ if $\frac{1}{\ell} \cdot D(p, q) \leq |u(p) - u(q)|$.*

Reverse-Lipschitz utility functions are less natural. This assumption implies that no pair of outcomes is valued very similarly. One natural setting where the reverse-Lipschitz condition holds nontrivially is in the case of binary outcomes, where each individual prefers one outcome over the other. Under these assumptions, we can show the following relationship between MEF and PIIF.

▶ **Theorem 10.** *Suppose $D : \Delta(C) \times \Delta(C) \to \mathbb{R}^+$ is a divergence, $d : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^+$ is a similarity metric, and $\mathcal{U} = \{u_i\}$ is a family of utility functions. Let $\succeq^{\mathcal{U}}$ denote the family of preferences induced by $\mathcal{U}$. Consider a policy $\pi : \mathcal{X} \to \Delta(C)$. For some constant $\ell \geq 1$:*

- *Suppose for all $i \in \mathcal{X}$, u_i is ℓ-Lipschitz with respect to D. Then,*

$$\Pi^{(D,d,\succeq^{\mathcal{U}})\text{-PIIF}} \subseteq \Pi^{(\ell\cdot d,\mathcal{U})\text{-MEF}}.$$

- *Suppose for all $i \in \mathcal{X}$, u_i is ℓ-reverse-Lipschitz with respect to D. Then,*

$$\Pi^{(d,\mathcal{U})\text{-MEF}} \subseteq \Pi^{(D,\ell\cdot d,\succeq^{\mathcal{U}})\text{-PIIF}}.$$

Proof. To see that PIIF implies MEF, we start with a policy π that satisfies $(D, d, \succeq^{\mathcal{U}})$-PIIF. To establish MEF, we compare the utility of individual i on their allocation $\pi(i)$ to that of another individual $\pi(j)$; we denote by $p^{i;j}$ the alternative allocation for i that satisfies the PIIF constraints.

$$\begin{aligned} u_i(\pi(i)) &\geq u_i(p^{i;j}) && (5)\\ &\geq u_i(\pi(j)) - \left[u_i(\pi(j)) - u_i(p^{i;j})\right] \\ &\geq u_i(\pi(j)) - \ell \cdot D\left(\pi(j), p^{i;j}\right) && (6)\\ &\geq u_i(\pi(j)) - \ell \cdot d(i,j) && (7)\end{aligned}$$

where (5) follows by the fact that π satisfies PIIF; (6) follows by the Lipschitz condition; and (7) follows again from the fact that π satisfies PIIF. Thus, $u_i(\pi(i)) \geq u_i(\pi(j)) - \ell \cdot d(i,j)$, so π is $(\ell \cdot d, \mathcal{U})$-MEF.

To see that MEF implies PIIF, we start with a policy π that satisfies $(d, \mathcal{U})$-MEF. To establish PIIF, we consider an arbitrary pair of individuals i and j, and exhibit an allocation $p^{i;j}$ that satisfies the PIIF conditions with respect to $\pi(i)$ and $\pi(j)$. Comparing individual i to individual j, we consider two cases.

First, suppose $u_i(\pi(i)) \geq u_i(\pi(j))$ and take $p^{i;j} = \pi(j)$. In this case, the Lipshitz constraint is trivially satisfied,

$$D(p^{i,j}, \pi(j)) = D(\pi(j), \pi(j)) = 0 \leq \ell \cdot d(i,j)$$

and the assumption that $u_i(\pi(i)) \geq u_i(\pi(j))$ implies that

$$\pi(i) \succeq_i \pi(j) = p^{i;j},$$

so the PIIF constraints are satisfied.

Next, suppose $u_i(\pi(i)) < u_i(\pi(j))$ and take $p^{i;j} = \pi(i)$. In this case, the preference condition is trivially satisfied,

$$\pi(i) \succeq_i \pi(i) = p^{i;j}$$

and the Lipschitz condition follows as

$$\begin{aligned} D(p^{i;j}, \pi(j)) &= D(\pi(i), \pi(j)) \\ &\leq \ell \cdot (u_i(\pi(j)) - u_i(\pi(i))) && (8)\\ &\leq \ell \cdot d(i,j) && (9)\end{aligned}$$

where (8) follows by the reverse-Lipschitz condition and (9) follows by the fact that π satisfies MEF. Thus, π is $(D, \ell \cdot d, \succeq^{\mathcal{U}})$-PIIF. ◀

Relating PIIF and MEF

Theorem 10 shows that under appropriate assumptions, we can relate the notions of PIIF and MEF. We interpret the theorem to say that, in most settings we would apply preference-informed fairness, MEF is a strictly more relaxed notion than PIIF; that is, every PIIF solution will be MEF, but there will be MEF solutions that do not satisfy PIIF.

Specifically, as we remarked earlier, it is reasonable to assume that individuals' utility functions are 1-Lipschitz with respect to D. In this case, small changes in the allocation according to D cannot result in dramatically different utilities, and Theorem 10 says that $(D, d, \succeq^{\mathcal{U}})$-PIIF implies $(d,\mathcal{U})$-MEF.

In general, with a rich set of outcomes, we do not expect that individuals' utility functions will be reverse-Lipschitz with respect to D. As such, there are cases when $(d,\mathcal{U})$-MEF will be considerably more relaxed than $(D, d, \succeq^{\mathcal{U}})$-PIIF, allowing for deviations from (D, d)-IF that do not give utility improvements for all individuals. To see this point, consider the following example with two individuals i, j, where $d(i, j) = 0.5$ and two outcomes p, q, with the utility functions of i and j defined as follows.

	p	q
u_i	1.0	0.5
u_j	0.5	1.0

We take D to be the total variation distance between allocations. It's easy to verify that all allocations that treat the individuals identically and the welfare-maximizing solution where i receives p and j receives q will be MEF; this can be seen by noting that each of these solutions satisfies EF, thus, also MEF. In fact, in this example, the utility functions are sufficiently Lipschitz to guarantee that all PIIF solutions will be MEF.

On the other hand, consider the allocation where i receives q and j receives p, deterministically. This solution is not IF, because $1 = D(q, p) > d(i, j) = 0.5$, nor EF, because both individuals envy the others' solution. Further, the solution is not PIIF. To see this, note that because each individual receives their least favorite outcome, the only surrogate $p^{i;j}$ that can be chosen for individual i such that $q \succeq_i p^{i;j}$ is $p^{i;j} = q$ (similarly, $p^{j;i} = p$ for individual j). As the actual allocation is not IF, one of the PIIF constraints will be violated.

Still, this allocation does satisfy MEF. Specifically, $0.5 = u_i(q) \geq u_i(p) - d(i, j) = 1.0 - 0.5$ and $0.5 = u_j(p) \geq u_j(q) - d(j, i) = 1.0 - 0.5$. In other words, in this instance, MEF allows for a solution that is not permitted by any of the other notions of individual fairness we consider. In particular, the allocation deviates from individual fairness in a way that does not help either individual. This example suggests that in reasonable settings, MEF is a strictly weaker concept than PIIF and may be too permissive.

3 Welfare under IF, EF, and PIIF

In order to motivate PIIF, we argued that IF may be overly-restrictive and limit the "quality" of solutions from the perspective of individuals. In this section, we formalize this claim, showing that PIIF admits solutions that can be significantly more preferable to individuals. We quantify the idea of individual quality using the game-theoretic notion of social welfare.

We restrict our attention to the common setting where individuals hold preference relations that admit a utility function. In this setting, given a policy π, we can track the *social welfare* of the policy, defined to be the overall utility experienced by individuals.

▶ **Definition 11.** *Given a policy $\pi : \mathcal{X} \to \Delta(C)$, social welfare $\mathcal{W}(\pi)$ is the sum of the individuals' utilities under π.*

$$\mathcal{W}(\pi) = \sum_{i \in \mathcal{X}} u_i(\pi(i)) \tag{10}$$

For a collection of allocations Π, we let $\mathcal{W}^*(\Pi) = \max_{\pi \in \Pi} \mathcal{W}(\pi)$ denote the optimal social welfare achievable by any allocation in Π, and let $\mathcal{W}^* = \mathcal{W}^*(\Delta(C)^{\mathcal{X}})$ denote the optimal (unconstrained) social welfare.

An important special case of preferences that admit a utility function are those that admit an *expected utility function*. Using such preferences is a standard approach in economics for modeling decision-making in the presence of uncertainty.[3]

▶ **Definition 12** (Expected utility representation)**.** *A preference relation $\succeq$ admits an expected utility representation if and only if there exists a function $u : C \to \mathbb{R}^+$, such that for any two allocations $p, q \in \Delta(C)$,*

$$p \succeq q \iff \sum_{c \in C} p_c \cdot u(c) \geq \sum_{c \in C} q_c \cdot u(c) \tag{11}$$

Individual fairness may restrict social welfare

Using the notation introduced above, note that $\mathcal{W}^*(\Pi^{\text{PIIF}}) = \mathcal{W}^*$ because the welfare-maximizing allocation is feasible for PIIF. Here, we aim to understand how much IF may restrict the best social welfare compared to PIIF, by relating $\mathcal{W}^*(\Pi^{\text{IF}})$ to $\mathcal{W}^*$.

Intuitively, social welfare can be hurt significantly by requiring IF compared to PIIF when many individuals are considered similar, but there is a diversity of preferences over outcomes. Formalizing this intuition, we argue that without any assumptions about the class of utility functions of individuals, the ratio between the best social welfare under IF and PIIF can grow with the number of individuals. Further, even under the stronger assumption that individuals' preferences admit an expected utility representation, the ratio can grow with the number of outcomes.

▶ **Theorem 13.** *There exists a family of instances such that*

$$\frac{\mathcal{W}^*}{\mathcal{W}^*\left(\Pi^{\text{IF}}\right)} \geq |\mathcal{X}|\,.$$

Additionally, there exists a family of instances where individuals' preferences admit an expected utility representation and

$$\frac{\mathcal{W}^*}{\mathcal{W}^*\left(\Pi^{\text{IF}}\right)} \geq |C|\,.$$

Proof. The two claims of the theorem follow by similar constructions. Suppose every individual is considered similar according to d; that is, for all $i, j \in \mathcal{X} \times \mathcal{X}$, $d(i, j) = 0$. This means that any IF solution must assign every individual the same distribution over outcomes. To show the gaps, we will compare the best IF solution (i.e. constant allocation) to the welfare-maximizing solution, which is feasible under PIIF.

[3] Although not all preference relations admit this form, a rich class of preferences do. For example, different levels of tolerance towards risk can be captured within this framework (e.g., a risk-averse individual would have a utility function u which is concave). Von Neumann and Morgensterm [33] provide a complete characterization of this class of preference relations.

To begin, suppose we allow individuals to specify arbitrary utility functions; let each individual $i \in \mathcal{X}$ hold a distinct $p_i \in \Delta(C)$ (i.e., $p_i \neq p_j$ for all $i \neq j$) such that $u_i(p_i) = 1$ and $u_i(q) = 0$ for any $q \neq p_i$. In this case, the optimal social welfare is $\mathcal{W}^* = |\mathcal{X}|$. For any fixed allocation, however, the best social welfare is to choose a distribution over the set of $\{p_i\}$. Any such distribution will achieve welfare 1; thus, $\mathcal{W}^*(\Pi^{\text{IF}}) = 1$.

Now, suppose every individual is required to specify an expected utility representation. Let each individual choose some $c \in C$, such that a $1/|C|$-fraction of individuals prefer each outcome c; let $u_i(c) = 1$ for their preferred outcome and $u_i(c) = 0$, otherwise. Again, the optimal social welfare is $\mathcal{W}^* = |\mathcal{X}|$. Under any policy that assigns every individual the same fixed allocation p, the social welfare is given by $\sum_{i\in\mathcal{X}} \sum_{c\in C} p_c \cdot u_i(c) = \frac{|\mathcal{X}|}{|C|} \cdot \sum_{c\in C} p_c = \frac{|\mathcal{X}|}{|C|}$. Thus, $\mathcal{W}^*(\Pi^{\text{IF}}) = \frac{|\mathcal{X}|}{|C|}$. ◀

We note that the gaps demonstrated in Theorem 13 are optimal in their settings. In particular, any constant allocation will be IF, and we can always recoup a $1/|\mathcal{X}|$ fraction of the social welfare with a constant allocation tailored for the individual with the highest utility. Further, in the case where preferences admit an expected utility representation, we can choose the constant allocation on the $c \in C$ of maximum welfare. Finally, we note that one unsatisfying aspect of these constructions is that they rely on the fact that all individuals are similar according to d. In Section 5.1, we show that in the multiple-task setting of [13], such gaps exist even with nontrivial metrics that seem to be aligned with social welfare.

PIIF does not guarantee social welfare

Because PIIF is a relaxation of IF, the best social welfare achievable under PIIF is always at least that of IF. That said, because PIIF is a strict relaxation of IF, it does not necessarily guarantee that *every* allocation's social welfare improves under PIIF. In particular, when the decision-maker seeks to optimize a utility function that runs against individuals' utilities within the set of PIIF solution, the obtained social welfare may be arbitrarily worse under the PIIF constraints than IF constraints.

Suppose that the decision-maker has an additive utility function of the form $f(\pi) = \sum_{i\in\mathcal{X}} f_i(\pi(i))$, for $f_i : \Delta(C) \to \mathbb{R}$. Let $\pi_f^{\text{IF}} = \text{argmax}_{\pi\in\Pi^{\text{IF}}} f(\pi)$ and $\pi_f^{\text{PIIF}} = \text{argmax}_{\pi\in\Pi^{\text{PIIF}}} f(\pi)$ denote the optimal IF (resp., PIIF) solution in terms of $f(\cdot)$.

▶ **Proposition 14.** *There exists a family of instances and an additive utility function f such that*

$$\mathcal{W}(\pi_f^{\text{PIIF}}) = 0 < \mathcal{W}(\pi_f^{\text{IF}}).$$

Proof. Suppose there are two disjoint classes of individuals, S and T, which each make up half of $\mathcal{X}$, and all individuals are similar; for all $i, j \in \mathcal{X} \times \mathcal{X}$, $d(i, j) = 0$. Suppose there are three outcomes $C = \{p, q, r\}$. Consider the utility functions defined as follows.

	p	q	r
$f_{i\in S}$	$1/2 + \varepsilon$	1	0
$f_{j\in T}$	$1/2 + \varepsilon$	0	1
$u_{i\in S}$	1	0	0
$u_{j\in T}$	1	0	0

Under IF, the decision-maker must treat all individuals identically. Given this constraint, the outcome that maximizes f is allocating p deterministically to everyone. This allocation π_f^{IF} achieves $\mathcal{W}(\pi_f^{\text{IF}}) = 1$. Without the constraint that all individuals' allocations are identical,

the allocation that assigns q to individuals from S and r to individuals from T maximizes f. In fact, this allocation will be feasible for PIIF: note that every individual experiences 0 utility from everyone's allocation, so no one envies anyone else; under PIIF, envy-free solutions are feasible. Thus, $\mathcal{W}(\pi_f^{\text{PIIF}}) = 0$. In fact, this reveals that the proposition holds not only for PIIF, but also for any notion that relaxes EF. ◀

This construction demonstrates that the PIIF constraints alone do not guarantee improved social welfare compared to the IF constraints. We remark, however, that this is in line with our initial motivation for PIIF: decoupling the objective of provably preventing discrimination from the objective of ensuring beneficial outcomes in aggregate. Finally, we note that if this is a concern, it can be addressed within our framework by adding a constraint to the optimization program, discussed in detail in Section 4, that ensures the social welfare is above some baseline. In particular, an appropriate individually fair solution could act as this baseline, by first computing the social welfare obtained by it and then requiring that the resulting PIIF solution has at least this social welfare. At the extreme, we could even add such a constraint on the utility experienced by each individual; thus, obtaining the guarantee that any deviations from an IF solution are optimal, from the individuals' perspective, compared to some benchmark IF solution.

4 Optimization subject to PIIF

As we have argued, satisfying PIIF is always feasible: on the one hand, we can take any IF solution, including a trivial policy that treats all individuals identically; alternatively, we can take any EF solution, including the welfare-maximizing policy that gives everyone their most-preferred allocation. In this section, we study the question of efficient optimization of a decision-maker's utility function subject to PIIF constraints. As is standard in much of learning and optimization, we frame this task as the following minimization problem:

$$\begin{aligned} &\underset{\pi:\mathcal{X}\to\Delta(C)}{\text{minimize}} && f(\pi) \\ &\text{subject to} && \pi \in \Pi^{\text{PIIF}} \end{aligned}$$

In this section, we answer the question of feasibility of efficient optimization in the positive when f is convex, and the preferences arise from a structured, but rich class of relations.

4.1 Structured preferences

In principle, PIIF can be instantiated with any notion of preference. Without assuming anything about the preferences, however, the PIIF constraints could be difficult to handle: the space of allocations, over which the PIIF constraints are defined, is exponential. In realistic settings, where the number of individuals or outcomes is large, this exponential dependence may be intractable. Towards efficient optimization, we focus on two rich and structured preference classes.

First, we include the prominent class of preferences that admit an expected utility representation, as defined in Definition 12. Additionally, we include the class of *stochastic domination* preferences. Stochastic domination formalizes the intuition that for any distribution over outcomes, a shift of probability mass from less desirable outcomes to more desirable outcomes is considered preferable. Viewing an allocation $p \in \Delta(C)$ as a discrete probability distribution, we denote by $c \sim p$ an outcome randomly sampled from p.

▶ **Definition 15** (Stochastic domination). *For an individual with a utility function $u : C \to [0, M]$ and for any two allocations $p, q \in \Delta(C)$, p stochastically dominates q if*

$$p \succeq q \iff \forall x \in [0, M], \quad \mathop{\mathbf{Pr}}_{c\sim p}[u(c) \geq x] \geq \mathop{\mathbf{Pr}}_{c\sim q}[u(c) \geq x]$$

That is, an allocation p is (weakly) preferred over q if for every possible level of utility x, the probability of achieving at least x is no worse under p than it is under q. Note that stochastic domination represents an interesting example of a non-total preferences, as two allocations may be incomparable.[4]

4.2 Efficient optimization subject to PIIF

Here, we prove that when individuals' preferences are of the forms defined above, the PIIF constraints admit efficient optimization. Formally, the following theorem demonstrates that when the divergence over allocations D is taken to be total variation distance D_{tv}, and assuming oracle access to the individual-fairness metric d, we can write the PIIF constraints as a set of (polynomially-many) linear inequalities; thus, we can efficiently minimize any convex objective f.

▶ **Theorem 16.** *Let $\succeq = \{\succeq_i\}_{i\in\mathcal{X}}$ be the set of individuals' preferences. If every $\succeq_i$ is either the stochastic domination relation or admits an expected utility representation, then the set of $(D_{\text{tv}}, d, \succeq)$-PIIF allocations forms a convex polytope in $\mathbb{R}^k$, where $k = \text{poly}(|\mathcal{X}|, |C|)$.*

Proof. We specify the PIIF constraints using the following variables: for all $i \in \mathcal{X}$, let $\pi(i) \in \Delta(C)$ be a vector denoting the actual allocation; for every pair of individuals $(i, j) \in \mathcal{X} \times \mathcal{X}$, let $p^{i;j} \in \Delta(C)$ be a vector denoting the alternative allocation for i when comparing to j. We argue that the PIIF constraints given in (3) and (4) can each be written as linear inequalities over these variables.

First, since D is taken to be the total variation distance we can translate (3) as $\frac{1}{2} \cdot \sum_{c\in C} \left|p^{i;j}_c - \pi(j)_c\right| \leq d(i, j)$. This can be written as $2 \cdot |C| + 1$ linear inequalities (with the introduction of $|C|$ additional variables representing the absolute values).

Next, we turn to the constraint given in (4). First, consider the case of the preference relations admitting an expected utility form. Let u_i be the utility function for individual i. By definition,

$$\pi(i) \succeq_i p^{i;j} \iff \sum_{c\in C} \pi(i)_c \cdot u_i(c) \geq \sum_{c\in C} p^{i;j}_c \cdot u_i(c).$$

Thus, for every $i \in \mathcal{X}$, the PIIF constraint given in (4) with respect to $j \in \mathcal{X}$ can be written as a linear inequality in the variables $p^{i;j}$ and $\pi(i)$.

Next, we consider the case of the stochastic domination preference relation. We introduce some notation as follows. Fix an individual i and their allocation, $\pi(i)$. Suppose $|C| = k$, and that the outcomes in C are labeled in decreasing order according to i's preferences: $u_i(c_0) \geq u_i(c_1) \geq \cdots \geq u_i(c_{k-1})$. With this ordering in place, we have that for any allocation $p \in \Delta(C)$ and every rank $r \in [k]$, $\mathbf{Pr}_{c\sim p}[u_i(c) \geq u_i(c_r)] = \sum_{t=1}^{r} p_t$. Thus, for each $i \in \mathcal{X}$ we can write the stochastic domination condition as k linear inequalities for each $j \in \mathcal{X}$, where

$$\pi(i) \succeq_i p^{i;j} \iff \forall r \in [k] : \sum_{t\in[r]} \pi(i)_t \geq \sum_{t\in[r]} p^{i;j}_t.$$

Importantly, this demonstrates that for this preference relation, the constraint given in (4) can be enforced using an additional $O(|C|)$ linear constraints, one for every $r \in [k]$. ◀

[4] We remark that this preference notion is a special case of the statistical concept of *first-order* stochastic domination [16, 5].

Other notions of preference

Theorem 16 focuses on the case in which individuals' preferences satisfy one of the two forms discussed above and formalized in Definitions 12 and 15. Naturally, however, not all preference relations satisfy one of these two forms. Appealing examples include preferences where the individual deems some of the outcomes to be substitutes (i.e., interested in exactly one) or complements (i.e., only interested in the complete set) or possibly preferences that value diversity of outcomes. We leave the question of whether PIIF admits efficient optimization over such non-convex preferences as an interesting direction for future research.

5 Fairness in Targeted Advertising: Multiple-Task PIIF

In this section, we extend the definition and study of preference-informed individual fairness to the *multiple-task* setting, formalized and studied by Dwork and Ilvento [13]. This setting was introduced as a model in which to study fairness in targeted advertising, a form of online advertising where ad platforms allow advertisers to specify the characteristics of users they would like to reach, and then make algorithmic decisions as to which users will see which ads based on the advertiser specifications, predictions of ad relevance to individuals, and the ad platform's revenue objectives. Targeted advertising has become pervasive and increasingly moderates individuals' exposure to opportunities. In recent years, numerous concerns have been raised about its fairness and discrimination implications, ranging from concerns about discriminatory advertiser targeting practices enabled by the platforms [3, 30, 2] to concerns about the ad delivery and allocation algorithms run by the platforms introducing bias where none was intended by the advertiser [11, 24, 1, 31, 29]. As part of a lawsuit settlement, the most prominent targeted advertising platform, Facebook, has begun to take steps to ensure advertisers cannot discriminate in their targeting practices [28]. However, the question of how to ensure that the ad delivery and allocation algorithms do not lead to discrimination is wide open [1, 25], in part due to lack of agreement over fairness definition(s) and ad platforms' concerns that existing definitions will restrict allocations in ways that significantly impact their revenue. As such, the multiple-task setting in the presence of individual preferences provides an important model to investigate formal guarantees of non-discrimination without being overly-restrictive for the decision-maker.

In the multiple task setting, we think of the set of outcomes C as arising from a collection of distinct tasks, e.g. deciding whether to show an ad for a user of each ad campaign $c \in C$. Importantly, in this setting, a separate fairness metric d_c is specified for each task (ad campaign), which naturally models real-world concerns in advertising, where different types of ads (e.g. housing, employment, product) are subject to different regulations and standards of fairness.

▶ **Definition 17** (Multiple-task IF). *An allocation $\pi : \mathcal{X} \to \Delta(C)$ is said to be $(D, \{d_1, \dots d_k\})$-*individually fair *in the multiple-task setting if for every two individuals $i, j \in \mathcal{X} \times \mathcal{X}$, the task-specific Lipschitz condition holds for each task:*

$$\forall c \in C : \quad D(\pi(i)_c, \pi(j)_c) \leq d_c(i, j).$$

In this setting, and particularly its application to ad delivery in the targeted advertising context, the benefits of a preference-informed approach to ensuring fairness become particularly salient. For instance, consider the following example, due to [13]. Suppose there are two ad campaigns, one for a high-paying tech job and another for childrens' toys. The ad-specific metrics capture the fact that differentiating based on a particular criteria could be

permissible in some cases and not in others. For example, the metric associated with the tech ad should assign a small distance to individuals of similar qualifications regardless of their status as a parent, whereas the metric for toys might reasonably assign significant distance between parents and non-parents. However, under Multiple-task IF, a parent that is qualified for the tech job ad but is interested in toys must see the tech ad with the same probability as a qualified non-parent – an overly restrictive requirement. PIIF in the multiple-task setting addresses precisely this issue.

▶ **Definition 18** (Multiple-task PIIF). *An allocation $\pi : \mathcal{X} \to \Delta(C)$ satisfies $(D, \{d_1, \dots d_k\}, \preceq)$-preference-informed individual fairness in the multiple-task setting if for all individuals $i \in \mathcal{X}$, for all other individuals $j \in \mathcal{X}$, there exists an allocation $p^{i;j} \in \Delta(C)$ such that:*

$$\forall c \in C: \quad D\left(p_c^{i;j}, \pi(j)_c\right) \leq d_c(i,j)$$
$$\pi(i) \succeq_i p^{i;j}$$

Again, in the multiple-task setting, the preference-informed extension of IF will require that for every individual $i \in \mathcal{X}$, when comparing to every other individual $j \in \mathcal{X}$, the individual i prefers their actual allocation to some alternative allocation, $p^{i;j}$. The main distinction is that now $p^{i;j}$ has to satisfy multiple-task IF with respect to j's current allocation.

Efficient optimization. Our results regarding efficient optimization subject to PIIF from the single-task setting (Section 4) directly extend to the multiple-task setting. In particular, given the ad-specific metrics, individuals' utilities and the advertisers' bids, the platform can efficiently compute the revenue- (or social welfare-) maximizing PIIF allocation.

An interesting direction for future work is relaxing the full information assumption. In particular, an online model, in which allocations are determined on a per-user basis, could naturally be more applicable, as well as allow for the preferences to be "discovered" through the allocation procedure (see [15] for a similar approach wrt the metric itself). This may necessitate investigation of non-trivial tradeoffs, as learning individuals' preferences requires some exploration, which may be at odds with ensuring fair treatment.

5.1 Fairness and social welfare in the multiple-task setting

The construction of Proposition 13 demonstrates that in the single-task setting, the gap between the best social welfare obtainable under IF and PIIF can be large even under very structured classes of preferences. This construction can be generalized to the multiple-task setting; however, an unconvincing aspect of it is the requirement that every individual is identical according to the metric. In such a setting, it's not surprising that IF is overly-constrained.

Here, we describe a family of instances in the multiple-task setting where the per-task similarity is *perfectly aligned with individuals' utilities*; that is, if two individuals benefit similarly from an outcome c, then they are similar. In such instances, we'd expect that the metric constraints would be perfectly aligned with social welfare. Still, we show that this intuition does not carry through for multiple-task IF: for a set of tasks, there are instances where the optimal social welfare under PIIF approaches a factor $|C|$ larger than the best IF solution.

▶ **Theorem 19.** *For any constant $\varepsilon > 0$, there is a sufficiently large $|\mathcal{X}|$ such that there exists a distribution of multiple-task instances where for each task $c \in C$, $d_c(i,j) = |u_i(c) - u_j(c)|$ and*

$$\frac{\mathcal{W}^*}{\mathcal{W}^*\left(\Pi^{\text{IF}}\right)} \geq |C| - \varepsilon.$$

Intuition. Our proof is inspired by a construction of [13], which shows the impossibility of multiple-task IF under "naive composition." We begin by adapting their construction to our setting. Suppose there are two subpopulations of individuals $S \subseteq \mathcal{X}$ and $T = \mathcal{X} \setminus S$. We assume that each task-specific similarity metric d_c is determined by individuals' utility: $d_c(i,j) = |u_i(c) - u_j(c)|$. Additionally, suppose there are two ad campaigns c_0 and c_S. c_0 is a generic campaign where for all individuals $i \in \mathcal{X}$, $u_i(c_0) = 1$; thus, $d_{c_0}(i,j) = 0$ for all $i,j \in \mathcal{X} \times \mathcal{X}$. c_S is targeted where subpopulation S receives nontrivial utility, but the rest of the population receives no utility; thus, d_{c_S} treats pairs within $S \times S$ similarly, pairs from $T \times T$ similarly, but for $i,j \in S \times T$, is arbitrarily large, say $d_{c_S}(i,j) = 1$.

Given these campaigns, a natural allocation of ads to individuals, which we call $\pi^{\mathcal{W}}$, deterministically assigns $\pi^{\mathcal{W}}(i) = c_S$ to all individuals in $i \in S$ since they receive positive utility from c_S. Further, it assigns the untargeted campaign $\pi^{\mathcal{W}}(j) = c_0$ to individuals in $j \in T$ because they benefit positively from seeing c_0, whereas they get no benefit from c_S. Indeed, $\pi^{\mathcal{W}}$ maximizes the social welfare; everyone sees their favorite ad. But $\pi^{\mathcal{W}}$ violates multiple-task IF on c_0; that is, for $i,j \in S \times T$, $\left|\pi^{\mathcal{W}}(j)_{c_0} - \pi^{\mathcal{W}}(i)_{c_0}\right| = 1$ but $d_{c_0}(i,j) = 0$. Intuitively, under multiple-task IF, because everyone in $\mathcal{X}$ is similar according to c_0, the platform must decide whether it is more beneficial to show c_S to the individuals in S at the expense of not being able to show c_0 to the individuals outside of T. The proposition follows by extending this construction beyond the case of two campaigns and two subgroups, and carefully constructing utility functions for individuals.

Proof. Suppose $|C| = n$. Let $t \in \mathbb{N}$ be some constant. Suppose the universe of individuals $\mathcal{X} = S_0 \cup S_1 \cup \ldots S_{n-1}$ is partitioned into disjoint subpopulations ($S_\ell \cap S_m = \varnothing$ for $\ell \neq m$) for $|\mathcal{X}| \geq t^n$. The subpopulations will become progressively smaller as ℓ increases; for each $\ell > 0$, $\frac{|S_\ell|}{|\mathcal{X}|} = 1/t^\ell$ and let $\frac{|S_0|}{|\mathcal{X}|} = 1 - \sum_{\ell=1}^{n-1} \frac{|S_\ell|}{|\mathcal{X}|}$.

Notationally, for all $\ell \in [n]$, let $T_\ell = \bigcup_{m \geq \ell} S_m$. We construct individuals' utilities as follows: for each $\ell \in [n]$, for each individual $i \in \mathcal{X}$,

$$u_i(c_\ell) = \begin{cases} t^\ell & \text{if } i \in T^\ell \\ 0 & \text{otherwise} \end{cases}$$

First, note that for individuals $i \in S_\ell$, c_ℓ maximizes their utility $u_i(c_\ell) = t^\ell$. So consider the welfare-maximizing allocation that assigns every individual in S_ℓ to campaign c_ℓ; this allocation satisfies PIIF. The average social welfare can then be written as:

$$\begin{aligned} \frac{1}{|\mathcal{X}|} \cdot \sum_{\ell=0}^{n-1} \sum_{i \in S_\ell} u_i(c_\ell) &= \frac{|S_0|}{|\mathcal{X}|} + \sum_{\ell=1}^{n-1} \frac{|S_\ell|}{|\mathcal{X}|} \cdot t^\ell \\ &= \left(1 - \sum_{\ell=1}^{n-1} t^{-\ell}\right) + \sum_{\ell=1}^{n-1} t^{-\ell} \cdot t^\ell \\ &= n - \sum_{\ell=1}^{n-1} t^{-\ell} \end{aligned}$$

Next, consider similarity metrics defined by the utilities: For each task c_ℓ, we take $d_\ell(i,j) = |u_i(c_\ell) - u_j(c_\ell)|$. By the definition of u_i, under these similarity metrics, every pair of individuals $i,j \in T_\ell \times T_\ell$ are considered similar $d_\ell(i,j) = 0$. We fix D to be the total variation distance, in other words, $D(p_c, q_c) = |p_c - q_c|$. As such, any allocation π that satisfies IF must show c_ℓ to every individual $i \in T_\ell$ with some fixed probability $\alpha_\ell = \pi(i)_{c_\ell}$. We can compute the expression for the average social welfare of any such assignment as a function of the α_ℓ.

$$\frac{1}{|\mathcal{X}|} \cdot \sum_{\ell=0}^{n-1} \alpha_\ell \cdot \sum_{i \in T_\ell} u_i(c_\ell) = \alpha_0 \cdot \frac{|S_0|}{|\mathcal{X}|} + \sum_{\ell=1}^{n-1} \alpha_\ell \cdot t^\ell \cdot \frac{|T_\ell|}{|\mathcal{X}|}$$

$$= \alpha_0 \cdot \left(1 - \sum_{\ell=1}^{n-1} t^{-\ell}\right) + \sum_{\ell=1}^{n-1} \alpha_\ell \cdot t^\ell \cdot \sum_{m=\ell}^{n-1} t^{-m} \tag{12}$$

$$\leq \alpha_0 + \sum_{\ell=1}^{n-1} \alpha_\ell + \sum_{\ell=1}^{n-1} \alpha_\ell \cdot \sum_{m=\ell+1}^{n-1} t^{-m+\ell}$$

$$\leq \left(\sum_{\ell=0}^{n-1} \alpha_\ell\right) \cdot \left(1 + \sum_{m=2}^{n-1} t^{-m}\right) \tag{13}$$

$$= 1 + \sum_{m=2}^{n-1} t^{-m} \tag{14}$$

where (12) follows by expanding $\frac{|T_\ell|}{|\mathcal{X}|}$ in terms of $\frac{|S_m|}{|\mathcal{X}|} = t^{-m}$; (13) applies Hölder's inequality; and (14) uses the fact that individuals $i \in S_{n-1}$ are members $i \in T_\ell$ for all $\ell \in [n]$, so the sum of the probabilities $\sum_\ell \alpha_\ell \leq 1$.

Given a desired ε, we can take t large enough, the ratio between the social welfares exceeds $n - \varepsilon$. ◀

Optimality under IF

Intuitively, this construction highlights the fact that allowing further targeting and more ad campaigns to participate allows the gap in social welfare between the best IF and PIIF solutions to grow considerably. Note that this gap applies even if the platform's objective is to optimize social welfare, so the proof also shows a gap in worst-case utility achievable by the decision-maker under IF.

We remark that a corollary of our result is that the Dwork-Ilvento "RandomizeThen-Classify" mechanism [13] for composition under multi-task IF achieves worst-case optimal performance (in terms of both social welfare and utility to the platform). In particular, [13] give an algorithm (in a setting with limited information modeling "competitive composition") that allocates a fixed distribution $p \in \Delta(C)$ to all individuals – thus, satisfying IF – that achieves a $1/|C|$-fraction of the best unconstrained utility. Our result shows that no IF solution, even with full information, can achieve a better fraction of the achievable utility.

6 Discussion

In this section, we review additional related work, note some possible extensions within the preference-informed fairness framework, and conclude with a discussion of the strengths and limitations of our current approach.

6.1 Further related works

Since [12], a number of recent works have aimed to extend the "fairness through awareness" framework, including [27, 23, 15, 22, 20]. These works focus on translating the theoretical IF framework into practically-motivated settings.

Three recent works have suggested incorporating notions of individuals' *preferences* into the fairness definitions. First, [4] present EF as an alternative to IF and study its learning-theoretic properties. Their focus is on the question of generalization: given a classifier that is envy-free on a sample, is it approximately envy-free on the underlying distribution? Their main technical result is a positive answer to this question, when learning from a particular structured family of classifiers. An interesting open question is whether the generalization results for IF from [27] and EF from [4] can be combined to give generalization for PIIF.

Second, [34] considers two notions of fairness at the (weaker) group level: treatment parity and impact parity. Their main contribution is a relaxation of both definitions, allowing for solutions where every protected group is "better off" *on average*. From a technical perspective, achieving their notion requires solving a non-convex optimization problem even in the simple case of linear classifiers for two disjoint groups. Our approach is different in that it focuses on defining both fairness and preferences at the *individual* level. This allows for a significantly stronger fairness guarantee, as well as a much more general framework that supports any notion of benefit or preference individuals may have. Importantly, our notion provably admits efficient optimization for a rich class of preference relations.

Finally, independent of our work, [9] study and quantify trade-offs between individual fairness and utility in an online version of the targeted advertising problem. [9] also observe that IF can come at a high cost to utility in the multiple-task setting of [13], but propose a different relaxation. Under their notion, every individual i chooses a subset of the outcomes $S_i \subseteq C$ and is guaranteed that their probability of seeing an ad from S_i is greater than the probability of every other individual of seeing an ad from S_i. Such a guarantee can be viewed as a variant of EF over a more restricted class of preferences than those we consider. The main distinction from PIIF is that this notion ignores the distance metrics entirely and in this sense resembles envy-freeness more than individual-fairness.

6.2 Preference-informed group fairness

In this work, our focus was on incorporating individual preferences into the metric-based individual fairness framework Dwork et al. [12]. The space of fairness definitions, however, is large, and different definitions may be more appropriate in different contexts.

A different approach for defining fairness, often referred to as "group fairness," proceeds as follows. A protected attribute, such as race or gender, induces a partition of the individuals into a small number of groups. For simplicity, we focus on the case where there is a single protected group, S, where the rest of the population is denoted $T = \mathcal{X} \setminus S$. A classifier is considered fair if it achieves parity of some statistical measure across these groups. Group fairness notions are typically weaker than individual notions of fairness: they only provide a guarantee for the "average" member of the protected groups and might allow blatant unfairness towards a single individual or even large subgroups; indeed, the shortcomings of group notions motivated the original work on "fairness through awareness" and subsequent works [12, 21, 17, 23]. Although group fairness notions can be fragile, they are widely studied and used due to their simplicity and due to the fact that they are easier to enforce and implement (for example, they do not require a task-specific similarity metric).

In principle, much of the reasoning behind our argument for incorporating preferences into IF [12] also extends to group-fairness notions. In this section, we show how we might augment a common group notion, called *Statistical Parity* (SP), to incorporate preferences. When there is a clearly "desirable" outcome, SP aims to protect the group S by guaranteeing equal average exposure to the desired outcome.

▶ **Definition 20** (Statistical parity). *A binary classifier $h : \mathcal{X} \to \{\pm 1\}$ satisfies (exact) statistical parity with respect to S if*

$$\mathop{\mathbf{Pr}}_{i\sim S}[h(i) = 1] = \mathop{\mathbf{Pr}}_{i\sim T}[h(i) = 1]$$

In our context, when individuals have diverse preferences over the outcome space, enforcing SP may again come at a cost to members of S, the group that SP aims to protect. As a concrete example, suppose everyone in $\mathcal{X}$ prefers the outcome $+1$, with the exception of some fraction of S, denoted S', who prefer the outcome -1. In this case, the statistical parity constraints prevents the solution where $h(i) = +1$ for $i \in X \setminus S'$ and $h(i) = -1$ for $i \in S$, which from the individuals' perspective is optimal.

Building on this intuition, we extend the set of classifiers we deem fair. Assuming every individual $i \in X$ has a preference relation over $\{\pm 1\}$ (or even distributions over $\{\pm 1\}$), *preference-informed statistical parity* (PISP) allows deviations from SP, as long as they are aligned with the individuals' preferences.

▶ **Definition 21** (Preference-informed statistical parity). *A binary classifier $h : X \to \{\pm 1\}$ satisfies preference-informed statistical parity with respect to S if there exists an alternative classifier, $h' : X \to \{\pm 1\}$, such that:*

$$\forall j \in T, h'(j) = h(j)$$
$$\forall i \in S, h(i) \succeq_i h'(i)$$
$$\mathop{\mathbf{Pr}}_{i\sim S}[h'(i) = 1] = \mathop{\mathbf{Pr}}_{i\sim T}[h'(i) = 1]$$

That is, fixing the outcomes members of T receive under h, every single member of S prefers their current outcome over what they would have received under a classifier satisfying statistical parity. Importantly, the guarantee is still with respect to the preferences of the *individual* members of S.

We conclude with several remarks regarding PISP. First, note that PISP only enriches the set of solutions that satisfy SP; any classifier that satisfies SP also satisfies PISP, by taking the alternative $h' = h$. The classifier welfare-maximizing classifier, where each individual is assigned their favorite outcome, is considered fair. For example, revisiting our example above, the classifier that gives $+1$ to $\mathcal{X} \setminus S'$, and -1 to S' is fair, because the alternative classifier that gives *everyone* $+1$ satisfies the PISP constraints. Finally, we argue that PISP maintains the core of the fairness guarantee of SP. For example, consider the classifier that assigns $+1$ to members of T and -1 to members of S. This classifier benefits the members of T in a way that is *not* aligned with the preferences of all members in S; rightfully, it does not satisfy PISP, because $i \in S \setminus S'$ are harmed.

6.3 Revisiting the assumptions underlying PIIF

Three main assumptions underlie our work. The first is that the outcome space is taken as a given. This could be problematic if the outcomes themselves are biased, e.g., tailored to the preferences of the majority, or worse yet, harmful to the minority. A biased outcome space would also present a problem for both IF and EF, which PIIF does not escape entirely. Still, PIIF may ameliorate the issue, by allowing the minority to receive outcomes that they prefer. We see a study of fairness of the outcomes themselves as an exciting direction for further inquiry.

The second assumption is that any deviation from an IF solution that is aligned with individuals' preferences should still be considered fair. This assumption follow from the perspective that "fair" allocation algorithms should protect the welfare of individuals; this

perspective naturally extends the perspective underlying IF that similar individuals should be treated similarly. As discussed in [18, 19], in other (legal) settings, the notion of "fairness" may necessarily imply "treatment as equal," and notions of individual fairness may not apply. In such settings, the societal notion of fairness may require going against individual preferences. Handling such settings lies beyond the scope of our current work that focuses on the computer science notions of individual fairness, in which the objective is to provide strong protections from discrimination to the individuals themselves.

The third assumption is that the individuals' preferences are known. This is certainly the most nontrivial technical assumption we make; nevertheless, there are established techniques for learning utility-functions from observed behaviour [8]. We also note that accurately learning preferences could often be in the interest of the decision-maker (for example, ad platforms often claim that their implementations of targeted advertising are in line with users' interests [35]). Still, any practical estimation of the preferences runs the risk of injecting further bias during the learning process (for example, if the minority's preferences are estimated with lesser accuracy) and, therefore, mandates special attention in future research.

On a Theorem of Lovász that $\hom(\cdot, H)$ Determines the Isomorphism Type of H

Abstract

Graph homomorphism has been an important research topic since its introduction [14]. Stated in the language of binary relational structures in that paper [14], Lovász proved a fundamental theorem that the graph homomorphism function $G \mapsto \hom(G, H)$ for 0-1 valued H (as the adjacency matrix of a graph) determines the isomorphism type of H. In the past 50 years various extensions have been proved by Lovász and others [15, 9, 1, 19, 17]. These extend the basic 0-1 case to admit vertex and edge weights; but always with some restrictions such as all vertex weights must be positive. In this paper we prove a general form of this theorem where H can have arbitrary vertex and edge weights. An innovative aspect is that we prove this by a surprisingly simple and unified argument. This bypasses various technical obstacles and unifies and extends all previous known versions of this theorem on graphs. The constructive proof of our theorem can be used to make various complexity dichotomy theorems for graph homomorphism *effective*, i.e., it provides an algorithm that for any H either outputs a P-time algorithm solving $\hom(\cdot, H)$ or a P-time reduction from a canonical #P-hard problem to $\hom(\cdot, H)$.

1 Introduction

More than 50 years ago the concept of graph homomorphism was introduced [14, 13]. Given two graphs G and H, a mapping from $V(G)$ to $V(H)$ is called a homomorphism if every edge of G is mapped to an edge of H. The graphs G and H can be either both directed or undirected. Presented in the language of binary relational structures, Lovász proved in that paper [14] the following fundamental theorem about graph homomorphism: If H and H' are two graphs, then they are isomorphic iff they define the same counting graph homomorphism

[1] Artem Govorov is the author's preferred spelling of his name, rather than the official spelling Artsiom Hovarau.

function, namely, for every G, the number of homomorphisms from G to H is the same as that from G to H'. This number is denoted by $\hom(G, H)$. (Formal definitions are in Section 2.)

In [14] the graph H is a 0-1 adjacency matrix; there are no vertex and edge weights. In [9] Freedman, Lovász and Schrijver define a weighted version of the homomorphism function $\hom(\cdot, H)$, where H has *positive* vertex weights and *real* edge weights. The paper [9] investigates what graph properties can be expressed as such graph homomorphism functions. They gave a necessary and sufficient condition for this expressibility. This work has been extended to the case with arbitrary vertex and edge weights in a field [5], and to "edge models", e.g., [20, 18]. A main technical tool introduced in [9] is the so-called graph algebras. In [15] Lovász further investigated these graph algebras and proved precise bounds for their dimensions. These dimensions are a quantitative account of the space of all isomorphisms from H to H'. They are expressed in a theory of labeled graphs. Schrijver [19] studied the function $\hom(\cdot, H)$ where H is an undirected graph with complex edge weights (but all vertex weights are restricted to 1). He also gave a characterization of a graph property expressible in this form, and proved that $\hom(\cdot, H) = \hom(\cdot, H')$ implies that $H \cong H'$ for undirected graphs with complex edge weights (but unit vertex weights). Regts in [18], in addition to finding interesting connections between edge-coloring models and invariants of the orthogonal group, also proved multiple theorems in the framework of graph homomophisms (corresponding to "vertex models") requiring that all (nonempty) sums of vertex weights be nonzero. The possibility that vertex weights may sum to zero has been a difficult point. Our main result is to extend this isomorphism theorem to both directed and undirected graphs with arbitrary vertex and edge weights. We also determine the precise values of the dimensions of the corresponding graph algebras. A variant of our result, in terms of dimensions of associated algebras was proved by Goodall, Regts and Vena [11]; please see Remark 12 in Section 5.

To prove our theorem, we introduce a surprisingly simple and completely elementary argument, which we call the *Vandermonde Argument*. All of our results are proved by this one technique.

Two vertices i and j in an unweighted graph H are called *twins* iff the neighbor sets of i and j are identical. For weighted graphs, i and j are called twins iff the edge weights $\beta(i, k) = \beta(j, k)$ (and for directed graphs also $\beta(k, i) = \beta(k, j)$) for all k. In order to identify the isomorphism class of H, a natural step is to combine twin vertices. This creates a super vertex with a combined vertex weight (even when originally all vertices are unweighted, i.e., have weight 1). After this "twin reduction" step, our isomorphism theorem can be stated. The following is a simplified form:

▶ **Theorem 1.** *Let $\mathbb{F}$ be a field of characteristic 0. Let H and H' be (directed or undirected) weighted graphs with arbitrary vertex and edge weights from $\mathbb{F}$. Without loss of generality all individual vertex weights are nonzero. Suppose H and H' are twin-free. If for all simple graphs G (i.e., without loops and multiedges),*

$$\hom(G, H) = \hom(G, H'), \tag{1}$$

then the graphs H and H' are isomorphic as weighted graphs, i.e., there is a bijective map from H to H' that preserves all vertex and edge weights.

Theorem 1 is the special case of $k = 0$ of the more general Theorem 2 which deals with k-labeled graphs. In Section 8 we also determine the dimensions of the corresponding graph algebras in terms of the rank of the so-called connection tensors, introduced in [5]. These improve the corresponding theorems in [15, 19, 18] as follows.

From the main theorem (Theorem 2.2) of [15] we generalize from positive vertex weights and real edge weights to arbitrary weights. The main technique in [15] is algebraic. The proof relies on the notion of quantum graphs and structures built from them, and uses idempotent elements in the graph algebras. Similarly, from the isomorphism theorem in [19] we generalize from unit vertex weights and complex edge weights to arbitrary weights. Also we allow directed and undirected weighted graphs H. Theorem 2 also weakens the condition (1) on G to simple graphs (i.e., no multiedges or loops). Schrijver's proof technique is different from that of Lovász [15], but is also algebraic and built on quantum graphs. He uses a Reynolds operator and the Möbius transform (of a graph). The results of Lovász [15] and Schrijver [19] are incomparable. While requiring all vertex weights to be positive is not unreasonable, it is nonetheless a severe restriction, and has been a technical obstacle to all existing proofs. In Regts' thesis [18], multiple theorems were proved with the explicit requirement that all (nonempty) sums of vertex weights be nonzero, which circumvented this issue. In this paper, we allow arbitrary vertex weights with no assumptions. In particular, H can have arbitrary complex vertex and edge weights.

However, more than the explicit strengthening of the theorems, we believe the most innovative aspect of this work is that we found a direct elementary argument that bypassed various technical obstacles and unified all previously known versions. We can also show that the only restriction – $\mathbb{F}$ has characteristic 0 – cannot be removed, and thus our results are the most general extensions on graphs. We give counterexamples for fields of finite characteristic in Section 7.

This line of work has already led to significant applications in the graph limit literature, such as on quasi-random graphs [16]. In [17] Lovász and B. Szegedy also studied these graph algebras where "contractors" and "connectors" are used. In our treatment these "contractors" and "connectors" can also be constructed with simple graphs.

In terms of applications to complexity theory, there has been a series of significant complexity dichotomy theorems on counting graph homomorphisms which show that the function $\hom(\cdot, H)$ is either P-time computable or #P-hard, *depending* on H [7, 8, 2, 12, 21, 10, 4, 6, 3]. These theorems differ in the scope of what types of H are allowed, from 0-1 valued to complex valued, from undirected to directed. In all these theorems a P-time tractability condition on H is given, such that if H satisfies the condition then $\hom(\cdot, H)$ is P-time computable, otherwise $\hom(\cdot, H)$ is #P-hard. In the latter case, the theorem asserts that there is a P-time reduction from a canonical #P-hard problem to $\hom(\cdot, H)$. *However*, various *pinning lemmas* are proved nonconstructively; for undirected complex weighted graphs [4] it was unknown how to make this constructive. Consequently, there was no known algorithm to produce a #P-hardness reduction from H. Because the proof in this paper is constructive, it can be applied as a crucial step in making all these dichotomy theorems *effective*, i.e., we can obtain an algorithm that for any H either outputs a P-time algorithm solving $\hom(\cdot, H)$ or a P-time reduction from a canonical #P-hard problem to $\hom(\cdot, H)$.

2 Preliminaries

We first recap the notion of weighted graph homomorphisms [9], but state it for an arbitrary field $\mathbb{F}$. We let $[k] = \{1, \ldots, k\}$ for integer $k \geq 0$. In particular, $[0] = \emptyset$. By covention $\mathbb{F}^0 = \{\emptyset\}$, and $0^0 = 1$ in $\mathbb{Z}$, $\mathbb{F}$, etc. Often we discuss both directed and undirected graphs together.

An ($\mathbb{F}$-)*weighted graph* H is a finite (di)graph with a weight $\alpha_H(i) \in \mathbb{F} \setminus \{0\}$ associated with each vertex i (0-weighted vertices can be deleted) and a weight $\beta_H(i, j) \in \mathbb{F}$ associated with each edge ij (or loop if $i = j$). For undirected graphs, $\beta_H(i, j) = \beta_H(j, i)$. It is convenient to assume that H is a complete graph with a loop at all nodes by adding all

missing edges and loops with weight 0. Then H is described by an integer $q = |V(H)| \geq 0$ (H can be the empty graph), a nowhere zero vector $\alpha = (\alpha_H(1), \ldots, \alpha_H(q)) \in \mathbb{F}^q$ and a matrix $B = (\beta_H(i,j)) \in \mathbb{F}^{q \times q}$. An isomorphism from H to H' is a bijective map from $V(H)$ to $V(H')$ that preserves vertex and edge weights.

According to [9], let G be an unweighted graph (with possible multiple edges, but no loops) and H a weighted graph given by (α, B), we define

$$\begin{aligned} \hom(G,H) &= \sum_{\phi\colon V(G)\to V(H)} \alpha_\phi \hom_\phi(G,H) \\ &= \sum_{\phi\colon V(G)\to V(H)} \prod_{u\in V(G)} \alpha_H(\phi(u)) \prod_{uv\in E(G)} \beta_H(\phi(u),\phi(v)). \end{aligned} \tag{2}$$

The unweighted case is when all node weights are 1 and all edge weights are 0-1 in H, and $\hom(G,H)$ is the number of homomorphisms from G into H.

A k-labeled graph ($k \geq 0$) is a finite graph in which k nodes are labeled by $1, 2, \ldots, k$ (the graph can have any number of unlabeled nodes). Two k-labeled graphs are isomorphic if there is a label-preserving isomorphism between them. U_k denotes the k-labeled graph on k nodes with no edges. In particular, U_0 is the empty graph with no nodes and no edges. The *product* of two k-labeled graphs G_1 and G_2 is defined as follows: take their disjoint union, and then identify nodes with the same label. Hence for two 0-labeled graphs, $G_1 G_2 = G_1 \sqcup G_2$ (disjoint union). Clearly, the graph product is associative and commutative with the identity U_k, so the set of all (isomorphism classes) of k-labeled graphs togegher with the product operation forms a commutative monoid which we denote by $\mathcal{PLG}[k]$. We denote by $\mathcal{PLG}^{\text{simp}}[k]$ the submonoid of simple graphs in $\mathcal{PLG}[k]$; these are graphs with no loops, at most one edge between any two vertices i and j, and no edge between labeled vertices. A directed labeled graph is simple if its underlying undirected one is simple; in particluar, for any i and j, we require that if $i \to j$ is an edge then $j \to i$ is not an edge. Clearly, $\mathcal{PLG}^{\text{simp}}[k]$ is closed under the product operation (for both directed and undirected types).

Fix a weighted graph $H = (\alpha, B)$. For any k-labeled graph G and mapping $\psi\colon [k] \to V(H)$, let

$$\hom_\psi(G,H) = \sum_{\substack{\phi\colon V(G)\to V(H) \\ \phi \text{ extends } \psi}} \frac{\alpha_\phi}{\alpha_\psi} \hom_\phi(G,H), \tag{3}$$

where ϕ extends ψ means that if $u_i \in V(G)$ is labeled by $i \in [k]$ then $\phi(u_i) = \psi(i)$, and $\alpha_\psi = \prod_{i=1}^k \alpha_H(\psi(i))$, $\alpha_\phi = \prod_{v\in V(G)} \alpha_H(\phi(v))$, so $\frac{\alpha_\phi}{\alpha_\psi}$ is the product of vertex weights of α_ϕ *not* in α_ψ. Then

$$\hom(G,H) = \sum_{\psi\colon [k]\to V(H)} \alpha_\psi \hom_\psi(G,H). \tag{4}$$

When $k = 0$, we only have the empty map $\emptyset$ with the domain $\emptyset$. Then $\hom(G,H) = \hom_\emptyset(G,H)$ for every $G \in \mathcal{PLG}[k]$. The functions $\hom_\psi(\cdot, H)$ where $\psi\colon [k] \to V(H)$ and $k \geq 0$ satisfy

$$\begin{cases} \hom_\psi(G_1G_2,H) = \hom_\psi(G_1,H)\hom_\psi(G_2,H), \quad G_1, G_2 \in \mathcal{PLG}[k], \\ \hom_\psi(U_k,H) = 1. \end{cases} \tag{5}$$

Given a directed or undirected $\mathbb{F}$-weighted graph H, we call two vertices $i, j \in V(H)$ *twins* if for every vertex $\ell \in V(H)$, $\beta_H(i,\ell) = \beta_H(j,\ell)$ and $\beta_H(\ell,i) = \beta_H(\ell,j)$. Note that the vertex weights $\alpha_H(w)$ do not participate in this definition. If H has no twins, we call it twin-free.

The twin relation partitions $V(H)$ into nonempty equivalence classes, $I_1, \ldots, I_s$ where $s \geq 0$. We can define a *twin contraction* graph $\widetilde{H}$, having $I_1, \ldots, I_s$ as vertices, with vertex weight $\sum_{t \in I_r} \alpha_H(t)$ for I_r, and edge weight from I_r to I_q to be $\beta_H(u, v)$ for some arbitrary $u \in I_r$ and $v \in I_q$. After that, we remove all vertices in $\widetilde{H}$ with zero vertex weights together with all incident edges (still called $\widetilde{H}$). This defines a twin-free $\widetilde{H}$. Clearly, $\hom(G, H) = \hom(G, \widetilde{H})$ for all G.

We denote by $\mathrm{Isom}(H, H')$ the set of $\mathbb{F}$-weighted graph isomorphisms from H to H' and by $\mathrm{Aut}(H)$ the group of ($\mathbb{F}$-weighted) graph automorphisms of H.

It is obvious that for directed (or undirected) $\mathbb{F}$-weighted graphs H and H', and the maps $\varphi\colon [k] \to V(H)$ and $\psi\colon [k] \to V(H')$ such that $\psi = \sigma \circ \varphi$ for some isomorphism $\sigma\colon V(H) \to V(H')$ from H to H', we have $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for every $G \in \mathcal{PLG}[k]$.

3 Our results

Theorem 1 is a direct consequence of the case $k = 0$ of the following Main Theorem.

▶ **Theorem 2.** *Let $\mathbb{F}$ be a field of characteristic 0. Let H, H' be (directed or undirected) $\mathbb{F}$-weighted graphs such that H is twin-free and $m = |V(H)| \geq m' = |V(H')|$. Suppose $\varphi\colon [k] \to V(H)$ and $\psi\colon [k] \to V(H')$ where $k \geq 0$. If $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for every $G \in \mathcal{PLG}^{\mathrm{simp}}[k]$ then there exists an isomorphism of $\mathbb{F}$-weighted graphs $\sigma\colon V(H) \to V(H')$ from H to H' such that $\psi = \sigma \circ \varphi$ (a fortiori, H' is twin-free and $m = m'$).*

In Section 8 we will give our results about the space of such isomorphisms, expressed in terms of the dimensions of the corresponding graph algebras.

In Corollaries 3 to 6, $\mathrm{char}\, \mathbb{F} = 0$. The following two corollaries extend Lovász's theorem (and lemmas that are of independent interest) in [15] from real edge weight and positive vertex weight. Furthermore, it holds for both directed and undirected graphs, and the condition on G is weakened so that it is sufficient to assume it for simple graphs only. The fact that the theorem holds under the condition $\hom(G, H) = \hom(G, H')$ for loopless graphs G is important in making the complexity dichotomies *effective* in the sense defined in Section 1.

Theorem 2 is stated in a technical way where we only assume H is twin-free and $|V(H)| \geq |V(H')|$. Corollary 3 is a symmetric statement.

▶ **Corollary 3.** *Let H, H' be (directed or undirected) $\mathbb{F}$-weighted twin-free graphs. Let $\varphi\colon [k] \to V(H)$ and $\psi\colon [k] \to V(H')$ where $k \geq 0$. If $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for every $G \in \mathcal{PLG}^{\mathrm{simp}}[k]$, then there exists an isomorphism σ from H to H' such that $\psi = \sigma \circ \varphi$.*

▶ **Corollary 4.** *Let H, H' be $\mathbb{F}$-weighted twin-free graphs, either both directed or both undirected. If $\hom(G, H) = \hom(G, H')$ for every* simple *graph G, then H and H' are isomorphic as $\mathbb{F}$-weighted graphs.*

For edge weighted graphs with unit vertex weight, the requirement of twin-freeness can be dropped. The following two corollaries directly generalize Schrijver's theorem (Theorem 2) in [19]. Corollary 6 is a restatement of Corollary 5 using the terminology in [19]. Here we strengthen his theorem by requiring the condition $\hom(G, H) = \hom(G, H')$ for only simple graphs G. Also our result holds for fields $\mathbb{F}$ of characteristic 0 generalizing from $\mathbb{C}$, and for directed as well as undirected graphs.

▶ **Corollary 5.** *Let H, H' be (directed or undirected) $\mathbb{F}$-edge-weighted graphs. If $\hom(G, H) = \hom(G, H')$ for every* simple *graph G, then H and H' are isomorphic as $\mathbb{F}$-weighted graphs.*

▶ **Corollary 6.** *Let $A \in \mathbb{F}^{m\times m}$ and $A' \in \mathbb{F}^{m'\times m'}$. Then $\hom(G, A) = \hom(G, A')$ for every* simple *graph G iff $m = m'$ and there is a permutation matrix $P \in \mathbb{F}^{m\times m}$ such that $A' = P^T AP$.*

Our proof of Theorem 2 will show that for any given H, H', there is an explicitly constructed finite family of graphs in $\mathcal{PLG}^{\text{simp}}[k]$ such that the condition for all $G \in \mathcal{PLG}^{\text{simp}}[k]$ can be replaced with for all G in this family, thus we have an explicit finitary family of test graphs. Moreover, this provides an explicit set of "witnesses" that can be used to make various complexity dichotomy theorems for graph homomorphism *effective*, in particular, making the pinning steps in [4] computable, which was an open problem.

4 Technical statements

We start with an exceedingly simple lemma, based on which all of our results will be derived. We will call this lemma and its corollary the *Vandermonde Argument*.

▶ **Lemma 7.** *Let $n \geq 0$, and $a_i, x_i \in \mathbb{F}$ for $1 \leq i \leq n$. Suppose*

$$\sum_{i=1}^{n} a_i x_i^j = 0, \qquad \text{for all } \ 0 \leq j < n. \tag{6}$$

Then for any function $f\colon \mathbb{F} \to \mathbb{F}$, we have $\sum_{i=1}^{n} a_i f(x_i) = 0$.

▶ Remark 8. The statement is vacuously true if $n = 0$, since an empty sum is 0. If (6) is true for $1 \leq j \leq n$, then the same conclusion holds for any function f satisfying $f(0) = 0$.

Proof. We may assume $n \geq 1$. We partition $[n]$ into $\bigsqcup_{\ell=1}^{p} I_\ell$ such that i, i' belong to the same I_ℓ iff $x_i = x_{i'}$. Then (6) is a Vandermonde system of rank p with a solution $(\sum_{i\in I_\ell} a_i)_{\ell\in[p]}$. Thus $\sum_{i\in I_\ell} a_i = 0$ for all $1 \leq \ell \leq p$. It follows that $\sum_{i=1}^{n} a_i f(x_i) = 0$ for any function $f\colon \mathbb{F} \to \mathbb{F}$. We also note that if (6) is true for $1 \leq j \leq n$, then the same proof works except when some $x_i = 0$. In that case, we can separate out the term $\sum_{i\in I_{\ell_0}} a_i$ for the unique I_{ℓ_0} that contains this i, and we get a Vandermonde system of rank $p - 1$ on the other terms $(\sum_{i\in I_\ell} a_i)_{\ell\in[p],\ell\neq\ell_0}$, which must be all zero. ◀

By iteratively applying Lemma 7 we get the following Corollary.

▶ **Corollary 9.** *Let I be a finite (index) set, $s \geq 1$, and $a_i, b_{ij} \in \mathbb{F}$ for all $i \in I, j \in [s]$. Further, let $I = \bigsqcup_{\ell\in[p]} I_\ell$ be the partition of I into equivalence classes, where i, i' are equivalent iff $b_{ij} = b_{i'j}$ for all $j \in [s]$. If $\sum_{i\in I} a_i \prod_{j\in[s]} b_{ij}^{\ell_j} = 0$, for all choices of $(\ell_1, \ldots, \ell_s)$ where each $0 \leq \ell_j < |I|$, then $\sum_{i\in I_\ell} a_i = 0$ for every $\ell \in [p]$.*

Proof. We iteratively apply Lemma 7. First, we define an equivalence relation where i, i' belong to the same equivalence class $\widetilde{I}$ iff $b_{is} = b_{i's}$. For any $\widetilde{I}$, choose f with $f(x) = 1$ for $x = b_{is}$ where $i \in \widetilde{I}$, and $f(x) = 0$ otherwise. After the first application we get $\sum_{i\in\widetilde{I}} a_i \prod_{j\in[s-1]} b_{ij}^{\ell_j} = 0$, for an arbitrary $\widetilde{I}$, and all $0 \leq \ell_j < |I|, j \in [s-1]$. The Corollary follows after applying Lemma 7 s times. ◀

5 Proof of Main Theorem

In this conference version for the sake of simplicity of presentation we prove for undirected graphs; the full version has proofs for directed graphs as well as other results.

We may assume that H is on the vertex set $V(H) = [m]$, given by vertex and edge weights $(\alpha_i)_{i\in[m]} \in (\mathbb{F} \setminus \{0\})^m$, $(\beta_{ij})_{i,j\in[m]} \in \mathbb{F}^{m\times m}$. Similarly, H' is on $V(H') = [m']$, given by $(\alpha'_i)_{i\in[m']} \in (\mathbb{F} \setminus \{0\})^{m'}$ and $(\beta'_{ij})_{i,j\in[m']} \in \mathbb{F}^{m'\times m'}$.

We first make a technical condition of "super surjectivity"; it will be removed in Theorem 2.

▶ **Lemma 10.** *Let H, H' be undirected $\mathbb{F}$-weighted graphs such that H is twin-free and $m \geq m'$. Suppose $\varphi\colon [k] \to V(H)$ and $\psi\colon [k] \to V(H')$ where $k \geq 0$. Assume φ is "super surjective", namely: $|\varphi^{-1}(u)| \geq 2m^2$ for every $u \in V(H)$. If $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for every $G \in \mathcal{PLG}^{\mathrm{simp}}[k]$ then there exists an isomorphism σ from H to H' such that $\psi = \sigma \circ \varphi$.*

Proof. Assume $m \geq 1$ (the case $m = 0$ is trivial). Taking any $u \in V(H)$, we get $k \geq |\varphi^{-1}(u)| \geq 2m^2 > 0$, thus $m' \geq |\psi([k])| \geq 1$. For each $\kappa = (b_i)_{i\in[k]} \in \{0,1\}^k$, we can define a graph $G_\kappa \in \mathcal{PLG}^{\mathrm{simp}}[k]$:

> $V(G_\kappa) = \{u_1, \ldots, u_k, v\}$, with each u_i labeled i. For each $i \in [k]$, there is an edge (v, u_i) iff $b_i = 1$. There are no other edges.

We now define a specific set of G_κ, given φ and ψ. We can partition $[k] = \bigsqcup_{i=1}^m I_i$ where each $I_i = \varphi^{-1}(i)$ and $|I_i| \geq 2m^2$. For every $i \in [m]$, since $|I_i| \geq 2mm'$, there exists $J_i \subseteq I_i$ such that $|J_i| \geq 2m > 0$ and the restriction $\psi_{|J_i}$ takes a constant value $s(i)$, for some function $s\colon [m] \to [m']$. Next, for each $i \in [m]$ and for every $0 \leq k_i < 2m$, we can fix $K_i \subset J_i$, with $|K_i| = k_i$. Then we let the tuple $\chi = \chi(K_1, \ldots, K_m) \in \{0,1\}^k$ take $\chi_{|K_i} = 1$, $i \in [m]$, and all other entries are 0. Let R be the set of all such tuples χ. Then $\hom_\varphi(G_\chi, H) = \hom_\psi(G_\chi, H')$ for every G_χ with $\chi \in R$ is expressed by: For all $0 \leq k_j < 2m$, $j \in [m]$,

$$\sum_{i=1}^{m} \alpha_i \prod_{j=1}^{m} \beta_{ij}^{k_j} = \sum_{i=1}^{m'} \alpha'_i \prod_{j=1}^{m} (\beta'_{is(j)})^{k_j}. \tag{7}$$

In (7) the sums on i come from assigning $v \in V(G_\chi)$ to $i \in V(H)$ or to $i \in V(H')$, respectively.

Because H is twin-free the m-tuples $(\beta_{ij})_{j\in[m]} \in \mathbb{F}^m$ for $1 \leq i \leq m$ are pairwise distinct. In (7) the sum in the LHS has m terms, while the sum in the RHS has $m' \leq m$ terms. Transferring the RHS to the LHS we get at most $2m$ terms. Now we apply Corollary 9 to the sum obtained by moving all terms of the RHS to the LHS in (7). By the pairwise distinctness of the m-tuples $(\beta_{ij})_{j\in[m]} \in \mathbb{F}^m$ for $1 \leq i \leq m$, and since there are only $m' \leq m$ terms from the RHS and every $\alpha_i \neq 0$, we see that each term from the LHS of (7) must be canceled by exactly one term from the RHS. And this can only occur if $m = m'$, and there is a bijective map $\sigma\colon [m] \to [m]$:

$$\alpha_i = \alpha'_{\sigma(i)} \quad \text{for } i \in [m], \qquad (\beta_{ij})_{j\in[m]} = (\beta'_{\sigma(i)s(j)})_{j\in[m]} \quad \text{for } i \in [m]. \tag{8}$$

Since H, H' are undirected graphs, we also have $\beta_{ij} = \beta_{ji} = \beta'_{\sigma(j)s(i)} = \beta'_{s(i)\sigma(j)}$ for $i, j \in [m]$.

Next we show that s is bijective. If for some $x, y \in [m]$ we have $s(x) = s(y)$, then

$$(\beta_{xj})_{j\in[m]} = (\beta'_{s(x)\sigma(j)})_{j\in[m]} = (\beta'_{s(y)\sigma(j)})_{j\in[m]} = (\beta_{yj})_{j\in[m]}.$$

Since H is twin-free we conclude that $x = y$. Thus the map $s\colon [m] \to [m]$ is injective and (since $[m]$ is finite) s is bijective. However, $\sigma\colon [m] \to [m]$ is also bijective, so it follows from (8) that the tuples $(\beta'_{ij})_{j\in[m]}$ for $i \in [m]$ are pairwise distinct, which means that H' is twin-free as well.

Next we show $\psi_{|I_i} = s(i)$ for all $i \in [m]$. If for all $i \in [m]$, we have $J_i = I_i$, then we are done. Otherwise, take any $w \in [m]$ such that J_w is a proper subset of I_w and we take any $t \in I_w \setminus J_w$. Observe that $t \notin K_i$ for all $i \in [m]$, in particular, $\chi(t) = 0$ for each $\chi \in R$.

For each $\chi \in R$, let χ_+ be the tuple obtained from χ by reassigning $\chi(t)$ (changing its t-th entry) from 0 to 1 and let R_+ be the set of all such χ_+. Then $\hom_\varphi(G_\kappa, H) = \hom_\psi(G_\kappa, H')$ for every G_κ with $\kappa \in R_+$ is expressed as (recall that we have already proved that $m' = m$)

$$\sum_{i=1}^{m} \alpha_i \beta_{iw} \prod_{j=1}^{m} \beta_{ij}^{k_j} = \sum_{i=1}^{m} \alpha'_i \beta'_{i\psi(t)} \prod_{j=1}^{m} (\beta'_{is(j)})^{k_j},$$

which can be compared to (7), and here for $\kappa \in R_+$ we have one extra edge (v, u_t) in G_κ, and $\varphi(t) = w$ since $t \in I_w$. So this holds for every $0 \le k_j < 2m$ where $j \in [m]$. Transferring the RHS to the LHS and using (8), we get

$$\sum_{i=1}^{m} (\alpha_i \beta_{iw} - \alpha'_{\sigma(i)} \beta'_{\sigma(i)\psi(t)}) \prod_{j=1}^{m} \beta_{ij}^{k_j} = 0,$$

for every $0 \le k_j < 2m$ where $j \in [m]$. Since $\alpha_i = \alpha'_{\sigma(i)} \neq 0$, and the tuples $(\beta_{ij})_{j\in[m]}$ for $1 \le i \le m$ are pairwise distinct, by Corollary 9, we get $\beta_{iw} - \beta'_{\sigma(i)\psi(t)} = 0$ for $i \in [m]$. On the other hand by (8), $\beta_{iw} = \beta'_{\sigma(i)s(w)}$ for $i \in [m]$. It follows that $\beta'_{\sigma(i)\psi(t)} = \beta'_{\sigma(i)s(w)}$ for $i \in [m]$. However, since $\sigma\colon [m] \to [m]$ is a bijection and, as shown before, H' is twin-free, this implies that $\psi(t) = s(w)$. Recall that $\psi_{|J_w} = s(w)$. This proves that on $I_w \setminus J_w$, ψ also takes the constant value $s(w)$. Thus $\psi_{|I_i} = s(i)$ for all $i \in [m]$.

Next we prove that $\beta_{ij} = \beta'_{\sigma(i)\sigma(j)}$ for all $i, j \in [m]$, i.e., σ preserves the edge weights.

For each $\lambda = (b_i)_{i\in[k]}$, $\tau = (c_i)_{i\in[k]} \in \{0,1\}^k$, we define a graph $G_{\lambda,\tau} \in \mathcal{PLG}^{\mathrm{simp}}[k]$:

$V(G_{\lambda,\tau}) = \{u_1, \dots, u_k, v, v'\}$, with each u_i labeled i. There is an edge (v, v') and, for each $i \in [k]$, there is an edge (v, u_i) if $b_i = 1$, and an edge (v', u_i) if $c_i = 1$. There are no other edges.

Let $R^2 = R \times R$. By the definition of R, every $(\lambda, \tau) \in R^2$ corresponds to a sequence of pairs (K_i, L_i), $i \in [m]$, where $K_i \subset J_i \subseteq I_i$ and $L_i \subset J_i \subseteq I_i$ such that $|K_i| = k_i, |L_i| = \ell_i$, where $0 \le k_i, \ell_i < 2m$, and $\lambda_{|K_i} = 1$, $\tau_{|L_i} = 1$, for $i \in [m]$, and all other entries are 0.

Then $\hom_\varphi(G_{\lambda,\tau}, H) = \hom_\psi(G_{\lambda,\tau}, H')$ for every $G_{\lambda,\tau}$ with $(\lambda, \tau) \in R^2$ is expressed as

$$\sum_{i,j=1}^{m} \alpha_i \alpha_j \beta_{ij} \prod_{r=1}^{m} (\beta_{ir}^{k_r} \beta_{jr}^{\ell_r}) = \sum_{i,j=1}^{m} \alpha'_i \alpha'_j \beta'_{ij} \prod_{r=1}^{m} \left((\beta'_{is(r)})^{k_r} (\beta'_{js(r)})^{\ell_r} \right).$$

This holds for all $0 \le k_r, \ell_r < 2m$ where $r \in [m]$. Transferring the RHS to the LHS and using (8), we get

$$\sum_{i,j=1}^{m} (\alpha_i \alpha_j \beta_{ij} - \alpha_i \alpha_j \beta'_{\sigma(i)\sigma(j)}) \prod_{r=1}^{m} (\beta_{ir}^{k_r} \beta_{jr}^{\ell_r}) = 0,$$

for every $0 \le k_r, \ell_r < 2m$, where $r \in [m]$. Since the tuples $(\beta_{ir}, \beta_{jr})_{r\in[m]}$ for $1 \le i, j \le m$ are pairwise distinct, and $\alpha_i \alpha_j \neq 0$, by Corollary 9,

$$\beta_{ij} = \beta'_{\sigma(i)\sigma(j)}, \quad \text{for } i, j \in [m]. \tag{9}$$

This means that the bijection $\sigma\colon [m] \to [m]$ preserves the edge weights in addition to the vertex weights by (8). Hence $\sigma\colon [m] \to [m]$ is an isomorophism of $\mathbb{F}$-weighted graphs from H to H'.

Finally, we show that $\psi = \sigma \circ \varphi$. From (8) and (9), we have $\beta'_{\sigma(i)s(j)} = \beta_{ij} = \beta'_{\sigma(i)\sigma(j)}$ for $i, j \in [m]$. As H' is twin-free and σ is bijective we get $\sigma(j) = s(j)$ for $j \in [m]$. Now let $x \in [k]$, then $x \in I_i$ for some $i \in [m]$. Therefore $\varphi(x) = i$ and so $\psi(x) = s(i) = \sigma(i) = \sigma(\varphi(x))$ confirming $\psi = \sigma \circ \varphi$. ◀

Proof of Theorem 2. Consider an arbitrary $\ell \geq k$ and let $G \in \mathcal{PLG}^{\mathrm{simp}}[\ell]$ be any ℓ-labeled graph. Let $G^* = \pi_{[k]}(G)$ be the graph obtained by unlabeling the labels not in $[k]$ from G (if $k = \ell$, then $G^* = G$). Clearly, $G^* \in \mathcal{PLG}^{\mathrm{simp}}[k]$ so $\hom_\varphi(G^*, H) = \hom_\psi(G^*, H')$. Expanding the sums on the LHS and the RHS of this equality representing the maps φ, ψ along the vertices formerly labeled by $[\ell] \setminus [k]$, and then regrouping the terms corresponding to the same extension maps of φ from $[\ell]$ to $[m]$ and of ψ from $[\ell]$ to $[m']$, respectively, and then bringing back the labels from $[\ell] \setminus [k]$, we get

$$\sum_{\substack{\mu\colon [\ell]\to[m] \\ \mu \text{ extends } \varphi}} \left(\prod_{k<i\leq\ell} \alpha_{\mu(i)} \right) \hom_\mu(G, H) = \sum_{\substack{\nu\colon [\ell]\to[m'] \\ \nu \text{ extends } \psi}} \left(\prod_{k<i\leq\ell} \alpha'_{\nu(i)} \right) \hom_\nu(G, H') \tag{10}$$

for every $G \in \mathcal{PLG}^{\mathrm{simp}}[\ell]$. (Here if $\ell = k$, the empty product $\prod_{k<i\leq\ell}$ is 1.)

Now choose $\ell \geq k$ so that we can extend φ to a map $\eta\colon [\ell] \to [m]$ such that $|\eta^{-1}(u)| \geq 2m^2$ for every $u \in V(H)$. Clearly $\ell \leq k + 2m^3$ suffices. (If φ already satisfies the property, we can take $\ell = k$ and $\eta = \varphi$.) We fix ℓ and η to be such. Define

$$I = \{\mu\colon [\ell] \to [m] \mid \big(\mu_{|[k]} = \varphi\big) \wedge \big((\exists \sigma \in \mathrm{Aut}(H))\ \mu = \sigma \circ \eta\big)\},$$
$$J = \{\nu\colon [\ell] \to [m'] \mid \big(\nu_{|[k]} = \psi\big) \wedge \big((\exists \sigma \in \mathrm{Isom}(H, H'))\ \nu = \sigma \circ \eta\big)\}.$$

Obviously, $\eta \in I$ so $I \neq \emptyset$. For now, we do not exclude the possibility $J = \emptyset$ but our goal is to show that this is not the case. If $\mu\colon [\ell] \to V(H)$ extends φ but $\mu \notin I$, then by Lemma 10, there exists a graph $G_{\eta,\mu} \in \mathcal{PLG}^{\mathrm{simp}}[\ell]$ such that $\hom_\eta(G_{\eta,\mu}, H) \neq \hom_\mu(G_{\eta,\mu}, H)$. Similarly, if $\nu\colon [\ell] \to V(H')$ extends ψ but $\nu \notin J$, then by Lemma 10, there exists a graph $G'_{\eta,\nu} \in \mathcal{PLG}^{\mathrm{simp}}[\ell]$ such that $\hom_\eta(G'_{\eta,\nu}, H) \neq \hom_\nu(G'_{\eta,\nu}, H')$. Let S be the set consisting of these graphs $G_{\eta,\mu}$ and $G'_{\eta,\nu}$ (we remove any repetitions). Note that if $\mu' \in I$, then $\hom_\eta(G, H) = \hom_{\mu'}(G, H)$ for any $G \in \mathcal{PLG}[\ell]$, and if $\nu' \in J$, then $\hom_\eta(G, H) = \hom_{\nu'}(G, H')$ for any $G \in \mathcal{PLG}[\ell]$. In particular, both equalities hold for each $G \in S$. We impose a linear order on S and regard any set indexed by S as a tuple. For any tuple $\bar{h} = (h_G)_{G\in S}$ of integers, where each $0 \leq h_G < 2m^\ell$, consider the graph $G_{\bar{h}} = \prod_{G\in S} G^{h_G} \in \mathcal{PLG}^{\mathrm{simp}}[\ell]$. Substituting $G = G_{\bar{h}}$ in (10) and using the multiplicativity of partial graph homomorphisms (5), we obtain

$$\sum_{\substack{\mu\colon [\ell]\to[m] \\ \mu \text{ extends } \varphi}} \left(\prod_{k<i\leq\ell} \alpha_{\mu(i)} \right) \prod_{G\in S} (\hom_\mu(G, H))^{h_G} = \sum_{\substack{\nu\colon [\ell]\to[m'] \\ \nu \text{ extends } \psi}} \left(\prod_{k<i\leq\ell} \alpha'_{\nu(i)} \right) \prod_{G\in S} (\hom_\nu(G, H'))^{h_G}$$

for every $0 \leq h_G < 2m^\ell$. By the previous observations and the fact that S contains each $G_{\eta,\mu}$ and $G'_{\eta,\nu}$, the tuple $(\hom_\eta(G, H))_{G\in S}$ coincides with the tuple $(\hom_\mu(G, H))_{G\in S}$ for $\mu \in I$ and it also coincides with the tuple $(\hom_\nu(G, H'))_{G\in S}$ for $\nu \in J$; on the other hand, this tuple $(\hom_\eta(G, H))_{G\in S}$ is different from the tuple $(\hom_\mu(G, H))_{G\in S}$ for each $\mu\colon [k] \to V(H)$ extending φ and not in I and it is also different from the tuple $(\hom_\nu(G, H'))_{G\in S}$ for each $\nu\colon [k] \to V(H')$ extending ψ and not in J. Transferring the RHS to the LHS and then applying Corollary 9, we conclude that

$$\sum_{\mu\in I} \left(\prod_{k<i\leq\ell} \alpha_{\mu(i)} \right) = \sum_{\nu\in J} \left(\prod_{k<i\leq\ell} \alpha'_{\nu(i)} \right). \tag{11}$$

If $\mu \in I$, then $\mu = \sigma \circ \eta$ for some $\sigma \in \mathrm{Aut}(H)$, and therefore $\alpha_{\mu(i)} = \alpha_{\sigma(\eta(i))} = \alpha_{\eta(i)}$ for $1 \le i \le \ell$. Hence $\prod_{k<i\le\ell} \alpha_{\mu(i)} = \prod_{k<i\le\ell} \alpha_{\eta(i)}$ (if $k = \ell$, then both sides are 1), so (11) transforms to

$$|I|_{\mathbb{F}} \cdot \prod_{k<i\le\ell} \alpha_{\eta(i)} = \sum_{\nu\in J} \left(\prod_{k<i\le\ell} \alpha'_{\nu(i)} \right). \tag{12}$$

Here we let$|I|_{\mathbb{F}} = |I| \cdot 1_{\mathbb{F}} = 1_{\mathbb{F}} + \ldots + 1_{\mathbb{F}} \in \mathbb{F}$ ($1_{\mathbb{F}}$ occurs $|I|$ times). Since all $\alpha_i \neq 0$, we have $\prod_{k<i\le\ell} \alpha_{\eta(i)} \neq 0$ (if $k = \ell$, this product is $1_{\mathbb{F}} \neq 0$). Because $I \neq \emptyset$ (as $\eta \in I$) we have $|I| \ge 1$; but $\mathrm{char}\,\mathbb{F} = 0$ so $|I|_{\mathbb{F}} \neq 0$ and therefore $|I|_{\mathbb{F}} \cdot \prod_{k<i\le\ell} \alpha_{\eta(i)} \neq 0$. This implies that the RHS of (12) is nonzero as well which can only occur when $J \neq \emptyset$. Take $\xi \in J$. Then $\xi = \sigma \circ \eta$ for some isomorphism of $\mathbb{F}$-weighted graphs $\sigma\colon V(H) \to V(H')$ from H to H'. Restricting to $[k]$, we obtain $\psi = \sigma \circ \varphi$ which completes the proof. ◀

▶ Remark 11. Theorem 2 shows that the condition $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for all $G \in \mathcal{PLG}^{\mathrm{simp}}[k]$ is equivalent to the existence of an isomorphism from H to H' such that $\psi = \sigma \circ \varphi$. This condition is effectively checkable. However, for the purpose of effectively producing a #P-hardness reduction in the dichotomy theorems, e.g., in [4], we need a witness G such that $\hom_\varphi(G, H) \neq \hom_\psi(G, H')$.

The proof of Theorem 2 gives an *explicit finite* list to check. For $\ell = k + 2m^3$, let $\mathcal{P}_{\ell,m} = \{\prod_{G\in S} G^{h_G} \mid 0 \le h_G < 2m^\ell\}$, where S is from the proof of Theorem 2 using the construction of Lemma 10. We then define $\mathcal{Q}_{k,m} = \pi_{[k]}(\mathcal{P}_{\ell,m}) \subseteq \mathcal{PLG}^{\mathrm{simp}}[k]$. Then the proof of Theorem 2 shows that: the existence of an isomorphism $\sigma\colon V(H) \to V(H')$ from H to H' such that $\varphi = \sigma \circ \psi$, is equivalent to $\hom_\varphi(G, H) = \hom_\psi(G, H')$ for every $G \in \mathcal{Q}_{k,m}$.

▶ Remark 12. In their proof of Theorem 2.1 in [11], Goodall, Regts and Vena noted in a footnote on p. 268 that "Even though Lovász [9] (this is [15]) works over $\mathbb{R}$ and assumes $a_i > 0$ for all i, it is easy to check that the proof of his Lemma 2.4 remains valid in our setting." The following is a sketch of this approach due to Goodall, Regts and Vena; we thank Guus Regts for enlightening discussions. Notations below can be found in [15].

Following the proof of Lemma 2.4 by Lovász in [15] one comes to Claim 4.2. On p. 968 the set Ψ is defined as consisting of all maps equivalent to μ. This set appears in the sum on line 2 of p. 969. Let Ψ_0 be the subset of all maps $\eta \in \Psi$ that restrict to ϕ. Since $\mu \in \Psi$ and μ restricts to ϕ, the subset Ψ_0 is nonempty; however it could have cardinality > 1. Then in the sum on line 2 of p. 969 when one collects all terms with the same restriction, ϕ appears with the coefficient $\sum_{\eta\in\Psi_0} \alpha(\eta(k+1))$. The crucial step in the proof of Claim 4.2 is that this sum is nonzero. In [15] this is nonzero since all vertex weights are positive. Without this positivity, it is possible that such a sum is 0. Thus one cannot directly follow the proof in [15] in the general case when a nonempty subset of vertex weights can sum to 0.

However, instead of Claim 4.2 in [15] on line 6 of p. 970 after the proof of Claim 4.4, one can extend ϕ to a surjective map $\mu : [\ell] \to [m]$ for some $\ell \ge k$. Then apply the trace operator of [15] $\ell - k$ times to an analogous sum defined on line -1 of p. 968, which is in $\mathcal{A}''_\ell$. This gives a sum $\Sigma = \sum_{\eta\in\Psi} \prod_{i\in[k+1:\ell]} \alpha(\eta(i))\eta_{\mathrm{res}}$, where η_{res} is the restriction of η to $[k]$.

Then use Claim 4.4, all $\alpha(\eta(i))$ are the same for $\eta \in \Psi$ and thus $P = \prod_{i\in[k+1:\ell]} \alpha(\eta(i))$ is a common factor. Since each $\alpha(\eta(i)) \neq 0$, this $P \neq 0$. Since $\mu \in \Psi$, $\phi = \mu_{\mathrm{res}}$ appears as a term in Σ with a coefficient $|S|P$, where S is the subset of Ψ consisting of maps that restrict to ϕ. As $\mathbb{F}$ has characteristic 0, this $|S|P \neq 0$.

Now since ψ is given as equivalent to ϕ, and the sum Σ is in $\mathcal{A}''_k$, ψ must have the same coefficient as that of ϕ, which has the form $|S'|P$, where S' is the subset of Ψ that restrict to ψ. So $|S'| = |S|$, in particular S' is nonempty. Thus there is some $\eta \in \Psi$ such that η extends ψ, and η is equivalent to μ.

This leads to the following theorem:

▶ Theorem 13. *Let $\mathbb{F}$ be a field of characterisitic 0. Let H be an undirected $\mathbb{F}$-weighted twin-free graph. For any $k \geq 0$, if $\varphi, \psi \colon [k] \to V(H)$ and $\hom_\phi(G, H) = \hom_\psi(G, H')$ for all undirected graphs G, where G may have multiloops and multiedges, then there is an automorphism σ of H such that $\phi = \sigma \circ \psi$.*

6 Effective GH Dichotomies

We briefly discuss how to use Theorem 2 to make complexity dichotomies for graph homomorphism effective. A long and fruitful sequence of work [7, 8, 2, 12, 21, 10] led to the following complexity dichotomy for weighted graph homomorphisms [4] which unifies these previous ones: There is a tractability condition $\mathcal{P}$ such thatfor any (algebraic) complex symmetric matrix H, if H satisfies $\mathcal{P}$ then $\hom(\cdot, H)$ is P-time computable, otherwise there is a P-time reduction from a canonical #P-hard problem to $\hom(\cdot, H)$. However, in the long sequence of reductions in [4] there are nonconstructive steps, a prominent example is the first pinning lemma (Lemma 4.1, p. 937). This involves condensing H by collapsing "equivalent" vertices, while introducing vertex weights. Consider all 1-labeled graphs G. We say two vertices $u, v \in V(H)$ are "equivalent" if $\hom_u(G, H) = \hom_v(G, H)$ where the notation $\hom_u(G, H)$ denotes the partial sum of $\hom(G, H)$ where we restrict to all mappings which map the labeled vertex of G to u, and similarly for $\hom_v(G, H)$. This is just the special case $k = 1$ in Theorem 2 (note that we first apply the twin compression step to H). Previously the P-time reduction was proved existentially. Using Theorem 2 (see Remark 11 after the proof), this step can be made effective.

There is a finer distinction between making the dichotomy effective in the sense discussed here versus the decidability of the dichotomy. The dichotomy criterion in [4] is decidable in P-time (measured in the size of the description of H); however, according to the proof in [4] which involves nonconstructive steps, when the decision algorithm decides $\hom(\cdot, H)$ is #P-hard it does not produce a reduction. The results in this paper can constructively produce such a reduction when $\hom(\cdot, H)$ is #P-hard.

Previous versions of Theorem 2 (e.g., [14, 15]) show that the above equivalence on u, v for suitably restricted classes of H can be decided by testing for graph isomorphism (with pinning). However, to actually obtain the promised P-time reduction one has to search for "witness" graphs G to $\hom_u(G, H) \neq \hom_v(G, H)$. Having no graph isomorphism mapping u to v does not readily yield such a "witness" graph G, although an open ended search is guaranteed to find one. Thus Theorem 2 gives a double exponential time (in the size of H) algorithm to find a reduction algorithm, while directly applying previous versions of the theorem gives a computable process with no definite time bound. (But we emphasize that no previous versions of Theorem 2 apply to the dichotomy in [4].)

7 Counterexample for fields of finite characteristic

In Lemma 10, the field $\mathbb{F}$ is arbitrary. By contrast, for Theorem 2 the proof uses the assumption that $\operatorname{char} \mathbb{F} = 0$. We show that this assumption cannot be removed, for any fixed k, by an explicit counterexample. The counterexample also applies to Corollaries 3 to 6.

Let $\operatorname{char} \mathbb{F} = p > 0$. For $n \geq 2$ and $\ell_1 > \ldots > \ell_n > 0$, define an (undirected) $\mathbb{F}$-weighted graph $H = H_{n,\ell_1,\ldots,\ell_n}$ with the vertex set $U \cup \bigcup_{i=1}^n V_i$ where $U = \{u_1, \ldots, u_n\}$ and $V_i = \{v_{i,j} \mid 1 \leq j \leq \ell_i p\}$, for $i \in [n]$, and the edge set being the union of the edge sets that form a copy of the complete graph K_n on U and $K_{1+\ell_i p}$ on $\{u_i\} \cup V_i$ for $i \in [n]$. H

is a simple graph with no loops. To make H an $\mathbb{F}$-weighted graph, we assign each vertex and edge weight 1. (So H is really unweighted.) It is easy to see that H is twin-free: First, any two distinct vertices from U or from the same V_i are not twins because H is loopless. (Note that for vertices i, j to be twin in an undirected graph, if (i, j) is an edge, then the loops (i, i), (j, j) must also exist.) Second, for any $i \in [n]$, $u_i \in U$ and any $v \in V_i$ are not twins by $\deg(u_i) > \deg(v)$. Third, $u_i \in U$ (or any $v \in V_i$) and any $w \in V_j$, for $j \neq i$, are not twins because w has some neighbor in V_j while u_i (or v) do not. Let $\sigma \in \mathrm{Aut}(H)$ be an automorphism of H. Each vertex $u \in U$ has the property that u has two neighbors (one in U and one not in U) such that they are not neighbors to each other. This property separates U from the rest. Furthermore $\deg(u_1) > \ldots > \deg(u_n)$. Therefore σ must fix U pointwise. Then it is easy to see that σ must permute each V_i.

For any $\varphi\colon [k] \to U \subset V(H)$ where $k \geq 0$, we claim that $\hom_\varphi(G, H) = \hom_\varphi(G, K_U)$ for every $G \in \mathcal{PLG}[k]$, where K_U is the complete graph with the vertex set U.

Let $\mathfrak{S}_N$ denote the symmetry group on N letters. We define a group action of $\prod_{i=1}^n \mathfrak{S}_{\ell_i p}$ on $\{\xi \mid \xi\colon V(G) \to V(H)\}$ which permutes the images of ξ within each of $V_1, \ldots, V_n$, and fixes U pointwise. Thus for $g = (g_1, \ldots, g_n) \in \prod_{i=1}^n \mathfrak{S}_{\ell_i p}$, if $\xi(w) \in V_i$, then $\xi^g(w) = g_i(\xi(w))$. This group action partitions all ξ into orbits. Consider any $\xi\colon V(G) \to V(H)$ extending φ, such that the image $\xi(V(G)) \not\subseteq U$. Let η be in the same orbit of ξ. The nonzero contributions to $\hom_\xi(G, H)$ and $\hom_\eta(G, H)$ come from either edge weights within U, where they are identical, or within each $\{u_i\} \cup V_i$. Hence by the definition of the group action, $\hom_\xi(G, H) = \hom_\eta(G, H)$. The stabilizer of ξ consists of those g such that each g_i fixes the image set $\xi(V(G)) \cap V_i$ pointwise. Since $\xi(V(G)) \not\subseteq U$, the orbit has cardinality, which is the index of the stablizer, divisible by some $\ell_i p$. In particular it is 0 mod p. Thus the total contribution from each orbit is zero in $\mathbb{F}$, except for those ξ with $\xi(V(G)) \subseteq U$. The claim follows.

For $k \geq 1$, we take $H' = H$. We say that maps $\varphi, \psi\colon [k] \to U$ have the *same type* if for every $i, j \in [k]$, $\varphi(i) = \varphi(j)$ iff $\psi(i) = \psi(j)$. Thus the inverse image sets $\varphi^{-1}(\varphi(i))$ and $\psi^{-1}(\psi(i))$ have the same cardinality for every $i \in [k]$. It follows that the image sets $\varphi([k])$ and $\psi([k])$, consisting of the elements of U having a nonempty inverse image sets under φ^{-1} and ψ^{-1} respectively, are of the same cardinality. So there is a bijection σ of U, mapping $U \setminus \varphi([k])$ to $U \setminus \psi([k])$, and also for every $i \in [k]$, $(\sigma \circ \varphi)(i) = \psi(i)$. Thus $\sigma \in \mathrm{Aut}(K_U)$ and $\sigma \circ \varphi = \psi$. Take $\varphi, \psi\colon [k] \to U$ such that $\varphi \neq \psi$, and they have the same type. For example, we can take $\varphi(i) = u_1$ and $\psi(i) = u_2$ for every $i \in [k]$. Since φ and ψ have the same type, clearly $\hom_\varphi(G, K_U) = \hom_\psi(G, K_U)$. For every $G \in \mathcal{PLG}[k]$, we have already shown that $\hom_\varphi(G, K_U) = \hom_\varphi(G, H)$, and since $H' = H$, $\hom_\psi(G, K_U) = \hom_\psi(G, H')$, implying that $\hom_\varphi(G, H) = \hom_\psi(G, H')$. If Theorem 2 were to hold for the field $\mathbb{F}$ of $\mathrm{char}\,\mathbb{F} = p > 0$, there would be an automorphism $\widehat{\sigma} \in \mathrm{Aut}(H)$ such that $\widehat{\sigma} \circ \varphi = \psi$. But every automorphism of H must fix U pointwise, and thus it restricts to the identity map on U. And since $\varphi([k]) \subseteq U$, we have $\widehat{\sigma} \circ \varphi = \varphi \neq \psi$, a contradiction.

When $k = 0$, in addition to $H = H_{n,\ell_1,\ldots,\ell_n}$ we also take $H' = H_{n,\ell'_1,\ldots,\ell'_n}$ on the vertex set $U \cup \bigcup_{i=1}^n V'_i$, where $n \geq 2$, $\ell'_1 > \ldots > \ell'_n > 0$ and $(\ell'_1, \ldots, \ell'_n) \neq (\ell_1, \ldots, \ell_n)$. As $k = 0$, the only possible choices are the empty maps $\varphi = \emptyset$ and $\psi = \emptyset$, and $\hom(G, H) = \hom(G, K_U) = \hom(G, H')$ still holds for every $G \in \mathcal{PLG}[0]$. However, the same property that every vertex $u \in U$ has two neighbors such that they are not neighbors to each other separates U from the rest in both H and H'. Then the monotonicity $\deg(u_1) > \ldots > \deg(u_n)$ within both H and H' shows that any isomorphism from H to H', if it exists, must fix U pointwise. Then it is easy to see that σ must be a bijection from V_i of H to the corresponding copy V'_i in H'. This forces $(\ell_1, \ldots, \ell_n) = (\ell'_1, \ldots, \ell'_n)$, a contradiction.

8 Rank of Connection Tensors and Dimension of Graph Algebras

The purpose of this section is to summarize the extensions of the main results from [15]. These are stated as Theorems 14 and 15.

An $\mathbb{F}$-valued *graph parameter* is a function from finite graph ismorphism classes to $\mathbb{F}$. For convinience, we think of a graph parameter as a function defined on finite graphs and invariant under graph isomorphism. We allow multiple edges in our graphs, but no loops, as input to a graph parameter. A graph parameter f is called *multiplicative*, if for any disjoint union $G_1 \sqcup G_2$ of graphs G_1 and G_2 we have $f(G_1 \sqcup G_2) = f(G_1)f(G_2)$. A graph parameter on a labeled graph ignores its labels. Every weighted graph homomorphism $f_H = \hom(\cdot, H)$ is a multiplicative graph parameter.

A (k-labeled, $\mathbb{F}$-)*quantum graph* is a finite formal $\mathbb{F}$-linear combination of finite k-labeled graphs. $\mathcal{G}[k] = \mathbb{F}\mathcal{PLG}[k]$ is the monoid algebra of k-labeled $\mathbb{F}$-quantum graphs. We denote by $\mathcal{G}^{\text{simp}}[k]$ the monoid algebra of *simple* k-labeled $\mathbb{F}$-quantum graphs; it is a subalgebra of $\mathcal{G}[k]$. U_k is the multiplicative identity and the empty sum is the additive identity in both $\mathcal{G}[k]$ and $\mathcal{G}^{\text{simp}}[k]$.

Let f be any graph parameter. For all integers $k, n \geq 0$, we define the following n-dimensional array $T(f, k, n) \in \mathbb{F}^{(\mathcal{PLG}[k])^n}$, which can be identified with $(V^{\otimes n})^*$, the dual space of $V^{\otimes n}$, where $V = \bigoplus_{\mathcal{PLG}[k]} \mathbb{F}$ is the infinite dimensional vector space with coordinates indexed by $\mathcal{PLG}[k]$. The entry of $T(f, k, n)$ at coordinate $(G_1, \ldots, G_n)$ is $f(G_1 \cdots G_n)$; when $n = 0$, we define $T(f, k, n)$ to be the scalar $f(U_k)$. The arrays $T(f, k, n)$ are symmetric with respect to its coordinates, i.e., $T(f, k, n) \in \text{Sym}(\mathbb{F}^{(\mathcal{PLG}[k])^n})$. Fix f, k and n, we call the n-dimensional array $T(f, k, n)$ the (k-th, n-dimensional) *connection tensor* of the graph parameter f. When $n = 2$, a connection tensor is exactly a *connection matrix* of the graph parameter f studied in [9], i.e., $T(f, k, 2) = M(f, k)$.

For graph parameters of the form $f_H = \hom(\cdot, H)$, where H has positive vertex weights and real edge weights, the main results of [15] are to compute the rank of the corresponding connection matrices, and the dimension of graph algebras, etc. We will prove these results for arbitrary $\mathbb{F}$-weighted graphs (without vertex or edge weight restrictions). Moreover we will prove these for connection tensors (see [5]). Below we let H be a (directed or undirected) $\mathbb{F}$-weighted graph.

For $k \geq 0$, let $N(k, H)$ be the matrix whose rows are indexed by maps $\varphi\colon [k] \to V(H)$ and columns are indexed by $\mathcal{PLG}[k]$, and the row indexed by φ is $\hom_\varphi(\cdot, H)$. We have a group action of $\text{Aut}(H)$ on the k-tuples from $V(H)^k = \{\varphi\colon [k] \to V(H)\}$ by $\varphi \mapsto \sigma \circ \varphi$ for $\sigma \in \text{Aut}(H)$ and $\varphi\colon [k] \to V(H)$. We use $\text{orb}_k(H)$ to denote the number of its orbits.

As mentioned before, $f_H = \hom(\cdot, H)$ ignores labels on a labeled graph, so we can think of f_H as defined on $\mathcal{PLG}[k]$ and then by linearity as defined on $\mathcal{G}[k]$. Then we can define the following bilinear symmetric form on $\mathcal{G}[k]$:

$$\langle x, y \rangle = f_H(xy), \quad x, y \in \mathcal{G}[k].$$

Let

$$\mathcal{K}_{[k]} = \{x \in \mathcal{G}[k]\colon f_H(xy) = \langle x, y \rangle = 0 \ \forall y \in \mathcal{G}[k]\}.$$

Clearly, $\mathcal{K}_{[k]}$ is an ideal in $\mathcal{G}[k]$, so we can form a quotient algebra $\mathcal{G}'[k] = \mathcal{G}[k]/\mathcal{K}_{[k]}$. It is easy to see that $h \in \mathcal{K}_{[k]}$ iff $M(f_H, k)h = 0$.

In order to be consistent with the notation in [15], when $f = f_H = \hom(\cdot, H)$ for an $\mathbb{F}$-weighted (directed or undirected) graph H, we let $T(k, n, H) = T(f_H, k, n)$ where $k, n \geq 0$ and $M(k, H) = M(f_H, k)$ where $k \geq 0$.

The following theorems extend Theorem 2.2, Corollary 2.3 and the results of Section 3 in [15].

▶ **Theorem 14.** *Let $\mathbb{F}$ be a field of characteristic 0. Let H be a (directed or undirected) $\mathbb{F}$-weighted twin-free graph. Then $\mathcal{G}'[k] \cong \mathbb{F}^{r_k}$ as isomorphic algebras, where*

$$r_k = \dim \mathcal{G}'[k] = \mathrm{rk}_{\mathsf{S}}\, T(k,n,H) = \mathrm{rk}\, T(k,n,H) = \mathrm{rk}\, M(k,H) = \mathrm{rk}\, N(k,H) = \mathrm{orb}_k(H)$$

for $k \geq 0$ and $n \geq 2$. Here rk_{S} denotes symmetric tensor rank, and rk on T and on M, N denote tensor and matrix rank, respectively. In particular, if H has no nontrivial $\mathbb{F}$-weighted automorphisms, then the above quantities are all equal to $|V(H)|^k$.

The following theorem generalizes Lemma 2.5 in [15]. Let $k \geq 0$ be an integer and H be an $\mathbb{F}$-weighted graph. We say that a vector $f\colon V(H)^k \to \mathbb{F}$ is *invariant under the automorphisms* of H if $f(\sigma \circ \varphi) = f(\varphi)$ for every $\sigma \in \mathrm{Aut}(H)$ and $\varphi \in V(H)^k$.

▶ **Theorem 15.** *Let $\mathbb{F}$ be a field of characteristic 0. Let H be a (directed or undirected) $\mathbb{F}$-weighted twin-free graph. Then for $k \geq 0$, the column space of $N(k,H)$ consists of precisely those vectors $f\colon V(H)^k \to \mathbb{F}$ that are invariant under the authomorphisms of H. Moreover, every such vector can be obtained as a finite linear combination of the columns of $N(k,H)$ indexed by $\mathcal{PLG}^{\mathrm{simp}}[k]$.*

From this theorem, we can immediately conclude the existence of simple contractors and connectors from $\mathcal{PLG}^{\mathrm{simp}}[k]$ when $\mathrm{char}\,\mathbb{F} = 0$ for GH functions (see [17] for the definitions).

Abstract

The use of monotonicity and Tarski's theorem in existence proofs of equilibria is very widespread in economics, while Tarski's theorem is also often used for similar purposes in the context of verification. However, there has been relatively little in the way of analysis of the complexity of finding the fixed points and equilibria guaranteed by this result. We study a computational formalism based on monotone functions on the d-dimensional grid with sides of length N, and their fixed points, as well as the closely connected subject of supermodular games and their equilibria. It is known that finding some (any) fixed point of a monotone function can be done in time $\log^d N$, and we show it requires at least $\log^2 N$ function evaluations already on the 2-dimensional grid, even for randomized algorithms. We show that the general Tarski problem of finding some fixed point, when the monotone function is given succinctly (by a boolean circuit), is in the class PLS of problems solvable by local search and, rather surprisingly, also in the class PPAD. Finding the greatest or least fixed point guaranteed by Tarski's theorem, however, requires $d \cdot N$ steps, and is NP-hard in the white box model. For supermodular games, we show that finding an equilibrium in such games is essentially computationally equivalent to the Tarski problem, and finding the maximum or minimum equilibrium is similarly harder. Interestingly, two-player supermodular games where the strategy space of one player is one-dimensional can be solved in $O(\log N)$ steps. We also show that computing (approximating) the value of Condon's (Shapley's) stochastic games reduces to the Tarski problem. An important open problem highlighted by this work is proving a $\Omega(\log^d N)$ lower bound for small fixed dimension $d \geq 3$.

1 Introduction

Equilibria are paramount in economics, because guaranteeing their existence in a particular strategic or market-like framework enables one to consider "What happens at equilibrium?" without further analysis. Equilibrium existence theorems are nontrivial to prove. The best known example is Nash's theorem [18], whose proof in 1950, based on Brouwer's fixed point theorem, transformed game theory, and inspired the Arrow-Debreu price equilibrium results [1], among many others. Decades later, complexity analysis of these theorems and corresponding solution concepts by computer scientists has created a fertile and powerful field of research [19].

Not all equilibrium theorems in economics, however, rely on Brouwer's fixed point theorem for their proof (even though, in a specific sense made clear and proved in this paper, they could have...). Many of the exceptions ultimately rely on *Tarski's fixed point theorem* [22], stating that all monotone functions on a complete lattice have a fixed point – and in fact a whole sublattice of fixed points with a largest and smallest element [23, 17, 24]. In contrast to the equilibrium theorems whose proof relies on Brouwer's fixed point theorem, there has been relatively little complexity analysis of Tarski's fixed point theorem and the equilibrium results it enables. (We discuss prior related work at the end of this introduction.)

Here we present several results in this direction. Let $[N] = \{1, \ldots, N\}$. To formulate the basic problem, we consider a monotone function f on the d-dimensional grid $[N]^d$, that is, a function $f : [N]^d \mapsto [N]^d$ such that for all $x, y \in [N]^d$, $x \geq y$ implies $f(x) \geq f(y)$; in the black-box oracle model, we can query this function with specific vectors $x \in [N]^d$; in the white-box model we assume that the function is presented by a boolean circuit[1]. Thus, d and N are the basic parameters to our model; it is useful to think of d as the dimensionality of the problem, while N is something akin to the inverse of the desired approximation ϵ.

- Tarski's theorem in the grid framework is easy to prove. Let $\bar{1} = (1, \ldots, 1)$ denote the (d-dimensional) all-1 vector. Consider the sequence of grid points $\bar{1}, f(\bar{1}), f(f(\bar{1})), \ldots, f^i(\bar{1}), \ldots$. From monotonicity of f, by induction on i we get, for all $i \geq 0$, $f^i(\bar{1}) \leq f^{i+1}(\bar{1})$. Unless a fixed point is arrived at, the sum of the coordinates must increase at each iteration. Therefore, after at most dN iterations of f applied to $\bar{1}$, a fixed point is found. In other words $f^{dN}(\bar{1}) = f^{dN+1}(\bar{1})$.
- This immediately suggests an $O(dN)$ algorithm. But an $O(\log^d N)$ algorithm is also known[2]: Consider the $(d-1)$-dimensional function obtained by fixing the "input value" in the d'th coordinate of the function f with some value r_d (initialize $r_d := \lceil N/2 \rceil$). Find a fixed point $z^* \in [N]^{d-1}$ of this $(d-1)$-dimensional monotone function $f(z, r_d)$ (recursively). If the dth coordinate $f_d(z^*, r_d)$ of $f(z^*, r_d)$, is equal to r_d, then (z^*, r_d) is a fixed point of the overall function f, and we are done. Otherwise, a binary search on the d'th coordinate is enabled: we need to look for a larger (smaller) value of r_d if $f_d(z^*, r_d) > r_d$ (respectively, if $f_d(z^*, r_d) < r_d$). By an easy induction, this establishes the $O(\log^d N)$ upper bound ([5]).
- We conjecture that this algorithm is essentially optimal in the black box sense, for small fixed constant dimension d. In Theorem 7 we prove this result for the $d = 2$ case. We provide a class of monotone functions that we call *the herringbones*: two monotonic paths,

[1] Naturally, one could have addressed the more general problem in which the lattice is itself presented in a general way through two functions *meet* and *join;* however, this framework (a) leads quickly and easily to intractability; and (b) does not capture any more applications in economics than the one treated here.

[2] This algorithm appears to have been first observed in [5].

one starting from $\bar{1}$ and the other from $\bar{N}$, meeting at the fixed point, while all other points in the $N \times N$ grid are mapped diagonally: $f(x) = x + (-1, +1)$ or $x + (+1, -1)$, whichever of the points is closer to the monotonic path that contains the fixed point. We prove that any randomized algorithm needs to make $\Omega(\log^2 N)$ queries (in expectation) to find the fixed point.

- Can this lower bound result be generalized to fixed $d \geq 3$? This is a key question left open by this paper. There are several obstacles to a proof establishing, e.g., a $\Omega(\log^3 N)$ lower bound in the 3-dimensional case ($d = 3$), and some possible ways for overcoming them. First, it is not easy to identify a suitable "herringbone-like" function in three or more dimensions – a monotone family of functions built around a path from $\bar{1}$ to $\bar{N}$. It nevertheless seems plausible that $\log^d N$ should still be (close to) a lower bound on any such algorithm (assuming of course that N is sufficiently larger than d, so that the dN algorithm does not violate the lower bound). We prove one encouraging result in this context: We give an alternative proof of the $d = 2$ lower bound, in which we establish that any *deterministic* black-box algorithm for TARSKI in two dimensions *must solve a sequence of* $\Omega(\log N)$ *one-dimensional problems* (Theorem 13), a result pointing to a possible induction on d (recall that this is precisely the form of the $\log^d N$ algorithm).
- Tarski's theorem further asserts that there is a greatest and a least fixed point, and these fixed points are especially useful in the economic applications of the result (see for example [17]). It is not hard to see, however, that finding these fixed points is **NP**-hard, and takes $\Omega(dN)$ time in the black box model (see Proposition 1).
- In terms of complexity classes, the problem TARSKI is obviously in the class **TFNP** of total function (total search) problems. But where exactly? We show (Theorem 4) that it belongs in the class PLS of local optimum search problems.
- Surprisingly, TARSKI is also in the class P^{PPAD} of problems reducible to a Brouwer fixed point problem (Theorem 5), and thus, by the known fact that the class PPAD is closed under polynomial time Turing reductions ([2]) it is in PPAD (Corollary 6). This result presents a heretofore unsuspected connection between two main sources of equilibrium results in economics.
- *Supermodular games* [23, 17, 24] – or games with strategic complementarities – comprise a large and important class of economic models, with complete lattices as strategy spaces, in which a player's best response is a monotone function (or monotone correspondence) of the other player's strategies. They always have pure Nash equilibria due to Tarski's theorem. We show that finding an equilibrium for a supermodular game with (discrete) Euclidean grid strategy spaces is essentially computationally equivalent to the problem of finding a Tarski fixed point of a monotone map (Proposition 14 and Theorem 16). If there are two players and one of them has a one-dimensional strategy space, we show that a Nash equilibrium can be found in logarithmic time (in the size of the strategy spaces).
- *Stochastic games* [21, 4]. We show that the problems of computing the (irrational) value of Shapley's discounted stochastic games to desired accuracy, and computing the exact value of Condon's simple stochastic games (SSG), are both P-time reducible to the Tarski problem. The proofs employ known characterizations of the value of both Shapley's stochastic games and Condon's SSGs in terms of monotone fixed point equations, which can also be viewed as monotone "polynomially contracting" maps with a unique fixed point, and from properties of polynomially contracting maps, see [12].

Prior related work. In recent years a number of technical reports and papers by Dang, Qi, and Ye, have considered the complexity of computational problems related to Tarski's theorem [5, 7, 6]. In particular, in [5] the authors provided the already-mentioned $\log^d N$

algorithm for computing a Tarski fixed point for a discrete map, $f : [N]^d \to [N]^d$, which is monotone under the coordinate-wise order. In [5] they also establish that determining the uniqueness of the fixed point of a monotone map under coordinate-wise order is coNP-hard, and that uniqueness under lexicographic order is also coNP-hard (already in one dimension). In [7] the authors studied another variant of the Tarski problem, namely computing another fixed point of a monotone function in an expanded domain where the smallest point is a fixed point; this variant is NP-hard (the claim in the paper that this problem is in PPA has been withdrawn by the authors [8]). In earlier work, Echenique [10], studied algorithms for computing all pure Nash equilibria in supermodular games (and games with strategic complementaries) whose strategy spaces are discrete grids. Of course computing all pure equilibria is harder than computing *some* pure equilibrium; indeed, we show that computing the least (or greatest) pure equilibrium of such a supermodular game is already NP-hard (Corollary 17). In earlier work Chang, Lyuu, and Ti [3] considered the complexity of Tarski's fixed point theorem over a general finite lattice given via an oracle for its partial order (not given it explicitly) and given an oracle for the monotone function, and they observed that the total number of oracle queries required to find some fixed point in this model is linear in the number of elements of the lattice. They did not study monotone functions on euclidean grid lattices, and their results have no bearing on this setting.

Organization of the paper. The rest of the paper is organized as follows. Section 2 provides basic definitions on lattices and monotone functions, and presents some simple basic results. In Section 3 we define the TARSKI problem and show that it is in PLS and PPAD. Section 4 proves the lower bound of $\log^2 N$ on black-box algorithms. Section 5 concerns supermodular games. Section 6 reduces Condon's and Shapley's stochastic games to the TARSKI problem. Finally, Section 7 concludes and discusses open problems. Several of the proofs are only sketched or omitted; more details can be found in the full version of the paper [11].

2 Basics

A partial order $(L, \leq)$ is a *complete lattice* if every nonempty subset S of L has a least upper bound (or supremum or join, denoted $\sup S$ or $\vee S$) and a greatest lower bound (or infimum or meet, denoted $\inf S$ or $\wedge S$) in L. A function $f : L \to L$ is *monotone* if for all pairs of elements $x, y \in L$, $x \leq y$ implies $f(x) \leq f(y)$. A point $x \in L$ is a *fixed point* of f if $f(x) = x$. Tarski's theorem ([22]) states that the set $Fix(f)$ of fixed points of f is a nonempty complete lattice under the same partial order $\leq$; in particular, f has a greatest fixed point (GFP) and a least fixed point (LFP).

In this paper we will take as our underlying lattice L a finite discrete Euclidean grid, which we fix for simplicity to be the integer grid $[N]^d$, for some positive integers N, d, where $[N] = \{1, \ldots, N\}$. Comparison of points is componentwise, i.e. $x \leq y$ if $x_i \leq y_i$ for all $i = 1, \ldots, d$. We will also consider the corresponding continuous box, $[1, N]^d$ that includes all real points in the box. Both, the discrete and continuous box are clearly complete lattices.

Given a monotone function f on the integer grid $[N]^d$, the problem is to compute a fixed point of f (any point in $Fix(f)$). A generally harder problem is to compute specifically the LFP of f or the GFP of f. We consider mostly the oracle model, in which the function f is given by a black-box oracle, and the complexity of the algorithm is measured in terms of the number of queries to the oracle. Alternatively, we can consider also an explicit model in which f is given explicitly by a polynomial-time algorithm (a polynomial-size Boolean circuit), and then the complexity of the algorithm is measured in the ordinary Turing model. Note

that the number of bits needed to represent a point in the domain is $d \log N$, so polynomial time here means polynomial in d and $n = \log N$. The number N^d of points in the domain is exponential.

Tarski's value iteration algorithm provides a simple way to compute the LFP of f: Starting from the lowest point of the lattice, which here is the all-1 vector 1, apply repeatedly f. This generates a monotonically increasing sequence of points $1 \leq f(1) \leq f^2(1) \leq \ldots$ until a fixed point is reached, which is the LFP of f. In every step of the sequence, at least one coordinate is strictly increased, therefore a fixed point is reached in at most $(N-1)d$ steps. In the worst case, the process may take that long, which is exponential in the bit size $d \log N$. Similarly, the GFP can be computed by applying repeatedly f starting from the highest point of the lattice, i.e., from the all-N point, until a fixed point is reached.

Another way to compute some fixed point of a monotone function f (not necessarily the LFP or the GFP) is by a divide-and-conquer algorithm. In one dimension, we can use binary search: If the domain is the set $L(l,h) = \{x \in Z | l \leq x \leq h\}$ of integers between the lowest point l and the highest point h, then compute the value of f on the midpoint $m = (l+h)/2$. If $f(m) = m$ then m is a fixed point; if $f(m) < m$ then recurse on the lower half $L(l,m)$, and if $f(m) > m$ then recurse on the upper half $L(m,h)$. The monotonicity of f implies that f maps the respective half interval into itself. Hence the algorithm correctly finds a fixed point in at most $\log N$ iterations, where N is the number of points.

In the general d-dimensional case, suppose that the domain is the set of integer points in the box defined by the lowest point l and the highest point h, i.e. $L(l,h) = \{x \in Z^d | l \leq x \leq h\}$. Consider the set of points with d-th coordinate equal to $m = (l+h)/2$; their first $d-1$ coordinates induce a $(d-1)$-dimensional lattice $L'(l,h) = \{x \in Z^{d-1} | l_i \leq x_i \leq h_i, i = 1, \ldots d-1\}$. Define the function g on $L'(l,h)$ by letting $g(x)$ consist of the first $d-1$ components of $f(x,m)$. It is easy to see that g is a monotone function on $L'(l,h)$. Recursively, compute a fixed point x^* of g. If $f_d(x^*,m) = m$, then (x^*,m) is a fixed point of f (this holds in particular if $l = h$). If $f_d(x^*,m) > m$, then recurse on $L(f(x^*,m),h)$. If $f_d(x^*,m) < m$, then recurse on $L(l,f(x^*,m))$. In either case, monotonicity implies that if the algorithm recurses, then f maps the smaller box into itself and thus has a fixed point in it. An easy induction shows that the complexity of this algorithm is $O((\log N)^d)$, ([5]).

Computing the least or the greatest fixed point is in general hard, even in one dimension, both in the oracle and in the explicit model.

▶ **Proposition 1.** *Computing the LFP or the GFP of an explicitly given polynomial-time monotone function in one dimension is NP-hard. In the oracle model, the problem requires $\Omega(N)$ queries for a domain of size N.*

Proof. We prove the claim for the LFP; the GFP is similar. Reduction from Satisfiability. Given a Boolean formula ϕ in n variables, let the domain $D = \{0, 1, \ldots, 2^n\}$, and define the function f as follows. For $x \leq 2^n - 1$, viewing x as an n-bit binary number, it corresponds to an assignment to the n variables of ϕ; let $f(x) = x$ if the assignment x satisfies ϕ, and let $f(x) = x+1$ otherwise. Define $f(2^n) = 2^n$. Clearly f is a monotone function and it can be computed in polynomial time. If ϕ is not satisfiable then the LFP of f is 2^n, while if ϕ is satisfiable then the LFP is not 2^n.

For the oracle model, use the same domain D and let f map every $x \leq 2^n - 1$ to x or $x+1$, and $f(2^n) = 2^n$. The LFP is not 2^n iff there exists an $x \leq 2^n - 1$ such that $f(x) = x$, which in the oracle model requires trying all possible $x \leq 2^n - 1$. ◀

In the case of a continuous domain $[1,N]^d$, we may not be able to compute an exact fixed point, and thus we have to be content with approximation. Given an $\epsilon > 0$, an ϵ-approximate fixed point is a point x such that $|f(x) - x| \leq \epsilon$, where we use the L_∞ (max)

norm, i.e. $|f(x) - x| = \max\{|f_i(x) - x_i| | i = 1, \ldots, d\}$. In this context, polynomial time means polynomial in $\log N, d$, and $\log(1/\epsilon)$ (the number of bits of the approximation). An ϵ-approximate fixed point need not be close to any actual fixed point of f. A problem that is generally harder is to compute a point that approximates some actual fixed point, and an even harder task is to approximate specifically the LFP or the GFP of f. Tarski's value iteration algorithm, starting from the lowest point converges in the limit to the LFP (and if started from the highest point, it converges to the GFP), but there is no general bound on the number of iterations needed to get within ϵ of the LFP (or the GFP). The algorithm reaches however an ϵ-approximate fixed point within Nd/ϵ iterations (note, this is exponential in $\log N, \log(1/\epsilon)$).

It is easy to see that the approximate fixed point problem for the continuous case reduces to the exact fixed point problem for the discrete case.

▶ **Proposition 2.** *The problem of computing an ϵ-approximate fixed point of a given monotone function on the continuous domain $[1, N]^d$ reduces to the exact fixed point problem on a discrete domain $[N/\epsilon]^d$.*

Proof. Given the monotone function f on the continuous domain $D_1 = [1, N]^d$, consider the discrete domain $D_2 = \{x \in Z^d | k \leq x_i \leq Nk, i = 1, \ldots, d\}$, where $k = \lceil 1/\epsilon \rceil$, and define the function g on D_2 as follows. For every $x \in D_2$, let $g(x)$ be obtained from $kf(x/k)$ by rounding each coordinate to the nearest integer, with ties broken (arbitrarily) in favor of the ceiling. Since f is monotone, g is also monotone. If x^* is a fixed point of g, then $kf(x^*/k)$ is within $1/2$ of x^* in every coordinate, and hence $f(x^*/k)$ is within $1/2k < \epsilon$ of x^*/k. Thus x^*/k is an ϵ-approximate fixed point of f. ◀

3 Computing a Tarski fixed point is in PLS ∩ PPAD

For a monotone function $f : [N]^d \to [N]^d$ (with respect to the coordinate-wise ordering), we are interested in computing a fixed point $x^* \in \text{Fix}(f)$, which we know exists by Tarski's theorem. We shall formally define this as a discrete total search problem, using a standard construction to avoid the "promise" that f is monotone.

Recall that a general discrete *total search problem* (with polynomially bounded outputs), Π, has a set of *valid input instances* $D_\Pi \subseteq \{0,1\}^*$, and associates with each valid input instance $I \in D_\Pi$, a non-empty set $\mathcal{O}_I \subseteq \{0,1\}^{p_\Pi(|I|)}$ of *acceptable outputs*, where $p_\Pi(\cdot)$ is some polynomial. (So the bit encoding length of every acceptable output is polynomially bounded in the bit encoding length of the input I.) We are interested in the complexity of the following total search problem:

▶ **Definition 3.** `Tarski`:

Input: *A function $f : [N]^d \to [N]^d$ with $N = 2^n$ for some $n \geq 1$, given by a boolean circuit, C_f, with $(d \cdot n)$ input gates and $(d \cdot n)$ output gates.*

Output: *Either a (any) fixed point $x^* \in \text{Fix}(f)$, or else a witness pair of vectors $x, y \in [N]^d$ such that $x \leq y$ and $f(x) \not\leq f(y)$.*

Note `Tarski` is a *total* search problem: If f is monotone, it will contain a fixed point in $[N]^d$, and otherwise it will contain such a witness pair of vectors that exhibit non-monotonicity. (If it is non-monotone it may of course have both witnesses for non-monotonicity and fixed points.)

Tarski ∈ PLS

Recall that a total search problem, Π, is in the complexity class PLS (*Polynomial Local Search*) if it satisfies all of the following conditions (see [16, 26]):

1. For each valid input instance $I \in D_\Pi \subseteq \{0,1\}^*$ of Π, there is an associated non-empty set $S_I \subseteq \{0,1\}^{p(|I|)}$ of *solutions*, and an associated *payoff function*[3], $g_I : S_I \to \mathbb{Z}$. For each $s \in S_I$, there is an associated set of *neighbors*, $\mathcal{N}_I(s) \subseteq S_I$.
   A solution $s \in S_I$ is called a *local optimum* (local maximum) if for all $s' \in \mathcal{N}_I(s)$, $g_I(s) \geq g_I(s')$. We let $\mathcal{O}_I$ denote the set of all local optima for instance I. (Clearly $\mathcal{O}_I$ is non-empty, because S_I is non-empty.)
2. There is a polynomial time algorithm, A_Π, that given a string $I \in \{0,1\}^*$, decides whether I is a valid input instance $I \in D_\Pi$, and if so outputs some solution $s_0 \in S_I$.
3. There is a polynomial time algorithm, B_Π, that given valid instance $I \in D_\Pi$ and a string $s \in \{0,1\}^{p(|I|)}$, decides whether $s \in S_I$, and if so, outputs the payoff $g_I(s)$.
4. There is a polynomial time algorithm, H_Π, that given valid instance $I \in D_\Pi$ and $s \in S_I$, decides whether s is a local optimum, i.e., whether $s \in \mathcal{O}_I$, and otherwise computes a strictly improving neighbor $s' \in \mathcal{N}_I(s)$, such that $g_I(s') > g_I(s)$.

▶ **Theorem 4.** Tarski ∈ PLS.

Proof Sketch. Each valid input instance $I_f \in D_{\texttt{Tarski}} \subseteq \{0,1\}^*$ of Tarski is an encoding of a function $f : [N]^d \to [N]^d$ via a boolean circuit C_f. We can view the problem Tarski as a polynomial local search problem, as follows:

Define the set of "solutions" associated with valid input I_f to be the disjoint union $S_{I_f} = S'_{I_f} \cup S''_{I_f}$, where $S'_{I_f} = \{x \in [N]^d \mid x \leq f(x)\}$ and $S''_{I_f} = \{(x,y) \in [N]^d \times [N]^d \mid x \leq y \wedge f(x) \not\leq f(y)\}$. Clearly, $\mathrm{Fix}(f) \subseteq S'_{I_f} \subseteq S_{I_f}$. Let the payoff function $g_{I_f} : S_{I_f} \to \mathbb{Z}$, be defined as follows. For $x \in S'_{I_f}$, $g_{I_f}(x) := \sum_{i=1}^d x_i$; for $(x,y) \in S''_{I_f}$, $g_{I_f}(x,y) := (dN)+1$. We define the neighbors of solutions as follows. For any $x \in S'_{I_f}$, if $f(x) \leq f(f(x))$ then let the neighbors of x be the singleton-set $\mathcal{N}_{I_f}(x) := \{f(x)\}$. Note that in this case again $f(x) \in S'_{I_f}$. Otherwise, if $f(x) \not\leq f(f(x))$, then let $\mathcal{N}_{I_f}(x) := \{(x, f(x))\}$. Note that in this case $(x, f(x)) \in S''_{I_f}$, since $f(x) \not\leq f(f(x))$. For $(x,y) \in S''_{I_f}$, let $\mathcal{N}_{I_f}(x,y) := \emptyset$ be the empty set. Thus, the set of local optima is by definition $\mathcal{O}_{I_f} = \{x \in S'_{I_f} \mid \sum_{i=1}^d x_i \geq \sum_{i=1}^d f_i(x)\} \cup S''_{I_f}$.

Observe that in fact $\mathcal{O}_{I_f} = \mathrm{Fix}(f) \cup S''_{I_f}$. Indeed, if $x \in \mathcal{O}_{I_f}$ then $x \in S'_{I_f}$ meaning $x \leq f(x)$, and also $\sum_{i=1}^d x_i \geq \sum_{i=1}^d f_i(x)$. But this is only possible if $f(x) = x$, i.e., $x \in \mathrm{Fix}(f)$. Likewise, if $(x,y) \in \mathcal{O}_{I_f}$ then $(x,y) \in S''_{I_f}$. On the other hand, if $x \in \mathrm{Fix}(f)$, then clearly $x \in S'_{I_f}$ and $\sum_{i=1}^d x_i = \sum_{i=1}^d f_i(x)$, hence $x \in \mathcal{O}_{I_f}$.

It is possible then to define polynomial time algorithms $A_{\texttt{Tarski}}$, $B_{\texttt{Tarski}}$ and $H_{\texttt{Tarski}}$, as required in conditions 2, 3, 4 in the definition of PLS; see the full paper for details. It follows that Tarski is in PLS. ◀

Tarski ∈ PPAD

To show that Tarski ∈ PPAD, we first show that Tarski $\in P^{\mathsf{PPAD}}$ meaning that the total search problem Tarski can be solved by a polynomial time algorithm, $\mathcal{M}$, with oracle access to PPAD. The algorithm $\mathcal{M}$ should take an input $I_f \in \{0,1\}^*$, and firstly decide whether it is a valid instance $I_f \in D_{\texttt{Tarski}}$, and if so it can make repeated, adaptive, calls to an

[3] Or, cost function, if we were considering local minimization. But here we focus on local maximization.

oracle for solving a PPAD total search problem. After at most polynomial time (and hence polynomially many such oracle calls) as a function of the input size $|I_f|$, $\mathcal{M}$ should output either an integer vector $x \in \mathrm{Fix}(f)$, or else output a pair of vectors $x, y \in [N]^d$ with $x \leq y$ and $f(x) \not\leq f(y)$, which witness non-monotonicity of the function $f : [N]^d \to [N]^d$ defined by the input instance I_f.

Once we have established that $\texttt{Tarski} \in P^{\mathsf{PPAD}}$, the fact that $\texttt{Tarski} \in \mathsf{PPAD}$ will follow as a simple corollary, using a prior result of Buss and Johnson [2], who showed that PPAD is closed under polynomial-time Turing reductions.

There are a number of equivalent ways to define the total search complexity class PPAD. Rather than give the original definition ([20]), we will use an equivalent characterization of PPAD (a.k.a., linear-FIXP) from [12]. Informally, according to this characterization, a discrete total search problem, Π, is in PPAD if and only if it can be reduced in P-time to computing a Brouwer fixed point of an associated "polynomial piecewise-linear" continuous function that maps a non-empty convex polytope to itself. That is, every instance I of Π can be associated with a polynomial piecewise-linear function F_I on a polytope $W(I)$, such that from any rational fixed point of F_I we can obtain in polynomial time an acceptable output for the instance I. By Brouwer's theorem, the set $\mathrm{Fix}(F_I) = \{x \in W(I) \mid F_I(x) = x\}$ of fixed points of F_I is non-empty. Moreover, because of the "polynomial piecewise-linear" nature of F_I, $\mathrm{Fix}(F_I)$ must also contain a *rational* fixed point x^*, with polynomial bit complexity as a function of $|I|$ (see [12], Theorem 5.2). See [12], section 5, for more details on this characterization of PPAD.

Given two vectors $l \leq h \in \mathbb{Z}^d$, let $L(l, h) = \{x \in \mathbb{Z}^d \mid l \leq x \leq h\}$, and let $B(l, h) = \{x \in \mathbb{R}^d \mid l \leq x \leq h\}$.

▶ **Theorem 5.** $\texttt{Tarski} \in P^{\mathsf{PPAD}}$.

Proof Sketch. Suppose we are given an instance $I_f \in D_{\texttt{Tarski}}$ of Tarski, corresponding to a function $f : [N]^d \to [N]^d$ (given by a boolean circuit C_f).

Let $a = \mathbf{1} \in \mathbb{Z}^d$, and $b = \mathbf{N} \in \mathbb{Z}^d$, denote the all 1, and all N, vectors respectively. We first extend the discrete function f to a (polynomial piecewise-linear) continuous function $f' : B(a, b) \to B(a, b)$, by a suitable linear interpolation. For this purpose we use a specific simplicial subdivision of $B(a, b)$, known as *Freudenthal's simplicial division* [15], which has a certain monotonicity property that is important for the proof. By Brouwer's theorem, f' has a fixed point in $B(a, b)$, and since it is polynomial piecewise-linear, finding a fixed point x^* is in PPAD. However, f' may have non-integer fixed points that do not correspond to (and are not close to) any fixed point of f (indeed, since we do not apriori know that f is monotone, there may not be any integer fixed points). Nevertheless, we show that finding any such fixed point x^* of f' allows us to make progress towards either finding a discrete fixed point of f (if it is monotone), or finding witnesses for a violation of monotonicity of f.

Specifically, we argue that there are two (integer) vertices $u \geq v$ of the simplex of the subdivision that contains x^* such that, if f is monotone, then $f(u) \geq u$ and $f(v) \leq v$ (in all coordinates). If $f(u) \not\geq u$, or $f(v) \not\leq v$, then f is not monotone, and we show that we can find a witness pair for the non-monotonicity of f.

Assume on the other hand that $f(u) \geq u$ and $f(v) \leq v$. Note that in that case, if f is monotone, then f maps the sublattice $L(u, b)$ to itself, and it also maps the disjoint sublattice $L(a, v)$ to itself. Thus, if f is monotone, f must have an integer fixed point in both $L(a, v)$ and $L(u, b)$.

So, we can choose the smaller of these two sublattices, consider the function f restricted to that sublattice, and continue recursively to find a fixed point in that sublattice (if f is monotone) or a violation of monotonicity. If f is not monotone, it is possible that it maps

some points in the sublattice $L(a, v)$ (or $L(u, b)$) to points outside. Therefore, in the recursive call for the sublattice, when we define the piecewise-linear function f' on the corresponding box $B(a, v)$ (or $B(u, b)$) we take the maximum with a and minimum with v (or u and b respectively), i.e., threshold it, so that it maps the box to itself, and hence it is a Brouwer function. When the PPAD oracle gives us back a fixed point for this (possibly thresholded) function f', we argue that if the thresholding mattered in this regard, then we can detect it and produce a violating pair to monotonicity.

Every iteration decreases the total number of points in our current lattice by a factor of 2, from the number of points in the original lattice $L(a, b)$. So after a polynomial number of iterations in $(d + \log N)$, we either find a fixed point of f, or we find a witness pair of integer vectors that witness the non-monotonicity of f. ◀

▶ **Corollary 6.** `Tarski` $\in$ PPAD.

Proof. This follows immediately from Theorem 5, combined with a result due to Buss and Johnson ([2], Theorem 6.1), who showed that PPAD is closed under polynomial-time Turing reductions. ◀

4 The 2-dimensional lower bound

Consider a monotone function defined on the $N \times N$ grid $f : [N]^2 \mapsto [N]^2$. Let A be any (randomized) *black-box algorithm* for finding a fixed point of the function by computing a sequence of queries of the form $f(x, y) =?$; A can of course be *adaptive* in that any query can depend in arbitrarily complex ways on the answers to the previous queries. For example, the divide-and-conquer algorithm described in the introduction is a black box algorithm. The following result suggests that this algorithm is optimal for two dimensions.

▶ **Theorem 7.** *Given black-box access to a monotone function $f : [N]^2 \to [N]^2$, any (randomized) algorithm for finding a fixed point of f requires $\Omega(\log^2 N)$ queries (in expectation).*

Below, we *sketch* a proof. For the full proof see [11]. The proof constructs a hard distribution of such functions.

The basic construction

Given a monotone path from $(1, 1)$ to (N, N) on the $N \times N$ grid graph and a point (i^*, j^*) on the path, we construct f as follows:

- We let (i^*, j^*) be the unique fixed point of f, i.e. $f(i^*, j^*) \triangleq (i^*, j^*)$.
- At all other points on the path, f is directed towards the fixed point. For a point (x, y) on the path that is dominated by (i^*, j^*), we let $f(x, y)$ be the next point on the path, i.e. $f(x, y) = (x + 1, y)$ or $f(x, y) = (x, y + 1)$. Similarly, for a point (x, y) that is on the path and dominates (i^*, j^*), we let $f(x, y)$ be the previous point on the path.
- For all points outside the path, f is directed towards the path. Observe that the path partitions $[N]^2$ into three (possibly empty) subsets: below the path, the path, and above the path. For a point (x, y) below the path, we set $f(x, y) \triangleq (x - 1, y + 1)$. Similarly, for a point (x, y) above the path, $f(x, y) \triangleq (x + 1, y - 1)$.

An example of such a function $f : [5]^2 \to [5]^2$ is given in Figure 1.

▷ Claim 8. For any choice of path and point (i^*, j^*) on the path, f constructed as above is monotone.

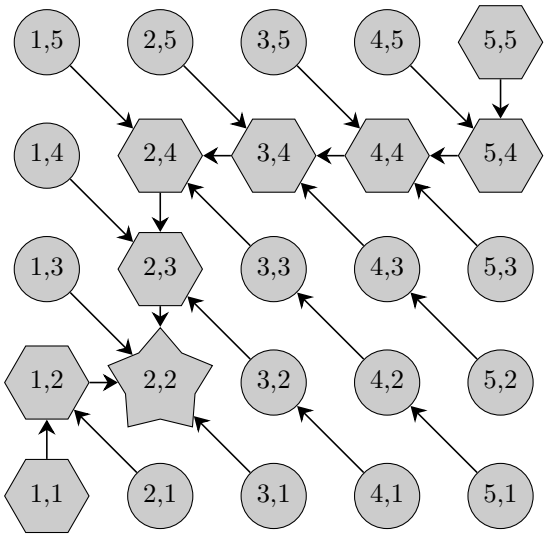

Figure 1 A 2-dimensional "*herringbone*" monotone function.

Choosing the fixed point

In our hard distribution, once we fix a path, we choose (i^*, j^*) uniformly at random among all points on the path.

▷ Claim 9. Given oracle access to f and the path, any (randomized) algorithm that finds a point (i', j') on the path that is within $\sqrt{N}$ (Manhattan distance) from (i^*, j^*) requires (in expectation) querying of f at $\Omega(\log N)$ points on the path that are pairwise at least $\sqrt{N}$ apart.

Proof. Observe that once we fix the path, the values of f outside the path do not reveal information about the location of (i^*, j^*). The lower bound now follows from the standard lower bound for binary search. ◁

Choosing the central path

Our goal now is to prove that it is hard to find many distant points on the path. To simplify the analysis, we will only consider the special case where all points (x, y) on the path satisfy $x - y \in \left[-N^{1/4}, N^{1/4}\right]$. We partition the $N \times N$ grid into $\Theta\left(\sqrt{N}\right)$ regions of the form $R_a \triangleq \left\{(x, y) \mid x + y \in [a, a + \sqrt{N})\right\}$. Notice that each region intersects the path at exactly $\sqrt{N}$ points. The path enters each region[4] at a point (x, y) for a value $x - y$ chosen uniformly at random among $\left[-N^{1/4}, N^{1/4}\right]$. We will argue (Lemma 12 below) that in order to find a point on the path in any region R_a, the algorithm must query the function at $\Omega(\log N)$ points in R_a or its neighboring regions.

Each region is further partitioned into $\Theta\left(N^{1/4}\right)$ sub-regions $S_a \triangleq \left\{(x, y) \mid x + y \in [a, a + 2N^{1/4})\right\}$. For each region, we choose a special sub-region uniformly at random. In all non-special sub-regions, the path proceeds while maintaining

[4] For the first and last region, the path is obviously forced to start at $(1, 1)$ (respectively end at (N, N)); but those two regions can only account for two of the $\Omega(\log N)$ distant path points required by Claim 9, so we can safely ignore them.

$x-y$ fixed, up to ± 1. Inside the special sub-region, the value of $x-y$ for path points changes from the value chosen at random for the current region, to the value chosen at random for the next region.

Given a choice of random $x-y$ entry point for each region, and a random special sub-region for each region, we consider an arbitrary path that satisfies the description above. This completes the description of the construction.

▷ Claim 10. Finding (i.e., querying any point in) the special sub-region in region R_a requires $\Omega(\log N)$ queries (in expectation) to points in R_a.

Let S_a and S_b be the special sub-regions of two consecutive regions. Let $T \triangleq \{(x,y) \mid x+y \in [a+2N^{1/4}, b)\}$ be the union of all the sub-regions between S_a and S_b. Observe that the value of $x-y$ remains fixed (up to ± 1) for all points in the intersection of the path with T. Also, the construction of f outside $S_a \cup T \cup S_b$ does not depend at all on this value.

▷ Claim 11. If the algorithm does not query any point in $S_a \cup S_b$, then in order to find (i.e., query) any point in the intersection of the path and T, the algorithm must query (in expectation) $\Omega(\log N)$ points from T.

By Claim 10, finding S_a or S_b requires at least $\Omega(\log N)$ queries to the regions containing them. Therefore, the above two claims together imply:

▶ **Lemma 12.** *In order to query a point in the intersection of the path and region R_a, any algorithm must query at least $\Omega(\log N)$ points (in expectation) in R_a or its neighboring regions.*

Therefore, in order to find $\Omega(\log N)$ points on the path that are pairwise at least $\sqrt{N}$ apart, the algorithm must make a total of $\Omega\left(\log^2 N\right)$ queries (in expectation), completing the proof of Theorem 7.

An alternative proof

In the full version of this paper (see [11]) we provide an alternative proof, showing that any *deterministic* black box algorithm requires $\Omega(\log^2 N)$ oracle queries to find a Tarski fixed point of a monotone function $f : [N]^2 \to [N]^2$ given by an oracle.

▶ **Theorem 13.** *Any deterministic black box algorithm for finding a Tarski fixed point in two dimensions needs $\Omega(\log^2 N)$ queries.*

The alternative proof appears to be more promising for generalization to higher dimensions. However, the underlying monotone functions $f : [N]^2 \to [N]^2$ on which the alternative lower bound is established are again the "*herringbone*" functions used in the proof of Theorem 7. The alternative proof uses a potential argument, and its gist amounts to showing that any such algorithm must solve $\Omega(\log N)$ *independent* one-dimensional problems.

5 Supermodular Games

A brief intro to supermodular games

A *supermodular game* is a game in which the set S_i of strategies of each player i is a complete lattice, and the utility (payoff) functions u_i satisfy certain conditions. Let k be the number of players and let $S = \Pi_{i=1}^{k} S_i$ be the set of strategy profiles. As usual, we use s_i to denote a strategy for player i and s_{-i} to denote a tuple of strategies for the other players. The conditions on the utility functions u_i are the following:

C1. $u_i(s_i, s_{-i})$ is upper semicontinuous in s_i for fixed s_{-i}, and it is continuous in s_{-i} for each fixed s_i, and has a finite upper bound.

C2. $u_i(s_i, s_{-i})$ is supermodular in s_i for fixed s_{-i}.

C3. $u_i(s_i, s_{-i})$ has increasing differences in s_i and s_{-i}.

A function $f : L \to \mathbb{R}$ is *supermodular* if for all $x, y \in L$, it holds $f(x) + f(y) \leq f(x \wedge y) + f(x \vee y)$. A function $f : L_1 \times L_2 \to \mathbb{R}$, where L_1, L_2 are lattices, has *increasing differences* in its two arguments, if for all $x' \geq x$ in L_1 and all $y' \geq y$ in L_2, it holds that $f(x', y') - f(x, y') \geq f(x', y) - f(x, y)$.

The broader class of *games with strategic complementarities* (GSC) relaxes somewhat the conditions C2 and C3 into C2', C3' which depend only on ordinal information on the utility functions, i.e. how the utilities compare to each other rather than their precise numerical values. The supermodularity requirement of C2 is relaxed to quasi-supermodularity, where a function $f : L \to \mathbb{R}$ is *quasi-supermodular* if for all $x, y \in L$, $f(x) \geq f(x \wedge y)$ implies $f(y) \leq f(x \vee y)$, and if the first inequality is strict, then so is the second. The increasing differences requirement of C3 is relaxed to the *single-crossing condition*, where a function $f : L_1 \times L_2 \to \mathbb{R}$, satisfies the single crossing condition, if for all $x' > x$ in L_1 and all $y' > y$ in L_2, it holds that $f(x', y) \geq f(x, y)$ implies $f(x', y') \geq f(x, y')$, and if the first inequality is strict then so is the second. All the structural and algorithmic properties below of supermodular games hold also for games with strategic complementarities.

We will consider here games where each S_i is a discrete (or continuous) finite box in d_i dimensions of size N in each coordinate. We let $d = \sum_{i=1}^{k} d_i$ be the total number of coordinates. In the discrete case, condition C1 is trivial. Condition C2 is trivial if $d_i = 1$ (all functions in one dimension are supermodular), but nontrivial for 2 or more dimensions. C3 is nontrivial.

Supermodular games (and GSC) have pure Nash equilibria. Furthermore, the pure Nash equilibria form a complete lattice [17], thus there is a highest and a lowest equilibrium. Another important property is that the best response correspondence $\beta_i(s_{-i})$ for each player i has the property that (1) both $\sup \beta_i(s_{-i})$ and $\inf \beta_i(s_{-i})$ are in $\beta_i(s_{-i})$, and (2) both functions $\sup \beta_i(\cdot)$ and $\inf \beta_i(\cdot)$ are monotone functions [24]. The function $\bar{\beta}(s) = (\sup \beta_1(s_{-1}), \ldots, \sup \beta_k(s_{-k}))$ of the supremum best responses is a monotone function from S to itself, and its greatest fixed point is the highest Nash equilibrium of the game. The function $\underline{\beta}(s) = (\inf \beta_1(s_{-1}), \ldots, \inf \beta_k(s_{-k}))$ of the infimum best responses is also a monotone function, and its least fixed point is the lowest Nash equilibrium of the game.

Complexity of equilibrium computation in supermodular games

Given a supermodular game, the relevant problems include: (a) find a Nash equilibrium (anyone)[5], and (b) find the highest or the lowest equilibrium. In the case of continuous domains, we again have to relax to an approximate solution. We assume that we have access to a best response function, e.g. $\bar{\beta}(\cdot)$ and/or $\underline{\beta}(\cdot)$, as an oracle or as a polynomial-time function. The monotonicity of these functions implies then easily the following:

[5] Whenever we speak of finding a Nash Equilibrium (NE) for a supermodular game, we mean a *pure* NE, as we know that these exists.

▶ **Proposition 14.**

1. *The problem of computing a pure Nash equilibrium of a k-player supermodular game over a discrete finite strategy space $\Pi_{i=1}^{k}[N]^{d_i}$ reduces to the problem of computing a fixed point of a monotone function over $[N]^d$ where $d = \sum_{i=1}^{k} d_i$. Computing the highest (or lowest) Nash equilibrium reduces to computing the greatest (or lowest) fixed point of a monotone function.*
2. *For games with continuous box strategy spaces, $\Pi_{i=1}^{k}[1, N]_i^d$, and Lipschitz continuous utility functions with Lipschitz constant K, the problem of computing an ϵ-approximate Nash equilibrium reduces to exact fixed point computation point for a monotone function with a discrete finite domain $[NK/\epsilon]^d$.*

Proof.

1. Follows from the monotonicity of $\bar{\beta}(\cdot)$ and $\underline{\beta}(\cdot)$. If s is fixed point of $\bar{\beta}(\cdot)$, then $s_i = \sup \beta_i(s_{-i})$ is a best response to s_{-i} for all i (since $\sup \beta_i(s_{-i}) \in \beta_i(s_{-i})$), therefore s is a Nash equilibrium of the game. The GFP of $\bar{\beta}(\cdot)$ is the highest Nash equilibrium. Similarly, every fixed point of $\underline{\beta}(\cdot)$ is an equilibrium of the game, and the LFP of $\underline{\beta}(\cdot)$ is the lowest equilibrium.
2. Suppose that the utility functions are Lipschitz continuous with Lipschitz constant K. To compute an ϵ-approximate Nash equilibrium of the game, it suffices to find a ϵ/K-approximate fixed point of the function $\bar{\beta}(\cdot)$. For, if s is such an approximate fixed point and $s' = \bar{\beta}(s)$, then $|s' - s| \leq \epsilon/K$ in every coordinate. Hence $|u_i(s_i, s_{-i}) - u_i(s_i', s_{-i})| \leq \epsilon$, and s_i' is a best response to s_{-i}, hence s is an ϵ-approximate equilibrium. Computing an ϵ/K-approximate fixed point of the function $\bar{\beta}(\cdot)$ on the continuous domain, reduces by Proposition 2 to the exact fixed point problem for the discrete domain $[NK/\epsilon]^d$. ◀

Not every monotone function can be the (sup or inf) best response function of a game. In particular, a best response function has the property that the output values for the components corresponding to a player depend only on the input values for the other components corresponding to the other players. Thus, for example, for two one-dimensional players, if the function $f(x, y)$ is the best response function of a game, it must satisfy $f_1(x, y) = f_1(x', y)$ for all x, x', y, and $f_2(x, y) = f_2(x, y')$ for all x, y, y'. This property helps somewhat in improving the time needed to find a fixed point, and thus an equilibrium of the game, as noted below. For example, in the case of two one-dimensional players, an equilibrium can be computed in $O(\log N)$ time, instead of the $\Omega(\log^2 N)$ time needed to find a fixed point of a general monotone function in two dimensions.

▶ **Theorem 15.** *Given a supermodular game with two players with discrete strategy spaces $[N]^{d_i}$, $i = 1, 2$ with access to the sup (or inf) best response function $\bar{\beta}(\cdot)$ (or $\underline{\beta}(\cdot)$), we can compute an equilibrium in time $O((\log N)^{\min(d_1, d_2)})$. More generally, for k players with dimensions $d_1, \ldots, d_k$, an equilibrium can be computed in time $O((\log N)^{d'})$, where $d' = \sum_i d_i - \max_i d_i$.*

Proof. Suppose that we have access to the sup best response $\bar{\beta}(\cdot)$. Assume without loss of generality that the first player has the maximum dimension, $d_1 = \max_i d_i$. We apply the divide-and-conquer algorithm, but take advantage of the property of the monotone function $\bar{\beta}$ that the first d_1 components of $\bar{\beta}(x)$ do not depend on the first d_1 coordinates of x. As a consequence, for any fixed assignment to the other coordinates, i.e. choice of a strategy profile s_{-1} for all the players except the first player, the induced function on the first d_1 coordinates maps every point to the best response $\bar{\beta}_1(s_{-1})$ of player 1. Thus the fixed point of the induced function is simply $\bar{\beta}_1(s_{-1})$, it can be computed with one call to $\bar{\beta}$, and there is no need to recurse on the first d_1 coordinates. It follows that the algorithm takes time at most $O((\log N)^{d'})$, where $d' = \sum_i d_i - \max_i d_i$. ◀

Conversely, we can reduce the fixed point computation problem for an arbitrary monotone function to the equilibrium computation problem for a supermodular game with two players.

▶ **Theorem 16.**

1. *Given a monotone function f on $[N]^d$ (resp. $[1,N]^d$) we can construct a supermodular game G with two players, each with strategy space $[N]^d$ (resp. $[1,N]^d$), so that the pure Nash equilibria of G correspond to the fixed points of f.*
2. *More generally, the fixed point problem for a monotone function f in d dimensions can be reduced to the pure Nash equilibrium problem for a supermodular game with any number $k \geq 2$ of players with any dimensions $d_1, \ldots, d_k$, provided that $\sum_i d_i \geq 2d$ and $\sum_i d_i - \max_i d_i \geq d$.*

Proof Sketch.

1. We will define the utility functions u_i so that the best responses β_i of both players are functions (i.e. are unique). For player 1, the best response will be $\beta_1(y) = y$, for all $y \in [N]^d$, and for player 2, the best response will be $\beta_2(x) = f(x)$, for all $x \in [N]^d$. If x is a fixed point of f, then (x,x) is an equilibrium of the game, since $\beta(x,x) = (x, f(x)) = (x,x)$. Conversely, if (x,y) is an equilibrium of the game, then $\beta(x,y) = (x,y)$, therefore $x = y$ and $y = f(x)$, hence $x = f(x)$. Thus, the set of equilibria of G is $\{(x,x) | x \in Fix(f)\}$.
   The utility function for player 1 is set to $u_1(x,y) = -(x-y)^2 = -\sum_{j=1}^{d}(x_j - y_j)^2$. The utility function for player 2 is $u_2(x,y) = -(f(x)-y)^2 = -\sum_{j=1}^{d}(f_j(x) - y_j)^2$. Obviously, the best response functions are as stated above, $\beta_1(y) = y$ and $\beta_2(x) = f(x)$.
   It can be verified that the utility functions u_1, u_2 satisfy conditions C2 and C3 in the definition of supermodular games (C2 with equality actually).
2. Order the players in increasing order of their dimension, let T be the ordering of all the $\sum_{i=1}^{k} d_i$ coordinates consisting first of the set $Co(1)$ of coordinates of player 1 (in any order), then the set $Co(2)$ of coordinates of player 2, and so forth. Number the coordinates in the order T from 1 to $\sum_{i=1}^{k} d_i$, and label them cyclically with the labels $1, \ldots, d$.
   We define the (unique) best response function β as follows. For every coordinate $j \leq d$ (in the ordering T), we set $\beta_j(x) = f_j(x')$, where x' is a subvector of x with d coordinates that have distinct labels $1, \ldots, d$ and which belong to different players than coordinate j. The subvector x' is defined as follows. Suppose that coordinate j belongs to player r ($j \in Co(r)$), and let $t = \sum_{i=1}^{r-1} d_i$. If $d_r \leq d$, then x' is the subvector of x that consists of the first t coordinates (in the order T) and the coordinates $t+1+d, \ldots, 2d$; note that all these coordinates do not belong to player r. If $d_r > d$, then $r < k$ (since $\sum_i d_i - \max_i d_i \geq d$). In this case, let x' be the subvector of x consisting of the last d coordinates (in T); all of these belong to player $k \neq r$. For coordinates $j > d$, we set $\beta_j(x) = x_{j'}$, where $j' \in [d]$ is equal to $j \mod d$, unless j' belongs to the same player r as j, in which case $d_r > d$, hence $r \neq k$; in this case we set $\beta_j(x) = x_{j"}$ for some (any) coordinate $j"$ of the last player k that is labeled j'.
   We define the utility functions of the players so that they yield the above best response function β. Namely, we define the utility function of player i to be $u_i(x) = -\sum_{j \in Co(i)}(x_j - \beta_j(x))^2$. It can be verified as in part 1 that the utility functions satisfy conditions C2 and C3. It can be easily seen also that at any equilibrium of the game, all coordinates with the same label must have the same value, and the corresponding d-vector x is a fixed point of f. Conversely, for any fixed point x of f, the corresponding strategy profile of the game is an equilibrium. ◀

Since the 2-dimensional monotone fixed point problem requires $\Omega(\log^2 N)$ queries by Theorem 7, it follows that the equilibrium problem for two 2-dimensional players also requires $\Omega(\log^2 N)$ queries, which is tight because it can be also solved in $O(\log^2 N)$ time by Theorem 15. Similarly, for higher dimensions d, if the monotone fixed point problem requires $\Omega(\log^d N)$ queries then the equilibrium problem for two d-dimensional players is also $\Theta(\log^d N)$.

The same reduction from monotone functions to supermodular games of Theorem 16, combined with Proposition 1 implies the hardness of computing the highest and lowest equilibrium.

▶ **Corollary 17.** *It is NP-hard to compute the highest and lowest equilibrium of a supermodular game with two 1-dimensional players with explicitly given polynomial-time best response (and utility) functions.*

6 Condon's and Shapley's stochastic games reduce to `Tarski`

In this section, we show that computing the exact (rational) value of Condon's simple stochastic games ([4]), as well as computing the (irrational) value of Shapley's more general (stopping/discounted) stochastic games [21] to within a given desired error $\epsilon > 0$ (given in binary), is polynomial time reducible to `Tarski`.

A *simple stochastic game*[6] (SSG) is a 2-player zero-sum game, played on the vertices of an edge-labeled directed graph, specified by $G = (V, V_0, V_1, V_2, \delta)$, whose vertices $V = \{v_1, \ldots, v_n\}$ include two special sink vertices, a **0**-sink, v_{n-1}, and a **1**-sink, v_n, and where the rest of the vertices $V \setminus \{v_{n-1}, v_n\} = \{v_1, \ldots, v_{n-2}\}$ are partitioned into three disjoint sets V_0 (random), V_1 (max), and V_2 (min). The labeled directed edge relation is $\delta \subseteq (V \setminus \{v_{n-1}, v_n\}) \times ((0, 1] \cup \bot) \times V$. For each "random" node $u \in V_0$, every outgoing edge $(u, p_{u,v}, v) \in \delta$ is labeled by a positive probability $p_{u,v} \in (0, 1]$, such that these probabilities sum to 1, i.e., $\sum_{\{v \in V | (u,p_{u,v},v) \in \delta\}} p_{u,v} = 1$. We assume, for computational purposes, that the probabilities $p_{u,v}$ are rational numbers (given as part of the input, with numerator and denominator given in binary). The outgoing edges from "max" (V_1) and "min" (V_2) nodes have an empty label, "$\bot$". We assume each vertex $u \in V \setminus \{v_{n-1}, v_n\}$ has at least one outgoing edge. Thus in particular, for any node $u \in V_1 \cup V_2$ there exists an outgoing edge $(u, \bot, v) \in \delta$ for some $v \in V$. Finally, there is a designated start vertex $s \in V$.

A play of the game transpires as follows: a token is initially placed on s, the start node. Thereafter, during each "turn", when the token is currently on a node $u \in V$, unless u is already a sink node (in which case the game halts), the token is moved across an outgoing edge of u to the next node by whoever "controls" u. For a random node $u \in V_0$, which is controlled by "nature", the outgoing edge is chosen randomly according to the probabilities $(p_{u,v})_{v \in V}$. For $u \in V_1$, the outgoing edge is chosen by player 1, the max player, who aims to maximize the probability that the token will eventually reach the **1**-sink. For $u \in V_2$, the outgoing edge is chosen by player 2, the min player, who aims to minimize the probability that the token will eventually reach the **1**-sink. The game halts if the token ever reaches either of the two sink nodes.

[6] The definition we give here for SSGs is slightly more general than Condon's original definition in [4]. Specifically, Condon allows edge probabilities of 1/2 only, and also assumed that the game is a "stopping game", meaning it halts with probability 1, regardless of the strategies of the two players. It is well known that our more general definition does not alter the difficulty of computing the game value and optimal strategies: solving general SSGs can be reduced in P-time to solving SSGs in Condon's more restricted form.

For every possible start node $s = v_i \in V$, this zero-sum game has a well defined *value*, $q_i^* \in [0,1]$. This is, by definition, a probability such that player 1, the max player (and, respectively, player 2, the min player) has a strategy to "force" reaching the 1-sink with probability at least (respectively, at most) q_i^*, irrespective of what the other player's strategy is. In other words, these games are *determined*. Moreover q_i^* is a rational value whose encoding size, with numerator and denominator in binary, is polynomial in the bit encoding size of the SSG ([4]). Furthermore, both players have deterministic, memoryless (a.k.a., pure, positional) optimal strategies in the game (which do not depend on the specific start node s), in which for each vertex $u \in V_1$ (or $u \in V_2$) the max player (respectively the min player) chooses the same specific outgoing edge every time the token visits vertex u, regardless of the prior history of play prior to that visit to u.

Given an SSG, the goal is to compute the value of the game (starting at each vertex). Condon ([4]) already showed that the problem of deciding whether the value is $> 1/2$ is in NP $\cap$ co-NP, and it is a long-standing open problem whether this is in P-time. Moreover, the search problem of computing the value for an SSG is known to be in both PLS and PPAD (see [25] and [12]). In the full paper we show the following:

▶ **Proposition 18.** *The following total search problem is polynomial-time reducible to* `Tarski`*: Given an instance G of Condon's simple stochastic game, and given a start vertex $s = v_i \in V$, compute the exact (rational) value q_i^* of the game.*

Shapley's original stochastic games are more general, and involve simultaneous (independent) choices by the two players at each state (they are thus imperfect information games). The value of the game is in general irrational (even when all the input data is rational). We show that approximating the value of a Shapley game to within any given desired accuracy, $\epsilon > 0$ (given in binary as part of the input), is polynomial time reducible to `Tarski`.

Shapley's games are a class of two-player zero-sum "stopping", or equivalently "discounted", stochastic games. An instance of Shapley's stochastic game is given by $G = (V, A, P, s)$, where $V = \{v_1, \ldots, v_n\}$ is a set of n vertices (or "states"). $A = (A^1, A^2, \ldots, A^n)$ is a n-tuple of matrices, where, for each vertex, $v_i \in V$, A^i is an associated $m_i \times n_i$ *reward matrix*, where m_i and n_i are positive integers denoting, respectively, the number of distinct "actions" available to player 1 (the maximizer) and player 2 (the minimizer) at vertex v_i, and where for each pair of such actions, $j \in [m_i]$ and $k \in [n_i]$, $A^i_{j,k} \in \mathbb{Q}$ is a reward for player 1 (which we assume, for computational purposes, is a rational number given as input by giving its numerator and denominator in binary). Furthermore, for each vertex $v_i \in V$, and each pair of actions $j \in [m_i]$ and $k \in [n_i]$, $P^i_{j,k} \in [0,1]^n$ is a vector of probabilities on the vertices V, such that $0 \leq P^i_{j,k}(r)$, and $\sum_{r=1}^n P^i_{j,k}(r) < 1$, i.e., the probabilities sum to *strictly less than* 1. Again, we assume each such probability $P^i_{j,k}(r) \in \mathbb{Q}$ is a rational number given as input in binary. Finally, the game specifies a designated start vertex $s \in V$.

A play of Shapley's game transpires as follows: a token is initially placed on s, the start node. Thereafter, during each "round" of play, if the token is currently on some node $v_i \in V$, both players simultaneously and independently choose respective actions $j \in [m_i]$ and $k \in [n_i]$, and player 1 then receives the corresponding reward $A^i_{j,k}$ from player 2; thereafter, for each $r \in [n]$ with probability $P^i_{j,k}(r)$ the token is moved from node v_i to node v_r, and with the remaining positive probability $q^i_{j,k} = 1 - \sum_{r=1}^n P^i_{j,k}(r) > 0$, the game "halts". Let $q = \min\{q^i_{j,k} \mid i,j,k\} > 0$ be the minimum such halting probability at any state, and under any pair of actions. Since q is positive, i.e., since there is positive probability $\geq q > 0$ of halting after each round, a play of the game eventually halts with probability 1. The goal of player 1 (player 2) is to maximize (minimize, respectively) the expected total reward that player 1 receives from player 2 during the entire play. A *strategy* for each player

specifies, based in principle on the entire history of play thusfar, a probability distribution on the actions available at the current token location. Given strategies σ_1 and σ_2 for player 1 and 2, respectively, let $r_i(\sigma_1, \sigma_2)$ denote the expected total payoff to player 1, starting at node $s = v_i \in V$. Shapley [21] showed that these games have a *value*, meaning that $\sup_{\sigma_1} \inf_{\sigma_2} r_i(\sigma_1, \sigma_2) = \inf_{\sigma_2} \sup_{\sigma_1} r_i(\sigma_1, \sigma_2)$. In fact, Shapley showed that both players have optimal stationary (but randomized) strategies in such games, i.e., optimal strategies that only depend on the current node where the token is located, not the prior history of play, but where players can randomize on their choice of actions at each node.

Let $r_i^* = \sup_{\sigma_1} \inf_{\sigma_2} r_i(\sigma_1, \sigma_2)$ denote the game value starting at vertex $s = v_i \in V$.[7] We show the following in the full paper.

▶ **Proposition 19.** *The following total search problem is polynomial-time reducible to* `Tarski`*: Given an instance G of Shapley's stochastic game, and given $\epsilon > 0$ (in binary), compute a vector $r' \in \mathbb{Q}^n$ such that $\|r^* - r'\|_\infty < \epsilon$.*

7 Conclusions and Discussion

We have studied the complexity of computing a Tarski fixed point for a monotone function over a finite discrete Euclidean grid, and we have shown that this problem essentially captures the complexity of computing a (ϵ-approximate) pure Nash equilibrium of a supermodular game. We have also shown that computing the value of Condon's and Shapley's stochastic games reduces to this `Tarski` fixed point problem, where the monotone function is given succinctly (by a boolean circuit).

We have provided several upper bounds for the `Tarski` problem, showing that it is contained in both PLS and PPAD. On the other hand, in the oracle model, for 2-dimensional monotone functions $f : [N]^2 \to [N]^2$, we have shown a $\Omega(\log^2 N)$ lower bound for the (expected) number of (randomized) queries required to find a Tarski fixed point, which matches the $O(\log^d N)$ upper bound for $d = 2$.

A key question left open by our work is to improve the lower bounds in the oracle model to higher dimensions. It is tempting to conjecture that for small (fixed) dimension d, a lower bound close to $\Omega(\log^d N)$ holds. On the other hand, we know that this cannot hold for arbitrary d and N, because we also have the dN upper bound, which is better than $\log^d N$ when $d = \omega(\frac{\log N}{\log \log N})$.

Another interesting open question is the relationship between the `Tarski` problem and the total search complexity class CLS [9], as well as the closely related recently defined class EOPL (which stands for "End of Potential Line" [13, 14]). EOPL is contained in CLS, which is contained in both PLS and PPAD. Is `Tarski` in CLS (or in EOPL)? That would be remarkable, as the proof that it is in PPAD is currently quite indirect. Conversely, can `Tarski` be proved to be CLS-hard (EOPL-hard)? (Recall from the previous section that some key problems in CLS related to stochastic games do reduce to `Tarski`.)

Another question worth considering is the complexity of the `unique-Tarski` problem, where the monotone function is further assumed (promised) to have a *unique* fixed point. Is `unique-Tarski` easier than `Tarski`? Note that our $\Omega(\log^2 N)$ lower bound in the oracle model, in dimension $d = 2$, applies on the family of "herringbone" functions which do have a unique fixed point.

[7] Note that we could also define r_i^* as $r_i^* = \max_{\sigma_1} \min_{\sigma_2} r_i(\sigma_1, \sigma_2)$, due to the existence of optimal strategies.

Finally, in this paper we have studied the Tarski fixed point problem only in the setting of monotone functions on the Euclidean grid $[N]^d$. Let us remark, however, that it is possible to consider a more general black box model, for monotone functions $f : L \to L$, over an arbitrary finite lattice $(L, \preceq)$, where the lattice's elements $L \subseteq \{0,1\}^n$ are encoded as binary strings of some given length n, and where we assume the entire lattice $(L, \preceq)$ is known *explicitly* by the querier, who moreover has unbounded computational power, but who only has oracle access to the monotone function $f : L \to L$. In the full version of this paper ([11]), generalizing the $\log^d N$ algorithm for Euclidean grids, we show that in this black box model there is a deterministic algorithm that computes a fixed point of $f : L \to L$ using $O(\log^d(|L|))$ queries to the function f, where d is the *dimension* of the lattice $(L, \preceq)$. The *dimension* of a lattice $(L, \preceq)$, and more generally the dimension of any partial order, can be defined as the smallest integer $d \geq 1$ such that the relation $\preceq$ is the intersection of d total orders on the same underlying set L. Equivalently, it is the smallest $d \geq 1$ such that there is an injective embedding of $(L, \preceq)$ in the Euclidean grid $([|L|]^d, \leq)$, where $\leq$ is the standard coordinate-wise partial order on $[|L|]^d$. Note that a lower bound of $\Omega(\log^2(|L|))$ queries for computing a fixed point of a monotone function $f : L \to L$ in this black box model follows directly from our lower bound of $\Omega(\log^2 N)$ for monotone functions on the 2D grid $f : [N]^2 \to [N]^2$. At present, we do not know any better lower bound than $\Omega(\log^2(|L|))$ in this black box model for arbitrary finite lattices.[8]

Abstract

Resolution over linear equations is a natural extension of the popular resolution refutation system, augmented with the ability to carry out basic counting. Denoted $\mathrm{Res}(\mathrm{lin}_R)$, this refutation system operates with disjunctions of linear equations with boolean variables over a ring R, to refute unsatisfiable sets of such disjunctions. Beginning in the work of [26], through the work of [17] which focused on tree-like lower bounds, this refutation system was shown to be fairly strong. Subsequent work (cf. [18, 17, 19, 13]) made it evident that establishing lower bounds against general $\mathrm{Res}(\mathrm{lin}_R)$ refutations is a challenging and interesting task since the system captures a "minimal" extension of resolution with counting gates for which no super-polynomial lower bounds are known to date.

We provide the first super-polynomial size lower bounds on general (dag-like) resolution over linear equations refutations in the large characteristic regime. In particular we prove that the subset-sum principle $1 + x_1 + \cdots + 2^n x_n = 0$ requires refutations of exponential-size over $\mathbb{Q}$. Our proof technique is nontrivial and novel: roughly speaking, we show that under certain conditions every refutation of a subset-sum instance $f = 0$, where f is a linear polynomial over $\mathbb{Q}$, must pass through a fat clause containing an equation $f = \alpha$ for each α in the image of f under boolean assignments. We develop a somewhat different approach to prove exponential lower bounds against tree-like refutations of any subset-sum instance that depends on n variables, hence also separating tree-like from dag-like refutations over the rationals.

We then turn to the finite fields regime, showing that the work of Itsykson and Sokolov [17] who obtained tree-like lower bounds over $\mathbb{F}_2$ can be carried over and extended to every finite field. We establish new lower bounds and separations as follows: (**i**) for every pair of distinct primes p, q, there exist CNF formulas with short tree-like refutations in $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_p})$ that require exponential-size tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_q})$ refutations; (**ii**) random k-CNF formulas require exponential-size tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_p})$ refutations, for every prime p and constant k; and (**iii**) exponential-size lower bounds for tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations of the pigeonhole principle, for *every* field $\mathbb{F}$.

Acknowledgements We wish to thank Dima Itsykson and Dima Sokolov for very helpful comments concerning this work, and telling us about the lower bound on random k-CNF formulas for tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_2})$ that can be achieved using the results of Garlik and Kołodziejczyk. We thank Edward Hirsch for spotting a gap in the initial proof of the dag-like lower bound concerning the use of the contraction.

1 Introduction

The resolution refutation system is among the most prominent and well-studied propositional proof systems, and for good reasons: it is a natural and simple refutation system, that, at least in practice, is capable of being easily automatized. Furthermore, while being non-trivial, it is simple enough to succumb to many lower bound techniques.

Formally, a resolution refutation of an unsatisfiable CNF formula is a sequence of clauses $D_1, \ldots, D_l = \emptyset$, where $\emptyset$ is the empty clause, such that each D_i is either a clause of the CNF or is derived from previous clauses $D_j, D_k, j \leq k < i$ by means of applying the following *resolution rule*: from the clauses $C \vee x$ and $D \vee \neg x$ derive $C \vee D$.

The *tree-like* version of resolution, where every occurrence of a clause in the refutation is used at most once as a premise of a rule, is of particular importance, since it helps us to understand certain kind of satisfiability algorithms known as DPLL algorithms (cf. [23]). DPLL algorithms are simple recursive algorithms for solving SAT that are the basis of successful contemporary SAT-solvers. The transcript of a run of DPLL on an unsatisfiable formula is a decision tree, which can be interpreted as a tree-like resolution refutation. Thus, lower bounds on the size of tree-like resolution refutations imply lower bounds on the run-time of DPLL algorithms (though it is important to clarify that contemporary SAT-solvers utilize more than the strength of tree-like resolution).

In contrast to the apparent practical success of SAT-solvers, a variety of hard instances that require exponential-size refutations have been found for resolution during the years. Many classes of such hard instances are based on principles expressing some sort of counting. One famous example is the *pigeonhole principle*, denoted PHP^m_n, expressing that there is no (total) injective map from a set with cardinality m to a set with cardinality n if $m > n$ [15]. Another important example is *Tseitin tautologies*, denoted TS_G, expressing that the sum of the degrees of vertices in a graph G must be even [28].

Since such counting tautologies are a source of hard instances for resolution, it is useful to study extensions of resolution that can efficiently count, so to speak. This is important firstly, because such systems may become the basis of more efficient SAT-solvers and secondly, in order to extend the frontiers of lower bound techniques against stronger and stronger propositional proof systems. Indeed, there are many works dedicated to the study of weak systems operating with De Morgan formulas with counting connectives; these are variations of resolution that operate with disjunctions of certain arithmetic expressions.

One such extension of resolution was introduced by Raz and Tzameret [26] under the name *resolution over linear equations* in which literals are replaced by linear equations. Specifically, the system R(lin), which operates with disjunctions of linear equations over $\mathbb{Z}$ was studied in [26]. This work demonstrated the power of resolution with counting over the integers, and specifically provided polynomial upper bounds for the pigeonhole principle and the Tseitin formulas, as well as other basic counting formulas. It also established exponential lower bounds for a subsystem of R(lin), denoted R^0(lin). Subsequently, Itsykson and Sokolov [17] studied resolution over linear equations over $\mathbb{F}_2$, denoted Res($\oplus$). They demonstrated the power of resolution with counting mod 2 as well as its limitations by means of several upper bounds and tree-like lower bounds. Moreover, [17] introduced DPLL algorithms, which can "branch" on arbitrary linear forms over $\mathbb{F}_2$, as well as parity decision trees, and showed a correspondence between parity decision trees and tree-like Res($\oplus$) refutations. In both [26] and [17] the dag-like lower bound question for resolution over linear equations remained open.

Apart from being a very natural refutation system, understanding the proof complexity of resolution over linear equations is important for the following reason: proving super-polynomial dag-like lower bounds against resolution over linear equations for prime fields and for the integers can be viewed as a first step towards the long-standing open problems of $\mathsf{AC}^0[p]$-Frege and TC^0-Frege lower bounds, respectively. We explain this in what follows.

Resolution operates with clauses, which are De Morgan formulas ($\neg$, unbounded fan-in $\vee$ and $\wedge$) of a particular kind, namely, of depth 1. Thus, from the perspective of proof complexity, resolution is a fairly weak version of the propositional-calculus, where the latter operates with arbitrary De Morgan formulas. Under a natural and general definition, propositional-calculus systems go under the name *Frege systems*: they can be (axiomatic) Hilbert-style systems or sequent-calculus style systems. A particular choice of the formalism is not important: a classical result by Reckhow [27] assures us that all Frege systems are polynomially equivalent. The task of proving lower bounds for general Frege systems is notoriously hard: no nontrivial lower bounds are known to date. Basically, the strongest fragment of Frege systems, for which lower bounds are known are AC^0-Frege systems, which are Frege proofs operating with constant-depth formulas. For example, both PHP_n^m and TS_G do not admit sub-exponential proofs in AC^0-Frege [1, 24, 20, 7, 16]. However, if we extend the De Morgan language with counting connectives such as unbounded fan-in mod p ($\mathsf{AC}^0[p]$-Frege) or threshold gates (TC^0-Frege), then we step again into the darkness: proving super-polynomial lower bounds for these systems is a long-standing open problem on what can be characterized as the "frontiers" of proof complexity. Recent works by Krajíček [18], Garlik-Kołodziejczyk [13] and Krajíček-Oliveira [19] had suggested possible approaches to attack dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_2})$ lower bounds (though this problem remains open to date).

1.1 Our Results and Techniques

In this work we prove a host of new lower bounds, separations and upper bounds for resolution over linear equations. Our main novel technical contribution is a dag-like refutation lower bound over large characteristic fields. Conceptually, the proof idea exploits two main properties that recently have been found useful in proof complexity:

(i) Single axiom: the hard instance consists of a single unsatisfiable axiom (for boolean assignments)

$$1 + x_1 + \cdots + 2^n x_n = 0 \tag{1}$$

(unlike, for instance, a set of clauses).

(ii) Large coefficients: the hard instance uses coefficients of exponential magnitude.

Although employing different approaches, both of these properties played a recent role in proof complexity lower bounds. Forbes et al. [12] used subset-sum variants (that is, unsatisfiable linear equations with boolean variables) to establish lower bounds on subsystems of the ideal proof system (IPS) over large characteristic fields, where IPS is the strong proof system introduced by Grochow and Pitassi [14]. It is essential in both [12] and our work that the hard instance takes the form of a single unsatisfiable axiom. Subsequently, in a very recent work, Alekseev et al. [3] established conditional exponential-size lower bounds on full IPS refutations over the rationals of the same subset-sum instance (1), where the use of big coefficients is again essential to the lower bound. We explain our dag-like lower bound in Section 1.1.2.

The other novel contribution we make is a systematic development of new kinds of lower bound techniques against *tree-like* resolution over linear equations, both over the rationals and over finite fields. To this end we develop new and extend existing combinatorial techniques such as the Prover-Delayer game method as originated in Pudlak and Impagliazzo [25] for resolution, and developed further by Itsykson and Sokolov [17]. Moreover, we provide new applications in proof complexity of different combinatorial results; this include bounds on the size of essential coverings of the hypercube from Linial and Radhakrishnan [21], a result about the hyperplane coverings of the hypercube by Alon and Füredi [4] and the notion of immunity from Alekhnovich and Razborov [2]. We further non-trivially extend the well-established principle of size-width tradeoffs in resolution [8] to the setting of Res(lin_R) (though it is important to note that most of our lower bounds do not follow from this tradeoff result).

1.1.1 Background

For a ring R, the refutation system Res(lin_R) is defined as an extension of the resolution refutation system as follows (see Raz and Tzameret [26]). The *proof-lines* of Res(lin_R) are called ***linear clauses*** (sometimes called simply *clauses*), which are defined as disjunctions of linear equations (with duplicate equations contracted). More formally, they are disjunctions of the form:

$$\left(\sum_{i=1}^{n} a_{1i}x_i + b_1 = 0\right) \vee \cdots \vee \left(\sum_{i=1}^{n} a_{ki}x_i + b_k = 0\right),$$

where k is some number (the *width* of the clause), and $a_{ji}, b_j \in R$. The *resolution rule* is the following:

$$\text{from } (C \vee f = 0) \text{ and } (D \vee g = 0) \text{ derive } (C \vee D \vee (\alpha f + \beta g) = 0),$$

where $\alpha, \beta \in R$, and where C, D are linear clauses. A Res(lin_R) *refutation* of an unsatisfiable over 0-1 set of linear clauses $C_1, \ldots, C_m$ is a sequence of proof-lines, where each proof-line is either C_i, for $i \in [m]$, a boolean axiom $(x_i = 0 \vee x_i = 1)$ for some variable x_i, or was derived from previous proof-lines by the above resolution rule, or by the *weakening rule* that allows to extend clauses with arbitrary disjuncts, or a *simplification rule* allowing to discard false constant linear forms (e.g., $1 = 0$) from a linear clause. The last proof-line in a refutation is the empty clause (standing for the truth value false).

The ***size*** of a Res(lin_R) refutation is the total size of all the clauses in the derivation, where the size of a clause is defined to be the total number of occurrences of variables in it plus the total size of all the coefficient occurring in the clause. The size of a coefficient when using integers (or integers embedded in characteristic zero rings) is the standard size of the binary representation of integers (nevertheless, when we talk about "big" or "exponential" coefficients and "polynomially bounded" coefficients, etc., we mean that the *magnitude* of the coefficients is big (exponential) or polynomially bounded).

We are generally interested in the following questions:

(Q1) For a given ring R, what kind of counting can be efficiently performed in Res(lin_R) and tree-like Res(lin_R)?

(Q2) Can dag-like Res(lin_R) be separated from tree-like Res(lin_R)?

(Q3) Can tree-like systems for different rings R be separated?

1.1.1.1 Tree-like Res(lin_R) with semantic weakening

In order to be able to do some non-trivial counting in *tree-like* versions of resolution over linear equations we define a semantic version of the system as follows.

The system $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ is obtained from $\mathrm{Res}(\mathrm{lin}_R)$ by replacing the weakening and the simplification rules, as well as the boolean axioms, with the *semantic weakening* rule (the symbol $\models$ will denote in this work semantic implication *with respect to 0-1 assignments*):[1]

$$\frac{C}{D}\,(C \models D)\,.$$

The reason for studying $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ is mainly the following: Let Γ be an arbitrary set of tautological R-linear clauses. Then, lower bounds for tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ imply lower bounds for tree-like $\mathrm{Res}(\mathrm{lin}_R)$ with formulas in Γ as axioms. For example, in case $\mathbb{F}$ is a field of characteristic 0, the possibility to do counting in tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ is quite limited. For instance, we show that $2x_1 + \cdots + 2x_n = 1$ requires refutations of exponential in n size (Theorem 35). On the other hand, such contradictions *do* admit short tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations in the presence of the following *generalized boolean axioms* (which is a tautological linear clause):

$$\mathsf{Im}(f) := \bigvee_{A \in im_2(f)} (f = A), \tag{2}$$

where $im_2(f)$ is the image of a linear polynomial f under 0-1 assignments. Similar to the way the boolean axioms $(x_i = 0) \vee (x_i = 1)$ state that the possible value of a variable is either zero or one, the $\mathsf{Im}(f)$ axiom states all the possible values that the linear form f can have. If a lower bound holds for tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ it also holds, in particular, for tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ with the axioms $\mathsf{Im}(f)$, and this makes tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ a useful system, for which lower bounds against are sufficiently interesting.

1.1.2 Characteristic Zero Lower Bounds

For characteristic zero fields we will use mainly the rational number field $\mathbb{Q}$ (though many of the results hold over any characteristic zero rings). First, we show that over $\mathbb{Q}$, whenever $\alpha_1 x_1 + \cdots + \alpha_n x_n + \beta = 0$ is unsatisfiable (over 0-1 assignments), it has polynomial dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutations if the coefficients are polynomially bounded in magnitude, while it requires exponential dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutations for some subset-sum instances with exponential-magnitude coefficients. Note that $\alpha_1 x_1 + \cdots + \alpha_n x_n + \beta = 0$ expresses the *subset-sum principle*: $\alpha_1 x_1 + \cdots + \alpha_n x_n = -\beta$ is satisfiable iff there is a subset of the integral coefficients α_i whose sum is precisely $-\beta$. The lower bound is stated in the following theorem:

▶ **Theorem** (Theorem 21; Main dag-like lower bound). *Any* $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ *refutation of* $x_1 + 2x_2 + \cdots + 2^n x_n + 1 = 0$ *requires size* $2^{\Omega(n)}$.

The proof of this theorem introduces a new lower bound technique. We show that every (dag- or tree-like) refutation π of $x_1 + 2x_2 + \cdots + 2^n x_n + 1 = 0$ can be transformed without much increase in size into a derivation of a certain "fat" (exponential-size) clause C_π from boolean axioms only.[2] In order to prove that C_π is fat, we ensure that every disjunct $g = 0$

[1] Let $k = char(R)$ be the characteristic of the ring R. In case $k \notin \{1, 2, 3\}$, deciding whether an R-linear clause D is a tautology (that is, holds for every 0-1 assignment to its variables) is at least as hard as deciding whether a 3-DNF is a tautology (because over characteristic $k \notin \{1, 2, 3\}$ linear equations can express conjunction of three conjuncts). For this reason $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ proofs cannot be checked in polynomial time and thus $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ is not a Cook-Reckhow proof system unless $\mathsf{P} = \mathsf{coNP}$ (namely, the correctness of proofs in the system cannot necessarily be checked in polynomial-time, as required by a Cook-Reckhow propositional proof system [11]; see Section 2.2).

[2] The notion of showing that a refutation must go though a fat (i.e., wide) clause is well established in resolution lower bounds. However, we note that our lower bound is completely different from the known size-width based resolution lower bounds (as formulated in a generic way in the work of Ben-Sasson and Wigderson [8]).

in C_π has at most 2^{cn} satisfying boolean assignments, for some constant $c < 1$. Because C_π is derived from boolean axioms alone, it must be a boolean tautology, that is, it must have 2^n satisfying assignment. Since every disjunct in C_π is satisfied by at most 2^{cn} assignments, the number of disjuncts in the clause is at least $2^{(1-c)n}$. Since our constructed derivation is not much larger than the original refutation, the size of the original refutation must be $2^{\Omega(n)}$.

This proof relies in an essential way on the fact that the coefficients of the linear form have exponential magnitude. Indeed, every contradiction of the form $f = 0$ can be shown to admit polynomial-size dag-like Res($\text{lin}_\mathbb{Q}$) refutations whenever the coefficients of f are polynomially bounded. A natural question is whether in the case of bounded coefficients, $f = 0$ can be efficiently refuted already by tree-like Res($\text{lin}_\mathbb{Q}$) refutations. The question turns out to be non-trivial, and we provide a negative answer:

▶ **Theorem** (Theorem 35; Subset-sum tree-like lower bounds). *Let f be any linear polynomial over $\mathbb{Q}$, which depends on n variables. Then tree-like* Res($\text{lin}_\mathbb{Q}$) *refutations of $f = 0$ are of size $2^{\Omega(\sqrt{n})}$.*

The proof is in two stages. First, we use a transformation analogous to the one used for the dag-like lower bound to reduce the lower bound problem for refutations of $f = 0$ to a lower bound problem for derivations of clauses of a certain kind. Namely, we transform any tree-like refutation π of $f = 0$ to a tree-like derivation of C_π from boolean axioms without much increase in size. The only difference is that this time we ensure that in every disjunct $g = 0$ of C_π, the linear polynomial g depends on at least $\frac{n}{2}$ variables.

Second, we prove that tree-like Res($\text{lin}_\mathbb{Q}$) derivations of such a C_π are large:

▶ **Theorem** (Theorem 33). *Any tree-like* Res($\text{lin}_\mathbb{Q}$) *derivation of any tautology of the form $\bigvee_{j\in[N]} g_j = 0$, for some positive N, where each g_j is linear over $\mathbb{Q}$ and depends on at least $\frac{n}{2}$ variables, is of size $2^{\Omega(\sqrt{n})}$.*

To prove this, as well as some other lower bounds, we extend the Prover-Delayer game technique as originated in Pudlak-Impagliazzo [25] for resolution, and developed further by Itsykson-Sokolov [17] for Res($\text{lin}_{\mathbb{F}_2}$), to general rings, including characteristic zero rings (see Sec. 5.2).[3]

We define a non-trivial strategy for Delayer in the corresponding game and prove that it guarantees $\sqrt{n}$ coins using a bound on the size of essential coverings of the hypercube from Linial and Radhakrishnan [21]. The relation between Prover-Delayer games and tree-like Res($\text{lin}_\mathbb{Q}$) refutations allows us to conclude that the size of tree-like Res($\text{lin}_\mathbb{Q}$) refutations must be $2^{\Omega(\sqrt{n})}$.

Moreover, as a corollary of Theorem 33 we obtain a lower bound on tree-like Res($\text{lin}_\mathbb{Q}$) *derivations* (in contrast to refutations) of $\mathsf{Im}(f)$:

▶ **Corollary** (Corollary 34). *Let f be any linear polynomial over $\mathbb{Q}$ that depends on n variables. Then tree-like* Res($\text{lin}_\mathbb{Q}$) *derivations of $\mathsf{Im}(f)$ are of size $2^{\Omega(\sqrt{n})}$.*

We also use Prover-Delayer games to prove an exponential-size $2^{\Omega(n)}$ lower bound on tree-like Res$_{sw}$($\text{lin}_\mathbb{F}$) refutations of the pigeonhole principle PHP^m_n *for every field* $\mathbb{F}$ (including finite fields). This extends a previous result by Itsykson and Sokolov [17] for tree-like Res($\text{lin}_{\mathbb{F}_2}$).

[3] We note here (see Remark 1 in the next sub-section) that the lower bounds that we prove using Prover-Delayer games techniques in case $char(\mathbb{F}) = 0$ *do not* follow from lower bounds for Polynomial Calculus using size-width relations.

▶ **Theorem** (Theorem 38; Pigeonhole principle lower bounds). *Let $\mathbb{F}$ be any (possibly finite) field. Then every tree-like* $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ *refutation of* $\neg\mathrm{PHP}_n^m$ *has size* $2^{\Omega\left(\frac{n-1}{2}\right)}$.

Together with the polynomial upper bounds for PHP_n^m refutations in dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ for fields $\mathbb{F}$ of characteristic zero demonstrated by Raz and Tzameret [26], Theorem 38 establishes a *separation between dag-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *and tree-like* $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ for characteristic zero fields, for the language of unsatisfiable formulas in CNF:

▶ **Corollary.** *Over fields of characteristic zero $\mathbb{F}$,* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *has an exponential speed-up over tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *as refutation systems for unsatisfiable formulas in CNF.*

To prove Theorem 38 we need to prove that Delayer's strategy from [17] is successful over any field. This argument is new, and uses a result of Alon-Füredi [4] about the hyperplane coverings of the hypercube.

We prove another separation between dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ and tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{Q}})$, as follows. For any ring R we define the *image avoidance principle* to be:

$$\mathsf{ImAv}\left(x_1+\cdots+x_n\right) := \left\{\langle x_1+\cdots+x_n \neq k\rangle\right\}_{k\in\{0,\ldots,n\}},$$

where $\langle x_1+\cdots+x_n \neq k\rangle := \bigvee_{k'\in\{0,\ldots,n\},\ k\neq k'} x_1+\cdots+x_n = k'$. In words, the image avoidance principle expresses the contradictory statement that for every $0 \leq i \leq n$, $x_1+\cdots+x_n$ equals some element in $\{0,\ldots,n\}\setminus i$. In more generality, let f be a linear form over $\mathbb{Q}$ and let $im_2(f)$ be the image of f under 0-1 assignments to its variables. Define $\langle f \neq A\rangle := \bigvee_{A\neq B\in im_2(f)}(f=B)$, where $A\in\mathbb{Q}$. We define

$$\mathsf{ImAv}\left(f\right) := \left\{\langle f\neq A\rangle : A\in im_2(f)\right\}. \tag{3}$$

▶ **Corollary** (Corollary 13). *For every ring R and every linear form f the contradiction* $\mathsf{ImAv}\left(f\right)$ *admits polynomial-size* $\mathrm{Res}(\mathrm{lin}_R)$ *refutations.*

▶ **Theorem** (Theorem 37). *We work over $\mathbb{Q}$. Let $f=\epsilon_1x_1+\cdots+\epsilon_nx_n$, where $\epsilon_i\in\{-1,1\}$. Then any tree-like* $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{Q}})$ *refutation of* $\mathsf{ImAv}\left(f\right)$ *is of size at least* $2^{\frac{n}{4}}$.

The lower bound in Theorem 37 is one more novel application of the Prover-Delayer game argument, combined with the notion of immunity from Alekhnovich and Razborov [2], as we now briefly explain.

Let f be a linear form as in Theorem 37. We consider an instance of the Prover-Delayer game for $\mathsf{ImAv}\left(f\right)$. A position in the game is determined by a *set Φ of linear non-equalities* of the form $g\neq 0$, which we think of as the set of non-equalities learned up to this point by Prover. In the beginning Φ is empty. We define Delayer's strategy in such a way that for Φ an end-game position, there is a satisfiable subset $\Phi'=\{g_1\neq 0,\ldots,g_m\neq 0\}\subseteq\Phi$ such that $\Phi'\models f=A$ for some $A\in\mathbb{F}$, and Delayer earns at least $|\Phi'|=m$ coins. Because $\mathbb{F}$ is of characteristic zero, it follows that $f\equiv A+1 \pmod 2$ $\models f\neq A\models g_1\cdot\ldots\cdot g_m=0$ and thus the $\frac{n}{4}$-immunity of $f\equiv A+1 (\mathrm{mod}\ 2)$ ([2]) implies $m\geq\frac{n}{4}$. To conclude, by a standard argument if Delayer always earns $\frac{n}{4}$ coins, then the shortest proof is of size at least $2^{\frac{n}{4}}$.

Table 1 sums up our knowledge up to this point with respect to $\mathbb{Q}$ (and for some cases any characteristic 0 field):

1.1.3 Finite Fields Lower Bounds

We now turn to resolution over linear equations in *finite fields.* We obtain many new tree-like lower bounds (see Table 2).

Table 1 Lower and upper bounds for $\mathbb{Q}$. The notation t-l Res(lin_R) stands for tree-like Res(lin_R). The rightmost column describes bounds on *derivations*, in contrast to refutations. All results except the upper bound on PHP are from the current work.

	$\sum_{i=1}^{n} 2x_i = 1$	$\sum_{i=1}^{n} 2^i x_i = -1$	$\mathsf{ImAv}\left(\sum_{i=1}^{n} x_i\right)$	PHP_n^m (CNF)	$\mathsf{Im}\left(\sum_{i=1}^{n} x_i\right)$
t-l Res($\text{lin}_{\mathbb{Q}}$)	$2^{\Omega(\sqrt{n})}$	$2^{\Omega(n)}$	$2^{\Omega(n)}$	$2^{\Omega(n)}$	$2^{\Omega(\sqrt{n})}$
t-l Res$_{sw}$($\text{lin}_{\mathbb{Q}}$)	poly	poly	$2^{\Omega(n)}$	$2^{\Omega(n)}$	poly
Res($\text{lin}_{\mathbb{Q}}$)	poly	$2^{\Omega(n)}$	poly	poly [26]	poly

We already discussed above lower bounds for the pigeonhole principle which hold both for positive and zero characteristic. We furthermore prove a separation between tree-like Res($\text{lin}_{\mathbb{F}_{p^k}}$) (resp. tree-like Res$_{sw}$($\text{lin}_{\mathbb{F}_{p^k}}$)) and tree-like Res($\text{lin}_{\mathbb{F}_{q^l}}$) (resp. tree-like Res$_{sw}$($\text{lin}_{\mathbb{F}_{q^l}}$)) for every pair of distinct primes $p \neq q$ and every $k, l \in \mathbb{N} \setminus \{0\}$. The separating instances are mod p Tseitin formulas $\text{TS}^{(p)}_{G,\sigma}$ (written as CNFs), which are reformulations of the standard Tseitin graph formulas TS_G for counting mod p. Furthermore, we establish an exponential lower bound for tree-like Res$_{sw}$($\text{lin}_{\mathbb{F}_{p^c}}$) on random k-CNFs.[4]

The lower bounds for tree-like Res($\text{lin}_{\mathbb{F}}$) for finite fields $\mathbb{F}$ are obtained via a variant of the size-width relation for tree-like Res($\text{lin}_{\mathbb{F}}$) together with a translation to polynomial calculus over the field $\mathbb{F}$, denoted $PC_{\mathbb{F}}$ [10], such that Res($\text{lin}_{\mathbb{F}}$) proofs of width ω are translated to $PC_{\mathbb{F}}$ proofs of degree ω (the *width* ω of a clause is defined to be the total number of disjuncts in a clause). This establishes the lower bounds for the size of tree-like Res($\text{lin}_{\mathbb{F}}$) proofs via known lower bounds on $PC_{\mathbb{F}}$ degrees ([2]).

We show that

$$\omega_0(\phi \vdash \bot) = O\left(\omega_0(\phi) + \log S_{\text{t-l Res}(\text{lin}_R)}(\phi \vdash \bot)\right),$$

where ω_0 is what we call the *principal width*, which counts the number of linear equations in clauses when we treat as identical those defining parallel hyperplanes, and $S_{\text{t-l Res}(\text{lin}_R)}(\phi \vdash \bot)$ denotes the minimal size of a tree-like Res(lin_R) refutation of ϕ.

Specifically, over finite fields the following upper and lower bounds provide exponential separations:

▶ **Theorem** (Theorem 44; Size-width relation). *Let ϕ be an unsatisfiable set of linear clauses over a field $\mathbb{F}$. The following relation between principal width and size holds for both tree-like* Res($\text{lin}_{\mathbb{F}}$) *and tree-like* Res$_{sw}$($\text{lin}_{\mathbb{F}}$)*: $S(\phi \vdash \bot) = 2^{\Omega(\omega_0(\phi \vdash \bot) - \omega_0(\phi))}$. If $\mathbb{F}$ is a finite field, then the same relation holds for the (standard) width of a clause ω.*

This extends to every field a result by Garlik-Kołodziejczyk [13, Theorem 14] who showed a size-width relation for a system denoted tree-like $\text{PK}^{\text{id}}_{O(1)}(\oplus)$, which is a system extending tree-like Res($\text{lin}_{\mathbb{F}_2}$) by allowing arbitrary constant-depth De Morgan formulas as inputs to $\oplus$ (XOR gates) (though note that our result does not deal with *arbitrary* constant-depth formulas).

▶ **Theorem** (Theorem 45). *Let $\mathbb{F}$ be a field and π be a* Res($\text{lin}_{\mathbb{F}}$) *refutation of an unsatisfiable CNF formula ϕ. Then, there exists a $PC_{\mathbb{F}}$ refutation π' of (the arithmetization of) ϕ of degree $\omega(\pi)$.*

[4] We thank Dmitry Itsykson for telling us about the lower bound for random k-CNF for the case of tree-like Res($\text{lin}_{\mathbb{F}_2}$), that was proved by Garlik and Kołodziejczyk using size-width relations (unpublished note). Our result extends Garlik and Kołodziejczyk's result to all finite fields. Similar to their result, we use a size-width argument and simulation by the polynomial calculus to establish the lower bound.

▶ **Corollary** (Corollary 46; Tseitin mod p lower bounds). *For any fixed prime p there exists a constant $d_0 = d_0(p)$ such that the following holds. If $d \geq d_0$, G is a d-regular directed graph satisfying certain expansion properties, and $\mathbb{F}$ is a finite field such that $char(\mathbb{F}) \neq p$, then every tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutation of the Tseitin mod p formula $\neg \mathrm{TS}^{(p)}_{G,\sigma}$ has size $2^{\Omega(dn)}$.*

▶ **Corollary** (Corollary 47; Random k-CNF formulas lower bounds). *Let ϕ be a randomly generated k-CNF with clause-variable ratio Δ, and where $\Delta = \Delta(n)$ is such that $\Delta = o\left(n^{\frac{k-2}{2}}\right)$, and let $\mathbb{F}$ be a finite field. Then, every tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutation of ϕ has size $2^{\Omega\left(\frac{n}{\Delta^{2/(k-2)} \cdot \log \Delta}\right)}$ with probability $1 - o(1)$.*

▶ Remark 1. We stress that the size-width relation of Theorem 44 **cannot** be used for transferring $PC_{\mathbb{F}}$ degree lower bounds to tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ size lower bounds in case $char(\mathbb{F}) = 0$. This is due to the essential difference between principal width and width in this case. Thus, all the lower bounds that we prove using Prover-Delayer games techniques in case $char(\mathbb{F}) = 0$ **do not** follow from lower bounds for $PC_{\mathbb{F}}$.

Table 2 shows the results for $\mathrm{Res}(\mathrm{lin}_R)$ over finite fields.

Table 2 Lower bounds over finite fields. Here G is d-regular graph and Δ is the clause density (number of clauses divided by the number of variables), $A\overline{x} = \overline{b}$ stands for a linear system over $\mathbb{F}_{p^k}$ that has no 0-1 solutions in the first and the third rows, and in the second row the linear system $A\overline{x} = \overline{b}$ is over $\mathbb{F}_2$. The notation $\mathrm{TS}^{(-)}_{G,\sigma}$ stands for $\mathrm{TS}^{(p)}_{G,\sigma}$ in the first and the third rows and for $\mathrm{TS}^{(2)}_{G,\sigma}$ in the second row. t-l $\mathrm{Res}(\mathrm{lin}_R)$ stands for tree-like $\mathrm{Res}(\mathrm{lin}_R)$, and $p \neq q$ are primes (in the second row and third column we assume $q \neq 2$). Circled "?" denotes an open problem. The results marked with [17, 13] were proved in the respective papers. All other results are from the current work.

	$A\overline{x} = \overline{b}$	$\mathrm{TS}^{(-)}_{G,\sigma}$	$\mathrm{TS}^{(q)}_{G,\sigma}$	random k-CNF	PHP^m_n
t-l $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_{p^k}})$	$2^{\Omega(n)}$	poly	$2^{\Omega(dn)}$	$2^{\Omega\left(\frac{n}{\Delta^{2/(k-2)} \cdot \log \Delta}\right)}$	$2^{\Omega(n)}$
t-l $\mathrm{Res}(\oplus)$	poly [17]	poly [17]	$2^{\Omega(dn)}$	$2^{\Omega\left(\frac{n}{\Delta^{2/(k-2)} \cdot \log \Delta}\right)}$ [13]	$2^{\Omega(n)}$ [17]
t-l $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}_{p^k}})$	poly	poly	?	?	$2^{\Omega(n)}$

1.1.4 Complexity of Linear Systems

The tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ upper bounds for mod p Tseitin formulas in the case $char(\mathbb{F}) = p$ stem from the following proposition:

▶ **Proposition** (Proposition 14; Upper bounds on unsatisfiable linear systems). *Let $\mathbb{F}$ be a field and assume that the linear system $A\,\overline{x} = \overline{b}$, where A is a $k \times n$ matrix over $\mathbb{F}$, has no solutions (over $\mathbb{F}$). Let ϕ be a CNF formula encoding the linear system $A\,\overline{x} = \overline{b}$. Then, there exist tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutations of ϕ of size polynomial in the sum of sizes of encodings of all coefficients in A.*

The upper bound in Proposition 14 applies only to linear systems that are unsatisfiable over the *whole* field $\mathbb{F}$. But does any system $A\,\overline{x} = \overline{b}$ over $\mathbb{F}$ that has a satisfying assignment over $\mathbb{F}$, but *not* over 0-1 assignments, admit polynomial-size $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations?

For fields $\mathbb{F}$ with $char(\mathbb{F}) \geq 5$ or $char(\mathbb{F}) = 0$ it is known that 0-1 satisfiability of $A\,\overline{x} = \overline{b}$ is NP-complete. This means that unless coNP = NP there exist 0-1 unsatisfiable linear systems that require superpolynomial dag-like Res($\text{lin}_{\mathbb{F}}$) refutations.

If $char(\mathbb{F}) \geq k+1$ or $char(\mathbb{F}) = 0$, the canonical reduction R from the language k-UNSAT of unsatisfiable k-CNFs maps every $\phi(\overline{x}) \in k$-UNSAT to the system $R_\phi(\overline{x}, \overline{y})$ by encoding every clause in $\phi(\overline{x})$ as a linear equality with extra variables. This simple reduction allows to establish tight connections between proof complexity of CNF formulas and linear systems.

Firstly, lower bounds on $R_\phi(\overline{x}, \overline{y})$ imply lower bounds on $\phi(\overline{x})$: by implicational completeness there are polynomial-size derivations of $\phi(\overline{x})$ from $R_\phi(\overline{x}, \overline{y})$ in Res($\text{lin}_{\mathbb{F}}$).

Secondly, if $\mathbb{F}$ is a finite field, tree-like Res($\text{lin}_{\mathbb{F}}$) lower bounds on $\phi(\overline{x})$ imply tree-like Res($\text{lin}_{\mathbb{F}}$) lower bounds on $R_\phi(\overline{x}, \overline{y})$. Each linear equation $l(\overline{x}, \overline{y}) = 0$ in $R_\phi(\overline{x}, \overline{y})$ is equivalent to a polynomial equation $l(\overline{x}, \overline{p}(\overline{x})) = 0$, where $\overline{p}$ are polynomials of constant degree. Therefore, there is a constant degree $PC_{\mathbb{F}}$ derivation π_ϕ of $R_\phi(\overline{x}, \overline{p}(\overline{x}))$ from $\phi(\overline{x})$ and vice versa. As any $PC_{\mathbb{F}}$ refutation of $R_\phi(\overline{x}, \overline{y})$ can be turned into a refutation of $R_\phi(\overline{x}, \overline{p}(\overline{x}))$ by substitution without much loss in degree, it is easy to see that $PC_{\mathbb{F}}$ refutes $R_\phi(\overline{x}, \overline{y})$ in degree d iff $PC_{\mathbb{F}}$ refutes $\phi(\overline{x})$ in degree $\Theta(d)$. By size-width relation for finite fields (Theorem 44), we obtain that for any formula $\phi(\overline{x})$ that is hard for $PC_{\mathbb{F}}$, $R_\phi(\overline{x}, \overline{y})$ is hard for tree-like Res($\text{lin}_{\mathbb{F}}$).

1.1.5 Nondeterministic Linear Decision Trees

There is a well-known size preserving (up to a constant factor) correspondence between tree-like resolution refutations for unsatisfiable formulas ϕ and decision trees, which solve the following problem: given an assignment ρ for the variables of ϕ, determine which clause $C \in \phi$ is falsified by querying values of the variables under the assignment ρ. In Itsykson-Sokolov [17] this correspondence was generalized to tree-like Res($\oplus$) refutations and parity decision trees. In the paper by Beame et al. [5] an analogous correspondence was shown for tree-like R(CP) refutations [5] and decision trees that brunch on linear inequalities. In the current work we initiate the study of linear decision trees and their properties over different characteristics, extending the correspondence of [17] to a correspondence between tree-like Res(lin_R) (and tree-like Res$_{sw}$(lin_R)) derivations to what we call *nondeterministic linear decision trees* (NLDT).

NLDTs for an unsatisfiable set of linear clauses ϕ are binary rooted trees, where every edge is labeled with a non-equality $f \neq 0$ for a linear form f and every leaf is labeled with a linear clause $C \in \phi$, which is violated by the non-equalities on the path from the root to the leaf. (Note that in the same manner that in a (boolean) decision tree (which corresponds to a tree-like resolution refutation) we go along a path from the root to a leaf, choosing those edges that violate a literal x_i or $\neg x_i$, in an NLDT we branch along a path that violates equalities $f = 0$, or equivalently, certifies non-equalities of the form $f \neq 0$.)

2 Preliminaries

2.1 Notation

Denote by $[n]$ the set $\{1, \ldots, n\}$. We use $x_1, x_2, \ldots$ to denote variables, both propositional and algebraic. Let f be a linear polynomial (equivalently, an affine function) over a ring R, that is, a function of the form $\sum_{i=1}^{n} a_i x_i + a_0$ with $a_i \in R$. We sometimes refer to a linear

[5] R(CP) is a system operating with disjunctions of integer linear inequalities $f \geq 0$

form as a *hyperplane*, since a linear form determines a hyperplane. We denote by $im_2(f)$ the image of f under 0-1 assignments to its variables; $\langle f \neq A\rangle := \bigvee_{A\neq B\in im_2(f)}(f = B)$, where $A \in R$.

A *linear clause* is a formula of the form $(\sum_{i=1}^{n} a_{1i}x_i + b_1 = 0)\vee\cdots\vee(\sum_{i=1}^{n} a_{ki}x_i + b_k = 0)$ with $x_1,\ldots,x_n$ variables, and a_{ij}, b_i's ring elements (when the ring is specified in advanced). We sometimes abuse notation by writing a linear equation as $\sum_{i=0}^{n} a_{1i}x_i = -b_1$ instead of $\sum_{i=0}^{n} a_{1i}x_i + b_1 = 0$. We assume that all the disjuncts in a linear clause are distinct.

For ϕ a set of clauses or linear clauses, $vars(\phi)$ denotes the set of variables occurring in ϕ and let Vars denote the set of *all* variables.

Let A be a matrix over a ring. We introduce the notation $Ax \doteqdot b$ for a system of linear non-equalities, where a ***non-equality*** means $\neq$ (note the difference between $Ax \doteqdot b$, which stands for $A_i \cdot x \neq b_i$, for *all* rows A_i in A, and $Ax \neq b$, which stands for $A_i \cdot x \neq b_i$, for *some* row A_i in A).

If f is a linear polynomial over R and A is a matrix over R, denote by $|f|$ the sum of sizes of encodings of coefficients in f and by $|A|$ the sum of sizes of encodings of elements in A.

If $C = (\bigvee_{i\in[m]} f_i = 0)$ is a linear clause, denote by $\neg C$ the *set* of non-equalities $\{f_i \neq 0\}_{i\in[m]}$. Conversely, if $\Phi = \{f_i \neq 0\}_{i\in[n]}$ is a set of non-equalities, denote $\neg\Phi := \bigvee_{i\in[m]} f_i = 0$.

If ϕ is a set of linear clauses over a ring R and D is a linear clause over R, denote by $\bigwedge_{C\in\phi} C \models D$ and $\bigwedge_{C\in\phi} C \models_R D$ semantic entailment over 0-1 and R-valued assignments respectively.

Let l be a linear polynomial not containing the variable x. If C is a linear clause, denote by $C\restriction_{x\leftarrow l}$ the linear clause, which is obtained from C by substituting l for x everywhere in C. If $\phi = \{C_i\}_{i\in I}$ is a set of clauses, denote $\phi\restriction_{x\leftarrow l} := \{C_i\restriction_{x\leftarrow l}\}_{i\in I}$. We define a *linear substitution* ρ to be a sequence $(x_1 \leftarrow l_1,\ldots,x_n \leftarrow l_n)$ such that each linear polynomial l_i does not depend on x_i. For a clause or a set of clauses ϕ we define $\phi\restriction_\rho := (\ldots((\phi\restriction_{x_1\leftarrow l_1})\restriction_{x_2\leftarrow l_2})\ldots)\restriction_{x_n\leftarrow l_n}$.

Denote UNSAT $\subset \{0,1\}^*$ (resp. k-UNSAT $\subset \{0,1\}^*$) the language of unsatisfiable propositional CNF (resp. k-CNF) formulas. Denote by $S(\pi)$, and alternatively by $|\pi|$, the size of the binary encoding of a proof π in a proof system Π. For $\phi \in$ UNSAT and a refutation system Π denote by $S_\Pi(\phi \vdash \bot)$ (we sometimes omit the subscript Π when it is clear from the context) the minimal size of a Π-refutation of ϕ.

2.2 Propositional Proof Systems

The *resolution* system (which we denote also by Res) is a refutation system, based on the following rule, allowing to derive new clauses from given ones:

$$\frac{C \vee x \qquad D \vee \neg x}{C \vee D} \quad \text{(Resolution rule)}.$$

A *resolution derivation* of a clause D from a set of clauses ϕ is a sequence of clauses $(D_1,\ldots,D_s \equiv D)$ such that for every $1 \leq i \leq s$ either $D_i \in \phi$ or D_i is obtained from previous clauses by applying the resolution rule. A *resolution refutation* of $\phi \in$ UNSAT is a resolution derivation of the empty clause from ϕ, which stands for the truth value False.

A resolution derivation is *tree-like* if every clause in it is used at most once as a premise of a rule. Accordingly, *tree-like resolution* is the resolution system allowing only tree-like refutations.

Let $\mathbb{F}$ be a field. A *polynomial calculus* [10] derivation of a polynomial $q \in \mathbb{F}[x_1,\ldots,x_n]$ from a set of polynomials $\mathcal{P} \subseteq \mathbb{F}[x_1,\ldots,x_n]$ is a sequence $(p_1,\ldots,p_s), p_i \in \mathbb{F}[x_1,\ldots,x_n]$ such that for every $1 \leq i \leq s$ either $p_i = x_j^2 - x_j$, $p_i \in \mathcal{P}$ or p_i is obtained from previous polynomials by applying one of the following rules:

$$\frac{f \qquad g}{\alpha f + \beta g} \quad (\alpha, \beta \in \mathbb{F}, f, g \in \mathbb{F}[x_1, \ldots, x_n]) \qquad \frac{f}{x \cdot f} \quad (f \in \mathbb{F}[x_1, \ldots, x_n]) \,.$$

A polynomial calculus refutation of $\mathcal{P} \subseteq \mathbb{F}[x_1, \ldots, x_n]$ is a derivation of 1. The degree $d(\pi)$ of a polynomial calculus derivation π is the maximal total degree of a polynomial appearing in it. This defines the proof system $PC_{\mathbb{F}}$ for the language of unsatisfiable systems of polynomial equations over $\mathbb{F}$. It can be turned into a proof system for k-UNSAT via *arithmetization of clauses* as follows: $(x_1 \vee \ldots \vee x_k \vee \neg y_1 \vee \ldots \vee \neg y_l)$ is represented as $(1 - x_1) \cdot \ldots \cdot (1 - x_k) \cdot y_1 \cdot \ldots \cdot y_l = 0$.

2.3 Hard Instances

2.3.1 Pigeonhole Principle

The *pigeonhole principle* states that there is no injective mapping from the set $[m]$ to the set $[n]$, for $m > n$. Elements of the former and the latter sets are referred to as *pigeons* and *holes*, respectively. The CNF formula, denoted PHP_n^m, encoding the negation of this principle is defined as follows. Let the set of propositional variables $\{x_{i,j}\}_{i \in [m], j \in [n]}$ correspond to the mapping from $[m]$ to $[n]$, that is, $x_{i,j} = 1$ iff the i^{th} pigeon is mapped to the j^{th} hole. Then $\neg\mathrm{PHP}_n^m := \mathsf{Pigeons}_n^m \cup \mathsf{Holes}_n^m \in \mathrm{UNSAT}$, where $\mathsf{Pigeons}_n^m = \{\bigvee_{j \in [n]} x_{i,j}\}_{i \in [m]}$ are axioms for pigeons and $\mathsf{Holes}_n^m = \{\neg x_{i,j} \vee \neg x_{i',j}\}_{i \neq i' \in [m], j \in [n]}$ are axioms for holes.

2.3.2 Mod p Tseitin Formulas

We use the version given in [2] (which is different from the one in [9, 26]). Let $G = (V, E)$ be a directed d-regular graph. We assign to every edge $(u, v) \in E$ a corresponding variable $x_{(u,v)}$. Let $\sigma : V \to \mathbb{F}_p$. The *Tseitin mod p formulas* $\neg\mathrm{TS}_{G,\sigma}^{(p)}$ are the CNF encoding of the following equations for all $u \in V$:

$$\sum_{(u,v) \in E} x_{(u,v)} - \sum_{(v,u) \in E} x_{(v,u)} \equiv \sigma(u) \mod p \,. \tag{4}$$

Note that we use the standard encoding of boolean functions as CNF formulas and the number of clauses, required to encode these equations is $O(2^d|V|)$. $\neg\mathrm{TS}_{G,\sigma}^{(p)}$ is unsatisfiable if $\sum_{u \in V} \sigma(u) \not\equiv 0 \mod p$. To see this, note that if we sum (4) over all nodes $u \in V$ we obtain precisely $\sum_{u \in V} \sigma(u)$ which is different from $0 \mod p$; but on the other hand, in this sum over all nodes $u \in V$ each edge $(u, v) \in E$ appears once with a positive sign as an outgoing edge from u and with a negative sign as an incoming edge to v, meaning the the total sum is 0, which is a contradiction.

In particular, $\neg\mathrm{TS}_{G,\sigma}^{(2)}$ are the classical Tseitin formulas [28] and $\mathrm{TS}_{G,1}^{(2)}$, where 1 is the constant function $v \mapsto 1$ (for all $v \in V$), expresses the fact that the sum of total degrees (incoming + outgoing) of the vertices is even.

The proof complexity of Tseitin tautologies depends on the properties of the graph G. For example, if G is just a union of K_{d+1} (the complete graphs on $d + 1$ vertices), then they are easy to prove. On the other hand, they are known to be hard for some proof systems if G satisfies certain expansion properties.

Let $G = (V, E)$ be an *undirected* graph. For $U, U' \subseteq V$ define $e(U, U') := \{(u, u') \in E \mid u \in U, u' \in U'\}$. Consider the following measure of expansion for $r \geq 1$:

$$c_E(r, G) := \min_{|U| \leq r} \frac{e(U, V \backslash U)}{|U|}$$

G is (r, d, c)-expander if G is d-regular and $c_E(r, G) \geq c$. There are explicit constructions of good expanders. For example:

▶ **Proposition 2** (Lubotzky *et. al* [22]). *For any d, there exists an explicit construction of d-regular graph G, called Ramanujan graph, which is $(r, d, d(1 - \frac{r}{n}) - 2\sqrt{d-1})$-expander for any $r \geq 1$.*

▶ **Proposition 3** (Alekhnovich-Razborov [2]). *For any fixed prime p there exists a constant $d_0 = d_0(p)$ such that the following holds. If $d \geq d_0$, G is a d-regular Ramanujan graph on n vertices (augmented with arbitrary orientation of its edges) and $char(\mathbb{F}) \neq p$, then for every function σ such that $\neg TS^{(p)}_{G,\sigma} \in UNSAT$ every $PC_{\mathbb{F}}$ refutation of $\neg TS^{(p)}_{G,\sigma}$ has degree $\Omega(dn)$.*

2.3.3 Random k-CNFs

A random k-CNF is a formula $\phi \sim \mathcal{F}_k^{n,\Delta}$ with n variables that is generated by picking randomly and independently $\Delta \cdot n$ clauses from the set of all $\binom{n}{k} \cdot 2^k$ clauses.

▶ **Proposition 4** (Alekhnovich-Razborov [2]). *Let $\phi \sim \mathcal{F}_k^{n,\Delta}, k \geq 3$ and $\Delta = \Delta(n)$ is such that $\Delta = o\left(n^{\frac{k-2}{2}}\right)$. Then every $PC_{\mathbb{F}}$ refutation of ϕ has degree $\Omega\left(\frac{n}{\Delta^{2/(k-2)} \cdot \log \Delta}\right)$ with probability $1 - o(1)$ for any field $\mathbb{F}$.*

3 Resolution over Linear Equations for General Rings

In this section we define and outline some basic properties of systems that are extensions of resolution, where clauses are disjunctions of linear equations over a ring R: $(\sum_{i=0}^{n} a_{1i}x_i + b_1 = 0) \vee \cdots \vee (\sum_{i=0}^{n} a_{ki}x_i + b_k = 0)$. Recall that disjunctions of this form are called *linear clauses*, and that we assume that all disjuncts are distinct, hence contract duplicate linear equations. We sometimes abuse notation by writing a linear equation as $(\sum_{i=0}^{n} a_{1i}x_i = -b_1)$ instead of $(\sum_{i=0}^{n} a_{1i}x_i + b_1 = 0)$.

The rules of Res(lin_R) are as follows (cf. [26]):

$$\text{(Resolution)} \quad \frac{C \vee f(\overline{x}) = 0 \qquad D \vee g(\overline{x}) = 0}{C \vee D \vee (\alpha f(\overline{x}) + \beta g(\overline{x})) = 0} \quad (\alpha, \beta \in R)$$

$$\text{(Simplification)} \ \frac{C \vee a = 0}{C} \ (0 \neq a \in R) \qquad \text{(Weakening)} \ \frac{C}{C \vee f(\overline{x}) = 0}$$

where $f(\overline{x}), g(\overline{x})$ are linear forms over R and C, D are linear clauses. Note that contraction of duplicates disjuncts is done automatically when applying the resolution rule. The *boolean axioms* are defined as follows:

$$x_i = 0 \vee x_i = 1, \ \text{ for } x_i \text{ a variable}$$

A Res(lin_R) *derivation* of a linear clause D from a set of linear clauses ϕ is a sequence of linear clauses $(D_1, \ldots, D_s \equiv D)$ such that for every $1 \leq i \leq s$ either $D_i \in \phi$ or is a boolean axiom or D_i is obtained from previous clauses by applying one of the rules above. A Res(lin_R)

refutation of an unsatisfiable set of linear clauses ϕ is a Res(lin_R) derivation of the empty clause (which stands for false) from ϕ. The ***size*** of a Res(lin_R) derivation is the total size of all the clauses in the derivation, where the size of a clause is defined to be the total number of occurrences of variables in it plus the total size of all the coefficient occurring in the clause. The size of a coefficient when using integers (or integers embedded in characteristic zero rings) will be the standard size of the binary representation of integers.

In this definition we assume that R is a non-trivial ($R \neq \mathbf{0}$) ring such that there are polynomial-time algorithms for addition, multiplication and taking additive inverses.

Along with size, we will be dealing with two complexity measures of derivations: *width* and *principal width*.

▶ **Definition 5.** *A clause $C = (f_1 = 0 \vee \cdots \vee f_m = 0)$ has **width** $\omega(C) = m$ and **principal width** $\omega_0(C) = \left|\{f_i\}_{i\in[m]}/_\sim\right|$ where $\sim$ identifies R-linear forms $f_i = 0$ and $f_j = 0$ if they define parallel hyperplanes, that is, if $f_i = Af_j + B$ or $f_j = Af_i + B$ for some $A, B \in R$. For $\mu \in \{\omega, \omega_0\}$, the measure μ associated with a* Res(lin_R) *derivation $\pi = (D_1, \ldots, D_s)$ is $\mu(\pi) := \max_{1\leq i\leq s} \mu(D_i)$. For $\phi \in$ UNSAT, denote by $\mu(\phi \vdash \bot)$ the minimal value of $\mu(\pi)$ over all* Res(lin_R) *refutations π.*

▶ **Proposition 6.** Res(lin_R) *is sound and complete. It is also implicationally complete, that is if ϕ is a set of linear clauses and C is a linear clause such that $\phi \models C$, then there exists a* Res(lin_R) *derivation of C from ϕ.*

Proof. The soundness can be checked by inspecting that each rule of Res(lin_R) is sound. Implicational completeness (and thus completeness) follows from Proposition 28. ◀

We now define two systems of resolution with linear equations over a ring, where some of the rules are semantic: Res$_{sw}$(lin_R) and Sem-Res(lin_R). Res$_{sw}$(lin_R) is obtained from Res(lin_R) by replacing the boolean axioms with $0 = 0$, discarding simplification rule and replacing the weakening rule with the following *semantic weakening rule*:

$$\text{(Semantic weakening)}\ \frac{C}{D}\ (C \models D)$$

The system Sem-Res(lin_R) has no axioms except for $0 = 0$, and has only the following *semantic resolution rule*:

$$\text{(Semantic resolution)}\ \frac{C \qquad C'}{D}\ (C \wedge C' \models D)$$

It is easy to see that Res(lin_R) $\leq_p$ Res$_{sw}$(lin_R) $\leq_p$ Sem-Res(lin_R), where $P \leq_p Q$ denotes that Q polynomially simulates P.

In contrast to the case $R = \mathbb{F}_2$ (see [17]), for rings R with $char(R) \notin \{1, 2, 3\}$ both Res$_{sw}$(lin_R) and Sem-Res(lin_R) are not Cook-Reckhow proof systems, unless P = NP:

▶ **Proposition 7.** *The following decision problem is* coNP*-complete: given a linear clause over a ring R with $char(R) \notin \{1, 2, 3\}$ decide whether it is a tautology under 0-1 assignments.*

Proof. Consider a 3-DNF ϕ and encode every conjunct $(x_{i_1}^{\sigma_1} \wedge \cdots \wedge x_{i_k}^{\sigma_k}) \in \phi, 1 \leq k \leq 3, \sigma_i \in \{0, 1\}$ as the equation $(1 - 2\sigma_1)x_1 + \cdots + (1 - 2\sigma_k)x_k = k - (\sigma_1 + \cdots + \sigma_k)$, where $x^0 := x, x^1 := \neg x$. Then ϕ is tautological if and only if the disjunction of these linear equations is tautological (that is, for every 0-1 assignment to the variables at least one of the equations hold, when the equations are computed over a ring with characteristic zero or finite characteristic bigger than 3). ◀

We leave it as an open question to determine the complexity of verifying a correct application of the semantic weakening in case $char(R) = 3$ or in case $char(R) = 2$ and $R \neq \mathbb{F}_2$. In the case $R = \mathbb{F}_2$ the negation of a clause is a system of linear equations and thus the existence of solutions for it can be checked in polynomial time. Therefore $\text{Res}_{sw}(\text{lin}_{\mathbb{F}_2})$ is a Cook-Reckhow propositional proof system. The definitions of $\text{Res}(\text{lin}_{\mathbb{F}_2})$, $\text{Res}_{sw}(\text{lin}_{\mathbb{F}_2})$ and Sem-Res$(\text{lin}_{\mathbb{F}_2})$ coincide with the definitions of syntactic Res$(\oplus)$, Res$(\oplus)$ and $\text{Res}_{\text{sem}}(\oplus)$ from [17], respectively[6]. As showed in [17], $\text{Res}(\text{lin}_{\mathbb{F}_2})$, $\text{Res}_{sw}(\text{lin}_{\mathbb{F}_2})$ and Sem-Res$(\text{lin}_{\mathbb{F}_2})$ are polynomially equivalent.

We now show that if $char(R) \notin \{1, 2, 3\}$, then $\text{Res}_{sw}(\text{lin}_R)$ is polynomially bounded as a proof system for 3-UNSAT (that is, admits polynomial-size refutation for every instance):

▶ **Proposition 8.** *If* $char(R) \notin \{1, 2, 3\}$*, then dag-like* $\text{Res}_{sw}(\text{lin}_R)$ *and tree-like* Sem-Res(lin_R) are polynomially bounded (not necessarily Cook-Reckhow) propositionally proof systems for 3-UNSAT.

Proof. Let $\phi(x_1, \ldots, x_n) = \{C_i\}_{i\in[m]} \in$ 3-UNSAT. Given $C = (x_{j_1}^{\sigma_1} \vee \ldots \vee x_{j_k}^{\sigma_k})$ define $lin(\neg C) := ((2\sigma_1 - 1)x_{j_1} + \ldots + (2\sigma_k - 1)x_{j_k} - (\sigma_1 + \ldots + \sigma_k))$ where $\sigma_i \in \{0, 1\}, j_l \in [n], x^0 := x, x^1 := \neg x$. The linear clause $lin(\neg\phi) := \bigvee_{i\in[m]} lin(\neg C_i) = 0$ is a tautology (under 0-1 assignments) and thus can be derived in $\text{Res}_{sw}(\text{lin}_R)$ in a single step as a weakening of $0 = 0$ or resolving $0 = 0$ with $0 = 0$ in tree-like Sem-Res(lin_R).

In tree-like Sem-Res(lin_R) the disjunct $lin(\neg C_i) = 0$ can be eliminated from $lin(\neg\phi)$ by a single resolution with C_i, thus the empty clause is derived by a sequence of m resolutions of $lin(\neg\phi)$ with $C_1, \ldots, C_m$.

Similarly, the disjuncts $lin(\neg C_i) = 0$ are eliminated from $lin(\neg\phi)$ in $\text{Res}_{sw}(\text{lin}_R)$, but with a few more steps. Let D_0 be the empty clause and $D_{s+1} := D_s \vee lin(\neg C_{s+1}) = 0, 0 \leq s < m$. Assume D_{s+1} is derived and assume without loss of generality, that $C_{s+1} = (x_1 = 1 \vee \ldots \vee x_k = 1)$ and thus $lin(\neg C_{s+1}) = (-x_1 - \ldots - x_k)$. Derive D_s as follows. Resolve D_{s+1} with C_{s+1} on $lin(\neg C_{s+1}) + (x_k - 1)$ to get the clause $E_1 := D_s \vee (-x_1 - \ldots - x_{k-1} - 1) = 0 \vee x_1 = 1 \vee \ldots \vee x_{k-1} = 1$ and apply semantic weakening to get $E_1' := D_s \vee x_1 = 1 \vee \ldots \vee x_{k-1} = 1$. Resolve D_{s+1} with E_1' on $lin(\neg C_{s+1}) + (x_{k-1} - 1)$ and apply semantic weakening to get the clause $E_2' := D_s \vee x_1 = 1 \vee \ldots \vee x_{k-2} = 1$. After k steps the clause $D_s = E_k'$ can be derived. ◀

The following proposition is straightforward, but useful as it allows, for example, to transfer results about $\text{Res}(\text{lin}_{\mathbb{Q}})$ to $\text{Res}(\text{lin}_{\mathbb{Z}})$.

▶ **Proposition 9.** *If* R *is an integral domain and* $Frac(R)$ *is its field of fractions, then* $\text{Res}(\text{lin}_R)$ *is equivalent to* $\text{Res}(\text{lin}_{Frac(R)})$ *and tree-like* $\text{Res}(\text{lin}_R)$ *is equivalent to tree-like* $\text{Res}(\text{lin}_{Frac(R)})$.

Proof. Every proof in $\text{Res}(\text{lin}_R)$ is also a proof in $\text{Res}(\text{lin}_{Frac(R)})$. To get the converse, just multiply every line by the least common multiple (lcm) of all the coefficients in the $\text{Res}(\text{lin}_{Frac(R)})$ proof. If $a_1, \ldots, a_N \in R$ is the list of denominators of all the coefficients in a $\text{Res}(\text{lin}_{Frac(R)})$ proof π, then under a reasonable encoding of R: $|lcm(a_1, \ldots, a_N)| \leq |a_1| + \cdots + |a_N| \leq |\pi|$. Therefore the corresponding $\text{Res}(\text{lin}_R)$ proof is of size at most $O(|\pi|^2)$. ◀

[6] There is, however, one minor difference in the formulation of syntactic Res$(\oplus)$ and $\text{Res}(\text{lin}_{\mathbb{F}_2})$: the former does not have the boolean axioms, but has an extra rule (*addition rule*).

3.1 Basic Counting in $\mathrm{Res}(\mathrm{lin}_{\boldsymbol{R}})$ and $\mathrm{Res}_{\boldsymbol{sw}}(\mathrm{lin}_{\boldsymbol{R}})$

Here we introduce several unsatisfiable sets of linear clauses that express some counting principles, and serve to exemplify the ability of dag-like $\mathrm{Res}(\mathrm{lin}_R)$, tree-like $\mathrm{Res}(\mathrm{lin}_R)$ and tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ to reason about counting, for a ring R. We then summarize what we know about refutations of these instances in our different systems, proving along the way some upper bounds and stating some lower bounds proved in the sequel.

Our unsatisfiable instances are the following:

Linear systems: If $A = (B|b)$ is an $m \times (n+1)$ matrix over R, where the B sub-matrix consists of the first n columns, such that $B\overline{x} = b$ has no 0-1 solutions, then (B_i is the ith row in B):

$$\mathsf{LinSys}(A) := \{B_i \cdot \overline{x} = b_i\}_{i\in[m]}\,. \tag{5}$$

Subset Sum: Let f be a linear form over R such that $0 \notin im_2(f)$. Then,

$$\mathsf{SubSum}(f) := \{f = 0\}\,. \tag{6}$$

Image avoidance: Let f be a linear form over R and recall the notation $\langle f \neq A\rangle$ from Sec. 2.1. We define

$$\mathsf{ImAv}\,(f) := \{\langle f \neq A\rangle : A \in im_2(f)\}\,. \tag{7}$$

We also consider the following (tautological) generalization of the boolean axiom $x = 0 \vee x = 1$.

Image axiom: For f a linear form, define

$$\mathsf{Im}(f) := \bigvee_{A\in im_2(f)} f = A\,. \tag{8}$$

Dag-Like $\mathrm{Res}(\mathrm{lin}_{\boldsymbol{R}})$

Upper bounds. For any given linear polynomial f, $\mathsf{Im}(f)$ has a $\mathrm{Res}(\mathrm{lin}_R)$-derivation of polynomial-size (in the size of $\mathsf{Im}(f)$):

▶ **Proposition 10.** *Let $f = \sum_{i=1}^{n} a_i x_i + b$ be a linear polynomial over R. There exists a $\mathrm{Res}(\mathrm{lin}_R)$ derivation of $\mathsf{Im}(f)$ of size polynomial in $|\mathsf{Im}(f)|$ and of principal width at most 3.*

Proof. We construct derivations of $\mathsf{Im}\left(\sum_{i=1}^{k} a_i x_i + b\right)$, $0 \le k \le n$, inductively on k.

Base case: $k = 0$. In this case $\mathsf{Im}(b)$ is just the axiom $b = b$ and thus derived in one step.

Induction step: Let $f_k := \sum_{i=1}^{k} a_i x_i + b$ and assume $\mathsf{Im}(f_k)$ was already derived. Derive $C_0 := \left(\bigvee_{A\in im_2(f_k)} f_k + a_{k+1}x_{k+1} = A\right) \vee x_{k+1} = 1$ from $\mathsf{Im}(f_k)$ by $|im_2(f_k)|$ many resolution applications with $x_{k+1} = 0 \vee x_{k+1} = 1$. Similarly derive $C_1 := \left(\bigvee_{A\in im_2(f_k)} f_k + a_{k+1}x_{k+1} = A + a_{k+1}\right) \vee x_{k+1} = 0$ and obtain $\mathsf{Im}(f_{k+1})$ by resolving C_0 with C_1 on x_{k+1}. The size of the derivation is $n \cdot |\mathsf{Im}(f)|$, and as there is no clause with more than 3 equations that determines non-parallel hyperplanes, hence the principal width of the derivation is at most 3. ◀

▶ **Proposition 11.** *For every linear polynomial f such that $0 \notin im_2(f)$, the contradiction $\mathsf{SubSum}(f)$ admits $\mathrm{Res}(\mathrm{lin}_R)$ refutation of size polynomial in $|\mathsf{Im}(f)|$.*

Proof. First construct the shortest derivation of $\mathsf{Im}(f)$, and then by a sequence of $|im_2(f)|$ many application of the resolution rule with $f = 0$ derive the empty clause. By Proposition 10 the resulting refutation is of polynomial in $|\mathsf{Im}(f)|$ size. ◀

▶ **Proposition 12.** *Let f be a linear polynomial over R, $a \in im_2(f)$ and $\phi = \{\langle f \neq b\rangle\}_{b \in im_2(f), b \neq a}$. Then there exists* $\mathrm{Res}(\mathrm{lin}_R)$ *derivation π of $f = a$ from ϕ, such that $S(\pi) = poly(|\phi|)$ and $\omega_0(\pi) \leq 3$.*

Proof. Let $A_1, \ldots, A_N = a$ be an enumeration of all the elements in $im_2(f)$. By Proposition 10 there exists a derivation of $\left(\bigvee_{i \geq 1} f = A_i\right)$ of principal width at most 3. For $1 < k < N$, we derive $C := \left(\bigvee_{i \geq k+1} f = A_i\right)$ from $\left(\bigvee_{i \geq k} f = A_i\right) = (C \vee f = A_k)$ and $\langle f \neq A_k\rangle = (C \vee f = A_1 \vee \cdots \vee f = A_{k-1})$ in $k-1$ steps as follows: at the sth step we get $(C \vee f - f = A_s - A_k \vee f = A_{s+1} \vee \cdots \vee f = A_{k-1}) = (C \vee f = A_{s+1} \vee \cdots \vee f = A_{k-1})$ by resolving $C \vee f = A_s \vee \cdots \vee f = A_{k-1}$ with $C \vee f = A_k$. We thus obtain a derivation of principal width $\omega_0 \leq 3$ and of size $(1 + \cdots + (N-2))|f| = \frac{(N-1)(N-2)}{2}|f|$. ◀

▶ **Corollary 13.** *For every ring R and every linear polynomial f the contradiction* $\mathsf{ImAv}(f)$ *admits polynomial-size* $\mathrm{Res}(\mathrm{lin}_R)$ *refutations.*

Proof. Pick some $a \in im_2(f)$. By Proposition 12 there is a derivation of $f = a$ from $\mathsf{ImAv}(f)$ of polynomial size. This derivation can be extended to a refutation of $\mathsf{ImAv}(f)$ by a sequence of resolution rule applications of $f = a$ with $\langle f \neq a\rangle \in \mathsf{ImAv}(f)$. ◀

All $\mathrm{Res}(\mathrm{lin}_R)$ upper bounds for $\mathsf{LinSys}(A)$ are tree-like. So for more $\mathsf{LinSys}(A)$ upper bounds we refer the reader to the tree-like $\mathrm{Res}(\mathrm{lin}_R)$ upper bounds further in this section.

Lower bounds. In Sec. 4 we prove an exponential lower bound for $\mathsf{SubSum}(f)$ in case f is a linear polynomial with large coefficients (Theorem 21).

Tree-Like $\mathrm{Res}(\mathrm{lin}_R)$

Upper bounds. In case R is a finite ring, in Sec. 5.1 we prove that the clauses in $\mathsf{Im}(f)$ admit derivations of polynomial size (Theorem 29). Obviously, in that case (R is finite) any unsatisfiable R-linear equation $f = 0$ has at most $|R|$ variables and $\mathsf{SubSum}(f)$ are always refutable in constant size. In contrast, in case $R = \mathbb{Q}$ we prove a lower bound for $\mathsf{Im}(f)$, $\mathsf{SubSum}(f)$ and $\mathsf{ImAv}(f)$ for a specific f with small coefficients (see the lower bounds below).

In case a matrix $A = (B|b)$ with entries in a field $\mathbb{F}$ defines a system of equations $B\overline{x} = b$, that is unsatisfiable under arbitrary $\mathbb{F}$-valued assignments (not just under 0-1 assignments), we prove a polynomial upper bound for tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations of $\mathsf{LinSys}(A)$.

▶ **Proposition 14.** *If a $m \times (n+1)$ matrix $A = (B|b)$ with entries in a field $\mathbb{F}$ is such that $B\overline{x} = b$ has no $\mathbb{F}$-valued solutions, then there exists tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutation of* $\mathsf{LinSys}(A)$ *of linear size.*

Proof. It is a well-known fact from linear algebra that $B\overline{x} = b$ has no $\mathbb{F}$-valued solutions iff there exists $\alpha \in \mathbb{F}^m$ such that $\alpha^T B = 0$ and $\alpha^T b = 1$. Therefore, by $m-1$ resolutions of $B_1\overline{x} - b_1 = 0, \ldots, B_m\overline{x} - b_m = 0$ we can derive $-\alpha_1(B_1\overline{x} - b_1) - \ldots - \alpha_m(B_m\overline{x} - b_m) = 0$, which is $1 = 0$. ◀

Lower bounds. In Sec. 4 we prove tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ exponential-size lower bounds for derivations of $\mathsf{Im}(f)$ and refutations of $\mathsf{SubSum}(f)$ for any f (Corollary 34 and Theorem 35). For $\mathsf{ImAv}(f)$ whenever f is of the form $f = \epsilon_1 x_1 + \ldots + \epsilon_n x_n - A$ for some $\epsilon_i \in \{-1, 1\}, A \in \mathbb{F}$ the lower bound holds even for the stronger system tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ (see below).

Tree-Like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$

Upper bounds. Most of the instances above admit short derivations/refutations in tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$: $\mathsf{Im}(f)$ is semantic weakening of $0 = 0$ and thus derivable in one step; The empty clause is a semantic weakening of $\mathsf{SubSum}(f)$ and $\mathsf{LinSys}(A)$ and thus can be refuted via deriving $\bigvee_{i\in[m]} \langle A_i\overline{x} - b_i \neq 0\rangle$ as a semantic weakening of $0 = 0$ and resolving it with equalities in $\mathsf{LinSys}(A) = \{A_i\overline{x} - b_i = 0\}_{i\in[m]}$.

Lower bounds. In case $\mathbb{F}$ is a field of characteristic zero, $\mathsf{ImAv}(f)$ are hard even for tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ whenever f is of the form $f = \epsilon_1 x_1 + \ldots + \epsilon_n x_n - A$ for some $\epsilon_i \in \{-1, 1\}, A \in \mathbb{F}$ (Theorem 37).

3.2 CNF Upper Bounds for $\mathrm{Res}(\mathrm{lin}_R)$

In this section we outline two basic polynomial upper bounds, which we use to establish our separations in subsequent sections: short tree-like $\mathrm{Res}(\mathrm{lin}_R)$ refutations for CNF encodings of linear systems over a ring R, and short $\mathrm{Res}(\mathrm{lin}_R)$ refutations for $\neg\mathrm{PHP}^m_n$. Together with our lower bounds, these imply the separation between tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ and tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}'})$, where $\mathbb{F}, \mathbb{F}'$ are fields of positive characteristic such that $char(\mathbb{F}) \neq char(\mathbb{F}')$. The short refutation of the pigeonhole principle will imply a separation between dag-like and tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ for fields $\mathbb{F}$ of characteristic 0.

In what follows we consider standard CNF encodings of linear equations $f = 0$ where the linear equations are considered as boolean functions (i.e., functions from 0-1 assignments to $\{0, 1\}$); we do not use extension variable in these encodings.

▶ **Proposition 15.** *Let $\mathbb{F}$ be a field and $A\overline{x} = b$ be a system of linear equations that has no solution over $\mathbb{F}$, where A is $k \times n$ matrix with entries in $\mathbb{F}$, and A_i denotes the ith row in A. Assume that ϕ_i is a CNF encoding of $A_i \cdot \overline{x} - b_i = 0$, for $i \in [k]$. Then, there exists a tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutation of $\phi = \{\phi_i\}_{i\in[k]}$ of size polynomial in $|\phi| + \sum_{i\in[k]} \left|A_i \cdot \overline{x} - b_i = 0\right|$.*

Proof. The idea is to derive the actual linear system of equations from their CNF encoding, and then refute the linear system using a previous upper bound (Proposition 14).

If n_i is the number of variables in $A_i \cdot \overline{x} - b_i = 0$, then $|\phi_i| = \Theta(2^{n_i})$. By Proposition 28 proved in the sequel there exists a tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ derivation of $A_i \cdot \overline{x} - b_i = 0$ from ϕ_i of size $O(2^{n_i}|A_i \cdot \overline{x} - b_i = 0|) = O(|\phi_i| \cdot \left|A_i \cdot \overline{x} - b_i = 0\right|)$.

By Proposition 14 there exists a tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutation of $\{A_i \cdot \overline{x} - b_i = 0\}_{i\in[k]}$ of size $O\left(\sum_{i\in[k]} |A_i \cdot \overline{x} - b_i = 0|\right)$. The total size of the resulting refutation of ϕ is $O\left(\sum_{i\in[k]} \left|\phi_i\right| \cdot |A_i \cdot \overline{x} - b_i = 0|\right)$ and thus is $O\left(\left(\sum_{i\in[k]} |\phi_i| + \sum_{i\in[k]} |A_i \cdot \overline{x} - b_i = 0|\right)^2\right) = O\left(\left(|\phi| + \sum_{i\in[k]} |A_i \cdot \overline{x} - b_i = 0|\right)^2\right)$. ◀

As a corollary we get the polynomial upper bound for the Tseitin formulas (see Sec. 2.3.2 for the definition):

▶ **Theorem 16.** *Let $G = (V, E)$ be a d-regular directed graph, p a prime number, $\sigma : V \to \mathbb{F}_p$ such that $\sum_{u \in V} \sigma(u) \not\equiv 0 \pmod p$, then $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ admit tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_p})$ refutations of polynomial size.*

Proof. $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ is an unsatisfiable system of linear equations over $\mathbb{F}_p$ (note that no assignment of $\mathbb{F}$-elements to the variables in $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ is satisfying, and so we do not need to use the (non-linear) boolean axioms to get the unsatisfiability of the system of equations). Therefore, by Proposition 15 there exists a tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_p})$ refutation of $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ of polynomial size. ◀

▶ **Theorem 17** (Raz and Tzameret [26])**.** *Let R be a ring such that $char(R) = 0$. There exists a $\mathrm{Res}(\mathrm{lin}_R)$ refutation of $\neg PHP^m_n$ of polynomial size.*

Proof. This follows from the upper bound of [26] for $\mathrm{Res}(\mathrm{lin}_{\mathbb{Z}})$ and the fact that any $\mathrm{Res}(\mathrm{lin}_{\mathbb{Z}})$ proof can be interpreted as $\mathrm{Res}(\mathrm{lin}_R)$ if R is of characteristic 0. ◀

4 Dag-Like Lower Bound

4.1 Lower Bound for Subset Sum with Large Coefficients

In this section we prove an exponential lower bound on the size of dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutations of $\mathsf{SubSum}(f)$, where $f = 1 + x_1 + \cdots + 2^n x_n$.

The lower bound is obtained by defining a mapping, that sends every refutation π of $f = 0$ to a derivation π' from the boolean axioms of some clause C_π, in such a way that π' satisfies two properties:

1. π' is at most polynomially larger than π;
2. C_π is exponentially large.

We ensure that the second property holds by defining the construction of π' in such a way that every disjunct $g = 0$ in C_π has a sufficiently small number Z_g of 0-1 solutions, namely Z_g is at most 2^{cn}, for some constant $c < 1$. This, together with the observation that C_π must be a boolean tautology, because it is derivable from the boolean axioms only, implies that C_π must be of exponential size (since C_π has 2^n satisfying assignments and each disjunct contributes at most 2^{cn} satisfying disjunctions). Therefore, by the first property, π must be of exponential size.

The fact that f has exponentially large coefficients is essential in our proof that C_π is of exponential size. All contradictions of the form $f = 0$, where f has polynomially bounded coefficients, have polynomial dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutations and, thus, there is no hope to prove strong bounds for dag-like refutations in this case. However, in Sec 5 we prove that any $f = 0$, as long as f depends on n variables, must have tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutations of size at least $2^{\Omega(\sqrt{n})}$. The argument relies on a similar transformation from refutations π of $f = 0$ to derivations of some C_π and in this way reduces the problem to proving size lower bounds against tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ derivations of C_π from the boolean axioms.

In order to deal with both tree-like and dag-like lower bounds we formulate and prove a generalised statement about the translation. For both dag-like and tree-like lower bounds we need that for all the disjuncts $g = 0$ in C_π a certain predicate $\mathcal{P}$ holds for g. In case of the dag-like bound, $\mathcal{P}(g) = 1$ iff $g = 0$ has at most 2^{cn} 0-1 solutions, while in case of the tree-like bound $\mathcal{P}(g) = 1$ iff g depends on at least $\frac{n}{2}$ variables. In Theorem 18 we prove that the translation can be achieved as long as $\mathcal{P}$ satisfies certain properties (in what follows $\mathbb{F}[x_1, \ldots, x_n]_{\leq 1}$ denotes the linear polynomials in $\mathbb{F}[x_1, \ldots, x_n]$).

▶ **Theorem 18.** *Let f be a linear polynomial over a field $\mathbb{F}$ with n variables and let $\mathcal{P} : \mathbb{P}(\mathbb{F}[x_1, \ldots, x_n]_{\leq 1}) \to \{0, 1\}$ be a predicate on the projective space[7] of linear polynomials over $\mathbb{F}$ satisfying the following properties:*

1. *for all linear polynomials g and for all but at most one $a \in \mathbb{F}$: $\mathcal{P}(g + af) = 1$;*
2. *for all $b \in \mathbb{F}$: $\mathcal{P}(b + f) = 1$.*

If there exists $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *(resp. tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$*) refutation of $f = 0$ of size S, then there exists* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *(resp. tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$*) derivation of size $O(n \cdot S^3)$ of a linear clause $\bigvee_{j \in [N]} g_j = 0$ (for some positive N), where $\mathcal{P}(g_j) = 1$ for every $j \in [N]$.*

Proof. We now sketch the plan of the proof. Assume that π is a $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutation of $f = 0$. By taking out resolutions with $f = 0$ we transform π into a derivation π' of some clause C such that $\mathcal{P}(g) = 1$ for every disjunct $g = 0$ in C. We do this in such a way that π' is not much larger than π: $|\pi'| = O(n \cdot |\pi|^3)$.

Denote $\pi_{\leq k}$ the fragment of π, consisting of the first k lines of π. By induction on k we define the sequence π'_k of derivations of some clauses D_k from boolean axioms. The derivations π'_k are defined together with a surjective function τ_k from lines of $\pi_{\leq k}$ to lines of π'_k such that if $D = \left(\bigvee_{t \in [m]} g_t = 0 \right)$ is a line in $\pi_{\leq k}$, then

$$\tau_k(D) = \left(\bigvee_{t \in [m]} g_t + a_t f = 0 \right) \vee \bigvee_{s \in [m']} h_s = 0$$

is a line in π'_k, where $a_t \in \mathbb{F}$ and each h_s is a linear polynomial. Moreover, $\tau_k(D)$ satisfies the following properties:

1. For each $h_s = 0$: $\mathcal{P}(h_s) = 1$.
2. The sets H_D of disjuncts $h_s = 0$ in $\tau_k(D)$ are not too large: $\left| \bigcup_{D \in \pi_{\leq k}} H_D \right| \leq 2|\pi_{\leq k}|$.
3. The numbers a_t and coefficients of h_s are not too large: their bit-size does not exceed the maximal bit-size of coefficients in π.

Before we proceed to the inductive definition of π'_k, we finish the proof assuming that π'_k described above exists. If l is the length of π, then $\pi' := \pi'_l$ contains a derivation of $\tau_l(\emptyset)$, where $\emptyset$ denotes the empty clause.

We now turn to the inductive definition of π'_k.

Base case: Define π'_0 to be the empty derivation.
Induction step: Assume π'_k and τ_k satisfy the properties above and k is smaller than the length of π. If D is the last line of $\pi_{\leq k+1}$, then τ_{k+1} extends τ_k to D and π'_{k+1} either extends π'_k with $\tau_{k+1}(D)$ or coincides with π'_k. Consider the possible cases in which the last line D of $\pi_{\leq k+1}$ is derived:

Case 1: Boolean axiom: $D = (x_i = 0 \vee x_i = 1)$. Then π'_{k+1} extends π'_k with D and $\tau_{k+1}(D) = D$.

Case 2: $D = (f = 0)$. Then π'_{k+1} extends π'_k with the axiom $0 = 0$ and $\tau_{k+1}(D) = (f - f = 0)$.

Case 3: D is derived by resolution: $D = (C_1 \vee C_2 \vee \alpha G_1 + \beta G_2 = 0)$ for some lines $(C_1 \vee G_1 = 0)$ and $(C_2 \vee G_2 = 0)$ in $\pi_{\leq k}$.

---

[7] Here, a *projective space* $\mathbb{P}(\mathbb{F}[x_1, \ldots, x_n]_{\leq 1})$ means the set of linear polynomials quotient by the relation $f \sim \alpha f$ for nonzero scalars α.

If $C_i = \bigvee_{t\in[m_i]} g_t^{(i)} = 0$, by induction hypothesis $\tau_k(C_i \vee G_i = 0)$ is of the form ($i = 1, 2$; $A_i \in \mathbb{F}$):

$$\tau_k(C_i \vee G_i = 0) = \left(G_i + A_i f = 0 \vee \bigvee_{t\in[m_i]} g_t^{(i)} + a_t^{(i)} f = 0 \right) \vee \bigvee_{s\in[m'_i]} h_s^{(i)} = 0$$

Define $\tau_{k+1}(D)$ to be the following resolution of $\tau_k(C_1 \vee G_1 = 0) \in \pi'_k$ with $\tau_k(C_2 \vee G_2 = 0) \in \pi'_k$:

$$\tau_{k+1}(D) := \left(\alpha G_1 + \beta G_2 + (\alpha A_1 + \beta A_2) f = 0 \vee \bigvee_{i=1,2} \bigvee_{t\in[m_i]} g_t^{(i)} + a_t^{(i)} f = 0 \right) \vee \vee \bigvee_{i=1,2} \bigvee_{s\in[m'_i]} h_s^{(i)} = 0$$

The derivation π'_{k+1} extends π'_k with $\tau_{k+1}(D)$. It remains to be shown that $\tau_{k+1}(D)$ is of required form and that τ_{k+1} satisfies the required properties.

If we consider the clause $(\alpha G_1 + \beta G_2 = 0 \vee C_1 \vee C_2)$ as a *multiset* of disjuncts and C_1, C_2, as usual, as sets of disjuncts, there can be up to three identical copies of $g = 0$ (from C_1, from C_2 and from $\{\alpha G_1 + \beta G_2 = 0\}$), that are contracted to a single element in the set D. In $\tau_{k+1}(D)$ these copies can be different because of different $+af$ terms and, thus, can be non-contractible.

For every disjunct $g = 0$ in D, denote $\mathcal{F}_g$ the set of disjuncts in $\tau_{k+1}(D)$ that correspond to g, namely, $(g_j^{(i)} + a_j^{(i)} f = 0) \in \mathcal{F}_g$ iff $g_j^{(i)} = g$ and $(\alpha G_1 + \beta G_2 + (\alpha A_1 + \beta A_2) f = 0) \in \mathcal{F}_g$ iff $\alpha G_1 + \beta G_2 = g$. For every $g = 0 \in D$, pick one element $g + af = 0 \in \mathcal{F}_g$, which minimises $\mathcal{P}(g + af)$, and denote X the set of these elements. Denote $Y := \left(\bigcup_{g=0\in D} \mathcal{F}_g\right) \setminus X$. Write $\tau_{k+1}(D)$ as follows:

$$\tau_{k+1}(D) = \left(\bigvee_{g+af=0\in X} g + af = 0 \right) \vee \left(\bigvee_{i=1,2} \bigvee_{s\in[m'_i]} h_s^{(i)} = 0 \vee \bigvee_{g+af=0\in Y} g + af = 0 \right)$$

We now show that τ_{k+1} satisfies all the desired properties:

1. For every $h_s^{(i)} = 0$, $\mathcal{P}(h_s^{(i)}) = 1$ holds by induction hypothesis. For every $g + af = 0 \in Y$, $\mathcal{P}(g + af) = 1$ holds by definition of Y.
2. Note that $|H_D \setminus \{h_s^{(i)} = 0\}_{i,s}| \leq 2|D|$. By induction hypothesis $|\bigcup_{\tilde{D}\in\pi_{\leq k}} H_{\tilde{D}}| \leq 2|\pi_{\leq k}|$. It follows that $|\bigcup_{\tilde{D}\in\pi_{\leq k}} H_{\tilde{D}} \cup H_D| = |\bigcup_{\tilde{D}\in\pi_{\leq k}} H_{\tilde{D}} \cup (H_D \setminus \{h_s^{(i)} = 0\}_{i,s})| \leq |\bigcup_{\tilde{D}\in\pi_{\leq k}} H_{\tilde{D}}| + |H_D \setminus \{h_s^{(i)} = 0\}_{i,s}| \leq 2|\pi_{\leq k}| + 2|D| \leq 2|\pi_{\leq k+1}|$.
3. The absolute values of coefficients in π'_{k+1} do not exceed the maximal absolute value of coefficients in π.

Case 4: D is derived by simplification from a line $D \vee b = 0$ in $\pi_{\leq k}$. If $D = \left(\bigvee_{t\in[m]} g_t = 0 \right)$, then $\tau_k(D \vee b = 0)$ has the form: $\tau_k(D \vee b = 0) = \left(\bigvee_{t\in[m]} g_t + a_t f = 0 \right) \vee b + af = 0$.

If $a = 0$, we apply simplification to $\tau_k(D \vee b = 0)$ to derive $\tau_{k+1}(D) := \left(\bigvee_{t\in[m]} g_t + a_t f = 0 \right)$ and let π'_{k+1} extend π'_k .

Otherwise, if $a \neq 0$, we define $\tau_{k+1}(D)$ to be $\tau_{k+1}(D) := \tau_k(D \vee b = 0)$ and $\pi'_{k+1} := \pi'_k$.

Case 5: D is derived by weakening from a line C of $\pi_{\leq k}$: $D = (C \vee g = 0)$ for some g. Define $\tau_{k+1}(D) := (\tau_k(C) \vee g = 0)$ and let π'_{k+1} extend π'_k with $\tau_{k+1}(D)$. ◀

▶ **Lemma 19.** *Let $g : \mathbb{Z}^n \to \mathbb{Z}$ be a linear function. For the sets $I(g) := im_2(g)$ and $K(g) := g^{-1}(0) \cap \{0,1\}^n$ it holds that $|I(g)| \cdot |K(g)| \leq 3^n$.*

Proof. For every element $a \in I(g)$ choose some $v_a \in \{0,1\}^n$ such that $g(v_a) = a$. Consider the set $X := \{v_a + u\}_{a \in I(g), u \in K(g)} \subset \{0,1,2\}^n$.

It is easy to see that $|X| = |I(g)| \cdot |K(g)|$. Indeed, if $v_a + u = v_{a'} + u'$, then $g(v_a) + g(u) - g(0) = g(v_a + u) = g(v_{a'} + u') = g(v_{a'}) + g(u') - g(0)$ and therefore $a = a', v_a = v_{a'}, u = u'$.

On the other hand, $|X| \leq 3^n$. ◀

▶ **Lemma 20.** *Let $f = 1 + 2x_1 + \cdots + 2^n x_n$ and $g : \mathbb{Z}^n \to \mathbb{Z}$ be a linear function. For any $a \in \mathbb{Z} \backslash \{0\}$ one of the following holds:*

1. *$g = 0$ has at most $3^{\frac{n}{2}}$ 0-1 solutions.*
2. *$g + af = 0$ has at most $3^{\frac{n}{2}}$ 0-1 solutions.*

Proof. For every $b \in \mathbb{Z}$, there exists at most one boolean assignment that satisfies both $g = b$ and $b + af = 0$. Therefore the number of 0-1 solutions of $g + af = 0$ is at most the size of the boolean image $im_2(g)$ of g. By Lemma 19 either $|im_2(g)| \leq 3^{\frac{n}{2}}$ or $|g^{-1}(0) \cap \{0,1\}^n| \leq 3^{\frac{n}{2}}$. ◀

▶ **Theorem 21.** *Let $f = 1 + 2x_1 + \cdots + 2^n x_n$. Any $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutation of $f = 0$ is of size $2^{\Omega(n)}$.*

Proof. Define the predicate $\mathcal{P}(g)$ on linear polynomials over $\mathbb{Q}$ as follows: $\mathcal{P}(g) = 1$ iff $g = 0$ has at most $2^{(0.5 \cdot \log 3)n}$ 0-1 solutions. By Lemma 20, $\mathcal{P}$ satisfies the properties in Theorem 18. Therefore, by Theorem 18, if π is a refutation of $f = 0$, then there exists a derivation π' of some clause $C = \bigvee_{j \in [N]} g_j = 0$ from the boolean axioms, where each $g_j = 0$ has at most $2^{(0.5 \cdot \log 3)n}$ 0-1 solutions. Moreover $|\pi'| = O(n \cdot |\pi|^3)$. As C must be a boolean tautology, that satisfied by 2^n assignments, it must contain at least $2^{(1-0.5 \cdot \log 3)n}$ disjuncts (because every disjunct contributes at most $2^{(0.5 \cdot \log 3)n}$ satisfying assignments). Therefore $|\pi| = 2^{\Omega(n)}$. ◀

5 Tree-Like Lower Bounds

5.1 Nondeterministic Linear Decision Trees

In this section we extend the classical correspondence between tree-like resolution refutations and decision trees (cf. [6]) to tree-like $\mathrm{Res}(\mathrm{lin}_R)$ and tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$. We define *nondeterministic linear decision trees* (NLDT), which generalize parity decision trees, proposed in [17] for $R = \mathbb{F}_2$, to arbitrary rings. We shall use these trees in the sequel to establish some of our upper and lower bounds (though not for our dag-like lower bounds).

Let ϕ be a set of linear clauses (that we wish to refute) and Φ a set of linear non-equalities over R (that we take as assumptions). Consider the following two decision problems:

DP1. Assume $\Phi \models \neg\phi$. Given a satisfying boolean assignment ρ to Φ, determine which clause $C \in \phi$ is violated by ρ by making queries of the form: which of $f|_\rho \neq 0$ or $g|_\rho \neq 0$ hold for linear forms f, g in case $f|_\rho + g|_\rho \neq 0$.

DP2. Similar to DP1, only that we assume $\Phi \models_R \neg\phi$, and given R-valued assignment ρ, satisfying Φ, we ask to find a clause $C \in \phi$ falsified by ρ.

Below we define NLDTs of types $\mathrm{DT}_{sw}(R)$ and $\mathrm{DT}(R)$, which provide solutions to DP1 and DP2, respectively. The root of a tree is labeled with a system Φ, the edges in a tree are labeled with linear non-equalities of the form $f \neq 0$ and the leaves are labeled with clauses $C \in \phi$. Informally, at every node v there is a set Φ_v of all *learned* non-equalities, which is the union of Φ and the set of non-equalities along the path from the root to the node. If v is an internal node, two outgoing edges $f \neq 0$ and $g \neq 0$ define a query to be made at v, where $f + g \neq 0$ is a consequence of Φ_v. If v is a leaf, then $\Phi_v \cup \Phi$ contradicts a clause $C \in \phi$.

Starting from the root, based on the assignment ρ, we go along a path, from the root to a leaf, by choosing in each node to go along the left edge $f \neq 0$ or the right edge $g \neq 0$, depending on whether $f|_\rho \neq 0$ or $g|_\rho \neq 0$. Note that $f|_\rho \neq 0$ and $g|_\rho \neq 0$ may not be mutually exclusive, and this is why the decision made in each node may be *nondeterministic*.

▶ **Definition 22** (Nondeterministic linear decision tree NLDT; $\mathrm{DT}(R)$, $\mathrm{DT}_{sw}(R)$)**.** *Let ϕ be a set of linear clauses and Φ be a set of linear non-equalities over a ring R. A nondeterministic linear decision tree T of type $DT(R)$ and of type $DT_{sw}(R)$ for (ϕ, Φ) is a binary rooted tree, where every edge is labeled with some linear non-equality $f \neq 0$, in such a way that the conditions below hold. In what follows, for a node v, we denote by $\Phi_{r \rightsquigarrow v}$ the set of non-equalities along the path from the root r to v and by Φ_v the set $\Phi_{r \rightsquigarrow v} \cup \Phi$. We say that Φ_v is the set of* learned *non-equalities at v.*

1. *Let v be an internal node. Then v has two outgoing edges labeled by linear non-equalities $f_v \neq 0$ and $g_v \neq 0$, such that:*
   - *If $T \in DT(R)$, then $\alpha f_v + \beta g_v \neq 0 \in \Phi_v \cup \{a \neq 0 \mid a \in R \setminus 0\}$ for some $\alpha, \beta \in R$.*
   - *If $T \in DT_{sw}(R)$, then $\Phi_v \models \alpha f_v + \beta g_v \neq 0$ for some $\alpha, \beta \in R$.*
2. *A node v is a leaf if there is a linear clause $C \in \phi \cup \{0 = 0\}$ which is violated by Φ_v in the following sense:*
   - *If $T \in DT(R)$, then $\neg C \subseteq \Phi_v \cup \{a \neq 0 \mid a \in R \setminus 0\}$.*
   - *If $T \in DT_{sw}(R)$, then $\Phi_v \models \neg C$.*

In case Φ is empty, we sometimes simply write that the NLDT is for ϕ instead of $(\phi, \emptyset)$.

Assume $\Phi \models \neg\phi$. Then an NLDT for $(\phi \cup \{x = 0 \vee x = 1 \,|\, x \in vars(\phi)\}, \Phi)$ of type $\mathrm{DT}(R)$ can be converted into an NLDT of type $\mathrm{DT}_{sw}(R)$ for (ϕ, Φ) by truncating all maximal subtrees with all leaves from $\{x = 0 \vee x = 1 \,|\, x \in vars(\phi)\}$ and marking their roots with arbitrary clauses from ϕ.

Below we give several examples (and basic properties) of NLDTs.

▶ **Example 23.** Let ϕ be a set of clauses, representing unsatisfiable CNF. Then any standard decision tree on boolean variables is an NLDT for $\phi \cup \{x = 0 \vee x = 1 \,|\, x \in vars(\phi)\}$ of type $\mathrm{DT}(R)$, where a branching on the value of a variable x is realized by branching on $(1 - x) + x \neq 0$ to either $1 - x \neq 0$ or $x \neq 0$.

This is illustrated by (the proof of) the following proposition:

▶ **Proposition 24.** *If Φ is a set of linear non-equalities and ϕ is a set of linear clauses over R such that $\Phi \models \neg\phi$, then there exists a $DT(R)$ tree for $(\phi \cup \{x = 0 \vee x = 1 \,|\, x \in vars(\phi \cup \{\neg\Phi\})\}, \Phi)$ of size $O(2^n|\Phi|)$, where $n = |vars(\phi \cup \{\neg\Phi\})|$.*

Proof. Let $vars(\phi \cup \{\neg\Phi\}) = \{x_1, \ldots, x_n\}$ and fix an ordering on these variables. Construct a tree T_0 with 2^n nodes, that branches on $x_1, \ldots, x_n$, in this order. Thus, in every leaf v of T_0 a total assignment to the variables is determined (i.e., $\Phi_v = \{x_i \neq \nu_i\}_{i \in [n]} \cup \Phi$ for some $\nu_i \in \{0, 1\}$). Since $\Phi \models \neg\phi$, this assignment violates either some clause $C = (f_1 = 0 \vee \cdots \vee f_m = 0)$ in ϕ or some non-equality $g \neq 0$ in Φ. We augment T_0 to T by attaching a subtree to every leaf v of T_0 depending on whether the former or latter condition holds for v, as follows:

Case 1: $\{x_i \neq \nu_i\}_{i\in[n]} \models \neg C$. We attach a subtree to v that makes m sequences of branches as follows. If $f_i = a_1x_1 + \ldots + a_nx_n + b$ then $a_1(1-\nu_1)+\ldots+a_n(1-\nu_n)+b \neq 0$ holds and the ith sequence is the following sequence of "substitutions": $(a_1x_1 + a_2(1-\nu_2) + \ldots + a_n(1-\nu_n)+b)+(a_1(1-\nu_1)-a_1x_1) \neq 0$ to $a_1x_1+a_2(1-\nu_2)+\ldots+a_n(1-\nu_n)+b \neq 0$ and $a_1(1-\nu_1)-a_1x_1 \neq 0, \ldots, (a_1x_1+\ldots+a_{n-1}x_{n-1}+a_n(1-\nu_n)+b)+(a_n(1-\nu_n)-a_nx_n) \neq 0$ to $f_i \neq 0$ and $a_n(1-\nu_n) - a_nx_n \neq 0$. All the right branches lead to nodes u such that $\{x_i \neq 0, x_i \neq 1\} \subseteq \Phi_u$ for some $i \in [n]$ and thus they satisfy the DT(R) leaf condition in Definition 22. Such a sequence indeed performs substitutions: the edge to the leftmost node is $f_i \neq 0$ and as we go upwards, we apply the substitutions $x_n \leftarrow 1-\nu_n$, $\ldots$, $x_1 \leftarrow 1-\nu_1$ to this non-equality.
In the leftmost node w in the end of the mth sequence, $\{f_1 \neq 0, \ldots, f_m \neq 0\} \subseteq \Phi_w$ holds and thus again C is violated at w in the sense of Definition 22 and therefore w is a legal DT(R)-leaf.

Case 2: $\{x_i \neq \nu_i\}_{i\in[n]} \models g = 0$, where $g \neq 0 \in \Phi_v$. Let $g = a_1x_1 + \ldots + a_nx_n + b$. Attach to v a subtree that makes the following branches: $(a_1(1-\nu_1)+a_2x_2+\ldots+a_nx_n+b)-(a_1(1-\nu_1)-a_1x_1) \neq 0$ to $(a_1(1-\nu_1)+a_2x_2+\ldots+a_nx_n+b) \neq 0$ and $a_1(1-\nu_1)-a_1x_1 \neq 0,\ldots,$ $(a_1(1-\nu_1)+\ldots+a_{n-1}(1-\nu_{n-1})+a_n(1-\nu_n)+b)-(a_n(1-\nu_n)-a_nx_n) \neq 0$ to $1 \neq 0$ and $a_1(1-\nu_1)-a_1x_1 \neq 0$. All leaves of the subtree satisfy the condition for DT(R) leaves in Definition 22.

The tree T is a DT(R) tree for (ϕ, Φ). ◀

▶ **Example 25.** Let ϕ be as in Example 23. *Parity decision trees*, as defined in [17], are NLDTs for ϕ of type $\mathrm{DT}_{sw}(\mathbb{F}_2)$: branching on the value of an $\mathbb{F}_2$-linear form f is realized by branching from $(1-f)+f \neq 0$ to $1-f \neq 0$ and $f \neq 0$. And the converse also holds: a branching of $f+g \neq 0$ to $f \neq 0$ and $g \neq 0$, where, say, f is a non-constant $\mathbb{F}_2$-linear form, is equivalent to branching on the value of f.

▶ **Example 26.** Let $\phi = \{f_1 = 0, \ldots, f_m = 0\}$, where $f_1, \ldots, f_m$ are R-linear forms such that $f_1 + \ldots + f_m = 1$. Then a polynomial-size NLDT of type DT(R) for ϕ makes the following branchings, where all right edges lead to a leaf: $(f_1 + \ldots + f_{m-1}) + f_m \neq 0$ (this is just $1 \neq 0$) to $f_1 + \ldots + f_{m-1} \neq 0$ and $f_m \neq 0$, $\ldots$, $f_1 + f_2 \neq 0$ to $f_1 \neq 0$ and $f_2 \neq 0$.

We now show the equivalence between NLDTs and tree-like $\mathrm{Res}(\mathrm{lin}_R)$ proofs.

▶ **Theorem 27.** *Let ϕ be a set of linear clauses over a ring R and Φ be a set of linear non-equalities over R. Then, there exist decision trees DT(R) (resp. $\mathrm{DT}_{sw}(R)$) for $(\phi \cup \{x = 0 \vee x = 1 \mid x \in vars(\phi)\}, \Phi)$ (resp. (ϕ, Φ)) of size s iff there exist tree-like $\mathrm{Res}(\mathrm{lin}_R)$ (resp. tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$) derivations of the clause $\neg\Phi = \bigvee_{f\neq 0\in\Phi} f = 0$ from ϕ of size $O(s)$.*

Proof. ($\Rightarrow$) Let T_ϕ be an NLDT of type DT(R) or $\mathrm{DT}_{sw}(R)$ for ϕ. We construct a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ or tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ derivation from T_ϕ, respectively, as follows. Consider the tree of clauses π_0, obtained from T_ϕ by replacing every vertex u with the clause $\neg\Phi_u$. This tree is not a valid tree-like derivation yet. We augment it to a valid derivation π by appropriate insertions of applications of weakening and simplification rules.

Case 1: If $\neg\Phi_u \in \pi_0$ is a leaf, then Φ_u violates a clause $D \in \phi \cup \{0 = 0\}$. By condition 2 in Definition 22, $\neg\Phi_u$ must be a weakening of D (syntactic for $T_\phi \in \mathrm{DT}(R)$ and semantic for $T_\phi \in \mathrm{DT}_{sw}(R)$) and we add D as the only child of this node.

Case 2: Let $\neg\Phi_u \in \pi_0$ be an internal node with two outgoing edges labeled with $f_u \neq 0$ and $g_u \neq 0$.

If $T_\phi \in \mathrm{DT}(R)$, then $\alpha f_u + \beta g_u \neq 0 \in \Phi_u \cup \{a \neq 0 \,|\, a \in R \setminus 0\}$. Apply resolution to $\neg\Phi_{l(u)} = (\neg\Phi_u \vee f_u = 0)$ and $\neg\Phi_{r(u)} = (\neg\Phi_u \vee g_u = 0)$ to derive $\neg\Phi_u \vee \alpha f_u + \beta g_u = 0$. In case $\alpha f_u + \beta g_u \neq 0 \in \Phi_u$ this clause coincides with $\neg\Phi_u$ and no additional steps are required. In case $\alpha f_u + \beta g_u \neq 0 \in \{a \neq 0 \,|\, a \in R \setminus 0\}$ insert an application of the simplification rule to get a derivation of $\neg\Phi_u$.

If $T_\phi \in \mathrm{DT}_{sw}(R)$, $\Phi_u \models \alpha f_u + \beta g_u \neq 0$, we derive $\neg\Phi_u \vee \alpha f_u + \beta g_u = 0$ from $\neg\Phi_{l(u)} = (\neg\Phi_u \vee f_u = 0)$ and $\neg\Phi_{r(u)} = (\neg\Phi_u \vee g_u = 0)$ by an application of the resolution rule and then deriving $\neg\Phi_u$ by an application of the semantic weakening rule.

($\Leftarrow$) Conversely, assume π is a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ or a tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ derivation of a (possibly empty) clause $\mathcal{C}$ from ϕ. In what follows, when we say weakening we mean syntactic or semantic weakening depending on π being a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ or a tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ derivation, respectively.

Let the edges in the proof-tree of π be directed from conclusion to premises. We turn this proof-tree into a decision tree T_π for $(\phi, \neg\mathcal{C})$ as follows. Every node of outgoing degree 2 in the proof-tree π is a clause obtained from its children by a resolution rule. For each such node $C \vee D \vee (\alpha f + \beta g = 0)$ we label its outgoing edges to $C \vee f = 0$ and $D \vee g = 0$ with $f \neq 0$ and $g \neq 0$, respectively. We contract all unlabeled edges, which are precisely those corresponding to applications of weakening and simplification rules. If $C_1, \ldots, C_k$ is a maximal (with respect to inclusion) sequence of weakening and simplification rule applications (the latter occur only in $\mathrm{Res}(\mathrm{lin}_R)$ derivations), then we contract it to C_k. In this way we obtain the tree T_π, where every edge is labeled with linear non-equality and every node u is labeled with a clause C_u such that if $f \neq 0$ and $g \neq 0$ are labels of edges to the left $l(u)$ and to the right $r(u)$ children respectively, then C_u is a weakening and a simplification (the latter again in case of $\mathrm{Res}(\mathrm{lin}_R)$) of the clause $C \vee D \vee \alpha f + \beta g = 0$ for some $\alpha, \beta \in R$, such that $C_{l(u)} = (C \vee f = 0)$, $C_{r(u)} = (D \vee g = 0)$.

We now prove that T_π is a valid decision tree of type $\mathrm{DT}(R)$ (respectively, $\mathrm{DT}_{sw}(R)$) if π is a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ derivation (respectively, tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ derivation).

Case 1: Assume π is tree-like $\mathrm{Res}(\mathrm{lin}_R)$ derivation. We prove inductively that for every node u in T_π we have $\neg C_u \subseteq \Phi_u$.

Base case: u is the root r. We have $\Phi_r = \neg\mathcal{C} = \neg C_r$.

Induction step: For any other node u assume $\neg C_p \subseteq \Phi_p \cup \{a \neq 0 \,|\, a \in R \setminus 0\}$ holds for its parent node p. Let $f \neq 0$ be the label on the edge from p to u. Then $C_u = (C \vee f = 0)$ for some clause C and C_p must be of the form $(C \vee D)$ for some clause D, and hence $\neg C_u \subseteq \neg C \cup \{f \neq 0\} \subseteq \neg C_p \cup \{f \neq 0\} \subseteq \Phi_p \cup \{f \neq 0\} = \Phi_u$.

Now we show that T_π satisfies the conditions of Definition 22 for $\mathrm{DT}(R)$ trees.

- (Internal nodes) Let u be an internal node of T_π with outgoing edges labeled with $f \neq 0$ and $g \neq 0$. C_u must be both a weakening and a simplification of $(C \vee \alpha f + \beta g = 0)$ for some $\alpha, \beta \in R$ and a linear clause C. If $\alpha f + \beta g \neq 0 \in \{a \neq 0 \,|\, a \in R \setminus 0\}$, then the condition trivially holds, otherwise $\alpha f + \beta g = 0$ cannot be eliminated via simplification and thus $\alpha f + \beta g \neq 0 \in \neg C_u$ and $\neg C_u \subseteq \Phi_u$ imply $\alpha f + \beta g \neq 0 \in \Phi_u$ and the condition for internal nodes in Definition 22 is satisfied.
- (Leaves) Let u be a leaf of T_π. Then C_u must be both a weakening and a simplification of some clause C in $\phi \cup \{x = 0 \vee x = 1 \,|\, x \in vars(\phi)\} \cup \{0 = 0\}$, that is $C_u = (C \vee D)$ for some clause D. Therefore $\neg C_u \subseteq \Phi_u$ implies that C is falsified by Φ_u.

Case 2: Assume π is a tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ derivation. We prove inductively that for every node u in T_π, $C_u \models \neg\Phi_u$ holds.

Base case: u is the root r and we have $\neg\Phi_r = \mathcal{C} = C_r$.

Induction step: u is a node which is not the root. If $C_p \models \neg\Phi_p$ holds for its parent p and $f \neq 0$ is the label on the edge from p to u, then $(C \vee D \vee \alpha f + \beta g = 0) \models C_p$, $C_u = (C \vee f = 0)$ for some $\alpha, \beta \in R$ a linear form g and some linear clauses C, D. Therefore, $C_u = (C \vee f = 0) \models (C_p \vee f = 0) \models (\neg\Phi_p \vee f = 0) = \neg\Phi_u$.

We now show that T_π satisfies the conditions of Definition 22 for $\mathrm{DT}_{sw}(R)$ trees.

- (Internal nodes) Let u be an internal node of T_π with outgoing edges labeled with $f \neq 0$ and $g \neq 0$. Then $(C \vee \alpha f + \beta g = 0) \models C_u$ for some $\alpha, \beta \in R$ and a linear clause C. Therefore $C_u \models \neg\Phi_u$ implies $\Phi_u \models \alpha f + \beta g \neq 0$.
- (Leaves) Let u be a leaf of T_π. Then C_u must be a weakening of some clause C in $\phi \cup \{0 = 0\}$, that is, $C_u = (C \vee D)$ for some clause D. Therefore $C_u \models \neg\Phi_u$ implies that C is falsified by Φ_u. ◀

An immediate corollary is the following:

▶ **Proposition 28.** *If $\phi \cup \{C\}$ is a set of linear clauses over a ring R such that $\phi \models C$, then there exists a tree-like* $\mathrm{Res}(\mathrm{lin}_R)$ *derivation of C from ϕ of size $O(2^n|C|)$, where $n = \big|vars(\phi \cup \{C\})\big|$.*

Proof. By Proposition 24 there exists a $\mathrm{DT}(R)$ tree for $(\phi \cup \{x = 0 \vee x = 1 \,|\, x \in vars(\phi \cup \{C\})\}, \neg C)$ of size $O(2^n|C|)$ and, thus, by Theorem 27 there exists a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ derivation of C from ϕ of size $O(2^n|C|)$. ◀

We construct an NLDT to prove the following upper bound:

▶ **Proposition 29.** *Let R be a finite ring, $f = a_1x_1 + \cdots + a_nx_n$ a linear form over R, s_f the size of* $\mathsf{lm}(f)$ *(i.e., the size of its encoding) and $d_f = |im_2(f)|$. Then, there exists a tree-like* $\mathrm{Res}(\mathrm{lin}_R)$ *derivation of* $\mathsf{lm}(f)$ *of size $O(s_f n^{2d_f})$.*

Proof. We construct a decision tree of type $\mathrm{DT}(R)$ of size $O(s_f n^{2d_f})$ with the system $\Phi_r = \{f \neq A\}_{A \in im_2(f)}$ at its root r. By Theorem 27 this implies the existence of a tree-like $\mathrm{Res}(\mathrm{lin}_R)$ proof of $\mathsf{lm}(f)$ of the same size.

Let $f^{(1)} := a_1x_1 + \cdots + a_{\lfloor \frac{n}{2} \rfloor}x_{\lfloor \frac{n}{2} \rfloor}$ and $f^{(2)} := a_{\lfloor \frac{n}{2} \rfloor + 1}x_{\lfloor \frac{n}{2} \rfloor + 1} + \cdots + a_nx_n$. The decision tree for $\mathsf{lm}(f)$ is constructed recursively as a tree of height $2d_f$, where a subtree for $\mathsf{lm}\big(f^{(1)}\big)$ or for $\mathsf{lm}\big(f^{(2)}\big)$ is hanged from each leaf. At every node u of depth d the system of non-equalities is of the form: $\Phi_u = \Phi_r \cup \Phi_u^{(1)} \cup \Phi_u^{(2)}$, where $\Phi_u^{(i)} \subseteq \{f^{(i)} \neq A\}_{A \in im_2(f^{(i)})}$, $i \in \{1, 2\}$ and $|\Phi_u^{(1)}| + |\Phi_u^{(2)}| = d$. A node u is a leaf if and only if $\Phi_u^{(i)} = \{f^{(i)} \neq A\}_{A \in im_2(f^{(i)})}$ for some $i \in \{1, 2\}$. The branching at an internal node u is made by the non-equality $f^{(1)} - A_1 + f^{(2)} - A_2 \neq 0$, for some $A_i \in im_2(f^{(i)})$ where $f^{(i)} - A_i \notin \Phi_u^{(i)}, i \in \{1, 2\}$. The size s_n of this tree can be upper bounded as follows: $s_n \leq 2^{2d_f} s_{\lfloor \frac{n}{2} \rfloor + 1} + s_f 2^{2d_f} = O(s_f n^{2d_f})$. ◀

5.2 Prover-Delayer Games

The *Prover-Delayer game* is an approach to obtain lower bounds on resolution refutations introduced by Pudlák and Impagliazzo [25]. The idea is that the non-existence of small decision trees, and hence small tree-like resolution refutations, for an unsatisfiable formula, can be phrased in terms of the existence of a certain strategy for Delayer in a game against Prover, associated to the unsatisfiable formula. We define such games G^R and G^R_{sw} for decision trees $\mathrm{DT}(R)$ and $\mathrm{DT}_{sw}(R)$, respectively. Below we show (Lemma 30) that the existence of certain strategies for the Delayer in G^R and G^R_{sw} imply lower bounds on the size of $\mathrm{DT}(R)$ and $\mathrm{DT}_{sw}(R)$ trees, respectively.

The game

Let ϕ be a set of linear clauses and Φ_s be a set of linear non-equalities. Consider the following game between two parties called Prover and Delayer. The game goes in rounds, consisting of one move of Prover followed by one move of Delayer. The position in the game is determined by a system of linear non-equalities Φ, which is extended by one non-equality after every round. The starting position is Φ_s.

In each round, Prover presents to Delayer a possible branching $f \neq 0$ and $g \neq 0$ over a linear non-equality $f + g \neq 0$, such that $f + g \neq 0 \in \Phi \cup \{a \neq 0 \,|\, a \in R \setminus 0\}$ or $\Phi \models f + g \neq 0$ in G^R and G^R_{sw}, respectively. After that, Delayer chooses either $f \neq 0$ or $g \neq 0$ to be added to Φ, or leaves the choice to the Prover and thus earns a coin. The game G^R finishes, when $\neg C \subseteq \Phi$ for some $C \in \phi \cup \{0 = 0\}$, and G^R_{sw} finishes, when $\Phi \models \neg C$ for some clause $C \in \phi \cup \{0 = 0\}$.

▶ **Lemma 30.** *If there exists a strategy with a starting position Φ_s for Delayer in the game G^R (respectively, G^R_{sw}) that guarantees at least c coins on a set of linear clauses ϕ, then the size of a $DT(R)$ (respectively $DT_{sw}(R)$) tree for ϕ, with the system Φ_s in the root, must be at least 2^c.*

Proof. Assume that T is a tree of type $\mathrm{DT}(R)$ (respectively, $\mathrm{DT}_{sw}(R)$) for ϕ. We define an embedding of the full binary tree B_c of height c to T inductively as follows. We simulate Prover in the game G^R (respectively, G^R_{sw}) by choosing branchings from T and following to a subtree chosen by the Delayer until Delayer decides to earn a coin and leaves the choice to the Prover or until the game finishes. In case we are at a position where Delayer earns a coin, and which corresponds to a vertex u in T, we map the root of B_c to u and proceed inductively by embedding two trees B_{c-1} to the left and right subtrees of u, corresponding to two choices of the Prover. ◀

5.3 Lower Bounds for the Subset Sum with Small Coefficients

We now turn to tree-like lower bounds. In this section we prove tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ lower bound for $\mathsf{SubSum}(f)$ including instances, where coefficients of f are small, and tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ lower bound for $\mathsf{ImAv}(\pm x_1 \pm \cdots \pm x_n)$.

The proof of tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ lower bound for $\mathsf{SubSum}(f)$ goes in two stages. Assume f depends on n variables. First, as in the proof of dag-like lower bound in Sec. 4 we use Theorem 18 to transform refutations π of $f = 0$ to derivations π' of a clause C_π from only the boolean axioms. We ensure that π' is not much larger than π and C_π possesses the following property, which makes it hard to derive: for every disjunct $g = 0$ in C_π the linear polynomial g depends on at least $\frac{n}{2}$ variables. Second, we use Prover-Delayer games to prove the lower bound for derivations of any clause with this property. The proof that Delayer's strategy succeeds to earn sufficiently many coins is guaranteed by a bound on size of essential coverings of hypercubes.

▶ **Definition 31.** *Let $\mathcal{H}$ be a set of hyperplanes in $\mathbb{Q}^n$. We say that $\mathcal{F}$ forms **essential cover** of the cube $B_n = \{0,1\}^n$ if:*

- *Every point of B_n is covered by some hyperplane in $\mathcal{H}$.*
- *No proper subset $\mathcal{H}' \subsetneq \mathcal{H}$ covers B_n.*
- *No axis in $\mathbb{Q}^n$ is parallel to all hyperplanes in $\mathcal{H}$. In other words, if $\mathcal{H} = \{H_1, \ldots, H_m\}$ and $f_i = 0$ is the linear equation defining H_i, $i \in [m]$, then every variable x_j, $j \in [n]$, occurs with nonzero coefficient in some f_i.*

▶ **Theorem 32** ([21]). *Any essential cover of the cube B_n in $\mathbb{Q}^n$ must contain at least $\frac{1}{2}(\sqrt{4n+1}+1)$ hyperplanes.*

We use Prover-Delayer games to prove the lower bound below.

▶ **Theorem 33.** *Any tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ *derivation of any tautology of the form $\bigvee_{j\in[N]} g_j = 0$, for some positive N, where each g_j is linear over $\mathbb{Q}$ and depends on at least $\frac{n}{2}$ variables, is of size $2^{\Omega(\sqrt{n})}$.*

Proof. According to the definitions in Sec. 5.2 the corresponding Prover-Delayer game is on $0 = 0$ and starts with the position

$$\Phi_r = \{g_j \neq 0 \mid j \in [N]\}.$$

The game finishes at a position Φ, where $\{x_i \neq 0,\ x_i \neq 1\} \subseteq \Phi$ for some $i \in [n]$ or $0 \neq 0 \in \Phi$.

We now define a Delayer's strategy that guarantees $\Omega(\sqrt{n})$ coins and by Lemma 30 obtain the lower bound.

If Φ is a position in the game, denote by $\Phi_c \subset \Phi$ the subset of so-called "coin" non-equalities, that is, non-equalities that were chosen by Prover when Delayer decided to leave the choice to Prover and earn a coin. The number $|\Phi_c|$ is then precisely the number of coins earned by Delayer at Φ. Throughout the game Delayer constructs a partial assignment ρ_I for variables in $I \subseteq [n]$ and a set of non-equalities $\Phi_I \subseteq \Phi_c$, such that:

1. $|\Phi_I| = \Omega(\sqrt{|I|})$;
2. for all $g \neq 0 \in (\Phi \restriction_{\rho_I}) \setminus (\Phi_c \restriction_{\rho_I})$, the function g depends on at least $\frac{n}{2} - |I|$ variables;
3. Φ_I contains variables only from I; and
4. $\Phi_c \restriction_{\rho_I}$ is 0-1 satisfiable.

In the beginning both ρ_I and Φ_I are empty.

Let the position in the game be defined by a system Φ and let the branching chosen by the Prover be $g_1 \neq 0$ and $g_2 \neq 0$, where $g_1 + g_2 \neq 0 \in \Phi$. Delayer does the following. Before making any decision Delayer checks if there exists some nonconstant linear g with variables in $[n] \setminus I$ such that $(\Phi_c \restriction_{\rho_I}) \cup \{g \neq 0\}$ is unsatisfiable over 0-1.

In case it holds, $\Psi := (\Phi_c \setminus \Phi_I) \restriction_{\rho_I} \cup \{g \neq 0\}$ must be 0-1 unsatisfiable. Consider a minimal subset $\Psi' \subseteq \Psi$ such that Ψ' is 0-1 unsatisfiable and denote $I' \subseteq [n]$ the set of variables that occur in Ψ'. As $\Psi'' := \Psi' \setminus \{g \neq 0\}$ is 0-1 satisfiable, there exists an assignment $\rho_{I'}$ for variables in I', that satisfies Ψ''. Delayer extends the assignment ρ_I with $\rho_{I'}$ to $\rho_{I\cup I'}$ and defines $\Phi_{I\cup I'} := \Phi_I \cup \Psi''$.

If $\Psi' = \{g_1 \neq 0, \ldots, g_k \neq 0\}$, then the hyperplanes $H_1, \ldots, H_k$ defined by the equations $g_1 = 0, \ldots, g_k = 0$ form an essential cover of the cube $B_{|I'|}$. Therefore, by Theorem 32, $|\Psi''| = |\Psi'| - 1 \geq \frac{1}{2} \cdot \sqrt{|I'|}$ and thus $|\Phi_{I\cup I'}| \geq \frac{1}{2} \cdot \sqrt{|I|} + \frac{1}{2} \cdot \sqrt{|I'|} \geq \frac{1}{2} \cdot \sqrt{|I \cup I'|}$.

If necessary, Delayer repeats the above procedure constructing extensions $\rho_{I_1} \subset \cdots \subset \rho_{I_L}$ and $\Phi_{I_1} \subset \cdots \subset \Phi_{I_L}$, where $I_1 = I \subset \ldots \subset I_L$, until there is no $g \neq 0$ inconsistent with $\Phi_c \restriction_{\rho_{I_L}}$ as described above. The new value of I is set to I_L. After that Delayer does the following:

1. if $g_1 \restriction_{\rho_I} = 0$, then choose $g_2 \neq 0$;
2. otherwise, if $g_2 \restriction_{\rho_I} = 0$, then choose $g_1 \neq 0$;
3. if none of the above cases hold, leave the choice to Prover and earn a coin.

Denote by Φ' and $\Phi'_c \subseteq \Phi'$ the new position and the subset of "coin" non-equalities, respectively, after the choice is made. It is easy to see that the property that any $g \neq 0 \in (\Phi' \restriction_{\rho_I}) \setminus (\Phi'_c \restriction_{\rho_I})$ depends on at least $\frac{n}{2} - |I|$ variables still holds.

It follows from the definition of Delayer's strategy that Φ_c is always 0-1 satisfiable. Therefore if Φ is the endgame position, that is if $0 \neq 0 \in \Phi$ or $\{x_i \neq 0, x_i \neq 1\} \subset \Phi$ for some $i \in [n]$, then $0 \neq 0 \in (\Phi \restriction_{\rho_I}) \setminus (\Phi_c \restriction_{\rho_I})$ or $\{x_i \neq 0, x_i \neq 1\} \subset (\Phi \restriction_{\rho_I}) \setminus (\Phi_c \restriction_{\rho_I})$ respectively. This implies that $|I| \geq \frac{n}{2} - 1$ and therefore $|\Phi_c| \geq |\Phi_I| \geq \frac{1}{2} \cdot \sqrt{|I|} = \Omega(\sqrt{n})$. Thus the number of coins earned by Delayer is $\Omega(\sqrt{n})$. ◀

▶ **Corollary 34.** *Let f be any linear polynomial over $\mathbb{Q}$ that depends on n variables. Then tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ *derivations of* $\mathsf{Im}(f)$ *are of size* $2^{\Omega(\sqrt{n})}$.

▶ **Theorem 35.** *If f is a linear polynomial over $\mathbb{Q}$, which depends on n variables and $0 \notin im_2(f)$, then every tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ *refutation of $f = 0$ is of size* $2^{\Omega(\sqrt{n})}$.

Proof. Consider the following predicate $\mathcal{P}$ on linear polynomials: $\mathcal{P}(g) = 1$ iff g depends on at least $\frac{n}{2}$ variables. It is easy to see that $\mathcal{P}$ satisfies the conditions in Theorem 18 with respect to f. Therefore by Theorem 18 for every refutation π of $f = 0$ there exists a derivation π' of a clause C_π from the boolean axioms such that $|\pi'| = O(n \cdot |\pi|^3)$ and $\mathcal{P}(g)$ for every $g = 0$ in C_π. Thus, by Theorem 33 $|\pi'| = 2^{\Omega(\sqrt{n})}$ and $|\pi| = 2^{\Omega(\sqrt{n})}$. ◀

▶ **Lemma 36.** *Let Φ be a satisfiable system of m non-equalities over $\mathbb{F}$. If $\Phi \models \epsilon_1 x_1 + \cdots + \epsilon_n x_n = A$ for some $\epsilon_i \in \{-1, 1\} \subset \mathbb{F}, A \in \mathbb{F}$, then $m \geq \frac{n}{4}$.*

Note that A must be an integer (inside $\mathbb{F}$), since the coefficients of variables are all $-1, 1$, and the variables themselves are boolean (since $\models$ stands for semantic implication over 0-1 assignments only).

Proof. Let $\Phi = \{\overline{a}_1 \cdot \overline{x} + b_1 \neq 0, \ldots, \overline{a}_m \cdot \overline{x} + b_m \neq 0\}$ and put $\sigma = A \mod 2$, $f = \epsilon_1 x_1 + \cdots + \epsilon_n x_n$. Then

$$f \equiv 1 - \sigma \pmod 2 \models f \neq A$$
$$\models (\overline{a}_1 \cdot \overline{x} + b_1) \cdot \ldots \cdot (\overline{a}_m \cdot \overline{x} + b_m) = 0.$$

By Theorem 4.4 in Alekhnovich-Razborov [2], the function $f \equiv 1 - \sigma \pmod 2$ is $\frac{n}{4}$-*immune*, that is, the degree of any non-zero polynomial g such that $f \equiv 1 - \sigma \pmod 2 \models g = 0$ must be at least $\frac{n}{4}$. Therefore $m \geq \frac{n}{4}$. ◀

▶ **Theorem 37.** *We work over $\mathbb{Q}$. Let $f = \epsilon_1 x_1 + \cdots + \epsilon_n x_n$, where $\epsilon_i \in \{-1, 1\}$. Then any tree-like* $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{Q}})$ *refutation of* $\mathsf{ImAv}(f)$ *is of size at least* $2^{\frac{n}{4}}$.

Proof. According to the definitions in Sec. 5.2 the corresponding Prover-Delayer game is on $\mathsf{ImAv}(f)$ and starts with the empty position. The game finishes at a position Φ, where $\Phi \models f - A = 0$ for some $A \in im_2(f)$.

We now define a Delayer's strategy that guarantees $\frac{n}{4}$ coins and by Lemma 30 obtain the lower bound.

The strategy is as follows. Let the position in the game be defined by a system Φ and let the branching chosen by the Prover be $g_1 \neq 0$ and $g_2 \neq 0$, where $\Phi \models g_1 + g_2 \neq 0$. Delayer does the following:

1. if $g_2 \neq 0$ is inconsistent with Φ, but $g_1 \neq 0$ is consistent with Φ, then choose $g_1 \neq 0$;
2. if $g_1 \neq 0$ is inconsistent with Φ, but $g_2 \neq 0$ is consistent with Φ, then choose $g_2 \neq 0$;
3. if none of the above holds, then leave the choice to the Prover and earn a coin.

We now prove that this strategy guarantees the required number of coins.

Suppose that the game has finished at a position Φ. The strategy of Delayer guarantees that Φ is satisfiable and Φ contradicts a clause $\langle f \neq A \rangle$ of $\mathsf{ImAv}(f)$, that is $\Phi \models f - A = 0$ for some $A \in im_2(f)$. Let $\zeta_1, \ldots, \zeta_\ell$ be the set of non-equalities in Φ, in the order they were added to Φ. Let $\Psi \subseteq \Phi$ be the set of all ζ_i, $i \in [\ell]$, such that ζ_i is not implied by previous non-equalities ζ_j, for $j < i$. Then, Delayer earns at least $|\Psi|$ coins, $\Psi \models f = A$, and by Lemma 36 we conclude that $|\Psi| \geq \frac{n}{4}$. ◀

5.4 Lower Bounds for the Pigeonhole Principle

Here we prove that every tree-like $\text{Res}_{sw}(\text{lin}_\mathbb{F})$ refutations of $\neg\text{PHP}_n^m$ must have size at least $2^{\Omega(\frac{n-1}{2})}$ (see Sec. 2.3.1 for the definition of $\neg\text{PHP}_n^m$). Together with the upper bound for dag-like $\text{Res}(\text{lin}_\mathbb{F})$ (Theorem 17) this provides a separation between tree-like and dag-like $\text{Res}_{sw}(\text{lin}_\mathbb{F})$ in the case $char(\mathbb{F}) = 0$, for formulas in CNF. The lower bound argument is comprised of exhibiting a strategy for Delayer in the Prover-Delayer game. Delayer's strategy is similar to that in [17]. However, the proof that Delayer's strategy guarantees sufficiently many coins relies on Lemma 39, which is a generalization of Lemma 3.3 in [17] for arbitrary fields. Since the proof of Lemma 3.3 in [17] for the $\mathbb{F}_2$ case does not apply to arbitrary fields, our proof is different, and uses a result from Alon-Füredi [4] on the hyperplane coverings of the hypercube.

▶ **Theorem 38.** *For every field $\mathbb{F}$, the shortest tree-like $\text{Res}_{sw}(\text{lin}_\mathbb{F})$ refutation of $\neg PHP_n^m$ has size $2^{\Omega(\frac{n-1}{2})}$.*

Proof. We prove that there exists a strategy for Delayer in the $\neg\text{PHP}_n^m$ game, which guarantees Delayer to earn $\frac{n-1}{2}$ coins. Following the terminology in [17], we call an assignment $x_{i,j} \mapsto \alpha_{ij}$, for $\alpha \in \{0,1\}^{mn}$, *proper* if it does not violate $\mathsf{Pigeons}_n^m$, namely, if it does not send two distinct pigeons to the same hole. We need to prove several lemmas before concluding the theorem.

▶ **Lemma 39.** *Let $A\overline{x} \doteq \overline{b}$ be a system of k linear non-equalities over a field $\mathbb{F}$ with n variables and where $\overline{x} = 0$ is a solution, that is, $0 \doteq \overline{b}$. If $k < n$, then there exists a non-zero boolean solution to this system.*

Proof. Let $\overline{a}_1, \ldots, \overline{a}_k$ be the rows of the matrix A. The boolean solutions to the system $A\overline{x} \doteq \overline{b}$ are all the points of the n-dimensional boolean hypercube $B_n := \{0,1\}^n \subset \mathbb{F}^n$, that are not covered by the hyperplanes $H := \{\overline{a}_1\overline{x} - b_1 = 0, \ldots, \overline{a}_k\overline{x} - b_k = 0\}$. We need to show that if $k < n$ and $0 \in B_n$ is not covered by H, then some other point in B_n is not covered by H as well. This follows from [4]:

▶ **Corollary from Alon-Füredi [4, Theorem 4].** *Let $Y(l) := \{(y_1, \ldots, y_n) \in \mathbb{F}^n \mid \forall i \in [n], 0 < y_i \leq 2, \text{ and } \sum_{i=1}^n y_i \geq l\}$. For any field $\mathbb{F}$, if k hyperplanes in $\mathbb{F}^n$ do not cover B_n completely, then they do not cover at least $M(2n-k)$ points from B_n, where*

$$M(l) := \min_{(y_1,\ldots,y_n)\in Y(l)} \prod_{1\leq i\leq n} y_i \,.$$

Thus, if $k < n$ hyperplanes do not cover B_n completely, then they do not cover at least $M(n+1)$ points. The set $Y(n+1)$ in the Corollary above consists of all tuples $(y_1, \ldots, y_n)$, where $y_i = 2$ for some $i \in [n]$ and $y_j = 1$ for $j \in [n], j \neq i$. Therefore $M(n+1) = 2$. ◀

For two boolean assignments $\alpha, \beta \in \{0,1\}^n$, denote by $\alpha \oplus \beta$ the bitwise XOR of the two assignments.

▶ **Lemma 40.** *Let $A\overline{x} \doteq \overline{b}$ be a system of k linear non-equalities over a field $\mathbb{F}$ with $n > k$ variables and let $\alpha \in \{0,1\}^n$ be a solution to the system. Then, for every choice I of $k+1$ bits in α, there exists at least one $i \in I$ so that flipping the ith bit in α results in a new solution to $A\overline{x} \doteq \overline{b}$. In other words, if $I \subseteq [n]$ is such that $|I| = k+1$, then there exists a boolean assignment $\beta \neq 0$ such that $\{i \mid \beta_i = 1\} \subseteq I$ and $A(\alpha \oplus \beta) \doteq \overline{b}$.*

Proof. Let $I \subseteq \{0,1\}^n$. Denote by $A^\star_I$ the matrix with columns $\{(1-2\alpha_i)\overline{a}_i \mid i \in I\}$, where $\overline{a}_i$ is the ith *column* of A. That is, $A^\star_I$ is the matrix A restricted to columns i with $i \in I$ and where column i flips its sign iff α_i is 1.

Assume that $\beta \in \{0,1\}^n$ is nonzero and all its 1's must appear in the indices in I, that is, $\{i \mid \beta_i = 1\} \subseteq I$. Given a set of indices $J \subseteq [n]$, denote by β_J the restriction of β to the indices in J. Similarly, for a vector $v \in \mathbb{F}^n$, v_J denotes the restriction of v to the indices in J.

▷ Claim. $A(\alpha \oplus \beta) \doteq \overline{b}$ iff $A^\star_I \beta_I \doteq \overline{b} - A\alpha$.

Proof. We prove that $A(\alpha \oplus \beta) = A^\star_I \beta_I + A\alpha$. Consider any row $\mathbf{v}$ in A, and the corresponding row $\mathbf{v}^\star_I$ in $A^\star_I$. Notice that $\mathbf{v} \cdot (\alpha \oplus \beta)$ (for "$\cdot$" the dot product) equals the dot product of $\mathbf{v}$ and $\alpha \oplus \beta$, where both vectors are restricted only to those entries in which α and β differ. Considering entries outside I, by assumption we have $\beta_{[n]\setminus I} = 0$, which implies that

$$\mathbf{v}_{[n]\setminus I} \cdot (\alpha \oplus \beta)_{[n]\setminus I} = \mathbf{v}_{[n]\setminus I} \cdot \alpha_{[n]\setminus I} \,. \tag{9}$$

On the other hand, considering entries inside I, we have

$$\mathbf{v}_I \cdot (\alpha \oplus \beta)_I = \mathbf{v}_I \cdot \alpha_I + \mathbf{v}^\star_I \cdot \beta_I \,. \tag{10}$$

Equation (10) can be verified by inspecting all four cases for the ith bits in α, β, for $i \in I$, as follows: for those indices $i \in I$, such that $\alpha_i = 1$ and $\beta_i = 0$, only $\mathbf{v}_I \cdot \alpha$ contributes to the right hand side in (10). If $\alpha_i = 1$ and $\beta_i = 1$, then by the definition of $A^\star_I$, the two summands in the right hand side in (10) cancel out. The cases $\alpha_i = 0, \beta_i = 1$ and $\alpha_i = \beta_i = 0$, can also be inspected to contribute the same values to both sides of (10).

The two equations (9) and (10) concludes the claim. ◁

We know that $A\alpha \doteq \overline{b}$, and we wish to show that for some nonzero $\beta \in \{0,1\}^n$ where $\{i \mid \beta_i = 1\} \subseteq I$, it holds that $A(\alpha \oplus \beta) \doteq \overline{b}$. By the claim above it remains to show the existence of such β where $A^\star_I \beta_I \doteq \overline{b} - A\alpha$. But notice that $\overline{b} - A\alpha \doteq 0$, since $A\alpha \doteq \overline{b}$, and that $A^\star_I \beta_I$ is a matrix of dimension $k \times (k+1)$. Therefore, by Lemma 39, the system $A^\star_I \beta_I \doteq \overline{b} - A\alpha$ has a nonzero solution, that is, there exists a $\beta \neq 0$ for which all ones are in the I entries, such that $A^\star_I \beta_I \doteq \overline{b} - A\alpha$. ◀

▶ **Lemma 41.** *Assume that a system $A\overline{x} \doteq \overline{b}$ of $k \leq \frac{n-1}{2}$ non-equalities over $\mathbb{F}$ with variables $\{x_{i,j}\}_{(i,j)\in[m]\times[n]}$ has a proper solution. Then, for every $i \in [m]$ there exists a proper solution to the system, that satisfies the clause $\bigvee_{j\in[n]} x_{i,j}$. In other words, for every pigeon, there exists a proper solution that sends the pigeon to some hole.*

Proof. We first show that if there exists a proper solution of $A\overline{x} \doteq \overline{b}$, then there exists a proper solution of this system with at most k ones. Let α be a proper solution with at least $k+1$ ones. If I is a subset of $k+1$ ones in α, then Lemma 40 assures us that some other

proper solution can be obtained from α by flipping some of these ones (note that flipping one to zero preserves the properness of assignments). Thus the number of ones can always be reduced until it is at most k.

Let α be a proper solution with at most k ones. The condition $k \leq \frac{n-1}{2}$ implies that there are $n - k \geq k + 1$ free holes. Let J be a subset of size $k + 1$ of the set of indices of free holes. Then for any $i \in [m]$ some of the bits in $I = \{(i, j) \mid j \in J\}$ can be flipped and still satisfy $A\overline{x} \doteqdot \overline{b}$, by Lemma 40. (As before, flipping from one to zero maintains the properness of the solution.) Hence, the resulting proper solution must satisfy the clause $\bigvee_{j\in[n]} x_{i,j}$. ◀

We now describe the desired strategy for Delayer.

Delayer's Strategy. Let a position in the game be defined by the system of non-equalities Φ and assume that the branching chosen by Prover is $f_0 \neq 0$ or $f_1 \neq 0$, where $\Phi \models f_0 + f_1 \neq 0$. The only objective of Delayer is to ensure that the system Φ has proper solutions. Delayer uses the opportunity to earn a coin whenever both $\Phi \cup \{f_0 \neq 0\}$ and $\Phi \cup \{f_1 \neq 0\}$ have proper solutions by leaving the choice to Prover. Otherwise, in case $\Phi \wedge \mathsf{Pigeons}_n^m \models f_i = 0$, for some $i \in \{0, 1\}$, Delayer chooses $f_{1-i} \neq 0$, which must satisfy $\Phi \wedge \mathsf{Pigeons}_n^m \models f_{1-i} \neq 0$, and so the sets of proper solutions of Φ and $\Phi \cup \{f_{1-i} \neq 0\}$ are identical.

This strategy ensures, that for every end-game position Φ, Φ has proper solutions and $\Phi \models \neg\mathsf{Holes}_n^m$. Note that Φ has the same proper solutions as Φ', obtained by throwing away from Φ all non-equalities that were added by Delayer when making a choice. Therefore, if $\Phi \models \neg\mathsf{Holes}_n^m$, then $\Phi' \wedge \mathsf{Pigeons}_n^m \models \neg\mathsf{Holes}_n^m$ and thus $|\Phi'| > \frac{n-1}{2}$ by Lemma 41.

Since $|\Phi'|$ is precisely the number of coins earned by Delayer, this gives the desired lower bound. ◀

6 Size-Width Relation and Simulation by Polynomial Calculus

In this section we prove a size-width relation for tree-like $\mathrm{Res}(\mathrm{lin}_R)$ (Theorem 44), which then implies an exponential lower bound on the size of tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_R)$ refutations in terms of the principal width of refutations (Definition 5). The connection between the principal width and the degree of PC refutations for finite fields $\mathbb{F}$, together with lower bounds on degree of PC refutations from [2] on Tseitin mod p formulas and random CNFs, imply exponential lower bounds for the size of tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$ for these instances (Corollaries 46 and 47).

▶ **Proposition 42.** *Let $\phi = \{C_i\}_{1\leq i\leq m}$ be a set of linear clauses and $x \in vars(\phi)$. Assume that l is a linear form in the variables $vars(\phi) \setminus \{x\}$. Then, there is a $\mathrm{Res}(\mathrm{lin}_R)$ derivation π of $\{C_i \restriction_{x\leftarrow l} \vee \langle x - l \neq 0\rangle\}_{1\leq i\leq m}$ from ϕ of size polynomial in $|\phi| + |\mathsf{lm}(l)|$ and such that $\omega_0(\pi) \leq \omega_0(\phi) + 2$.*

Proof. The clause $x - l = 0 \vee \langle x - l \neq 0\rangle$ is derivable in $\mathrm{Res}(\mathrm{lin}_R)$ in polynomial in $|\mathsf{lm}(l)|$ size by Proposition 10. Assume

$$C = \left(\bigvee_{j\in[k]} f_j + a_j x + b_j^{(1)} = 0 \vee \cdots \vee f_j + a_j x + b_j^{(N_j)} = 0\right),$$

where $x \notin vars(f_i)$ and we have grouped disjuncts so that $\omega_0(C) = k$. Then we resolve these groups one by one with $x - l = 0 \vee \langle x - l \neq 0\rangle$ and after $N_1 + \ldots + N_k$ steps yield $\left(\bigvee_{j\in[k]} f_j + a_j l + b_j^{(1)} = 0 \vee \cdots \vee f_j + a_j l + b_j^{(N_j)} = 0 \vee \langle x - l \neq 0\rangle\right)$. It is easy to see that the principal width never exceeds $k + 2$ along the way. Therefore $\omega_0(\pi) \leq \omega_0(\phi) + 2$. ◀

▶ **Corollary 43.** *Let $\phi = \{C_i\}_{1\leq i\leq m}$ be a set of linear clauses and $x \in vars(\phi)$. Suppose that l is a linear form with variables $vars(\phi)\setminus\{x\}$ and that π is a $\mathrm{Res}(\mathrm{lin}_R)$ refutation of $\phi\restriction_{x\leftarrow l}\cup\{l=0\vee l=1\}$. Then, there exists a $\mathrm{Res}(\mathrm{lin}_R)$ derivation $\widehat{\pi}$ of $\langle x-l\neq 0\rangle$ from ϕ, such that $S(\widehat{\pi}) = O(S(\pi)+|\mathsf{lm}(l)|)$ and $\omega_0(\widehat{\pi})\leq \max(\omega_0(\pi)+1,\omega_0(\phi)+2)$. Additionally, there is a refutation $\widehat{\pi}'$ of $\phi\cup\{x-l=0\}$ where $\omega_0(\widehat{\pi}')\leq\max(\omega_0(\pi),\omega_0(\phi)+2)$.*

Proof. By Proposition 42 there exists a derivation π_s of

$$\{C_i\restriction_{x\leftarrow l}\vee\langle x-l\neq 0\rangle\}_{1\leq i\leq m}\cup\{l=0\vee l=1\vee\langle x-l\neq 0\rangle\}$$

from ϕ of width at most $\omega_0(\phi)+2$. Composing π_s with $\pi\vee\langle x-l\neq 0\rangle$ yields the derivation $\widehat{\pi}$ of $\langle x-l\neq 0\rangle$ from ϕ.

Moreover, by taking the derivation π_s and adding to it the axiom $x-l=0$, and then using a sequence of resolutions of π_s with $x-l=0$, we obtain a derivation of $\phi\restriction_{x\leftarrow l}\cup\{l=0\vee l=1\}$ from $\phi\cup\{x-l=0\}$. The latter derivation composed with π yields the refutation $\widehat{\pi}'$ of $\phi\cup\{x-l=0\}$ of width at most $\max(\omega_0(\pi),\omega_0(\phi)+2)$. ◀

▶ **Theorem 44.** *Let ϕ be an unsatisfiable set of linear clauses over a field $\mathbb{F}$. The following size-width relation holds for both tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ and tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$:*

$$S(\phi\vdash\bot) = 2^{\Omega(\omega_0(\phi\vdash\bot)-\omega_0(\phi))}.$$

Proof. We prove by induction on n, the number of variables in ϕ, the following:

$$\omega_0(\phi\vdash\bot)\leq\lceil\log_2 S(\phi\vdash\bot)\rceil+\omega_0(\phi)+2\,.$$

Base case: $n=0$. Thus ϕ must contain only linear clauses $a=0$, for $a\in\mathbb{F}$, and the principal width for refuting ϕ is therefore 1.

Induction step: Let π be a tree-like refutation of $\phi=\{C_1,\ldots,C_m\}$ such that $S(\pi)=S(\phi\vdash\bot)$ (i.e., π is of minimal size). Without loss of generality, we assume that the resolution rule in π is only applied to simplified clauses, that is clauses not containing disjuncts $1=0$ in case of tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ and not containing unsatisfiable $f=0$, $0\notin im_2(f)$ in case of tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$. The former can be eliminated by the simplification rule and the latter by the semantic weakening rule. By this assumption, the empty clause at the root of π is derived in tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ (resp. tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_{\mathbb{F}})$) as a simplification (resp. weakening) of an unsatisfiable $h=0$ ($1=0$ in case of tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$) equation, which is derived by application of the resolution rule. Denote the left and right subtrees, corresponding to the premises of $h=0$, by π_1 and π_2, respectively.

The roots of π_1 and π_2 must be of the form $f_1=0$ and $f_2=0$, respectively, where $f_1-f_2=h$. Therefore,

$$f_1=l(x_1,\ldots,x_{n-1})+a_nx_n\quad\text{and}\quad f_2=l(x_1,\ldots,x_{n-1})+a_nx_n-h\,,$$

for some $l(x_1,\ldots,x_{n-1})=\sum_{i=1}^{n-1}a_ix_i+B$, where $a_i,B\in\mathbb{F}$.

Assume without loss of generality that $a_n\neq 0$ and $S(\pi_1)\leq S(\pi_2)$. We now use the induction hypothesis to construct a narrow derivation $\pi_1^\bullet$ of $f_1=0$ such that

$$\begin{aligned}\omega_0(\pi_1^\bullet)&\leq\lceil\log_2 S(\pi_1)\rceil+1+\omega_0(\phi)+2\\&\leq\lceil\log_2 S(\pi)\rceil+\omega_0(\phi)+2\,.\end{aligned}$$

For every nonzero $A \in im_2(f_1)$ define the partial linear substitution ρ_A as $x_n \leftarrow (A - l(x_1, \ldots, x_{n-1}))a_n^{-1}$. Thus, $f_1 \restriction \rho_A = A$. The set of linear clauses

$$\phi \restriction_{\rho_A} \cup \left\{(A-l)a_n^{-1} = 0 \vee (A-l)a_n^{-1} = 1\right\} \tag{11}$$

is unsatisfiable and has $n-1$ variables, and is refuted by $\pi_1 \restriction_{\rho_A}$.

By induction hypothesis there exists a (narrow) refutation π_1^A of (11) with

$$\begin{aligned}\omega_0(\pi_1^A) &\leq \lceil \log_2 S(\pi_1 \restriction_{\rho_A}) \rceil + \omega_0(\phi) + 2 \\ &\leq \lceil \log_2 S(\pi_1) \rceil + \omega_0(\phi) + 2\,.\end{aligned}$$

By Corollary 43 there exists a derivation $\widehat{\pi}_1^A$ of $\langle l + a_n x_n \neq A \rangle$ from ϕ such that $\omega_0(\widehat{\pi}_1^A) \leq \max(\omega_0(\pi_1^A) + 1, \omega_0(\phi) + 2) \leq \lceil \log_2 S(\pi_1) \rceil + \omega_0(\phi) + 3$. By Proposition 12 there exists a derivation $\pi_1^\bullet$ of $f_1 = 0$ such that $\omega_0(\pi_1^\bullet) \leq \lceil \log_2 S(\pi_1) \rceil + \omega_0(\phi) + 3 \leq \lceil \log_2 S(\pi) \rceil + \omega_0(\phi) + 2$.

Consider the following substitution ρ: $x_n \leftarrow -l \cdot a_n^{-1}$. Then, $\pi_2|_\rho$ is a derivation of $h = 0$ from $\phi|_\rho \cup \{-l \cdot a_n^{-1} = 0 \vee -l \cdot a_n^{-1} = 1\}$, which we augment to refutation π_2' by taking composition with simplification (resp. weakening) in case of tree-like $\mathrm{Res}(\mathrm{lin}_\mathbb{F})$ (resp. tree-like $\mathrm{Res}_{sw}(\mathrm{lin}_\mathbb{F})$). By induction hypothesis there exists a refutation $\pi_2^\bullet$ of width

$$\begin{aligned}\omega_0(\pi_2^\bullet) &\leq \lceil \log_2(S(\pi_2') + 1) \rceil + \omega_0(\phi) + 2 \\ &\leq \lceil \log_2 S(\pi) \rceil + \omega_0(\phi) + 2\,,\end{aligned}$$

and thus by Corollary 43 there exists a refutation $\widehat{\pi}_2^\bullet$ of $\phi \cup \{f_1 = 0\}$ of width $\omega_0(\widehat{\pi}_2^\bullet) \leq \lceil \log_2 S(\pi) \rceil + \omega_0(\phi) + 2$. The combination of $\widehat{\pi}_2^\bullet$ and $\pi_1^\bullet$ gives a refutation of ϕ of the desired width. ◀

▶ **Theorem 45.** *Let $\mathbb{F}$ be a field and π be a* $\mathrm{Res}(\mathrm{lin}_\mathbb{F})$ *refutation of an unsatisfiable set of linear clauses ϕ. Then, there exists a $PC_\mathbb{F}$ refutation π' of (the arithmetization of) ϕ of degree $\omega(\pi)$.*

Proof. The idea is to replace every clause $C = (f_1 = 0 \vee \ldots \vee f_m = 0)$ in π by its arithmetization $a(C) := f_1 \cdot \ldots \cdot f_m$, and then augment this sequence to a valid $PC_\mathbb{F}$ derivation by simulating all the rule applications in π by several $PC_\mathbb{F}$ rule applications.

Case 1: If $D = (C \vee g_1 = 0 \vee \ldots \vee g_m = 0)$ is a weakening of C, then apply the product and the addition rules to derive $a(D) = a(C) \cdot g_1 \cdot \ldots \cdot g_m$ from $a(C)$.

Case 2: If D is a simplification of $D \vee 1 = 0$, then $a(D) = a(D \vee 1 = 0)$.

Case 3: If $D = (x = 0 \vee x = 1)$ is a a boolean axiom, then $a(D) = x^2 - x$ is an axiom of $PC_\mathbb{F}$.

Case 4: If $D = (C \vee C' \vee E \vee \alpha f + \beta g = 0)$ is a result of resolution of $(C \vee E \vee f = 0)$ and $(C' \vee E \vee g = 0)$, where C and C' do not contain the same disjuncts, then by the product and addition rules of PC we derive $a(C) \cdot a(C') \cdot a(E) \cdot f$ from $a(C \vee E \vee f = 0) = a(C) \cdot a(E) \cdot f$, and also derive $a(C) \cdot a(C') \cdot a(E) \cdot g$ from $a(C' \vee E \vee f = 0) = a(C') \cdot a(E) \cdot f$, and then apply the addition rule to derive $a(C) \cdot a(C') \cdot a(E) \cdot (\alpha f + \beta g) = a(D)$.

It is easy to see that the degree of the resulting $PC_\mathbb{F}$ refutation is at most $\omega(\pi)$. ◀

As a consequence of Theorems 44 and 45, and the relation $\omega_0 \geq \frac{1}{|\mathbb{F}|}\omega$ as well as the results from [2], we have the following:

▶ **Corollary 46.** *For every prime p there exists a constant $d_0 = d_0(p)$ such that the following holds. If $d \geq d_0$, G is a d-regular Ramanujan graph on n vertices (augmented with arbitrary orientation to its edges) and $\mathbb{F}$ is a finite field with $char(\mathbb{F}) \neq p$, then for every function σ such that $\neg TS_{G,\sigma}^{(p)} \in UNSAT$, every tree-like* $\mathrm{Res}(\mathrm{lin}_\mathbb{F})$ *refutation of $\neg TS_{G,\sigma}^{(p)}$ has size $2^{\Omega(dn)}$.*

Proof. Corollary 4.5 from [2] states that the degree of $PC_{\mathbb{F}}$ refutations of $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ is $\Omega(dn)$. Theorem 45 implies that the principal width of $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations of $\neg\mathrm{TS}^{(p)}_{G,\sigma}$ is $\Omega(\frac{1}{|\mathbb{F}|}dn) = \Omega(dn)$ and thus by Theorem 44 the size is $2^{\Omega(dn)}$. ◀

▶ **Corollary 47.** *Let $\phi \sim \mathcal{F}^{n,\Delta}_k, k \geq 3$ and $\Delta = \Delta(n)$ be such that $\Delta = o(n^{\frac{k-2}{2}})$ and let $\mathbb{F}$ be any finite field. Then every tree-like* $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ *refutation of ϕ has size $2^{\Omega\left(\frac{n}{\Delta^{2/(k-2)}\cdot\log\Delta}\right)}$ with probability $1-o(1)$.*

Proof. Corollary 4.7 from [2] states that the degree of $PC_{\mathbb{F}}$ refutations of $\phi \sim \mathcal{F}^{n,\Delta}_k$, where $k \geq 3$, is $\Omega(dn)$ with probability $1-o(1)$. Theorem 45 implies that the principal width of $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ refutations of $\phi \sim \mathcal{F}^{n,\Delta}_k$ is $\Omega(\frac{1}{|\mathbb{F}|}dn) = \Omega(dn)$ and thus by Theorem 44 the size of the refutations is $2^{\Omega(dn)}$ with probability $1-o(1)$. ◀

7 Conclusion

By the discussion in Sec. 1.1.4, for finite fileds we can take any CNF $\phi(\overline{x})$ known to be hard for $PC_{\mathbb{F}}$ (e.g. Tseitin formulas, random CNFs etc) and turn it into the linear system $R_{\phi}(\overline{x},\overline{y})$, which we can prove is hard for tree-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$. It is reasonable to conjecture that these linear systems are also hard for dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ and to try to prove a lower bound for them. However, this would require dealing with particular systems, arising from these CNFs and, therefore, having a specific structure. Alternatively, we may turn our attention to fields $char(\mathbb{F}) = 0$: the hard instance in this case can be chosen freely among systems $L(\overline{x})$, where all coefficients are bounded by a constant: every equation in $L(\overline{x})$ can be coded as a short CNF formula, which admits short $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ derivations from $L(\overline{x})$. $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ lower bound for such a linear system would imply $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ CNF lower bound if $char(\mathbb{F}) = 0$ and by generalization of the proof of simulation of $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}_2})$ by $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ in [17] to arbitrary finite fields, this would imply CNF $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}'})$ bounds for any finite field $\mathbb{F}'$.

Thus, for any field $\mathbb{F}$, the general dag-like $\mathrm{Res}(\mathrm{lin}_{\mathbb{F}})$ lower bound problem for CNF can be reduced to the following problem: find a 0-1 unsatisfiable linear system $L(\overline{x})$ over $\mathbb{Z}$ with coefficients bounded by a constant such that any $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ refutation of $L(\overline{x})$ is of superpolynomial size.

Note that $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ is pretty strong proof system: classical tautologies such as Pigeonhole Principle, Clique-Coclique Principle or (mod p)-Tseitin Tautologies are all easy for $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$[26]. Therefore, even indentifying explicit hard candidate for $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ is a non-trivial problem. Linear systems in many respects are more handy to work with while indentifying hardness conditions as well as analysing structure of $\mathrm{Res}(\mathrm{lin}_{\mathbb{Q}})$ proofs.

Abstract

We study a new model of space-bounded computation, the *random-query* model. The model is based on a branching-program over input variables $x_1, \ldots, x_n$. In each time step, the branching program gets as an input a random index $i \in \{1, \ldots, n\}$, together with the input variable x_i (rather than querying an input variable of its choice, as in the case of a standard (oblivious) branching program). We motivate the new model in various ways and study time-space tradeoff lower bounds in this model.

Our main technical result is a quadratic time-space lower bound for zero-error computations in the random-query model, for XOR, Majority and many other functions. More precisely, a zero-error computation is a computation that stops with high probability and such that conditioning on the event that the computation stopped, the output is correct with probability 1. We prove that for any Boolean function $f : \{0,1\}^n \to \{0,1\}$, with sensitivity k, any zero-error computation with time T and space S, satisfies $T \cdot (S + \log n) \geq \Omega(n \cdot k)$. We note that the best time-space lower bounds for standard oblivious branching programs are only slightly super linear and improving these bounds is an important long-standing open problem.

To prove our results, we study a memory-bounded variant of the coupon-collector problem that seems to us of independent interest and to the best of our knowledge has not been studied before. We consider a zero-error version of the coupon-collector problem. In this problem, the coupon-collector could explicitly choose to stop when he/she is sure with zero-error that all coupons have already been collected. We prove that any zero-error coupon-collector that stops with high probability in time T, and uses space S, satisfies $T \cdot (S + \log n) \geq \Omega(n^2)$, where n is the number of different coupons.

1 Introduction

In this paper, we introduce a new model for studying time-space tradeoff lower bounds for computation, the *random-query* model. The model is based on a *branching program*. Roughly speaking, a branching program of length T and width 2^S, over input variables $x_1, \ldots, x_n$, is a directed (multi) graph with vertices arranged in $T + 1$ layers containing at most 2^S vertices each. Intuitively, each layer represents a time step and each vertex represents a memory state of the program. In layer-0 of the program, there is only one vertex, called the start vertex. Each leaf of the program is labelled by an element from $\{0, 1\}$ that we think of as the output of the program on that leaf.

In a standard branching program, every non-leaf vertex v in the program is labeled by an input variable x_v and has 2 outgoing edges, labeled by 0 and 1, going into vertices in the next layer. Intuitively, x_v is the input variable read by the vertex v. The program is called *oblivious* if all the vertices in the same layer read the same input variable. Given a branching program, the input $x_1, \ldots, x_n$ defines a computation-path, by starting from the start vertex and following in each step the edge labeled by the value of the corresponding input variable. The program outputs the label of the leaf reached by the computation path.

In the random-query model, every non-leaf vertex v in the program has $2n$ outgoing edges, labeled by each element of $\{1, \ldots, n\} \times \{0, 1\}$ exactly once. Given such a program and input $x_1, \ldots, x_n$, the computation-path starts from the start vertex and follows in each step the edge labeled by (i, x_i), where $i \in \{1, \ldots, n\}$ is random. (Intuitively, the program reads a random index $i \in \{1, \ldots, n\}$, together with the input variable x_i). As before, the program outputs the label of the leaf reached by the computation path.

1.1 Motivation

We have various motivations to study the new model. First, it seems to us an interesting model in its own right. The standard model of space-bounded computation is not always fully convincing in all settings, as it is not clear why would a machine be able to store for free the n input variables, while at the same time have a very restricted (typically, of size much smaller than n) additional memory. Moreover, in various situations the random-query model seems to be the natural one to use. Consider for example the following situation: you are at a party and you want to know if the majority of the participants prefer coffee or tea. (Assume that you know the number of participants in the party, that that number is odd and that you know all participants (or they are labeled $1, \ldots, n$)). Assume that at each time step you meet a random participant and she/he tells you their preference. How long would it take to figure out if the majority prefers coffee or tea if your memory is bounded? Another example may be a distributed setting where n players have one input variable each and they keep sending these input variables to a central player who needs to compute a Boolean function of all of them. However, the input variables arrive to the central player in an arbitrary order.

Second, we study time-space lower bounds for the random-query model in order to make progress in proving time-space lower bounds for standard (oblivious) branching programs. Time-space lower bounds for branching programs have been studied in numerous works (see for example [3, 2, 1, 5, 6]). Currently, the best time-space lower bounds for any explicit function are only slightly super linear and improving these lower bounds has been a very important and long standing open problem in computational complexity. In section 5, we show that various extensions of our results would imply such strong time-space lower bounds. Roughly speaking, our time-space lower bounds for the random-query model are proved for the case where the indices $i_1, i_2, i_3, \ldots$ of the input variables read by the program at time steps $1, 2, 3, \ldots$ are mutually independent random variables, while in order to extend these lower bounds to standard branching programs one needs to generalize the proofs to the case where some of these indices are known to be the same. Interestingly, the key component of our proof, Theorem 2, does apply to the more general case where some of the indices are known to be the same. However, the main results do not.

Third, the new model is related to several other problems that have been studied recently. First, it is related to the recent line of works on proving time-space lower bounds for learning (see for example [16, 18, 14, 11, 12, 15, 13, 4, 8, 7, 17, 9]). Indeed, computing a function $f : \{0, 1\}^n \to \{0, 1\}$ in the random-query model is equivalent to the task of distinguishing

between the following two families of distributions (which is a learning task[1]): For $x \in \{0,1\}^n$, let $\mathcal{D}_x$ be the distribution of the random variable (i, x_i), where $i \in \{1, \ldots, n\}$ is uniformly distributed. The task is to distinguish between a distribution taken from $\{\mathcal{D}_x\}_{x:f(x)=0}$ and a distribution taken from $\{\mathcal{D}_x\}_{x:f(x)=1}$, from a stream of independent samples. Second, the random-query model is similar to a recently studied model of streaming complexity, where a source of i.i.d samples of edges of a graph is considered [10]. In particular, [10] studied approximation algorithms for the maximum matching problem in that model. The main difference from our model is that they studied the space needed for approximate computation in the case where the number of samples is smaller than the number of input variables, while we study time-space tradeoffs for exact computation in the case where the number of samples may be much larger than the number of input variables.

Finally, it turns out that in the zero-error case, the random-query model is closely related to a memory-bounded variant of the coupon-collector problem, a problem that seems to be of independent interest and to the best of our knowledge has not been studied before. In our variant of the problem, the coupon collector gets a stream of random elements from the set $\{1, \ldots, n\}$ and needs to stop when she is sure with zero-error that all elements of $\{1, \ldots, n\}$ have already passed. The question is what is the time T needed when the memory size of the coupon collector is bounded by S.

1.2 Our Results

In Theorem 5, we prove that any algorithm for the zero-error coupon-collector problem that runs in time T and space S satisfies $T \cdot (S + \log n) \geq \Omega(n^2)$. This result is essentially tight. In Theorem 6, we prove that in the random-query model, any zero-error computation of XOR or Majority (or any other function with sensitivity $\Omega(n)$) that runs in time T and space S satisfies $T \cdot (S + \log n) \geq \Omega(n^2)$. The results for XOR and Majority are essentially tight (See Remarks 8 and 9 for the discussions on tightness). More generally, in the random-query model, any zero-error computation of a function with sensitivity k that runs in time T and space S satisfies $T \cdot (S + \log n) \geq \Omega(n \cdot k)$.

A very interesting open problem is to prove similar time-space lower bounds for the random-query model in the bounded-error case, rather than the zero-error case (Conjecture 1).

In Theorem 2, we prove time-space lower bounds for a special type of branching programs called set-labeled branching programs, in the random-query model. Intuitively, a set-labeled branching program is a branching-program for the coupon-collector problem, such that each vertex in the program "remembers" a set of coupons that must have been collected if that vertex was reached.

1.3 Paper Organization

The paper is organized as follows. In section 3, we prove the tight time-space lower bound for set-labeled branching programs, in the random-query model. In section 4, we reduce zero-error computation tasks in the random-query model, including the coupon-collector problem and function evaluation, to set-labeled branching programs, and hence prove tight time-space lower bounds for both problems. In section 5, we illustrate how lower bounds in the random-query model with special input distribution imply lower bounds for oblivious branching programs.

[1] Technically it is a testing task, which is easier than learning.

2 Preliminaries

For an integer n, we use $[n]$ to denote $\{1, 2, \ldots, n\}$. For any set A and an n-tuple $x \in A^n$, we use x_i to denote the i-th element of x. For any $x \in \{0,1\}^n$, let $x^{(i)}$ be the vector that is the same as x but with the i-th coordinate flipped. Given a boolean function $f : \{0,1\}^n \to \{0,1\}$, let $s(f, x)$ be the sensitivity of f at x, that is the number of coordinates $i \in [n]$ such that $f(x^{(i)}) \neq f(x)$, and let $s(f) = \max_x s(f, x)$ be the sensitivity of f.

2.1 Coupon-Collector Problem

The classical coupon-collector problem asks how large T should be, so that a uniformly random T-tuple in $[n]^T$ contains every element of $[n]$ with high probability. Generalizing the goal to a subset $A \subseteq [n]$, we have the following answer:

▶ **Proposition 1.** *Given any subset $A \subseteq [n]$, for a uniformly random $i \in [n]^T$, the probability that $A \nsubseteq \{i_1, \ldots, i_T\}$ is at most $n(1 + \log |A|)T^{-1}$.*

The proof follows directly from the fact that the expected waiting time for every element in A to appear is $n \sum_{j=1}^{|A|} j^{-1} \geq n(1 + \log |A|)$, and Markov's inequality.

In this paper, we consider a zero-error version of the coupon-collector problem. In this problem, the coupon collector could explicitly choose to stop when she is sure with zero-error that every element in A has already been collected. The results in this paper show that with bounded memory, the zero-error coupon-collector cannot stop within few (say, $O(n \log |A|)$) turns with high probability, in contrast to the proposition above.

2.2 Random-Query Model

In the random-query model, at each step $t \in \mathbb{N}_+$ a uniformly random index $i_t \in [n]$ is provided. When the problem specifies an input $x \in \{0,1\}^n$, at each step t the value of the bit $x_{i_t} \in \{0,1\}$ is also given along with the random index i_t. In this paper, we consider two cases for the joint distribution of the indices:

Independent The indices $i_1, i_2, \ldots$ are mutually independent.

Recurring The only dependencies allowed among $i_1, i_2, \ldots$ are equalities. More formally, there is a partition $p : \mathbb{Z}_+ \to \mathbb{Z}_+$, such that $i_t = i'_{p(t)}$ for every $t \in \mathbb{Z}_+$, where $i'_1, i'_2, \ldots$ are mutually independent and uniformly random over $[n]$.

For the rest of the paper, we refer to the two cases as *independent distribution* and *recurring distributions*. Notice that the independent distribution is a special case of the recurring ones. The recurring distributions are closely related to oblivious branching programs; see Section 5 for a detailed discussion.

2.3 Computational Models

The computational models we consider are based on branching programs. A *branching program* of length T and width 2^S is a directed (multi) graph with vertices arranged in $T+1$ layers containing at most 2^S vertices each. Denote the set of vertices in the i-th layer by $\mathcal{L}_i$, for $i = 0, 1, \ldots, T$. In $\mathcal{L}_0$ there is only one vertex, called the *start vertex*. Every vertex in $\mathcal{L}_T$ has out-degree 0, and is called a *leaf*. The outgoing edges from every non-leaf vertex in $\mathcal{L}_i$ only go to vertices in $\mathcal{L}_{i+1}$, for every $i < T$.

A simple branching program is one such that every non-leaf vertex has n outgoing edges, labeled with each element in $[n]$ exactly once. We consider two types of simple branching programs:

- A set-labeled branching program is a simple branching program, where every vertex v is labeled with a set $H(v) \subseteq [n]$, satisfying the following *soundness* condition: if an edge from vertex u to vertex v is labeled with $i \in [n]$, it must hold that $H(v) \subseteq H(u) \cup \{i\}$. The start vertex must be labeled with $\varnothing$.
- A branching program for the coupon-collector problem is a simple branching program such that every leaf is labeled with either "accept" or "reject".

When the indices $i_1, \ldots, i_T \in [n]$ are given, the computation path in a simple branching program starts from the start vertex, and at step t follows the edge labeled with i_t until reaching a leaf v, and outputs the label of v.

Given a function $f : \{0,1\}^n \to \{0,1\}$, a branching program computing f is one such that every non-leaf vertex has $2n$ outgoing edges, labeled with each element in $[n] \times \{0,1\}$ exactly once. Every leaf v in the program is labeled with an output $\tilde{f}_v \in \{0,1,\square\}$. When an input $x \in \{0,1\}^n$ and the indices $i_1, \ldots, i_T \in [n]$ are given, the computation path in the branching program starts from the start vertex, and at step t follows the edge labeled with (i_t, x_{i_t}) until reaching a leaf v, and outputs $\tilde{f}_v$.

In the random-query model where the indices $i_1, \ldots, i_T$ are given according to a specified distribution, we define the success of every type of branching program as follows:

- We say that a set-labeled branching program *succeeds on* $A \subseteq [n]$, if the probability that the output of the branching program $H(v) \supseteq A$ is at least $1/2$.
- For the coupon-collector problem, we say the branching program *collects* $A \subseteq [n]$ *with zero-error*, if the probability that the branching program outputs "accept" is at least $1/2$, and conditioned on outputting "accept", the probability that $\{i_1, \ldots, i_T\} \supseteq A$ is 1.
- For computing a function f, we say that the branching program *computes* f *with error* ε, if for every $x \in \{0,1\}^n$, the probability that the output of the branching program $\tilde{f}_v = f(x)$ is at least $1 - \varepsilon$. We say that the branching program *computes* f *with zero-error*, if for every $x \in \{0,1\}^n$, the probability that the output of the branching program $\tilde{f}_v \in \{0,1\}$ is at least $1/2$, and the probability that $\tilde{f}_v = 1 - f(x)$ is zero.

3 Lower Bounds for Set-Labeled Branching Programs

In this section, we prove the following theorem:

▶ **Theorem 2.** *Under the random-query model with any recurring distribution, for any set $A \subseteq [n]$, any set-labeled branching program of width $2^S \geq |A|$ that succeeds on A must have length at least $\frac{n|A|}{8S}$ for sufficiently large n.*[2]

Fix such a set-labeled branching program. We first prove an upper bound on the probability of the computation path reaching two given vertices:

▶ **Lemma 3.** *For any two vertices u, v in a set-labeled branching program, where $u \in \mathcal{L}_i$, $v \in \mathcal{L}_j$ and $i < j$. Under the random-query model with any recurring distribution,*

$$\Pr[\textit{reaching } u \wedge \textit{reaching } v] \leq \left(\frac{j-i}{n}\right)^{|H(v) \setminus H(u)|}.$$

[2] Notice that by definition, a branching program of width $2^S < |A|$ is also a branching program of width $|A|$. Therefore for smaller widths, the theorem still holds, but with an additional $\log|A|$ overhead on S. Theorems 5 and 6 work similarly.

Proof. Let $p : \mathbb{Z}_+ \to \mathbb{Z}_+$ be the partition for the recurring distribution. Let $\ell = |\{p(k) \mid i < k \le j\}|$. The indices received from the random queries between layer i and layer j are uniformly distributed over $[n]^\ell$. Let G be the random variable that represents the set of indices received between layer i and layer j. By the soundness requirement of set-labeled branching programs, if the computation path reaches u and then v, the set G corresponding to this path must satisfy $H(v) \subseteq H(u) \cup G$. Therefore,

$$\Pr[\text{reaching } u \wedge \text{reaching } v] \le \Pr[H(v) \subseteq H(u) \cup G] = \Pr[H(v) \setminus H(u) \subseteq G].$$

If $\ell < |H(v) \setminus H(u)|$ then the above probability is zero. Otherwise by (over)counting the positions where the elements of $|H(v) \setminus H(u)|$ appear and the union bound we have

$$\begin{aligned}\Pr[H(v) \setminus H(u) \subseteq G] &\le \frac{\ell!}{(\ell - |H(v) \setminus H(u)|)!} \cdot n^{-|H(v)\setminus H(u)|} \\ &\le \left(\frac{\ell}{n}\right)^{|H(v)\setminus H(u)|} \\ &\le \left(\frac{j-i}{n}\right)^{|H(v)\setminus H(u)|}.\end{aligned}$$

◀

▶ Remark 4. For the independent distribution, the above argument yield:

$$\Pr[\text{reaching } v \mid \text{reaching } u] \le \left(\frac{j-i}{n}\right)^{|H(v)\setminus H(u)|}.$$

The weaker result in Lemma 3, however, holds more generally for any recurring distribution. It is also strong enough for proving Theorem 2.

Proof for Theorem 2. Suppose the length of the set-labeled branching program is T. Define the weight of a vertex v as $W(v) = \Pr[\text{reaching } v]$. For a set of vertices $\mathcal{A}$, let $W(\mathcal{A}) = \sum_{v\in\mathcal{A}} W(v)$. Since the leaves are all in $\mathcal{L}_T$, for every $0 \le i \le T$ we have $W(\mathcal{L}_i) = 1$. The fact that the branching program succeeds on $A \subseteq [n]$ translates to:

$$\sum_{\substack{v\in\mathcal{L}_T \\ A\subseteq H(v)}} W(v) \ge 1/2. \tag{1}$$

We divide the branching program into $\frac{|A|}{2S}$ stages, each consists of a consecutive part of the layers. For every $0 \le k \le \frac{|A|}{2S}$, let i_k be the smallest index of a layer $\mathcal{L}_i$ such that

$$\sum_{\substack{v\in\mathcal{L}_i \\ |H(v)|\ge 2kS}} W(v) \ge \frac{kS}{|A|}.$$

By (1) we know such a layer must exist. Now the k-th stage consists of the layers from $\mathcal{L}_{i_k}$ to $\mathcal{L}_{i_{k+1}-1}$. Let

$$\mathcal{A}_k = \{u \in \mathcal{L}_{i_k} \mid |H(u)| \ge 2kS\}, \qquad \mathcal{B}_k = \{u \in \mathcal{L}_{i_k-1} \mid |H(u)| < 2kS\}.$$

By the definitions of i_k, we know that $W(\mathcal{A}_k) \ge kS/|A|$, $W(\mathcal{B}_k) > 1 - kS/|A|$.

Now we show that every stage contains at least $(n/3-1)$ layers. Suppose for contradiction that for some k, it holds that $i_{k+1} - i_k < n/3 - 1$. For any two vertices $u \in \mathcal{B}_k$ and $v \in \mathcal{A}_{k+1}$, by Lemma 3 we have

$$\Pr[\text{reaching } u \wedge \text{reaching } v] \le \left(\frac{i_{k+1} - i_k + 1}{n}\right)^{|H(v)\setminus H(u)|} < 3^{-2S}.$$

Therefore, applying the union bound gives:

$$\begin{aligned}
&\Pr[\text{reaching } \mathcal{L}_{i_k-1} \wedge \text{reaching } \mathcal{L}_{i_{k+1}}] \\
\leq &\Pr[\text{reaching } \mathcal{L}_{i_k-1} \setminus \mathcal{B}_k] + \Pr[\text{reaching } \mathcal{L}_{i_{k+1}} \setminus \mathcal{A}_{k+1}] + \Pr[\text{reaching } \mathcal{B}_k \wedge \text{reaching } \mathcal{A}_{k+1}] \\
\leq &1 - W(\mathcal{B}_k) + 1 - W(\mathcal{A}_{k+1}) + \sum_{\substack{u\in\mathcal{B}_k \\ v\in\mathcal{A}_{k+1}}} \Pr[\text{reaching } u \wedge \text{reaching } v] \\
< &\frac{kS}{|A|} + 1 - \frac{(k+1)S}{|A|} + 2^S \cdot 2^S \cdot 3^{-2S} < 1.
\end{aligned}$$

The second last step is because there are at most 2^S vertices in each layer, and the last step is because $2^S \geq |A|$. However, since the computation path must pass through both $\mathcal{L}_{i_k-1}$ and $\mathcal{L}_{i_{k+1}}$, the probability above must be 1, which is a contradiction.

Thus we conclude that, for n large enough, $i_{k+1} - i_k \geq n/3 - 1 \geq n/4$. Therefore,

$$T \geq \sum_{0\leq k<|A|/2S} (i_{k+1} - i_k) \geq \frac{n|A|}{8S}$$ ◀

4 Lower Bounds for Zero-error Computations under Independent Distribution

▶ **Theorem 5.** *Under the random-query model with the independent distribution, for any set $A \subseteq [n]$, any branching program for the coupon-collector problem of width $2^S \geq |A|$ which collects A with zero-error must have length at least $\frac{n|A|}{8S}$ for sufficiently large n.*

Proof. We show that for such a branching program, we can assign each vertex v with a label $H(v) \subseteq [n]$ so that the branching program is set-labeled. Let $P(v)$ be the collection of directed paths from the starting vertex to v. For every directed path p let $h(p)$ be the collection of indices labeled on the edges of p. Then we define $H(v) = \cap_{p\in P(v)} h(p)$.

The starting vertex is clearly labeled with the empty set. To check the soundness, consider an edge e from vertex u to vertex v labeled with i. For every path $p \in P(u)$, the concatenation pe is a path in $P(v)$, and $h(pe) = h(p) \cup \{i\}$. Therefore $H(v) \subseteq \cap_{p\in P(u)} h(pe) = H(u) \cup \{i\}$.

Notice that every path from the starting vertex to a leaf corresponds to a collection of indices $i_1, \ldots, i_T$, that are given with probability $n^{-T} > 0$ under the independent distribution. Since the branching program collects A with zero-error, for every path to an "accept" leaf it must holds $A \subseteq \{i_1, \ldots, i_T\}$, so every "accept" leaf v is now labeled with $H(v) \supseteq A$. Therefore, as a set-labeled branching program it succeeds on A. By Theorem 2 we know the length of the branching program is at least $\frac{n|A|}{8S}$ for sufficiently large n. ◀

▶ **Theorem 6.** *Let $f : \{0,1\}^n \to \{0,1\}$ be a boolean function with sensitivity $s(f)$. Under the random-query model with the independent distribution, any branching program of width $2^S \geq n$ which computes f with zero-error must have length at least $\frac{n\cdot s(f)}{8S}$ for sufficiently large n.*

Proof. Suppose there is a branching program $\mathcal{P}$ of width 2^S and length T that computes f with zero-error. Let $x \in \{0,1\}^n$ be an input such that $s(f) = s(f,x)$, and let $A = \{i \in [n] \mid f(x) \neq f(x^{(i)})\}$. We show below that from $\mathcal{P}$, one can extract a simple branching program $\mathcal{P}'$ for the coupon-collector problem of width at most 2^S and length T, which collects A with zero-error. Since $|A| = s(f)$, by Theorem 5 we know $T \geq \frac{n\cdot s(f)}{8S}$ for sufficiently large n.

We construct $\mathcal{P}'$ inductively to simulate $\mathcal{P}$ on input x. For vertex v in $\mathcal{P}$ we use v' to denote its corresponding vertex in $\mathcal{P}'$. The start vertex v'_0 in $\mathcal{P}'$ corresponds to the start vertex v_0 in $\mathcal{P}$. If in $\mathcal{P}$ there exists an edge from u to v labeled with (i, x_i), and u' is in $\mathcal{P}'$, then add v' to $\mathcal{P}'$ (if v' is not already there), and add an edge from u' to v' labeled with i. Finally, for every leaf v' in $\mathcal{P}'$, label v' with "accept" if $\tilde{f}_v = f(x)$, otherwise label v' with "reject".

First notice that under the independent distribution, the probability of reaching a vertex v' in $\mathcal{P}'$ is exactly the same as the probability of reaching v in $\mathcal{P}$ with the input x. Since the probability that $\mathcal{P}$ outputs $f(x)$ on input x is at least $1/2$, the probability that $\mathcal{P}'$ outputs "accept" is also at least $1/2$.

We now show that conditioned on reaching a leaf v' in $\mathcal{P}'$ labeled with "accept", it must hold that $A \subseteq \{i_1, \ldots, i_T\}$. Suppose not, then for some index $i \in A$ there is a path p' from the start vertex to v' where no edge is labeled with i. Consider the corresponding path p in $\mathcal{P}$. On input $x^{(i)}$, the computation follows the path p with non-zero probability and outputs $\tilde{f}_v = f(x) \neq f(x^{(i)})$, which contradicts the zero-error property of $\mathcal{P}$. That concludes the proof that $\mathcal{P}'$ collects A with zero-error. ◀

For the large class of functions with sensitivity $\Omega(n)$, Theorem 6 provides the quadratic time-space lower bound:

▶ **Corollary 7.** *Let f be a boolean function on n-bits with sensitivity $\Omega(n)$ (For instance, AND, XOR, Majority, s-t connectivity, etc.). Under the random-query model with the independent distribution, any branching program of width $2^S \geq n$ which computes f with zero-error must have length $\Omega(n^2/S)$.*

▶ Remark 8. Theorem 6 is tight up to logarithmic factors, in the sense that for every $m \leq n$, the function $x_1 \oplus \cdots \oplus x_m$ can be computed with zero-error within S space and $O(nmS^{-1} \log n)$ steps. We briefly sketch the algorithm here: Equally partition $[m]$ into $O(mS^{-1})$ parts, each of size $O(S)$. For each part P, use $O(n \log n)$ steps to record the values x_i for all indices $i \in P$. If any $i \in P$ does not appear within these $O(n \log n)$ steps, output $\square$. Otherwise compute the partial parity $\bigoplus_{i \in P} x_i$, and accumulate the partial parities.

As the lower bound in Theorem 6 is derived directly from Theorem 5 and further from Theorem 2, variants of the above algorithm also imply that Theorems 2 and 5 are tight up to logarithmic factors.

Similar to the case in the coupon-collector problem, the zero-error guarantee is crucial to Theorem 6, since for instance, the n-bit AND function can be computed with constant error by a branching program of length $O(n)$ and width $O(1)$. However, when specified to the parity function, the best trade-off seems to be still quadratic even in the bounded-error setting. We propose the following conjecture:

▶ **Conjecture 1.** *Under the random-query model with the independent distribution, any branching program of length T and width 2^S which computes $x_1 \oplus \cdots \oplus x_n$ with error $1/3$ must satisfy $TS = \widetilde{\Omega}(n^2)$.*

▶ Remark 9. Besides the algorithm mentioned above, there is another essentially different algorithm for computing parity (which actually computes the Hamming weight) with bounded error: Equally partition $[n]$ into $O(S/\log n)$ parts. For each part P, record the number of steps t when a pair (i, x_i) such that $i \in P$ and $x_i = 1$ is received, and finally approximate the partial sum $\sum_{i \in P} x_i$ with the integer closest to tn/T. By Chernoff bound, $T = O(n^2 S^{-1} \log^2 n)$ is enough so that the approximation of each part is wrong with probability $O(n^{-1})$.

Notice that this algorithm does not work in the zero-error setting. While the previous algorithm corresponds directly to a set-labeled branching program, it is not clear whether this approximation algorithm is related to set-labeled branching programs or not.

5 Oblivious Branching Programs and Random-Query Model

The random input model with recurring distributions is closely related to oblivious branching programs. In this section, we present two potential directions to prove strong lower bounds for oblivious branching programs, both via proving lower bounds in the random-query model. Let $\mathrm{SURJ}_{n,m} : [n]^m \to \{0,1\}$ be the surjectivity function: $\mathrm{SURJ}_{n,m}(i) = 1$ if and only $\{i_1, \ldots, i_m\} = [n]$.

▶ **Theorem 10.** *For any $m \geq 2n(\log n + 1)$, any deterministic oblivious branching program computing $\mathrm{SURJ}_{n,m}$ is also a branching program for the coupon-collector problem that collects $[n]$ with zero-error under some recurring distribution.*

Proof. Suppose at level $t-1$ the oblivious branching program reads $i_{p(t)}$, for some function $p : \mathbb{Z}_+ \to [m]$. Use p as the partition in the recurring distribution in the random-query model, then the computation of the branching program for the coupon-collector problem is exactly the same as in the oblivious branching program with a uniformly random input $i \in [n]^m$. Proposition 1 shows that the probability of $\mathrm{SURJ}_{n,m}(i) = 1$ is at least $1/2$. As the deterministic oblivious branching program always outputs correctly, as a branching program for the coupon-collector problem it succeeds with zero-error. ◀

For any function $f : \{0,1\}^n \to \{0,1\}$ and $m \geq n$, let $f^* : [n]^m \times \{0,1\}^m \to \{0,1\}$ be a partial function defined as follows: $f^*(i,y)$ is well-defined for $i \in [n]^m$ and $y \in \{0,1\}^m$, if and only if $\mathrm{SURJ}_{n,m}(i) = 1$, and whenever $i_j = i_k$ it must hold $y_j = y_k$. When $f^*(i,y)$ is well-defined, the value of $f^*(i,y)$ is $f(y_{j_1}, \ldots, y_{j_n})$, where for every $\iota \in [n]$, j_ι is some $j \in [m]$ such that $i_j = \iota$.

▶ **Theorem 11.** *Given any function $f : \{0,1\}^n \to \{0,1\}$. For any $m \geq 3n(\log n + 1)$, if there is a deterministic oblivious branching program computing f^* of length T and width 2^S (on the inputs where f^* is well-defined), then there is a branching program of the same length and width, that computes f with error $1/3$ in the random-query model under some recurring distribution.*

Proof. Add dummy levels to the oblivious branching program to double the length, such that if originally at level t the branching program reads either i_j or y_j, now it reads i_j at level $2t$ and y_j at level $2t+1$. The oblivious branching program now can be regarded as the one of length T and width 2^S that at each level t reads a pair $(i_{p(t)}, y_{p(t)})$, for some function $p : \mathbb{Z}_+ \to [m]$. Use p as the partition in the recurring distribution. For any fixed $x \in \{0,1\}^n$, the computation in the random-query model on input x is exactly the same as in the oblivious branching program with a uniformly random $i \in [n]^m$, and input $y \in \{0,1\}^m$ defined as $y_j = x_{i_j}$. For such i and y, $f^*(i,y)$ is well-defined if and only if $\mathrm{SURJ}_{n,m}(i) = 1$, and Proposition 1 indicates the probability that $f^*(i,y)$ is well-defined is at least $2/3$. Since whenever $f^*(i,y)$ is well-defined, the deterministic oblivious branching program correctly outputs $f(y_{j_1}, \ldots, y_{j_n}) = f(x)$, as a branching program under the random-query model it computes f with error $1/3$. ◀

As a corollary, if in the random-query model we were able to prove a time-space lower bound that holds under any recurring distribution, either for the zero-error coupon-collector problem, or for any bounded-error computation, we would immediately have the same lower bound (up to logarithmic factors) on deterministic oblivious branching programs.

Strategy-Stealing Is Non-Constructive

Greg Bodwin

Abstract

In many combinatorial games, one can prove that the first player wins under best play using a simple but non-constructive argument called *strategy-stealing*. This work is about the complexity behind these proofs: how hard is it to actually find a winning move in a game, when you know by strategy-stealing that one exists? We prove that this problem is PSPACE-Complete already for *Minimum Poset Games* and *Symmetric Maker-Maker Games*, which are simple classes of games that capture two of the main types of strategy-stealing arguments in the current literature.

1 Introduction

Theoretical Computer Science includes a rich theory of the complexity class TFNP, defined as the set of NP search problems where a solution always exists. The interesting subclasses of TFNP are based on simple yet non-constructive existence proofs for these solutions. For example: given a circuit

$$C : \{0,1\}^n \to \{0,1\}^{n-1},$$

one sees immediately by the Pigeonhole Principle that there exist distinct inputs x_1, x_2 with matching output $C(x_1) = C(x_2)$. But can one find such a pair of inputs computationally? This problem is complete for a complexity class PWPP $\subseteq$ TFNP, and a similar story holds for various other problems with other non-constructive proofs of solution existence.

A major motivation for TFNP as an object of study is that it gives satisfying formalizations of the natural question of whether a type of proof is constructive ("is the Pigeonhole Principle constructive?" roughly corresponds to "is P = PWPP?"). But really, some non-constructive proof methods in mathematics do not correspond to NP search problems at all. Thus, we argue, a valuable direction for research in the spirit of TFNP is to look outside TFNP itself to analyze the constructiveness of proofs in other complexity classes. This paper is about one such instance: *strategy-stealing proofs*, which are fundamental existence results in combinatorial game theory that naturally lie in PSPACE.

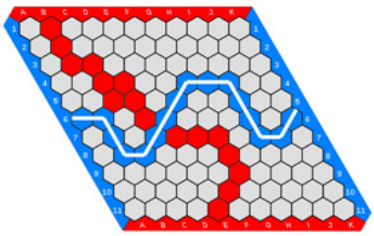

Figure 1 A Hex board with a winning configuration for Blue [1].

1.1 Combinatorial Games and Strategy-Stealing

A *combinatorial game* is a finite two-player game of perfect information. The players take turns choosing *moves* that manipulate a game board by some predefined rules, eventually reaching one out of a set of *terminal states* which determine the outcome of the game. Examples of combinatorial games include chess, go, tic-tac-toe, and some others that we will describe in detail shortly.

In general, deciding which player has a winning strategy in a combinatorial game is computationally hard. However, certain classes of games admit slick proofs that a certain player wins under best play (and thus determining who has a winning strategy in these games is not computationally hard). A famous example is the game *Hex*, in which two players named Red and Blue alternately color in hexagons in a symmetric board (pictured in Figure 1); Red wins if there is a continuous path of red hexagons connecting the top and bottom, and Blue wins if there is a continuous path of blue hexagons connecting the left and right. The *Hex Theorem* states that exactly one of the two players will achieve a winning configuration once all hexagons have been colored, so there are no draws. It was observed by Nash [15] that:

▶ **Theorem 1** ([15]). *The first player has a winning strategy in the game of Hex.*

Proof Sketch. Suppose for contradiction that the second player has a winning strategy. The first player can then make an arbitrary first move and then "steal" the winning strategy of the second player. That is, he will now pretend he is the second player, and play according to the second player's winning strategy. This will lead to a win for the first player anyways since their arbitrary initial move can only help them achieve a winning configuration. ◀

This has been dubbed the first *strategy-stealing* proof, referring to a now-broad collection of proofs that assume for contradiction that the second player can win, then repurpose the winning strategy to create a win for the first player. Another illustrative example is the game *Chomp*. Here, the game board is an $m \times n$ chocolate bar in which the top right square has been poisoned. The players alternately choose an uneaten square, and then eat that square and all remaining squares down and to the left. A player loses if they eat the poisoned square.

The following strategy stealing argument applies to Chomp:

▶ **Theorem 2** (Folklore). *The first player has a winning strategy in the game of Chomp.*

Proof Sketch. Consider the possible first move where the first player chomps off only the bottom-left-most square. There are two cases. Maybe the second player does not have a winning response, in which case the game is a win for the first player. Alternately, suppose the second player has a winning response by chomping off an $a \times b$ block. Since this block

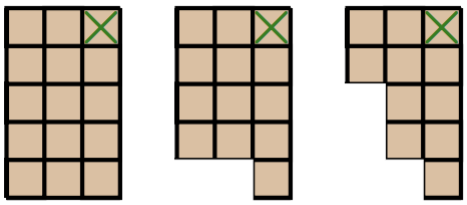

Figure 2 A valid two-move sequence from the starting position in 5×3 Chomp.

necessarily contains the bottom-left-most square, the board state is the same as if an $a \times b$ block had been chomped off with the first move of the game. It follows that this $a \times b$ chomp, instead, would have been a winning first move for the first player. ◀

Both of the proofs above *seem* non-constructive, in the sense that they do not yield an actual winning first move. Our central research question is whether this is inherent:

Are strategy-stealing proofs constructive?

To tackle this problem, we consider games that admit strategy stealing proofs, and we investigate the computational hardness of finding winning moves in such games. With this view, one can see that strategy-stealing proofs can essentially be *arbitrarily* non-constructive: for any combinatorial game X with two players P1 and P2, we can define a game X' in which the first player can decide whether he wishes to play as P1 or P2 in game X.[1] Then finding a winning move for P1 is the same as determining the winner of X, which in general is computationally hard. (We discuss this point in a little more detail in the conclusion.)

Thus, a more interesting direction is not to proceed in the maximally general case, but rather to investigate whether hardness persists in special classes of games to which strategy-stealing applies. In particular, we will study games which (to our eye) are the minimal natural classes captured by the two strategy-stealing arguments given above.

1.2 Our Results

To capture "Hex-type strategy stealing," we consider the well-studied class of *symmetric Maker-Maker games*:

▶ **Definition 3** (Symmetric Maker-Maker Game[2])**.** *In a* Maker-Maker Game*, two players alternately claim elements of a finite universe U. There are families of* winning sets *$W_1, W_2 \subseteq P(U)$; the first player wins as soon as they claim all the elements of any winning set $S \in W_1$, the second player wins as soon as they claim all the elements of any winning set $S \in W_2$, and the game is a draw if all of U is claimed without either player winning. The game is* symmetric *if W_1, W_2 are isomorphic, i.e., there is a permutation π of U and a bijection $\phi : W_1 \to W_2$ such that for all $S_1 = \{s_1, \ldots, s_k\} \in W_1$, we have $\phi(S_1) = \{\pi(s_1), \ldots, \pi(s_k)\}$.*

[1] Notice the strategy stealing argument that the first player has a winning strategy in the game X': suppose otherwise. Then we know if the first player chooses to play as P1, the second player has a winning strategy, so P2 has a winning strategy in X. But then the first player can choose to play as P2 in X' and use the winning strategy for P2 in X.

[2] This is a generalization of the usual definition: in the literature, a "Maker-Maker game" often implies $W_1 = W_2$.

Hex is a symmetric Maker-Maker (SMM) game, and indeed the proof of Theorem 1 generalizes immediately to imply that any SMM game is not a win for the second player. There are many other examples of SMM games, which will be surveyed later. In general an SMM game can be a draw under best play, but some games like Hex are *draw-free* and so a first-player win is the only remaining possibility. We associate a computational problem to these games as follows:

▶ **Definition 4** (SMMMove). *The problem* SMMMove *is defined as follows:*

- *Input: Circuits C_1, C_2, both with input wires labelled $x_1, \ldots, x_n$. C_1 and C_2 are the same up to relabelling of the wires. Call $X = \{x_1, \ldots, x_n\}$. The Maker-Maker game associated with this input is where W_1 contains any set of inputs $Y \subseteq X$ for which C_1 evaluates to true when the inputs in Y are set to true and $X \setminus Y$ to false. W_2 is defined similarly with respect to C_2.*
- *Output: any optimal first move for the first player in the associated game.*

We prove:

▶ **Theorem 5.** SMMMove *is* PSPACE*-hard,*[3] *even under the additional promise that the input defines a draw-free game with $W_1 = W_2$.*

Thus, Hex-type strategy stealing is a formally non-constructive style of proof, and additional draw-freeness results like the Hex Theorem do not generally help. To capture "Chomp-type strategy stealing," we consider:

▶ **Definition 6** (Minimum Poset Games). *In a* poset game*, two players alternately choose remaining elements of a poset P, removing the chosen element and all lesser elements at each step. A player loses if it is their turn but the poset is empty. The game is* minimum *if P has a minimum element (i.e., $m \in P$ that is comparable to and less than every other element in P).*

(For both these types of games, we refer to [4, 11] for some of their history and prior work.) Chomp is a minimum poset game, where the associated poset holds the squares of the chocolate bar, with the poisoned square removed, and squares are compared by the usual poset relation on $\mathbb{Z}^2$ (note that the bottom-left-most square is a minimum element). Theorem 2 generalizes to show that any minimum poset game is a win for the first player. Other examples of poset games, which may or may not have a minimum, include Nim, Hackendot, certain cases of Hackenbush, and many others. Computationally, we have:

▶ **Definition 7** (MPMove). *The problem* MPMove *is defined as follows:*

- *Input: a poset P (with elements and relations between them enumerated explicitly) with a minimum element.*
- *Output: any winning move for the first player in the poset game defined by P.*

▶ **Theorem 8.** MPMove *is* PSPACE*-hard.*

From a technical standpoint, both Theorems 5 and 8 are proved roughly as follows. We start with a theorem in prior work stating that it is PSPACE-hard to decide the winner in a related class of games: Hex from an arbitrary starting position [16], or a certain class of poset

[3] A straightforward algorithm solves SMMMove in polynomial space, so in some sense it is complete (ignoring subtleties in the terminology), but we will not discuss these easy upper bounds in this paper. A similar comment holds for MPMove below.

games [9]. We then apply transformations that introduce the necessary strategy-stealing properties to these games while arguing that the winner in the original game is implicitly encoded by the first player's winning move(s). In the case of minimum poset games, this is an easy extension of the theorem in [9]; we include this mostly to illustrate our conceptual goal of computationally formalizing non-constructiveness. For SMM games, the transformation is nontrivial and requires significant new ideas. Thus, the SMM result constitutes our main technical contribution.

1.3 Related Work

As mentioned, this paper is conceptually related to the study of the complexity class TFNP, defined in [14] and including notable subclasses PPAD, PPA, CLS, PPP, PWPP, PLS, among others. These classes all hold search problems in NP that admit proofs that a solution always exists. Our work is related in that our goal is to prove hardness of searching for a winning moves in games, when there are strategy-stealing proofs that one always exists. The key difference is that our problems are not in NP; there is not generally a short certificate that an optimal move is indeed the first one in some optimal strategy.

In [5], the author proves that it is PSPACE-hard to decide whether an SMM game is a win for the first player or a draw. Our work differs in that (1) to minimally generalize Hex we restrict attention to *draw-free* games, in which this decision problem is trivial, and (2) we are interested in constructively finding a winning move rather than deciding existence. Similarly related is [16], in which it is proved to be PSPACE-hard to decide whether Hex from a partially-filled board is a win for the first or second player. This can be viewed as a Maker-Maker game, but since the board is partially filled, it is not generally a symmetric Maker-Maker game and thus strategy-stealing does not apply.

There is a rich and developed theory of Maker-Maker games, poset games, and variants, most of which focuses on understanding these games under best play (rather than computational aspects of playing the games). See books [4, 11] for more information.

2 Non-Constructiveness of Strategy-Stealing

We will now prove our main results.

2.1 Symmetric Maker-Maker Games

Our first topic will be Symmetric Maker-Maker games, and eventually a proof of Theorem 5.

Examples

We first survey some famous examples of SMM games in the literature.

- Hex is an SMM game, as discussed above, which is draw-free and has non-equal winning sets.
- In the (n, k)-*Clique game*, the game board is a complete graph on n nodes and the players take turns claiming its edges. The first player to claim all edges in a k-clique wins. This is a symmetric Maker-Maker game, even with identical winning sets $W_1 = W_2$ (i.e., the underlying permutation is the identity). An interesting property of this game is that, for all k, if n is sufficiently large then the game is draw-free. This follows from *Ramsey's Theorem*, which states that any 2-coloring of the edges of the complete graph has a monochromatic clique of size $\Omega(\log n)$. Hence, for large enough n, strategy-stealing implies specifically that the first player has a winning strategy. For work on the Clique game and some natural variants, see e.g., [2, 7, 6, 3, 12].

- Tic-Tac-Toe is an SMM game, where the winning sets are the 8 possible "lines" in the 3×3 grid. This game is not draw-free.
- In (k, d) Tic-Tac-Toe, the game board is the elements of the k^d hypercube ($\{1, 2, \ldots, k\}^d$), and the winning sets $W_1 = W_2$ are the k-element subsets which are colinear in the hypercube. The *Hales-Jewett Theorem* [10] implies that for every k, if d is sufficiently large then the game is draw-free. For work on this game, see e.g., [4, 8].
- In the (n, k) *Arithmetic Progression game*, the universe is the set of integers $\{1, \ldots, n\}$, and the winning sets are any k elements that form an arithmetic progression (i.e., the difference between successive integers is equal). *Van-der-Waerden's Theorem* [17] implies that for every k, if n is sufficiently large then the game is draw-free. The Arithmetic Progression game has been studied e.g., in [13, 2, 12].

All of these games are SMM and hence admit strategy-stealing proofs that the second player does not win under best play. The problem of finding an optimal first move for the first player can thus be captured as a special case of SMMMove. All of these games are draw-free in the appropriate range of parameters (except standard Tic-Tac-Toe), and thus here they even fit the promise that the input to SMMMove defines a draw-free game. Of course, these special cases need not be as hard as SMMMove: for example, it is trivial to find a winning first move in the (n, k)-Clique game, since by symmetry of the game board all first moves are equivalent. (Perhaps a more interesting version of the Clique game computational problem is to determine the first player's optimal move on their second turn, since the game necessarily still retains the symmetry needed for a strategy-stealing argument after each player claims only one edge.)

Hardness for SMMMove

We now show computational hardness for SMMMove. We first outline the proof ideas, and then provide a full proof. Our starting point is the following result from prior work:

▶ **Definition 9** (DecisionHex). *The problem* DecisionHex *is defined as follows:*

- *Input: a partially-filled Hex board Q*
- *Output: does Red have a winning strategy in the Hex game starting from Q (assuming it is currently Red's turn to play)?*

▶ **Theorem 10** ([16]). DecisionHex *is* PSPACE*-complete.*

Our goal is to reduce DecisionHex to SMMMove. First, let us remark on why Theorem 10 does not *directly* give hardness for SMMMove, given that Hex is an SMM game. The result that DecisionHex is hard means that there exist families of positions from which deciding the winner is hard. However, these positions are not generally symmetric, so the game starting from these positions is not SMM. Additionally, a talented player *playing from the starting position* could still potentially be able to win the game while avoiding these hard settings of the game board, thus winning without ever really encountering a PSPACE-complete problem.

So, we are given a partially filled (possibly asymmetric) board Q on input to DecisionHex, representing a Hex game between Red and Blue where it is Red's turn to move, and our goal is to create a new SMM draw-free game between players First and Second that captures the structure of Q in some useful way. To build intuition, let us start with a first (incorrect) attempt at such a game G. Suppose we add two new elements to the universe called r and b. The idea will be that claiming r is choosing to play as Red in the Hex game defined by Q, and claiming b is choosing to playing as Blue. More formally, the winning sets $W_1 = W_2$ of the new SMM game would be:

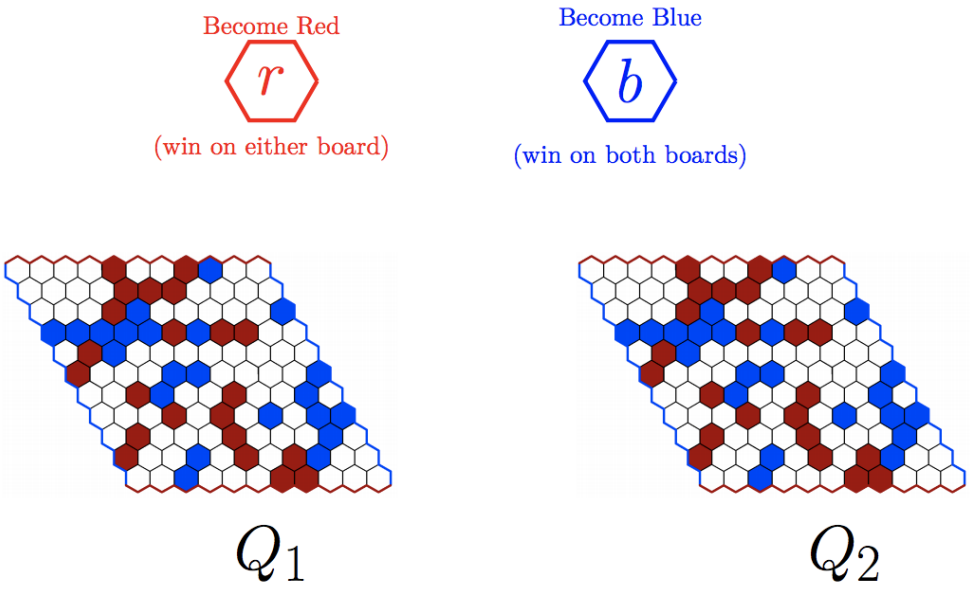

Figure 3 The universe used in our definition of an SMM game G.

- r and any set of hexagons that complete a win for Red in Q,
- b and any set of hexagons that complete a win for Blue in Q, and
- $\{r, b\}$.

If SMMMove$(G) = r$, this solves Q: the second player must claim b with their next move to block the winning set $\{r, b\}$, and then the game reduces to Q itself where First plays as Red and Second plays as Blue. Thus, if r is a winning move for First, then Q is a win for Red. Unfortunately, the other cases of the proof break down. For example: suppose the position on the board Q is such that whoever has the next move wins (so Q is a win for Red). Then it is winning for First to claim *either* r or b with their first move, meaning the output of SMMMove(G) is not very informative. Our fix is, intuitively, to amplify the game to avoid the possibility that the game winner depends on the turn order.

Proof of Theorem 5. We will prove that SMMMove is hard by reducing DecisionHex to it. Let Q an instance of DecisionHex. We will construct a Symmetric Maker-Maker game G which is draw-free and $W_1 = W_2$, such that finding a winning move in G allows us to find who has a winning strategy in Q.

The universe of our new game G will contain *two* identical copies Q_1, Q_2 of the input to DecisionHex, as well as new elements r, b like before. The winning sets $W_1 = W_2$ in G are (see Figure 3):

- r and any set of hexagons that completes a win for Red in *either* Q_1 or Q_2,
- b and any set of hexagons that completes a win for Blue in *both* Q_1 and Q_2, and
- $\{r, b\}$.

It is immediate that G is an SMM game, since the winning sets are identical. Additionally, we have:

▶ **Lemma 11.** *G is draw-free.*

Proof. Let S be any subset of the universe in G. We will show that either S or its complement S^C contains a winning set. First, if $r, b \in S$ then $\{r, b\} \subseteq S$, or if $r, b \notin S$ then $\{r, b\} \subseteq S^C$. So the nontrivial case is when S contains exactly one of r, b; let us assume without loss of generality that $r \in S, b \notin S$ (else switch the roles of S and S^C). For either board Q_i, by the Hex Theorem and the fact that the union of S_i, S_i^C covers the board, exactly one of the following two statements hold:

1. The elements of S on the board Q_i (call this S_i), combined with the elements on Q_i which are initially marked red, form a winning configuration for red on Q_i.
2. The elements of S^C on the board Q_i (call this set S_i^C), combined with the elements on Q_i which are initially marked blue, form a winning configuration for blue on Q_i.

Therefore, we conclude that in each board Q_i, either the elements of S complete a win for Red (we call Q_i a "red" board in this case), or the elements of S^C complete a win for Blue (we call Q_i a "blue" board in this case). If at least one of Q_1, Q_2 is red, then S contains r and a Red winning set. If both Q_1, Q_2 are blue, then S^C contains b and a Blue winning set on each board. In either case the lemma holds. ◀

Our goal is now to show that the winning move(s) for First in G completely determine the winner of Q. We consider two cases:

▶ **Lemma 12.** *If Blue has a winning strategy in Q, then the unique winning move for First in G is to claim b.*

Proof. We first show that claiming b is a winning move for First. In response, Second is forced to claim r to block the winning set $\{r, b\}$. First then claims an arbitrary hexagon, and then each time Second claims a hexagon on Q_1 or Q_2, First claims a hexagon on the same board to execute a winning strategy for Blue. Thus, First will have b and also a winning set for Blue on both boards, meaning First wins in G. (Note that Second will be unable to ever obtain a red winning set on either board, since it is not possible for both sides to obtain a winning configuration on any individual Hex board.)

We then show that, if First does not claim b with their first move, then it is a winning response for Second to claim b. Here we consider two cases. If First claims r, then after Second claims b, in each subsequent turn, each time First claims a hexagon on Q_1 or Q_2, Second can claim a hexagon on the same board to execute a winning strategy for Blue on that board, thus obtaining a winning set for Blue on both boards and hence winning in G. In the other case, if First claims a hexagon in (say) Q_1 with their first move, then after Second claims b, First must immediately claim r to block the winning set $\{r, b\}$. Second then claims a hexagon on Q_1 and from here this case reduces to the first one. ◀

▶ **Lemma 13.** *If Red has a winning strategy in Q, then it is not a winning move for First in G to claim b.*

Proof. Suppose that First claims b. The winning response for Second is to claim r. Without loss of generality, First then claims a hexagon in Q_1. Second then decides to permanently ignore Q_1 and focus entirely on Q_2, claiming exclusively hexagons in Q_2 for the rest of the game. Since Second is the first to move on Q_2, they can execute a winning strategy for Red on Q_2. Thus Second will eventually claim r and a winning set for Red on Q_2, meaning that Second wins in G. (Note, again, that First cannot possibly obtain a winning set in the meantime, since they cannot possibly hold a winning set for Blue on Q_2.) ◀

We now put the pieces together: after constructing the game G as described above, from Lemmas 12 and 13 we have

$$\text{SMMMove}(G) = b \quad \text{if and only if} \quad \neg\text{DecisionHex}(Q).$$

Since DecisionHex is PSPACE-complete, it follows that SMMMove is PSPACE-hard. ◀

2.2 Minimum Poset Games

Next, we prove Theorem 8. Our starting point is:

▶ **Definition 14** (DecisionPoset). *The problem* DecisionPoset *is defined as follows:*

- *Input: a poset P, described by explicitly listing its elements and the relations between them.*
- *Output: is the poset game (see Definition 6) associated to P a win for the first player under best play?*

▶ **Theorem 15** ([9]). DecisionPoset *is* PSPACE*-complete.*

We then argue:

Proof of Theorem 8. Given a poset game defined by P, generate a new poset P' by adding a new element m, defined to be less than every other element in P. We now argue that $\text{MPMove}(P') = m$ if and only if the original poset game defined by P was a win for the second player:

- Suppose P is a win for the first player. If in P' the first player claims m with their first move, then the game becomes equivalent to P with the turn order reversed. Thus claiming m is a losing move for the first player, and so $\text{MPMove}(P') \neq m$.
- Suppose P is a win for the second player. If in P' the first player claims m with their first move, then again the game is equivalent to P with the turn order reversed, so the first player has a winning strategy. This means we *can* have $\text{MPMove}(P') = m$, but since MPMove might return any winning move, we also need to rule out the possibility that any other move is winning. For this, we observe that any other first move in P' necessarily removes m and at least one other element from P', thus giving a position that can possibly be obtained after one move in P. Since P is a win for the second player, any such position must be losing for the player who creates it, and thus we have $\text{MPMove}(P') \notin P' \setminus \{m\}$, so $\text{MPMove}(P') = m$.

This completes the reduction from DecisionPoset to MPMove, and thus MPMove is PSPACE-hard. ◀

3 Open Questions

We conclude by listing some conceptual open questions left by this work.

TFPSPACE

Can we similarly analyze the computational properties of other interesting non-constructive proof techniques that lie outside of NP? Is there a satisfying theory of TFPSPACE, in analogy with TFNP?

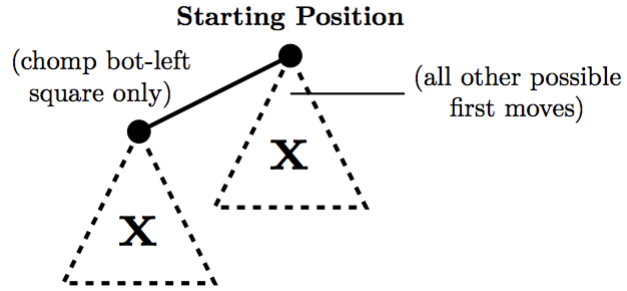

Figure 4 Due to the symmetry in the game tree of Chomp illustrated here, the value of the game tree can be expressed as X or $\neg X$, where X is the game tree after a 1×1 square has been chomped.

Bounded Computational Power

The existence of a winning strategy in a game does not necessarily shed much light on how *computationally bounded* players would play the game. To illustrate, consider the following game: player 1 declares a circuit C of their choice. Then, player 2 wins if they can declare an input x such that $C(x) = 1$. Then, player 1 then wins if *they* can declare an input x with $C(x) = 1$. If both players fail to declare such an input x, then player 2 wins. Here, there is clearly a winning strategy for the second player: if there exists an x such that $C(x) = 1$, then declare that x and win immediately; if there is no such x then player 2 also wins. However, if the players are represented by Turing machines that can only run for a polynomial amount of time, then the game is (probably) a win for player 1: for example, player 1 can pick a one way function f, compute it on some random x' of his choice to get output y, and then have the circuit C output 1 on all x such that $f(x) = y$. Under standard cryptography assumptions, player 2 will be unable to find such an x, and then player 1 will win in the next turn by declaring the x used to create the circuit.

Interestingly, for draw-free SMM games, such situations will not arise: even for computationally bounded players, it is preferable to play first, since playing an extra move is never disadvantageous. In contrast, this is not clearly true for poset games, where the wrong first move can possibly throw the game. Hence, this might be an interesting avenue to separate the computational properties of these two strategy-stealing arguments (since they are both PSPACE-hard under "best play," i.e., unbounded computational power). More generally, it would be interesting to further understand and formalize the effects of bounded computational power on various existence proofs for winning strategies in combinatorial game theory.

Generalized Strategy-Stealing

Many strategy-stealing arguments can be viewed as a reduction of the game tree to a tautology. To illustrate, the game tree of Chomp may be phrased as follows. Let X be the subgame tree from the starting chocolate bar with the bottom-left-most square removed. The proof of Theorem 2 essentially observes that the Chomp game tree is equal to X or $\neg X$, which is true as a formula (meaning a win for the first player) regardless of the value of X (see Figure 4).

Naturally, a reduction of the game tree to *any* tautology implies a first-player win, including more complicated tautologies in which multiple variables are assigned to multiple subgames. We might call this type of argument *generalized strategy-stealing*, as it extends the usual proofs

in the literature that use only X or $\neg X$. For any given tautology it is easy enough to invent an artificial game that admits a generalized strategy-stealing proof via that tautology. However, it would be interesting to find a "natural" game that admits a generalized strategy-stealing proof, using a tautology formally distinct from X or $\neg X$.

Hardness for Specific Games

While we have proved hardness for finding winning moves in game classes that include Hex and Chomp, our results do not imply hardness for Hex and Chomp specifically. In particular, it would be interesting to determine whether or not the following problem is in FP: given game board dimensions for Hex or Chomp (or basically any other game mentioned in this paper), written in unary, output a winning move for the first player. This problem is in PSPACE, but it will not be readily possible to prove it PSPACE-hard for the following reason: it is known that no unary language can be NP-complete unless P = NP; thus, a unary language complete for PSPACE would imply that P = NP or NP ≠ PSPACE, which is not known and would constitute a breakthrough in complexity theory. Thus it is unclear what hardness notion should be used to approach this question.

Other Notions of Constructiveness

We have proved that it is generally hard to find a winning move in a game, even when strategy-stealing arguments apply. Finding a good first move is one natural formalization of "constructiveness" in PSPACE, but there are others. For example, here is an open question that we have not addressed: for (say) the game Hex, does there necessarily exist a polynomial-size circuit that plays the game optimally, even if it is computationally hard to find the circuit?

Distribution-Free Testing of Linear Functions on $\mathbb{R}^n$

Noah Fleming[1]

Abstract

We study the problem of testing whether a function $f\colon \mathbb{R}^n \to \mathbb{R}$ is linear (i.e., both additive and homogeneous) in the *distribution-free* property testing model, where the distance between functions is measured with respect to an unknown probability distribution over $\mathbb{R}^n$. We show that, given query access to f, sampling access to the unknown distribution as well as the standard Gaussian, and $\varepsilon > 0$, we can distinguish additive functions from functions that are ε-far from additive functions with $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ queries, independent of n. Furthermore, under the assumption that f is a continuous function, the additivity tester can be extended to a distribution-free tester for linearity using the same number of queries. On the other hand, we show that if we are only allowed to get values of f on sampled points, then any distribution-free tester requires $\Omega(n)$ samples, even if the underlying distribution is the standard Gaussian.

1 Introduction

Property testing of Boolean functions studies the problem where, given query access to a function $f\colon \{0,1\}^n \to \{0,1\}$ and a parameter $\varepsilon > 0$, the goal is to distinguish with high probability the case that f satisfies some predetermined property P from the case that f is ε-far from satisfying P. That is, whether we need to change the values of $f(x)$ for at least an ε-fraction of $x \in \{0,1\}^n$ before f satisfies P. Since the seminal work by Blum, Luby and Rubinfeld [11], property testing has become a thriving field, and many properties of Boolean functions have been shown to be testable with a number of queries independent of n, including linear functions [11], low-degree polynomials [8, 26] and k-juntas [9, 10, 18]. For an introductory survey, we recommend [21].

In contrast to Boolean functions, only a few properties of functions on a Euclidean space, that is, $\mathbb{R}^n$, have been studied. For a measurable function $f\colon \mathbb{R}^n \to \mathbb{R}$, $\varepsilon > 0$, and a property P, we say that f is *ε-far* from P if

$$\Pr_{x\sim\mathcal{N}(0,I)}[f(x) \neq g(x)] > \varepsilon,$$

[1] Work done while visiting the National Institute of Informatics.

for any measurable function $g\colon \mathbb{R}^n \to \mathbb{R}$ satisfying P, where $\mathcal{N}(0, I)$ is the standard Gaussian. We say that an algorithm is a *tester* for a property P if, given query access to a measurable function $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to the standard Gaussian, and $\varepsilon > 0$, it accepts with probability at least $2/3$ when f satisfies P, and rejects with probability at least $2/3$ when f is ε-far from P. Testability of a variety of properties has been considered, including surface area of a set [29,34], half spaces [31–33], linear separators [3], high-dimensional convexity [13], and linear k-junta [15].

Although the standard Gaussian is natural, it rarely appears in practice. In fact, we typically have little, if any, information about the underlying distribution. This raises the question of whether we can test when the underlying distribution of the data is unknown. For a measurable function $f\colon \mathbb{R}^n \to \mathbb{R}$, $\varepsilon > 0$, a distribution $\mathcal{D}$ over $\mathbb{R}^n$, and a property P, we say that f is *ε-far* from P with respect to $\mathcal{D}$ if

$$\Pr_{x\sim\mathcal{D}}[f(x) \neq g(x)] > \varepsilon,$$

for any measurable function $g\colon \mathbb{R}^n \to \mathbb{R}$ satisfying P. We say that an algorithm is a *distribution-free tester* for a property P if, given query access to a measurable function $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to an *unknown* distribution $\mathcal{D}$ over $\mathbb{R}^n$ as well as the standard Gaussian, and $\varepsilon > 0$, it accepts with probability at least $2/3$ when f satisfies P, and rejects with probability at least $2/3$ when f is ε-far from P with respect to $\mathcal{D}$. Distribution-free property testing is an attractive model because it makes minimal assumptions on the environment, and models the scenario most often occurring in practice.

We say that a function $f\colon \mathbb{R}^n \to \mathbb{R}$ is *additive* if $f(x) + f(y) = f(x + y)$ for any $x, y \in \mathbb{R}^n$. In this work, we consider distribution-free testing of additivity of functions $f\colon \mathbb{R}^n \to \mathbb{R}$ and show the following.

▶ **Theorem 1.** *There exists a one-sided error distribution-free tester for additivity of $f\colon \mathbb{R}^n \to \mathbb{R}$ with $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ queries.*

Previously no algorithm was known even when the underlying distribution $\mathcal{D}$ is the standard Gaussian. As there is a trivial lower bound of $\Omega\left(\frac{1}{\varepsilon}\right)$, the query complexity of our tester is almost tight.

We say that a function $f\colon \mathbb{R}^n \to \mathbb{R}$ is *homogeneous* if $cf(x) = f(cx)$ for any $x \in \mathbb{R}^n$ and $c \in \mathbb{R}$. A function that is both additive and homogeneous is said to be *linear*. Although additivity and linearity are equivalent for functions over finite groups, there are (pathological) functions $f\colon \mathbb{R}^n \to \mathbb{R}$ that are additive but not homogeneous. Hence, the testability of additivity does not immediately imply the testability of linearity. However, when the input function is guaranteed to be continuous, we can also test linearity.

▶ **Theorem 2.** *Suppose that the input function is guaranteed to be continuous. Then, there exists a one-sided error distribution-free tester for linearity with $O\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ queries.*

It is also natural to assume that we can get values of the input function only on sampled points. Specifically, we say that a (distribution-free) tester is *sample-based* if it accesses the input function $f\colon \mathbb{R}^n \to \mathbb{R}$ through points sampled from the distributions $\mathcal{D}$ and $\mathcal{N}(0, I)$. We show a strong lower bound for sample-based testers.

▶ **Theorem 3.** *Any sample-based tester for the linearity of functions $f\colon \mathbb{R}^n \to \mathbb{R}$ requires $\Omega(n)$ samples, even when $\mathcal{D} = \mathcal{N}(0, I)$.*

This lower bound is tight; it is not difficult to see that $O(n)$ samples suffices to test linearity. Indeed $O(n)$ samples will, with high probability, contain n linearly independent vectors. The evaluations of f on these vectors uniquely determines the linear function. This theorem shows

a sharp contrast between query-based and sample-based testers for properties of functions on a Euclidean space. We note that we can show the same lower bound for testing additivity with an almost identical proof.

1.1 Related Work

The question of property testing first appeared (implicitly) in the work of Blum, Luby and Rubinfeld [11]. Among the problems that they studied was linearity testing. Their algorithm, now famously known as the BLR test, has played a key role in the design of probabilistically checkable proofs [2, 5, 25] and this connection was some of the early motivation for the field of property testing. Since the original paper, the parameters of the BLR test have been extensively refined. Much of this work focused on reducing the amount of randomness, due to this being a key parameter in probabilistically checkable proofs, as well as analyzing the rejection probability (see [36] for a survey). Another line of works considered the testing linearity over more general domains. The works of [7, 11, 35] showed that the BLR test can be used to test the linearity of any function with $f\colon G \to H$ for finite groups G and H with $O(1/\varepsilon)$ queries. Following this, a body of work [1, 17, 19, 27] constructed testers for linearity of functions $f\colon S \to \mathbb{R}$, where S is a finite subset of rational numbers, and the distance is measured with respect to the uniform distribution over S. See [28] for a survey. These results were phrased in terms of approximate self-testing and correcting programs. In this setting the queries to f return a finite approximation of $f(x)$. Although these results are arguably the most related to our work, our proof differs significantly from theirs and instead takes inspiration from the original BLR test.

Distribution-free testing (for graph properties) was first defined by Goldreich et al. [22], though the first distribution-free testers for non-trivial properties appeared much later in the work of Halevy and Kushilevitz [23]. Subsequently, distribution-free testers have been considered for a variety of Boolean functions including low-degree polynomials, dictators, and monotone functions [23], k-juntas [6,12,23,30], conjunctions, decision lists, and linear threshold functions [20], monotone and non-monotone monomials [16], and monotone conjunctions [14, 20]. However, to our knowledge the only (partial) distribution-free tester for a class of functions on the Euclidean space is due to Harms [24] who gave an efficient tester for half spaces, that is, functions $f\colon \mathbb{R}^n \to \{0,1\}$ of the form $f(x) = \operatorname{sgn}(w^\top x - \theta)$ for some $w \in \mathbb{R}^n$ and $\theta \in \mathbb{R}$, over any rotationally invariant distribution.

1.2 Proof Technique

The construction of our tester for additivity will be done in two steps. First, we construct a constant-query tester for additivity over the standard Gaussian distribution $\mathcal{N}(0, I)$. Our tester will accept linear functions with probability 1, and so the majority of the work is in showing that if the test accepts the given function $f\colon \mathbb{R}^n \to \mathbb{R}$ with high probability, then f is close to an additive function. To do so, we show that if f passes a series of tests then there exists a related function $g\colon \mathbb{R}^n \to \mathbb{R}$, defined from f, which is additive. Furthermore, if f is linear then $f = g$. The definition of g will allow us to obtain query access to it with high probability, and so we can simply estimate the distance between f and g. At a high-level, this is somewhat similar to the BLR test, however operating over $\mathcal{N}(0, I)$ rather than the uniform distribution presents its own set of non-trivial challenges. We discuss these, as well as the definition of g at the start of Section 3.1.

It is fairly straightforward to generalize this tester for additivity to a distribution-free tester. To do so, we run the additivity tester for the standard Gaussian, except that testing the distance between f and g will now be done using samples from the unknown $\mathcal{D}$. This crucially relies on our ability to draw samples from the standard Gaussian.

Any additive function $f\colon \mathbb{R}^n \to \mathbb{R}$ is linear over the rationals, meaning that $f(qx) = qf(x)$ for every $q \in \mathbb{Q}$. Therefore, in order to test linearity it remains to test whether this holds also for irrationals. Assuming that f is continuous we are able to modify our tester to show that this implies that the additive function g is continuous as well. We then leverage the fact that any continuous additive function is linear in order to obtain our linearity tester.

To prove Theorem 3, the lower bound on sample-based testers for linearity, we construct two distributions, one supported on linear functions, and the other supported on functions which are far from linear. Consider drawing a function f from one of these two distributions with equal probability. By Yao's minimax principle it suffices to show that any deterministic algorithm which receives n samples from $\mathcal{N}(0, I)$, together with their evaluations on f, is unable to distinguish, with high probability, which of the two distribution f came from. To construct the distribution on linear functions, we sample $w \sim \mathcal{N}(0, I)$ and return $f(x) := w^\top x$. Our distribution on functions which are far from linear is designed so that any function f from this distribution satisfies $f(x + y) \neq f(x) + f(y)$ with probability 1 over $x, y \sim \mathcal{N}(0, I)$. To do so, for every $x \in \mathbb{R}^n$ we sample ε_x from a one-dimensional Gaussian and return $f(x) := w^\top x + \varepsilon_x$. It is not difficult to show that such functions are far from linear.

1.3 Organization

The remainder of the paper is organized as follows. In Section 2 we review several useful facts about probability distributions. In Section 3 we develop our distribution-free tester for additivity by first constructing a tester for additivity over the standard Gaussian in Section 3.1. We generalize this tester to the distribution-free setting in Section 3.2 and to a tester for linearity in Section 4. Finally, we end with our lower bound on the sampling model in Section 5.

2 Preliminaries

Let $\mathcal{D}$ and $\mathcal{D}'$ be probability distributions on the same domain Ω. Then, the *total variation distance* between them, denoted by $\mathrm{d_{TV}}(\mathcal{D}, \mathcal{D}')$, is defined as

$$\mathrm{d_{TV}}(\mathcal{D}, \mathcal{D}') := \frac{1}{2} \int_\Omega |\mathcal{D}(x) - \mathcal{D}'(x)| dx.$$

The *Kullback-Leibler divergence* (or *KL-divergence*) of $\mathcal{D}'$ from $\mathcal{D}$, denoted $\mathrm{d_{KL}}(\mathcal{D} \| \mathcal{D}')$, is defined as

$$\mathrm{d_{KL}}(\mathcal{D} \| \mathcal{D}') = \int_\Omega \mathcal{D}(x) \log \left(\frac{\mathcal{D}(x)}{\mathcal{D}'(x)} \right) dx.$$

We will use the KL-divergence to upper bound the total variation distance, using the following inequality.

▶ **Theorem 4** (Pinsker's Inequality). *Let $\mathcal{D}$ and $\mathcal{D}'$ be probability distributions on the same domain Ω. Then,*

$$\mathrm{d_{TV}}(\mathcal{D}, \mathcal{D}') \leq \sqrt{\frac{1}{2} \mathrm{d_{KL}}(\mathcal{D} \| \mathcal{D}')}.$$

The following allows us to bound the KL-divergence between two Gaussian distributions.

▶ **Lemma 5.** *Let $\mathcal{D} = \mathcal{N}(\mu_1, \Sigma_1)$ and $\mathcal{D}' = \mathcal{N}(\mu_2, \Sigma_2)$ be multivariate Gaussian distributions with $\mu_1, \mu_2 \in \mathbb{R}^n$ and invertible $\Sigma_1, \Sigma_2 \in \mathbb{R}^{n \times n}$. Then,*

$$\mathrm{d}_{\mathrm{KL}}(\mathcal{D} \| \mathcal{D}') = \frac{1}{2}\left(\log\left(\frac{\det \Sigma_2}{\det \Sigma_1}\right) + \mathrm{tr}\left((\Sigma_2)^{-1}\Sigma_1\right) - n + (\mu_2 - \mu_1)^\top \Sigma_2^{-1}(\mu_2 - \mu_1)\right).$$

We record a useful lemma about total variation distance of Gaussians with shared covariance matrices.

▶ **Lemma 6.** *Consider two Gaussian distributions $\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)$ with shared invertible covariance matrices $\Sigma \in \mathbb{R}^{n \times n}$. Then $\mathrm{d}_{\mathrm{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) \leq \phi$ holds if $\|\mu_1 - \mu_2\|_2 \leq 2\phi/\sqrt{\|\Sigma^{-1}\|_2}$.*

Proof. Denote $\mu := \mu_1 - \mu_2$. By Lemma 5, $\mathrm{d}_{\mathrm{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) = \sqrt{\frac{1}{4}\mu^\top \Sigma^{-1}\mu}$. Now, because Σ is PSD, $\mu^\top \Sigma^{-1}\mu \leq \|\mu\|_2^2 \|\Sigma^{-1}\|_2$, where $\|\cdot\|_2$ is the spectral matrix norm. Therefore, we have $\mathrm{d}_{\mathrm{TV}}(\mathcal{N}(\mu_1, \Sigma), \mathcal{N}(\mu_2, \Sigma)) \leq \frac{1}{2}\|\mu\|_2 \sqrt{\|\Sigma^{-1}\|_2} \leq \phi$. ◀

3 Testing Additivity

In this section, we develop our distribution-free tester for additivity. For convenience, we first describe a simpler tester for additivity over the standard Gaussian distribution $\mathcal{N}(0, I)$ in Section 3.1. Then, in Section 3.2, we describe how to generalize this algorithm to test additivity over an unknown distribution.

3.1 Tester for the Standard Gaussian

Our goal in this section is to design a constant-query tester for the additivity of a measurable function $f \colon \mathbb{R}^n \to \mathbb{R}$ over the standard Gaussian.

▶ **Theorem 7.** *There exists a one-sided error $\Omega\left(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$-query tester for additivity over the standard Gaussian.*

At a high-level, our tester consists of two steps. First, we test whether f satisfies additivity over a set of samples drawn from the distribution. If f passes this test, then we conclude that there must be an additive function $g \colon \mathbb{R}^n \to \mathbb{R}$, which is a self-corrected version of f. Second, by testing the value of f on a correlated set of points, we are able to get query access to g with high probability, and therefore we can simply estimate the distance between f and g. Our tester relies on the fact that it has one-sided error: if f is additive then our test passes with probability 1. Otherwise, if f is non-additive and the second step passes with high probability, then f and g must be close.

The first step is inspired by the BLR test. Indeed, the evaluation of the function g at a point p is defined as the (weighted) majority value of $f(p - x) + f(x)$ over all $x \sim \mathcal{N}(0, I)$ (where, $f(p - x) + f(x)$ is weighted according to the probability of drawing $x \sim \mathcal{N}(0, I)$). However, there are some significant challenges in generalizing the BLR test to the standard Gaussian, the most obvious of which is that unlike the uniform distribution, every point in the support of the distribution does not have equal probability. In particular, $p - x$ is not distributed as $x \sim \mathcal{N}(0, I)$ for fixed $p \neq 0$. In order to overcome this, we exploit the fact that for additive functions f, we have $f(x) = qf(x/q)$ for every rational q. This allows us to restrict attention to a small ball $\mathrm{B}(0, 1/r)$ of radius $1/r$ centered at the origin. Then, for $p \in \mathrm{B}(0, 1/r)$, $p - x$ is approximately distributed as x for small enough $1/r$. Thus, we get around the issue of unevenly weighted points by defining g within $\mathrm{B}(0, 1/r)$, and then extrapolating to define g over $\mathbb{R}^n$.

Algorithm 1 Standard Gaussian Additivity Tester.

Given: Query access to $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to the distribution $\mathcal{N}(0, I)$;
Reject if TestAdditivity(f) returns **Reject**;
for $N_1 := O(1/\varepsilon)$ *times* **do**
  Sample $p \sim \mathcal{N}(0, I)$;
  Reject if $f(p) \neq$ Query-$g(p, f)$ or if Query-$g(p, f)$ returns **Reject**.
Accept.

Algorithm 2 Subroutines.

Procedure TestAdditivity(f)
  Given: Query access to $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to the distribution $\mathcal{N}(0, I)$;
  for $N_2 := O(1)$ *times* **do**
    Sample $x, y, z \sim \mathcal{N}(0, I)$;
    Reject if $f(-x) \neq -f(x)$;
    Reject if $f(x - y) \neq f(x) - f(y)$;
    Reject if $f\left(\frac{x-y}{2}\right) \neq f\left(\frac{x-z}{2}\right) + f\left(\frac{z-y}{2}\right)$;
  Accept.
Procedure Query-$g(p, f)$
  Given: $p \in \mathbb{R}^n$, query access to $f\colon \mathbb{R}^n \to \mathbb{R}$, sampling access to $\mathcal{N}(0, I)$;
  $N_2' := O(\log \frac{1}{\varepsilon})$;
  Sample $x_1, \ldots, x_{N_2'} \sim \mathcal{N}(0, I)$;
  Reject if there exists $i, j \in [N_2']$ such that
   $f(p/k_p - x_i) + f(x_i) \neq f(p/k_p - x_j) + f(x_j)$;
  return $k_p\,(f(p/k_p - x_1) + f(x_1))$.

Concretely, we will define g as follows. First, let r be a sufficiently large integer ($r = 50$ suffices). For each point $p \in \mathbb{R}^n$ define

$$k_p := \begin{cases} 1 & \text{if } \|p\|_2 \leq 1/r, \\ \lceil r \cdot \|p\|_2 \rceil & \text{if } \|p\|_2 > 1/r. \end{cases}$$

Now, define $g\colon \mathbb{R}^n \to \mathbb{R}$ as

$$g(p) := k_p \cdot \operatorname*{maj}_{\mathcal{N}(0,I)} \left[f\left(\frac{p}{k_p} - x\right) + f\left(x\right) \right],$$

where $\operatorname{maj}_{\mathcal{N}(0,I)}$ is the *weighted majority function* where a value $f(p/k_p - x) + f(x)$ is weighted according to its probability mass under $x \sim \mathcal{N}(0, I)$. Observe that either $p \in \mathrm{B}(0, 1/r)$, or $g(p)$ first maps p to a point p/k_p in $\mathrm{B}(0, 1/r)$. The value of g is the most likely value (according to $\mathcal{N}(0, I)$) of $f(p/k_p - x) + f(x)$. If f is close to additive, then taking this majority should allow us to correct for the errors in f.

An equivalent definition of g which will be useful is the following. For $p \in \mathbb{R}^n$ let P_p be the Lebesgue measurable function such that $\int_A P_p(x)dx$ gives the probability (over $\mathcal{N}(0, I)$) that $f(p/k_p - x) + f(x)$ takes value in A. Then g is defined as $g(p) := \operatorname{argmax}_x P_p(x)$ if $P_p(x) \geq 1/2$.

Our algorithm is given in Algorithm 1, which uses subroutines given in Algorithm 2. The Query-g subroutine allows us to obtain query access to g with high probability, while the TestAdditivity subroutine tests the conditions that we require in order to prove that g is additive.

▶ **Lemma 8.** *If* TestAdditivity(f) *accepts with probability at least* $1/10$*, then* g *is a well-defined, additive function, and furthermore,* $\Pr_{x\sim\mathcal{N}(0,I)}[g(p) \neq k_p(f(p/k_p - x) + f(x))] < 1/2$.

We first prove Theorem 7 assuming that Lemma 8 holds.

Proof of Theorem 7. First, observe that if f is an additive function then Algorithm 1 always accepts. It is immediate that TestAdditivity(f) always accepts. To see that it also passes the remaining tests, observe that by additivity, $k_p\left(f(p/k_p - x) + f(x)\right) = k_p f(p/k_p) = f(p)$, where the final inequality holds because $k_p \in \mathbb{Z}$ and by homogeneity over the rationals $f(qx) = qf(x)$ for every $q \in \mathbb{Q}$.

We now show that if f is ε-far from additive functions, then Algorithm 1 rejects with probability at least $2/3$. If TestAdditivity(f) accepts with probability at most $1/10$, we can reject f with probability at least $1 - 1/10 > 2/3$. Hence, we assume that TestAdditivity(f) accepts with probability at least $1/10$. Then by Lemma 8, the function g is additive and hence f is ε-far from g. Now, we want to bound the probability that Step 2 of Algorithm 1 passes.

First, we bound the probability that Query-$g(p, f)$ fails to recover the value of $g(p)$. That is, we bound the probability that $f(p/k_p - x_i) + f(x_i) = f(p/k_p - x_j) + f(x_j)$ for all $i, j \in [N_2']$, but $g(p) \neq k_p\left(f(p/k_p - x_i) + f(x_i)\right)$. By Lemma 8, the probability that we draw N_2' points which satisfy this is at most $2^{-N_2'} \leq \varepsilon/2$ by choosing the hidden constant in N_2' to be large enough. Therefore, the probability that we correctly recover $g(p)$ is at least $1 - \varepsilon/2$.

Now that we have established that we can obtain query access to g with high probability, it remains to show that we can test whether f and g are close. Indeed, the probability that Step 2 of Algorithm 1 fails to reject is at most

$$\begin{aligned}
&\left(\Pr_{p\sim\mathcal{N}(0,I)}[f(p) = g(p) \vee \text{Query-}g(p,f) \text{ fails to correctly recover } g(p)]\right)^{N_1} \\
\leq&\left(1 - \Pr_{p\sim\mathcal{N}(0,I)}[f(p) \neq g(p)] + \Pr_{p\sim\mathcal{N}(0,I)}[\text{Query-}g(p,f) \text{ fails to correctly recover } g(p)]\right)^{N_1} \\
<&\left(1 - \frac{\varepsilon}{2}\right)^{N_1} < \frac{1}{10},
\end{aligned}$$

by choosing the hidden constant in N_1 to be large enough. Therefore, Algorithm 1 rejects with probability at least $1 - 1/10 > 2/3$. ◀

It remains to prove Lemma 8 showing that if Algorithm 1 succeeds, then g is an additive function with high probability.

3.1.1 Additivity of the Function g

First, we record the basic, but useful observation that if the TestAdditivity subroutine passes then each of its tests hold with high probability over $\mathcal{N}(0, I)$.

▶ **Lemma 9.** *If* TestAdditivity*(f) accepts with probability at least* $1/10$*, then*

$$\Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)=f(x)-f(y)]\geq\frac{99}{100}, \tag{1}$$

$$\Pr_{x\sim\mathcal{N}(0,I)}[f(-x)=-f(x)]\geq\frac{99}{100}, \tag{2}$$

$$\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\left(\frac{x-y}{2}\right)=f\left(\frac{x-z}{2}\right)+f\left(\frac{z-y}{2}\right)\right]\geq\frac{99}{100}. \tag{3}$$

Proof. Suppose for contradiction that at least one of (1), (2), and (3) does not hold. We here assume that (1) does not hold as other cases are similar.

We accept only when all the sampled pairs (x,y) satisfy $f(x+y)=f(x)+f(y)$. By setting the hidden constant in N_2 to be large enough, this happens with probability at most

$$\left(1-\Pr_{x,y\sim\mathcal{N}(0,I)}[f(x+y)\neq f(x)+f(y)]\right)^{N_2}<\left(\frac{99}{100}\right)^{N_2}<\frac{1}{10},$$

which is a contradiction. ◀

In order to argue that g is additive, we will first argue that g is additive on points within the tiny ball $\mathrm{B}(0,1/r)$. To do so, we will crucially use the fact that $p-x$ is distributed approximately as $x\sim\mathcal{N}(0,I)$ if $\|p\|_2$ is small. By Lemma 6 we have a bound on the total variation distance between x and $x+p$.

▷ Claim 10. Let $p\in\mathbb{R}^n$ satisfying $\|p\|_2\leq k/r$ for some $k\in\mathbb{Z}^{>0}$. Then $\mathrm{d_{TV}}(\mathcal{N}(0,I),\mathcal{N}(p,I))\leq k/100$.

Proof. By Lemma 6, for $\mathrm{d_{TV}}(\mathcal{N}(0,I),\mathcal{N}(p,I))\leq k/100$ it is enough that p satisfies $\|0-p\|_2\leq 2k/(100\sqrt{\|I\|_2})$. Because $\|p\|_2\leq k/r=2k/100=2k/(100\sqrt{\|I\|_2})$. ◁

After arguing that g is additive in $\mathrm{B}(0,1/r)$, it will follow that g is additive elsewhere because g is defined by extrapolating the value of g within this ball. Therefore, we will focus on proving the additivity of g within $\mathrm{B}(0,1/r)$.

▶ **Lemma 11.** *Suppose that* (1) – (3) *of Lemma 9 hold. For every* $p,q\in\mathbb{R}^n$ *with* $\|p\|_2,\|q\|_2,\|p+q\|_2\leq 1/r$ *it holds that* $g(p+q)=g(p)+g(q)$*.*

The proof of this lemma will crucially rely on the following two lemmas, which say that the conclusions of Lemma 9 hold with high probability even when one of the points are fixed to a point $\mathrm{B}(0,1/r)$. A consequence of this is that g is well-defined.

▶ **Lemma 12.** *Suppose that* (1) – (3) *of Lemma 9 hold, then* g *is well-defined, and for every* $p\in\mathbb{R}^n$ *with* $\|p\|_2\leq 1/r$*,*

$$\Pr_{x\sim\mathcal{N}(0,I)}[g(p)=f(p-x)+f(x)]\geq\frac{9}{10}.$$

Proof. Fix a point $p\in\mathbb{R}^n$ with $\|p\|_2\leq 1/r$. We will bound the following probability.

$$A:=\Pr_{x,y\sim\mathcal{N}(0,I)}[f(p-x)+f(x)=f(p-y)+f(y)].$$

Observe that

$$\begin{aligned}
A &= \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x)-f(y)\neq f(p-y)-f(p-x)] \\
&\leq \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x)-f(y)\neq f(x-y)] + \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)\neq f(p-y)-f(p-x)] \\
&< \frac{1}{100} + \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)\neq f(p-y)-f(p-x)] && \text{(By Lemma 9)}
\end{aligned}$$

It remains to bound the second term. Intuitively, because $x-p, y-p \sim \mathcal{N}(-p, I)$ and $p \approx 0$, the random variables $p-x$ and $p-y$ should be distributed similarly to x and y. Indeed,

$$\begin{aligned}
&\Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)\neq f(p-y)-f(p-x)] \\
&= \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-p+p-y)\neq f(p-y)-f(p-x)] \\
&= \Pr_{x,y\sim\mathcal{N}(-p,I)}[f(x-y)\neq f(-y)-f(-x)] \\
&\leq \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)\neq f(-y)-f(-x)] + 2\,\mathrm{d_{TV}}\left(\mathcal{N}(0,I),\mathcal{N}(-p,I)\right) \\
&\leq \Pr_{x,y\sim\mathcal{N}(0,I)}[f(x-y)\neq f(x)-f(y)] + \frac{2}{100} + 2\Pr_{x\sim\mathcal{N}(0,I)}[f(-x)\neq f(x)] && \text{(Claim 10)} \\
&\leq \frac{3}{100} + \frac{2}{100} = \frac{5}{100}. && \text{(By (1) and (2) in Lemma 9)}
\end{aligned}$$

Plugging this into our previous bound on A, we can conclude that

$$A \geq 1 - \left(\frac{1}{100} + \frac{5}{100}\right) = 1 - \frac{6}{100} > \frac{9}{10}.$$

Next, we bound A above in terms of the probability that $g(p) \neq f(p-x)+f(x)$. Define $P_p\colon \mathbb{R}^n \to \mathbb{R}^+$ to be the bounded Lebesgue-measurable function such that $\int_B P_p(x)dx$ is the probability that $f(p-x)+f(x)$ takes value in the (measurable) set B. By Hölder's inequality with $p=1, q=\infty$ we have

$$A = \int_{\mathbb{R}} P_p^2(x)dx \leq \|P_p\|_\infty \int_{\mathbb{R}} P_p(x)dx = \|P_p\|_\infty,$$

where the last equality follows because P_p is a density and $\int_{\mathbb{R}} P_p(x)dx = 1$ holds. Therefore,

$$\frac{9}{10} \leq A \leq \|P_p\|_\infty.$$

Because $\operatorname{argmax}_x P_p(x) \geq 9/10 > 1/2$, we have $g(p) = \operatorname{argmax}_x P_p(x)$ and hence $\Pr_{x\sim\mathcal{N}(0,I)}[g(p) = f(p-x)+f(x)] \geq 9/10$. ◀

The following lemma is essentially condition (3) of Lemma 9 with two fixed points.

▶ **Lemma 13.** *Suppose that* (1) – (3) *of Lemma 9 hold then, for every* $p, q \in \mathbb{R}^n$ *with* $\|p\|_2, \|q\|_2, \|p+q\| \leq 1/r$,

$$\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[g(p+q) \neq f\left(p-\frac{x-z}{2}\right) + f\left(q-\frac{z-y}{2}\right) + f\left(\frac{x-y}{2}\right)\right] \leq \frac{2}{10}.$$

Proof. Fix a pair of points $p, q \in \mathbb{R}^n$ with $\|p\|_2, \|q\|_2 \le 1/r$. We can bound the probability

$$\begin{aligned}
&\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[g(p+q) \neq f\Big(p-\frac{x-z}{2}\Big)+f\Big(q-\frac{z-y}{2}\Big)+f\Big(\frac{x-y}{2}\Big)\right]\\
\le&\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[g(p+q) \neq f\Big(p+q-\frac{x-y}{2}\Big)+f\Big(\frac{x-y}{2}\Big)\right]\\
&+\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\Big(p+q-\frac{x-y}{2}\Big) \neq f\Big(p-\frac{x-z}{2}\Big)+f\Big(q-\frac{z-y}{2}\Big)\right]
\end{aligned}$$

To bound the first term, observe that if $x, y \sim \mathcal{N}(0, I)$, then the random variable $(x-y)/2$ is also distributed according to $\mathcal{N}(0, I)$. Furthermore, because $\|p+q\|_2 \le 1/r$, we can apply Lemma 12 and conclude that

$$\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[g(p+q) \neq f\Big(p+q-\frac{x-y}{2}\Big)+f\Big(\frac{x-y}{2}\Big)\right] \le \frac{1}{10}.$$

To bound the second term, observe that

$$\begin{aligned}
&\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\Big(p+q-\frac{x-y}{2}\Big) \neq \Big(p-\frac{x-z}{2}\Big)+\Big(q-\frac{z-y}{2}\Big)\right]\\
=&\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\left(\frac{(2q+y)-(x-2p)}{2}\right) \neq \left(\frac{(2q+y)-z}{2}\right)+\left(\frac{z-(x-2p)}{2}\right)\right]\\
=&\Pr_{\substack{x\sim\mathcal{N}(-2p,I)\\ y\sim\mathcal{N}(2q,I)\\ z\sim\mathcal{N}(0,1)}}\left[f\Big(\frac{y-x}{2}\Big) \neq \Big(\frac{y-z}{2}\Big)+\Big(\frac{z-x}{2}\Big)\right]\\
\le&\Pr_{x,y,z\sim\mathcal{N}(0,I)}\left[f\Big(\frac{x-y}{2}\Big) \neq \Big(\frac{x-z}{2}\Big)+\Big(\frac{z-y}{2}\Big)\right]+\mathrm{d_{TV}}\left(\mathcal{N}(0,I),\mathcal{N}(-2p,I)\right)\\
&+\mathrm{d_{TV}}\left(\mathcal{N}(0,I),\mathcal{N}(2q,I)\right)\\
\le&\frac{1}{100}+\frac{2}{100}+\frac{2}{100}=\frac{5}{100}. \qquad \text{(By Lemma 9 and Claim 10)}
\end{aligned}$$

Combining both of these bounds, we have $\Pr_{x,y,z\sim\mathcal{D}}[g(p+q) \neq f(p-\frac{x-z}{2})+f(q-\frac{z-y}{2})+f(\frac{x-y}{2})] \le 1/10+5/100 \le 2/10$. ◀

The additivity of g within $\mathrm{B}(0, 1/r)$ is an immediate consequence of these two lemmas.

Proof of Lemma 11. Let $p, q \in \mathbb{R}^n$ be any pair of points satisfying $\|p\|_2, \|q\|_2, \|p+q\|_2 \le 1/r$. Our aim is to show that $g(p+q) = g(p)+g(q)$. By a union bound over Lemmas 12 and 13, the probability that $x, y, z \sim \mathcal{N}(0, I)$ simultaneously satisfy

1. $g(p+q) = f(p-\frac{x-z}{2})+f(q-\frac{z-y}{2})+f(\frac{x-y}{2})$,
2. $g(p) = f(p-\frac{x-z}{2})+f(\frac{x-z}{2})$,
3. $g(q) = f(q-\frac{z-y}{2})+f(\frac{z-y}{2})$,
4. $f(\frac{x-y}{2}) = f(\frac{x-z}{2})-f(\frac{z-y}{2})$

is at least $1-(2/10+2\cdot 1/10+1/10) > 0$. Here we are using the fact that $((x-y)/2)$ is distributed as $\mathcal{N}(0, I)$. Fixing such a triple (x, y, z), we conclude that

$$\begin{aligned}
g(p+q) &= f\Big(p-\frac{x-z}{2}\Big)+f\Big(q-\frac{z-y}{2}\Big)+f\Big(\frac{x-y}{2}\Big)\\
&= g(p)+g(q)+f\Big(\frac{x-y}{2}\Big)-f\Big(\frac{x-z}{2}\Big)-f\Big(\frac{z-y}{2}\Big)\\
&= g(p)+g(q).
\end{aligned}$$

Therefore g is additive within $\mathrm{B}(0, 1/r)$. ◀

Finally, we argue that g is additive everywhere. Intuitively this should be true because the values of g on points outside of $\mathrm{B}(0,1/r)$ are defined by extrapolating the values of g on points within $\mathrm{B}(0,1/r)$, where we know g is additive. For the proof, it will be useful to record the following fact.

▶ Fact 14. Provided that (1) – (3) of Lemma 9 hold then, for every $p \in \mathbb{R}^n$ with $\|p\|_2 \leq 1/r$ and $c \in \mathbb{Z}^{>0}$, we have $g(p) = cg(p/c)$.

Proof. Observe that $g(p) = g((c/c)p) = g\left(\sum_{i=1}^{c} p/c\right) = \sum_{i=1}^{c} g(p/c) = c \cdot g(p/c)$, where the third equality follows by Lemma 11, noting that $\|kp/c\|_2 \leq 1/r$ for every $k \in [c-1]$. ◀

Proof of Lemma 8. Fix a pair of points $p, q \in \mathbb{R}^n$, we will argue that $g(p+q) = g(p) + g(q)$. Recall that $g(p) := k_p g(p/k_p)$, $g(q) := k_q g(q/k_q)$, and $g(p+q) := k_{p+q} g((p+q)/k_{p+q})$. Then,

$$g(p)+g(q) = k_p \cdot g\left(\frac{p}{k_p}\right) + k_q \cdot g\left(\frac{p}{k_q}\right) = k_p k_q k_{p+q} \cdot g\left(\frac{p}{k_p k_q k_{p+q}}\right) + k_p k_q k_{p+q} \cdot g\left(\frac{p}{k_p k_q k_{p+q}}\right),$$

where the second equality follows by Fact 14, noting that $k_p, k_q, k_{p+q} \in \mathbb{Z}^{>0}$ and so $p/k_p, q/k_q \in \mathrm{B}(0,1/r)$. Furthermore, because $p/(k_p k_q k_{p+q}), q/(k_p k_q k_{p+q})$, $(p+q)/(k_p k_q k_{p+q}) \in \mathrm{B}(0,1/r)$, we can apply Lemma 11 to obtain

$$\begin{aligned} k_p k_q k_{p+q}\left(g\left(\frac{p}{k_p k_q k_{p+q}}\right) + g\left(\frac{p}{k_p k_q k_{p+q}}\right)\right) &= k_p k_q k_{p+q} \cdot g\left(\frac{p+q}{k_p k_q k_{p+q}}\right) \\ &= k_{p+q} \cdot g\left(\frac{p+q}{k_{p+q}}\right) \\ &= g(p+q), \end{aligned}$$

where the second equality follows by Fact 14, noting that $k_p k_q \in \mathbb{Z}^{>0}$ and $(p+q)/k_{p+q} \in \mathrm{B}(0,1/r)$.

Finally, by Lemma 12, g is well-defined within $\mathrm{B}(0,1/r)$. Because g is defined by extrapolating from its value within this ball, it is well-defined everywhere. ◀

▶ Remark 15. This tester (and the same proof) will in fact work over any Gaussian $\mathcal{N}(0,\Sigma)$ for arbitrary covariance matrix $\Sigma \in \mathbb{R}^{n \times n}$ by setting the value of r to be $50\sqrt{\|\Sigma^{-1}\|_2}$.

3.2 Distribution-Free Tester

In this section, we prove Theorem 1 by adapting our tester for additivity over the standard Gaussian (Algorithm 1) to a distribution-free tester.

Assuming that we are able to draw samples from the standard Gaussian (or in fact any Gaussian), the modification to Algorithm 1 is straight forward. Indeed, we will only have to modify Algorithm 1, the two subroutines will remain the same. Let $\mathcal{D}$ be our unknown distribution by which we will measure the distance of f to an additive function. The high-level idea is to first run the TestAdditivity subroutine over the standard Gaussian. If it passes, then we know that with high probability g is additive. We can obtain query access to $g(p)$ (with high probability) as before by sampling points $x \sim \mathcal{N}(0,I)$ and checking that the values of $k_p(f(p/k_p - x) + f(x))$ agree for all of the x that we sample. To test whether f and g are ε-far according to $\mathcal{D}$ it suffices to sample points $p \sim \mathcal{D}$ and check whether $f(p)$ and $g(p)$ agree.

Our algorithm is given in Algorithm 3. We stress that both subroutines TestAdditivity and Query-$g(p_i)$ are being performed over $\mathcal{N}(0,I)$, i.e., they do not use $\mathcal{D}$.

Algorithm 3 Distribution-Free Additivity Tester.

Given: query access to $f : \mathbb{R}^n \to \mathbb{R}$, sampling access to an unknown distribution $\mathcal{D}$, and sampling access to $\mathcal{N}(0, I)$;

1 **Reject** if TestAdditivity(f) returns **Reject**;
2 **for** $N_3 := O(1/\varepsilon)$ *times* **do**
3 Sample $p \sim \mathcal{D}$;
4 **Reject** if $f(p) \neq$ Query-$g(p, f)$ or if Query-$g(p, f)$ returns **Reject**.
5 **Accept**.

Proof of Theorem 1. The proof is nearly identical to the proof of Theorem 7. Again, observe that if f is an additive function then Algorithm 3 always accepts.

It remain to show that if f is ε-far from additive functions, then Algorithm 3 rejects with probability at least 2/3. If TestAdditivity(f) accepts with probability at most 1/10, we can reject f with probability at least $1 - 1/10 > 2/3$. Hence, we assume that TestAdditivity(f) accepts with probability at least 1/10. By Lemma 8, the function g is additive and hence f is ε-far from g. Note that the probability that Query-$g(p, f)$ fails to correctly recover $g(p)$ is at most $\varepsilon/2$ by the same argument as before. It remains to bound the probability that Step 3 fails to reject, which is

$$\left(\Pr_{p\sim\mathcal{N}(0,I)}[f(p) = g(p) \vee \text{Query-}g(p) \text{ fails to correctly recover } g(p)]\right)^{N_3} < \left(1 - \frac{\varepsilon}{2}\right)^{N_3} < \frac{1}{10}$$

by choosing the hidden constant in N_3 to be large enough, by the same argument as before. Therefore, Algorithm 3 rejects with probability at least $1 - 1/10 > 2/3$. ◀

4 Testing Linearity of Continuous Functions

In this section, we prove Theorem 2 by adapting the tester from the previous section (Algorithm 3) to test whether f is linear, given that f is a continuous function.

We would like to argue that if f is continuous and Algorithm 3 passes then g is in fact a linear function with high probability. However, in order to exploit continuity, we need f to satisfy $f(-x) = -f(x)$ for every $x \in \mathbb{R}^n$. First, we will show how to argue that g is linear assuming that $f(-x) = -f(x)$. After that, we will handle the case when this property does not hold.

▶ **Lemma 16.** *If $f : \mathbb{R}^n \to \mathbb{R}$ is a continuous function satisfying $f(-x) = -f(x)$ and the assumptions of Lemma 8 hold, then the function g is linear.*

The proof will rely on the following claim which was originally proved by Darboux in 1875.

▷ Claim 17. Any additive function $f : \mathbb{R}^n \to \mathbb{R}$ which is continuous at a point $x_0 \in \mathbb{R}^n$ is a linear function.

Proof. First, it is well-known that any additive function which is continuous at a point is continuous everywhere (see e.g., [4]). Next, we argue that the continuity of f implies that $f(rx) = rf(x)$ for every $r \in \mathbb{R}$ and $x \in \mathbb{R}^n$. Because f is additive, this homogeneity holds for every $r \in \mathbb{Q}$, so it suffices to assume that r is irrational.

Fix $x \in \mathbb{R}^n$ and irrational r. Then for any $\zeta > 0$, we can always find $\tilde{r} \in \mathbb{Q}$ such that $|\tilde{r} - r| < \zeta$ and $\|\tilde{r}x - rx\|_2 < \zeta$. Now, by the continuity of f, for any $\xi > 0$ there exists $\zeta > 0$ such that whenever $\|\tilde{r}x - rx\|_2 < \zeta$, we have $|f(\tilde{r}x) - f(rx)| < \xi$. Now, take a sequence $\{\xi_i\}_i$ with $\xi_i \to 0$ and consider the corresponding sequence $\{\zeta_i\}_i$ with $\zeta_i \to 0$. Let $\{\tilde{r}_i\}_i$ with $r_i \in \mathbb{Q}$ be the sequence of approximations such that $|\tilde{r}_i - r| \leq \zeta_i$ and $\|\tilde{r}_i x - rx\|_2 \leq \zeta_i$. Then,

$$|f(rx) - rf(x)| \leq |f(rx) - f(\tilde{r}_i x)| + |f(\tilde{r}_i x) - rf(x)| \leq \xi_i + |\tilde{r}_i f(x) - rf(x)| \leq \xi_i + \zeta_i |f(x)|.$$

Because $\zeta_i, \xi_i \to 0$, $|f(rx) - rf(x)| \to 0$ and so $f(rx) = rf(x)$. ◁
